(**a**) In the Hartmann test the pattern is obtained in focused convergent light beam, near the focus. On the other hand, in the Hartmann-Shack the test is made in a nearly collimated beam of light.

(**b**) A practical advantage of the Hartmann-Shack method is that any positive or negative power can be easily detected and measured.

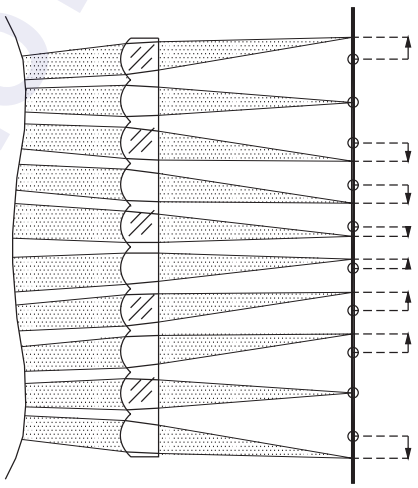

FIGURE 7 Hartmann-Shack Test.

(**c**) A second advantage is that each of the spots is individually focused on the detector, making the light energy density of the spot higher than in the Hartmann test.

(**d**) The Hartmann-Shack lenticular screen can be made with two identical layers of cylindrical lenses perpendicular to each other, or with a lenslet arrays in molded plastic, glass, or fused silica.

If the wavefront is flat, the light beam passing through each lens is focused close to the optical axis of each lenslet. Since the lens array is not perfect, the lenticular array must be previously calibrated with a reference well-known flat wavefront.

The spot displacement on the detector is equal to the wavefront slope multiplied by the focal length of the lenslet, thus, a shorter focal length will give a greater dynamic range but a reduced angular sensitivity. The optimum focal length depends on the application.

13.4 INTERFEROMETRIC TESTS

Classical geometrical tests are very simple, but they do not provide the accuracy of the interferometric tests. Quite generally, an interferometric test produces an interferogram by producing the interference between two wavefronts. One of these two wavefronts is the wavefront under test. The other wavefront is either a perfectly spherical or flat wavefront, or a copy of the wavefront under test.

When the second wavefront is perfectly spherical or flat, this wavefront acts as a reference. The separation between the two wavefronts, or optical path difference OPD(x, y), is a direct indication of the deformations $W(x, y)$ of the wavefront under test. Then, we may simply write $W(x, y) = \text{OPD}(x, y)$. There are many types of interferometers producing interferograms of these type of interferograms, for example, the Twyman-Green and the Fizeau interferometers. Some other interferometers can be considered as modifications of these two basic interferometers, such as the Point Diffraction and the Burch interferometers, and many others that will not be described.

Twyman-Green Interferometer

The Twyman-Green interferometer is illustrated in Fig. 8. The light from a monochromatic point light source is collimated to produce a flat wavefront. Then, the two interfering wavefronts are generated by means of a partially reflective and partially transmitting glass plate, called beam splitter.

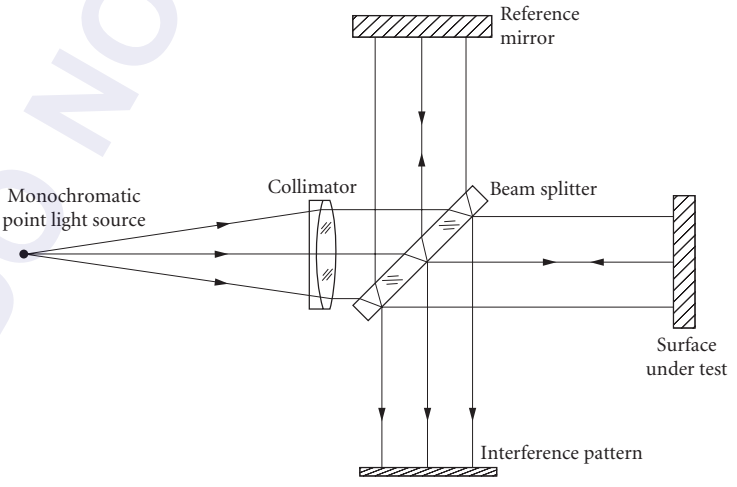

FIGURE 8 Twyman-Green interferometer.

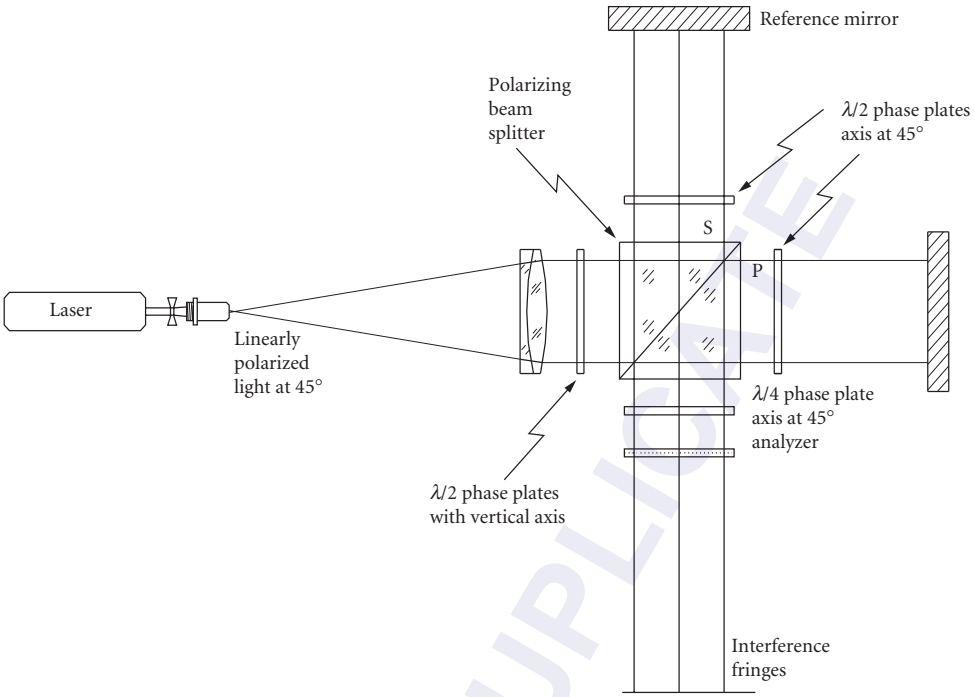

FIGURE 9 Twymann-Green interferometer with polarized beam splitter.

After the beam splitter two flat wavefronts travel in orthogonal directions, one of them to the flat reference mirror and the other to the surface or optical element under test. After returning to the beam splitter, the two wavefronts are recombined to produce an interference pattern. The beam splitter can be oriented at 45° as in Fig. 8, but sometimes a different angle is chosen, for example, a Brewster angle to avoid the reflected beam from the second face on the beam splitter.

Instead of a plane parallel beam splitter, sometimes a polarizing cube beam splitter is used, as in Fig. 9. In this system the plane wavefront entering the beam splitter is linearly polarized at an angle of 45° with respect to the plane of the interferometer. Then, the two wavefronts exiting the cube in orthogonal directions will also be linearly polarized but one of them in the vertical plane and the other in the horizontal plane. A $\lambda/4$ phase plate is located at each of the two exiting faces on the cube. These phase plates produce circularly polarized beams, one going to the reference mirror and the other to the surface under test, but one is right handed and the other is left handed. When arriving back to the cube, after passing twice through the phase plates, the two beams will be again linearly polarized, one in the vertical plane and the other in the horizontal plane. However, these planes of polarization will be orthogonal to the planes of polarization when the wavefront exited the cube. Thus, the two wavefronts are sent to the observation plane and not back to the light source.

Two important facts should be noticed: (a) that the two wavefronts are orthogonally polarized and hence they can not interfere and (b) that there are not any light beams going back to the light source to produce a complementary pattern as in the classic Twyman-Green interferometer. In order to produce observable fringes a linear polarizer should be placed just before the observing plane.

This interferometer with a polarizing beam splitter has many practical advantages.

Fizeau Interferometer

A Fizeau interferometer, illustrated in Fig. 10, is also a two-beam system like the Twyman-Green interferometer. The main difference is that the plate beam splitter is not at 45° with the illuminated

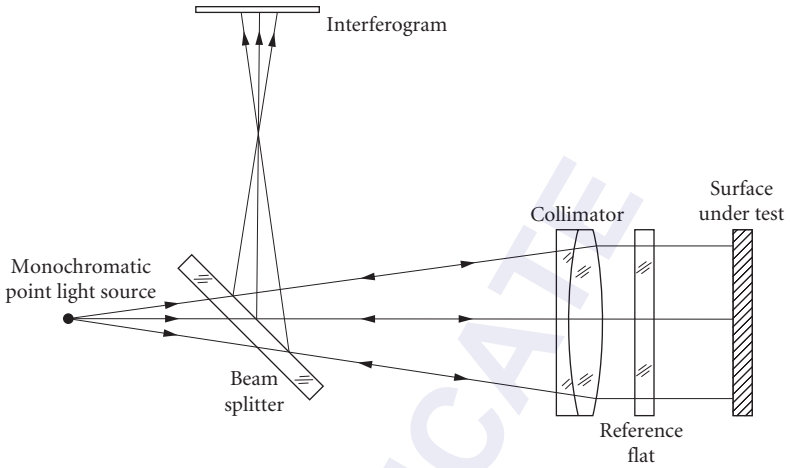

FIGURE 10 Fizeau interferometer.

collimated beam, but perpendicular to its incidence path. Some important practical advantages are that (a) the beam splitter can be smaller for the same aperture, (b) it is more compact, and (c) it is easier to align.

Figure 11 shows some typical interferograms for the Seidel primary aberrations obtained with a Twyman-Green or a Fizeau interferometer.[1] The mathematical analysis of interferograms for wavefronts with arbitrary deformations is a research topic of great interest that has been described in a large number of publications.[7]

Common Path Interferometer

A common path interferometer is one for which the two interfering beams travel the same paths. The optical path difference at the center of the optical axis is zero and cannot be modified. Thus interference with a white light source can be easily achieved. An example of this kind of interferometer is the point-diffraction interferometer first described by Linnik in 1933 and later rediscovered by Smart and Strong.[8] The lens of optical element under test focuses the light at the center of a small diffracting plate as illustrated in Fig. 12. This diffracting plate is coated with a thin partially transmitting film with a small uncoated disk at its center. The diameter of the central clear disk is about the size of the diffraction air disk produced by a perfect optical system. If the wavefront from the system is not spherical but distorted, the focused spot would be larger than the central disk. Then, two wavefronts are produced. One is a reference spherical wavefront arising from the light diffracted at the central disk. The undiffracted light passing outside of the disk is the wavefront under test.

The fringe patterns in the point diffraction interferometer are identical to those produced by the Twyman-Green interferometer.

Lateral Shearing Interferometers

When the second wavefront is not perfectly flat or spherical, but a copy of the wavefront under test, its relative dimensions or orientation must be changed (sheared) in some way with respect to the wavefront under test. Otherwise, no information about the wavefront deformations is obtained, because the fringes will always be straight and parallel independent of any aberrations. There are several kinds of shearing interferometers, depending on the kind of transformation applied to the reference wavefront.

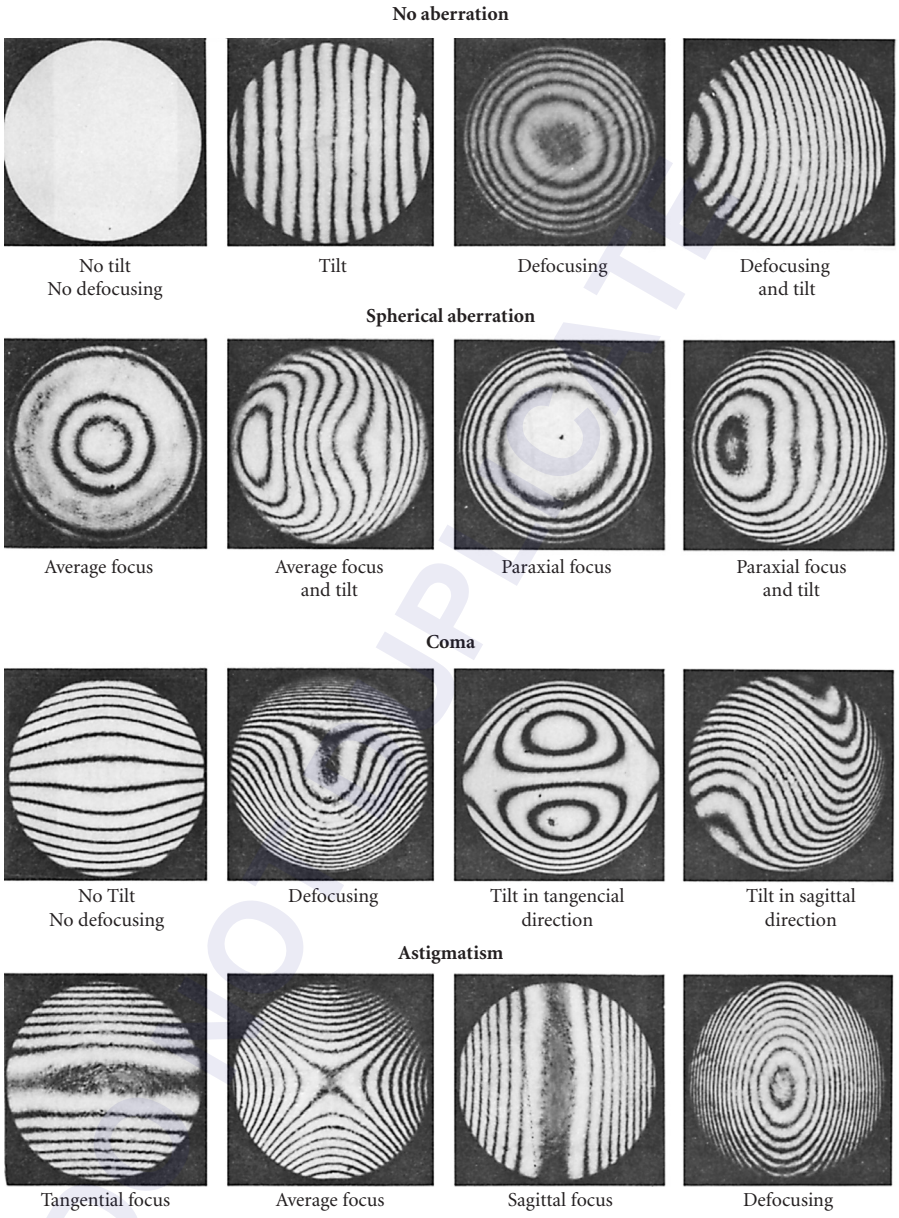

FIGURE 11 Twyman-Green interferograms. (*From Malacara.*[1])

The most popular of these instruments is the lateral shearing interferometer, with the reference wavefront laterally displaced with respect to the other, as in the interferograms in Fig. 13 shows. The optical path difference OPD(x, y) and the wavefront deformations $W(x, y)$ are related by

$$\text{OPD}(x, y) = W(x, y) - W(x - S, y) \tag{6}$$

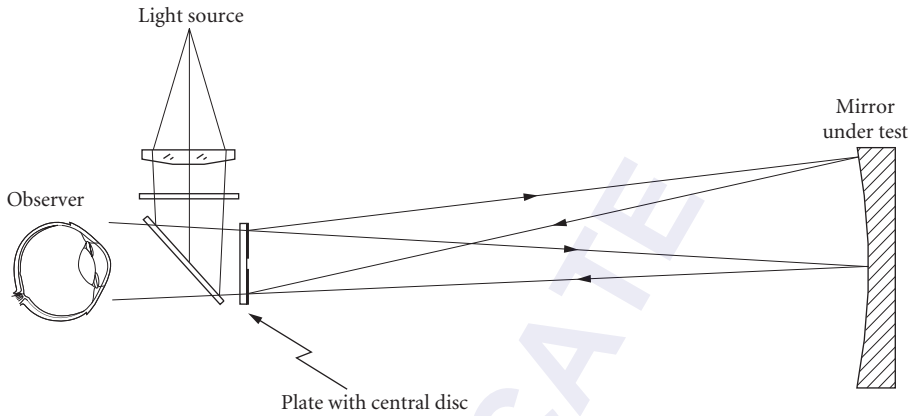

FIGURE 12 Point diffraction interferometer.

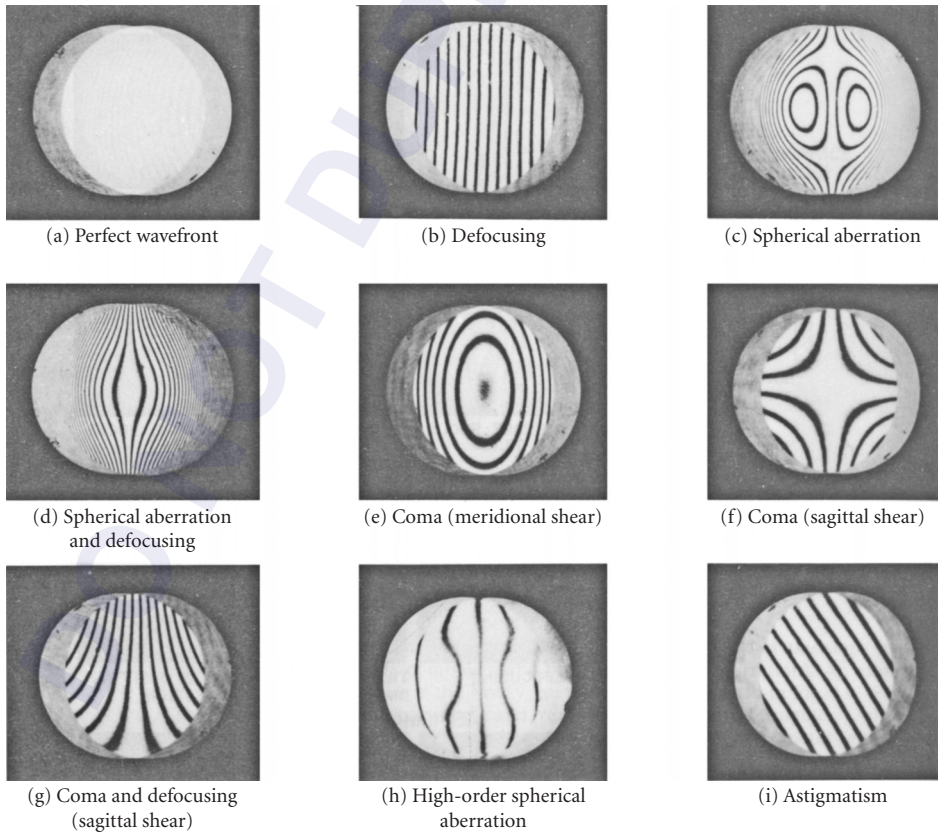

FIGURE 13 Laterally sheared interferograms. (*From Malacara.*[1])

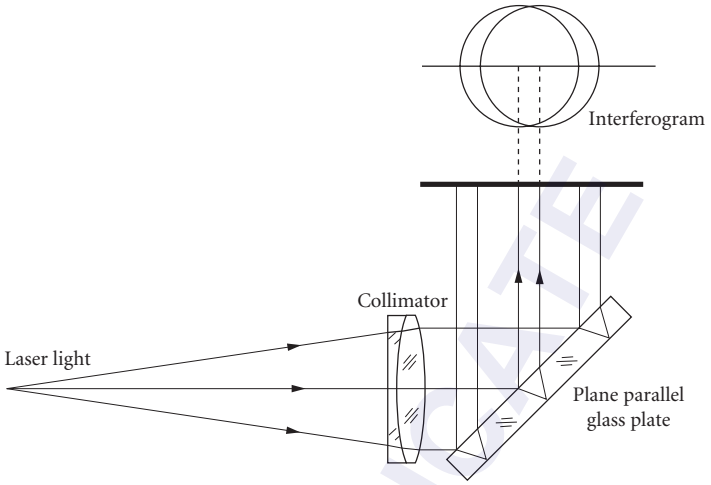

FIGURE 14 Murty's lateral shear interferometer.

where S is the lateral shear of one wavefront with respect to the other. If the shear is small with respect to the diameter of the wavefront, this expression may be approximated by

$$\mathrm{OPD}(x, y) = -S\frac{\partial W(x, y)}{\partial x} = -\frac{S}{r}TA_x(x, y) \tag{7}$$

This relation suggests that the parameter being directly measured is the slope in the x direction of the wavefront (x component TAx of the transverse aberration). An example of a lateral shear interferometer is the Murty interferometer, illustrated in Fig. 14.

Radial, Rotational, and Reversal Shearing Interferometers

There are also radial, rotational, and reversal shearing interferometers, where the interfering wavefronts are as illustrated in Fig. 15. A radial shear interferometer with a large shear approaches an interferometer with a perfect reference wavefront. These interferometers procedure fringe patterns by the interference of two wavefronts with the same aberrations and deformations. The difference between the two interfering wavefronts is their size or orientation.

The optical path in the radial shear interferometer can be represented by

$$\mathrm{OPD}(x, y) = W(x, y) - W(\rho x, \rho y) \tag{8}$$

A typical radial shear interferogram is in Fig. 16.

In the rotational shear interferometer. The two interfering wavefronts have the same size, but one of those is rotated with respect to the other. In the particular case on a 180° rotation the sensitivity of the interferometer is zero for symmetrical (even) aberrations, like spherical aberration. However, the sensitivity is doubled for antisymmetrical (odd) aberrations, like coma.

In a reversing shear interferometer one of the two wavefronts is reversed with respect to the other about any diameter on the wavefront's pupil. As in the rotational shear interferometer, the sensitivity to aberrations is symmetric with respect to the axis of reversion. Also, the sensitivity to aberration antisymmetric about the axis of reversion is doubled.

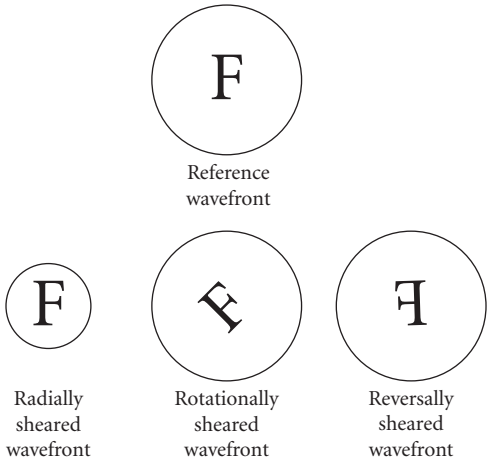

FIGURE 15 Wavefronts in radial, rotational, and reversal shear interferometers.

FIGURE 16 A radial shear interferogram.

13.5 INCREASING THE SENSITIVITY OF INTERFEROMETERS

The sensitivity of interferometers is a small fraction of the wavelength being used (about $\lambda/20$). There are several methods to increase this sensitivity, but the most common methods will now be described.

Multiple-Reflection Interferometers

A method to increase the sensitivity of interferometric methods is to use multiple reflections, as in the Fabry-Perot interferometer. The Newton as well as the Fizeau interferometers can be made multiple-reflection interferometers by coating the reference surface and the surface under test with a high-reflection film. Then, the fringes are greatly narrowed and their deviations from straightness are more accurately measured.[9]

Multiple-Pass Interferometers

Another method to increase the sensitivity of interferometers is by double, or even multiple, pass. An additional advantage of double-pass interferometry is that the symmetrical and antisymmetrical parts of the wavefront aberration may be separated. This makes their identification easier, as Hariharan and Sen[10] have proved. Several arrangements have been devised to use multiple pass.[11]

Zernike Tests

The Zernike phase-contrast method is another way to improve the sensitivity of an interferometer to small aberrations. It was suggested by Zernike as a way to improve the knife-edge test.[12] There are several versions of this test. The basic principle in all of them is the introduction of a

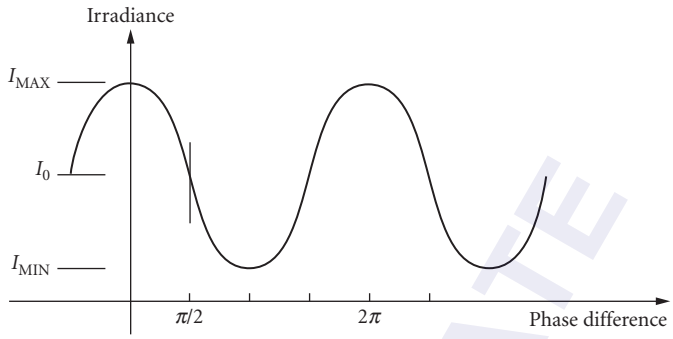

FIGURE 17 Irradiance in an interference pattern, as a function of the phase difference between the two interfering waves.

phase difference equal to $\lambda/2$ between the wavefront under test and the reference wavefront. To understand why this phase difference is convenient, let us consider two interfering beams and irradiances $I_1(x, y)$ and $I_2(x, y)$ and a phase $\varphi(x, y)$ between them. The final irradiance $I(x, y)$ in the interferogram is given by

$$I(x, y) = I_1(x, y) + I_2(x, y) + 2\sqrt{I_1(x, y) I_2(x, y)} \cos\phi(x, y) \tag{9}$$

Thus, the irradiance $I(x, y)$ of the combination would be a sinusoidal function of the phase, as illustrated in Fig. 17. If the phase difference is zero for a perfect wavefront, deformations of the wavefront smaller than the wavelength of the light will not be easy to detect, because the slope of the function is zero for a phase near zero. The slope of this function is larger and linear for a phase value of 90°. Thus, the small wavefront deformations are more easily detected if the interferometer is adjusted, so that the wavefronts have a phase difference equal to 90° when the wavefront under test is perfect.

13.6 INTERFEROGRAM EVALUATION

An interferogram may be analyzed in several manners. One way begins by measuring several points on the interferogram, on top of the fringes. Then, the wavefront values between the fringes are interpolated. Another way uses a Fourier analysis of the interferogram. A third method interprets the fringe deformations as a phase modulation.

Fixed Interferogram Evaluation

Once the interferogram has been formed, a quantitative evaluation of it is a convenient method to find the wavefront deformations. The fixed interferogram evaluation by fringe measurements is done by measuring the position of several data points located on top of the fringes. These measurements are made in many ways, for example, with a measuring microscope, with a digitizing tablet, or with a video camera connected to a computer.

The fringe centers can be located either manually, using a digitizing tablet, or automatically, with the computer directly examining a single fringe image that has been captured using a digital frame grabber. After locating the fringe centers, fringe order numbers must be assigned to each point. The wavefront can then be characterized by direct analysis of the fringe centers. If desired, instead of global interpolation, a local interpolation procedure may be used.

To analyze the fringes by a computer, they must first be digitized by locating the fringe centers, and assigning fringe order numbers to them. The optical path difference (OPD) at the center of any fringe is a multiple m of the wavelength (OPD = $m\lambda$), where m is the fringe order. To obtain the

wavefront deformation, only the relative values of the fringe order are important. So any value of the fringe order may be assigned to the first fringe being measured. However, for the second fringe, it may be increased or decreased by one. This choice affects only the sign of the OPD. An important disadvantage of the fixed interferogram analysis is that the sign of the OPD cannot be obtained from the interferogram alone. This information can be retrieved if the sign of any term in the wavefront deformation expression, like defocusing or tilt, is previously determined when taking the interferogram.

Fringes have been digitized using scanners,[13] television cameras,[14] photoelectric scanners, and digitizing tablets. Review articles by Reid[15,16] give useful references for fringe digitization using television cameras.

Global and Local Interpolation of Interferograms

After the measurements are made, the wavefront is computed with the measured points. The data density depends on the density of fringes in the interferogram. Given a wavefront deformation, the ratio of the fringe deviations from straightness to the separation between the fringes remains a constant, independently of the number of fringes introduced by tilting of the reference wavefront. If the number of fringes is large due to a large tilt, the fringes look more straight than if the number of fringes is small. Thus, the fringe deviations may more accurately be measured if there are few fringes in the interferogram. Thus, information about many large zones is lost. A way to overcome this problem is to interpolate intermediate values by any of several existing methods. One method is to fit the wavefront data to a two-dimensional polynomial with a least-squares fitting, as described by Malacara et al.[17] or by using splines as described by Hayslett and Swantner[18] and Becker et al.[19] Unfortunately, this procedure has many problems if the wavefront is very irregular. The values obtained with the polynomial may be wrong, especially near the edge, or between fringes if the wavefront is too irregular.

The main disadvantage of global fits is that they smooth the measured surface more than desired. Depending on the degree of the polynomial, there will only be a few degrees of freedom to fit many data points. It is even possible that the fitted surface will pass through none of the measured points. If the surface contains irregular features that are not well described by the chosen polynomial, such as steps or small bumps, the polynomial fit will smooth these features. Then, they will not be visible in the fitted surface.

Global interpolation is done by least-squares fitting the measured data to a two-dimensional polynomial in polar coordinates. The procedure to make the least-squares fitting begins by defining the variance of the discrete wavefront fitting as follows:

$$\sigma = \frac{1}{N}\sum_{i=1}^{N}[W_i' - W(\rho_i, \theta_i)]^2 \tag{10}$$

where N is the number of data points, W_i is the measured wavefront deviation for data point i, and $W(i, \theta_i)$ is the functional wavefront deviation after the polynomial fitting. The only requirement is that this variance or fit error is minimized. It is well known that the normal least-squares procedure leads to the inversion of an almost singular matrix. Then, the round-off errors will be so large that the results will be useless. To avoid this problem, the normal approach is to fit the measured points to a linear combination of polynomials that are orthogonal over the discrete set of data points. Thus, the wavefront is represented by

$$W(\rho_i, \theta_i) = \sum_{i=1}^{L} B_n V_n(\rho_i, \theta_i) \tag{11}$$

$V(\rho, \theta)$ are polynomials of degree r and not the monomials x. These polynomials satisfy the orthogonality condition

$$\sum_{i=1}^{N} V_n(\rho_i, \theta_i) V_m(\rho_i, \theta_i) = F_n \rho_{nm} \tag{12}$$

where $F_n = \sum V_n^2$.

The advantage of using these orthogonal polynomials is that the matrix of the system becomes diagonal and there is no need to invert it.

The only problem that remains is to obtain the orthogonal polynomials by means of the Gram-Schmidt orthogonalization procedure. It is important to notice that the set of orthogonal polynomials is different for every set of data points. If only one data point is removed or added, the orthogonal polynomials are modified. If the number of data points tends to infinity and they are uniformly distributed over a circular pupil with unit radius, these polynomials $V_r(\rho, \theta)$ approach the Zernike polynomials.[20]

Several properties of orthogonal polynomials make them ideal for representing wavefronts, but the most important of them is that we may add or subtract one or more polynomial terms without affecting the fit coefficients of the other terms. Thus, we can subtract one or more fitted terms—defocus, for example—without having to recalculate the least-squares fit. In an interferometric optical testing procedure the main objective is to determine the shape of the wavefront measured with respect to a best-fit sphere. Nearly always it will be necessary to add or subtract some terms.

The only problem with these orthogonal polynomials over the discrete set of data points is that they are different for every set of data points. A better choice for the wavefront representation is the set of Zernike polynomials, which are orthogonal on the circle with unit radius, as follows:

$$\int_0^1 \int_0^{2\pi} U_n(\rho, \theta) U_m(\rho, \theta) \rho d\rho d\theta = F_{nm} \delta_{nm} \tag{13}$$

These polynomials are not exactly orthogonal on the set of data points, but they are close to satisfying this condition. Therefore, it is common to transform the wavefront representation in terms of the polynomials V_n to another similar representation in terms of Zernike polynomials $U_n(\rho, \theta)$, as

$$W(\rho, \theta) = \sum_{n=1}^{L} A_n U_n(\rho, \theta) \tag{14}$$

Fourier Analysis of Interferograms

A completely different way to analyze an interferogram without having to make any interpolation between the fringes is by a Fourier analysis of the interferogram. An interpolation procedure is not needed because the irradiance at a fine two-dimensional array of points is measured and not only at the top of the fringes. The irradiance should be measured directly on the interferogram with a two-dimensional detector or television camera, and not on a photographic picture. Womack,[21] Macy,[22] Takeda et al.,[23] and Roddier and Roddier[24] have studied in detail the Fourier analysis of interferograms to obtain the wavefront deformations.

Consider an interferogram produced by the interference of the wavefront under test and a flat reference wavefront, with a large tilt between them, as in the interferogram in Fig. 18. The tilt is about the y axis, increasing the distance between the wavefronts in the x direction. The picture of this interferogram may be thought of as a hologram reconstructing the wavefront. Thus, three wavefronts (images) are generated when this hologram is illuminated with a flat wavefront. In order to have complete separation between these images, the tilt between the wavefronts must be large enough, so that the angle between them is not zero at any point over the interferogram. This is equivalent to saying that the fringes must be open, and never cross any line parallel to the x axis more than once. One image is the wavefront under test and another is the conjugate of this wavefront.

If the tilt between the wavefront is θ and the wavefront shape is $W(x, y)$, the irradiance is given by

$$I(x, y) = I_1(x, y) + I_2(x, y) + 2\sqrt{I_1(x, y) I_2(x, y)} \cos(\phi_0 + kx \sin\theta + kW(x, y)) \tag{15}$$

where $k = 2\pi/\lambda$. This expression may be rewritten as

$$I = [I_1 + I_2] + \sqrt{I_1 I_2}\, e^{i(kx \sin\theta + kW)} + \sqrt{I_1 I_2}\, e^{-i(kx \sin\theta + kW)} \tag{16}$$

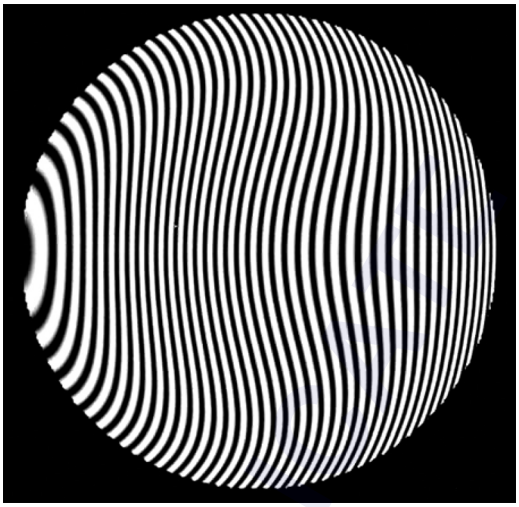

FIGURE 18 Interferogram with a large tilt (linear carrier) to avoid closed fringes.

The first term represents the zero order, the second is the real image, and the third is the virtual image. We also may say that the Fourier transform of the interferogram is formed by a Dirac impulse $\delta(f)$ at the origin and two terms shifted from the origin, at frequencies $+f_0$ and $-f_0$. The quantity f is the spatial frequency, defined by the tilt between the reference wavefront and the wavefront under test ($f = \sin\theta/\lambda$). These terms may be found by taking the Fourier transform of the interferogram. The term at f_0 is due to the wavefront under test. This wavefront may be obtained by taking the Fourier transform of this term, mathematically isolated from the others. This method is performed in a computer by using the fast Fourier transform. The undesired terms are simply eliminated before taking the second fast Fourier transform in order to obtain the wavefront.

Direct Interferometry

This is another method to obtain the wavefront from an interferogram without the need of any interpolation. As in the Fourier method, the image of the interferogram is directly measured with a two-dimensional detector or television camera. The interferogram must have many fringes, produced with a large tilt between the wavefronts. The requirements for the magnitude of this tilt are the same as in the Fourier method.

Consider the irradiance in the interferogram in Fig. 18 along a line parallel to the x axis. This irradiance plotted versus the coordinate x is a perfectly sinusoidal function only if the wavefront is perfect, that is, if the fringes are straight, parallel, and equidistant. Otherwise, this function appears as a wave with a phase modulation. The phase-modulating function is the wavefront shape $W(x, y)$. If the tilt between the wavefronts is θ, the irradiance function is described by Eq. (15). If φ_o is a multiple of 2π, this expression may be rewritten as

$$I(x, y) = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos(kx\sin\theta + kW) \tag{17}$$

Multiplying this phase-modulated function by a sinusoidal signal with the same frequency as the carrier $\sin(kx \sin\theta)$ a new signal S is obtained. Similarly, multiplying by a cosinusoidal signal

cos ($kx \sin \theta$) a new signal C is obtained. If all terms in the signals S and C with frequencies equal to or greater than the carrier frequency are removed with a low-pass filter, they become

$$S(x, y) = -\sqrt{I_1 I_2} \sin kW(x, y) \tag{18}$$

$$C(x, y) = \sqrt{I_1 I_2} \cos kW(x, y) \tag{19}$$

then, the wavefront $W(x, y)$ is given by

$$W(x, y) = -\frac{1}{k} \tan^{-1} \left[\frac{S(x, y)}{C(x, y)} \right] \tag{20}$$

which is our desired result.

13.7 PHASE-SHIFTING INTERFEROMETRY

All the methods just described are based on the analysis of a single static interferogram. Static fringe analysis is generally less precise than phase-shifting interferometry, by more than one order of magnitude. However, fringe analysis has the advantage that a single image of the fringes is needed. On the other hand, phase-shifting interferometry requires several images, acquired over a long time span during which the fringes must be stable. This is the main reason why phase-shifting interferometry has seldom been used for the testing of astronomical optics.

Phase-shifting interferometry[25,26] is possible, thanks to modern tools like array detectors and microprocessors. Figure 19 shows a Twyman-Green interferometer adapted to perform phase-shifting interferometry. Most conventional interferometers, like the Fizeau and the Twyman-Green, have been used to do phase shifting. A good review about these techniques may be found in the review article by Creath.[27]

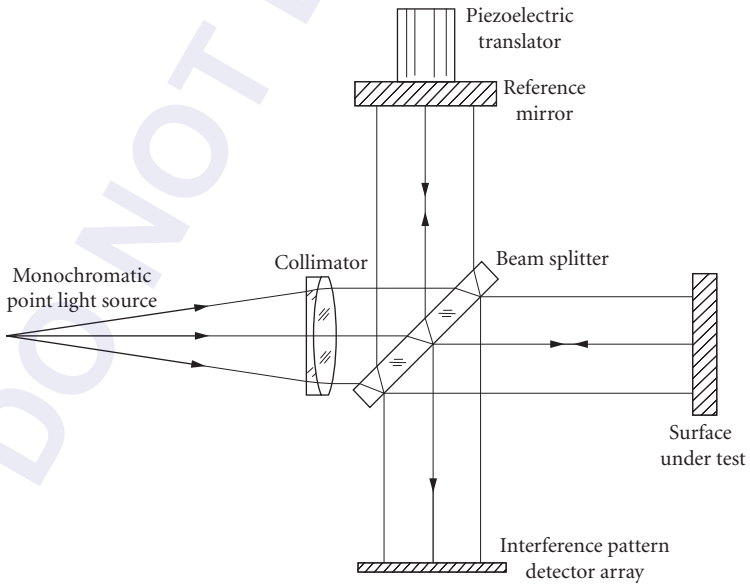

FIGURE 19 Twyman-Green interferogram adapted to do phase shifting.

In phase-shifting interferometers, the reference wavefront is moved along the direction of propagation, with respect to the wavefront under test, changing in this manner their phase difference. This phase shifting is made in steps or in a continuous manner. Of course, this relative displacement of one wavefront with respect to the other may only be achieved through a momentary or continuous change in the frequency of one of the beams, for example, by Doppler shift, moving one of the mirrors in the interferometer. In other words, this change in the phase is accomplished when the frequency of one of the beams is modified in order to form beats.

By measuring the irradiance changes for different values of the phase shifts, it is possible to determine the initial difference in phase between the wavefront under test and the reference wavefront, for that measured point over the wavefront. By obtaining this initial phase difference for many points over the wavefront, the complete wavefront shape is thus determined. If we consider any fixed point in the interferogram, the initial phase difference between the two wavefronts has to be changed in order to make several measurements.

One method that can be used to shift this phase is by moving the mirror for the reference beam along the light trajectory, as in Fig. 19. This can be done in many ways, for example, with a piezoelectric crystal or with a coil in a magnetic field. If the mirror moves with a speed V, the frequency of the reflected light is shifted by an amount equal to $\Delta\nu = 2V/\lambda$.

Another method to shift the phase is by inserting a plane parallel glass plate in the light beam (see Fig. 20). Then the plate is rotated about an axis perpendicular to the optical axis. The phase may also be shifted by means of the device shown in Fig. 21. The first quarter-wave retarding plate is stationary, with its slow axis at 45° with respect to the plane of polarization of the incident linearly polarized light. This plate also transforms the returning circularly polarized light back to linearly

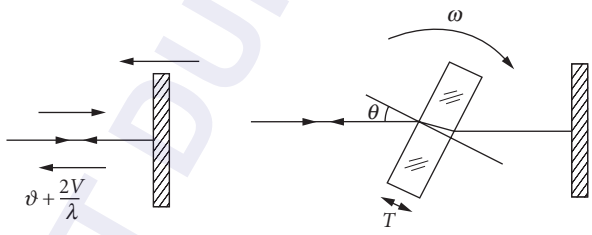

FIGURE 20 Obtaining the phase shift by means of a moving mirror or a rotating glass plate.

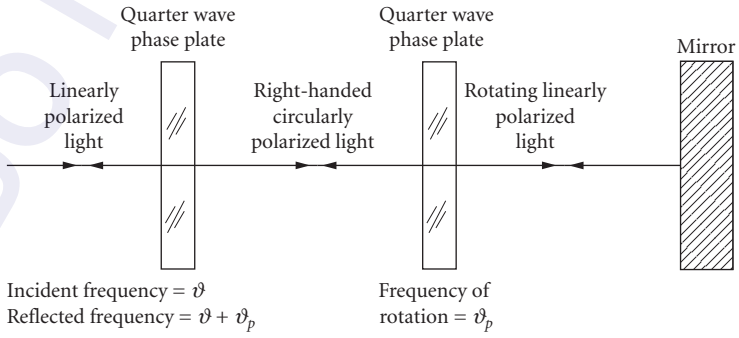

FIGURE 21 Obtaining the phase shift by means of phase plates and polarized light, with a double pass of the light beam.

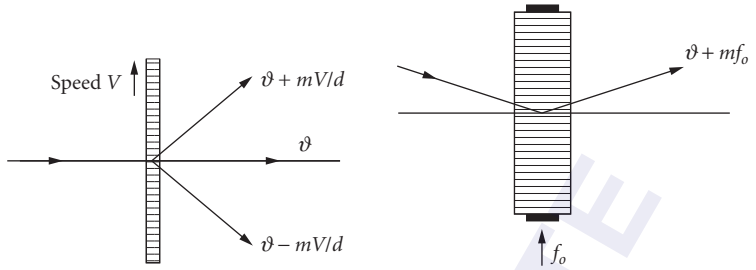

(a) Moving diffraction grating (b) Bragg cell

FIGURE 22 Obtaining the phase shift by means of diffraction: (*a*) with a diffraction grating and (*b*) with an acousto-optic Bragg cell.

polarized. The second phase retarder is also a quarter-wave plate, it is rotating, and the light goes through it twice; therefore, it is acting as a half-wave plate.

Still another manner to obtain the shift of the phase is by a diffraction grating moving perpendicularly to the light beam, as shown in Fig. 22*a*, or with an acousto-optic Bragg cell, as shown in Fig. 22*b*. The change in the frequency is equal to the frequency f of the ultrasonic wave times the order of diffraction m. Thus: $\Delta\nu = mf$.

The nonshifted relative phase of the two interfering wavefronts is found by measuring the irradiance with several predefined and known phase shifts. Let us assume that the irradiance of each of the two interfering light beams at the point x, y in the interference patterns are $I_1(x, y)$ and $I_2(x, y)$ and that their phase difference is $\varphi(x, y)$. It was shown before, in Eq. (9), that the resultant irradiance $I(x, y)$ is a sinusoidal function describing the phase difference between the two waves. The basic problem is to determine the nonshifted phase difference between the two waves, with the highest possible precision. This may be done by any of several different procedures.

Phase-Stepping and Four Steps Algorithms

This method[27] consists of measuring the irradiance values for several known increments of the phase. There are several versions of this method, which will be described later. The measurement of the irradiance for any given phase takes some time, since there is a time response for the detector. Therefore, the phase has to be stationary during a short time in order to take the measurement. Between two consecutive measurements, the phase is changed by an increment α_i. For those values of the phase, the irradiance becomes

$$I(x, y) = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos(\phi + \alpha_i) \tag{21}$$

There are many different algorithms, with many different phase steps, as shown in Fig. 23. The minimum number of steps needed to reconstruct this sinusoidal function is three. As an example with four steps,

$$I_A = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\phi \tag{22}$$

$$I_B = I_1 + I_2 - 2\sqrt{I_1 I_2}\sin\phi \tag{23}$$

$$I_C = I_1 + I_2 - 2\sqrt{I_1 I_2}\cos\phi \tag{24}$$

$$I_D = I_1 + I_2 + 2\sqrt{I_1 I_2}\sin\phi \tag{25}$$

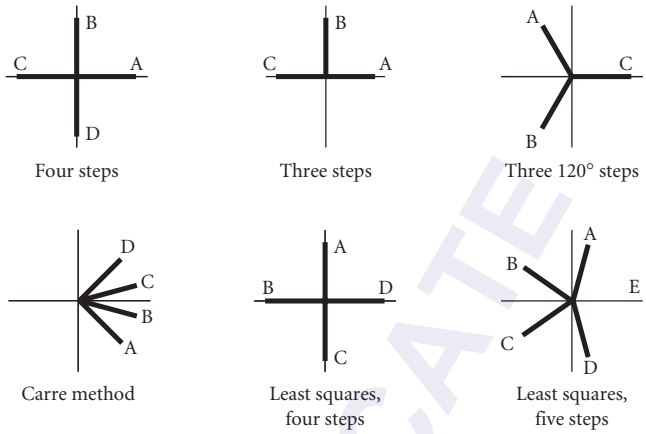

FIGURE 23 Six different ways to shift the phase using phase steps.

Integrating Bucket

In the integrating phase-shifting method the detector continuously measures the irradiance during a fixed time interval, without stopping the phase. Since the phase changes continuously, the average value of the irradiance during the measuring time interval is measured. Thus, the integrating phase-stepping method may be mathematically considered a particular case of the phase-stepping method if the detector has an infinitely short time response. Then, the measurement time interval is reduced to zero. If the measurement is taken, as in Fig. 24, from $\alpha_i + \Delta/2$ to $\alpha_i - \Delta/2$ with center at α_i, then

$$I = \frac{1}{\Delta}\int_{\alpha-\Delta/2}^{\alpha+\Delta/2}[I_1 + I_2 + 2\sqrt{I_1 I_2}\cos(\phi+\alpha_i)]d\alpha \tag{26}$$

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\,\mathrm{sinc}(\Delta/2)\cos(\phi+\alpha_i) \tag{27}$$

In general, in the phase-stepping as well as in the integrating phase-shifting methods, the irradiance is measured at several different values of the phase α_i, and then the phase is calculated.

Two Steps Plus One Method

As pointed out before, phase-shifting interferometry is not useful for testing systems with vibrations or turbulence because the three or four interferograms are taken at different times. An attempt

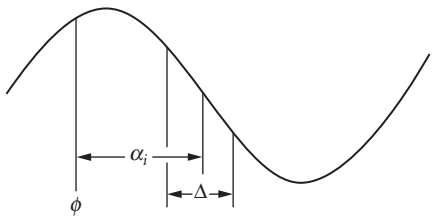

FIGURE 24 Averaged signal measurements with the integrating phase-shifting method.

to reduce this time is the so-called two steps plus one method, in which only two measurements separated by 90° are taken.[28] A third reading is taken any time later, of the sum of the irradiance of the beams, independently of their relative phase. This last reading may be taken using an integrating interval $\Delta = 2\pi$. Thus,

$$I_A = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\phi \tag{28}$$

$$I_B = I_1 + I_2 + 2\sqrt{I_1 I_2}\sin\phi \tag{29}$$

$$I_C = I_1 + I_2 \tag{30}$$

Therefore,

$$\phi = \tan^{-1}\left\{\frac{I_B - I_C}{I_A - I_C}\right\} \tag{31}$$

Other Phase-Stepping Algorithms

When calculating the phase with several different three or more phase steps, several sources of error affect the accuracy of the result, for example:

(**a**) A line miscalibration of the phase shifter. Then the introduced phase steps will have a linear error, which can be interpreted as a change of the reference frequency fr, making it different from the signed frequency as it should be.

(**b**) A nonlinearity in the phase shifter or on the detector that introduces light order harmonics in the detected signed.

These phase errors can be reduced or minimized by property selecting the number phase steps and their phase increments. Using Fourier theory as shown by Freischlad and Koliopolus,[29] a large number of different algorithms with different contributors and number of phase steps have been described in the literature. Depending on the kind of source error and the maximum number of phase steps desired, the proper algorithm can be selected.

Simultaneous Measurement

It has been said several times that the great disadvantage of phase-shifting interferometry is its great sensitivity to vibrations and atmospheric turbulence. To eliminate this problem, it has been proposed that the different interferograms corresponding to different phases be taken simultaneously.[30,31] To obtain the phase-shifted interferogram, they have used polarization-based interferometers. The great disadvantage of these interferometers is their complexity. To measure the images these interferometers have to use several television cameras.

Heterodyne Interferometer

When the phase shift is made in a continuous manner rather than in steps, the frequency of the shifting beam is permanently modified, and a beating between the two interferometer beams is formed.[32]

The phase of the modulated or beating wave may be determined in many ways. One way is by electronic analog techniques, for example, using leading-edge detectors. Another way is by detecting when the irradiance passes through zero, that is, through the axis of symmetry of the irradiance function.

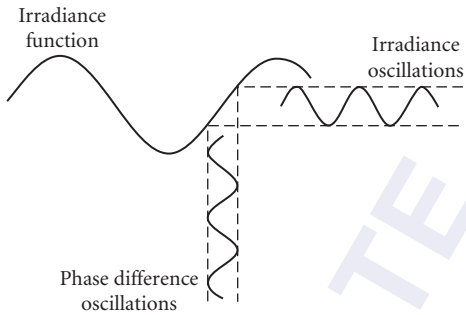

FIGURE 25 Phase-lock method to find the phase with a small sinusoidal modulation of the phase.

Phase Lock

The phase-lock method[31–35] can be explained with the help of Fig. 25. Assume that an additional phase difference is added to the initial phase $\varphi(x, y)$. The additional phase being added has two components: one of them with a fixed value and the other with a sinusoidal time shape. Both components can have any predetermined desired value. Thus, the resultant phase φ_r is given by

$$\phi_r = \phi(x, y) + \delta(x, y) + a\sin\omega t \tag{32}$$

then, the irradiance $I(x, y)$ would be given by

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos[\phi + \delta + a\sin\omega t] \tag{33}$$

The amplitude of the phase oscillations $a \sin t$ is much smaller than π. We may now adjust the fixed phase to a value such that $\varphi + \delta = \pi/2 + n\pi$. Then the value of cos $(\varphi + \delta)$ is zero. The curve is antisymmetric at this point; hence, only odd harmonics remain on the irradiance signal. This is done in practice by slowly changing the value of the phase δ, while maintaining the oscillation $a \sin \omega t$, until the maximum amplitude of the first harmonic, or fundamental frequency, is obtained. At this point, then, we have $\delta + \varphi = \pi/2 + n\pi$, and since the value of δ is known, the value φ has been determined.

13.8 MEASURING ASPHERICAL WAVEFRONTS

The most common type of interferometer, with the exception of lateral or rotational shearing interferometers, produces interference patterns in which the fringes are straight, equidistant, and parallel, when the wavefront under test is perfect and spherical with the same radius of curvature as the reference wavefront.

If the surface under test does not have a perfect shape, the fringes will not be straight and their separations will be variable. The deformations of the wavefront may be determined by a mathematical examination of the shape of the fringes. By introducing a small spherical curvature on the reference wavefront (focus shift) or by changing its angle with respect to the wavefront under test (tilt), the number of fringes in the interferogram may be changed. This is done to reduce the number of fringes as much as possible, since the greater the number of fringes, the smaller the sensitivity of the test. However, for aspherical surfaces this number of fringes cannot be smaller than a certain minimum. The larger the asphericity is, the greater is this minimum number of fringes. Since the fringe

separations are not constant, in some places the fringes will be widely spaced, but in some others the fringes will be too close together.

The sensitivity of the test depends on the separation between the fringes, because an error of one wavelength in the wavefront distorts the fringe shape by an amount equal to the separation between the fringes. Thus, the sensitivity is directly proportional to the fringe separation. When the fringes are widely separated, the sampled points will be quite separated from each other, leaving many zones without any information. On the other hand, where the fringes are very close to each other, there is a high density of sampled data points, but the sensitivity is low.

Then, it is desirable that the spherical aberration of the wavefront under test is compensated in some way, so that the fringes appear straight, parallel, and equidistant, for a perfect wavefront. This is called a null test and may be accomplished by means of some special configurations. These special configurations may be used to conduct a null test of a conic surface. These are described in several books.[1] Almost all of these surfaces have rotational symmetry.

If no testing configuration can be found to get rid of the spherical aberration, additional optical components, called null compensators, have to be used. Many different types of compensators have been invented. The compensators may be refractive (lenses), reflective (mirrors), or diffractive (real or computer-generated holograms).

Refractive or Reflective Compensators

The simplest way to compensate the spherical aberration of a paraboloid or a hyperboloid tested at the center of curvature is a single convergent lens placed near the point of convergence of the rays, as Fig. 26 shows. This lens is called a Dall compensator. Unfortunately, the correction due to a single lens is not complete, so a system of two lenses must be used to obtain a better compensation. This system is called an Offner compensator and is shown in Fig. 27. The field lens *L* is used to image the surface under test on the plane of the compensating lens *L*. Mirrors may also be used to design a null compensator.

As the sad experience of the Hubble space telescope proves, the construction parameters in a lens compensator have to be very carefully measured and adjusted, otherwise an imperfect correction is

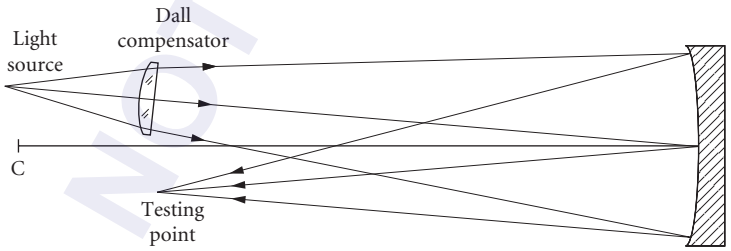

FIGURE 26 The Dall compensator.

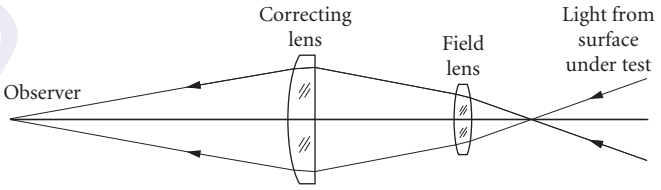

FIGURE 27 The Offner compensator. Only the reflected beam is shown.

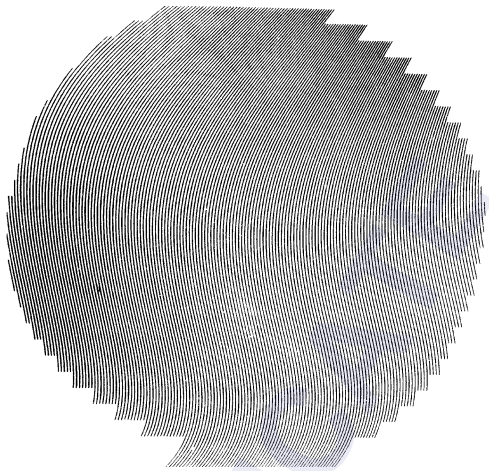

FIGURE 28 Computer-generated hologram for testing an aspherical wavefront. (*From Wyant.*[37])

obtained either by undercorrection or overcorrection. The distance from the compensator to the surface under test is one of those parameters to be carefully measured. A way around this problem would be to assume that the compensator detects smoothness imperfections but not the exact degree of asphericity. This degree of asphericity may then be measured with some independent measurement like the Hartmann test.

Holographic Compensators

Diffractive holographic elements also may be used to compensate the spherical aberration of the system and to obtain a null test. The hologram may be real, produced by photographing an interferometric pattern. This pattern has to be formed by superimposing on the screen a wavefront like the one we have to test and a perfectly flat or spherical wavefront. The only problem with this procedure is that a perfect wavefront with the same shape as the wavefront to be tested has first to be produced. This is not always easy.

A better approach is to simulate the holographic interference pattern in a computer,[36] as in Fig. 28. Then this image is transferred to a small photographic plate, with the desired dimensions. There are many experimental arrangements to compensate the aspherical wavefront aberration with a hologram. One of these is illustrated in Fig. 29.

Infrared Interferometry

Another simple approach to reduce the number of fringes in the interferogram is to use a long infrared wavelength. Light from a CO_2 laser has been used with this purpose. It can also be used when the surface is still quite rough.

Two-Wavelength Interferometry

In phase-shifting interferometry, each detector must have a phase difference smaller than π from the closest neighboring detector, in order to avoid 2π phase ambiguities and ensure phase continuity. In

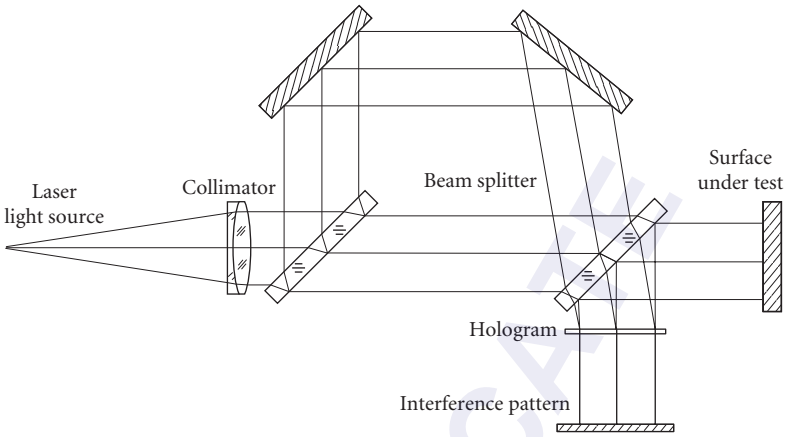

FIGURE 29 An optical arrangement for testing an aspherical wavefront with a computer-generated hologram.

other words, there should be at least two detector elements for each fringe. If the slope of the wavefront is very large, the fringes will be too close together and the number of detector elements would be extremely large.[37]

A solution to this problem is to use two different wavelengths λ_1 and λ_2 simultaneously. The group wavelength or equivalent wavelength λ_{eq} is longer than any of the two components and is given by

$$\lambda_{eq} = \frac{\lambda_1 \lambda_2}{|\lambda_1 - \lambda_2|} \tag{34}$$

Under these conditions, the requirement in order to avoid phase uncertainties is that there should be at least two detectors for each fringe produced if the wavelength is λ_{eq}. The great advantage of this method is that we may test wavefronts with large asphericities, limited in asphericity by the group wavelength, and accuracy limited by the shortest wavelength of the two components.

Moiré Tests

An interferogram in which a large amount of tilt has been introduced is an ideal periodic structure to form moiré patterns. A moiré pattern represents the difference between two periodic structures. Thus, a moiré formed by two interferograms represents the difference between the two interferograms. There are several possibilities for the use in optical testing of this technique, as shown by Patorski.[38]

Let us assume that the two interferograms are taken from the same optical system producing an aspherical wavefront, but with two different wavelengths λ_1 and λ_2. The moiré obtained represents the interferogram that would be obtained with an equivalent wavelength λ_{eq} given by Eq. (31). If the tilt is of different magnitude in the two interferograms, the difference appears as a tilt in the moiré between them. Strong aspheric wavefronts may be tested with this method.

A second possibility is to produce the moiré between the ideal interferogram for an aspheric wavefront and the actual wavefront. Any differences between both would be easily detected.

Another possibility of application is for eliminating the wavefront imperfections in a low-quality interferometer. One interferogram is taken with the interferometer alone, without any optical piece under test. The second interferogram is taken with the optical component being tested. The moiré

represents the wavefront deformations due to the piece being tested, without the interferometer imperfections.

Sub-Nyquist Interferometry

It was pointed out before that in phase-shifting interferometry each detector must have a phase difference smaller than π from the closest neighboring detector, in order to avoid 2π phase ambiguities and to ensure phase continuity. In other words, there should be at least two detector elements for each fringe. This condition is known as the Nyquist condition.

Since there is a minimum practical distance between detectors, the maximum asphericity in a surface to be tested by phase-shifting interferometry is only a few wavelengths. This condition may be relaxed[39] if the wavefront and its slope are assumed to be continuous on the whole aperture. Then, optical surfaces with larger asphericities may be tested.

Wavefront Stitching

When an aspheric and a flat reference wavefronts interfere, the fringe spacing is minimum where the angle between the two wavefronts is larger. When the aspheric wavefront has rotational symmetry and there is no angle between them (no tilt) near the optical axis, the minimum fringe spacing occurs at the edge of the pupil. The maximum fringe spacing is at the center, where the two wavefronts are parallel to each other.

Most times the fringe pattern is imaged on a CCD detector with a rectangular array of small square pixels. According to the Nyquist sampling conduction, the fringes can be detected only if the detector has more than two pixels per fringe spacing. With strongly aspheric wavefronts this condition can not be satisfied near the pupil edge.

If the flat reference wavefront is tilted or made slightly spherical, the zone of the interferogram with maximum fringe spacing can be located at any desired. Then the interferogram can be measured at a zone around this point with maximum fringe spacing where the Nyquist conduction is satisfied. By moving this point the whole interferogram can thus be measured in small pieces. Then, all pieces should be joined together in a process called wavefront stitching,[40] as illustrated in Fig. 30.

14.1 GLOSSARY

CGH	computer-generated hologram
M	linear, lateral magnification
N	diffracted order number
n	integers
P	number of distortion-free resolution points
r	radius
S	maximum wavefront slope (waves/radius)
$x, \Delta x$	distance
$\Delta\theta$	rotational angle error
$\Delta\phi$	wavefront phase error
θ	rotational angle
λ	wavelength
$\phi(\ )$	wavefront phase described by hologram

14.2 INTRODUCTION

Holography is extremely useful for the testing of optical components and systems. If a master optical component or optical system is available, a hologram can be made of the wavefront produced by the component or system and this stored wavefront can be used to perform null tests of similar

optical systems. If a master optical system is not available for making a hologram, a synthetic or a computer-generated hologram (CGH) can be made to provide the reference wavefront.[1–8] When an aspheric optical element with a large departure from a sphere is tested, a CGH can be combined with null optics to perform a null test.

There are several ways of thinking about CGHs. For the testing of aspheric surfaces, it is easiest to think of a CGH as a binary representation of the ideal interferogram that would be produced by interfering the reference wavefront with the wavefront produced by a perfect sphere. In the making of the CGH the entire interferometer should be ray traced to determine the so-called perfect aspheric wavefront at the hologram plane. This ray trace is essential because the aspheric wavefront will change as it propagates, and the interferometer components may change the shape of the perfect aspheric wavefront.

Figure 1 shows an example of a CGH. Since the amplitude of the aspheric wavefront is constant across the wavefront, best results are obtained if the lines making up the hologram have approximately one-half the spacing of the lines (i.e., fringe spacing) at the location of the lines. Thus, the line width will vary across the hologram. The major difference between the binary synthetic hologram

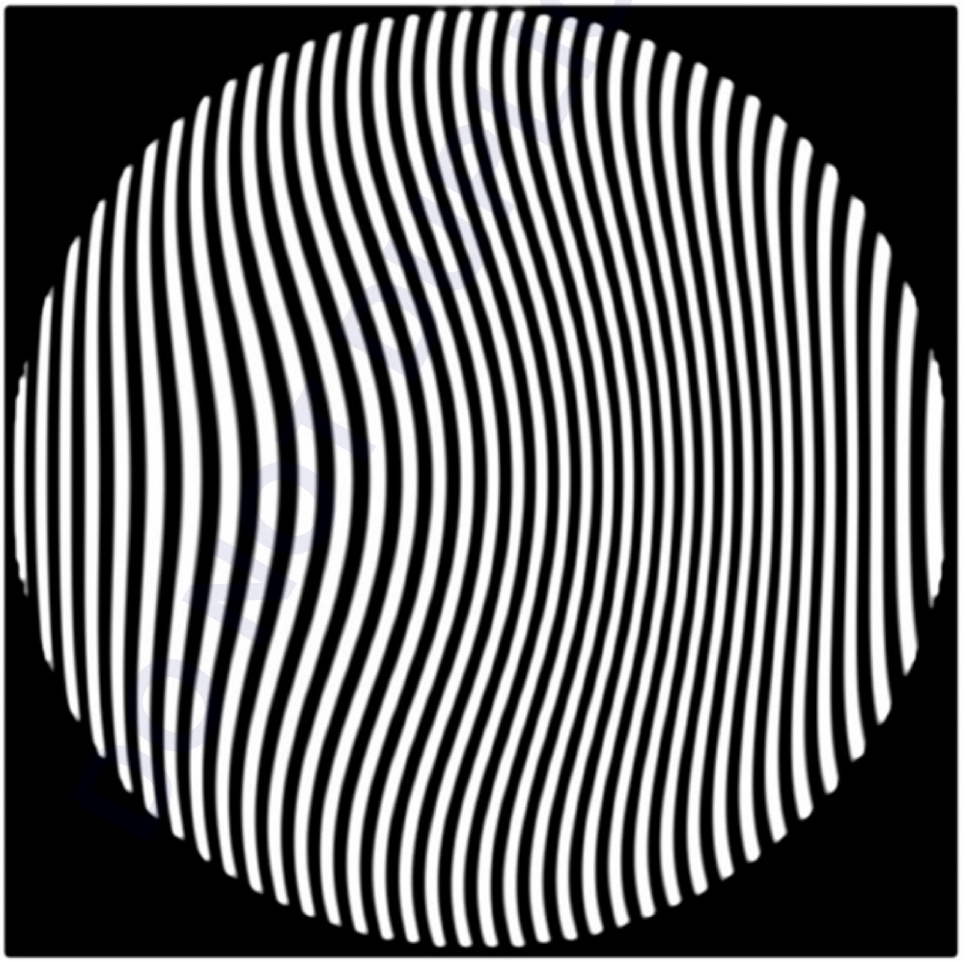

FIGURE 1 Sample computer-generated hologram (CGH).

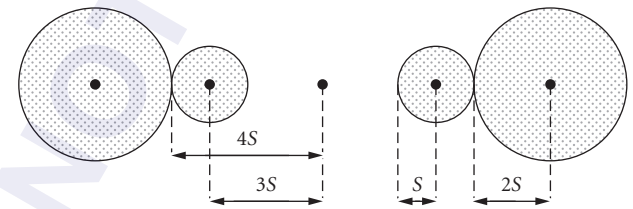
and the real grayscale hologram that would be produced by interfering a reference wavefront and the aspheric wavefront is that additional diffraction orders are produced. These additional diffraction orders can be eliminated by spatial filtering.

14.3 PLOTTING CGHs

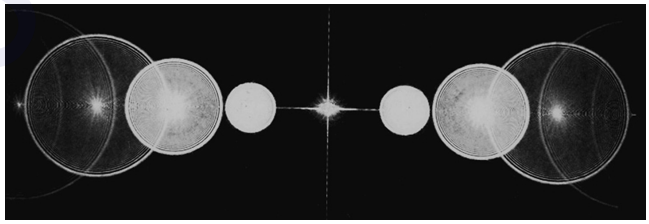
The largest problem in making CGHs is the plotting. The accuracy of the plot determines the accuracy of the wavefront. It is easier to see the plotting accuracy by comparing a binary synthetic hologram with an interferogram. In an interferogram, a wavefront error of $1/n$ waves causes a fringe to deviate from the ideal position by $1/n$ the fringe spacing. The same is true for CGHs. A plotting error of $1/n$ the fringe spacing will cause an error in the produced aspheric wavefront of $1/n$ wave. As an example, assume the error in drawing a line is 0.1 μm and the fringe spacing is 20 μm, then the wavefront produced by the CGH will have an error in units of wave of 0.1/20, or 1/200 wave.

To minimize wavefront error due to the plotter, the fringe spacing in the CGH should be as large as possible. The minimum fringe spacing is set by the slope difference between the aspheric wavefront and the reference wavefront used in the making of the synthetic hologram. While it is not mandatory, the interferogram is cleaner if the slope difference is large enough to separate the diffraction orders so spatial filtering can be used to select out only the first order. Figure 2 shows a photograph of the diffracted orders. As shown in Fig. 2, to ensure no overlapping of the first and second orders in the Fourier plane, the tilt angle of the reference beam needs to be greater than three times the maximum slope of the aberrated wave.[9] This means that, in general, the maximum slope difference between the reference and test beams is four times the maximum slope of the test beam. Thus, the error produced by plotter distortion is proportional to the slope of the aspheric wavefront being produced.

Many plotters have been used to plot holograms, but the best holograms are now made using either laser-beam recorders or more commonly electron-beam (e-beam) recorders of the type used for producing masks in the semiconductor industry.[10] The e-beam recorders write onto photoresist



(a)



(b)

FIGURE 2 Diffracted orders in Fourier plane of CGH: (*a*) drawing and (*b*) photograph.

deposited on an optical-quality glass plate and currently produce the highest-quality CGHs. Typical e-beam recorders will write areas larger than 100 mm × 100 mm with positional accuracies of less than 100 nm.[11]

If needed, plotter distortion can be measured and calibrated out in the making of the hologram.[12,13] The easiest way of determining plotter distortion is to draw straight lines and then treat this plot as a diffraction grating. If the computer-generated grating is illuminated with two plane waves, and the $-N$ order of beam 1 is interfaced with the $+N$ order of beam 2, the resulting interferogram gives us the plotter distortion. If the lines drawn by the plotter are spaced a distance Δx, a fringe error in the interferogram corresponds to a distortion error of $\Delta x/2N$ in the plot.

14.4 INTERFEROMETERS USING COMPUTER-GENERATED HOLOGRAMS

Many different experimental setups can be used for the holographic testing of optical elements. Figure 3 shows one common setup. The setup must be ray traced so the aberration in the hologram plane is known. While in theory there are many locations where the hologram can be placed, it is convenient to place the hologram in a plane conjugate to the asphere under test so the intensity across the image of the asphere is uniform. The longitudinal positional sensitivity for the hologram is reduced if the hologram is made in a region where the beams are collimated. Another advantage of this setup is that both the test and the reference beams pass through the hologram so errors resulting from hologram substrate thickness variations are eliminated without requiring the hologram be made on a good optical flat.

Another common setup for using a CGH to test aspheres is shown in Fig. 4.[14] The largest advantage of this setup is that it works well with commercial Fizeau interferometers. The only addition to the commercial interferometer is a mount to hold the CGH between the transmission sphere and the optics under test. Since the light is diffracted by the CGH twice, the CGH must be a phase

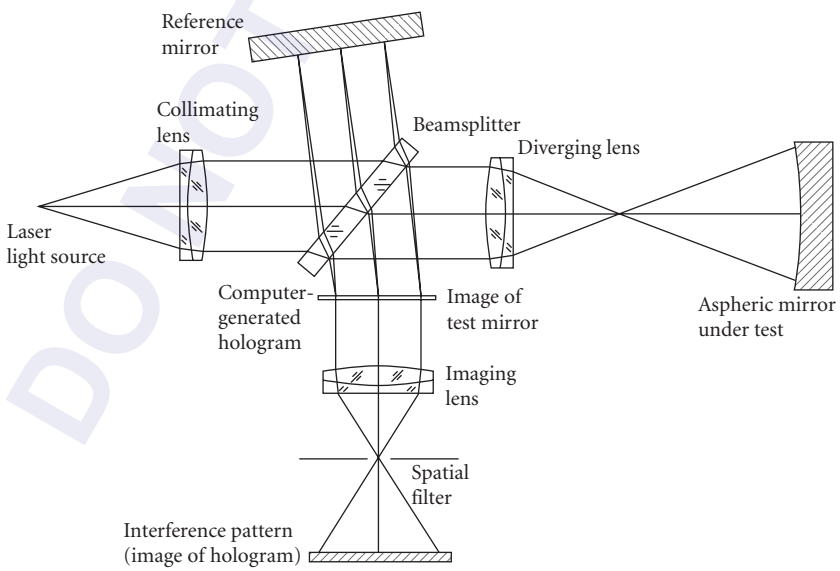


FIGURE 3 Interferometer setup using CGHs to test aspheric wavefronts.

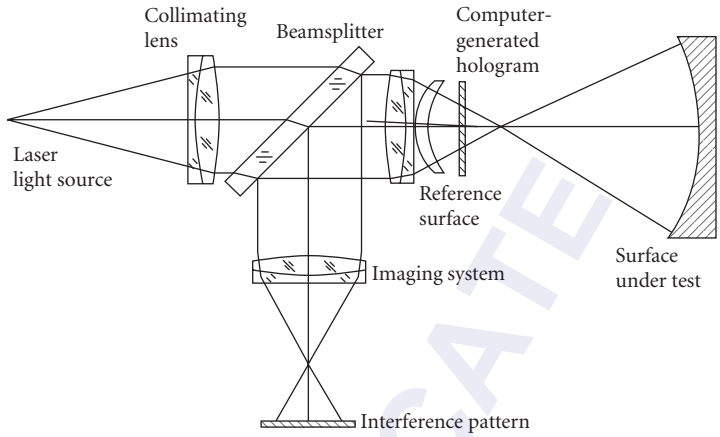

FIGURE 4 Use of CGH with Fizeau interferometer.

hologram so the diffraction efficiency is good, and since only the test beam is transmitted through the CGH, the substrate must either be high quality or thickness variations in the substrate must be measured and subtracted from the test results.

Figure 5 shows a setup for testing convex surfaces. In this case an on-axis CGH is used and the CGH is made on the concave reference surface.[15] The light waves are perpendicular to the concave reference surface and then after diffraction they become perpendicular to the surface under test. The CGH pattern may be drawn exposing photoresist, ablating a metallic coating, or by creating a thin oxidation layer by heating a metal coating with a focused laser beam.[16]

CGHs can also be combined with partial null optics to test much more complicated aspherics than can be practically tested with either a CGH or null optics. This combination gives the real power of computer-generated holograms.[17]

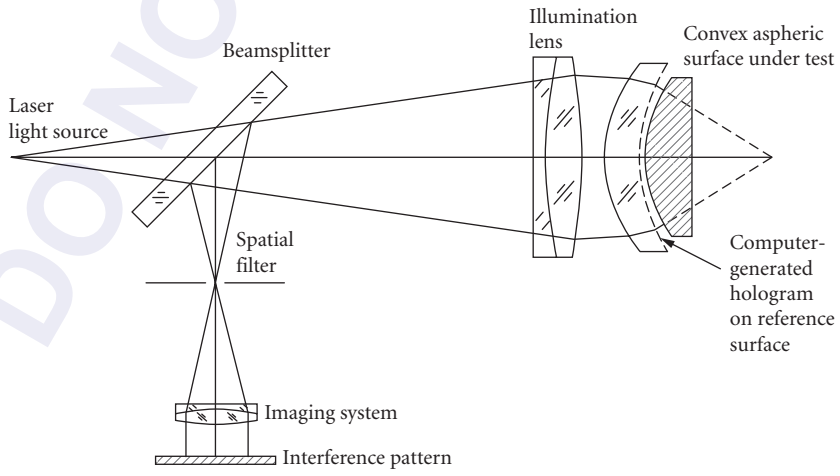

FIGURE 5 Using CGH to test convex surface.

14.5 ACCURACY LIMITATIONS

The largest source of error is the error due to plotter distortion as discussed previously. The other large sources of error are improper positioning of the hologram in the interferometer, and incorrect hologram size.

Any translation or rotation of the hologram produces error.[2] If the hologram is made conjugate to the exit pupil of the master optical system, the exit pupil of the system under test must coincide with the hologram. If the test wavefront in the hologram plane is described by the function $\phi(x, y)$, a displacement of the hologram a distance Δx in the x direction produces an error

$$\Delta\phi(x, y) \approx \frac{\partial\phi(x, y)}{\partial x}\Delta x \tag{1}$$

where $\partial\phi/\partial x$ is the slope of the wavefront in the x direction. Similarly, for a wavefront described by $\phi(r, \theta)$, the rotational error $\Delta\theta$ is given by

$$\Delta\phi(r, \theta) \approx \frac{\partial\phi(r, \theta)}{\partial\theta}\Delta\theta \tag{2}$$

Another source of error is incorrect hologram size. If the aberrated test wavefront in the plane of the hologram is given by $\phi(r, \theta)$, a hologram of incorrect size will be given by $\phi(r/M, \theta)$, where M is a magnification factor. The error due to incorrect hologram size will be given by the difference $\phi(r/M, \theta) - \phi(r, \theta)$, and can be written in terms of a Taylor expansion as

$$\begin{aligned}\phi\left(\frac{r}{M}, \theta\right) - \phi(r, \theta) &= \phi\left[r + \left(\frac{1}{M} - 1\right)r, \theta\right] - \phi(r, \theta) \\ &= \left[\frac{\partial\phi(r, \theta)}{\partial r}\right]\left(\frac{1}{M} - 1\right)r + \cdots\end{aligned} \tag{3}$$

where terms higher than first order can be neglected if M is sufficiently close to 1, and a small region is examined. Note that this error is similar to a radial shear. When the CGH is plotted, alignment aids, which can help in obtaining the proper hologram size, can be drawn on the hologram plot. Figure 6 shows a CGH where the hologram is made in the center of the substrate and alignment aids are placed on the outer portion of the CGH.[11] Not only can the alignment aids help in putting the CGH in the proper position, but they can be used to help position the optics being tested. Figure 7

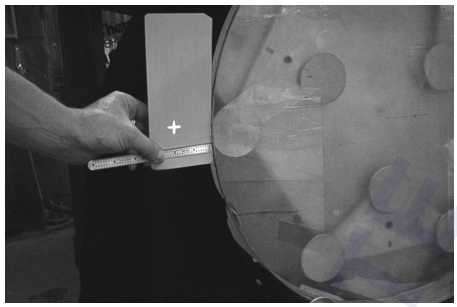

FIGURE 7 Use of crosshair produced by CGH to aid in the alignment of an off-axis parabola mirror.

shows a crosshair produced by a CGH that aids in the alignment of an off-axis parabolic mirror. The same CGH used to produce the crosshair produces the aspheric wavefront required to provide a null test of the off-axis parabola.[11]

14.6 EXPERIMENTAL RESULTS

Figure 8 shows the results of using the setup shown in Fig. 3 to measure a 10-cm-diameter F/2 parabola using a CGH generated with an e-beam recorder. The fringes obtained in a Twyman-Green interferometer using a helium-neon source without the CGH present are shown in Fig. 8*a.* After the CGH is placed in the interferometer, a much less complicated interferogram is obtained as shown in Fig. 8*b.* The CGH corrects for about 80 fringes of spherical aberration, and makes the test much easier to perform.

To illustrate the potential of a combined CGH/null-lens test, results for a CGH/null-lens test of the primary mirror of an eccentric Cassegrain system with a departure of approximately 455 waves (at 514.5 nm) and a maximum slope of approximately 1500 waves per radius are shown.[17] The mirror was a 69-cm diameter off-axis segment whose center lies 81 cm from the axis of symmetry of the parent aspheric surface. The null optics was a Maksutov sphere (as illustrated in Fig. 9), which reduces the departure and slope of the aspheric wavefront from 910 to 45 waves, and 300 to 70 waves per radius, respectively. A hologram was then used to remove the remaining asphericity.

Figure 10*a* shows interferograms of the mirror under test obtained using the CGH Maksutov test. Figure 10*b* shows the results when the same test was performed using a rather expensive refractive

FIGURE 10 Results obtained using Fig. 9: (*a*) CGH-Maksutov test (λ = 514.5 nm) and (*b*) using null lens (λ = 632.8 nm).

null lens. When allowance is made for the fact that the interferogram obtained with the null lens has much more distortion than the CGH Maksutov interferogram, and for the difference in sensitivity (λ = 632.8 nm for the null-lens test and 514.5 nm for the CGH-Maksutov test), the results for the two tests are seen to be very similar. The "hills" and "valleys" on the mirror surface appear the same for both tests, as expected. The peak-to-valley surface error measured using the null lens was 0.46 waves (632.8 nm), while for the CGH-Maksutov test it was 0.39 waves (514.5 nm). The rms surface error measured was 0.06 waves (632.8 nm) for the null lens, while the CGH Maksutov test gave 0.07 wave (514.5 nm). These results certainly demonstrate that expensive null optics can be replaced by a combination of relatively inexpensive null optics and a CGH.

14.7 DISCUSSION

The difficult problem of testing aspheric surfaces, which are becoming increasingly popular in optical design, is made easier by the use of CGHs. The technology has reached the point that commercial interferometers using computer-generated holograms are now available. The main problem with testing aspheric optical elements is reducing the aberration sufficiently to ensure that light gets back through the interferometer. Combinations of simple null optics with a CGH to perform a test enable the measurement of a wide variety of optical surfaces. The making and use of a CGH are analogous to using an interferometer setup that yields a large number of interference fringes, and measuring the interferogram at a large number of data points. Difficulties involved in recording and analyzing a high-density interferogram and making a CGH are very similar. In both cases, a large number of data points are necessary, and the interferometer must be ray traced so that the aberrations due to the interferometer are well known. The advantage of the CGH technique is that once the CGH is made, it can be used for testing a single piece of optics many times or for testing several identical optical components. Additional alignment aids can be placed on the CGH to aid in the alignment of the CGH and the optics under test.

15.1 GLOSSARY

λ	wavelength
$d\lambda$	differential wavelength
M_λ	spectral radiant exitance
T	absolute temperature
c_1	first radiation constant
c_2	second radiation constant
h	Planck's constant
c	velocity of light
k	Boltzmann constant
λ_{max}	wavelength at peak of radiant exitance
K	factor
R	radius of the interior surface of the cavity
r	radius of the aperture
S	interior surface area of the cavity
s	aperture area
ε	emissivity
ε_0	uncorrected emissivity

15.2 INTRODUCTION

Whereas most of the sources described in this chapter can be used for any purpose for which one can justify their use, the emphasis is on the production of the appropriate radiation for the calibration of measurement instrumentation. This implies that the basis for their use is supported by their

*Retired

traceabilities to calibrated standards of radiation from an internationally known and respected standards laboratory such as the National Institute of Standards and Technology (NIST) in the United States or, say, the National Physical Laboratory (NPL) in the United Kingdom. Because calibration implies a high degree of accuracy, the chapter initially contains a short exposition on the so-called Planckian, or blackbody radiation standard, and the equation which describes the Planck radiation.

This chapter deals with artificial sources of radiation as subdivided into two classes: laboratory and field sources. Much of the information on commercial sources is taken from a chapter previously written by the author.[1] Where it was feasible, similar information here has been updated. When vendors failed to comply to requests for information, the older data were retained to maintain completeness, but the reader should be aware that some sources cited here may no longer exist, or perhaps may not exist in the specification presented. Normally, laboratory sources are used in some standard capacity and field sources are used as targets. Both varieties appear to be limitless. Only laboratory sources are covered here.

The sources in this chapter were chosen arbitrarily, often depending on manufacturer response to requests for information. The purpose of this chapter is to consolidate much of this information to assist the optical-systems designer in making reasonable choices. To attempt to include the hundreds of types of lasers, however, and the thousands of varieties, would be useless for several reasons, but particularly because they change often.

Complementing the material in the following chapter on Lasers, a fairly comprehensive source of information on lasers can be found in the *CRC Handbook of Laser Science and Technology,* Supplement 1: published by the CRC Press, Inc., 2000 Corporate Blvd., N.W., Boca Raton, Florida, 33431. Of course, the literature is laden with material on lasers, including the chapter on Lasers in this *Handbook*, and the reader would be wise to consult the Internet from which compilations such as the one cited above or a host of others can be obtained from companies like Amazon.com, or, better yet, by accessing a literature-rich source such as Google.

Regarding the selection of a source, Worthing[2] suggests that one ask the following questions:

1. Does it supply energy at such a rate or in such an amount as to make measurements possible?
2. Does it yield an irradiation that is generally constant or that may be varied with time as desired?
3. Is it reproducible?
4. Does it yield irradiations of the desired magnitudes over areas of the desired extent?
5. Has it the desired spectral distribution?
6. Has it the necessary operating life?
7. Has it sufficient ruggedness for the proposed problem?
8. Is it sufficiently easy to obtain and replace, or is its purchase price or its construction cost reasonable?

15.3 RADIATION LAW

All of the radiation sources described in this chapter span the region of the electromagnetic spectrum mainly from the visible region (starting from about 400) through the infrared (around 400 μm and beyond). Given that they have a demonstrable temperature, they relate in their own peculiar ways, depending on material properties, to the radiation called "blackbody" radiation, which is described by the Planck radiation law. Many attempts were made in the latter part of the nineteenth century and the early twentieth century to describe blackbody radiation mathematically, all doomed to failure before the recognition of quantum concepts, in particular, by Max Planck. Any attempt to describe the mechanisms surrounding the Planck theory would be superfluous here. Suffice it to say that the basis for the theory can be explained from an examination of the experimental curve shown in Fig. 1 (borrowed from Richtmeyer and Kennard[3]) determined from the examination of the radiation from a "blackbody" at several different temperatures. By plotting the points one concludes, as shown on the graph, that the spectral radiant exitance, M_λ, is equal to the product of the negative fifth power of λ times some function of the product, λT, where λ is the wavelength (in micrometers) of the radiation and T is the absolute temperature of the radiator (in Kelvins). Confirmation of this fact is shown in Table 1. The radiant exitance values in the table were calculated

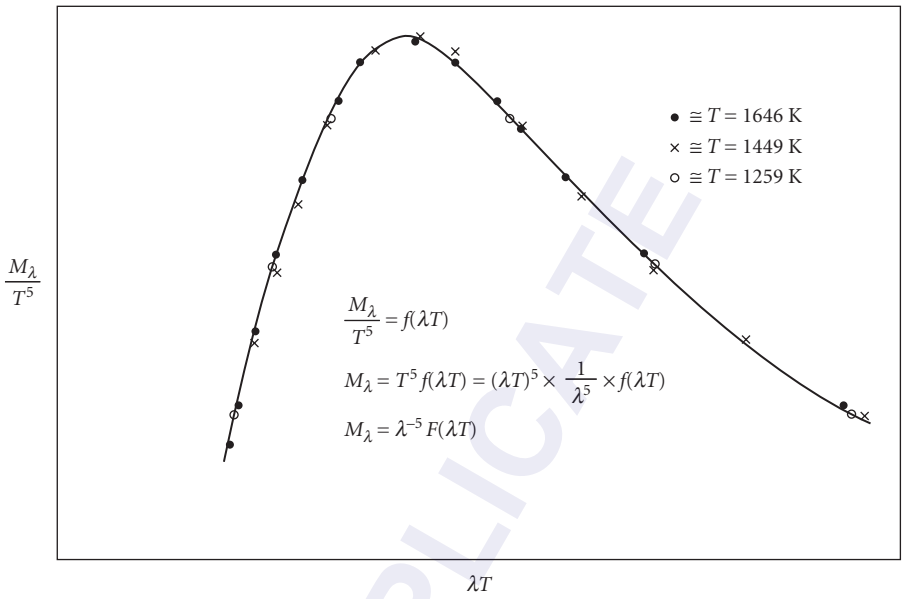

FIGURE 1 Experimental verification of the blackbody displacement law.

T = deg Kelvin; λ = μm; M_λ = radiant exitance; W-cm^{-2}-ster^{-1}-μm^{-1}

using the Infrared Radiance Calculator created by the author and found by choosing the term "Calculators" from the Military Sensing Information Analysis Center (SENSIAC) in a search of the Internet under www.sensiac.gatech.edu.

Postulating the quantum nature of the radiation, Planck, in a clever demonstration of the entropies resulting from small and large values of λT, was able to establish an expression for blackbody radiation as

$$M_\lambda(\lambda)d\lambda = c_1\lambda^{-5}(e^{c_2/\lambda T} - 1)^{-1}d\lambda$$

where

$$c_1 = 2\pi hc^2 = 3.7413 \times 10^4 \text{ W-cm}^{-2}\text{-}\mu\text{m}^4 \text{ (first radiation constant)}$$

and

$$c_2 = hc/k = 14388 \ \mu\text{m-K (second radiation constant)}$$

h = Planck's constant = 6.6252×10^{-34} W-s^2
k = Boltzmann constant = 1.38042×10^{-23} W-s-K^{-1}
c = Velocity of light = 2.99793×10^{10}-s^{-1}

He later established the same equation from first principles.

When the Planck function is plotted on log-log paper the graph of Fig. 2 results. The special feature of this type of plot is that, regardless of the temperature of the blackbody, the shape of the curve is constant. It merely moves up and to the left (i.e., toward shorter wavelengths) as the temperature increases. The straight line, with a slope of −5, drawn through the set of curves of Fig. 2, depicts the

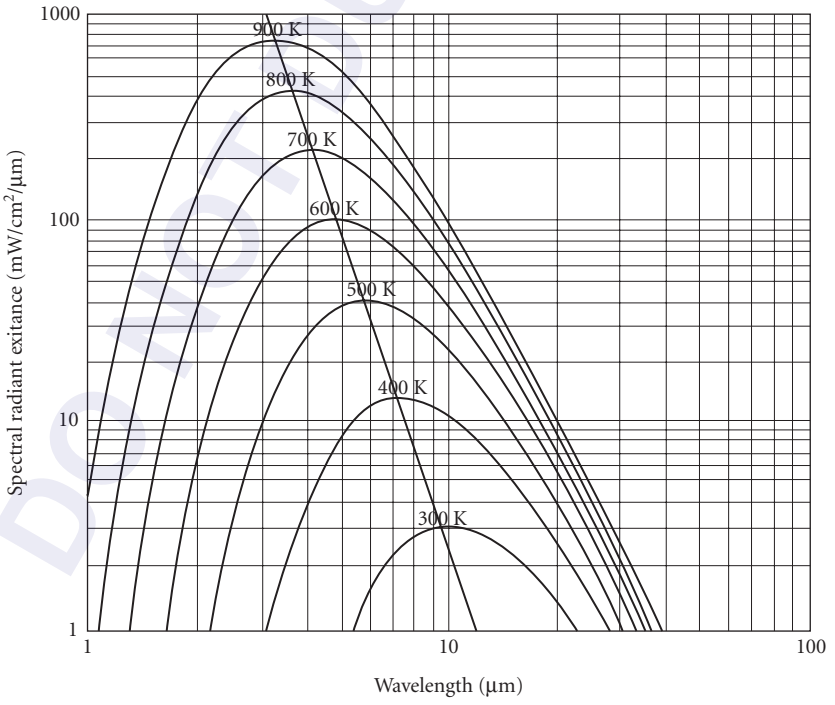

FIGURE 2 Spectral radiant exitance versus wavelength.

wavelength at which each one peaks, resulting in what is known as the Wein displacement law given for a specific temperature by

$$\lambda_{\max} T = 2897.9\ \mu\text{m}-\text{K}^{-1}$$

Thus the peak of any Planck curve can be determined, given the temperature of the blackbody.

15.4 LABORATORY SOURCES

Standard Sources

The reader may be interested in the exposition by Quinn[4] on the calculation of the emissivity of cylindrical cavities in which the method of DeVos[5] is used. In a more recent paper Irani[6] refers to the method of Gouffé[7] for the construction of blackbody calibration sources. Quinn states that for certain constructions there are errors in the method of Gouffé. However, for a well-constructed source the shape of the construction is least at fault, since any heat-resistant material with a reasonably high surface emissivity will produce a resultant emissivity of better than 0.99. However, the accuracy of the value of the radiation for a given temperature depends not only on the emissivity but on generally high numerical powers of the temperature especially for high-temperature blackbodies. Therefore, very small variations of temperature over the inner surface of the source can cause relatively large errors in the radiation accuracy. Thus, great caution is used in creating a uniform temperature, resulting in the use of the fixed-point temperatures of various metals for the most basic and accurate calibration standards.

Blackbody Cavity Theory Radiation levels can be standardized by the use of a source that will emit a quantity of radiation that is both reproducible and predictable. Cavity configurations can be produced to yield radiation theoretically sufficiently close to Planckian that it is necessary only to determine what the imprecision is. Several theories have been expounded over the years to calculate the quality of a blackbody simulator.*

The Method of Gouffé.[7] For the total emissivity of the cavity forming a blackbody (disregarding temperature variations) Gouffé gives

$$\varepsilon_0 = \varepsilon_0'(1+K) \tag{1}$$

where

$$\varepsilon_0' = \frac{\varepsilon}{\varepsilon\left(1-\dfrac{s}{S}\right)+\dfrac{s}{S}} \tag{2}$$

and $K = (1-\varepsilon)[(s/S)-(s/S_0)]$, and is always nearly zero—it can be either positive or negative.

ε = emissivity of materials forming the blackbody surface
s = area of aperture
S = area of interior surface
S_0 = surface of a sphere of the same depth as the cavity in the direction normal to the aperture

Figure 3 is a graph for determining the emissivities of cavities with simple geometric shapes. In the lower section, the value of the ratio s/S is given as a function of the ratio $1/r$. (Note the scale

*Generically used to describe those sources designed to produce radiation that is nearly Planckian.

change at the value for $1/r = 5$.) The values of ε_0' is found by reading up from this value of the intrinsic emissivity of the cavity material. The emissivity of the cavity is found by multiplying ε_0' by the factor $(1 + K)$.

When the aperture diameter is smaller than the interior diameter of the cylindrical cavity, or the base diameter of a conical cavity, it is necessary to multiply the value of s/S determined from the graph by $(r/R)^2$, which is the ratio of the squares of the aperture and cavity radii (Fig. 3).

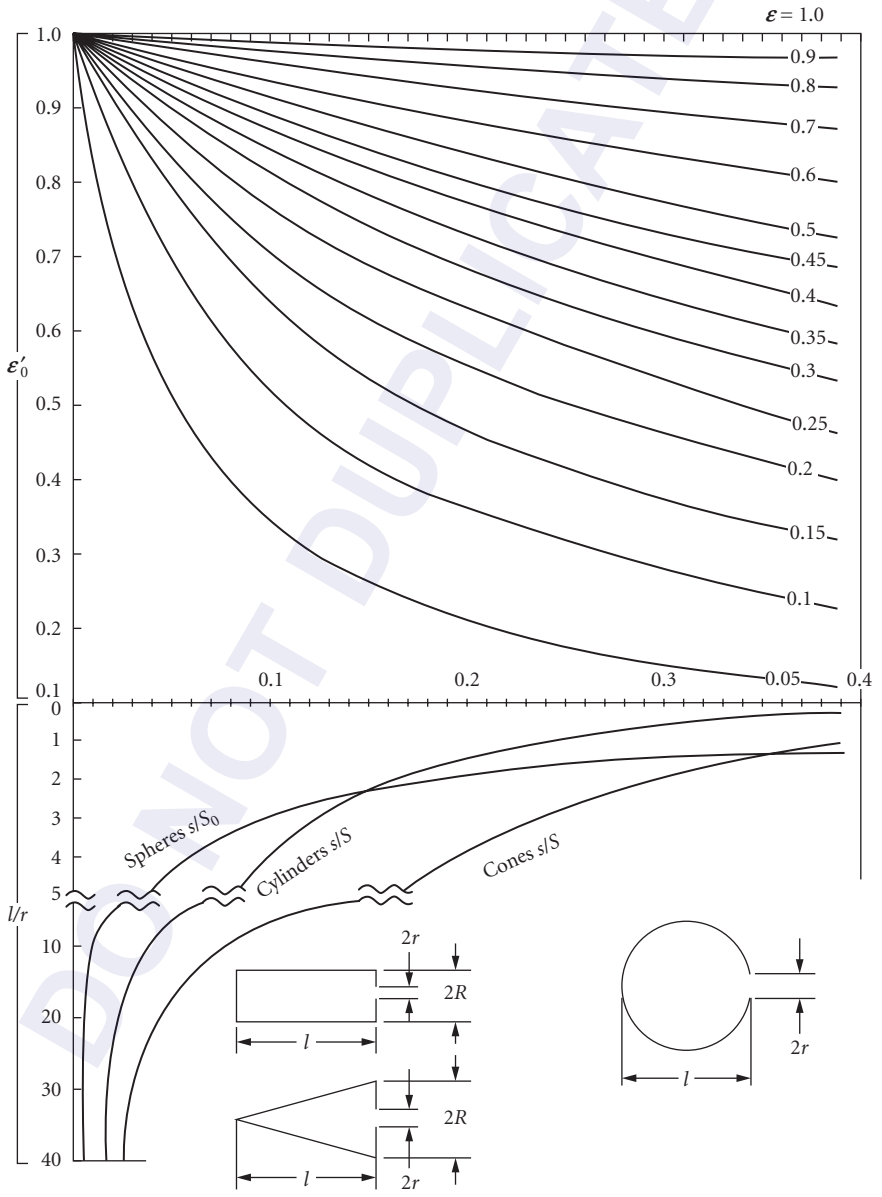

FIGURE 3 Emissivities of conical, spherical, and cylindrical cavities.

It is important to be aware of the effect of temperature gradients in a cavity. This factor is the most important in determining the quality of a blackbody, since it is not very difficult to achieve emissivities as near to unity as desired.

Manufacturers of blackbody simulators strive to achieve uniform heating of the cavity because it is only under this condition that the radiation is Planckian. The ultimate determination of a radiator that is to be used as the standard is the quality of the radiation that it emits.

A recent investigation on comparison of IR radiators is presented by Leupin et al.[8] There has been, incidentally, a division historically between the standards of photometry and those used to establish thermal radiation and the thermodynamic temperature scale. Thus, in photometry the standard has changed from the use of candles, the Carcel lamp, the Harcourt pentane lamp, and the Hefner lamp[9] to more modern radiators.

Baseline Standard of Radiation Although there is no internationally accepted standard of radiation, the National Institute of Standards and Technology (NIST) uses as its substitute standard the goldpoint blackbody (see Fig. 4),[10] which fixes one point on the international temperature scale, now reported to be 1337.33 + 0.34 K. Starting from this point, NIST is able to transfer fixed radiation values to working standards of radiation through an accurately constructed variable-temperature radiator as shown in Fig. 5.[11]

The goldpoint blackbody is shown mainly for information. It is quite feasible to build a replica of the variable-temperature radiator, especially in the laboratory equipped to do fundamental radiation measurements.

Working Standards of Radiation For the calibration of instruments in the ordinary laboratory, the user is likely to use a source which is traceable to NIST, and generally supplied by NIST or one of the recognized vendors of calibrated sources, mainly in the form of a heated filament, a gaseous arc enclosed in an envelope of glass or quartz (or fused silica), or in glass with a quartz or sapphire window.

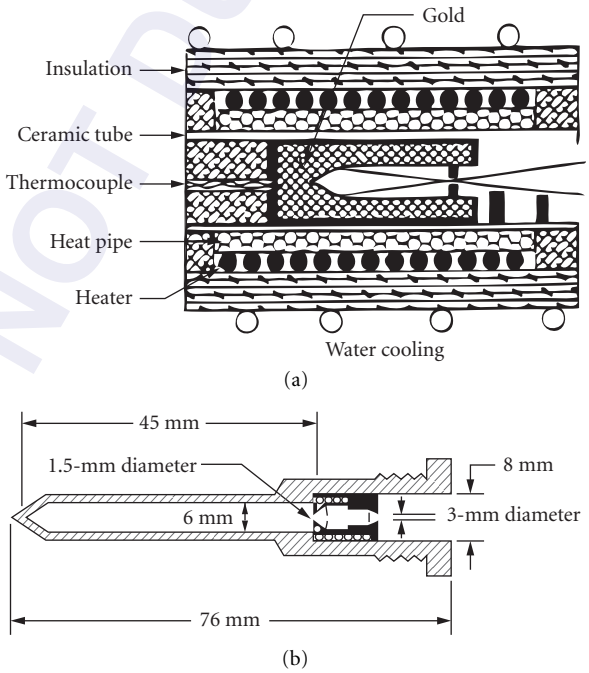

FIGURE 4 (*a*) Cross section of heat-pipe blackbody furnace. (*b*) Blackbody inner cavity dimensions.

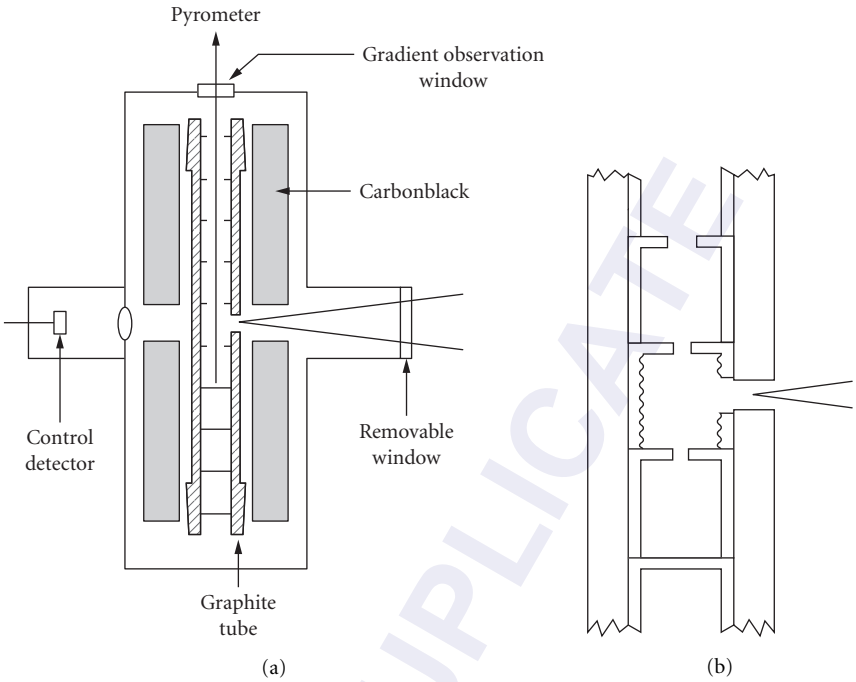

FIGURE 5 (*a*) Variable-temperature blackbody schematic. (*b*) Central section of variable-temperature blackbody.

Any source whose radiation deviates from that described by Planck's law is nonblackbody. Even the sources previously described are not strictly blackbodies, but can come as close as the user desires within the constraints of bulk and price. Any other source has an emissivity less than unity and can, and usually does, have a highly variable spectral emissivity. The lamps used by NIST, for example (see the following), fit into this category, but they differ in one large respect. They are transfer standards which have been carefully determined to emit specified radiation within certain specific spectral regions.

The following discussion of these types of sources is reproduced (in some cases with slight modifications), with permission, from the NIST Special Publication 250.[12] For specific details of calibration, and for the exact source designations, the user should contact NIST at

Photometric Standards

The following text on working standards is left untouched from the presentation of the earlier edition of the *Handbook* because there do not appear to be significant changes since the publication of that material. However, to the extent that information on the Internet is current, a reasonable complement to the information published in this chapter would be a search of the Internet at the location designated www.physics.nist.gov. The reader will find numerous features of the National Institute of Science and Technology from which to choose the service or other information required.

Luminous Flux Standard (Miniature Lamps 7 sizes 6 to 400 lm)
Airway Beacon Lamps for Color Temperature (500-W, 1 point in range, 2000 to 3000 K)

2. General Information

Calibration services provide access to the photometric scales realized and maintained at NIST. Lamp standards of luminous intensity, luminous flux, and color temperature, as described next, are calibrated on a routine basis.

a. Luminous Intensity Standards

Luminous intensity standard lamps supplied by NIST [100-W (90–140 cd), 500-W (approximately 700 cd), and 1000-W (approximately 1400 cd) tungsten filament lamps with C-13B filaments in inside-frosted bulbs and having medium bipost bases] are calibrated at either a set current or a specified color temperature in the range 2700 to 3000 K. Approximate 3-sigma uncertainties are 1 percent relative to the SI unit of luminous intensity and 0.8 percent relative to NIST standards.

b. Luminous Flux Standards

Vacuum tungsten lamps of 25 W and 60-, 100-, 200-, and 500-W gas-filled tungsten lamps that are submitted by customers are calibrated. Lamps must be base-up burning and rated at 120 V. Approximate 3-sigma uncertainties are 1.4 percent relative to SI units and 1.2 relative to NIST standards. Luminous flux standards for miniature lamps producing 6 to 400 lm are calibrated with uncertainties of about 2 percent.

c. Airway Beacon Lamps

Color temperature standard lamps supplied by NIST (airway beacon 500-W meduim bipost lamps) are calibrated for color temperature in the range 2000 to 3000 K with 3-sigma uncertainties ranging from 10 to 15°.

IR Radiometric Standards

General Information

a. Spectral Radiance Ribbon Filament Lamps

These spectral radiance standards are supplied by NIST. Tungsten, ribbon filament lamps (30A/T24/13) are provided as lamp standards of spectral radiance. The lamps are calibrated at 34 wavelengths from 225 to 2400 nm, with a target area 0.6 mm wide by 0.8 mm high. Radiance temperature ranges from 2650 K at 225 nm and 2475 K at 650 nm to 1610 K at 2400 nm, with corresponding uncertainties of 2, 0.6, and 0.4 percent. For spectral radiance lamps, errors are stated as the quadrature sum of individual uncertainties at the three standard deviation level.

Figure 6 summarizes the measurement uncertainty for NIST spectral radiance calibrations.

b. Spectral Irradiance Lamps

These spectral irradiance standards are supplied by NIST. Lamp standards of spectral irradiance are provided in two forms. Tungsten filament, 1000 W quartz halogen-type FEL lamps are calibrated at 31 wavelengths in the range 250 to 2400 nm. At the working distance of 50 cm, the

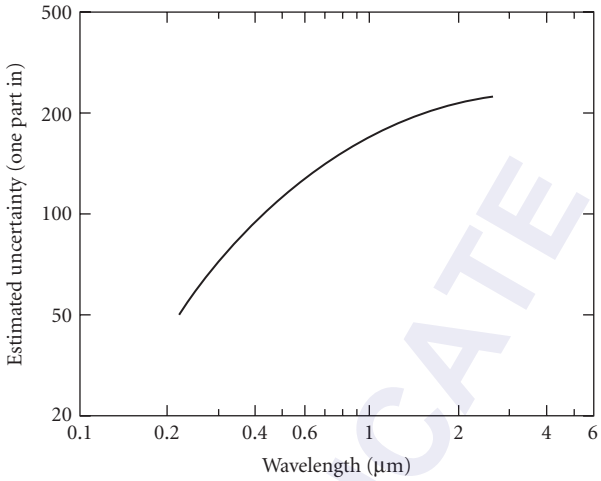

FIGURE 6 Uncertainties for NIST spectral radiance calibrations.

lamps produce 0.2 W/cm^2/cm at 250 nm, 220 W/cm^2/cm at 900 nm, 115 W/cm^2/cm at 1600 nm, and 40 W/cm^2/cm at 2400 nm, with corresponding uncertainties of 2.2, 1.3, 1.9, and 6.5 percent. For spectral irradiance lamps, errors are stated as the quadrature sum of individual uncertainties at the three standard deviation level. Deuterium lamp standards of spectral irradiance are also provided and are calibrated at 16 wavelengths from 200 to 350 nm. At the working distance of 50 cm, the spectral irradiance produced by the lamp ranges from about 0.5 W/cm^2/cm at 200 nm and 0.3 W/cm^2/cm at 250 nm to 0.07 W/cm^2/cm at 350 nm. The deuterium lamps are intended primarily for the spectral region 200 to 250 nm. The approximate uncertainty relative to SI units is 7.5 percent at 200 nm and 5 percent at 250 nm. The approximate uncertainty in relative spectral distribution is 3 percent. It is strongly recommended that the deuterium standards be compared to an FEL tungsten standard over the range 250 to 300 nm each time the deuterium lamp is lighted to take advantage of the accuracy of the relative spectral distribution.

Figure 7 summarizes the measurement uncertainty for NIST spectral irradiance calibrations of type FEL lamps.

Radiometric Sources in the Far Ultraviolet

1. Sources
Spectral Irradiance Standard, Argon Mini-Arc (140 to 330 nm)
Spectral Radiance Standard, Argon Mini-Arc (115 to 330 nm)
Spectral Irradiance Standard, Deuterium Arc Lamp (165 to 200 nm)

2. General Information
a. Source Calibrations in the Ultraviolet

NIST maintains a collection of secondary sources such as argon maxi-arcs, argon mini-arcs, and deuterium arc lamps in the near and vacuum ultraviolet radiometric standards program to provide calibrations for user-supplied sources. The calibrations of these sources are traceable to a hydrogen arc whose radiance is calculable and which NIST maintains as a primary standard. The collection also includes tungsten strip lamps and tungsten halogen lamps whose calibrations are based on a blackbody rather than a hydrogen arc. Customer-supplied sources are calibrated in both radiance and irradiance by comparing them with NIST secondary standards.

Argon arcs are used to calibrate other sources in the wavelength range 115 to 330 nm for radiance and 140 to 330 nm for irradiance. The lower wavelength limit is determined in radiance by the cutoff of the magnesium fluoride windows used in the arcs, and in irradiance by the decrease

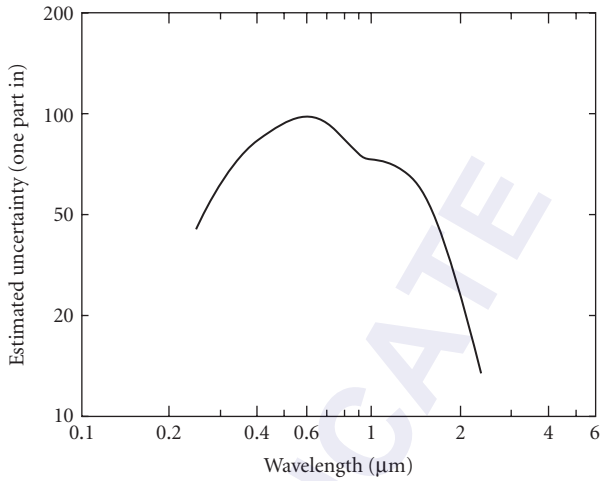

FIGURE 7 Uncertainties for NIST spectral irradiance calibrations of type FEL lamps.

in signal produced by the addition of a diffuser. Deuterium arc lamps are used in the range 165 to 200 nm, with the low wavelength cutoff due to the onset of blended molecular lines.

The high wavelength limit is the starting point of the range for the Radiometric Standards group. The tungsten lamps are used at 250 nm and above, since their signals are too weak at shorter wavelengths. It should be noted that the wavelength range of the NIST arcs partially overlap the range of tungsten lamps, thus providing an independent check on calibrations.

An argon mini-arc lamp supplied by the customer is calibrated for spectral irradiance at 10-nm intervals in the wavelength region 140 to 300 nm. Absolute values are obtained by comparison of the radiative output with laboratory standards of both spectral irradiance and spectral radiance. The spectral irradiance measurement is made at a distance of 50 cm from the field stop. Uncertainties are estimated to be less than ±10 percent in the wavelength region 140 to 200 nm and within ±5 percent in the wavelength region 200 to 330 nm. A measurement of the spectral transmission of the lamp window is included in order that the calibration be independent of possible window deterioration or damage. The uncertainties are taken to be two standard deviations.

The spectral radiance of argon mini-arc radiation sources is determined to within an uncertainty of less than 7 percent over the wavelength range 140 to 330 nm and 20 percent over the wavelength range 115 to 140 nm. The calibrated area of the 4-mm diameter radiation source is the central 0.3-mm diameter region. Typical values of the spectral radiance are: at 250 nm, L(A) = 30 mW/cm^2/nm/sr; and at 150 nm, $L(\lambda)$ = 3 mW/cm^2/nm/sr. The transmission of the demountable lamp window and that of an additional MgF_2 window are determined individually so that the user may check periodically for possible long-term variations.

The deuterium arc lamp is calibrated at 10 wavelengths from 165 to 200 nm, at a distance of 50 cm, at a spectral irradiance of about 0.5 W/cm^2/cm at 165 nm, 0.5 W/cm^2/cm at 170 nm, and 0.5 W/cm^2/cm at 200 nm. The approximate uncertainty relative to SI units is estimated to be less than 10 percent. The lamp is normally supplied by NIST and requires 300 mA at about 100 V.

15.5 COMMERCIAL SOURCES

The commercial sources described here are derived from the 1995 edition of *The Handbook of Optics*, which were taken from catalogs available at the time and from the literature of the day and prior thereto, providing choices that have obviously been available for years. Evidently changes in

the makeup of these products are slower than those of other areas of technology, making it reasonable to retain the same sources in this chapter, mainly as examples of the types that are available. With the universality of the Internet, accessibility of information on various sources of radiation, far beyond what is attainable from a limited collection of company catalogs, is at one's fingertips. Thus, it is recommended that, in seeking information on various sources, one use the examples in the text as a reference to what can be found currently on the Internet. Experience demonstrates that, in many cases, due to the stability of the lamp industry, there will be few changes between what is found currently on the Internet and what appears in the text of this chapter.

Obviously the choice of a source is dependent on the application. Many, if not most of the sources described are multipurpose ones, although most of them have been selected specifically for scientific study, tailored in a way to produce an image amenable to different optical systems. For basic research it is usually essential to have a blackbody source, especially for infrared research, that is traceable to a Standards Laboratory, along with traceable secondary standards for calibrating research instrumentation. Many of the sources can be used to produce spectra, which are capable of calibrating spectral measuring instrumentation. Other sources are included mostly to provide the user with an array of choices.

Blackbody Simulators

Virtually any cavity can be used to produce radiation of high quality, but practicality limits the shapes to a few. The most popular shapes are cones and cylinders, the former being more popular. Spheres, combinations of shapes, and even flat-plate radiators are used occasionally. Blackbodies can be bought rather inexpensively, but there is a fairly direct correlation between cost and quality (i.e., the higher the cost the better the quality).

Few manufacturers specialize in blackbody construction. Some, whose products are specifically described here, have been specializing in blackbody construction for many years. Other companies of this description may be found, for example, in the latest *Lasers and Optronics Buying Guide*[13] or the latest *Photonics Directory of Optical Industries*.[14] These references are the latest as of the writing of this work. It is expected that they will continue in succeeding years.

A large selection of standard (or blackbody) radiators is offered by Electro-Optical Industries, Inc. (EOI), Santa Barbara, California.* Most blackbodies can be characterized as one of the following: primary, secondary, or working standard. The output of the primary must, of course, be checked with those standards retained at NIST. Figure 8 pictures an EOI blackbody and its controller. Figure 9 pictures a similar blackbody from Mikron, Inc. and its controller. All of the companies sell separate apertures (some of which are water cooled) for controlling the radiation output of the radiators. Another piece of auxiliary equipment which can be purchased is a multispeed chopper. It is impossible to cite all of the companies that sell these kinds of sources; therefore, the reader is referred to one of the buyers' guides already referenced for a relatively complete list. It is prudent to shop around for the source that suits one's own purpose.

Figure 10 demonstrates a less conventional working standard manufactured by EOI. Its grooves-and-honeycomb structure is designed to improve the absorptance of such a large and open structure. A coating with a good absorbing paint increases its absorptance further.

Incandescent Nongaseous Sources (Exclusive of High-Temperature Blackbodies)

Nernst Glower† The Nernst glower is usually constructed in the form of a cylindrical rod or tube from refractory materials (usually zirconia, yttria, beria, and thoria) in various sizes. Platinum leads at the ends of the tube conduct power to the glower from the source. Since the resistivity of

*Many of the sources in the text are portrayed using certain specific company products, only for the sake of demonstration. This does not necessarily imply an endorsement of these products by the author. The reader is encouraged in all cases to consult the *Photonics Directory of Optical Industries*[14] or a similar directory for competitive products.

†Since Nernst glower is probably obsolete, this section is retained only for historical purpose.

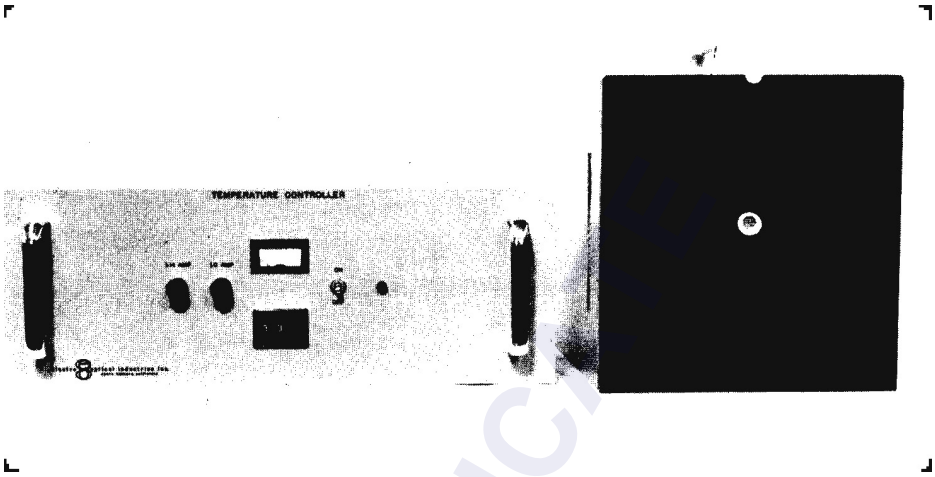

FIGURE 8 EOI blackbody.

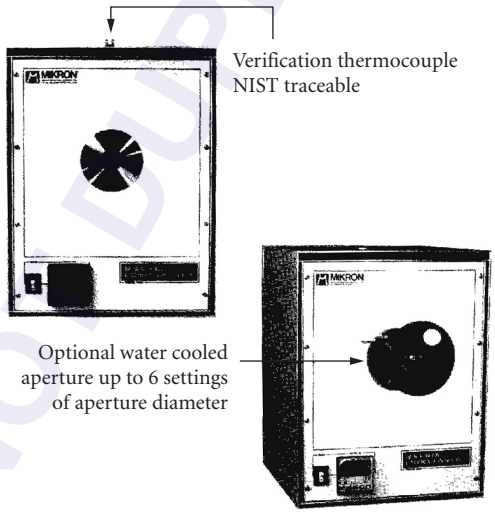

FIGURE 9 Mikron blackbody.

the material at room temperature is quite high, the working voltage is insufficient to get the glower started. Once started, its negative temperature coefficient-of-resistance tends to increase current, which would cause its destruction, so that a ballast is required in the circuit. Starting is effected by applying external heat, either with a flame or an adjacent electrically heated wire, until the glower begins to radiate.

Data from a typical glower are as follows:

1. Power requirements: 117 V, 50 to 60 A, 200 W
2. Color temperature range: 1500 to 1950 K
3. Dimension: 0.05-in. diameter by 0.3 in.

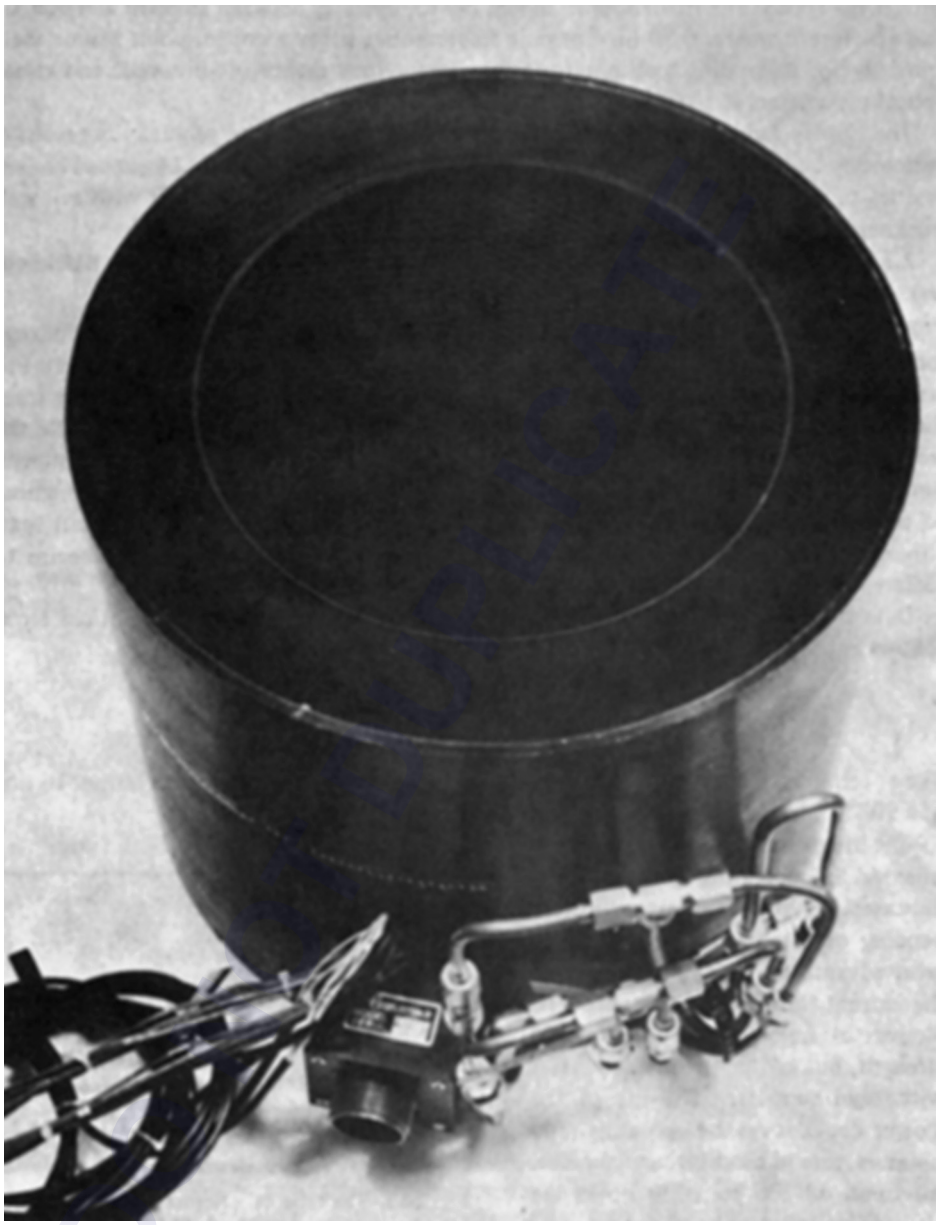

FIGURE 10 EOI model 1965. This model is 12 in. in diameter and 9 in. deep. The base is an array of intersecting conical cavities. The walls are hex-honeycomb and the temperature range is 175 to 340 K.

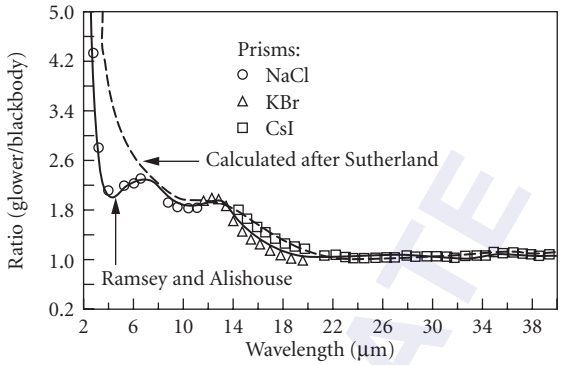

FIGURE 11 The ratio of a Nernst glower to a 900°C blackbody versus wavelength.

The spectral characteristics of a Nernst glower in terms of the ratio of its output to that of a 900°C blackbody are shown in Fig. 11.

The life of the Nernst glower diminishes as the operating temperature is increased. Beyond a certain point, depending on the particular glower, no great advantage is gained by increasing the current through the element. The glower is fragile, with low tensile strength, but can be maintained intact with rigid support. The life of the glower depends on the operating temperature, care in handling, and the like. Lifetimes of 200 to 1000 hours are claimed by various manufacturers.

Since the Nernst glower is made in the form of a long thin cylinder, it is particularly useful for illuminating spectrometer slits. Its useful spectral range is from the visible region to almost 30 μm, although its usefulness compared with other sources diminishes beyond about 15 μm. As a rough estimate, the radiance of a glower is nearly that of a graybody at the operating temperature with an emissivity in excess of 75 percent, especially below about 15 μm. The relatively low cost of the glower makes it a desirable source of moderate radiant power for optical uses in the laboratory. The makers of spectroscopic equipment constitute the usual source of supply of glowers (or of information about suppliers).

Globar The globar is a rod of bonded silicon carbide usually capped with metallic caps which serve as electrodes for the conduction of current through the globar from the power source. The passage of current causes the globar to heat, yielding radiation at a temperature above 1000°C. A flow of water through the housing that contains the rod is needed to cool the electrodes (usually silver). This complexity makes the globar less convenient to use than the Nernst glower and necessarily more expensive. This source can be obtained already mounted, from a number of manufacturers of spectroscopic equipment. Feedback in the controlled power source makes it possible to obtain high radiation output.

Ramsey and Alishouse[15] provide information on a particular sample globar as follows:

1. Power consumption: 200 W, 6 A
2. Color temperature: 1470 K

They also provide the spectral characteristics of the globar in terms of the ratio of its output to that of a 900°C blackbody. This ratio is plotted as a function of wavelength in Fig. 12. Figure 13[16] is a representation of the spectral emissivity of a globar as a function of wavelength. The emissivity values are only representative and can be expected to change considerably with use.

Gas Mantle The Welsbach mantle is typified by the kind found in high-intensity gasoline lamps used where electricity is not available. The mantle is composed of thorium oxide with some additive

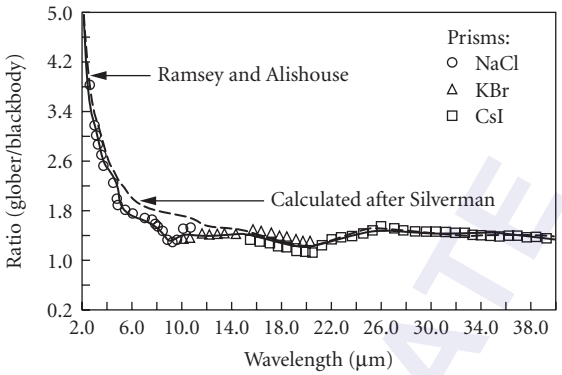

FIGURE 12 The ratio of a globar to a 900°C blackbody versus wavelength.

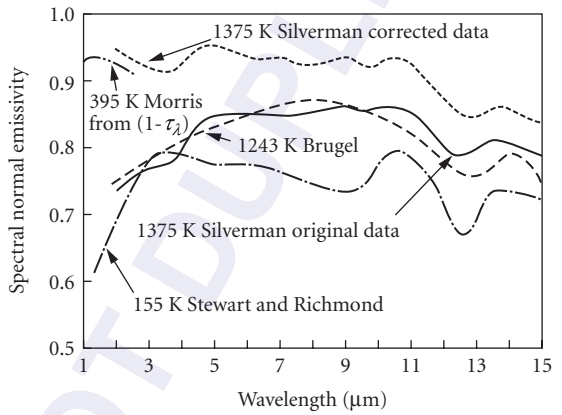

FIGURE 13 The spectral emissivity of a globar.

to increase its efficiency in the visible region. Its near-infrared emissivity is quite small, except for regions exemplified by gaseous emission, but increases considerably beyond 10 μm.

Ramsey and Alishouse[15] provide information on a propane-heated sample from an experiment in which a comparison of several sources is made:

1. Color temperature: 1670 K
2. Dimensions: 25.4 by 38.1 mm

The spectral characteristics of the mantle in terms of the ratio of its output to that of a 900°C blackbody are shown in Fig. 14.

Pfund modified the gas mantle so that it became more a laboratory experimental source than an ordinary radiator. By playing a gas flame on an electrically heated mantle, he was able to increase its radiation over that from the gas mantle itself.[17] Figure 15 shows a comparison of the gas mantle and the electrically heated gas mantle, with a Nernst glower. Strong[18] points out that playing a flame against the mantle at an angle produces an elongated area of intense radiation useful for illuminating the slits of a spectrometer.

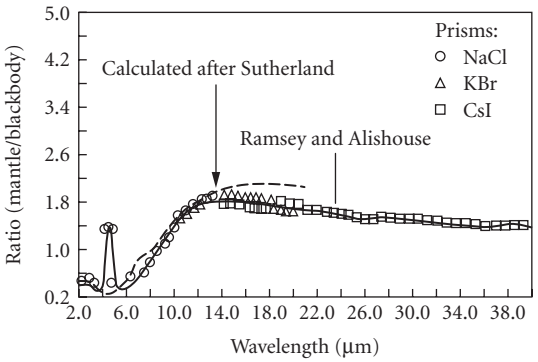

FIGURE 14 The ratio of the gas mantle to a 900°C blackbody versus wavelength.

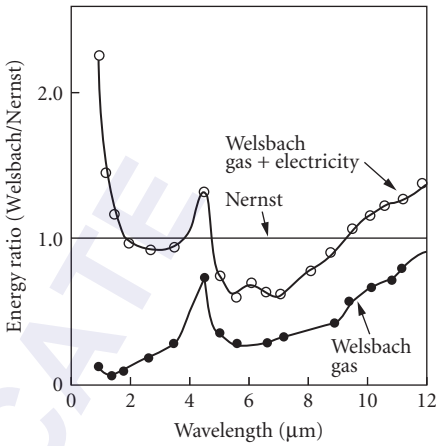

FIGURE 15 Emission relative to that of a Nernst glower (2240 K) of the gas-heated mantle (lower curve) and that of the mantle heated by gap plus electricity (upper curve).

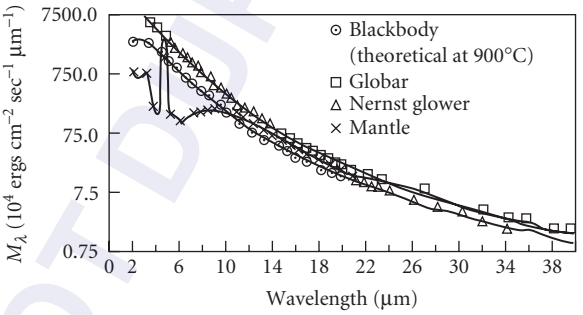

FIGURE 16 The spectral radiant emittances of a globar, Nernst glower, 900°C blackbody, and gas mantle versus wavelength.

Comparison of Nernst Glower, Globar, and Gas Mantle Figure 16 compares these three types of sources, omitting a consideration of differences in the instrumentation used in making measurements of the radiation from the sources.

Availability, convenience, and cost usually influence a choice of sources. At the very long wavelength regions in the infrared, the gas mantle and the globar have a slight edge over the Nernst glower because the Nernst glower (a convenient, small, and inexpensive source) does not have the power of the gas mantle and globar.

Tungsten-Filament Lamps A comprehensive discussion of tungsten-filament lamps is given by Carlson and Clark.[19] Figures 17 to 19 show the configurations of lamp housings and filaments. The types and variations of lamps are too numerous to be meaningfully included in this chapter. The reader is referred to one of the buyer's guides for a comprehensive delineation of manufacturers from whom unlimited literature can be obtained.

Tungsten lamps have been designed for a variety of applications; few lamps are directed toward scientific research, but some bear directly or indirectly on scientific pursuits insofar as they can

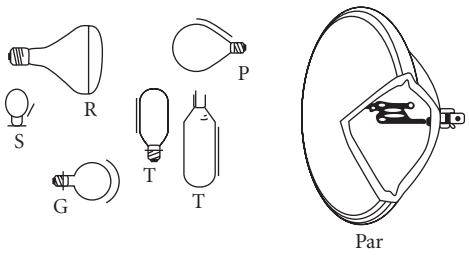

FIGURE 17 Bulk shapes most frequently used for lamps in optical devices. Letter designations are for particular shapes.

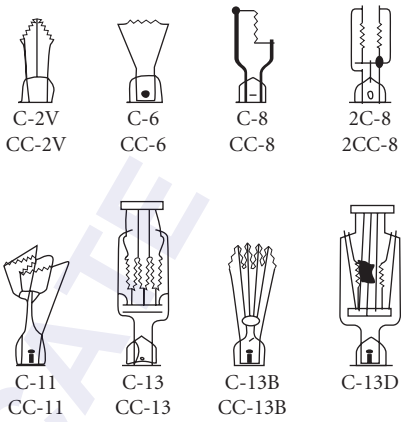

FIGURE 18 Most commonly used filament forms. Letters designate the type of filament.

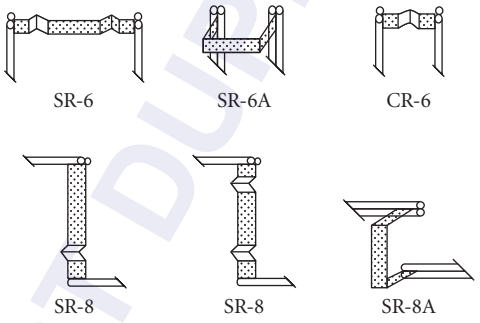

FIGURE 19 Ribbon-type tungsten filaments. Type designations are by number.

provide steady sources of numerous types of radiation. One set of sources cited here, particularly for what the manufacturer calls their scientific usefulness, is described in *Lamps for Scientific Purposes*.[20] Their filament structures are similar to those already described, but their designs reduce extraneous radiation and ensure the quality and stability of the desired radiation. The lamps can be obtained with a certification of their calibration values.

The physical descriptions of some of these sources are given in Fig. 20. Applications (according to the manufacturer, Osram) are photometry, pyrometry, optical radiometry, sensitometry, spectroscopy, spectrometry, polarimetry, saccharimetry, spectrophotometry, colorimetry, microscopy, microphotography, microprojection, and stroboscopy.

Quartz Envelope Lamps These are particularly useful as standards because they are longer lasting (due to action of iodine in the quartz-iodine series), can be heated to higher temperatures, are sturdier, and can transmit radiation to longer wavelengths in the infrared than glass-envelope lamps. Studer and Van Beers[21] have shown the spectral deviation to be expected of lamps containing no iodine. The deviation, when known, is readily acceptable in lieu of the degradation in the lamp caused by the absence of iodine. The particular tungsten-quartz-iodine lamps used in accordance

Lamps for scientific purposes are gas-filled, incandescent lamps for calibration of luminous intensity, luminous flux, luminance (spectral radiant temperature), color temperature (luminance temperature and spectral radiance distribution). A test certificate can be issued for these types of lamps.

Also for other types of lamp with sufficiently constant electric and photometric data, a test certificate can be issued. To order a test certificate, the order reference of the lamp, the type of measurement, and the desired burning position have to be given. Example: Lamp 41/G, measurement of the electric data and the luminous intensity for T_f = 2856 K (light type A), burning position vertical, base up.

Variables for which test certificates can be issued are shown in the following table by +. The sigh (+) indicates that certificates can be issued for variables although the lamps were not designed for such measurements.

Description

WI 9:
Lamp with uncoiled straight filament.

WI 14:
Tungsten ribbon lamp with tubular bulb. The portion of the tungsten ribbon to be utilized for measurement is mounted parallel to the lamp axis and positioned approx. 8 mm off-axis in the measuring direction.

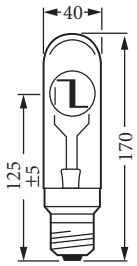
* The color temperature of 2856 K corresponds with light-type A (DIN 5035).
† *s* = vertical (base down): *h* = vertical (base up).
‡ Only for additional measurement of luminance or color temperature.

FIGURE 20*a* Lamps for scientific purposes. (Note dimensions in mm.)

with the NIST are described earlier in this chapter. Others can be obtained in a variety of sizes and wattages from General Electric, Sylvania, and a variety of other lamp manufacturers and secondary sources.

Carbon Arc

The carbon arc has been passed down from early lighting applications in three forms: low-intensity arc, flame, and high-intensity arc. The low- and high-intensity arcs are usually operated on direct



WI 16/G:
Tungsten ribbon lamp with spherical bulb. Horizontal tungsten ribbon with a small notch to indicate the measuring point. The ribbon is positioned approx. 3 mm off-axis.

WI 17/G:
Tungsten ribbon lamp with horn-shaped bulb. The bulb has a tubular extension with a sealed-on quartz glass window (homogenized ultrasil). Vertical tungsten ribbon with a small notch to indicate the measuring point.

WI 40/G:
Standard lamp for total radiation, luminous flux, and color temperatures with conic bulb. The bulb shape prevents reflections in the direction of the plane normal of the luminous area, which is formed by the meandrous-shaped filament.

WI 41/G:
Standard lamp for light intensity and color temperature with conic bulb. Differs from the WI 40/G lamp by a black, opaque coating which covers one side of the bulb. A window is left open in the coating opposite the filament, through which over an angle of approx. ±3° a constant light intensity is emitted. The black coating prevents stray light being reflected in the measuring direction.

current; the flame type adapts to either direct or alternating current. In all cases, a ballast must be used. In the alternating current arc, the combined radiation from the two terminals is less than that from the positive crater of the direct-current arc of the same wattage.[22]

Spatial variation in the amount of light energy across the crater of dc arcs for different currents is shown in Fig. 21.

The carbon arc is a good example of an open arc, widely used because of its very high radiation and color temperatures (from approximately 3800 to 6500 K, or higher). The rate at which the material is consumed and expended during burning (5 to 30 cm/h) depends on the intensity of the arc. The arc is discharged between two electrodes that are moved to compensate for the rate of consumption of the material. The anode forms a crater of decomposing material which provides a center of very high luminosity. Some electrodes are hollowed out and filled with a softer carbon material which helps keep the arc fixed in the anode and prevents it from wandering on the anode surface.

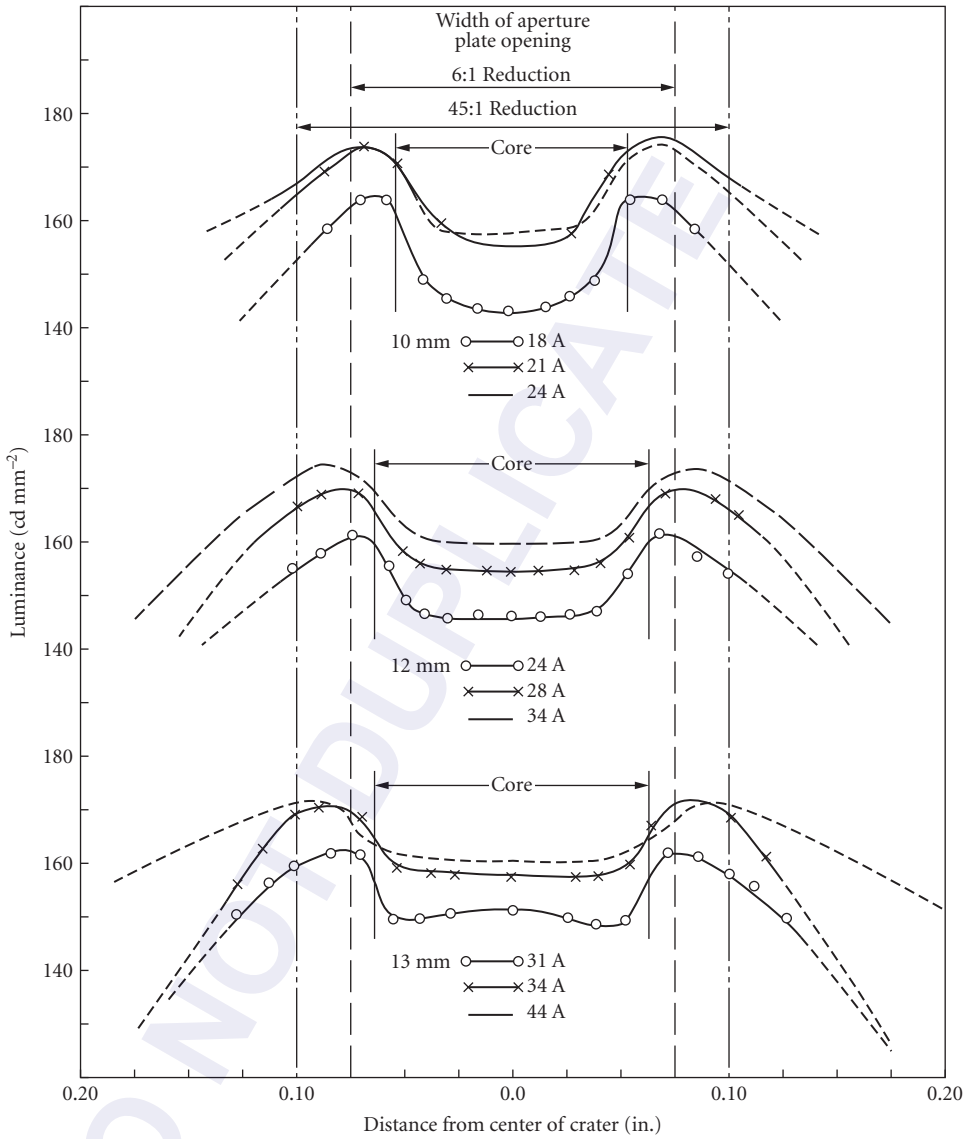

FIGURE 21 Variations in brightness across the craters of 10-, 12-, and 13-mm positive carbons of dc plain arcs operated at different currents in the regions of recommended operation.

In some cored electrodes, the center is filled with whatever material is needed to produce desired spectral characteristics in the arc. In such devices, the flame between the electrodes becomes the important center of luminosity, and color temperatures reach values as high as 8000 K.[22] An example of this so-called flaming arc is shown in Fig. 22*a*. Figure 22*b* and *c* shows the low-intensity dc carbon arc and the high-intensity dc carbon arc with rotating positive electrodes. Tables 2 and 3 give characteristics of dc high-intensity and flame carbon arcs.

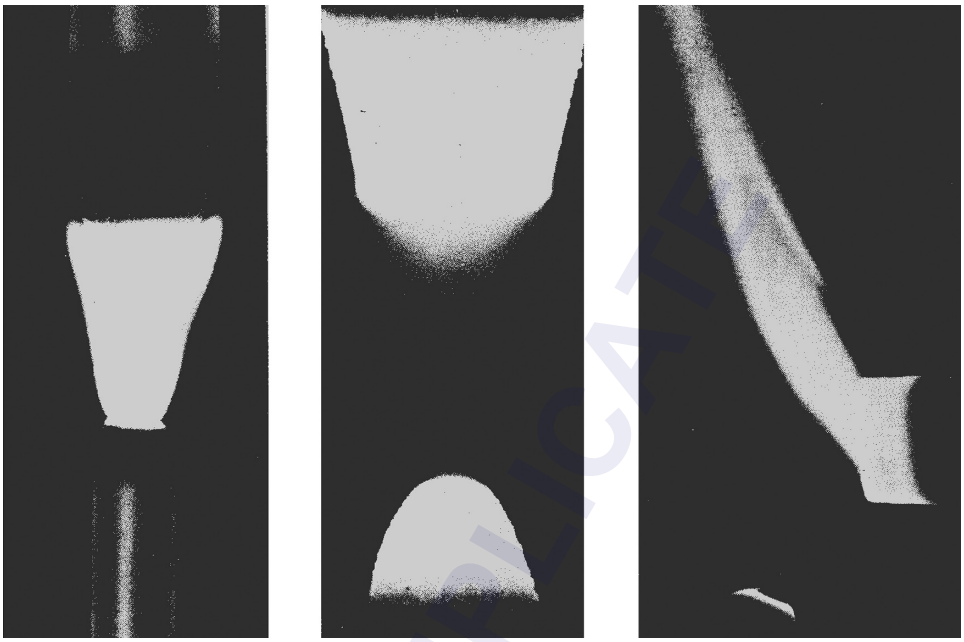

FIGURE 22 Various types of carbon arc: (*a*) flame type; (*b*) low-intensity dc arc; and (*c*) high-intensity dc arc with rotating positive carbon.

A spectrum of low-intensity arc (Fig. 23) shows the similarity between the radiation from it and a 3800-K blackbody, except for the band structure at 0.25 and 0.39 μm. In Koller[22] an assortment of spectra are given for cored carbons containing different materials. Those for a core of soft carbon and for a polymetallic core are shown in Figs. 24 and 25. Because radiation emitted from the carbon arc is very intense, this arc supplants, for many applications, sources which radiate at lower temperatures. Among the disadvantages in using the carbon arc are its inconvenience relative to the use of other sources (e.g., lamps) and its relative instability. However, Null and Lozier[23] have studied the properties of the low-intensity carbon arc extensively and have found that under the proper operating conditions the carbon arc can be made quite stable; in fact, in their treatise they recommend its use as a standard of radiation at high temperatures.

Enclosed Arc and Discharge Sources (High-Pressure)

Koller[22] states that the carbon arc is generally desired if a high intensity is required from a single unit but that it is less efficient than the mercury arc. Other disadvantages are the short life of the carbon with respect to mercury, and combustion products which may be undesirable. Worthing[2] describes a number of the older, enclosed, metallic arc sources, many of which can be built in the laboratory for laboratory use. Today, however, it is rarely necessary to build one's own source unless it is highly specialized.

The Infrared Handbook[1] compiles a large number of these types of sources, some of which will be repeated here, in case that publication would not be currently available to the reader. However, the reader should take caution that many changes might have occurred in the characteristics of these sources and in the supplier whose product is preferred. Consultation with the Photonics Directory (see preceding) is usually a good procedure. In some cases a certain type of source described previously

may not still exist. Thus, whereas some manufacturers were less compliant in providing data, they should be expected to respond more readily to a potential customer.

Uviarc* This lamp is an efficient radiator of ultraviolet radiation. The energy distribution of one type is given in Fig. 26. Since the pressure of this mercury-vapor lamp is intermediate between the usual high- and the low-pressure lamps, little background (or continuum) radiation

*Registered trademark of General Electric.

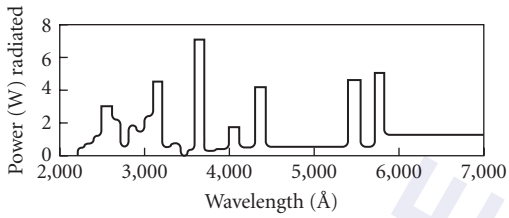

FIGURE 26 Intensity distribution of UA-2 intermediate-pressure lamp.

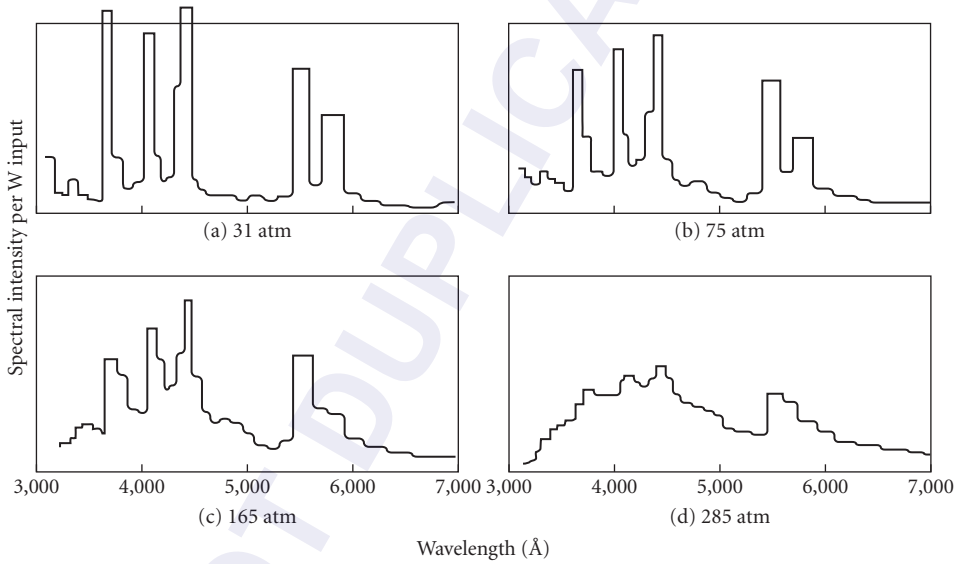

FIGURE 27 Emission spectrum of high-pressure mercury-arc lamps showing continuum background.

is present. In the truly high-pressure lamp, considerable continuum radiation results from greater molecular interaction. Figure 27[24] shows the dependence on pressure of the amount of continuum in mercury lamps of differing pressure. Bulb shapes and sizes are shown in Fig. 28.

Mercury Arcs A widely used type of high-pressure, mercury-arc lamp and the components necessary for its successful operation are shown in Fig. 29. The coiled tungsten cathode is coated with a rare-earth material (e.g., thorium). The auxiliary electrode is used to help in starting. A high resistance limits the starting current. Once the arc is started, the operating current is limited by ballast supplied by the high reactance of the power transformer. Spectral data for clear, 400-W mercury lamps of this type are given in Fig. 30.

Multivapor Arcs In these lamps, argon and mercury provide the starting action. Then sodium iodide, thallium iodide, and indium iodide vaporize and dissociate to yield the bulk of the lamp radiation. The physical appearance is like that of mercury lamps of the same general nature. Ballasts are similar to their counterparts for the mercury lamp. Up-to-date information on these sources should be obtained from the General Electric Corporation Lamp Division in Nela Park near Cleveland, Ohio. Spectral features of these sources are given in Fig. 31.

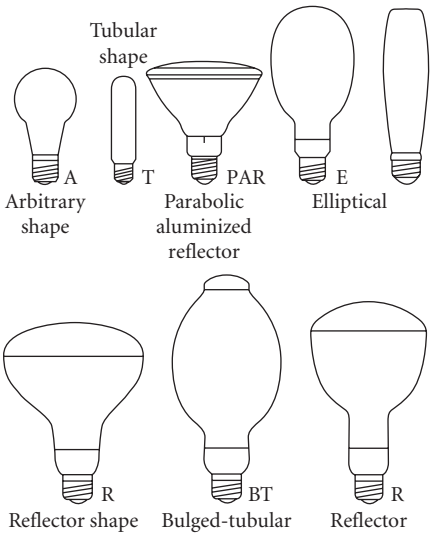

FIGURE 28 Bulb shapes and sizes (not to scale).

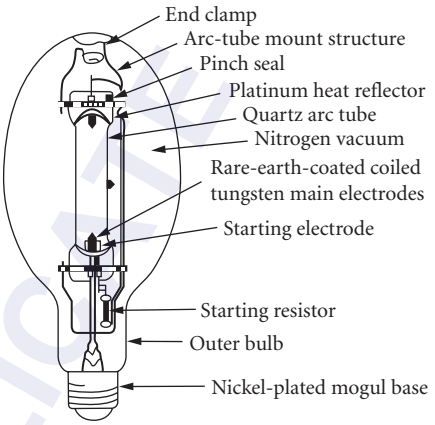

FIGURE 29 High-pressure mercury lamp showing various components.

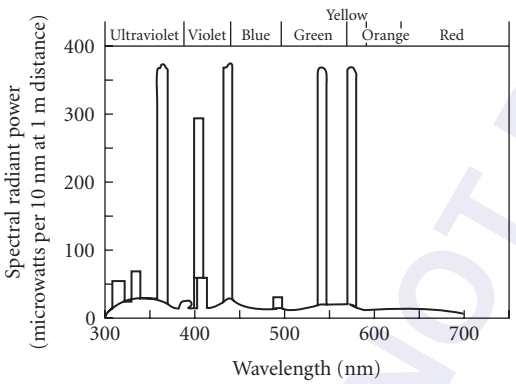

FIGURE 30 Spectral energy distribution for clear mercury-arc lamp.

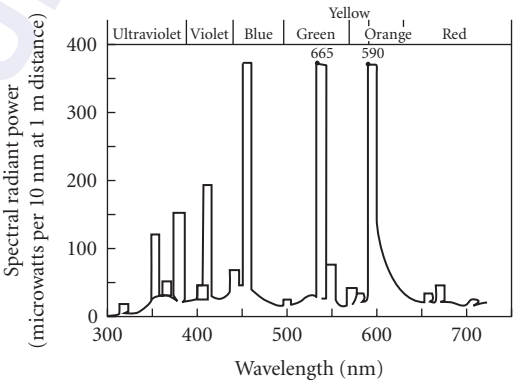

FIGURE 31 Spectral energy distribution of multivapor-arc lamp.

Lucalox®* Lamps The chief characteristics of this lamp are high-pressure sodium discharge and a high temperature withstanding ceramic, Lucalox (translucent aluminum oxide), to yield performance typified in the spectral output of the 400-W Lucalox lamp shown in Fig. 32. Ballasts for this lamp are described in the General Electric *Bulletin TP-109R*.[25]

Capillary Mercury-Arc Lamps[22] As the pressure of the arc increases, cooling is required to avoid catastrophic effects on the tube. The AH6 tube (Fig. 33) is constructed with a quartz bulb wall and a quartz outer jacket, to allow 2800 K radiation to pass, or a Pyrex®† outer jacket to eliminate ultraviolet. Pure water is forced through at a rapid rate, while the tube is maintained at a potential of 840 V.

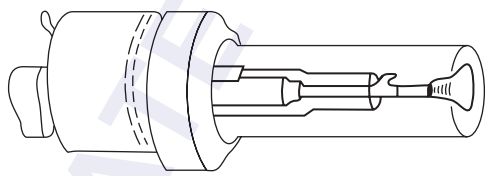

FIGURE 33 Water-cooled high-pressure (110 atm) mercury-arc lamp showing lamp in water jacket.

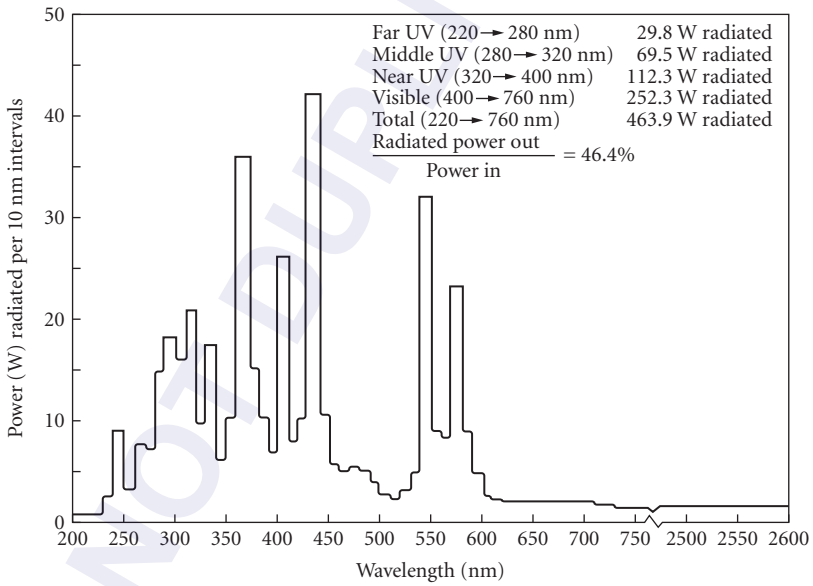

FIGURE 34 Spectral energy distribution of type BH6-1 mercury capillary lamp.

The spectral characteristics of certain tubes[26] are shown in Fig. 34. This company does not appear in the *Photonics Guide of 1989,* so the catalog referenced in the figure may not be current.

Compact-Source Arcs[19,27] Some common characteristics of currently available compact-source arc lamps are as follows:

1. A clear quartz bulb of roughly spherical shape with extensions at opposite ends constituting the electrode terminals. In some cases, the quartz bulb is then sealed within a larger glass bulb, which is filled with an inert gas.
2. A pair of electrodes with relatively close spacing (from less than 1 mm to about 1 cm); hence the sometimes-used term short-arc lamps.

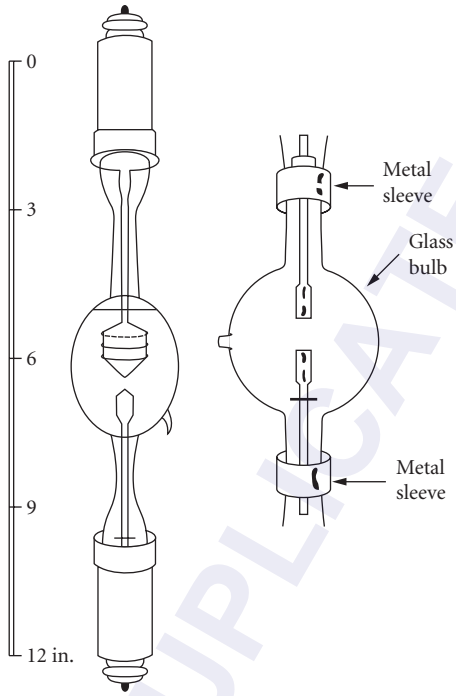

FIGURE 35 Construction of different lamps showing differences in relative sizes of electrodes for dc (*left*) and ac (*right*) operation.

3. A filling of gas or vapor through which the arc discharge takes place.
4. Extreme electrical loading of the arc gap, which results in very high luminance, internal pressures of many atmospheres, and bulb temperatures as high as 900°C. Precautions are necessary to protect people and equipment in case the lamps should fail violently.
5. The need for a momentary high-voltage ignition pulse, and a ballast or other auxiliary equipment to limit current during operation.
6. Clean, attention-free operation for long periods of time.

These lamps are designated by the chief radiating gases enclosed as mercury, mercury xenon, and xenon lamps.

Figure 35 shows a compact-source construction for a 1000-W lamp. Since starting may be a problem, some lamps (Fig. 36) are constructed with a third (i.e., a starting) electrode, to which a momentary high voltage is applied for starting (and especially restarting) while hot. The usual ballast is required for compact-source arcs. For stability, these arcs, particularly mercury and mercury-xenon, should be operated near rated ‘power on a well-regulated power supply.[27]

The spatial distribution of luminance from these lamps is reported in the literature already cited, and typical contours are shown in Fig. 37. Polar distributions are similar to those shown in Fig. 38. Spectral distributions are given in Figs. 39 through 41 for a 1000-W ac mercury lamp, a 5-kW dc xenon lamp, and 1000-W dc mercury-xenon lamp. Lamps are available at considerably less wattage.

Cann[27] reports on some interesting special lamps tested by Jet Propulsion Laboratories for the purpose of obtaining a good spectral match to the solar distribution. The types of lamps tested were Xe, Xe-Zn, Xe-Cd, Hg-Xe-Zn, Hg-Xe-Cd, Kr, Kr-Zn, Kr-Cd, Hg-Kr-Zn, Hg-Kr-Cd, Ar, Ne, and Hg-Xe with variable mercury-vapor pressure. For details, the reader should consult the literature.

A special design of a short-arc lamp manufactured by Varian[28] is shown in Fig. 42. Aside from its compactness and parabolic sector, it has a sapphire window which allows a greater amount of IR energy to be emitted. It is operated either dc or pulsed, but the user should obtain complete specifications, because the reflector can become contaminated, with a resultant decrease in output.

FIGURE 42 High-pressure, short-arc xenon illuminators with sapphire windows. Low starting voltage, 150 through 800 W; VIX150, VIX300, VIX500, VIX800.

Enclosed Arc and Discharge Sources (Low-Pressure)[22]

With pressure reduction in a tube filled with mercury vapor, the 2537 Å line becomes predominant so that low-pressure mercury tubes are usually selected for their ability to emit ultraviolet radiation.

Germicidal Lamps These are hot-cathode lamps which operate at relatively low voltages. They differ from ordinary fluorescent lamps which are used in lighting in that they are designed to transmit ultraviolet, whereas the wall of the fluorescent lamp is coated with a material that absorbs ultraviolet and reemits visible light. The germicidal lamp is constructed of glass of 1-mm thickness which transmits about 65 percent of the 2537 Å radiation and virtually cuts off shorter wavelength ultraviolet radiation.

Sterilamp®* Types These cold cathode lamps start and operate at higher voltages than the hot-cathode type and can be obtained in relatively small sizes as shown in Fig. 43. Operating characteristics of the Sterilamps should be obtained from the manufacturer.

Black-Light Fluorescent Lamps This fluorescent lamp is coated with a phosphor efficient in the absorption of 2537Å radiation, emitting ultraviolet radiation in a broadband around 3650 Å. The phosphor is a cerium-activated calcium phosphate, and the glass bulb is impervious to shorter wavelength ultraviolet radiation. Characteristics of one type are given in Table 4.

Hollow Cathode Lamps A device described early in this century and used for many years by spectroscopists is the hollow-cathode tube. The one used by Paschen[2] consisted of a hollow metal cylinder and contained a small quantity of inert gas, yielding an intense cathode-glow characteristic of the cathode constituents. Materials that vaporize easily can be incorporated into the tube so that their spectral characteristics predominate.[2]

Several companies sell hollow-cathode lamps which do not differ significantly from those constructed in early laboratories. The external appearance of these modern tubes shows the marks of mass production and emphasis on convenience. They come with a large number of vaporizable elements, singly or in multiples, and with Pyrex® or quartz windows. A partial list of the characteristics or the lamps available from two manufacturers is given in Table 5. Their physical appearance is shown in Fig. 44*a*. A schematic of the different elements obtainable in various lamps is shown in Fig. 44*b*.[29]

***Electrodeless Discharge Lamps*[30–32]** The electrodeless lamp gained popularity when Meggers used it in his attempt to produce a highly precise standard of radiation. Simplicity of design makes laboratory construction of this type of lamp easy. Some of the simplest lamps consist of a tube, containing the radiation-producing element, and a microwave generator, for producing the electric field (within the tube) which in turn excites the elemental spectra. Lamps of this type can be purchased with specially designed microwave cavities for greater efficiency in coupling. Those made of fused quartz can transmit from ultraviolet to near infrared. The electrodeless lamp is better able than the

arc lamp to produce stable radiation of sharp spectral lines; this makes it useful in spectroscopy and interferometry. The Hg 198 lamp makes a suitable secondary standard of radiation.

Spectral Lamps[31] Some manufacturers produce groups of arc sources, which are similar in construction and filled with different elements and rare gases, and which yield discontinuous or monochromatic radiation throughout most of the ultraviolet and visible spectrum. They are called

spectral lamps. The envelopes of these lamps are constructed of glass or quartz, depending on the part of the spectrum desired. Thus, discrete radiation can be obtained from around 2300 Å into the near infrared. Figure 45[31] represents the various atomic lines observable from Osram spectral lamps. Figure 46[33] gives a physical description of various spectral lamps obtainable from Philips. Table 6 lists the characteristics of the various types of lamps obtainable from Philips.

87265	Water Vapor

*Consists of glass tube with overall length of 25 cm with capillary portion about 8.5 to 10 cm long. Glass-to-metal seal wires are welded in metal caps with loops for wire connection are firmly sealed to the ends. Power supply no. 87208 is recommended as a source of excitation.

Pluecker Spectrum Tubes[34] These are inexpensive tubes made of glass (Fig. 47) with an overall length of 25 cm and capillary portion of 8.5 to 10 cm long. They operate from an ordinary supply with a special transformer which supports the tubes in a vertical position and maintains the voltage and current values adequate to operate the discharge and regulate the spectral intensity. Table 7 lists the various gases in available tubes.

Concentrated Arc Lamps

Zirconium Arc[25] The cathodes of these lamps are made of a hollow refractory metal containing zirconium oxide. The anode, a disk of metal with an aperture, resides directly above the cathode with the normal to the aperture coincident with the longitudinal axis of the cathode. Argon gas fills the tube. The arc discharge causes the zirconium to heat (to about 3000 K) and produce an intense, very small source of light. These lamps have been demonstrated in older catalogs from the Cenco Company in a number of wattages (from 2 to 300). The end of the bulk through which the radiation passes comes with ordinary curvature or (for a slight increase in price) flat. Examples are shown in Fig. 48.

Tungsten-Arc (Photomicrographic) Lamp[25] The essential elements of this discharge-type lamp (see Fig. 49) are a ring electrode and a pellet electrode, both made of tungsten. The arc forms between these electrodes, causing the pellet to heat incandescently. The ring also incandesces, but to a lesser extent. Thus, the hot pellet (approximately 3100 K) provides an intense source of small-area

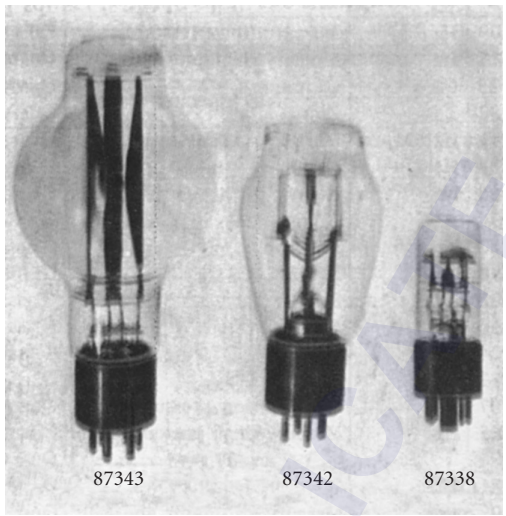

FIGURE 48 Physical construction of some zirconium arc lamps. Two 2-W lamps are available but not shown here.

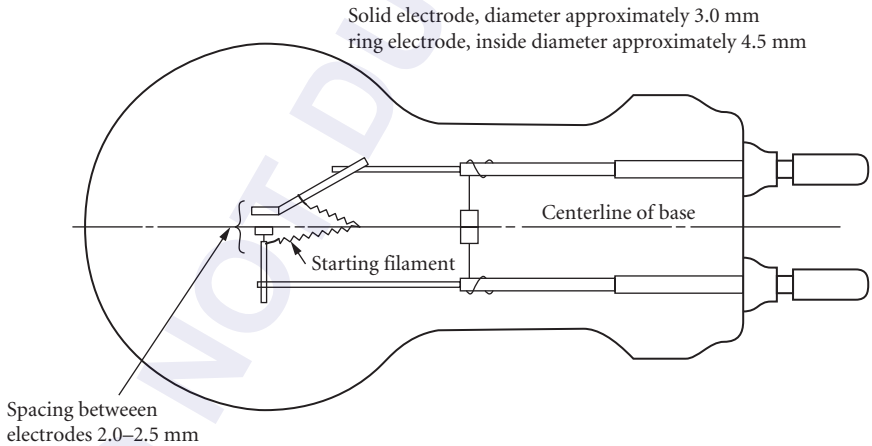

FIGURE 49 Construction of tungsten-arc lamp. The lamp must be operated baseup on a well-ventilated housing and using a special high-current socket which does not distort the position of the posts.

radiation. A plot of the spectral variation of this radiation is given in Fig. 50. As with all tungsten sources, evaporation causes a steady erosion of the pellet surface with the introduction of gradients, which is not serious if the pellet is used as a point source.

General Electric, manufacturer of the 30A/PS22 photomicrographic lamp, which uses a 30 Å operating current, states that this lamp requires a special heavy-duty socket obtainable through certain manufacturers suggested in its brochure, which may now be out of print in the original, but obtainable presumably as a copy from GE.

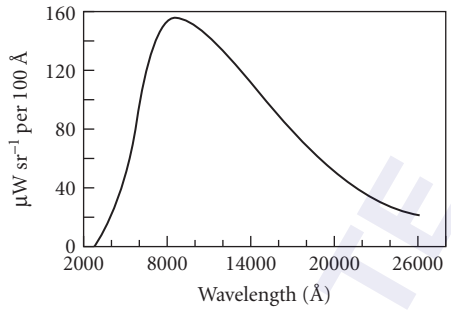

FIGURE 50 Spectral distribution of a 30/PS-22 photomicrographic lamp (superceded by the 330 watt, 30 amp PS-70).

Glow Modulator Tubes[35]

According to technical data supplied by Sylvania, these are cold-cathode light sources uniquely adaptable to high-frequency modulation. (These tubes are now manufactured by The English Electric Valve Company, Elmsford, New York.) Pictures of two types are shown in Fig. 51. The cathode is a small hollow cylinder, and the high ionization density in the region of the cathode provides an intense source of radiation. Figure 52 is a graph of the light output as a function of tube current. Figure 53 is a graph depicting the response of the tube to a modulating input. The spectral outputs of a variety of tubes are shown in Fig. 54. Table 8 gives some of the glow-modulator specifications.

Hydrogen and Deuterium Arcs

For applications requiring a strong continuum in the ultraviolet region, the hydrogen arc at a few millimeters pressure provides a useful source. It can be operated with a cold or hot cathode. One hot-cathode type is shown in Fig. 55. Koller[22] plots a distribution for this lamp down to about 200 Å.

Deuterium lamps (Fig. 56) provide a continuum in the ultraviolet with increased intensity over the hydrogen arc. Both lamps have quartz envelopes. The one on the left is designed for operation down to 2000 Å; the one on the right is provided with a Suprasil®* window to increase the ultraviolet range down to 1650 Å. NIST is offering a deuterium lamp standard of spectral irradiance between 200 and 350 nm. The lamp output at 50 cm from its medium bipost base is about 0.7 W cm^{-3} at 200 nm and drops off smoothly to 0.3 W cm^{-3} at 250 nm and 0.07 W cm^{-3}at 350 nm. A working standard of the deuterium lamp can be obtained also, for example, from Optronic Laboratories, Incorporated, Orlando, Florida.

Other Commercial Sources

Activated-Phosphor Sources Of particular importance and convenience in the use of photometers are sources composed of a phosphor activated by radioactive substances. Readily available, and not subject to licensing with small quantities of radioactive material, are the $_{14}$C-activated phosphor light sources. These are relatively stable sources of low intensity, losing about 0.02 percent per year due to the half-life of $_{14}$C and the destruction of phosphor centers.

*Registered trademark of Heraeus-Amersil.

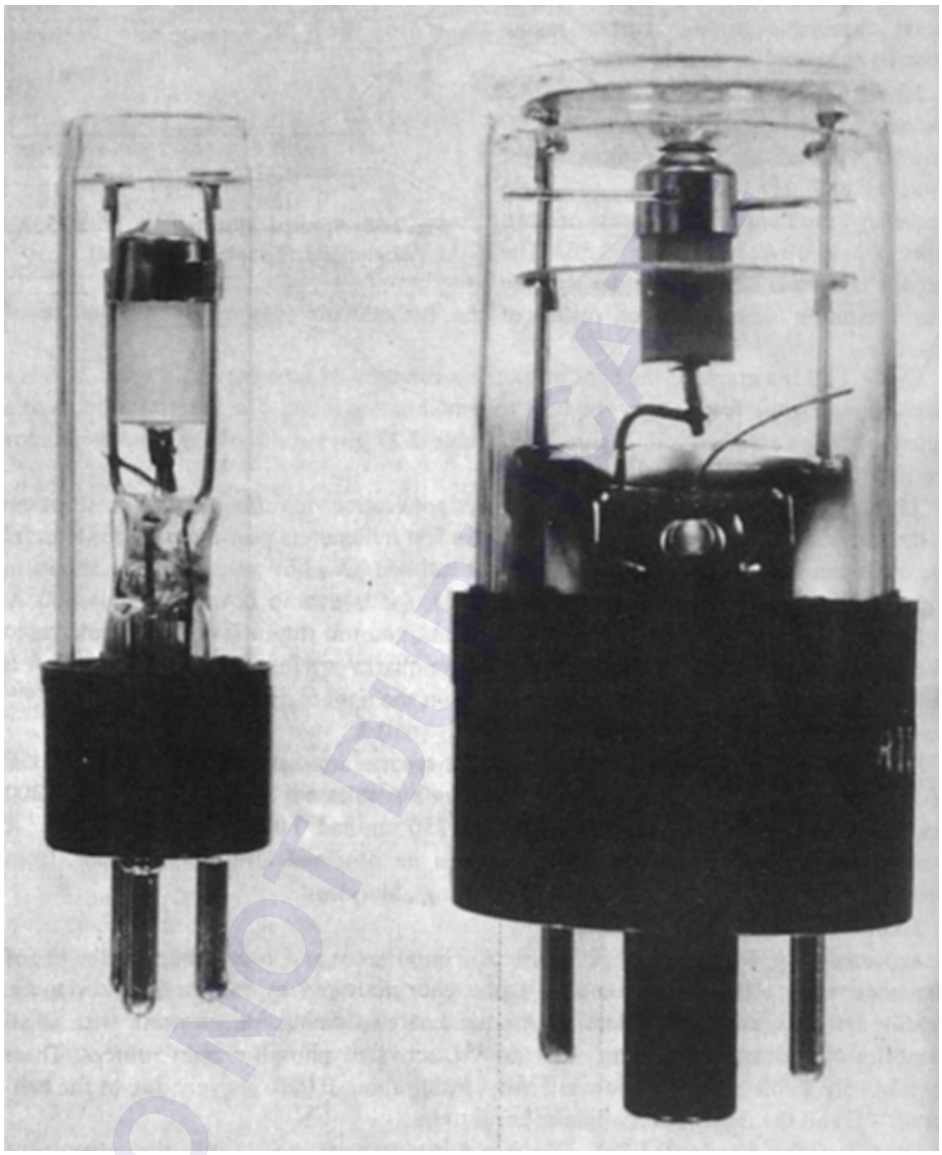

FIGURE 51 Construction of two glow modulator tubes.

Other (High-Energy) Sources Radiation at very high powers can be produced. Sources are synchrotrons, plasmatrons, arcs, sparks, exploding wires, shock tubes, and atomic and molecular beams, to name but a few. Among these, one can purchase in convenient, usable form precisely controlled spark-sources for yielding many joules of energy in a time interval of the order of microseconds. The number of vendors will be few, but check the directories.

Other Special Sources An enormous number of special-purpose sources are obtainable from manufacturers and scientific instrument suppliers. One source that remains to be mentioned is the so-called miniature, sub- and microminiature lamps. These are small, even tiny, incandescent bulbs of glass or quartz, containing tungsten filaments. They serve excellently in certain applications where small, intense radiators of visible and near-infrared radiation are needed. Second-source vendors advertise in the trade magazines.

LASERS

William T. Silfvast

CREOL, The College of Optics and Photonics
University of Central Florida
Orlando, Florida

16.1 GLOSSARY

A_2	radiative transition probability from level 2 to all other possible lower-lying levels
A_{21}	radiative transition probability from level 2 to level 1
a_L	scattering losses within a laser cavity for a single pass through the cavity
B_{12}	Einstein B coefficient associated with absorption
B_{21}	Einstein B coefficient associated with stimulated emission
E_1, E_2	energies of levels 1 and 2 above the ground state energy for that species
g_1, g_2	stability parameters for laser modes when describing the laser optical cavity
g_1, g_2	statistical weights of energy levels 1 and 2 that indicate the degeneracy of the levels
g_{21}	gain coefficient for amplification of radiation within a medium at a wavelength of λ_{21}
I_{sat}	saturation intensity of a beam in a medium; intensity at which exponential growth will cease to occur even though the medium has uniform gain (energy/time-area)
N_1, N_2	population densities (number of species per unit volume) in energy levels 1 and 2
r_c	radius of curvature of the expanding wavefront of a gaussian beam
R_1, R_2	reflectivities of mirrors 1 and 2 at the desired wavelength
T_1	lifetime of a level when dominated by collisional decay
T_2	average time between phase-interrupting collisions of a species in a specific excited state
t_{opt}	optimum mirror transmission for a laser of a given gain and loss
$w(z)$	beam waist radius at a distance z from the minimum beam waist for a gaussian beam
w_o	minimum beam waist radius for a gaussian mode
α_{12}	absorption coefficient for absorption of radiation within a medium at wavelength λ_{21}
γ_{21}	angular frequency bandwidth of an emission or absorption line
Δt_p	pulse duration of a mode-locked laser pulse
$\Delta\nu$	frequency bandwidth over which emission, absorption, or amplification can occur

$\Delta\nu_D$ frequency bandwidth (FWHM) when the dominant broadening process is Doppler or motional broadening
η index of refraction of the laser medium at the desired wavelength
λ_{21} wavelength of a radiative transition occurring between energy levels 2 and 1
ν_{21} frequency of a radiative transition occurring between energy levels 2 and 1
σ_{21} stimulated emission cross section (area) associated with levels 2 and 1
σ_{21}^{D} stimulated emission cross section at line center when Doppler broadening dominates (area)
σ_{21}^{H} stimulated emission cross section at line center when homogeneous broadening dominates (area)
τ_2 lifetime of energy level 2
τ_{21} lifetime of energy level 2 if it can only decay to level 1

16.2 INTRODUCTION

A laser is a device that amplifies light and produces a highly directional, high-intensity beam that typically has a very pure frequency or wavelength. It comes in sizes ranging from approximately one-tenth the diameter of a human hair to the size of a very large building, in powers ranging from 10^{-9} to 10^{20} W and in wavelengths ranging from the microwave to the soft-x-ray spectral regions with corresponding frequencies from 10^{11} to 10^{17} Hz. Lasers have pulse energies as high as 10^4 J and pulse durations as short as 6×10^{-15} seconds. They can easily drill holes in the most durable of materials and can weld detached retinas within the human eye.

Lasers are a key component of some of our most modern communication systems and are the "phonograph needle" of compact disc players. They are used for heat treatment of high-strength materials, such as the pistons of automobile engines, and provide a special surgical knife for many types of medical procedures. They act as target designators for military weapons and are used in the checkout scanners we see everyday at the supermarket.

The word *laser* is an acronym for *L*ight *A*mplification by *S*timulated *E*mission of *R*adiation. The laser makes use of processes that increase or amplify light signals after those signals have been generated by other means. These processes include (1) stimulated emission, a natural effect that arises out of considerations relating to thermodynamic equilibrium, and (2) optical feedback (present in most lasers) that is usually provided by mirrors. Thus, in its simplest form, a laser consists of a gain or amplifying medium (where stimulated emission occurs) and a set of mirrors to feed the light back into the amplifier for continued growth of the developing beam (Fig. 1).

The entire spectrum of electromagnetic radiation is shown in Fig. 2, along with the region covered by currently existing lasers. Such lasers span the wavelength range from the far infrared part of

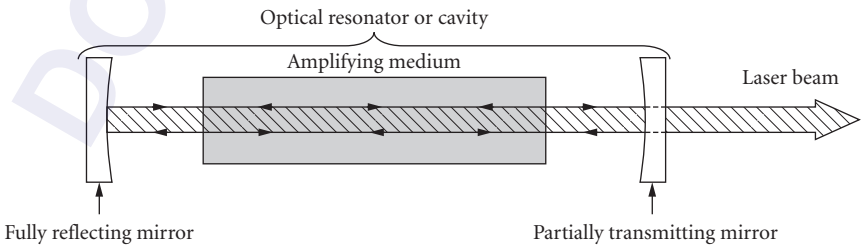

FIGURE 1 Simplified diagram of a laser, including the amplifying medium and the optical resonator.

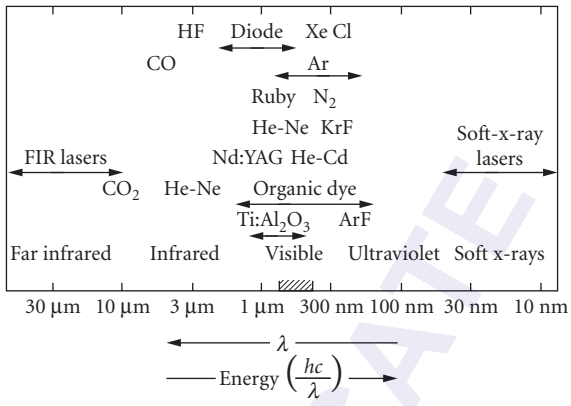

FIGURE 2 The portion of the electromagnetic spectrum that involves lasers, along with the general wavelengths of operation of most of the common lasers.

the spectrum ($\lambda = 1000$ μm) to the soft-x-ray region ($\lambda = 3$ nm), thereby covering a range of almost six orders of magnitude! There are several types of units that are used to define laser wavelengths. These range from micrometers (μm) in the infrared to nanometers (nm) and angstroms (Å) in the visible, ultraviolet (UV), vacuum ultraviolet (VUV), extreme ultraviolet (EUV or XUV), and soft-x-ray (SXR) spectral regions.

This chapter provides a brief overview of how a laser operates. It considers a laser as having two primary components: (1) a region where light amplification occurs which is referred to as a *gain medium* or an *amplifier*, and (2) a *cavity*, which generally consists of two mirrors placed at either end of the amplifier.

Properties of the amplifier include the concept of discrete excited energy levels and their associated finite lifetimes. The broadening of these energy levels will be associated with the emission linewidth which is related to decay of the population in these levels.

Stimulated emission will be described, and the formulas for calculating the amount of gain that can occur via stimulated emission will be given in terms of the radiative properties of the medium. The concept of the saturation intensity will be introduced and related to the amount of gain that is necessary for laser output. The addition of mirrors at the ends of the amplifier will be used to increase the gain length and to reduce the divergence of the amplified beam. The threshold conditions for laser output will be described in terms of the amplifier properties and the mirror reflectivities. This section will conclude with a review of excitation or pumping processes that are used to produce the necessary population density in the upper laser level.

Cavity properties will begin with a discussion of both longitudinal and transverse cavity modes which provide the laser beam with a gaussian-shaped transverse profile. The properties of those gaussian beams will be reviewed. The types of optical cavities that allow stable operation of laser modes will then be described. A number of special types of laser cavity arrangements and techniques will be reviewed, including unstable resonators, Q-switching, mode-locking, and ring lasers. A brief review will then be given of the various common types of gaseous, liquid, and solid-state lasers.

Additional information related to spectral lineshape and the mechanisms of spectral broadening can be found in Chap. 10 (Vol. I), "Optical Spectroscopy and Spectroscopic Lineshapes." Other related material can be found in Chap. 8 (Vol. IV), "Fundamental Optical Properties of Solids," and Chap. 33 (Vol. I), "Holography and Holographic Instruments." As lasers are widely used in many of the devices and techniques discussed in other chapters in this *Handbook,* the reader is directed to those topics for information on specific lasers.

16.3 LASER PROPERTIES ASSOCIATED WITH THE LASER GAIN MEDIUM

Energy Levels and Radiation[1,2]

Nearly all lasers involve electronic charge distributions of atoms, molecules, organic dye solutions, or solids that make transitions from one energy state or level E_2 to another lower-lying level E_1. The loss of energy resulting from this transition is given off in the form of electromagnetic radiation. The relationship between the energy difference between the levels, $E_2 - E_1$ or ΔE_{21}, and the frequency ν_{21} of radiation occurring as a result of the transition, is determined by the Einstein relationship $E_{21} = h\nu_{21}$ where h is Planck's constant. It was first shown by Bohr in 1913 that the discrete set of emission wavelengths from a hydrogen discharge could be explained by the occurrence of discrete energy levels in the hydrogen atom that have a fixed relationship. This discrete arrangement of energy levels was later shown to occur in other atoms, in molecules, and also in liquids and solids. In atoms these energy levels are very precisely defined and narrow in width ($\approx 10^9$ Hz) and can be accurately calculated with sophisticated atomic physics codes. In molecules and high-density materials the locations of the levels are more difficult to calculate and they tend to be much broader in width, the largest widths occurring in liquids and solids (up to 5×10^{13} Hz).

The lowest energy level of a species is referred to as the *ground state* and is usually the most stable state of the species. There are some exceptions to this, for example, ground states of ionized species or unstable ground states of some molecular species such as excimer molecules. Energy levels above the ground state are inherently unstable and have lifetimes that are precisely determined by the arrangement of the atoms and electrons associated with any particular level as well as to the particular species or material. Thus, when an excited state is produced by applying energy to the system, that state will eventually decay by emitting radiation over a time period ranging from 10^{-15} seconds or less to times as long as seconds or more, depending upon the particular state or level involved. For *strongly allowed* transitions that involve the electron charge cloud changing from an atomic energy level of energy E_2 to a lower-lying level of energy E_1, the radiative decay time τ_{21} can be approximated by $\tau_{21} \approx 10^4 \lambda_{21}^2$ where τ_{21} is in seconds and λ_{21} is the wavelength of the emitted radiation in meters. λ_{21} is related to ν_{21} by the relationship $\lambda_{21}\nu_{21} = c/\eta$ where c is the velocity of light (3×10^8 m/s) and η is the index of refraction of the material. For most gases, η is near unity and for solids and liquids it ranges between 1 and 10, with most values ranging from ≈ 1.3 to 2.0.

Using the expression suggested above for the approximate value of the lifetime of an excited energy level, one obtains a decay time of several ns for green light ($\lambda_{21} = 5 \times 10^{-7}$ m). This represents a minimum radiative lifetime since most excited energy levels have a weaker radiative decay probability than mentioned above and would therefore have radiative lifetimes one or two orders of magnitude longer. Other laser materials such as molecules, organic dye solutions, and semiconductor lasers have similar radiative lifetimes. The one exception is the class of dielectric solid-state laser materials (both crystalline and glass) such as ruby and Nd:YAG, in which the lifetimes are of the order of 1 μs to 3 ms. This much longer radiative lifetime in solid-state laser materials is due to the nature of the particular state of the laser species and to the crystal matrix in which it is contained. This is a very desirable property for a laser medium since it allows excitation and energy storage within the laser medium over a relatively long period of time.

Emission Linewidth and Line Broadening of Radiating Species[1,3]

Assume that population in energy level 2 decays to energy level 1 with an exponential decay time of τ_{21} and emits radiation at frequency ν_{21} during that decay. It can be shown by Fourier analysis that the exponential decay of that radiation requires the frequency width of the emission to be of the order of $\Delta\nu \cong 1/2\pi\tau_{21}$. This suggests that the energy width ΔE_2 of level 2 is of the order of $\Delta E_2 = h/2\pi\tau_{21}$. If the energy level 2 can decay to more levels than level 1, with a corresponding decay time of τ_2, then its energy is broadened by an amount $\Delta E_2 = h/2\pi\tau_2$. If the decay is due primarily to

radiation at a rate A_{2i} to one or more individual lower-lying levels *i*, then $1/\tau_2 = A_2 = \sum_i A_{2i}$. A_2 represents the total radiative decay rate of level 2, whereas A_{2i} is the specific radiative decay rate from level 2 to a lower-lying level *i*.

If population in level 2 decays radiatively at a radiative rate A_2 and population in level 1 decays radiatively at a rate A_1, then the emission linewidth of radiation from level 2 to 1 is given by

$$\Delta\nu_{21} = \frac{\sum_i A_{2i} + \sum_j A_{1j}}{2\pi} \tag{1}$$

which is referred to as the *natural linewidth* of the transition and represents the sum of the widths of levels 2 and 1 in frequency units. If, in the above example, level 1 is a ground state with infinite lifetime or a long-lived metastable level, then the natural linewidth of the emission from level 2 to level 1 would be represented by

$$\Delta\nu_{21} = \frac{\sum_i A_{2i}}{2\pi} \tag{2}$$

since the ground state would have an infinite lifetime and would therefore not contribute to the broadening. This type of linewidth or broadening is known as *natural broadening* since it results specifically from the radiative decay of a species. Thus the natural linewidth associated with a specific transition between two levels has an inherent value determined only by the factors associated with specific atomic and electronic characteristics of those levels.

The emission-line broadening or natural broadening described above is the minimum line broadening that can occur for a specific radiative transition. There are a number of mechanisms that can increase the emission linewidth. These include collisional broadening, phase-interruption broadening, Doppler broadening, and isotope broadening. The first two of these, along with natural broadening, are all referred to as *homogeneous broadening*. Homogeneous broadening is a type of emission broadening in which all of the atoms radiating from the specific level under consideration participate in the same way. In other words, all of the atoms have the identical opportunity to radiate with equal probability.

The type of broadening associated with either Doppler or isotope broadening is referred to as *inhomogeneous broadening*. For this type of broadening, only certain atoms radiating from that level that have a specific property such as a specific velocity, or are of a specific isotope, participate in radiation at a certain frequency within the emission bandwidth.

Collisional broadening is a type of broadening that is produced when surrounding atoms, molecules, solvents (in the case of dye lasers), or crystal structures interact with the radiating level and cause the population to decay before it has a chance to decay by its normal radiative processes. The emission broadening is then associated with the faster decay time T_1, or $\Delta\nu = 1/2\pi T_1$.

Phase-interruption broadening or *phonon broadening* is a type of broadening that does not increase the decay rate of the level, but it does interrupt the phase of the rotating electron cloud on average over a time interval T_2 which is much shorter than the radiative decay time τ_2 which includes all possible radiative decay channels from level 2. The result of this phase interruption is to increase the emission linewidth beyond that of both natural broadening and T_1 broadening (if it exists) to an amount $\Delta\nu = 1/2\pi T_2$.

Doppler broadening is a type of inhomogeneous broadening in which the Doppler effect shifts the frequencies of radiating atoms moving toward the observer to a higher value and the frequencies of atoms moving away from the observer to a lower value. This effect occurs only in gases since they are the only species that are moving fast enough to produce such broadening. Doppler broadening is the dominant broadening process in most visible gas lasers. The expression for the Doppler linewidth (FWHM) is given by

$$\Delta\nu_D = 7.16 \cdot 10^{-7} \nu_o \sqrt{\frac{T}{M}} \tag{3}$$

in which ν_o is the center frequency associated with atoms that are not moving either toward or away from the observer, T is the gas temperature in kelvin and M is the atomic or molecular weight (number of nucleons/atom or molecule) of the gas atoms or molecules.

Isotope broadening also occurs in some gas lasers. It becomes the dominant broadening process if the specific gas consists of several isotopes of the species and if the isotope shifts for the specific radiative transition are broader than the Doppler width of the transition. The helium-cadmium laser is dominated more by this effect than any other laser since the naturally occurring cadmium isotopic mixture contains eight different isotopes and the isotope shift between adjacent isotopes (adjacent neutron numbers) is approximately equal to the Doppler width of the individual radiating isotopes. This broadening effect can be eliminated by the use of isotopically pure individual isotopes, but the cost for such isotopes is often prohibitive.

All homogeneous broadening processes have a frequency distribution that is described by a Lorentzian mathematical function

$$I_{21}(\nu) = I_o \frac{\gamma_{21}/4\pi^2}{(\nu-\nu_o)^2 + (\gamma_{21}/4\pi)^2} \tag{4}$$

in which γ_{21} represents the decay rate of level 2, I_o is the total emission intensity of the transition over the entire linewidth, and ν_o is the center frequency of the emission line. In Eq. (4), γ_{21} is determined by the relationship $\gamma_{21} = 2\pi\Delta\nu_{21}$. For natural broadening, $\Delta\nu_{21}$ is given by either Eq. (1) or Eq. (2), whichever is applicable. For T_1-dominated broadening, $\Delta\nu_{21} = 1/2\pi T_1$, and for T_2-dominated broadening, $\gamma_{21} = 1/2\pi T_2$.

The frequency distribution for Doppler broadening is described by a gaussian function

$$I(\nu) = \frac{2(\ln 2)^{1/2}}{\pi^{1/2}\Delta\nu_D} I_o \exp - \left[\frac{4\ln 2(\nu-\nu_o)^2}{\Delta\nu_D^2} \right] \tag{5}$$

Both of these lineshape functions are indicated in Fig. 3. In this figure, both the total emission intensity integrated over all frequencies and the emission linewidth (full width at half maximum or FWHM) for both functions are identical.

Isotope broadening involves the superposition of a series of either lorentzian shapes or gaussian shapes for each isotope of the species, separated by the frequencies associated with the isotope shifts of that particular transition.

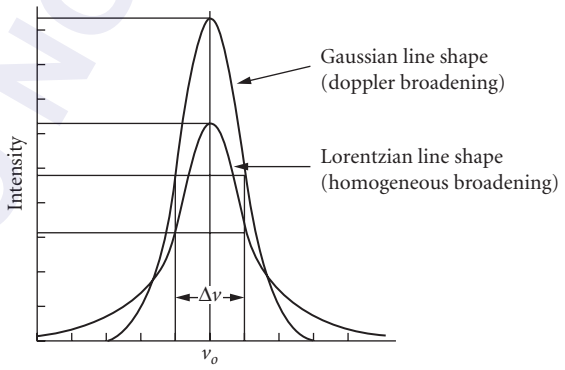

FIGURE 3 Lineshape functions for both homogeneous broadening, with a lorentzian shape, and Doppler broadening (inhomogeneous), with a gaussian shape. Both lines are arranged with equal linewidths (FWHM) and equal total intensities.

TABLE 1 Amplifier Parameters for a Wide Range of Lasers

Type of Laser	λ_{21} (nm)	τ_2 (s)	$\Delta\nu_{21}$ (Hz)	$\Delta\lambda_{21}$ (nm)	$\sigma_{21}(m^2)$	$\Delta N_{21}(m^{-3})$	L(m)	$g_{21}(m^{-1})$
Helium-Neon	632.8	3×10^{-7}	2×10^{9}	2×10^{-3}	3×10^{-17}	5×10^{15}	0.2	0.15
Argon	488.0	1×10^{-8}	2×10^{9}	1.6×10^{-3}	5×10^{-16}	1×10^{15}	0.2–1.0	0.5
He-Cadmium	441.6	7×10^{-7}	2×10^{9}	1.3×10^{-3}	8×10^{-18}	4×10^{16}	0.2–1.0	0.3
Copper vapor	510.5	5×10^{-7}	2×10^{9}	1.3×10^{-3}	8×10^{-18}	6×10^{17}	1.0–2.0	5
CO_2	10,600	4	6×10^{7}	2.2×10^{-2}	1.6×10^{-20}	5×10^{19}	0.2–2.0	0.8
Excimer	248.0	9×10^{-9}	1×10^{13}	2	2.6×10^{-20}	1×10^{20}	0.5–1.0	2.6
Dye (Rh6G)	577.0	5×10^{-9}	5×10^{13}	60	1.2×10^{-20}	2×10^{22}	0.01	240
Semiconductor	800	1×10^{-9}	1×10^{13}	20	1×10^{-19}	10^{24}	0.00025	100,000
Nd:Yag	1064.1	2.3×10^{-4}	1.2×10^{11}	0.4	6.5×10^{-23}	1.6×10^{23}	0.1	10

Cr:LiSAF	840	6.7×10^{-5}	9.0×10^{13}	250	5.0×10^{-24}	2×10^{24}	0.1	10
Ti:Al_2O_3	760	3.2×10^{-6}	1.5×10^{14}	400	4.1×10^{-23}	5×10^{23}	0.1	20

Table 1 gives examples of the dominant broadening process and the value of the broadening for most of the common commercial lasers.

Bandwidths of laser transitions in semiconductors are actually made narrower by making the active regions of the material extremely thin in one or more dimensions. In doing so the energy levels become quantized and thus behave more like single atom atomic levels. Quantizing in one dimension, by making the thickness of the order of 50 to 100 nm, leads to a quantum well laser. Narrowing and thereby quantizing in two dimensions is referred to as a quantum wire and in three dimensions, a quantum dot. The advantages of quantizing the dimensions is that the reduced thickness leads to a significantly reduced heat loss during the excitation of the semiconductor as well as a narrower laser emission linewidth because of the smaller size of the electron energy distribution in the upper laser level. In the case of the quantum dot, the material takes on atom-like properties because the energies are quantized in all three dimensions and the lasing threshold is reduced much more so than even with the quantum well laser. Of course there is less laser gain medium produced in such materials per unit volume, because of the reduced gain volume, and thereby less laser power per unit volume. This can be made up by having many such gain media in parallel and/or in series, taking into account the heat removal requirements of the pumping process.

Stimulated Radiative Processes—Absorption and Emission[1,2]

Two types of stimulated radiative processes, absorption and stimulated emission, occur between energy levels 1 and 2 of a gain medium when light of frequency ν_{21} corresponding to an energy difference $\Delta E_{21}=(E_2-E_1)=h\nu_{21}$ passes through the medium. These processes are proportional to the light intensity I as indicated in Fig. 4 for a two-level system as well as to the stimulated absorption and emission coefficients B_{12} and B_{21}, respectively. These coefficients are related to the frequency ν_{21} and the spontaneous emission probability A_{21} associated with the two levels. A_{21} has units of (1/s).

Absorption results in the loss of light of intensity I when the light interacts with the medium. The energy is transferred from the beam to the medium by raising population from level 1 to the higher-energy level 2. In this situation, the species within the medium can either reradiate the energy and return to its initial level 1, it can reradiate a different energy and decay to a different level, or it can lose the energy to the surrounding medium via collisions, which results in the heating of the medium, and return to the lower level. The absorption probability is proportional to the intensity I which has units of energy/s-m^2 times B_{12}, which is the absorption probability coefficient for that transition. B_{12} is one of the Einstein B coefficients and has the units of m^3/energy-s^2.

Stimulated emission results in the increase in the light intensity I when light of the appropriate frequency ν_{21} interacts with population occupying level 2 of the gain medium. The energy is given

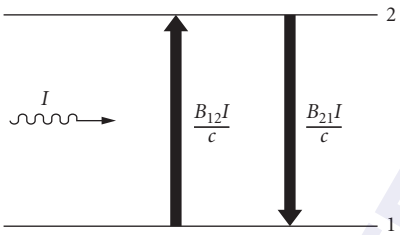

FIGURE 4 Stimulated emission and absorption processes that can occur between two energy levels, 1 and 2, and can significantly alter the population densities of the levels compared to when a beam of intensity I is not present.

up by the species to the radiation field. In the case of stimulated emission, the emitted photons or bundles of light have exactly the same frequency ν_{21} and direction as the incident photons of intensity I that produce the stimulation. B_{21} is the associated stimulated emission coefficient and has the same units as B_{12}. It is known as the other Einstein B coefficient.

Einstein showed the relationship between B_{12}, B_{21}, and A_{21} as

$$g_2 B_{21} = g_1 B_{12} \tag{6}$$

and

$$A_{21} = \frac{8\pi h \nu_{21}^3}{c^3} B_{21} \tag{7}$$

where g_2 and g_1 are the statistical weights of levels 2 and 1 and h is Planck's constant. Since $A_{21} = 1/\tau_{21}$ for the case where radiative decay dominates and where there is only one decay path from level 2, B_{21} can be determined from lifetime measurements or from absorption measurements on the transition at frequency ν_{21}.

Population Inversions[1,2]

The two processes of absorption and stimulated emission are the principal interactions involved in a laser amplifier. Assume that a collection of atoms of a particular species is energized to populate two excited states 1 and 2 with population densities N_1 and N_2 (number of species/m^3) and state 2 is at a higher energy than state 1 by an amount ΔE_{21} as described in the previous section. If a photon beam of energy ΔE_{21}, with an intensity I_o and a corresponding wavelength $\lambda_{21} = c/\nu_{21} = hc/\Delta E_{21}$, passes through this collection of atoms, then the intensity I after the beam emerges from the medium can be expressed as

$$I = I_o e^{\sigma_{21}(N_2 - (g_2/g_1)N_1)L} = I_o e^{\sigma_{21}\Delta N_{21} L} \tag{8}$$

where σ_{21} is referred to as the *stimulated emission cross section* with dimensions of m^2, L is the thickness of the medium (in meters) through which the beam passes, and $N_2 - (g_2/g_1)N_1 = \Delta N_{21}$ is known as the *population inversion density*. The exponents in Eq. (8) are dimensionless quantities than can be either greater or less than unity, depending upon whether N_2 is greater than or less than $(g_2/g_1)N_1$.

The general form of the stimulated emission cross section per unit frequency is given as

$$\sigma_{21} = \frac{\lambda_{21}^2 A_{21}}{8\pi \Delta\nu} \tag{9}$$

in which $\Delta\nu$ represents the linewidth over which the stimulated emission or absorption occurs.

For the case of homogeneous broadening, at the *center* of the emission line, σ_{21} is expressed as

$$\sigma_{21}^H = \frac{\lambda_{21}^2 A_{21}}{4\pi^2 \Delta\nu_{21}^H} \tag{10}$$

where $\Delta\nu_{21}^H$ is the homogeneous emission linewidth (FWHM) which was described earlier for several different situations.

For the case of Doppler broadening, σ_{21}^D can be expressed as

$$\sigma_{21}^D = \sqrt{\frac{\ln 2}{16\pi^3}} \frac{\lambda_{21}^2 A_{21}}{\Delta\nu_{21}^D} \tag{11}$$

at the *center* of the emission line and $\Delta\nu_{21}^D$ is the Doppler emission linewidth expressed earlier in Eq. (3).

For all types of matter, the population density ratio of levels 1 and 2 would normally be such that $N_2 \ll N_1$. This can be shown by the Boltzmann relationship for the population ratio in thermal equilibrium which provides the ratio of N_2/N_1 to be

$$\frac{N_2}{N_1} = \frac{g_2}{g_1} e^{-\Delta E_{21}/kT} \tag{12}$$

in which T is the temperature and k is Boltzmann's constant. Thus, for energy levels separated by energies corresponding to visible transitions, in a medium at or near room temperature, the ratio of $N_2/N_1 \cong e^{-100} = 10^{-44}$. For most situations in everyday life we can ignore the population N_2 in the upper level and rewrite Eq. (8) as

$$I = I_o e^{-\sigma_{12} N_1 L} = I_o e^{-\alpha_{12} L} \tag{13}$$

where $\sigma_{21} = (g_2/g_1)\sigma_{12}$ and $\alpha_{12} = \sigma_{12} N_1$. Equation (13) is known as Beer's law, which is used to describe the absorption of light within a medium. α_{12} is referred to as the absorption coefficient with units of m^{-1}.

In laser amplifiers we cannot ignore the population in level 2. In fact, the condition for amplification and laser action is

$$N_2 - (g_2/g_1)N_1 > 0 \quad \text{or} \quad g_1 N_2 / g_2 N_1 > 1 \tag{14}$$

since, if Eq. (14) is satisfied, the exponent of Eq. (8) will be greater than 1 and I will emerge from the medium with a greater value than I_o, or amplification will occur. The condition of Eq. (14) is a necessary condition for laser amplification and is known as a population inversion since N_2 is greater than $(g_2/g_1)N_1$. In most cases, (g_2/g_1) is either unity or close to unity.

Considering that the ratio of $g_1 N_2 / g_2 N_1$ [Eq. (14)] could be greater than unity does not follow from normal thermodynamic equilibrium considerations [Eq. (12)] since it would represent a population ratio that could never exist in thermal equilibrium. When Eq. (14) is satisfied and amplification of the beam occurs, the medium is said to have *gain* or *amplification*. The factor $\sigma_{21}(N_2 - (g_2/g_1)N_1)$ or $\sigma_{21}\Delta N_{21}$ is often referred to as the *gain coefficient* g_{21} and is given in units of m^{-1} such that $g_{21} = \sigma_{21}\Delta N_{21}$. Typical values of σ_{21}, ΔN_{21}, and g_{21} are given in Table 1 for a variety

of lasers. The term g_{21} is also referred to as the *small-signal gain coefficient* since it is the gain coefficient determined when the laser beam intensity within the laser gain medium is small enough that stimulated emission does not significantly alter the populations in the laser levels.

Gain Saturation[2]

It was stated in the previous section that Eq. (14) is a necessary condition for making a laser but it is not a sufficient condition. For example, a medium might satisfy Eq. (14) by having a gain of $e^{g_{21}L} \approx 10^{-10}$, but this would not be sufficient to allow any reasonable beam to develop. Lasers generally start by having a pumping process that produces enough population in level 2 to create a population inversion with respect to level 1. As the population decays from level 2, radiation occurs spontaneously on the transition from level 2 to level 1 equally in all directions within the gain medium. In most of the directions very little gain or enhancement of the spontaneous emission occurs, since the length is not sufficient to cause significant growth according to Eq. (8). It is only in the elongated direction of the amplifier, with a much greater length, that significant gain exists and, consequently, the spontaneous emission is significantly enhanced. The requirement for a laser beam to develop in the elongated direction is that the exponent of Eq. (8) be large enough for the beam to grow to the point where it begins to significantly reduce the population in level 2 by stimulated emission. The beam will eventually grow, according to Eq. (8), to an intensity such that the stimulated emission rate is equal to the spontaneous emission rate. At that point the beam is said to reach its saturation intensity I_{sat}, which is given by

$$I_{\text{sat}} = \frac{h\nu_{21}}{\sigma_{21}^{H}\tau_{21}} \tag{15}$$

The saturation intensity is that value at which the beam can no longer grow exponentially according to Eq. (8) because there are no longer enough atoms in level 2 to provide the additional gain. When the beam grows above I_{sat} it begins to extract significant energy since at this point the stimulated emission rate exceeds the spontaneous emission rate for that transition. The beam essentially takes energy that would normally be radiated in all directions spontaneously and redirects it via stimulated emission, thereby increasing the beam intensity.

Threshold Conditions with No Mirrors

I_{sat} can be achieved by having any combination of values of the three parameters σ_{21}^{H}, ΔN_{21}, and L large enough that their product provides sufficient gain. It turns out that the requirement to reach I_{sat} can be given by making the exponent of Eq. (8) have the following range of values:

$$\sigma_{21}^{H}\Delta N_{21}L \approx 10-20 \quad \text{or} \quad g_{21}^{H}L \approx 10-20 \tag{16}$$

where the specific value between 10 and 20 is determined by the geometry of the laser cavity. Equation (16) suggests that the beam grows to a value of $I/I_o = e^{10-20} = 2\times10^{4} - 5\times10^{8}$, which is a very large amplification.

Threshold Conditions with Mirrors

One could conceivably make L sufficiently long to always satisfy Eq. (16), but this is not practical. Some lasers can reach the saturation intensity over a length L of a few centimeters, but most require much longer lengths. Since one cannot readily extend the lasing medium to be long enough to achieve L_{sat}, the same result is obtained by putting mirrors around the gain medium. This effectively increases the path length by having the beam pass many times through the amplifier.

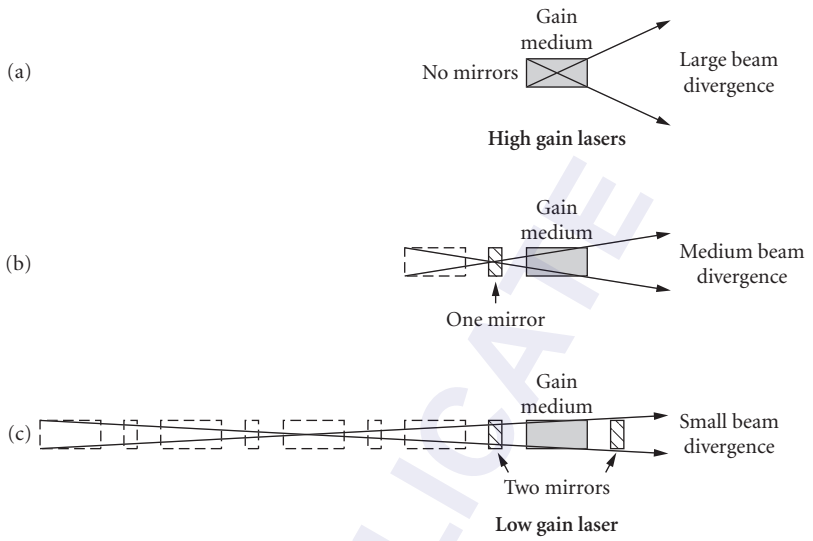

FIGURE 5 Laser beam divergence for amplifier configurations having high gain and (*a*) no mirrors or (*b*) one mirror, and high or low gain and (*c*) two mirrors.

A simple understanding of how the mirrors affect the beam is shown in Fig. 5. The diagram effectively shows how multiple passes through the amplifier can be considered for the situation where flat mirrors are used at the ends of the amplifier. The dashed outlines that are the same size as the gain media represent the images of those gain media produced by their reflections in the mirrors. It can be seen that as the beam makes multiple passes, its divergence narrows up significantly in addition to the large increase in intensity that occurs due to amplification. For high-gain lasers, such as excimer or organic dye lasers, the beam only need pass through the amplifier a few times to reach saturation. For low-gain lasers, such as the helium-neon laser, it might take 500 passes through the amplifier in order to reach I_{sat}.

The laser beam that emerges from the laser is usually coupled out of the amplifier by having a partially transmitting mirror at one end of the amplifier which typically reflects most of the beam back into the medium for more growth. To ensure that the beam develops, the transmission of the output coupling mirror (as it is usually referred to) must be lower than the gain incurred by the beam during a round-trip pass through the amplifier. If the transmission is higher than the round-trip gain, the beam undergoes no net amplification. It simply never develops. Thus a relationship that describes the threshold for laser oscillation balances the laser gain with the cavity losses. In the most simplified form, those losses are due to the mirrors having a reflectivity less than unity. Thus, for a round-trip pass-through the laser cavity, the threshold for inversion can be expressed as

$$R_1R_2e^{\sigma_{21}\Delta N_{21}2L} > 1 \quad \text{or} \quad R_1R_2e^{g_{21}2L} > 1 \tag{17a}$$

which is a similar requirement to that of Eq. (16) since it defines the minimum gain requirements for a laser.

A more general version of Eq. (17*a*) can be expressed as

$$R_1R_2(1-a_L)^2e^{(\sigma_{21}\Delta N_{21}-\alpha)2L} = 1 \quad \text{or} \quad R_1R_2(1-a_L)^2e^{(g_{21}-\alpha)2L} = 1 \tag{17b}$$

in which we have included a distributed absorption α throughout the length of the gain medium at the laser wavelength, as well as the total scattering losses a_L per pass through the cavity (excluding the gain medium and the mirror surfaces). The absorption loss α is essentially a separate absorbing transition within the gain medium that could be a separate molecule as in an excimer laser,

absorption from either the ground state or from the triplet state in a dye laser, or absorption from the ground state in the broadband tunable solid-state lasers and in semiconductor lasers or from the upper laser state in most solid-state lasers. The scattering losses a_L, per pass, would include scattering at the windows of the gain medium, such as Brewster angle windows, or scattering losses from other elements that are inserted within the cavity. These are typically of the order of one or two percent or less.

Laser Operation above Threshold

Significant power output is achieved by operating the laser at a gain greater than the threshold value defined above in Eqs. (16) and (17). For such a situation, the higher gain that would normally be produced by increased pumping is reduced to the threshold value by stimulated emission. The additional energy obtained from the reduced population inversion is transferred to the laser beam in the form of increased laser power. If the laser has low gain, as most cw (continuously operating) gas lasers do, the gain and also the power output tend to stabilize rather readily.

For solid-state lasers, which tend to have higher gain and also a long upper-laser-level lifetime, a phenomenon known as *relaxation oscillations*[7] occurs in the laser output. For pulsed (non-Q-switched) lasers in which the gain lasts for many microseconds, these oscillations occur in the form of a regularly repeated spiked laser output superimposed on a lower steady-state value. For cw lasers it takes the form of a sinusoidal oscillation of the output. The phenomenon is caused by an oscillation of the gain due to the interchange of pumped energy between the upper laser level and the laser field in the cavity. This effect can be controlled by using an active feedback mechanism, in the form of an intensity-dependent loss, in the laser cavity.

Laser mirrors not only provide the additional length required for the laser beam to reach I_{sat}, but they also provide very important resonant cavity effects that will be discussed in a later section. Using mirrors at the ends of the laser gain medium (or amplifier) is referred to as having the gain medium located within an optical cavity.

How Population Inversions Are Achieved[4]

It was mentioned earlier that population inversions are not easily achieved in normal situations. All types of matter tend to be driven toward thermal equilibrium. From an energy-level standpoint, to be in thermal equilibrium implies that the ratio of the populations of two excited states of a particular material, whether it be a gaseous, liquid, or solid material, is described by Eq. (12). For any finite value of the temperature this leads to a value of $N_2/(g_2/g_1)N_1$ that is always less than unity and therefore Eq. (14) can never be satisfied under conditions of thermal equilibrium. Population inversions are therefore produced in either one of two ways: (1) selective excitation (pumping) of the upper-laser-level 2, or (2) more rapid decay of the population of the lower-laser-level 1 than of the upper-laser-level 2, even if they are both populated by the same pumping process.

The first requirement mentioned above was met in producing the very first laser, the ruby laser.[5] In this laser the flash lamp selectively pumped chromium atoms to the upper laser level (through an intermediate level) until the ground state (lower laser level) was depleted enough to produce the inversion (Fig. 6). Another laser that uses this selective pumping process is the copper vapor laser[6] (CVL). In this case, electrons in a gaseous discharge containing the copper vapor have a much preferred probability of pumping the upper laser level than the lower laser level (Fig. 7). Both of these lasers involve essentially three levels.

The second type of excitation is used for most solid-state lasers, such as the Nd^{3+} doped yttrium aluminum garnet laser[7] (commonly referred to as the Nd:YAG laser), for organic dye lasers,[8] and many others. It is probably the most common mechanism used to achieve the necessary population inversion. This process involves four level[2] (although it can include more) and generally occurs via excitation from the ground state 0 to an excited state 3 which energetically lies above the upper-laser-level 2. The population then decays from level 3 to level 2 by nonradiative processes (such as

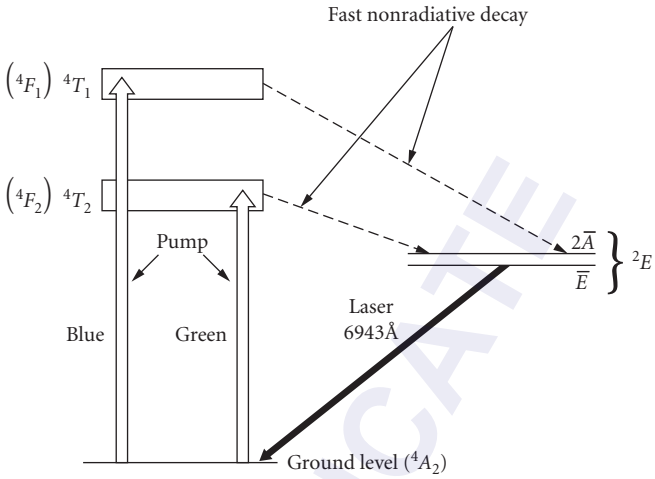

FIGURE 6 Energy-level diagram for a ruby laser showing the pump wavelength bands and the laser transition. The symbols $^4T_1$ and $^4T_2$ are shown as the appropriate designations for the pumping levels in ruby along with the more traditional designations in parenthesis.

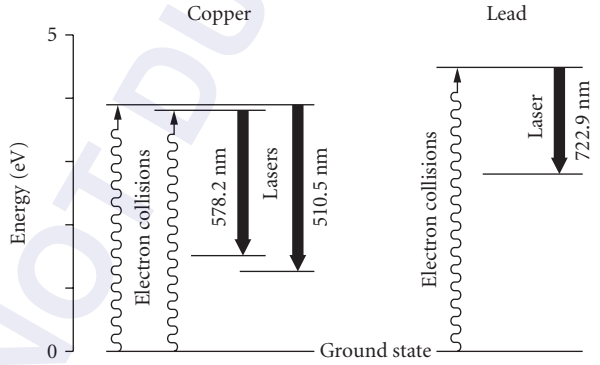

FIGURE 7 Energy-level diagrams of the transient three-level copper and lead vapor lasers showing the pump processes as well as the laser transitions.

collisional processes in gases), but can also decay radiatively to level 2. If the proper choice of materials has been made, the lower-laser-level 1 in some systems will decay rapidly to the ground state (level 0) which allows the condition $N_2 > (g_2/g_1)N_1$ to be satisfied. This situation is shown in Fig. 8 for an Nd:YAG laser crystal.

Optimization of the Output Coupling from a Laser Cavity[9]

A laser will operate with any combination of mirror reflectivities subject to the constraints of the threshold condition of Eq. (17*a* or *b*). However, since lasers are devices that are designed to use the

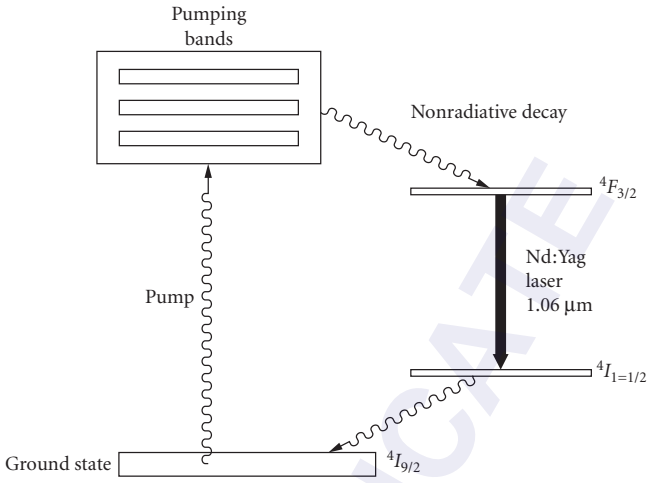

FIGURE 8 Energy-level diagram of the Nd:YAG laser indicating the four-level laser excitation process.

laser power in various applications, it is desirable to extract the most power from the laser in the most efficient manner. A simple expression for the optimum laser output coupling is given as

$$t_{\text{opt}} = (a_L g_{21} L)^{1/2} - a_L \tag{18}$$

in which a_L is the absorption and scattering losses per pass through the amplifier (the same as in Eq. (17*a* and *b*), g_{21} is the small signal gain per pass through the amplifier, and L is the length of the gain medium. This value of t_{opt} is obtained by assuming that equal output couplings are used for both mirrors at the ends of the cavity. To obtain all of the power from one end of the laser, the output transmission must be doubled for one mirror and the other mirror is made to be a high reflector.

The intensity of the beam that would be emitted from the output mirror can be estimated to be

$$I_{t_{\max}} = \frac{I_{\text{sat}} t_{\text{opt}}^2}{2a_L} \tag{19}$$

in which I_{sat} is the saturation intensity as obtained from Eq. (15). If all of the power is desired from one end of the laser, as discussed above, then $I_{t_{\max}}$ would be doubled in the above expression.

Pumping Techniques to Produce Inversions

Excitation or pumping of the upper laser level generally occurs by two techniques: (1) particle pumping and (2) optical or photon pumping. No matter which process is used, the goal is to achieve sufficient pumping flux and, consequently enough, population in the upper-laser-level 2 to exceed the requirements of either Eq. (16) or Eq. (17).

Particle Pumping[20] Particle pumping occurs when a high-speed particle collides with a laser species and converts its kinetic energy to internal energy of the laser species. Particle pumping occurs mostly with electrons as the pumping particles. This is especially common in a gas discharge where a voltage is applied across a low-pressure gas and the electrons flow through the tube in the form of a discharge current that can range from a few milliamps to tens of amperes, depending upon the particular laser and the power level desired. This type of excitation process is used for lasers such as the argon (Fig. 9) and krypton ion lasers, the copper vapor laser, excimer lasers, and the molecular nitrogen laser.

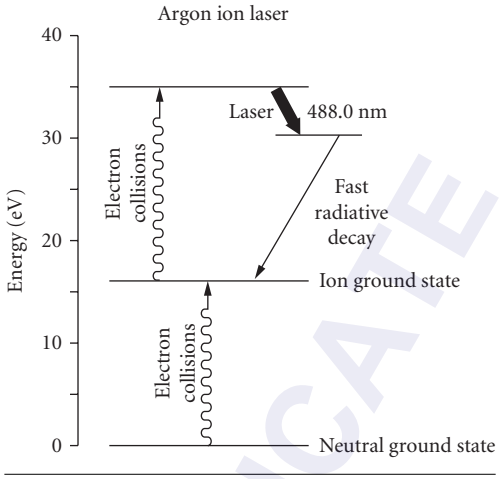

FIGURE 9 Energy-level diagram of the argon ion laser indicating the two-step excitation process.

Two other well-known gas lasers, the helium-neon laser and the helium-cadmium laser, operate in a gas discharge containing a mixture of helium gas and the laser species (neon gas or cadmium vapor). When an electric current is produced within the discharge, the high-speed electrons first pump an excited metastable state in helium (essentially a storage reservoir). The energy is then transferred from this reservoir to the upper laser levels of neon or cadmium by collisions of the helium metastable level with the neon or cadmium ground-state atoms as shown in Fig. 10. Electron collisions with the cadmium ion ground state have also been shown to produce excitation in the case of the helium-cadmium laser.

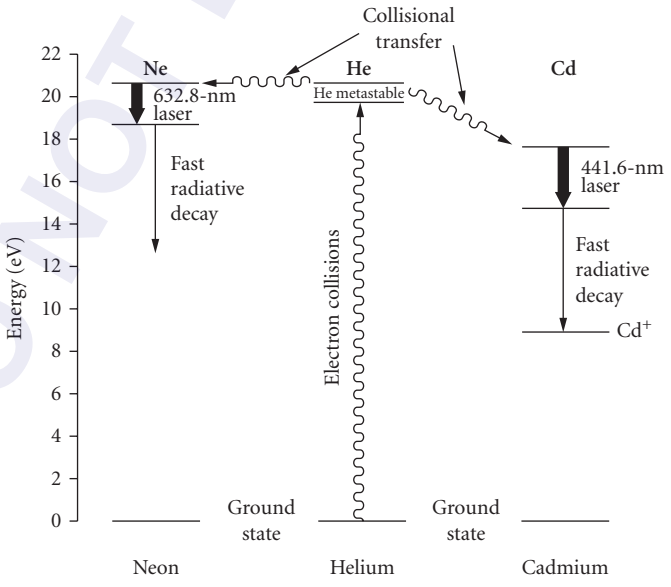

FIGURE 10 Energy-level diagrams of the helium-neon (He-Ne) laser and the helium-cadmium (He-Cd) laser that also include the helium metastable energy levels that transfer their energy to the upper laser levels by collisions.

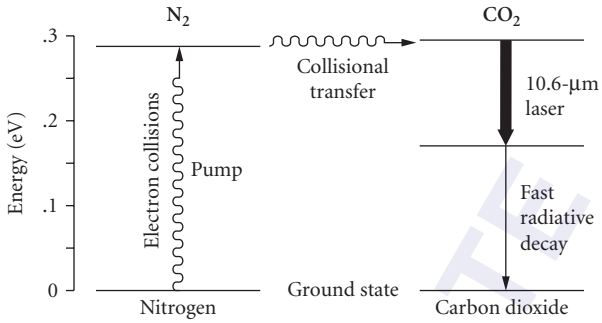

FIGURE 11 Energy-level diagram of the carbon dioxide (CO_2) laser along with the energy level of molecular nitrogen that collisionally transfers its energy to the CO_2 upper laser level.

In an energy-transfer process similar to that of helium with neon or cadmium, the CO_2 laser operates by using electrons of the gas discharge to produce excitation of molecular nitrogen vibrational levels that subsequently transfer their energy to the vibrational upper laser levels of CO_2 as indicated in Fig. 11. Helium is used in the CO_2 laser to control the electron temperature and also to cool (reduce) the population of the lower laser level via collisions of helium atoms with CO_2 atoms in the lower laser level.

High-energy electron beams and even nuclear reactor particles have also been used for particle pumping of lasers, but such techniques are not normally used in commercial laser devices.

Optical Pumping[7] Optical pumping involves the process of focusing light into the gain medium at the appropriate wavelength such that the gain medium will absorb most (or all) of the light and thereby pump that energy into the upper laser level as shown in Fig. 12. The selectivity in pumping the laser level with an optical pumping process is determined by choosing a gain medium having significant absorption at a wavelength at which a suitable pump light source is available. This of course implies that the absorbing wavelengths provide efficient pumping pathways to the upper laser level. Optical pumping requires very intense pumping light sources, including flash lamps and other lasers. Lasers that are produced by optical pumping include organic dye lasers and solid-state lasers. The two types of energy level arrangements for producing lasers via optical pumping were described in detail in the section "How Population Inversions Are Achieved" and shown in Figs. 6 and 8.

Flash lamps used in optically pumped laser systems are typically long, cylindrically shaped, fused quartz structures of a few millimeters to a few centimeters in diameter and 10 to 50 cm in

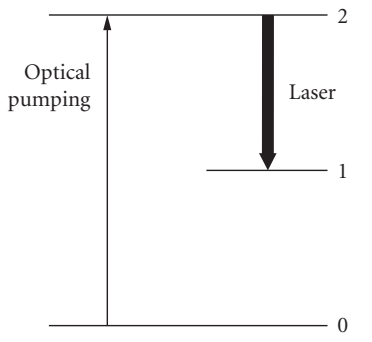

FIGURE 12 A general diagram showing optical pumping of the upper laser level.

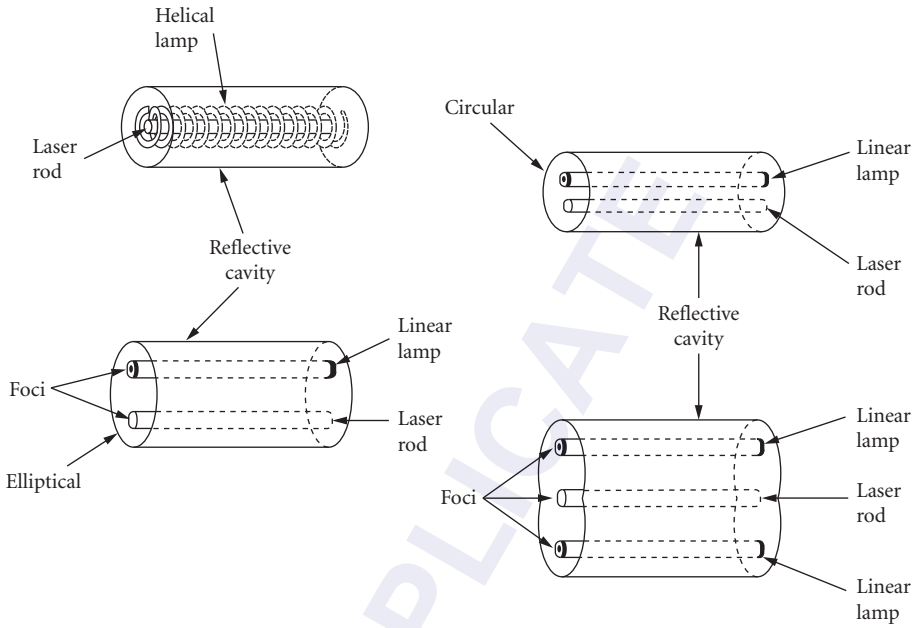

FIGURE 13 Flash lamp pumping arrangements for solid-state laser rods showing the use of helical lamps as well as linear lamps in a circular cavity, a single elliptical cavity, and a double elliptical cavity.

length. The lamps are filled with gases such as xenon and are initiated by running an electrical current through the gas. The light is concentrated into the lasing medium by using elliptically shaped reflecting cavities that surround both the laser medium and the flash lamps as shown in Fig. 13. These cavities efficiently collect and transfer to the laser rod most of the lamp energy in wavelengths within the pump absorbing band of the rod. The most common flash lamp-pumped lasers are Nd:YAG, Nd:glass, and organic dye lasers. New crystals such as Cr:LiSAF and HoTm:YAG are also amenable to flash lamp pumping.

Solid-state lasers also use energy-transfer processes as part of the pumping sequence in a way similar to that of the He-Ne and He-Cd gas lasers. For example, Cr^{3+} ions are added into neodymium-doped crystals to improve the absorption of the pumping light. The energy is subsequently transferred to the Nd^{3+} laser species. Such a process of adding desirable impurities is known as *sensitizing*.

Lasers are used as optical pumping sources in situations where (1) it is desirable to be able to concentrate the pump energy into a small-gain region or (2) it is useful to have a narrow spectral output of the pump source in contrast with the broadband spectral distribution of a flash lamp.

Laser pumping is achieved by either transverse pumping (a direction perpendicular to the direction of the laser beam) or longitudinal pumping (a direction in the same direction as the emerging laser beam). Frequency doubled and tripled pulsed Nd:YAG lasers are used to transversely pump organic dye lasers[8] that provide continuously tunable laser radiation over the near-ultraviolet, visible, and near-infrared spectral regions (by changing dyes at appropriate wavelength intervals). For transverse pumping, the pump lasers are typically focused into the dye medium with a cylindrical lens to provide a 1- to 2-cm-long (but very narrow) gain medium in the liquid dye solution. The dye concentration is adjusted to absorb the pump light within a millimeter or so into the dye cell to provide the very high concentration of gain near the surface of the cell.

Both cw and mode-locked argon ion lasers and Nd:YAG lasers are typically used for longitudinal or end pumping of cw and/or mode-locked organic dye lasers and also of solid-state gain media. In this pumping arrangement the pump laser is focused into a very thin gain region, which is provided by either a thin jet stream of flowing dye solution (Fig. 14) or a solid-state crystal such as $Ti:Al_2O_3$.

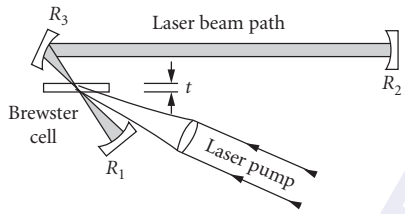

FIGURE 14 End-pumping cavity arrangement for either organic dye lasers or solid-state lasers.

The thin gain medium is used, in the case of the generation of ultrashort mode-locked pulses, so as to allow precise timing of the short-duration pump pulses with the ultrashort laser pulses that develop within the gain medium as they travel within the optical cavity.

Thin-disk lasers are diode-pumped solid-state lasers that efficiently produce high output power with good beam quality. Such lasers have gain media with a very short axial dimension of several hundred microns and wide transverse dimensions of several centimeters. The disks are antireflection coated for both the lasing and pumping wavelengths on the front side and a high reflection coating on the rear side. The laser crystal is mounted on a heat sink to efficiently remove the wasted heat of the pumping process. An output coupling mirror is mounted in front of the disk to provide multiple passes of the beam through the gain medium, for maximum power extraction, and to provide good mode quality. Yb:YAG is the most successful laser material for this type of laser.

Gallium arsenide semiconductor diode lasers, operating at wavelengths around 0.8 μm, can be effectively used to pump Nd:YAG lasers because the laser wavelength is near that of the strongest absorption feature of the pump band of the Nd:YAG laser crystal, thereby minimizing excess heating of the laser medium. Also, the diode lasers are very efficient light sources that can be precisely focused into the desired mode volume of a small Nd:YAG crystal (Fig. 15*a*) which results in minimal waste of the pump light. Figure 15*b* shows how close-coupling of the pump laser and the Nd:YAG crystal can be used to provide compact efficient diode laser pumping. The infrared output of the

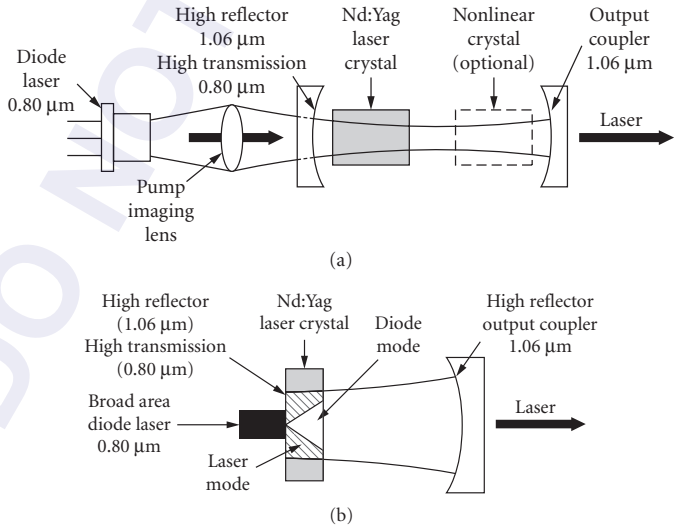

FIGURE 15 Pumping arrangements for diode-pumped Nd:YAG lasers showing both (*a*) standard pumping using an imaging lens and (*b*) close-coupled pumping in which the diode is located adjacent to the laser crystal.

Nd:YAG laser can then also be frequency doubled as indicated in Fig. 15*a*, using nonlinear optical techniques to produce a green laser beam in a relatively compact package.

Semiconductor Diode Laser Pumping Semiconductor laser pumping occurs when electrons are made to flow from an *n*-type semiconductor to a *p*-type semiconductor. In this case, as opposed to particle pumping described previously, it is not the kinetic energy of the electrons that does the excitation. Instead, it is the electrons themselves flowing into a *p*-doped material that produces the inversion. An analogy might be the water in a mountain region approaching a waterfall. The water is already at the upper energy site and loses its energy when it cascades down the waterfall. In the same sense, the electrons already have sufficient potential energy when they are pulled into the *p*-type material via an external electric field. Once they arrive, a population inversion exists where they recombine with the holes and cascade downward to produce the recombination radiation.

16.4 LASER PROPERTIES ASSOCIATED WITH OPTICAL CAVITIES OR RESONATORS

Longitudinal Laser Modes[1,2]

When a collimated optical beam of infinite lateral extent (a plane wave) passes through two reflecting surfaces of reflectivity R and also of infinite extent that are placed normal (or nearly normal) to the beam and separated by a distance d, as shown in Fig. 16*a*, the plot of transmission versus wavelength for the light as it emerges from the second reflecting surface is shown in Fig. 16*b*. The transmission reaches a maximum of 100 percent (if there are no absorption losses at the reflecting surfaces) at frequency spacings of $\Delta\nu = c/2\eta d$ where c is the speed of light in a vacuum, and η is the index of refraction of the medium between the mirrors. This frequency-selective optical device is known as a Fabry-Perot interferometer and has many useful applications in optics.

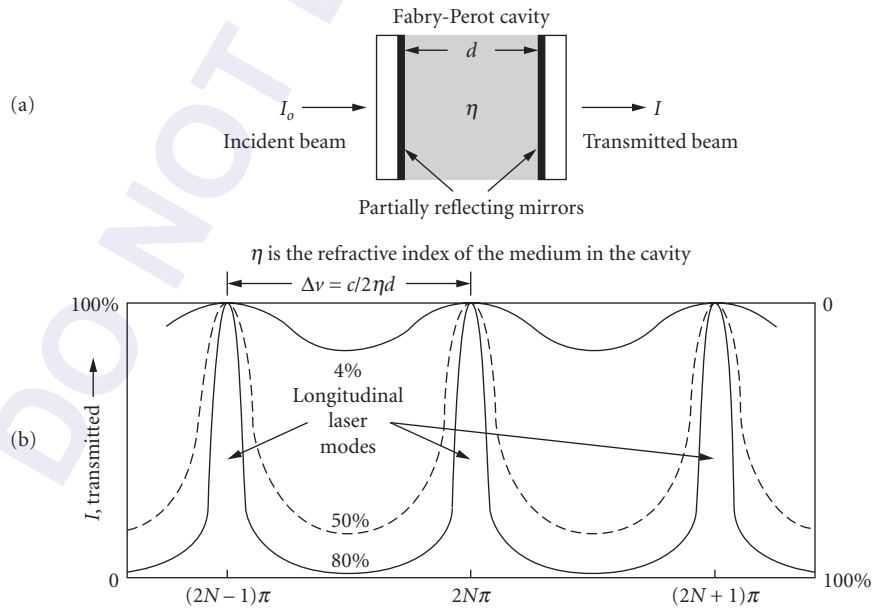

FIGURE 16 Fabry-Perot optical cavity consisting of two plane-parallel mirrors with a specific reflectivity separated by a distance d indicating the frequency spacing of longitudinal modes.

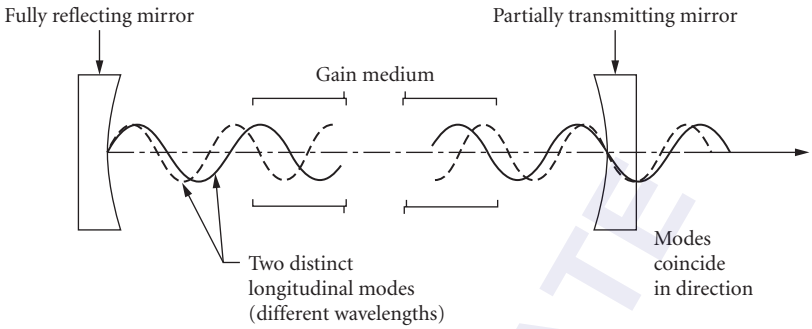

FIGURE 17 Laser resonator showing two distinct longitudinal modes traveling in the same direction but with slightly different frequencies.

The transmission through this device, as shown in Fig. 16*b* is enhanced at regular frequency or wavelength intervals due to the development of standing waves that resonate within the optical cavity. The enhancement occurs at frequencies (or wavelengths) at which complete sinusoidal half-cycles of the electromagnetic wave exactly "fit" between the mirrors such that the value of the electric field of the wave is zero at the mirror surfaces.

If a laser amplifier is placed between two mirrors in the same arrangement as described above, the same standing waves tend to be enhanced at frequency intervals of

$$\nu = n(c/2\eta d) \tag{20}$$

where n is an integer that indicates the number of half wavelengths of the laser light that fit within the spacing d of the two mirrors. In a typical laser operating in the visible spectral region, n would be of the order of 30,000 to 40,000. In such a laser, the output of the laser beam emerging from the cavity is very strongly enhanced at the resonant wavelengths as shown in Fig. 17, since these are the wavelengths that have the lowest loss within the cavity. The widths of the resonances shown in Fig. 17 are those of a passive Fabry-Perot cavity. When an active gain medium is placed within the cavity, the linewidth of the beam that is continually amplified as it reflects back and forth between the mirrors is narrowed even further.

These enhanced regions of very narrow frequency output are known as *longitudinal modes* of the laser. They are referred to as modes since they represent discrete values of frequency associated with the integral values of n at which laser output occurs. Lasers operating on a single longitudinal mode with ultrastable cavities and ultrahigh reflectivity mirrors have generated linewidths as narrow as a few hundred hertz or less. Since the longitudinal or temporal coherence length of a beam of light is determined by $c/\Delta\nu$, a very narrow laser linewidth can provide an extremely long coherence length and thus a very coherent beam of light.

For a typical gas laser (not including excimer lasers), the laser gain bandwidth is of the order of 10^9 to 10^{10} Hz. Thus, for a laser mirror cavity length of 0.5 m, the mode spacing would be of the order of 300 MHz and there would be anywhere from 3 to 30 longitudinal modes operating within the laser cavity. For an organic dye laser or a broadband solid-state laser, such as a Ti:Al_2O_3 laser, there could be as many as one million distinct longitudinal modes, each of a slightly different frequency than the next one, oscillating at the same time. However, if mode-locking is not present, typically only one or a few modes will dominate the laser output of a homogeneously broadened laser gain medium.

Transverse Laser Modes[11–14]

The previous section considered the implications of having a collimated or parallel beam of light of infinite lateral extent pass through two infinite reflecting surfaces that are arranged normal to the direction of propagation of the beam and separated by a specific distance d. We must now

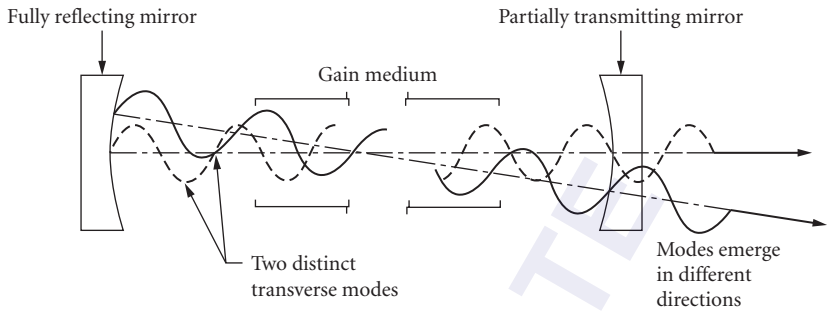

FIGURE 18 Laser resonator showing two distinct transverse modes traveling in different directions with slightly different frequencies.

consider the consequences of having the light originate within the space between the two mirrors in an amplifier that has only a very narrow lateral extent limited by either the diameter of the mirrors or by the diameter of the amplifying medium. The beam evolves from the spontaneous emission within the gain medium and eventually becomes a nearly collimated beam when it reaches I_{sat} since only rays traveling in a very limited range of directions normal to the laser mirrors will experience enough reflections to reach I_{sat}. The fact that the beam has a restricted aperture in the direction transverse to the direction of propagation causes it to evolve with a slight transverse component due to diffraction, which effectively causes the beam to diverge. This slight divergence actually consists of one or more distinctly separate beams that can operate individually or in combination.

These separate beams that propagate in the z direction are referred to as *transverse modes* as shown in Fig. 18. They are characterized by the various lateral spatial distributions of the electric field vector $\mathbf{E}(x, y)$ in the x-y directions as they emerge from the laser. These transverse amplitude distributions for the waves can be described by the relationship.

$$E_{pq}(x, y) = H_p\left(\frac{\sqrt{2}x}{w}\right) H_a\left(\frac{\sqrt{2}y}{w}\right) e^{-(x^2+y^2)/w^2} \tag{21}$$

In this solution, p and q are positive integers ranging from zero to infinity that designate the different modes which are associated with the order of the Hermite polynomials. Thus every set of p, q represents a specific distribution of wave amplitude at one of the mirrors, or a specific transverse mode of the open-walled cavity. We can list several Hermite polynomials as follows:

$$\begin{aligned} &H_0(u) = 1 \qquad H_1(u) = 2u \\ &H_2(u) = 2(2u^2 - 1) \\ &H_m(u) = (-1)^m e^{u^2} \frac{d^m(e^{-u^2})}{du^m} \end{aligned} \tag{22}$$

The spatial intensity distribution would be obtained by squaring the amplitude distribution function of Eq. (21). The transverse modes are designated TEM for transverse electromagnetic. The lowest order mode is given by TEM_{00}. It could also be written as TEM_{n00} in which n would designate the longitudinal mode number [Eq. (20)]. Since this number is generally very large for optical frequencies, it is not normally given.

The lowest order TEM_{00} mode has a circular distribution with a gaussian shape (often referred to as the *gaussian mode*) and has the smallest divergence of any of the transverse modes. Such a mode can be focused to a spot size with dimensions of the order of the wavelength of the beam. It has a minimum width or waist $2w_o$ that is typically located between the laser mirrors (determined

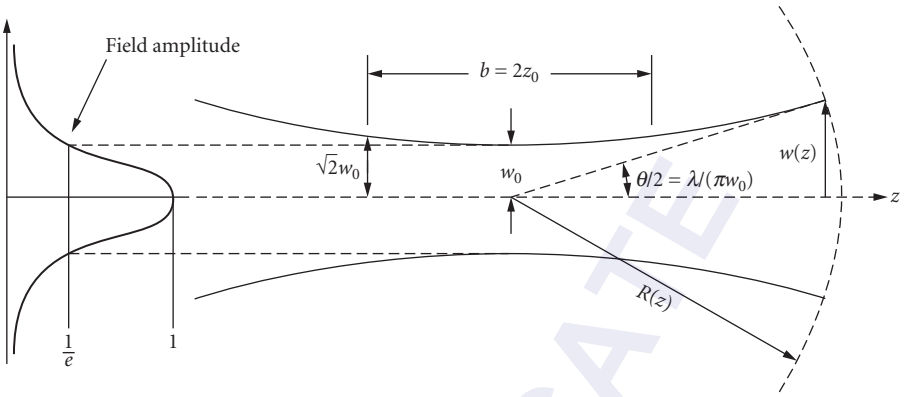

FIGURE 19 Parameters of a gaussian-shaped beam which are the features of a TEM_{00} transverse laser mode.

by the mirror curvatures and separation) and expands symmetrically in opposite directions from that minimum waist according to the following equation:

$$w(z)=w_o\left[1+\left(\frac{\lambda z}{\eta\pi w_o^2}\right)^2\right]^{1/2}=w_o\left[1+\left(\frac{z}{z_o}\right)^2\right]^{1/2} \tag{23}$$

where $w(z)$ is the beam waist at any location z measured from w_o, η is the index of refraction of the medium, and $z_o=\eta\pi w_o^2/\lambda$ is the distance over which the beam waist expands to a value of $\sqrt{2}w_o$.

The waist $w(z)$ at any location, as shown in Fig. 19, describes the transverse dimension within which the electric field distribution of the beam decreases to a value of 37 percent $(1/e)$ of its maximum on the beam axis and within which 86.5 percent of the beam energy is contained. The TEM_{00} mode would have an intensity distribution that is proportional to the square of Eq. (21) for $p=q=0$ and, since it is symmetrical around the axis of propagation, it would have a cylindrically symmetric distribution of the form

$$I(r,z)=I_o e^{-2r^2/w^2(z)} \tag{24}$$

where I_o is the intensity on the beam axis.

The beam also has a wavefront curvature given by

$$R(z)=z\left[1+\left(\frac{\eta\pi w_o^2}{\lambda z}\right)^2\right] \tag{25}$$

which is indicated in Fig. 19, and a far-field angular divergence given by

$$\theta=\lim_{z\to\infty}\frac{2w(z)}{z}=\frac{2\lambda}{\pi w_o}=0.64\frac{\lambda}{w_o} \tag{26}$$

For a symmetrical cavity formed by two mirrors, each of radius of curvature R, separated by a distance d and in a medium in which $\eta=1$ the minimum beam waist w_o is given by

$$w_o^2=\frac{\lambda}{2\pi}[d(2R-d)]^{1/2} \tag{27}$$

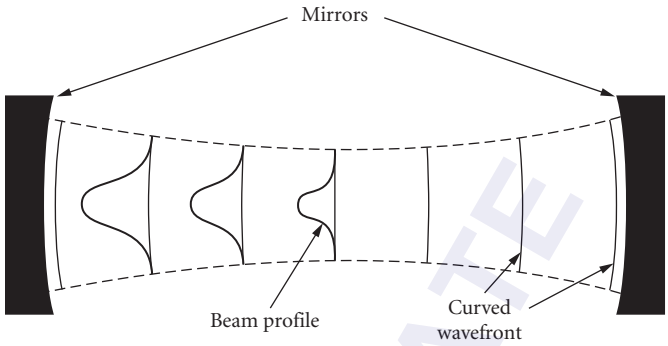

FIGURE 20 A stable laser resonator indicating the beam profile at various locations along the beam axis as well as the wavefront at the mirrors that matches the curvature of the mirrors.

and the radius of curvature r_c of the wavefront is

$$r_c = z + \frac{d(2R-d)}{4z} \tag{28}$$

For a confocal resonator in which $R=d$, w_o is given by

$$w_o = \sqrt{\frac{\lambda d}{2\pi}} \tag{29}$$

and the beam waist (spot size) at each mirror located a distance $d/2$ from the minimum is

$$w = \sqrt{\frac{\lambda d}{\pi}} \tag{30}$$

Thus, for a confocal resonator, $w(d/2)$ at each of the mirrors is equal to $\sqrt{2}w_o$ and thus at that location, $z=z_o$. The distance between mirrors for such a cavity configuration is referred to as the *confocal parameter b* such that $b=2z_o$. In a stable resonator, the curvature of the wavefront at the mirrors, according to Eqs. (25) and (28), exactly matches the curvature of the mirrors as shown in Fig. 20.

Each individual transverse mode of the beam is produced by traveling a specific path between the laser mirrors such that, as it passes from one mirror to the other and returns, the gain it receives from the amplifier is at least as great as the total losses of the mirror, as indicated from Eq. (17), plus the additional diffraction losses produced by either the finite lateral extent of the laser mirrors or the finite diameter of the laser amplifier or some other optical aperture placed in the system, whichever is smaller. Thus the TEM_{00} mode is produced by a beam passing straight down the axis of the resonator as indicated in Fig. 19.

Laser Resonator Configurations and Cavity Stability[4,14]

There are a variety of resonator configurations that can be used for lasers. The use of slightly curved mirrors leads to much lower diffraction losses of the transverse modes than do plane parallel mirrors, and they also have much less stringent alignment tolerances. Therefore, most lasers use curved mirrors for the optical cavity. For a cavity with two mirrors of curvature R_1 and R_2, and a separation distance d, a number of possible cavity configurations are shown in Fig. 21.

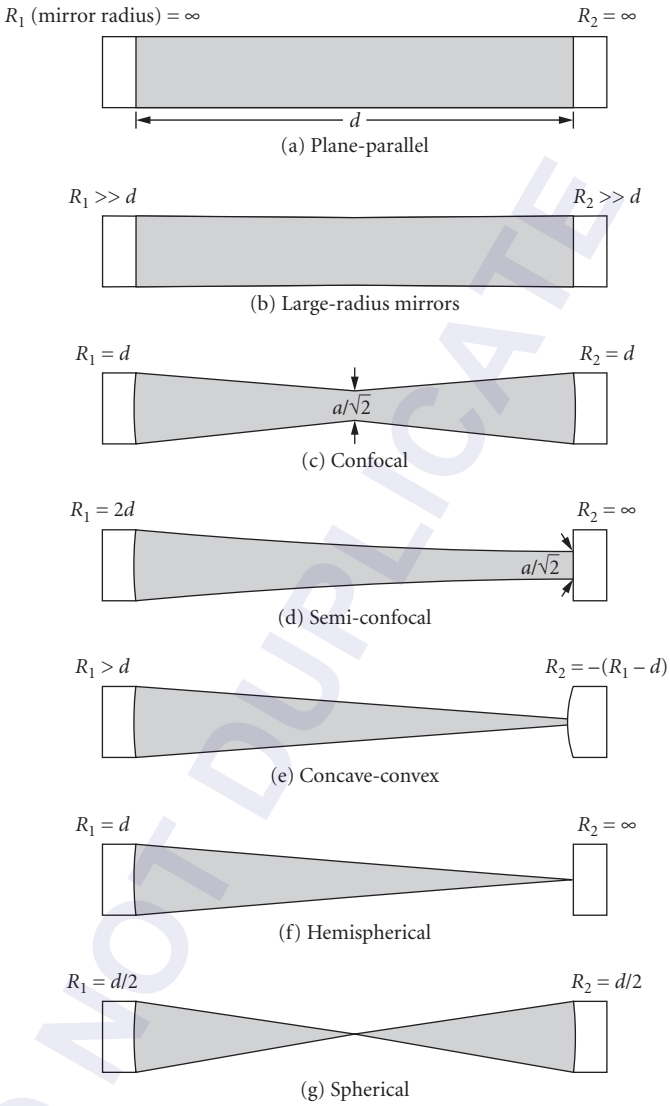

FIGURE 21 Possible two-mirror laser cavity configurations indicating the relationship of the radii of curvature of the mirrors with respect to the separation between mirrors.

A relationship between the radii of curvature and the separation between mirrors can be defined as

$$g_1 = 1 - \frac{d}{R_1} \quad \text{and} \quad g_2 = 1 - \frac{d}{R_2} \tag{31}$$

such that the condition for stable transverse modes is given by

$$0 < g_1 g_2 < 1 \tag{32}$$

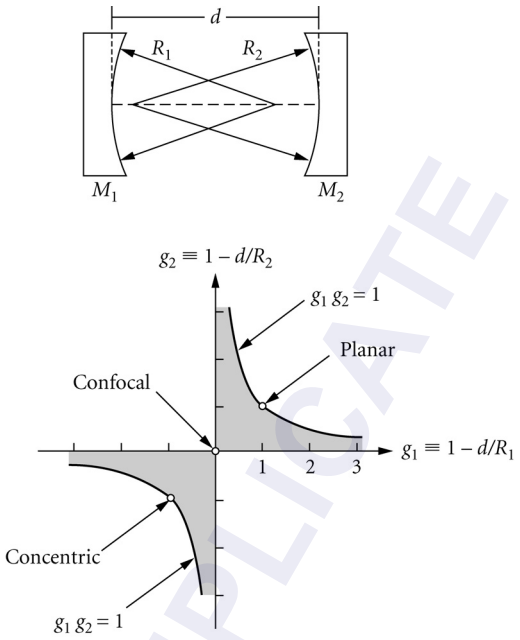

FIGURE 22 Stability diagram for two-mirror laser cavities indicating the shaded regions where stable cavities exist.

A stable mode is a beam that can be maintained with a steady output and profile over a relatively long period of time. It results from a cavity configuration that concentrates the beam toward the resonator axis in a regular pattern as it traverses back and forth within the cavity, rather than allowing it to diverge and escape from the resonator. In considering the various possible combinations of curved mirror cavities, one must keep the relation between the curvatures and mirror separation d within the stable regions of the graph, as shown in Fig. 22, in order to produce stable modes. Thus it can be seen from Fig. 22 that not all configurations shown in Fig. 21 are stable. For example, the planar, confocal, and concentric arrangements are just on the edge of stability according to Fig. 22.

There may be several transverse modes oscillating simultaneously "within" a single longitudinal mode. Each transverse mode can have the same value of n [Eq. (20)] but will have a slightly different value of d as it travels a different optical path between the resonator mirrors, thereby generating a slight frequency shift from that of an adjacent transverse mode. For most optical cavities, the mode that operates most easily is the TEM_{00} mode, since it travels a direct path along the axis of the gain medium.

16.5 SPECIAL LASER CAVITIES

Unstable Resonators[14]

A laser that is operating in a TEM_{00} mode, as outlined above, typically has a beam within the laser cavity that is relatively narrow in width compared to the cavity length. Thus, if a laser with a relatively wide gain region is used, to obtain more energy in the output beam, it is not possible to extract the energy from that entire region from a typically very narrow low-order gaussian mode.

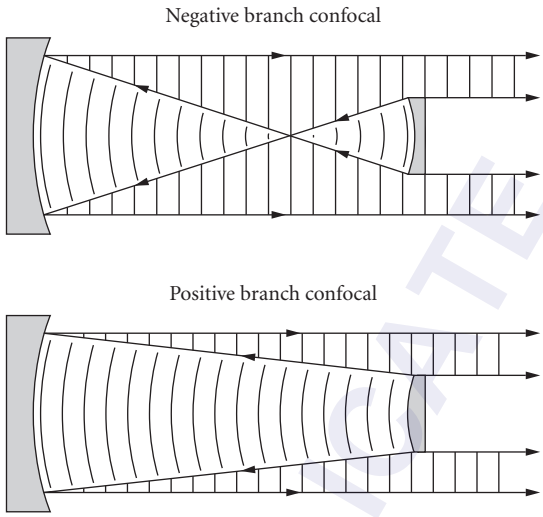

FIGURE 23 Unstable resonator cavity configurations showing both the negative and positive branch confocal cavities.

A class of resonators has been developed that can extract the energy from such wide laser volumes and also produce a beam with a nearly gaussian profile that makes it easily focusable. These resonators do not meet the criteria for stability, as outlined above, but still provide a good beam quality for some types of lasers. This class of resonators is referred to as *unstable resonators*.

Unstable resonators are typically used with high-gain laser media under conditions such that only a few passes through the amplifier will allow the beam to reach the saturation intensity and thus extract useful energy. A diagram of two unstable resonator cavity configurations is shown in Fig. 23. Figure 23*b* is the positive branch confocal geometry and is one of the most common unstable resonator configurations. In this arrangement, the small mirror has a convex shape and the large mirror a concave shape with a separation of length d such that $R_2 - R_1 = 2d$. With this configuration, any ray traveling parallel to the axis from left to right that intercepts the small convex mirror will diverge toward the large convex mirror as though it came from the focus of that mirror. The beam then reflects off of the larger mirror and continues to the right as a beam parallel to the axis. It emerges as a reasonably well-collimated beam with a hole in the center (due to the obscuration of the small mirror). The beam is designed to reach the saturation intensity when it arrives at the large mirror and will therefore proceed to extract energy as it makes its final pass through the amplifier. In the far field, the beam is near gaussian in shape, which allows it to be propagated and focused according to the equations described in the previous section. A number of different unstable resonator configurations can be found in the literature for specialized applications.

Q-Switching[15]

A typical laser, after the pumping or excitation is first applied, will reach the saturation intensity in a time period ranging from approximately 10 ns to 1 μs, depending upon the value of the gain in the medium. For lasers such as solid-state lasers the upper-laser-level lifetime is considerably longer than this time (typically 50 to 200 μs). It is possible to store and accumulate energy in the form of population in the upper laser level for a time duration of the order of that upper-level lifetime. If the laser cavity could be obscured during this pumping time and then suddenly switched into the system at a time order of the upper-laser-level lifetime, it would be possible for the gain, as well as

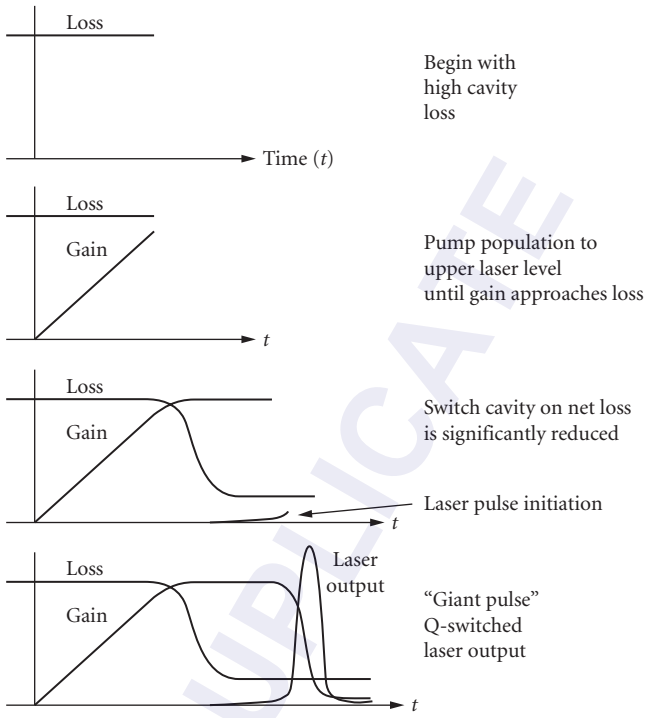

FIGURE 24 Schematic diagram of a Q-switched laser indicating how the loss is switched out of the cavity and a gaint laser pulse is produced as the gain builds up.

the laser energy, to reach a much larger value than it normally would under steady-state conditions. This would produce a "giant" laser pulse of energy from the system.

Such a technique can in fact be realized and is referred to as *Q-switching* to suggest that the cavity Q is changed or switched into place. The cavity is switched on by using either a rapidly rotating mirror or an electro-optic shutter such as a Pockel cell or a Kerr cell. Nd:YAG and Nd:glass lasers are the most common Q-switched lasers. A diagram of the sequence of events involved in Q-switching is shown in Fig. 24.

Another technique that is similar to Q-switching is referred to as *cavity dumping*. With this technique, the intense laser beam inside of a normal laser cavity is rapidly switched out of the cavity by a device such as an acousto-optic modulator. Such a device is inserted at Brewster's angle inside the cavity and is normally transparent to the laser beam. When the device is activated, it rapidly inserts a high-reflecting surface into the cavity and reflects the beam out of the cavity. Since the beam can be as much as two orders of magnitude higher in intensity within the cavity than that which leaks through an output mirror, it is possible to extract high power on a pulsed basis with such a technique.

Mode-Locking[14]

In the discussion of longitudinal modes it was indicated that such modes of intense laser output occur at regularly spaced frequency intervals of $\Delta\nu = c/2\eta d$ over the gain bandwidth of the laser medium. For laser cavity lengths of the order of 10 to 100 cm these frequency intervals range from approximately 10^8 to 10^9 Hz. Under normal laser operation, specific modes with the highest gain

tend to dominate and quench other modes (especially if the gain medium is homogeneously broadened). However, under certain conditions it is possible to obtain all of the longitudinal modes lasing simultaneously, as shown in Fig. 25*a*. If this occurs, and the modes are all phased together so that they can act in concert by constructively and destructively interfering with each other, it is possible to produce a series of giant pulses separated in a time Δt of

$$\Delta t = 2\eta d/c \tag{33}$$

or approximately 1 to 10 ns for the cavity lengths mentioned above (see Fig. 25*b*). The pulse duration is approximately the reciprocal of the separation between the two extreme longitudinal laser modes or

$$\Delta t_p = \frac{1}{n\Delta\nu} \tag{34}$$

as can also be seen in Fig. 25*b*. This pulse duration is approximately the reciprocal of the laser gain bandwidth. However, if the index of refraction varies significantly over the gain bandwidth, then all of the frequencies are not equally spaced and the mode-locked pulse duration will occur only within the frequency width over which the frequency separations are approximately the same.

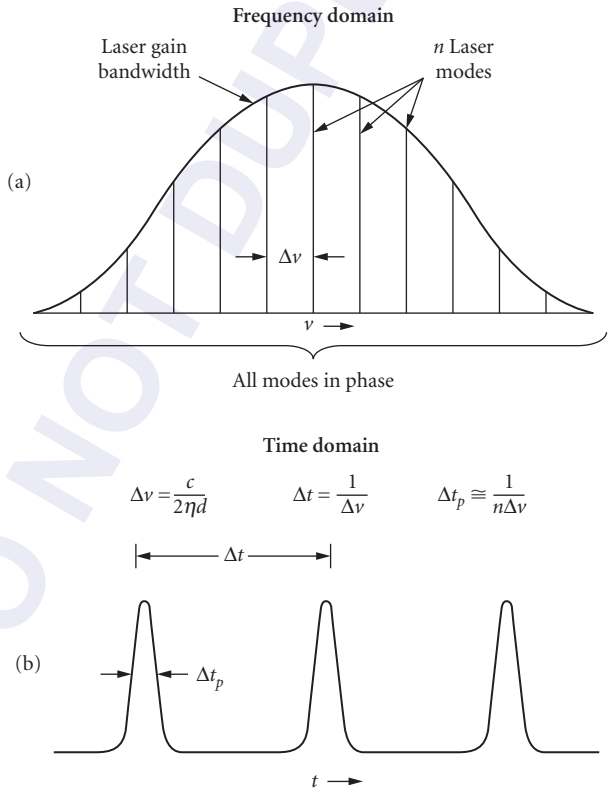

FIGURE 25 Diagrams in both the frequency and time domains of how mode-locking is produced by phasing n longitudinal modes together to produce an ultrashort laser pulse.

The narrowest pulses are produced from lasers having the largest gain bandwidth such as organic dye lasers, and solid-state lasers including Ti:Al_2O_3, Cr:Al_2O_3, and Cr:LiSAlF. The shortest mode-locked pulses to date, 4.4×10^{-15} seconds, have been produced in Ti:sapphire at a center wavelength of 820 nm at a rep rate of 80 MHz. Using pulse compression techniques, such pulses have been made as short as 3.5×10^{-15} seconds.

Such short-pulse operation is referred to as *mode-locking* and is achieved by inserting a very fast shutter within the cavity which is opened and closed at the intervals of the round-trip time of the short laser pulse within the cavity. This shutter coordinates the time at which all of the modes arrive at the mirror and thus brings them all into phase at that location. Electro-optic shutters, short duration gain pumping by another mode-locked laser, or passive saturable absorbers are techniques that can serve as the fast shutter. The second technique, short-duration gain pumping, is referred to as *synchronous pumping*. Three fast saturable absorber shutter techniques for solid-state lasers include colliding pulse mode-locking,[16] additive pulse mode-locking,[17] and Kerr lens mode-locking.[18]

Extremely short soft-x-ray pulses have also been produced via the interaction of intense laser beams with atoms. These pulses have been made as short as 70 as (70×10^{-18} seconds).

Distributed Feedback Lasers[19]

The typical method of obtaining feedback into the laser gain medium is to have the mirrors located at the ends of the amplifier as discussed previously. It is also possible, however, to provide the reflectivity within the amplifying medium in the form of a periodic variation of either the gain or the index of refraction throughout the medium. This process is referred to as *distributed feedback* (DFB). Such feedback methods are particularly effective in semiconductor lasers in which the gain is high and the fabrication of periodic variations is not difficult. The reader is referred to the reference section at the end of this chapter for further information concerning this type of feedback.

Ring Lasers[14]

Ring lasers are lasers that have an optical path within the cavity that involves the beam circulating in a loop rather than passing back and forth over the same path. This requires optical cavities that have more than two mirrors. The laser beam within the cavity consists of two waves traveling in opposite directions with separate and independent resonances within the cavity. In some instances an optical device is placed within the cavity that provides a unidirectional loss. This loss suppresses one of the beams, allowing the beam propagating in the other direction to become dominant. The laser output then consists of a traveling wave instead of a standing wave and therefore there are no longitudinal modes. Such an arrangement also eliminates the variation of the gain due to the standing waves in the cavity (spatial hole burning), and thus the beam tends to be more homogeneous than that of a normal standing-wave cavity. Ring lasers are useful for producing ultrashort mode-locked pulses and also for use in laser gyroscopes as stable reference sources.

16.6 SPECIFIC TYPES OF LASERS

Lasers can be categorized in several different ways including wavelength, material type, and applications. In this section we will summarize them by material type such as gas, liquid, solid-state, and semiconductor lasers. We will include only lasers that are available commercially since such lasers now provide a very wide range of available wavelengths and powers without having to consider special laboratory lasers.

Gaseous Laser Gain Media

Helium-Neon Laser[10] The helium-neon laser was the first gas laser. The most widely used laser output wavelength is a red beam at 632.8 nm with a cw output ranging from 1 to 100 mW and sizes ranging from 10 to 100 cm in length. It can also be operated at a wavelength of 543.5 nm for some specialized applications. The gain medium is produced by passing a relatively low electrical current (10 mA) through a low pressure gaseous discharge tube containing a mixture of helium and neon. In this mixture, helium metastable atoms are first excited by electron collisions as shown in Fig. 10. The energy is then collisionally transferred to neon atom excited states which serve as upper laser levels.

Argon Ion Laser[10] The argon ion laser and the similar krypton ion laser operate over a wide range of wavelengths in the visible and near-ultraviolet regions of the spectrum. The wavelengths in argon that have the highest power are at 488.0 and 514.5 nm. Power outputs on these laser transitions are available up to 20 W cw in sizes ranging from 50 to 200 cm in length. The gain medium is produced by running a high electric current (many amperes) through a very low pressure argon or krypton gas. The argon atoms must be ionized to the second and third ionization stages (Fig. 9) in order to produce the population inversions. As a result, these lasers are inherently inefficient devices.

Helium-Cadmium Laser[10] The helium-cadmium laser operates cw in the blue at 441.6 nm, and in the ultraviolet at 353.6 and 325.0 nm with powers ranging from 20 to 200 mW in lasers ranging from 40 to 100 cm in length. The gain medium is produced by heating cadmium metal and evaporating it into a gaseous discharge of helium where the laser gain is produced. The excitation mechanisms include Penning ionization (helium metastables collide with cadmium atoms) and electron collisional ionization within the discharge as indicated in Fig. 10. The laser uses an effect known as *cataphoresis* to transport the cadmium through the discharge and provide the uniform gain medium.

Copper Vapor Laser[10] This pulsed laser provides high-average powers of up to 100 W at wavelengths of 510.5 and 578.2 nm. The copper laser and other metal vapor lasers of this class, including gold and lead lasers, typically operate at a repetition rate of up to 20 kHz with a current pulse duration of 10 to 50 ns and a laser output of 1 to 10 mJ/pulse. The copper lasers operate at temperatures in the range of 1600°C in 2- to 10-cm-diameter temperature-resistant tubes typically 100 to 150 cm in length. The lasers are self-heated such that all of the energy losses from the discharge current provide heat to bring the plasma tube to the required operating temperature. Excitation occurs by electron collisions with copper atoms vaporized in the plasma tube as indicated in Fig. 7.

Carbon-Dioxide Laser[10] The CO_2 laser, operating primarily at a wavelength of 10.6 μm, is one of the most powerful lasers in the world, producing cw powers of over 100 kW and pulsed energies of up to 10 kJ. It is also available in small versions with powers of up to 100 W from a laser the size of a shoe box. CO_2 lasers typically operate in a mixture of carbon dioxide, nitrogen, and helium gases. Electron collisions excite the metastable levels in nitrogen molecules with subsequent transfer of that energy to carbon dioxide laser levels as shown in Fig. 11. The helium gas acts to keep the average electron energy high in the gas discharge region and to cool or depopulate the lower laser level. This laser is one of the most efficient lasers, with conversion from electrical energy to laser energy of up to 30 percent.

Excimer Laser[20] The rare gas-halide excimer lasers operate with a pulsed output primarily in the ultraviolet spectral region at 351 nm in xenon fluoride, 308 nm in xenon chloride, 248 nm in krypton fluoride, and 193 nm in argon fluoride. The laser output, with pulse durations of 10 to 50 ns, is typically of the order of 0.2 to 1.0 J/pulse at repetition rates up to several hundred hertz. The lasers are relatively efficient (1 to 5 percent) and are of a size that would fit on a desktop. The excitation occurs via electrons within the discharge colliding with and ionizing the rare gas molecules and at the same time disassociating the halogen molecules to form negative halogen ions. These two species

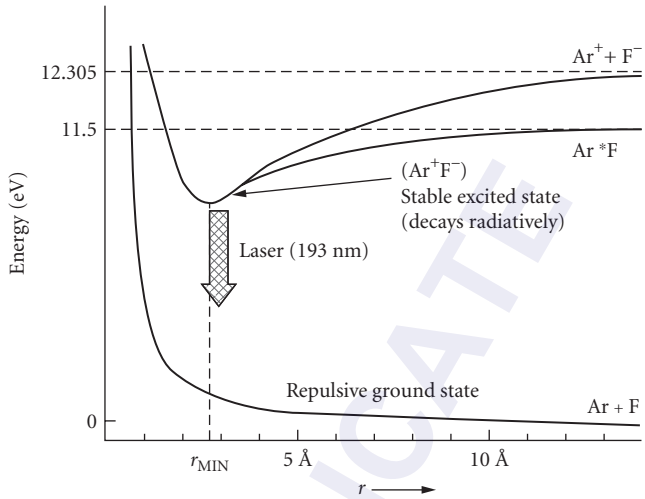

FIGURE 26 Energy-level diagram of an argon fluoride (ArF) excimer laser showing the stable excited state (upper laser level) and the unstable or repulsive ground state.

then combine to form an excited molecular state of the rare gas-halogen molecule which serves as the upper laser state. The molecule then radiates at the laser transition and the lower level advantageously disassociates since it is unstable, as shown in Fig. 26, for the ArF excimer molecule. The excited laser state is an excited state dimer which is referred to as an *excimer state*.

***X-Ray Laser*[21]** Laser output in the soft-x-ray spectral region has been produced in plasmas of highly ionized ions of a number of atomic species. The highly ionized ions are produced by the absorption of powerful solid-state lasers focused onto solid material of the desired atomic species. Since mirrors are not available for most of the soft-x-ray laser wavelengths (4 to 30 nm), the gain has to be high enough to obtain laser output in a single pass through the laser amplifier [Eq. (16)]. The lasers with the highest gain are the selenium laser (Se^{24+}) at 20.6 and 20.9 nm and the germanium laser (Ge^{22+}) at 23.2, 23.6, and 28.6 nm.

Liquid Laser Gain Media

***Organic Dye Lasers*[8]** A dye laser consists of a host or solvent material, such as alcohol or water, into which is mixed a laser species in the form of an organic dye molecule, typically in the proportion of one part in ten thousand. A large number of different dye molecules are used to make lasers covering a wavelength range of from 320 to 1500 nm with each dye having a laser bandwidth of the order of 30 to 50 nm. The wide, homogeneously broadened gain spectrum for each dye allows laser tunability over a wide spectrum in the ultraviolet, visible, and near-infrared. Combining the broad gain spectrum (Fig. 27) with a diffraction-grating or prism-tuning element allows tunable laser output to be obtained over the entire dye emission spectrum with a laser linewidth of 10 GHz or less. Dye lasers are available in either pulsed (up to 50 to 100 mJ/pulse) or continuous output (up to a few watts) in tabletop systems that are pumped by either flash lamps or by other lasers such as frequency doubled or tripled YAG lasers or argon ion lasers. Most dye lasers are arranged to have the dye mixture circulated by a pump into the gain region from a much larger reservoir since the dyes degrade at a slow rate during the excitation process.

Dye lasers, with their broad gain spectrum, are particularly attractive for producing ultrashort mode-locked pulses. Some of the shortest light pulses ever generated, of the order of 6×10^{-15} seconds,

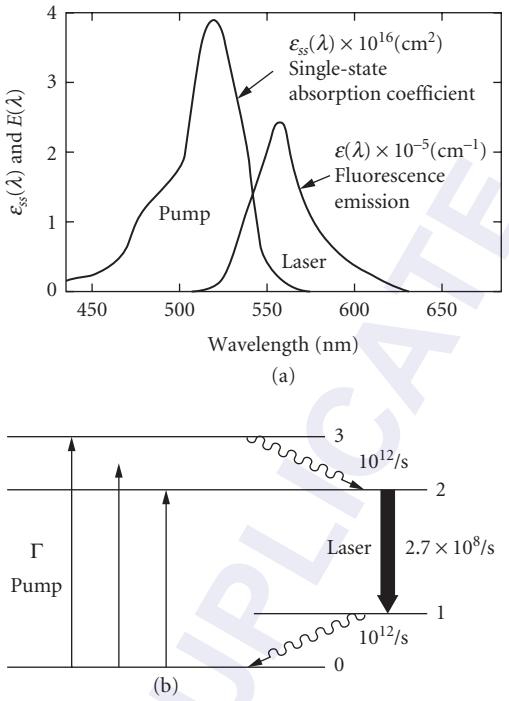

FIGURE 27 Absorption and emission spectra along with the energy-level diagram of an Rh6G organic dye laser showing both (*a*) the broad pump and emission bandwidths and (*b*) the fast decay of the lower laser level.

were produced with mode-locked dye lasers. A mode-locked dye laser cavity is shown in Fig. 14 with a thin dye gain region located within an astigmatically compensated laser cavity.

Dielectric Solid-State Laser Gain Media

Ruby Laser[5,7] The ruby laser, with an output at 694.3 nm, was the first laser ever developed. It consisted of a sapphire ($A1_2O_3$) host material into which was implanted a chromium laser species in the form of Cr^{3+} ions at a concentration of 0.05 percent as the amplifying medium. The ruby laser involves a three-level optical pumping scheme, with the excitation provided by flash lamps, and operates either in a pulsed or cw mode. The three-level scheme for the ruby laser (Fig. 6) requires a large fraction of the population to be pumped out of the ground state before an inversion occurs. Therefore, the ruby laser is not as efficient as other solid-state lasers such as the Nd:YAG laser which employs a four-level pumping scheme (Fig. 8). It is therefore no longer used as much as it was in the early days.

Nd:YAG and Nd:Glass Lasers[7] Neodymium atoms, in the form of Nd^{3+} ions, are doped into host materials, including crystals such as yttrium-aluminum-garnet (YAG) and various forms of glass, in concentrations of approximately one part per hundred. The pumping scheme is a four-level system as shown in Fig. 8. When implanted in YAG crystals to produce what is referred to as an Nd:YAG laser, the laser emits primarily at 1.06 μm with continuous powers of up to 250 W and with pulsed

powers as high as several mega watts. Difficulties in growing Nd:YAG crystals limit the size of commonly used laser rods to a maximum of 1 cm in diameter and 10 cm in length. Although this size limitation is somewhat restrictive, a YAG crystal has the advantage of high thermal conductivity allowing the rapid removal of wasted heat due to inefficient excitation. Efforts are being made to use Nd:YAG powders to be able to construct larger Nd:YAG laser rods, thereby providing the advantages of Nd:YAG laser without their usual size and laser power limitations. Slab geometries have recently been developed to compensate for focusing due to thermal gradients and gradient-induced stresses within the amplifier medium, thereby allowing higher average powers to be achieved. Efficient GaAs laser diodes are also being used to pump Nd:YAG amplifiers (see Fig. 15) since the diode pump wavelength matches a very strong pump absorption wavelength for the Nd^{3+} ion. This absorption wavelength is near the threshold pump energy, thereby minimizing the generation of wasted heat. Also, the diode pump laser can be made to more efficiently match the Nd laser mode volume than can a flash lamp.

Under long-pulse, flash lamp-pumped operation, Nd:YAG lasers can produce 5 J/pulse at 100 Hz from a single rod. The pulses are trains of relaxation oscillation spikes lasting 3 to 4 ms which is obtained by powerful, long-pulse flash lamp pumping. Q-switched Nd:YAG lasers, using a single Nd:YAG laser rod, can provide pulse energies of up to 1.5 J/pulse at repetition rates up to 200 Hz (75 W of average power).

Currently power levels of solid state Nd:YAG lasers are approaching 2 kW with repetition rates of nearly 10 kHz. These lasers are presently being developed for use in EUV microlithography as well as in applications such as liquid crystal display production, micromachining, and silicon processing (where carbon dioxide lasers are presently being used.)

Nd:glass lasers have several advantages over Nd:YAG lasers. They can be made in much larger sizes, allowing the construction of very large amplifiers. Nd:glass has a wider gain bandwidth which makes possible the production of shorter mode-locked pulses and a lower stimulated emission cross section. The latter property allows a larger population inversion to be created and thus more energy to be stored before energy is extracted from the laser. Nd:glass amplifiers operate at a wavelength near that of Nd:YAG, at 1.054 μm, for example, with phosphate glass, with a gain bandwidth 10 to 15 times broader than that of Nd:YAG. This larger gain bandwidth lowers the stimulated emission cross section compared to that of Nd:YAG, which allows increased energy storage when used as an amplifier, as mentioned above.

The largest laser system in the world is located at the National Ignition Facility (NIF) at Lawrence Livermore National Laboratories in Livermore, California. It consists of 192 separate laser beams traveling about 1000 ft from their origination (one of two master laser oscillators), to the center of a target chamber. The amplifiers are Nd-doped phosphate glass disc-shaped amplifiers with diameters of over a meter, installed at Brewster's angle within the laser beam path to reduce reflection losses. The beam of each of the 192 amplifiers is capable of producing an energy of 20,000 J with pulse durations ranging from 100 fs to 25 ps. One of the objectives of the laser facility is to test the concept of laser fusion as a source of useful commercial power production.

Neodymium-YLF Lasers Nd:YLF has relatively recently become an attractive laser with the successful implementation of diode laser pumping of solid state laser materials. It has the advantage over Nd:YAG in that the upper-laser-level lifetime is twice as long, thereby allowing twice the energy storage. Its lower stimulated emission cross section than that of Nd:YAG also increases the energy storage and thus the power output per unit volume of the crystal. It has a relatively large thermal conductivity, similar to Nd:YAG. Also the output is polarized and the crystal exhibits low thermal birefringence. Because its emission wavelength matches that of phosphate glass, the laser makes an ideal laser oscillator for seeding large Nd:glass amplifiers for laser fusion studies.

Neodymium:Yttrium Vanadate Lasers The Nd:VO_4 laser has also come into prominence with the use of diode pumping. Its advantages over Nd:YAG include a 5 times larger stimulated emission cross section (and hence higher gain) as well as a four times stronger absorption cross section with a 6 times wider pump absorption cross section centered at 809 nm. Therefore it can be effectively pumped in crystals of only a few millimeters in length and is therefore attractive for use in producing

small diode-pumped lasers. Typically this laser is frequency doubled or tripled intracavity to produce several watts of power at either 532 or 355 nm. It can be operated either cw or Q-switched at repetition rates of up to 100 KHz. It can also be operated at 1.342 μm.

Fiber Lasers The first major application of fiber lasers was in their use as amplifiers in the field of optical communications. The erbium-doped fiber is installed directly in the fiber-optic transmission line and pumped through the fiber itself. The useful wavelengths are in the 1.53 μm region where optical fibers have their lowest loss. A more recent application is in the production of high power output from large mode-area fibers. These lasers utilize single-emitter semiconductor diodes as the light source to pump the cladding of rare-earth doped optical fibers. Pulsed Ytterbium fiber lasers have demonstrated high average powers and peak powers of up to 25 kW with variable repetition rates from a few kilohertz to up to 400 kHz. Fiber lasers are being considered as the replacement technology for conventional solid state lasers due to their compactness, high wall-plug efficiency, high average and peak powers, stability, close to diffraction-limited beam quality and lack of thermal effects.

Ti:Al_2O_3 Laser and Other Broad Bandwidth Solid-State Lasers[7]

Another class of solid-state lasers provides emission and gain over a bandwidth of the order of 100 to 400 nm in the near-infrared, as indicated in Fig. 28. The pump absorption band is in the visible spectrum, thus allowing such pump sources as flash lamps and other lasers. The Ti:AL_2O_3 laser is perhaps the most well-known laser of this category in that it has the widest bandwidth, covering a wavelength range from 0.67 μm to greater than 1.07 μm. Other lasers of this type include alexandrite (Cr:$BeAl_2O_4$), lasing from 0.7 to 0.8 μm, and Cr:LiSAF which lases from 0.8 to 1.05 μm. These lasers are used in applications where either wide tunability or short-pulse production are desired. Pulses as short as 4 fs have been produced with mode-locked versions of these lasers. Ti:Al_2O_3 lasers, although offering very wide gain bandwidth, have relatively short upper-laser-level lifetimes (3 μs), thereby making them less efficient when pumping with conventional flash lamps. Cr:LiSAF lasers

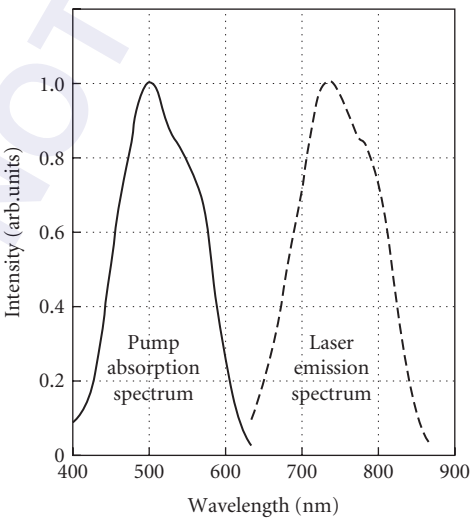

FIGURE 28 Absorption and emission spectra of a Ti:Al_2O_3 laser crystal showing the extremely broad emission (gain) spectrum for this material.

have longer upper-level lifetimes (67 μs), closer to that of Nd:YAG or Nd:glass and have demonstrated efficient laser operation with pumping technologies developed for Nd:YAG lasers.

Color-Center Laser[22] Color-center laser gain media are produced by a different form of impurity species than most solid-state lasers. Special defect centers (F-centers) are produced within alkali-halide crystals at a density of 1 part in 10,000 by irradiation with x rays. These defect centers have absorbing regions in the visible portion of the spectrum and emission (and gain) in the near-infrared. A variety of crystals are used to span the laser wavelength spectrum from 0.8 to 4.0 μm. Disadvantages of color-center lasers include operation at temperatures well below room temperature and the necessity to re-form the color centers at intervals of weeks or months in most cases.

Semiconductor Laser Gain Media

Semiconductor Lasers[23] Semiconductor or diode lasers, typically about the size of a grain of salt, are the smallest lasers yet devised. They consist of a *p-n* junction formed in semiconductor crystal such as GaAs or InP in which the *p*-type material has an excess of holes (vacancies due to missing electrons) and the *n*-type material has an excess of electrons. When these two types of materials are brought together to form a junction, and an electric field in the form of a voltage is applied across the junction in the appropriate direction, the electrons and holes are brought together and recombine to produce recombination radiation at or near the wavelength associated with the bandgap energy of the material. The population of electrons and holes within the junction provides the upper-laser-level population, and the recombination radiation spectrum is the gain bandwidth $\Delta\nu$ of the laser, typically of the order of 0.5 to 1.0 nm.

The extended gain length required for these lasers is generally provided by partially reflecting cleaved parallel faces at the ends of the crystals which serve as an optical cavity. Because the cavity is so short, the longitudinal modes are spaced far apart in frequency ($\Delta\nu \cong 1-5\times10^{11}$ Hz or several tenths of a nanometer), and thus it is possible to obtain single longitudinal mode operation in such lasers. They require a few volts to operate with milliamperes of current.

Heterostructure semiconductor lasers include additional layers of different materials of similar electronic configurations, such as aluminum, indium, and phosphorous, grown adjacent to the junction to help confine the electron current to the junction region in order to minimize current and heat dissipation requirements (see Fig. 29). The laser mode in the transverse direction is either

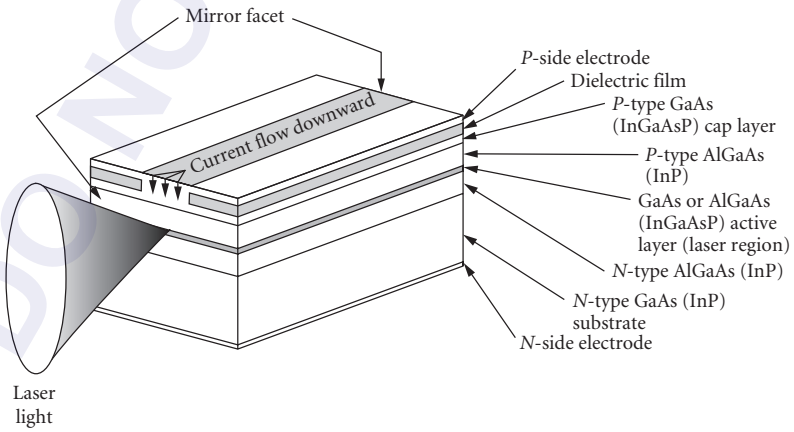

FIGURE 29 A typical heterostructure semiconductor laser showing the various layers of differential materials and the narrow region where current flows to produce the gain region in the active layer.

controlled by gain guiding, in which the gain is produced over a specific narrow lateral extent determined by fabrication techniques, or by index guiding, in which the index of refraction in the transverse direction is varied to provide total internal reflection of a guided mode. Quantum-well lasers have a smaller gain region (cross section), which confines the excitation current and thus the laser mode to an even smaller lateral region, thereby significantly reducing the threshold current and also the heat dissipation requirements. Because of these low threshold requirements, quantum-well semiconductor lasers are used almost exclusively for most semiconductor laser applications.

Multiple semiconductor lasers fabricated within the same bulk structure, known as *semiconductor arrays,* can be operated simultaneously to produce combined cw power outputs of up to 10 W from a laser crystal of dimensions of the order of 1 mm or less. Semiconductor lasers have also been fabricated in multiple arrays mounted vertically on a chip with the mirrors in the plane of the chip. They are known as *vertical cavity semiconductor lasers* (see below). Each of the individual lasers has dimensions of the order of 5 μm and can be separately accessed and excited.

Semiconductor lasers operate over wavelengths ranging from 400 nm to 2.2 μm by using special doping materials to provide the expanded or contracted bandgap energies that provide the varied wavelengths. The newest additions to this class of lasers are based upon the GaN laser materials with the active region consisting of various combinations of InGaN dopings that provide laser wavelengths in the green, blue, and violet portions of the spectrum.

Quantum Cascade Lasers Laser action in semiconductor lasers typically occurs when recombination radiation occurs across the band gap of the semiconductor. Quantum cascade lasers are different in that the radiation occurs from transitions between quantized conduction band states. Such transitions are inherently low-energy transitions and hence the laser output occurs in the middle infrared at wavelengths ranging from 3 to 24 μm. In the laser process, electrons are fed into the injector region of each stage via an electric field and transition across a mini-band from $n = 3$ to $n = 2$ quantum well levels thereby emitting the near infrared radiation. Several of these stages are stacked together in series to produce high power output. The active region is typically made up of aluminum indium arsenide and gallium indium arsenide. The lasers are particularly useful for operation in the two atmospheric windows at 3 to 5 μm and 8 to 13 μm.

Vertical Cavity Surface-Emitting Lasers (VCSELs) The vertical cavity laser is a different type of semiconductor laser than the typical edge-emitting lasers in that the emission occurs from the top surface of the laser and the cavity mirrors are comprised of multilayer dielectric coatings on the top and bottom surfaces of the very thin gain medium. These lasers can be made, using lithographic techniques, in large arrays on a microchip and can also be tested on the chip before being cleaved into individual lasers. Applications include optical fiber data transmission, absorption spectroscopy, and laser printers.

Laser Gain Media in Vacuum

Free Electron Laser[24] Free-electron lasers are significantly different than any other type of laser in that the laser output does not result from transitions between discrete energy levels in specific materials. Instead, a high-energy beam of electrons, such as that produced by a synchrotron, traveling in a vacuum with kinetic energies of the order of 1 MeV, are directed to pass through a spatially varying magnetic field produced by two regular arrays of alternating magnet poles located on opposite sides of the beam as shown in Fig. 30. The alternating magnetic field causes the electrons to oscillate back and forth in a direction transverse to the beam direction. The frequency of oscillation is determined by the electron beam energy, the longitudinal spacing of the alternating poles (the magnet period), and the separation between the magnet arrays on opposite sides of the beam. The transverse oscillation of the electrons causes them to radiate at the oscillation frequency and to thereby stimulate other electrons to oscillate and thereby radiate at the same frequency, in phase with the originally oscillating electrons. The result is an intense tunable beam of light emerging from the end

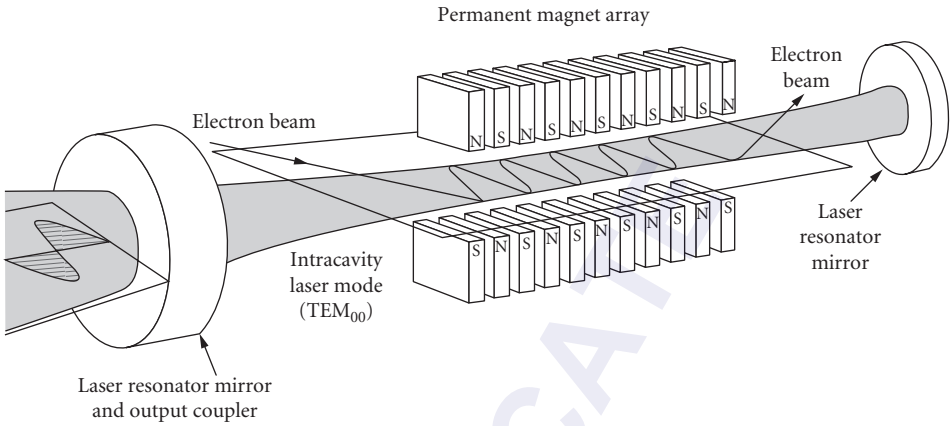

FIGURE 30 A general diagram of a free-electron laser showing how the electron beam is introduced into the cavity and how the alternating magnets cause the beam to oscillate to produce laser radiation.

of the device. Mirrors can be placed at the ends of the radiated beam to produce feedback and extra amplification.

Free-electron lasers have operated at wavelengths ranging from the near-ultraviolet (0.25 μm) to the far-infrared (6 mm) spectral regions. They are efficient devices and also offer the potential of very high average output powers.

17.1 GLOSSARY

c	velocity of light
E_g	semiconductor energy bandgap
h	Planck' s constant
I_T	total LED current
J	LED current density
k	Boltzmann's constant
M	magnification
n_0	low index of refraction medium
n_1	high index of refraction medium
q	electron charge
T	temperature
V	applied voltage
η_i	internal quantum efficiency
θ_c	critical angle
λ	emission wavelength
τ	total minority carrier lifetime
τ_n	nonradiative minority carrier lifetime
τ_r	radiative minority carrier lifetime

17.2 INTRODUCTION

Over the past 25 years the light-emitting diode (LED) has grown from a laboratory curiosity to a broadly used light source for signaling applications. In 1992 LED production reached a level of approximately 25 billion chips, and $2.5 billion worth of LED-based components were shipped to original equipment manufacturers.

This chapter covers light-emitting diodes from the basic light-generation processes to descriptions of LED products. First, we will deal with light-generation mechanisms and light extraction. Four major types of device structures—from simple grown or diffused homojunctions to complex double heterojunction devices are discussed next, followed by a description of the commercially important semiconductors used for LEDs, from the pioneering GaAsP system to the AlGaInP system that is currently revolutionizing LED technology. Then processes used to fabricate LED chips are explained—the growth of GaAs and GaP substrates, the major techniques used for growing the epitixal material in which the light-generation processes occur, and the steps required to create LED chips up to the point of assembly. Next the important topics of quality and reliability—in particular, chip degradation and package-related failure mechanisms—will be addressed. Finally, LED-based products, such as indicator lamps, numeric and alphanumeric displays, optocouplers, fiber-optic transmitters, and sensors, are described.

This chapter covers the mainstream structures, materials, processes, and applications in use today. It does not cover certain advanced structures, such as quantum well or strained layer devices, a discussion of which can be found in Chap. 19, "Semiconductor Lasers." The reader is also referred to Chap. 19 for current information on edge-emitting LEDs, whose fabrication and use are similar to lasers.

For further information on the physics of light generation, the reader should consult Refs. 1 to 11. Semiconductor material systems for LEDs are discussed in Refs. 13 to 24. Crystal growth, epitaxial, and wafer fabrication processes are discussed in detail in Refs. 25 to 29.

17.3 LIGHT-GENERATION PROCESSES

When a *p*-*n* junction is biased in the forward direction, the resulting current flow across the boundary layer between the *p* and *n* regions has two components: holes are injected from the *p* region into the *n* region and electrons are injected from the *n* region into the *p* region. This so-called minority-carrier injection disturbs the carrier distribution from its equilibrium condition. The injected minority carriers recombine with majority carriers until thermal equilibrium is reestablished. As long as the current continues to flow, minority-carrier injection continues. On both sides of the junction, a new steady-state carrier distribution is established such that the recombination rate equals the injection rate.[1,2]

Minority-carrier recombination is not instantaneous. The injected minority carriers have to find proper conditions before the recombination process can take place. Both energy and momentum conservation have to be met. Energy conservation can be readily met since a photon can take up the energy of the electron-hole pair, but the photon doesn't contribute much to the conservation of momentum. Therefore, an electron can only combine with a hole of practically identical and opposite momentum. Such proper conditions are not readily met, resulting in a delay. In other words, the injected minority carrier has a finite lifetime τ_r before it combines radiatively through the emission of a photon.[2] This average time to recombine radiatively through the emission of light can be visualized as the average time it takes an injected minority carrier to find a majority carrier with the right momentum to allow radiative recombination without violating momentum conservation.

Unfortunately, radiative recombination is not the only recombination path. There are also crystalline defects, such as impurities, dislocations, surfaces, etc., that can trap the injected minority carriers. This type of recombination process may or may not generate light. Energy and momentum conservation are met through the successive emission of phonons. Again, the recombination process is not instantaneous because the minority carrier first has to diffuse to a recombination site. This nonradiative recombination process is characterized by a lifetime τ_n.[2]

Of primary interest in design of light-emitting diodes is the maximization of the radiative recombination relative to the nonradiative recombination. In other words, it is of interest to develop conditions where radiative recombination occurs fairly rapidly compared with nonradiative recombination. The effectiveness of the light-generation process is described by the fraction of the injected minority carriers that recombine radiatively compared to the total injection. The internal quantum efficiency η_i can be calculated from τ_r and τ. The combined recombination processes lead to a total minority-carrier lifetime τ given by Eq. (1):

$$\frac{1}{\tau} = \frac{1}{\tau_r} + \frac{1}{\tau_n} \tag{1}$$

η_i is simply computed from Eq. (1) as the fraction of carriers recombining radiatively:[2]

$$\eta_i = \frac{\tau_n}{\tau_r + \tau_n} \tag{2}$$

Of interest are two simple cases: in the case of excellent material quality (large τ_n) or efficient radiative recombination conditions (small τ_r), the internal quantum efficiency approaches 100 percent. For the opposite case ($\tau_n \ll \tau_r$), we find $\eta_i \approx \tau_n/\tau_r \ll 1$. As discussed under "Material Systems," there are several families of III–V compounds with internal quantum efficiencies approaching 100 percent. There are also other useful semiconductor materials with internal quantum efficiencies in the 1- to 10-percent range.

To find material systems for LEDs with a high quantum efficiency, one has to understand the band structure of semiconductors. The band structure describes the allowed distribution of energy and momentum states for electrons and holes (see Fig. 1 and Ref. 2). In practically all semiconductors the lower band, also known as the *valence band,* has a fairly simple structure, a

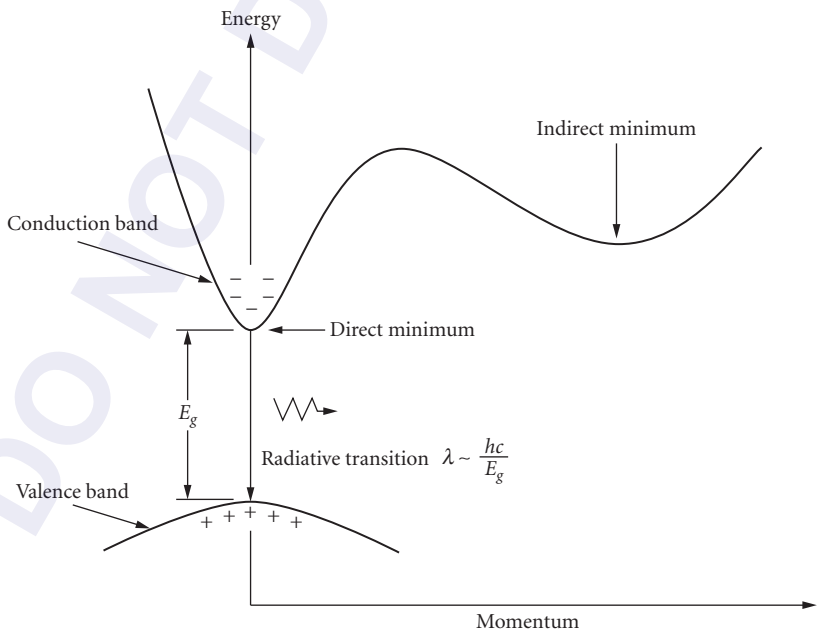

FIGURE 1 Energy band structure of a direct semiconductor showing radiative recombination of electrons in the conduction band with holes in the valence band.

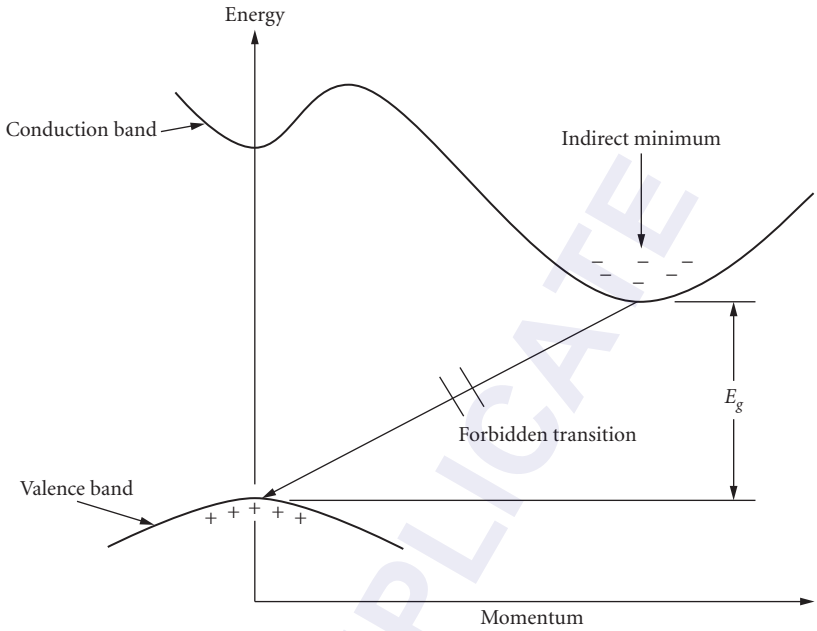

FIGURE 2 Energy band structure of an indirect semiconductor showing the conduction-band minima and valence-band maximum at different positions in momentum space. Radiative recombination of conduction-band electrons and valence-band holes is generally forbidden.

paraboloid around the $\langle 0, 0, 0 \rangle$ crystalline direction. Holes will take up a position near the apex of the paraboloid and have very small momentum. The upper band, also known as the *conduction band,* is different for various semiconductor materials. All semiconductors have multiple valleys in the conduction band. Of practical interest are the valleys with the lowest energy. Semiconductor materials are classified as either *direct* or *indirect.*[1–3] In a direct semiconductor, the lowest valley in the conduction band is directly above the apex of the valence-band paraboloid. In an indirect semiconductor, the lowest valleys are not at $\langle 0, 0, 0 \rangle$, but at different positions in momentum per energy space (see Fig. 2). Majority or minority carriers mostly occupy the lowest energy states, i.e., holes near the top of the valence band paraboloid and electrons near the bottom of the lowest conduction-band valley.

In the case of a direct semiconductor the electrons are positioned directly above the holes at the same momentum coordinates. It is relatively easy to match up electrons and holes with proper momentum-conserving conditions. Thus, the resulting radiative lifetime τ_r is short. On the other hand, electrons in an indirect valley will find it practically impossible to find momentum-matching holes and the resulting radiative lifetime will be long. Injected carriers in indirect material generally recombine nonradiatively through defects.

In a direct semiconductor, such as GaAs, the radiative lifetime τ_r is in the range of 1 to 100 ns, depending on doping, temperature, and other factors. It is relatively easy to grow crystals with sufficiently low defect density such that τ_n is in the same range as τ_r.

For indirect semiconductors, such as germanium or silicon, the radiative recombination process is extremely unlikely, and τ_r is in the range of seconds.[1] In this case, $\tau_r \gg \tau_n$, and practically all injected carriers recombine nonradiatively.

The wavelength of the photons emitted in a radiative recombination event is determined by the energy difference between the recombining electron-hole pair. Since carriers relax quickly to an energy level near the top of the valence band (holes), or the bottom of the conduction band

(electrons), we have the following approximation for the wavelength λ of the emitted photon (see Fig. 1):

$$\lambda \approx hc/E_g \tag{3}$$

where h = Planck' s constant, c = velocity of light, and E_g = bandgap energy.

This relation is only an approximation since holes and electrons are thermally distributed at levels slightly below the valence-band maximum and above the conduction-band minimum, resulting in a finite linewidth in the energy or wavelength of the emitted light. Another modification results from a recombination between a free electron and a hole trapped in a deep acceptor state. See Ref. 2 for a discussion of various recombination processes.

To change the wavelength or energy of the emitted light, one has to change the bandgap of the semiconductor material. For example, GaAs with a bandgap of 1.4 eV has an infrared emission wavelength of 900 nm. To achieve emission in the visible red region, the bandgap has to be raised to around 1.9 eV. This increase in E_g can be achieved by mixing GaAs with another material with a wider bandgap, for instance GaP with E_g = 2.3 eV. By adjusting the ratio of arsenic to phosphorous the bandgap of the resulting ternary compound, GaAsP, can be tailored to any value between 1.4 and 2.3 eV.[3]

The resulting band structure with varying As to P ratio is illustrated in Fig. 3. Note, the two conduction-band valleys do not move upward in energy space at the same rate. The direct valley moves up faster than the indirect valley with increasing phosphorous composition. At a composition of around 40 percent GaP and 60 percent GaAs, the direct and indirect valleys are about equal in energy. When the valleys are approximately equal in energy, electrons in the conduction band can scatter from the direct valley into the indirect valley. While the direct valley electrons still undergo rapid radiative recombination, the indirect valley electrons have a long radiative lifetime and either have to be scattered back to the direct valley or they will recombine nonradiatively. In other words, near this crossover

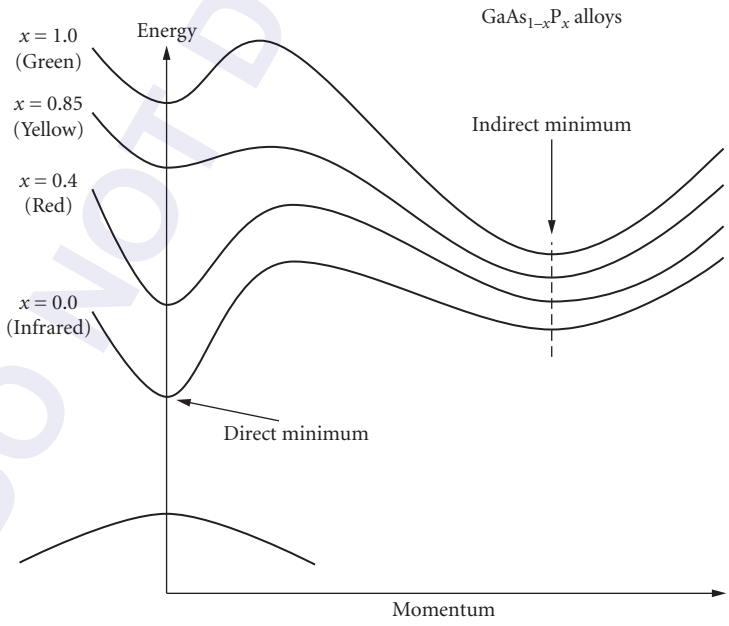

FIGURE 3 Energy band diagram for various alloys of the $GaAs_{1-x}P_x$ material system showing the direct and indirect conduction-band minima for various alloy compositions.

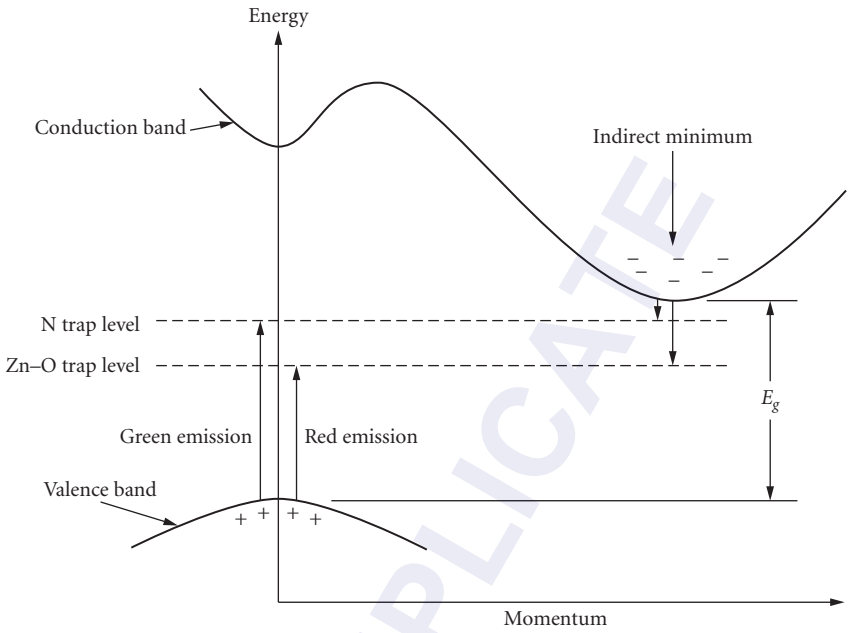

FIGURE 4 Formation of excitons (electron-hole pairs) by the addition of isoelectronic dopants N and ZnO to an indirect semiconductor. The excitons have a high probability to recombine radiatively.

between direct and indirect valleys, the radiative efficiency drops off dramatically, and for compositions with greater than 40 percent phosphorous the direct radiative recombination is practically nonexistent.[3,4]

The above discussion indicates that indirect semiconductors are not suitable for efficient generation of light through minority-carrier recombination. Fortunately, the introduction of so-called isoelectronic impurities can circumvent this limitation and introduces a new radiative recombination process.[5] A commonly used isoelectronic trap is generated by substituting a nitrogen atom for phosphorous in the GaAsP system[6–11] (see Fig. 4). Since N and P both have five electrons in their outer shell, the trap is electrically neutral. However, the stronger electronegativity of N relative to P can result in capture of an electron from the conduction band. Since the electron is very tightly bound to the impurity atom, its wave function in momentum space is spread out and has reasonable magnitude at $\langle k = 0 \rangle$ in momentum space.[10] The negatively charged defect can attract a free hole to form a loosely bound electron-hole pair or "exciton." This electron-hole pair has a high probability to recombine radiatively. The energy of the emitted light is less than E_g. Another isoelectronic trap in GaP is formed by ZnO pairs (Zn on a Ga site and O on a P site) (see Fig. 4). The ZnO trap is deeper than the N trap, resulting in longer wavelength emission in the red region of the spectrum.[1]

The recombination process for exciton recombination is quite complex. For a detailed analysis, the reader is referred to Ref. 10. One result of this analysis is the recognition that the bound exciton has a relatively long lifetime in the range of 100 to 1000 ns. Light emission by exciton recombination is generally slower than emission due to direct band-to-band recombination.

17.4 LIGHT EXTRACTION

Generating light efficiently within a semiconductor material is only one part of the problem to build an efficient light source. The next challenge is the extraction of light from within the LED chip to the outside. The designer must consider total internal reflection.[1] According to Snell' s law, light can

escape from a medium of high index of refraction n_1 into a medium of low index refraction n_0 only if it intersects the surface between the two media at an angle from normal less than the critical angle θ_c with θ_c being defined by Eq. (4):

$$\theta_c = \text{arc sin}\, n_0/n_1 \tag{4}$$

Most semiconductor LEDs have an isotropic emission pattern as seen from within the light-generating material. Assuming a cubic shape for the LED chip, because of internal reflections, only a small fraction of the isotropically emitted light can escape any of the six surfaces. As a case in point, let us calculate the emission through the top surface. For typical light-emitting semiconductors, n_1 is in the range of 2.9 to 3.6. If $n_1 = 3.3$ and $n_0 = 1.0$ (air), we find $\theta_c = 17.6°$. The emission from an isotropic source into a cone with a half angle of θ_c is given by $(1 - \cos \theta_c)/2$. After correcting for Fresnel reflections, only 1.6 percent of the light generated escapes through the LED top surface into air. Depending on chip and *p-n* junction geometry, virtually all of the remaining light (98.4 percent) is reflected and absorbed within the LED chip.

The fraction of light coupled from chip to air is a function of the number of surfaces through which the chip can transmit light effectively. Most LED chips are called "absorbing substrate" (AS) chips. In such a chip, the starting substrate material (discussed later under "Substrate Technology") has a narrow bandgap and absorbs all the light with energy greater than the bandgap of the substrate. Consider the case of a GaAsP LED grown on a GaAs substrate. The emitted light (E_g>1.9eV) is absorbed by the GaAs substrate ($E_g = 1.4$ eV). Thus, a GaAsP-emitting layer on a GaAs substrate can transmit only through its top surface. Light transmitted toward the side surfaces or downward is absorbed.

To increase light extraction, the substrate or part of the epitaxial layers near the top of the chip has to be made of a material transparent to the emitted light. The "transparent substrate" (TS) chip is designed such that light transmitted toward the side surfaces within θ_c half-angle cones can escape. Assuming that there is negligible absorption between the point of light generation and the side walls, this increases the extraction efficiency by a factor of 5 (5 instead of 1 escape cones).

In a TS chip, additional light can be extracted if the side walls are nonplanar, i.e., if light from outside an escape cone can be scattered into an escape cone. This process increases the optical path within the chip and is very dependent on residual absorption. In a chip with low absorption and randomizing side surfaces, most of the light should escape. Unfortunately, in practical LED structures, there are several absorption mechanisms left such as front and back contacts, crystal defects, and absorption in areas where secondary radiative recombination is inefficient.

A common approach is to use a hybrid chip with properties between AS and TS chips. These chips utilize a thick, transparent window layer above the light-emitting layer. If this layer is sufficiently thick, then most of the light in the top half of the cones transmitted toward the side surfaces will reach the side of the chip before hitting the substrate. In this case of hybrid chips, the efficiency is between that of AS and TS chips as shown in Table 1.

Another important way to increase extraction efficiency is derived from a stepwise reduction in the index of refraction from chip to air. If the chip is first imbedded in a material with an intermediate index, i.e., plastic with $n_2 = 1.5$, then the critical angle θ_c between chip and plastic is increased to 27°. The extraction efficiency relative to air increases by the ratio of $(n_2/n_0)^2$ plus some additional correction for Fresnel-reflection losses. The gain from plastic encapsulation is usually around

TABLE 1 Extraction Efficiency into Air or Plastic for Three Types of Commonly Used LED Chips

		Typical extraction efficiency	
Chip Type	No. Cones	Air (%)	Plastic (%)
AS	1	1.5	4
Thick window	3	4.5	12
TS	5	7.5	20

2.7 times compared to air. Chips with multipath internal reflection will result in lower gains. It is important to note that this gain can be achieved only if the plastic/air interface can accommodate the increased angular distribution through proper lenslike surface shaping or efficient scattering optics. Table 1 illustrates the approximate extraction efficiencies achieved by the three dominant chip structures in air and in plastic. The numbers assume only first-pass extraction, limited absorption, and no multiple reflections within the chip.

17.5 DEVICE STRUCTURES

LED devices come in a broad range of structures. Each material system (see following section) requires a different optimization. The only common feature for all LED structures is the placement of the *p-n* junction where the light is generated. The *p-n* junction is practically never placed in the bulk-grown substrate material for the following reasons:

- The bulk-grown materials such as GaAs, GaP, and InP usually do not have the right energy gap for the desired wavelength of the emitted light.
- The light-generating region requires moderately low doping that is inconsistent with the need for a low series resistance.
- Bulk-grown material often has a relatively high defect density, making it difficult to achieve high efficiency.

Because of these reasons, practically all commercially important LED structures utilize a secondary growth step on top of a single-crystal bulk-grown substrate material. The secondary growth step consists of a single-crystal layer lattice matched to the substrate. This growth process is known as *epitaxial growth* and is described in a later section of this chapter.

The commonly used epitaxial structures can be classified into the following categories:

- Homojunctions
  - grown
  - diffused
- Heterojunctions
  - single confinement
  - double confinement

Grown Homojunctions

Figure 5 illustrates one of the simplest design approaches to an LED chip. An *n*-type GaAs layer with low to moderate doping density is grown on top of a highly doped *n*-type substrate by a vapor or liquid-phase epitaxial process (see "Epitaxial Technology"). After a growth of 5 to 10 μm, the doping is changed to *p* type for another 5 to 10 μm. A critical dimension is the thickness of the epitaxial *p* layer. The thickness should be larger than the diffusion length of electrons. In other words, the electrons should recombine radiatively in the epitaxially grown *p* layer before reaching the surface. The *p* layer should be of sufficiently high quality to meet the condition for efficient recombination, i.e., $\tau_n \gg \tau_r$. In addition, the side surfaces may have to be etched to remove damage. Damage and other defects where the *p-n* junction intercepts the chip surface can lead to a substantial leakage current that reduces efficiency, especially at low drive levels.

The structure of Fig. 5 was used in some of the earliest infrared emitters (wavelength 900 nm). Efficiency was low, typically 1 percent. Modern infrared emitters use Si-doped GaAs (see Fig. 6). The detailed recombination mechanism in GaAs:Si even today is quite controversial and goes beyond the scope of this publication. The recombination process has two important characteristics: (1) the radiative lifetime τ_r is relatively slow, i.e., in the range of 1 μs and (2) the wavelength is shifted to 940 nm.

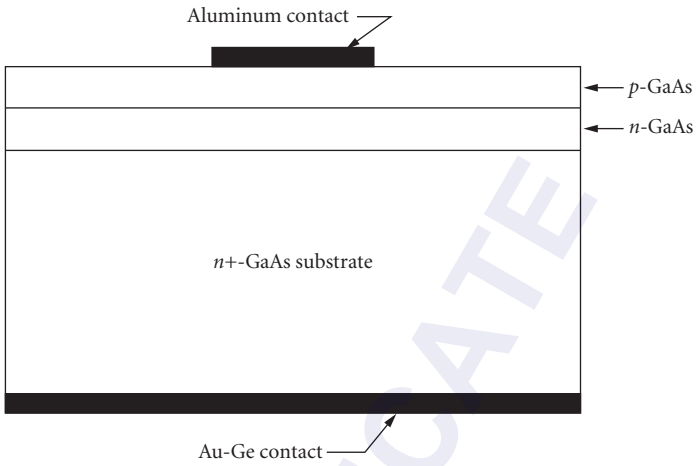

FIGURE 5 Cross section of an infrared LED chip. A *p-n* junction is formed by epitaxially growing *n*- and *p*-doped GaAs onto an n+-doped GaAs substrate.

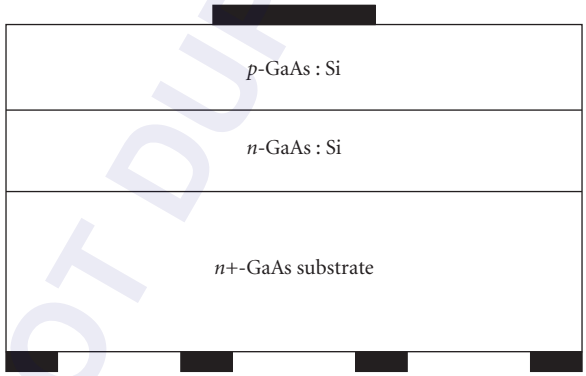

FIGURE 6 A high-efficiency IR LED made by LPE growth of GaAs that is doped with silicon on both the *p* and *n* sides of the junction. To increase external quantum efficiency, a partly reflective back contact is employed.

At this wavelength the GaAs substrate is partly transparent, making this device a quasi-TS structure with efficiencies into plastic of 5 to 10 percent.

Diffused Homojunction

The chip structure of Fig. 5 can also be produced by a zinc (Zn) diffusion into a thick *n* layer. The commercially most significant structure of this type is shown in Fig. 7. By replacing 40 percent of the As atoms with P atoms, the bandgap is increased to 1.92 eV to make a GaAsP LED that emits visible red light. In this case, the *p-n* junction is diffused selectively by using a deposited layer of silicon-nitride as a diffusion mask. This structure of Fig. 7 has several advantages over the structure of Fig. 5. Lateral diffusion of Zn moves the intersection of the junction with the chip surface

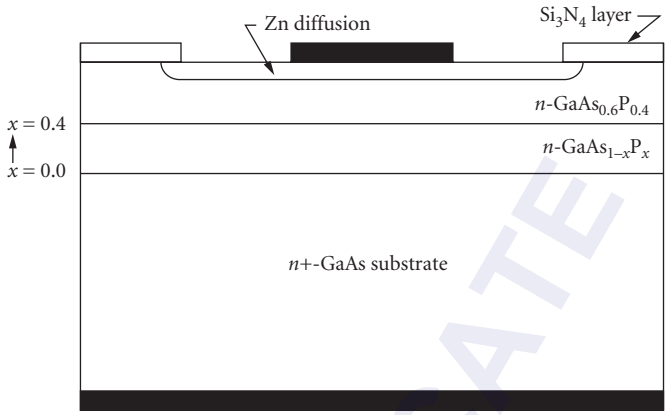

FIGURE 7 GaAsP LED which emits at 650 nm. On a GaAs substrate, a layer is grown whose composition varies linearly from GaAs to $GaAs_{0.6}P_{0.4}$, followed by a layer of constant composition. Zinc is selectively diffused using an Si_3N_4 mask to form the light-emitting junction.

underneath the protecting Si_3N_4 layer. This layer protects the junction from contamination and adds to the long-term stability of the device. In addition, it is important for applications requiring more than one clearly separated light-emitting area. For instance, seven-segment displays, such as those used in the early handheld calculators, are made by diffusing seven long and narrow stripes into a single chip of GaAsP material. (See Fig. 8.) This chip consists of eight (seven segments plus decimal point) individually addressable *p*-regions (anodes) with a common *n*-type cathode. Such a chip is feasible only in an AS-type structure because the individual segments have to be optically isolated from each other. A TS-type structure results in unacceptable levels of crosstalk.

Figure 7 shows another feature of practical LED devices. The composition with 40 percent P and 60 percent As has a lattice constant (atomic spacing) that is different from the GaAs substrate. Such a lattice mismatch between adjacent layers would result in a very high density of dislocations. To reduce this problem to an acceptable level, one has to slowly increase the phosphorous composition from 0 percent at the GaAs interface to 40 percent over a 10- to 20-μm-thick buffer layer. Typically, the buffer layer is graded linearly. The phosphorous composition is increased linearly from bottom to top. The thicker the buffer layer, the lower is the resulting dislocation density. Cost constraints keep the layer in the 10- to 15-μm range. The layer of constant composition (40 percent P) has to be thick enough to accommodate the Zn diffusion plus the diffusion length of minority carriers. A thickness range of 5 to 10 μm is typical.

Another variation of a homojunction is shown in the TS-chip structure of Fig. 9. Instead of an absorbing GaAs substrate, one starts with a transparent GaP substrate. The graded layer has an inverse gradient relative to the chip shown in Fig. 7. The initial growth is 100 percent GaP phasing in As linearly over 10 to 15 μm. At 15 percent As, the emission is in the yellow range (585 nm), at 25 percent in the orange range (605 nm), and at 35 percent in the red range (635 nm). Figure 3 shows the approximate band structure of this material system. The composition range mentioned above has an indirect band structure. To obtain efficient light emission, the region of minority-carrier injection is doped with nitrogen forming an isoelectronic recombination center (see exciton recombination in the first section).

Figure 9 shows an important technique to increase extraction efficiency. In a TS-chip, the major light loss is due to free carrier absorption at the alloyed contacts. Rather than covering the entire bottom surface of the chip with contact metal, one can reduce the contact area either by depositing small contact islands (see Fig. 6) or by placing a dielectric mirror (deposited SiO_2) between the substrate and the unused areas of the back contact (Fig. 9). This dielectric mirror increases the efficiency by 20 to 50 percent at the expense of higher manufacturing cost.

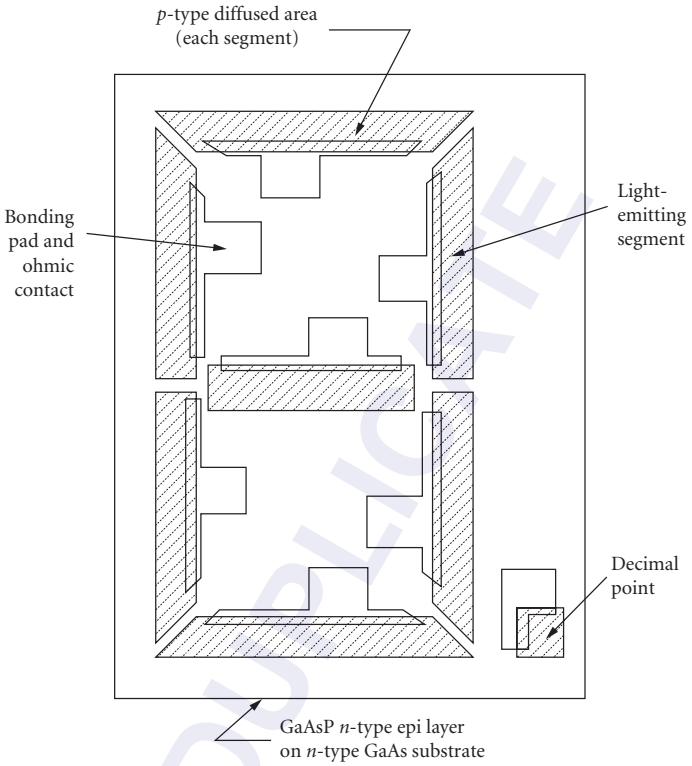

FIGURE 8 Monolithic seven-segment display chip with eight separate diffused regions (anodes) and a common cathode (the GaAs substrate).

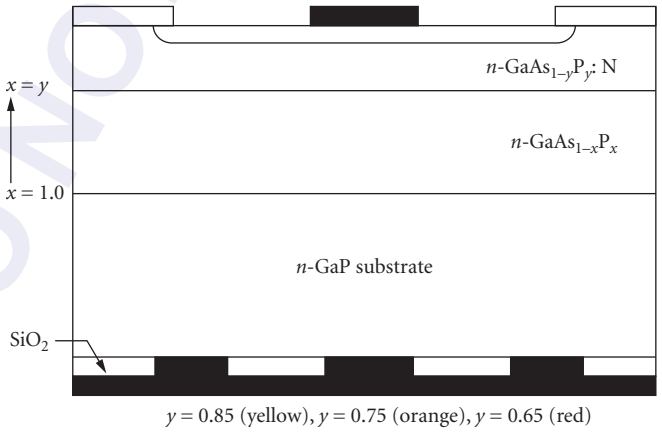

FIGURE 9 Cross section of a $GaAs_{1-x}P_x$ LED which, by changing the composition "*x*," produces red, orange, or yellow light. The top layer is doped with nitrogen to increase the quantum efficiency. The GaP substrate is transparent to the emitted light. Also shown is a reflective back contact made by depositing the contact metallization on top of SiO_2.

Single Heterojunctions

Heterojunctions introduce a new variable: local variation of the energy bandgap resulting in carrier confinement. Figure 10 shows a popular structure for a red LED emitter chip. A *p*-type layer of GaAlAs with 38 percent Al is grown on a GaAs substrate. The GaAlAs alloy system can be lattice-matched to GaAs; therefore, no graded layer is required as in the GaAsP system of Fig. 7. Next, an *n*-type layer is grown with 75 percent Al. The variation of E_g from substrate to top is illustrated in Fig. 11. Holes accumulate in the GaAlAs *p* layer with the narrower bandgap. Electrons are injected from the *n* layer into this *p* layer. The holes have insufficient energy to climb the potential barrier into the wide-bandgap material. Holes are confined to the *p* layer. In the *p* layer, the radiative recombination time is very short because of the high concentration of holes. As a result, the internal quantum efficiency is quite high. A variation of this structure is a widely used infrared emitter that emits at 880 nm.

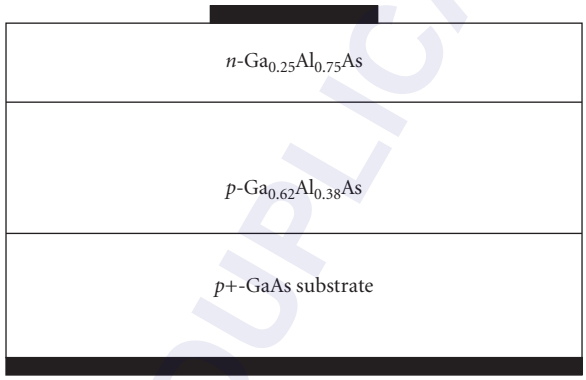

FIGURE 10 Cross section of a single heterostructure LED.

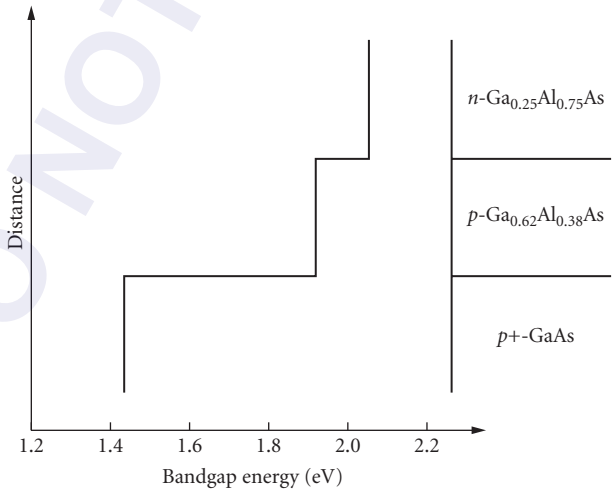

FIGURE 11 Variation in energy bandgap for the various layers in the GaAlAs LED shown in Fig. 10.

Double Heterostructures

The double heterostructure shown in Fig. 12 repeats the *p*-side confinement of Fig. 10 on the *n* side. An *n*-type buffer layer is grown on the GaAs substrate to create a high-quality surface onto which the first *n*-type GaAlAs confinement layer with 75 percent Al is grown. The active or light-generation layer is a 3-μm-thick *p*-type layer with 38 percent Al. The top *p*-type confinement layer again uses 75 percent Al. This structure with the energy-band diagram of Fig. 13 has two advantages: (1) There is no hole injection into the *n*-type layer with reduced efficiency and a slow hole recombination in the lowly doped *n* layer. (2) The high electron and hole density in the active layer reduces τ_r, thus increasing device speed and efficiency. The increased speed is quite important for LED sources in fiber-optic communication applications. (See "Fiber Optics" subsection later in this chapter.)

The double heterostructure of Fig. 12 represents a one-dimensional containment of injected carriers. Injection and light emission occurs across the entire lateral dimension of the chip. For fiber-optic applications, the light generated over such a large area cannot be effectively coupled into small-diameter fiber. A rule of thumb for fiber coupling requires that the light-emitting area be equal to or, preferably, smaller than the fiber core diameter. This rule requires lateral constraint of carrier injection. The localized diffusion of Fig. 7 is not applicable to grown structures such as those in Fig. 12. The preferred solution inserts an *n* layer between buffer and lower confinement layer (see Fig. 14). A hole etched into the *n* layer allows current flow. Outside of this hole, the *p*-*n* junction between *n* layer and lower confinement layer is reverse-biased, thus blocking any current flow. The disadvantage of this approach is a complication of the growth process. In a first growth process, the *n* layer is grown. Then a hole is etched into the *n* layer using standard photolithographic etching techniques. Finally, a second epitaxial growth is used for the remaining layers.

Another technique to constrain current injection utilizes a small ohmic contact.[12] It is used frequently in conjunction with InP-based fiber-optic emitters (see Fig. 15). An SiO_2 layer limits contact to a small-diameter (typically 25 μm) hole that results in a relatively small light-emitting area. The etched lens shown for this structure helps to collimate the light for more efficient coupling onto the fiber.[12]

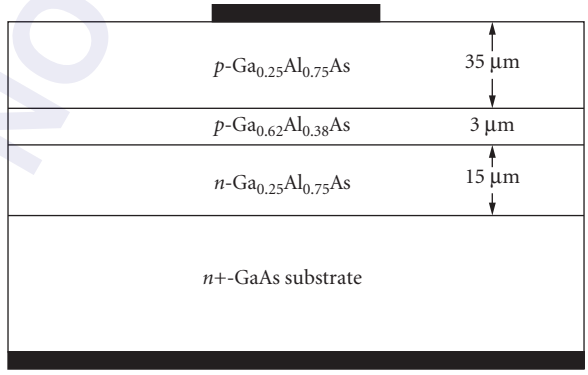

FIGURE 12 Structure of a double heterostructure (DH) GaAlAs LED. The DH is composed of a $Ga_{0.62}Al_{0.38}As$ layer surrounded on either side by a $Ga_{0.25}Al_{0.75}As$ layer. The thick top layer acts as window to increase light extraction through the side walls of the chip.

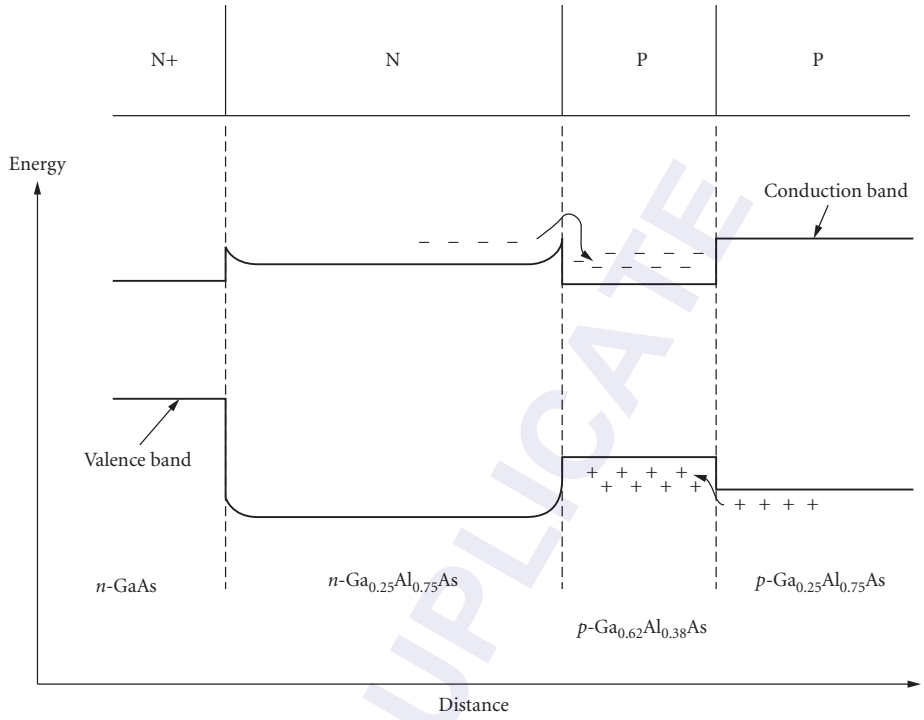

FIGURE 13 Energy band diagram of the GaAlAs LED shown in Fig. 12. The LED is forward biased. Electrons and holes are confined in the *p*-doped $Ga_{0.62}Al_{0.38}As$ layer, which increases the radiative recombination efficiency.

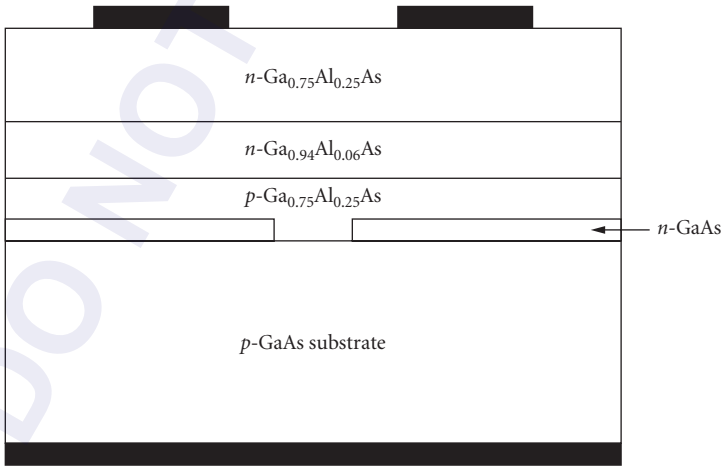

FIGURE 14 Cross section of an LED with three-dimensional carrier confinement. A DH structure is used to confine injected carriers in the $Ga_{0.94}Al_{0.06}As$ layer (direction perpendicular to the junction). The patterned, *n*-type GaAs layer is used to limit current flow in the lateral direction. The small emitting area and the 820-nm emission of this LED makes it ideal for fiber-optic applications.

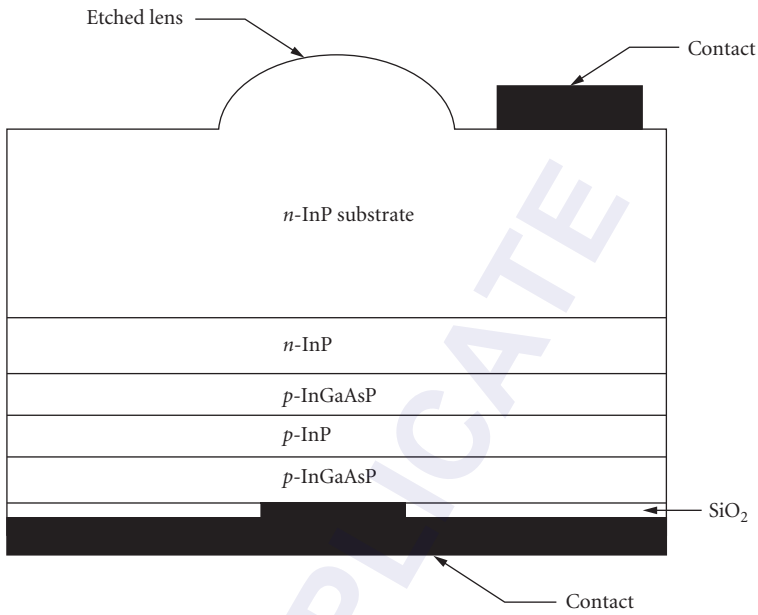

FIGURE 15 Structure of a 1300-nm LED used for optical fiber communications. The cross section shows the DH-layer configuration, limited area back contact for emission-size control, and an etched lens at the top of the chip which, magnifies ($M = 2$) the source area and collimates the light for effective coupling into a fiber.

17.6 MATERIAL SYSTEMS

The $GaAs_{1-x}P_x$ System

The most widely used alloy for LEDs is the ternary $GaAs_{1-x}P_x$ system, including its two binary components GaAs and GaP. This system is best described by the composition parameter x with $0 \le x \le 1$. For $x = 0$, we have GaAs and for $x = 1$ the composition is GaP. For $x \le 0.4$, the alloy has a direct bandgap. GaAs was developed in the early 1960s as an infrared emitter with a wavelength of 910 nm and an efficiency in the range of 1 percent. This emitter was soon followed by a Si-doped variety. As discussed earlier, this leads to an emission wavelength of 940 nm, a wavelength at which the GaAs substrate is partly transparent. The resulting efficiency is increased substantially and, depending on configuration, is in the 5- to 10-percent range. However, the recombination process is quite slow, resulting in rise and fall times in the 50-ns to 1.0-μs range (see Table 2). One other drawback is caused by the low absorption coefficient of Si detectors at 940 nm. To absorb 90 percent of the light requires a detector thickness of 60 to 70 μm. Conventional photo transistors are quite suitable as detectors. Integrated photo ICs with their 5- to 7-μm-thick epitaxial layers are very inefficient as detectors at 940 nm.

To shift the wavelength toward the near-infrared or into the visible spectrum, one has to grow a ternary alloy, a mixture between GaAs and GaP. Of commercial interest are two alloys with $x = 0.3$ and $x = 0.4$ grown on a GaAs substrate (see Table 2). The $x = 0.4$ alloy was the first commercially produced material with a wavelength in the visible range of the spectrum. Grown on an absorbing substrate, it has a modest luminous efficacy of around 0.2 lm/A. [Luminous efficacy is the luminous (visible) flux output measured in lumens divided by the electrical current input.] The absorbing substrate allows the integration of multiple light sources into a single chip without crosstalk. Such

TABLE 2 Performance Summary of LED Chips in the $GaAs_{1-x}P_x$ System

x	Growth Process*	Isoel. Dopant	Substrate†	Dominant Wavelength (nm)	Colon‡	Luminous Efficacy§ (lm/A)	Quantum Efficiency§ (%)	Speed (ns)

monolithic seven-segment displays became the workhorse display technology for handheld calculators from 1972 to 1976.[9,13] Today this alloy is used in LED arrays for printers.[14]

The $x = 0.3$ alloy with a wavelength of 700 nm became important in the mid 1970s as a light source in applications using integrated photodetectors. It has 3 to 5 times the quantum efficiency of the $x = 0.4$ alloy (see Table 2), but has a lower luminous efficacy because of the much-reduced eye sensitivity at 700 nm.

For $x > 0.4$, the GaAsP material system becomes indirect (see earlier under "Light-Generation Processes" and Fig. 3). The quantum efficiency decreases faster than the increase in eye sensitivity.[4] The only way to achieve a meaningful efficiency is through the use of isoelectronic dopants as described earlier. The choices for isoelectronic dopants that have been successful are N for GaAsP[11] and N or ZnO for GaP. Nitrogen doping is used widely for alloys with $x = 0.65$ to $x = l.0$.[6–10] The resulting light sources cover the wavelength range from 635 nm to approximately 565 nm (see Table 2). Since these alloys are either GaP or very close in composition to GaP, they are all grown on GaP substrates. The resulting transparent-substrate chip structure increases the luminous efficacy.

In the case of the binary GaP compound, the dominant wavelength depends on N concentration. With low concentrations, practically all N atoms are isolated in single sites. With increasing concentration, N atoms can arrange themselves as pairs or triplets. The resulting electron traps have lower energy states, which shift the emitted light toward longer wavelength. Phonon coupling can also reduce the emission energy. Commercially significant are two compositions: (1) undoped GaP which emits at 565 nm (dominant wavelength) with a reasonably green appearance and a low efficiency of around 1 lm/A, and (2) GaP with a nitrogen concentration in the range of 10^{19} cm^{-3} with a substantially higher luminous efficiency of around 6 lm/A at 572 nm. At this wavelength, the color appearance is yellow-green, often described as chartreuse.

Three nitrogen-doped ternary alloys of GaAsP are commercially important for red, orange, and yellow. The red source with $x = 0.65$ has an efficiency in the range of 2 to 3 lm/A. With increasing bandgap or decreasing wavelength, the drop in quantum efficiency is compensated by an increase in eye sensitivity, resulting in a practically wavelength-independent luminous efficiency for the range of 635 to 585 nm.[8,15]

ZnO-doped GaP is an interesting material. The quantum efficiency of such chips is relatively high, around 3 percent. However, the linewidth is quite broad. The quantum efficiency peaks at 700 nm, but the luminous efficiency peaks at 640 nm (dominant wavelength). In other words, most of the photons are emitted at wavelengths with low eye sensitivity. Another problem of GaP:ZnO is saturation. The deep ZnO electron trap causes very slow exciton recombination. At high injection currents, all traps are saturated and most of the injected carriers recombine

nonradiatively. At low injection levels (≤1 A/cm^2), the efficacy is relatively high, 3 to 5 lm/A. At a more useful density of 10 to 30 A/cm^2, the emission saturates, resulting in an efficacy of around 1 lm/A.

The $Al_xGa_{1-x}As$ System

The $Al_xGa_{1-x}As$ material system has a direct bandgap for $0 \le x \le 0.38$. This system has one very significant advantage over the GaAsP system described earlier, the entire alloy range from $x = 0$ to $x = 1$ can be lattice-matched to GaAs. In other words, every alloy composition can be directly grown on any other alloy composition without the need for transition layers. This feature allows the growth of very abrupt heterojunctions, i.e., abrupt transition in composition and bandgap. These heterojunctions add one important property not available in the GaAsP system: carrier containment (see earlier under "Device Structures"). Carrier containment reduces the movement of injected carriers in a direction perpendicular to the junction. Thus, carrier density can be increased beyond the diffusion-limited levels. This results in increased internal quantum efficiency and higher speed. Another benefit is reduced absorption and improved extraction efficiency (under "Light Extraction").

Of practical significance are two compositions: $x = 0.06$ and $x = 0.38$ (see Table 3). Both compositions exist in single and double heterojunction variations (see under "Device Structures"). The double heterojunctions usually have a 1.5 to 2.0 times advantage in efficiency and speed. In all cases, the efficiency strongly depends on the thickness of the window layer and, to a lesser degree, on the thickness of the transparent layer between active layer and absorbing substrate (see Fig. 12). Chips with a transparent substrate have an additional efficiency improvement of 1.5 to 3.0 times again, depending on layer thickness and contact area. The efficiency variation is best understood by counting exit cones as described in the text in conjunction with Table 1. For $x = 0.06$, the internal quantum efficiency of a double heterojunction approaches 100 percent. For $x = 0.38$, the direct and indirect valleys are practically at the same level and the internal quantum efficiency is reduced to the range of 50 percent, again dependent upon the quality of the manufacturing process.

The best compromise for efficiency and speed is the $x = 0.06$ alloy as a double heterostructure. Depending on layer thickness, substrate, and contact area, these devices have efficiencies of 5 to 20 percent and rise/fall times of 20 to 50 ns. This alloy is becoming the workhorse for all infrared applications demanding power and speed. A structural variation as shown in Fig. 14 is an important light source for fiber-optic communication.

The $x = 0.38$ alloy is optimized for applications in the visible spectrum. The highest product of quantum efficiency and eye response is achieved at $x = 0.38$ and $\lambda = 650$ nm. The single heterostructure on an absorbing substrate has an efficacy of around 4 lm/A. The equivalent double heterostructure is in the 6- to 8-lm/A range. On a transparent GaAlAs substrate, the efficacy is typically in the 15- to 20-lm/A range and results of as high as 30 lm/A have been reported in the literature.[16] The major application for these red LEDs is in light-flux-intensive applications, such as message panels and automotive stoplights. A variation optimized for speed is widely used for optical communication using plastic fiber.

TABLE 3 Performance Summary of LED Chips in the $Al_xGa_{1-x}As$ System

x	λ (nm)	Substrate*	Structure†	Efficiency or Efficacy	Speed (ns)
0.06	820	AS, TW	DH	8%	30
0.06	820	TS	DH	15%	30
0.38	650	AS, TW	SH	4 lm/A	
0.38	650	AS, TW	DH	8 lm/A	
0.38	650	TS	DH	16 lm/A	

*AS = absorbing substrate; TW = thick window layer; TS = transport substrate.
†DH = double heterostructure; SH = single heterostructure.

The AlInGaP System

The AlInGaP system has most of the advantages of the AlGaAs system with the additional advantage that it has a higher-energy direct energy gap of 2.3 eV that corresponds to green emission at 540 nm. AlInGaP can be lattice-matched to GaAs substrates. Indium occupies about half of the Group III atomic sites. The ratio of aluminum to gallium can be changed without affecting the lattice match, just as it can in the AlGaAs material system, since A1P and GaP have nearly the same lattice spacing. This enables the growth of heterostructures that have the efficiency advantages described in the previous section.

Various AlInGaP device structures have been grown. A simple DH structure with an AlInGaP active layer surrounded by higher bandgap AlInGaP confining layers has been effective for injection lasers, but has not produced efficient surface-emitting LEDs.[17] The main problem has been that AlInGaP is relatively resistive and the top AlInGaP layer is not effective in distributing the current uniformly over the chip. This is not a problem with lasers since the top surface is covered with metal and the light is emitted from the edge of the chip.

The top layer must also be transparent to the light that is generated. Two window layers used are AlGaAs or GaP on top of the AlInGaP heterostructure.[18,19] AlGaAs has the advantage that it is lattice-matched and introduces a minimum number of defects at the interface, but it has the disadvantage that it is somewhat absorptive to the yellow and green light which is generated for high-aluminum compositions. The highest AlInGaP device efficiencies have been achieved using GaP window layers.[18,20] GaP has the advantage that it is transparent to shorter wavelengths than AlGaAs and that it is easy to grow thick GaP layers, using either VPE or LPE, on top of the AlInGaP DH that was grown by MOVPE. Both VPE and LPE have substantially higher growth rates than MOCVD. The various growth techniques are discussed later under "Epitaxial Technology."

AlInGaP devices with 45-μm-thick GaP window layers have achieved external quantum efficiencies exceeding 5 percent in the red and yellow regions of the emission spectrum.[21] This is more than twice as bright as devices that have thinner AlGaAs window layers.

Green-emitting AlInGaP devices have also been grown which are brighter than the conventional GaP and GaP:N green emitters.[18,20,21] Substantial further improvement in green is expected since the quantum efficiency is not as high as would be expected based on the energy position of the transition from a direct to an indirect semiconductor.

The performance of AlInGaP LEDs compared to the most important other types of visible emitters is shown in Figs. 16 and 17. GaAsP on a GaAs substrate and GaP: ZnO are not shown since their luminous efficacy are off the chart at the bottom and the lower-right-hand corner, respectively. It is clear from Fig. 17 that the luminous efficacy of AlInGaP is substantially higher than the other technologies in all color regions except for red beyond 640 nm. Since forward voltage is typically about 2 V, the lumen per watt value for a given device is about one-half the lumen per ampere value that is given in Tables 2 and 3. The quantum efficiency of AlInGaP is also better than all of the other technologies except for the highest-performance AlGaAs devices operating at about 650 nm. Because of the eye sensitivity variations (see C.I.E. curve in Fig. 16), the 620 nm (red/orange) AlInGaP devices have a higher luminous efficiacy than 650 nm AlGaAs LEDs (see Fig. 17).

Blue LED Technology

Blue emitters have been commercially available for more than a decade, but have only begun to have a significant impact on the market in the last few years. SiC is the leading technology for blue emitters with a quantum efficiency of about 0.02 percent and 0.04 lm/A luminous performance. SiC devices are not much used due to their high price and relatively low performance efficiency.

Other approaches for making blue LEDs are the use of II–VI compounds such as ZnSe or the nitride system GaN, AlGaN, or AlGaInN. It has been difficult to make good *p-n* junctions in these materials. Recently improved *p-n* junctions have been demonstrated in both ZnSe[22,23] and GaN.[24]

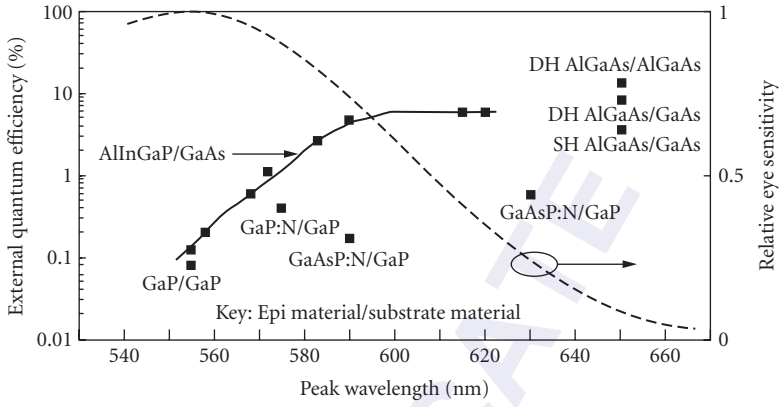

FIGURE 16 External quantum efficiency as a function of peak wavelength for various types of visible LEDs. Below 590 nm the efficiency of AlInGaP LEDs decreases due to the approaching transition from direct to indirect semiconductor. The human eye sensitivity curve is also shown. Since the eye response increases sharply from 660 to 540 nm, it partially makes up for the drop in AlInGaP LED efficiency. The resulting luminous performance is shown in Fig. 17.

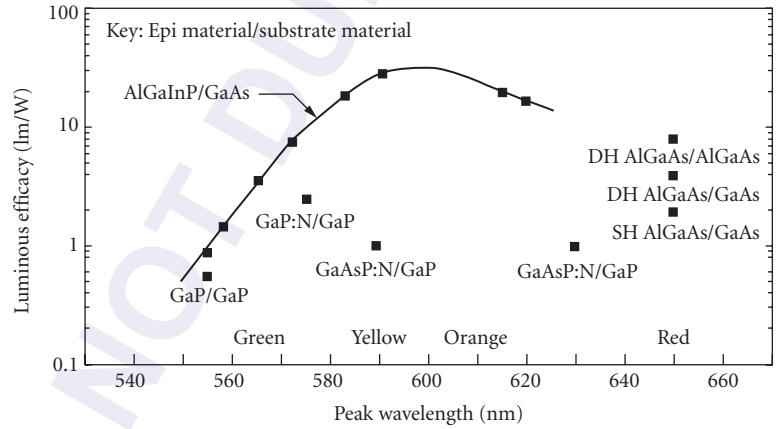

FIGURE 17 Luminous efficacy for AlInGaP LEDs versus wavelength compared to other LED technologies. AlInGaP LEDs are more than an order of magnitude brighter in the orange and yellow regions than other LEDs. AlInGaP LEDs compare favorably to the best AlGaAs red LEDs.

Device performance is still in the 0.1-lm/A range and reliability is unproven. However, this recent progress is very encouraging for blue-emission technology and could lead to a high-performance device in the next few years. Both ZnSe and the nitride system have a major advantage over SiC because they are direct bandgap semiconductors, so a much higher internal quantum efficiency is possible. However, it is difficult to find suitable lattice-matched substrates for these materials.

17.7 SUBSTRATE TECHNOLOGY

Substrate Criteria

There are several requirements for substrates for LEDs. The substrate must be as conductive as possible both thermally and electrically to minimize power loss. In order to minimize defects it should match the epitaxial layers as closely as possible in atomic lattice spacing, and in the coefficient of thermal expansion. The substrate should also have a low defect density itself. Finally, the substrate should, if possible, be transparent to the light generated by the LED structure since this will enhance the external quantum efficiency.

Substrate Choices

The substrates used for nearly all visible LEDs are GaAs and GaP. GaAs or InP is used for infrared devices, depending upon the device structure required. Substrate parameters are summarized in Table 4, along with Si and Ge for comparison. GaAs is used for the AlGaAs and AlInGaP material systems since they can be lattice-matched to it. GaAs is also used for the $GaAs_{1-x}P_x$, system for $x \leq 0.4$ because it is more nearly latticed-matched and, since it is absorbing, it is useful in multiple-junction devices where optical crosstalk must be minimized (see under "Diffused Homojunction" and Fig. 8). GaP is used for compositions of $x > 0.6$ due to its transparency and closer lattice match. However, neither GaP nor GaAs are well matched to GaAsP, and grading layers are required to grow epitaxial layers with decent quality. InP is the choice for long wavelength emitters made using the InGaAs or InGaAsP materials systems, due to the better lattice match.

Substrate Doping

Generally, substrates are *n* type and are doped with Te, S, or Si, although sometimes Se and Sn are also used. In some cases, particularly for some AlGaAs LEDs and laser structures, *p*-type substrates are required and Zn is nearly always the dopant. The doping levels are typically in the 10^{18}-cm^{-3} range. Basically, the substrates are doped as heavily as possible to maximize conductivity. However, the doping must be below the solubility limit to eliminate precipitates and other defects. In the case of substrates that are transparent to the light which is generated, such as GaP, with a $GaAs_{1-x}P_x$ epitaxial layer, the doping should also remain below the level at which substantial free carrier absorption occurs.

Growth Techniques

Substrates can be grown by either the Bridgeman or Liquid Encapsulated Czochralski (LEC) technique. The LEC technique is the most widely used. Both techniques are described in detail elsewhere and will be only briefly summarized here.[25]

TABLE 4 Properties of Common Semiconductor Substrates

Substrate	Lattice Parameter	Energy Gap @ 300 K (eV)		Melting Point (°C)
GaAs	5.653	1.428	Direct	1238
GaP	5.451	2.268	Indirect	1467
InP	5.868	1.34	Direct	1062
Si	5.431	1.11	Indirect	1415
Ge	5.646	0.664	Indirect	937

The LEC technique for GaAs consists of a crucible containing a molten GaAs solution, into which a single crystal "seed" is dipped. The temperature is carefully controlled so that the molten GaAs slowly freezes on the seed as the seed is rotated and raised out of the molten solution. By properly controlling the temperature, rotation rate, seed lift rate, etc., the seed can be grown into a single crystal weighing several kilograms and having a diameter of typically 2 to 4 in for GaAs and for 2 to 2.5 in for GaP. At the GaAs and GaP melting points As and P would rapidly evaporate from the growth crucible if they were not contained with a molten boric oxide layer covering the growth solution. This layer is the reason for the name "liquid encapsulated." The seed is dipped through the boric oxide to grow the crystal. The growth chamber must be pressurized to keep the phosphorus and arsenic from bubbling through the boric oxide. The growth pressure for GaP is 80 atm, and for GaAs is 20 atm or less, depending upon the approach for synthesis and growth. The LEC technique, used for GaAs, GaP, and InP, is similar to the Czochralski technique used for silicon, but the silicon process is much simpler since encapsulation is not required and the growth can be done at atmospheric pressure.

The Bridgeman and the gradient-freeze technique, which is a variation of the Bridgeman technique, can also be used to grow compound semiconductors. In this technique the growth solution and seed are contained in a sealed chamber so liquid encapsulation is not required. Growth is accomplished by having a temperature gradient in the solution, with the lowest temperature at the melting point in the vicinity of the seed. Growth can be accomplished by lowering the temperature of the entire chamber (gradient freeze), or by physically moving the growth chamber relative to the furnace (Bridgeman technique) to sweep the temperature gradient through the molten solution. The growing crystal can be in either a vertical or horizontal position.

GaAs for LEDs is commonly grown using either LEC or horizontal gradient freeze, also called "boat grown," but sometimes a vertical Bridgeman approach is used. GaP and InP are almost always grown using LEC but sometimes a vertical Bridgeman approach has also been used.

17.8 EPITAXIAL TECHNOLOGY

Growth Techniques Available

Epitaxial layers are grown using one of several techniques, depending on the material system. The most common techniques are liquid phase epitaxy (LPE), which is primary used to grow GaAs, GaP, and AlGaAs and vapor phase epitaxy (VPE), which is used to grow GaAsP. Metalorganic vapor phase epitaxy (MOVPE) is also used to grow AlGaAs, GaInAsP, and AlInGaP. Molecular beam epitaxy (MBE) is used for lasers and high-speed devices but is not used for high-volume commercial LEDs at this time. It has been used to grow blue ZnSe-based lasers and LEDs and could be important in the future. All of these epitaxial techniques have been discussed extensively elsewhere and will be only briefly described here.

LPE

LPE growth consists of a liquid growth solution, generally gallium, which is saturated with the compound to be grown.[26] The saturated solution is placed in contact with the substrate at the desired growth temperature, and cooled. As the solution cools, an epitaxial film is grown on the substrate. The technique has the advantage that it is relatively easy to grow high-quality epitaxial layers, and materials containing aluminum (such as AlGaAs) can be readily grown. The disadvantages are that composition control can be difficult. Also, the growth of epitaxial structures involving more than two or three layers, particularly thin layers, can be mechanically complicated since each layer requires a separate growth solution that must be carefully saturated and sequentially brought into contact with the substrate.

One important use of the LPE technique has been for the growth of GaP:ZnO and GaP:N for red and green LEDs, respectively. These devices each consist of two relatively thick layers: an *n*-type layer,

followed by the growth of a *p*-type layer. While other growth techniques can be used to grow GaP LEDs, the best results have been obtained using LPE. As a result of a high-volume, low-cost production technology has evolved, which produces more visible LED chips than any other technique. Another major use of LPE is for the growth of GaAs: Si for infrared emitters. LPE is the only technique with which it has been possible to produce the recombination center that gives rise to the 940-nm emission characteristic of this material. The GaAs: Si structures are generally grown from a single growth solution. At high temperatures the silicon is incorporated on Ga sites and the layers are *n* type. As the solution cools the silicon becomes preferentially incorporated on the As sites and the layer becomes *p* type.

AlGaAs devices for both visible (red) and IR devices are also generally grown by LPE. AlGaAs devices can also be grown by MOCVD, but LPE has the advantage that thick layers can be more easily grown. This is important for high extraction efficiency (see under "Device Structures" and Fig. 12). In the case of visible devices at 650 nm, the internal quantum efficiency is also higher using LPE than MOCVD. This is not understood, but the result is that virtually all of the visible AlGaAs LEDs are produced using LPE.

VPE

VPE is the other major commercial epitaxial technology for LEDs.[9,27] VPE consists of a quartz chamber containing the substrate wafers at the appropriate growth temperature. The reactants are transported to the substrates in gaseous form. The technique is mainly used for the growth of GaAsP which, along with GaP, dominates the high-volume visible LED market. In this case HC1 is passed over Ga metal to form gallium chlorides, and AsH_3 and PH_3 are used to provide the As and P compounds. Appropriate dopant gases are added to achieve the *n*- and *p*-type doping. NH_3 is used to achieve nitrogen doping for the growth of GaAsP:N. The VPE technique has the advantages that it is relatively easy to scale up the growth chamber size so large quantities of material can be grown and layer composition and thickness can be easily controlled by adjusting the flow conditions. A limitation of VPE is that it has not been possible to grow high-quality compounds containing aluminum because the aluminum-bearing reactants attack the quartz chamber resulting in contaminated films. Thus, AlGaAs and AlInGaP, the emerging high-brightness technologies, cannot be grown using this technique.

MOCVD

MOCVD growth, like conventional VPE, uses gases to transpose the reactants to the substrates in a growth chamber.[28] However, in this case metallorganic compounds such as trimethylgallium (TMG) are used for one or more of the reactants. A major difference between VPE and MOCVD is that in the case of MOCVD the decomposition of the source gas (e.g., TMG) occurs as a reaction at or near the substrate surface, and the substrate is in the hottest area of the reactor such that the decomposition occurs on the substrate instead of the walls of the growth chamber. The walls of the growth chamber remain relatively cool. This is the key factor that makes MOCVD suitable for the growth of aluminum-bearing compounds which, unlike the VPE situation, do not react significantly with the cooler reactor walls. Thus AlGaAs and AlInGaP can be readily grown with MOCVD, and this technology is widely used for infrared AlGaAs LEDs and lasers, and for the emerging visible AlInGaP laser and LED technology.

MOCVD is also used for the growth of GaN and AlGaN that are candidates for blue emission, and for the growth of II–VI compounds, such as ZnSe, that is also a potential blue emitter. However, at this time the key limitation in obtaining blue ZnSe emitters is the growth of low-resistivity *p*-type ZnSe. For reasons that are not yet understood, low-resistivity *p*-type ZnSe has been grown using MBE only.

MBE

MBE is a high vacuum growth technique in which the reactants are essentially evaporated onto the substrates under very controlled conditions.[29] MBE, like MOCVD, can be used to deposit compounds

containing aluminum. The growth rates using MBE are generally slower than the other epitaxial techniques, so MBE is most suitable for structures requiring thin layers and precise control of layer thickness. MBE equipment is somewhat more expensive than the equipment used for the other types of epitaxial growth, so it has not been suitable for the high-volume, low-cost production that is required for most types of LEDs. MBE has generally been utilized for lasers and high-speed devices where control of complicated epitaxial structures is critical and where relatively low volumes of devices are required. One advantage that MBE has over the other growth technologies is that the reactants utilized are generally less hazardous. Consequently, MBE equipment is often cheaper and easier to install since there are less safety issues and safety-code restrictions to deal with.

17.9 WAFER PROCESSING

Wafer Processing Overview

Wafer processing of compound semiconductors for LED applications has many of the same general steps used to process silicon integrated-circuit wafers, namely passivation, diffusion, metallization, testing, and die fabrication. The LED device structures are much simpler, so fewer steps are required; but, due to the materials involved, the individual steps are generally different and sometimes more complicated.

Compound semiconductor processing has been described in detail elsewhere, so only a brief summary is discussed here.[30] Some types of LED structures require all of the processing steps listed here, but in many cases fewer process steps are required. An example is a GaP or AlGaAs device with a grown *p-n* junction. For these devices no passivation or diffusion is required.

Passivation

Some types of LED structures, particularly multijunction structures, require a passivation layer prior to diffusion, as shown in Fig. 7. This layer must be deposited relatively free of pinholes, be patternable with standard photolithographic techniques, and must block the diffusing element, generally zinc. In the case of silicon, a native oxide is grown which is suitable for most diffusions. Unfortunately, the compound semiconductors do not form a coherent native oxide as readily as silicon. Silicon nitride (Si_3N_4) is the most widely used passivation layer for LEDs. Si_3N_4 is grown by reacting silane (SiH_4) and ammonia at high temperature in a furnace. S_3N_4 blocks zinc very effectively, and is easily grown, patterned, and removed. Sometimes an SiO_2 layer is used in conjunction with Si_3N_4 for applications such as protecting the surface of the compound semiconductor during high-temperature processing. Silicon oxynitride can also be used instead of or in addition to pure Si_3N_4. Silicon oxynitride is somewhat more complicated to deposit and control, but can have superior properties, such as a better match of coefficient of expansion, resulting in lower stress at the interface.

Diffusion

Generally, only *p*-type impurities, usually Zn, are diffused in compound semiconductors. *N*-type impurities have prohibitively small diffusion coefficients for most applications. Zn is commonly used because it diffuses rapidly in most materials and because it is nontoxic in contrast to Be, which also diffuses rapidly. Mg is another reasonable *p*-type dopant, but it diffuses more slowly than zinc. Diffusions are generally done in evacuated and sealed ampoules using metallic zinc as source material. A column V element such as As is also generally added to the ampoule to provide an overpressure that helps to prevent decomposition of the semiconductor surface during diffusion. Diffusion conditions typically range from 600 to 900°C for times ranging from minutes to days, depending upon the material and device involved. Junction depths can range from a fraction of a μm to a more than 10 μm.

Open-tube diffusions have also been employed but have generally been harder to control than the sealed ampoule approach, often because of surface decomposition problems. Open-tube diffusions have the advantage that one does not have to deal with the expense and hazard of sealing, breaking, and replacing quartz ampoules.

A third type of diffusion that has been used is a "semisealed" ampoule approach in which the ampoule can be opened and reused. The diffusion is carried out at atmospheric pressure and the pressure is controlled by having a one-way pressure relief valve on the ampoule.

Contacting

The contacts must make good ohmic contact to both the *p*- and *n*-type semiconductor, and the top surface of the top contact must be well suited for high-speed wire bonding. Generally, multilayer contacts are required to meet these conditions. Evaporation, sputtering, and *e*-beam deposition are all employed in LED fabrication. The *p*-type contact generally uses an alloy of either Zn or Be to make the ohmic contact. An Au-Zn alloy is the most common due to the toxicity of Be. The Au-Zn can be covered with a layer of Al or Au to enable high-yield wire bonding. A refractory metal barrier layer may be included between the Au-Zn and top Al or Au layer to prevent intermixing of the two layers and the out-diffusion of Ga, both of which can have a deleterious effect on the bondability of the Al or Au top layer. The *n*-type contact can be similar to the *p*-type contact except that an element which acts as an *n*-type dopant, commonly Ge, is used instead of Zn. An Au-Ge alloy is probably most frequently used to form the *n*-type ohmic contact since it has a suitably low melting point. If the *n*-type contact is the top, or bonded, contact it will be covered by one or more metallic layers to enhance bondability.

Testing

The key parameters that need to be tested are light output, optical rise and fall times, emission wavelength, forward voltage, and leakage current. The equipment used is similar to that used to test other semiconductor devices except that a detector must be added to measure light output. Rise and fall times and wavelength are generally measured on only a sample basis and not for each device on a wafer. In order to test the individual LEDs, the devices must be isolated on the wafer. This occurs automatically for LEDs that are masked and diffused, but if the LEDs are sheet diffused or have a grown junction, the top layer must be processed to isolate individual junctions. This can be accomplished by etching or sawing with a dicing saw. Generally, sawing is used, followed by an etch to remove saw damage, because the layers are so thick that etching deep (>10 μm) grooves is required. It is advisable to avoid deep groove etching because undercutting and lateral etching often occur and the process becomes hard to control. In many cases LED junctions are not 100 percent tested. This is particularly true of GaP and AlGaAs red-emitting devices in which the top layer may be 30 μm thick. Wafers of this type can be sampled by "coring" through the top layer of the wafer in one or more places with an ultrasonic tool in order to verify that the wafer is generally satisfactory. Later, when chips are fully processed, chips can be selected from several regions of the wafer and fully tested to determine if the wafer should be used or rejected.

Die Fab

Die fab is the process of separating the wafer into individual dice so they are ready for assembly. Generally, the wafer is first mounted on a piece of expandable tape. Next the wafer is either scribed or sawed to form individual dice. Mechanical diamond scribing or laser scribing were the preferred technologies in the past. Mechanical scribing has zero kerf loss, but the chips tend to have jagged edges and visual inspection is required. Laser scribing provides uniform chips but the molten waste material from between the chips damages neighboring chips, and in the case of full function chips

the edges of the junction can be damaged by the laser. As a result of the limitations of scribing, sawing (using a dicing saw with a thin diamond impregnated blade) has become the technology of choice for most LEDs.

The kerf loss for sawing has been reduced to about 40 μm and the chip uniformity is excellent such that a minimum of inspection and testing is required. For most materials a "cleanup" etch is required after sawing to remove work damage at the edges of the chips, which can both affect the electrical performance and absorb light. The wafer remains on the expandable tape during the sawing process. After sawing, the tape is expanded so that the chips are separated. The tape is clamped in a ring that keeps it expanded and the chips aligned. In this form the chips are easily individually picked off the tape by the die-attach machine that places the chips in the LED package.

17.10 LED QUALITY AND RELIABILITY

LEDs offer many advantages over other types of light sources. They have long operating life, they operate over a wide temperature range, and they are unaffected by many adverse environmental conditions. LED devices also are mechanically robust, making them suitable for applications where there is high vibration, shock, or acceleration. Excellent quality and reliability are obtainable when an LED product is properly designed, fabricated, packaged, tested, and operated.

Product quality is defined as "fitness for use" in a customer's application. Quality is measured in units of the average number of defective parts per million shipped (i.e., ppm), and is inferred from product sampling and testing. LED product quality is assured by (1) robust chip and product design, (2) high-quality piece parts, (3) well-controlled fabrication processes, (4) use of statistical process control during manufacturing, (5) careful product testing, and (6) proper handling and storage. Most III–V LEDS are comparable in quality to the best silicon devices manufactured today. Well-designed LED products have total defect levels well below 100 ppm.

Reliability measures the probability that a product will perform its intended function under defined use conditions over the useful life of the product. Probability of survival is characterized by a failure rate, which is calculated by dividing the number of failures by the total number of operating hours (number of products tested per x hours operated). Common measures for reliability are percent failures per 1000 hours (percent/khr) and number failures per 10^9 hours (FITS). LED failure rates typically are better than 0.01 percent per khr at 50°C.

The reliability of an LED product is dependent on the reliability of the LED semiconductor chip and on the robustness of the package into which the chip is placed. Interactions between the chip and package can affect product reliability as well. Aspects of LED packaging and LED chip reliability are discussed in the following paragraphs.

LED Package Reliability

The package into which the LED chip is assembled should provide mechanical stability, electrical connection, and environmental protection. To evaluate package integrity, stress tests such as temperature cycling, thermal and mechanical shock, moisture resistance, and vibration are used to establish the worst-case conditions under which a product can survive. Generally, product data sheets contain relevant information about safe conditions for product application and operation.

Plastic materials are commonly used to package LEDs (see under "LED-Based Products"). Thermal fatigue is a limiting factor in plastic-packaged LEDs. Take the case of the plastic LED lamp shown later in Fig. 21. Because of the different materials used (epoxy plastic, copper lead frame, gold wire, III–V LED, etc.) and the different coefficients of expansion of these materials, temperature changes cause internal stresses. If the package is not well designed and properly assembled, thermal changes can cause cracking, chip-attach failure, or failure of the wire bond (open circuits). Careful design can reduce these problems to negligible levels over wide temperature ranges. Today's high-quality plastic lamps are capable of being cycled from −55 to +100°C for 100 cycles without failure.

Long-term exposure to water vapor can lead to moisture penetration through the plastic, subjecting the chips to humidity. High humidity can cause chip corrosion, plastic delamination, or surface leakage problems. Plastic-packaged LEDs are typically not harmed when used under normal use conditions. Accelerated moisture resistance testing can be used to test the limits of LED packages. Plastic materials have been improved to the point that LED products can withstand 1000 hours of environmental testing at elevated temperatures and high humidity (i.e., 85°C and 85 percent RH).

The thermal stability of plastic packaging materials is another important parameter. Over normal service conditions, the expansion coefficient of plastic is relatively constant. Above the so-called glass transition temperature T_g the coefficient increases rapidly. Reliable operation of plastic-packaged LEDs generally requires operation at ambient temperatures below T_g. Failures associated with improper soldering operations, such as too high a soldering temperature or for too long a time can cause the package to fail. Excessive storage temperatures also should be avoided. When an LED product is operated, internal ohmic heating occurs; hence, the safe operating maximum temperature is generally somewhat lower than the safe storage temperature.

LED Chip Reliability

The reliability characteristics of the LED chip determine the safe limits of operation of the product. When operated at a given temperature and drive current there is some probability that the LED will fail. In general, LED failure rates can be separated into three time periods: (1) infantile failure, (2) useful life, and (3) the wearout period (see Fig. 18). During the infant mortality period, failures occur due to weak or substandard units. Typically, the failure rate decreases during the infantile period until no weak units remain. During the "useful life" period, the failure rate is relatively low and constant. The number of failures that do occur are random in nature and cannot be eliminated by more testing. The useful life of an LED is a function of the operating temperature and drive conditions. Under normal use conditions, LEDs have useful lives exceeding 100,000 hours. The wearout period is characterized by a rapidly rising failure rate. Generally, wearout for LEDs is not a concern, as the useful life far exceeds the useful life of the product that the LEDs are designed into.

The principle failure mode for LED chips is light-output degradation. In the case of a visible lamp or display, failure is typically defined as a 50 percent decrease in light output from its initial

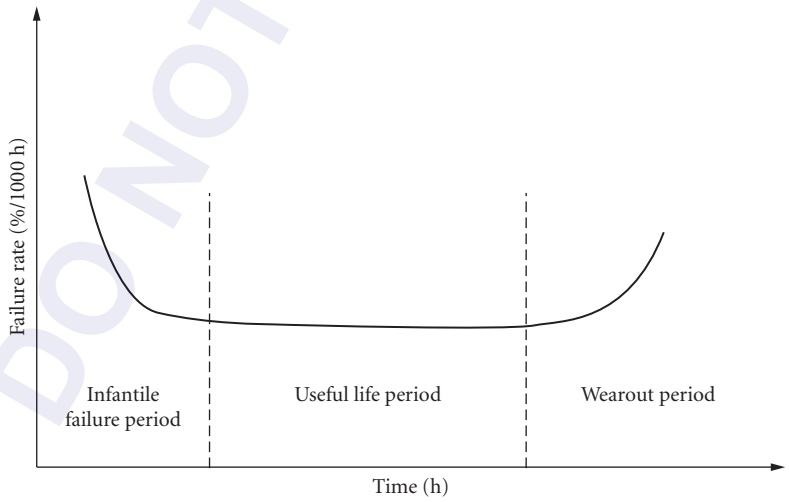

FIGURE 18 Plot of LED failure rate versus time, showing the infantile failure period (decreasing rate), the useful life period (constant, low rate), and the wear-out period (rapidly rising rate).

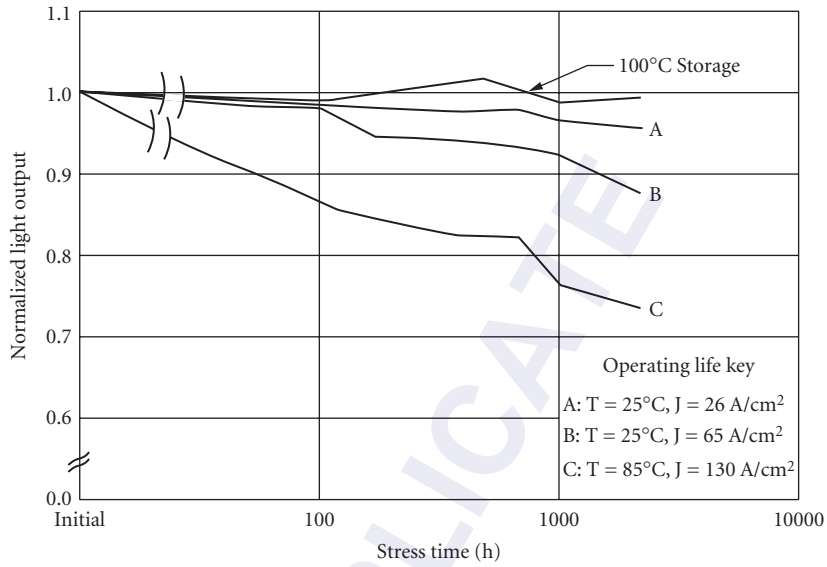

FIGURE 19 Curves of light output versus time for GaAsP indicator lamps stressed under various conditions. Light output is normalized to the initial value. Each curve shows the average degradation of 20 lamps

value, since that is the level where the human eye begins to observe a noticeable change. For infrared emitters or visible LEDs where flux is sensed by a semiconductor detector, failure is commonly defined as a 20 to 30 percent decrease in flux output.

Figure 19 shows degradation curves for a direct bandgap GaAsP LED packaged in a 5-mm plastic lamp.[31] Current must flow for degradation to occur, as negligible change is observed after 1 khr of 100°C storage. Degradation is a function of the temperature at the *p-n* junction and the junction current density. As shown in Fig. 19, a larger decline in light output is observed as junction current density and/or temperature at the junction increases. The dependence of degradation on current density J is superlinear, varying as J^x with $1.5 < x < 2.5$. Hence, accelerated-aging tests typically use high currents and temperatures to shorten the time needed to observe LED degradation. The maximum stress level shown in Fig. 19 is 200 percent of the maximum allowable drive current specified in the data sheet.

Light-output degradation in GaAsP LEDs is due to an increase in the nonradiative space-charge recombination current. Total current flowing through the LED is made up of the sum of diffusion current and space-charge recombination current, as shown in the following equations:

$$I_T(V, t) = A(t)e^{qV/kT} + B(t)e^{qV/2kT} \tag{5}$$

where q is electron charge, k is Boltzmann's constant, and T is temperature.[32] The first term is diffusion current that produces light output, while the second term is space-charge recombination that is nonradiative. At fixed I_T, if $B(t)$ increases, then the diffusion term must decrease and, hence, the light output decreases. The reason for the increase in space-charge recombination in GaAsP LEDs is not fully understood.

The degradation characteristics of GaAlAs LEDs differ from those of GaAsP LEDs. Typical curves of normalized light output versus time for GaAlAs LEDs are shown in Fig. 20. "Good" units show negligible decrease in light output when operated under normal service conditions. Gradual degradation may occur, but it is relatively uncommon. The predominate failure mode in GaAlAs LEDs is catastrophic degradation. The light emission decreases very rapidly over a period of less than 100 hours

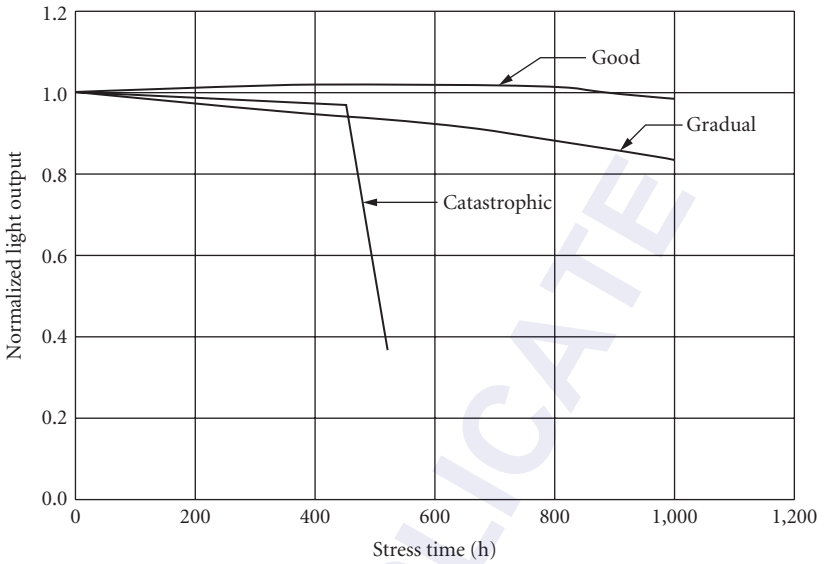

FIGURE 20 Light output degradation of AlGaAs LEDs. Three modes are shown: "good" devices with negligible light-output decrease over time, devices which degrade gradually over time, and "catastrophic" degradation devices where the flux rapidly decreases over a short time period

and simultaneously nonradiative regions ("dark-spot" or "dark-line defects") are observed to form. The catastrophic degradation mechanism is described in detail in Refs. 33 and 34. In brief, the dark regions are caused by nonradiative recombination at dislocation networks that grow rapidly from a crystal dislocation located in the light-emitting region of the LED. Network formation depends on carrier recombination, both nonradiative, which creates mobile point defects, and radiative recombination, which enhances the movement of the point defects to the growing network.

Formation of dark-line defects is enhanced by mechanical stress either present in the LED chip or occurring during assembly. Properly designed products reduce such stress by minimizing bending caused by the different coefficients of expansion in the LED, and by stress-free die attach, wire bond, and encapsulation of the LED during assembly.

Failures due to dark-spot or dark-line defects can be effectively screened out by operating the LED at high current and temperature. Units with defects typically fail within the first few hundred hours. GaAlAs LEDs with dark-spot or dark-line defects are screened out by means of visual inspection and/or by eliminating units with large decreases in light output. GaAlAs LEDs used for fiber-optic applications have small emitting areas (see under "Fiber Optics" discussion and Fig. 14). Due to the high current densities present in such devices, high temperature and current burn-in is used extensively for these types of LEDs.

Another degradation mode in LEDs is the change in the reverse breakdown characteristics over time. The reverse characteristics become soft and the breakdown voltage may decrease to a very low value. Several mechanisms have been observed in LEDs. One cause is localized avalanche breakdown due to microplasma formation at points where electric fields are high. Microplasmas have been observed in GaAs and GaAsP LEDs.

Damage or contamination of the edges of an LED chip can cause increased surface leakage and reduced reverse breakdown. Incomplete removal of damage during die separation operations and damage induced during handling and assembly are known to cause reverse breakdown changes. Die-attach materials also can unintentionally contaminate the edges of LEDs. Copper, frequently found in LED packaging materials, can diffuse into the exposed surfaces of the LED, causing excess leakage and, in some cases, light-output degradation.[35] Chips whose *p-n* junction extends to the edges (i.e., Fig. 6) are very susceptible to damage and/or contamination.

17.11 LED-BASED PRODUCTS

Indicator Lamps

The simplest LED product is an indicator lamp or its infrared equivalent. The most frequently used lamp is shown in Fig. 21. A LED chip with a typical dimension of 250 × 250 μm is attached with conductive silver-loaded epoxy into a reflective cavity coined into the end of a silver-plated copper or steel lead frame. The top of the LED chip is connected with a thin 25-μm gold wire to the second terminal of the lead frame. The lead frame subassembly is then embedded in epoxy. The epoxy serves several functions: (1) it holds the assembly together and protects the delicate chip and bond wire; (2) it increases the light extraction from the chip (see under "Light Extraction," discussed earlier); and (3) it determines the spatial light distribution.

There are a large number of variations of the lamp shown in Fig. 21. Besides the obvious variation of source wavelength, there are variations of size, shape, radiation pattern, etc. The cross section of the plastic body ranges from 2 to 10 mm. The radiation pattern is affected by three factors: the shape of the dome, the relative position of the chip/reflector combination, and by the presence of a diffusant in the epoxy. Figure 22*a* shows the radiation pattern of a lamp using clear plastic as an encapsulant. The rays emanating from chip and reflector are collimated into a narrow beam. For many indicator lamps a broader viewing angle is desired such as that shown in the radiation pattern of Fig. 22*b.* This effect is achieved by adding a diffusant, such as glass powder, to the clear plastic. Another variation is shape. Common shapes are round, square, rectangular, or triangular.

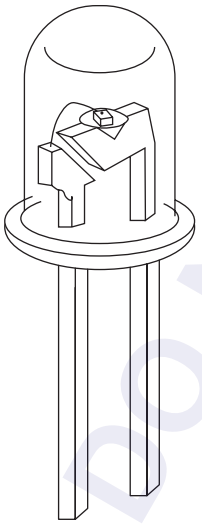

FIGURE 21 Plastic indicator lamp. The LED chip is placed in a reflector coined into the end of one electrode lead. The top of the chip is connected with a gold wire to the second electrode. The electrodes are encapsulated in plastic to form a mechanically robust package.

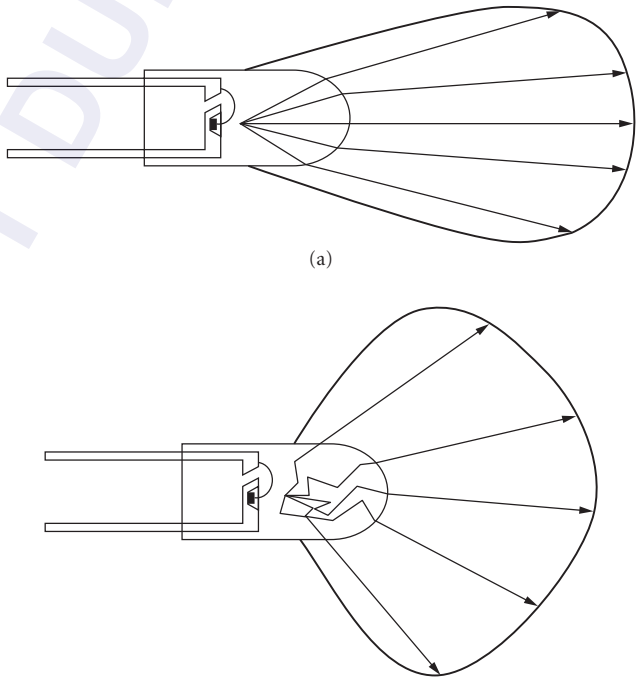

FIGURE 22 Radiation pattern of two types of LED indicator lamps: *(a)* lamp with clear plastic package with a narrow beam and *(b)* lamp with a diffusing plastic package (glass powder added) with a broader radiation pattern.

Another variation is achieved by placing two different chips into the reflector cup. For instance, a lamp with green and red chips connected to the second post in an antiparallel fashion can operate as a red indicator if the reflector post is biased positive, and as a green indicator if it is biased negative. Rapidly switching between the two polarities one can achieve any color between the two basic colors, i.e., yellow or orange, depending on current and duty cycle.

A number of chips can be combined in a single package to illuminate a rectangular area. These so-called annunciator assemblies range in size from 1 to several cm. They typically use 4 chips per cm^2. By placing an aperture-limiting symbol or telltale in front of the lit area, these structures are cost-effective means to display a fixed message, such as warning lights in an automotive dashboard.

Numeric Displays

Numeric displays are usually made up of a nearly rectangular arrangement of seven elongated segments in a figure-eight pattern. Selectively switching these segments generates all ten digits from 0 to 9. Often decimal point, colon, comma, and other symbols are added.

There are two main types of LED numeric displays: (1) monolithic displays and (2) stretched segment displays. All monolithic displays are based on GaAs-GaAsP technology. Seven elongated *p*-doped regions and a decimal point are diffused into an *n*-type epitaxial layer of a single or monolithic chip (see Fig. 8). Electrically, this is a structure with eight anodes and one common cathode. This monolithic approach is relatively expensive. For arms-length viewing, a character height of 3 to 5 mm is required. Adding space for bonding pads, decimal point, and edge separation, such a display consumes around 10 mm^2 of expensive semiconductor material per digit. One way to reduce material and power consumption is optical magnification. Viewing-angle limitation and distortion limit the magnification M to $M \leq 2.0$. Power consumption is reduced by M^2—an important feature for battery-powered applications.

For digits >5 mm, a stretched segment display is most cost effective. The design of Fig. 23 utilizes a 250 × 250 μm chip to generate a segment with dimensions of up to 8 × 2 mm for a 20-mm digit height. This corresponds to a real magnification of $M^2 = 256$, or an equivalent linear magnification of $M = 16$. This magnification is achieved without a reduction in viewing angle by using scattering optics. An LED chip is placed at the bottom of a cavity having the desired rectangular exit shape and

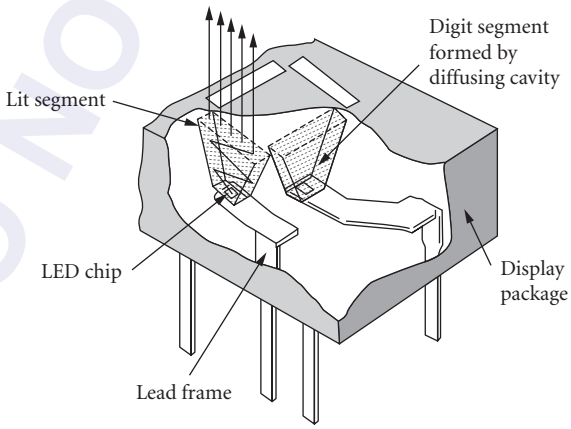

FIGURE 23 Cutaway of a seven-segment numeric LED display, showing how light from a small LED chip is stretched to a large character segment using a diffusing cavity. Characters 0 to 9 are created by turning on appropriate combinations of segments.

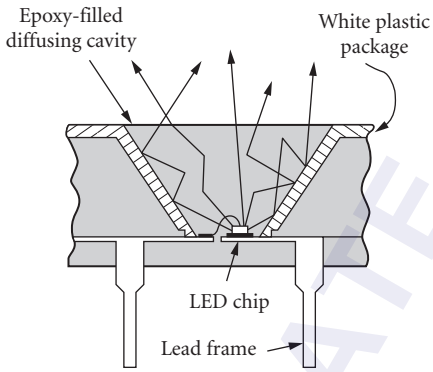

FIGURE 24 Cross section through one segment of the seven-segment numeric display shown in Fig. 23. A LED chip is placed at the bottom of a highly reflective, white plastic cavity which is filled with clear plastic containing a diffusant. Light is scattered within the cavity to produce uniform emission at the segment surface.

the cavity is filled with a diffusing plastic material (see Fig. 24). The side and bottom surfaces of the cavity are made as reflective as possible. Highly reflective white surfaces are typically used. A good white plastic surface measured in air may have a reflectivity of 94 percent compared with 98 percent for Ag and 91 percent for Al. Ag and Al achieve this reflectivity only if evaporated on a specularly smooth surface. Measured in plastic, the reflectivity of the white surface increases from 94 to 98 percent, the Ag surface remains at 98 percent, while the Al surface decreases to 86 percent. Both metallic surfaces have substantially lower reflectivities if they are evaporated onto a nonspecular surface, or if they are deposited by plating. Practically all numeric LED displays above 5-mm character heights are made using white cavity walls and diffusing epoxy within the cavity.

This case of magification by scattering does not result in a power saving as in the case of magnification of monolithic displays. Since there is practically no reduction in emission angle, the law of energy conservation requires an increased light flux from the chip that equals the area magnification plus reflection losses in the cavity.

Alphanumeric Displays

There are two ways LEDs are used to display alphanumeric information: either by using more than seven elongated segments, i.e., 14, 16, or 24; or by using an array of LED chips in a 5×7 dot matrix format. The multiple segment products are similar in design to the monolithic or stretched segment numeric displays described above.

In the case of small monolithic characters, the number of input terminals quickly exceeds conventional pin spacing. These products are usually clusters of 4 to 16 characters combined with a decoder/driver integrated circuit within the same package. To reduce cost and power, some modest optical magnification is usually used. The segmented displays are usually larger, i.e., 12 to 25 mm and limited to 14 segments per character. At this size, there is no pin density constraint and the decoder is usually placed outside the package.

The most frequently used alphanumeric LED display is based on a 5×7 matrix per character. For small characters in the range of 5 to 8 mm, the LED chips are directly viewed and pin density limitations require an on-board decoder/driver IC. Products are offered as end-stackable clusters of 4, 8, and 16 characters.

For larger displays, the LED chip is magnified by the same optical scattering technique described earlier for numerics. Exit apertures per pixel have a diameter of 2 to 5 mm. Products are offered as 5×7 single characters or end-stackable 20×20 tiles for large message- or graphics-display panels. At this size, pin density is not a limitation.

Optocouplers

An optocoupler is a device where signal input and signal output have no galvanic connection. It is mainly used in applications as the interface between the line voltage side of a system and the low-voltage circuit functions, or in systems where the separate ground connection of interconnected subsystems causes magnetic coupling in the galvanic loop between signal and ground connections. By interrupting the galvanic loop with an optical signal path, many sources of signal interference are eliminated.

The oldest optocouplers consist of an IR LED and a photodetector facing each other in an insulating tube. The second generation utilized the so-called dual-in-line package widely used by logic ICs. In this package an IR emitter and a phototransistor are mounted face to face on two separate lead frames. The center of the package between emitter and detector is filled with a clear insulating material. The subassembly is then molded in opaque plastic to shield external light and to mechanically stabilize the assembly (Fig. 25). The second generation optocouplers have limited speed performance for two reasons: (1) the slow response time of the GaAs:Si LED and (2) the slow response of the photo-transistor detector because of the high collector-base capacitance.

The third generation of optocouplers overcomes the speed limitation. It uses an integrated photodetector and a decoupled gain element. Integration limits the thickness of the effective detection region in silicon to 5 to 7 μm. This thickness range forces a shift of the source to wavelengths shorter than the 940-nm sources used in the second-generation couplers. Third-generation couplers use GaAsP (700 nm) or AlGaAs emitters (880 nm).

Within the last decade, the optocoupler product family has seen further proliferation by adding features on the input or output side of the coupler. One proliferation resulted in couplers behaving

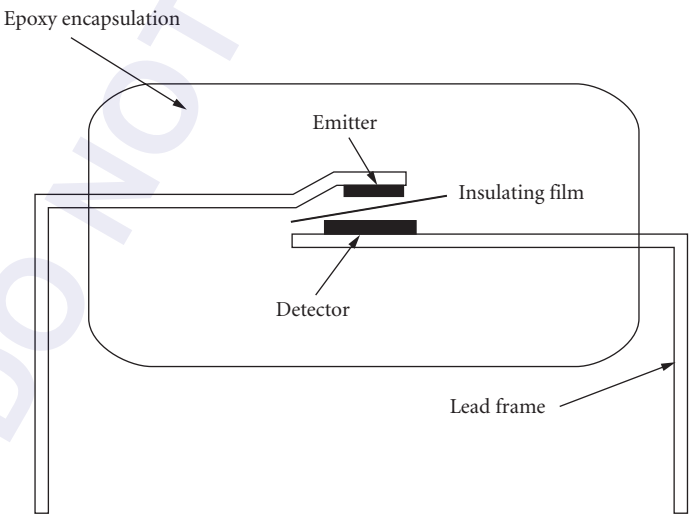

FIGURE 25 Optocoupler consisting of face-to-face emitter and detector chips. An insulating film is placed between the chips to increase the ability of the optocoupler to withstand high voltages between input and output electrodes

like logic gates. Another variation used MOS FET devices on the output side, eliminating the offset voltages of bipolar devices. These couplers are comparable to the performance of conventional relays and are classified as solid-state relays. Other types use a CMOS input driver and CMOS output circuitry to achieve data transfer rates of 50 Mb/s and CMOS interface compatibility.

Fiber Optics

LEDs are the primary light source used in fiber-optic links for speeds up to 200 Mb/s and distances up to 2 km. For higher speed and longer distances, diode lasers are the preferred source.

For fiber-optic applications, LEDs have to meet a number of requirements that go well beyond the requirements for lamps and displays. The major issues are minimum and maximum flux coupled into the fiber, optical rise and fall times, source diameter, and wavelength. Analysis of flux budget, speed, fiber dispersion, wavelength, and maximum distance is quite complex and goes far beyond the scope of this work. A simplified discussion for the popular standard, Fiber Distributed Data Interface (FDDI) will highlight the issues. For a detailed discussion, the reader is referred to Ref. 36.

Flux Budget The minimum flux that has to be coupled into the fiber is determined by receiver sensitivity (−31 dBm), fiber attenuation over the 2-km maximum distance (3 dB), connector and coupler losses (5 dB), and miscellaneous penalties for detector response variations, bandwidth limitations, jitter, etc. (3 dB). With this flux budget of 11 dB, the minimum coupled power has to be −20 dBm. Another flux constraint arises from the fact that the receiver can only handle a maximum level of power before saturation (−14 dBm). These two specifications bracket the power level coupled into the fiber at a minimum of −20 dBm (maximum fiber and connector losses) and at a maximum of −14 dBm (no fiber or connector losses for the case of very short fiber).

Speed The transmitter speed or baud rate directly translates into a maximum rise and fall time of the LED. The 125 Mdb FDDI specifications call for a maximum rise and fall time of 3.5 ns. As a rule of thumb, the sum of rise and fall time should be a little shorter than the inverse baud period (8 ns for 125 Mbd).

Source Diameter and Fiber Alignment Efficient coupling of the LED to the fiber requires a source diameter that is equal to or preferably smaller than the diameter of the fiber core. For sources smaller than the core diameter, a lens between source and fiber can magnify the source to a diameter equal to or larger than the core diameter. The magnification has two benefits: (1) It increases the coupling efficiency between source and fiber. The improvement is limited to the ratio of source area to core cross-sectional area. (2) It increases the apparent spot size to a diameter larger than the fiber core. This effect relaxes the alignment tolerance between source and core and results in substantially reduced assembly and connector costs.

Wavelength The LEDs used in fiber-optic applications operate at three narrowly defined wavelength bands 650, 820 to 870, and 1300 nm, as determined by optical fiber transmission characteristics.

650 nm This band is defined by an absorption window in acrylic plastic fiber. It is a very narrow window between two C-H resonances of the polymer material. The bottom of the window has an absorption of approximately 0.17 dB/m. However, the effective absorption is in the 0.3 to 0.4 dB/m range because the LED linewidth is comparable to the width of the absorption window and the LED wavelength changes with temperature. The 650-nm LEDs use either $GaAs_{1-x}P_x$ with $x = 0.4$ or $GaAl_xAs_{1-x}$ with $x = 0.38$. Quantum efficiencies are at 0.2 and 1.5 percent, respectively. Maximum link length is in the range of 20 to 100 m, depending on source efficiency, detector sensitivity, speed, and temperature range.

820 to 870 nm This window was chosen for several reasons. GaAlAs emitters (see Fig. 14) and Si detectors are readily available at this wavelength. Early fibers had an absorption peak from water

contamination at approximately 870 nm. As fiber technology improved, the absorption peak was eliminated and the wavelength of choice moved from 820- to the 850 to 870-nm range. Fiber attenuation at 850 nm is typically 3 dB/km. Maximum link length in the 500- to 2000-m range, depending on data rate. In the 850 to 870-nm window the maximum link length is limited by chromatic dispersion. GaAlAs emitters have a half-power linewidth of approximately 35 nm. The velocity of light in the fiber is determined by the index of refraction of the fiber core. The index is wavelength-dependent resulting in dispersion of the light pulse. This dispersion grows with distance. The compounded effect of LED linewidth and fiber dispersion is a constant distance-speed product. For a typical multimode fiber and GaAlAs LED combination, this product is in the range of 100 Mbd-km.[36]

1300 nm At this wavelength, the index of refraction as a function of wavelength reaches a minimum. At this minimum, the velocity of light is practically independent of wavelength, and chromatic dispersion is nearly eliminated. The distance-speed limitation is caused by modal dispersion. Modal dispersion can be envisioned as a different path length for rays of different entrance angles into the fiber. A ray going down the middle of the core will have a shorter path than a ray entering the fiber at the maximum acceptance angle undergoing many bends as it travels down the fiber. The resulting modal dispersion limits multimode fibers to distance bandwidth products of approximately 500 Mbd-km. LED sources used at this wavelength are GaInAsP emitters, as shown in Fig. 15. At this wavelength, fiber attenuation is typically <1.0 dB/km and maximum link length is in the range of 500 to 5000 m, depending on data rate and flux budget.

Sensors

LED/detector combinations are used in a wide range of sensor applications. They can be grouped into three classes: transmissive, reflective, and scattering sensors.

Transmissive Sensors The most widely used transmissive sensor is the slot interrupter. A U-shaped plastic holder aligns an emitter and detector face to face. It is used widely for such applications as sensing the presence or absence of paper in printers, end-of-tape in tape-recorders, erase/overwrite protection on floppy disks, and many other applications where the presence or absence of an opaque obstruction in the light path determines a system response.

A widely used slot interrupter is a two- or three-channel optical encoder. A pattern of opaque and transmissive sections moves in front of a fixed pattern with the same spatial frequency. Two optical channels positioned such that they are 90° out of phase to each other with regard to the pattern allow the measurement of both distance (number of transmissive/opaque sequences) and direction (phase of channel A with regard to channel B). Such encoders are widely used in industrial control applications, paper motion in printers, pen movement in plotters, scales, motor rotation, etc. A third channel is often used to detect an index pulse per revolution to obtain a quasi-absolute reference.

Reflective Sensors In a reflective sensor an LED, detector, and associated optical elements are positioned such that the detector senses a reflection when a reflective surface (specular or diffuse) is positioned within a narrow sensing range. A black surface or nonaligned specular surface or the absence of any reflective surface can be discriminated from a white surface or properly aligned specular surface. Applications include bar-code reading (black or white surface), object-counting on a conveyer belt (presence or no presence of a reflecting surface), and many others. Many transmissive sensor applications can be replaced by using reflective sensors and visa versa. The choice is usually determined by the optical properties of the sensing media or by cost. An emerging application for reflective sensors is blood gas analysis. The concentration of O_2 or CO_2 in blood can be determined by absorption at two different LED wavelengths, i.e., red and infrared.

Scattering Sensors One design of smoke detectors is based on light scattering. The LED light beam and the detector path are crossed. In the absence of smoke, no light from the LED can reach the detector. In the presence of smoke, light is scattered into the detector.

HIGH-BRIGHTNESS VISIBLE LEDS

Winston V. Schoenfeld

CREOL, The College of Optics and Photonics
University of Central Florida
Orlando, Florida

18.1 INTRODUCTION

Over the past decade a transformation in light emitting diode (LED) application has occurred from indicator use to the more demanding solid-state lighting and illumination markets. This includes areas such as backlighting in consumer hand-held products, outdoor displays, traffic signals, and general room lighting through the replacement of incandescent and fluorescent light sources. This transformation has been driven directly by the significant increases in LED efficiency that has enabled LEDs to penetrate into such markets. These new high-efficiency LEDs are typically referred to as high-brightness LEDs (HB-LEDs), and utilize quantum well active regions to achieve their high efficiency and lumen output.

Quantum well-active regions can have either a single quantum well (SQW) or multiple quantum well (MQW) structure, reducing internal reabsorption and increasing the radiative recombination rate of the device through greater spatial overlap of electrons and holes. A discussion of quantum wells can be found in Chap. 19, "Semiconductor Lasers." Figure 1 provides a basic structure for a modern HB-LED. It is similar to the DH structure, but utilizes a MQW active region between the *n* and *p*-type layers of the device, composed of quantum wells (QWs) that are on the order of a few nanometers in thickness. By adjusting either the composition or width of the QW, the emission wavelength of the LED can be tuned. The use of QW active regions in LEDs has not only allowed for an increase in the efficiency of the devices, it has also resulted in the ability to obtain new wavelength emissions that were not previously available due to epitaxial strain and lattice matching constraints.

18.2 THE MATERIALS SYSTEMS

There are two main semiconductor material systems currently exploited for visible HB-LEDs. These are the AlInGaP and AlInGaN systems. A detailed discussion of the AlInGaP system is in Chap. 17, "Light-Emitting Diodes." AlInGaP is used for amber and red LEDs that fall within the 590- to 650-nm wavelength region. It is limited to this wavelength range because the AlInGaP quaternary shifts to an indirect band gap as wavelengths below 590 nm are targeted. This left a void in the blue and green spectral regions for visible HB-LEDs.

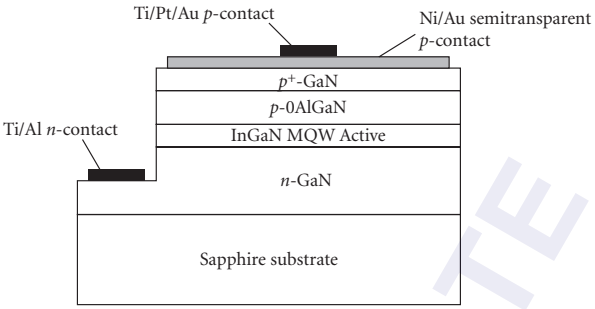

FIGURE 1 Typical structure for a modern InGaN HB-LED showing associated epitaxial layers, including the multiquantum well (MQW) active region.

In the past decade, this void has been quickly filled with MQW LEDs made from the AlInGaN material system. GaN has a wurtzite crystal structure and band gap at room temperature of about 3.2 eV (385 nm). By alloying with Al or In, the band gap can be shifted to shorter or longer wavelengths, respectively. This has led to the realization of InGaN QW active regions in HB-LEDs offering light output in the blue to green spectral regions. Although InN has a direct energy gap of 0.7 eV, phase segregation in InGaN alloys limits the ability to obtain active regions emitting at wavelengths above 530 nm. Despite this, InGaN QW active regions have successfully been used to create blue and green HB-LEDs with complete wavelength tunability across the visible 400- to 530-nm range.

18.3 SUBSTRATES AND EPITAXIAL GROWTH

Current AlInGaN HB-LEDs use one of two substrates: sapphire or silicon carbide (SiC). Despite considerable lattice mismatch between these and GaN (roughly 16 percent for sapphire and 3.5 percent for SiC), low-temperature buffer layer technologies have been developed to allow for nucleation and growth of high-quality AlInGaN HB-LEDs. Low-temperature AlN buffer layers on sapphire substrates are directly formed by MOCVD that result in dislocation entanglement just above the nucleation interface. As depicted in Fig. 2, many of the dislocations interact and annihilate. The subsequent growth of a thick (typically 3 to 4 μm) *n*-GaN buffer layer further reduces dislocation density below 10^9 per cm^2. The use of 6H-SiC substrates offers closer lattice matching and lower defect densities, although this comes with a higher cost that has kept sapphire as a more popular substrate solution. Recent research has aimed to produce native or lattice-matched substrate solutions for GaN growth. Native GaN substrates have been produced, although the diameter of such substrates and cost remain a challenge. A sister wide band gap compound, ZnO, has strikingly similar properties

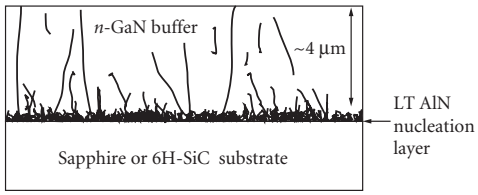

FIGURE 2 Cross-section schematic of the dislocation reduction that occurs due to use of a low temperature (LT) AlN nucleation layer. Dislocations originate from the large lattice mismatch of the nitrides with SiC or sapphire substrates, but can be reduced well below $10^9/cm^2$ when a LT-AlN nucleation layer and thick GaN buffer layer are used.

to GaN and is currently considered a good candidate for a lattice matched substrate for AlInGaN HB-LED growth. ZnO has the same wurtzite crystal structure as GaN, is nearly lattice matched to GaN, and can be easily doped *n*-type to form a conductive substrate. Lattice matched substrates made from ZnO have just become commercially available through hydrothermal growth.

Growth of AlInGaN HB-LEDs is accomplished commercially with MOCVD (a short discussion of MOCVD was provided in Sec. 17.8 in Chap. 17). While high quality growth of AlInGaN epitaxial films has been demonstrated by MBE, typical HB-LED structures require 4- to 5-μm-thick films that are not economically realizable in MBE systems due to the slow growth rate and limited number of substrates per growth. MOCVD reactors are able to accommodate multiple 2″ substrates per growth (as many as 40 in larger systems) with the necessary uniformity and control of film thickness. One of the initial challenges in AlInGaN HB-LED growth was *p*-type doping of GaN. The metal-organic precursor sources of MOCVD introduce a considerable amount of hydrogen into the films that directly compensates *p*-type acceptors. This issue was resolved through post-growth annealing at temperatures above 800°C in which the excess hydrogen is driven out of the epitaxial films. Upon out-diffusion of the hydrogen, the *p*-type acceptors become active and the necessary hole injection into the structures is then possible.

18.4 PROCESSING

Many of the steps covered in Sec. 17.9 of Chap. 17 are used in the fabrication of HB-LED epitaxial wafers. Sapphire substrates are electrically insulating, imposing the need for creating both *n*- and *p*-type contacts on the front of the HB-LED surface as was shown in Fig. 1. As a result, the epitaxial structure must be etched down to the *n*-GaN layer in order to make electrical contact to the *n*-side of the HB-LED structure. AlInGaN is relatively resistant to wet chemical etching and must be dry etched using reactive ion etching (RIE) or inductively coupled plasma (ICP) methods. RIE/ICP is capable of high etch rates that are anisotropic, meaning that they are capable of etching vertically down into the structure with little to no lateral etching. SiC substrates are electrically conductive and thus allow for the *n*-contact to be formed on the back side of the substrate without the need for etching of the front surface.

The typical fabrication process for AlInGaN HB-LEDs utilizes four lithographic steps. These include the mesa etch, SiO_2 passivation, *n*-contact, and *p*-contact layers. A top view and associated cross section of a standard HB-LED device are given in Fig. 3, indicating these layers. Prior to the

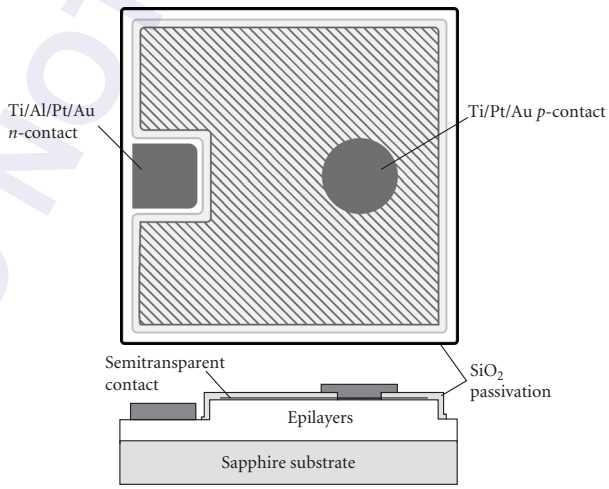

FIGURE 3 Top view and cross-section schematic of a standard nitride HB-LED. A mesa is etched to allow for contact to the *n*-type underlayer. A semitransparent contact on top of the mesa is used to promote uniform hole injection due to poor hole mobility in the *p*-GaN.

first lithographic step a semitransparent top contact is deposited on the surface (*p*-side) of the entire epi wafer. This is necessary in order to achieve uniform current injection across the device due to the higher resistivity of the *p*-GaN in comparison to the *n*-GaN. The most common semitransparent contacts are Ni/Au and indium tin oxide (ITO), with Ni/Au being the most widely used. Once the semitransparent contact is formed the lithographic steps are then carried out. The mesa etch is a dry etch step to access the *n*-GaN layers for the *n*-type contact as required when using sapphire substrates. The SiO_2 passivation step covers the side walls of the mesa and protects its lateral edges. Once the passivation is in place, the last two lithographic steps define the *n*- and *p*-type contacts to the device through a lift-off process. Common metallizations are Ti/Al/Pt/Au for the *n*-contact and Ti/Pt/Au for the *p*-contact to the semitransparent contact underlayer. To separate the individual LEDs on the fabricated wafer, the substrate must first be thinned from its typical 400 μm thickness to on the order of 80 to 100 μm using a multiple step wafer polishing method on automated multiwafer polishers. Once thinned, singulation of the individual die is accomplished either by a scribe and break method or by using laser separation. The sawing method typically employed for other III–V LEDs is not possible due to the substantial hardness of sapphire and SiC that greatly limits their ability to be cut using a dicing saw.

18.5 SOLID-STATE LIGHTING

The current push towards energy conservation has created a considerable interest in the replacement of conventional lighting by solid-state LED fixtures. LEDs offer the potential to considerably reduce power consumption while maintaining the necessary lumen output for lighting. Generating white light from HB-LEDs is typically accomplished by one of two methods as depicted in Fig. 4. The first method, shown in Figs. 4*a* and *b*, utilizes an AlInGaN-LED in conjunction with one or more phosphors. When a UV-LED is used, the UV light emission is absorbed and re-emitted by a mixture of red, green, and blue phosphors. As indicated in Fig. 4*a* the phosphors down-convert the UV light (dashed line) to visible light (solid line), and when the appropriate ratio of phosphors is used, white light is emitted. A more common LED/phosphor combination used for general illumination is the combination of a blue (~465 nm) AlInGaN-LED and a yttrium aluminum garnet (YAG) phosphor such as cerium doped $Y_3Al_5O_{12}$. In this approach (Fig. 4*b*) a portion of the blue LED emission is absorbed by the YAG phosphor and down-converted to the yellow spectral region. When the proper ratio of YAG phosphor is used, the resulting binary complimentary output of the blue LED and yellow YAG phosphor creates white light as perceived by observers. The second method for white light emission is preferred when color tuning is necessary, such as in outdoor displays. As indicated in Fig. 4*c*, by using red, green, and blue LEDs, one can create white light when the appropriate ratio of each is selected. This RGB approach has the added benefit of allowing the user to create any color within the associated color gamut by balancing the ratio of the individual LEDs.

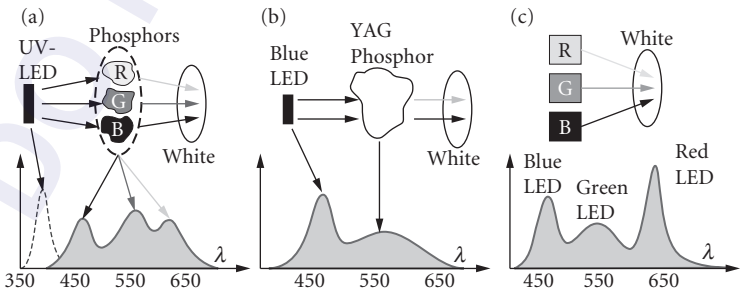

FIGURE 4 Methods for white light generation using HB-LEDs. White light is achieved by using a HB-LED and phosphors (*a* and *b*), or the combination of a red, green, and blue HB-LED (*c*).

This method also allows for active adjustment of the color temperature of white light emission which is not possible using the LED/phosphor approach.

The primary figure of merit for solid-state lighting is the luminous efficacy of the fixture. Luminous efficacy refers to the ratio of lumen output from the source to the power input, and has the units of lumens per Watt (lm/W). Conventional incandescent and fluorescent lights have typical luminous efficacies of 15 lm/W and 70 lm/W, respectively, varying somewhat depending on manufacturer. As of early 2008, currently available LED-based replacements have luminous efficacies as high as 80 lm/W, exceeding compact fluorescents. By comparison, lab demonstrations of white LEDs are commonly breaking 120 lm/W, with the expectation of reaching 150 lm/W in the near future. Despite these accomplishments the added cost of solid-state white lighting has slowed the market acceptance. A common cost comparison is the first cost of a light source, typically measured in terms of the cost per kilolumen (klm). Incandescent and fluorescent light sources fall in the $0.5 to $3.00 per klm, while current light emitting diode sources fall easily in the $20 to $30 per klm range. Considerable progress in efficiency continues to climb and it is expected that as the luminous efficacy and lifetime of solid-state white LEDs continues to rise that the cost per kilolumen will decrease while market acceptance increases.

18.6 PACKAGING

HB-LEDs chips for standard current use (20 to 70 mA) have lateral geometries on the order of $350 \times 350\ \mu m^2$. Such LED chips are commonly packaged similarly to IR-LEDs in a 5-mm T1-3/4 format, as shown in Figs. 21 and 22 in Chap. 17. For AlInGaP HB-LEDs the substrate is conductive and silver filled epoxy is used for attaching the die to the lead frame to form one of the contacts. The other contact is formed using standard ball wire bonding to the top of the LED chip. For AlInGaN HB-LEDs, commonly grown on insulating sapphire substrates, two wire bonds are required to make the electrical connections to the lead frame. Silver-filled epoxy is still used for such LEDs since the sapphire is transparent and emission can be effectively redirected upward from the epoxy surface below the chip. In addition to the 5-mm T1-3/4 package, a considerable number of new surface mount device (SMD) packages have become available to support the introduction of HB-LEDs into the consumer hand-held device market. A schematic of a typical SMD package is provided in Fig. 5. The LED is placed on a metal lead frame that is encased in a plastic outer shell. Once the HB-LED has been die bonded into the package with silver-filled epoxy, it is then wire bonded and encapsulated with transparent epoxy for protection. Such SMD packages are typically several millimeters on a side; however, smaller versions with formats nearly identical to chip resistors are available that have

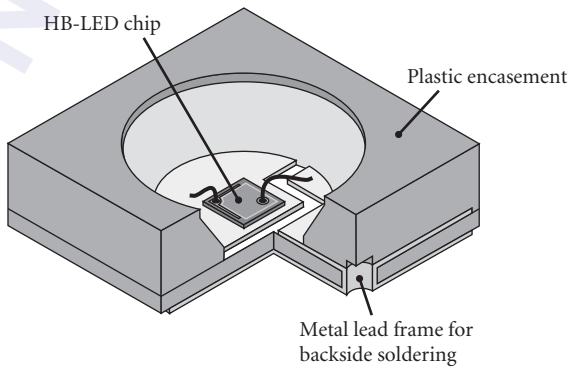

FIGURE 5 Schematic of a standard surface mount device (SMD) package for HB-LEDs.

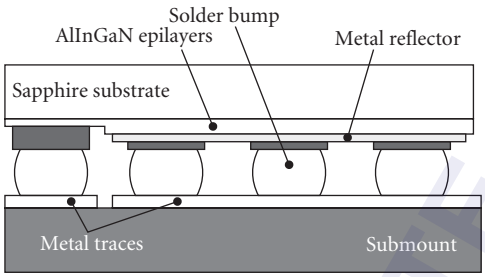

FIGURE 6 Cross-section schematic of the flip chip geometry used for high-power nitride LEDs. Flip chip packaging allows for increased heat dissipation from the LED junction, enabling them to be driven at much higher current densities.

very small form factors providing the low profile necessary for applications such as cell phone key pad backlighting.

In recent years the push for solid-state white lighting has resulted in a transition to larger HB-LED chip sizes and an increase in the operating current densities. The latter brings new constraints to packaging due to the increased need for thermal management in an effort to keep the junction temperature of the HB-LED as low as possible. While the traditional packaging formats have proven very effective for standard drive current use, they are not suitable for high drive current applications using large area HB-LEDs since they do not provide adequate thermal management. This has forced a significant change in not only the design of packaging for high drive current, large area HB-LEDs, but also the devices themselves. Most HB-LEDs use sapphire substrates that provide very poor heat dissipation from the LED junction due to the low thermal conductivity of sapphire. This has been overcome by using a flip chip approach, where the LED chip is flipped over onto a carrier and attached using solder bump methods similar to the silicon IC industry. A rough schematic of a flip chip geometry is shown in Fig. 6. The HB-LED chip is designed to support multiple solder bump attachments to the submount. A highly reflective metal layer is formed on the *p*-side of the device to redirect light emission through the backside of the device. The solder bumps affix the LED die firmly to the submount and create the electrical connections to the metal traces below, allowing for subsequent wire bonding between the submount and the external leads of the package. The solder bumps also serve as a route for efficient heat transfer from the LED junction to the submount enabling the junction temperature of the LED chip to remain low under high drive current conditions. There are a variety of external package geometries that have been developed to support flip chip HB-LEDs with no specific convention between manufacturers. Among the main considerations in the package design has been the encapsulant around the LED and providing a low thermal resistance path to the external housing. Standard clear epoxies that are used in conventional packages typically cannot withstand temperatures much above 100°C. In flip chip high drive packages this can be easily exceeded and would cause thermal damage to conventional epoxies. This has led many companies to develop a variety of new high-index encapsulants, such as silicones, that are able to withstand the higher temperature demands of high drive solid-state lighting. Low thermal resistance packaging has also followed many new routes such as packages with copper tungsten metal bases, metal core board, and high thermal conducting insulating materials (e.g., BeO and AlN).

SEMICONDUCTOR LASERS

Pamela L. Derry, Luis Figueroa, and Chi-Shain Hong

Boeing Defense & Space Group
Seattle, Washington

19.1 GLOSSARY

A	Constant approximating the slope of gain versus current or carrier density
C	Capacitance
c	Speed of light
D	Density of states for a transition
D_c	Density of states for the conduction band
D_v	Density of states for the valence band
d	Active layer thickness
d_{eff}	Effective beam width in the transverse direction
d_G	Guide layer thickness
dg/dN	Differential gain
E	Energy of a transition
E_c	Total energy of an electron in the conduction band
E_g	Bandgap energy
E_n	The nth quantized energy level in a quantum well
E_n^c	The nth quantized energy level in the conduction band
E_n^v	The nth quantized energy level in the valence band
E_v	Total energy of a hole in a valence band
e	Electronic charge
F_c	Quasi-Fermi level in the conduction band
F_v	Quasi-Fermi level in the valence band
f_c	Fermi occupation function for the conduction band
f_d	Damping frequency
f_o	Resonant frequency of an LRC circuit
f_p	Peak frequency

f_r	Resonance frequency
f_v	Fermi occupation function for the valence band
g	Model gain per unit length
g_{th}	Threshold modal gain per unit length
H	Heavyside function
h	Refers to heavy holes
$\hbar$	Plank's constant divided by 2π
I	Current
I_{off}	DC bias current before a modulation pulse
I_{on}	Bias current during a modulation pulse
I_{th}	Threshold current
J	Current density
J_o	Transparency current density
J_{th}	Threshold current density
K	Constant dependent on the distribution of spectral output function
$\mathbf{k}$	Wavevector
k	Boltzmann constant
L	Inductance
L	Laser cavity length
L_c	Coherence length
L_z	Quantum well thickness
l	Refers to light holes
$\|M\|^2$	Matrix element for a transition
m	Effective mass of a particle
m_c	Conduction band mass
m_r	Effective mass of a transition
m_v	Valence band mass
N	Carrier density
N_o	Transparency carrier density
n_{eff}	Effective index of refraction
n_r	Index of refraction
n_{sp}	Spontaneous emission factor
P	Photon density
P_{off}	Photon density before a modulation pulse
P_{on}	Photon density during a modulation pulse
R	Resistance
R_F	Front facet reflectivity
R_R	Rear facet reflectivity
T	Temperature
w	Laser stripe width
α	Absorption coefficient
α	Linewidth enhancement factor
α_i	Internal loss per unit length
β	Spontaneous emission factor
Γ	Optical confinement factor

$\Delta f_{1/2}$	Frequency spectral linewidth
$\Delta\lambda_L$	Longitudinal mode spacing
$\Delta\lambda_{1/2}$	Half-width of the spectral emission in terms of wavelength
λ	Wavelength
λ_o	Wavelength of the stimulated emission peak
τ_d	Turn-on time delay
τ_p	Photon lifetime
τ_s	Carrier lifetime

19.2 INTRODUCTION

This chapter is devoted to the performance characteristics of semiconductor lasers. In addition, some discussion is provided on fabrication and applications. In the first section we describe some of the applications being considered for semiconductor lasers. The following several sections describe the basic physics, fabrication, and operation of a variety of semiconductor laser types, including quantum well and strained layer lasers. Then we describe the operation of high-power laser diodes, including single element and arrays. A number of tables are presented which summarize the characteristics of a variety of lasers. Next we discuss the high-speed operation and provide the latest results, after which we summarize the important characteristics dealing with the spectral properties of semiconductor lasers. Finally, we discuss the properties of surface emitting lasers and summarize the latest results in this rapidly evolving field.

More than 260 references are provided for the interested reader who requires more information. In this *Handbook,* Chap. 17 (LEDs) also contains related information. For further in-depth reviews of semiconductor lasers we refer the reader to the several excellent books which have been written on the subject.[1–5]

19.3 APPLICATIONS FOR SEMICONDUCTOR LASERS

The best-known application of diode lasers is in optical communication systems. However, there are many other potential applications. In particular, semiconductor lasers are being considered for high-speed optical recording,[6] high-speed printing,[7] single- and multimode database distribution systems,[8] long-distance transmission,[9] submarine cable transmission,[10] free-space communications,[11] local area networks,[12] Doppler optical radar,[13] optical signal processing,[14] high-speed optical microwave sources,[15] pump sources for other solid-state lasers,[16] fiber amplifiers,[17] and medical applications.[18]

For very high-speed optical recording systems (>100 MB/s), laser diodes operating at relatively short wavelengths (λ <0.75 μm) are required. In the past few years, much progress has been made in developing short-wavelength semiconductor lasers, although the output powers are not yet as high as those of more standard semiconductor lasers.

One of the major applications for lasers with higher power and wide temperature of operation is in local area networks. Such networks will be widely used in high-speed computer networks, avionic systems, satellite networks, and high-definition TV. These systems have a large number of couplers, switches, and other lossy interfaces that determine the total system loss. In order to maximize the number of terminals, a higher-power laser diode will be required.

Wide temperature operation and high reliability are required for aerospace applications in flight control and avionics. One such application involves the use of fiber optics to directly link the flight control computer to the flight control surfaces, and is referred to as fly-by-light (FBL). A second application involves the use of a fiber-optic data network for distributing sensor and video information.

Finally, with the advent of efficient high-power laser diodes, it has become practical to replace flash lamps for the pumping of solid-state lasers such as Nd:YAG. Such an approach has the advantages

of compactness and high efficiency. In addition, the use of strained quantum well lasers operating at 0.98 μm has opened significant applications for high-gain fiber amplifiers for communications operating in the 1.55-μm wavelength region.

19.4 BASIC OPERATION

Lasing in a semiconductor laser, as in all lasers, is made possible by the existence of a gain mechanism plus a resonant cavity. In a semiconductor laser the gain mechanism is provided by light generation from the recombination of holes and electrons (see Fig. 1). The wavelength of the light is determined by the energy bandgap of the lasing material. The recombining holes and electrons are injected, respectively, from the *p* and *n* sides of a *p-n* junction. The recombining carriers can be generated by optical pumping or, more commonly, by electrical pumping, i.e., forward-biasing the *p-n* junction. In order for the light generation to be efficient enough to result in lasing, the active region of a semiconductor laser, where the carrier recombination occurs, must be a direct bandgap semiconductor. The surrounding carrier injection layers, which are called *cladding layers,* can be indirect bandgap semiconductors. For a discussion of semiconductor band levels see any solid-state physics textbook such as that by Kittel.[19] For a more detailed discussion of carrier recombination see Chap. 17 in this *Handbook.*

For a practical laser, the cladding layers have a wider bandgap and a lower index of refraction than the active region. This type of semiconductor laser is called a *double heterostructure* (DH) laser, since both cladding layers are made of a different material than the active region (see Fig. 2). The first semiconductor lasers were homojunction lasers,[21–24] which did not operate at room temperature; it is much easier to achieve lasing in semiconductors at low temperatures. Today, however, all semiconductor lasers contain heterojunctions. The narrower bandgap of the active region confines carrier recombination to a narrow optical gain region. The sandwich of the larger refractive index active region surrounded by cladding layers forms a waveguide, which concentrates the optical modes generated by lasing in the active region. For efficient carrier recombination the active region must be fairly thin, typically on the order of 1000 Å, so a significant fraction of the optical mode spreads into the cladding layers. In order to completely confine the optical mode in the semiconductor structure, the cladding layers must be fairly thick, usually about 1 μm.

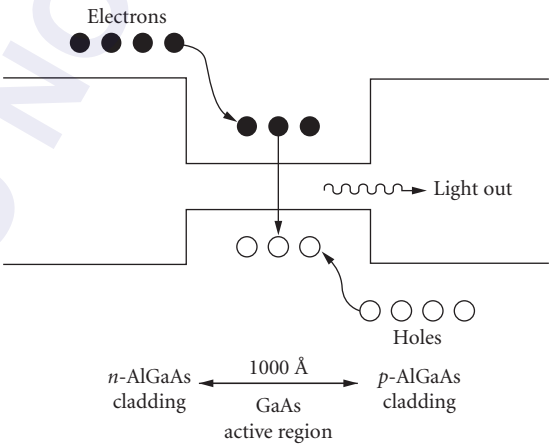

FIGURE 1 Schematic diagram of the recombination of electrons and holes in a semiconductor laser.

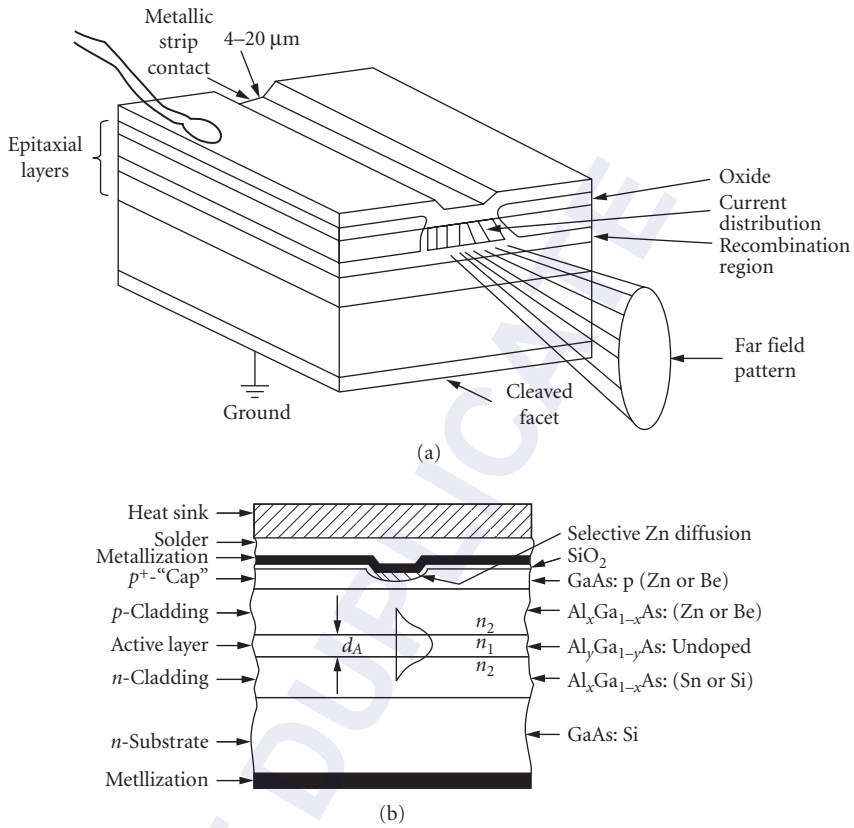

FIGURE 2 (*a*) Schematic diagram of a simple double heterostructure laser and (*b*) cross-sectional view showing the various epitaxial layers. (*After Ref. 20.*)

The resonant cavity of a simple semiconductor laser is formed by cleaving the ends of the structure. Lasers are fabricated with their lasing cavity oriented perpendicular to a natural cleavage plane. For typical semiconductor materials this results in mirror reflectivities of about 30 percent. If necessary, the reflectivities of the end facets can be modified by applying dielectric coatings to them.[25] For applications where it is not possible to cleave the laser facets, it is also possible to etch them,[26–28] although this is much more difficult and usually does not work as well. Laser cavity lengths can be anywhere from about 50 to 2000 μm, although commercially available lasers are typically 200 to 1000 μm long.

Unpumped semiconductor material absorbs light of energy greater than or equal to its bandgap. When the semiconductor material is pumped optically or electrically, it reaches a point at which it stops being absorbing. This point is called *transparency.* If it is pumped beyond this point, it will have optical gain, which is the opposite of absorption. A semiconductor laser is subject to both internal and external losses. For lasing to begin, i.e., to reach threshold, the gain must be equal to these optical losses. The threshold gain per unit length is given by

$$g_{\text{th}} = \alpha_i + \frac{1}{2L}\ln\left(\frac{1}{R_F R_R}\right) \tag{1}$$

where α_i is the internal loss per unit length, L is the laser cavity length, and R_F and R_R are the front and rear facet reflectivities. (For semiconductor lasers, gain is normally quoted as gain per unit

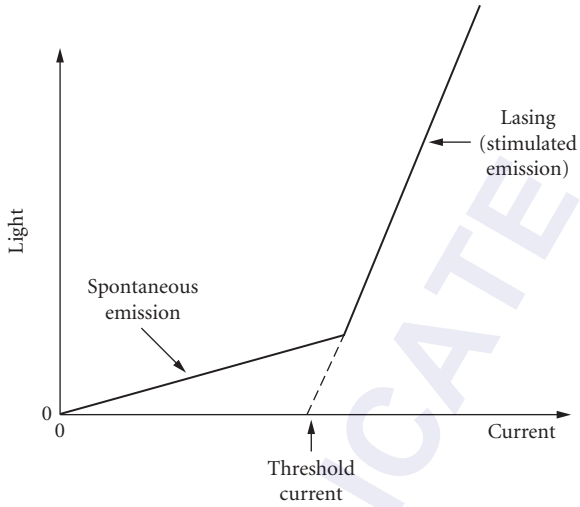

FIGURE 3 An example of the light-versus-current relationship of a semiconductor laser illustrating the definition of threshold current.

length in cm^{-1}. This turns out to be very convenient, but unfortunately is confusing for people in other fields, who are used to gain being unitless.)

The internal loss is a material parameter determined by the quality of the semiconductor layers. Mechanisms such as free-carrier absorption and scattering contribute to α_i.[1] The second term in Eq. (1) is the end loss. A long laser cavity will have reduced end loss, since the laser light reaches the cavity ends less frequently. Similarly, high facet reflectivities also decrease the end loss, since less light leaves the laser through them.

For biases below threshold, a semiconductor laser emits a small amount of incoherent light spontaneously (see Fig. 3). This is the same type of light emitted by an LED (see Chap. 17). Above threshold, stimulated emission results in lasing. The relationship between lasing emission and the bias current of a healthy semiconductor laser is linear. To find the threshold current of a laser this line is extrapolated to the point at which the stimulated emission is zero (see Fig. 3).

For further discussion of optical gain in semiconductors, see under "Quantum Well Lasers" later in this chapter. For more detail, see one of the books that has been written about semiconductor lasers.[1–5]

19.5 FABRICATION AND CONFIGURATIONS

In order to fabricate a heterostructure laser, thin semiconductor layers of varying composition must be grown on a semiconductor substrate (normally GaAs or InP). There are three primary epitaxial methods for growing these layers: liquid phase epitaxy (LPE), molecular beam epitaxy (MBE), and metalorganic chemical vapor deposition (MOCVD), which is also called organometallic vapor phase deposition (OMVPE).

Most of the laser diode structures which have been developed were first grown by LPE.[29] For a description of LPE see Chap. 17. Most commerically available lasers are grown by LPE; however, it is not well suited for growing thin structures such as quantum well lasers, because of lack of control and uniformity, especially over large substrates.[30] MBE and MOCVD are better suited for growths of thin, uniform structures.

MOCVD[31,32] is basically a specialized form of chemical vapor deposition. In MOCVD, gases reacting over the surface of a substrate form epitaxial layers; some of the gases are metalorganics. MOCVD is well suited for production environments, since epitaxial layers can be grown simultaneously on multiple large-area substrates and quickly, compared to MBE. It is expected that more commercial laser diodes will be grown by MOCVD in the future.

In the simplest terms, MBE[30,33–35] is a form of vacuum evaporation. In MBE growth occurs through the thermal reaction of thermal beams of atoms and molecules with the substrate, which is held at an appropriate temperature in an ultrahigh vacuum. MBE is different from simple vacuum evaporation for several reasons: the growth is single crystalline; the growth is much more controlled; and the vacuum system, evaporation materials, and substrate are cleaner.

With MOCVD the sources are gases, while with MBE they are solids. There are advantages and disadvantages to both types of sources. With gaseous sources the operator must work with arsine and/or phosphine, which are extremely hazardous gases. Solid-source phosphorus, however, is very flammable. Also, with MBE balancing the ratios of arsenic and phosphorus is extremely difficult; therefore, MOCVD is the preferred method for growth of GaInAsP and InP. MBE is a slower growth process (on the order of 1 to 2 μm/h) than MOCVD. MBE therefore has the control necessary to grow very thin structures (10 Å), but MOCVD is more efficient for production. MBE has a cleaner background environment, which tends to make it better suited for growths at which background impurities must be kept at a minimum. Newer growth techniques,[36,37] which combine some of the advantages of both MBE and MOCVD, are gas source MBE, metalorganic MBE (MOMBE), and chemical beam epitaxy (CBE). In these growth techniques the background environment is that of MBE, but some or all of the sources are gases, which makes them more practical for growth of phosphorus-based materials.

Double heterostructure (DH) semiconductor lasers can be fabricated from a variety of lattice-matched semiconductor materials. The two material systems most frequently used are GaAs/$Al_xGa_{1-x}As$ and $In_{1-x}Ga_xAS_yP_{1-y}$/InP. All of these semiconductors are III–V alloys. The GaAs/$Al_xGa_{1-x}As$ material system has the advantage that all compositions of $Al_xGa_{1-x}As$ are closely lattice-matched to GaAs, which is the substrate. For GaAs-based lasers, the active region is usually GaAs or low-Al-concentration $Al_xGa_{1-x}As$ ($x < 0.15$), which results in lasing wavelengths of 0.78 to 0.87 μm. $Al_xGa_{1-x}As$ quantum well lasers with wavelengths as low as 0.68 μm have been fabricated,[38] but the performance is reduced.

In the $In_{1-x}Ga_xAs_yP_{1-y}$/InP material system, the active region is $In_{1-x}Ga_xAs_yF_{1-y}$ and the cladding layers and substrate are InP. Not all compositions of $In_{1-x}Ga_xAs_yP_{1-y}$ are lattice-matched to InP; x and y must be chosen appropriately to achieve both lattice match and the desired lasing wavelength.[4] The lasing wavelength range of InP-based lasers, 1.1 to 1.65 μm, includes the wavelengths at which optical fibers have the lowest loss (1.55 μm) and material dispersion (1.3 μm). This match with fiber characteristics makes $In_{1-x}Ga_xAs_yP_{1-y}$/InP lasers the preferred laser for long-distance communication applications. InP-based lasers can also include lattice-matched $In_{1-x-y}Al_xGa_yAs$ layers,[39–42] but the performance is reduced.

There is a great deal of interest in developing true visible lasers for optical data storage applications. $(Al_xGa_{1-x})_{05}In_{05}P$ lasers[43–46] lattice-matched to GaAs have proven superior to very short wavelength GaAs/$Al_xGa_{1-x}As$ lasers. Higher Al concentration layers are cladding layers and a low Al concentration layer or $Ga_{05}In_{05}P$ is the active region. In this material, system lasers with a lasing wavelength as low as 0.63 μm which operate continuously at room temperature have been fabricated.[46]

In order to fabricate a blue semiconductor laser, other material systems will be required. Recently, lasing at 0.49 μm at a temperature of 77 K was demonstrated in a ZnSe- (II–VI semiconductor) based laser.[47]

Very long-wavelength (>2 μm) semiconductor lasers are of interest for optical communication and molecular spectroscopy. The most promising results so far have been achieved with GaInAsSb/AlGaAsSb lattice-matched to a GaSb substrate. These lasers have been demonstrated to operate continuously at 30°C with a wavelength of 2.2 μm.[48]

Lead salt lasers ($Pb_{1-x}Eu_xSe_yTe_{1-y}$, $Pb_{1-x}Sn_xSe$, $PbS_{1-x}Se$, $PbS_{1-x}Sn_xTe$, $Pb_{1-x}Sr_xS$) can be fabricated for operation at even longer wavelengths,[4,49–52] but they have not been demonstrated at room temperature. Progress has been made, however, increasing the operating temperature; currently $Pb_{1-x}Eu_xSe_yTe_{1-y}$/PbTe lasers operating continuously at 203 K with a lasing wavelength of 4.2 μm have been

demonstrated.[53] Other very long-wavelength lasers are possible; recently, HgCdTe lasers with pulsed operation at 90 K and a lasing wavelength of 3.4 μm have been fabricated.[54]

Laser Stripe Structures

We have discussed the optical and electrical confinement provided by a double heterostructure parallel to the direction of epitaxial growth; practical laser structures also require a confinement structure in the direction parallel to the substrate.

The simplest semiconductor laser stripe structure is called an *oxide stripe laser* (see Fig. 4*a*). The metallic contact on the *n*-doped side of a semiconductor laser is normally applied with no definition for current confinement; current confinement is introduced on the *p* side of the device. For a wide-stripe laser, a dielectric coating (usually SiO_2 or Si_3N_4) is evaporated on the *p* side of the laser. Contact openings in the dielectric are made through photolithography combined with etching of the dielectric. The *p* metallic contact is then applied across the whole device, but makes electrical contact only at the dielectric openings. A contact stripe works very well for wide stripes, but in narrow stripes current spreading is a very significant drawback, because there is no mechanism to prevent current spreading after the current is injected. Also, since the active region extends outside of the stripe, there is no mechanism to prevent optical leakage in a contact-stripe laser. Lasers like this, which provide electrical confinement, but no optical confinement, are called *gain-guided lasers.*

Another type of gain-guide laser is an ion bombardment stripe (see Fig. 4*b*). The material outside the stripe is made highly resistive by ion bombardment or implantation, which produces lattice defects.[55] Implantation causes optical damage,[56] so implantation should not be heavy enough to reach the active region.

A more complicated stripe structure with electrical and optical confinement is required for an efficient narrow-stripe laser. A number of structures which accomplish the necessary confinement have been developed. These structures are called *index-guided lasers,* since optical confinement is achieved through a change in refractive index.

The buried heterostructure laser (BH) was first developed by Tsukada.[57] To form a BH stripe, a planar laser structure is first grown. Stripe mesas of the laser structure are formed by photolithography combined with etching. For a GaAs-based BH laser, AlGaAs is then regrown around the lasing stripe. Figure 4*c* is a schematic diagram of a buried heterostructure. Since the active region is completely surrounded by AlGaAs, a BH has tight optical confinement. If the regrown layers are doped to produce a reverse-biased junction or are semi-insulating, a BH laser can also provide good current confinement. There are many variations on the BH structure. In some cases the active region is grown in the second growth step (see Fig. 4*d*). The tight optical confinement of BH lasers allows practical fabrication of very narrow stripes, on the order of 1 to 2 μm.

There are many other stripe structures that provide weaker optical confinement than a buried heterostructure. One of the simplest and most widely used of these is the ridge waveguide laser (RWG) (Fig. 4*e*). After epitaxial growth, most of the *p*-cladding layer is etched away, leaving a mesa where the lasing stripe will be. Only this mesa is contacted, which provides electrical confinement. The change in surrounding refractive index produces an effective change in refractive index in the active region beyond the mesa and provides optical confinement. Other stripe structures are described later in this chapter under "High-Power Semiconductor Lasers."

Another type of laser stripe is one in which confinement is provided by the *p-n* junction. The best-known laser of this type is the transverse junction stripe[58–60] (see Fig. 4*f*). In order to fabricate a TJS laser, both cladding layers are grown as *n*-AlGaAs. Zn diffusion is then used to create a *p-n* junction and contacts are applied on either side of the junction. In this laser the current flows parallel to the substrate rather than perpendicular to it. In a TJS laser the active region is limited to the small region of GaAs in which the Zn diffusion front ends.

The examples of laser stripe structures described here are GaAs/AlGaAs lasers. Long-wavelength laser structures (InP-based) are very similar,[4] but the active region is InGaAsP and the cladding layers are InP. With an *n*-InP substrate the substrate can be used as the *n*-type cladding, which allows greater flexibility in designing structures such as that illustrated in Fig. 4*d.* For a more detailed discussion of GaAs-based laser stripe structures see Casey and Panish[2] or Thompson.[3]

19.6 QUANTUM WELL LASERS

The active region in a conventional DH semiconductor laser is wide enough (~1000 Å) that it acts as bulk material and no quantum effects are apparent. In such a laser the conduction band and valence band are continuous (Fig. 5*a*). In bulk material the density of states, $D(E)$, for a transition energy E per unit volume per unit energy is[26]

$$D(E)=\sum_{i=l,h}\frac{m_r^i}{\pi^2\hbar^3}\sqrt{2m_r^i(E-E_g)} \qquad E>E_g \tag{2}$$

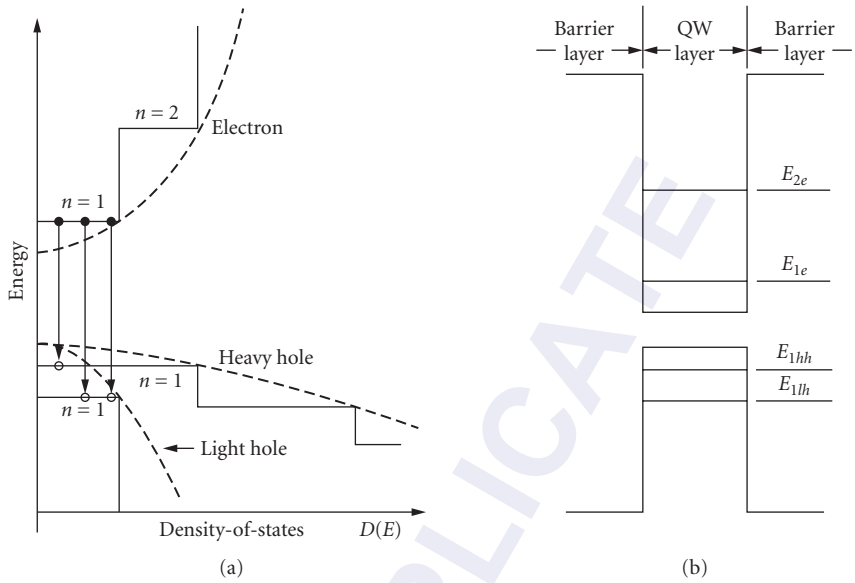

FIGURE 5 Schematic diagrams of (*a*) the density of states for a quantum well (solid line) and for a bulk DH (dotted line) and (*b*) quantized energy levels in a quantum well for $n = 1$ and 2 for the conduction band and for the light and heavy hole bands. (*After Ref. 63.*)

where E_g is the bandgap energy, $\hbar$ is Plank's constant divided by 2π, *l* and *h* refer to light and heavy holes, and m_r is the effective mass of the transition which is defined as

$$\frac{1}{m_r} = \frac{1}{m_c} + \frac{1}{m_v} \tag{3}$$

where m_c is the conduction band mass and m_v is the valence band mass. (The split-off hole band and the indirect conduction bands are neglected here and have a negligible effect on most semiconductor laser calculations.)

If the active region of a semiconductor laser is very thin (on the order of the DeBroglie wavelength of an electron) quantum effects become important. When the active region is this narrow (less than ~200 Å) the structure is called a *quantum well* (QW). (For a review of QWs see Dingle,[61] Holonyak et al.,[62] Okamoto,[63] or the book edited by Zory.[64]) Since the quantum effects in a QW are occurring in only one dimension they can be described by the elementary quantum mechanical problem of a particle in a one-dimensional quantum box.[65] In such a well, solution of Schrödinger's equation shows that a series of discrete energy levels (Fig. 5*b*) *are* formed instead of the continuous energy bands of the bulk material. With the approximation that the well is infinitely deep, the allowed energy levels are given by

$$E_n = \frac{(n\pi\hbar)^2}{2mL_z^2} \tag{4}$$

where $n = 1, 2, 3, \ldots,$ *m* is the effective mass of the particle in the well, and L_z is the quantum well thickness. Setting the energy at the top of the valence band equal to zero, the allowed energies for an electron in the conduction band of a semiconductor QW become $E = E_g + E_n^c$, where E_n^c is E_n with *m*

equal to m_c. The allowed energies for a hole in the valence band are then $E = -E_n^v$, where E_n^v is E_n with m equal to m_v. The allowed transition energies E are limited to

$$E = E_g + E_n^c + E_n^v + \frac{\hbar^2 \mathbf{k}^2}{2m_r} \tag{5}$$

where $\mathbf{k}$ is the wavevector, rigorous $\mathbf{k}$-selection is assumed, and transitions are limited to those with $\Delta n = 0$.

This quantization of energy levels will, of course, change the density of states. For a QW the density of states is given by

$$D(E) = \sum_{i=l,h} \sum_{n-1}^{\infty} \frac{m_r^i}{L_z \pi \hbar^2} H(E - E_g - E_n^c - E_{n,i}^v) \tag{6}$$

where H is the heavyside function. The difference in the density of states directly affects the modal optical gain generated by the injection of carriers. The modal gain is proportional to the stimulated emission rate:[1,66,67]

$$g(E, N) = \alpha \frac{\Gamma D(E) |M|^2 (f_c(E, N) - f_v(E, N))}{E} \tag{7}$$

where I is the optical confinement factor, $|M|^2$ is the matrix element for the transition, N is the carrier density of either electrons or holes (the active region is undoped so they have equal densities), and $f_c(E, N)$ and $f_v(E, N)$ are the Fermi occupation factors for the conduction and valence bands. (For a detailed review of gain in semiconductor lasers see Ref. 67.)

The optical confinement factor Γ is defined as the ratio of the light intensity of the lasing mode within the active region to the total intensity over all space. Since a QW is very thin, Γ_{QW} will be much smaller than Γ_{DH}. Γ_{DH} is typically around 0.5 whereas for a single QW, Γ_{QW} is around 0.03.

The Fermi occupation functions describe the probability that the carriers necessary for stimulated emission have been excited to the states required. They are given by[1,19]

$$f_c(E_c, N) = \frac{1}{1 + \exp((E_g + E_c - F_c)/kT)} \tag{8}$$

and

$$f_v(E_v, N) = \frac{1}{1 + \exp(-(E_v - F_v)/kT)} \tag{9}$$

where k is the Boltzmann constant, T is temperature, E_c is the energy level of the electron in the conduction band relative to the bottom of the band (including both the quantized energy level and kinetic energy), E_v is the absolute value of the energy level of the hole in a valence band, and F_c and F_v are the quasi-Fermi levels in the conduction and valence bands. Note that E_c and E_v are dependent on E, so f_c and f_v are functions of E. f_c and f_v are also functions of N through F_c and F_v. F_c and F_v are obtained by evaluating the expressions for the electron and hole densities:

$$N = \int D_c(E_c) f_c(E_c) dE_c \tag{10}$$

and

$$N = \int D_v(E_v) f_v(E_v) dE_v \tag{11}$$

where $D_c(E_c)$ and $D_v(E_v)$ are the densities of states for the conduction and valence bands and follow the same form as $D(E)$ for a transition.

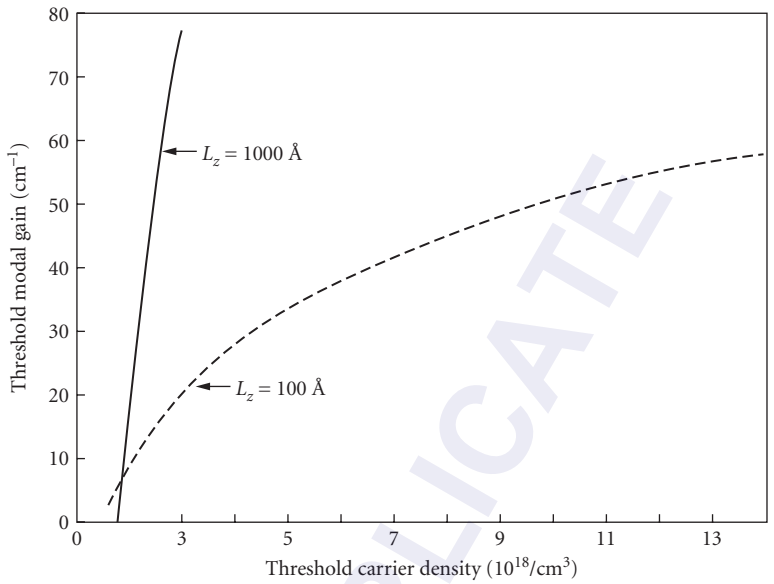

FIGURE 6 Threshold modal gain as a function of threshold carrier density for a conventional (Al, Ga)As double heterostructure with an active region thickness of 1000 Å and for a 100-Å single quantum well. (*From Ref. 68.*)

In Fig. 6, the results of a detailed calculation[68] based on Eq. (7) for the threshold modal gain as a function of threshold carrier density are plotted for a 100-Å single QW. The corresponding curve for a DH laser with an active region thickness of 1000 Å is also shown. The gain curves for the QWs are very nonlinear because of saturation of the first quantized state as the carrier density increases. The transparency carrier density N_0 is the carrier density at which the gain is zero. From Fig. 6 it is clear that the transparency carrier densities for QW and DH lasers are very similar and are on the order of 2×10^{18} cm^{-3}.

The advantage of a QW over a DH laser is not immediately apparent. Consider, however, the transparency current density J_o. At transparency[28]

$$J_o = \frac{N_0 L_z e}{\tau_s} \tag{12}$$

where L_z is the active layer thickness, e is the charge of an electron, and τ_s is the carrier lifetime near transparency. τ_s is approximately 2 to 4 ns for either a QW or a DH laser. Since N_0 is about the same for either structure, any difference in J_o will be directly proportional to L_z. But L_z is approximately 10 times smaller for a QW; therefore, J_o will be approximately 10 times lower for a QW than for a conventional DH laser. (A lower J_o will result in a lower threshold current density since the threshold current density is equal to J_o plus a term proportional to the threshold gain.) Note that this result is not determined by the quantization of energy levels; it occurs because fewer carriers are needed to reach the same carrier density in a QW as in a DH laser. In other words, this result is achieved because the QW is thin!

In this discussion we are considering current density instead of current. The threshold current density (current divided by the length and width of the stripe) is a more meaningful measure of the relative quality of the lasing material than is current. Current depends very strongly on the geometry and stripe fabrication of the device. In order to eliminate geometry-induced variations, current density is normally measured on broad-area (50 to 150 μm wide) oxide stripe lasers (see earlier under

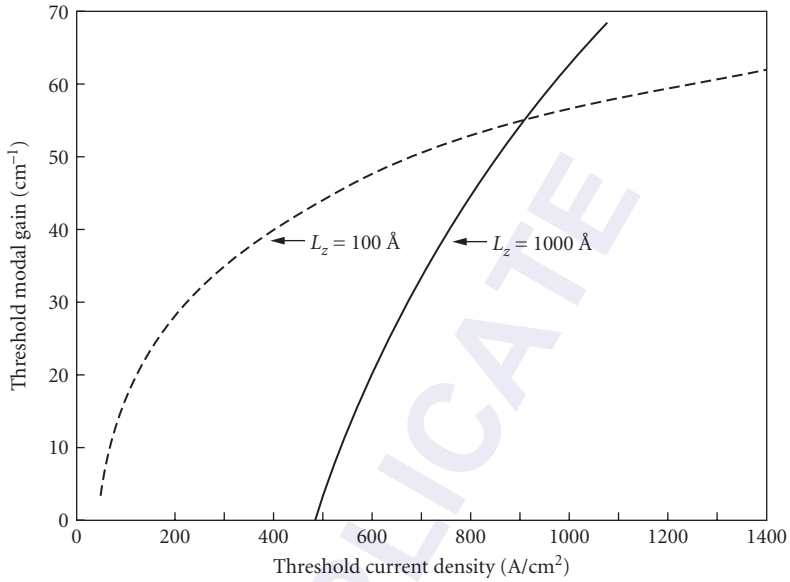

FIGURE 7 Threshold modal gain as a function of threshold current density for a conventional (Al, Ga)As double heterostructure with an active region thickness of 1000 Å and for a 100-Å single quantum well. (*From Ref. 68.*)

"Fabrication and Configurations"). With a narrow stripe the current spreads beyond the intended stripe width, so it is difficult to accurately measure the current density.

Figure 7 shows the results of a detailed calculation[68] of the threshold modal gain versus the threshold current density for a DH laser with an active region thickness of 1000 Å and for a 100-Å single QW. The potential for lower threshold current densities for QW lasers is clear for threshold gains less than that where the curve for the DH laser intercepts those of the QWs. With low losses, the threshold current of a QW laser will be substantially lower than that of a DH laser, since the threshold gain will be below the interception point.

To get an appreciation for how the threshold current density of a single QW will compare to that of a DH laser, consider that near transparency, the modal gain is approximately linearly dependent on the current density:

$$g(J) = A(J - J_o) \tag{13}$$

where A is a constant which should have a similar value for either a QW or a DH laser (this can be seen visually on Fig. 7). Taking Eq. (13) at threshold we can equate it to Eq. (1) and solve for J_{th} (the threshold current density):

$$J_{\text{th}} = J_o + \frac{\alpha_i}{A} + \frac{1}{2AL}\text{In}\left(\frac{1}{R_F R_R}\right) \tag{14}$$

α_i is related primarily to losses occurring through the interaction of the optical mode with the active region. In a QW, the optical confinement is lower, which means that the optical mode interacts less with the active region and α_i tends to be smaller. Let's substitute in the numbers in order to get an idea for the difference between a QW and a DH laser. Reasonable values are[69] $A_{\text{QW}} \sim 0.7\text{A}^{-1}$ cm, $A_{\text{DH}} \sim 0.4$ A^{-1} cm, $J_o^{\text{QW}} \sim 50$ A/cm^2, $J_o^{\text{DH}} \sim 500$ A/cm^2, $\alpha_i^{\text{QW}} \sim 2$ cm^{-1}, $\alpha_i^{\text{DH}} \sim 15$ cm^{-1}, L ~400 μm, and for uncoated facets $R_F = R_R = 0.32$. Substituting in we get $J_{\text{th}}^{\text{QW}} \sim 95$ A/cm^2 and $J_{\text{th}}^{\text{DH}} \sim 610$ A/cm^2.

It is clear that changes in the losses will have a more noticeable effect on threshold current for a QW than for a DH laser since losses are responsible for a more significant portion of the threshold current of a QW laser. The gain curve of a QW laser saturates due to the filling of the first quantized energy level, so operating with low losses is even more important for a QW than is illustrated by the above calculation. When the gain saturates, the simple approximation of Eq. (13) is invalid. Operating with low-end losses is also important for a QW, since they are a large fraction of the total losses. This explains why threshold current density results for QW lasers are typcially quoted for long laser cavity lengths (greater than 400 μm), while DH lasers are normally cleaved to lengths on the order of 250 μm. High-quality broad-area single QW lasers (without strain) have threshold current densities lower than 200 A/cm^2 (threshold current densities as low as 93 A/cm^2 have been achieved[69–71]), while the very best DH lasers have threshold current densities around 600 A/cm^2.[72] The end loss can also be reduced by the use of high-reflectivity coatings.[25] The combination of a single QW active region with a narrow stripe and high-reflectivity coatings has allowed the realization of submilliampere threshold current semiconductor lasers[68,69,73] and high-temperature operation.[74,75,76]

A disadvantage of QW lasers compared to DH lasers is the loss of optical confinement. One of the advantages of a DH laser is that the active region acts as a waveguide, but in a QW the active region is too thin to make a reasonable waveguide. Guiding layers are needed between the QW and the (Al, Ga)As cladding layers. As the bandgap diagram of Fig. 8 illustrates, a graded layer of intermediate aluminum content can be inserted between the QW and each cladding layer. The advantage of this structure, which is called a *graded-index separate-confinement heterostructure* (GRIN SCH),[77,78] is separate optical and electrical confinement. The carriers are confined in the QW, but the optical mode is confined in the surrounding layers. The grading can be either parabolic (as illustrated in Fig. 8) or linear. Experimentally it has been found that the optimum AlAs mole fraction x for layers around a GaAs QW is approximately 0.2.[79] Typically, each additional layer is on the order of 2000 Å thick. In order to confine the optical model, the cladding layers need a low index of refraction compared to that of an $x = 0.2$ layer. In a simple DH laser, the cladding layers typically have x between 0.3 and 0.4, but for good confinement in an $x = 0.2$ layer, more aluminum should be incorporated into the cladding layers; x should be between 0.5 and 0.7.

In the discussion so far we have considered only single QWs. Structures in which several quantum wells are separated by thin AlGaAs barriers are called *multiquantum wells* (MQWs) and also have useful properties. For a given carrier density, an MQW with n QWs of equal thickness, L_z has gain which is approximately n times the gain for a single QW of the same thickness L_z, but the current

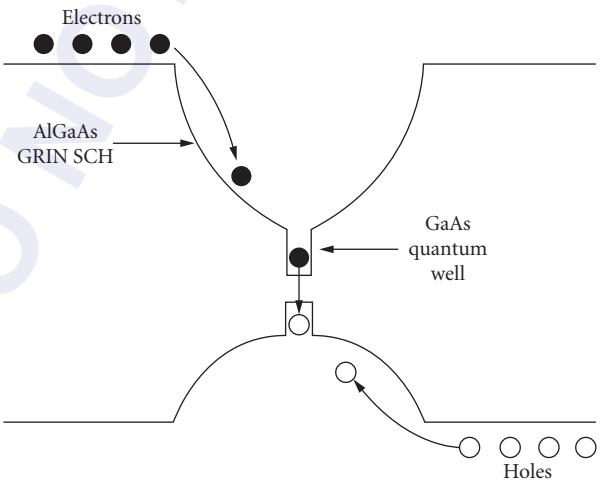

FIGURE 8 Schematic energy-band diagram for a GRIN SCH single QW.

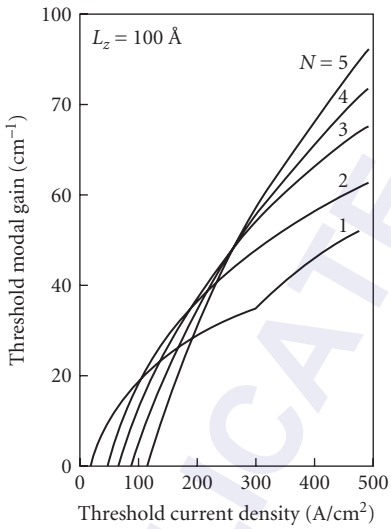

FIGURE 9 Threshold modal gain as a function of threshold current density for (Al, Ga) As single QW and MQWs with 2, 3, 4, and 5 QWs. Each QW has a thickness of 100 Å. (*From Ref. 80.*)

density is also approximately increased by a factor of n.[80] The transparency current density will be larger for the MQW than for the single QW since the total active region thickness is larger. Figure 9 shows that, as a function of current density, the gain in the single QW will start out higher than that in the MQW because of the lower transparency current, but the gain in the MQW increases more quickly so the MQW gain curve crosses that of the single QW at some point.[81]

Which QW structure has a lower threshold current will depend on how large the losses are for a particular device structure and on where the gain curves cross. The best structure for low threshold current in a GaAs-based laser is normally a single QW, but for some applications involving very large losses and requiring high gain an MQW is superior. For applications in which high output power is more important than low current an MQW is appropriate. An MQW is also preferred for high-modulation bandwidth (see "Spectral Properties" later in this chapter).

An advantage of a QW structure over a bulk DH laser is that the lasing wavelength, which is determined by the bulk bandgap plus the first quantized energy levels, can be changed by changing the quantum well thickness [see Eq. (4)]. A bulk GaAs laser has a lasing wavelength of about 0.87 μm, while a GaAs QW laser of normal thickness (60 to 120 Å) has a lasing wavelength of 0.83 to 0.86 μm. Further bandgap engineering can be introduced with a strained QW.[67,81,82]

Strained Quantum Well Lasers

Normally, if a semiconductor layer of significantly different lattice constant is grown in an epitaxial structure, it will maintain its own lattice constant and generate misfit dislocations. If this layer is very thin, below a certain critical thickness,[81,83–85] it will be distorted to match the lattice constant (perpendicular to the substrate) of the surrounding layers and will not generate misfit locations. A layer with thickness above the critical thickness is called "relaxed," one below is called "strained."

Straining a semiconductor layer changes the valence-band structure. Figure 10*a* shows the band structure of an unstrained III–V semiconductor, while Fig. l0*b* and *c* show the band structure under biaxial tension and compression, respectively.[81,82] For the unstrained semiconductor, the light and

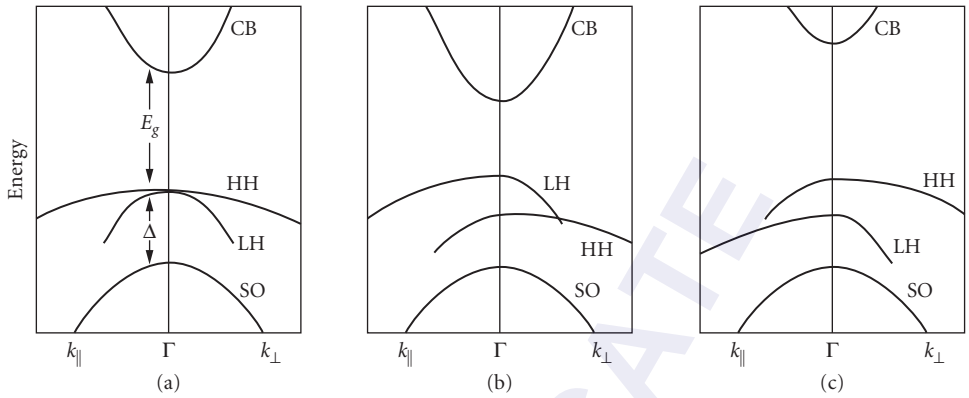

FIGURE 10 Schematic diagrams of the band structure of a III–V semiconductor: (*a*) unstrained; (*b*) under tensile strain; and (*c*) compressively strained. (*After Ref. 81.*)

heavy hole bands are degenerate at $\mathbf{k}=0(\Gamma)$. Strain lifts this degeneracy and changes the effective masses of the light and heavy holes. In the direction parallel to the substrate the heavy hole band becomes light and the light hole band becomes heavy. Under biaxial tension (Fig. l0*b*) the bandgap decreases and the "heavy" hole band lies below the "light" hole band. Under biaxial compression the bandgap increases and the "heavy" hole band lies above the "light" hole band.

Figure 10 is a simplification of the true band structure.[81,82] The bands are not really exactly parabolic, especially the hole bands, and strain increases the nonparabolicity of the hole bands. The details of the band structure can be derived using $\mathbf{k}\cdot\mathbf{p}$ theory.[86–90]

For a GaAs-based QW, strain can be introduced by adding In to the QW. Since InAs has a larger lattice constant than GaAs, this is a compressively strained QW. In the direction of quantum confinement the highest quantized hole level is the first heavy hole level. This hole level will, therefore, have the largest influence on the density of states and on the optical gain. The effective mass of holes in this level confined in the QW is that parallel to the substrate and is reduced by strain. The reduction of the hole mass within the QW results in a reduced density of hole states [see Eq. (6)].

The reduction in density of hole states is a significant improvement. In order for a semiconductor laser to have optical gain (and lase), $f_c(E, N) - f_v(E, N)$ must be greater than zero [see Eq. (7)]. In an unstrained semiconductor the electrons have a much lighter mass than the heavy holes; the holes therefore have a higher density of states than the electrons. F_c and $f_c(E, N)$ change much more quickly with the injection of carriers than F_v and $f_v(E, N)$. Since approximately equal numbers of holes and electrons are injected into the undoped active layer, reducing the mass of the holes by introducing compressive strain reduces the carrier density required to reach transparency and therefore reduces the threshold current of a semiconductor laser.[91]

This theoretical prediction is well supported by experimental results. Strained InGaAs single-QW lasers with record-low threshold current densities of 45 to 65 A/cm^2 have been demonstrated.[92–95] These very high-quality strained QW lasers typically have lasing wavelengths from 0.98 to 1.02 μm, QW widths of 60 to 70 Å, and In concentrations of 20 to 25 percent. InGaAs QWs with wavelengths as long as 1.1 μm have been successfully fabricated,[96,97] but staying below the critical thickness of the InGaAs layers becomes a problem since the wavelength is increased by increasing the In concentration. (With higher In concentration the amount of strain is increased and the critical thickness is reduced.)

Strained InGaAs QWs have another advantage over GaAs QWs. Strained QW lasers are more reliable than GaAs lasers, i.e., they have longer lifetimes. Even at high temperatures (70 to 100°C), they are very reliable.[75,76] The reasons for this are not well understood, but it has been suggested that the strain inhibits the growth of defects in the active region.[98–100] Improving the reliability of GaAs-based lasers is of great practical significance since GaAs lasers are generally less reliable than InP-based lasers.[4,101,102]

Up to this point our discussion of QW lasers has been limited to GaAs-based QW lasers. QW lasers can also be fabricated in other material systems. GaInP/AlGaInP visible lasers have been improved significantly with the use of a single strained QW active region.[103–105] These are also compressively strained QWs formed by adding excess In to the active region. This is a much less developed material system than GaAs, so recent results such as 215 A/cm^2 for a single strained $Ga_{0.43}In_{0.57}P$ QW[103] are very impressive.

Long-Wavelength (1.3 and 1.55 μm) Quantum Well Lasers

Long-wavelength (InGaAsP/InP) QWs generally do not perform as well as GaAs-based QWs; however, with the advent of strained QW lasers significant progress has been made. Narrow bandgap lasers are believed to be significantly affected by nonradiative recombination processes such as Auger recombination[4,106–108] and intervalence band absorption.[109] In Auger recombination (illustrated in Fig. 11) the energy from the recombination of an electron and a hole is transferred to another carrier (either an electron or a hole). This newly created carrier relaxes by emitting a phonon; therefore, no photons are created. In intervalence band absorption (IVBA) a photon is emitted, but is reabsorbed to excite a hole from the split-off band to the heavy hole band. These processes reduce the performance of long-wavelength QW lasers enough to make an MQW a lower threshold device than a single QW. As illustrated by Fig. 9, this means that the threshold gain is above the point where the gain versus current density curve of a single QW crosses that of an MQW. Good threshold current density results for lasers operating at 1.5 μm are 750 A/cm^2 for a single QW and 450 A/cm^2 for an MQW.[110]

Long-wavelength QW lasers can be improved by use of a strained QW. For these narrow bandgap lasers strain has the additional benefits of suppressing Auger recombination[111,112] and intervalence band absorption.[111] Several groups have demonstrated excellent results with compressively strained InGaAsP/InP QW lasers.[113–115] Compressively strained single QW lasers operating at 1.5 μm have been demonstrated with threshold current densities as low as 160 A/cm^2.[115]

Surprisingly, tensile strained InGaAsP/InP QW lasers also show improved characteristics.[115–117] Tensile strained QW lasers operating at 1.5 μm have been fabricated with threshold current densities as low as 197 A/cm^2.[16] These results had not been expected (although some benefit could be expected through suppression of Auger recombination), but have since been explained in terms of TM-mode lasing[118,119] (normally, semiconductor lasers lase in the TE mode) and suppression of spontaneous emission.[118]

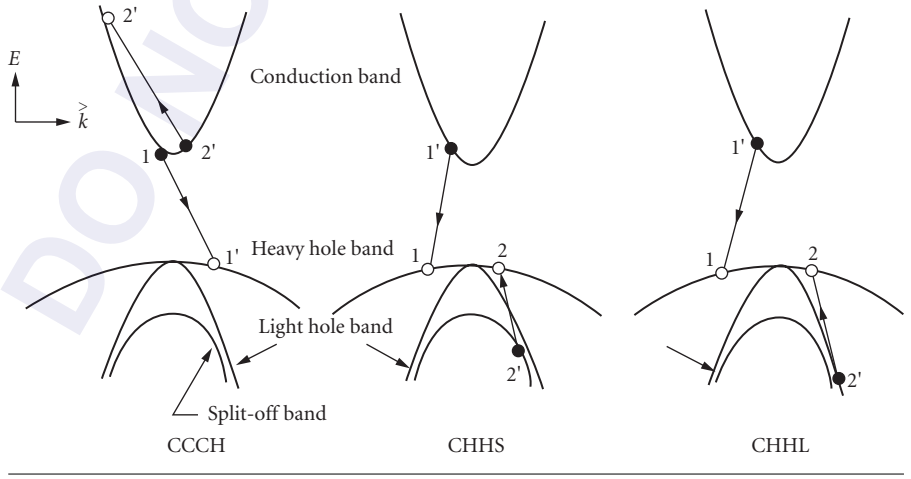

FIGURE 11 Schematic diagrams of band-to-band Auger recombination processes. (*After Ref. 4.*)

Long-wavelength semiconductor lasers are more sensitive to increases in operating temperature than GaAs-based semiconductor lasers. This temperature sensitivity has been attributed to the strong temperature dependence of Auger recombination[106–108] and intervalence-band absorption.[109] The use of a strained QW should therefore improve the high-temperature operation of these lasers. This is in fact the case the best results are reported for tensile strained QW lasers with continuous operation at 140°C.[115,117]

In summary, the use of QW active regions has significantly improved the performance of semiconductor lasers. In this section we have emphasized the dramatic reductions in threshold current density. Improvements have also been realized in quantum efficiency,[119] high-temperature operation,[74–76,115,117] modulation speed (discussed later in this chapter), and spectral linewidth (discussed later). We have limited our discussion to quantum wells. It is also possible to provide quantum confinement in two directions, which is called a *quantum wire,* or three directions, which is called a *quantum dot* or *quantum box.* It is much more difficult to fabricate a quantum wire than a QW, but quantum wire lasers have been successfully demonstrated.[121] For a review of these novel structures we refer the reader to Ref. 122.

19.7 HIGH-POWER SEMICONDUCTOR LASERS

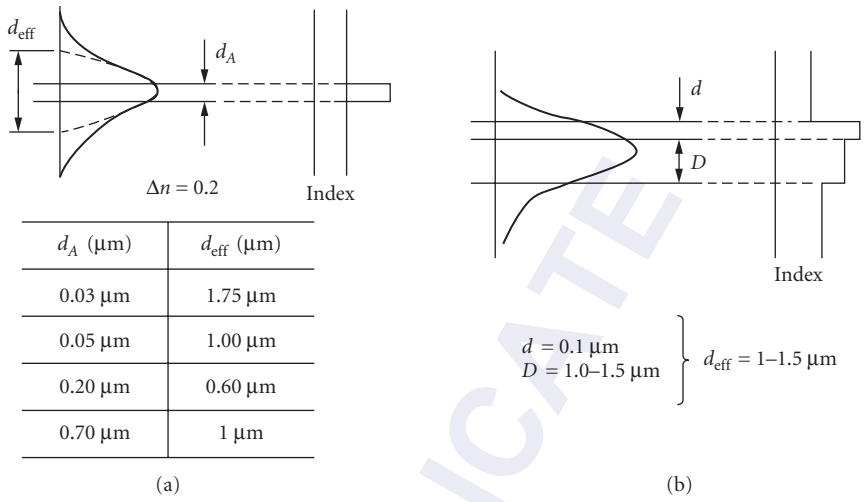
There are several useful methods for stabilizing the lateral modes of an injection laser.[123–129] In this section, we will discuss techniques for the achievement of high-power operation in a single spatial and spectral mode. There are several physical mechanisms that limit the output power of the injection laser: spatial hole-burning effects lead to multispatial mode operation and are intimately related to multispectral mode operation, temperature increases in the active layer will eventually cause the output power to reach a maximum, and catastrophic facet damage will limit the ultimate power of the laser diode (GaAlAs/GaAs). Thus, the high-power laser designer must optimize these three physical mechanisms to achieve maximum power. In this section, we discuss the design criteria for optimizing the laser power.

High-Power Mode-Stabilized Lasers with Reduced Facet Intensity

One of the most significant concerns for achieving high-power operation and high reliability is to reduce the facet intensity while, at the same time, providing a method for stabilizing the laser lateral mode. Over the years, researchers have developed four approaches for performing this task: (1) increasing the lasing spot size, both perpendicular to and in the plane of the junction, and at the same time introducing a mechanism for providing lateral mode-dependent absorption loss to discriminate against higher-order modes; (2) modifying the facet reflectivities by providing a combination of high-reflectivity and low-reflectivity dielectric coatings; (3) eliminating or reducing the facet absorption by using structures with nonabsorbing mirrors (NAM); (4) using laser arrays and unstable resonator configurations to increase the mode volume. Techniques 1 and 2 are the commonly used techniques and will be further discussed in this section. Techniques 3 and 4 (laser arrays) will be discussed shortly.

Given the proper heat sinking, in order to increase the output power of a semiconductor GaAlAs/GaAs laser, we must increase the size of the beam and thus reduce the power density at the facets for a given power level. The first step in increasing the spot size involves the transverse direction (perpendicular to the junction). There are two approaches for accomplishing this, with the constraint of keeping threshold current low: (1) thinning the active layer in a conventional double-heterostructure (DH) laser (Fig. 12*a*) below 1000 Å and (2) creating a large optical cavity structure (Fig. 12*b*).

Thinning the active layer from a conventional value of 0.2 to 0.03 μm causes the transverse-mode spot size to triple for a constant index of refraction step, Δn_r.[130] The catastrophic power level is proportional to the effective beam width in the transverse direction, d_{eff}, the asymmetric large optical



d_A (μm)	d_{eff} (μm)
0.03 μm	1.75 μm
0.05 μm	1.00 μm
0.20 μm	0.60 μm
0.70 μm	1 μm

(a) (b)

cavity (A-LOC) concept[3,131] involves the epitaxial growth of an additional cladding layer referred to as the *guide layer* (d_G), with index of refraction intermediate between the *n*-AlGaAs cladding layer and the active layer. By using a relatively small index of refraction step ($\Delta n_r = 0.1$) versus 0.20 to 0.30 for DH lasers, it is possible to force the optical mode to propagate with most of its energy in the guide layer. The effective beam width for the A-LOC can be approximately expressed as

$$d_{\text{eff}} = d_A + d_G \tag{15}$$

where d_A is the active layer thickness. Mode spot sizes in the transverse direction of approximately 1.5 μm can be achieved.

Important Commercial High-Power Diode Lasers

In the last few years, several important high-power laser geometries have either become commercially available or have demonstrated impressive laboratory results. Table 1 summarizes the characteristics of the more important structures. It is evident that the structures that emit the highest cw (continuous wave) power (>100 mW), QW ridge waveguide (QWR), twin-ridge structure (TRS), buried TRS (BTRS), current-confined constricted double-heterostructure large optical cavity (CC-CDH-LOC), and buried V-groove-substrate inner stripe (BVSIS)) have several common features: (1) large spot size (CDH-LOC, TRS, BTRS, QW ridge), (2) low threshold current and high quantum efficiency, and (3) a combination of low- and high-reflectivity coatings. All the lasers with the highest powers, except for the CDH-LOC, use the thin active laser design. A recent trend has been the use of quantum well-active layers.

Figure 13 contains schematic diagrams for five of the more common DH laser designs for high cw power operation, and Fig. 14 shows plots of output power versus current for various important geometries listed in Table 1.

The CC-CDH-LOC device with improved current confinement[136] (Fig. 13*a*) is fabricated by one-step liquid-phase epitaxy (LPE) above a mesa separating two dovetail channels. Current confinement is provided by a deep zinc diffusion and a narrow oxide stripe geometry. The final cross-sectional

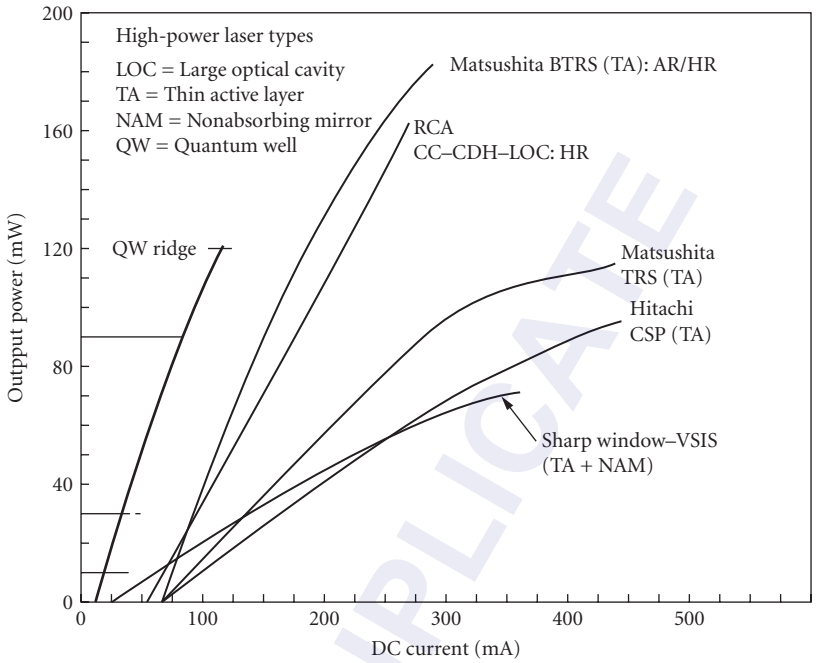

FIGURE 14 Plots showing output power versus cw current for the major high-power laser diodes. The maximum power in a single spatial mode is in the range of 100 to 150 mW and total cw power can approach 200 mW.

geometry of the device is very dependent on the exact substrate orientation and LPE growth conditions.[145] By properly choosing these conditions, it is possible to grow a convex-lens-shaped active layer ($Al_{0.07}Ga_{0.93}As$) on top of a concave-lens-shaped guide layer ($Al_{0.21}Ga_{0.79}As$). The combination of the two leads to a structure with antiwaveguiding properties and a large spot size. Discrimination against higher-order modes is provided by a leaky-mode waveguide. The cw threshold current is in the range of 50 to 70 mA. Single-mode operation has been obtained to 60 mW under 50 percent duty cycle, and the maximum cw power from the device is 165 mW. The power conversion efficiency at this power level is 35 percent considering only the front facet.

The channeled substrate planar (CSP) laser[127] (Fig. 13*b*) is fabricated by one-step LPE above a substrate channel. The current stripe is purposely made larger than the channel to ensure uniform current flow across the channel. However, this leads to some waste of current and thus a lower differential efficiency than other similar high-power laser structures (BVSIS, BTRS). Lateral mode control is very effectively obtained by the large difference in the absorption coefficient α between the center and edges of the channel and by changes in the index of refraction that result from changes in the geometry. By proper control of the active and *n*-cladding layer thicknesses, it is possible to obtain $\Delta\alpha \cong 1000\ \text{cm}^{-1}$ (see Ref. 146) and $\Delta n_r \cong 10^{-2}$. Threshold currents are in the range of 55 to 70 mA. The transverse far field is relatively narrow due to the very thin active layer. Researchers from RCA have obtained power levels in excess of 150 mW (cw) with a CSP-type laser.[137] A detailed study of the CSP laser has been presented by Lee et al., in a recent publication.[147]

Matsushita[133] has also developed a CSP-like structure called the twin-ridge structure (TRS) that uses a 400-Å active layer thickness (Fig. 13*c*). The structure has demonstrated fundamental-mode cw power to 200 mW and single-longitudinal-mode cw power to 100 mW. The maximum available power for the TRS laser is 115 mW, and threshold currents are in the range of 80 to 120 mA. It appears that even though their geometry is similar to that of the CSP, lasers with ultrathin and

planar-active layers have been fabricated. It should be further pointed out that one of the keys to achieving ultrahigh power from CSP-like structures is the achievement of ultrathin (<1000 Å) active layers that are highly uniform in thickness. Small nonuniformities in the active layer thickness lead to a larger Δn_r difference, and thus a smaller lateral spot size, which will lead to lower power levels and reduced lateral mode stability.

Metalorganic chemical vapor deposition (MOCVD, discussed earlier) has been used to fabricate lasers with higher layer uniformity, which leads to a reduced spectral width and more uniform threshold characteristics. Several MOCVD laser structures with demonstrated high-power capability are schematically shown in Fig. 13, and their characteristics are summarized in Table 1. Figure 13*d* shows the twin-channel substrate mesa (TCSM) laser.[140] The fabrication consists of growing a DH laser structure over a chemically etched twin-channel structure using MOCVD. Optical guiding is provided by the curvature of the active layer. The TCSM laser has achieved cw powers of 40 mW in a single spatial mode and 65 mW in a single longitudinal mode. The inverted channel substrate planar (ICSP) laser[135] is schematically shown in Fig. 13*e*. This structure is one MOCVD version of the very successful CSP structure (Fig. 13*b*).[141] The ICSP laser has achieved powers in excess of 150 mW (50 percent duty cycle) in a single spatial mode and a 100-mW (cw) catastrophic power level.

More recently, quantum well lasers using the separate carrier and optical confinement (see previous section, "Quantum Well Lasers") and ridge waveguide geometries have been used for producing power levels in excess of 150 mW (cw) in a single spatial mode.[143,144] The QW ridge resembles a standard RWG (Fig. 4*e*), but with a QW active region. Such laser structures have low threshold current density and low internal absorption losses, thus permitting higher-power operation.

Future Directions for High-Power Lasers

Nonabsorbing Mirror Technology The catastrophic facet damage is the ultimate limit to the power from a semiconductor laser. In order to prevent catastrophic damage, one has to create a region of higher-energy bandgap and low surface recombination at the laser facets. Thus, the concept of a laser with a nonabsorbing mirror (NAM) was developed. The first NAM structure was demonstrated by Yonezu et al.[148] by selectively diffusing zinc along the length of the stripe, except near the facets. This created a bandgap difference between the facet and bulk regions and permitted a three- to fourfold increase in the cw facet damage threshold and a four- to fivefold increase in pulse power operation.[149] More recent structures have involved several steps of liquid-phase epitaxy.[150,151]

The incorporation of the NAM structure is strongly device dependent. For example, in the diffused device structures, such as deep-diffused stripe (DDS)[148] and transverse junction stripe (TJS) lasers, NAM structures have been formed by selective diffusion of zinc in the cavity direction.[149] The *n*-type region will have a wider bandgap than the diffused region, and thus there will be little absorption near the facets. However, most index-guided structures require an additional growth step for forming the NAM region.[150,151] The NAM structures in the past have suffered from several problems: (1) Due to their complex fabrication, they tend to have low yields. Furthermore, cw operation has been difficult to obtain. (2) Cleaving must be carefully controlled for NAM structures having no lateral confinement, in order to avoid excessive radiation losses in the NAM region. The NAM length is a function of the spot size. (3) The effect of the NAM structure on lateral mode control has not been documented, but could lead to excessive scattering and a rough far-field pattern.

It is now becoming more clear that the use of a NAM structure will be required for the reliable operation of high-power GaAlAs/GaAs laser diodes. Experimental results[152] appear to indicate that laser structures without a NAM region show a decrease in the catastrophic power level as the device degrades. However, most of the approaches currently being implemented require elaborate processing steps. A potentially more fundamental approach would involve the deposition of a coating that would reduce the surface recombination velocity and thus enhance the catastrophic intensity level.[153,154] Such coatings have been recently used by researchers from Sharp and the University of Florida to increase the uncoated facet catastrophic power level by a factor of 2.[155,156]

Recently, the use of NAM technology has been appearing in commercial products. The crank transverse junction stripe (TJS) laser (a TJS laser with NAM) can operate reliably at an output

power of 15 mW (cw), while the TJS laser without the NAM can operate only at 3 mW (cw).[147] The Ortel Corporation has developed a buried heterostructure (BH) laser with significantly improved output power characteristics compared to conventional BH lasers.[142] The NAM BH laser is rated at 30 mW (cw)[142] compared to 3 to 10 mW for the conventional BH/LOC device.

Last, the use of alloy disordering, whereby the bandgap of a quantum well laser can be increased by diffusion of various types of impurities (for example, Zn and Si),[157] can lead to a very effective technique for the fabrication of a NAM structure. Such structures have produced an enhancement of the maximum pulsed power by a factor of 3 to 4.

High-Power 1.3/1.48/1.55-μm Lasers Previous sections have discussed high cw power operation from (GaAl)As/GaAs laser devices. In the past several years there have been reports of the increasing power levels achieved with GaInAsP/InP lasers operating at $\lambda = 1.3$ μm. The physical mechanisms limiting high-power operation in this material system are quite different than those for GaAlAs/GaAs lasers. The surface recombination at the laser facets is significantly lower than in GaAlAs/GaAs, and thus catastrophic damage has not been observed. Maximum output power is limited by either heating or carrier leakage effects. With the advent of structures having low threshold current density and high quantum efficiency, it was just a matter of time before high-power results would become available. Furthermore, since facet damage is not a problem, the only real need for facet coatings is for improving the output power from one facet and sealing the device for improved reliability.

In Fig. 15, we schematically show the two most common long-wavelength laser structures that have demonstrated high cw power operation. In Fig. 15*a*, the double-channel planar buried heterostructure (DC-PBH) is systematically shown.[158,159] The structure requires a two-step LPE growth process. The first step is the growth of the first and top cladding layers in addition to the active layer. This is followed by the etching of the structure, which is followed by a regrowth to form the blocking and contact layers. LPE growth of this material system is such that if the mesa region is narrow enough, no growth occurs on top of it during the deposition of the blocking layer, and this occurs for mesa widths of less than ~5 μm. Low threshold current is achieved due to the narrow mesa geometry and the good carrier and current confinement.

The DC-PBH has proved to be a laser structure with excellent output characteristics and high reliability. NEC has been able to obtain thresholds as low as 10 mA with 70 percent quantum efficiency. Degradation rates of the order of 10^{-6}/h for an output power of 5 mW at a temperature of 70°C have also been obtained. More recently, NEC has obtained 140-mW power in a single spatial mode.[158] Lasers at 50 mW and 25°C have been placed on lifetest and show relatively low degradation rates after several hundred hours. Degradation rates at 20 and 30 mW (50°C) are 1.3×10^{-5}/h and $2.22 \times KT^{-5}$/h, respectively. TRW has also worked with DC-PBH/PBC-(planar buried cresent) type laser diodes and has obtained 100 mW(cw).[159] A summary of the various high-power $\lambda = 1.3$-μm laser diode structures and characteristics is given in Table 2.

The other structure that has demonstrated high cw power is the buried crescent laser first investigated by Mitsubishi (Fig. 15*b*).[160] The structure is grown using a two-step LPE process and a *p* substrate. The final structure resembles a channel laser with an active layer that tapers to zero near the edges of the channel. The tapering provides good carrier and optical confinement. Researchers from Oki with a structure similar to the Mitsubishi structure have demonstrated maximum power levels of 200 and 140 mW in a single spatial mode.[162] Lifetests[163] on these lasers demonstrated a mean time to failure of $\sim 7 \times 10^5$/h (at 20°C) at 75 percent of the maximum cw output power (maximum = 25 to 85 mW). These results appear to indicate that 1.3-μm lasers are reliable for high-power applications.

A more recent development has been the use of multiquantum well (MQW) high-power lasers in the 1.5 to 1.55-μm wavelength band. The use of an MQW ridge waveguide structure has produced power levels of ~170 mW (cw).[164] The MQW structure consists of five wells of InGaAs, 60 Å thick, separated by four GaInAsP barriers of 100-Å thickness. The two thicker, outermost barriers of GaInAsP provide a separate confinement heterostructure (SCH) waveguide. In addition, buried heterostructure (BH) lasers[165] with power levels in excess of 200 mW have been achieved by incorporating strain into MQW structures. A review article by Henshall describes the state of the art in more detail.[166]

High-Power Strained Quantum Well Lasers Over the last several years, there has been extensive research in the area of strained layer quantum well high-power lasers. As with GaAs QW high-power lasers, the geometry is typically a QW ridge. Table 3 summarizes some of the latest single-spatial-mode high-power results.

Thermal Properties An important parameter in the operation of high-power laser diodes is the optimization of thermal properties of the device. In particular, optimizing the laser geometry for achieving high-power operation is an important design criterion. Arvind et al.[167] used a simple one-dimensional thermal model for estimating the maximum output power as a function of laser geometry (cavity length, active layer thickness substrate type, etc.). The results obtained for GaInAsP/InP narrow stripe PH lasers were as follows:

- Maximum output power is achieved for an optimum active layer thickness in the 0.15-μm region. This result applies only to nonquantum well lasers.
- Significantly higher output powers (25 to 60 percent) are obtained for lasers fabricated on *p* substrates compared to those on *n* substrates. The result is based on the lower electrical resistance of the top epitaxial layers in the *p* substrate compared to *n* substrate.
- Significantly higher output powers (~60 percent) are obtained for lasers mounted on diamond rather than silicon heat sinks as a result of the higher thermal conductivity of diamond compared to silicon, 22 versus 1.3 W/(°C-cm).
- Significantly higher output powers (~100 percent) are obtained for lasers having a length of 700 μm compared to the conventional 300 μm. The higher power results from the reduced threshold current density and thermal resistance for the longer laser devices.

A plot of the calculation and experimental data from Oki[162] is given in Fig. 16. Note that there are no adjustable parameters in the calculation.

An important conclusion from the thermal modeling is that longer cavity semiconductor lasers (700 to 1000 μm) will be able to operate at higher heat sink temperatures when the power level is nominal (~5 mW) compared to shorter cavity devices (~100 to 300 μm). In addition, the reliability of the longer cavity devices is also expected to be better. More recent calculations and experimental results using strained layer lasers have verified this.[95]

Semiconductor Laser Arrays

One of the most common methods used for increasing the power from a semiconductor laser is to increase the width of the emitting region. However, as the width is increased, the occurrence of multilateral modes, filaments, and lateral-mode instabilities becomes more significant. A far-field pattern is produced that is not diffraction-limited and has reduced brightness. The most practical method to overcome this problem is to use a monolithic array of phase-locked semiconductor lasers. Such lasers have been used to generate powers in excess of 10 W (cw)[170] and over 200 W[171] from a single laser bar.

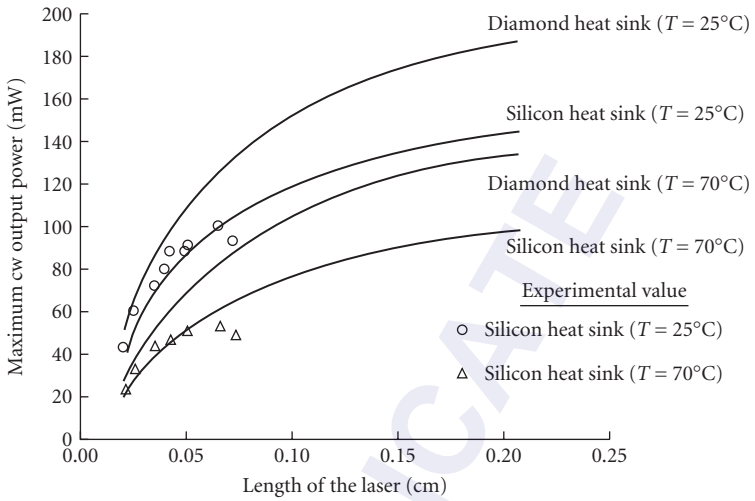

FIGURE 16 Calculation of maximum output power per facet as a function of device length for *n*-*p*-substrate-type lasers and different heat sinks.[167] Note the increased power level achieved for longer lasers and *p*-type substrates.

It was not until 1978 that Scifres and coworkers[172] first reported on the phase-locked operation of a monolithic array consisting of five closely coupled proton-bombarded lasers. The original coupling scheme involved branched waveguides, but this was quickly abandoned in favor of evanescent field coupling by placing the individual elements of the array in close proximity (Fig. 17*a*). More recently, arrays of index-guided lasers[173] have been fabricated; one example is shown in Fig. 17*b*.

Recent emphasis has been on achieving higher cw power and controlling the output far-field distribution. Some of the more significant events in the development of practical semiconductor laser arrays are summarized in Table 4.

The subject of array-mode stability has become of great interest. In a series of significant papers, Butler et al.[190] and Kapon et al.[191] recognized that to a first approximation, an array can be modeled as a system of n weakly coupled waveguides. The results indicate that the general solution for the field amplitudes will consist of a superposition of these array modes. The analytic results permitted, for the first time, a simple explanation for the observed far-field patterns and provided a means for designing device structures that would operate in the fundamental array mode (i.e., all elements in phase). This particular mode will provide the greatest brightness.

Many techniques have been used for improving array-mode selection[179,188,192,197] and thus achieving a well-controlled spatial mode. Two of the more successful earlier techniques involve (1) incorporation of optical gain in the interelement regions (gain coupling of the laser array[179–184,193]) and (2) use of interferometric techniques that involves *Y*-coupled junctions.[186,188,192]

The gain-coupled arrays achieve mode selectivity by introducing optical gain in the interelement regions and thus increasing the gain of the fundamental array mode since this mode has a significant portion of its energy in the interelement regions. The first demonstration of this approach was the twin-channel laser (TCL) developed by researchers from TRW;[180,181] since then, there have been other demonstrations.[182,184,193]

The theoretical foundations of the *Y*-coupled junction were first described in a paper by Chen and Wang.[192] Mode-selectivity is accomplished because the in-phase mode adds coherently at each *Y* junction, while the out-of-phase mode has destructive interference, since the single waveguides after the *Y* junction can support only the fundamental mode. Similar interferometric and mode-selective techniques have been used in the development of optical modulators.[198]

Finally, the most recent mode control mechanism for laser arrays involves the resonant phase-locking of leaky-mode elements.[189] With a properly optimized geometry, the fundamental array mode has significant mode discrimination analogous to the high discrimination found in single-element leaky-mode devices. Recent results indicate power levels in excess of 360 mW (cw) in the fundamental array mode, and the beam broadens to ~2 times diffraction limited for output powers of ~500 mW (cw).

At the present time, it is not clear which technique will be most useful for achieving stable, fundamental array mode operation. The gain-coupling concept works well for two or three elements.[199] However, array-mode selection described by the difference in gain between the first and second array modes rapidly decreases as the number of array elements increases beyond two or three.[199] The *Y* junction and leaky-mode approaches do not appear to have the same limitations. The resonant leaky-mode arrays appear to have the most promising performance at high-power levels; however, the structures are complex and thus yield and reliability need to be more fully addressed.

Two-Dimensional, High-Power Laser Arrays

There has been a significant amount of research activity in the past few years in the area of very high-power diode lasers.[200–205] The activity has been driven by the significant reductions in threshold current density of GaAlAs/GaAs lasers that can be achieved with metalorganic chemical vapor deposition (MOCVD), utilizing a quantum well design. Threshold current densities as low as 200 to 300 A/cm^2 with external efficiencies exceeding 80 percent have been achieved using GRIN-SCH quantum well lasers.[200,201] CW powers of ~6 to 9 W have been achieved from single-laser bars. Such power levels correspond to a maximum of 11 W/cm from a single-laser bar. Table 5 lists some of the more recent results on very high-power diode laser arrays.

In order to increase the output power from laser array structures, researchers have investigated the use of a two-dimensional laser array. One particular configuration, referred to as the "rack-stack approach," is schematically shown in Fig. 18. In essence, the approach involves stacking a linear array of edge emitters into a two-dimensional array. The two-dimensional arrays are fabricated[203] by (1) cleaving linear arrays of laser diodes from a processed wafer, (2) mounting the bars on heat sinks, and (3) stacking the heat sinks into a two-dimensional array.

As shown in Table 5, the main players in this business are McDonnell-Douglas and Spectra Diode Labs. The largest stacked[204] two-dimensional array has been manufactured by McDonnell-Douglas and has an active area with five laser bars 8 mm in length. The array was operated with 150-μs pulses to the limit of the driver[204] at pulse repetition rates of 20 to 666 Hz. Approximately 2.5 kW/cm^2 was obtained at 20 Hz (average power ~300 W) and 0.9 kW/cm^2 at 666 Hz (average power ~92 W). Higher output powers will be obtained as a result of achieving the ultimate limits in

TABLE 5 Summary of High-Power Laser Array Results*

Laboratory [Reference]	Array Type	Maximum Output Power	Power Efficiency (%)	Slope Efficiency (W/A)	Power Density (W/cm^2)

threshold current density and optical losses in the individual with advances in nonabsorbing mirror and active cooling techniques. Some recent progress has been seen in the latter with the use of etched silicon grooves for fluid flow, which function as radiator elements to remove the heat.

19.8 HIGH-SPEED MODULATION

In many applications semiconductor lasers are modulated in order to carry information. Semiconductor laser dynamics are usually described by the rate equations for the photon and carrier densities:[3–5,205,206]

$$\frac{dN}{dt} = \frac{I}{edLw} - \frac{cg}{n_r \Gamma} p - \frac{N}{\tau_s} \tag{16}$$

$$\frac{dP}{dt} = \frac{c}{n_r} g P - \frac{P}{\tau_p} + \Gamma \beta \frac{N}{\tau_s} \tag{17}$$

where N is the carrier density, P is the photon density, I is the current, e is the charge of an electron, d is the active layer thickness, L is the laser cavity length, w is the laser stripe width, c is the speed of light, n_r is the refractive index of the active region, g is the threshold modal gain, Γ is the optical confinement factor, τ_s is the carrier lifetime, β is the spontaneous emission factor, and τ_p is the photon lifetime of the cavity. [When these equations are written in terms of total gain instead of modal gain, Γ does not appear in Eq. (16), but multiplies the gain in Eq. (17).]

$$\tau_p = \frac{n_r}{c(\alpha_i + (1/2L)\ln(1/R_F R_R))} \tag{18}$$

where α_i is the internal loss and R_F and R_R are the front- and rear-facet reflectivities, β is the ratio of spontaneous emission power into the lasing mode to the total spontaneous emission rate.[207] (Do not confuse β with the other spontaneous emission factor, which is used in linewidth theory and is defined as the ratio of the spontaneous emission power into the lasing mode to the stimulated emission power of the mode.)

When a semiconductor laser is modulated there is some delay before it reaches a steady state. Because it takes time for a carrier population to build up, there will be a time delay τ_d before the final photon density P_{on} is reached (see Fig. 19). Once P_{on} is reached, additional time is required for the carrier and photon populations to come into equilibrium. The output power therefore goes through relaxation oscillations before finally reaching a steady state. This type of oscillation has many parallels in other second-order systems,[208] such as the vibration of a damped spring or an *RLC* circuit.

The frequency of these relaxation oscillations, f_r is called the relaxation, resonance, or corner frequency. By considering small deviations from the steady state where $N = N_{th} + \Delta N$ and $P = P_{on} + \Delta P$, we can solve Eqs. (16) and (17) for f_r with the result:[5,205]

$$f_r \cong \frac{1}{2\pi}\sqrt{\frac{c}{n_r\Gamma}\frac{dg}{dN}\frac{P_{on}}{\tau_p}} = \frac{1}{2\pi}\sqrt{\frac{c}{n_r}\frac{dg}{dN}\frac{(I-I_{th})}{edLw}} \tag{19}$$

where dg/dN is the differential modal gain. For bulk double-heterostructure lasers the gain is linearly dependent on the carrier density and $(c/n_r)dg/dN$ is replaced by A, where A is a constant. As discussed earlier in the chapter, the gain-versus-carrier-density relationship of a quantum well is nonlinear, so A is not a constant for a QW laser.

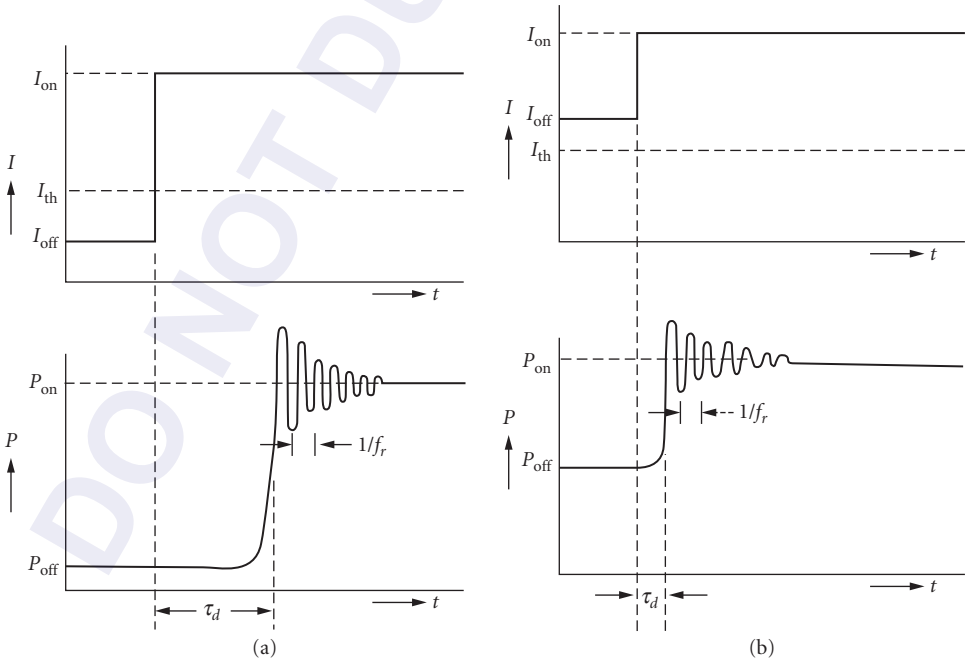

FIGURE 19 Schematic diagrams of the turn on delay and relaxation oscillations for a semiconductor laser (*a*) prebiased below threshold and (*b*) prebiased above threshold. (*After Ref. 206.*)

Let us return our attention to the turn on delay τ_d between a current increase and the beginning of relaxation oscillations as illustrated in Fig. 19. If the initial current I_{off} is below I_{th}, the initial photon density P_{off} can be neglected in Eq. (16). Assuming an exponential increase in carrier density we can derive[206]

$$\tau_d = \tau_s \ln\left(\frac{I_{on} - I_{off}}{I_{on} - I_{th}}\right), \quad I_{off} < I_{th} < I_{on} \tag{20}$$

Since τ_s is on the order of several nanoseconds, τ_d is usually very large for semiconductor lasers with I_{off} below I_{th}. For example, with $\tau_s = 4$ ns, $I_{on} = 20$ mA, $I_{th} = 10$ mA, and $I_{off} = 5$ mA, τ_d will be 1.6 ns. If a short current pulse is applied to a laser biased below threshold, τ_d may be so long that the laser barely responds (see Fig. 20). When a current pulse ends, it takes time for the carrier population to decay. If another identical pulse is applied before the carrier population decays fully, it will produce a larger light pulse than the first current pulse did. This phenomenon, which is illustrated in Fig. 20, is called the *pattern effect.*[209] The pattern effect is clearly undesirable as it will distort information carried by the laser modulation. The pattern effect can be eliminated by prebiasing the laser at a current sufficient to maintain a carrier population; for most semiconductor lasers this will mean prebiasing at or above threshold. In order to modulate with a prebias below threshold, I_{on} must be much greater than I_{th}. For most lasers this will require an unpractically large I_{on}, but if I_{th} is very low, it may be possible.[211,212]

Even a semiconductor biased above threshold will have a nonzero τ_d before it reaches its final photon density. Equations (16) and (17) may be solved for τ_d above threshold:[206]

$$\tau_d = \frac{1}{2\pi f_r}\sqrt{2\ln\left(\frac{P_{on}}{P_{off}}\right)} = \frac{1}{2\pi f_r}\sqrt{2\ln\left(\frac{I_{on} - I_{th}}{I_{off} - I_{th}}\right)} \quad I_{th} < I_{off} < I_{on} \tag{21}$$

τ_d will be much shorter for a prebias above threshold. For example if $f_r = 5$ GHz, $I_{on} = 40$ mA, $I_{off} = 15$ mA, and $I_{th} = 10$ mA, $\tau_d = 60$ ps. τ_d will be shortest for large P_{on} and P_{off}, so the shortest time

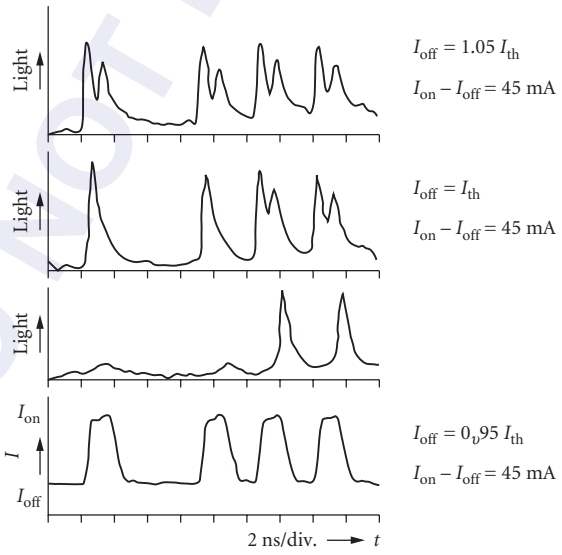

FIGURE 20 An illustration of the pattern effect for a AlGaAs laser diode with a 280 Mbit/s 10111 return to zero pattern. (*From Ref. 210.*)

delays will be achieved for small-scale modulation at high photon density. For digital applications in which fairly large-scale modulation is required, the maximum modulation speed of a semiconductor laser is to a large extent determined by τ_d.

For very high-speed microwave applications, lasers are prebiased at a current greater than the threshold current and modulated at high frequencies through small amplitudes about the continuous current prebias. The frequency response of a semiconductor laser has the typical shape expected from a second-order system. (For a discussion of the frequency response of a second-order system see Ref. 208.) The laser amplitude response is fairly uniform at frequencies less than the relaxation oscillation frequency. At f_r the response goes through a resonance and then drops off sharply. The relaxation oscillation frequency is therefore the primary intrinsic parameter determining the modulation bandwidth. The actual useful bandwidth is generally considered to be the frequency at which the response of the laser drops by 3 dB. Figure 21 is an example of the frequency response of a semiconductor laser under amplitude modulation.[213,214] In this example, the maximum 3-dB bandwidth is 16 GHz. If the 3-dB bandwidth is measured in electrical dB, as in our example, it is located at approximately $1.55f_r$. Sometimes the 3-dB frequency is quoted as that at which the optical power is reduced by a factor of 2; this actually corresponds to 6 dB in electrical power and occurs at approximately $1.73f_r$. The 0-dB frequency occurs at approximately $1.41f_r$.[213–215]

The description of the relaxation oscillation frequency given here is rather simplistic since it is based on rate equations, which consider only one type of carrier, neglect the spatial dependances of the carrier and photon distributions, and neglect the effects of carrier diffusion and nonlinear gain. In addition, the spontaneous emission term of Eq. (17) was neglected in the derivation. The neglected effects are particularly important when considering damping of the

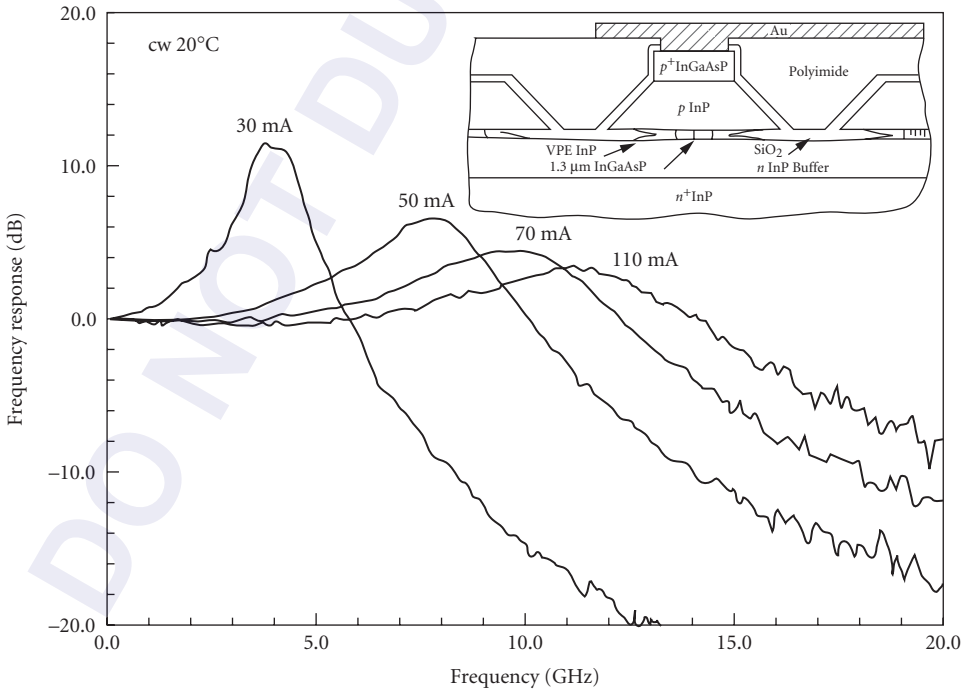

FIGURE 21 The small-signal modulation response of a 1.3-μm InGaAsP-constricted mesa laser for different bias levels. The cavity length is 170 μm and the stripe width is 1 μm. Inset: Schematic diagram of a 1.3-μm InGaAsP-constricted mesa laser. (*From Refs. 213 and 214.*)

relaxation oscillations.[204–206] With significant damping[215] the measured peak frequency f_p will be more accurately determined by

$$f_p^2 = f_r^2 - \frac{f_d^2}{4} \tag{22}$$

where f_d is the damping frequency.

We have also neglected, however, the electrical parasitics of the laser and its operating circuit (bonding wires, etc.). Figure 22 is a simple equivalent circuit, which describes the parasitic elements influencing a semiconductor laser. Here L is the inductance of bond wire, R is the laser resistance including contact resistance, and C is capacitance primarily due to bonding-pad capacitance and capacitance of the current-confining structure of the laser stripe.[213,214] The 50-Ω resistance is included to represent a 50-Ω drive. The resonant frequency of this circuit is

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{R+50}{LRC}} \tag{23}$$

The circuit is strongly damped so no resonance peak occurs; instead, the response simply drops off.[205,218] The amplitude response of a modulated semiconductor laser will begin to drop off at frequencies at which the response of the parasitics drops off even if the intrinsic peak frequency of the laser is higher. Therefore, the maximum practical modulation bandwidth may be determined *by* f_o instead of f_r. Figure 23 shows the modulation response of a semiconductor laser strongly affected by parasitics.[219]

The most significant parasitic limiting the performance of a semiconductor laser is normally the capacitance.[205] In order to achieve high speeds, the laser stripe must be very narrow [see Eq. (18)]; practical narrow stripe lasers are often some form of buried heterostructure (see Fig. 4*c*). The substrate doping and confinement-layer doping of buried heterostructure form a parallel plate capacitor. In order to reduce the capacitance the laser can be fabricated on a semi-insulating substrate,[205,218] the confinement layers can be semi-insulating,[124] the active area of the device can be isolated from the confinement layers by etching trenches on either side of it,[124,125] or the confinement layers can be replaced by a thick dielectric layer such as polyimide.[213,214] The inset on Fig. 21 is a schematic diagram of the high-speed laser stripe whose frequency response is shown in Fig. 21.

Assuming that the parasitics have been minimized, consider how a semiconductor laser can be optimized for high-speed operation. As already mentioned, minimizing the stripe width is desirable.

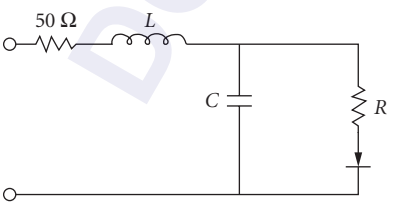

FIGURE 22 Simple equivalent circuit of the parasitics affecting the modulation of a semiconductor laser.

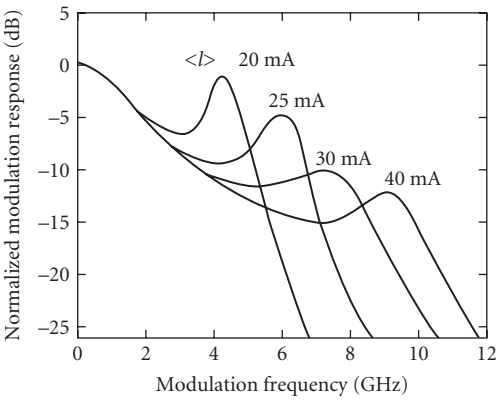

FIGURE 23 The modulation response of a 1.3-μm double-channel, planar-buried heterostructure laser with a cavity length of 80 μm and a threshold current of 18 mA. The effect of parasitics is apparent. (*From Ref. 219.*)

Figure 21 illustrates that increasing the photon density (or equivalently the current) increases the speed. Of course, there will be a limit as to how much the photon density can be increased; when the photon density of a semiconductor laser is increased, eventually a maximum power is reached at which the laser fails due to catastrophic facet damage. InGaAsP/InP lasers have a higher threshold for catastrophic facet damage than AlGaAs/GaAs lasers; InGaAsP/InP lasers, therefore, tend to have higher bandwidths.[214]

Consideration of Eq. (19) shows that decreasing the cavity length will also increase the speed.[205,213,214,218,219] (Decreasing the length reduces τ_p.) Increasing dg/dN will also increase the speed. With a bulk active region dg/dN is approximately constant, so use of a short cavity length will not affect it. As illustrated in Fig. 6, however, dg/dN of a QW laser will decrease with increasing threshold gain, and therefore with decreasing cavity length. A single QW laser will, therefore, make a relatively poor high-speed laser. An MQW laser, however, will have higher dg/dN than a single QW. In the past, the highest modulation bandwidths were achieved with InGaAsP/InP bulk active region InGaAsP/InP *lasers*[213,214,222,223] with the best results on the order of 24 GHz[223] for room-temperature CW measurements. The advent of strained MQW lasers has, however, recently resulted in higher bandwidths because strain increases dg/dN.[224–226] Strained GaAs-based $In_{0.3}Ga_{0.7}As$MQW lasers with bandwidths as high as 28 GHz have been demonstrated.[226]

So far our discussion has dealt only with the amplitude response to modulation. The phase and lasing wavelength (or optical frequency) are also affected by modulation. Figure 24 is an example of the phase response which accompanies the amplitude response of a semiconductor laser under modulation.

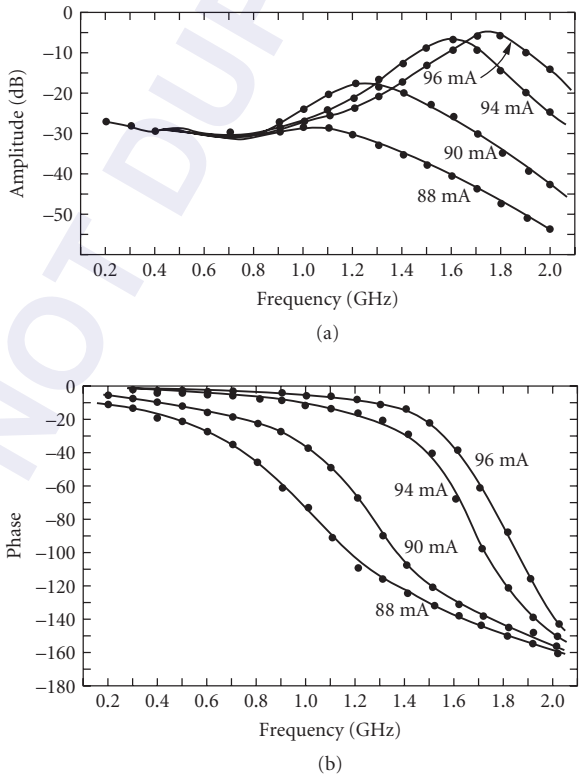

FIGURE 24 The modulation response of a proton stripe laser at various bias currents: (*a*) amplitude response and (*b*) phase. The threshold current is approximately 80 mA. (*From Ref. 205.*)

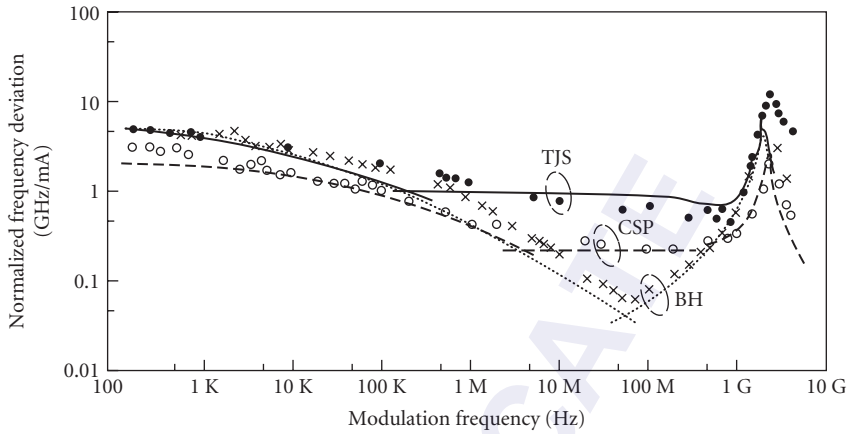

FIGURE 25 The FM response of TJS, BH, and channeled substrate planar (CSP) lasers. All the lasers are biased at 1.2 times threshold. (*From Ref. 229.*)

Assuming that a semiconductor laser lases in a single longitudinal mode under static conditions, high-frequency modulation can cause it to shift to another mode or to become multimode.[227] The tendency to become multimode increases with the depth of modulation. For many applications single-mode operation under modulation is required. In this case a laser with built-in frequency selectivity such as a distributed feedback laser[228] (DFB) (see "Spectral Properties" following) can be used to maintain single-mode operation. Even with single-mode operation under modulation the linewidth of the lasing mode will be broadened.[206,227] This broadening which is often called *chirp,* is discussed in more detail in the next section.

While the frequency changes associated with small-scale modulation are generally undesirable in amplitude modulation (AM), they can be utilized for frequency modulation[206,229,230] (FM). In digital systems, FM is often called frequency shift keying (FSK). FM requires only a very small amplitude modulation, so it normally refers to the effect of modulation on a single mode. In FM modulation, very fine shifts in optical frequency are detected; frequency stabilized lasers such as DFB lasers[230] as well as standard semiconductor lasers will show an FM response. Typically, FM response shows a low frequency decay below f_r and a resonance at f_r[206,229] (see Fig. 25).

If the reader requires more in-depth information on high-speed modulation of semiconductor lasers, the book by Petermann[206] or the review by Lau and Yariv[205] will be particularly helpful. For a recent review of the state of the art see the tutorial by Bowers.[215] References 3, 4, and 5 also contain chapters on high-speed modulation.

19.9 SPECTRAL PROPERTIES

One of the most important features of a semiconductor laser is its high degree of spectral coherence. There are several aspects to laser coherence. First, the laser must have spatial coherence in the various transverse directions. This is usually accomplished by controlling both the geometry and the lateral-mode geometry using a structure with a built-in index as discussed earlier under "Fabrication and Configurations." In order to achieve high spectral coherence, the semiconductor laser must operate in a single longitudinal mode. There are four technical approaches for accomplishing this:[231,232] (1) coupled cavity, (2) frequency selective feedback, (3) injection locking, and (4) geometry control. The various techniques for achieving spectral control are described in Fig. 26.

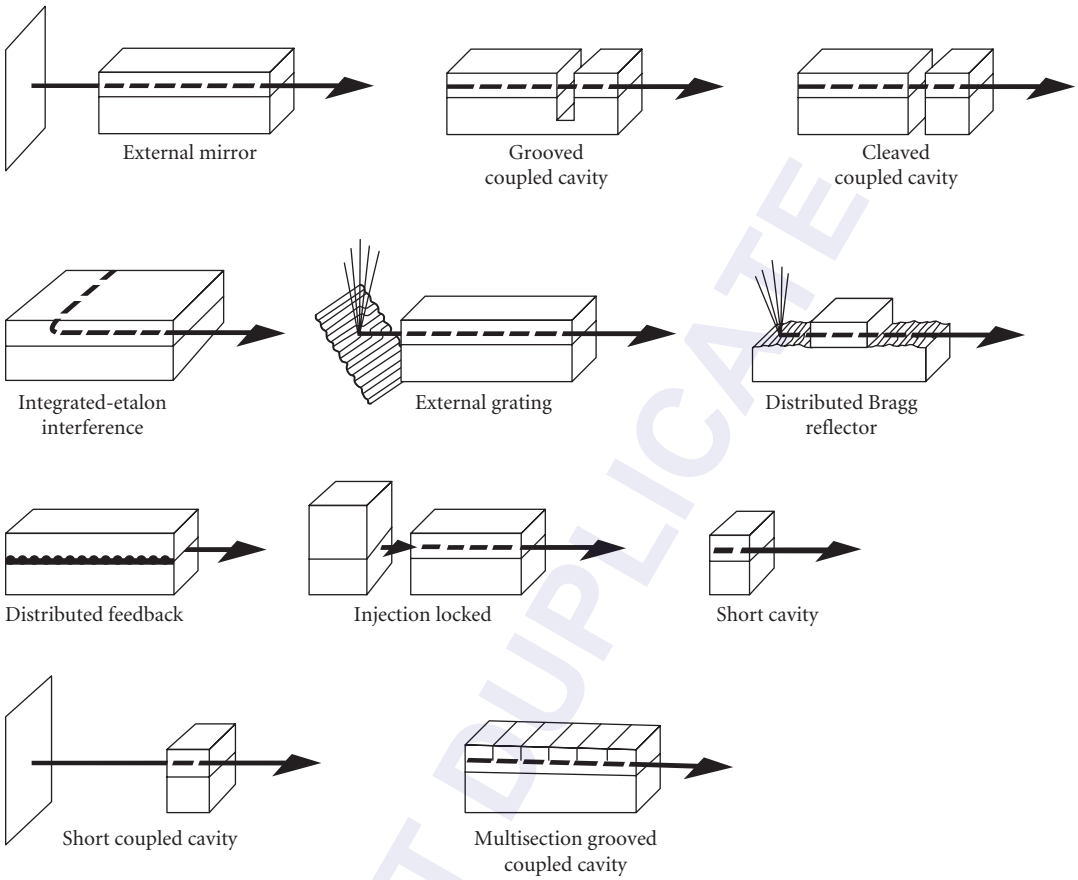

FIGURE 26 Eleven major designs for single-frequency lasers. The three in the top row and the first in the second row are coupled cavity lasers; the next three are frequency-selective-feedback lasers; the next is an injection-locked laser; the last one in the third row is a geometry-controlled laser. The left two are hybrid designs. (*From Ref. 232.*)

The temporal coherence of the laser is related to the spectral width of the stimulated emission spectrum by

$$L_c = K\frac{\lambda_0^2}{\Delta\lambda_{1/2}} \tag{24}$$

where K is a constant dependent on the distribution of spectral output function, L_c is coherence length, λ_0 is the wavelength of the stimulated emission peak, and $\Delta\lambda_{1/2}$ is the halfwidth of the spectral emission. $K = 1$ for rectangular, $K = 0.32$ for a lorentzian, and $K = 0.66$ for a gaussian.

The spectral linewidth, $\Delta f_{1/2}$, for a single longitudinal mode can be expressed as[233]

$$\Delta f_{1/2} = \frac{n_{sp}}{4\pi\tau_p}\left(\frac{J}{J_{th}} - 1\right)^{-1}(1+\alpha^2) \tag{25}$$

where n_{sp} is the spontaneous emission factor, defined as the ratio of spontaneous to stimulated emission in the lasing mode, τ_p is the cavity lifetime, and α is the linewidth enhancement factor.

Typical linewidths for a solitary single-longitudinal-mode laser are in the range of 5 to 20 MHz. Narrower linewidths can be achieved by using some of the techniques described in Fig. 26. More recently, the use of QW lasers, as described earlier, has led to a significant reduction in the linewidth enhancement factor and the corresponding laser linewidths.[234] Typical linewidths in the range of 0.9 to 1.3 MHz have been achieved.

Coupled cavity lasers make up a family of devices, whereby spectral control is achieved by reinforcing certain wavelengths which resonate in several cavities.[235] A typical configuration is shown in Fig. 26, whereby the long cavity is cleaved into two smaller cavities. By properly controlling the length ratios and the gap width, good longitudinal mode discrimination (better than 20-dB side-mode suppression) can be obtained.

Another important technique is the use of an external resonant optical cavity (frequency-selective feedback) as shown in Fig. 27. This technique has been used by researchers at Boeing to achieve extremely narrow linewidth ($\Delta f_{1/2} \sim 1-2$ KHz) single-longitudinal-mode operation.[236]

Frequency-selective feedback can also be achieved by using either a distributed feedback (DFB) or distributed Bragg reflector (DBR) laser. As shown in Fig. 26, it differs from other types of lasers in that the feedback is provided by a grating internal to the diode laser. By using a DFB/DBR in combination with a long external cavity, it is possible to achieve linewidths below 1 MHz in a monolithic diode.[237]

Injection-locked lasers have also been under investigation at several research labs.[238] In this technique, a low-power, single-frequency laser, which does not have to be a semiconductor laser, is coupled to a single-mode semiconductor laser by injecting the continuous wave emission of a single wavelength of radiation into the laser's cavity.

The last technique for achieving single-longitudinal-mode operation involves the geometry-controlled cavity. Basically, this involves a short cavity 50 μm or less in length, since the longitudinal-mode spacing $\Delta\lambda_L$ in a semiconductor laser is given by[128]

$$\Delta\lambda_L = \frac{\lambda_0^2}{2n_{\text{eff}}L} \tag{26}$$

where n_{eff} is the effective index of refraction and L is the cavity length. Then if $L < 50$ mm, $\Delta\lambda_L > 20$ Å and the gain available to modes away from the gain maximum falls rapidly, the laser operates in a

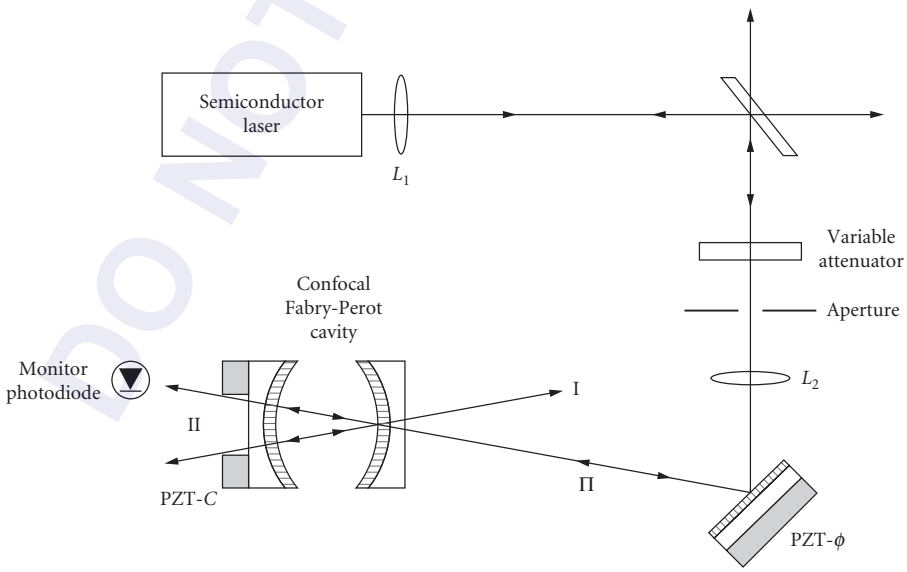

FIGURE 27 Semiconductor laser using resonant optical feedback.

single longitudinal mode. However, the width of the spectral model can still be rather large as dictated by Eq. (25), unless special precautions are made (e.g., ultrahigh mirror reflectivities).

19.10 SURFACE-EMITTING LASERS

Monolithic two-dimensional (2D) laser arrays are key to many important applications such as massive parallel data transfer, interconnect, processing, computing, and high-power, diode-pumped, solid-state lasers. Conventional lasers, as described in previous sections, require a pair of parallel crystalline facets (by cleaving) for delineating the laser cavity, thus limiting laser emission parallel to the junction plane. In this section, we describe laser structures and fabrication techniques which allow light to emit perpendicular to the junction plane, namely, surface-emitting lasers (SEL). SEL structures are compatible with monolithic 2D laser array integration and requirements.

There are three designs for the fabrication of surface-emitting lasers and arrays: (1) in-plane laser with a 45° mirror, (2) in-plane laser with a distributed grating coupler, and (3) vertical cavity laser. The main body of the first two structures is very similar to the conventional cavity design with the axis parallel to the junction plane (in-plane). Light is coupled out from the surface via an integrated mirror or grating coupler. The third structure is an ultrashort cavity (10 μm) "microlaser" requiring no cleaving and compatible with photodiode and integrated-circuit processing techniques. High-density, surface-emitting laser arrays of this type have been demonstrated jointly by AT&T and Bellcore.[239] The following subsections will summarize each of the three structures.

Integrated Laser with a 45° Mirror

The development of this SEL structure requires the wafer processing of two 90° laser mirrors as well as a 45° mirror for deflecting the laser output from the junction plane as shown in Fig. 28. Dry etching techniques such as reactive ion (beam) etching (RIE), chemical-assisted ion beam etching (CAIBE), and ion beam milling are usually used for the fabrication. In combination with a mass-transport process,[240] a smooth parabolic sidewall has been demonstrated for the 45° mirror of InGaAsP/InP lasers.

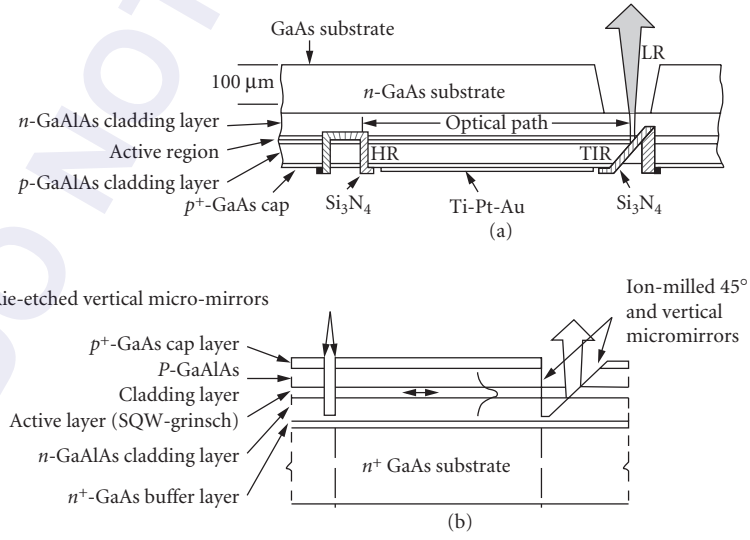

FIGURE 28 Monolithic in-plane-cavity surface-emitting lasers with 45° mirrors: (*a*) Junction-down and (*b*) junction-up configurations. (*From Ref. 241.*)

This approach for an SEL takes advantage of well-established layer structure growth for typical lasers. The laser performance relies on the optical quality and reliability of the facet mirrors formed. The etched-mirror lasers have been improved over the past decade to the stage very comparable with the cleaved lasers. Two-dimensional, high-power (over 1 W) laser arrays have been demonstrated by both TRW[241] and MIT Lincoln Laboratory.[240] These structures would require injection-locking or other external optical techniques in order to achieve coherent phased array operation as mentioned in the high-power laser section.

Distributed Grating Surface-Emitting Lasers

Distributed feedback (DFB) (see under "Spectral Properties," discussed earlier) and distributed Bragg reflector (DBR) lasers were proposed and demonstrated in the early 1970s. It is well known that for the second-order gratings fabricated in the laser, the first-order diffraction will be normal to the grating surface, as shown in Fig. 29. Since early demonstrations, it has taken over 10 years for both the applications and processing techniques to become mature. Low-threshold, high-reliability DFB lasers with true single-mode characteristics are readily fabricated. The critical issue involved in the fabrication of the laser structure is the fabrication of the gratings with a period on the order of 2000 Å. Holographic interference techniques with an Ar^+ or He-Cd laser are generally used in many laboratories. The fabrication of large-area gratings with good throughput can be easily achieved by this technique. Another technique involves direct electron-beam writing, which is effective for design iterations.

The development of DBR structure with second-order gratings for surface-emitting lasers did not occur until it was funded by the U.S. Air Force pilot program. This type of laser does not require discrete mirrors for the laser action, so that one could link an array of the lasers with residual in-plane light injection (leaking) across neighboring lasers for coherent operation. A near-diffraction-limited array operation has been demonstrated with this type of SEL. The concept was recently used

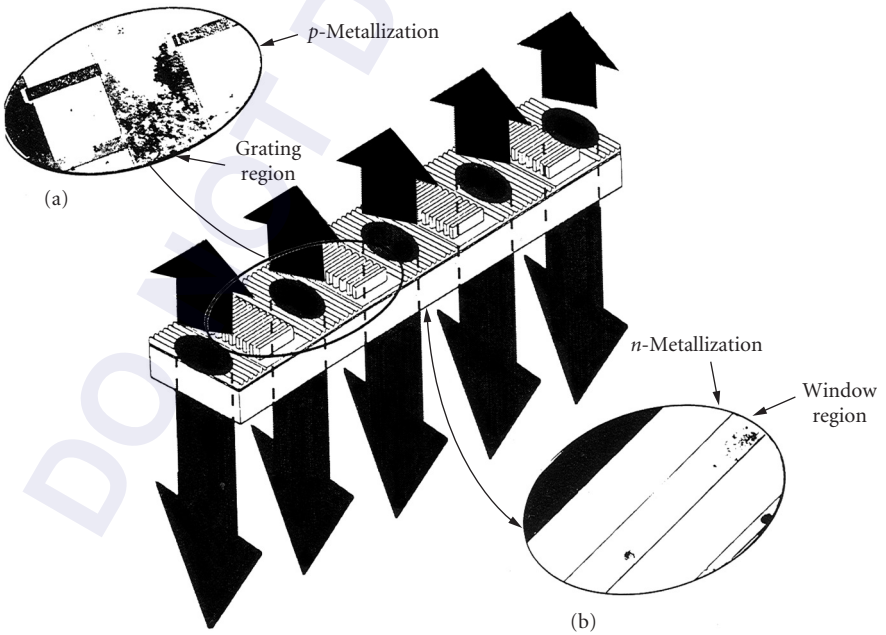

FIGURE 29 Grating surface-emitting laser array. Groups of 10 parallel ridge-guide lasers are laterally coupled in each gain section. (*From Ref. 242.*)

for a high-power MOPA (master oscillator power amplifier) laser amplifier demonstration with the slave lasers' grating slightly off the resonant second-order diffraction condition. High-power laser arrays of this type have been demonstrated by SRI DSRC[242] and Spectra Diode Laboratories.[243] Coherent output powers of 3 to 5 W with an incremental quantum efficiency in excess of 30 percent have been obtained with the array.

Vertical Cavity Lasers

The term "vertical" refers to the laser axis (or cavity) perpendicular to the wafer surface when it is fabricated. Conventional lasers have a relatively long cavity, on the order of 250 μm. It is not practical to grow such a thick layer for the laser. From the analysis, if we reduce the cavity length down to 10 μm, one needs to have a pair of very high reflectivity mirrors to make it lase at room temperature. To satisfy these conditions, researchers at Tokyo Institute of Technology[244] have used a metal thin-film or a quarter-wavelength stack of dielectric layers (Bragg reflectors) of high- and low-index material for the mirror post to the growth of laser layers. The advances in epitaxial growth techniques allow an accurate control of semiconductor layer compositions and thicknesses such that Bragg reflectors with 99.9 percent reflectivity can be attained. Therefore, a complete vertical cavity laser structure as shown in Fig. 30 consisting of a gain medium- and high-reflectivity (more than 10 periods of alternate layers due to incremental index difference) mirrors can be grown successfully in one step by MBE or MOCVD techniques.

It is important to optimize the structure for optical gain. To maximize the modal gain, one can locate the standing wave field peak at the thin quantum well-active layer(s) (quantum well lasers were discussed earlier in this chapter) to form a resonant periodic gain structure.[245] The issue associated with the semiconductor superlattice Bragg reflectors is the built-in carrier resistance across the abrupt heterojunction discontinuity. Without modifying the structure, the series resistance is on the order of several hundred to a thousand ohms. There have been two techniques applied to lower the resistance, namely, the use of graded junctions[246] and peripheral Zn diffusion[247] for conducting current to the active region. Both have demonstrated improvement over the original design.

The laser size is defined by etching into a circular column that can be mode-matched to a single-mode fiber for high coupling efficiency. It is desirable that the lasers can be planarized. Proton-bombardment-defined lasers[248] with good performance and high yield have been obtained. Meanwhile, the small size of the laser has resulted in low threshold currents close to 1 mA.[249] The differential quantum efficiency has been improved from a few percent to more than 30 percent; the output power level, modulation frequency, and maximum operating temperature have also increased over the past several years. As mentioned previously, the advantage of this SEL structure is the potential of high packing density. Bellcore researchers[250] have demonstrated a novel WDM (wavelength division multiplexing) laser source with a good histogram of wavelength distribution. The grading of layer thickness across the wafer during a portion of growth translates into different lasing wavelengths. Two-dimensional, individually addressable lasers in a matrix form have also been demonstrated.[251] In the future, 2D laser arrays operating at a visible wavelength will be very useful for display and optical recording/reading applications. The performance characteristics of vertical cavity SELs reported are shown in Table 6.

19.11 CONCLUSION

In this chapter we have introduced the basic properties of semiconductor lasers and reviewed some areas of the field, including high-power operation, high-speed operation, coherence, and surface-emitting lasers. We have particularly emphasized the advantages of quantum well lasers and strained quantum well lasers. Up until very recently, all the major laser diodes were fabricated using GaAs/GaAlAs and GaInAsP/InP heterostructures. However, there have been such significant advances in the use of strained quantum wells that these lasers have performance levels which exceed, in many

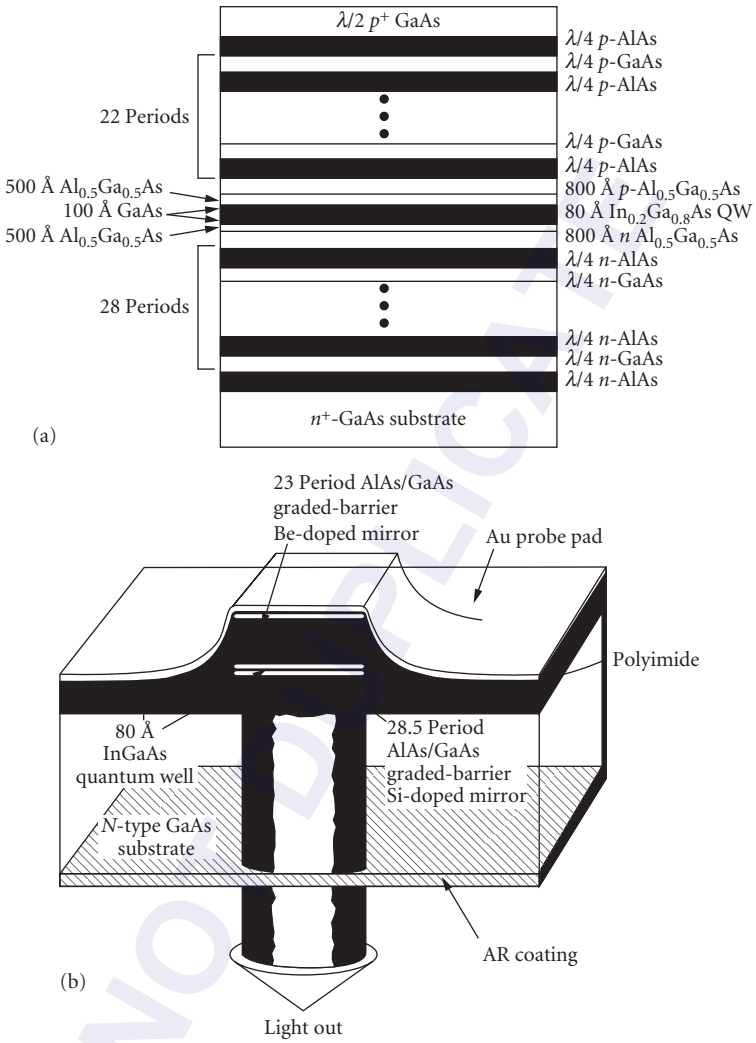

FIGURE 30 Vertical cavity surface-emitting laser with (*a*) layer structure and (*b*) device geometry. (*From Ref. 249.*)

cases, that found for the unstrained lasers. Coupled with the measured excellent reliability results and better output power/temperature performance, these types of lasers will experience a high demand in the future. High-power strained InGaAs/GaAs quantum well lasers are also of interest because their lasing wavelength range includes 0.98 μm, which makes them useful for pumping erbium-doped fiber amplifiers.[17]

Another trend in the future will be the extension of commercial semiconductor lasers to a wider variety of lasing wavelengths. Just as with the standard lasers, strained quantum wells result in significant performance improvements in these more novel laser systems. Shorter wavelength ($\lambda < 0.75$ μm) lasers with high output powers are of interest for high-density optical recording and printing. In the last few years, much progress has been made in developing short-wavelength semiconductor lasers. In the near future, practical visible wavelength lasers will be in the red-to-yellow range, but progress has begun on even shorter wavelengths in the blue. Recent work on very

long-wavelength (λ >2.0 μm) GaInAsSb/AlGaAsSb lasers is also very promising. Long wavelengths (>1.55 μm) are of interest for eye-safe laser radar, metrology, and medical instrumentation.

Currently, commercial lasers are of the edge-emitting variety, but two-dimensional surface-emitting laser arrays have advanced considerably in the past few years. When they reach maturity, they will be used for pixel interconnect and display applications.

In a limited chapter such as this it is impossible to cover all areas of the field of semiconductor lasers in depth. One of the most important areas neglected is that of tunable lasers.[255–257] Single-mode tunable DFB and DBR lasers are of great interest for future coherent optical transmission systems. These lasers lase in a single longitudinal mode, but that mode can be tuned to a range of frequencies.

Another area not discussed in detail here is amplifiers. Amplifiers are of great interest for long-haul communication systems, for example, submarine cable systems. Amplifiers can be laser pumped fiber amplifiers[17] or laser amplifiers.[258–262] A laser amplifier has a structure similar to that of a semiconductor laser and has some optical gain, but only enough to amplify an existing signal, not enough to lase on its own.

It is hoped that the information presented in this chapter will satisfy readers who are interested in the basics of the subject and will give readers interested in greater depth the understanding necessary to probe further in order to satisfy their specific requirements.

20.1 INTRODUCTION

It is considered an easy task to control waveforms down to a few cycles with electronic circuits, at frequencies in the megahertz range. Ultrafast optics has seen the development of the same capability at optical frequencies, i.e., in the peta Hertz range. Laser pulses of a few optical cycles (pulse duration of a few femtoseconds) are routinely generated, with a suboptical cycle accuracy. The high power of these ultrashort bursts of electromagnetic radiation have led to new type of high field interactions. Electrons ejected from an atom/molecule by tunnel or multiphoton ionization can be recaptured by the next half optical cycle of opposite sign. The interaction of the returning electron with the atom/molecule is rich of new physics, including high harmonic generation, generation of single attosecond pulses of attosecond pulse trains, scattering of returning electrons by the atom/molecule, etc. Generation, amplification, control, and manipulation of optical pulses is an important starting point for these high field studies.

As compared to fast electronics, ultrafast optical pulses have reached a considerable higher level of accuracy. Pulse trains can be generated, of which the spacing between pulses (of the order of nanoseconds) is a measurable number of optical cycles (one optical cycle being approximately 2 fs in the visible). The frequency spectrum of these pulse trains is a frequency comb, of which each tooth can be an absolute standard with a subhertz accuracy. These frequency combs have numerous applications in metrology and physics—for instance, determining the eventual drift of physical constants, or in astronomy, a considerable improvement in the determination of Doppler shifts of various sources. In addition to the high level of accuracy and control in time and frequency, the femtoseconds sources have a remarkable amplitude stability. This stability is the result of nonlinear intracavity losses being minimum for a particular intensity.

This chapter starts with a detailed description of an optical pulse and an optical pulse train. Nonlinear mechanisms are described that can be exploited to control pulse duration, chirp, intensity

of the mode-locked lasers. In particular, a mode-locked laser with two intracavity pulses will be discussed, and its analogy with a quantum mechanical two-level system.

20.2 DESCRIPTION OF OPTICAL PULSES AND PULSE TRAINS

Single Optical Pulse

In this first section we will summarize the essential notations and definitions used throughout the chapter. Ideally, a mode-locked laser emits a continuous train of identical ultrashort pulses. To this infinite series of identical pulses corresponds, in the frequency domain, a finite (but large) number of equally spaced modes, generally referred to as a *frequency comb*. Inside the laser typically, only one pulse circulates. The shape of an intracavity pulse results from a steady-state equilibrium between various mechanisms of pulse stretching (saturable gain, dispersion), compression (saturable absorption, combination of self-phase modulation, and dispersion), amplification, and losses.

The pulse is characterized by measurable quantities which can be directly related to the electric field. A complex representation of the field amplitude is particularly convenient in dealing with propagation problems of electromagnetic pulses.

The complex spectrum of the pulse $\tilde{E}(\Omega)^*$ is defined by taking the complex Fourier transform $\mathcal{F}$ of the real electric field $E(t)=\varepsilon(t)\cos[\omega t+\varphi(t)]$:

$$\tilde{E}(\Omega)=\mathcal{F}\{E(t)\}=\int_{-\infty}^{\infty}E(t)e^{-i\Omega t}dt=\left|\tilde{E}(\Omega)\right|e^{i\Phi(\Omega)}=\tilde{\varepsilon}(\Omega-\omega)=\tilde{\varepsilon}(\Delta\Omega) \tag{1}$$

In the definition (1), $|\tilde{E}(\Omega)|$ denotes the spectral amplitude and $\Phi(\Omega)$ is the spectral phase Since $E(t)$ is a real function, its Fourier transform is symmetric, and its negative frequency part can be considered as redundant information. We will therefore choose to represent the light pulse by either the positive frequency function $\tilde{E}(\Omega)=E(\Omega)e^{i\Phi(\Omega)}$ (defined as being equal to zero for $\Omega<0$) or its complex inverse Fourier transform in the time domain

$$\tilde{E}(t)=\frac{1}{2\pi}\int_{0}^{\infty}\tilde{E}(\Omega)e^{i\Omega t}d\Omega=\frac{1}{2}\tilde{\varepsilon}(t)e^{i\omega t}=\frac{1}{2}\varepsilon(t)e^{i[\omega t+\varphi(t)]} \tag{2}$$

The relation with the real physical measurable field $E(t)$ is

$$E(t)=\tilde{E}(t)+\text{c.c.}=\varepsilon(t)\cos[\omega t+\varphi(t)] \tag{3}$$

The latter part of Eq. (2) defines a pulse envelope function $\varepsilon(t)$, a carrier frequency ω and a phase $\varphi(t)$. The decomposition is somewhat arbitrary, since the instantaneous frequency is given by

$$\omega(t)=\omega+\frac{4}{dt}\varphi(t) \tag{4}$$

In general, the carrier frequency ω will be chosen such that the average contribution from the phase factor $\varphi(t)$ is zero:

$$\left\langle\varphi(t)\right\rangle=\frac{\int_{-\infty}^{\infty}\varepsilon(t)^2\dot{\varphi}(t)dt}{\int_{-\infty}^{\infty}\varepsilon(t)^2dt}=0 \tag{5}$$

*Complex quantities related to the field will be represented with a tilde.

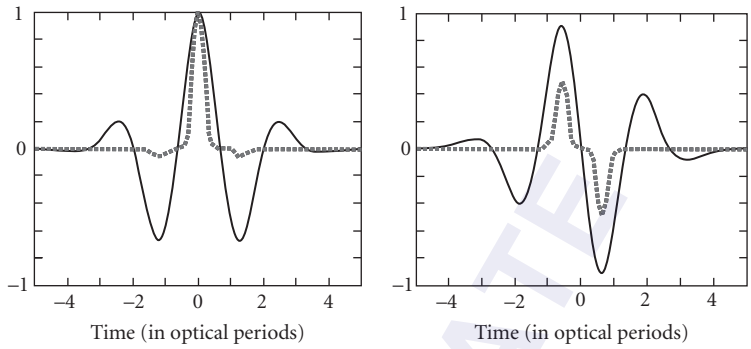

FIGURE 1 Comparison of a two-cycle pulse with $\varphi_e = 0$ (left) and $\varphi_e = \pi/2$ (right). The solid line traces the instantaneous electric field normalized to the peak value of its envelope, as a function of time in units of the optical period. The dotted lines correspond to the seventh power of the electric field, which would be driving a seven photon process.

For pulses of a few optical cycles, the variation of the phase factor can often be neglected across the pulse, and $\varphi(t) = \varphi_e$ is constant. Even for a single pulse, the phase factor φ_e is of practical significance, when a nonlinear phenomena traces the electric field under the envelope of a pulse of only a few cycle duration. If the phase φ_e is zero, the time dependence of the electric field is symmetric, with a peak in the center at $t = 0$, larger than the two opposite maxima at $t = \pm T/2$. If the phase $\varphi_e = \pi/2$, the time dependence of the electric field is antisymmetric, with equal opposite extrema at $t = \pm\pi/4$. These two pulses can give a different response in highly nonlinear phenomena. Let us consider for instance the shortest pulse that can be generated at 800 nm, which has a full width at half maximum (FWHM) of the intensity of 2.5 fs. Its complex electric field envelope can be written as $\tilde{\varepsilon}(t) = (\varepsilon_0/2)\exp[-(t/2T)^2 + i\varphi_e]$, which corresponds to the real electric field $E(t) = \varepsilon_0 \exp[-(t/2T)^2]\cos[2\pi(t/2T) + \varphi_e]$ which is plotted as a solid line in Fig. 1 for $\varphi_e = \pi/2$ (left) and $\varphi_e = \pi/2$ (right). If we consider that this pulse is used to excite a seven-photon process (for instance a seven-photon ionization), the driving function for that process is the seventh power of the field, which is plotted as a dotted line in Fig. 1. One can see that the different values of φ_e make a significant difference on how the process is driven. For $\varphi_e = 0$, the excitation is a single spike, as close approximation as practical to a δ-function. In the case of $\varphi_e = \pi/2$ (right), the excitation consists in a succession of positive and negative spikes.

Train of Pulses

The "ideal" mode-locked laser emits a train of identical pulses, at equal time interval. The period of the pulse train is τ_{RT}, defined as the separation between two successive envelopes. In the particular case that the pulse separation is an integer number of optical cycles $\tau_{RT} = NT = N/\nu$ (T being the light period and $\nu = \omega/(2\pi)$ the optical frequency) the successive pulses are identical. This will generally not be the case, and there will be a phase shift $\varphi_p = \omega\tau_{RT} \neq 2N\pi$ between successive pulses. The complex electric field of the total pulse train $\tilde{E}_{pt}$ is

$$\tilde{E}_{pt}(t) = e^{i\omega t}[\tilde{\varepsilon}(t) + \tilde{\varepsilon}(t - \tau_{RT})e^{i\varphi_p} + \tilde{\varepsilon}(t - 2\tau_{RT})e^{2i\varphi_p} + \cdots] \tag{6}$$

where $\tilde{\mathcal{E}}(t)=\mathcal{E}(t)e^{i\varphi_e}$ is the electric field of one particular pulse. The nth pulse has the phase factor $\exp[i(\varphi_e+n\varphi_p)]$, different from the previous and next pulse. To the change in phase between successive pulses φ_p, corresponds a frequency:

$$f_0=\frac{1}{2\pi}\frac{\varphi_p}{\tau_{RT}} \tag{7}$$

This frequency is called the *carrier to envelope offset*. The *carrier to envelope offset* is an important parameter of pulse trains, where the change in phase from pulse to pulse is a measurable quantity, independent of the duration of the individual pulse in the train.

One can "idealize" to the extreme the concept of a pulse train, by considering an infinite train of δ-functions, equally spaced by the period of the train τ_{RT}, as shown in Fig. 2*a*. The Fourier transform of this ideal pulse train shown in Fig. 2*b* is an identical picture in the frequency domain: a comb of infinite extent (because the pulses were δ-function in time), with δ-function teeth (because of the infinite extent of the train).

Since the comb extends to infinity, there is no particular tooth that can be called an average frequency. Each mode ν_m of index m carries the same weight, and corresponds in the time domain to an infinite sine wave, which is a particular term of a Fourier series representation of δ-function. The first tooth at frequency $\nu_0=f_0$ represents the carrier to envelope offset defined above. The corresponding carrier to envelope phase φ_e defined previously can be identified in the time domain, even with a train of δ-functions. The harmonic wave corresponding to the mode ν_2 is shown in Fig. 2*a*,* and the phase φ_e is identified as the phase at which each δ-function crosses the harmonic field. In the sketch of Fig. 2*a*, $\varphi_e=0$ for the first pulse, and φ_p is then the carrier to envelope phase φ_e of the second pulse as indicated in the figure.

A somewhat more mundane train of pulses of finite duration τ† is sketched in Fig. 3*a*. In the frequency domain (Fig. 3*b*), the infinite pulse train is represented by a finite frequency comb. The

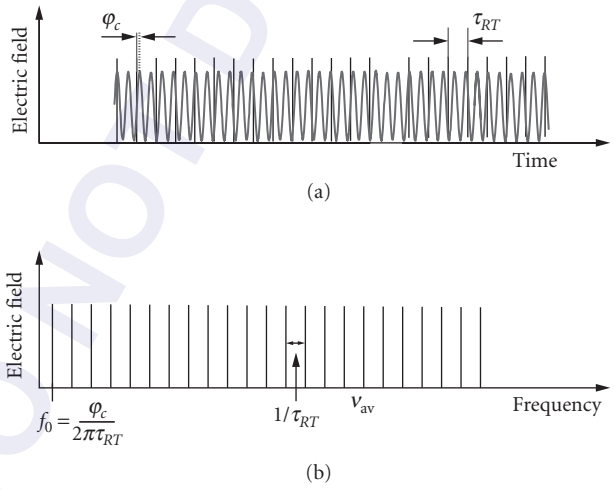

FIGURE 2 Idealized infinite train of δ-function pulses (*a*), and its Fourier transform (*b*). In (*a*), the carrier to envelope phase φ_e of the first pulse is assumed to be zero.

*This harmonic wave sketched is associated with ν_2 because there are two periods between pulses. In the Fourier spectrum of a train of δ-functions, any mode ν_n can be chosen as being the "average frequency".

†When not otherwise specified, the pulse duration will be the full width at half maximum (FWHM) of the pulse intensity profile.

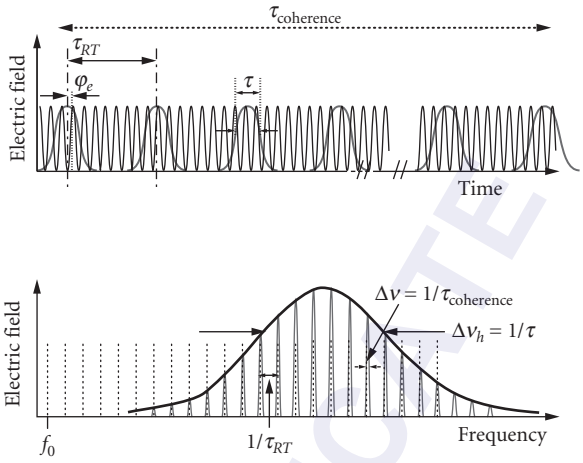

FIGURE 3 (*a*) Train of pulses of finite duration τ. The successive pulse envelope repeats every τ_{RT}. Within the coherence time of the train $T_{coherence}$, it is the same carrier at the optical frequency that is modulated by the successive envelopes. (*b*) The Fourier transform of the pulse train shown in (*a*).

envelope of the comb is the Fourier transform of the envelope of a single pulse of the train, thus of extension $\approx 1/\tau$. The teeth of the frequency comb are no longer δ-functions, but sharp peaks of width $1/\tau_c$, where τ_c is the coherence time of the pulse train. The carrier to envelope phase φ_p is indicated for a pulse of the time sequence in Fig. 3*a*. Note that this phase is changing from one pulse to the next. The rate of change $\varphi_p/(2\pi\tau_{RT})$ is the frequency f_0, which is indicated in the frequency picture by the lowest frequency tooth of the extension (dashed lines in Fig. 3*b*).

The angular frequency ω_m of the mth mode of the comb is given by

$$\omega_m = 2\pi f_0 + m\frac{2\pi}{\tau_{RT}} \tag{8}$$

In the case of a train of pulses of finite duration, the frequency f_0 is no longer a real tooth of the comb, but the first mode of an extension of the frequency comb beyond the pulse bandwidth as shown by the dotted line in (Fig. 3*b*).

It can be seen from this definition that f_0 is indeed the change of phase per round-trip between the envelope and the carrier. By definition of τ_{RT}, the pulse envelope peaks exactly at the same locations after one round-trip. With respect to this envelope, the shift of phase of the mode m is obtained by multiplying Eq. (8) by τ_{RT}:

$$\omega_m \tau_{RT} = 2\pi f_0 \tau_{RT} + 2m\pi \tag{9}$$

which, after substitution of the definition of f_0 Eq. (7), is indeed the phase φ_p defined earlier.

Soliton Solution and Steady-State Pulse Train

As mentioned in the introduction, if a laser is to generate a pulse of well defined duration and shape, there has to be compression and broadening mechanisms that balance each other, and lead to

a stable pulse. The mechanisms that lead to an emergence of a pulse out of noise in a laser cavity are usually dissipative, i.e., the pulse that emerges dissipates a minimum amount of energy by nonlinear loss mechanisms and extracts the maximum amount of gain from the active laser medium. We will consider in this section only nondissipative interaction that plays a dominant role for the stable formation of the shortest pulses. First we consider the evolution of a single pulse as it propagates through a cavity. Next we will study the formation of a pulse train with a similar nondissipative model.

Evolution of a Single Pulse in an "Ideal" Cavity When a laser is in continuous operation, the cavity gain and losses are in equilibrium. In the case of femtosecond mode-locked lasers, the major pulse-shaping mechanism is a combination of self-phase modulation and dispersion at each round-trip. The self-phase modulation results from a nonlinear index of refraction $n_2 I$ (I being the intensity in W/cm^2, n_2 being the nonlinear index in cm^2/W of a nonlinear element of length ℓ in the cavity). The dispersion k'' results from the frequency dependence of the average index of refraction n_{av} defined previously, and is characterized by the second derivative of a cavity averaged k vector with respect to frequency. In what follows, for simplicity, we will neglect higher-order terms in Kerr effect and in dispersion. The evolution of a pulse in the mode-locked laser cavity can be considered as a propagation (of a nondiffracting beam) through an infinite lossless medium, with a positive Kerr nonlinearity ($n_2 > 0$) and a negative dispersion (as can be introduced with intracavity prisms[1] or chirped mirrors[2] in the cavity). The pulse evolution generally converges toward a steady-state solution, designated as "solitons," which can be explained as follows. The nonlinearity is responsible for spectral broadening and up-chirp. Because of the anomalous dispersion, $k'' < 0$, the high-frequency components produced in the trailing part of the pulse, travel faster than the low-frequency components of the pulse leading edge. Therefore, the tendency of pulse broadening owing to the exclusive action of group velocity dispersion can be counterbalanced. To determine the approximate parameters of that solution, let us assume a Gaussian pulse $\varepsilon(t) = \varepsilon_0 \exp[-(t/\tau_{G0})^2]$, and let us state that the chirp produced in the pulse center by the nonlinearity and the dispersion are of equal magnitude (but of opposite sign). Under this equilibrium condition the pulse circulates in the cavity without developing a frequency modulation and spectral broadening. The effect of group velocity dispersion is to create a pulse broadening and a down-chirp (in a medium of negative dispersion). The change (per round-trip) of the second derivative of the phase versus time, at the center of the pulse, is given, in a first-order approximation, by Ref. 3:

$$\Delta\left(\left.\frac{\partial^2 \varphi(t)}{\partial t^2}\right|_{(t=0)}\right) = \frac{4k''_{av}}{\tau_{G0}^4} P \tag{10}$$

where $k''_{av} = d^2 k_{av}/d\Omega^2$ is the second-order dispersion averaged over the cavity of perimeter P, which is < 0 for an optical element with negative dispersion. Assuming that the cavity contains an element with a nonlinear index $n = n_0 + n_2 I$ of length ℓ_{Kerr}, the phase induced by self-phase modulation, near the center of the Gaussian pulse, is

$$\Delta\varphi(t) = -k_{NL} \cdot \ell_{Kerr}\Big|_{(t=0)} = \frac{2\pi n_2}{\lambda} \ell_{Kerr} I \approx \frac{4\pi n_2 I_0 \ell_{Kerr}}{\lambda} \frac{t}{\tau_{G0}^2} \tag{11}$$

where we have used a quadratic approximation for the Gaussian near $t = 0$. Taking the second derivative yields the chirp induced by phase modulation at the pulse center:

$$\Delta\left(\frac{\partial^2 \varphi(t)}{\partial t^2}\right) \approx \frac{8\pi n_2 I_0 \ell_{Kerr}}{\lambda \tau_{G0}^2} \tag{12}$$

The peak intensity of the pulse (at $t = 0$) is $I_0 = \varepsilon_0^2/2\eta$; $\eta = \sqrt{\mu_0/\epsilon}$ being the characteristic impedance of the medium. Expressing that the chirps induced by phase modulation [Eq. (12)] and dispersion [Eq. (10)] should cancel each other leads to

$$I_0 \tau_{G0}^2 = -\frac{\lambda k''_{\text{av}}}{2\pi n_2} \frac{P}{\ell_{\text{Kerr}}} \tag{13}$$

This expression leads to a value for the pulse duration given by

$$\tau_{G0}^2 = \frac{\lambda \left| k''_{\text{av}} \right|}{2\pi n_2 I_0} \frac{P}{\ell_{\text{Kerr}}} \tag{14}$$

In a Ti:sapphire laser, $n_2 = 10.5 \cdot 10^{16}$ cm^2/W; the crystal length is typically $\ell = 4$ mm, and a well-designed laser can produce a train of 10 fs pulses with an intracavity average power of the order of 10 W. These numbers can be used in Eq. (14) to determine the negative cavity dispersion k''_{av} required for stable laser operation.

How Unequally Spaced Modes Lead to a Perfect Frequency Comb The physical reason for a non-zero carrier to envelope offset f_0 is the dispersion of the laser cavity in which a pulse is circulating. The components of the laser cavity impose different group velocities on the pulse. We can define an average group velocity $v_g = P/\tau_{RT}$ of the pulse envelope, where P represents twice the length of a linear cavity, or the perimeter of a ring cavity. That group velocity is different from the phase velocity c/n_{av} (n_{av} being the linear index of refraction averaged over the laser components). The two quantities are related by

$$\frac{1}{v_g} = \frac{n_{\text{av}}}{c} + \frac{\omega}{c} \frac{dn_{\text{av}}}{d\Omega}\bigg|_{\omega} \tag{15}$$

Note that these quantities n_{av} and v_g are function of the spectral frequency of the pulse. The "ideal mode-locked laser" considered in this section already poses a conceptual dilemma. Mode-locking is generally described as putting the modes of a laser cavity in phase. If the cavity has dispersion, we have seen that the mode-comb issued from the laser does not start at zero frequency but with a frequency offset f_0. Keeping in mind that a cavity with dispersion has unequally spaced modes, is contradictory to the fact that the frequency comb has rigourously equally spaced teeth.* To resolve this apparent contradiction, we will look at the pulse train formation, and discuss how an initially irregular set of modes can lead to a perfect frequency comb.

As shown above, a minimum negative cavity dispersion k''_{av} is required for stable mode-locked operation. Such a cavity dispersion implies that the index of refraction n_{av} is frequency (wavelength) dependent, hence the spacing of the cavity modes $c/[n_{\text{av}}(\Omega)P]$ varies across the pulse spectrum.

The laser is modeled by a circulating pulse, which enters a Kerr medium of thickness ℓ, resulting in phase modulation at each passage, and a medium that represents the linear dispersive properties of the cavity. We will assume that the balance of gain and losses maintains a constant Gaussian shape for the envelope of the circulating pulse. At each passage through the cavity, the phase of the pulse is modified in the time domain through the Kerr effect, and in the frequency domain through dispersion. We consider first the modulation in the time domain:

$$\varphi(t) = -k_{NL} \ell_{\text{Kerr}} = -\frac{2\pi n_2 \ell_{\text{Kerr}}}{\lambda} I_0 e^{-2(t/\tau_G)^2} \tag{16}$$

*A fact that has been verified experimentally with millihertz accuracy.[4]

where τ_G is the $1/e$ half-width of the pulse electric field envelope (the FWHM of the intensity is $\tau_p = \sqrt{2\ln 2}\tau_G$). Ignoring at this point the influence of dispersion (which will be introduced after Fourier transformation into the frequency domain), the pulse *train* issued from the laser can be represented by

$$\sum_{q=0}^{\infty} \varepsilon(t-\tau_q) e^{iq\varphi(t-\tau_q)} e^{i\omega t} \tag{17}$$

where τ_q is the time of arrival of the center of gravity of the successive pulses. At this point τ_q is not set to any value. It is assumed here that at $t = 0$, the first pulse is unmodulated. Using a parabolic approximation for the Gaussian intensity profile, the time-dependent phase is

$$\varphi(t-\tau_q) \approx \frac{4\pi n_2 I_0 \ell_{\text{Kerr}}}{\lambda}\left(\frac{t-\tau_q}{\tau_G}\right)^2 = a\left(\frac{t-\tau_q}{\tau_G}\right)^2 \tag{18}$$

The Fourier transform of the pulse train given by Eq. (17) is

$$\varepsilon(\Delta\Omega)\left[\sum_{q=0}^{\infty} e^{i\Delta\Omega\tau_q} e^{iq\Delta\Omega^2\tau_k^2}\right] \tag{19}$$

where

$$\begin{aligned} \Delta\Omega &= \Omega - \omega \\ \varepsilon(\Delta\Omega) &= \frac{\varepsilon_0\sqrt{\pi}\tau_G}{\sqrt[4]{1+a^2}} \exp\left\{-\frac{\Delta\Omega^2\tau_G^2}{4(1+a^2)}\right\} \\ \tau_k^2 &= \frac{a\tau_G^2}{4(1+a^2)} \end{aligned} \tag{20}$$

The width of the Gaussian pulse spectrum, broadened by the Kerr effect, is the inverse of the characteristic time τ_k. Let us now take dispersion into account. The operation representing the dispersion of the cavity is a product of the spectral field by $\exp[-ik_{\text{av}}(\Delta\Omega)P]$, where $-k_{\text{av}}(\Delta\Omega)P^*$ is the phase change per round-trip. The combined Kerr effect and dispersion, in the frequency domain, leads to the output spectral field:

$$\varepsilon_{\text{out}}(\Delta\Omega) = \varepsilon(\Delta\Omega)\left[\sum_{q=0}^{\infty} e^{i\Delta\Omega\tau_q} e^{iq\Delta\Omega^2\tau_k^2} e^{-iqk_{\text{av}}(\Delta\Omega)P}\right] \tag{21}$$

Expanding the wave vector $k_{\text{av}}(\Delta\Omega)$ in series, to second order:

$$\begin{aligned} k_{\text{av}}(\Delta\Omega)P &= k_{\text{av}}(\Delta\Omega=0)P + \Delta\Omega k'_{\text{av}}P + \frac{\Delta\Omega^2}{2}k''_{\text{av}}P \\ &= k_{\text{av}}(\Delta\Omega=0)P + \Delta\Omega\tau_{RT} + \frac{k''_{\text{av}}P}{2}\Delta\Omega^2 \end{aligned} \tag{22}$$

*In the argument of k_{av}, the light frequency ω is taken as origin ($\Delta\Omega = 0$) of the frequency scale.

where the derivatives k'_{av} and k''_{av} are calculated at the light frequency $\omega(\Delta\Omega=0)$. Note that $k'_{av}=1/v_g=\tau_{RT}/P$ [cf. Eq. (15)] are material properties independent of the index q, as is the cavity perimeter P. The modes of the cavity are not equally spaced. The parameter k'' characterizes the departure from equal spacing. Substituting (22) in Eq. (21),

$$\mathcal{E}_{out}(\Delta\Omega)=\mathcal{E}(\Delta\Omega)\left[\sum_{q=0}^{\infty}e^{i\Delta\Omega(\tau_q-q\tau_{RT})}e^{iq\Delta\Omega^2(\tau_k^2-k''_{av}P/2)}\right] \tag{23}$$

The conditions

$$\tau_k^2=-\frac{k''_{av}P}{2} \tag{24}$$

$$\tau_q=(q+1)\tau_{RT} \tag{25}$$

leads to modes that are exactly equally spaced. The inverse Fourier transform of the frequency comb becomes then

$$\tilde{\mathcal{E}}_{out}(t)=\mathcal{E}(t)+\mathcal{E}(t-\tau_{RT})e^{-ik_{av0}P}+\mathcal{E}(t-2\tau_{RT})e^{-2k_{av0}P}+\cdots \tag{26}$$

This last equation corresponds indeed to the description of the ideal frequency comb, with equally spaced pulses in time and frequency, and a carrier to envelope phase shift of $\varphi_p=-k_{av0}P$. In the case of small Kerr modulation, $a<<1$, it can easily be verified that the condition in Eq. (24) is identical to the soliton Eq. (14). Indeed, substituting

$$\tau_k^2=\frac{a\tau_G^2}{4(1+a^2)}\approx\frac{4\pi n_2 I_0 \ell_{Kerr}\tau_G^2}{4\lambda}=\frac{k''_{av}P}{2} \tag{27}$$

which is indeed equivalent to Eq. (14). One can thus conclude that the mechanism that leads to an equal spacing for the teeth of the frequency comb emitted by the laser is the same Kerr effect responsible for creating maximum intracavity pulse compression.

20.3 PULSE EVOLUTION TOWARD STEADY STATE

A Simple Model

In the previous section we have considered the dispersive mechanisms that ultimately give the final shape in amplitude and phase to the steady-state pulse. This mechanism dominates in the subpicosecond regime, where dissipative mechanism have reached equilibrium. Other elements play a decisive role in initiating the mode-locking, which are usually referred to as the passive mode-locking elements. The latter can most often be represented by intensity-dependent intracavity loss. Larger losses at low intensity imply that the laser has less gain—and may be below threshold—for low-intensity continuous wave (cw) radiation than for pulses with higher peak intensity. This leads to the emergence of a pulse out of the amplified spontaneous emission noise of the laser. Rather than concentrating on the primary process of formation of a precursor of a pulse from random noise, let us follow the evolution of the pulse from its birth from noise until it has blossomed into a fully shaped stable laser pulse. In this intermediate stage of the evolution toward steady state, the main shaping elements are dissipative, as opposed to the purely dispersive interaction considered in the previous section. We will look for simple evolution equations for the pulse energy $W=\int_{-\infty}^{\infty}I(t)dt$, with $I(t)$ being the pulse intensity. The element responsible for saturable losses (gain) should have

typically a *linear* loss (gain) factor at low energies, and a *constant* loss (gain) at higher energies. We thus have, at low energies: $dW/dz = \mp\alpha W$. At large energies $W \gg W_s$: $dW/dz = \mp W_s$ where W_s is the saturation energy for the chosen geometry. The simplest differential equation to combine these two limits is

$$\frac{dW}{dz} = \alpha_g W_{sg}\left[1 - e^{W/W_{sg}}\right] \tag{28}$$

Equation (28) is written for a medium with a linear gain α_g and a saturation energy W_{sg}. It can be integrated to yield the energy W_2 at the end of the amplifier of thickness d_g, as a function of the input energy W_1:

$$W_2 = G(W_2, W_1)W_1 = W_{sg} \ln\left\{1 - e^{\alpha_g d_g}(1 - e^{W_1/W_{sg}})\right\} \tag{29}$$

A similar equation applies to the saturable absorber, with a negative absorption coefficient $-\alpha_a$ and a smaller saturation energy W_{sa}:

$$W_2 = A(W_2, W_1)W_1 = W_{sa} \ln\left\{1 - e^{\alpha_a d_a}(1 - e^{W_1/W_{sa}})\right\} \tag{30}$$

The dominant linear loss element is the output coupler, with (intensity) reflectivity r. The transfer function for that element is simply

$$W_2 = L(W_2, W_1)W_1 = rW_1 \tag{31}$$

and the energy of the output pulse is $(1-r)W_1$. The evolution of the pulse energy in a single round-trip can be simply calculated from the product of all three transfer functions given by Eqs. (29), (30), and (31). For instance, if we consider a ring laser with the sequence: mirror, gain, and absorber, the pulse energy W_4 after the absorber is given by the product $A(W_4, W_3)G(W_3, W_2)L(W_2, W_1)$. One can also express the relation between the energy W_4 and the pulse energy W_1 before the output mirror by the algebraic relation:

$$1 + a[e^{W_4/W_{sa}} - 1] = \left\{1 + g[e^{rW_1/W_{sg}} - 1]\right\}^{W_{sg}/W_{sa}} \tag{32}$$

where $a = \exp\{-\alpha_a d_a\}$ is the *linear* small-signal attenuation of the passive element and $g = \exp\{\alpha_g d_g\}$ is the *linear* small-signal amplification.

High-Gain Oscillators

Unlike laser amplifiers, where it is desirable to use a gain medium with as high a saturation energy density as possible, mode-locked oscillators will often use high-gain laser media. These are opposite requirements: the larger the amplification cross section σ_g, the larger the gain $\alpha_g = \Delta N \sigma_g$, and the smaller the saturation energy density $W_s = \hbar\omega/(2\sigma_g)$. Both numbers a and g can be large, and the reflectivity of the output coupler r can be even lower than 50 percent. Examples are dye lasers, semiconductor lasers with tapered amplifiers, and to a smaller extend the T:sapphire laser. As a result, the order of the elements matters in the design of the laser, and in its performances. To illustrate this point, let us assume that the passive element is totally saturated in normal operation. In full saturation, the input energy $W(0)$ is related to the output energy $W(d)$ by

$$W(d) = W(0) - \alpha_a d_a W_{sa} \tag{33}$$

Given an initial energy W_1, the energy W_4 for a single passage through three different sequences of the same elements is given below. For the sequence mirror-absorber-gain

$$e^{W_4/W_{sg}} = 1 - g\left[1 - e^{(rW_1 - \alpha_a d_a W_{sa})/W_{sg}}\right] \tag{34}$$

For the sequence absorber-mirror-gain

$$e^{W_4/W_{sg}} = 1 - g\left[1 - e^{r(W_1 - \alpha_a d_a W_{sa})/W_{sg}}\right] \tag{35}$$

For the sequence absorber-gain-mirror

$$e^{W_4/W_{sg}} = \left\{1 - g\left[1 - e^{(W_1 - \alpha_a d_a W_{sa})/W_{sg}}\right]\right\}^{1/r} \tag{36}$$

Let us take a numerical example for a high-gain system such as the flash-lamp pumped Nd: glass laser, with $W_{sa}/W_{sg} = 0.1$, $\alpha_a d_a = 1$, $\alpha_g d_g = 1.5$ and output coupling of $r = 0.5$. For an initial energy $W_1/W_{sg} = 0.5$, we find for the sequence absorber-mirror-gain $W_4/W_{sg} = 0.689$, and for the sequence absorber-gain-mirror $W_4/W_{sg} = 0.582$. The order of the elements, the relative saturation of the gain to that of the passive element, as well as the output coupling influence the stability and output power of the laser, as shown in Ref. 5. The evolution of the pulse in the cavity can be calculated by repeated applications of products of operations such as $A(W_4, W_3)G(W_3, W_2)L(W_2, W_1)$ for the sequence (passive element, gain, output coupler), starting from a minimum value of W_1 above threshold for pulsed operation, and recycling at each step the value of W_4 as the new input energy W_1. Figure 4 shows the growth of intracavity pulse energy as a function of the round-trip index j, for different orders of the elements. The initial pulse energy is 1 percent of the saturation energy W_{sg} in the gain medium. The saturation energy and optical thickness of the absorbing medium are, respectively, $W_{sa} = 0.8W_{sg}$ and $\alpha_a d_a = 1.2$. The linear gain is $\alpha_g d_g = 1.5$ and the output coupling $r = 0.8$.

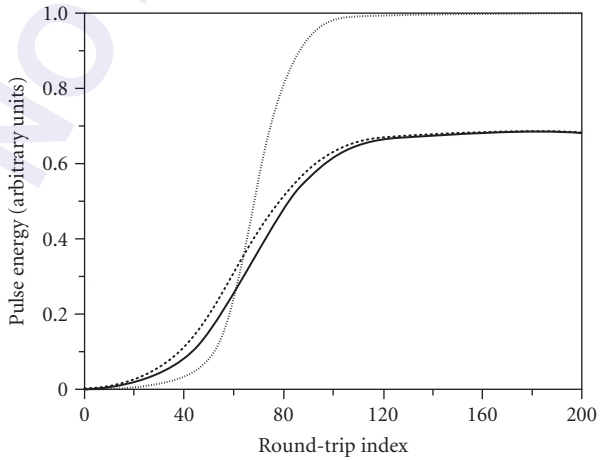

FIGURE 4 Intracavity pulse energy versus round-trip index j. The solid, dashed, and dotted lines correspond to the sequence m(irror)–a(bsorber)–g(ain), a–g–m and a–m–g, respectively.

The main point of this exercise is that the order of the elements is important, a fact confirmed by measurement on moderate-gain lasers such as Ti:Al_2O_3. Such dependence on the order of the elements indicates that analytical theories based on the approximation of infinitesimal change per element and per cavity round-trip are not quite adequate. Numerical codes have been developed that attempt to include all physical phenomena affecting pulse shape and duration. Unfortunately, the shear number of these mechanisms makes it difficult to reach a physical understanding of the pulse-generation process, or even identify the essential parameters. Therefore, the most popular approach is to construct a simplified analytical model on a selected mechanism.

20.4 COUPLING CIRCULATING PULSES INSIDE A CAVITY

Pulse Train Interferometry

A pulse train combines the temporal resolution of a single pulse, and the spectral resolution of a cw beam. It is therefore not surprising that new interferometric technique can be developed exploiting these properties.

Because the ratio of pulse duration to the period of the train is generally less than $1{:}10^5$, interferences of pulse trains of different repetition rates will not be considered here. We will instead focus on a situation where two pulse trains of identical repetition rate, but different carrier to envelope phase, are made to interfere. It will be shown in the next section how pulse trains of identical repetition rate are generated. The experimental arrangement for pulse train interferometry is depicted in Fig. 5. The two pulse trains are combined by a beam splitter, and their relative delay adjusted in an optical delay line, in order to have superposition of the pulse envelopes on the detector. If the carrier to envelope phase is identical for both pulse trains, the detector will simply register a constant signal, with an amplitude dependent on the relative phase of the two trains at the detector.

If instead the two pulse trains have a different carrier to envelope phase, successive pulses will interfere differently. The envelope of the interfering pulse trains, as seen by the detector, will be modulated at the frequency $f_{01} - f_{02}$, where f_{01} and f_{02} are the carrier to envelope offsets of either pulse trains.

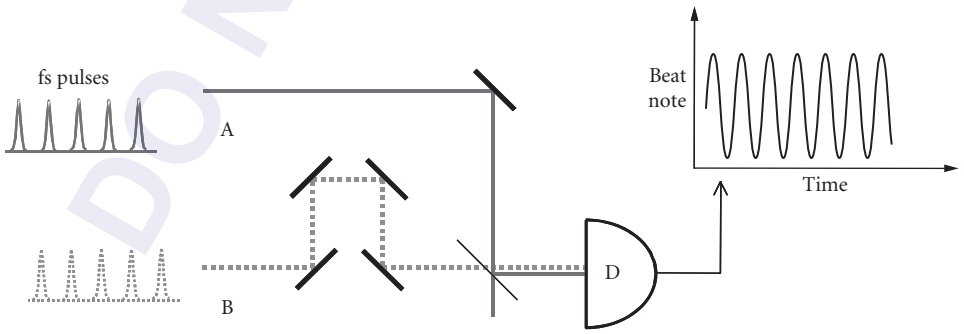

FIGURE 5 Interference of two pulse trains of the same repetition rate. An optical delay line is required to ensure temporal overlap of the pulses in either train.

Interwoven Pulse Trains Generated by Two Intracavity Pulses

We have seen the interference of pulse trains. These can be generated by a laser cavity. Inside the laser, there are then two or more pulses circulating in the cavity. The interactions of these two pulses will determine the relative properties of the pulse trains. The common picture of the mode locked laser is that of a resonator cavity with gain in which a single pulse circulates. It is interesting to consider, both from the point of view of fundamental understanding of the laser operation and applications to sensors, the situation where several pulses circulate in the cavity. Mode-locking with multiple pulses/round-trip is sometimes referred to as "harmonic mode-locking" 6–10. Techniques of harmonic mode-locking have been developed for telecommunications, where a pulse rate of over a GHz is desirable. The fundamental clock remains the round-trip time, which may typically be of the order of 100 MHz. If there are m pulses in the cavity, there will be m values of interpulse delay, which, in the frequency domain, will mean some splitting of the modes, which, is small, may be seen as a slight broadening of the tooth of the comb.

In the following we will consider only the case of two pulses circulating in the cavity, separated exactly by half the cavity round-tip time. Such a situation is encountered in bidirectional ring lasers, but also in linear cavities. Of particular interest is to determine the type of coupling that may or may not exist between the two pulses, and the resulting correlation between the two pulse trains. As will be the case in most sensor applications,[11] we will assume in the following that the two pulses experience a relative shift in phase δ at each round-trip.

Locking Two Pulse Trains by Backscattering

Whether in a ring or linear laser, the two circulating pulses will meet at two points of the cavity. Unless the meeting point is in vacuum, there will be some coupling introduced by the medium in which the pulses meet. The most common case is that of a medium with random scattering. Using the plane wave description of Eq. (2), the backscattering component $\tilde{r}_{ij} = r\exp(\theta_{ij})$ of scattering will couple the pulse with field envelope $\tilde{\varepsilon}_j$ into the pulse with field envelope $\tilde{\varepsilon}_i$:

$$\begin{aligned}\frac{\partial\tilde{\varepsilon}_1}{\partial t} &= i\frac{\delta}{2\tau_{RT}}\tilde{\varepsilon}_1 + \frac{1}{\tau_{RT}}\tilde{r}_{12}\tilde{\varepsilon}_2 \\ \frac{\partial\tilde{\varepsilon}_2}{\partial t} &= \frac{1}{\tau_{RT}}\tilde{r}_{21}\tilde{\varepsilon}_1 - i\frac{\delta}{2\tau_{RT}}\tilde{\varepsilon}_2\end{aligned} \tag{37}$$

Of particular interest here is the impact of the coupling on the phase of the two fields, since the balance of saturable gain and losses will in general restore a steady-state value of the pulses energy. Expressing the fields in terms of amplitude and phase as in Eq. (2) in the system of Eqs. (37), and taking the difference of the imaginary parts, yields:

$$\frac{\partial(\varphi_2-\varphi_1)}{\partial t} = \frac{\partial\psi}{\partial t} = \frac{\delta}{\tau_{RT}} + \frac{r}{\varepsilon_1\varepsilon_2\tau_{RT}}[\varepsilon_1^2\sin(\theta_{21}-\psi) - \varepsilon_2^2\sin(\theta_{12}+\psi)] \tag{38}$$

In the absence of coupling ($r = 0$), the carrier frequency of the two pulses would differ by $\dot{\psi} = \delta/\tau_{RT}$, a frequency difference that can easily be detected by beating the two output pulse trains of the laser (corresponding to either pulse in the cavity) against each other on a detector.

Distributed Backscattering In presence of a sufficient coupling $r \neq 0$, there is generally a solution $\partial\psi/\partial t$ to Eq. (38), such that the two circulating pulses are identical, only differing by a phase factor. If we take for instance the particular case of $\theta_{12} = \theta_{21} = 0$, the constant phase difference is ψ_0 given by

$$\sin\psi_0 = \frac{2\varepsilon_1\varepsilon_2}{\varepsilon_1^2+\varepsilon_2^2}\frac{\delta}{2r} \tag{39}$$

Any backscattering such that

$$r \geq \frac{\delta\varepsilon_1\varepsilon_2}{\varepsilon_1^2+\varepsilon_2^2} \tag{40}$$

will lock the carrier frequency of the two waves to each other. This implies that the mode frequencies, the repetition rates, and the CEO of the two pulse trains are identical.

Interface Coupling A reciprocal backscattering, where $\theta_{12} = \theta_{21}$ is the norm when dealing with distributed scattering of a solid, liquid, or gaseous medium.[12,13] The situation is different however in a short pulse laser, where the meeting points of the two pulses are localized rather than being distributed over the whole length of the laser resonator. In the case of the mode-locked laser, the backscattering can be due to an interface, in which case $\tilde{r}_{21} = -\tilde{r}_{12}^* = -\tilde{r}^*$; and $\theta_{21} = \theta_{12} + \pi = \theta + \pi$. This type of coupling does not prevent lock-in, since Eq. (38) becomes

$$\frac{\partial\psi}{\partial t} = \frac{\delta}{\tau_{RT}} - \frac{r}{\varepsilon_1\varepsilon_2\tau_{RT}}[\varepsilon_1^2+\varepsilon_2^2]\sin(\theta+\psi) \tag{41}$$

which, for sufficient large r, still has a lock-in solution ψ_0 for which $\partial\psi/\partial t = 0$.

Phase Conjugated Coupling Not all couplings lead to identical mode frequencies of the two output pulse trains of the laser. In a phase conjugated coupling, a fraction r_c of the complex conjugate of one field is coupled into the other field. Such a phase conjugated coupling[14] does preserve the phase identity of each intracavity pulse. The coupled equations for the two pulses are then

$$\begin{aligned}\frac{\partial\tilde{\varepsilon}_1}{\partial t} &= i\frac{\delta}{2\tau_{RT}}\tilde{\varepsilon}_1 + \frac{r_c}{\tau_{RT}}\tilde{\varepsilon}_2^* \\ \frac{\partial\tilde{\varepsilon}_2}{\partial t} &= \frac{r_c}{\tau_{RT}}\tilde{\varepsilon}_1^* - i\frac{\delta}{2\tau_{RT}}\tilde{\varepsilon}_2\end{aligned} \tag{42}$$

Subtracting the imaginary parts of this equation:

$$\frac{\partial\psi}{\partial t} = \frac{\delta}{\tau_{RT}} \tag{43}$$

and there is no "lock-in" possible with this type of coupling.

Repetition Rate Coupling It has been observed that the repetition rate in both directions can be locked by a saturable absorber. The mechanism by which the average group velocity of the two pulses are locked to each other is described below. This mechanism leaves the carrier frequencies of the two pulses uncoupled.

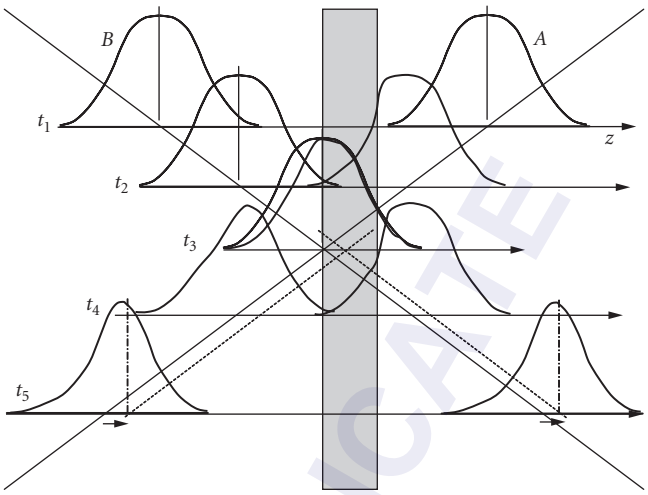

FIGURE 6 Representation of the intracavity pulses entering a saturable absorber. The pulses are plotted as a function of space (z) at successive times. The saturable absorber is initially at the left of the pulse crossing point. Because of mutual saturation, there is only significant absorption when only one of the pulses is present in the absorber. Therefore, the leading edge of pulse A is attenuated more, resulting in an apparent slowing down of the pulse. Similarly, the trailing edge of pulse B is absorbed more, resulting in an apparent acceleration of that pulse. The effect of the absorption combined with mutual saturation is to "pull" the pulse crossing point toward the center of the absorber.

To appreciate this envelope coupling, let us consider a saturable absorber of smaller longitudinal dimensions than the optical pulse, as sketched in Fig. 6. In the figure, the meeting point of the two pulses is on the left of the saturable absorber. Therefore, the pulse A entering from the left enters first the absorber, and its leading edge is attenuated. The absorption is saturated when the two pulses meet in the absorber. The pulse B coming from the left is still partly in the absorber when pulse A has left the absorber. Therefore, its tail will be more absorbed. The net effect is a shift of the center of gravity of both pulses, such that at the next round-trip they will meet closer to the middle of the absorber.

20.5 DESIGNS OF CAVITIES WITH TWO CIRCULATING PULSES

The properties of interwoven intracavity pulses have been discussed in the preceding sections. A few examples of laser cavity designs where two pulses are circulating independently are presented next.

Ring Dye Laser

In a bidirectional ring laser, two pulses circulate in opposite direction. The first realization was a dye laser,[15,16] in which the gain is provided by a jet of Rhodamine 6G in ethylene glycol (pumped by an argon ion laser). A saturable absorber jet of DODCI* has three functions: (i) to mode-lock the laser,

*Di-oxa-di-carbo-cyanide-iodide.

(ii) to ensure bidirectional operation of the laser, and (iii) to define and maintain the pulse crossing point of the envelopes. Bidirectional operation is favored over unidirectional operation because, for the same pulse energy and duration, a single pulse will suffer more intracavity losses than two pulses creating a standing wave by crossing in the absorber.[3] The pulse crossing point is set and maintained by the mechanism just described in Section "Locking Two Pulse Trains by Backscattering". The saturable absorber has to be located approximately 1/4 cavity perimeter ($P/4$) away from the gain jet, in order for each counter-circulating pulse to enter the gain medium at equal time interval ($P/2c$). The phase difference per round-trip between the clockwise (CW) and counter-clockwise (CCW) pulses is measured by combining the CW and CCW pulses on a detector.

Ti:Sapphire Ring Laser with Saturable Absorber

A similar cavity configuration has been used with a Ti:sapphire laser as a gain medium, and a saturable absorber jet of HITCI* for repetition rate synchronization between the two counter-circulating pulses. A sketch of such a cavity is shown in Fig. 7.

The nonlinear index of the gain medium results in a lensing effect, which can be approximated by a positive lens colocated with the gain medium. In mode-locked operation, Kerr lensing induces a positive lens at the location of the gain medium, which modifies the beam size distribution. For the empty cavity, the beam size versus position is represented by the solid line in the graph of Fig. 8. The beams size distribution modified by the self-lensing in the gain rod is indicated by the dotted line in the figure. An aperture located at the position A_1 will favor mode-locked operation, since the losses will decrease with intensity. An aperture located at A_2 will create increasing losses with intensity. This negative feedback stabilizes the mode-locked laser operation. Kerr lensing, which could be considered as an instantaneous saturable absorption,[3] is the technique commonly used to generate the shortest pulses with Ti:sapphire lasers. It is however not a preferred technique for achieving stable bidirectional operation, when, as is typically the case, the active element for Kerr lensing is the gain medium. There is a competition in the gain medium between mutual Kerr lensing, favoring bidirectional operation (with the pulses crossing in the gain medium) and mutual gain saturation favoring unidirectional operation, with the latter generally dominating. An experimental study of a Kerr-lens mode-locked Ti:sapphire laser[18] showed unidirectional operation, switching direction periodically (approximately every 0.1 second). The operation became bidirectional after insertion of a dilute saturable absorber jet inside the cavity.[18]

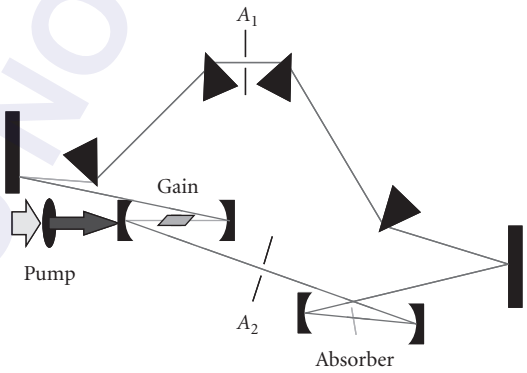

FIGURE 7 Ti:sapphire mode-locked ring laser mode-locked with a saturable absorber jet. Four prisms are used for the control of cavity dispersion.[17]

*Hexa-methyl-indo-carbo-cyanide-iodide.

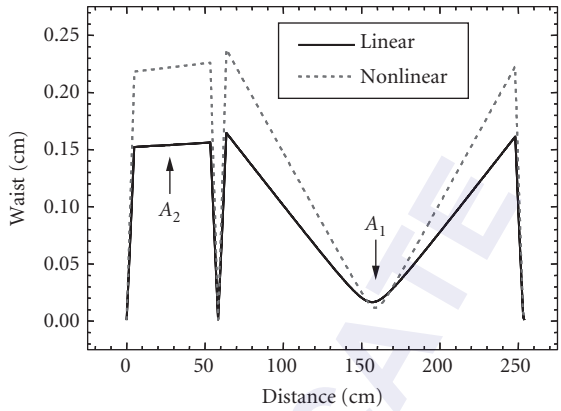

FIGURE 8 Calculation of the cavity mode as a function of position along the cavity, for the empty cavity (solid line) and the cavity modified by nonlinear lensing at the position of the gain medium (dotted line).

The use of a liquid saturable absorber flowing at high velocity (several meters per second) through a narrow nozzle (typically 100 μm thick and 5 mm wide) is essential to ensure the absence of phase coupling between the two pulses. If the saturable absorber were a nonmoving solid, the coupling by scattering would result in a mutual locking of the carrier frequency of the two pulses, as discussed in section "Locking Two Pulse Trains by Backscattering." In the case of the moving fluid of the absorbing dye jet, θ_{12} and θ_{21} are both random functions of time, varying much faster than ψ. Over the time scale that the variation of ψ is negligible, the last terms of Eq. (38) average to zero. Therefore, the dead band has been eliminated, as has been verified experimentally.[19]

Ring Laser with Additional Kerr Crystal

Another technique to achieve bidirectional operation for a Kerr-lens mode-locked laser[20,21] is to insert a nonlinear crystal (for which the nonlinear phase shift is larger than that produced in the gain medium) 1/4 cavity perimeter away from the gain medium. The laser cavity is sketched in Fig. 9.

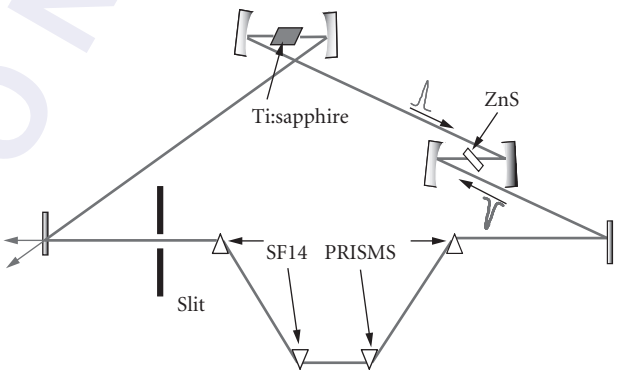

FIGURE 9 Ring laser mode-locked with a nonlinear crystal (ZnS).

The modification to the nonlinear index of refraction due to two counter-propagating fields of direction *i* and *j* is

$$n_2^i = n_2(I_i + 2I_j) \tag{44}$$

The factor 2 on the right hand side of Eq. (44) reflects the well-known act that cross-phase modulation is twice as effective as self-phase modulation for the same intensity.[22] Assuming equal intensity in the counter-propagating fields and similar waists for single pulse operation versus bidirectional operation yields the following approximate relationship for the nonlinear index of refraction in the ZnS crystal for single pulse (unidirectional) versus double pulse (bidirectional) operation:

$$\Delta n_{\text{bidirectional}} \sim \frac{3}{2}\Delta n_{\text{single}}\left[\frac{\text{interaction length}}{\text{crystal length}}\right] \tag{45}$$

Because the overlap region of the pulse envelopes is approximately the pulsewidth/*c*, the mutual Kerr-lens will dominate only if the length of the Kerr medium is not much longer than the pulsewidth. Depending on the pulsewidth and crystal thickness, there may be enough nonlinearity to distinguish between single-pulse operation and bidirectional operation. To enhance the mutual Kerr effect, a crystal of ZnS was chosen, because its nonlinear index is 50 times larger than that of Ti:sapphire.[21] Pulses as short as 60 fs were generated, meeting in the ZnS crystal used as a nonlinear element. Because the two countercirculating pulses have different intensities, a differential phase shift between the two directions results in a difference of cavity modes of 60 kHz. In addition to the relative shift of the modes, this laser system has the additional complexity that the center of spectral envelope of either countercirculating pulse is shifted by 2 nm.

Imperfection in the ZnS crystal used as nonlinear element resulted in coupling of the beams by scattering. The amount of coupling can be measured through the spectrum of the beat note of the two pulse trains. Such a spectrum shows for instance a fundamental at 60 kHz and harmonics at 120 kHz and 180 kHz. Such a spectrum can lead to the lock-in frequency between the two beams,[23] which in the case of the experiment cited is 1.8 kHz.[21]

Linear Lasers

Considering the ring laser sketched on the top of Fig. 7, it is possible to visualize stretching the cavity by the two mirrors at the extreme left and right, while keeping the perimeter constant. The limit of the stretched out ring is a linear cavity in which two pulses circulate.

As an example, let us consider a linear cavity used to measure with high accuracy the electro-optic coefficient.[24] The laser cavity is similar to the typical linear cavity mode-locked Ti:sapphire laser, but with a saturable absorber (a jet of HITCI dye dissolved in ethylene gylcol) placed in the center of the cavity, as sketched in Fig. 10. As in the case of the ring laser discussed above, Kerr-lens mode-locking does not appear to be possible with double pulse operation. Instead, a saturable absorber is positioned in the middle of the cavity by translating one of the end mirrors. The distance that the end mirror can be translated while maintaining double pulses is about 2 cm, in excess of the pulse length of approximately 0.6 mm (2-ps pulses). The 2-cm distance is a 120-ps delay and corresponds to the lifetime of the dye. The dye concentration is not a critical parameter and can be varied over a broad range without affecting the performance of the laser. The 140-MHz output from one end of the laser, detected on a fast photodiode, is filtered, its frequency divided by 2 in an ECL logic. The resulting 70-MHz signal is which yielded a 70-MHz sinusoidal signal. Finally the signal is amplified again and applied to synchronize the measurement to be performed. In the case of measurement of an electro-optic coefficient, the 70-MHz signal is applied directly to electrode on the crystal to be measured, in parallel with a 50-ohm terminator.[24]

Whether to use a ring or linear cavity depends on the quantity to be measured. The ring laser is sensitive to rotation, and to fresnel drag in one of its arms.[25] Without any rotation or modulation a

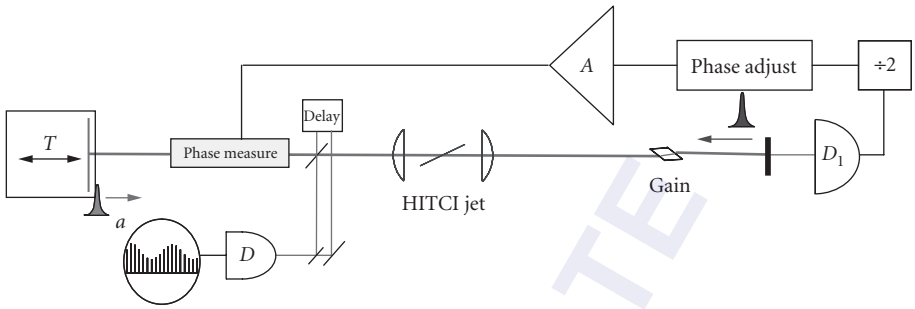

FIGURE 10 Linear laser mode-locked with a saturable absorber to produce two pulses/cavity round-trip. The end mirror on the left is on a translation stage *T*, in order to set the position of the saturable absorber in the middle of the cavity. The saturable absorber is a jet of HITCI dissolved in ethylene glycol, between two focusing elements. The output pulse train, recorded on a photodiode, reduced to half frequency, is used to synchronize a phase measurement. Each of the two intracavity pulses experience a different phase shift per round-trip, hence a different carrier frequency. The two intracavity pulses are extracted from the cavity with a beam splitter, and recombined after an appropriate optical delay. The two interfering pulse trains show a beat signal on the detector *D*.

mode-locked ring laser normally has a beat frequency offset of at least 100 Hz and often as high as 100 kHz.[26] This is a result of the asymmetry in the CW and CCW pulse. Because of the nonlinear intracavity elements, the order in which the pulse encounters the optical elements will affect the pulsewidth and pulse amplitude.[3,27,28] Any variation in pulse amplitude or pulsewidth will be seen as a beat signal. Since the pulses in a linear cavity travel through the same optical elements in the same order, there is no asymmetry. Therefore, one advantage of a linear cavity versus a ring geometry is the improvement in the frequency offset.

As the electronic delay of the signal applied to the sample is varied, the beat note shows a sinusoidal dependence, as shown in Fig. 11, which is a plot of the beat frequency versus the delay. The optimum timing occurs when one pulse sees a voltage on the sample of $+V_0$ and the second pulse sees a voltage of $-V_0$ at the sample. The line plotted in Fig. 11 is not a fit, but a plot of $V_0\left|\sin\left(\frac{2\pi c}{2L}\tau-\phi_0\right)\right|$, where the fixed phase ϕ_0 was the only free parameter.

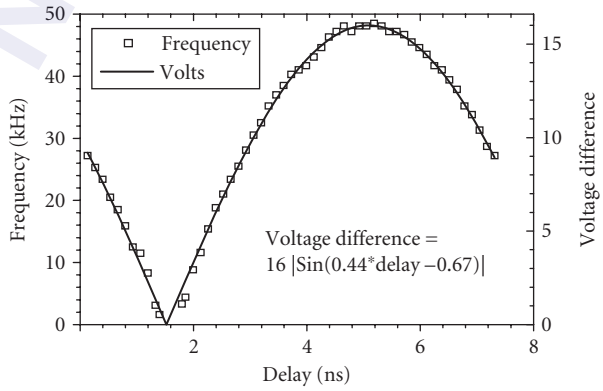

FIGURE 11 Delay dependence of the beat note frequency.

Optical Parametric Oscillators

The coupling between oppositely circulating beams in a ring laser is eliminated if a laser operates with ultrashort pulses* circulating in opposite direction and crossing in a nonscattering medium such as vacuum or air. It is however quite a challenge to find means to couple the pulse envelopes, without introducing any phase coupling. One solution described in the previous sections is to couple the pulses in amplitude in a medium that moves transversally to the beam, such as a jet of liquid saturable absorber. Another solution is the synchronously pumped optical parametric oscillator (OPO), which offers the possibility to decouple relative phase and repetition rates of the oscillating signals, without the need for any moving element.

A simple configuration is that of an OPO-pumped extracavity by a Ti:sapphire mode-locked laser, as sketched in Fig. 12. The position of the crossing point of the two circulating pulses in the OPO is simply determined by the timing of the pump pulses, rather than by a saturable absorber[19] or a nonlinear crystal.[21] The mode frequencies are still set by the cavity. Another advantage over other systems is the tunability, which is important for applications such as detecting ultra low magnetic fields, where the laser radiation has to be tuned to a narrow atomic transition.

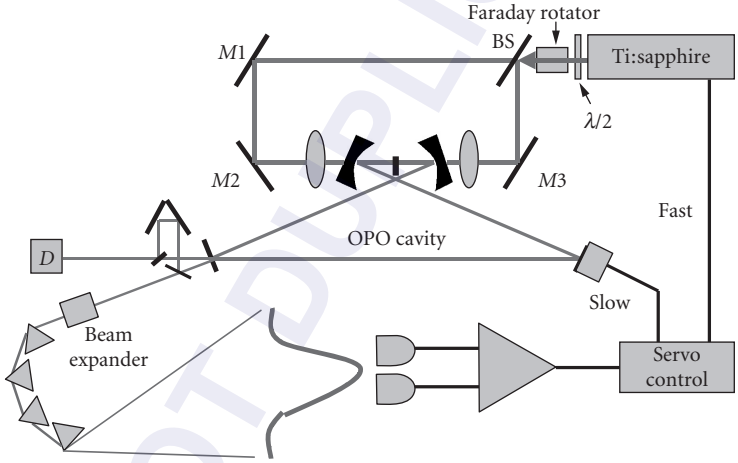

FIGURE 12 Illustration of the OPO cavity pumped by the Ti:sapphire laser. The reflected and transmitted parts of the beam splitter BS are focused into the periodically poled lithium niobate crystal via the two branches of an antiresonant ring. The beams should destructively interfere at the antiresonant ring output, which is monitored with a CCD. Since all the radiation is, in exact alignment, reflected back into the laser, a two-stage optical isolator is required to prevent disruption of the mode-locked operation. The nonlinear crystal is a 0.8-mm-long periodically poled lithium niobate (PPLN) crystal with a period of 19.75 μm, temperature stabilized at 353 K to prevent photorefractive damage and achieve quasi-phase-matching condition for generation of a signal of 1.35 μm with an average power of 30 mW per direction. The difference between the two optical paths from the beam splitter to the crystal determines the crossing point of the signal pulses in the OPO cavity. The two output pulses are made to interfere on a detector *D* after an optical delay line brings them in coincidence. A four-prism sequence sends the pulse spectrum onto a pair of detectors. The difference between the two detected signals is amplified and applied to a piezo to stabilize the cavity length.

*Pulse duration τ in the range from femtoseconds to a few picoseconds, pulse length $C\tau$ much shorter than any linear dimension in the cavity.

A periodically poled $LiNbO_3$ crystal (PPLN) is excited by a "pump pulse" at an optical frequency ω_p to provide gain at a "signal" frequency ω_s through the process $\omega_p = \omega_s + \omega_i$ where ω_i is the "idler." The OPO is an oscillator which uses the gated gain at ω_s. Therefore, as opposed to a conventional gain medium, in an OPO, the timing, direction, and position of the gain are determined by the time of arrival, k vector and focal spot location of the pump pulse in the parametric crystal. A Ti: sapphire laser provides a train of gating pump pulses of 200-fs duration at 789 nm, 143-MHz repetition rate, and 400-mW average power. The cavity of the pump laser is in a ring configuration, and operates unidirectionally. Such a configuration is less sensitive to feedback than a linear cavity. A double stage Faraday isolator (providing −60-db isolation) is still required to prevent the feedback from the OPO antiresonant ring pumping arrangement (Fig. 12)[29,30] from destroying the mode-locked operation. The sensitivity of the OPO wavelength to cavity mismatch can be exploited to stabilize the synchronously pumped OPO. Indeed, since the repetition rate of the OPO is fixed by the pump laser, the signal wavelength will adjust to a value for which the round-trip rate matches the pump rate.[31,32] As a result, any fluctuation of OPO cavity length relative to that of the pump cavity will be translated into a change in wavelength of the OPO laser. In the arrangement skeched in Fig. 12, motions of the spectrum are detected by spectrally dispersing (with 4 prisms) an expanded output from the counter-clockwise OPO beam. The signal spectrum, centered at 1.35 μm, is split into two parts and collected by a pair of lenses into two infrared photodiodes (Fig. 12). The difference signal of the two detectors monitoring two spectral components on either side of the pulse spectrum is sent through a high-gain amplifier ($\omega_{3db} = 1\,\text{kHz}$) to drive piezoelectric transducers (PZT) translating an OPO (slow servo loop) and a Ti:sapphire mirror (fast servo loop).

The beat note observed with the configuration of Fig. 12 has a bandwidth of tens of kilohertz,[33] because of the extreme (nanometer) sensitivity of the OPO to the pump spot position, as demonstrated experimentally in reference.[34] The beat note bandwidth is thus fundamentally due to fluctuations in the gain spot position for either circulating pulse, due to the beam pointing instability of the pump laser. The basic remedy is to make the two pump spots part of the same spatial mode of a cavity. One solution that has been implemented[34] is to insert the OPO crystal inside the cavity of the pump laser. Implementation of an OPO pumped intracavity by a linear Ti:sapphire laser is shown in Fig. 13. Four LaKL21 prisms are incorporated in the pump cavity to compensate the group velocity dispersion (GVD) from the Ti:sapphire crystal, the PPLN crystal, and other intracavity elements such as lenses and mirrors. This four-prisms configuration was necessitated by the desire to have large GVD compensation (needed because of the large positive GVD of $LiNbO_3$) and a reasonably short cavity length (1/2 of the perimeter of the OPO cavity). Two quantum wells (MQW) of AlGaAs on top of a mirror structure are used in the cavity as a saturable absorber to mode-lock the laser. The

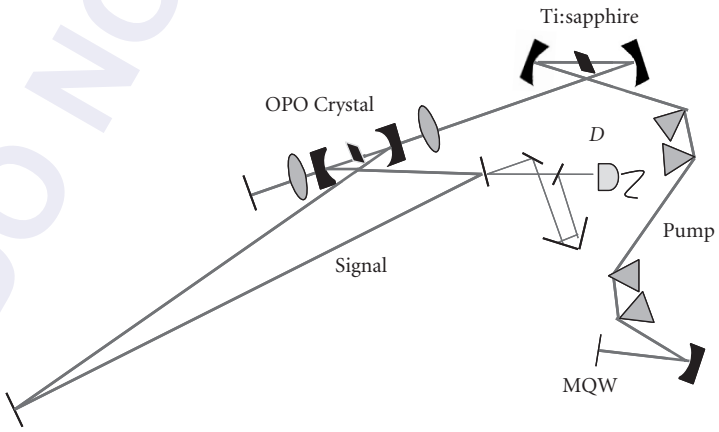

FIGURE 13 Illustration of the intracavity OPO pumped by the Ti:sapphire laser. The main control of the GVD compensation is the prism spacing L_2.

Ti:sapphire laser radiation consists of 200-fs pulses centered at 785 nm, repetition rate of 95 MHz. The OPO crystal is a 3-mm-long Brewster cut PPLN crystal (HC Photonics, Taiwan) with a period of 19.4 μm (quasi-phase matching for signal near 1.36 μm), which is temperature stabilized at 408 K to prevent photorefractive damage. Attempts to use OPO crystals cut near normal incidence and antireflection coated failed, because the Ti:sapphire mode-locked operation was prevented by the smallest feedback from the antireflection coating. This feedback problem was completely eliminated through the use of a Brewster angle cut, but at the price of a considerably more difficult alignment procedure. Because of the Brewster angle cut of $LiNbO_3$, the idler, the pump radiation and its second harmonic all exited the crystal at a different angle, and could not be used for alignment of the OPO cavity (the OPO cavity mirrors were reflecting at the signal wavelength of 1.4 μm and at the second harmonic of the pump).

20.6 ANALOGY OF A TWO-LEVEL SYSTEM

In the previous section, some methods for mode-locking a laser with two intracavity pulses were described. Inside the cavity, these two pulses can couple to each other in diverse ways which were analyzed in Sec. 20.4. The purpose of circulating two pulses in a laser cavity is that intracavity perturbations created by the quantity to be measured will alter the carrier frequency of a pulse, a shift in frequency that can easily be detected by interfering the output pulse trains. The laser itself is used as an interferometer, with the remarkable properties that the phase shift occurring in the cavity is transformed in a frequency shift. There are numerous factors influencing the accuracy as well as the sensitivity of a measurement performed intracavity. A better understanding of the two pulse per cavity laser can be reached by noting the complete analogy with a quantum mechanical two-level system. In the quantum mechanical situation an atomic or molecular system can be in one or two quantum states $|k\rangle$, with $k = 1$ and 2, of energy $\pm\omega_0/2$. Each of these states correspond to pulse $|2\rangle$ and pulse $|2\rangle$ in the laser cavity. For instance, in a ring laser, one of the states would correspond to a counterclockwise circulating pulse, the other to the clockwise circulating pulse. The interaction of a two-level system with a near resonant field is the most thoroughly studied problem in atomic and molecular physics. Techniques developed to achieve sublinewidth resolution in atomic physics may be transposed to the laser situation, and, thanks to the analogy, lead to methods to enhance the resolution of intracavity laser sensors.

Review of Coherent Interaction of Two-Level Systems

Considering the case of two level with a dipole allowed transition, in presence of a near resonant electromagnetic field $E = 1/2\tilde{\mathcal{E}}(t)\exp(i\omega t) + \text{c.c.}$ In presence of this electric field, the state of the atomic/molecular system is described by the wavefunction ψ, a solution of the time-dependent Schrödinger equation:

$$H\psi = i\hbar\frac{\partial\psi}{\partial t} \tag{46}$$

with the total Hamiltonian given by

$$H = H_0 + H' = H_0 - p\cdot E(t) \tag{47}$$

where p is the dipole moment. In the standard technique for solving time dependent problems, the wave function ψ is written as a linear combination of the basis functions $|k\rangle$:

$$\psi(t) = \sum_k a_k(t)|k\rangle \tag{48}$$

This expression for ψ is inserted in the time dependent Schrödinger Eq. (46). Taking into account the normalization conditions for the basis functions ψ_k, one finds the coefficients a_k have to satisfy the following set of differential equations:

$$\frac{da_k}{dt} = -i\omega_k a_k + \sum_j \frac{i}{2\hbar} p_{k,j}[\tilde{\varepsilon} e^{i\omega_\ell t} + \tilde{\varepsilon}^* e^{-i\omega_\ell t}]a_j \tag{49}$$

where $p_{k,j}$ are the components of the dipole coupling matrix for the transition $k \to j$, and a_k are the amplitudes of the eigenstates. Phase and amplitude relaxation have been neglected so far and will be introduced later. It should be noted that Eq. (49) is of a quite general nature, is ideally suited to numerical integration, and is not limited to two level systems. Similarly, the laser analogy can be extended to lasers with more than two intracavity pulses. We will consider here only two levels, with a very small detuning $\Delta\omega = \omega_0 - \omega \ll \omega_0$:

$$\Delta\omega = \omega_0 - \omega \tag{50}$$

Consistent with the approximation of small detuning, we replace the set of coefficients a_k, which have temporal variations at optical frequencies, by the "slowly varying" set of coefficients c_k, using the transformation:

$$a_k = e^{-ik\omega_\ell t} c_k \tag{51}$$

Inserting in the pair of Eqs. (49), leads to the pair of differential equations for the two coefficients c_k:

$$\frac{d}{dt}\begin{pmatrix} c_1 \\ c_2 \end{pmatrix} = \begin{pmatrix} i\dfrac{\Delta\omega}{2} & i\dfrac{1}{2}\dfrac{p}{\hbar}\tilde{\varepsilon} \\ -i\dfrac{1}{2}\dfrac{p}{\hbar}\tilde{\varepsilon}^* & -i\dfrac{\Delta\omega}{2} \end{pmatrix}\begin{pmatrix} c_1 \\ c_2 \end{pmatrix} \tag{52}$$

where $\kappa|\tilde{\varepsilon}| = (p/\hbar)|\tilde{\varepsilon}|$ (p being the dipole moment of the single photon transition) is the Rabi frequency.

The Laser as a Two-Level System

The two-level system considered above is isolated, hence the total population is conserved. The analogue of the electromagnetic field coupling states $|1\rangle$ and $|2\rangle$ is a conservative intracavity coupling $\tilde{r}_{12} = -\tilde{r}_{21}^*$. Such a type of coupling can only be considered in the case of mode-locked lasers, where the localization of the radiation in the cavity enables one to select a truly conservative coupling. The coupling, localized at the crossing point of the two circulating pulses, can be produced by the backscattering at a dielectric interface† between two media a and b, for which $\tilde{r}_{ab} = \tilde{r}$ and $\tilde{r}_{ba} = -\tilde{r}^*$. It can easily be verified that the total intensity change introduced by this coupling is zero, as expected for a conservative coupling. In fact, the phase relation between the two reflections at either sides of the interface is a consequence of energy conservation.

In the analogy of the laser, the coefficients $c_i(t)$ correspond to the complex field amplitudes $\tilde{\varepsilon}_i$ (the tilde indicating a complex quantity) of each pulse circulating in the ring cavity (round-trip

†In the case of a linear laser with two pulses/round-trip, the conservative coupling is only possible when there are two crossing points in the cavity, and that the interface is located at one of the crossing points.

time τ_{RT}). The state of the system is also defined by $\psi(t)=\tilde{\varepsilon}_1(t)|1\rangle+\tilde{\varepsilon}_2(t)|2\rangle$. The evolution equation of these fields are

$$\frac{d}{dt}\begin{pmatrix}\tilde{\varepsilon}_1\\ \tilde{\varepsilon}_2\end{pmatrix}=\frac{1}{\tau_{RT}}\begin{pmatrix}\tilde{r}_{11} & \tilde{r}_{12}\\ \tilde{r}_{21} & \tilde{r}_{22}\end{pmatrix}\begin{pmatrix}\tilde{\varepsilon}_1\\ \tilde{\varepsilon}_2\end{pmatrix}=\frac{1}{\tau_{RT}}||R||\cdot||E|| \tag{53}$$

In order to have an equivalence between Eqs. (52) and (53), the matrix $||R||$ should be *Anti-Hermitian*, which, in addition to the condition $\tilde{r}_{21}=-\tilde{r}_{12}^*$, imposes and that $\tilde{r}_{kk}$ be purely imaginary. It can also easily be verified that this is the only form of interaction matrix for which energy is conserved $d/dt\left(|\tilde{\varepsilon}_1|^2+|\tilde{\varepsilon}_2|^2\right)=0$. The real parts of the diagonal elements of the matrix $||R||$ represent gain and loss in the cavity. In steady state, the gain and loss are in equilibrium, and the real parts of $\tilde{r}_{kk}$ are zero. A gain (or absorber) with a recovery (relaxation) time longer than $\tau_{RT}/2$ will cause transients in population. The laser equivalent to the detuning $\Delta\omega$ is a differential phase shift for the pulses $|1\rangle$ and $|2\rangle$ in the cavity. Such a differential phase shift is introduced either by rotation in a ring laser,[15,16] or with an electro-optic modulator in a linear laser.[24] In the latter case, the electro-optic phase modulator imposes an opposite phase shift ($\Delta\phi/2$ and $-\Delta\phi/2$) for either pulse, thereby modifying the resonance of the cavity for the pulse $\tilde{\varepsilon}_1$ by $\Delta\omega/2=\Delta\phi/(2\tau_{RT})$, and for pulse $\tilde{\varepsilon}_2$ by $-\Delta\omega/2=-\Delta\phi/(2\tau_{RT})$. These detuning terms contribute to the diagonal terms of the matrix $||R||$: $\tilde{r}_{11}=-\tilde{r}_{22}=i\Delta\phi/2$.

The analogy between the laser and a two-level system applies also to the set of density matrix equations. These can be obtained by rewriting Eq. (53) in terms of the intensities in either sense of rotation $\rho_{22}=\tilde{\varepsilon}_2\tilde{\varepsilon}_2^*$ and $\rho_{11}=\tilde{\varepsilon}_1\tilde{\varepsilon}_1^*$, and the quantities $\rho_{12}=\tilde{\varepsilon}_1\tilde{\varepsilon}_2^*$ and $\rho_{21}=\tilde{\varepsilon}_2\tilde{\varepsilon}_1^*$:

$$\frac{d(\rho_{22}-\rho_{11})}{dt/\tau_{RT}}=-4\mathrm{Re}(\tilde{r}_{12}\rho_{21})-\frac{(\rho_{22}-\rho_{11})}{T_1} \tag{54}$$

$$\frac{d\rho_{21}}{dt/\tau_{RT}}=-i\Delta\omega\tau_{RT}\rho_{21}+\tilde{r}_{12}^*(\rho_{22}-\rho_{11})-\frac{\rho_{21}}{T_2} \tag{55}$$

where, as in the case of the two-level system interacting with a near resonant field, phenomenological relaxation times T_1 and T_2 have been introduced. One recognizes here Bloch's equation for a two-level system driven off-resonance by a step function Rabi frequency of amplitude $\tilde{r}/\tau_{RT}$.[35] The difference in intensities $(\rho_{22}-\rho_{11})$ is the direct analogue of the population difference between the two levels. The off-diagonal matrix element ρ_{21} is the interference signal obtained by beating the two outputs of the laser on a detector. As in the case of the two-level system, one can introduce phenomenological relaxation times T_1 for the energy relaxation (diagonal matrix element) and T_2 for the coherence relaxation (off-diagonal matrix elements). As for the quantum mechanical two-level system, $1/T_2$ is the homogeneous component of the linewidth of the beat note between the two pulse trains. There is also an "inhomogeneous" component to that linewidth, which has as physical origin the mechanical vibration of the laser components, causing random fluctuations of the beat note. Because of mechanical vibrations, each pulse sees random differences in the cavity length caused by mirror motion over a time of $\tau_{RT}/2$).

Table 1 summarizes the main points of the analogy between a laser with two pulses/cavity and the coherent interaction of a two-level system with a near resonant electromagnetic field.

Experimental Demonstration of the Analogy

The most typical manifestation of a two-level system interacting with a step function electromagnetic pulse is Rabi cycling, which is a periodic transfer of population from one state to the other. To observe such a periodic transfer, the system should be in one of the two states at $t = 0$. One method to prepare the ring laser with one state (direction) dominating, is to feedback one direction into the other outside of the cavity (Fig. 14). The output pulse from one direction is extracted, and fed back (<1 percent) with a mirror, after appropriate optical delay, into the opposite direction. By using a fast switch (turn-off time of less than the cavity round-trip time of 10 ns) at the Pockel's cell, the coupling can be turned off, to let the counter-circulating fields evolve in the cavity.

TABLE 1 Summary of the Analogy between a Two-Level System and the Laser with Two Circulating Intracavity Pulses

	Two-Level System	Laser
Basic states	$\|k\rangle; k=1,2$	$\|k\rangle\, k=1,2$
corresponding to	energy level $\pm\frac{\omega_0}{2}$	Intracavity pulses 1, 2 selected by geometry
Coupling through	Near-resonant E-field at ω	Backscattering at interface
Detuning	$\Delta\omega = \omega_0 - \omega$	$\Delta\omega = \Delta\phi\,\tau_{RT}$
Slowly varying	$\Delta\omega << \omega$	$\Delta\omega << 1/\tau_{RT}$
Wave function	$\psi(t) = a_1(t)\|1\rangle + a_2(t)\|2\rangle$	$\psi(t) = \varepsilon_1(t)\|1\rangle + \varepsilon_2(t)\|2\rangle$
Density matrix	$\rho_{kk} - a_k a_k^*$ Populations	$\rho_{kk} = \tilde{\varepsilon}_k \varepsilon_k^*$ (Intensities)
elements	$\rho_{kk} = -a_i a_j^*$	$\rho_{ij} = \tilde{\varepsilon}_i \varepsilon_i^*$ (beat signal)

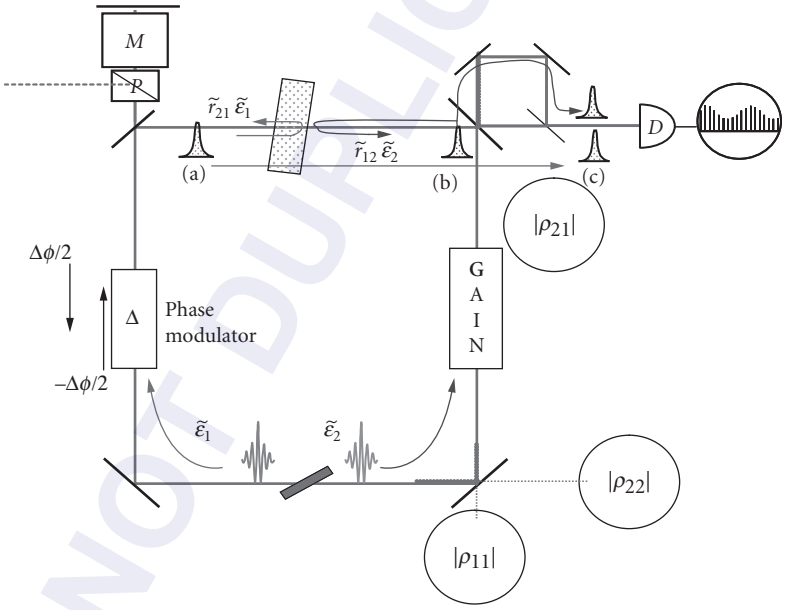

FIGURE 14 Sketch of the ring laser used to demonstrate the analogy with a two-level system. In the bidirectional mode-locked ring laser two circulating pulses meet in a saturable absorber jet. Three successive positions: (a), (b), and (c) of the two pulses are shown. An interface, positioned at or near the opposite crossing point of the two pulses, controls the amplitude of the coupling parameter $\tilde{r}_{ij}$. The circulating intensities in the laser, measured for each direction by quadratic detectors, are the diagonal elements (populations) of the density matrix of the equivalent two-level system. The absence of phase modulation corresponds to the two levels being on resonance, driven at the Rabi frequency $(p/\hbar)\varepsilon$ by a resonant field (the Rabi frequency $(p/\hbar)\varepsilon = \kappa\varepsilon$ corresponds to the frequency r_{12}/τ_{RT} in the ring laser analogy). The backscattering at the interface provides thus coherent coupling (Rabi cycling) between the two states, while other noncoherent decays tend to equalize the population in the two directions, and washes out the phase information. The detuning $\Delta\omega$ corresponds to the phase difference per round–trip $\Delta\phi/\tau_{RT}$, imposed by an electro-optic phase modulator driven exactly at the cavity round-trip time. A beat-note detector measuring the interference between the two fields, records the off-diagonal matrix element. A combination of a Pockel's cell M and polarizer P controls a feedback of the clockwise pulse into the counterclockwise one.

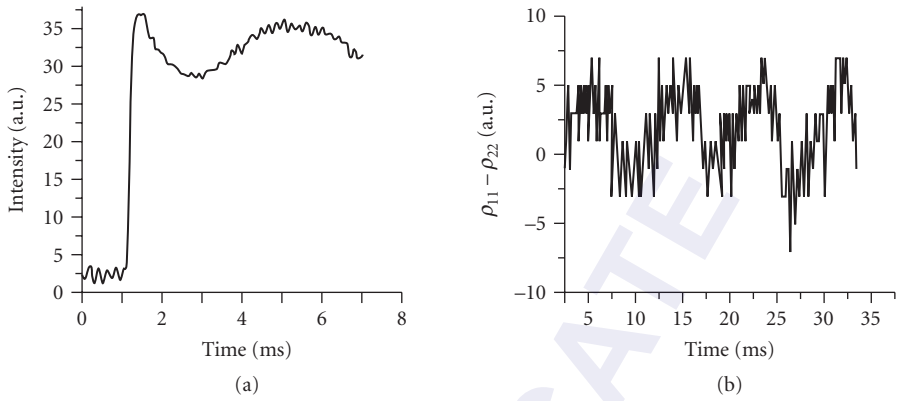

FIGURE 15 The evolution of the intensities are shown after switching the Pockels' cell. (*a*) The counterclockwise direction is shown—the intensity at clockwise direction is 180° out of phase with this graph, with population dropping from the maximum initial value. The fast initial transient reflects the gain and cavity dynamics associated with the sudden change in cavity loss at the switching time. Thereafter, a slow oscillation due to population transfer or Rabi oscillation between two directions is observed. (*b*) Population difference showing the Rabi cycling.

Rabi Cycling on Resonance In the measurements that follow, the system is "at resonance"; (i.e., $\Delta\omega = 0$). An example of "Rabi cycling" is shown in Fig. 15. The counterclockwise intensity (ρ_{22}) is plotted as a function of time [(Fig. 15*a*)]. The clockwise intensity ρ_{11} (not shown) is complementary. The system is prepared so that the ρ_{11} is initially populated ($\rho_{11} = 0.8, \rho_{22} = 0.2$). As the feedback that creates the initial state is switched off at $t = 1$ ms, there is a fast (approximately 10 μs) transient. This risetime reflects combined dynamics of the gain and cavity, as the laser adapts to the different (now symmetrical) cavity losses. This risetime corresponds roughly to the fluorescence lifetime of the upper state of Ti:sapphire. The "Rabi cycling" of the "population difference" $\rho_{22} - \rho_{11}$ is plotted in Fig. 15*b*. One can also record the beat note frequency (off-diagonal element $|\rho_{12}|$) as sketched in Fig. 14. As can easily be seen from the Bloch vector model of Feynman et al.,[35] the oscillation of the diagonal elements and the off-diagonal elements are 90° out of phase. This property can indeed be seen in Fig. 16*a*. The Rabi frequency $|\tilde{r}|/\tau_{RT}$ can be varied by changing the position of the scattering surface, as shown in Fig. 16*b*. The maximum value measured[36] for this interface corresponds to a

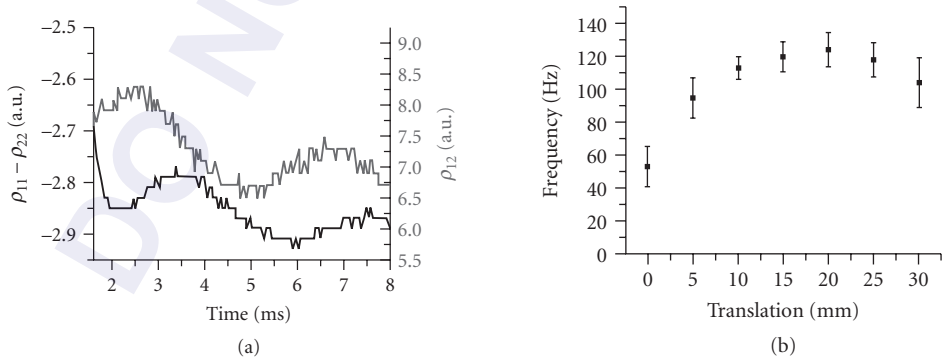

FIGURE 16 (*a*) Comparison of the oscillation of the population difference $\rho_{22} - \rho_{11}$ and the off-diagonal element (beat note) ρ_{12}. (*b*) Rabi frequency as a function of position of the glass at the meeting point of the two directions. Translation of the glass-air interface along the beam results in different values of coupling $\tilde{r}$.

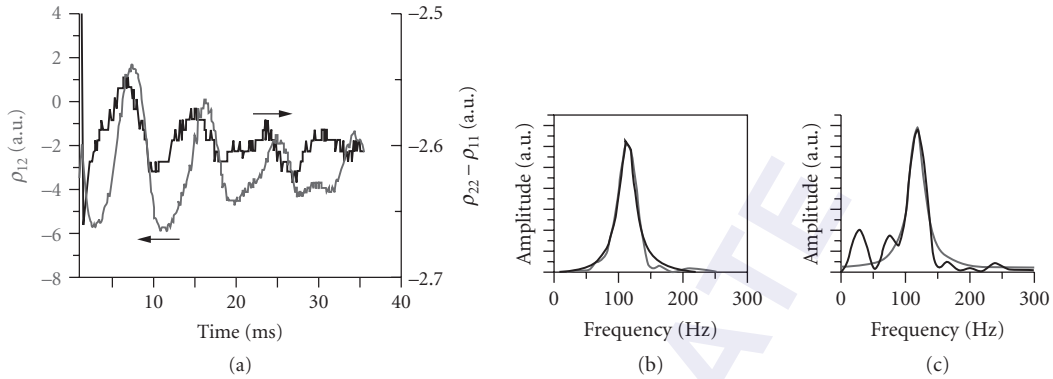

FIGURE 17 (*a*) Measurement of the decay of the Rabi oscillations $\rho_{22}-\rho_{11}$ and ρ_{21}. (*b* and *c*) The Fourier transforms of the relative measurements are shown on the right.

backscattering coefficient of $|\tilde{r}| \approx 1 \cdot 10^{-6}$. Note that the Rabi frequency provides a direct measurement of very minute backscattering coefficients, without the need to trace a complete gyroscopic response as in Refs. 36 and 37.

In the case of a two-level system, the phenomenological "longitudinal" and "transverse" relaxation times have been identified as energy relaxation time (fluorescence decay) and phase relaxation time (due for instance to atomic collisions). Figure 17 shows a measurement of the decay of the Rabi oscillation for the diagonal and off-diagonal elements. The decay is measured by fitting the Fourier transform of the measurement to a Lorentzian, and measuring its FWHM. The values are 27 and 30 Hz. As noted previously, there are at least two origins to the decay of the off-diagonal element: vibration of mirrors, and coupling through absorption (gain). The latter affects equally the diagonal and off-diagonal elements. The former can be seen as a type of "inhomogeneous broadening," since it has its origin in random cavity length fluctuation, expressed as randomness in the value of $\Delta\omega$. The approximately 30-Hz bandwidth of both decays is consistent with 0.3-μm amplitude vibrations at 100 Hz of cavity components, causing differential cavity fluctuations of 0.3 pm/round-trip.

The role of the gain coupling is particularly important in the present Ti:sapphire laser because of the long-gain recovery time. A better candidate for this analogy would be a dye or semiconductor laser for which the gain lifetime is shorter than the cavity round-trip time. An OPO provides an even better situation, since the gain exists only at the time of pumping.

Rabi Cycling Off-Resonance

If the radiation of amplitude ε (Rabi frequency $\kappa\varepsilon$) is off-resonance with a two-level system by an amount $\Delta\omega$, the Rabi frequency becomes $\sqrt{\kappa^2\varepsilon^2+\Delta\omega^2}$. In the case of the ring laser, we can control the off-resonance amount $\Delta\omega$ with a Pockel's cell (Fig. 14), the initial condition is set favorable to the counter-clockwise direction as shown in Fig. 15*a*. The Rabi cycling is measured indeed to correspond to $\sqrt{|\tilde{r}|^2/\tau^2+\Delta\omega^2}$. In resonance case $\Delta\omega=0$), measurement of ρ_{12} leads to $r/\tau_{RT}=138\,\text{Hz}\pm15\,\text{Hz}$. With $\Delta\omega$ of $171\,\text{Hz}\pm12\,\text{Hz}$, the off-resonant measurement is $r/\tau_{RT}=237\,\text{Hz}\pm21\,\text{Hz}$, which follows the behavior of an off-resonance two-level system.

Impact of the Analogy

The analogy between two-level and laser systems may be more than just a scientific curiosity. A thorough understanding of two-level systems led to powerful spectroscopic techniques, using sophisticated

pulse sequences. Rather than using optical pulses, sublinewidth molecular spectroscopy has been successfully realized by pulsing the detuning by the Stark shifts.[38–40] In the case of the ring laser, similar pulse sequences can be applied to the detuning. The information sought in spectroscopy is contained in the measurement of $|\rho_{12}|$, as a function of the driving field (measurement of the Rabi frequency $\kappa\varepsilon$ leading to the determination of the dipole moment) or detuning $\Delta\omega$. In the case of the ring laser, the measurement of $|\rho_{12}|$ is linked to the properties of some sample inserted in the cavity.[11] Any resolution enhancing technique that has been devised in spectroscopy, such as the Ramsey fringes,[41, 42] could be transposed to a laser phase sensor with two intracavity pulses.

20.7 CONCLUSION

This chapter started with a mathematical description of short optical pulses and optical pulse train. Basic physics of short pulse generation in a mode-locked laser are discussed. It is shown in particular that the mechanism by which a steady-state pulse is generated inside the laser, is also responsible for creating equally spaced modes in the frequency domain. It is shown that pulse train interferometry combines the properties of temporal and spatial resolution. The laser can be used as a most sensitive interferometer, when the reference and sample pulses are circulating in the same cavity. Measurements of extreme sensitivity can be performed by interfering the two pulse trains emitted by such a laser. The exquisite sensitivity to phase results from the fact that a phase shift is transposed into a frequency shift inside the active cavity. Exploitation of such lasers as sensors requires a thorough understanding of the coupling between the two intracavity pulses. A new modeling of the laser with two intracavity pulses is introduced by making an analogy with a quantum mechanical two-level system. Beyond its physical elegance, this analogy inspires new sensitivity enhancement techniques for the use of the two-pulse per cavity laser sensor.

21.1 GLOSSARY

A	electric field envelope of a laser pulse
E	kinetic energy of an electron in a laser field
ε_L	electric field strength of a laser pulse at a given time
$E_{\max}$	maximum kinetic energy of an electron
ε_x	electric field strength of an attosecond XUV pulse at a given time
f_0	carrier-envelope offset frequency of a frequency comb
f_{rep}	repetition frequency of a pulse train
G	temporal gate function
φ_{CE}	carrier-envelope phase (also called absolute phase) of a laser pulse
h	Planck constant
$\hbar$	Planck constant divided by 2π
I	laser
I_p	ionization potential of an atom
λ_0	center wavelength of a laser pulse
S	trace of the frequency-resolved optical gating
τ	time delay between a laser pulse and an attosecond XUV pulse
U_p	ponderomotive potential of an electron in a laser field
ν_c	frequency of the cutoff harmonic order
ω_0	carrier angular frequency of a laser pulse

21.2 INTRODUCTION

Since the invention of the laser in 1960, the duration of coherent optical pulses has decreased from hundreds of microseconds[1,2] to 6 femtoseconds in the first 27 years.[3] Such tremendous progress was driven by the desire to generate high peak power, study dynamics in matter, increase the speed of telecommunications, and many other applications. However, by the year 1987, the optical pulse length was approaching the limit, i.e., one optical cycle of visible light, which is a few femtoseconds. The bandwidth required to support such few-cycle pulses is generated by perturbative nonlinear interactions such as self-phase modulation.

The characteristic time scale of electron motion in atoms is one atomic unit of time, which is 24.2 attoseconds. One attosecond is 10^{-18} seconds. In the Bohr's model of the atom, the electron orbital time around the hydrogen nucleus is 152 attoseconds. The study of electron dynamics in atoms and molecules called for optical pulses with attosecond duration.[4–6] In the frequency domain, a transform-limited Gaussian pulse with 24 attosecond full width at half maximum (FWHM) corresponds to a 73 eV FWHM power spectrum, which is much broader than the entire visible light range. In other words, attosecond pulses are inherently XUV light or x rays. The duration of such extremely short pulses was first measured in 2001.[7,8] The required ultrabroad spectrum was obtained by using a nonperturbative nonlinear optics process called high-order harmonic generation, discovered in 1987–1988.[9,10]

High Harmonic Generation

When a linearly polarized, short-pulse laser beam with an intensity on the order of 10^{14} W/cm^2 interacts with noble gases, odd harmonics of the fundamental frequency—up to tens or even hundreds in order—emerge in the output beam,[11,12] as depicted in Fig. 1. The intensity of the first few order harmonics decreases quickly as the order increases, then the intensity remains almost unchanged over many harmonic orders, forming a plateau. Finally, the signal cuts off abruptly at the highest order. The broad width of the plateau provided the required spectral bandwidth to support attosecond pulses. The appearance of the intensity plateau is the signature of this nonperturbative laser-atom interaction, which can be described by a semiclassical model.

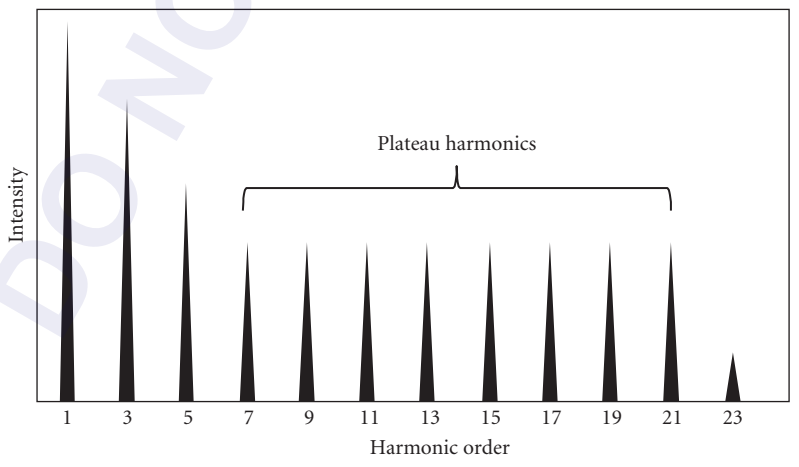

FIGURE 1 High-order harmonic spectrum.

Semiclassical Model

It is also called three-step or two-step model, rescattering model. The electric field acting on an atom changes sinusoidally within one laser cycle. As the laser intensity reaches the level of 10^{14} W/cm^2, the field near the peak of the oscillation is comparable to the atomic Coulomb field. The superposition of the laser field and the Coulomb field transforms the potential well that binds the electron into a potential barrier. As a result, the electron in the ground state tunnels through the barrier (the first step). The freed electron moves in the laser field like a classical particle and its trajectory can be calculated using Newton's second law. In one laser cycle, the electron first moves away from the nucleus, then is driven back when the force changes direction. During the returning journey, the electron can acquire kinetic energy up to hundreds of electron volts (the second step). Finally, the electron recombines with the parent ion with the emission of a photon (the third step).[13,14]

When all electrons released near one peak of a laser cycle are considered, the emitted photons form an attosecond pulse. Since there are two field maxima in one laser cycle, two attosecond pulses are generated. For a laser pulse that contains many cycles, an attosecond pulse train is produced. The pulse train corresponds to discrete harmonic peaks in the frequency domain. In other words, high harmonic generation and the attosecond pulse train are two manifestations of the same nonperturbative interaction.

The photon energy of the cutoff harmonic order, $h\nu_c$, is determined by the maximum kinetic energy of the electron gained in the laser field, $E_{\max}$. It can be shown that $h\nu_c = I_p + E_{\max} \approx I_p + 3U_p$. Here I_p is the ionization potential of the atom and U_p is the ponderomotive potential of the electron in the laser field. Apparently, the width of the plateau and therefore the minimum attosecond pulse duration is limited by $h\nu_c$. The cutoff order is also affected by the depletion of the ground state population due to the ionization.[15]

Ponderomotive Potential

The ponderomotive potential is the cycle-averaged kinetic energy of an electron in a laser field, $U_p[eV] = 9.33 \times 10^{-14} I \cdot \lambda_0^2$, where I is the laser intensity in W/cm^2 and λ_0 is the center wavelength of the laser in micrometer. It is clear that the cutoff photon energy of the high harmonic spectrum can be extended by using longer wavelength driving lasers.[16]

Strong Field Approximation

A fully quantum three-step model was developed in 1994.[17] It is valid when the ponderomotive potential is much larger than the ionization potential. It assumes that the harmonic emission is the result of the dipole transition between the ground state and the continuum states only, with the excitation states playing no role. Solving the Schrödinger equation results in an analytical solution of the dipole moment, from which one can obtain both the phase and the intensity of each harmonic order. The model reveals that there are two quantum trajectories that contribute to each plateau harmonic. One is called the long trajectory and the other is the short trajectory. The phase of each harmonic depends on the laser intensity. The intensity dependence of the dipole phase (also called intrinsic phase) is different for the two trajectories.

Quantum Trajectories

By solving the equation of motion, it can be shown that an electron released right at the peak of the laser field will return to the starting point one cycle later, with zero kinetic energy. As the releasing time from the field peak increases, the returning energy increases first, reaches the maximum value ($3\ U_p$), then decreases to zero. Therefore electrons releasing at two different moments can come back to the parent ion with the same kinetic energy, which corresponds to the same harmonic order.[13,14]

The electron that starts the journey earlier returns later. Its path is called the long trajectory. The other one is the short trajectory. Quantum mechanically, there are many trajectories contribute to each harmonics (Feynman's path-integral), but the dominating contributions are from the two trajectories corresponding to the classical ones.[17]

Phase-Matching

The semiclassical model and the strong field approximation describe the single atom response. To generate a high-intensity high harmonic beam, many atoms must contribute to the output constructively.[18] Ionization of the atom is unavoidable in high harmonic generation because it is the first step of the process. In highly ionized gas targets, the phase velocity of the laser field (and thus the polarization) is greater than that of the harmonic field. The resulting phase mismatch can be compensated for by several approaches. One of them utilizes the intensity dependent phase.[19] In most cases, only the short trajectory is phase matched. Nevertheless, low laser to harmonic conversion efficiency is still a major problem that needs to be solved. The spatial coherence of the high harmonic/attosecond train beam is excellent when the phase matching conditions are fulfilled. The divergence angle of the XUV beam is smaller than the driving laser beam.[12]

Single Isolated Pulses

The attosecond pulse train corresponding to high order harmonics is useful for some applications. In general, however, single isolated attosecond pulses are required for performing pump-probe experiments with arbitrary delay between the pump and the probe pulses. Such pulses can be generated by suppressing all the pulses in the train except one, which can be accomplished by using single-cycle driving lasers[20] or pulse extraction switches with a subcycle opening time.[21] Also the pulses from the gas target are positively chirped.[22] Dispersion compensation over a broad XUV spectral range is a major challenge. By 2008, the shortest single isolated pulses, which were generated from neon gas by using 3.3-fs driving lasers centered at 720 nm, were 80 attoseconds and contained ~0.5 nJ of energy.[23] Their spectrum was centered at 80 eV.

21.3 THE DRIVING LASER

There are several basic requirements on the driving lasers for the generation of single isolated attosecond pulses. First, the intensity at the focus must be high enough, on the order of 10^{14} to 10^{15} W/cm^2, which is a faction of an atomic unit of intensity (3.55×10^{16} W/cm^2). The corresponding pulse energy is 100 μJ or higher. The spectral bandwidth of the attosecond pulses is proportional to the driving laser intensity. Second, the laser pulse duration must be short enough. The ionization of the target atoms by the laser field before the cycle where the attosecond pulse is generated must not deplete the ground state population completely. Depending on the generation scheme, acceptable laser pulses range from 3 to 30 fs. Third, the carrier-envelope phase needs to be stabilized. Since the single attosecond pulses are generated in a faction of the laser cycle, a shift in the carrier-envelope phase results in shot-to-shot variations of the attosecond pulses. Finally, the repetition rate of the laser should be high, on the order of kilohertz. Many attosecond characterization and application schemes rely on photoelectron measurements. There is an upper limit on the number of electrons per shot to avoid the space charge effect. Thus the signal count rate is primarily determined by the repetition rate. The energy stability of high-repetition-rate lasers is also better than those with low repetition rates.

High power lasers pulses with duration around 30 fs can be generated with chirped pulse amplification. Pulses down to ~4 fs with submillijoule energy can be obtained by spectral broadening in hollow-core fibers filled with gases, followed by dispersion compensation using chirped mirrors or phase modulators,[24–27] as illustrated by the block diagram in Fig. 2.

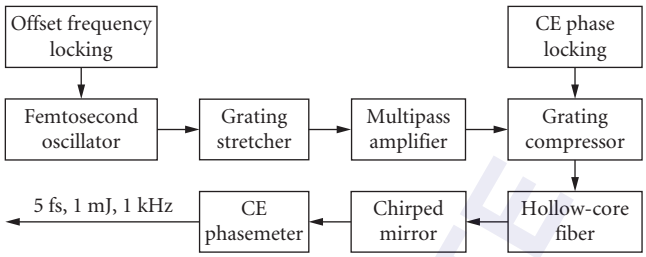

FIGURE 2 A carrier-envelop phase stabilized, few-cycle laser system.

Chirped Pulse Amplification (CPA)

Ti:Sapphire is a commonly used gain medium for femtosecond lasers primarily because of its broad gain bandwidth.[28] Its center wavelength is ~800 nm, which corresponds to a ~2.6-fs optical period. Femtosecond oscillators that use Ti:Sapphire as the gain medium can generate pulses with nanojoule level energy. Direct amplification of the pulse to millijoule level may cause damage to the laser crystal. In a chirped amplifier, the pulses from the oscillator are stretched to hundreds of picoseconds to lower the peak power. Then the pulses are amplified in multipass or regenerative amplifiers. The high energy pulses are finally compressed to femtosecond duration.[29,30] Most high energy (>5 mJ) lasers use grating pairs to stretch and compress pulses.

Carrier-Envelope Phase

The effects of the magnetic field of the laser on high harmonic generation can be ignored because the electron velocity during the three-step journey is much slower than the speed of light. The electric field of a linearly polarized laser pulse can be expressed as $\varepsilon_L(t) = A(t)cos(\omega_0 t + \varphi_{CE})$. Here $A(t)$ is the pulse envelope, ω_0 is the carrier frequency, φ_{CE} is the carrier-envelope (CE) phase that specifies the offset between the peak of the pulse envelope and the closest maximum of the oscillating field. To stabilize the carrier-envelope phase of the laser pulses from chirped pulse amplifiers followed by the hollow-core fiber compressors, the carrier-envelope offset frequency of the oscillator must first be stabilized. Furthermore, the CE phase drifts in the chirped pulse amplifier and in the hollow-core fiber compressor must be compensated.[31,32]

Carrier-Envelope Offset Frequency

The technique for stabilizing carrier-envelope offset frequency was originally developed for frequency metrology in 2000.[33,34] Most femtosecond oscillators used for seeding amplifiers work at a repetition rate f_{rep} ~80 MHz. The oscillator output is a femosecond pulse train that corresponds to a frequency comb. The frequency of the nth tooth of the comb is $f_0 + nf_{rep}$, where f_0 is the frequency of the zeroth tooth. The rate of carrier-envelope phase change is determined by the offset frequency f_0, which can be stabilized by using f-to-$2f$ technology. For this to work, the laser spectrum must cover an octave. The f_0 is measured by beating the $2n$th tooth with the frequency doubled nth tooth, that is $f_0 = 2[f_0 + nf_{rep}] - (f_0 + 2nf_{rep})$. It was found that f_0 can be stabilized by controlling the pump power to the gain medium of chirped mirror based oscillators. When f_0 is fixed to f_{rep}/m, the CE phase of every mth pulse from the oscillator is the same. It is common practice to choose $m = 4$.

Carrier-Envelope Phase of Chirped Pulse Amplifiers

The oscillator pulses with the same CE phase are switched out by a Pockels cell and sent to Ti:Sapphire amplifiers that operate at kilohertz repetition rates. When grating pairs are used to stretch and compress laser pulses for the chirped pulse amplification, a submicrometer change of separation between gratings can lead to a 2π CE phase shift.[35] This effect has been used to correct the slow CE phase variation introduced by the amplifier components. It was accomplished by measuring the CE phase variation after the amplifier and using the measured signal for feedback control of the grating separation.[36] The CE phase error of CPA systems can be controlled to <200 mrad over hours. The relative CE phase variation can be measured by a single shot *f*-to-2*f* interferometer, whereas the absolute phase value can be determined by a phasemeter (discussed below), which measures electrons from the above-threshold ionization of atoms by the laser pulses.

Single Shot *f*-to-2*f* Interferometer

The laser pulse from the hollow-core fiber compressor is a white-light continuum that can cover an octave spectral range. One can select a narrow range near 1000 nm and frequency double it to interfere with the light around 500 nm. The interferogram in the frequency domain is a sinusoidal fringe. The period of the fringe pattern is inversely proportional to the delay between the two interfering pulses. A CE phase shift will cause the fringes to shift. Thus by measuring the interferogram with a spectrometer, the CE phase variation can be measured.[37]

Carrier-Envelope Phasemeter

In the three-step semiclassical model, the attosecond photon pulses are generated by the recombination of the returning electrons. A returning electron can also scatter away from the parent ion. The kinetic energy distribution of the rescattered electrons after the laser field vanishes can extend to $10U_p$. There is also a plateau in the electron spectrum similar to the high harmonic spectrum. This electron emission process is called above-threshold ionization. The angular distribution of the electrons is concentrated along the field polarization direction. When the laser pulse is only a few cycles long, the number of plateau electrons flying to one direction can be different from those to the opposite direction. The asymmetry depends on the carrier-envelope phase of the laser. Thus, by simultaneously measuring electrons in two directions, the absolute CE phase value can be determined.[38]

21.4 ATTOSECOND PULSE GENERATION

A typical attosecond pulse generation setup consists of a kilohertz femtosecond Ti:Sapphire laser system, a vacuum chamber where the gas target is located, and an XUV spectrometer/attosecond streak camera that characterizes the pulses in the spectral domain and the time domain, as shown in Fig. 3. The attosecond pulses are XUV or soft x-ray light that cannot propagate in air because of high absorption. The gas density in the laser interaction region is on the order of 10^{17} to 10^{18} atoms/cm^3. The interaction length is typically a few millimeters for gas cells or gas jets. It should be smaller than the Rayleigh range of the focusing laser beam, so that the carrier-envelope phase does not change significantly due to the Gouy phase shift inside the target. The target is located after the focal point to achieve good phase-matching.

Attosecond Pulse Train

Such pulses are generated with linearly polarized laser pulses that contain many optical cycles. When only the fundamental frequency is used, the spacing between two neighboring harmonic

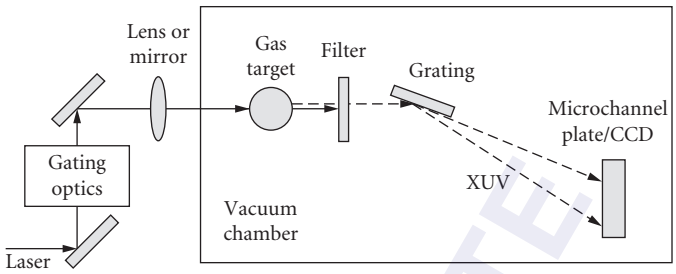

FIGURE 3 Setup for generating attosecond pulses and measuring their spectrum.

peaks is two-photon energies. In the time domain, the spacing between adjacent pulses is one-half of an optical cycle; 1.3 fs for Ti:Sapphire lasers.[7,39] The amplitude changes from pulse to pulse. Since many-cycle lasers (>20 fs) can be generated directly from high power (terawatt) chirped pulses amplifiers, the attosecond pulse energy can be high enough to perform nonlinear physics experiments.[40]

Two-Color Gating

When the many-cycle driving laser is a combination of the fundamental frequency and its second harmonic, the breaking of symmetry of the laser field leads to the generation of both odd and even high harmonics and thus the spacing between two neighboring harmonic peaks is one photon-energy. In the time domain, the spacing between adjacent pulses becomes a full optical cycle.[41] Such pulse trains are useful for performing experiments using the powerful attosecond streaking technique.

Amplitude Gating

As the driving laser approaches a single optical cycle, the cycle-to-cycle field amplitude variation becomes significant. When the carrier-envelope phase of the pump laser is set to zero, the spectrum of the attosecond pulses generated near the peak of the laser pulse envelope extends to a shorter XUV wavelength range as compared to the adjacent attosecond pulses emitted when the laser field is weaker. As a result, the high-order harmonic spectrum becomes a continuum in the cutoff region.[20] Discrete harmonics remain in other portions of the spectrum. The shorter the driving laser is, the broader the XUV continuum becomes. A single isolated attosecond pulse as short as 80 attoseconds was obtained by selecting the continuum region of the XUV spectrum with a high-pass filter, using <4-fs pump lasers.[21] The scaling of the attosecond pulse energy is limited by the maximum energy of the driving laser from the hollow-core fiber compressor. Combining this type of gating with the two-color gating can relax the requirement of the laser pulse duration.

Polarization Gating

In the plateau region, four attosecond pulses are produced in one laser cycle taking into account both the long and short trajectory's contributions. However, only the two pulses from the short trajectory can be phase matched on axis. Consequently, the spacing between pulses is still half of a laser cycle. Single isolated attosecond pulses can be extracted by a scheme called polarization gating.[21] It uses a laser field with a rapid change of ellipticity. Since XUV attosecond pulses can only be efficiently generated with linearly polarized driving fields, a single attosecond pulse is emitted if the laser field

is linearly polarized in only a short time range and elliptically polarized in the other portion of the driving pulse. The time range over which the attosecond pulse is generated is called the polarization gate. So far, single isolated XUV pulses as short as 130 attoseconds were generated with this method using 5 fs pump lasers.[42] For the same driving laser pulse duration, polarization gating has the potential to generate shorter attosecond pulses because it can create a broader continuum in the plateau region.[43]

Double Optical Gating

The few-cycle laser pulses used in amplitude gating and polarization gating are difficult to generate daily. A method called double optical gating was proposed to allow the generation of single isolated attosecond pulses with longer pump lasers.[44] It is a combination of the two-color gating and the polarization gating. A second harmonic field is added to the fundamental field in order to break the symmetry of the field and increases the spacing between the adjacent attosecond pulses to one optical cycle. When the polarization gating is applied, the polarization gate width equals one optical cycle to select one isolated XUV pulse. The depletion of the ground state population by the leading edge of the laser pulses can be significantly reduced with this scheme; as a result, multicycle lasers can be used. This scheme has been demonstrated with laser pulses as long as 20 fs. Since such lasers do not necessarily need hollow-core fiber compressors, they are much easier to operate. The laser pulse energy can also be much higher, which is important for the energy scaling of the attosecond pulses.

21.5 ATTOSECOND PULSE CHARACTERIZATION

Measurement of the optical pulse duration requires a temporal gate. For femtosecond lasers, nonlinear optics phenomena such as second harmonic generation can serve as the gating, which is the foundation of widely implemented autocorrelation and the frequency-resolved optical gating (FROG) techniques.[45] The intensity of the attosecond pulses is not high enough to generate second harmonic light yet. Most of the methods for determining the width of the attosecond pulses require the measurements of photoelectrons or ions. The XUV beam is focused to a gas target to generate the photoelectrons/ions. The charged particles are detected by a time-of-flight spectrometer. A second beam, either an XUV or an intense laser beam is also focused to the same target, overlapping spatially and temporally with the first beam. The interaction of the two pulses in the gas serves as the temporal gate. A typical setup is shown in Fig. 4, where the attosecond XUV pulses are generated in the first gas target and are measured in the second gas target. Similar apparatus have been used for studying electron dynamics in atoms.

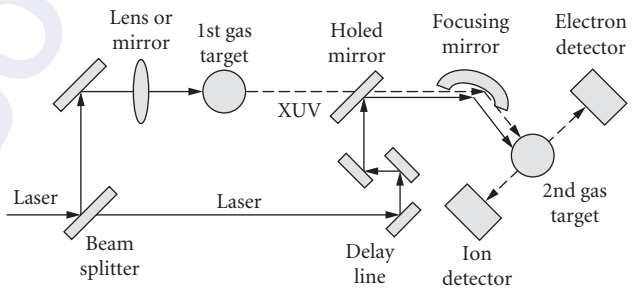

FIGURE 4 Setup for measuring the attosecond pulse duration.

Second-Order Autocorrelator or FROG

This technique resembles the second harmonic autocorrelation in femtosecond optics. Ionization of atoms (such as helium) or Coulomb explosion of molecules (such as N_2) by nonresonant two-photon absorption can serve as the nonlinearity. The ion signal as a function of the time delay between the two attosecond pulses is measured to yield the second order autocorrelation function.[40] By assuming a certain pulse shape, the pulse duration can be obtained by fitting the autocorrelation trace. The interferometric second-order autocorrelations have been used to characterize attosecond pulse trains generated with low-repetition rate femtosecond lasers with tens of millijoule pulse energy.

When the photoelectron kinetic energy spectrum is measured as a function of the delay, a two-dimensional frequency-resolved optical gating pattern is obtained. Both the phase and pulse profile of subfemtosecond pulses can be reconstructed using this method.[46]

RABITT (Reconstruction of Attosecond Beating by Interference of Two-Photon Transition)

When the attosecond pulse train is generated with the fundamental wave of kilohertz lasers, the intensity of the XUV light may not be strong enough to cause measurable nonlinear effects. A cross-correlation method based on the two-color above-threshold ionization was developed to determine the duration of the pulses in the train.[7] A high harmonic beam interacting with atomic gases alone will generate photoelectron peaks separated by two laser photon-energies. Adding a dressing laser with intensity of 10^{11} W/cm^2 generates an electron sideband located in the middle of two peaks. By measuring sideband intensity as a function of the delay between the XUV pulse and the dressing laser, relative phase between adjacent harmonics can be determined. Combining this with the high harmonic power spectrum, one can deduce the attosecond pulse duration. This approach assumes that the width of all the pulses in the train is the same.

Attosecond Streak Camera

The photoelectron replicas generated by attosecond XUV pulses have durations shorter than the optical cycle of the driving lasers. When the photoelectrons are released in the presence of a laser field, their momentum after the laser pulse is gone will be different from the initial value. The momentum shift is determined by the vector potential of the laser field at the time the electron is released. Thus, the leading edge of the electron pulse will gain an additional momentum that is different from the electron in the trailing edge. By measuring the momentum distribution of photoelectrons, the width of the photoelectron pulse (and thus the XUV pulse) can be determined.[47,48] The required laser intensity is on the order of 10^{12} to 10^{13} W/cm^2. This approach is similar to the picosecond optical streak camera. It has been used to measure single isolated attosecond pulses and the pulse trains generated from the two-color gating. It is, however, difficult to measure pulses with half laser cycle spacing with this method.

FROG-CRAB (Frequency-Resolved Optical Gating for Complete Reconstruction of Attosecond Bursts)

The momentum streaking of the photoelectrons in a laser field can also be described as the phase shift of an electron wave packet. The phase shift of the electron wave by the laser field can be considered as a temporal phase gate, $G(t)$. When the photoelectron spectrum is measured as a function of the delay τ between the XUV field $\varepsilon_x(t)$ and the laser field, a FROG trace is obtained, given by $S(E,\tau)=\left|\int_{-\infty}^{\infty} dt\varepsilon_x(t-\tau)G(t)e^{j(E+I_p)t/\hbar}\right|^2$. Here E is the energy of the photoelectron. Such a spectrogram can be processed using a FROG retrieval algorithm to fully characterize the XUV pulse as well as the electric field of the near IR laser pulse.[49,50] This method works well for measuring both attosecond pulse trains and single isolated pulses.

University of Colorado and National Institute of Standards and Technology
Boulder, Colorado

22.1 INTRODUCTION AND OVERVIEW

For laser applications in which measurement precision is a key feature, frequency-stabilized lasers are preferred, if not essential. This observation was true in the gas laser days when the 10^{-6} fractional Doppler width set the uncertainty scale. Now we have diode-pumped solid state lasers with fractional tuning range approaching 10^{-2} or more, and laser diode systems with several percent tuning. Such tuning is useful to find the exact frequency for our locking resonance, but then stabilization will be essential. Locking to cavities and atomic references can provide excellent stability, even using a widely tunable laser source. Indeed, laser frequency stability between independent systems has been demonstrated at 1×10^{-15} in 1 s averaging time, and more than a decade better at 300 seconds. This incredible performance enhancement is possible because of a feedback system, beginning from measurement of the laser's frequency error from our chosen setpoint, suitable processing of this error signal by a filter/amplifier system, and finally application of a correction signal to an actuator on the laser itself, which changes its frequency in response. While such feedback in response to performance may be the most important principle in evolution, in machines and lasers feedback enables the design of lighter, less costly systems. The accuracy is obtained, not by great bulk and stiffness, but rather by error correction, comparing the actual output against the ideal. This continuous correction will also detect and suppress the system's internal nonlinearity and noise. The performance limitation ultimately is set by imprecision of the measurement, but naturally there is a lot of care required to get into that domain: we must have a very powerful and accurate correction effort to completely hide the original sins.

This chapter is our attempt to lead the worker newly interested in frequency control of lasers on a guided tour of stabilized lasers, ideally providing enough insight for recruiting yet another colleague into this wonderful arena. As nonlinear optics becomes just part of our everyday tools, the buildup cavities which enhance the nonlinear couplings are taking on a more critical role: this is the reason that we focus on the taming of piezoelectric-based (PZT-based) systems. We then cover locking with other transducers, and present some details about their construction and use. We consider the frequency discriminator, which is a key element for these control systems. The chapter concludes with description of the design and performance of several full practical systems, including subhertz linewidth systems.

*Matthew S. Taubman is now with the Pacific Northwest National Laboratories, Richland WA.

Quantifying Frequency Stability

In thinking about the stability of our lasers, one may first wonder whether time- or frequency-domain pictures will be more powerful and instructive. Experience shows that time-domain perturbations of our lasers are usually associated with unwelcome sounds—door slamming, telephone bells, and loud voices. Eventually these time-localized troubles can be eliminated. But what remains is likely the sum of zillions of smaller perturbations: none too conspicuous, but too many in number to attack individually. This perspective leads to a frequency-domain discussion where we can add the Fourier amplitudes caused by the many little sources. Eventually we are led to idealize our case to a continuum of spectrally-described perturbations. This physical outlook is one reason we will mainly be specifying our performance measures in the frequency domain: We have already removed the few really glaring problems and now begin to see (too) many small ones.

Another important issue concerns the nifty properties of Mr. Fourier's description: in the frequency domain, cascaded elements are represented by the multiplication of their individual transfer functions. If we had chosen instead the time domain, we would need to work with convolutions, nonlocal in time. Today's result in time is the sum of all previous temporal events that have the proper delay to impact us now. So it seems clear that frequency domain is good for analysis. What about describing the results?

Frequency versus Time: Drift—the Allan Variance Method

At the other end of our laser stabilization project, describing the results, it is convenient to measure and record the frequency as a function of time. We can measure the frequency averaged over one-second gating time, for example, and stream 100 points to a file. This would be a good way to see the variations around a mean for the 1-second time intervals. This measurement could be repeated using a succession of gate times, 3 s, 10 s, 30 s, 100 s. . . . Surely it will be attractive to make this measurement just once and numerically combine the data to simulate the longer gate times. Thinking this way brings us a new freedom: we can process this data to recover more than just the mean and the standard deviation. Of course, we can expect to eventually see some drift, particularly over long times. When we look at the drift and slowly varying laser frequency, one wishes for a method to allow us to focus on the random noise effects which are still visible, even with the extended gate times. This is where the resonance physics is, while the drift is mainly due to technical problems. Dave Allan introduced the use of first differences, which has come to be called the Allan Variance method.[1] If we take the difference between adjacent samples of the measured frequency, we focus on the random processes which are averaged down to small, but not insignificant values within each gate time τ. These first differences (normalized by $1/\sqrt{2}$ to account for random noise in each entry) form a new data set which is first-order insensitive to long-term processes such as drift which dominate the directly recorded data.

Essentially the Allan Variance calculation presents us with a display of the laser's fractional frequency variation, σ_y, as a function of the time over which we are interested. At medium times, say τ of a few seconds, most laser stabilization systems will still be affected by the random measurement noise arising from shot noise and perhaps laser technical noise. At longer times the increased signal averaging implies a smaller residual fluctuation due to random processes. It is easy to show that the dependence of σ_y versus τ can be expected to be $1/\tau^{1/2}$, in the domain controlled by random (white) noise. The Allan deviation also has a great utility in compressing our statement of laser stability: we might say, for example, "the (in-)stability is 2×10^{-12} at 1 second, with the $1/\tau^{1/2}$ dependence which shows that only random noise is important out to a time of 300 s."

Allan Deviation Definition

With a counter linked to a computer, it is easy to gather a file of frequency values f_i measured in successive equal gate time intervals, t_g. Usually there is also some dead time, say t_d, while the counter-to-computer data transfers occur via the GPIB connection. This leads to a sample-to-sample time interval

of $t_s = t_g + t_d$. Allan variance is one half of the average squared difference between adjacent samples, and the usually quoted quantity, the Allan Deviation, is the square root of this averaged variance,

$$\sigma_y(\tau) = \left[\frac{1}{2(N-1)} \sum_{n=1}^{N-1} (f_{n+1} - f_n)^2 \right]^{1/2} \tag{1}$$

The dependence of σ_y upon the measuring time τ contains information essential for diagnosis of the system performance. These values for several times can be efficiently calculated from the (large) data set of frequencies observed for a fixed minimum gate time by adding together adjacent measurements to represent what would have been measured over a longer gate time. (This procedure neglects the effects of the small dead-time t_d, which are negligible for the white frequency noise $1/\sqrt{\tau}$ of usual interest but, for systems with drift and increased low-frequency noise, the dead-time effects can seriously impact the apparent results.) In any case, fewer samples will be available when the synthetic gate time becomes very long, so the uncertainty of this noise measurement increases strongly. Usually one insists on three or four examples to reduce wild variations, and so the largest synthetic gate time τ_{max} will be taken to be the total measurement time/3. For a serious publication we might prefer 5 or 10 such synthetic measurements for the last point on the graph.

The Allan Deviation has one curiosity in the presence of a distinct sinusoidal modulation of the laser's frequency: when the gate time is 1/2 the sinusoid's period, adjacent samples will show the maximum deviation between adjacent measurements, leading to a localized peak in σ_y versus τ. Interestingly, there will be "ghosts" or aliases of this when the gate time/modulation period ratio is 1/4, 1/8, and so on. For longer gate times compared with the modulation, some fractional cycle memories can be expected also. So a clean slope of –1/2 for a log-log plot of σ_y versus τ shows that there is no big coherent FM process present.

Historically, Allan Variance has been valuable in locating time scales at which new physical processes must be taken into account. For example, at long times it is usual for a laser or other stable oscillator to reach a level of unchanging σ_y versus τ. We speak of this as a "flicker" floor. It arises from the interplay of two opposing trends: the first is the decreasing random noise with increasing τ (decreasing σ_y versus τ). At longer times one sees an increasing σ_y versus τ, due to drifts in the many system parameters (electronic offsets, temperature . . .), which make our lasers lock at points increasingly offset from the ideal one. If we wait long enough, ever larger changes become likely. So for several octaves of time, the combination of one decreasing and one increasing contribution leads to a flat curve. Eventually significant drift can occur even within one measurement time, and this will be mapped as a domain of rising σ_y increasing as the +1 power of τ.

It is useful to note that the frequency/time connection of the Allan Variance transformation involves very strong data compression and consequently cannot at all be inverted to recover the original data stream in the way we know from the Fourier transform pair. However in the other direction, we can obtain the Allan Deviation from the Phase Spectral Density.[2]

Spectral Noise Density

As noted earlier, when the number of individual contributions to the noise becomes too large to enumerate, it is convenient to move to a spectral density form of representation. To carry this idea forward, two natural quantities to use would be the frequency deviations occurring at some rate and the narrow bandwidth within which they occur. To work with a quantity that is positive definite and has additive properties, it is convenient to discuss the squared frequency deviations $<(f^2_N)>$ which occur in a noise bandwidth B around the Fourier frequency f. This Frequency Noise Power Spectral Density, $S_f \equiv <(f^2_N)>/B$, will have dimensions of Hz^2 (deviation^2)/Hz (bandwidth). The summation of these deviations over some finite frequency interval can be done simply by integrating S_f between the limits of interest.

Connecting Allan Deviation and Spectral Density Sometimes one can estimate that the system has a certain spectrum of frequency variations described by $S_f(f)$, and the question arises of what Allan

Deviation this would represent. We prefer to use the Allan presentation only for experimental data. However Ref. 2 indicates the weighted transform from S_f to Allan Variance.

Connecting Linewidth and Spectral Density A small surprise is that an oscillator's linewidth generally will not be given by the summation of these frequency deviations! Why? The answer turns on the interesting properties of Frequency Modulated (FM) signals. What counts in distributing power is the Phase Modulation Index β, which is the peak modulation-induced phase shift or, equivalently, the ratio of the peak frequency excursion compared with the modulation rate. Speaking of pure tone modulation for a moment, we can write the phase-modulated field as

$$E(t) = \sin(\Omega t + \beta\ \mathrm{Sin}(\omega t))$$

$$= J_0(\beta)\exp(i\Omega t) + \sum_{n=1}^{\infty} J_n(\beta)\exp(i(\Omega + n\omega)t) + \sum_{n=1}^{\infty} J_n(\beta)(-1)^n \exp(i(\Omega - n\omega)t) \qquad (2)$$

where Ω is the "carrier" frequency, and $\omega = 2\pi f$ and its harmonics are the modulation frequencies. The frequency offset of one of these "sidebands," say the nth one, is n times the actual frequency of the process' frequency f. The strength of the variation at such an nth harmonic decreases rapidly for $n > \beta$ according to the Bessel function $J_n(\beta)$. We can distinguish two limiting cases.

Large excursions, slow frequency rate This is the usual laboratory regime with solid state or HeNe and other gas lasers. The dominant perturbing process is driven by laboratory vibrations that are mainly at low frequencies (5–200 Hz). The extent of the frequency modulation they produce depends on our mechanical design, basically how efficient or inefficient an "antenna" have we constructed to pick up unwanted vibrations. Clearly a very stiff, lightweight structure will have its mechanical resonances at quite high frequencies. In such case, both laser mirrors will track with nearly the same excursion, leading to small differential motion, i.e., low pickup of the vibrations in the laser's frequency. On the other hand, heavy articulated structures, particularly mirror mounts with soft springs, have resonances in the low audio band and lead to big FM noise problems. A typical laser construction might use a stiff plate, say 2 inches thick of Al or honeycomb-connected steel plates. The mirror mounts would be clamped to the plate, and provide a laser beam height of 2 inches above the plate. Neglecting air pressure variations, such a laser will have vibration-induced excursions $(<f^2_N>)^{1/2}$ of << 100 kHz. An older concept used low expansion rods of say 15 mm diameter Invar, with heavy Invar plates on the ends, and kinematic but heavy mirror mounts. This system may have a vibration-induced linewidth $(<f^2_N>)^{1/2}$ in the megahertz range. Only when the "rods" become several inches in diameter is the axial and transverse stiffness adequate to suppress the acceleration-induced forces. With such massive laser designs we have frequency excursions of tens to thousands of kilohertz, driven by low-frequency laboratory vibrations in a bandwidth $B < 1$ kHz. In this case $(<f^2_N>)^{1/2} >> B$, and the resulting line shape is Gaussian. The linewidth is given by Ref. 3, $\Delta f_{\mathrm{FWHM}} = [8\ \ln(2)\ (<f^2_N>)\ ]^{1/2} \cong 2.355\ (<f^2_N>)^{1/2}$.

The broadband fast, small excursion limit This is the domain in which we can usually end up if we can achieve adequate servo gain to reduce the vibration-induced FM. Since the drive frequency of the perturbation is low, it is often feasible to obtain a gain above 100, particularly if we use a speedy transducer such as an acousto-optic modulator (AOM) or an electro-optic modulator (EOM). In general we will find a noise floor fixed, if by nothing else than the broadband shot noise which forms a minimum noise level in the measurement process. Here we can expect small frequency excursions at a rapid rate, $(<f^2_N>)^{1/2} << B$, leading to a small phase modulation index. If we approximate that the Spectral Noise Frequency Density $S_f = (<f^2_N>)/B$ is flat, with the value S_f Hz^2 (deviation^2)/Hz (bandwidth), then the linewidth in this domain is Lorentzian,[3] with the $\Delta f_{\mathrm{FWHM}} = \pi S_f = \pi(<f^2_N>)/B$.

This summary of frequency-domain measures is necessarily brief and the interested reader may find additional discussion useful.[3–5] A number of powerful consequences and insights flow from reworking the above discussions in terms of a Phase Noise Power Spectral Density, $S_\phi = S_f/f^2$. The National Institute of Standards and Technology (NIST) Frequency and Time Division publishes collections

of useful tutorial and overview articles from time to time. The currently available volume[2] covers these topics in more detail. Vendors of rf-domain spectrum analyzers also have useful application notes.[6]

22.2 SERVO PRINCIPLES AND ISSUES[7,8]

Bode Representation of a Servo System

We will describe our systems by transfer functions, output/input, as a function of Fourier frequency ω. We begin purely in the domain of electronics. The amplifier gain is $G(\omega)$. The electrical feedback is represented as $H(\omega)$. Both will have voltage as their physical domain, but are actually dimensionless in that they are output/input ratios. Considering that we will have to represent phase of these AC signals, both $G(\omega)$ and $H(\omega)$ will generally be complex. It will be fundamental to view these functions with their dependence on frequency, for both the amplitude and phase response.

Imagine a closed loop system with this amplifier as the forward gain $G(\omega)$ between input V_i and output V_o. Some fraction of the output is tapped off and sent back to be compared with the actual input. For more generality we will let $H(\omega)$ represent this feedback transfer ratio. The actual input, minus this sampled output will be our input to our servo amplifier $G(\omega)$. After a line of algebra we find the new gain of the closed loop—in the presence of feedback—is

$$A_{\text{cl}} = \frac{V_o}{V_i} = \frac{G(\omega)}{1+G(\omega)H(\omega)} \tag{3}$$

A particularly instructive plot can be made for the product $G(\omega)H(\omega)$, called the "open loop gain," which appears in the denominator. In this so-called Bode plot, the gain and phase are separately plotted. Also, from inspection of Eq. (3) we can learn one of the key advantages which feedback brings us: if the feedback factor GH were >>1, the active gain G would basically cancel out and we would be left with $A_{\text{cl}} \sim 1/H$. We imagine this feedback channel will be passive, formed from nearly ideal nondistorting components. The noise, exact value of the gain, and distortion introduced by it are seen to be nearly unimportant, according to the large magnitude of $1 + GH$. Gentle amplifier overload will lead to overtone production, but could alternatively be represented by a decrease of G with signal. Since the output doesn't depend sensitively upon G anyway, we are sure these distortion products and internally generated noise will be suppressed by the feedback. We can identify the denominator $1 + GH$ as the noise and distortion reduction factor.

What is the cost of this reduced dependence on the active components $G(\omega)$ and their defects? Basically it is that the gain is reduced and we must supply a larger input signal to obtain our desired output. For a music system one can then worry about the distortion in the preamplifier system. However, we want to make quiescent lasers, without the slightest hint of noise. So it is nice that the amplification of internal noise is reduced.

To be concrete, the circuit of Fig. 1 represents a common building block in our servo design. It also represents a simple case of feedback. We show it as a current summing input node: the subtraction at the input arises here because the sign of the gain is negative. With the nearly ideal high-gain operational amplifiers now available, $G >> 1$ and we can closely approximate the closed loop gain by $1/H(\omega)$, yielding a flat gain above and a rising gain below some corner frequency $\omega_0 = 1/\tau_0$, with $\tau_0 = R_f C$. Remember $1/H(\omega)$ is the closed loop gain between V_o and V_i. To find the exact relationship between the signals V_s and V_o, we notice the related voltage-divider effect gives $V_i = (1 - H(\omega))V_s$, which leads to

$$\frac{V_o}{V_s} = -\frac{R_f}{R_i}\frac{(1+j\,\omega/\omega_0)}{j\,\omega/\omega_0} = -\frac{R_f}{R_i}\frac{(1+j\omega\tau_0)}{j\omega\tau_0} \tag{4}$$

The negative sign arises from the fact that the forward gain is negative. When the corner frequency ω_0 is chosen to be sufficiently high, we may have to consider the bandwidth issue of the OpAmp: $G(\omega)$ could

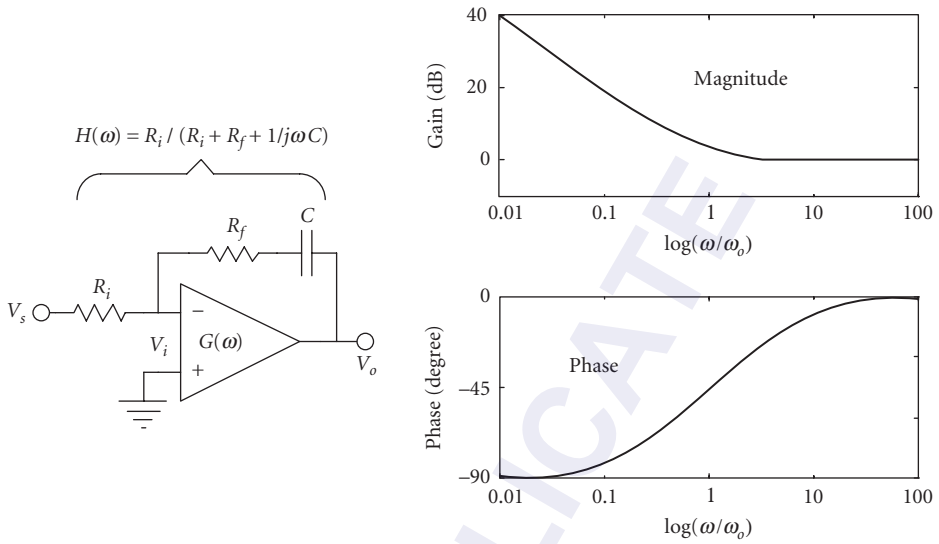

FIGURE 1 Phase and amplitude response of a Proportional-Integral (PI) amplifier circuit. The PI function is implemented using an inverting OpAmp.

start to roll off and no longer satisfy the approximation of $G >> 1$. A more complex network is needed to compensate for the gain roll-off and that is exactly the topic of feedback we wish to cover below.

Phase and Amplitude Responses versus Frequency

We can plot[9] the gain magnitude and phase of this elementary feedback example in Fig. 1, where we can see the flat gain at high frequencies and the rising response below ω_0. Our laser servo designs will need to echo this shape, since the drift of the laser will be greater and greater at low frequencies, or as we wait longer. This will require larger and larger gains at low frequencies (long times) to keep the laser frequency nearby our planned lock point. The phase in Fig. 1 shows the lag approaching 90° at the lowest frequencies. (An overall minus sign is put into the subtractor unit, as our circuit shows an adder.) The time-domain behavior of this feedback system is a prompt inverted output, augmented later by the integration's contribution.

As a first step toward modeling our realistic system, Fig. 2 shows the laser included in our control loop. The servo system's job is to keep the laser output at the value defined by the reference or setpoint input. Some new issues will arise at the high-frequency end with the physical laser, as its piezo-electric transducer (PZT) will have time delay, finite bandwidth, and probably some resonances.

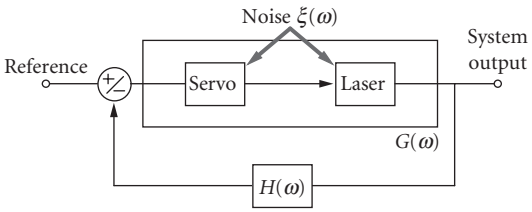

FIGURE 2 Model of laser system, including frequency noise, as part of a servo control loop.

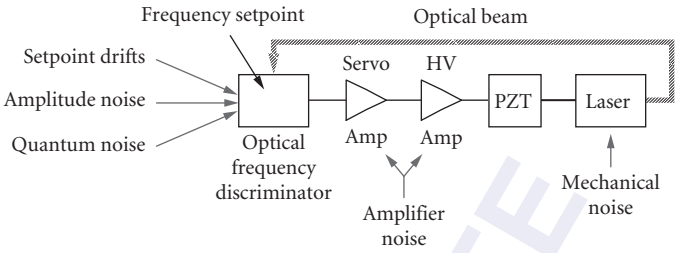

FIGURE 3 Detailed model of a frequency-controlled laser.

One way we should expand the model is to include the laser's operation as a frequency transducer, converting our control voltage to a frequency change. Probably the laser will have some unwanted frequency noises, and in Fig. 3 we can indicate their unwanted contributions arriving in the optical frequency discriminator, which functions like a summing junction. The emitted laser field encounters an optical frequency discriminator and the laser frequency is compared with the objective standard, which we will discuss below. In our diagram we show this laser frequency discriminator's role as an optical frequency–to–voltage converter element. More exactly, laser frequency *differences* from the discriminator's reference setpoint are converted to voltage outputs. Laser amplitude noises (due to the intrinsic property of the laser itself or external beam propagation) and vibration effects on the discriminator will appear as undesired additive noises also.

The first simple idea is that the feedback loop can be closed when the servo information, carried as a voltage signal in our amplifier chain, is converted to a displacement (in meters) by the PZT, then into laser frequency changes by the laser's standing-wave boundary condition. As the length changes, the "accordian" in which the waves are captive is expanded or compressed, and along with it the wavelength and frequency of the laser's light.

A second truth becomes clear as well: there is freedom in designating the division into the forward gain part and the feedback path part. Actually, we probably would like the laser to be tightly locked onto the control cavity/discriminator, and then we will tune the whole system by changing the set point, which is the discriminator's center frequency. This leads us to view the optical frequency discriminator as the summing junction, with the amplifier and PZT transducer as the forward gain part. The output is taken as an optical frequency, which would be directly compared to the setpoint frequency of the discriminator. So the feedback path $H = 1$.

We should consider some magnitudes. Let K_{PZT} represent the tuning action of the PZT transducer, expressed as displacement meter per volt. A typical value for this would be $K_{PZT} = 0.5$ nm/V. The laser tunes a frequency interval $c/2L$ for a length change by $\lambda/2$, so the PZT tuning will be ~600 V/order at 633 nm.

$$K_V = K_{PZT} \frac{2}{\lambda} \frac{c}{2L} \tag{5}$$

So we obtain a tuning sensitivity $K_V \sim 800$ kHz/V tuning for a foot-long laser, assuming a disk-type PZT geometry. See the section below on PZT design.

Measurement Noise as a Performance Limit—It Isn't

Usually our desire for laser stability exceeds the range of the possible by many orders, and we soon wonder about the ultimate limitations. Surely the ultimate limit would be due to measurement noise. However, we rarely encounter the shot-noise-limited case, since the shot noise-limited S/N of a 100 μW locking signal is $\sim 6 \times 10^6$ in a 1 Hz bandwidth. (See section on "The Optical Cavity-Based Frequency Discriminator" later.) Rather we are dealing with the laser noise remaining because our

servo gain is inadequate to reduce the laser's intrinsic noise below the shot noise limit, the clear criterion of gain sufficiency. So our design task is to push up the gain as much as possible to reduce the noise, limited by the issue of stability of the thus-formed servo system.

Closed-Loop Performance Expectations When Transducer Resonance Limits the Usable Gain

Servo Stability: Larger Gain at Lower Frequencies, Decreasing to Unity Gain and Below Our need for high gain is most apparent in the low-frequency domain ~1 kHz and below. Vibrations abound in the dozens to hundreds of hertz domain. Drifts can increase almost without limit as we wait longer or consider lower Fourier frequencies. Luckily, we are allowed to have more gain at low frequencies without any costs in stability. At high frequencies, it is clear we will not help reduce our noise if our correction is applied too late and so no longer has an appropriate phase. One important way we can characterize the closed-loop behavior of our servo is by a time delay t_{delay}. Here we need to know the delay time before any servo response appears; a different (longer) time characterizes the $1/e$ response. The latter depends on the system gain, while the ultimate high-speed response possible is controlled by the delay until the first action appears. A good criterion is that the useful unity gain frequency can be as high as $f_\tau = 1/(2\pi t_{\text{delay}})$, corresponding to 1 rad extra phase-shift due to the delay. Below this ultimate limit we need to increase the gain—increase it a lot—to effectively suppress the laser's increased noise at low frequencies. This brings us to address the closed-loop stability issue.

Closed-Loop Stability Issues

One can usefully trace the damping of a transient input as it repetitively passes the amplifier and transducer, and is reintroduced into the loop by the feedback. Evidently stability demands that the transient is weaker on each pass. The settling dynamics will be more beautiful if the second-pass version of the perturbation is reduced in magnitude and is within say ±90° of the original phase. Ringing and long delay times result when the return phasor approaches −1 times the input signal vector, as then we are describing a sampled sinewave oscillation. These time-domain pictures are clear and intuitive, but require treatment in terms of convolutions, so here we will continue our discussion from the frequency-domain perspective that leads to more transparent algebraic forms. We can build up an arbitrary input and response from a summation of sinusoidal inputs. This leads to an output as the sum of corresponding sinusoidal outputs, each including a phase shift.

In our earlier simple laser servo example, no obvious limitation of the available closed-loop gain was visible. The trouble is we left out two fundamental laboratory parasites: time delay, as just noted, and mechanical resonances. We will usually encounter the mechanical resonance problem in any servo based on a PZT transducer. For design details, see the "Practical Issues" section. A reasonable unit could have its first longitudinal resonance at about 25 kHz, with a Q ~10. In servo terms, the actual mechanical PZT unit gives an added 2-pole roll-off above the resonance frequency and a corresponding asymptotic phase lag of 180°. Including this reality in our model adds another transfer function $R_{\text{PZT}} = \omega_0^2/(\omega_0^2 + 2\omega\ \eta\ \omega_0 + \omega^2)$, where ω_0 is 2π times the resonance frequency, and $\eta = 1/2Q$ is the damping factor of the resonance. This response is shown in Fig. 4.

We now talk of stabilizing this system. The elements are the laser and some means to correct its frequency, a frequency discriminator to measure the difference between the actual and the setpoint frequencies, and a feedback amplifier. Here we propose to do the frequency control by means of a PZT transducer to change the laser frequency. For the present discussion, we assume the frequency discriminator has a flat response. For the feedback amplier, the first appealing option is to try a pure integrator. The problem then is that we are limited in gain by the peakheight of the resonance which must remain entirely below unity gain to avoid instability. In Fig. 5 case (a) we see that the unity gain frequency is limited to a value of 1.5 kHz. Some margin is left to avoid excessive ringing near the resonant frequency, but it is still visible in the time domain. Techniques that help this case include a roll-off filter between the unity gain and PZT resonance frequencies.

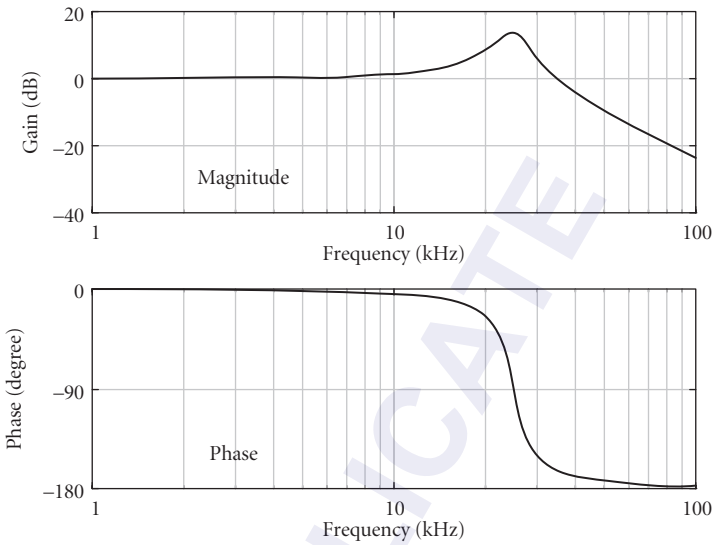

FIGURE 4 The amplitude and phase response of a tubular PZT transducer and an 8-mm-diameter by 5-mm-thick mirror. The resonance is at 25 kHz with a *Q* of 10.

Figure 5 shows the "open loop" gain function GH of the feedback equation, and the corresponding phase response. We already noted the dangerous response function of –1 where the denominator of Eq. (3) vanishes. In the time-domain iterative picture, the signal changes sign on successive passes and leads to instability/oscillation. We need to deal with care as we approach near this point in order to obtain maximum servo gain: it is useful to consider two stability margins. The *phase stability margin* is the phase of the open-loop function when the gain is unity. It needs to be at least 30°. The *gain*

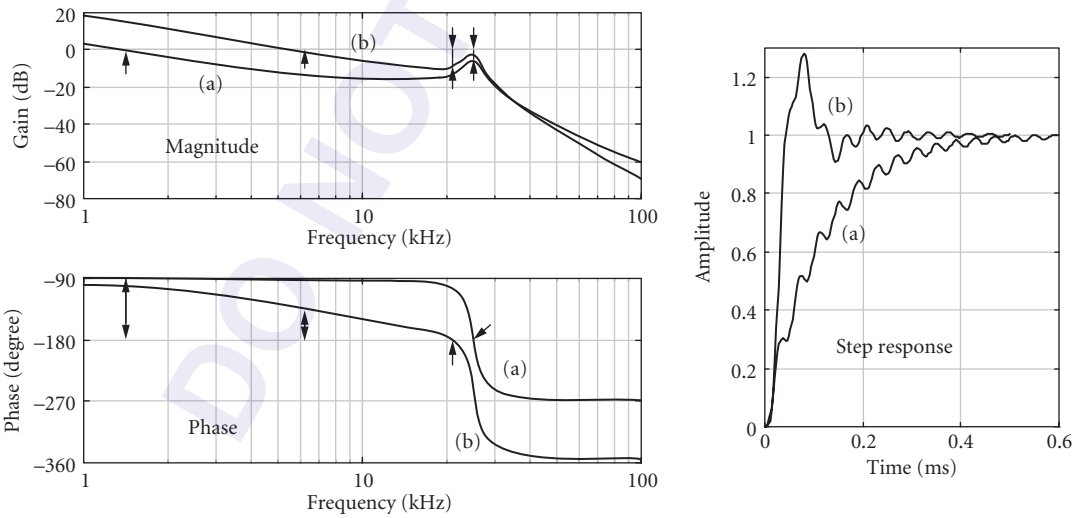

FIGURE 5 (*a*) Integrator gain function alone. Gain must be limited so that gain is <1 even at the resonance. (*b*) Single-pole low pass at 6 kHz inserted. Now unity gain can increase to 6 kHz and time response is ~3-fold faster. Small arrows in the graph indicate the phase margin at the unity gain frequency (gain = 0 dB) and gain margin at a phase shift of –180°.

margin is the closed loop gain when the phase is 180°. In Fig. 5 case (a) we see that the phase is not shifted very much until we really "sense" the amplitude increase from the resonance. So this resonance may tend to fix an apparently solid barrier to further servo improvement. But as shown in Fig 5 case (b), just a low-pass to push down the PZT resonance is very helpful.

In fact, there are many ways of improving the low frequency gain of this system. They include: (1) imposing yet another high frequency roll-off (or multi-pole low pass filter) just before the resonance thus pushing its height down and allowing the open loop transfer function to come up, (2) adding lag compensators before the resonance to push the low frequency gain up while keeping the high frequency response relatively unchanged, (3) adding a lead compensator just above the resonance to advance the phase and increase the unity gain point, (4) or placing a notch at the resonant frequency to "cut it out" of the open loop transfer function. The last two options in this list are quite promising and are discussed in more detail below.

Proportional Integral Derivative (PID) Controller versus Notch Filters Like many "absolute" barriers, it is readily possible to shoot ahead and operate with a larger closed loop bandwidth than that represented by the first PZT resonance. The issue is that we must control the lagging phase that the resonance introduces. A good solution is a differentiator stage, or a phase lead compensator, which could also be called a high frequency boost/gain-step circuit. In Fig. 6 case (a) we show the Bode plot of our PZT-implemented laser frequency servo, based on a PID (Proportional Integral Differentiator) controller design. Just a few moments of design pay a huge benefit, as the unity gain frequency has now been pushed to 40 kHz, almost a factor of 2 *above* the PZT's mechanical resonance. For this PID controller example, unity gain occurs at a 7-fold increased frequency compared with Fig. 5 case (b). Thus at the lower frequencies we would hope to have increased the servo gain by a useful factor of 7x or 17 dB. However, comparison of Fig. 5 (b) and 6 (a) shows that the low frequency gain is hardly changed, even though we greatly increased the servo bandwidth.

So, how *do* we go forward? We could in principle continue to increase the gain and unity gain frequency, but this is not really practical, however, since we will again be limited by additional structure resonances that exist beyond the first resonance. Also, the Derivatives needed to tame these resonances cost low frequency gain, and it is hard to win overall system performance. To make

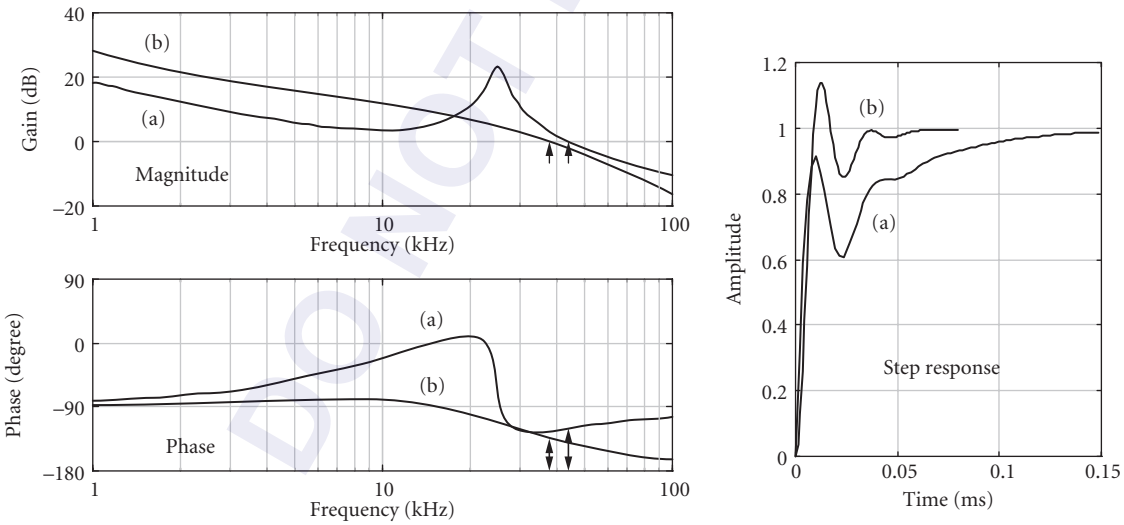

FIGURE 6 Two methods of working through and beyond a resonance. (*a*) PID controller where the Derivative term advances the phase near the resonance. (*b*) Adding a notch is a better approach, where the notch function approximates the inverse of the resonance peak. Transient response settles much more quickly. Again, we use the small arrows in the graph to indicate the phase margin at the unity gain frequency.

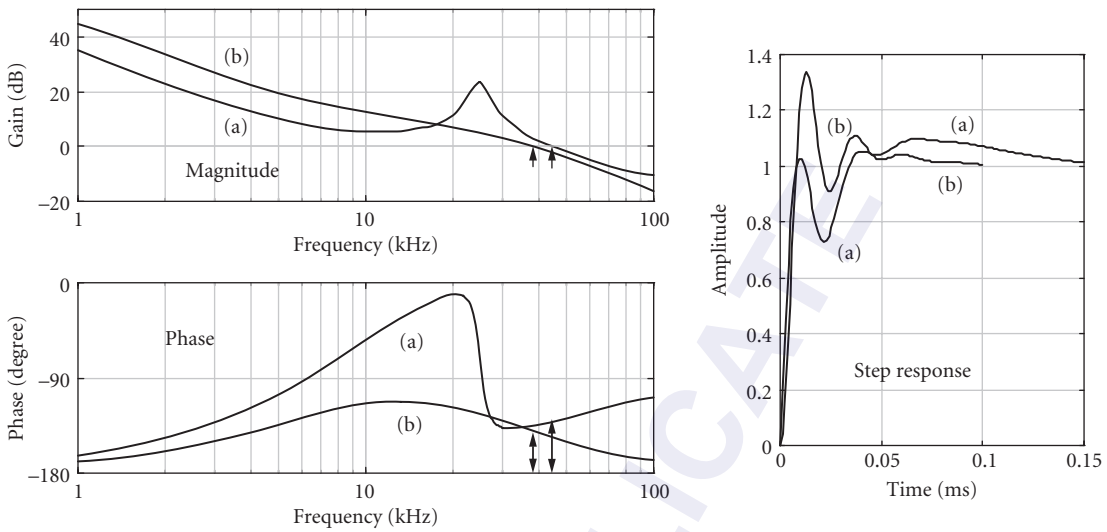

FIGURE 7 Adding an additional PI stage to (*a*) the PID and (*b*) the PI-plus-notch stabilizers of Fig. 6. Note that low frequency gain is strongly increased.

progress, we use a notch as an alternative technique to suppress the resonance. Now a D term is not needed, and we can conserve the gain at low frequencies. The notch filter, combined with a PI stage, gives unity gain at higher frequencies, and increases gain for low ones. See Fig. 6 case (b). Then Fig. 7 compares adding another PI stage to the two cases of Fig. 6, adding a PID in (a) and a Notch plus PI in (b). The time-domain approach, shown in Fig. 7, shows case (b) settles rather nicely. *And* the gain has increased more than 20 dB at frequencies of 1 kHz and below. So this is very encouraging.

While we have come to the cascaded-integrators approach cautiously in this discussion, in fact at least 2 integrators would always be used in practice. Workers with serious gain requirements, for example, the LIGO and VIRGO interferometric gravitational wave detector groups, may use the equivalent of 4 cascaded integrators! Such a design is "conditionally stable" only, meaning that the gain cannot be smoothly reduced or increased. Such aggressive stabilizer designs have their place, but not for a first design!

"Rule of Thumb" PID Design for System with a Transducer Resonance Optimizing servo performance is an elegant art, turned into science by specification of our "cost function" for the system performance shortcomings. In the case that we wish to minimize the time-integrated magnitude of the residuals following a disturbance, one comes to the case studied by Ziegler and Nichols for the PID controller used in a system with a combined roll-off and time delay.[8] Such a case occurs also in thermal controllers. With only the *P* term, one first looks for the frequency f_{osc} where the system first oscillates when the gain is increased. The PD corner is then set 1.27× higher than this $f_{osc,}$ the *P* gain is reset at 0.6 of the oscillation gain, and the PI corner is set at 0.318 times the oscillation frequency. This "rule of thumb" design of the phase compensation produces a transient response which settles reasonably well, so as to minimize the Time Integrated Error. For phase-locking lasers, a cost function with more emphasis on long-lasting errors leads to another kind of "optimum" tuning, but with qualitatively similar results.

When a notch is used to suppress the resonance, there is no longer an anomalous gain at the resonant frequency and one is returned to the same case as in its absence. A reasonable servo approach to using two PI stages is to design with only one, achieving the desired unity gain frequency. The second PI is then added to have its corner frequency at this same point or up to 10-fold lower in frequency, depending on whether we wish the most smooth settling or need the highest feasible low frequency gain. Figures 6*b* and 7 show the Bode plot of such designs, along with the system's

closed-loop transient response. An elegant strategy is to use adaptive clamping to softly turn on the extra integrator stage when the error is small enough, thus dynamically increasing the order of the controller when it will not compromise the dynamics of recovery.

22.3 PRACTICAL ISSUES

Here we offer a number of important tidbits that are useful background material for a successful application of the grand schemes discussed above.

Frequency Discriminators for Laser Locking—Overview

So far we have devoted our main effort to addressing the issues of the feedback scheme. Of equal importance is the subject of frequency reference system. After all, a good servo eliminates intrinsic noises of the plant (laser), and replaces them with the measurement noise associated with the reference system. Indeed, development of prudent strategies in high precision spectroscopy and the progress of laser stabilization have been intimately connected to each other through the years,[10] with the vigorous pursuit of resolution and sensitivity resulting in amazing achievements in both fields.

To stabilize a laser, one often employs some kind of resonance information to derive a frequency/phase-dependent discrimination signal. The resonance can be of material origin, such as modes of an optical interferometer; or of natural origin, such as atomic or molecular transitions. If the desired use of a stabilized laser is to be an optical frequency standard, its long-term stability or reproducibility will be key, so the use of a natural resonance is preferred. Reproducibility is a measure of the degree to which a standard repeats itself from unit to unit and upon different occasions of operation. The ultimate reproducibility is limited to the accuracy of our knowledge of the involved transitions of free atoms or molecules. The term "free" means the resonance under study has a minimum dependence on the laboratory conditions, such as the particle moving frame (velocity), electromagnetic fields, collisions, and other perturbations. To realize these goals, modern spectroscopy has entered the realm of quantum-limited measurement sensitivities and exquisite control of internal and external degrees of freedom of atomic motions.

A careful selection of a high-quality resonance can lead to superior system performance and high working efficiency. For example, the combined product of the transition quality factor Q and the potential signal-to-noise ratio (S/N) is a major deciding factor, since this quantity controls the time scale within which a certain measurement precision (fractional frequency) can be obtained. This importance is even more obvious when one considers the waiting time for a systematic study is proportional to the inverse square of $(Q \times S/N)$. A narrower transition linewidth of course also helps to reduce the susceptibility to systematic errors. The resonance line shape is another important aspect to explore. By studying the line shape we will find out whether we have come to a complete understanding of the involved transition and whether there are other unresolved small lines nearby ready to spoil our stabilization system.

Sometimes it may not be sufficient to use the natural resonance alone for stabilization work, or may not be necessary. The saturation aspect of the atomic transition limits the attainable S/N. To stabilize a noisy laser we need to use, for example, an optical resonator, which can provide a high-contrast and basically unlimited S/N of the resonance information. Careful study of the design and control of the material properties can bring the stability of material reference to a satisfactory level. See below for a more detailed discussion on this topic.

Ideally, a resonance line shape is even symmetric with respect to the center frequency of the resonance, and deviations from this ideal case will lead to frequency offsets. However, for the purpose of feedback, the resonance information needs to be converted to an odd symmetric discriminator shape: we need to know in which direction the laser is running away from the resonance. A straightforward realization of an error signal using direct absorption technique is to have the laser tuned to the side of resonance.[11] The slope of the line is used to convert the laser frequency noise to amplitude information

for the servo loop. This technique is essentially a DC approach and can suffer a huge loss in *S*/*N* due to the low-frequency amplitude noise of the laser. A differential measurement technique using dual beams is a requirement if one wishes to establish a somewhat stable operation. With a dual beam approach, the information about the laser noise can be measured twice and therefore it is possible to completely eliminate the technical noise and approach the fundamental limit of shot noise using clever designs of optoelectronic receivers. Conventional dual beam detection systems use delicate optical balancing schemes,[12] which are often limited by the noise and drift of beam intensities, residual interference fringes, drift in amplifiers, and spatial inhomogenity in the detectors. Electronic auto-cancellation of the photodetector currents has provided near shot noise-limited performance.[13] Although this process of input normalization helps to increase *S*/*N* of the resonance, the limitation on the locking dynamic range remains a problem. The servo loop simply gets lost when the laser is tuned to the tail or over the top of the resonance. Further, it is found that transient response errors basically limit the servo bandwidth to be within the cavity linewidth.[14] Another effective remedy to the DC measurement of resonances is the use of zero-background detection techniques, for example, polarization spectroscopy.[15,16] In polarization spectroscopy the resonance information is encoded in the differential phase shifts between two orthogonally polarized light beams. Heterodyne detection between the two beams can reveal an extremely small level of absorption-induced polarization changes of light, significantly improving the detection sensitivity. However, any practical polarizer has a finite extinction ratio (ε) which limits the attainable sensitivity. Polarization spectroscopy reduces the technical noise level by a factor of $\sqrt{\varepsilon}$, with $\varepsilon \sim 10^{-7}$ for a good polarizer. Polarization techniques do suffer the problem of long-term drifts associated with polarizing optics.

Modulation techniques are of course often used to extract weak signals from a noisy background. Usually noises of technical origins tend to be more prominent in the low frequency range. Small resonance information can then be encoded into a high-frequency region where both the source and the detector possess relatively small noise amplitudes. Various modulation schemes allow one to compare on-resonant and off-resonant cases in quick succession. Subsequent demodulations (lock-in detection) then simultaneously obtain and subtract these two cases, hence generating a signal channel with no output unless there is a resonance. Lorentzian signal recovery with the frequency modulation method has been well documented.[17] The associated lock-in detection can provide the first, second, and third derivative type of output signals. The accuracy of the modulation waveform can be tested and various electronic filters can be employed to minimize nonlinear mixing among different harmonic channels and excellent accuracy is possible. In fact, the well-established 633-nm HeNe laser system[18] is stabilized on molecular iodine transitions using this frequency dither technique and third harmonic (derivative) signal recovery. Demodulation at the third or higher order harmonics helps to reduce the influence of other broad background features.[19] The shortcoming of the existence of dither on the output beam can be readily cured with an externally implemented "un-dithering" device based on an AOM.[20] However, in this type of modulation spectroscopy the modulation frequency is often chosen to be relatively low to avoid distortions on the spectral profile by the auxiliary resonances associated with modulation-induced spectral sidebands. An equivalent statement is that the line is distorted because it cannot reach an equilibrium steady state in the face of the rapidly tuning excitation. This low-frequency operation (either intensity chopping or derivative line shape recovery) usually is still partly contaminated by the technical noise and the achievable signal-to-noise ratio (*S*/*N*) is thereby limited. To recover the optimum signal size, large modulation amplitudes (comparable to the resonance width) are also employed, leading to a broadened spectral linewidth. Therefore the intrinsic line shape is modified by this signal recovery process and the direct experimental resolution is compromised.

A different modulation technique was later proposed and developed in the microwave magnetic resonance spectroscopy and similarly in the optical domain.[21–23] The probing field is phase-modulated at a frequency much larger than the resonance linewidth under study. When received by a square-law photodiode, the pure FM signal will generate no photocurrent at the modulation frequency unless a resonance feature is present to upset the FM balance. Subsequent heterodyne and rf phase-sensitive detection yield the desired signal. The high sensitivity associated with the FM spectroscopy is mainly due to its high modulation frequency, usually chosen to lie in a spectral region where the amplitude noise level of the laser source approaches the quantum (shot noise) limit. The redistribution of some of the carrier

power to its FM sidebands causes only a slight penalty in the recovered signal size. Another advantage of FM spectroscopy is the absence of linewidth broadening associated with low-frequency modulation processes. The wide-spread FM spectra allows each individual component to interact with the spectral features of interest and thereby preserves the ultrahigh resolution capability of contemporary narrow-linewidth lasers.

Since its invention, FM spectroscopy has established itself as one of the most powerful spectroscopic techniques available for high-sensitivity, high-resolution, and high-speed detection. The high bandwidth associated with the radio frequency (rf) modulation enables rapid signal recovery, leading to a high Nyquist sampling rate necessary for a high-bandwidth servo loop. The technique has become very popular in nonlinear laser spectroscopy,[24] including optical heterodyne saturation spectroscopy,[23] two-photon spectroscopy,[25] Raman spectroscopy,[26] and heterodyne four-wave mixing.[27] Recent developments with tunable diode lasers have made the FM technique simpler and more accessible. The field of FM-based laser diode detection of trace gas and remote sensing is rapidly growing. In terms of laser frequency stabilization, the rf sideband based Pound-Drever-Hall locking technique[28] has become a uniformly adopted fast stabilization scheme in the laser community. The resonance-based error signal in a high-speed operating regime is shown to correspond to the instantaneous phase fluctuations of the laser, with the atom or optical cavity serving the purpose of holding the phase reference. Therefore a properly designed servo loop avoids the response time of the optical phase/frequency storage apparatus and is limited only by the response of frequency-correcting transducers.

In practice some systematic effects exist to limit the ultimate FM sensitivity and the resulting accuracy and stability. Spurious noise sources include residual amplitude modulation (RAM), excess laser noise, and étalon fringes in the optical system.[29] A number of techniques have been developed to overcome these problems. In many cases FM sidebands are generated with electro-optic modulators (EOM). A careful design of EOM should minimize the stress on the crystal and the interference between the two end surfaces (using angled incidence or antireflection coatings). Temperature control of the EOM crystal is also important and has been shown to suppress the long-term variation of RAM.[30] The RAM can also be reduced in a faster loop using an amplitude stabilizer[31] or a tuning filter cavity.[32] The étalon fringe effect can be minimized by various optical or electronic means.[33] An additional low-frequency modulation (two-tone FM[34]) can be used to reduce drifts and interference of the demodulated baseline.

In closing this section, we note that a laser is not always stabilized to a resonance but is sometimes referenced to another optical oscillator.[35] Of course the working principle does not change: one still compares the frequency/phase of the laser with that of reference. The technique for acquiring the error information is however more straightforward, often with a direct heterodyne detection of the two superposed waveforms on a fast photo detector. The meaning of the fast photo detector can be quite extensive, sometimes referring to a whole table-top system that provides THz-wide frequency gap measurement capabilities.[36–38] Since it is the phase information that is detected and corrected, an optical phase locked loop usually provides a tight phase coherence between two laser sources. This is attractive in many measurement applications where the relative change of optical phase is monitored to achieve a high degree of precision. Other applications include phase-tracked master-slave laser systems where independent efforts can be made to optimize laser power, tunability and intrinsic noise.

The Optical Cavity-Based Frequency Discriminator

It is difficult to have both sensitive frequency discrimination and short time delay, unless one uses the reflection mode of operation: these issues have been discussed carefully elsewhere.[28] With ordinary commercial mirrors, we can have a cavity linewidth of 1 MHz, with a contrast C above 50 percent. We can suppose using 200 μW optical power for the rf sideband optical frequency discriminator, leading to a dc photo current i_0 of ~100 μA and a signal current of ~25 μA. The shot noise of the dc current is $i_n = \sqrt{2ei_0}$ in a 1-Hz bandwidth, leading to an S/N of ~4×10^6. The frequency noise-equivalent would then be 250 milliHertz/√Hz. If we manage to design enough useful gain in the controller to suppress

the laser's intrinsic noise below this level, the laser output frequency spectrum would be characterized by this power spectral density. Under these circumstances, according to the earlier discussion in the Introduction and Overview Section, the output spectrum would be Lorentzian, of width $\Delta\nu_{FWHM} = \pi S_f = \pi\ (0.25\ \text{Hz})^2/\text{Hz} \sim 0.8$ Hz. One comes to impressive predictions in this business! But usually the results are less impressive.

What goes wrong? From measurements of the servo error, we can see that the electronic lock is very tight indeed. However, the main problem is that vibrations affect the optical reference cavity's length and hence its frequency. For example measurements show the JILA Quiet Room floor has a seismic noise spectrum which can be approximated by 4×10^{-9} m rms/$\sqrt{\text{Hz}}$ from below 1 Hz to about 20 Hz, breaking there to an f^{-2} roll-off. Below 1 Hz the displacement noise climbs as f^{-3}. Horizontal and vertical vibration spectra are similar. Accelerations associated with these motions lead to forces on the reference cavity that will induce mechanical distortion and hence frequency shifts. To estimate the resulting frequency shift, simple approximate analysis leads to a dynamic fractional modulation of the cavity length l by the (colinear) acceleration a, as

$$\frac{\Delta l}{l}\Big|_{\text{axial}} = -\frac{\Delta f}{f} = \frac{a\rho l\varepsilon}{2Y} \tag{6}$$

where $Y \sim 70$ GPa is the Young's modulus and $\rho \sim 2.2$ gm/cm^3 is the density for the ULE (or Zerodur) spacer. The factor ε $(-1 < \varepsilon < 1\ )$ is a geometrical design factor. For example, suppose the cavity is hanging vertically, suspended from the top. Then the cavity is stretched by its weight, and $\varepsilon = 1$. Using $l = 10$ cm and a = 1 g, we expect $\Delta l/l = -\Delta f/f \sim 1.5 \times 10^{-8} \rightarrow \sim 8.7$ MHz/g, supposing $\lambda = 532$ nm. (This is equivalent to 885 kHz/ms^{-2}.) If the cavity were vertical, but supported from below, it would be in compression and $\varepsilon = -1$. Evidently there is an interesting regime in which the cavity is supported near its middle height, where there will be a strong cancelation of the net vertical length change. We return below to this case where $\varepsilon \sim 0$.

First, let us suppose our reference cavity bar is uniformly supported horizontally from a flat horizontal surface. Even in this transverse case, vertically accelerating the interferometer produces length changes through the distortion coupling between the transverse compression and lengthwise extension, the effect of "extrusion of the toothpaste." So the longitudinal displacement of Eq. (6) is reduced by this Poisson ratio $\sigma = 0.17$. Also the vertical weight now comes from the cavity's height, which is now really the spacer's diameter φ, typically about 5-fold less than the length. So we have

$$\frac{\Delta l}{l}\Big|_{\text{transverse}} = \frac{a\varphi\rho\sigma}{2Y} \tag{7}$$

We come to a predicted sensitivity then of ~300 kHz/g for vertically applied uniform force (equivalent to 30 kHz/ms^{-2}).

Some important things have been so far left out of this discussion. For one, to make a stable reference cavity the details of the mounting and cavity support can be very important, since the expansion coefficient of the metal vacuum envelope is likely three orders of magnitude greater than that of ULE near its critical temperature-stable point. To prevent the vacuum shell's dimensional expansion from causing stresses in the cavity, it makes sense to use a pendulum suspension of the cavity. With two loops around the horizontal bar, forming a dual pendulum suspension, the cavity motion is mainly restricted to the axial direction, and the horizontal acceleration forces at high frequency are filtered down. Now we have the question:

What should be the spacing B between the two suspension loops? Put them close together and the expansion of the metal outer shell has even less impact on the cavity length. But the cavity rod (or bar, or tube) now takes on a stronger static bend, which shortens the cavity and the resulting cross-term in the cosine projection leads to a first-order length response with vertical acceleration noise. Furthermore, the bending-induced misalignment of the cavity mirrors means the intracavity resonant mode will displace laterally across the mirror surface to again have the optimal standing-wave buildup. Certainly the mirrors are rather nicely polished on their surfaces, but at least one is

a curved surface. So with our greedy dream of 10^{-15} frequency stability, wiping the beam vertically across the curvature will introduce disastrous optical length changes.

What about a wider spacing of the supports? Luckily for us the "two-point suspension problem" was addressed by G. B. Airy in the nineteenth century. He established that a support-spacing-to-length ratio of $B/L = 0.577$ was an ideal design for such a suspension, as it restored the parallelism of the two end faces of the measurement bar. A series of JILA experiments explored this domain.[39] These showed a vertical acceleration sensitivity of the horizontally suspended bar of 2200 kHz/ms^{-2} at $B/L = 0.11$, reduced to 150 kHz/ms^{-2} at the Airy spacing $B/L = 0.577$. Our "theory" in Eq. (7) doesn't consider static bending of the bar, but would lead to 90 kHz/ms^{-2} if scaled for the $5.7 \times 7.1 \times 27.7$ cm dimensions of our cavity's spacer-bar (suspended with the 5.1-cm direction vertical). Regrettably, the sign of the vibration-induced response was not determined: cavity bending shortens the optical path, while vertical squeezing would lengthen it.

Integrating the acceleration produced by the mid-band floor vibration spectrum quoted above leads to a broadband noise of a few dozen hertz in both H and V planes. Left out however is the 1 milli-"g" vibration near 30 Hz due to ac motors in JILA (Pepsi refrigerators!). So we should have a vibration-induced linewidth of something like 1/2 kHz, which correlates adequately well with experience. Passive air-table antivibration measures suppress this vibration (acceleration) spectrum to $\sim 2 \times 10^{-6}$ ms$^{-2}/\sqrt{\text{Hz}}$, again roughly flat over 2 to 20 Hz band by filtering the floor's vibrational noise above ~2 Hz Fourier frequency. The calculated Fourier frequency at which the phase modulation processes have removed 1/2 the laser carrier power (approximate half-linewidth of the locked laser) is ~1 Hz, but nonmodeled noise led to experimental values more like 5 Hz. Elegant passive vibration-damping suspensions at NIST have led to record-level subhertz cavity-locked laser linewidths.[40] It has been suggested that much of the remaining noise is associated with thermal mechanical displacement noise in the mirror coatings.[41] Later measurements confirmed that the thermal noise was indeed the dominant source limiting the laser linewidth.[42]

Returning to the cavity-mounting problem, we introduced the symmetry factor ε in the axial direction, because it is clear that holding the cavity in the midplane seems wise. Then the acceleration-induced net length change would tend be cancelled: one half of the length is under compression, the other half is under tension at a particular moment in the ac vibration cycle. We denote this cancellation by symmetry as ε, with $-1 \le \varepsilon \le 1$. Some experiments were made with short vertically mounted cavities.[43] The hand-assembly of the central disk limited the observed asymmetry value for our vertical mountings to a ~20-fold reduction of the vibration sensitivity ($\varepsilon \ge 0.05$), to about ~10 kHz/ms^{-2}, measured at the Nd fundamental wavelength. It was directly possible to observe subhertz laser beats! A computer design[44] for a more optimal cavity is shown as Fig. 8.

Quantum Resonance Absorption[45]

Establishing a long-term stable optical frequency standard requires a natural reference of atomic or molecular origin. Historically, the use of atomic/molecular transitions was limited to those that had accidental overlap with some fixed laser wavelengths. With the advent of tunable lasers, research on quantum absorbers has flourished. A stabilized laser achieves fractional frequency stability

$$\frac{\delta\nu}{\nu} = \frac{1}{Q}\,\frac{1}{S/N}\,\frac{1}{\sqrt{\tau}}$$

where Q is the quality factor of the transition involved, S/N is the recovered signal-to-noise ratio of the resonance information, and τ is the averaging time. Clearly one wishes to explore the limits on both resolution and sensitivity of the detected signal. The nonlinear nature of a quantum absorber, while on one hand limiting the attainable S/N, permits sub-Doppler resolutions. With sensitive techniques such as FM-based signal modulation and recovery, one is able to split a MHz scale linewidth by a factor of 10^4 to 10^5, at an averaging time of 1 s or so. Sub-Hertz long-term stability can be achieved with carefully designed optical systems where residual effects on baseline stability are minimized. However, a pressing question is: How accurate is our knowledge of the center of the resonance? Collisions, electromagnetic fringe fields, probe field wavefront curvature, and probe

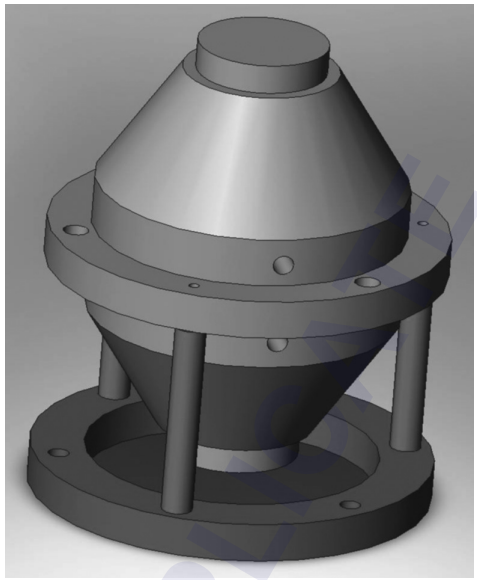

FIGURE 8. Computer model of vibration-resistant optical reference cavity.

power can all bring undesired linewidth broadening and center shifts. Distortion in the modulation process and other physical interactions can produce asymmetry in the recovered signal line shape. These issues will have to be addressed carefully before one can be comfortable talking about accuracy. A more fundamental issue related to time dilation of the reference system (second-order Doppler effect) can be solved in a controlled fashion: one simply knows the sample velocity accurately (e.g., by velocity selective Raman process), or the velocity is brought down to a negligible level using cooling and trapping techniques.

The simultaneous use of quantum absorbers and an optical cavity offers an attractive laser stabilization system. On one hand, a laser prestabilized by a cavity offers a long phase-coherence time, reducing the need of frequent interrogations of the quantum absorber. In other words, information of the atomic transition can be recovered with an enhanced S/N and the long averaging time translates into a finer examination of the true line center. On the other hand, the quantum absorber's resonance basically eliminates inevitable drifts associated with material standards. The frequency offset between the cavity mode and atomic resonance can be bridged by an AOM. In this case the cavity can be made of totally passive elements: mirrors are optically contacted to a spacer made of ultralow expansion material such as ULE or Zerodur. In case that the cavity needs to be made somewhat tunable, an intracavity Brewster plate driven by Galvo or a mirror mounted on PZT is often employed. Of course, these mechanical parts bring additional thermal and vibrational sensitivities to the cavity, along with nonlinearity and hysteresis. Temperature tuning of a resonator is potentially less noisy but slow. Other tuning techniques also exist, for example, through the use of magnetic force or pressure (change of intracavity refractive index or change of cavity dimension by external pressure). An often-used powerful technique called frequency-offset-locking brings the precision rf tuning capability to the optical world.[14]

Transducers

PZT Transducer Design: Disk versus Tube Designs We will usually encounter the mechanical resonance problem in any servo based on a PZT transducer: Small mirrors clearly are nice as they can have higher resonance frequencies. A mirror, say 7.75 mm $\Phi \times 4$ mm high, might be waxed onto a

PZT disk 10 mm diameter × 0.5 mm thick. The PZT, in turn, is epoxied onto a serious backing plate. This needs to be massive and stiff, since the PZT element will produce a differential force between the mirror and the backing plate. At short times there will be a "reduced mass" kind of splitting of the motion between the mirror and the support plate. At lower frequencies, one hates to get a lot of energy coupled into the mirror mount since it will have a wealth of resonances in the sub-kHz range. For this size mirror, the backing plate might be stainless steel, 1 inch diameter by ~3/4 inch wedged thickness, and with the PZT deliberately decentered to break down high Q modes. The piston mode will be at ~75 kHz.

Tubular PZT Design Often it is convenient to use a tubular form of PZT, with the electric field applied radially across a thin wall of thickness t. This gives length expansion also, transverse to the field using a weaker d_{31} coefficient, but wins a big geometric factor in that the transverse field is generating a length response along the entire tube height h. The PZT tube could be 1/2 inch diameter by 1/2 inch length, with a wall thickness t =1.25 mm. This geometry leads to a ~7-fold sensitivity win, when $d_{31} \approx 0.7\ d_{33}$ is included. Typical dimensions for the mirror might be 12.5 mm diameter × 7 mm high. The PZT tube also is epoxied onto a serious backing plate. For the high voltage isolation of the PZT electrodes at the tube ends, a thin sheet (say < 0.5 mm) of stiff ceramic, alumina for example, will suffice. An alternative way to provide the electrical isolation of the ends involves removing the silver electrodes for several millimeters at the end. A new technique uses a diamond-charged tubular core drill mounted into a collet in a lathe. The active tool face projects out only 2 mm so that handheld PZT grinding leads to clean electrode removal, inside and out. This end of the PZT tube is attached to the backing mass with strong epoxy. The mirror is attached to the open PZT tube end with melted wax. This is vastly better than epoxy in that it does not warp the optic, and the small energy dissipation occurs at the best place to damp the Q of the PZT assembly. If done well, this unit will have its first longitudinal resonance at about 25 kHz, with a Q ~10. As noted above, in servo terms, the actual mechanical PZT unit gives an added 2-pole roll-off above the resonance frequency and a corresponding asymptotic phase lag of 180°. So it is useful to design for high resonant frequency and low Q.

Comparing disk and tubular designs, the disk approach can have a three-fold higher resonance frequency, while the tubular design is ~7-fold more sensitive. Perhaps more important is the tube's reduced stiffness, moving the PZT/mirror resonance down into the 20-kHz domain. This brings us to the subject of spectral shaping of the amplifier gain and limitations of servo performance due to electronic issues.

Amplifier Strategies for PZT Driver We enjoy the tubular PZT for its large response per volt and its relatively high resonance frequencies. But it gives a problem in having a large capacitance, for example, of 10 nf in the above design. Even with the high sensitivity of 70 V/order, achieving a tight lock requires high frequency corrections and can lead to a problem in supplying the necessary ac current, supposing that we ask the HV amplifier alone to do the job. An apparent answer is to use a pair of amplifiers, one fast and the other HV, separately driving the two sides of the PZT. This alone doesn't solve the problem, as the big high-frequency ac current is only returned via the HV amplifier. The answer is to use a crossover network on the HV amplifier side. A capacitor to ground, of perhaps 3- or 5-fold larger value than the PZT will adequately dump the fast currents coming through the PZT's capacitance. A resistor to this PZT/shunt capacitor junction can go to the HV amplifier. Now this HV amp has indeed more capacitance to drive, but is only needed to be active below a few hundred hertz where the current demand becomes reasonable. An alternative topology sums the two inputs on one side of the PZT.

Other Useful Transducers—Slow but Powerful Commercial multiple wafer designs utilize 100 or more thin PZT sheets mechanically in series and electrically in parallel to produce huge excursions such as 10 μm for 100 V. Of course the capacitance is ~0.1 μF and the stability leaves something to be desired. These are useful for applications that can tolerate some hysteresis and drift, such as grating angle tuning in a diode laser. When a large dynamic range is needed to accommodate wide tuning range or to correct for extensive laser frequency drifts at low frequencies, a galvo-driven Brewster

plate can be used inside the optical cavity. Typically a Brewster plate inflicts an insertion loss less than 0.1 percent if its angular tuning range is limited within ±4°. Walk-off of the optical beam by the tuning plate can be compensated with a double-passing arrangement or using dual plates. In the JILA-designed Ti:Sapphire laser, we use the combination of PZT and Brewster plate for the long-term frequency stabilization. The correction signal applied to the laser PZT is integrated and then fed to the Brewster plate to prevent saturation of the PZT channel. At higher frequencies we use much faster transducers, such as AOM and EOM, which are discussed below.

Temperature control of course offers the most universal means to control long-term drifts. Unfortunately the time constant associated with thermal diffusion is usually slow and therefore the loop bandwidth of thermal control is mostly limited to Hertz scale. However, thoughtful designs can sometimes push this limit to a much higher value. For example, a Kapton thin-film heater tape wrapped around the HeNe plasma tube has produced a thermal control unity gain bandwidth in excess of 100 Hz.[46] The transducer response is reasonably modeled as an integrator above 0.3 Hz and excessive phase shifts associated with the thermal diffusion does not become a serious issue until ~200 Hz. This transfer function of the transducer can be easily compensated with an electronic PI filter to produce the desired servo loop response. Radiant heating of a glass tube by incandescent lamps has achieved a time delay <30 ms and has also been used successfully for frequency control of HeNe lasers.[47] If a bipolar thermal control is needed, Peltier-based solid state heat pumps (thermoelectric coolers) are available and can achieve temperature differences up to 70°C, or can transfer heat at a rate of 125 W, given a proper configuration of heat sinking. Parallel use of these Peltier devices results in a greater amount of heat transfer while a cascaded configuration achieves a larger temperature difference.

Combining various servo transducers in a single feedback loop requires thorough understanding of each actuator, their gains and phase shifts, and the overall loop filter function one intends to construct. Clearly, to have an attractive servo response in the time domain, the frequency transfer functions of various gain elements need to crossover each other smoothly. A slow actuator may have some resonance features in some low-frequency domain, hence the servo action needs to be relegated to a faster transducer at frequency ranges beyond those resonances. The roll-off of the slow transducer gain at high-frequencies needs to be steep enough, so that the overall loop gain can be raised without exciting the associated resonance. On the other hand, the high-frequency channel typically does not have as large a dynamic range as the slow ones. So one has to pay attention not to overload the fast channel. Again, a steep filter slope is needed to rapidly relinquish the gain of the fast channel toward the low-frequency range. However, we stress here that the phase difference between the two channels at the crossover point needs to be maintained at less than 90°. In the end, predetermined gains and phase shifts will be assigned to each transducer so that the combined filter function resembles a smooth single channel design. Some of these issues will be addressed briefly in the section below on example designs.

Servo Design in the Face of Time Delay: Additional Transducers Are Useful As one wishes for higher servo gain, with stability, it means a higher closed-loop bandwidth must be employed. Eventually the gain is sufficiently large that the intrinsic laser noise, divided by this gain, has become less than the measurement noise involved in obtaining the servo error signal. This should be sufficient gain. However, it may not be usable in a closed-loop scenario, due to excessive time delay. If we have a time delay of t_{delay} around the loop from an injection to the first receipt of correction information, a consideration of the input and response as vectors will make it clear that no real servo noise suppression can occur unless the phase of the response at least approximates that required to subtract from the injected error input to reduce its magnitude on the next cycle through the system. A radian of phase error would correspond to a unity-gain frequency of $1/(2\pi t_{\text{delay}})$, and we find this to be basically the upper useful limit of servo bandwidth. One finds that to correct a diode laser or dye laser to leave residual phase errors of 0.1 rad, it takes about 2 MHz servo bandwidth. This means a loop delay time, at the absolute maximum, of $t_{\text{delay}} = 1/2\pi\ 2\text{MHz} = 80$ ns. Since several amplifier stages will be in this rf and servo-domain control amplifier chain, the individual bandwidths need to be substantially beyond the 12 MHz naively implied by the delay spec. In particular rf modulation frequencies need to be unexpectedly large, 20 MHz at least, and octave rf bandwidths need to

be utilized, considering that the modulation content can only be 1/2 the bandwidth. Suppression of even-order signals before detection is done with narrow resonant rf notches.

Of course a PZT transducer will not be rated in the nanosecond regime of time delay. Rather, one can employ an AOM driven by a fast-acting Voltage-Controlled Oscillator to provide a frequency shift. Unfortunately the acoustic time delay from the ultrasonic transducer to the optical interaction seems always to be 400 ns, and more if we are dealing with a very intense laser beam and wish to avoid damage to the delicate AO transducer. The AOM approach works well with diode-pumped solid state lasers, where the bandwidth of major perturbations might be only 20 kHz. By double-passing the AOM the intrinsic angular deflection is suppressed. Usually the AOM prefers linear polarization. To aid separation of the return beam on the input side, a spatial offset can be provided with a collimating lens and roof prism, or with a cat's-eye retroreflector. Amplitude modulation or leveling can also be provided with the AOM's dependence on rf drive, but it is difficult to produce a beam still at the shot noise level after the AOM.

The final solution is an *EOM phase modulator.* In the external beam, this device will produce a phase shift per volt, rather than a frequency shift. So we will need to integrate the control input to generate a rate of change signal to provide to the EOM, in order to have a frequency relationship with the control input.[48] Evidently this will bring the dual problems of voltage saturation when the output becomes too large, and a related problem, the difficulty of combining fast low-delay response with high-voltage capability. The standard answer to this dilemma was indicated in our PZT section, namely, one applies fast signals and high-voltage signals independently, taking advantage of the fact that the needed control effort at high frequencies tends to cover only a small range. So fast low-voltage amplifier devices are completely adequate, particularly if one multipasses the EOM crystal several times. A full discussion of the crossover issues and driver circuits will be prepared for another publication.

Representative/Example Designs

Diode-Pumped Solid State Laser Diode-pumped solid state lasers are viewed as the most promising coherent light sources in diverse applications, such as communications, remote detection, and high precision spectroscopy. The diode-pumped Nd:YAG laser is probably the most highly developed of the rapidly expanding universe of diode-pumped solid state lasers, and it has enjoyed continuous improvements in its energy efficiency, size, lifetime, and intrinsic noise levels. The laser's free-running linewidth of ~10 kHz makes it a straightforward task to stabilize the laser via an optical cavity or an optical phase locked loop. In our initial attempt to stabilize the laser on a high finesse ($F \sim 100{,}000$, linewidth ~ 3 kHz) cavity, we employ an external AOM along with the laser internal PZT which is bonded directly on the laser crystal. The frequency discrimination signal between the laser and cavity is obtained with 4-MHz FM sidebands detected in cavity reflection. The PZT corrects any slow but potentially large laser frequency noise. Using the PZT alone allows the laser to be locked on the cavity. However, the loop tends to oscillate around 15 kHz and the residual noise level is more than 100 times higher than that obtained with the help of an external AOM. The AOM is able to extend the servo bandwidth to ~150 kHz, limited by the propagation time delay of the acoustic wave inside the AOM crystal. The crossover frequency between the PZT and AOM is about 10 kHz. Such a system has allowed us to achieve a residual frequency noise spectral density of 20 mHz/√Hz. The laser's linewidth relative to cavity is thus a mere 1.3 mHz,[49] even though the noise spectral density is still 100 times higher than the shot noise. This same strategy of servo loop design has also been used to achieve a microradian level phase locking between two Nd:YAG lasers.[50]

It is also attractive to stabilize the laser directly on atomic/molecular transitions, given the low magnitude of the laser's intrinsic frequency noise. Of course the limited S/N of the recovered resonance information will not allow us to build speedy loops to clean off the laser's fast frequency/phase noise. Rather we will use the laser PZT alone to guide the laser for a long-term stability. An example here is the 1.064 μm radiation from the Nd:YAG, which is easily frequency doubled to 532 nm where strong absorption features of iodine molecules exist.[51,52] The doubling is furnished with a noncritical phase-matched KN_bO_3 crystal located inside a buildup cavity. 160 mW of green light

output is obtained from an input power of 250 mW of IR. Only mW levels of the green light are needed to probe the iodine saturated absorption signal. Low vapor pressure (~0.5 Pa) of the iodine cell is used to minimize the collision-induced pressure shift and to reduce the influence on baseline by the linear Doppler absorption background. The signal size decreases as the pressure is reduced. However, this effect is partly offset due to the reduced resonance linewidth (less pressure broadening) which helps to increase the slope of the frequency locking error signal. A lower pressure also helps to reduce power-related center frequency shifts since a lower power is needed for saturation. With our 1.2-m long cells, we have achieved an *S*/*N* of 120 in a 10-kHz bandwidth, using the modulation transfer spectroscopy.[53] (Modulation transfer is similar to FM except that we impose the frequency sideband on the saturating beam and rely on the nonlinear medium to transfer the modulation information to the probe beam which is then detected.) Normalized to 1-s averaging time, this *S*/*N* translates to the possibility of a residual frequency noise level of 10 Hz when the laser is locked on the molecular resonance, given the transition linewidth of 300 kHz. We have built two such iodine-stabilized systems and the heterodyne beat between the two lasers permits systematic studies on each system and checks the reproducibility of the locking scheme.[54] With a 1 second counter gate time, we have recorded the beat frequency between the two lasers. The standard deviation of the beat frequency noise is ~20 Hz, corresponding to ~14-Hz rms noise per IR laser, basically a S/N limited performance. The beat record can be used to calculate the Allan standard deviation: starting at 5×10^{-14} at 1 second, decreasing with a slope of $1/\sqrt{\tau}$ up to 100 second. (τ is the averaging time.) After 100-s the deviations reach the flicker noise floor of $\sim 5 \times 10^{-15}$. At present, the accuracy of the system is limited by inadequate optical isolation in the spectrometer and the imperfect frequency modulation process (residual amplitude noise, RAM) used to recover the signal. This subject is under intense active study in our group.[55]

External Cavity Diode Lasers Diode lasers are compact, reliable, and coherent light sources for many different applications.[56] The linewidth of a free-running diode laser is limited by the fundamental spontaneous emission events, enhanced by the amplitude-phase coupling inside the gain medium. With a low-noise current driver, a typical milliwatt scale AlGaAs diode laser has a linewidth of several MHz. To reduce this fast frequency noise, one typically employs an external cavity formed between one of the diode laser facets and a grating (or an external mirror that retroreflects the first-order grating diffraction).[57–59] This optical feedback mechanism suppresses the spontaneous emission noise, replaced by much slower fluctuations of mechanical origin. The linewidth of the grating-stabilized external cavity diode laser (ECDL) is usually between 100 kHz and 1 MHz, determined by the quality factor of the optical feedback. The ECDL also offers much better tuning characteristics compared against a solitary diode. To do such tuning, the external grating (or the mirror that feeds the grating-dispersed light back to the laser) is controlled by a PZT for scanning. Synchronous tuning of the grating dispersion and the external cavity mode can be achieved with a careful selection of the grating rotation axis position. Similarly, this PZT-controlled grating can be used to stabilize the frequency of an ECDL. However, owing to the low bandwidth limited by the mechanical resonance of PZT, a tight frequency servo is possible only through fast transducers such as the laser current or intracavity phase modulators.

This hybrid electro-optic feedback system is attractive, and ECDLs have been demonstrated to show hertz level stability under a servo bandwidth of the order of 1 MHz. For a solitary diode, feedback bandwidth of tens of megahertz would have been needed in order to bring the frequency noise down to the same level. However, considering that the optical feedback has a strong impact on the laser frequency noise spectrum, one finds the frequency response of the compound laser system is clearly dependent upon the optical alignment. Therefore, for each particular ECDL system, we need to measure the frequency response function of the laser under the optimally aligned condition. We are dealing with a multichannel feedback system (e.g., PZT plus current), so that designing smooth crossovers between different transducers requires knowledge of the transfer functions of each transducer. Normally the current-induced FM of a solitary diode has a flat response up to ~100 kHz, and then starts to roll off in the region between 100 kHz and 1 MHz, initially with a single-pole character. This is due to the time response of the current-induced thermal change of the refractive index inside the diode. (At a faster time scale, the carrier density variation will remain and then dominate

the laser frequency response.) Design of a fast feedback loop needs to take into account this intrinsic diode response. Fortunately the time delay associated with the current response is low, typically below 10 ns.

In our example system, the frequency discrimination signal of the ECDL is obtained from a 100 kHz linewidth cavity with a sampling frequency of 25 MHz. The error signal is divided into three paths: PZT, current modulation through the driver, and direct current feedback to the diode head. The composite loop filter function is shown in Fig. 9. The crossover between the slow current channel and the PZT usually occurs around 1 kHz, in order to avoid the mechanical resonance of the PZT at a few kHz. In our system, the frequency response of the PZT/grating is 10 GHz/V. To furnish this in-loop gain of ~1000 at 1 kHz, we need to supply an electronic gain of 0.1, given that the error signal has a slope of 1 V/1 MHz.

Toward the lower frequency range, the PZT gain increases by 40 dB/decade (double integrators) to suppress the catastrophically rising laser frequency noise. It is obvious from Fig. 9 that the intermediate current channel tends to become unstable at a few hundred kHz, due to the excessive phase shift there. The fast current loop, bypassing the current driver to minimize additional time delay and phase shift, has a phase lead compensator to push the unity gain bandwidth to 2 MHz. With this system we can lock the ECDL robustly on the optical cavity, with a residual noise spectral density of 2 Hz/√Hz, leading to a relative linewidth of 12 Hz. The achieved noise level is about 100 times higher than the fundamental measurement limit set by shot noise. We note in passing that when an ECDL gradually goes out of alignment, the previously adjusted gain of the current loop will tend to make the servo oscillate so we know a new alignment is needed. The laser FM sideband used to generate

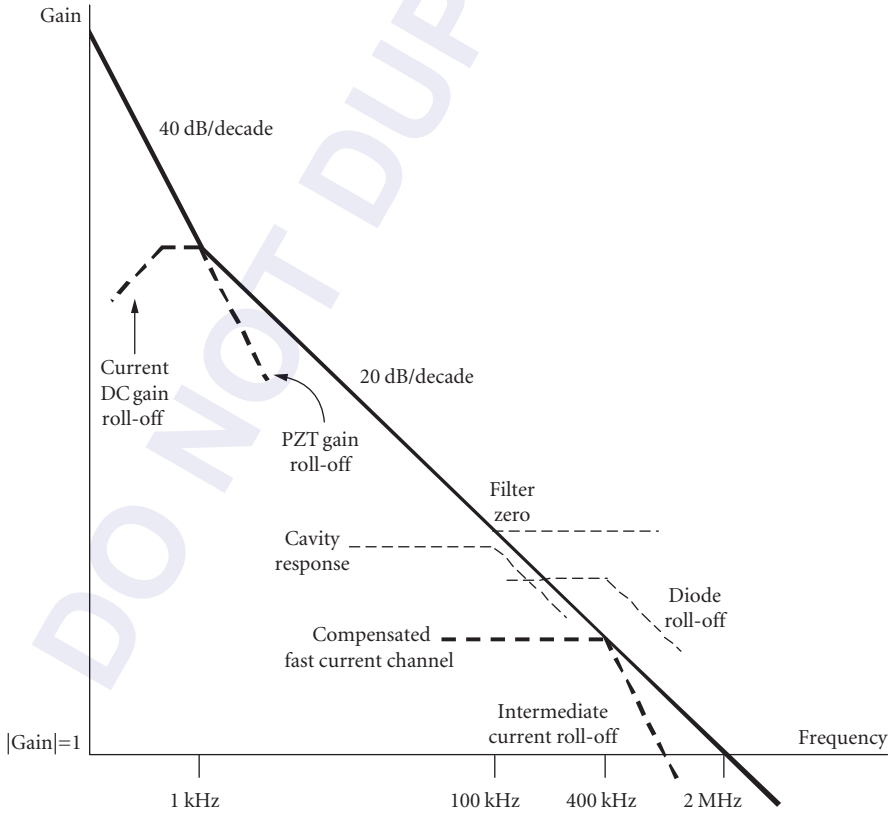

FIGURE 9 The combined loop filter function for ECDL frequency stabilization.

the locking signal is produced directly by current modulation. An electronic filter network is employed to superimpose the slow servo, fast servo, and modulation inputs to the diode. Exercise caution when accessing the diode head, as a few extra mA current increase can lead to drastic output power increase and melted laser facets, all in 1 μs!

Since 2000 this art of locking diode lasers to cavities has been progressing rapidly and in many labs worldwide. To note just one recent measurement of subhertz linewidths, we may note the results[60] in JILA, where two diode lasers were locked to two independent vertical cavities, giving 10^{-15} frequency stability at 1-second averaging time. In another Boulder collaboration, subhertz optical beat linewidths have been measured[61] between a JILA diode laser source at 689 nm and another stabilized laser used as the local oscillator for the Hg^+ clock, at a different wavelength of 1126 nm, and located 4 km away in the NIST labs. Two optical frequency Combs were employed, along with a Nd:YAG laser whose wavelength could be transmitted by the 4-km fiber link. (This Comb technology seems to have gone quickly from being a research topic to a reliable and versatile tool!)

22.4 SUMMARY AND OUTLOOK

The technology of laser frequency stabilization has been refined and simplified over the years and has become an indispensable research tool in any modern laboratories involving optics. Research on laser stabilization has been and still is pushing the limits of measurement science. Indeed, a number of currently active research projects on fundamental physical principles benefit a great deal from stable optical sources and will need a continued progress of the laser stabilization front.[62] Using extremely stable phase coherent optical sources, we will be entering an exciting era when the LISA interferometer will achieve picometer resolution over a five million kilometer distance in space[63] and a few Hertz linewidth of an ultraviolet resonance will be probed with a high *S*/*N*.[64, 65] One has to be optimistic looking at the stabilization results of all different kinds of lasers. To list just a few examples of cw tunable lasers, we notice milliHertz linewidth stabilization (relative to a cavity) for diode-pumped solid state lasers; dozen milliHertz linewidth for Ti:Sapphire lasers; and sub-Hertz linewidths for diode and dye lasers. Long-term stability of lasers referenced to atoms and molecules[66] has reached mid 10^{-16} levels in an averaging time as short as ~300 s. Phase locking between different laser systems is now routinely employed, even for diode lasers that have fast frequency noise.

An important new capability comes from the accurate frequency transfer via noise-compensated optical fiber, which allows groups to collaborate in the testing of their state-of-the-art systems, thus tapping into the fruits of our neighbors' achievements in stabilizing lasers.[67] The Optical Comb makes it possible to use nearly any stable frequency as the reference. The fiber transport allowed measurement of the inaccuracy issues affecting four potential atomic clocks, based on a trapped Hg^+ ion,[68] Al^+ trapped ions,[68] on cold and free Ca atoms,[69] and on cold Sr atoms confined in an optical lattice.[66] Measurements confirmed that the Sr, Hg^+, and Al^+ systems can be expected to yield sub-1×10^{-16} independent reproducibility (the same quality as *accuracy*, except for the authority of Cs definition as the unit of time.) Thus for the first time there is not one, but even three(!) frequency reference systems which surpass the performance of the present best standard in Physics, namely the Cs Fountain Clock. Likely there will be other optically-based systems (such as Yb in a lattice[70]) which may soon be in this performance category. Clearly there will be great laser and physics fun coming in the next times! For example, an extended series of comparisons between Hg^+ and Al^+ was carried out at NIST under strict conditions, and provided a $< 1 \times 10^{-16}$ /year checking for possible drift in the fundamental "constants" of physics.[68] By the way, do *you* believe that the frequencies of nuclear Mössbauer transitions will stay at the same frequency, as measured by these atomic frequency sources? With the rapid progress in producing VUV Combs by Higher Harmonic Generation,[71, 72] one can begin to dream about coherent Mössbauer spectroscopy so we can find out. In the optical comparisons, we're looking in the seventeenth decimal digit now!

Another highway toward fundamental physics involves precision laser spectroscopy of simple atoms, such as H and He^+, but laser cooling is a challenge due to the low available power. The exciting program[73] at MPQ in Munich can now generate enough VUV 121.5-nm light to begin this story!

Quantum noise is the usual limit of the measurement process and therefore may be the limit of the stabilization process as well. To circumvent the quantum noise altogether is an active research field itself.[74] We, however, have not reached this quantum limit just yet. For instance, we have already stated that the Nd:YAG laser should be able to reach microHertz stability if the shot noise is the true limit. What have we done wrong? A part of the deficiency is due to the inadequacy of the measurement process, namely the lack of accuracy. This is because the signal recovery effort—modulation and demodulation process—is contaminated by spurious optical interference effects and RAM associated with the modulation frequency. Every optical surface along the beam path can be a potential time bomb to damage the modulation performance. In cases that some low contrast interference effects are not totally avoidable, we would need to have the whole system controlled in terms of the surrounding pressure and temperature. The degree to which we can exert control of course dictates the ultimate performance. The second fundamental limitation appears to be thermally generated mechanical noise of the optical coatings, which was already noted,[41,42] but there are already schemes being discussed to buy us another decade or two.

22.5 CONCLUSIONS AND RECOMMENDATIONS

It becomes clear that there are many interlinking considerations involved in the design of laser stabilization systems, and it is difficult to present a full description in an chapter such as this. Still it is hoped that the reader will see some avenues to employ feedback control methods to the laser systems of her current interest. We are optimistic that some of this technology may become commercially available in the future, thus simplifying the user's task.

22.6 ACKNOWLEDGMENTS

The work discussed here has profited from interactions with many colleagues, postdoctoral researchers, and graduate students over many years. In particular we must thank Leo Hollberg and Miao Zhu for their earlier contributions. More recent contributors are Long Sheng Ma, and Mark Notcutt. Especially we thank Mark for his experimental work with the vertically mounted cavities, and for his useful suggestions for improving this text. The now-retired one of us (JLH) declares his joy to see the JILA laboratory prospering in the strong hands of Jun Ye. Jan also is particularly grateful to his wife Lindy for patience "beyond the call of duty" during these many years of laser research. The work at JILA has been supported over many years by the Office of Naval Research, the National Science Foundation, the Air Force Office of Scientific Research, NASA, and the National Institute of Standards and Technology, as part of its frontier research into basic standards and their applications.

23.1 GLOSSARY

Section 23.3

$a_k, a_k^\dagger$	annihilation, creation operator for photons in the kth mode
A	Einstein coefficient for spontaneous emission
$\mathbf{A}_k(\mathbf{r})$	kth electric mode function at position $\mathbf{r}$

*Deceased.

B	Einstein coefficient for absorption and stimulated emission
$\mathbf{B}(\mathbf{r}, t)$	magnetic field at position $\mathbf{r}$ and time t
$\mathbf{B}_k(\mathbf{r})$	kth magnetic mode function at position $\mathbf{r}$
c	speed of light
$\mathbf{e}_k$	polarization unit vector of the kth mode
$\mathbf{E}_\perp(\mathbf{r}, t)$	transverse electric field at position $\mathbf{r}$ and time t
$h, \hbar$	*Planck's constant* $[\hbar = h/(2\pi)]$
$\mathbf{k}, k$	wave vector, its length
$(d\mathbf{k})$	three-dimensional volume element in $\mathbf{k}$ space
k_B	Boltzmann's constant
$\mathbf{n}_k$	propagation unit vector of the kth mode
N	photon number operator
N_e	number of excited-state atoms
N_g	number of ground-state atoms
$\mathbf{r}$	position vector
$(d\mathbf{r})$	three-dimensional volume element in $\mathbf{r}$ space
t, dt	time, time interval
T	temperature
$U_{1\text{ph}}$	energy density for a one-photon state
dV	volume element
$\lvert\mathbf{vac}\rangle, \langle\mathbf{vac}\rvert$	ket and bra of the photon vacuum
$\overline{w^2}$	mean square energy fluctuations
W	spectral-spatial energy density of blackbody radiation
α_k	coherent state amplitudes
$\lvert\{\alpha\}_c\rangle$	ket of a coherent state
δ_{jk}	Kronecker's delta symbol
$\delta_\perp(\mathbf{r})$	transverse delta function at $\mathbf{r}$ (a dyadic)
ε_0	dielectric constant $[\varepsilon_0 = 1/(\mu_0 c^2) \simeq 8.854 \times 10^{-2}\ \text{F/m}]$
μ_0	permeability constant $(4\pi \times 10^{-7}\ \text{H/m})$
$\nu, d\nu$	light frequency, frequency interval
ν_k	frequency of the kth mode
ϱ_{ph}	statistical operator of the photon field
ρ	probability amplitude for reflection
τ	probability amplitude for transmission
ψ_k, ψ_{jk}	probability amplitudes of the one-photon, two-photon states
$\lvert\{\psi\}_1\rangle, \lvert\{\psi\}_2\rangle$	kets for one-photon, two-photon states
∇	gradient vector differential operator

Section 23.4

A	destruction operator for the field
$\mathscr{A}$	laser gain coefficient
$a, a^\dagger$	photon ladder operators
$\mathscr{B}$	laser saturation parameter
$b_k, b_k^\dagger$	destruction and creation operators for the reservoir modes
$\mathscr{D}$	largest eigenvalue of the laser equation

$F(t)$	field noise operator
$F_\alpha(t), F_\gamma$	noise operators associated with gain and loss, respectively
$F(1, x, y)$	hypergeometric function
g	radiant frequency stating the strength of atom-photon coupling
g_k	couping coefficient between reservoir and field
$G^{(1)}(t_0 + t, t_0)$	field correlation function
$\mathcal{H}, \mathcal{H}_0, \mathcal{H}_1$	total, free, and interaction hamiltonians for atom-field interaction
k	wave vector for the field
K	kick operator
$\mathcal{L}$	superoperator for cavity damping
$M(\tau)$	superoperator describing the effect of a single inverted atom on the field
$\overline{n}, \overline{n^2}$	mean and mean squared number of photons in a laser
n_m	maximum of the photon distribution of a laser
n_{th}	mean number of photons in a thermal reservoir
N_{ex}	number of atoms traversing the cavity during the lifetime of the cavity field
$N(t_i, t, \tau)$	notch function
p	transition dipole moment
$p(n)$	photon distribution function
$P(\tau)$	distribution function for the interaction times
q	a nonnegative integer
Q	Mandel Q function
r	atom injection rate inside a laser and micromaser
$S(\omega)$	spectrum of the laser field
T	temperature
t_m	measurement time
U	time evolution operator
$U_{\text{af}}(\tau)$	atom-field time evolution operator
$\mathcal{V}$	interaction picture Hamiltonian
$\alpha(t, t')$	gain function of a laser
Γ	atomic decay rate via spontaneous emission
$\gamma, \gamma_a, \gamma_b$	atomic decay rates
$\delta_{nn'}$	Kronecker delta function
ν_k	frequency of the reservoir mode
σ_+, σ_-	ladder operators for a two-level atom
σ_z	atomic inversion operator
ω_0	radiant frequency of an atomic transition
λ	eigenvalue
λ_j	eigenvalues of the laser equation
$\rho(t)$	reduced density operator for the field
ρ_{at}	total density operator for the atom-field system
$\rho_{nn'}$	matrix elements of the field density operator
$\rho_n^{(k)}$	off-diagonal density matrix element
κ	cavity loss rate
χ	square of the ratio of vacuum Rabi frequency and the atomic decay rate
$\theta(t)$	step function
$\phi(t)$	phase of the field

Section 23.5

a, b, c, d	parameters appearing in Table 1
$\underline{E}$	electric field strength
$\overline{E}$	mean field
$F(M), F_0$	free energy of a ferromagnet, its value for $M = 0$
g_k	undefined in Eqs. (126) and (127)
$G(E), G_0$	free energy of a laser, its value for $E = 0$
H	external magnetic field
H_{n0}	heating rate
K	one-fourth the spontaneous emission rate
K_{n0}	cooling rate
n_0	number of atoms in the Bose-Einstein condensate
$\langle n_0 \rangle$	mean number of atoms in the condensate
$\langle \dot{n}_0 \rangle$	time derivative of $\langle n_0 \rangle$
$\langle n_k \rangle_{n_0}$	average number of atoms in the kth excited state, given n_0 atoms in the condensate
N	total number of Bose atoms
N', N''	normalization constants in Table 1
M	magnetization of a ferromagnet
$P(M)$	probability density for a ferromagnet
$P(E)$	probability density for a laser
$P(\alpha, \alpha^*)$	P representation for the field
S	injected signal
T_c	critical temperature
W_k	heat bath density of states
x, y	$x = \text{Re}\ \alpha, y = \text{Im}\ \alpha$
X	zero-field susceptibility of a ferromagnet
$Z(T, N)$	canonical partition function
α	eigenvalue of the coherent state $\lvert\alpha\rangle$
ε	scaled temperature (inversion) of a ferromagnet (laser) in Fig. 9
$\zeta(3)$	Riemann's zeta function $\zeta(3) = 1.2020569\ldots$
η	scaled thermodynamical variable (in Fig. 9)
$\langle \eta_k \rangle$	average occupation number of the kth heat bath oscillator
$\Theta(\ )$	Heaviside's unit step function
$\mathbf{k}$	undefined in Eq. (15)
ξ	laser analog of X
$\rho_{n0,\,n0}$	probability for having n_0 atoms in the condensate
$\dot{\rho}_{n0,\,n0}$	time derivative of $\rho_{n0,\,n0}$
σ	population inversion
σ_t	threshold inversion
$\Phi_e(\eta)$	scaled thermodynamical potential (in Fig. 9)
Ω	trap frequency

Section 23.6

A	phase-shifted destruction operator for a free-electron laser (FEL)
c_b, c_c	probability amplitudes for atom to be in levels $\lvert b\rangle$ and $\lvert c\rangle$, respectively

$\mathcal{D}(\theta)$	phase diffusion function
$\mathcal{E}$	slowly varying field amplitude
g	coupling constant for the electron-field interaction in an FEL
j	parameter for the gain in an FEL
k	wavevector for the laser field in an FEL
$\mathcal{L}$	linear gain ($i = j$) and cross-coupling ($i \neq j$) Liouville operators
m	mass of electron
$O(A, A^\dagger)$	arbitrary operator containing A, $A^\dagger$
p	electron momentum
$\overline{p}$	eigenvalue of electron momentum operator
P_b, P_c	probability of atom being in states $\|b\rangle$ and $\|c\rangle$, respectively
P_{emission}	probability of emission of radiation
$S(T)$	time-evolution operator for the electron-photon state
T	electron-photon interaction time
$\mathcal{T}$	time-ordering operator
z	electron coordinate
α_i	eigenvalue of the coherent state $\|\alpha_i\rangle$
α_{ij}	constants depending upon parameters of gain medium in a correlated emission laser (CEL)
β	normalized electron momentum
γ	relativistic factor for an electron
Δ	atom-field detuning in lasing without inversion (LWI)
ν_1, ν_2	frequencies of the two modes in a CEL
$\rho(t_i)$	atomic density operator at initial time t_i
$\rho_{ij}^{(0)}$	initial values of the ijth atomic matrix elements
ρ_i	classical amplitude of the ith mode
$\rho(a_1, a_1^\dagger; a_2, a_2^\dagger)$	reduced density operator for the two-mode field in a CEL
θ_i	phase of the ith field
ω_0	microwave frequency
ω_a, ω_b, ω_c	frequencies associated with atomic levels
λ_s	wavelength of the field emitted in an FEL
λ_w	the period of the magnetic wiggler
κ	gain coefficient
$\kappa_{a\to b}$, $\kappa_{a\to c}$	constants depending upon the matrix elements between the relevant levels
ϕ	relative phase between atomic levels
Φ	total phase angle in two-mode CEL schemes
ψ	relative phase $\Phi + \theta_1 - \theta_2$

23.2 INTRODUCTION

Most lasers, and in particular all commercially sold ones, emit electromagnetic radiation whose properties can be accounted for quite well by a *semiclassical* description. In such a treatment, quantum aspects (level spacings, oscillator strengths, etc.) of the matter (atoms, molecules, electron-hole pairs, etc.) that constitute the gain medium are essential, but those of the electromagnetic field are disregarded. Quantum properties of the radiation are, however, of decisive importance for laser systems "at the limit" which reach fundamental bounds for the linewidth, for the regularity of photon statistics, or for other quantities of interest.

Recognition and understanding of these fundamental limitations are furnished by the quantum theory of the laser, whose foundations were laid in the 1960s. The two main approaches, the master-equation formalism and the Langevin method—equivalent in the physical contents and supplementing each other like spouses—can be roughly, and somewhat superficially, associated with the Schrödinger and the Heisenberg pictures of quantum mechanics. The master-equation method corresponds to the former, the Langevin approach to the latter. Both are reviewed in Sec. 23.4, but more room is given to the master-equation treatment. This bias originates in our intention to present a parallel exposition for both the standard laser theory and the theory of the micromaser, which in turn is traditionally and most conveniently treated by master equations.

The micromaser, in which the dynamic is dominated by the strong coupling of a single mode of the radiation field to a single atomic dipole transition, is the prototype of an open, driven quantum system. Accordingly, micromaser experiments are *the* test ground for the quantum theory of the laser; therefore, micromaser theory deserves the special attention that it receives in Sec. 23.4.

As a logical and historical preparation, we recall in Sec. 23.3, the theoretical and experimental facts that are evidence for quantum properties of electromagnetic radiation in general, and the reality of photons in particular. Some special issues are discussed in Sees. 23.5 and 23.6. In Sec. 23.5, we stress the analogy between the threshold behavior of a laser and the phase transition of a ferromagnet, and note the recent lessons about Bose-Einstein condensates taught by this analogy. Section 23.6 summarizes the most important features of some exotic lasers and masers, which exploit atomic coherences or the quantum properties of the atomic center-of-mass motion. Basics of the so-called free-electron laser are reported as well.

The quantum theory of the laser is a central topic in the field of quantum optics. An in-depth understanding of the various facets of quantum optics can be gained by studying the pertinent textbooks.[1–18]

23.3 SOME HISTORY OF THE PHOTON CONCEPT

Early History: Einstein's Light Quanta

Planck's formula of 1900[19] marks the beginning of quantum mechanics, and in particular of the quantum theory of light. It reads

$$W = \frac{8\pi\nu^2}{c^3}\frac{h\nu}{\exp(h\nu/k_B T)-1} \tag{1}$$

and relates the spectral-spatial energy density W of blackbody radiation to the frequency ν of the radiation and the temperature T of the blackbody. Boltzmann's constant k_B and Planck's constant h are conversion factors that turn temperature and frequency into energy, and c is the speed of light. A volume dV contains electromagnetic energy of the amount $W\,d\nu\,dV$ in the frequency range $\nu \cdots \nu + d\nu$.

The first factor in Eq. (1) is the density of electromagnetic modes. It obtains as a consequence of the classical wave theory of light and owes its simplicity to an implicit short-wavelength approximation. For wavelengths of the order of magnitude set by the size of the cavity that contains the radiation, appropriate corrections have to be made that reflect the shape and size of the cavity. This is of great importance in the context of micromasers, but need not concern us presently.

The second factor in Eq. (1) is the mean energy associated with radiation of frequency ν. It is a consequence of the quantum nature of light. In the limits of very high frequencies or very low ones, it turns into the respective factors of Wien[20] and Rayleigh-Jeans:[21,22]

$$\begin{aligned} &\frac{h\nu}{\exp(h\nu/k_B T)-1} && \text{(Planck)} \\ &\to \begin{cases} h\nu \exp -\dfrac{h\nu}{k_B T} & \text{for } \nu \gg \dfrac{k_B T}{h} \quad \text{(Wien)} \\ k_B T \quad \text{for } \nu \ll \dfrac{k_B T}{h} & \text{(Rayleigh-Jeans)} \end{cases} \end{aligned} \tag{2}$$

The relevant frequency scale is set by $k_B T/h$; at a temperature of $T = 288$ K it is about 6×10^{12} Hz, corresponding to a wavelength of 50 μm.

Ironically, Planck—whose stroke of genius was to interpolate between the two limiting forms of Eq. (2)—was not convinced of the quantum nature of electromagnetic radiation until much later. Legend has it that it was the discovery of Compton scattering in 1923 that did it.[23] We are, however, getting ahead of the story.

The true significance of Planck's formula, Eq. (1), started to emerge only after Einstein[24] had drawn the conclusions that led him to his famous *light-quantum hypothesis* of 1905, the *annus mirabilis*. In Pauli's words,

> He immediately applied [it] to the photoelectric effect and to Stokes' law for fluorescence, later also to the generation of secondary cathode rays by X-rays and to the prediction of the high frequency limit in the *Bremsstrahlung*.[25]

Quite a truckload, indeed.

The conflict with the well-established wave theory of light was, of course, recognized immediately, and so the introduction of light quanta also gave birth to the wave-particle duality. Upon its extension to massive objects by de Broglie in 1923 to 1924,[26–27] it was instrumental in Schrödinger's wave mechanics.[28]

Taylor's 1909 experiment,[29] in which feeble light produced interference fringes, although at most one light quantum was present in the interferometer at any time, addressed the issue of wave-particle duality from a different angle. Its findings are succinctly summarized in Dirac's dictum that "a photon interferes only with itself"[30]—a statement that became the innocent victim of misunderstanding and misquotation in the course of time.[31]

Another important step was taken the same year by Einstein.[32] By an ingenious application of thermodynamic ideas to Planck's formula, in particular consequences of Boltzmann's relation between entropy and statistics, he derived an expression for the mean-square energy fluctuations $\overline{w^2}$ of the radiation in a frequency interval $\nu \cdots \nu + d\nu$ and a volume dV:

$$\overline{w^2} = \left(\frac{c^3}{8\pi\nu^2} W + h\nu \right) W \, d\nu \, dV \tag{3}$$

where W is the spectral-spatial density of Eq. (1), so that $W \, d\nu \, dV$ is the mean energy in the frequency interval and volume under consideration. The first term is what one would get if classical electrodynamics accounted for all properties of radiation. There is no room for the second term in a wave theory of light; it is analogous to the fluctuations in the number of gas molecules occupying a given volume. This second term therefore supports Einstein's particle hypothesis of 1905,[24] in which electromagnetic energy is envisioned as being concentrated in localized lumps that are somehow distributed over the volume occupied by the electromagnetic wave.

Wave aspects (first term) and particle aspects (second term) enter Eq. (3) on equal footing. Since the thermodynamic considerations have no bias toward either one, one must conclude that Planck's formula, Eq. (1), is unbiased as well. Electromagnetic radiation is as much a particle phenomenon as it is a wave phenomenon.

Einstein left the center stage of quantum theory for some years, returning to it after completing his monumental work on general relativity. In 1913, Bohr's highly speculative postulates[33] had suddenly led to a preliminary understanding of many features of atomic spectra (the anomalous Zeeman effect was one big exception; it remained a bewildering puzzle for another decade). In the course, "quantum theory was liberated from the restriction to such particular systems as Planck's oscillators" (Pauli[25]).

Here was the challenge to rederive Planck's formula from Bohr's postulates, assuming that they hold for arbitrary atomic systems. Einstein's famous paper of 1917[34] accomplished just that, and more.

He considered radiation in thermal equilibrium with a dilute gas of atoms at temperature T. We shall here give a simplified treatment that contains the essential features without accounting for all

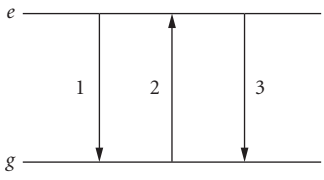

FIGURE 1 Transitions of three kinds happen between the excited level *e* and the ground level *g*: (1) spontaneous emission [see Eq. (4)], (2) absorption [see Eq. (5)], and (3) stimulated emission [see Eq. (6)].

details of lesser significance. Suppose that the energy spacing between two atomic levels *e* and *g* equals $h\nu$, so that the transition from the more energetic level *e* to the energetically lower level *g* (excited to ground state) is accompanied by the emission of a light quantum of frequency ν. According to Einstein, three processes are to be taken into account (see Fig. 1): spontaneous emission, absorption, and stimulated emission. The latter has no analog in Maxwell's electrodynamics.

Each of the three processes leads to a rate of change of the number of gas atoms in states *e* and *g*. Denoting these numbers by N_e and N_g we have the following contributions to their time derivatives. The *spontaneous emission* rate is proportional to the number of excited-state atoms:

$$\text{Spontaneous emission} \qquad \frac{d}{dt}Ne = -\frac{d}{dt}N_g = -AN_e \tag{4}$$

where *A* is the first Einstein coefficient of the transition in question. The *absorption* rate is proportional to the number of ground-state atoms and to the energy density *W* of the radiation:

$$\text{Absorption} \qquad \frac{d}{dt}N_e = -\frac{d}{dt}N_g = BWN_g \tag{5}$$

where *B* is the second Einstein coefficient. The *stimulated emission* rate is proportional to the number of excited state atoms and to the radiation energy density:

$$\text{Stimulated emission} \qquad \frac{d}{dt}N_e = -\frac{d}{dt}N_g = BWN_e \tag{6}$$

where the same *B* coefficient appears as in the absorption rate.

The *detailed balance* between states *e* and *g* therefore requires

$$\text{Total} \qquad \frac{d}{dt}Ne = -\frac{d}{dt}N_g = -AN_e + BWN_g - BWN_e = 0 \tag{7}$$

under the circumstances of thermal equilibrium. Therefore, *W* can be expressed in terms of the ratios A/B and N_g/N_e:

$$W = \frac{A/B}{N_g/N_e - 1} = \frac{A/B}{\exp(h\nu/k_B T) - 1} \tag{8}$$

where the second equality recognizes that Boltzmann's factor relates N_e to N_g. [The absence of additional weights here is the main simplification alluded to before; if taken into account, these weights would also require two closely related *B* coefficients in Eqs. (5) and (6).] In Eq. (8) we encounter the

denominator of Planck's factor from Eq. (2), and Planck's formula, Eq. (1), is recovered in full if the relation

$$A = \frac{8\pi h\nu^3}{c^3} B \tag{9}$$

is imposed on Einstein's coefficients.

The main ingredients in this derivation of Eq. (1) are the postulate of the process of stimulated emission, with a strength proportional to the density of radiation energy, and the relation between the coefficients for spontaneous emission and stimulated emission, Eq. (9).

All of this is well remembered, but there was in fact more to the 1917 paper.[34] It also contains a treatment of the momentum exchange between atoms and light quanta, and Einstein succeeded in demonstrating that the Maxwell velocity distribution of the atoms is consistent with the recoil they suffer when absorbing and emitting quanta. Insights gained in his study of Brownian motion (another seminal paper of 1905[35]) were crucial for this success. When taken together, the considerations about energy balance and those concerning momentum balance are much more convincing than either one could have been alone.

The discovery of the Compton effect in 1923[23] finally convinced Bohr and other skeptics of the reality of the particlelike aspects possessed by light. But Bohr, who until then was decidedly opposed to Einstein's light-quantum hypothesis and the consequent wave-particle duality, did not give in without a last try. Together with Kramers and Slater,[36] he hypothesized that perhaps energy-momentum conservation does not hold for each individual scattering event, but only in a statistical sense for a large ensemble. Then one could account for Compton's data without conceding a particle nature to light in general, and X rays in particular. The refined measurements that were immediately carried out by Bothe and Geiger[37] showed, however, that this hypothesis is wrong: energy and momentum are conserved in each scattering event, not just statistically.

And then there was, also in 1924, Bose's seminal observation that it is possible to derive Planck's radiation law [Eq. (1)] from purely corpuscular arguments without invoking at all the wave properties of light resulting from Maxwell's field equations.[38,39] The main ingredient in Bose's argument was the indistinguishability of the particles in question and a new way of counting them—now universally known as *Bose-Einstein statistics*—which pays careful attention to what is implied by their being indistinguishable. In the case of light quanta, an additional feature is that their number is not conserved, because light is easily emitted and absorbed. Massive particles (atoms, molecules, etc.), by contrast, are conserved; therefore, as Einstein emphasized,[40–42] their indistinguishability has further consequences, of which the phenomenon of Bose-Einstein condensation (or should one rather say "Einstein condensation of a Bose gas"?) is the most striking one.

Quantum Electrodynamics

Theoretical studies of the quantum nature of light had a much more solid basis after Dirac's introduction of quantum electrodynamics (QED) in his seminal paper of 1927.[43] The basic ingredients of QED were all present in Dirac's formulation, although it is true that a consistent understanding of QED was not available until renormalized QED was developed 20 years later (see the papers reprinted in Ref. 44). In particular, the photon concept was clarified in the sense described in the following paragraphs.

The infinite number of degrees of freedom of the electromagnetic field—an operator field in QED—become manageable with the aid of a mode expansion. For the transverse part $\mathbf{E}_\perp(\mathbf{r}, t)$ of the electric field, for example, it reads

$$\mathbf{E}_\perp(\mathbf{r}, t) = \sum_k \sqrt{\frac{h\nu_k}{2\varepsilon_0}} [a_k(t)\mathbf{A}_k(\mathbf{r}) + a_k^\dagger(t)\mathbf{A}_k^*(\mathbf{r})] \tag{10}$$

The mode functions $\mathbf{A}_k(\mathbf{r})$ are complex vector functions of the position vector $\mathbf{r}$ that are eigenfunctions of the Laplace differential operator,

$$-\nabla^2\mathbf{A}_k(\mathbf{r})=\left(\frac{2\pi\nu_k}{c}\right)^2\mathbf{A}_k(\mathbf{r}) \tag{11}$$

where the eigenvalue is determined by the frequency ν_k (>0) of the mode in question. The boundary conditions that the electric and magnetic field must obey at conducting surfaces imply respective boundary conditions on the $\mathbf{A}_k(\mathbf{r})$s.

The corresponding mode expansion for the magnetic field is given by

$$\mathbf{B}(\mathbf{r},t)=\sum_k\sqrt{\frac{\mu_0 h\nu_k}{2}}[-ia_k(t)\mathbf{B}_k(\mathbf{r})+ia_k^\dagger(t)\mathbf{B}_k^*(\mathbf{r})] \tag{12}$$

where

$$\mathbf{B}_k(\mathbf{r})=\frac{c}{2\pi\nu_k}\nabla\times\mathbf{A}_k(\mathbf{r});\qquad \mathbf{A}_k(\mathbf{r})=\frac{c}{2\pi\nu_k}\nabla\times\mathbf{B}_k(\mathbf{r}) \tag{13}$$

relates the two kinds of mode functions to each other.

Among others, the mode functions $\mathbf{A}_k(\mathbf{r})$ have the following important properties:

Transverse
$$\nabla\cdot\mathbf{A}_k(\mathbf{r})=0 \tag{14a}$$

Orthonormal
$$\int(d\mathbf{r})\mathbf{A}_j^*(\mathbf{r})\cdot\mathbf{A}_k(\mathbf{r})=\delta_{jk} \tag{14b}$$

Complete
$$\sum_k\mathbf{A}_k(\mathbf{r})\mathbf{A}_k^*(\mathbf{r}')=\delta_\perp(\mathbf{r}-\mathbf{r}') \tag{14c}$$

The same statements hold for the $\mathbf{B}_k(\mathbf{r})$s as well. The property in Eq. (14*a*) states the radiation-gauge condition. The integration in Eq. (14*b*) covers the entire volume bounded by the conducting surfaces just mentioned; the eigenvalue equation Eq. (11) holds inside this volume, the so-called quantization volume. In the completeness relation in Eq. (14*c*), both positions $\mathbf{r}$ and $\mathbf{r}'$ are inside the quantization volume, and $\delta_\perp$ is the transverse delta function, a dyadic that is explicitly given by

$$\delta_\perp(\mathbf{r})=\int\frac{(d\mathbf{k})}{(2\pi)^3}\exp(i\mathbf{k}\cdot\mathbf{r})\left(1-\frac{\mathbf{kk}}{k^2}\right) \tag{15}$$

where 1 is the unit dyadic and $k=\sqrt{\mathbf{k}\cdot\mathbf{k}}$ is the length of the wave vector $\mathbf{k}$ integrated over. The transverse character of $\delta_\perp(\mathbf{r})$ ensures the consistency of the properties in Eqs. (14*a*) and (14*c*).

The time dependence of $\mathbf{E}_\perp(\mathbf{r},t)$ and $\mathbf{B}(\mathbf{r},t)$ stems from the ladder operators $a_k(t)$ and $a_k(t)$, which obey the bosonic equal-time commutation relations

$$[a_j,a_k]=0\qquad[a_j,a_k^\dagger]=\delta_{jk}\qquad[a_j^\dagger,a_k^\dagger]=0 \tag{16}$$

The photon number operator

$$N=\sum_k a_k^\dagger a_k \tag{17}$$

has eigenvalues $N'=0, 1, 2, \ldots$; its eigenstates with $N'=1$ are the one-photon states, those with $N'=2$ are the two-photon states, and so on. The unique eigenstate with $N'=0$ is the photon vacuum.

We denote its ket by $|\mathbf{vac}\rangle$. It is, of course, the joint eigenstate of all *annihilation operators* a_k with eigenvalue zero:

$$a_k|\mathbf{vac}\rangle = 0 \quad \text{for all } k \tag{18}$$

Application of the *creation operator* $a_k^\dagger$ to $|\mathbf{vac}\rangle$ yields a state with one photon in the kth mode:

$$a_k^\dagger|\mathbf{vac}\rangle = \{\text{state with 1 photon of the type } k\} \tag{19}$$

More generally, the ket of a pure one-photon state is of the form

$$|\{\psi\}_1\rangle = \sum_k \psi_k a_k^\dagger|\mathbf{vac}\rangle \quad \text{with} \quad \sum_k |\psi_k|^2 = 1 \tag{20}$$

where $|\psi_k|^2$ is the probability for finding the photon in the kth mode. Similarly, the kets of pure two-photon states have the structure

$$|\{\psi\}_2\rangle = \frac{1}{\sqrt{2}}\sum_{j,k}\psi_{jk}a_j^\dagger a_k^\dagger|\mathbf{vac}\rangle \quad \text{with} \quad \psi_{jk} = \psi_{kj} \quad \text{and} \quad \sum_{j,k}|\psi_{jk}|^2 = 1 \tag{21}$$

and analogous expressions apply to pure states with 3, 4, 5, . . . photons.

Einstein's light quanta are one-photon states of a particular kind. In a manner of speaking, they are localized lumps of electromagnetic energy. In technical terms this means that the energy density

$$\begin{aligned} U_{1\text{ph}}(\mathbf{r},t) &= \left\langle \{\psi\}_1 \left| :\left[\mathbf{E}^2/(2\varepsilon_0) + \left(\frac{\mu_0}{2}\right)\mathbf{B}^2\right]: \right| \{\psi\}_1 \right\rangle \\ &= \frac{h}{2}\sum_{j,k}\psi_j^*\psi_k\sqrt{\nu_j\nu_k}\,(\mathbf{A}_k^*\cdot\mathbf{A}_j + \mathbf{B}_k^*\cdot\mathbf{B}_j) \end{aligned} \tag{22}$$

is essentially nonzero in a relatively small spatial region only. The time dependence is carried by the probability amplitudes ψ_k, the spatial dependence by the mode functions $\mathbf{A}_k$ and $\mathbf{B}_k$. An arbitrarily sharp localization is not possible, but it is also not needed. The pair of colons :: symbolize the injunction to order the operator in between in the *normal* way: all creation operators $a_k^\dagger$ to the left of all annihilation operators a_k. This normal ordering is an elementary feature of renormalized QED.

At high frequencies, or when the quantization volume is unbounded, the eigenvalues of $-\nabla^2$ in Eq. (11) are so dense that the summations in Eqs. (10), (12), and (14*b*) are effectively integrations, and the Kronecker delta symbol in Eq. (14*b*) is a Dirac delta function. Under these circumstances, it is often natural to choose plane waves

$$\mathbf{A}_k(\mathbf{r}) \sim \mathbf{e}_k \exp\left(i\frac{2\pi\nu_k}{c}\mathbf{n}_k\cdot\mathbf{r}\right) \qquad \mathbf{B}_k(\mathbf{r}) \sim \mathbf{n}_k \times \mathbf{e}_k \exp\left(i\frac{2\pi\nu_k}{c}\mathbf{n}_k\cdot\mathbf{r}\right) \tag{23}$$

for the mode functions. The unit vector $\mathbf{e}_k$ that specifies the polarization is orthogonal to the unit vector $\mathbf{n}_k$ that specifies the direction of propagation.

With

$$\psi_k(t) \sim \exp(-i2\pi\nu_k t) \tag{24}$$

in Eq. (22), one then meets exponential factors of the form

$$\exp\left[i\frac{2\pi\nu_k}{c}(\mathbf{n}_k\cdot\mathbf{r} - ct)\right]$$

As a consequence, an einsteinian light quantum propagates without dispersion, which is the anticipated behavior.

The one-photon energy density in Eq. (22) illustrates the general feature that quantum-mechanical probabilities (the ψ_ks) with their interference properties appear together with the classical interference patterns of superposed mode functions [the $\mathbf{A}_k(\mathbf{r})$s and $\mathbf{B}_k(\mathbf{r})$s]. In other words, interference phenomena of two kinds are present in QED: (1) the classical interference of electromagnetic fields in the three-dimensional $\mathbf{r}$ space, and (2) the quantum interference of alternatives in the so-called Fock space; that is, the Hilbert space spanned by the photon vacuum $|\,\mathbf{vac}\rangle$, the one-photon states $|\{\psi\}_1\rangle$, the two-photon states $|\{\psi\}_2\rangle$, and all multiphoton states.

In the early days of QED, this coexistence of classical interferences and quantum interferences was a research topic, to which Fermi's paper of 1929 "Sulla teoria quantistica delle frange di interferenza" is a timeless contribution.[45] He demonstrated, at the example of Lippmann fringes, a very general property of single-photon interference patterns: the photon-counting rates, as determined from quantum-mechanical probabilities, are proportional to the corresponding classical intensities.

Electromagnetic radiation is easily emitted and absorbed by antennas, processes that change the number of photons. Accordingly, the number of photons is not a conserved quantity, and therefore states of different photon numbers can be superposed. Particularly important are the *coherent states*

$$|\{\alpha\}_c\rangle = \exp\left(-\frac{1}{2}\sum_k |\alpha_k|^2 + \sum_k \alpha_k a_k^\dagger\right)|\,\mathbf{vac}\rangle \tag{25}$$

that are characterized by a set $\{\alpha\}_c$ of complex amplitudes α_k. As revealed in Glauber's 1963 papers,[46–48] they play a central role in the coherence theory of light.

Since the coherent states are common eigenstates of the annihilation operators

$$a_k\,|\{\alpha\}_c\rangle = |\{\alpha\}_c\rangle\alpha_k \tag{26}$$

the expectation values of the electric and magnetic field operators of Eqs. (10) and (12)

$$\begin{aligned}
\langle\{\alpha(t)\}_c\,|\,\mathbf{E}_\perp(\mathbf{r},t)\,|\{\alpha(t)\}_c\rangle &= \sum_k \sqrt{\frac{h\nu_k}{(2\varepsilon_0)}}\,[\alpha_k(t)\mathbf{A}_k(\mathbf{r}) + \alpha_k^*(t)\mathbf{A}_k^*(\mathbf{r})] \\
\langle\{\alpha(t)\}_c\,|\,\mathbf{B}_\perp(\mathbf{r},t)\,|\{\alpha(t)\}_c\rangle &= \sum_k \sqrt{\frac{\mu_0 h\nu_k}{2}}\,[-i\alpha_k(t)\mathbf{B}_k(\mathbf{r}) + i\alpha_k^*(t)\mathbf{B}_k^*(\mathbf{r})]
\end{aligned} \tag{27}$$

have the appearance of classical Maxwell fields. In more general terms, if the statistical operator ϱ_{ph} of the photonic degrees of freedom—in other words, the statistical operator of the radiation field—is a mixture of (projectors to) coherent states

$$\varrho_{\mathrm{ph}} = \sum_{\{\alpha\}_c} |\{\alpha\}_c\rangle\, w(\{\alpha\}_c)\langle\{\alpha\}_c| \tag{28}$$

with

$$w(\{\alpha\}_c) \geq 0 \quad \text{and} \quad \sum_{\{\alpha\}_c} w(\{\alpha\}_c) = 1 \tag{29}$$

then the electromagnetic field described by ϱ_{ph} is very similar to a classical Maxwell field. Turned around, this says that whenever it is impossible to write a given ϱ_{ph} in the form of Eq. (28), then some statistical properties of the radiation are decidedly nonclassical.

During the 20-year period from Dirac's paper of 1927 to the Shelter Island conference in 1947, QED remained in a preliminary state that allowed various studies—the most important ones included the Weisskopf-Wigner treatment of spontaneous emission[49] and Weisskopf's discovery that the self-energy of the photon is logarithmically divergent[50]—although the not-yet-understood divergences

were very troublesome. The measurement by Lamb and Retherford[51] of what is now universally known as the *Lamb shift*, first reported at the Shelter Island conference, was the crucial experimental fact that triggered the rapid development of renor-malized QED by Schwinger, Feynman, and others.

Theoretical calculations of the Lamb shift rely heavily on the quantum properties of the electromagnetic field, and their marvelous agreement with the experimental data proves convincingly that these quantum properties are a physical reality. In other words, photons exist. The same remark applies to the theoretical and experimental values of the anomalous magnetic moment of the electron, one of the early triumphs of Schwinger's renormalized QED,[52] which finally explained an anomaly in the spectra of hydrogen and deuterium that Pasternack had observed in 1938[53] and a discrepancy in the measurements by Millman and Kusch[54] of nuclear magnetic moments.

Photon-Photon Correlations

Interferometers that exploit not the spatial intensity variations (or, equivalently, the photon-detection probabilities) but correlations between intensities at spatially separated positions became important tools in astronomy and spectroscopy after the discovery of the Hanbury-Brown-Twiss (HB&T) effect in 1954.[55–57] A textbook account of its classical theory is given in Sec. 4.3 of Ref. 58.

In more recent years, the availability of single-photon detectors made it possible to study the HB&T effect at the two-photon level. The essentials are depicted in Fig. 2. Two light quanta are incident on a half-transparent mirror from different directions, such that they arrive simultaneously. If their frequency contents are the same, it is fundamentally impossible to tell if an outgoing light quantum was reflected or transmitted. This indistinguishability of the two light quanta is of decisive importance in the situation where one is in each output channel. The two cases *both reflected* and *both transmitted* are then indistinguishable and, according to the laws of quantum mechanics, the corresponding probability amplitudes must be added.

Now, denoting the probability amplitudes for single-photon reflection and transmission by ρ and τ, respectively, the probability for one light quantum in each output port is given by

$$|\rho^2+\tau^2|^2=\left|\left(\frac{1}{\sqrt{2}}\right)^2+\left(\frac{i}{\sqrt{2}}\right)^2\right|^2=0 \tag{30}$$

where we make use of $\rho=1/\sqrt{2}$ and $\tau=i/\sqrt{2}$, which are the values appropriate for a symmetric half-transparent mirror. Thus, the situation of one light quantum in each output port does not occur. Behind the half-transparent mirror, one always finds both light quanta in the same output port.

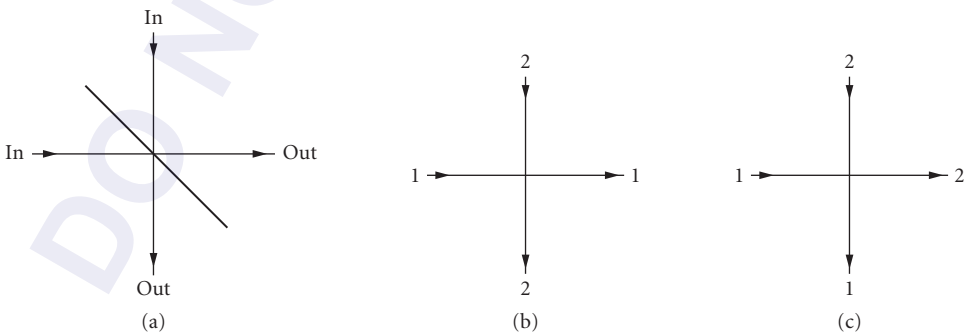

FIGURE 2 Essentials of the Hanbury-Brown–Twiss effect at the two-photon level. (*a*) Two light quanta are simultaneously incident at a symmetric half-transparent mirror. To obtain one quantum in each output port, the quanta must be either both transmitted (*b*) or both reflected (*c*). The probability amplitude for (*b*) is $(1/\sqrt{2})^2=1/2$, that for (*c*) is $(i/\sqrt{2})^2=-1/2$. If the two cases are indistinguishable, the total amplitude is $1/2-1/2=0$.

If the light quanta arrived at very different times, rather than simultaneously, they would be distinguishable and one would have to add probabilities instead of probability amplitudes, so that

$$|\rho^2|^2 + |\tau^2|^2 = \frac{1}{2} \tag{31}$$

would replace Eq. (30). Clearly, there are intermediate stages at which the temporal separation is a fraction of the temporal coherence length and the two quanta are neither fully distinguishable nor utterly indistinguishable. The probability for one light quantum in each output port is then a function of the separation, a function that vanishes when the separation does.

Experiments that test these considerations[59] employ correlated photon pairs produced by a process known as *parametric downconversion*. Roughly speaking, inside a crystal that has no inversion symmetry a high-frequency photon is absorbed and two lower-frequency photons are emitted, whereby the conservation of energy and momentum imposes geometrical restrictions on the possible propagation directions of the three photons involved. Downconversion sources with a high luminosity are available.[60,61]

The HB&T effect of Fig. 2 as well as closely related phenomena are crucial in many experiments in which entangled photons are a central ingredient. In particular, the recent realizations[62,63] of schemes for quantum teleportation[64] and the experiment[65] that demonstrated the practical feasibility of quantum-dense coding[66] are worth mentioning here.

None of these exciting developments could be understood without the quantum properties of radiation. Since the photon concept, in the sense of the discussion of Eqs. (10), (12), (19), (20), and so on is an immediate consequence of these quantum properties, the existence of photons is an established experimental fact beyond reasonable doubt.

23.4 QUANTUM THEORY OF THE LASER

The quantum theory of laser radiation is a problem in nonequilibrium statistical mechanics. There are several alternative, but ultimately equivalent, approaches to the characterization of the field inside the resonator. As is customary in the Scully-Lamb quantum theory, we describe the state of the laser field by a density operator.[67,68] In this section our main focus is on the review of the equation of motion, the so-called master equation, for this density operator as it emerges from an underlying physical model, with statistical considerations and some simplifying assumptions. The alternative procedure based on the quantum theory of noise sources introduced in Refs. 69 and 70 and summarized in Refs. 71 to 74 will also be briefly reviewed at the end of the section. For a recent, more detailed overview of the quantum Langevin point of view, we refer the reader to Ref. 75.

In general, a laser model should be based on the interaction of multimode fields with multilevel atoms as the active medium, and a detailed consideration of all possible processes among all the levels involved should be given. Decay channels and decay rates, in particular, play a crucial role in determining the threshold inversion and, thus, the necessary pumping rates. Of course, the pumping mechanisms themselves can be quite complicated. It is well established that a closed two-level model cannot exhibit inversion and, hence, lasing. In order to achieve inversion three- and four-level pumping schemes are employed routinely. On the other hand, to illustrate the essential quantum features a single mode field can serve as paradigm. The single-mode laser field inside the resonator interacts with one particular transition of the multilevel system—the lasing transition—and the role of the entire complicated level structure is to establish inversion on this transition—that is, to put more atoms in the upper level than there are in the lower one. If one is not interested in the details of how the inversion builds up, it is possible to adopt a much simpler approach than the consideration of a multilevel-multimode system. In order to understand the quantum features of the single-mode field it is sufficient to focus only on the two levels of the lasing transition and their interaction with the laser field. In this approach, the effect of pumping, decay, and so on in the multilevel structure is simply replaced by an initial condition; it is assumed that the atom is in its upper state immediately before the interaction with the laser mode begins. Since here we are primarily interested

in the quantum signatures of the laser field and not in the largely classical aspects of cavity design, pumping mechanisms, and so on, we shall follow this simpler route from the beginning. The model that accounts for the resonant interaction of a two-level atom with a single quantized mode in a cavity was introduced by Jaynes and Cummings.[76]

We shall make an attempt to present the material in a tutorial way. We first derive an expression for the change of the field density operator due to the interaction with a single two-level atom, initially in its upper state, using the Jaynes-Cummings model. This expression will serve as the seed for both the laser and micromaser theories. We next briefly review how to account for cavity losses by using standard methods for modeling the linear dissipation loss of the cavity field due to mirror transmission. Then we show that with some additional assumptions the single-atom-single-mode approach can be used directly to derive what has become known as the Scully-Lamb master equation for the more traditional case of the laser and the micromaser. The additional assumptions include the Markov approximation or, equivalently, the existence of very different time scales for the atomic and field dynamics so that adiabatic elimination of the atoms and introduction of coarse-grained time evolution for the field become possible. The main difference between the laser and micromaser theories is that the interaction time of the active atoms with the field is governed by the lifetime of the atoms in the laser and by the transit time of the atoms through the cavity in the micromaser. In the laser case, the atoms decay out of the lasing levels into some far-removed other levels, and they are available for the lasing transition during their lifetime on the average. In the micromaser case, the transit time is approximately the same for all atoms in a monoenergetic pumping beam. Thus, the laser involves an extra averaging over the random interaction times. If we model the random interaction times by a Poisson distribution and average the change of the field density operator that is due to a single atom—the kick—over the distribution of the interaction times, we obtain the master equation of a laser from that of the micromaser. Historically, of course, the development was just the opposite: the master equation was derived in the context of the laser much earlier. However, it is instructive to see how the individual Rabi oscillations of single nondecaying atoms with a fixed interaction time, as in the micromaser, give rise to the saturating, nonoscillatory collective behavior of an ensemble of atoms, as in the laser, upon averaging over the interaction times. As applications of this fully quantized treatment we study the photon statistics, the linewidth, and spectral properties. Finally, we briefly discuss other approaches to the quantum theory of the laser.

Time Evolution of the Field in the Jaynes-Cummings Model

We shall consider the interaction of a single two-level atom with a single quantized mode of a resonator using the rotating-wave approximation (for a recent review of the Jaynes-Cummings model see Ref. 77). The arrangement is shown in Fig. 3.

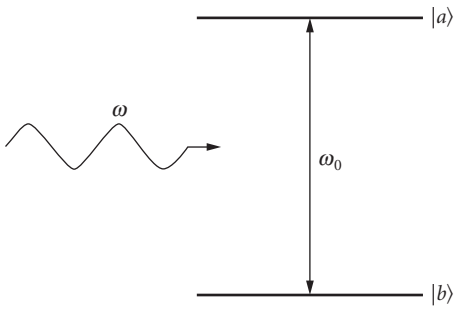

FIGURE 3 Scheme of a two-level atom interacting with a single mode quantized field. The text focuses on the resonant case, $\omega = \omega_0$.

The hamiltonian for this system is given by

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_1 \tag{32}$$

where

$$\mathcal{H}_0 = \frac{1}{2}\hbar\omega_0\sigma_z + \hbar\omega_0 a^\dagger a \tag{33}$$

and

$$\mathcal{H}_1 = \hbar g(\sigma_+ a + a^\dagger \sigma_-) \tag{34}$$

Here a and $a^\dagger$ are the annihilation and creation operators for the mode. The upper level of the lasing transition is denoted by $|a\rangle$ and the lower level by $|b\rangle$. The atomic lowering and raising operators are expressed in terms of the state vectors as $\sigma_- = (\sigma_+)^\dagger = |b\rangle\langle a|$ and the population operator as $\sigma_z = |a\rangle\langle a| - |b\rangle\langle b|$ ω_0 is the frequency of the $|a\rangle - |b\rangle$ transition. For simplicity we assume perfect resonance with the mode. Finally, g is the coupling constant between the atom and the mode. In terms of atomic and field quantities it is given by $g = p\sqrt{\omega_0/2\hbar\varepsilon_0 v}$ where p is the transition dipole moment and v the quantization volume (the volume of the active medium, in our case). Again, for simplicity, p is assumed to be real.

In the interaction picture with respect to $\mathcal{H}_0$, the interaction hamiltonian becomes

$$\mathcal{V} = \exp\left(\frac{i\mathcal{H}_0 t}{\hbar}\right)\mathcal{H}_1 \exp\left(-\frac{i\mathcal{H}_0 t}{\hbar}\right) = \hbar g\left(\sigma_+ a + a^\dagger \sigma_-\right) \equiv \mathcal{H}_1 \tag{35}$$

since $\mathcal{H}_0$ and $\mathcal{H}_1$ commute.

In the two-dimensional Hilbert space spanned by the state vectors $|a\rangle$ and $|b\rangle$ the interaction hamiltonian can be written as

$$\mathcal{H}_1 = \hbar g\begin{pmatrix} 0 & a \\ a^\dagger & 0 \end{pmatrix} \tag{36}$$

The time evolution operator for the coupled atom-field system satisfies the equation of motion in this picture

$$\frac{i\hbar dU}{dt} = \mathcal{V}U \tag{37}$$

and since $\mathcal{H}_1$ is time independent the solution is formally

$$U(\tau) = \exp\left(-\frac{i}{h}\mathcal{V}\tau\right) \tag{38}$$

Using the properties of the σ_- and σ_+ matrices, it is easy to show that $U(\tau)$ can be written in the preceding 2×2 matrix representation as

$$U(\tau) = \begin{pmatrix} \cos\left(g\tau\sqrt{aa^\dagger}\right) & -i\dfrac{\sin\left(g\tau\sqrt{aa^\dagger}\right)}{\sqrt{aa^\dagger}}a \\ -ia^\dagger\dfrac{\sin\left(g\tau\sqrt{aa^\dagger}\right)}{\sqrt{aa^\dagger}} & \cos\left(g\tau\sqrt{a^\dagger a}\right) \end{pmatrix} \tag{39}$$

Let us now assume that initially, at t_0, the atom is in its upper state given by the atomic density operator $\varrho_{\rm at}(t_0)=|a\rangle\langle a|$ and the field is in an arbitrary state which, in general, can be described by the density operator $\varrho(t_0)$, so that the joint atom-field system is characterized by the initial density operator $\varrho_{\rm af}(t_0)=\varrho_{\rm at}(t_0)\otimes\varrho(t_0)$. After the interaction, $\varrho_{\rm af}(t_0+\tau)=U(\tau)\varrho_{\rm af}(t_0)U(\tau)^{-1}$. Our main interest here is in the evolution of the field density operator. This we obtain if we trace the atom-field density operator over the atomic states, yielding

$$\begin{aligned}\varrho(t_0+\tau)&=\mathrm{Tr}_{\rm atom}[\varrho_{\rm af}(t+\tau)]\\&=\cos(g\tau\sqrt{aa^\dagger})\varrho(t_0)\cos(g\tau\sqrt{aa^\dagger})+a^\dagger\frac{\sin(g\tau\sqrt{aa^\dagger})}{\sqrt{aa^\dagger}}\varrho(t_0)\frac{\sin(g\tau\sqrt{aa^\dagger})}{\sqrt{aa^\dagger}}a\\&\equiv M(\tau)\varrho(t_0)\end{aligned}\tag{40}$$

Here in the last step we just introduced the superoperator M, which describes the effect of a single inverted atom on the field and is a key ingredient of laser and micromaser theory. The matrix elements in photon number representation take the form

$$(M(\tau)\varrho)_{nn'}=A_{nn'}(\tau)\varrho_{nn'}+B_{n-1n'-1}(\tau)\varrho_{n-1n'-1}\tag{41}$$

where the coefficients are given by

$$A_{nn'}(\tau)=\cos(g\tau\sqrt{n+1})\cos(g\tau\sqrt{n'+1})\tag{42}$$

$$B_{nn'}(\tau)=\sin(g\tau\sqrt{n+1})\sin(g\tau\sqrt{n'+1})\tag{43}$$

For later purposes, we also introduce the change in the state of the field due to the interaction with a single inverted atom as

$$\varrho(t_0+\tau)-\varrho(t_0)=M(\tau)\varrho(t_0)-\varrho(t_0)=(M-1)\varrho(t_0)\equiv K\varrho(t_0)\tag{44}$$

The operator K, sometimes called the *kick operator*, contains all the information we will need to build the quantum theory of the single-mode laser and micromaser. In matrix representation, $[K(\tau)\varrho]_{nn'}=[A_{nn'}(\tau)-\delta_{nn'}]\varrho_{nn'}+B_{n-1n'-1}(\tau)\varrho_{n-1n'-1}$.

For more elaborate systems (multimode lasers driven by multilevel atoms, for example) one cannot give M in such a simple analytical form, but the principle remains always the same. One should find the superoperator M or, equivalently, the kick operator $K = M - 1$ which gives the action of a single (possibly multilevel) atom on the (possibly multimode) field from the general expression $\varrho(t_0+\tau)=\mathrm{Tr}_{\rm atom}[U_{\rm af}(\tau)\varrho_{\rm at}(t_0)\otimes\varrho(t_0)U_{\rm af}(\tau)^{-1}]\equiv M(\tau)\varrho(t_0)$. In order to determine the full time-evolution operator $U_{\rm af}(\tau)$ of the coupled atom-field system, however, one usually needs to resort to approximation methods, such as perturbation theory, in the more complicated multilevel-multimode cases.

Derivation of the Scully-Lamb Master Equation

In 1954, Gordon, Zeiger, and Townes showed that coherent electromagnetic radiation can be generated in the radio frequency range by the maser (acronym for *microwave amplification by stimulated emission of radiation*).[78] The first maser action was observed in a beam of ammonia.[79] The maser principle was extended to the optical domain by Schawlow and Townes,[80] and also by Prokhorov

and Basov,[81] thus obtaining a laser (acronym for *light amplification by stimulated emission of radiation*). A laser consists of a large ensemble of inverted atoms interacting resonantly with the electromagnetic field inside a cavity. The cavity selects only a specific set of modes corresponding to a discrete set of eigenfrequencies. The active atoms—that is, the ones that are pumped to the upper level of the laser transition—are in resonance with one of the eigenfrequencies of the cavity in the case of the single-mode laser and with a finite set of frequencies in the case of the multimode laser. As discussed in the introduction to this section, for the discussion of the essential quantum features of the radiation field of a laser it is sufficient to confine our treatment to the single-mode case, and that is what we will do for the remainder of this section. A resonant electromagnetic field gives rise to stimulated emission, and the atoms thereby transfer their energy to the radiation field. The emitted radiation is still at resonance. If the upper level is sufficiently populated, this radiation gives rise to further transitions in other atoms. In this way, all the excitation energy of the atoms is transferred to the single mode of the radiation field.

The first pulsed laser operation was demonstrated by Maiman in ruby.[82] The first continuous wave (CW) laser, a He-Ne gas laser, was built by Javan et al.[83] Since then a large variety of systems have been demonstrated to exhibit lasing action. Coherent radiation has been generated this way over a frequency domain ranging from infrared to soft X rays. These include dye lasers, chemical lasers, solid-state lasers, and semiconductor lasers.

Many of the laser properties can be understood on the basis of a semiclassical theory. In such a theory the radiation field is treated classically, but the active medium is given a full quantum-mechanical treatment. Such a theory can readily explain threshold and saturation, transient dynamics, and general dependence on the external parameters (pumping and losses). It is not our aim here to give an account of the semiclassical theory; therefore, we just refer the reader to the ever instructive and wonderfully written seminal paper by Lamb[84] and a more extended version in Ref. 67. Although quantum effects play only a minor role in usual practical laser applications because of the large mean photon numbers, they are essential for the understanding of the properties of micromasers, in which excited two-level atoms interact one after the other with a single mode of the radiation field.[85] Nevertheless, the quantum properties of the laser field are of fundamental interest as well. They have been thoroughly investigated theoretically with respect to the photon statistics and the spectrum of the laser. In particular, the quantum limitation of the laser linewidth caused by the inevitably noisy contribution of spontaneous emission has attracted much attention. It gives rise to the so-called Schawlow-Townes linewidth, which is inversely proportional to the laser intensity (see Ref. 80). Because of the importance of stable coherent signals for various high-precision measurements, the problem of the intrinsic quantum-limited linewidth has gained renewed interest recently, and the investigations have been extended to cover bad-cavity lasers and several more exotic systems. In this review, however, we shall restrict ourselves to good-cavity lasers in which the cavity damping time is long compared to all other relevant time scales, and present a fully quantized theory of the most fundamental features.

Cavity Losses To account for the decay of the cavity field through the output mirror of the cavity, we simply borrow the corresponding result from reservoir theory. Its usage has become fairly standard in laser physics and quantum optics (see, for example, Refs. 67 and 68), and here we just quote the general expression without actually deriving it.

$$\left(\frac{d\varrho}{dt}\right)_{\text{loss}} = \mathcal{L}\varrho \equiv -\frac{\kappa}{2} n_{\text{th}} (aa^\dagger \varrho + \varrho aa^\dagger - 2a^\dagger \varrho a) - \frac{\kappa}{2}(n_{\text{th}} + 1)(a^\dagger a\varrho + \varrho a^\dagger a - 2a\varrho a^\dagger) \tag{45}$$

This equation refers to a loss reservoir which is in thermal equilibrium at temperature T, with n_{th} being the mean number of thermal photons $n_{\text{th}} = [\exp(\hbar\omega_0 / kT) - 1]^{-1}$, and κ is the cavity damping rate. For the laser case, it is sufficient to take the limiting case of a zero temperature reservoir since $\hbar\omega_0 \gg kT$ and n_{th} is exponentially small. We obtain this limit by substituting $n_{\text{th}} = 0$ into Eq. (45). For the description of most micromaser experiments, however, we need the finite temperature version, since even at very low temperatures the thermal photon number is comparable to the total number of photons in the cavity.

The Laser Master Equation After introducing the loss part of the master equation, we now turn our attention to the part that stems from the interaction with the gain reservoir. The gain reservoir is modeled by an ensemble of initially excited two-level atoms allowed to interact with the single-mode cavity field. A central role in our subsequent discussions will be played by the so-called kick operator, $K = M - 1$, describing the change of the field density operator due to the interaction with a single atom. This quantity was introduced in Eq. (44). While in the micromaser case the effect of each of the atoms can be represented by the same kick operator, since in a monoenergetic pumping beam each atom has the same interaction time with the cavity field, this is no longer the case for a laser. In a typical CW gas laser, such as the He-Ne laser, atoms are excited to the upper level of the lasing transition at random times and, more important, they can also interact with the field for a random length of time. The interaction time thus becomes a random variable. Since at any given time the number of atoms is large (about 10^6 to 10^7 active atoms in the lasing volume of a CW He-Ne laser), it is a legitimate approach to describe their effect on the field by an average kick operator. We can arrive at the interaction-time-averaged master equation quickly if we take the average of Eq. (44) with respect to the interaction time τ:

$$(M-1)\boldsymbol{\varrho}(t)=\int_0^\infty d\tau P(\tau)(M(\tau)-1)\boldsymbol{\varrho}(t) \tag{46}$$

where the distribution function for the interaction time $P(\tau)$ is defined as

$$P(\tau)=\gamma e^{-\gamma\tau} \tag{47}$$

This distribution function corresponds to the exponential decay law. Individual atoms can decay from the lasing levels at completely random times, but for an ensemble of atoms the probability of finding an initially excited atom still in the lasing levels in the time interval $(\tau, \tau+d\tau)$ is given by Eq. (47). With increasing τ it is increasingly likely that the atoms have decayed outside the lasing transition. Also note that our model corresponds to an open system: the atoms decay to other non-lasing levels both from the upper state $|a\rangle$ and the lower state $|b\rangle$, and, in addition, we assume that decay rate γ is the same for both levels, as indicated in Fig. 4.

Obviously, these restrictions can be relaxed and, indeed, there are various more general models available. For example, the upper level $|a\rangle$ can have two decay channels. It can decay to the lower level $|b\rangle$ and to levels outside the lasing transition. Or, in some of the most efficient lasing schemes, the lower level decays much faster than the upper one, $\gamma_b \gg \gamma_a$. In these schemes virtually no population builds up in the lower level; hence, saturation of the lasing transition occurs at much higher

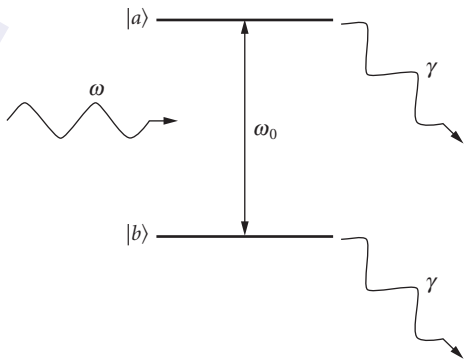

FIGURE 4 Scheme of a two-level atom, with atomic decay permitted, interacting with a single-mode quantized field.

intensities than in lasers with equal decay rates for both levels. These generalizations, however, are easily accounted for (see Ref. 67) and it is not our concern here to provide the most general treatment possible. Instead, we want to focus on the essential quantum features of the laser field and employ the simple two-level model with equal decay rates for both.

The formal averaging in Eq. (46) can be performed most easily if we transform to a particular representation of the density matrix. For our purposes, the photon number representation suffices, although other options are readily available and some of them will be summarized briefly at the end of this section. Taking the n, n' elements of Eq. (46) and using Eqs. (42) and (43), the averaging yields

$$[(M-1)\varrho]_{nn'} = -\frac{\chi(n+1+n'+1)+\chi^2(n-n')^2}{1+2\chi(n+1+n'+1)+\chi^2(n-n')^2}\varrho_{nn'} + \frac{2\chi\sqrt{nn'}}{1+2\chi(n+n')+\chi^2(n-n')^2}\varrho_{n-1n'-1} \tag{48}$$

where the notation $\chi = g^2/\gamma^2$ is introduced. Finally, taking into account cavity losses $(\mathcal{L}\varrho)_{nn'}$ from Eq. (45), with $n_{\text{th}} = 0$, we obtain the following master equation for our quantum-mechanical laser model:

$$\dot{\varrho}_{nn'} = -\frac{\mathcal{N}'_{nn'}\mathcal{A}}{1+\mathcal{N}_{nn'}\mathcal{B}/\mathcal{A}}\varrho_{nn'} + \frac{\sqrt{nn'\mathcal{A}}}{1+\mathcal{N}_{n-1n'-1}\mathcal{B}/\mathcal{A}}\varrho_{n-1n'-1} - \frac{\kappa}{2}(n+n')\varrho_{nn'} + \kappa\sqrt{(n+1)(n'+1)}\varrho_{n+1n'+1} \tag{49}$$

Here we introduced the original notations of the Scully-Lamb theory—the linear gain coefficient:

$$\mathcal{A} = 2r\chi \tag{50}$$

the self-saturation coefficient:

$$\mathcal{B} = 4\chi\mathcal{A} \tag{51}$$

and the dimensionless factors:

$$\mathcal{N}' = \frac{1}{2}(n+1+n'+1) + \frac{(n-n')^2\mathcal{B}}{8\mathcal{A}} \tag{52}$$

and

$$\mathcal{N} = \frac{1}{2}(n+1+n'+1) + \frac{(n-n')^2\mathcal{B}}{16\mathcal{A}} \tag{53}$$

Equation (49) is the Scully-Lamb master equation, which is the central equation of the quantum theory of the laser. Along with the notations introduced in Eqs. (50) to (53), it constitutes the main result of this section and serves as the starting point for our treatment of the quantum features of the laser. Among the specific problems we shall consider are the photon statistics, which is the physical information contained in the diagonal elements, and the spectrum, which is the physical information contained in the off-diagonal elements of the field density matrix.

The Micromaser Master Equation The development of the single-atom maser or micro-maser plays a particularly important role in cavity quantum electrodynamics because it realizes one of the most fundamental models, the Jaynes-Cummings hamiltonian. The experimental situation[86] is very close to the idealized case of a single two-level atom interacting with a single-mode quantized field, as previously discussed, and allows a detailed study of fundamental quantum effects in the atom-field interaction.

In the micromaser, a stream of two-level atoms is injected into a superconducting microwave cavity of very high quality Q. The injection rate r is low enough to ensure that at most only one atom is present inside the cavity at any given time and that most of the time the cavity is empty. The decay time of the high-Q cavity field is very long compared to both the interaction time τ, which is set by the transit time of atoms through the cavity, and the inverse of the single-photon Rabi frequency g^{-1}. In typical experimental situations, however, $g\tau \simeq 1$. Therefore, a field is built up in the cavity provided the interval between atomic injections does not significantly exceed the cavity decay time. Sustained oscillation is possible with less than one atom on the average in the cavity.

In addition to the progress in constructing superconducting cavities, advances in the selective preparation of highly excited hydrogenlike atomic states, called *Rydberg states*, have made possible the realization of the micromaser. In Rydberg atoms the probability of induced transitions between adjacent states is very large, and the atoms may undergo several Rabi cycles— that is, several periodic energy exchanges between the atom and the cavity field may take place in the high-Q cavity. The lifetime of Rydberg states for spontaneous emission decay is also very long, and atomic decay can be neglected during the transit time in the cavity.

Here we set out to derive a master equation for the micromaser. For this, we consider a single-mode resonator into which two-level atoms are injected in their upper states. Due to the different time scales, the effect of cavity damping can be neglected during the interaction. Then the effect of a single atom on the field density operator, injected at t_i and interacting with the field for a time τ, is given by Eq. (44) with t_0 replaced by t_i. If several atoms are injected during a time interval Δt which is still short on the time scale governed by the cavity decay time κ^{-1} but long on the time scale of the interaction time τ, then the cumulative effect on the field is simply the sum of changes

$$\Delta\varrho = \sum_{t\le t_i\le t+\Delta t} (M(\tau)-1)\varrho(t_i) = r\int_t^{t+\Delta t} (M(\tau)-1)\varrho(t_i)dt_i \tag{54}$$

where in the last step we turned the sum into an integral by using the injection rate r as the number of excited-state atoms entering the cavity per unit time.

At this point we introduce some of the most important approximations of laser physics, or reservoir theory in general—the so-called Markov or adiabatic approximation and coarse time graining. These approximations are based on the existence of three very different time scales in the problem. First, the interaction time τ for individual atoms is of the order of the inverse single-photon Rabi frequency g^{-1}, and is the shortest of all. In fact, on the time scale set by the other relevant parameters, it appears as a delta-function-like kick to the state of the field with the kick operator K of Eq. (44). The second time scale is set by r^{-1}, the average time separation between atomic injections. It is supposed to be long compared to τ but short compared to the cavity-damping time κ^{-1}. Thus, we have the following hierarchy of timescales: $\tau \ll r^{-1} \ll \kappa^{-1}$. When we turned the sum in Eq. (54) into an integral we already tacitly assumed that there is a time scale on which the injection appears to be quasicontinuous. We now see that it is the time scale set by κ^{-1}. This is the time scale that governs the time evolution of the cavity field. In the evaluation of the integral in Eq. (54) we assume that Δt is an intermediate time interval such that $r^{-1} < \Delta t < \kappa^{-1}$. Then during this interval the state of the field does not change appreciably, and we can replace $\varrho(t_i)$ on the right-hand side of Eq. (54) by $\varrho(t)$. This is the essential step in transforming the integral equation into a differential equation, and it constitutes what is called the *Markov approximation*. It is also called the *adiabatic approximation* since the field changes very slowly (adiabatically) on the time scale set by the atoms. As a result, $\varrho(t)$ can now be taken out of the integral, and the integration in Eq. (54) yields $\Delta\varrho = r\Delta t\big(M-1\big)\varrho(t)$. Dividing both sides by Δt, we obtain

$$\frac{\Delta\varrho}{\Delta t} = r(M(\tau)-1)\varrho \tag{55}$$

The left-hand side is not a true derivative; it only appears to be one on the time scale of the cavity decay time. However, if we are interested in the large-scale dynamics of the field, we can still regard it as a good approximation to a time derivative. It is called the *coarse-grained derivative* and the Eq. (55)

now properly describes the time rate of change of the field due to the interaction with an ensemble of active atoms, the gain reservoir.

Equation (55) gives the time rate of change of the field density operator due to the gain reservoir $(d\boldsymbol{\varrho}/dt)_{\text{gain}}$. To this, we add the time rate of change of the density operator due to the cavity losses by hand. For the parameters of the Garching micromaser experiment, $T = 0.5$ K and $\omega_0/2\pi = 21.5$ GHz, yielding $n_{\text{th}} = 0.15$. The thermal background cannot be neglected since, as we shall see, the steady-state field contains but a few photons. The complete master equation for the micromaser, including both gain and loss, is then simply the sum of Eqs. (55) and (45):

$$\frac{d\boldsymbol{\varrho}}{dt} = \left(\frac{d\boldsymbol{\varrho}}{dt}\right)_{\text{gain}} + \left(\frac{d\boldsymbol{\varrho}}{dt}\right)_{\text{loss}} = r(M(\tau)-1)\boldsymbol{\varrho} + \mathcal{L}\boldsymbol{\varrho} \tag{56}$$

For later purposes, we also give the master equation in matrix representation:

$$\begin{aligned}\frac{d\boldsymbol{\varrho}_{nn'}}{dt} = {} & r[(A_{nn'}(\tau)-1)\boldsymbol{\varrho}_{nn'} + B_{n-1n'-1}(\tau)\boldsymbol{\varrho}_{n-1n'-1}] \\ & -\frac{\kappa}{2}n_{\text{th}}[(n+n'+2)\boldsymbol{\varrho}_{nn'} - 2\sqrt{nn'}\,\boldsymbol{\varrho}_{n-1n'-1}] \\ & -\frac{\kappa}{2}(n_{\text{th}}+1)[(n+n')\boldsymbol{\varrho}_{nn'} - 2\sqrt{(n+1)(n'+1)}\,\boldsymbol{\varrho}_{n+1n'+1}]\end{aligned} \tag{57}$$

Here $A_{nn'}(\tau)$ and $B_{nn'}(\tau)$ are given by Eqs. (42) and (43). Equation (57) is identical to the one obtained by more standard methods[87] and employed widely in the context of micromasers. It forms the basis for most studies (with a few notable exceptions, as discussed at the end of this section) on the quantum statistical properties of the micromaser and, naturally, it will be our starting point as well.

Physics on the Main Diagonal: Photon Statistics

To begin to bring to light the physical consequences of the laser and maser master equations, we shall first focus on the diagonal elements of the field density matrix $\boldsymbol{\varrho}_{nn}$, which give us the photon-number distribution since $\boldsymbol{\varrho}_{nn} = p(n)$ is the probability of finding n photons in the cavity mode. The case of the laser is sufficiently different from that of the micromaser that we shall deal with them separately.

Laser Photon Statistics Taking the diagonal $n = n'$ elements in Eq. (49) and regrouping the terms, we obtain the following equation for the photon-number probabilities:

$$\dot{p}(n) = -\frac{(n+1)\mathcal{A}}{1+(n+1)\mathcal{B}/\mathcal{A}}p(n) + \kappa(n+1)p(n+1) + \frac{n\mathcal{A}}{1+n\mathcal{B}/\mathcal{A}}p(n-1) - \kappa n p(n) \tag{58}$$

Here the overdot stands for the time derivative. Note that diagonal elements are coupled only to diagonal elements. This holds quite generally; Eq. (49) describes coupling along the same diagonal only. For example, elements on the first side diagonal are coupled to other elements on the first side diagonal, and so on, and in general only elements with the same difference $n - n'$ are coupled. The quantity $k = n - n'$ corresponds to elements on the kth side diagonal. Elements on different diagonals are not coupled, which greatly simplifies the solution of laser-related problems.

Before we begin the solution of Eq. (58), we want to give a simple intuitive physical picture of the processes it describes in terms of a probability flow diagram, shown in Fig. 5.

The left-hand side is the rate of change of the probability of finding n photons in the cavity. The right-hand side contains the physical processes that contribute to the change. Each process is

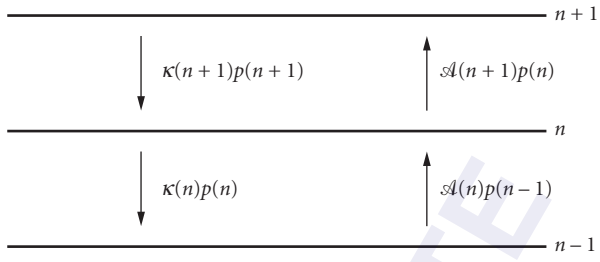

FIGURE 5 Probability flow diagram for the laser.

represented by an arrow in the diagram. The processes are proportional to the probability of the state they are starting from and this will be the starting point of the arrow. The tip of the arrow points to the state the process is leading to. There are two kinds of elementary processes: emission of a photon into the cavity mode (upward arrows) and loss of a photon from the cavity through the output mirror (downward arrows). Furthermore, the processes that start from a given state and end in a different one will decrease the probability of the state they are starting from and increase the probability of the state they are ending at. For example, the first term on the right-hand side describes emission of a photon into the cavity mode provided there are n photons already present before the emission event takes place. Since there will be $n + 1$ photons after the emission, this process decreases the probability of finding n photons, hence the minus sign. The total emission rate $\mathcal{A}(n+1)$ has a contribution from stimulated emission, the $\mathcal{A}(n)$ term, and another one from spontaneous emission, the $\mathcal{A}$ term. The third term on the right-hand side corresponds similarly to emission, conditioned on the presence of $n - 1$ photons in the cavity initially. After the emission, there will be n photons, hence the plus sign. The second term describes the loss of a photon through the cavity mirror, provided there are n photons initially. After the escape of a photon, there will be $n - 1$ photons; therefore, this term decreases $p(n)$. Finally, the last term corresponds similarly to a loss process, with initially $n + 1$ photons in the cavity. After the escape of a photon there will be n photons left, so this term increases the probability $p(n)$ of finding n photons in the cavity.

After this brief discussion of the meaning of the individual terms, we now turn our attention to the solution of the equation. Although it is possible to obtain a rather general time-dependent solution to Eq. (58), our main interest here is in the steady-state properties of the field. To obtain the steady-state photon statistics, we replace the time derivative with zero. Note that the right-hand side of the equation is of the form $F(n + 1) - F(n)$, where

$$F(n)=\kappa n p(n)-\frac{n\mathcal{A}}{1+n\mathcal{B}/\mathcal{A}}p(n-1) \tag{59}$$

simply meaning that in steady-state $F(n + 1) = F(n)$. In other words, $F(n)$ is independent of n and is, therefore, a constant c. Furthermore, the equation $F(n) = c$ has normalizable solution only for $c = 0$. From Eq. (59) we then immediately obtain

$$p(n)=\frac{\mathcal{A}/\kappa}{1+n\mathcal{B}/\mathcal{A}}p(n-1) \tag{60}$$

which is a very simple two-term recurrence relation to determine the photon-number distribution. Before we present the solution, a remark is called for here. The fact that $F(n) = 0$ and $F(n + 1) = 0$ hold separately is called the *condition of detailed balance*. As a consequence, we do not need to deal with all four processes affecting $p(n)$. It is sufficient to balance the processes connecting a pair of adjacent levels in Fig. 5, and instead of solving the general three-term recurrence relation resulting from the steady-state version of Eq. (58), it is enough to solve the much simpler two-term recursion, Eq. (60).

It is instructive to investigate the photon statistics in some limiting cases before discussing the general solution. Below threshold the linear approximation holds. Since only very small n states are

populated appreciably, the denominator on the right-hand side of Eq. (60) can be replaced by unity in view of $n\mathscr{B}/\mathscr{A} \ll 1$. Then

$$p(n) = p(0)\left(\frac{\mathscr{A}}{\kappa}\right)^n \tag{61}$$

The normalization condition $\sum_{n=0}^{\infty} p(n) = 1$ determines the constant $p(0)$, yielding $p(0) = (1 - \mathscr{A}/\kappa)$. Finally,

$$p(n) = \left(1 - \frac{\mathscr{A}}{\kappa}\right)\left(\frac{\mathscr{A}}{\kappa}\right)^n \tag{62}$$

Clearly, the condition of existence for this type of solution is $\mathscr{A} < \kappa$. Therefore, $\mathscr{A} = \kappa$ is the threshold condition for the laser. At threshold, the photon statistics change qualitatively and very rapidly in a narrow region of the pumping parameter. It should also be noted that below threshold the distribution function Eq. (62) is essentially of thermal character. If we introduce an effective temperature T defined by

$$\exp\left(-\frac{\hbar\omega_0}{kT}\right) = \frac{\mathscr{A}}{\kappa} \tag{63}$$

we can cast Eq. (62) to the form

$$p(n) = \left[1 - \exp\left(-\frac{\hbar\omega_0}{kT}\right)\right]\exp\left(-\frac{n\hbar\omega_0}{kT}\right) \tag{64}$$

This is just the photon-number distribution of a single mode in thermal equilibrium with a thermal reservoir at temperature T. The inclusion of a finite temperature-loss reservoir to represent cavity losses will not alter this conclusion about the region below threshold.

There is no really good analytical approximation for the region around threshold, although the lowest-order expansion of the denominator in Eq. (60) yields some insight. The solution with this condition is given by

$$p(n) = p(0)\left(\frac{\mathscr{A}}{\kappa}\right)^n \prod_{k=0}^{n}\left(1 - \frac{k\mathscr{B}}{\mathscr{A}}\right) \tag{65}$$

This equation clearly breaks down for $n > \mathscr{A}/\mathscr{B} = n_{\max}$, where $p(n)$ becomes negative. The resulting distribution is quite broad, exhibiting a long plateau and a rapid cutoff at $n_{\max}$. The broad plateau means that many values of n are approximately equally likely; therefore, the intensity fluctuations are large around threshold. The most likely value of $n = n_{\text{opt}}$ can be obtained from the condition $p(n_{\text{opt}} - 1) = p(n_{\text{opt}})$ since $p(n)$ is increasing before $n = n_{\text{opt}}$ and decreasing afterwards. This condition yields $n_{\text{opt}} = (\mathscr{A} - \kappa)/\mathscr{B}$, which is smaller by the factor $\kappa/\mathscr{A}$ than the value obtained from the full nonlinear equation [cf. Eq. (70) following].

The third region of special interest is the one far above threshold. In this region, $\mathscr{A}/\kappa \gg 1$ and the n values contributing the most to the distribution function are the ones for which $n \gg \mathscr{A}/\mathscr{B}$. We can then neglect 1 in the denominator of Eq. (60), yielding

$$p(n) = \exp\left(-\bar{n}\,\frac{\bar{n}^n}{n!}\right) \tag{66}$$

with $\bar{n} = \mathscr{A}^2/(\kappa\mathscr{B})$. Thus, the photon statistics far above threshold are poissonian, the same as for a coherent state. This, however, does not mean that far above threshold the laser is in a coherent state. As we shall see later, the off-diagonal elements of the density matrix remain different from those of a coherent state for all regimes of operation.

After developing an intuitive understanding of the three characteristically different regimes of operation, we give the general solution of Eq. (60), valid in all three regimes:

$$p(n) = p(0)\prod_{k=1}^{n}\frac{(\mathcal{A}/\kappa)}{(1+k(\mathcal{B}/\mathcal{A})} \tag{67}$$

The normalization constant $p(0)$ may be expressed in terms of the confluent hypergeometric function

$$p(0) = \left[\sum_{n=0}^{\infty}\frac{\left(\frac{\mathcal{A}}{\mathcal{B}}\right)!\left(\frac{\mathcal{A}^2}{\mathcal{B}\kappa}\right)^n}{\left(n+\frac{\mathcal{A}}{\mathcal{B}}\right)!}\right]^{-1}$$

$$= \left[F\left(1;\frac{\mathcal{A}}{\mathcal{B}}+1;\frac{\mathcal{A}^2}{\mathcal{B}\kappa}\right)\right]^{-1} \tag{68}$$

In Fig. 6, the photon-number distribution is displayed for various regimes of operation.

It is interesting to note that $p(n)$ is a product of n factors of the form $(\mathcal{A}/\kappa)/(1 + k\,\mathcal{B}/\mathcal{A})$. This is an increasing function of k as long as the factors are larger than 1 and decreasing afterward. The maximum of the distribution function can be found from the condition

$$\frac{(\mathcal{A}/\kappa)}{(1+n_m\mathcal{B}/\mathcal{A})} = 1 \tag{69}$$

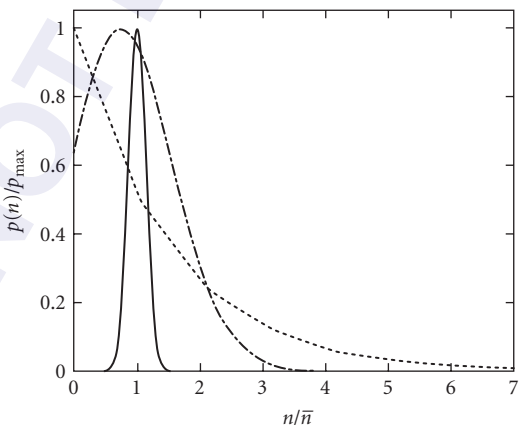

FIGURE 6 Photon statistics of the laser for various regimes of operation. Dotted line: laser 50 percent below threshold ($\mathcal{A}/\kappa = 1/2$), distribution thermal in character, Mandel $Q_M = 1$. Dot-dashed line: laser 10 percent above threshold, ($\mathcal{A}/\kappa = 1.1$), distribution is broad, $Q_M = 5$. Solid line: laser 100 percent above threshold ($\mathcal{A}/\kappa = 2$), distribution super-Poissonian, $Q_M = 1$. Since in the various regimes the actual photon numbers and $p(n)$ values differ by several orders of magnitude, in order to comparatively display the statistics in one figure, we plot $p(n)/p_{\max}$ versus $n\sqrt{n}$. This way the maximum of each curve is 1 and unity on the horizontal axis corresponds to the average photon number. $\mathcal{A}/\mathcal{B} = 50$ is used for all plots, for illustrative purposes only. For more realistic values, the above-threshold distributions are much narrower on this scale.

or

$$n_m = \frac{\mathscr{A}}{\mathscr{B}} \frac{\mathscr{A} - \kappa}{\kappa} \tag{70}$$

Clearly, for $\mathscr{A} < \kappa$ the maximum is at $n = 0$ and the distribution is monotonically decreasing, which is characteristic of a thermal distribution. This is in agreement with the previous findings for the below-threshold region. Around $\mathscr{A} \simeq \kappa$ the distribution quickly changes its character. The factor $\mathscr{A}/\mathscr{B}$ governs the magnitude of the photon number while $(\mathscr{A} - \kappa)/\kappa$ is a measure of how far away from threshold the laser is operating. Typical values for CW gas lasers (the He-Ne laser, for example) are $\mathscr{A}/\mathscr{B} \simeq 10^6$ and $\kappa \simeq 10^6$ Hz. Around threshold, $\mathscr{A} \simeq \kappa$ and the factors appearing in $p(n)$, given by Eq. (69), are effectively unity for a broad range of n. For example, for $\mathscr{A}/\kappa = 1.001$ (i.e., one-tenth of a percent above threshold), the factors are slightly above 1 for $1 < n < 1000$. So, in the threshold region, the distribution very quickly changes from a thermal one, dominated by the vacuum state, to a broad distribution with large intensity fluctuations. Farther above threshold the distribution becomes more and more peaked around n_m and becomes essentially poissonian for $\mathscr{A}/\kappa > 2$.

It is easy to obtain the mean photon number $\bar{n}$ from Eq. (67):

$$\bar{n} = \sum_{n=0}^{\infty} n p(n) \frac{\mathscr{A}}{\mathscr{B}} = \frac{\mathscr{A} - \kappa}{\kappa} + \frac{\mathscr{A}}{\mathscr{B}} p(0) \tag{71}$$

Above threshold, $p(0) \ll 1$ and the last term becomes quickly negligible. Then $\bar{n}$ coincides with n_m, the maximum of the distribution. We can obtain $\bar{n}^2$ similarly. The result is

$$\bar{n}^2 = \bar{n}^2 + \frac{\mathscr{A}^2}{\mathscr{B}\kappa} \tag{72}$$

Using Eq. (71), the variance can be expressed as

$$\sigma^2 = \bar{n}^2 - \bar{n}^2 = \bar{n} \frac{\mathscr{A}}{\mathscr{A} - \kappa} \tag{73}$$

From here we see that the variance always exceeds that of a poissonian distribution ($\sigma^2 > \bar{n}$), but it approaches one far above threshold. A good characterization of the photon-number distribution is given by the Mandel Q_M parameter:

$$Q_M = \frac{\bar{n}^2 - \bar{n}^2}{\bar{n}} - 1 \tag{74}$$

For our case, it is given by

$$Q_M = \frac{\kappa}{\mathscr{A} - \kappa} \tag{75}$$

Since $Q_M > 0$ above threshold, the field is superpoissonian. Very far above threshold, when $\mathscr{A} \gg \kappa$, Q_M approaches zero, which is characteristic of a poissonian distribution, again in agreement with our discussion of the far-above-threshold region.

Micromaser Photon Statistics As a first application of the micromaser master equation, Eq. (56), we shall study the steady-state photon statistics arising from it. To this end we take the diagonal $n = n'$ elements, and after regrouping the terms we obtain:

$$\begin{aligned} \dot{p}(n) = &-N_{\text{ex}} \sin^2(g\tau\sqrt{n+1})\, p(n) + (n_{\text{th}} + 1)(n+1)\, p(n+1) - n_{\text{th}}(n+1)\, p(n) \\ &+ N_{\text{ex}} \sin^2(g\tau\sqrt{n})\, p(n-1) - (n_{\text{th}} + 1) n p(n) + n_{\text{th}} n p(n-1) \end{aligned} \tag{76}$$

Here the overdot stands for derivative with respect to the scaled time $t' = \kappa t$. $N_{ex} = r/\kappa$ is the number of atoms traversing the cavity during the lifetime of the cavity field, and the diagonal matrix elements of the density operator $p(n) = \varrho_{nn}$ are the probabilities of finding n photons in the cavity. The various processes in the right-hand side of this equation are again visualized in Fig. 5. They have the structure $F(n+1) - F(n)$ where $F(n+1)$ corresponds to the processes connecting $p(n+1)$ to $p(n)$. In the steady state the left-hand side is zero and $F(n+1) = F(n)$, yielding $F(n) =$ constant. The only normalizable solution to the photon statistics arises when this constant is zero, $F(n) = 0$. Once again, this is the condition of detailed balance because the probability flows between adjacent levels are separately balanced. More explicitly, this leads to the following recurrence relation for the photon-number probabilities:

$$p(n) = \frac{N_{ex} \sin^2(g\tau\sqrt{n})/n + n_{th}}{n_{th} + 1} p(n-1) \tag{77}$$

The solution to this simple recurrence relation is straightforward:

$$p(n) = p(0) \prod_{i=1}^{n} \frac{N_{ex} \sin^2(g\tau\sqrt{i})/i + n_{th}}{n_{th} + 1} \tag{78}$$

where $p(0)$ is determined from the normalization condition $\sum_{n=0}^{\infty} p(n) = 1$. The photon-number distribution $p(n)$ versus n can be multipeaked in certain parameter regimes. This can be easily understood on the basis of Fig. 5. The gain processes (upward arrows) balance the loss (downward arrows). Since the gain is an oscillatory function of n, several individual peaks [with the property $p(n+i) = p(n)$] will develop for those values of n where the gain perfectly balances the loss. The resulting mean photon number (first moment of the distribution) and photon-number fluctuations (second moment Q_M) versus the scaled interaction parameter $\theta = g\tau\sqrt{N_{ex}}$ are displayed in Fig. 7.

The mean photon number is an oscillatory function of the scaled interaction time. The oscillations correspond to subsequent Rabi cycles the atoms are undergoing in the cavity as function of the interaction time. The first threshold occurs at $\theta = 1$; the higher ones occur where θ is approximately an integer multiple of 2π. Around the thresholds the micromaser field is superpoissonian; in the parameter region between the thresholds it is subpoissonian, which is a signature of its nonclassicality.

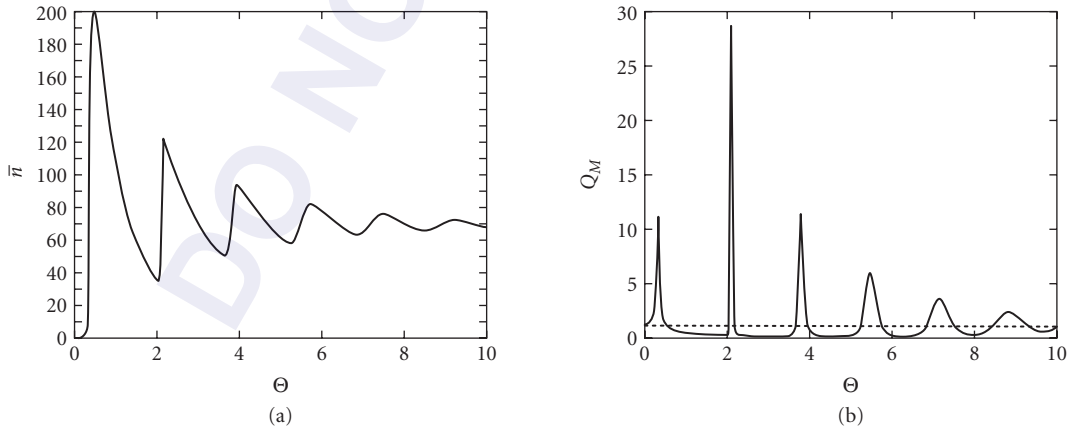

FIGURE 7 (*a*) Mean photon number and (*b*) Mandel Q_M parameter versus interaction parameter for the micromaser, for $N_{ex} = 200$.

Physics off the Main Diagonal: Spectrum and Linewidth

In the subsection on laser photon statistics we have shown that the laser has poissonian photon statistics far above threshold, just as a coherent state would. However, it is erroneous to conclude from this that the laser field is in a coherent state far above threshold. Only the intensity of the laser becomes stabilized due to a delicate balance of the nonlinear gain and loss. Any deviation from the steady-state intensity induces a change that tries to restore the steady-state value; as a result, the intensity is locked to this value. The phase of the field, on the other hand, evolves freely and is not locked to any particular value. In fact, it performs a random walk due to the separate spontaneous emission events. Each such event contributes a small random phase change to the instantaneous phase of the field. The mean of these changes averages to zero, but the mean of the square of these changes remains finite. As a result, the phase undergoes a diffusionlike process and will become uniformly distributed over the 2π interval. Any information contained in the instantaneous phase will be erased in this process. The time scale for the decay of the phase information is given by the rate of the phase diffusion. In the following, we shall determine this characteristic time scale, the so-called phase diffusion constant for the laser and micromaser.

Spectral Properties of the Laser Field The decay of the phase information can be directly read out from the temporal behavior of the two-time correlation function of the field amplitude:

$$g^{(1)}(t_0+t,t_0)=\frac{\langle a^\dagger(t_0+t)a(t_0)\rangle}{\langle a^\dagger(t_0)a(t_0)\rangle} \tag{79}$$

With increasing time difference between their amplitudes, the fields become less and less correlated since spontaneous emission randomizes their phases. At steady state, the two-time correlation function [Eq. (79)] depends only on the time difference t and is independent of the choice of the initial time t_0.

A quantum regression "theorem,"[88] based on a system-reservoir factorization of the density matrix, was developed to permit the time evolution of the two-time correlation function at steady state to be calculated from the time evolution of the single-time correlation function for a Markov process. The unusual success of this procedure (see Ref. 89 for a comparison between experiment and theory for the phase linewidth, the intensity linewidth, the photo-count distribution, and the spectral moments) requires additional explanation. This was supplied in a proof that regression is valid when the system is markovian.[90] In the quantum case, the system is only approximately markovian. But this assumption has already been made in all cases for which solutions have been found. Therefore, it is sufficient for us to study the time evolution of the amplitude itself:

$$\langle a^\dagger(t)\rangle=\sum_{n=0}^{\infty}\sqrt{n+1}\,\varrho_{nn+1} \tag{80}$$

At this point it is useful to define a column vector with the components $\varrho_n^{(k)}\equiv\varrho_{nn+k}$ This way, we simply arrange the elements of the kth diagonal in the form of a vector. For example, elements on the first side diagonal correspond to $k=1$, and so on. Let us note that the equation of motion for the off-diagonal matrix elements of the density operator can now be written in a simple matrix form

$$\dot{\varrho}_n^{(k)}=A_{nn'}\,\varrho_{n'}^{(k)} \tag{81}$$

where summation is implied over repeated indexes and the matrix elements $A_{nn'}$ can be read out from Eq. (49). They are given by

$$A_{nn'}=-\left[\frac{\mathcal{N}'_{nn+k}\mathcal{A}}{1+\mathcal{N}_{nn+k}\mathcal{B}/\mathcal{A}}+\kappa\left(n+\frac{k}{2}\right)\right]\delta_{nn'}+\frac{\sqrt{n(n+k)\mathcal{A}}}{1+\mathcal{N}_{n-1n+k-1}\mathcal{B}/\mathcal{A}}\delta_{nn'+1}$$
$$+\kappa\sqrt{(n+1)(n+k+1)}\,\delta_{nn'-1} \tag{82}$$

Clearly, $A_{nn'}$ is a tridiagonal matrix. Due to its linearity, we can look for the solution of Eq. (81) by the simple exponential Ansatz, $\varrho_n^{(k)}(t)=e^{-\lambda t}\varrho_n^{(k)}(0)$. With this substitution, Eq. (81) can be written in the form of an eigenvalue equation to determine λ,

$$\lambda\varrho_n^{(k)}=-\sum_{n-1}^{n+1}A_{nn'}\varrho_{n'}^{(k)} \tag{83}$$

We restrict the following treatment to $k=1$ because that is what we need for the calculation of the $g^{(1)}$ correlation function. Higher-order correlation functions, $g^{(k)}$ with $k>1$, are related to $\varrho_n^{(k)}$ with $k>1$. From the structure of the $-A$ matrix, one can show that all eigenvalues are positive. There is a smallest eigenvalue, which we denote by D. This eigenvalue will dominate the longtime behavior of the field amplitude, as can easily be seen from the following considerations. Let us denote the set of eigenvalues by $\{D, \lambda_j\}$ with $j=1, 2, 3, \ldots$. Then $\varrho_n^{(1)}(t)$ can be written as

$$\varrho_n^{(1)}(t)=\varrho_{n0}^{(1)}(0)\exp(Dt)+\sum_{j=1}^{\infty}\varrho_{nj}^{(1)}(0)\exp(-\lambda_j t) \tag{84}$$

From this we see that, indeed, the longtime behavior of the off-diagonal elements will be governed by the first term, since the other terms decay faster according to our assumption of D being the smallest positive eigenvalue. Therefore, our task is reduced to the determination of D. In order to obtain an analytical insight, we can proceed as follows. First, let us note that in the longtime limit all elements of the vector $\varrho_n^{(1)}(t)$ decay the same way—they are proportional to exp $(-Dt)$. Therefore, the sum of the elements also decays with the same rate, D, in this limit. It is quite easy to obtain an equation of motion for the sum of the elements. Starting from Eq. (81) and using Eq. (82) for the case $k=1$, we immediately obtain

$$\dot{\varrho}^{(1)}=-\sum_{n=0}^{\infty}\left[\frac{n+3/2-\sqrt{(n+1)(n+2)}}{1+(n+3/2)\mathcal{B}/\mathcal{A}}\mathcal{A}+\kappa(n+1/2-\sqrt{n(n+1)}\right]\varrho_n^{(1)} \tag{85}$$

Here we introduced the notation $\sum_{n=0}^{\infty}\varrho_n^{(1)}=\varrho^{(1)}$ and used the fact that $\mathcal{N}'_{nn+1}=n+3/2+\mathcal{B}/(8\mathcal{A})\approx n+3/2$ and $\mathcal{N}_{nn+1}=n+3/2+\mathcal{B}/(16\mathcal{A})\approx n+3/2$ since $\mathcal{B}/\mathcal{A}\approx 10^{-6}$and can therefore safely be neglected next to 3/2. In the longtime limit the time derivative on the left-hand side can simply be replaced by $-D$ due to Eq. (84). It is also plausible to assume that in the same limit those values of n will contribute the most that lie in the vicinity of $\bar{n}$. Then we can expand the coefficients around the steady-state value of the photon number. This is certainly a good approximation in some region above threshold. The key point is that after the expansion the coefficients of $\varrho_n^{(1)}$ on the right-hand side become independent of the summation index n and can be factored out from the sum. Then, after the summation, the quantity $\varrho^{(1)}$ also appears on the right-hand side of the equation:

$$D\varrho^{(1)}=\frac{\mathcal{A}+\kappa}{8\bar{n}}\varrho^{(1)} \tag{86}$$

From this we can simply read out the decay rate:

$$D=\frac{\mathcal{A}+\kappa}{8\bar{n}} \tag{87}$$

This quantity, called the *phase diffusion coefficient*, plays a crucial role in determining the transient behavior of the laser as well as its spectral properties. It exhibits the characteristic line narrowing for high intensity, first found by Schawlow and Townes.[80] The mean amplitude, Eq. (80), can now be written as

$$\langle a^{\dagger}(t)\rangle=e^{-Dt}\langle a^{\dagger}(0)\rangle \tag{88}$$

The decay of any initial coherent component of the laser field is governed by the phase diffusion constant, due to the randomization of the initial phase information. The randomization is due to two separate processes, as can be read out from the analytical expression, Eq. (87) of the phase diffusion constant. The part proportional to the spontaneous emission rate $\mathcal{A}$ is due to the random addition of photons to the field via spontaneous emission; the part proportional to the cavity decay rate is due to leaking of vacuum fluctuations into the cavity through the output mirrors. Both processes randomize the phase of the initial field; as a result, the phase performs a random walk with a diffusion rate given by Eq. (87). Ultimately, of course, vacuum fluctuations are also responsible for spontaneous emission.

The phase diffusion constant also determines the linewidth of the spectrum of the laser field. Using the quantum regression theorem, we immediately find that the (nonnormalized) steady-state field correlation function is given by

$$g^{(1)}(t_0+t,t_0)=\langle a^\dagger(t_0+t)a(t_0)\rangle=\bar{n}\exp(i\omega_0 t-Dt) \tag{89}$$

where ω_0 denotes the operating frequency of the laser, as before. The power spectrum is given by the Fourier transform of the field correlation function:

$$S(\omega)=\frac{1}{\pi}\mathrm{Re}\int_0^\infty g^{(1)}(t_0+t,t_0)e^{-i\omega t}dt=\frac{\bar{n}}{\pi}\frac{D}{(\omega-\omega_0)^2+D^2} \tag{90}$$

This is a lorentzian spectrum centered around the operating frequency, $\omega=\omega_0$. The full width at half-maximum (FWHM) is given by $2D$. Figure 8 depicts the normalized spectrum $S(\omega)/S(\omega_0)$ versus the detuning $\Delta=(\omega-\omega_0)/D$.

It should be emphasized that our method of obtaining the preceding analytical approximations is justified only if the mean photon number is large, the photon-number distribution consists of a single large peak, and cross-coupling between intensity and phase, arising from the nonlinearity of the gain very far above threshold, is negligible. These conditions are met for a laser in some region above threshold. Near the threshold, however, the intensity fluctuations cannot be neglected. From

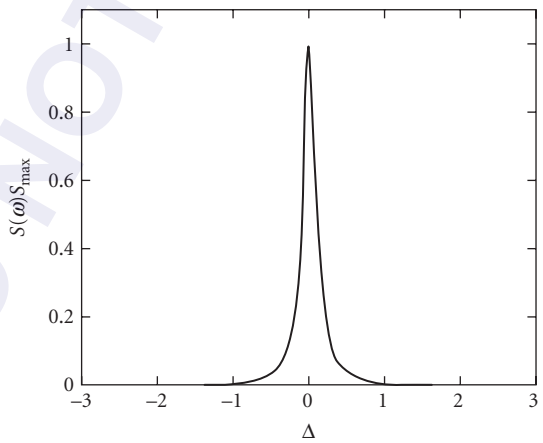

FIGURE 8 Laser spectrum $S(\omega)/S_{\max}$ versus detuning $\Delta=(\omega-\omega_0)/\kappa$, for a laser 100 percent above threshold (note that detuning is in units of bare-cavity linewidth). For our parameters the spectral width D is about 1 percent of the bare-cavity linewidth, an example of the Schawlow-Townes narrowing

numerical studies[91] it was concluded that their contribution to the linewidth is approximately equal to the phase diffusion constant, and the linewidth in this region is about twice what is predicted by Eq. (90); i.e., it is $4D$; and far above threshold (for $\mathcal{A}\kappa > 2$), the linewidth is smaller than the prediction of Eq. (90). These numerical findings are confirmed by a recent analytical approach to the problem.[92] One of the earliest quantum calculations of the laser linewidth[69] was based on the quantum theory of noise sources.[70] The laser linewidth above threshold was established to be due mostly to phase noise,[69] and it was explained that the factor of 2, too large, was obtained by many previous authors because they had permitted amplitude fluctuations, which were valid near threshold but not far above. These ideas were confirmed by analytic calculations below and above threshold[93] and by a numerical solution of the associated Fokker-Planck equation.[94,95] Moreover, the effects of laser detuning on the linewidth were determined without assuming that the light field decays much slower than the atomic decay rates. It was found that the effective linewidth was a harmonic mean between the field and electronic decay rates, as shown in Eq. (35) of Ref. 69.

The calculations of the phase linewidth done in this section are equivalent to the quasilinear approximation employed in the Langevin noise source procedure in Ref. 93 and shown in Ref. 94 to be valid for dimensionless pump rates $p > 10$. Below threshold, $p < -10$, the components of the electromagnetic field can be treated as uncoupled gaussian variables, leading to the Schawlow-Townes formula. Only the region in the immediate vicinity of threshold requires careful analysis. In that region, it is shown in footnote 10 in Ref. 93 that the coefficients in the Fokker-Planck equation can be expanded in powers of n, retaining only the first nonlinear term. The result then reduces to the rotating-wave Van der Pol oscillator. One advantage of this reduction is that the equation can be scaled in time and in amplitude, leaving the dimensionless pump parameter p as the only remaining parameter. This greatly reduces any subsequent numerical calculations. The ability to retain only one nonlinear term is based only on the requirement that we are dealing with a good oscillator—that is, one whose signal-to-noise ratio is large. Equivalent approximations can be introduced in the density matrix treatment, as well.

The assumption made here that the phase linewidth comes predominantly from the smallest decay eigenvalue was established in Ref. 94, where the actual line shape is shown to be a sum of lorentzians, and the percentage from each lorentzian is calculated. The intensity fluctuations are also expressed as a sum of lorentzians but several modes contribute, not just the lowest. The percentage in each is given in Ref. 94. Part of the reason for this is that the modes approach degeneracy in pairs as one moves above threshold. The lifting of such a degeneracy was shown in Ref. 96 to be associated with a phase transition. Since our system is finite, the phase change occurs gradually and can be observed. The view of lasing as a phase transition will be explored in more detail in Sec. 23.5.

Spectral Properties of the Micromaser Field If we take the n, $n+1$ matrix elements of Eq. (57), then, following the methods of the previous subsection, it is straightforward to derive the diffusion constant. In particular, elements of the first side diagonal can again be arranged in the form of a column vector, and this vector again satisfies an equation of motion similar to Eq. (81), with an appropriate redefinition of the tridiagonal matrix appearing in the equation:

$$\begin{aligned} A_{nn'} = &-\{r[1-\cos(g\tau\sqrt{n+1})\cos(g\tau\sqrt{n+2})]+\kappa(2n_{\text{th}}(n+1)+n+1/2)\}\delta_{nn'} \\ &+(r\sin(g\tau\sqrt{n})\sin(g\tau\sqrt{N+1})+\kappa n_{\text{th}}\sqrt{n(n+1)})\delta_{nn'+1} \\ &+\kappa(n_{\text{th}}+1)\sqrt{(n+1)(n+2)}\delta_{nn'-1} \end{aligned} \tag{91}$$

The exponential Ansatz for the decay of the column vector again turns the equation of motion into an eigenvalue equation for the matrix A and the longtime behavior will again be governed by the smallest eigenvalue, which we denote by D. Summing over all elements of the resulting eigenvalue

equation and replacing the coefficients on the right-hand side by their longtime value—that is, expanding the coefficients around $n=\bar{n}$—will finally yield

$$D=2r\sin^2\left(\frac{g\tau}{4\sqrt{\bar{n}}}\right)+\kappa\frac{(2n_{\text{th}}+1)}{8\bar{n}} \tag{92}$$

for the phase diffusion constant of the micromaser. Here $\bar{n}$ is the mean photon number of the (single-peaked) distribution. This expression was first derived by Scully et al.[97] It leads to a lorentzian spectrum similar to Eq. (90) but with D appropriately replaced by that of the micromaser. It should be noted, however, that the analytical formula has a more restricted validity than in the case of the laser. Namely, in the case of the micromaser, the photon-number distribution can be multipeaked, and the simple expansion around the $\bar{n}$ value corresponding to a single dominating peak may not hold. For this more general case several numerical approaches have been developed (see Ref. 98). When Eq. (92) is valid it coincides with the results of the numerical calculations.

For small values of the argument in the sine function, Eq. (92) can be cast to a form which is formally identical to the usual laser phase diffusion constant [99][cf. Eq. (87)]:

$$\begin{aligned} D&=r\frac{g^2\tau^2}{8\bar{n}}+\kappa\frac{2n_{\text{th}}+1}{8\bar{n}} \\ &=\frac{\mathcal{A}+\kappa(2n_{\text{th}}+1)}{8\bar{n}} \end{aligned} \tag{93}$$

Here we introduced the small signal gain $\mathcal{A}\equiv rg^2\tau^2$, in analogy to the laser gain. However, for other values of the argument the first term in Eq. (92) may dominate, and the phase diffusion constant can exceed the bare-cavity linewidth, which is a unique quantum feature of the micromaser and makes it distinctly different from the classical Schawlow-Townes-type behavior.

Without going into the specifics, we just mention a few other aspects of the quantum theory of the micromaser. As we have just seen a steady state is reached due to the equilibrium between the gain and loss processes. In some cases, however, a steady state can be reached even in a lossless cavity. This happens if the probability flow in Fig. 5 due to the gain process is interrupted for some value of the interaction parameter. The upward flow is interrupted when

$$g\tau\sqrt{n_q+1}=q\pi \tag{94}$$

and the downward flow is interrupted when

$$g\tau\sqrt{n_q}=q\pi \tag{95}$$

with $q=1, 2, \ldots$ in both cases. They are called the *upward* and *downward trapping state*, respectively.[100] In such cases the state of the field is a number state. The signature of the number state is a large maximum in the linewidth at the corresponding interaction parameter. It can easily be understood qualitatively: since the state of the field is a number state, it cannot have any phase information. Therefore, the phase randomizes on a very rapid time scale; in other words, the phase correlations decay very rapidly, and a large phase diffusion constant ensues. Further, if the atoms are injected in a coherent superposition of their upper and lower levels in the cavity then, under certain conditions, the so-called tangent and cotangent states of the field may develop.[101] Finally, it should be mentioned that the master equations Eqs. (49) and (56) hold only for the case when the time interval between consecutive atomic injections is completely random. Other arrival times statistics, including the case of regular injections, have been investigated by a number of authors.[102] A closely related area of recent theoretical studies pertains to the detection of the statistical properties of the (experimentally inaccessible) intracavity field via monitoring the statistics of the outgoing atoms for poissonian[103] as well as nonpoissonian[104] pumping. For regular (subpoissonian) pumping, transient oscillations in field correlation function and a corresponding multipeaked spectrum were predicted.[105]

Most of the predictions of this theory have been confirmed by experiments. For example, trapping states have been observed in recent experiments by the Garching group.[106] Without providing an exhaustive list, we just refer the reader to recent progress in the experimental department.[107]

Other Approaches

So far we have considered laser theory based on a density-operator approach. An equivalent approach to a laser theory can be formulated using a Heisenberg-Langevin approach. In this approach explicit equations of motion are derived for the field operator.

The quantum-noise operator formalism was presented in essentially its final form by Lax at the 1965 meeting on the *Physics of Quantum Electronics*.[69] There, it was applied to the laser, calculating, the laser linewidth in its most general form. For the general theory, see the 1966 Brandeis lecture notes of Lax.[71]

In the present formulation, our goals are more specific—namely, the Heisenberg-picture quantum theory of the laser. To that end, we will here give a quantum-noise treatment along the lines of that followed in the previous subsection—namely, a single laser mode damped at a rate κ by a (dissipative) reservoir and driven by atoms injected into the laser cavity at random times t_j.

First we discuss the simple example of damping of the field by a reservoir and derive the quantum Langevin equation for the field operator. We then discuss the gain noise in a laser and derive the laser linewidth.

Damping of Field by Reservoir We consider the damping of a single-mode field of frequency ν interacting with a reservoir consisting of simple harmonic oscillators. The system describes, for example, the damping of a single-mode field inside a cavity with lossy mirrors. The reservoir in this case consists of a large number of phononlike modes in the mirror.

The field is described by the creation and destruction operators $a^\dagger$ and a, whereas the harmonic oscillators of frequency $\nu_k = ck$ are described by the operators $b_k^\dagger$ and b_k. The field-reservoir system evolves in time under the influence of the total hamiltonian:

$$\mathcal{H} = \hbar\omega_0(a^\dagger a + \frac{1}{2}) + \hbar\sum_k \nu_k\left(b_k^\dagger b_k + \frac{1}{2}\right) + \hbar\sum_k g_k(ab_k^\dagger + b_k a^\dagger) \tag{96}$$

Here g_k *are* the coupling constants and we have made the rotating-wave approximation. We are interested in the evolution of the field operator a. The Heisenberg equations of motion for the field and reservoir are

$$\dot{a}(t) = -i\omega_0 a(t) - i\sum_k g_k b_k(t) \tag{97}$$

$$\dot{b}_k(t) = -i\nu_k b_k(t) - ig_k a(t) \tag{98}$$

The equation for b_k can be formally solved, and the resulting expression is substituted in Eq. (97). In the Weisskopf-Wigner approximation, the annihilation operator in the interaction picture $a = a(t)$ exp $[i\omega_0(t - t_0)]$ satisfies a Langevin equation

$$\dot{a} = -\frac{\kappa}{2}a + F(t) \tag{99}$$

where

$$F(t) = -i\sum_k g_k b_k(0)\exp[-i(\nu_k - \omega_0)(t - t_0)] \tag{100}$$

is a noise operator. Equation (99) clearly indicates that the damping of the field (represented by the term $-\kappa a/2$) is accompanied by noise.

For the damping of the single-mode field inside a cavity via transmission losses, the damping constant κ is related to the quality factor Q of the cavity via $\kappa = \omega_0/Q$.

Atomic (Gain) Noise and Laser Linewidth As discussed earlier, the natural linewidth of the laser arises due to spontaneous emission by the atoms. In the density-operator approach, a fully nonlinear treatment was followed. Here, we present a simple linear analysis to calculate the laser linewidth in the Heisenberg-Langevin approach. We assume that the atoms are long lived, and that they interact with the cavity field for a time τ. This treatment allows us to include the memory effects inside a laser, and is one of the simplest examples of a nonmarkovian process.[108,109]

We start with the hamiltonian describing the atom-field interaction:

$$\mathcal{H} = \mathcal{H}_F + \mathcal{H}_{\text{atom}} + \hbar g \sum_i \{\sigma^i a^\dagger N(t_i, t, \tau) + Hc\} \tag{101}$$

where $\mathcal{H}_F$ and $\mathcal{H}_{\text{atom}}$ describe the field and atoms, respectively; g is the atom-field coupling constant; and σ_i is the lowering operator for the ith atom; Hc is the injunction to add the Hermitian conjugate. The operators a and $a^\dagger$ represent the annihilation and creation operators, and $N(t_i, t, \tau)$ is a notch function which has the value

$$N(t_i, t, \tau) = \begin{cases} 1 & \text{for } t_i \le t < \tau \\ 0 & \text{otherwise} \end{cases} \tag{102}$$

Using this hamiltonian, we write the equations for the atom-field operators in the interaction picture as

$$\begin{aligned} \dot{a} &= -ig \sum_i \sigma^i N(t_i, t, \tau) - \frac{1}{2}\kappa a(t) + F_\kappa(t) \\ \dot{\sigma}^i &= igN(t_i, t, \tau)\sigma_z^i a(t) \end{aligned} \tag{103}$$

where the effects of cavity damping are determined by the cavity decay rate κ and the associated Langevin noise source F_κ. Integrating the equation for the atom operator and substituting it into that for the field operator, we obtain

$$\dot{a}(t) = \int_{-\infty}^{t} dt' \alpha(t, t') a(t') - \frac{1}{2}\gamma a + F_\alpha(t) + F_\kappa(t) \tag{104}$$

where

$$\alpha(t, t') = g^2 \sum_i N(t_i, t, \tau) N(t_i, t', \tau) \sigma_z^i(t') \tag{105}$$

$$F\alpha(t) = -ig \sum_i N(t_i, t, \tau) \sigma^i(t_i) \tag{106}$$

Here, the noise operator Eq. (106) may be seen to have the moments

$$\langle F_\alpha(t) \rangle = 0 \tag{107}$$

$$\langle F_\alpha^\dagger(t) F_\alpha(t') \rangle = g^2 \sum_{ij} N(t_i, t, \tau) N(t_i, t', \tau) \langle \sigma^{\dagger i}(t_i) \sigma^j(t_j) \rangle \tag{108}$$

Because we are injecting our lasing atoms in the upper state, the atomic average is given by $\langle \sigma^{\dagger i}(t_i) \sigma^j(t_j) \rangle = \delta_{ij}$. After replacing the sum upon i in Eq. (108) by an integration over injection times t_j, we find

$$\langle F_\alpha^\dagger(t) F_\alpha(t') \rangle = rg^2 \{N(t' - \tau, t, \tau)[t - (t' - \tau)] - N(t', t, \tau)[t - (t' + \tau)]\} \tag{109}$$

where r is the atomic injection rate. The phase variance can then be calculated through the noise operator product:

$$\langle \phi^2(t) \rangle = -\frac{1}{2\pi} \int_0^t dt' \int_0^t dt'' \langle F^\dagger(t') F(t'') \exp\{i[\phi(t') - \phi(t'')]\} \tag{110}$$

On insertion of Eq. (109) into Eq. (110), the expression for the generalized maser phase diffusion noise $\langle \phi^2(t) \rangle$ is found to be

$$\langle \phi^2(t) \rangle = \left(\frac{\mathcal{A}}{2\bar{n}}\right)\left[\left(\frac{t^2}{\tau} - \frac{t^3}{3\tau^2}\right)\theta(\tau - t) + \left(t - \frac{\tau}{3}\right)\theta(t - \tau)\right] \tag{111}$$

Here $\mathcal{A} = rg^2\tau^2$ is the small-signal gain of the maser [cf. Eq. (93), with $n_{th} = 0$ and using that in steady state $\mathcal{A} = \kappa$]. In the case involving atoms which are injected at random times t_i but which decay via spontaneous emission to far-removed ground states at a rate γ, a similar but more complicated analysis can be carried out. The result in this case is given by

$$\langle \phi^2(t) \rangle = \left(\frac{\mathcal{A}}{2\bar{n}}\right)[t + \gamma^{-1}(e^{-\gamma} - 1)] \tag{112}$$

Here $\mathcal{A} = 2rg^2/\gamma^2$ is the small-signal gain of the laser [cf. Eq. (50)]. In both of the preceding cases, we find that for times $t = t_m$ small compared to the atomic lifetime, the phase diffusion is quadratic in the measurement time t_m; that is, we now have a phase error which goes as

$$\Delta\phi^2 = \left(\frac{\mathcal{A}t_m}{2n}\right)\left(\frac{\gamma t_m}{2}\right) \tag{113}$$

Therefore, we see that the quantum noise due to spontaneous emission is reduced from the Schawlow-Townes linewidth $2D = \mathcal{A}/2\bar{n}$ by the factor $\gamma t_m/2$, which can be a significant reduction for short measurement times. For times long compared to the atomic lifetime, however, the Schawlow-Townes result is obtained from both Eqs. (111) and (112) as expected.

23.5 THE LASER PHASE-TRANSITION ANALOGY

Considerations involving the analogies between phase transitions in ferromagnets, superfluids, and superconductors have emphasized the similarities between these systems near their critical temperatures.[110]

A natural comparison can be made between second-order phase transitions, such as the order-disorder transitions of ferromagnetic and ferroelectric materials or the vapor-liquid transition of a pure fluid, and the laser threshold. As we have discussed in Sec. 23.4, the state of a laser changes abruptly upon passing through the threshold point. This point is characterized by a threshold population inversion.

The physical basis for this similarity becomes evident when it is recalled that the usual treatments of laser behavior are self-consistent theories. In the laser analysis we assume that each atom evolves in a radiation field due to all the other atoms, and then calculate the field produced by many such evolving atoms in a self-consistent fashion. In this way the laser problem is similar to that of a ferromagnet, in which each spin sees a mean magnetic field due to all the other spins and aligns itself accordingly, thus contributing to the average magnetic field.

Following this point of view, we can discuss the laser theory using the language of second-order phase transitions.

The density matrix of the laser field obeys Eq. (49). The time dependence of the expectation value $\bar{E}$ of the electric field operator $E=(a+a^{\dagger})$ is there given by the following equation:

$$\dot{\bar{E}}=\frac{1}{2}(\mathscr{A}-\kappa)\bar{E}-\frac{\mathscr{B}}{2}\overline{E^3} \tag{114}$$

Here we have assumed that the laser is operating close to threshold ($\mathscr{B}\bar{n}/\mathscr{A}\ll 1$) so that we retain only the terms proportional to $\mathscr{B}$. In addition, we assume $\bar{E}\gg 1$. We can then replace $\overline{E^3}$ by $\bar{E}^3$ and Eq. (114) becomes the well-known result of Lamb's semiclassical theory. The steady-state properties of the laser oscillator are described by the following equation of state:

$$(\mathscr{A}-\kappa)\bar{E}-\mathscr{B}\overline{E^3}=0 \tag{115}$$

The threshold condition is given by $\mathscr{A}=\kappa$ as before. Upon putting $\mathscr{A}=a\sigma$, $\mathscr{B}=b\sigma$, and $\kappa=a\sigma_t$ where σ_t is the threshold population inversion, the steady-state solution of Eq. (115) is

$$\begin{aligned} &\bar{E}=0 && \text{if } \sigma-\sigma_t<0 \text{ (below threshold)} \\ &\bar{E}=\left[\frac{a}{b}\left(\frac{\sigma-\sigma_t}{\sigma}\right)^{1/2}\right] && \text{if } \sigma-\sigma_t>0 \text{ (above threshold)} \end{aligned} \tag{116}$$

Equation (116) is formally identical to the equation for a ferromagnet in the Weiss mean-field theory. The electric field E corresponds to the static magnetization M, which is the order parameter in the ferromagnetic transition. The quadratic polarization $P=(\mathscr{A}\bar{E}-\mathscr{B}\bar{E}^3)/2$ in Eq. (115) corresponds to the magnetic field H generated by a magnetization M, and the term $\kappa\bar{E}/2$ corresponds to a local magnetic field which is assumed proportional to M in the mean-field theory. Furthermore, the steady-state points depend $\sigma-\sigma_t$ in the same way that M in the ferromagnetic case depends on $T-T_c$, where T_c is the critical temperature. Therefore, σ and σ_T correspond to T and T_c, respectively. The similarity between these two systems is summarized in Table 1 and illustrated in Fig. 9.

We recall that the probability density $P(M)$ for a ferromagnetic system with magnetization M near a phase transition is given by, in thermal equilibrium,

$$P(M)=N''\exp\left(-\frac{F(M)}{k_{\mathrm{B}}T}\right) \tag{117}$$

where

$$F(M)=\frac{1}{2}c(T-T_c)M^2+\frac{1}{4}dTM^4 \tag{118}$$

is the free energy. In the corresponding laser analysis, the probability density for the electromagnetic field $P(E)$ is derived in the form

$$P(E)=N'\exp\left(-\frac{G(E)}{k_{\mathrm{B}}\sigma}\right) \tag{119}$$

For this purpose we transform the laser equation for the density matrix for the field [Eq. (49)] into an equivalent equation in terms of the $P(\alpha,\alpha^*)$ representation defined by

$$\rho=\int d^2\alpha P(\alpha,\alpha^*)|\alpha\rangle\langle\alpha| \tag{120}$$

where $|\alpha\rangle$ is an eigenstate of the annihilation operator a with eigenvalue α. The P representation allows us to evaluate any normally ordered correlation function of the field operators using the

TABLE 1 Summary of Comparison between the Laser and a Ferromagnetic System Treated in a Mean-Field Approximation

Parameter	Ferromagnet	Laser
Order parameter	Magnetization M	Electric field strength E
Reservoir variable	Temperature T	Population inversion σ
		Threshold inversion σ_t
Coexistence curve*	$M=\Theta(T_c-T)\left[\frac{c}{d}\frac{T-T_c}{T}\right]^{1/2}$	$E=\Theta(\sigma-\sigma_t)\left[\frac{a}{b}\frac{\sigma-\sigma_t}{\sigma}\right]^{1/2}$
Symmetry breaking mechanism	External field H	Injected signal S
Critical isotherm†	$M=\left[\frac{H}{dT_c}\right]^{1/2}$	$E=\left[\frac{2S}{b\sigma_t}\right]^{1/2}$
Zero field susceptibility*	$X\equiv\left(\frac{\partial M}{\partial H}\right)\Big\|_{H=0}$	$\xi\equiv\left(\frac{\partial E}{\partial S}\right)\Big\|_{S=0}$
	$=\Theta(T_c-T)[2c(T_c-T)]^{-1}$	$=\Theta(\sigma_t-\sigma)\left[\frac{a(\sigma_t-\sigma)}{2}\right]^{-1}$
	$+\Theta(T-T_c)[c(T-T_c)]^{-1}$	$+\Theta(\sigma-\sigma_t)[a(\sigma-\sigma_t)]^{-1}$
Thermo-dynamic potential	$F(M)=\frac{1}{2}c(T-T_c)M^2$	$G(E)=-\frac{a}{4}(\sigma-\sigma_t)E^2$
	$+\frac{1}{4}dTM^4$	$+\frac{1}{8}b\sigma E^4$
	$-HM+F_0$	$-SE+G_0$
Statistical distribution	$P(M)=N''\exp\left(-\frac{F(M)}{k_BT}\right)$	$P(E)=N'\exp\left(-\frac{G(E)}{k_B\sigma}\right)$

*Θ ( ) is Heaviside's unit step function.
†Value of order parameter at critical point.

methods of classical statistical mechanics. The quantity $P(\alpha,\alpha^*)$ represents the probability density for finding the electric field corresponding to α.

Near threshold, $P(\alpha,\alpha^*)$ obeys the following Fokker-Planck equation:

$$\frac{\partial P}{\partial t}=-\frac{\partial}{\partial\alpha}\left[\frac{1}{2}(\mathcal{A}-\kappa)\alpha P-\frac{1}{2}\mathcal{B}|\alpha|^2\,\alpha P\right]$$
$$-\frac{\partial}{\partial\alpha*}\left[\frac{1}{2}(\mathcal{A}-\kappa)\alpha^*P-\frac{1}{2}\mathcal{B}|\alpha|^2\,\alpha^*P\right]+\mathcal{A}\frac{\partial^2P}{\partial\alpha\partial\alpha^*} \tag{121}$$

The steady-state solution of this equation is given by

$$P(\alpha,\alpha^*)=\mathcal{N}\exp\left[\frac{(\mathcal{A}-k)|\alpha|^2-\mathcal{B}|\alpha|^4/2}{2\mathcal{A}}\right] \tag{122}$$

where $\mathcal{N}$ is a normalization constant. The P representation can be rewritten in terms of the variables $x=\mathrm{Re}\ \alpha$ and $y=\mathrm{Im}\ \alpha$ as

$$P(x,y)=\mathcal{N}\exp\left[-\frac{G(x,y)}{K\sigma}\right] \tag{123}$$

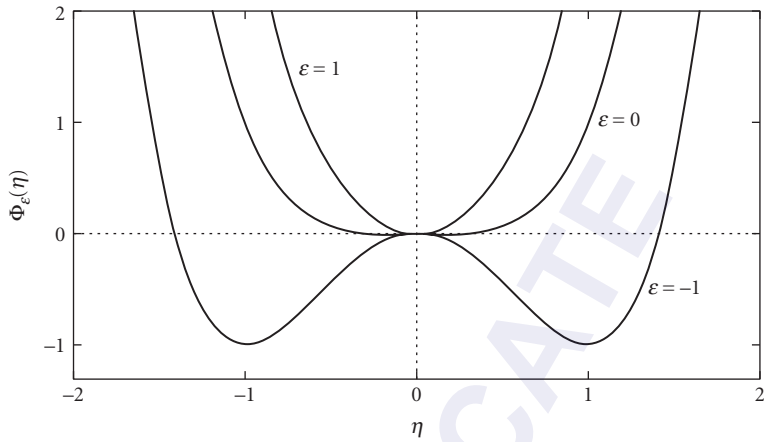

FIGURE 9 Scaled thermodynamical potentials. The $H = 0$ version of $F(M)$ and the $S = 0$ version of $G(E)$ can be expressed in terms of $\Phi_\varepsilon(\eta) = 2\varepsilon\eta^2 + \eta^4$ because

$$\Phi_\varepsilon(\eta) = \begin{cases} \dfrac{[F(M) - F_0]}{\dfrac{c^2 T_c}{4d}} & \text{with} \quad M = (c/d)^{1/2}(T/T_c)^{1/4}\eta \\ & \text{and} \quad \varepsilon = (T - T_c)/(TT_c)^{1/2} \\ \dfrac{[G(E) - G_0]}{\dfrac{a^2\sigma_t}{8b}} & \text{with} \quad E = (a/b)^{1/2}(\sigma_t/\sigma)^{1/4}\eta \\ & \text{and} \quad \varepsilon = (\sigma_t - \sigma)/(\sigma\sigma_t)^{1/2} \end{cases}$$

are equivalent to the respective entries in Table 1. The plot shows $\Phi_\varepsilon(\eta)$ for $\varepsilon = 1$ (ferromagnet above, T_c, laser below threshold), $\varepsilon = 0$ (ferromagnet at T_c, laser at threshold), and $\varepsilon = -1$ (ferromagnet below T_c, laser above threshold).

with

$$G(x, y) = -\frac{1}{4}a(\sigma - \sigma_t)(x^2 + y^2) + \frac{1}{8}b\sigma(x^2 + y^2)^2 \tag{124}$$

Here $K = a/4$ is one-fourth of the gain of one atom, $a(\sigma - \sigma_t) = \mathcal{A} - \kappa$, and $b\sigma = \mathcal{B}$.

We can see that the steady-state situation of the laser corresponds to the minimum value of G, i.e., $\partial G/\partial x = \partial G/\partial y = 0$. These solutions are $x = y = 0$ and $|\alpha|^2 = (x^2 + y^2) = a(\sigma - \sigma_t)/b\sigma$. Thus, for $(\sigma - \sigma_t) < 0$, the only allowed solution is $x = y = 0$. However, for $(\sigma - \sigma_t) > 0$, $x = y = 0$ is an unstable solution as the second derivative of G with respect to x and y is positive. This is seen clearly in Fig. 9, where we have plotted G versus $x = E$ for $y = 0$.

We thus see that G behaves in essentially the same way as the free energy of a thermodynamic system.

It should be emphasized that in the thermodynamic treatment of the ferromagnetic order-disorder transition, there are three variables required: (1) magnetization M, (2) external magnetic field H, and (3) temperature T. In order to have a complete analogy, it is important to realize that in addition to the electric-field-magnetization, population inversion-temperature correspondences, there must exist a further correspondence between the external magnetic field and a corresponding symmetry-breaking mechanism in the laser analysis. As shown in Ref. 111 and illustrated in Fig. 10, this symmetry breaking mechanism in the laser problem corresponds to an injected classical signal S. This leads to a skewed effective free energy.

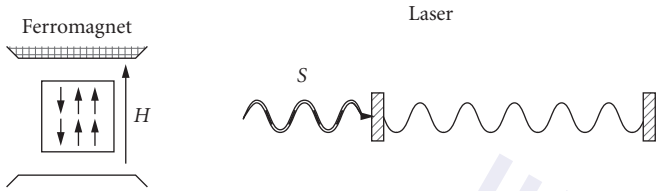

FIGURE 10 Figure depicting the broken symmetry mode of operation for both a ferromagnet and a laser.

An example of how the analogy can provide us with deeper insight is contained in the fact that we are able to *guess* correctly the $P(E)$ for a laser influenced by an injected signal, by analogy with the corresponding magnetic problem in the broken symmetry mode of operation.

More recently we have been turning the tables and using the quantum laser theory to learn about Bose-Einstein condensation (BEC). Recent experiments on BEC in laser-cooled gases,[112–114] and in He^4 in porous gel,[115] have stimulated a wealth of theoretical work[116–118] on the equilibrium and nonequilibrium properties of confined quantum degenerate gases.[119–124] Presently the partition function, critical temperature, and other such quantities are of interest for N bosons in a box below T_c. But the canonical ensemble is difficult to use in practice, because the state sums must be restricted to N particles. Indeed, the canonical partition function for a Bose gas of N particles at temperature T has not been so widely studied as one might have thought. To quote Herzog and Olshanii,

> To our knowledge there is no simple analytic expression for the canonical partition function in [the case of N bosons in a three-dimensional trap].[121]

Furthermore, there are questions of principle concerning the critical temperature and the validity of using phase-transition concepts in a mesoscopic sample having a small number of particles ($N \simeq 10^3$). In fact, Uhlenbeck pointed out to Einstein many years ago that BEC rigorously occurs only in the limit of infinite particle number.[125] Indeed, for a finite number of atoms there is no sharp "critical point " or critical temperature T_c. But the same can be said for the laser threshold. There is a *gradual* transition from disorder to order in both cases. However, as discussed later, even when fluctuations are present, T_c for a Bose gas and the laser threshold inversion are well defined.

Motivated by the preceding, we extend the laser-phase transition analogy to include BEC. We present a new approach to the problem of N bosons in thermal equilibrium below T_c. We emphasize that the present work provides another example[126] in which steady-state (detailed balance) solutions to nonequilibrium equations of motion provide a supplementary approach to conventional statistical mechanics (e.g., partition-function calculations). The present approach lends itself to different approximations; yielding, among other things, a simple (approximate) analytic expression for the ground-state density matrix for N trapped bosons and the partition function for same.

Thus, we seek a nonequilibrium equation of motion for the ground state of an ideal Bose gas in a three-dimensional harmonic trap coupled to the thermal reservoir, as shown elsewhere.[127]

$$\begin{aligned}\dot{\rho}_{n_0,n_0} &= -K_{n_0}(n_0+1)\rho_{n_0,n_0} + K_{n_0-1}n_0\rho_{n_0-1,n_0-1} \\ &\quad -H_{n_0}n_0\rho_{n_0,n_0} + H_{n_0+1}(n_0+1)\rho_{n_0+1,n_0+1}\end{aligned} \tag{125}$$

The cooling and heating coefficients K_{n_0} and H_{n_0} are given by

$$K_{n_0} = \sum_k 2\pi W_k g_k^2 \langle \eta_k + 1 \rangle \langle n_k \rangle_{n_0} \tag{126}$$

and

$$H_{n_0} = \sum_k 2\pi W_k g_k^2 \langle \eta_k \rangle \langle n_k + 1 \rangle_{n_0} \tag{127}$$

where W_k is the heat-bath density of states, $\langle \eta_k \rangle$ is the average occupation number of the kth heat-bath oscillator, and $\langle \eta_k \rangle_{n_0}$ is the average number of atoms in the kth excited state, given n_0 atoms in the condensate. Here the coefficient K_{n_0} denotes the cooling rate from the excited states to the ground state, and similarly H_{n_0} stands for the heating rate for the ground state.

The heating term is approximately

$$H_{n_0} \simeq \kappa \sum_k \langle \eta(\varepsilon_k) \rangle = \kappa \sum_{\ell,m,n} \left[\exp\left(\frac{\hbar\Omega}{k_B T} \right) (\ell + n + m) - 1 \right]^{-1} \tag{128}$$

In the weak trap limit, this yields

$$H_{n_0} \simeq \kappa \left(\frac{k_B T}{\hbar\Omega} \right)^3 \zeta(3) \tag{129}$$

where $\zeta(3)$ is the Riemann zeta function and Ω is the trap frequency. Likewise, the cooling term in Eq. (125) is governed by the total number of excited state bosons,

$$K_{n_0} \simeq \kappa \sum_k \langle n_k \rangle_{n_0} = \kappa (N - n_0) \tag{130}$$

By writing the equation of motion for $\langle n_0 \rangle$ from Eq. (125), using H_{n_0} in the weak trap limit, and Eq. (130) for K_{n_0}, we find

$$\langle \dot{n}_0 \rangle = \kappa \left[(N+1) \langle n_0 \rangle - \langle (n_0 + 1)^2 \rangle - \zeta(3) \left(\frac{k_B T}{\hbar\Omega} \right)^3 \langle n_0 \rangle \right] + \kappa (N+1) \tag{131}$$

Noting that near T_c, $\langle n_0 \rangle = N$, we may neglect $\langle (n_0 + 1)^2 \rangle$ compared to $N \langle n_0 \rangle$, and neglecting the spontaneous emission term $\kappa(N+1)$, Eq. (131) becomes

$$\langle \dot{n}_0 \rangle = \kappa \left[N - \zeta(3) \left(\frac{k_B T}{\hbar\Omega} \right)^3 \right] \langle n_0 \rangle \tag{132}$$

We now define the critical temperature (in analogy with the laser threshold) such that cooling (gain) equals heating (loss) and $\langle \dot{n}_0 \rangle = 0$ at $T = T_c$; this yields

$$T_c = \left(\frac{\hbar\Omega}{k_B} \right) \left[\frac{N}{\zeta(3)} \right]^{1/3} \tag{133}$$

Thus, by defining the critical temperature as that temperature at which the rate of removal of atoms from the ground state equals the rate of addition, we arrive at the usual definition for the critical temperature, even for mesoscopic systems.

23.6 EXOTIC MASERS AND LASERS

Lasing without Inversion

For a long time, it was considered that population inversion was necessary for laser action to take place. Recently, it has been shown both theoretically[128–130] and experimentally[131–134] that it is also

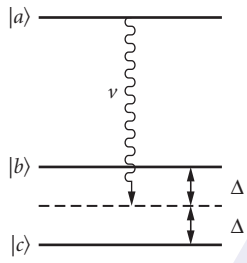

FIGURE 11 Level diagram for lasing without inversion.

possible to achieve lasing without inversion (LWI). In LWI, the essential idea is the cancellation of absorption by atomic coherence and interference.

Consider a system of three-level atoms interacting with a laser field in a cavity. The simple model we will focus on is that of Fig. 11. The atoms have one upper level $|a\rangle$ and two lower levels $|b\rangle$ and $|c\rangle$, with energies $\hbar\omega_a$, $\hbar\omega_b$, and $\hbar\omega_c$, respectively. The cavity field of frequency ν can be detuned from the atomic transition, as shown in the figure. The transitions $|a\rangle \rightarrow |b\rangle$ and $|a\rangle \rightarrow |c\rangle$ are now induced by one classical light field of frequency ν. The transition $|b\rangle \rightarrow |c\rangle$ is dipole forbidden. The atoms are pumped at a rate r_a in a coherent superposition of states

$$\rho(t_i) = \rho_{aa}^{(0)}|a\rangle\langle a| + \rho_{bb}^{(0)}|b\rangle\langle b| + \rho_{cc}^{(0)}|c\rangle\langle c| + \rho_{bc}^{(0)}|b\rangle\langle c| + \rho_{cb}^{(0)}|c\rangle\langle b| \tag{134}$$

Here $\rho_{\alpha\alpha}^{(0)}(\alpha = a, b, c)$ are the level populations and $\rho_{\alpha\alpha'}^{(0)}(\alpha \neq \alpha')$ are the atomic coherences. We give a simple argument to show how cancellation of absorption can lead to lasing without inversion in this scheme.

As the levels $|b\rangle$ and $|c\rangle$ are independent, the probability of emission is given by

$$\begin{aligned} P_{\text{emission}} &= P_b + P_c \\ &= (|\kappa_{a\to b}|2\mathscr{E}^2 + |\kappa_{a\to c}|2\mathscr{E}^2)\rho_{aa}^{(0)} \end{aligned} \tag{135}$$

where $\kappa_{a\to b}$ and $\kappa_{a\to c}$ are constants which depend on the matrix element between the relevant levels and the coupling of the atom with the field. On the other hand, the absorption probability is given by

$$\begin{aligned} P_{\text{absorption}} &= \kappa|C_b + C_c|2\mathscr{E}^2 \\ &= \kappa(\rho_{bb}^{(0)} + \rho_{cc}^{(0)} + \rho_{bc}^{(0)} + \rho_{cb}^{(0)})\mathscr{E}^2 \end{aligned} \tag{136}$$

where c_a and c_b are the probability amplitudes for the states $|b\rangle$ and $|c\rangle$. Therefore, the rate of growth of the laser field amplitude, under appropriate conditions, becomes

$$\dot{\mathscr{E}} = \frac{\mathscr{A}}{2}(\rho_{aa}^{(0)} - \rho_{bb}^{(0)} - \rho_{cc}^{(0)} - \rho_{bc}^{(0)} - \rho_{cb}^{(0)})\mathscr{E} \tag{137}$$

Here $\mathscr{A}$ is a constant. Thus, if the terms $\rho_{bc}^{(0)}$ and $\rho_{cb}^{(0)}$ cancel $\rho_{bb}^{(0)}$ and $\rho_{cc}^{(0)}$, we have

$$\dot{\mathscr{E}} = \frac{\mathscr{A}}{2}\rho_{aa}^{(0)}\mathscr{E} \tag{138}$$

and we can have lasing even if only a small fraction of atoms is in the excited state $|a\rangle$, that is, even if $\rho_{aa} < (\rho_{bb} + \rho_{cc})$.

Physically, the lack of absorption in the three-level system considered here is a manifestation of quantum coherence phenomena. When an atom makes a transition from the upper level to the two lower levels, the total transition probability is the sum of $|a\rangle \rightarrow |b\rangle$ and $|a\rangle \rightarrow |c\rangle$ probabilities. However, the transition probability from the two lower levels to the single upper level is obtained by squaring the sum of the two probability amplitudes. When there is coherence between the two lower levels, this can lead to interference terms yielding a null in the transition probability corresponding to photon absorption.

Correlated (Spontaneous) Emission Laser

As discussed earlier, the fundamental source of noise in a laser is spontaneous emission. A simple pictorial model for the origin of the laser linewidth envisions it as being due to the random phase diffusion process arising from the addition of spontaneously emitted photons with random phases to the laser field. Here we show that the quantum noise leading to the laser linewidth can be suppressed below the standard Schawlow-Townes limit by preparing the atomic systems in a coherent superposition of states as in the Hanle-effect and quantum-beat experiments. In such coherently prepared atoms, the spontaneous emission is said to be *correlated*. Lasers operating via such a phase-coherent atomic ensemble are known as *correlated emission lasers* (CELs).[135]

An interesting aspect of the CEL is that it is possible to eliminate the spontaneous emission quantum noise in the relative linewidths by correlating the two spontaneous emission noise events.

A number of schemes exist in which quantum noise quenching below the standard limit can be achieved. In two-mode schemes a correlation between the spontaneous emission events in two different modes of the radiation field is established via atomic coherence so that the relative phase between them does not diffuse or fluctuate. In a Hanle laser[136] and a quantum-beat laser[137] this is achieved by pumping the atoms coherently such that every spontaneously emitting atom contributes equally to the two modes of the radiation, leading to a reduction and even vanishing of the noise in the phase difference. In a two-photon CEL, a cascade transition involving three-level atoms is coupled to only one mode of the radiation field.[138] A well-defined coherence between the upper and lower levels $|a\rangle$ and $|c\rangle$ leads to a correlation between the light emitted by an $|a\rangle \rightarrow |b\rangle$ and a subsequent $|b\rangle \rightarrow |c\rangle$ transition.

The quantum theory of quantum-beat or Hanle-effect lasers may be conveniently cast in terms of the equation of motion for the density matrix describing the laser radiation field $\rho(a_1, a_1^\dagger; a_2, a_2^\dagger)$; that is,

$$\dot{\rho} = \sum_{ij} \mathcal{L}_{ij} \rho \tag{139}$$

where the linear gain and cross-coupling Liouville operators are given by

$$\mathcal{L}_{ii}\rho = -\frac{1}{2}[\alpha_{ii}\rho a_i a_i^\dagger + \alpha_{ii}^* a_i a_i^\dagger \rho - (\alpha_{ii} + \alpha_{ii}^*) a_i^\dagger \rho a_i] \tag{140}$$

$$\mathcal{L}_{12}\rho = -\frac{1}{2}[\alpha_{12}\rho a_2 a_1^\dagger + \alpha_{21}^* a_2 a_1^\dagger \rho - (\alpha_{12} + \alpha_{21}^*) a_1^\dagger \rho a_2] e^{i\Phi} \tag{141}$$

$$\mathcal{L}_{21}\rho = -\frac{1}{2}[\alpha_{21}\rho a_1 a_2^\dagger + \alpha_i^* a_1 a_2^\dagger \rho - (\alpha_i + \alpha_i^*) a_2^\dagger \rho a_1] e^{i\Phi} \tag{142}$$

Here α_{ij} are constants that depend on the parameters of the gain medium such as detunings, Rabi frequency of the driving field, and so on. When the coherent mixing of levels $|a\rangle$ and $|b\rangle$ is produced via a microwave signal having frequency ω_0, the phase angle ϕ is given by $\Phi(t) = (\nu_1 - \nu_2 - \omega_0)t - \phi$ where ϕ is the (microwave determined) atomic-phase difference $\phi_a - \phi_b$. In the case of polarization-induced

coherent mixing, the phase angle is $\Phi(t)=(\nu_2-\nu_2)t-\phi$, where ϕ is again the relative phase between levels $|a\rangle$ and $|b\rangle$ but determined this time by the state of elliptic polarization of the pump light used to excite the atoms.

The Liouville equation (31) for the reduced-density operator for the field can be converted into an equivalent Fokker-Planck equation by introducing coherent state representation for a_1 and a_2 and the P representation $P(\alpha, \alpha^*)$ for ρ. If we define the coherent states as

$$a_i\,|\alpha_1, \alpha_2|\rangle=\alpha_i\,|\alpha_1, \alpha_2|\rangle; i=1, 2 \tag{143}$$

where α is an arbitrary complex number, and we represent α_i as

$$\alpha_i=\rho_i \exp(i\theta_i); i=1, 2 \tag{144}$$

then the Fokker-Planck equation in terms of ρ_i, θ_i will contain a term which describes diffusion of relative phase $\theta=\theta_1-\theta_2$ as

$$\dot{P}=\frac{\partial^2}{\partial\theta^2}[\mathcal{D}(0)P] \tag{145}$$

with

$$\mathcal{D}=\frac{1}{16}\left\{\left(\frac{\alpha_{11}}{\rho_1^2}+\frac{\alpha_{22}}{\rho_2^2}\right)-\frac{(\alpha_{12}+\alpha_{21}^*)e^{-i\psi}}{\rho_1\rho_2}\right\} \tag{146}$$

and $\psi=\Phi+\theta_1-\theta_2$ with θ_i being the phase of the ith field. The diffusion constant $\mathcal{D}$ for the relative phase vanish for $\psi=0$, $\rho_1=\rho_2$, and $\alpha_{11}=\alpha_{22}=\alpha_{12}=\alpha_{21}^*$, thus leading to CEL action.

Free-Electron Laser

A coherent emission of radiation in a free-electron laser (FEL) is due to the bunching of a relativistic electron beam propagating along a periodic magnetic structure. The electrons experience a Lorentz force and thus follow oscillating orbits and radiate. This spontaneous emission coupled with the periodic magnetic structure give rise to a periodic ponderomotive potential. The electrons bunch together and radiate coherently.[139] The spontaneous emission pattern of a relativistic electron of energy $E=\gamma mc^2$ with $\gamma \gg 1$ is mostly in the forward direction. For a magnetic wiggler of period λ_W, the spectrum in the forward direction is symmetric about the wavelength $\lambda_s \cong \lambda_W/2\gamma^2$. Thus, a change of the periodicity of the wiggler λ_W can be used to tune the coherent light emitted by the FEL over a very wide range.

Many interesting features of FEL can be understood classically. However, the quantum-statistical properties of radiation emitted by FEL exhibit many interesting features such as squeezing and sub-poissonian statistics.[140–142]

Here we describe a free-electron amplifier in the small-signal noncollective regime. Such an FEL can be described by the one-electron nonrelativistic Bambini-Renieri hamiltonian which refers to a moving frame, where the laser and the wiggler frequencies coincide with $\omega=ck/2$.[143] In this frame, resonance occurs when the electron is at rest; therefore, the electron can be treated nonrelativistically. The hamiltonian is given by

$$\mathcal{H}=\frac{p^2}{2m}+\hbar\omega A^\dagger A+i\hbar g(A-A^\dagger) \tag{147}$$

with $A = a \exp(ikz)$. Here a is the annihilation operator of the laser field, p and z are the electron's momentum and coordinate with $[z, p] = i\hbar$, $[A, A^\dagger] = 1$, $[p, A] = \hbar k A$, m is the effective mass of the electron, and

$$g = \left(\frac{e^2 B}{mk}\right)\left(\frac{2}{V\varepsilon_0 \hbar\omega}\right)^{1/2} \tag{148}$$

with V the quantization volume and B the magnetic-field strength of the wiggler field in the moving frame. In Eq. (147) we have already taken the classical limit of the wiggler field. By transforming to the interaction picture we obtain

$$\mathcal{H}_I = ig\hbar\left\{\exp\left[-\frac{it(\hbar k^2 + 2kp)}{2m}\right]A^\dagger - Hc\right\} \tag{149}$$

We now consider an initial state made up by an electron with momentum p and the field vacuum, i.e., $|\text{in}\rangle = \overline{p}|\overline{p}, 0\rangle$

$$p|\overline{p}, 0\rangle = \overline{p}|\overline{p}, 0\rangle \tag{150}$$

$$A|\overline{p}, 0\rangle = 0 \tag{151}$$

$$A^\dagger|\overline{p}, 0\rangle = |\overline{p} - \hbar k, 1\rangle \tag{152}$$

The final-state expectation value of any operator $O(A, A^\dagger)$ is then

$$\langle \text{out}|O|\text{out}\rangle = \langle \overline{p}, 0|\overline{s}^\dagger(T)OS(T)|\overline{p}, 0\rangle \tag{153}$$

where

$$S(T) = T\exp\left[-\frac{i}{\hbar}\int_{-T/2}^{T/2} dt\, H_I(t)\right] \tag{154}$$

is the time-evolution operator for the electron-photon state.

The evaluation of Eq. (153) is straightforward in the small-signal limit along the lines given in Ref. 141, and we obtain

$$(\Delta A_1)^2 = \frac{1}{4} - \frac{\hbar k^2}{2m} j\frac{\partial j}{\partial \beta} \tag{155a}$$

$$(\Delta A_1)^2 = \frac{1}{4} + \frac{\hbar k^2}{2m} j\frac{\partial j}{\partial \beta} \tag{155b}$$

$$(\Delta A_1)(\Delta A_2) = \frac{1}{4} \tag{155c}$$

$$\Delta n^2 - \langle n\rangle = -\frac{2\hbar k^2}{m} j^3 \frac{\partial j}{\partial \beta} \tag{155d}$$

where

$$j = \left(\frac{2g}{\beta}\right)\sin\left(\frac{\beta T}{2}\right) \tag{156}$$

$$\beta = \frac{k\overline{p}}{m} \tag{157}$$

In our notation, the gain of the free-electron laser is proportional to $-j\partial j/\partial\beta$. Hence, Eqs. (155*a*) and (155*b*) show that, depending on the sign of the gain, either A_1 or A_2 is squeezed while, because of Eq. (155*c*), minimum uncertainty is maintained. Here, we have defined squeezing with respect to the operator A instead of the annihilation operator a of the radiation field. This must be so because we employ electron-photon states, and the annihilation of a photon always comes up to increasing the momentum of the electron by $\hbar k$. Finally, Eq. (155*d*) shows that we have subpoissonian, poissonian, or superpoissonian statistics if the electron momentum is below resonance ($\beta<0$), at resonance ($\beta=0$), or below resonance ($\beta>0$), respectively.

Exploiting the Quantized Center-of-Mass Motion of Atoms

In the treatment of the interaction of a two-level atom with photons of a single, dynamically privileged mode by the Jaynes-Cummings model, as discussed in Sec. 23.4, the center-of-mass motion of the atom is regarded as classical. This is a well-justified approximation, since the atom's kinetic energy of typically $\sim 10^{-2}$ eV is many orders of magnitude larger than the interaction energy of typically $\sim 10^{-11}$ eV if the atom belongs to a thermal beam. For ultracold atoms, however, matters can be quite different, and the quantum properties of the center-of-mass motion must be taken into account.

Early studies showed that very slow atoms can be reflected at the entry port of a resonator[144] or trapped inside.[145] The reflection probability is considerable even if the photon lifetime is not short as compared with the relatively long interaction time.[146]

Whereas Refs. 144 to 146 deal mainly with the mechanical effects on the center-of-mass motion of the atom, the modifications in the maser action are addressed in Refs. 147 to 150. For thermal atoms, the emission probability displays the usual Rabi oscillations (see Sec. 23.4) as a function of the interaction *time*. For very slow atoms, however, the emission probability is a function of the interaction *length* and exhibits resonances such as the ones observed in the intensity transmitted by a Fabry-Perot resonator. The resonances occur when the resonator length is an integer multiple of half the de Broglie wavelength of the atom inside the cavity.

A detailed calculation[147] shows that the emission probability is 50 percent at a resonance, irrespective of the number of photons that are present initially. Owing to this unusual emission probability, a beam of ultracold atoms can produce unusual photon distributions, such as a shifted thermal distribution. In the trilogy (Refs. 148 to 150) this *microwave amplification by z-motion-induced emission of radiation* (mazer) is studied in great detail.

In order to see the mazer resonances for atoms with a certain velocity spread, the interaction length has to be small. Therefore, micromaser cavities of the usual cylindrical shape, for which the smallest cavity length is given by half the wavelength of the microwaves, cannot be used for this purpose. But cavities of the reentrant type (familiar as components of klystrons) allow for an interaction length that is much smaller than the wavelength. With such a device, an experiment with realistic parameters seems possible.[149] As a potential application, we mention that a working mazer could be used as a velocity filter for atoms.[151]

23.7 ACKNOWLEDGMENTS

The authors gratefully acknowledge the generous support of the Office of Naval Research over the many years spent on completing the works reviewed here. It is also a pleasure to acknowledge the Max-Planck-Institute for Quantum Optics (Garching, Germany) for providing the excellent working atmosphere and the intellectual stimulus for the most interesting works in this field.

PHOTODETECTORS

Paul R. Norton

U.S. Army Night Vision and Electronics Directorate
Fort Belvoir, Virginia

*Second revision and update from an article by Stephen F. Jacobs**

24.1 SCOPE

The purpose of this chapter is to describe the range of detectors commercially available for sensing optical radiation. Optical radiation over the range from vacuum ultraviolet to the far-infrared or submillimeter wavelength (25 nm to 1000 μm) is considered. We will refer to the following spectral ranges:

25–200 nm	vacuum ultraviolet	VUV
200–400 nm	ultraviolet	UV
400–700 nm	visible	VIS
700–1000 nm	near infrared	NIR
1–3 μm	short-wavelength infrared	SWIR
3–5 μm	medium-wavelength infrared	MWIR
5–14 μm	long-wavelength infrared	LWIR
14–30 μm	very long wavelength infrared	VLWIR
30–100 μm	far-infrared	FIR
100–1000 μm	submillimeter	SubMM

We begin by giving a brief description of the photosensitive mechanism for each type of detector. The usefulness and limitations of each detector type are also briefly described. Definitions of the technical terms associated with the detection process are listed. The concept of sensitivity is defined, and D-star (D^*) is presented as a measure of ideal performance. Examples are then given of the limiting cases for D^* under several conditions. In addition, other detector performance parameters are described which may be of critical interest in a specific application, including spectral response, responsivity, quantum efficiency, noise, uniformity, speed, and stability. Finally, manufacturers' specifications for a range of available detectors are compiled and a list of manufacturers is included for each type of detector.

*In *Handbook of Optics*, first edition, McGraw-Hill, 1978. Section 4, "Nonimaging Detectors," by Stephen F. Jacobs, Optical Sciences Center, University of Arizona, Tucson, Arizona.

The sensitivity of many detectors has reached the limit set by room-temperature background photon fluctuations (radiation shot noise). For these detectors, sensitivity may be enhanced by providing additional cooling, while restricting their spatial field of view and/or spectral bandwidth. At some point, other factors such as amplifier noise may limit the improvement.

Techniques for evaluating detector performance are not covered in this treatment but can be found in Refs. 1–6.

24.2 THERMAL DETECTORS

Thermal detectors sense the change in temperature produced by absorption of incident radiation. Their spectral response can therefore be as flat as the absorption spectrum of their blackened coating and window* will allow. This makes them useful for spectroscopy and radiometry. These detectors are generally operated at room temperature, where their sensitivity is limited by thermodynamic considerations[7,8] to 3 pW for 1-s measurement time and 1-mm^2 sensitive area. This limit has been very nearly reached in practice, whereas cooled bolometers have been made to reach the background photon noise limit. Figure 1 illustrates the basic structural elements of a thermal detector.

Construction of the detector seeks to minimize both the thermal mass of the sensitive element and the heat loss from either conductive or convective mechanisms. Heat loss may ideally be dominated by radiation. This allows the incident photon flux to give a maximum temperature rise (maximum signal), but results in a correspondingly slow response time for this class of detectors. The response time τ of thermal detectors is generally slower than 1 ms, depending on thermal capacity C and heat loss per second per degree G, through the relation

$$\tau = C/G$$

A short time constant requires a small C. However, for room-temperature operation, ultimate sensitivity is limited by the mean spontaneous temperature fluctuation:

$$\Delta T = T\sqrt{\frac{k}{C}}$$

where k is Boltzmann's constant. There is thus a trade-off between time constant and ultimate sensitivity.

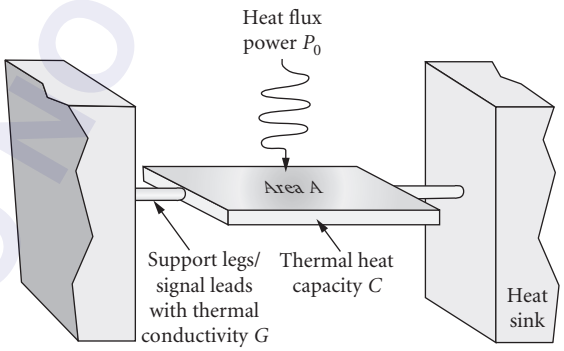

FIGURE 1 Structural elements of a thermal detector. Sensitive area A with a thermal heat capacity of C, supported by leads having thermal conductivity G, and with a heat flux of P_0 incident on the pixel.

*No windows exist without absorption bands anywhere between the visible and millimeter region. Some useful window materials for the far-infrared are diamond, silicon, polyethylene, quartz, and CsI.

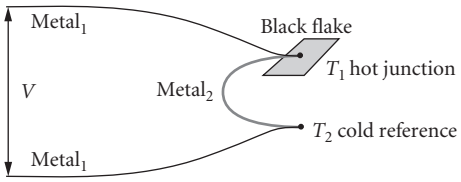

FIGURE 2 Thermocouple detector structure.

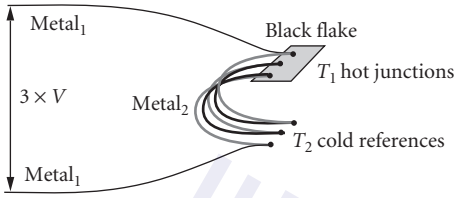

FIGURE 3 Thermopile detector structure.

Thermocouple/Thermopile

The thermocouple receiver, illustrated in Fig. 2, is a thin, blackened flake connected thermally to the junction of two dissimilar metals or semiconductors. Heat absorbed by the flake causes a temperature rise of the junction, and hence a thermoelectric emf is developed which can be measured, for example, with a voltmeter.

Thermocouples are limited in sensitivity by thermal (Johnson-Nyquist) noise but are nevertheless respectably sensitive. Their usefulness lies in the convenience of room temperature operation, wide spectral response, and their rugged construction. Thermocouples are widely used in spectroscopy.

Thermopiles consist of thin-film arrays of thermocouples in series, as illustrated in Fig. 3. This device multiplies the thermocouple signal corresponding to the number of junctions in series. The device may be constructed with half the thermocouples acting as reference detectors attached to a heat sink.

Bolometer/Thermistor

The receiver is a thin, blackened flake or slab, whose impedance is highly temperature dependent—see Fig. 4. The impedance change may be sensed using a bridge circuit with a reference element in the series or parallel arm. Alternatively, a single bolometer element in series with a load and voltage source may be used.

Most bolometers in use today are of the thermistor type made from oxides of manganese, cobalt, or nickel. Their sensitivity closely approaches that of the thermocouple for frequencies higher than 25 Hz. At lower frequencies there may be excess or $1/f$ noise. Construction can be very rugged for systems applications. Some extremely sensitive low-temperature semiconductor and superconductor bolometers are available commercially.

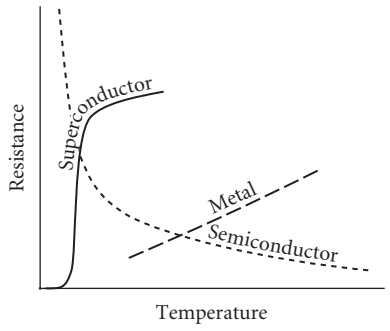

FIGURE 4 Temperature dependence characteristics of three bolometer material types.

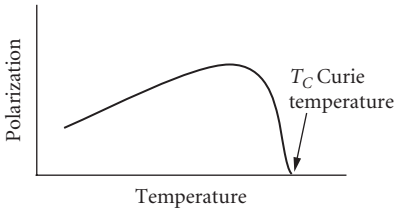

FIGURE 5 Ferroelectric materials exhibit residual polarization with no applied bias.

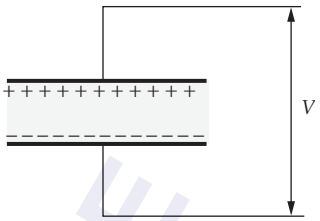

FIGURE 6 The pyroelectric effect produces a surface charge when the temperature changes.

Pyroelectric

Ferroelectric material exhibits a residual polarization in the absence of any electric field, as illustrated in Fig. 5. Dipole moments, initially aligned by applying an external field, result in a surface charge which is normally slowly neutralized by leakage. This polarization is temperature-dependent (pyroelectric effect), and when incident radiation heats an electroded sample, there is a change in surface charge (open-circuit voltage) which is proportional to the incident radiation power—see Fig. 6. Electrically, the device behaves like a capacitor, requiring no bias and therefore exhibiting no current noise. The signal, however, must be chopped or modulated. Sensitivity is limited either by amplifier noise or by loss-tangent noise. Response speed can be engineered, with a proportional decrease in sensitivity, making pyroelectric detectors useful for moderately fast laser pulse detection. Other common applications include power meters. Microphonic noise in applications associated with vibrations can be a problem with some of these devices.

24.3 QUANTUM DETECTORS

Photon detectors respond in proportion to incident photon rates (quanta) rather than to photon energies (heat). Thus, the spectral response of an ideal photon detector is flat on an incident-photon-rate basis but linearly rising with wavelength on an incident-power (per watt) basis. The sensitivity of efficient quantum detectors can approach the limits of photon noise fluctuations provided that the detector temperature is sufficiently low for photon-induced mechanisms to dominate thermally induced mechanisms in the detector. Quantum detectors generally have submicrosecond time constants. Their main disadvantage is the associated cooling required for optimum sensitivity. (These remarks do not apply to photographic detection, which measures cumulative photon numbers.)

Photoemissive

The radiation is absorbed by a photosensitive surface which usually contains alkali metals (cesium, sodium, or potassium). Incident quanta release photoelectrons (Fig. 7), via the photoelectric effect, which are collected by a positively biased anode. This is called a diode phototube; it can be made the basis for the multiplier phototube (photomultiplier phototube, or photomultiplier) by the addition of a series of biased dynodes which serve as secondary emission multipliers.

In spectral regions where quantum efficiency is high (λ <550 nm), the photoemissive detector is very nearly ideal. Sensitivity is high enough to count individual photons. Amplification does not degrade the signal-to-noise ratio. The sensitive area is conveniently large. Photomultiplier signal response time (transit spread time) can be made as short as 0.1 ns. Since the sensitivity in red-sensitive tubes is limited by thermally generated electrons, sensitivity can be improved by cooling.

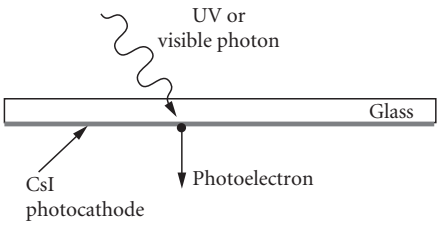

FIGURE 7 Electrons are ejected from a photoemissive surface when excited by photons.

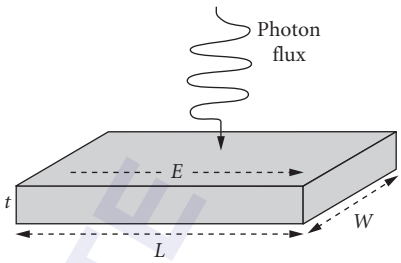

FIGURE 8 Photoconductor device structure.

Photoconductive

The radiation is absorbed by a photoconductive (PC) material, generally a semiconductor, either in thin-film or bulk form, as illustrated in Fig. 8. Each incident quantum may release an electron-hole pair or an impurity-bound charge carrier, thereby increasing the electrical conductivity. The devices are operated in series with a bias voltage and load resistor. Very low impedance photoconductors may be operated with a transformer as the load. Since the impedance of photoconductors varies with device type and operating conditions from less than 50 Ω to more than 10^{14} Ω, the load resistor and preamplifier must be chosen appropriately. Figure 9 shows the current-voltage characteristics of a photoconductor.

Photoconductors that utilize excitation of an electron from the valence to conduction band are called *intrinsic* detectors. Those which operate by exciting electrons into the conduction band or holes into the valence band from states within the band—impurity-bound states, quantum wells, or quantum dots—are called *extrinsic* detectors. Figure 10 illustrates these two mechanism types. Intrinsic detectors are most common at the short wavelengths, out to about 20 μm. Extrinsic detectors are most common at longer wavelengths. A key difference between intrinsic and extrinsic detectors is that intrinsic detectors do not require as much cooling to achieve high sensitivity at a given spectral response cutoff as extrinsic detectors. Thus, intrinsic photoconductors such as HgCdTe will operate out to 15 to 20 μm at 77 K, while comparable extrinsic detectors with similar cutoff must be cooled below 30 to 40 K.

A further distinction may be made by whether the semiconductor material has a direct or indirect bandgap. This difference shows up near the long-wavelength limit of the spectral response

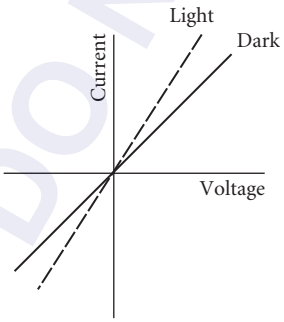

FIGURE 9 Photoconductor current-voltage characterisitics in the dark and in the light.

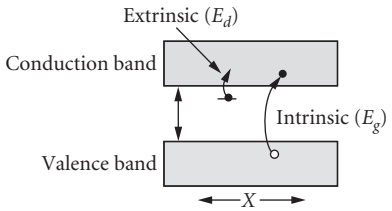

FIGURE 10 Intrinsic detectors excite electrons between the valence and conduction band. Extrinsic detectors excite electrons (or holes) from states within the band to the conduction (valence) band.

where detectors made from direct bandgap materials such as InGaAs, InSb, or HgCdTe have a sharper spectral cutoff than indirect bandgap materials such as silicon and germanium.

Photoconductors can have high quantum efficiency from the visible region out to the far infrared but lack the nearly ideal high amplification of photomultipliers. They are therefore most commonly used in the spectral region beyond 1 μm, where efficient photoemitters are unavailable. Photoconductors do, however, provide current gain which is equal to the recombination time divided by the majority-carrier transit time. This current gain leads to higher responsivity than is possible with (nonavalanching) photovoltaic (PV) detectors. For applications where photovoltaic detection would be amplifier noise limited, the larger photoconductive responsivity makes it possible to realize greater sensitivity with the photoconductor. In general, lower-temperature operation is associated with longer-wavelength sensitivity in order to suppress noise due to thermally induced transitions between close-lying energy levels. Ideally, photoconductors are limited by generation-recombination noise in the photon-generated carriers. Response time can be shorter than 1 μs and in some cases response times can be shorter than 1 ns for small elements. Response across a photoconductive element can be nonuniform due to recombination mechanisms at the electrical contacts, and this effect may vary with electrical bias.

Photovoltaic*

The most widely used photovoltaic detector is the *pn* junction type (Fig. 11), where a strong internal electric field exists across the junction even in the absence of radiation. Photons incident on the junction of this film or bulk material produce free hole-electron pairs which are separated by the internal electric field across the junction, causing a change in voltage across the open-circuit cell or a current to flow in the short-circuited case.

As with the photoconductor, quantum efficiency can be high from the visible to the very long-wavelength infrared, generally about 20 to 25 μm. The limiting noise level can ideally be $\sqrt{2}$ times lower than that of the photoconductor, thanks to the absence of recombination noise. Lower temperatures are associated with longer-wavelength operation. Response times can be less than a nanosecond,

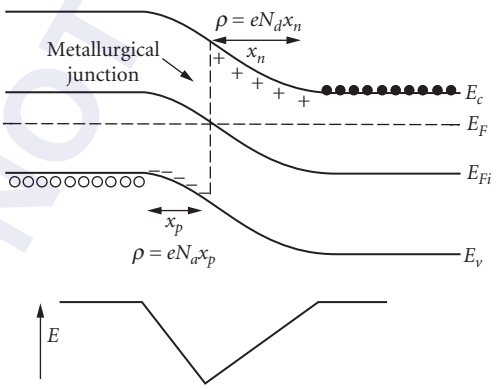

FIGURE 11 *pn* junction showing how the band bends across the junction. The junction width is given by $W = x_p + x_n$.

*The use of a photovoltaic detector at other than zero bias is often referred to as its photoconductive mode of operation because the circuit then is similar to the standard photoconductor circuit. This terminology is confusing with regard to detection mechanism and will not be used here.

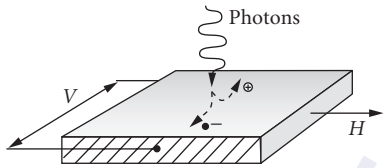

FIGURE 12 Photoelectromagnetic detector configuration—incident photons create electron-hole pairs that diffuse away from the surface. A magnetic field perpendicular to the diffusion separates the charges toward opposite sides, creating a voltage.

and are generally limited by device capacitance and detection-circuit resistance. The *pin* diode has been developed to minimize capacitance for high-bandwidth applications. The advantages of nearly ideal internal amplification have now become available in avalanche photodiodes sensitive out to 1.55 μm. This internal gain is most important for high-frequency operation, where external load resistance must be kept small and would otherwise introduce limiting thermal noise, and for situations involving low signal flux where amplifier noise is otherwise dominant.

Photoelectromagnetic

A thin slab of photoconductive material is oriented with radiation incident on a large face and a magnetic field perpendicular to it, as illustrated in Fig. 12. Electron-hole pairs generated by the incident photons diffuse through the material and are separated by the magnetic field, causing a potential difference at opposite ends of the detector.

These detectors require no cooling or biasing electric field but do require a (permanent) magnetic field. Photoelectromagnetic InSb at room temperature has response up to 7.5 μm, where it is as sensitive as a thermocouple of equal size, and has a response time less than 1 μs. Another competing uncooled detector is InAs, which is far more sensitive out to 3.5 μm. HgCdTe is also available in the photoelectromagnetic (PEM) configuration out to the LWIR spectral region. Cooled infrared detectors are one to two orders of magnitude more sensitive.

Photographic

The receiver is an emulsion containing silver halide crystals. Incident photons are absorbed by the halide ion, which subsequently loses its electron. This electron eventually recombines with a silver ion and reduces it to a neutral silver atom. As more photons are absorbed, this process is repeated until a small but stable cluster of reduced silver atoms is formed within the crystal (latent image). Internal amplification is provided by introduction of an electron donor (photographic) developer, which, using the latent image as a catalytic center, reduces all the remaining silver ions within the exposed crystal to neutral silver atoms. The density of reduced crystals is a measure of the total radiation exposure.

The spectral region of sensitivity for photographic detection coincides rather closely with that of the photoemissive detector. For $\lambda > 1.2$ μm (~1 eV) there is too little energy in each photon to form a stable latent image. The basic detection process for both detectors operates well for higher energy, shorter wavelength radiation. The problem in ultraviolet and x-ray operation is one of eliminating nonessential materials, for example, the emulsion which absorbs these wavelengths.

The photographic process is an integrating one in that the output (emulsion density) measures the cumulative effect of all the radiation incident during the exposure time. The efficiency of the photographic process can be very high, but it depends upon photon energy; for example, in the

visible region it takes only 10 to 100 photons to form a stable latent image (developable grain). The photographic process enjoys a large and efficient internal amplification ability (development) wherein the very small energy of the photons' interaction is converted into readily observed macroscopic changes. An extensive discussion of photographic detection is found in Chap. 29, "Photographic Films."

Photoionization

The radiation is absorbed by a gas. If the photon energy exceeds the gas-ionization threshold, ion pairs can be produced with very high efficiency. They are collected by means of an applied voltage. Operating in a dc mode, these detectors are known as ionization and gas-gain chambers. When a pulse mode is used, the detectors are known as proportional and photon (Geiger) counters.

Photoionization detectors have a high sensitivity and a low noise level. They may also be quite selective spectrally since the choice of window and gas independently set upper and lower limits on detectable photon energies. Manufacturers' specifications are not discussed for these detectors as applications are still few enough to be treated as individual cases.[9]

24.4 DEFINITIONS

The following definitions will be used:

Avalanche photodiode (*APD*) A photodiode designed to operate in strong reverse bias where electron and/or hole impact ionization produces multiplication of photogenerated carriers.

Background temperature The effective temperature of all radiation sources viewed by the detector exclusive of the signal source.

Blackbody D star D^*_{BB} (cm $Hz^{1/2}$/W also called "Jones") Similar to $D^*(\lambda)$ or $D^*(T_B f)$ except that the source is a blackbody whose temperature must be specified.

Blackbody detectivity D_{BB} (W^{-1}) A measure of detector sensitivity, defined as DBB $(NEP_{BB})^{-1}$.

Blackbody noise-equivalent power NEP_{BB} Same as spectral NEP, except that the source has blackbody spectral character whose temperature must be specified, for example, NEP (500 K, 1, 800) means 500-K blackbody radiation incident, 1-Hz electrical bandwidth, and 800-Hz chopping frequency.

Blackbody responsivity R_{BB} Same as spectral sensitivity except that the incident signal radiation has a blackbody spectrum (whose temperature must be specified).

Blip detector or blip condition Originally meaning background-limited impurity photoconductor, this term has come to mean performance of any detector where the limiting noise is due to fluctuations in the arrival rate of background photons.

Cutoff wavelength λ_c The wavelength at which the detectivity has degraded to one-half its peak value.

Dark current The output current which flows even when input radiation is absent or negligible. (Note that although this current can be subtracted out for the dc measurements, the shot noise on the dark current can become the limiting noise.)

Detective quantum efficiency The square of the ratio of measured detectivity to the theoretical limit of detectivity.

Detective time constant $\tau_d = 1/2\pi f_d$ where f_d is the frequency at which D^* drops to 0.707 $(1/\sqrt{2})$ times its maximum value. A physics convention defines it as $1/e$, or 0.368 of the maximum value.

Dewar A container (cryostat) for holding detector coolant.

Equivalent noise input (*ENI*) A term meaning nearly the same thing as NEP_{BB} (287 K, 1, f). The difference is that the peak-to-peak value of square-wave chopped input flux is used, rather than the rms value of the sinusoidally chopped input flux. (See recommendation IRE.[2])

Excess noise A term usually referring to noises other than generation-recombination, shot, or thermal.

Extrinsic semiconductor transition Incident photons produce a free electron in the conduction band and bound hole at a donor impurity site or a bound electron at an acceptor impurity site and a free hole in the valence band by excitation of an impurity level.

Field of view (*FOV*) The solid angle from which the detector receives radiation.

Flicker noise See Modulation noise.

Generation noise Noise produced by the statistical fluctuation in the rate of production of photoelectrons.

Generation-recombination (*GR*) *noise* Charge carriers are generated both by (optical) photons and (thermal) phonons. Fluctuations in these generation rates cause noise; fluctuations in carrier-recombination times cause recombination noise. The phonon contribution can be removed by cooling. The remaining photon contribution is indistinguishable from radiation shot noise (photon noise). With photovoltaic *pn* junctions, carriers are swept away before recombination, so that recombination noise is absent.

Guard ring An electrically biased field plate or surrounding diode used in some photodiodes, usually used to control surface recombination effects and thus reduce the leakage current in the detection circuit.

Intrinsic semiconductor transition Incident photons produce a free electron-free hole pair by direct excitation across the forbidden energy gap (valence to conduction band).

Johnson noise Same as Thermal noise.

Jones Unit of measure for D^* cm $Hz^{1/2}/W$.

Maximized D star, $D^*(\lambda_{pk} f_o)$, cm $Hz^{1/2}/W$ *or Jones* The value of $D^*(\lambda_{pk} f)$ corresponding to wavelength λ_{pk} and chopping frequency of maximum D^*.

Modulation (*or 1/f*) *noise* A consensus regarding the origin(s) of the mechanism has not been established, and although a quantum theory has been proposed, other mechanisms may dominate. As its name implies, it is characterized by a $1/f^n$ noise power spectrum, where $0.8 < n < 2$. This type of noise is prominent in thermal detectors and may dominate the low-frequency noise characteristics of photoconductive and photovoltaic quantum detectors as well as other electronic devices such as transistors and resistors.

Multiplier phototube or multiplier photodiode Phototube with built-in amplification via secondary emission from electrically biased dynodes.

NEI photons/(cm^2 sec) noise equivalent irradiance is the signal flux level at which the signal produces the same output as the noise present in the detector. This unit is useful because it directly gives the photon flux above which the detector will be photon noise limited. See also Spectral noise equivalent power (NEP).

Noise spectrum The electrical power spectral density of the noise.

Nyquist noise Same as Thermal noise.

Photo cell See Photodiode.

Photoconductive gain The ratio of carrier lifetime divided by carrier transit time in a biased photoconductor.

Photodiode The term photodiode has been applied both to vacuum- or gas-filled photoemissive detectors (diode phototubes, or photo cells) and to photovoltaic detectors (semiconductor *pn* junction devices).

Photomultiplier Same as Multiplier phototube.

Photon counting Digital counting of individual photons from the photoelectrons produced in the detector in contrast to averaging of the photocurrent. This technique leads to very great sensitivity but can be used only for quite low light levels.

Quantum efficiency The ratio of the number of countable output events to the number of incident photons, for example, photoelectrons per photon, usually referred to as a percentage value.

RMS noise $V_{n,\text{rms}}$ That component of the electrical output which is not coherent with the radiation signal (generally measured with the signal radiation removed).

RMS signal $V_{s,\text{rms}}$ That component of the electrical output which is coherent with the input signal radiation.

Response time τ Same as Time constant.

Responsive quantum efficiency See Quantum efficiency.

Sensitivity Degree to which detector can sense small amounts of radiation.

Shot noise This current fluctuation results from the random arrival of charge carriers, as in a photodiode. Its magnitude is set by the size of the unit charge.

$$i_{n,\text{rms}} = (2ei_{\text{dc}}\Delta f)^{1/2}$$

Spectral D-double-star $D^{**}(\lambda, f)$ A normalization of D^* to account for detector field of view. It is used only when the detector is background-noise-limited. If the FOV is 2π sr, $D^{**} = D^*$.

Spectral D-star $D^*(\lambda, f)$ (*cm* $Hz^{1/2}/W$ or *Jones*) A normalization of spectral detectivity to take into account the area and electrical bandwidth dependence, for example, D^*(1 μm, 800 Hz) means D^* at $\lambda = 1$ μm and chopping frequency 800 Hz; unit area and electrical bandwidth are implied. For background-noise-limited detectors the FOV and the background characteristics must be specified. For many types of detectors this normalization is not valid, so that care should be exercised in using D^*.

Spectral detectivity $D(\lambda)$ (W^{-1}) A measure of detector sensitivity, defined as $D(\lambda) = (\text{NEP}_\lambda)^{-1}$. As with NEP, the chopping frequency electrical bandwidth, sensitive area, and, sometimes, background characteristics should be specified.

Spectral noise equivalent power NEP_λ The rms value of sinusoidally modulated monochromatic radiant power incident upon a detector which gives rise to an rms signal voltage equal to the rms noise voltage from the detector in a 1-Hz bandwidth. The chopping frequency, electrical bandwidth, detector area, and, sometimes, the background for characteristics should be specified. NEP (1 μm, 800 Hz) means noise equivalent power at 1-μm wavelength, 1-Hz electrical bandwidth, and 800-Hz chopping rate. Specification of electrical bandwidth is often simplified by expressing NEP in units of $\text{W/Hz}^{1/2}$.

Spectral responsivity $R(\lambda)$ The ratio between rms signal output (voltage or current) and the rms value of the monochromatic incident signal power or photon flux. This is usually determined by taking the ratio between a sample detector and a thermocouple detector. The results are given as relative response/watt or relative response/photon, respectively.

Temperature noise Fluctuations in the temperature of the sensitive element, due either to radiative exchange with the background or conductive exchange with a heat sink, produce a fluctuation in signal voltage. For thermal detectors, if the temperature noise is due to the former, the detector is said to be at its theoretical limit. For thermal detectors:

$$\overline{(\Delta T)^2} = \frac{4kT^2G\Delta f}{K^2 + 4\pi^2 f^2 C^2}$$

where $\overline{(\Delta T)^2}$ = mean square temperature fluctuations
K = thermal conductance
C = heat capacity

Thermal noise (*also known as Johnson or Nyquist noise*) Noise due to the random motion of charge carriers in a resistive element:

$$V_{n,\text{rms}} = (4kTR\Delta f)^{1/2} \qquad k = \text{Boltzmann's constant}$$

Thermopile A number of thermocouples mounted in series in such a way that their thermojunctions lie adjacent to one another in the plane of irradiation.

Time constant τ (see also *detective time constant*) A measure of the detector's speed of response. $\tau = 1/(2\pi f_c)$, where f_c is that chopping frequency at which the responsivity has fallen to 0.707 $(1/\sqrt{2})$ times its maximum value. Sometimes a physics convention defines it as 1/e, or 0.368 of the maximum value:

$$R(f) = \frac{R_0}{(1+4\pi^2 f^2 \tau^2)^{1/2}}$$

24.5 DETECTOR PERFORMANCE AND SENSITIVITY

*D**

A figure of merit defined by Jones in 1958 is used to compare the sensitivity of detectors.[10] It is called D^*. Although the units of measure are cm $\text{Hz}^{1/2}$/W, this unit is now referred to as a *Jones*. D^* is the signal-to-noise (S/N) ratio of a detector measured under specified test conditions, referenced to a 1-Hz bandwidth and normalized by the square root of the detector area (A) in square centimeters. Specified test conditions usually consist of the blackbody signal source temperature, often 500 K for infrared detectors, and the signal chopping frequency. If the background temperature is other than room temperature (295 or 300 K in round numbers), then that should be noted.

By normalizing the measured S/N ratio by the square root of the detector area, the D^* figure of merit recognizes that the statistical fluctuations of the background photon flux incident on the detector (photon noise) are dependent upon the square root of the number of photons and thus increase as the square root of the detector area, while the signal will increase in proportion to the detector area itself. This figure of merit therefore provides a valid comparison of detector types that may have been made and tested in different sizes.

The ultimate limit in S/N ratio for any radiation power detector is set by the statistical fluctuation in photon arrival times. For ideal detectors which are photon-noise-limited, and where only generation noise is present, we shall discuss limiting detectivity for three cases:

1. Photon detector where arrival rate of signal photons far exceeds that of background photons (all other noise being negligible)
2. Photon detector where background photon arrival rate exceeds signal photon rate (all other noise being negligible)
3. Thermal detector, background limited

The rate of signal-carrier generation is

$$n = \eta \text{AN}_s \tag{1}$$

where η = detector quantum efficiency and AN_s = average rate of arrival of signal photons.

It can be shown[11] that in a bandwidth Δf, the rms fluctuation in carrier-generation rate is

$$\delta n_{\text{rms}} = (2P_N \Delta f)^{1/2} \tag{2}$$

where P_N is the frequency dependence of the mean square fluctuations in the rate of carrier generation, that is,

$$P_N = A\int_0^\infty \eta(\nu)(\Delta N)^2 d\nu \tag{3}$$

where $(\Delta N)^2$ is the mean square deviation in the total rate of photon arrivals per unit area and frequency interval including signal and background photons. For thermally produced photons of frequency ν (see Ref. 12).

$$(\Delta N)^2 = \overline{N}\frac{e^{h\nu/kT}}{e^{h\nu/kT}-1} = \frac{2\pi\nu^2}{c^2}\frac{e^{h\nu/kT}}{(e^{h\nu/kT}-1)^2} \tag{4}$$

where $\overline{N}$ is the average rate of photon arrivals per unit area and frequency interval. Then, for the special case of $h\nu >> kT$

$$\delta n_{\text{rms}} = (2A\eta\overline{N}\Delta f)^{1/2} \tag{5}$$

This is also the case for a laser well above threshold. Here the photon statistics become Poisson, and $(\Delta N)^2 = \overline{N}$ even when $h\nu$ is not greater than kT.

Photon Detector, Strong-Signal Case This is generally a good approximation for visible and higher photon energy detectors since the background radiation is often weak or negligible. When signal photons arrive at a much faster rate than background photons

$$\delta n_{\text{rms}} = (2A\eta\overline{N}_s\Delta f)^{1/2} \tag{6}$$

then

$$\text{NEP} = \frac{N_s A h\nu}{n/\delta n_{\text{rms}}(\Delta f)^{1/2}} = \left(\frac{2N_s A}{\eta}\right)^{1/2} h\nu \tag{7}$$

or the noise-equivalent quantum rate is

$$\text{NEQ} = \left(\frac{2\times \text{incident photon rate}}{\text{quantum efficiency}}\right)^{1/2} \tag{8}$$

Photon Detector, Background-Limited Case This is usually a good approximation for detecting low signal levels in the infrared where background flux levels exceed signal flux levels in many applications. When the background photon noise rate N_B exceeds the signal photon rate ($N_B >> N_S$)

$$\delta n_{\text{rms}} \approx (2A\eta\overline{N}_B\Delta f)^{1/2} \tag{9}$$

the noise-equivalent power is

$$\text{NEP} = \frac{N_s A h\nu}{(n/\delta n_{\text{rms}})(\Delta f)^{1/2}} = \left(\frac{2N_B A}{\eta}\right)^{1/2} h\nu \tag{10}$$

The noise-equivalent quantum rate is

$$\text{NEQ} = \left(\frac{2\times \text{incident background photon rate}}{\text{quantum efficiency}}\right)^{1/2} \tag{11}$$

or

$$D^* = \frac{A^{1/2}}{\text{NEP}} = \left(\frac{\eta}{2N_B}\right)^{1/2} \frac{1}{h\nu} \tag{12}$$

or

$$\text{Area-normalized quantum detectivity} = \frac{A^{1/2}}{\text{NEQ}} = \left(\frac{\eta}{2\bar{N}_B}\right)^{1/2} \tag{13}$$

For the general case of a detector with area A seeing 2π sr of blackbody background at temperature T, $(\Delta N)^2$ is that in Eq. (4)

$$\overline{(\delta n)^2} = 2A\Delta f \int_0^\infty \eta(\nu)(\Delta N)^2 d\nu = 4\pi A\Delta f \int_0^\infty \eta(\nu)\nu^2 \frac{e^{h\nu/KT}}{(e^{h\nu/kT}-1)^2} d\nu \tag{14}$$

Then for $\Delta f = 1$ Hz,

$$\text{NEP} = \frac{h\nu}{c\eta}\left[4\pi A\int_0^\infty \eta(\nu)\frac{\nu^2 e^{h\nu/kT}}{(e^{h\nu/kT}-1)} d\nu\right]^{1/2} \tag{15}$$

or

$$D^*(T,\lambda) = \frac{c\eta}{2\pi^{1/2}h\nu}\left[\int_0^\infty \eta(\nu)\nu^2 \frac{e^{h\nu/kT}}{(e^{h\nu/kT}-1)^2} - d\nu\right]^{-1/2} \tag{16}$$

Assuming $\eta(\nu)$ is independent of frequency but falls back to zero for $\nu < \nu_c$

$$D^*(T,\lambda) = \frac{c\eta^{1/2}}{2\pi^{1/2}h\nu}\left[\int_0^\infty \nu^2 \frac{e^{h\nu/kT}}{(e^{h\nu/kT}-1)^2} - d\nu\right]^{-1/2} \tag{17}$$

Figure 13 shows photon-noise-limited D^* versus cutoff wavelength λ_c for various thermal-background temperatures.[13] Note that these curves are not independent. $D^*(T, \lambda_c)$ is related to $D^*(T, \lambda'_c)$ by the formula

$$D^*(T,\lambda_c) = \left(\frac{T'}{T}\right)^{5/2} D^*(T,\lambda'_c) \qquad \text{where } \lambda'_c = \frac{T}{T'}\lambda_c \tag{18}$$

This relation is useful for determining values of $D^*(T, \lambda_c)$, which do not appear in Fig. 13, in terms of a value of $D^*(T', \lambda'_c)$, which does appear. For example, to find D^*(1000 K, 4 μm) from the 500-K curve

$$D^*(1000,4) = \left(\frac{500}{1000}\right)^{5/2} D^*\left(500, 4\times\frac{1000}{500}\right) = 2.3\times10^9 \text{ Jones} \tag{19}$$

If higher accuracy is desired than can be determined from Fig. 13, one can use the preceding formula in combination with Table 1, which gives explicit values of $D^*(\lambda_c)$ versus λ_c for $T = 295$ K.

The effect on D^* of using a narrow bandwidth detection system is illustrated in Fig. 14. Such a system may be configured with a cold narrow bandwidth filter, or with a narrow bandwidth amplifier—in order to limit the background flux noise or the electrical bandwidth noise, respectively. Q refers to the factor of the reduction provided.

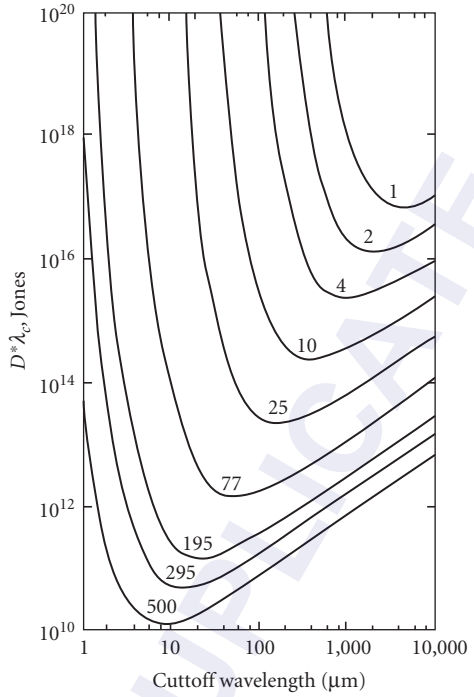

FIGURE 13 Photon-noise-limited D^* at peak wavelength—assumed to be cut-off wavelength—for background temperatures 1, 2, 4, 10, 25, 77, 195, 295, and 500 K (assumes 2π FOV and $\eta = 1$). (*Reprinted from Ref. 13.*)

TABLE 1 D^* versus λ_c for $T = 295$ K

λ_c, μm	$D^*(\lambda_c)$	λ_c, μm	$D^*(\lambda_c)$	λ_c, μm	$D^*(\lambda_c)$	λ_c, μm	$D^*(\lambda_c)$

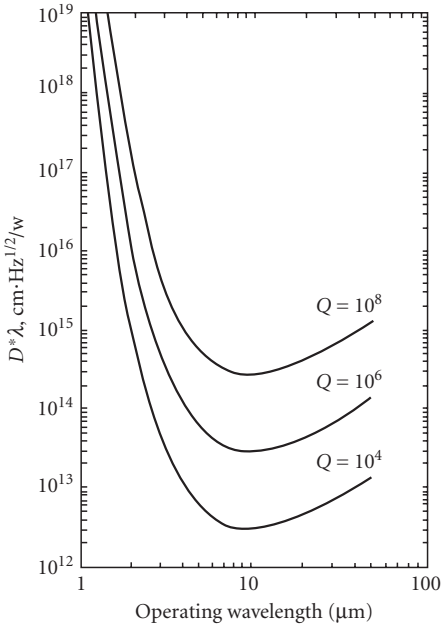

FIGURE 14 Photon noise limit of a narrow-band quantum counter as a function of operating wavelength for a 290-K background, 2π FOV, and $\eta = 1$. (*From Ref. 14.*)

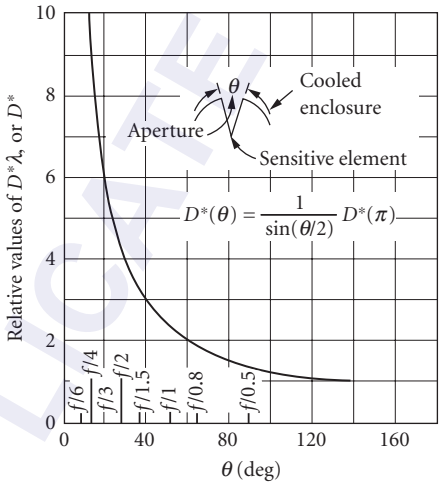

FIGURE 15 Relative increase in photon-noise-limited $D^*(\lambda_{pk})$ or D^* achieved by using a cooled aperture in front of lambertian detector. (*From Ref. 14.*)

Figure 15 shows the relative increase in photon-noise-limited D^* achievable by limiting the FOV through use of a cooled aperture.

The photon-noise-limited sensitivity shown in Fig. 13 and Table 1 apply to photovoltaic and photoemissive detectors. Figure 14 is for photoconductors. For photoconductors, recombination noise results in a $\sqrt{2}$ reduction in D^* at all wavelengths.

Thermal Detectors Limiting sensitivity of an ideal thermal detector has been discussed previously.[12,14,15] Assuming no shortwave- or long-wavelength cutoffs exist,

$$D^* = \frac{\varepsilon}{[8\varepsilon\sigma k(T_1^5 + T_2^5)]^{1/2}} = \frac{4\times10^{16}\,\varepsilon^{1/2}}{(T_1^5 \times T_2^5)^{1/2}} \text{ Jones} \tag{20}$$

where T_1 = detector temperature
T_2 = background temperature
ε = detector emissivity
σ = Stefan-Boltzmann constant
k = Boltzmann constant

D^* versus T_2 is plotted for various T_1 in Fig. 16. Figure 17 shows the effect of both short- and long-wavelength cutoffs on bolometer sensitivity,[16] with the ideal photoconductor curve for reference. D^* can be seen to increase rapidly when the cutoff is set to avoid the high flux density from the 300-K background that peaks around 10 μm.

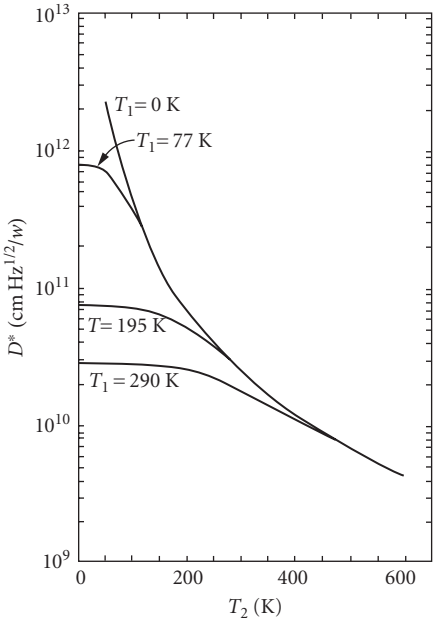

FIGURE 16 Photon-noise-limited D^* for thermal detectors as a function of detector temperature T_1 and background temperature T_2 (2π FOV: $\eta = 1$). (*From Ref. 14.*)

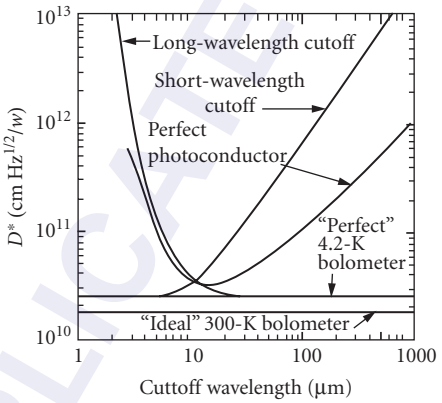

FIGURE 17 The detectivity of a "perfect" bolometer plotted as a function of both short- and long-wavelength cutoffs. Plots for a perfect photoconductor and two other cases are included for comparison. The background temperature is 300 K. (*From Ref. 16.*)

24.6 OTHER PERFORMANCE PARAMETERS

Spectral Response

Spectral response provides key information regarding how the detector will respond as a function of wavelength or photon energy. Spectral response may be limited by the intrinsic detector material properties, a coating on the detector, or by a window through which the radiation must pass. Relative response is the spectral response ratioed against a detector with a nominally wavelength independent response, such as a thermocouple having a spectrally-broad black coating. Relative response is plotted as a function of wavelength with either a vertical scale of W^{-1} or photon^{-1}. Thermal detectors tend to be spectrally flat in the first case while quantum detectors are generally flat in the second case. The curves are typically shown with the peak value of the spectral response normalized to a value of 1. The spectral response curve can be used together with the blackbody D^* to calculate D^* as a function of wavelength, which is shown in Fig. 18 for selected detectors.

Responsivity and Quantum Efficiency

Responsivity and quantum efficiency are important figures of merit relating to the detector signal output. Responsivity is a measure of the transfer function between the input signal photon power or flux and the detector electrical signal output. Thermal detectors will typically give this responsivity in volts/watt. Photoconductors will usually quote the same units, but will also frequently reference the value to the peak value of relative response per watt from the spectral response curve. This value

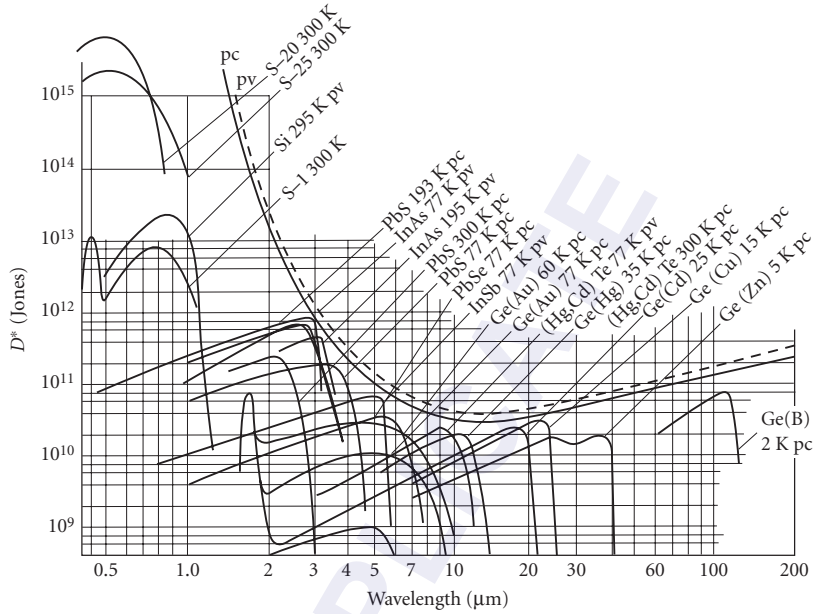

FIGURE 18 D^* versus λ for selected detectors.

is actually realized if the detector bias circuit load resistor is significantly larger than the detector resistance. Photoconductor responsivity is given by:

$$\text{Responsivity}_{\text{peak}} = \frac{\eta \mathbf{q} \mathbf{R}_d \mathbf{E} \tau (\mu_n + \mu_p)}{h\nu\ell} \tag{21}$$

where η is the quantum efficiency, $\mathbf{q}$ is the electronic charge, $\mathbf{R}_d$ is the detector resistance, $\mathbf{E}$ is the electric field, τ is time constant, μ are the mobilities for electrons (n) and holes (p), $h\nu$ is the photon energy, and ℓ is the device length. Photomultiplier tubes and photovoltaic detectors will usually reference the responsivity in amperes per watt, again referenced to peak spectral response.

Detector response performance is also conveyed from the detector quantum efficiency. In the case of photovoltaic detectors which, in the absence of avalanche operation have a gain of unity, quantum efficiency is essentially the current per photon. For a blip photovoltaic detector, the quantum efficiency also determines the D^*. Quantum efficiency is not readily measured for photoconductors and photomultiplier tubes unless the internal gain is carefully calibrated. It is sometimes inferred from the measured D^* for photoconductive devices which are blip—see definition of detective quantum efficiency.

Noise, Impedance, Dark and Leakage Current

Noise has a number of potential origins. Background photon flux–limited detectors have noise dominated by the square root of the number of background photons striking the detector per second [see Eq. (9)]. Other noise sources may contribute or dominate. Among these are

- Johnson, Nyquist, or thermal noise which is defined by the detector temperature and impedance
- Modulation or $1/f$ noise which may dominate at lower frequencies
- Amplifier noise
- Shot noise from dark or leakage current

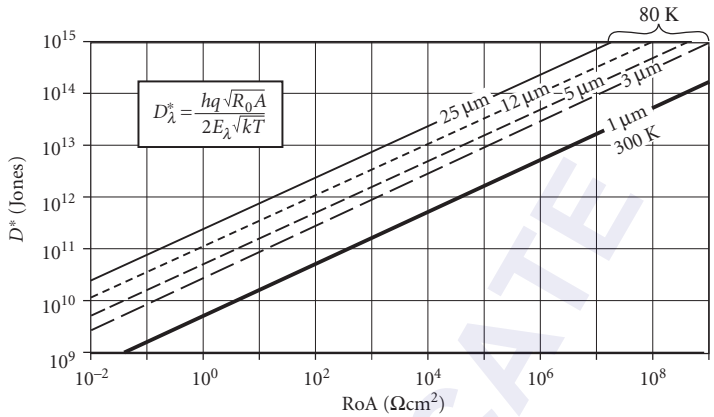

FIGURE 19 Zero-bias impedance-area product (R_0A or shunt resistance per unit area) of a photodiode can limit the D^* as shown. The limiting D^* depends on R_0A, temperature, and photon energy or wavelength. Examples are illustrated for a 1-μm cutoff diode at 300 K, and for 3-, 5-, 12-, and 25-μm cutoff devices at 80 K. Other noise mechanisms, such as photon noise, typically limit D^* to lower values than the highest values shown here.

The impedance of a photodiode may limit performance, depending upon the detector operating conditions. Figure 19 illustrates the diode impedance per unit area (R_0A) limiting value of D^* for silicon detectors at room temperature and longer-wavelength infrared photodiodes at 80 K.

Measurement of the noise as a function of frequency can be valuable for characterizing the relevant noise sources. Selection of an appropriate preamplifier is also critical, particularly for detectors having very low or very high impedance. Integration of preamplifiers together with detectors has significantly improved the overall performance of many detectors. The use of phase-sensitive lock-in amplifiers in combination with a modulated signal can also improve the signal-to-noise ratio.

Uniformity

One cannot assume that the response of a detector will be uniform across its sensitive area. Material inhomogeneity and defects and/or fabrication variables can give rise to nonuniformity. Lateral collection from near the perimeter of a photodiode may give a gradual response decrease away from the edge—this effect will typically be accompanied by a change in response speed as well. Recombination at the electrical contacts to a photoconductor can limit the lifetime, and hence the photoconductive gain, for carriers generated near the contact, a phenomenon called sweep-out. Recombination may be enhanced at surfaces and edges also. Laser spot scanning is useful to check the detector spatial uniformity, although laser sources may not be readily available at all the wavelengths of interest. An alternative method is to move the detector around under a fixed small aperture in conjunction with a light source.

Speed

Detector response speed is often related inversely to detector sensitivity. Thermal detectors often show this characteristic because the signal is proportional to the inverse of response speed, while the noise is amplifier or Johnson limited. Excluding detectors with internal carrier multiplication mechanisms, the best detectors from broad experience seem limited to a D^*f^* product of a few times 10^{17} Jones Hz. D^*f^* may be proportionally higher for devices with gain, since speed can be increased to a greater extent by using a lower value of load resistance without becoming Johnson-noise-limited. The user should be aware that with many detectors it is possible to operate them in a circuit to maximize

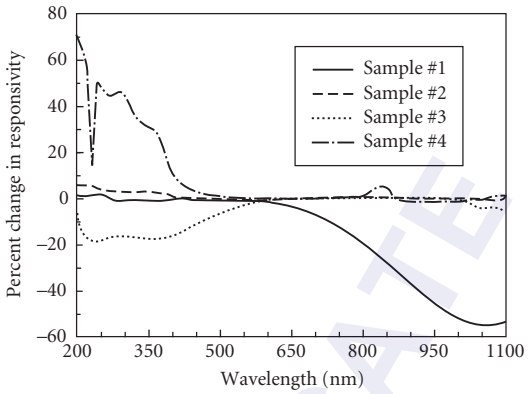

FIGURE 20 After only 3 hours of UV irradiation, these silicon detectors showed great variations in responsivity. (*Reprinted from the September 1993 issue of Photonics Spectra, © Laurin Publishing Co., Inc.*)

sensitivity or speed, but not both at the same time. Speed may vary across the sensitive area of the detector and with temperature, wavelength, and electrical bias.

Stability

Detector performance may change or drift with time. Changes in operating temperature, humidity, and exposure to elevated temperatures as well as to visible, ultraviolet, and high-energy radiation can affect device operation. These effects arise from the temperature dependence of electronic properties in solids, as well as from the critical role played by electrical charge conditions near the surface of many device types. Sensitivity changes in a sample of silicon detectors from four vendors illustrate this point. Wide variations in responsivity change after UV exposure, as shown in Fig. 20. In applications where stability is of significant concern, these effects must be carefully reviewed along with the detector supplier's experience in these matters.

24.7 DETECTOR PERFORMANCE

Manufacturers' Specifications

Table 2 lists the detector materials covered in Sec. 24.7.

TABLE 2 Detector Materials Covered in Sec. 24.7

Thermocouple	GaAsP	Ge:Au
Thermopile	CdS, CdSe	HgCdTe
Thermistor bolometer	CdTe	PbSnTe
Pyroelectric	GaAs	Ge:Hg
InSb hot electron bolometer	Si	Si:Ga
Ge:Ga bolometer	InGaAs	Si:B
Photoemissive	Ge	Ge:Cu
GaN, InGaN	PbS	Ge:Zn
SiC	InAs	Ge:Ga
TiO_2	PbSe	Photographic
GaP	InSb	

Detector sensitivity can be the determining factor in the design and performance of a sensor system. Detector performance is subject to the development of improved materials, fabrication techniques, and the ingenuity of device engineers and inventors. The descriptions given here may improve with time, and consultation with manufacturers and users is recommended. Today, the internet can be the quickest and most up-to-date source of currently available manufacturers and specifications for the devices they offer. Many suppliers noted in this section may have gone out of business—a search on the internet is the best choice for finding active vendors. Other than a general Web search, some collections of device suppliers can be found at

http://www.photonics.com/bgHome.aspx

http://laserfocusworld.365media.com/laserfocusworld/search.asp

http://www.physicstoday.org/ptbg/search.jsp

Thermocouple The thermocouple offers broad uniform spectral response, a high degree of stability, and moderate sensitivity. Its slow response and relative fragility have limited its use to laboratory instruments, such as spectrometers.

Compared with thermistors, thermocouples are slower, require no bias, and have higher stability but much lower impedance and responsivity. This increases the amplification required for the thermocouple; however, the only voltage appearing is the signal voltage, so that the serious thermistor problem of bridge-circuit bias fluctuations is avoided. With proper design, performance should not be amplifier-limited but limited instead by the Johnson noise of the thermocouple. Thermocouples perform stably in dc operation, although the instability of dc amplifiers usually favors ac operation.

The inherent dc stability of thermocouples is attractive for applications requiring no moving parts, and recently a relatively rugged solid-backed evaporated thermocouple has been developed whose sensitivity approaches that of the thermistor bolometer.

Sensitivity: D^* 1×10^9 Jones for 20-ms response time; spectral response depends on black coating (usually gold black) (see Fig. 21)

Noise: White Johnson noise, falling off with responsivity (see Fig. 22)

Resistance: 5 to 15 Ω typical

Responsivity: 5 V/W (typical), 20 to 25 V/W (selected)

Time constant: 10 to 20 ms (typical)

Operating temperature: Normally ambient

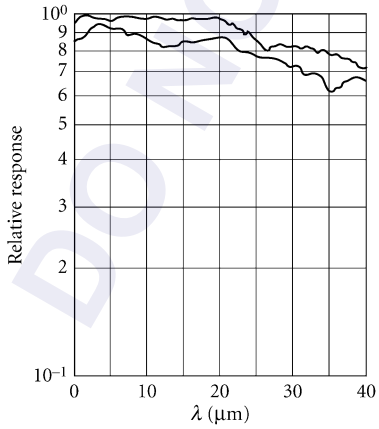

FIGURE 21 Typical thermocouple spectral response curves (CsI window) for two different manufactures.

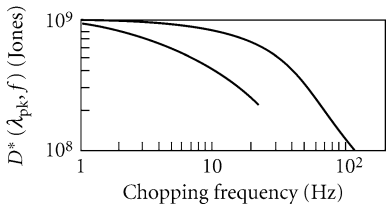

FIGURE 22 Typical thermocouple D^* (noise) frequency response for two manufacturers. (*From Ref. 1.*)

Sensitive area: 0.1 × 1 to 0.3 × 3 or 0.6 × 2 mm (typical)

Linearity: 0.1 percent in region investigated (6×10^{10} to 6×10^{8} W incident)

Recommended circuit: Transformer coupled into low-noise (bipolar or JFET) amplifier with good low-frequency noise characteristics

Manufacturers: Perkin-Elmer, Charles Reeder, Beckman Instruments, Farrand, Eppley Laboratory

Thermopile Thermopiles are made by evaporating an array of metal junctions, such as chromel-constantan or manganin-constantan, onto a substrate. The thin-film construction is rugged, but the Coblentz-type may be quite delicate. Wire-wound thermopile arrays are also available which are very robust. Devices with arrays of semiconductor silicon junctions are also available. The array may typically be round, square, or rectangular (for matching a spectrometer slit) and consist of 10 to 100 junctions. Configuration options include matched pairs of junction arrays or compensated arrays to provide an unilluminated reference element. A black coating, such as 3M black or lampblack, is used to provide high absorption over a broad spectral range, as illustrated in Figs. 23 and 24. The housing window may limit the spectral range of sensitivity. Typical applications include power meters and radiometers.

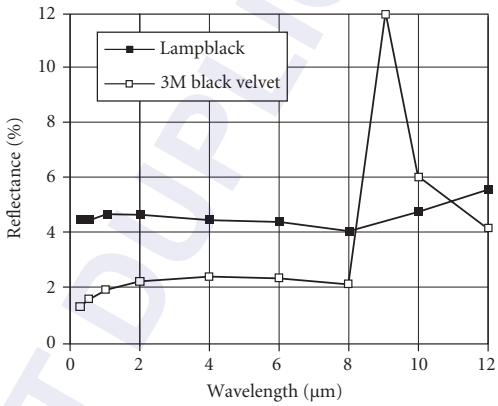

FIGURE 23 Spectral reflectance of two black coatings used in the construction of thermopile detectors. (*From Eppley Laboratory studies.*)

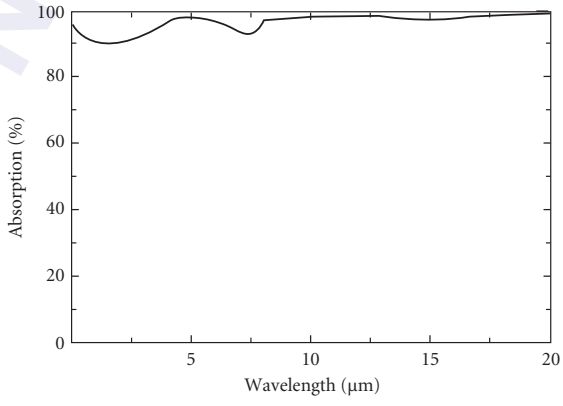

FIGURE 24 Spectral absorption of a thermopile detector coating made from a black metal oxide. (*Oriel Corporation.*)

Sensitivity: D^* 0.5 to 4×10^8 Jones for 30-ms typical response time. D^* may be dependent upon sensitive area; spectral response depends on black coating and window (see Fig. 23 and Fig. 24)

Noise: White Johnson noise, falling off with responsivity, typical range is 5 to 30 $nV/Hz^{1/2}$

Resistance: 2Ω to 60 kΩ typical

Responsivity: 4 to 250 V/W (typical) depends on the number of junctions and time constant

Time constant: 10 ms to 2 s (typical)

Operating temperature: Normally ambient

Sensitive area: 0.5 to 6-mm diameter, 0.025×0.025 to 3×3 mm, various rectangular, 0.4×3, 0.6×2, 0.6×4 mm (typical)

Recommended circuit: Low noise (0.5 $V_{p\text{-}p}$, dc to 1 Hz), low drift with voltage gain of 1000 and input impedance of 1 MΩ

Manufacturers: Armtech, Beckman Instruments, Concept Engineering, Dexter Re search Center, Edinburgh Instruments, Eppley Laboratory, Farrand, Gentech, Molectron Detector, Ophir Optronics, Oriel, Scientech, Scitec, Swan Associates

Thermistor Bolometer Thermistors offer reliability, moderate sensitivity, and broad spectral coverage without cooling. Construction is rugged and highly resistant to vibration, shock, and other extreme environments. Response is slower than 1 ms, and trade-off exists between speed and sensitivity.

Thermistor elements are made of polycrystalline Mn, Ni, and Co oxides. In their final form they are semiconductor flakes 10 μm thick, which undergo a temperature resistance change of ~4 percent per Kelvin. Since thermistor resistance changes with ambient temperature enough to alter the biasing significantly, it is usually operated in a bridge circuit, with a nearly identical thermistor shielded from signal radiation and used for a balance resistor.

Sensitivity:

$$\text{NEP} = 8.9 \times 10^{-10} \sqrt{\frac{A(\text{mm}^2)}{\tau_{\text{rms}}}} \text{ W}$$

$$D^* = 1.1 \times 10^9 \sqrt{\tau_{\text{rms}}} \text{ Jones}$$

Spectral response: Depends on coating (usually Zapon lacquer); see Fig. 25.

Quantum efficiency: Depends on blackening coating, typically 80 percent.

Noise: Thermal-noise-limited above 20 Hz ($V_{\text{noise}} = \sqrt{4kTR\Delta f}$); below that, $1/f$ type noise—see Fig. 26. Used in balanced-bridge circuit (two flakes in parallel); limiting noise due to thermal noise in both flakes.

Resistance: For standard 10-μm-thick flakes, two different resistivities are available: 2.5 MΩ/sq or 250 kΩ/sq. Note that in a bolometer bridge, the resistance between the output connection and ground is half that of single flake.

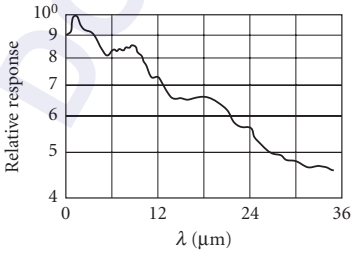

FIGURE 25 Typical thermistor spectral response (no window).

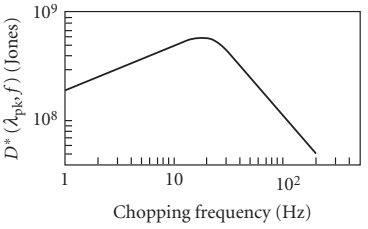

FIGURE 26 Typical thermistor D^* (noise) frequency spectrum. (*From Ref. 1.*)

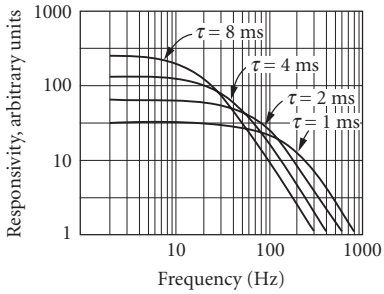

FIGURE 27 Relative response vs. frequency for various time-constant thermistor detectors ($A = 1 \times 1$ mm). (*From Barnes Engineering, Bull. 2–100.*)

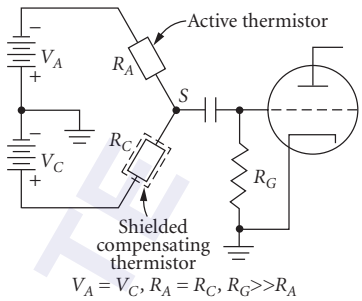

FIGURE 28 Bolometer electrical circuit. (*From Barnes Engineering, Bull. 2–100.*)

Time constant: τ is 1- to 20-ms standard for nonimmersed detectors and 2- to 10-ms standard for immersed detectors.

Sensitive area: 0.1×0.1 mm, 5×5 mm standard.

Operating temperature: Normally ambient, 285–370 K.

Responsivity: Depends on bias, resistance, area, and time constant $\mathcal{R} \propto \sqrt{R\tau/A} \approx 10^3$ V/W for 0.1×0.1 mm area, 250 kΩ resistance, and $\tau = 4$ ms (see Fig. 27 for frequency-time-constant dependence with given area). Output voltage (responsivity) can be increased to a limited degree by raising bias voltage. Figure 29 shows the deviation from Ohm's law due to heating. Bias should be held below 60 percent of peak voltage. Listed responsivity is that of active flake. In the bridge circuit, responsivity is half this value.

Sensitivity profile: Approximately 10 percent for 10-μm scan diameter over a 1×1 mm cell.

Linearity: ±5 percent 10^{-6} to 10^{-1} W/cm^2.

Recommended circuit: See Figs. 28 and 29.

Manufacturers: Servo Corporation of America, Thermometrics.

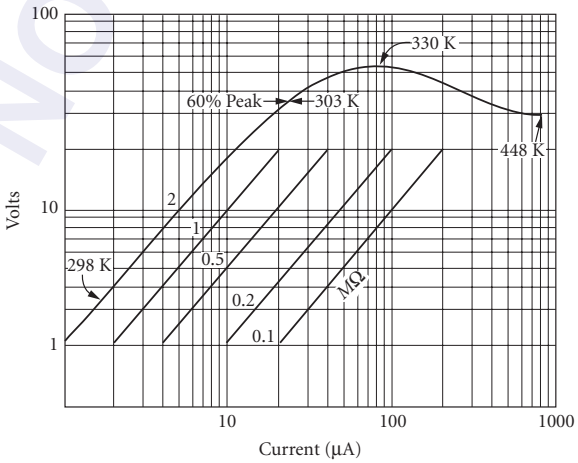

FIGURE 29 Thermistor voltage-current characteristics, showing typical flake temperatures under different conditions. (*From Barnes Engineering, Bull. 2–100.*)

Pyroelectric Lithium tantalate ($LiTaO_3$), triglycine sulfate (TGS), and other pyroelectric materials provide an uncooled thermal detector with good sensitivity. The devices are capable of fast response, limited inversely by the preamplifier feedback resistance, but with responsivity and D^* traded for speed. This detector's, principle of operation is the pyroelectric effect, which is the change of electric polarization with temperature. Pyroelectric detectors offer rugged construction and the absence of $1/f$ noise because no bias is involved.

Lack of $1/f$ noise, combined with the ability to easily trade off speed and sensitivity, makes pyroelectric detectors useful for scanning applications and energy measurement of pulsed optical sources. In addition, the NEP is independent of area at low frequencies (10 Hz), so that these detectors are useful for large-area applications (preamplifier $1/f$ noise may limit, however). Pyroelectric detectors are useful for calorimetry since the pyroelectric effect is an integrated volume effect and the output signal is unaffected by spatial or temporal distribution of the radiation, up to damage threshold or depolarizing temperature. For higher damage thresholds, lead zirconate titanate ceramic (Clevite PZT-5) exhibits a much smaller pyroelectric effect than TGS, but its high Curie temperature of 638 K makes it more useful than TGS for high-energy applications.

Sensitivity: Sensitive from ultraviolet to millimeter wavelengths. For $\lambda < 2$ μm, TGS must be blackened, which slows response. Normally ($\lambda > 2$ μm) a transparent electrode is used, since TGS absorption is high from 2 to 300 μm. Beyond 300 μm, poor absorption and increased reflectivity reduce sensitivity. Spectral response depends largely on coating. See Fig. 30 for spectral response with modified 3M black. Figure 31 illustrates the relative spectral response for a $LiTaO_3$ device.

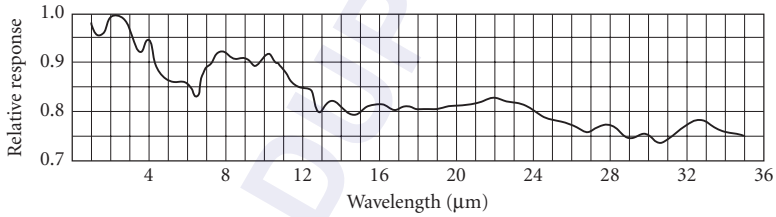

FIGURE 30 Relative spectral response of TGS detectors with modified 3M black. (*From Barnes Engineering, Bull. 2–100.*)

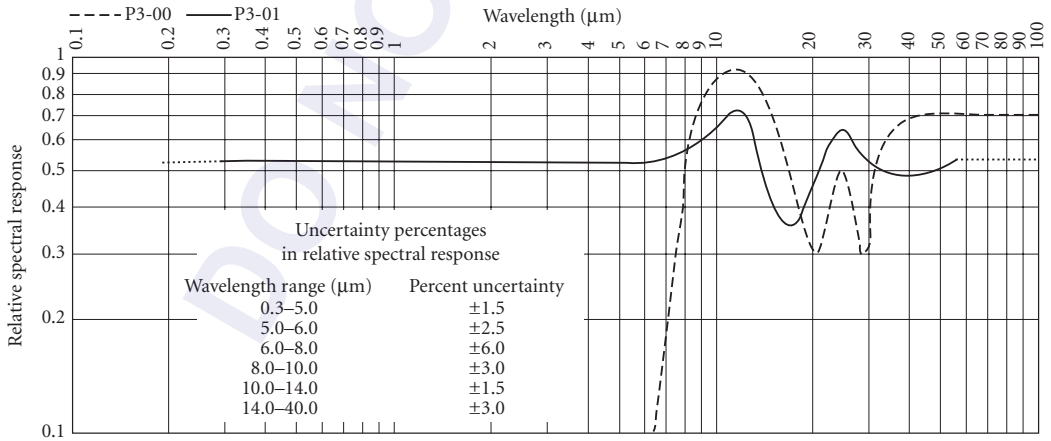

FIGURE 31 Relative spectral response of $LiTaO_3$, pyroelectric detectors showing both a black spectral coating and an optional coating tuned to the 8 to 14-μm LWIR band. (*From Molectron Detector, Inc.*)

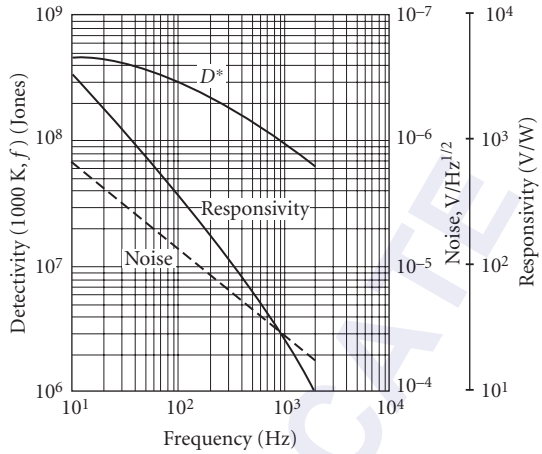

FIGURE 32 Typical D^*, responsivity, and noise versus frequency for TGS ($A = 1 \times 1$ mm; $T = 296$ K). (*From Barnes Engineering, Bull. 2–220A.*)

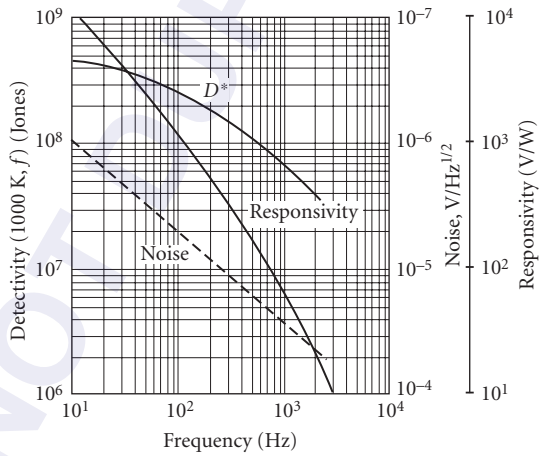

FIGURE 33 Typical D^*, responsivity, and noise versus frequency for TGS ($A = 1 \times 1$ mm; $T = 296$ K). (*From Barnes Engineering, Bull. 2–220A.*)

D^* is independent of A at low frequencies (10 Hz) (see Figs. 32 and 33). Figure 34 shows NEP versus A for various frequencies.

Quantum efficiency: Depends on coating absorptivity (for 3M black typically η >75 percent).

Noise: (See Figs. 32 and 33). Limited by loss-tangent noise up to frequencies that become limited by amplifier short-circuit noise (see Fig. 35).

Operating temperature: Ambient, up to 315 K. Can be repolarized if $T > T_{\text{curie}} = 322$ K for TGS. Irreversible damage at $T = 394$ K (see Fig. 36). Other pyroelectric materials have significantly higher Curie temperatures (398 to 883 K).

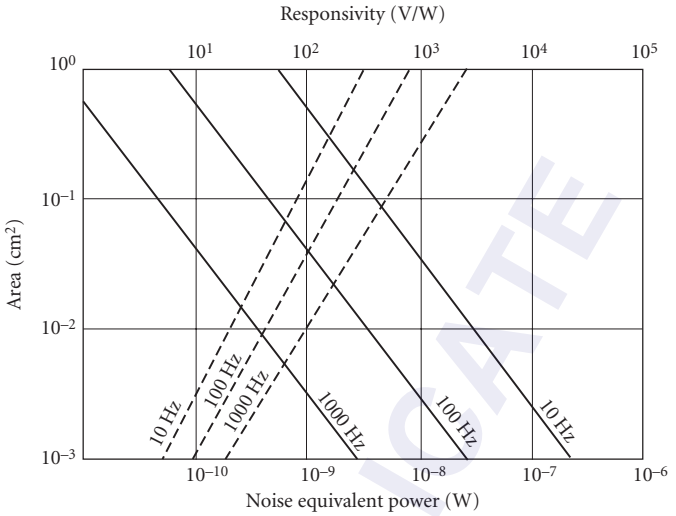

FIGURE 34 Noise equivalent power in watts (broken lines) and responsivity (solid lines) versus TGS detector area for various frequencies. (*From Barnes Engineering, Bull. 2–220B.*)

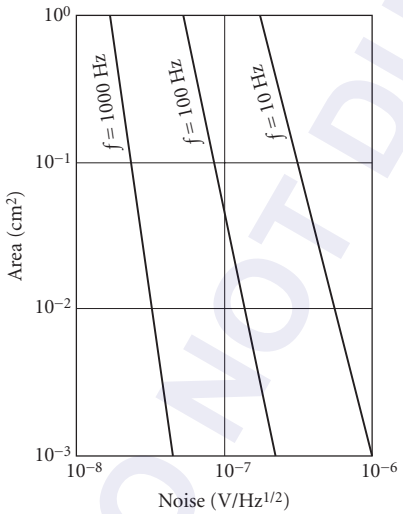

FIGURE 35 TGS noise versus detector area for various operating frequencies. (*From Barnes Engineering, Bull. 2–100.*)

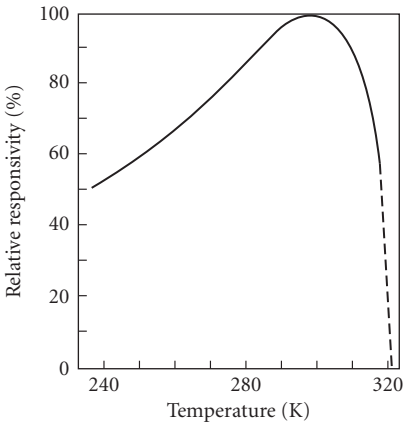

FIGURE 36 Relative responsivity versus temperature for TGS. (*From Barnes Engineering, Bull. 2–220B.*)

Output impedance: 50 Ω to 10 KΩ, set by built-in amplifier (see Fig. 37).

Responsivity: See Figs. 32 to 34, 36, and 38.

Capacitance: 5 pF for 0.5 × 0. 5 mm; 20 pF for 1 × 1 mm; 100 pF for 5 × 5 mm.

Sensitive area: 2 to 50-mm diameter round, 0.5 × 0. 5-mm to 10 × 10-mm square, typical.

Time constant: Not pertinent, response speed set by the preamplifier feedback resistor (see Fig. 38).

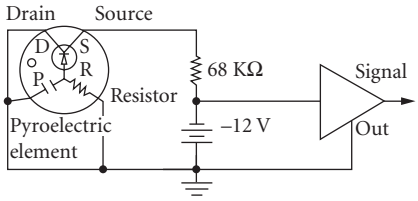

FIGURE 37 Pyroelectric detector amplifier circuit. (*From Barnes Engineering, Bull. 2–220A.*)

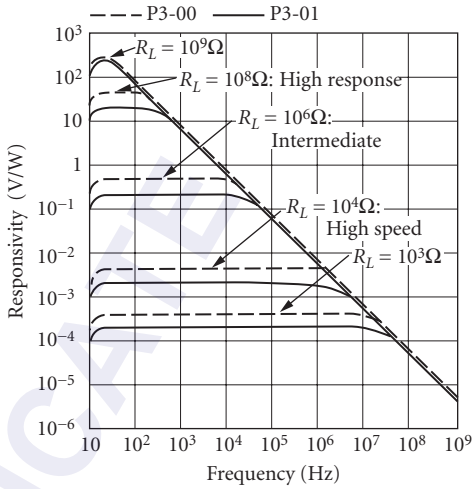

FIGURE 38 Responsivity vs. frequency for two pyroelectric models using various feedback resistors. (*From Molectron Detector, Inc.*)

Linearity: 5 percent between 10^{-6} and 10^{-1} W/cm^2.

Sensitivity profile: Depends on coating or transparent electrode; 5 to 7 percent across 12 × 12-mm; spot size < 250 μm.

Recommended circuit: See Figs. 37 and 39. Field effect transistor (FET) amplification stage usually built in. Since $\mathcal{R} \propto 1/f$, use of an amplifier with $1/f$ noise and gain $\propto f$ is recommended. Then output signal and signal-to-noise ratio are independent of frequency.

Manufacturers: Alrad Instruments, Belov Technology, CSK Optronics, Delta Developments, EG&G Heimann, Electro-Optical Systems, Eltec, Gentec, Graseby, International Light, Laser Precision, Molectron Detector, Oriel, Phillips Infrared Defence Components, Sensor-Physics, Servo Corporation of America, Spiricon, Thermometrics.

InSb Hot-Electron Bolometer At temperatures of liquid helium and lower, free carriers in indium antimonide (InSb) can absorb radiation in the far-infrared and submillimeter spectral region. Because the mobility of the electrons varies as $T_e^{3/2}$ under these conditions, the conductivity of the material is modulated. This mechanism offers submicrosecond response and broad far-infrared coverage out to millimeter wavelengths but requires liquid-helium cooling and very sophisticated receiver design.

Technically, these devices may be classed as bolometers, since incident radiation power produces a heating effect which causes a change in free-charge mobility. In the normal bolometer, the crystal lattice absorbs energy and transfers it to the free carriers via collisions. However, in InSb bolometers incident radiation power is absorbed directly by free carriers, the crystal lattice temperature remaining essentially constant. Hence the name electron bolometer. Note that this mechanism differs from photoconductivity in that free-electron mobility rather than electron number is altered by incident light (hence there is no photoconductive gain).

Sensitivity: $D^*(2\text{ mm}, 900) = 4 \times 10^{11}$ Jones (see Fig. 40).

Noise: See Figs. 41 and 42.

Responsivity: 1000 V/W.

Time constant: 250 ns.

Sensitive area: 5 × 5 mm typical.

Operating temperature: 1.5 to 4.2 K.

Impedance: Without bias, 200 Ω; optimum bias, 150 Ω, depends on bias (see Fig. 29).

Recommended circuit: Optimum bias 0.5 mA (see Fig. 43).

Manufacturer: Infrared Laboratories.

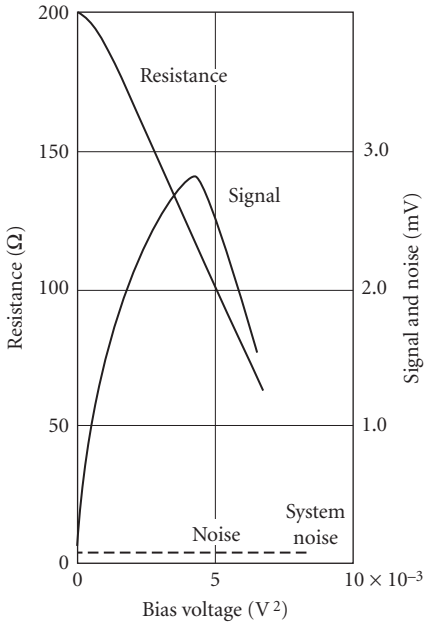

FIGURE 41 InSb electron bolometer, typical resistance, signal, and noise versus bias voltage squared ($T = 5$ K; $R_L = 200$ Ω; gain = 2.4×10^4; $F = 1100$ Hz). (*From Santa Barbara Research Center, Prelim. Res. Rep., 1967.*)

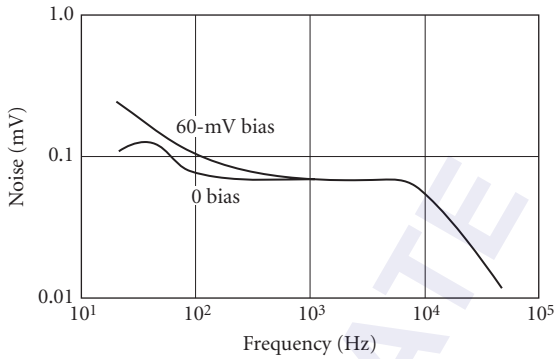

FIGURE 42 InSb electron bolometer, typical noise spectrum ($T = 5$ K; $R_L = 200\ \Omega$; gain $= 2.4 \times 10^4$; $\Delta f = 5.6$ Hz). (*From Santa Barbara Research Center, Prelim. Res. Rep., 1967.*)

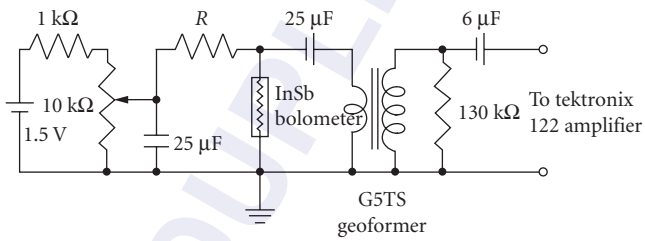

FIGURE 43 Electron bolometer biasing circuit. (*From Santa Barbara Research Center, Prelim. Res. Rep., 1967.*)

Ge(Ga) Low-temperature Bolometer The Ge(Ga) bolometer offers very high sensitivity and broad spectral coverage in the region 1.7 to 2000 μm. Liquid-helium cooling is required. A trade-off exists between response time (seconds) and sensitivity (10^{-14}-W NEP). Operation at 1000 Hz can be achieved still maintaining 2×10^{-13} W NEP.

Sensitivity: Depends on thermal conductance G (see Figs. 44 and 45). NEP(λ, 10 Hz) $= V_n/S = 3 \times 10^{-14}$ W for $G = 1$ μW/K; $A = 1$ mm^2, $D^*(\lambda, 10\text{ Hz}) = 3 \times 10^{13}$ Jones ($Q < 0.2$ μW). For this detector, NEP $\approx 4T\ (kG)^{1/2}$ and does not vary with $A^{1/2}$ (T is heat-sink temperature, and k is Boltzmann's constant). Thus D^* cannot be used as a valid means of comparison with other detectors; 300-K background-limited performance is achievable for 2π FOV when the bolometer is operated at 4.25 K with $G = 10^{-3}$ W/K. (For $A = 0.1$ cm^2, the time constant is 50 s.)

Responsivity: Typically, responsivity $= 2.5 \times 10^5$ V/W $= 0.7(R/TG)^{1/2}$, where R = resistance. Responsivity, and hence NEP, depends on thermal conductance G, which in turn is set by background power. G ranges from 0.4 to 1000 μW/K.

Thermal conductance: Typically $G = 1$ μW/K for background $Q < 0.2$ μW; note that $Q < 1/2$ (optimum bias power P).

Sensitive area: 0.25×0.25 to 10×10 mm.

Resistance: 0.5 MΩ.

Operating temperature: 2 K (see Fig. 44). In applications where radiation noise can be eliminated there is much to be gained by operating at the lowest possible temperature. Figure 45 shows the theoretical NEP and time constant at 0.5 K, assuming that current noise remains unimportant.

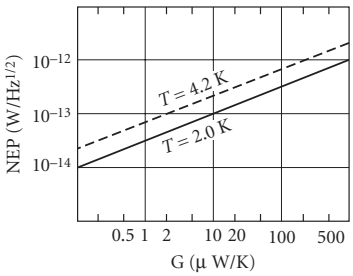

FIGURE 44 Germanium bolometer NEP versus conductance. (*Infrared Laboratories, Inc.*)

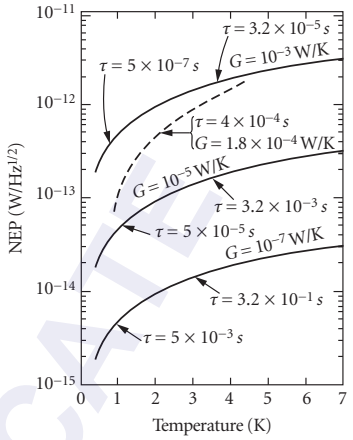

FIGURE 45 Germanium bolometer NEP versus temperature. Solid curves are theoretical: NEP ≈ 4T(kG)$^{1/2}$.(*From Ref. 17.*)

Quantum efficiency: Depends on blackened coating and window. For λ <100 μm, absorptivity exceeds 95 percent. For λ >100 μm, efficiency varies with geometry.

Time constant: Response time constant is proportional to G^{-1}. Therefore, if G must be increased to accommodate larger background, the time constant is decreased proportionally. Responsivity and NEP, however, are degraded as $G^{-1/2}$.

Noise: $V_n = 1 \times 10^{-8}$ V/Hz$^{1/2}$; thermal noise is due to R and R_L.

Recommended circuit: Standard photoconductive circuit, with load resistor, grid resistor, and blocking capacitor at low temperature (see Fig. 46). See Fig. 47 for typical electrical characteristics. Bias power $P = 0.1\ TG$.

Manufacturer: Infrared Laboratories, Inc.

Photoemissive Detectors Photoemissive detector is generally the detector of choice in the UV, visible, and near-IR where high quantum efficiency is available. In the spectral region $\lambda < 600$ nm, the photomultiplier, or multiplier phototube, has close to ideal sensitivity; that is, selected photomultiplier tubes (PMT) are capable of detecting single photon arrivals (but at best only with about 30 percent quantum efficiency) and amplifying the photocurrent (pulse) enormously without seriously degrading the signal-to-noise ratio. Time resolution can be as short as 0.1 ns. Only very specialized limitations have precluded their use for λ <800 nm, for example, cost, ruggedness, uniformity of manufacture, or need for still faster response. Recently these limitations have all been met individually but generally not collectively. Where adequate light is available, the simple phototube has advantages over the multiplier phototube in that high voltages are not required, the output level is not sensitive to applied voltage, and dynode fatigue is eliminated.

Microchannel plate tubes (MCPT) are a variant of the photomultiplier tube where the current amplifying dynode structure is replaced by an array of miniature tubes in which the photocathode current is amplified. MCP tubes are more compact than PMTs and are reliable in operating conditions of high environmental stress. The same range of photocathode materials is available in MCPTs as PMTs. MCPTs can provide a wide range of electron gain as available depending upon whether a single MCP or a stack of MCPs is used. The structure of a PMT and MCPT are compared in Fig. 48.

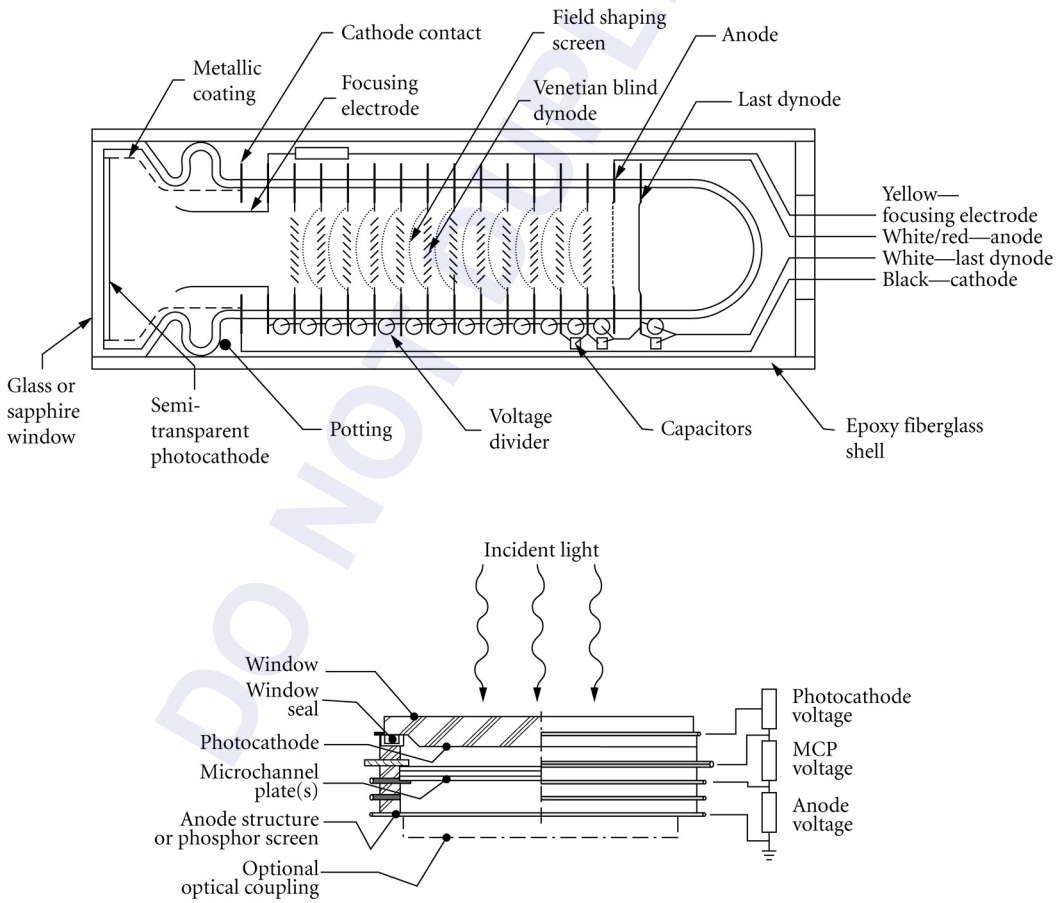

FIGURE 48 Comparison of photomultiplier tube (PMT) and microchannel plate tube (MCPT) construction. (*EMR Photoelectric.*)

Sensitivity In modern phototubes, shot noise due to the cathode dark current is by far the most important noise source. The most common descriptions of phototube sensitivity list both current responsivity (amperes per watt), dark current, and dark noise. Several useful measures of sensitivity are noise equivalent input (NEI) (see Sec. 24.4 "Definitions"), noise equivalent power (NEP), or its reciprocal $D \equiv 1/\text{NEP}$. NEP and NEI in the range 10^{-14} to 10^{-17} W/Hz$^{1/2}$ are not uncommon.

Detectivity is generally limited by dark-current shot noise. Dark current depends on photocathode material, area, and temperature. Thus the best detectivity is obtained with small effective sensitive area. Cooling is especially useful for red-sensitive and near-IR tubes and is generally not worthwhile for others (see "Operating temperature"). Special tube housings which can provide thermoelectric cooling are available.

The spectral response curves shown in Fig. 49 are for the combination of photocathode and window. Historically, this method of description gave rise to the S-response designations, most of which are now obsolete. It is often desirable to separate photocathode response from window transmission. Thus, Fig. 50 shows the quantum efficiency (electrons per incident photon) of a number of photocathodes without window losses. For $\lambda < 400$ nm, each photocathode should maintain its peak quantum efficiency, up to photon energies where multiple photoemissions take place. In Fig. 51, the spectral dependence of quantum efficiency for a variety of modern photocathode/window combinations is illustrated.

D^* is a meaningful figure of merit for phototubes whose sensitivity is limited by dark noise (shot noise on the dark current) and whose emitting photocathode area is clearly defined, but D^* must be used with caution because, although modern phototubes are generally dark-noise-limited devices, they are often limited by noise in signal, that is, the noise content of the signal itself.[18] Serious errors in predicting the detection capability of phototubes will arise if noise in signal is ignored and D^* is presumed to be the important limiting parameter [see Eqs. (6) to (8)]. Very little reliable data are presently available on D^* for photoemitters. However D^* curves for S-1, S-20, and S-25 are shown in Figs. 52 (300 K) and 53 (PMT cooled to 200 K).

Short-wavelength considerations Window considerations are as follows:

For $\lambda > 200$ nm: Windows are essential, as all useful photocathode materials are oxidized and performance would otherwise be destroyed.

200 nm $> \lambda >$ 105 nm: Photocathode materials are not oxidized by dry air (moisture degrades performance). Windows are optional. LiF windows have shortest known cutoff, 105 nm. For $\lambda <$180 nm, it is generally advisable to flush with dry nitrogen.

$\lambda <$105 nm: No windows are available.

Since air absorbs radiation in the region 0.2 to 200 nm (ozone absorbs 200 to 300 nm), it is necessary to include the (windowless) detector in a vacuum enclosure with the source.

A useful technique for avoiding the far-ultraviolet window-absorption problem (provided $\lambda >$ vacuum ultraviolet) is to coat the outside of the window of a conventional PMT with an efficient fluorescent material, for example, sodium salicylate, which absorbs in the ultraviolet and reemits in the blue, and is efficiently detected by most photocathodes.[9]

Solar-blind considerations are as follows—although most photocathodes have high quantum efficiency at short wavelengths, background-noise considerations often preclude their use at very short wavelengths, and very wide bandgap semiconductor photocathodes such as CsI, KBr, Cs_2Te, and Rb_2Te (having peak quantum efficiency a little greater than 10 percent) often give better signal-to-noise ratio. This sacrifice in quantum efficiency to obtain insensitivity to wavelengths greater than those of interest would not be necessary if suitable short-wavelength pass filters were readily available.

For applications where it is desirable that the detector not see much solar radiation, one can use photocathodes whose high work function precludes photoemission for photons of too low an energy. Figure 54 shows quantum efficiency versus λ for three such photocathodes, tungsten, CsI, and Cs_2Te, compared with Cs_3Sb and GaAs(Cs), which are not solar blind.

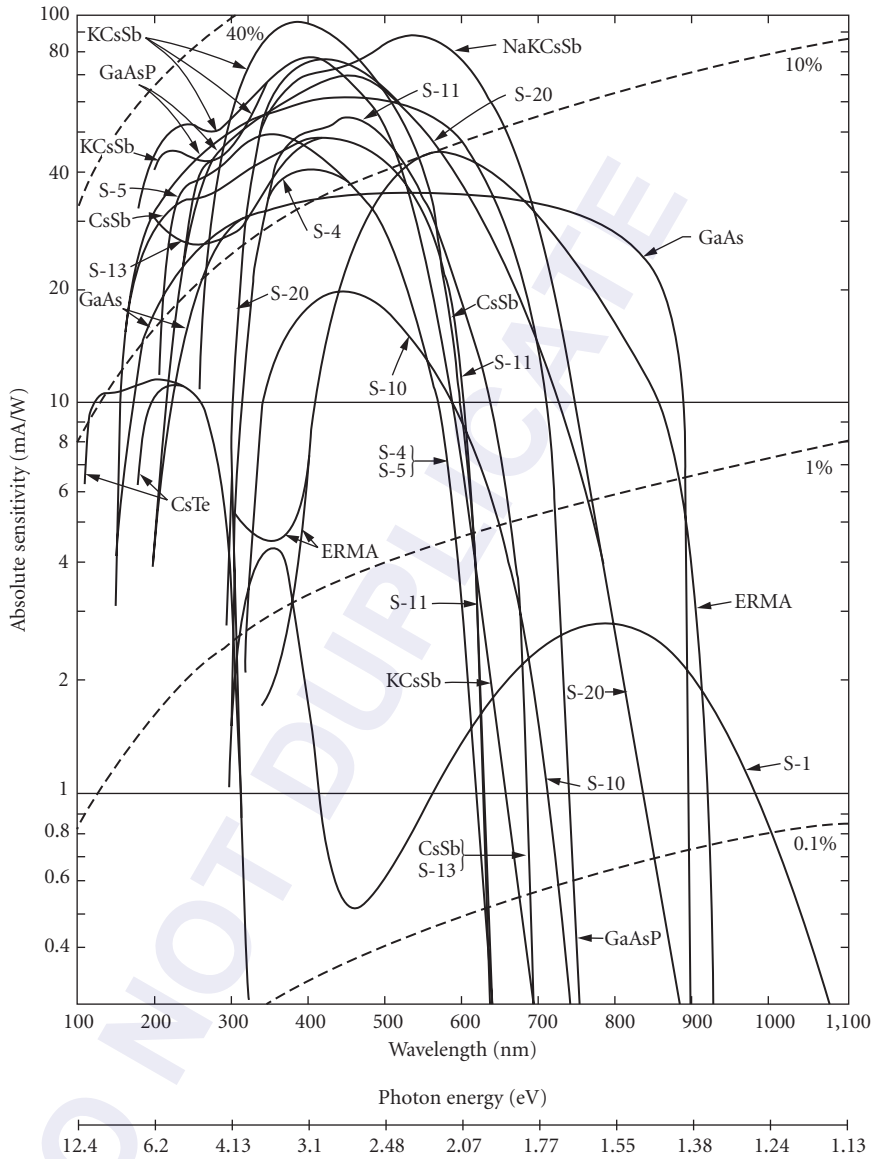

FIGURE 49 Spectral sensitivity of various photoemitters. Dotted lines indicate photocathode quantum efficiency. Chemical formulas are abbreviated to conserve space. S-1 = AgOCs with lime or borosilicate crown-glass window; S-4 = Cs_3Sb with lime or borosilicate crown-glass window (opaque photocathode); S-5 = Ss_3Sb with ultraviolet-transmitting glass window; S-8 = Cs_3Bi with lime or borosilicate crown-glass window; S-10 = AgBiOCs with lime or borosilicate crown-glass window; S-11 = Cs_3Sb with lime or borosilicate crown-glass window (semitransparent photocathode); S-13 = Cs_3Sb with fused-silica window (semitransparent photocathode); S-19 = Cs_3Sb with fused-silica window (opaque semicathode); S-20 = Na_2 KCsSb with lime or borosilicate glass window. ERMA = extended red multialkali (RCA; ITT uses MA for multialkali). This curve is representative of several manufacturers' products. Many variations of this response are available, for example, trade-offs between short- and long-wavelength response. (*From RCA Electronic Components, chart. PIT–701 B.*)

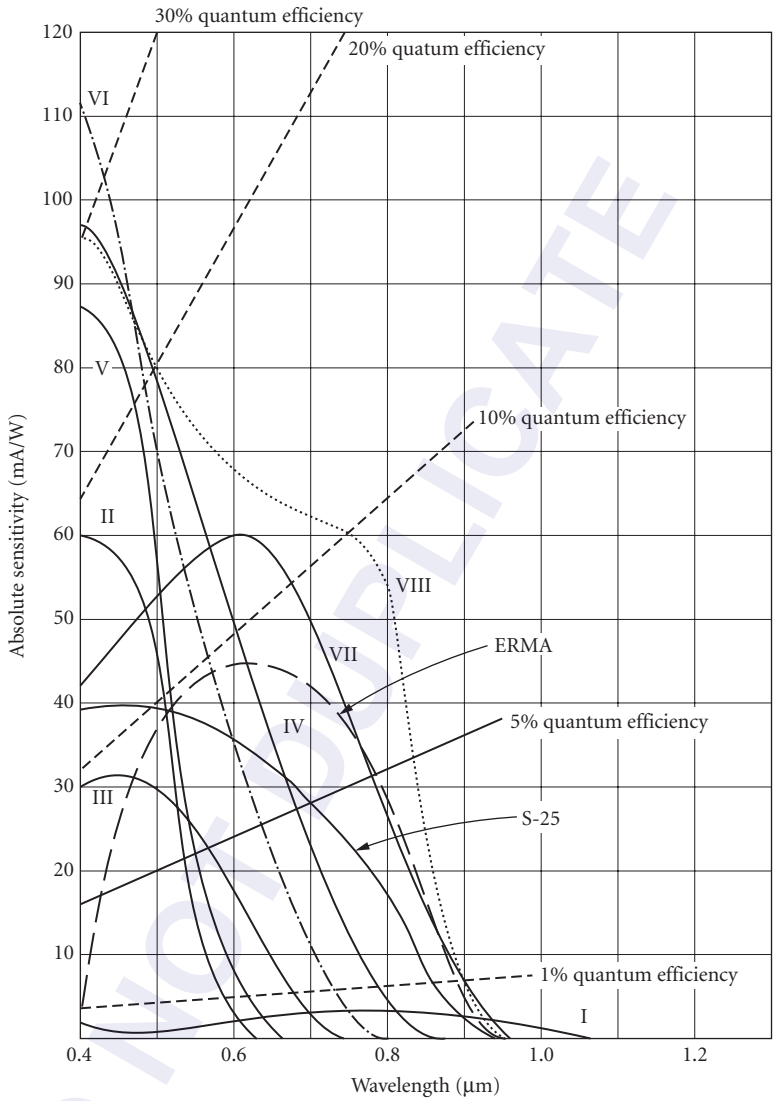

FIGURE 50 Photocathode responsivity and quantum efficiency versus wavelength (no windows). For abbreviations, see Fig. 49. I = S-1, II = S-11, III = S-10, IV = S-20, V = K_2CsSb, VI = $K_2CsSb(O)$, VII = $NaKCsSb_3$, VIII = GaAs(Cs). (*Based on material from RCA.*)

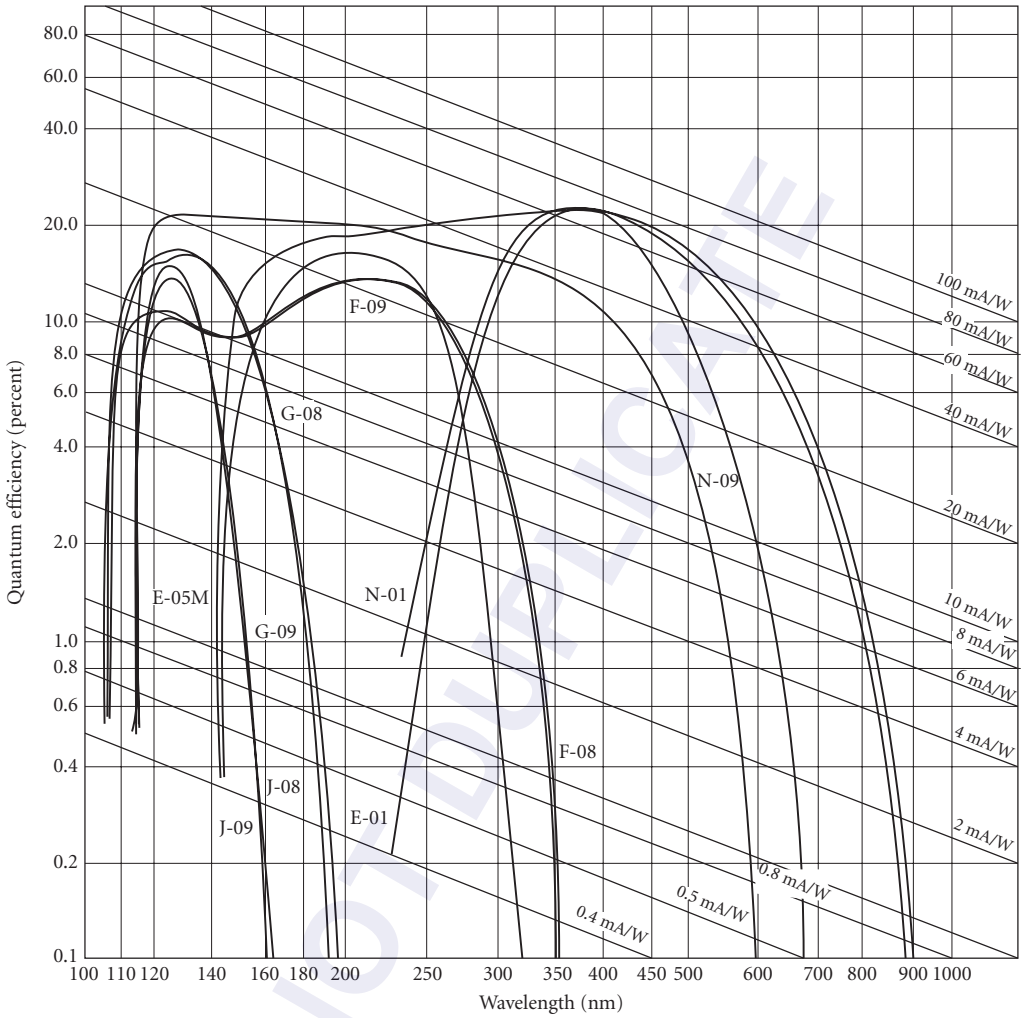
Quantum efficiency Figures 49, 50, 51, and 54 show photocathode spectral quantum efficiency (probability that one photoelectron is emitted when a single photon is incident). Note that there are fairly few basic photocathode materials and that the window often determines effective quantum efficiency at short wavelengths.

For $\lambda < 40$ nm, a wide variety of photocathode materials are available with high quantum efficiency. Many of these materials, such as tungsten, are not destroyed by being subjected to air, so that open structures can be used, consisting of a photocathode multiplier chain without window. The complete windowless structure is then placed in a vacuum enclosure with the source of radiation.



Photocathode key

Key letter	Description	Long-wavelength cutoff (Note 1)	Long-wavelength sensitivity (Note 2)
E	Tri-alkali (S-20)	850 nm	780 nm
F	Cesium telluride	355 nm	340 nm
G	Cesium iodide	195 nm	185 nm
J	Potassium bromide	165 nm	150 nm
N	High-temperature Bi-alkali	690 nm	640 nm
Q	Rubidium telluride	320 nm	300 nm

Note 1—Point at which QE becomes 1% (typical) of peak QE.
Note 2—Point at which QE is 1% (typical).

Window material key

Key no.	Description	Short-wavelength cutoff*
01	Borosilicate Glass	270 nm
05	UV Grade Sapphire	145 nm
08	UV Grade Lithium Fluoride	105 nm
09	Magnesium Fluoride	115 nm

*10% Energy transmission

FIGURE 51 Quantum efficiency of photocathode/window combinations as a funtion of wavelength. (*EMR Photoelectric*)

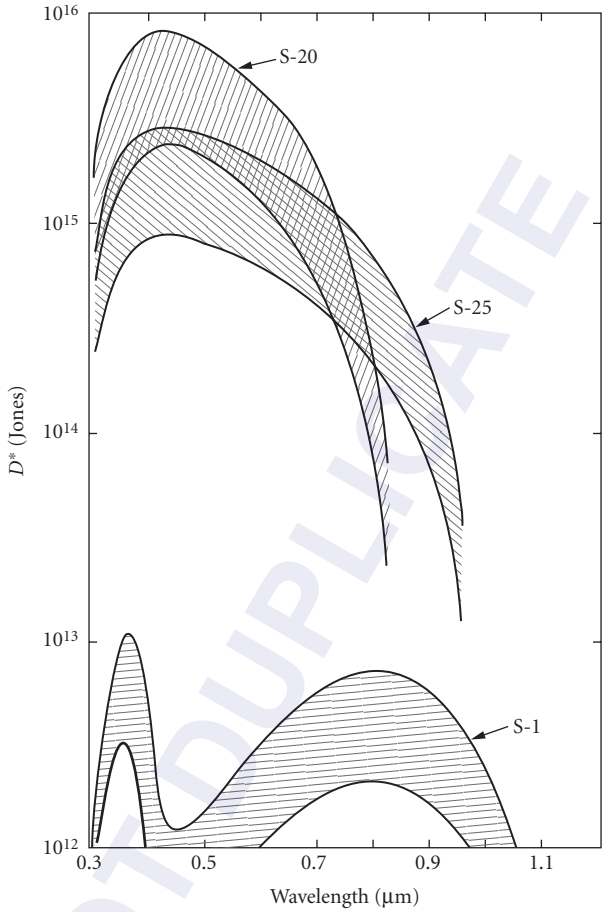


FIGURE 52 Range of D^* for uncooled photomultiplier tubes (T = 300 K). For abbreviations, see Fig. 49. S-25 = same as S-20 but different physical processing. (*Based on material from RCA*)

The quantum efficiency at any wavelength can be calculated from the formula

$$\eta = \frac{\mathcal{R} \times 1239.5}{\lambda} \tag{22}$$

where $\mathcal{R}$ = photocathode response, A/W, and λ = wavelength, nm.

A useful technique for improving quantum efficiency, reported by Livingston[19] and Gunter,[20] involves multipassing the photocathode by trapping the light inside the photocathode using a prism.

Responsivity PMT responsivity depends upon photocathode quantum efficiency and subsequent dynode gain. For most purposes, the dynode gain in a well-designed PMT introduces no significant degradation in the photocathode signal-to-noise ratio. Figure 49 shows photocathode response expressed in photocurrent (amperes) per incident radiation power (watts).

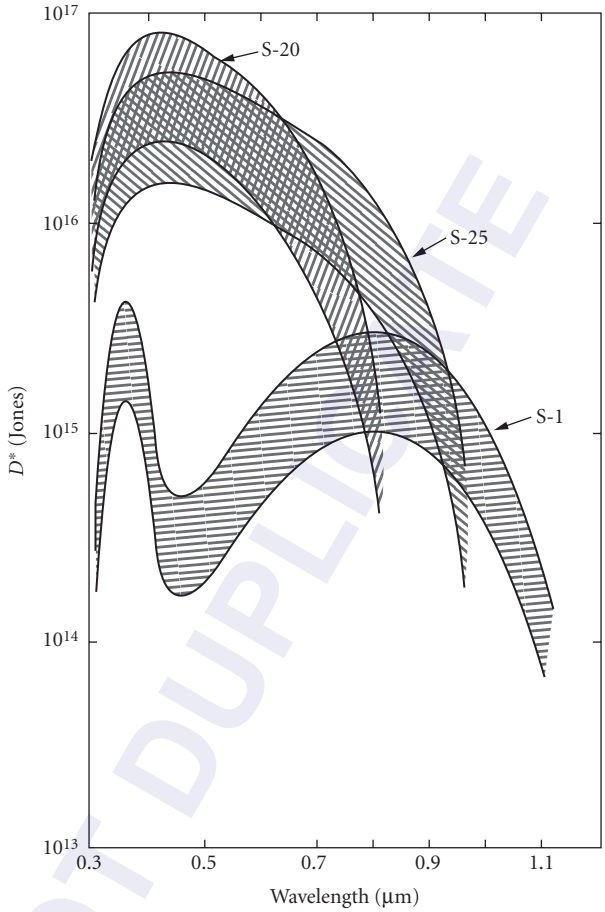

FIGURE 53 Range of D^* for uncooled photomultiplier tubes ($T = 300$ K). For abbreviations, see Fig. 49. S-25 = same as S-20 but different physical processing. Eberhardt, "D^* of Photomultiplier Tubes and Image Detectors", ITT Industrial Labs, 1969.*)

Noise The limiting noise in a PMT depends on the level of illumination. For low-level detection, limiting noise is the shot noise on the dark current,

$$i_n = (2ei_{\text{dark}}\Delta f)^{1/2} \tag{23}$$

For high illumination levels the shot noise on the signal photocurrent

$$i_n = (2ei_{\text{signal}}\Delta f)^{1/2} \tag{24}$$

far exceeds that on the dark current. Manufacturers usually express noise as photocathode dark current or anode dark current for given gain, which is therefore traceable to photocathode dark current.

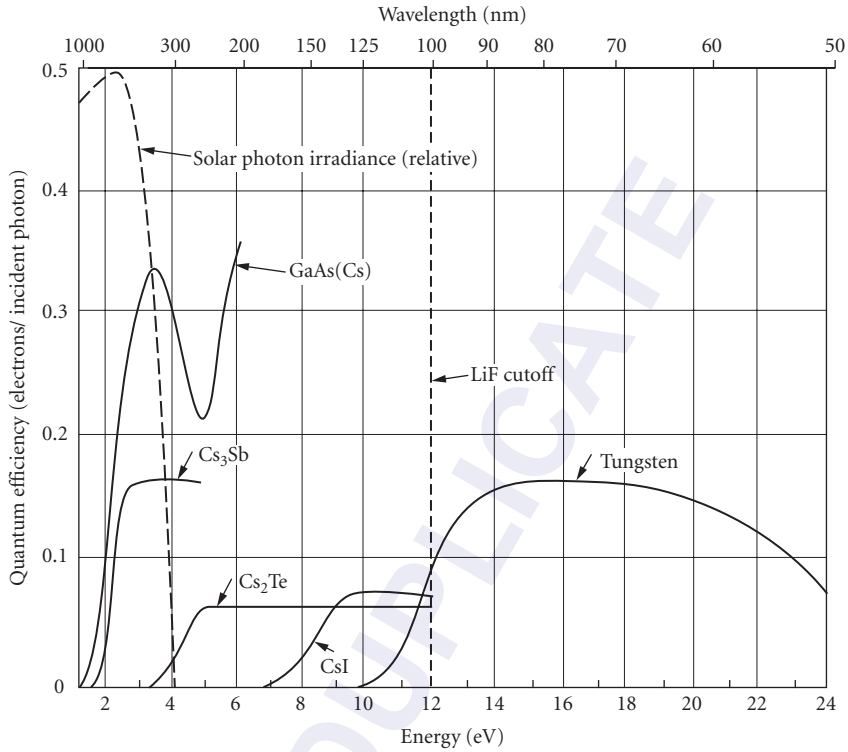

FIGURE 54 Quantum efficiency versus wavelength (photon energy) for several photoemitters.

Photocathode dark current is approximately proportional to photocathode area so that small photocathode effective areas can be expected to have reduced noise. Figure 55 shows how anode dark current and gain increase with applied voltage for a typical PMT.

Minimum detectable power is related to limiting noise through responsivity via

$$\text{NEP} = i_n / \mathcal{R} \tag{25}$$

where $\mathcal{R}$ is in amperes per watt.

Operating temperature Dark current due to thermionic emission, usually greater in red-sensitive tubes, can be reduced by cooling (see Ref. 21). The trialkali (S-20) performance does not benefit from cooling below 255 K. Maximum beneficial cooling (three to four dark counts per second) for AgOCs (S-1), $(Cs)Na_2KSb$ (S-20), and Cs_3Sb (S-11) is 195, 255, and 239 K, respectively. Most photocathodes become noisier as temperature rises above ambient because of increased thermionic emission. Because its thermionic emission starts at a very low value, $(Cs)Na_2KSb$ is a useful photocathode up to temperatures of approximately 373 K.

Response time The rise time of photomultiplier tubes depends chiefly on the spread in transit time during the multiplication process. For photomultiplier tubes, this spread is about 10 ns. Some tubes with specially designed electron optics can give spread as low as 1 ns. The crossed-field PMT makes possible a spread as small as 0.1 ns. Microchannel plate tubes have response times of a nanosecond or less.

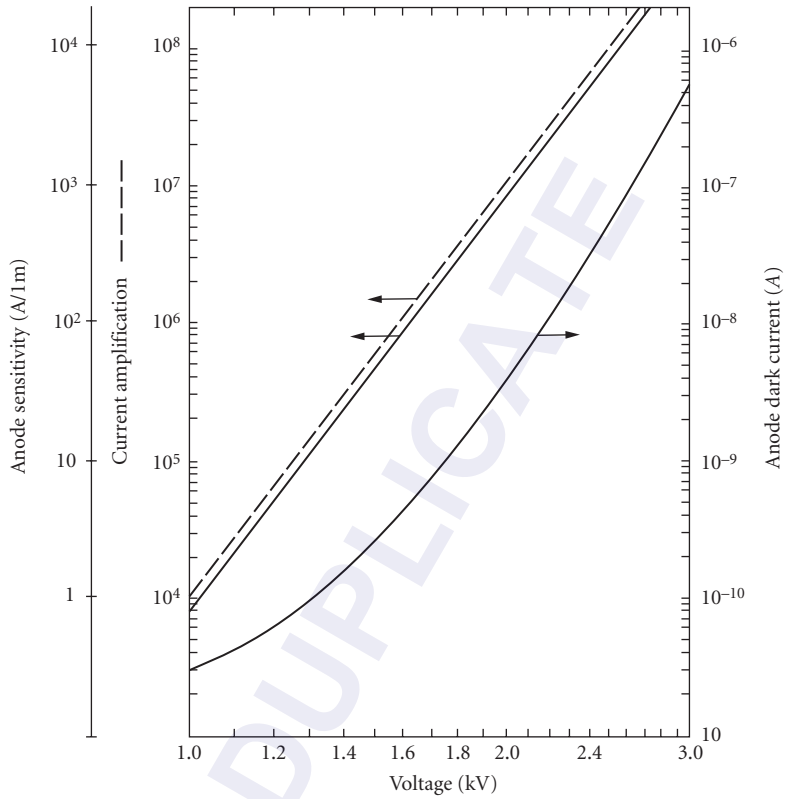

FIGURE 55 Typical current amplification and anode dark current as a function of applied voltage. (*Based on E.H. Eberhardt, "D* of Photomultiplier Tubes and Image Detectors," ITT Industrial Labs, 1969.*)

For high-speed work (<1 ns rise time), good transmission-line technique must be used to obtain impedance match and to avoid reflection. The bandwidth of the output circuit will depend upon the total capacitance (PMT circuit plus stray capacitances) and the value of the load resistance.

Linearity Photomultiplier tubes are nearly all linear to about 1 percent for cathode currents of 0.1 μA or less. Some tubes may be linear to better than 0.1 percent but must be individually selected.[22] Probably most of the nonlinearity results from the dynode structure.

Sensitive area No fundamental limitation. Only recently available with very small effective areas for extremely low dark current. Magnetic focusing has been used so that only a small fraction of the photocathode is used electron-optically.

Sensitivity profile Usually uniform within 20 to 50 percent. Microchannel plate detectors may have uniformity of ±5 percent.

Stability PMTs are subject to short- and long-term drift which can depend upon anode current, changes in anode current, storage times, and aging or anode life. They are also subject to change if exposed to magnetic fields or changes in temperature. Vibration of the tube may modulate the signal (microphonic effect).

Recommended circuit See Fig. 56.

1. Since a PMT is a current generator, increasing output resistance R_1 increases output voltage. An upper limit to R_1 may be imposed either by the time-constant limitation or by nonlinearity, which results from a space charge produced near the anode when the anode is left nearly floating electrically.
2. The rated photocathode current (referred to anode current through gain) should not be exceeded.
3. Care should be taken not to destroy the photocathode with light (heating).
4. When large currents are drawn, it may affect later dynode interstage voltage and hence gain, causing nonlinearity; for example, in Fig. 44, if the photocurrent from DY 10 to anode becomes comparable to the biasing current, through R_{11}, the gain of the final stage is reduced. This can be avoided by biasing the dynodes with constant-voltage sources.
5. To avoid dynode damage, final dynode current must not exceed the value suggested by the manufacturer.

Photon counting At the photocathode, the shot-noise-limited signal-to-noise ratio (with negligible dark current) is

$$\frac{i_s}{i_n}\frac{i_s}{(2ei_s\Delta f)^{1/2}}\left(\frac{i_s}{2e\Delta f}\right)^{1/2}=\left(\frac{N_s}{2\Delta f}\right)^{1/2} \tag{26}$$

where N_s is the photoelectron rate at the photocathode. Thus, for extremely low levels of illumination, the ideal signal-to-noise ratio becomes very poor. At this point there is much to be gained by abandoning attempts to measure the height of the fluctuating signal (Fig. 57*a*) in favor of digitally recording the presence or absence of individual pulses (Fig. 57*e*).

Single photoelectron counting can be achieved by using a pulse amplifier (see Fig. 58), which suppresses spurious dark-noise pulses not identical in amplitude and shape to those produced by photoelectrons.

An upper practical limit for (random) photon counting is set by convenient amplifier bandwidths at about $10^5\ s^{-1}$. For reasonable (1 percent) statistical accuracy, this implies a 10-MHz bandwidth.

Gallium phosphide dynodes The development of GaP dynodes for increased secondary-electron production[23,24] makes possible unambiguous discrimination of small numbers of individual photoelectron counts which was not previously possible with lower dynode gains. This is shown in Fig. 59, where the spread in number of secondary electrons ($N\times$ gain) is just $(N\times \text{gain})^{1/2}$.

In addition to the aforementioned fundamental advantage of high dynode gain, the large gain per stage in the first dynodes also helps discriminate against noise introduced by later stages of amplification. Also, fewer stages of amplification are required.

GaN and AlGaN Gallium nitride photovoltaic detectors, with a bandgap of 3.39 eV have spectral response in the ultraviolet (UV) from 200 to 365 nm, as illustrated in Fig. 60. By using aluminum-gallium nitride—an alloy mixture of AlN and GaN—the spectral response can be tuned to shorter wavelength cutoffs. Spectral response examples are shown in Figs. 61 to 64 to compare GaN with one particular AlGaN alloy. Some devices may be tailored to custom UV bands, such as UVA (320 to 400 nm), UVB (280 to 320 nm), or UVC (100 to 280).

Response at visible wavelengths is low or absent, so that no special filtering may be required to detect UV in the presence of visible lighting or solar radiation—but see the logrithmic spectral Figs. 62 and 64 to see the degree of longer wavelength response. These solid-state devices are potentially useful for operation at elevated temperatures, in high-vibration environments, and in other environments unsuitable for photomultiplier tubes.

The photoconductive GaN devices use interdigitated contact electrodes because of the very high impedance of the GaN films, but currently there may not be any available commercially.

SiC Silicon carbide UV detectors are available in photovoltaic structures. The 3-eV bandgap of SiC is slightly narrower than GaN, thereby giving a response may extend to slightly longer wavelength. However, because the bandgap of SiC is indirect, unlike GaN which is direct, the response cut-on is more gradual in SiC, peaking at a wavelength much shorter than the wavelength corresponding to 3 eV (413 nm)—see Fig. 65. SiC detectors with integrated filters are available.

GaAsP Gallium arsenide phosphide alloys can provide photodiodes that cover from the UV to the near-infrared spectral region. The bandgap of GaP is 2.26 eV and is indirect, while that of GaAs is 1.43 eV and is direct. GaAsP alloys from 0 to ~50% GaP are direct bandgap materials while those with higher percentages of GaP are indirect*. A variety of alloys are available, covering the following spectral bands:

Spectral Band (nm)	λ Peak (nm)	Response at Peak (A/W)	Sizes (mm)
400–760	710	0.4	1.3 × 1.3, 2.7 × 2.7, 5.6 × 5.6
300–680	640	0.3	1.3 × 1.3, 2.7 × 2.7, 5.6 × 5.6
300–580	470	0.25	0.8 × 0.8
280–580	470	0.2	0.8 × 0.8
260–400	370	0.06	0.8 × 0.8
190–760	710	0.22	2.3 × 2.3, 4.6 × 4.6
190–680	610	0.18	10.1 × 10.1

Spectral responses of these alloys are shown in Figs. 68 to 73 (*ref: http://jp.hamamatsu.com/products/sensor-ssd/pd140/pd143/index_en.html?sort=WAVE_LENGTH4&desc=1&style=F1 for all six figures*).

CdS and CdSe Cadmium sulfide and cadmium selenide photoconductors are available for detection of visible light out to 700 to 800 nm. CdS and CdSe films have sheet resistivity in the range of 20 mΩ per square at an illumination level of 2 footcandles. The devices are typically made in a linear or serpentine configuration consisting of 2 to 500 squares to maximize the length-to-width ratio. A variety of material "types" are available, offering unique spectral curves for various applications, depending upon the source color. CdS and CdSe are typically slow detectors, with response times of 5 to 100 ms, with speed improving at higher light levels. These devices exhibit "memory" or "history" effects, where the response is dependent upon the storage condition preceding use—the length of storage and time in use, and differences between the storage light level and the light level during use. These history effects may amount to changes in resistance from less than 10 percent to over 500 percent. CdSe has comparably greater memory effect than CdS.

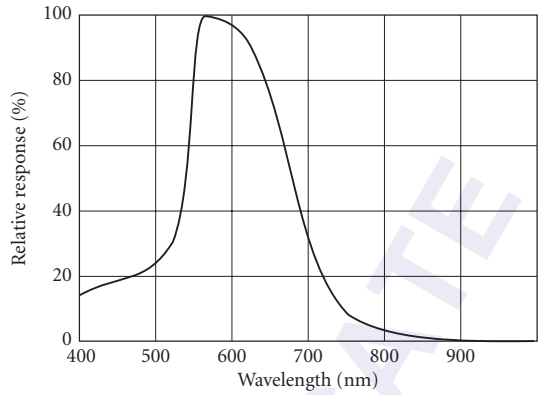

FIGURE 74 Relative spectral response of a "Type 0" CdS photocell. (*http://optoelectronics.perkinelmer.com/content/RelatedLinks/Brochures/BRO_PhotoconductiveCellsAndAnalogOptoiso.pdf.*)

CdS and CdSe are useful for a variety of commercial applications, both analog and digital, such as camera exposure control, automatic focus and brightness controls, densitometers, night light controls, etc. They are comparatively inexpensive and are available in a wide range of packages and resistance values, including dual cell configurations.

Spectral response: See Figs. 74 to 76.

Resistance and sensitivity: See Figs. 77 to 78.

Temperature coefficient of resistance: See Figs. 79, 80.

Light history effects: See Table 3.

Detector size: 4×4 mm to 12×12 mm approximate, dual elements available.

Manufacturers: In the previous edition, the listed supplier was EG&G VACTEK. Their product line has been acquired by Perkin Elmer. In this transition, all but two of the detector "types" have

TABLE 3 Typical Variation of Resistance with Light History Expressed as a Ratio R_{LH}/R_{DH} at Various Test Illumination Levels in Foot Candles.

Illumination (foot candles)	0.01	0.1	1.0	10	100
R_{LH}/R_{DH} ratio	1.55	1.35	1.20	1.10	1.10

(http://optoelectronics.perkinelmer.com/content/RelatedLinks/Brochures/BRO_PhotoconductiveCellsAndAnalogOptoiso.pdf.)

R_{LH} is the resistance after "infinite" exposure to light, while R_{DH} is the resistance after "infinite" exposure to a dark environment. Infinite may be approximated by 24 hours.

CdTe Cadmium telluride and cadmium zinc telluride detectors are chemical group II-VI materials having an energy bandgap of about 1.6 eV, corresponding to a spectral cutoff in the vicinity of 775 nm. These devices, however, are principally used for gamma ray detection because of their high *z* number which translates into a high absorption coefficient for gamma rays. The principal advantage of CdTe in this application is its ability to operate at room temperature, in comparison with Ge gamma ray detectors which must typically be cooled to 77 K. Figure 81 illustrates the absorption of CdTe as a function of gamma ray energy out to 300 keV.

Sensitivity: See Fig. 81.

Standard sizes: Wafers in 10- and 16-mm diameter; rods 7 × 2 × 2 mm; cubes 2 × 2 × 2 mm.

Standard thickness: 1 and 2 mm.

Bias voltage: 150 to 300 V/cm.

Operating temperature range: –10 to +55°C

Leakage current: 10 to 300 nA

Capacitance: 10 pF

Response time: < 1 μs.

Manufacturers: Acrorad: http://www.acrorad.co.jp/us/index.html, Aurora, II-VI eV Products: http://www.evproducts.com/, Perkin Elmer, Radiation Monitoring Devices: http://www.rmdinc.com/products/p007.html

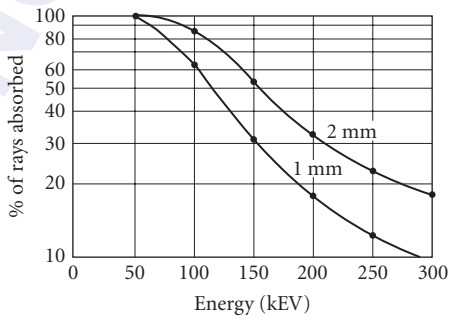

FIGURE 81 The high percentage of rays absorbed by CdTe makes these detectors highly sensitive. At 100 keV, a 2-mm-thick detector absorbs 85 percent of the rays. (*Radiation monitoring devices, Cadmium Telluride brochure.*)

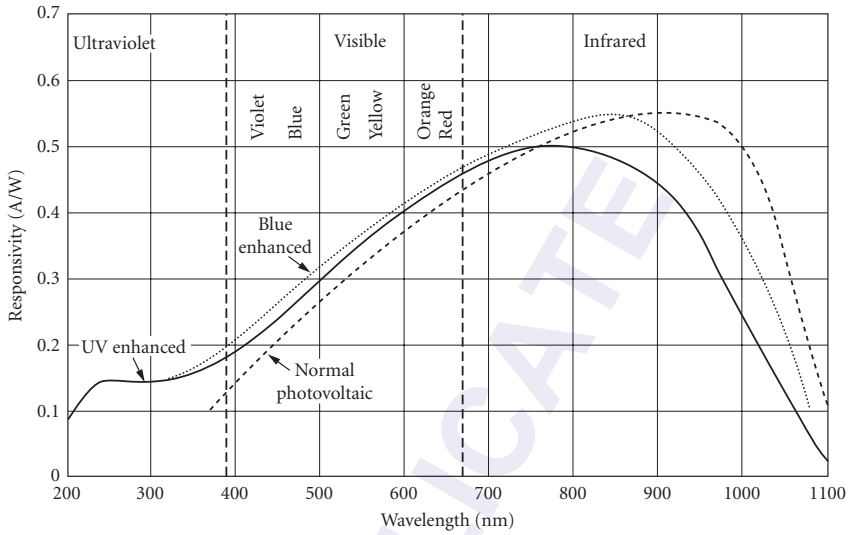

FIGURE 82 Typical spectral response for *pn* junction, blue-enhanced, and UV-enhanced silicon photodiodes. (*UDT Sensors, Inc., Optoelectronic Components Catalog.*)

Si Silicon photovoltaic detectors are widely available. They are useful at wavelengths shorter than about 1.1 μm and can even be used for x-ray and gamma-ray detection. There are four main silicon detector types:

- *pn* junction photodiodes, generally formed by diffusion, but ion implantation can also be used.
- *pin* junctions, which have lower capacitance and hence higher speed, and because of a thicker active region have enhanced near-IR spectral response.
- UV- and blue-enhanced photodiodes
- Avalanche photodiodes with significant internal gain, combining high speed and sensitivity

The main parameters of interest are spectral response (see Fig. 82), time constant, and zero-bias resistance or reverse-bias leakage current. Silicon material has an indirect bandgap and hence the spectral cutoff is not very sharp near its long-wavelength limit as shown in Fig. 82. The effective time constant of *pn* junction silicon detectors is generally limited by resistance-capacitance (RC) considerations rather than by the inherent speed of the detection mechanism (drift and/or diffusion). High reverse bias may or may not shorten charge collection time, but it generally reduces cell capacitance, and therefore the RC product, therefore, reverse bias usually results in faster response.

On the other hand, increased reverse bias causes increased noise, so that a trade-off exists between speed and sensitivity. For high-frequency applications, load resistance should be made small, although this makes Johnson (thermal) noise comparatively larger, which limits sensitivity (see Fig. 83). In order to keep sensitivity high when using these devices at high frequency, operational (current-mode) amplifiers, which can be built into the detector package, and avalanche photodiodes, which incorporate built-in gain before the load resistor is encountered, have been developed. Very careful regulation of the detector bias is required for stable operation of avalanche photodiodes.

Silicon pn junction photodiodes These are general purpose when high sensitivity is required and time constants on the order of a microsecond are permissible. The device construction is illustrated in Fig. 84. These devices are typically operated in a photovoltaic mode at zero bias, but can be used in a photoconductive mode in which the device is reverse biased.

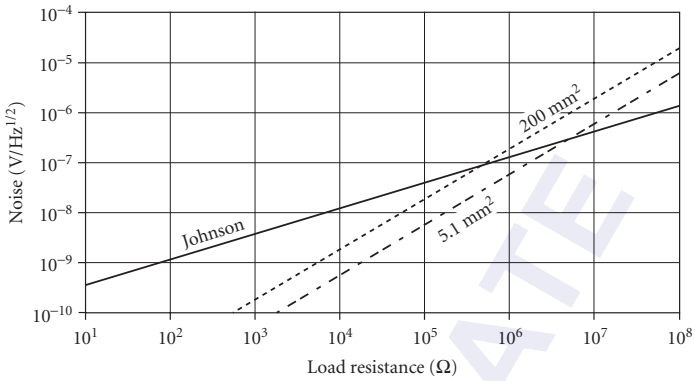

FIGURE 83 Output noise as a function of circuit load resistance for *pin* silicon photodiodes with areas of 5.1 and 200 mm^2, compared with the Johnson noise of the load resistor. Dark current measured at 10-V reverse bias for the detector with area of 5. 1 mm^2 is 10 nA, and 100 nA for the detector with an area of 200 mm^2. Note that good preamplifiers have a noise level of about 1 nV/Hz$^{1/2}$, depending upon the bandwidth. (*Detector data from UDT Sensors, Optoelectronic Components Catalog.*)

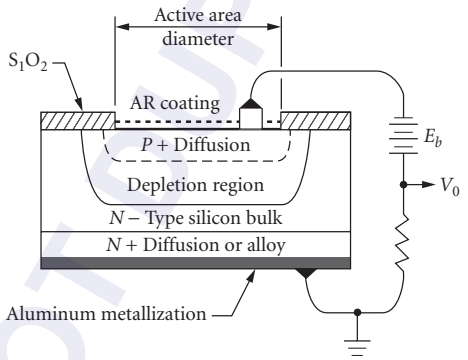

FIGURE 84 Planar diffused silicon photodiode construction. (*UDT Sensors, Inc., Optoelectronic Components Catalog.*)

Sensitivity: $D^*(\lambda_{pk}) \approx$ mid-10^{12} to 10^{13} Jones, $D^*(2800\ \text{K}) \approx 2 \times 10^4$ Jones, becoming amplifier-limited for small-area detectors (see Figs. 85 and 86). D^* can also be estimated from the R_0A product (detector zero-bias resistance or shunt resistance diode area), which is illustrated in Fig. 87, in combination with Fig. 19, which illustrates the dependence of D^* on R_0A product.

Noise: See Figs. 88 (noise vs. bias) and 89 (noise vs. temperature); as T drops, impedance rises, so that decreasing noise current produces increasing noise voltage. However, the signal increases even faster, yielding an improved signal-to-noise ratio with cooling. Figure 90 (noise vs. frequency) shows the dependence on bias.

Capacitance: Capacitance is proportional to area and increases slightly with temperature (see Fig. 91).

Responsivity: See Figs. 82 and 88.

Quantum efficiency: >90 percent quantum efficiency achievable with antireflection coating.

Sensitive area: 0. 2 to 600 mm^2 areas are readily available.

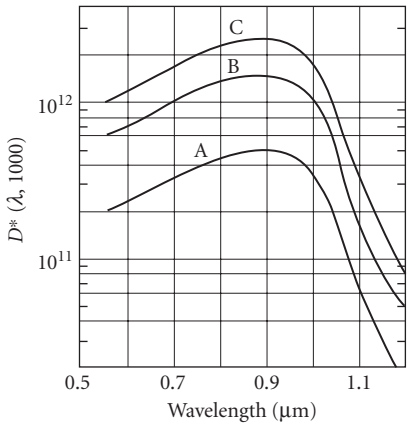

FIGURE 85 D^* versus 1 for small-area junction silicon photodiodes: curves A, B, and C correspond to areas of 0.02, 0.2, and 1 cm^2. The lower D^* for smaller area detector performance is due to amplifier limitations rather than intrinsically poorer D^*, for small-area detectors. (*Texas Instruments, Infrared Devices, SC-8385-366. Reprinted by permission of Texas Instruments.*)

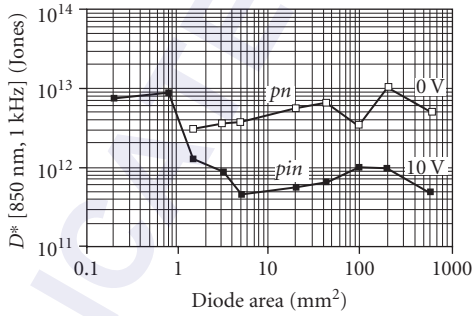

FIGURE 86 D^* as a function of diode area for *pn* junction silicon photodiodes operated in the photovoltaic mode (0 V) and *pin* junction diodes operated in the photoconductive or reverse-bias mode (10 V). (*UDT Sensors, Optoelectronic Components Catalog.*)

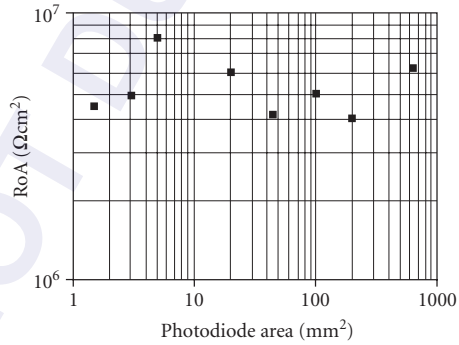

FIGURE 87 The resistance-area product (R0A) at zero bias and 295 K of silicon *pn* junction photodiodes. The lack of area dependence is evidence that intrinsic properties of the junction, rather than surface effects, are dominant in these devices.

Time constant: Inherently slow for high-sensitivity applications, generally limited by RC (depends directly on device area), but can be limited by carrier diffusion outside the depletion region or by trapping of carriers in deep impurity centers. Typical data for a circuit using a 50-Ω load resistor is illustrated in Fig. 92.

Operating temperature: Ambient, but noise (leakage current) can be reduced by operating at lower temperatures (see Fig. 76 for typical signal and noise vs. temperature).

Uniformity: Typically ±8 percent across a diode area with a 40-μm focused light spot.

Linearity: 5 percent or better over 10 orders of magnitude flux from 10^{-13} to 10^{-3} *W*/cm^2.

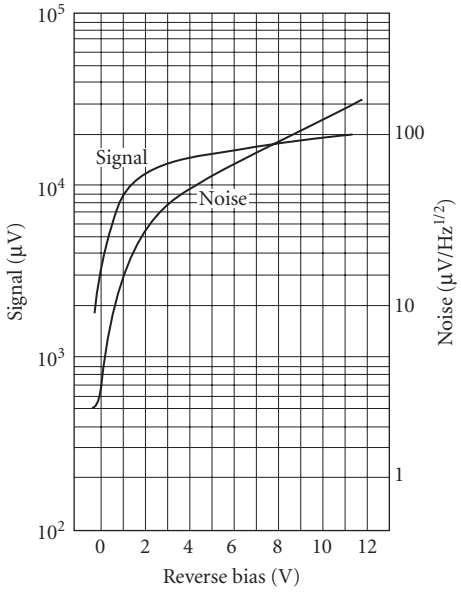

FIGURE 88 Typical *pn* junction signal and noise versus reverse bias ($R_L = 10$ MΩ). (*Electronuclear Laboratories, Bull. 1053, 1966.*)

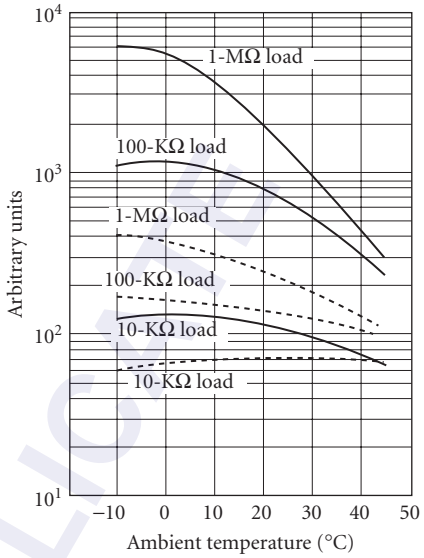

FIGURE 89 Relative signal and noise versus temperature for *pn* junction silicon photodiode at zero bias; — = signal; --- = noise. (*Electronuclear Laboratories, Bull. 1052, 1966.*)

Recommended circuit: See Fig. 93. High-impedance FET current-mode amplifier to supply fixed bias voltage, regardless of current.

Stability: See Fig. 20 and section relating to stability. Check with manufacturer.

Manufacturers: Advanced Photonix, EG&G Canada, EG&G Heimann, Edmund Optics, Electro Optical Systems, Electro-Optics Technology, International Radiation Detectors, Janos Technology, Laser Precision Corp, Laser Systems Devices, Melles Griot, Newport/Klinger, Ophir Optronics, Optical Signature, Opto-Electronics, Optometrics, Oriel, Photonic Detectors, RMD, Sapidyne, Scientific Instruments, SEMICOA, Silonex, Spire, UDT Sensors.

Silicon pin junction photodiodes The *pin* junction detector is faster but is also somewhat less sensitive than conventional *pn* junction detectors. *PIN* photodiodes have slightly extended red

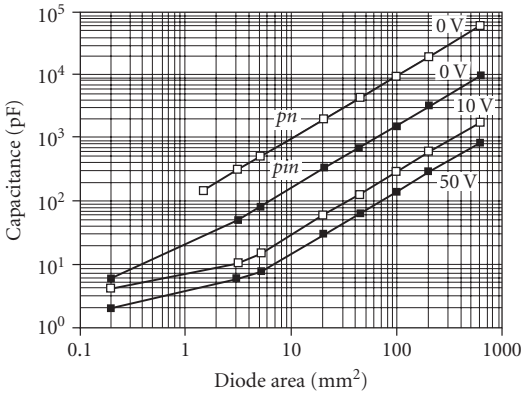

FIGURE 91 Capacitance as a function of detector area for *pn* junction silicon photodiodes operated in the photovoltaic mode (0 V) and *pin* junction photodiodes at 0-, 10-, and 50-V reverse bias. The larger depletion width, which is a consequence of the lightly doped "*i*" region in the *pin* device, gives *pin* diodes lower capacitance for the same device area. (*UDT Sensors, Optoelectronic Components Catalog.*)

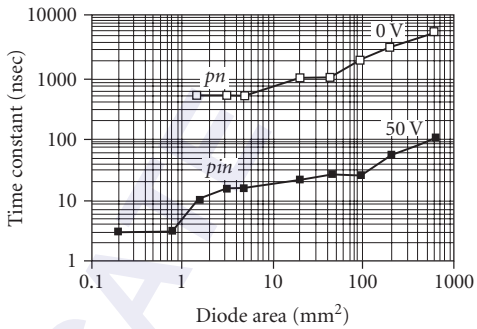

FIGURE 92 Time constant for *pn* junction silicon photodiodes operated in the photovoltaic mode (0 V) and a *pin* junction detector in the photoconductive or reverse-bias mode (50 V). A 50-Ω load was used in both cases, which limits sensitivity because of Johnson noise (see also Fig. 83). (*UDT Sensors, Optoelectronic Components Catalog.*)

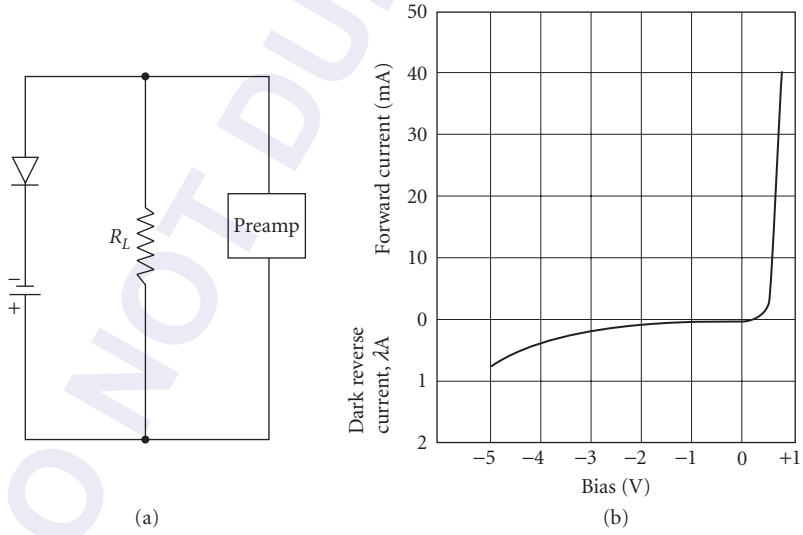

FIGURE 93 *pn* junction silicon photodiode: (*a*) recommended circuit; (*b*) typical electrical characteristics. (*Texas Instruments, Bull. SC-8385-366. Reprinted by permission of Texas Instruments.*)

response. In the normal *pn* junction, charge-collection time has a slow and a fast component. The fast component is due to photons absorbed in the depletion layer of the *pn* junction. Since the electric field in the depletion region is strong, carriers are quickly separated by drift through the electric field across the depletion region. However, photons absorbed deeper in the material, beyond the depletion region, produce carriers which must diffuse to the junction before they are collected, and diffusion times are on the order of a microsecond. This component becomes more significant near the

long-wavelength limit of the spectral response. Application of reverse bias in an ordinary *pn* junction detector reduces the capacitance, shortening the RC time constant, and increases the width of the depletion layer thereby increasing the fraction of photons absorbed within the high field region and proportionally increasing the fraction of the fast component of the response.

However, the doping level of the ordinary *pn* junction limits the extent of the depletion layer increase to only 5 to 10 μm at a reverse bias of 50 V (this assumes an abrupt junction with a concentration of 1×10^{15} cm^{-3}). *pin* detectors incorporate a very lightly doped region between the *p*- and *n*-regions that allows a modest reverse bias to form a depletion region the full thickness of the material (500 μm for a typical silicon wafer). Extended red response in a pin device is a consequence of the extended depletion layer width, since longer wavelength photons will be absorbed in the active device region. Unfortunately, the higher dark current collected from generation within the wider depletion layer results in lower sensitivity. Generation of carriers can be minimized by minimizing the concentration of deep-level impurity centers in the detector with careful manufacturing. Operation at lower temperature will also reduce the dark current.

Sensitivity: D^*_{pk} 1×10^{12} Jones for 2-mm^2 area (depends slightly on bias, see Figs. 86 and 94). For high-speed operation, detectivity is lower (see Fig. 83).

Noise: Depends upon diode area and circuit load resistance. Johnson noise will dominate at low values of load resistance when circuit is optimized for fast response. Preamp noise may also limit. See Fig. 83.

Responsivity: Similar to *pn* junction. See Fig. 82.

Quantum efficiency: 90 percent quantum efficiency achievable with antireflection coating.

Capacitance: Proportional to detector area. See Fig. 91.

Operating temperature: See Fig. 95.

Time constant: Varies with capacitance (device area); see Fig. 92.

Sensitive area: 0. 2 to 600 mm^2 readily available.

Recommended circuit: Same as for *pn* junction photodiodes. See Figs. 93 and 96.

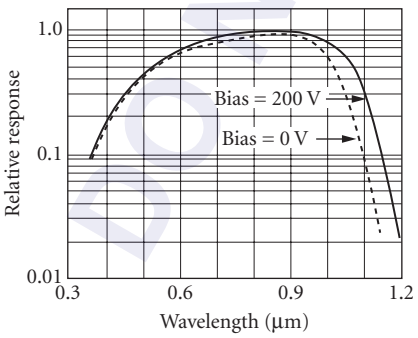

FIGURE 94 Dependence of spectral response on bias for silicon photodiodes. (*Electronuclear Laboratories, Bull. 1076, 1968.*)

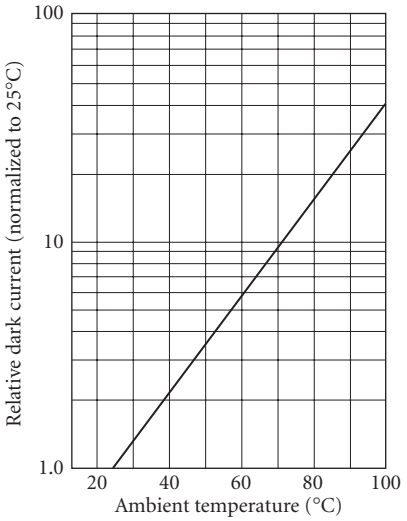

FIGURE 95 Relative dark current versus temperature for *pin* junction silicon photodiodes—bias 100 V. (*Electronuclear Laboratories, Bull. 1076, 1969.*)

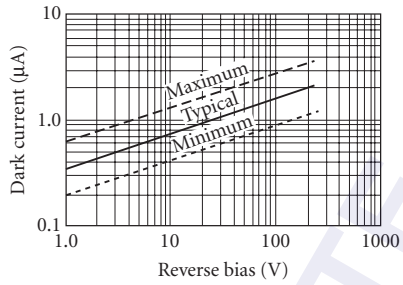

FIGURE 96 Typical dark current versus bias for *pin* silicon phototdiode ($A = 1 \times 1$ mm). (*Electronuclear Laboratories, Bull. 1078, 1968.*)

Stability: See Fig. 20 and section relating to stability. Check with manufacturer.

Manufacturers: Same as for *pn* junction photodiodes.

UV -and blue-enhanced photodiodes Blue- and UV-enhanced photodiodes may improve the quantum efficiency by 50 to 100 percent over standard photodiodes in the blue and UV spectral region. The quantum efficiency of ordinary *pn* and *pin* junction photodiodes degrades rapidly in the blue and UV spectral regions. This is because the high absorption coefficient of silicon at these wavelengths causes the photocarriers to be generated within the heavily doped *p*- (or *n*-) type contact surface where the lifetime is short due to the high doping and/or surface recombination. Blue- and UV-enhanced photodiodes optimize the response at short wavelengths by minimizing near-surface carrier recombination. This can be achieved by using very thin and highly graded *p* (or *n* or metal Schottky) contacts, by using lateral collection to minimize the percentage of the surface area which is heavily doped, and/or passivating the surface with a fixed surface charge to repel minority carriers from the surface. These devices typically have quartz windows or UV-transmissive glass, compatible with good transmission into the UV spectrum. The user should be aware that UV and higher energy radiation in particular can alter the fixed charge conditions in the surface region of silicon and other detectors (typically in the surface oxide) which can cause the detector performance to drift and/or be unstable (see Fig. 20).

Sensitivity: See Figs. 82 and 97; D^*_{pk} 3–5 $\times 10^{12}$ Jones for diodes with areas of 1–100 mm^2 at $V_R = 0$, $R_L = 40$ MΩ.

Quantum efficiency: Same as *pn* junction photodiodes, but enhanced in the UV and blue regions by 50 percent or more (see Fig. 82).

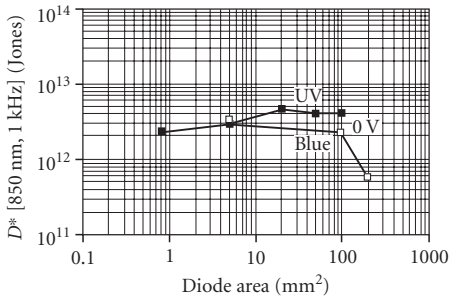

FIGURE 97 D^* as a function of diode area for blue- and UV-enhanced silicon photodiodes operating in the photovoltaic mode (0-V bias). (*UDT Sensors, Optoelectronic Components Catalog.*)

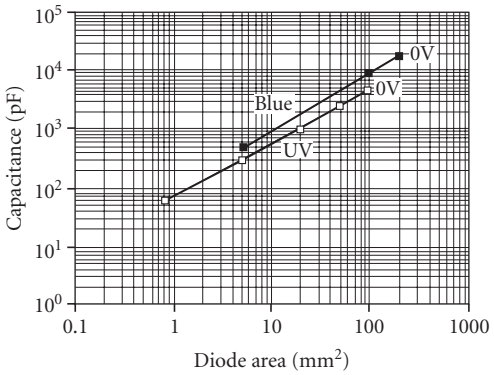

FIGURE 98 Capacitance as a function of detector area for blue- and UV-enhanced silicon photodiodes operated in the photovoltaic mode (0 V). The capacitance per unit area is close to that of *pn* junction photodiodes shown in Fig. 91. (*UDT Sensors, Opto electronic Components Catalog.*)

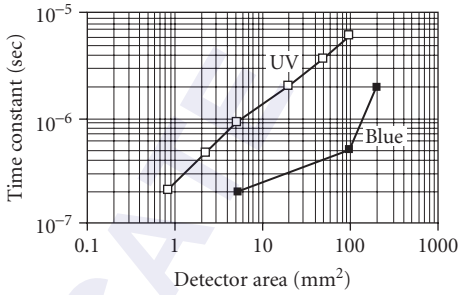

FIGURE 99 Time constant for UV- and blue-enhanced silicon photodiodes as a function of detector area at zero-volts bias. A 50-Ω load was used in both cases. (*UDT Sensors, Optoelectronic Components Catalog.*)

Responsivity: see Fig. 82.

Capacitance: Comparable to *pn* junction photodiodes (See Fig. 98).

Operating temperature: Ambient.

Time constant: Dependent upon device type. Increases with device area; 200 ns to 6 μs for areas 1 to 100 mm^2 (see Fig. 99).

Sensitive area: 1 to 200 mm^2 readily available.

Recommended circuit: Same as *pn* junction photodiodes.

Stability: See Fig. 20 and section relating to stability. Check with manufacturer.

Manufacturers: See list for silicon *pn* junction photodiodes.

Silicon avalanche photodiodes The avalanche photodiode, is especially useful where both fast response and high sensitivity are required. Whereas normal photodiodes become Johnson- or thermal-noise-limited when used with a low-impedance load resistor for fast response, avalanche photodiodes make use of internal multiplication, associated with reverse breakdown in the *pn* junction in order to keep the detector noise above the Johnson-noise level. [Because the response time is usually RC-limited, small load resistors (often 50 Ω) are used to achieve fast signal response.] However, as the load resistor is decreased, the detector noise voltage decreases in direct proportion, whereas the Johnson noise decreases only as the square root of the load resistor. Thus, the detector noise voltage can become lower than the Johnson noise for load resistance values smaller than a critical value. With an APD device, lower values of load resistors can be used without reaching the critical value because the internal gain boosts the detector noise voltage.

Stable avalanche or multiplication is made possible by a guard-ring construction using n^+pp^+, Schottky-nn^+, or $n^+p\pi p^+$ structure; beveled *pin* structure (see Fig. 100); mesa structures; or other structures which prevent surface breakdown.[25] However, very careful bias control is essential for stable performance. An optimum gain exists below which the system is limited by receiver noise and above which shot noise dominates receiver noise and the overall noise increases faster than the signal (Fig. 101).

In addition to fast-response applications, avalanche photodiodes are useful whenever amplifier noise is limiting, for example, small-area devices. Signal-to-noise-ratio improvements of one to two orders of magnitude over a nonavalanche detector can be achieved.

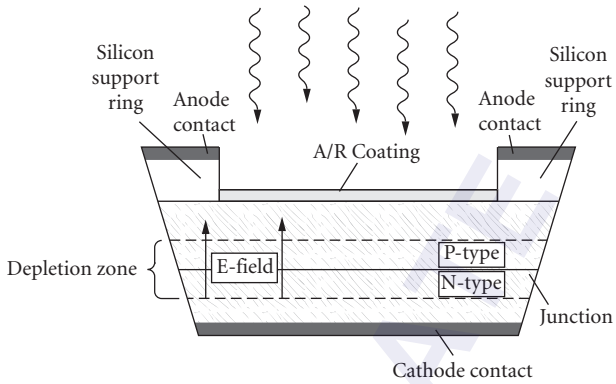

FIGURE 100 Cross section of a beveled-edge silicon avalanche photodiode. The beveled edge prevents early breakdown. (*Advanced Photonix. Avalanche Photodiode Catalog.*)

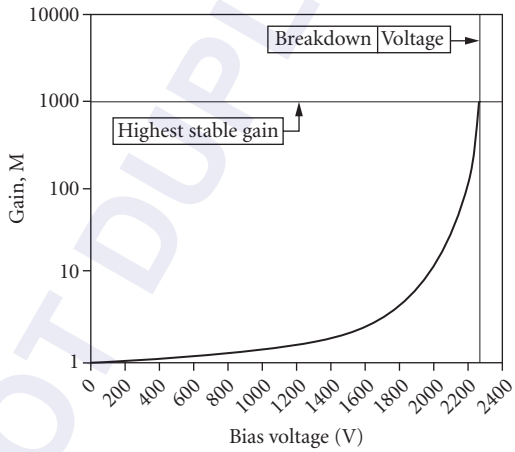

FIGURE 101 Gain as a function of reverse bias can reach 1000. This operating point is very close to breakdown and requires careful bias control. (*Advanced Photonix. Avalanche Photodiode Catalog.*)

APDs are sometimes used in combination with scintillator crystals such as CsI to detect high-energy radiation in the range of 10 to 1000 keV.

Sensitivity: D^* 3–5 × 10^{13} Jones (see Fig. 102).

Noise: Function of detector area. As gain increases, noise (dark current) increases (see Fig. 103). Optimum gain is where avalanche noise equals system noise. Thus, optimum gain is a function of system noise.

Responsivity: Photocurrent is the product of the incident optical power in watts, wavelength in micrometers, and quantum efficiency (η) divided by 1.24 and multiplied by the avalanche gain M.

$$I_{\text{photo}} = M(P\,\eta\,\lambda/1.24) \qquad \text{(See Figs. 101 and 104)}$$

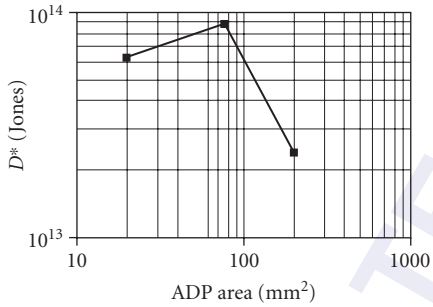

FIGURE 102 D^* for three silicon avalanche photodiodes shown as a function of diode area. (*Advanced Photonix. Avalanche Photodiode Catalog.*)

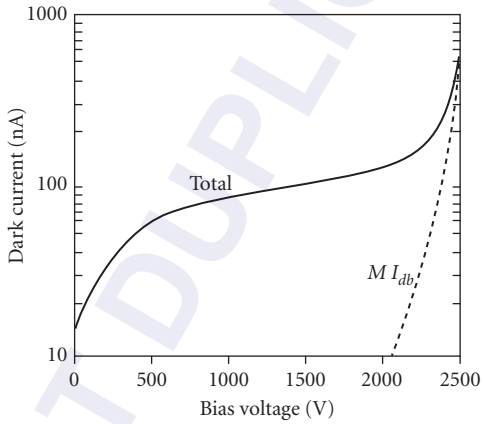

FIGURE 103 Dark current as a function of reverse bias for a 16-mm-diameter APD. At low-bias surface dark current dominates, but avalanche-multiplied bulk dark current increases rapidly as the gain increases. (*Advanced Photonix. Avalanche Photodiode Catalog.*)

Quantum efficiency: Typically 85-percent peak (see Fig. 104).

Capacitance: Depends on bias and area (see Fig. 105).

Sensitive area: 20 to 200 mm^2.

Series resistance: Depends on area; typical values are 40 Ω for 5-mm diameter to 5 Ω for 16-mm diameter

Time constant: See Fig. 106.

Recommended circuit: Requires a filtered high-voltage dc supply that itself must have very low noise and a load resistor. The output may be ac- or dc-coupled. (See Fig. 107.)

Operating temperature: 40 to 45°C.

Stability: Exposure to UV or high-energy radiation may affect dark current. See Fig. 20 and section relating to stability. Check with manufacturer.

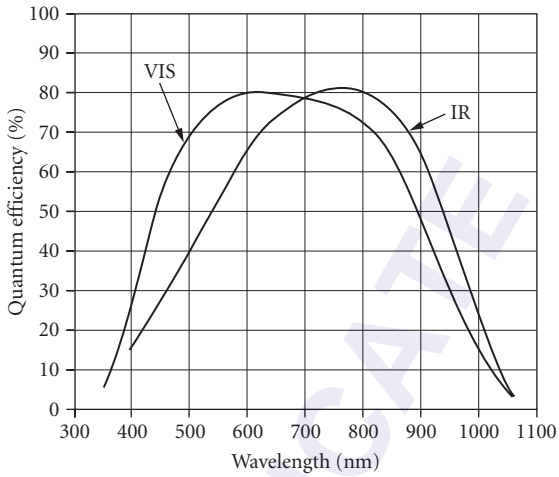

FIGURE 104 APD quantum efficiency at high gain. Adjustment of the oxide deposited on the surface produces two different curves. (*Advanced Photonix. Avalanche Photodiode Catalog.*)

Manufacturers: Advanced Photonix, Devar, EG&G Judson, EG&G Vactec, EG&G Canada, Edmund Optics, Electro-Optical Systems, Hamamatsu, Janos Technology, Newport/Klinger, Opto-Electronics (Ontario), Oriel, Photonic Detectors, Photonic Packaging Technologies, RMD, Texas Optoelectronics, Thorn EMI Electron Tubes.

InGaAs Indium gallium arsenide detectors have been developed for optimum performance with fiber-optic communications at 1.3 and 1.55 μm. This detector material has a direct bandgap and represents one of several compound semiconductor alloy systems specially developed for photodetectors. In the case of this alloy of two group III-V chemical compound semiconductors, the ratio of InAs to GaAs controls the spectral cutoff, allowing the detector to be optimized for a particular wavelength. InGaAs detectors have generally been specialized for high-speed applications with

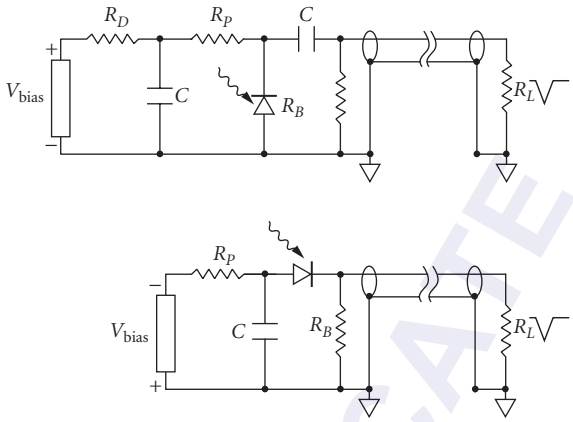

FIGURE 107 AC- and DC-coupled APD circuits with a filter following the power supply and a coaxial cable on the output. (*Adanced Photonix, Avalanche Photodiode Catalog.*)

optimum sensitivity since these performance factors can drive a fiber-optic system throughput and cost. For this reason, available devices include

- *PIN* photodiodes
- Avalanche photodiodes

The significance of these devices to fiber-optic applications is reflected in the number of vendors who sell integrated packages of InGaAs photodetectors combined with preamplifiers and fiber-optic pigtails.

The InGaAs alloy system allows the spectral response to be tailored to longer wavelengths than the quartz fiber-optic bands and devices with cutoffs of 2.2 and 2.6 μm are also available.

InGaAs pin photodiode

Sensitivity: D^* mid-10^{12} Jones for 1.67-μm cutoff; $D^* \approx 1 \times 10^{12}$ Jones for 2.2-μm cutoff, and $D^* \approx 5 \times 10^{11}$ Jones for 2.6-μm cutoff.

Responsivity: 0. 85 to 0. 95 A/W in the range of 1.3 to 1.55 μm.

Quantum efficiency: For 1.67-μm cutoff, see Fig. 108.

Dark current: See Fig. 109.

Capacitance: 0.7 to 1.2×10^4 pF/cm for 1.7-μm cutoff; 2.5×10^4 pF/cm for 1.85-μm cutoff; 3×10^4 pF/cm for 2.15-μm cutoff; 5×10^4 pF/cm for 2.65-μm cutoff. See also Fig. 110 for bias dependence.

Time constant: Varies with resistance-capacitance time (see Fig. 111). Since capacitance depends upon reverse bias, the time constant varies proportionally (see Fig. 110 for dependence of capacitance on bias).

Size: 0. 05 to 3-mm diameter.

Recommended circuit: Standard photodiode options; zero bias for best sensitivity, reverse bias for maximum speed.

InGaAs avalanche photodiode

Sensitivity: $D^* \approx 5 \times 10^{11}$ Jones for 1.7-μm cutoff. In the fiber-optics industry, the sensitivity is also given in power units of dBm. Figure 112 compares InGaAs *pin*, APD, and Ge APD sensitivities.

Ge Germanium intrinsic photodetectors are similar to intrinsic silicon detectors but offer spectral response out to 1.5 to 1.8 μm. *PN* junction photodiodes offer submicrosecond response or high sensitivity from the visible region to 1.8 μm. Zero bias is generally used for high sensitivity and large reverse bias for high speed. As in the case of silicon, germanium has an indirect bandgap and soft spectral cutoff. The previous discussion on silicon detectors applies in general, with the exception that blue- and UV-enhanced devices are not relevant to germanium detectors. Germanium detectors, because of their narrower bandgap, have higher leakage currents at room temperature, compared to silicon detectors. Detector impedance increases about an order of magnitude by cooling 20°C below room temperature. Thus, performance can improve significantly with thermoelectric cooling or cooling to liquid nitrogen temperature.

As with silicon, the device structure and bias configuration can affect spectral response and rise time. Three detector types are available:

- *pn* junction
- *pin* junction
- Avalanche photodiode

Germanium pn and pin

Sensitivity: D^*(peak, 300 Hz, room temperature) $>2 \times 10^{11}$ Jones, increases significantly with cooling by thermoelectric cooler or liquid nitrogen. (See Figs. 121, 122, and 123.)

Quantum efficiency: >50 percent with antireflection coating.

Noise: See Figs. 124 and 125.

Responsivity: 0.9 A/W at peak wavelength. See Fig. 121.

Capacitance: Lower for *pin* structure compared with *pn* diode. See Fig. 126.

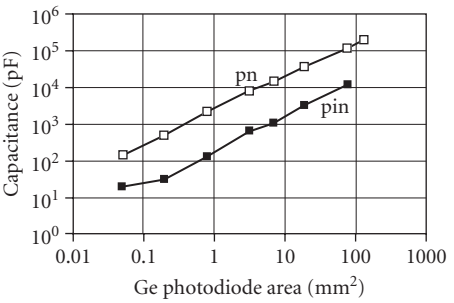

FIGURE 126 Capacitance for germanium *pn* and *pin* photodiodes shown as a function of diode area. (*EG&G Judson, Infrared Detectors, 1994.*)

Time constant: PIN diodes provide faster response. See Fig. 127.

Sensitive area: 0.25 to 13-mm diameter standard.

Operating temperature: Ambient, TE-cooled, or liquid nitrogen.

Profile: ±2 percent across active area at 1.3 μm.

Linearity: Excellent over 10 orders of magnitude. See Fig. 128.

Recommended circuit: See previous section on silicon photodiodes.

Manufacturers: Edinburgh Instruments, Electro-Optical Systems, Judson, Electro-Optical Systems, Fastpulse Technology, Germanium Power Devices, Infrared Associates, Newport, North Coast Scientific, Opto-Electronics, Oxford Instruments, Scientific Instruments.

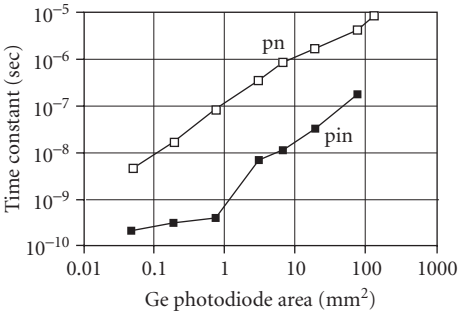

FIGURE 127 Time constant for germanium *pn* and *pin* photodiodes shown as a function of diode area. (*EG&G Judson, Infrared Detectors, 1994.*)

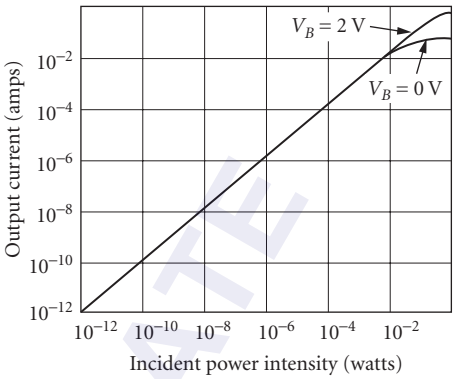

FIGURE 128 Linearity of a germanium *pn* junction photodiode. (*EG&G Judson, Infrared Detectors, 1994.*)

Germanium avalanche photodiode The germanium avalanche photodiode is similar to the silicon APD but has lower optimum gain, longer cut-off wavelength (1.7 μm), and higher leakage current. Germanium APDs combine the sensitivity of a Ge *pn* photodiode and the speed of a *pin* Ge photodiode.

Sensitivity: D^* 2×10^{11} Jones at 30 MHz for a diode with area of 5×10^{-2} mm^2 or about the same as for a *pn* Ge diode with the same area, and about a factor of 4 higher than a *pin* Ge photodiode (compare with Figs. 122 and 123). D^* depends on gain.

Gain: See Fig. 129.

Dark current: See Fig. 130.

Capacitance: 2 pF at 20-V reverse bias for 100-μm diameter, 8 pF at 20-V reverse bias for 300-μm diameter.

Quantum efficiency: 60 to 70 percent at 1.3 μm.

Responsivity: Photocurrent is the product of the incident optical power in watts, wavelength in micrometers, and quantum efficiency (η) divided by 1.24 and multiplied by the avalanche gain M. $I_{photo} = M(P\lambda\eta/1.24)$. (See Figs. 121 and 129).

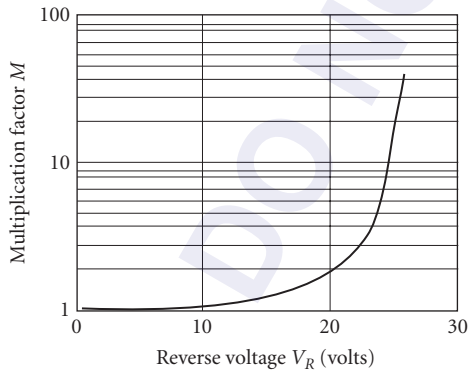

FIGURE 129 Gain as a function of reverse bias for germanium avalanche photodiode. (*EG&G Judson, Infrared Detectors, 1994.*)

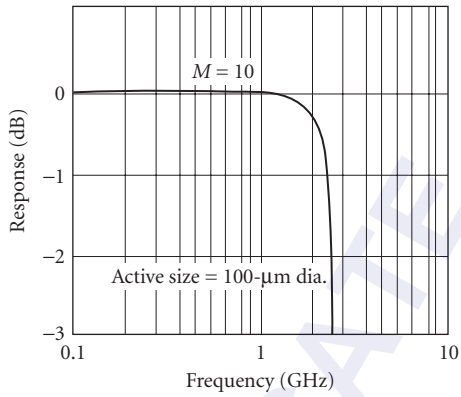

FIGURE 131 Frequency response of a germanium avalanche photodiode at two gain operating points. (*EG&G Judson, Infrared Detectors, 1994.*)

Operating temperature: Ambient or TE-cooled.

Time constant: 0.2 ns for 100-μm diameter; 0.3 ns for 300-μm diameter; both at 1.3 μm, $M = 10$ and with $R_L = 50\ \Omega$. See Fig. 131.

Sensitive area: 100- and 300-μm diameter standard.

Recommended circuit: See circuit recommended for Si APD.

Manufacturers: Edmund Optics, Metrotech, North Coast Scientific, Teledyne Judson Technologies.

PbS Photoconductive lead sulfide was one of the earliest and most successful infrared detectors. Even today it is one of the most sensitive uncooled detectors in the 1.3- to 3-μm spectral region. With cooling, PbS sensitivity is competitive with other detectors out to about 4.2 μm; however, its response time is slow.

Many PbS characteristics can be varied by adjusting the chemistry of the deposition process and/or the post-deposition heat treatment. These characteristics include spectral detectivity, time constant, resistance, and upper limit of operating temperature.[26] PbS is generally made by chemical reaction of Pb acetate and thiourea, except for high-temperature (373 K) applications, where evaporation is used. The material is deposited as a thin film (1 to 2 μm thick) on a variety of substrates, such as sapphire. With photolithographic processing, small sensitive areas can be made with comparatively high D^* values.

PbS may be tailored for ambient or room-temperature operation (ATO), intermediate or thermoelectrically cooled operation (ITO), and low-temperature or nitrogen-cooled operation (LTO). They are manufactured differently for particular temperature ranges, as shown in Table 4.

Sensitivity: D^* 1.5×10^{11} Jones at 295 K. See Figs. 132 to 137.

Responsivity: Depends on detector area, bias, resistance, and operating temperature (see Figs. 138 and 139).

Quantum efficiency: Generally limited by incomplete absorption in the thin film to 30 percent as estimated from blip D^* values.

Noise: Dominated by $1/f$ noise at low frequencies. See Figs. 135 and 140.

Time constant: Can be varied in manufacturing. Typical values are 0.2 ms at 295 K, 2 to 5 ms at 193 and 77 K. See Fig. 139.

Sensitive area: Typical sizes are square elements with dimensions of 0.5, 1, 2, and 5 mm on a side.

TABLE 4 PbS Performance Characteristics

	Typical operating temperature, K			
	350	273 (ATO)	193 (ITO)	77 (LTO)
Sensitivity	†	Figs. 132, 138	Figs. 133, 136, 138	Figs. 134, 138
$D^*(\lambda_{max})/D^*$ (500 K)		105	55	17
Noise, V/Hz$^{1/2}$		Fig. 140	Fig. 140	Fig. 140
Dark resistance, MΩ/sq	<0.3	<2	<10	<20
Time constant, μs‡	50	100–500	5000	3000

†At 350 K, cuttoff wavelength moves into ~2.4 μm, with $D^*(\lambda_{max}) \approx 10^{10}$ Jones.
‡These are typical values; the time constant can be adjusted over two orders of magnitude in fabrication, but D^* is affected.

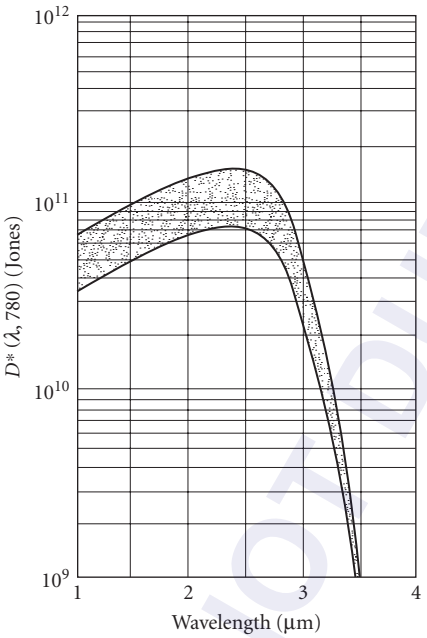

FIGURE 132 Range of spectral detectivities for PbS (ATO) at 295 K; 2π FOV, 295-K background. (*Santa Barbara Research Center.*)

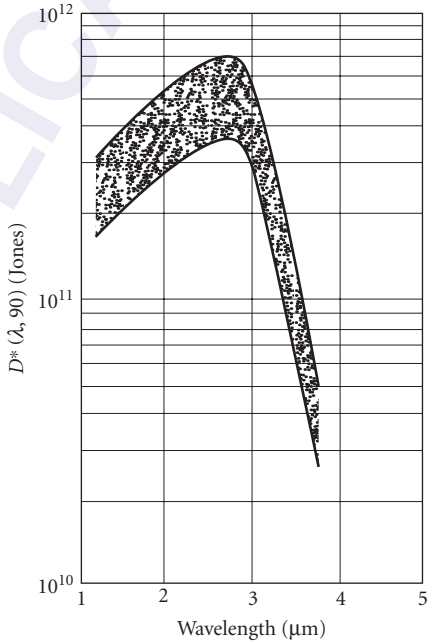

FIGURE 133 Range of spectral detectivities for PbS (ITO) at 193 K; 2π FOV, 295-K background. (*Santa Barbara Research Center.*)

Capacitance: <1 pF (limited by mounting configuration).

Recommended circuit: Standard photoconductor.

Stability: Exposure to visible and/or UV radiation can induce instability and drift. Stability will recover with storage in the dark, or by baking.

Sensitivity profile: Uniform within 10 percent.

Linearity: Excellent over broad range 10^{-8} to 10^{-3} W.

Manufacturers: Alpha Omega Instruments, Cal-Sensors, Edmund Optics, Electro-Optical Systems, Hamamatsu, New England Photoconductor, Teledyne Judson Technologies, OptoElectronics, Orielt.

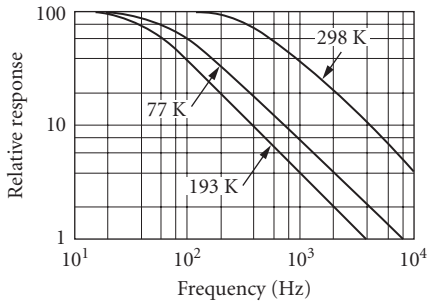

FIGURE 139 Example of signal versus frequency for PbS detectors. (*Santa Barbara Research Center.*)

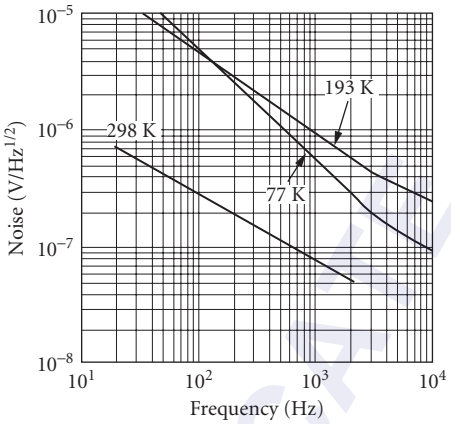

FIGURE 140 Example of noise versus frequency for PbS detectors. (*Santa Barbara Research Center.*)

InAs (Photovoltaic) InAs detectors are single-crystal, intrinsic, direct-bandgap photovoltaic devices for use in the 1- to 4-μm region (spectral cutoff varies with temperature). At room temperautre, InAs provides good sensitivity and submicrosecond response times. At 195 K, InAs performance equals or betters the sensitivity of any other detector in the 1 to 3.5-μm region. Devices with sapphire immersion lenses are available to increase signal responsivity for operation at higher temperatures where the detector is thermal-noise-limited. Compared to PbS and PbSe detectors, InAs has very little low frequency (1/f) noise if operated in the photovoltaic mode.

Sensitivity: D^*(peak) varies from 1.2×10^9 Jones at 295 K to 6×10^{11} Jones at 77 K. See Fig. 141.

Quantum efficiency: Maximum of about 75 percent without antireflection coating.

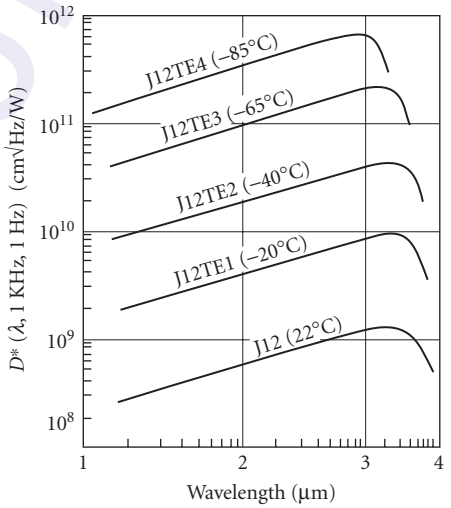

FIGURE 141 D^* versus wavelength for InAs detector operating at temperatures ranging between 77 K and 295 K. (*Teledyne Judson Technologies, 2008.*)

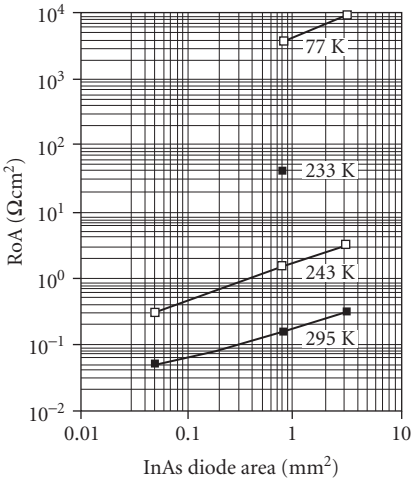

FIGURE 142 R_0A of InAs photodiodes shown as a function of diode area. Lower impedance per unit area for smaller devices indicates that these devices are surface-leakage-limited. (*Santa Barbara Research Center.*)

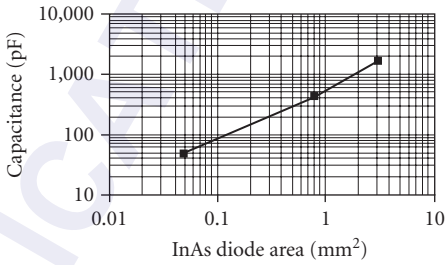

FIGURE 143 Capacitance of InAs photodiodes shown as a function of diode area. Capacitance will not change appreciably with temperature. (*Teledyne Judson Technologies, 2008.*)

Noise: Low impedance tends to make preamplifier noise dominate at room temperature; background limited (for 300 K background) at operating temperatures below 200 K.

Time constant: Less than 0.5 μs at all temperatures when low values of load resistor are used to reduce the RC time constant.

Responsivity: 0.5 to 1.25 A/W at peak.

Dynamic resistance: See Fig. 142.

Diode capacitance: See Fig. 143.

Sensitive area: Standard sizes 0.25 to 2-mm diameters.

Operating temperatures: 77 to 300 K.

Linearity: Anticipated to be very good over many decades.

Sensitivity profile: ±15 percent.

Recommended circuits:

Open circuit: PV InAs detectors with areas less than 2×10^{-2} cm require no bias when operated and can be connected directly into the input stage of amplifier (capacitor ensures elimination of dc bias from amplifier) (Fig. 144*a*).

Transformer: Useful when using InAs at zero bias, particularly at room temperature where diode impedance is low (Fig. 144*b*).

Reversed bias: At temperatures greater than 225 K considerable gain in impedance and responsivity is achieved by reverse-biasing (Fig. 144*c*).

Fast response: To utilize the short intrinsic time constant, it is sometimes necessary to load the detector to lower the RC of the overall circuit (reverse bias will also lower detector capacitance) (Fig. 144*d*).

Manufacturers: Electro-Optical Systems, Hamamatsu, Teledyne Judson Technologies.

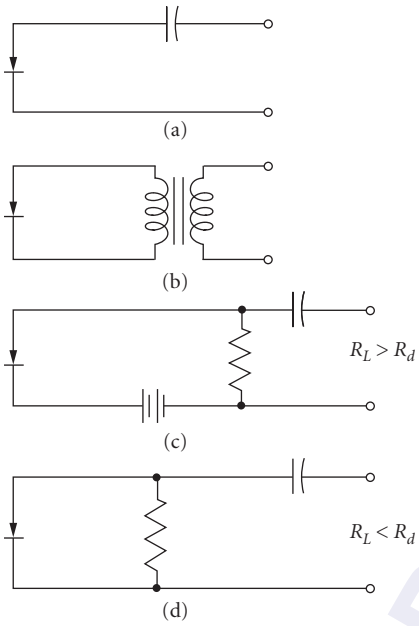

FIGURE 144 Recommended circuits for InAs detectors: (*a*) open circuit, (*b*) transformer, (*c*) reversed bias, (*d*) fast response.

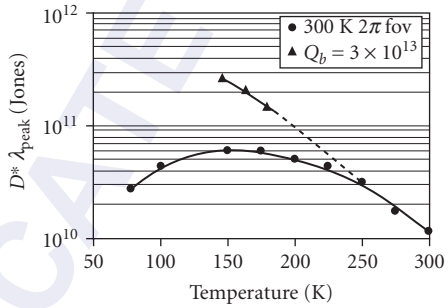

FIGURE 145 D^* of PbSe as a function of a function of temperature for two background flux conditions: high background of 2π field of view and reduced background of 3×10^{13} phtons/cm^2/s. D^* at the higher background flux reaches a maximum around 160 K because the background noise increases at lower temperatures due to the increase in long-wavelength spectral reponse of the detector. (*Santa Barbara Research Center.*)

PbSe Lead selenide is an intrinsic, thin-film photoconductor, whose long-wavelength spectral response and speed of response exceeds that of PbS. At room temperature, PbSe has peak D^* which can exceed 1×10^{10} Jones with a spectral cutoff out to 4.4 μm. At liquid-nitrogen temperature, InSb offers twice the D^*, largely because PbSe offers response out to 7 μm at 77 K, considerably longer than InSb. However, for intermediate temperatures, from 180 K to room temperature, PbSe offers competitive D^* combined with moderately fast response.[26] PbSe technology has made a significant advance in the past decade in some vendors being able to reproducibly make high-performance detectors.

Sensitivity: $D^* \approx 1 \times 10^{10}$ Jones at 300 K, increases with cooling (see Figs. 137 and 145). D^* is limited by $1/f$ noise at low frequencies (see Fig. 146).

Response: Figure 147 shows responsivity in amperes per watt for a high-quality detector with a length of 0.016 cm and width of 0. 024 cm. Responsivity in volts per watt is obtained by multiplying A/W data by resistance (see Fig. 148). Responsivity will vary inversely with detector length (see Figs. 149 and 150).

Noise: Figure 151 shows the noise as a function of temperature for a detector with a length of 0.016 cm and width of 0. 024 cm. Noise as a function of frequency is shown in Fig. 152.

Resistance: Figure 148 shows the resistance as a function of temperature for a detector with a length of 0.016 cm and width of 0. 024 cm.

Capacitance: 1 pF (limited by mounting configuration).

Time constant: See Figs. 153 and 154. Time constant will be longer when detector is operated in reduced background flux condition.

Stability: Exposure to visible and/or UV radiation can induce instability and drift. Stability will recover with storage in the dark at room temperature.

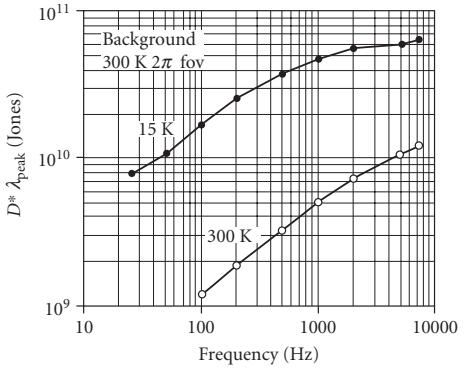

FIGURE 146 D^* of PbSe as a function of frequency for two temperatures. PbSe has considerable 1/f noise which reduces D^* at lower frequencies. (*Santa Barbara Research Center.*)

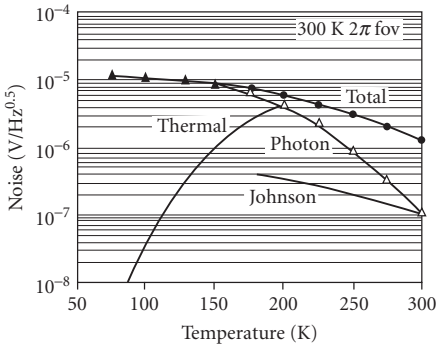

FIGURE 151 Noise voltage (per square root of bandwidth) of PbSe thin-film photoconductive detectors as a function of temperature for a high back ground flux level. Photon noise is dominant below 200 K. Thermal noise is dominant at higher temperatures. Total noise levels are well above typical preamplifier noise. (*Santa Barbara Research Center.*)

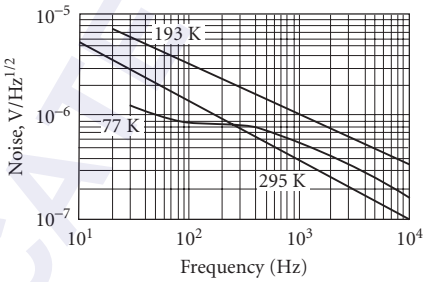

FIGURE 152 Example of noise versus frequency for PbSe detectors (ATO, ITO and LTO types) (1 × 1 mm). (*Santa Barbara Research Center.*)

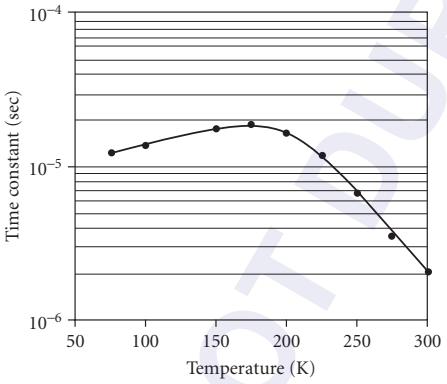

FIGURE 153 Time constant of PbSe thin-film photoconductive detectors as a function of temperature. (*Santa Barbara Research Center.*)

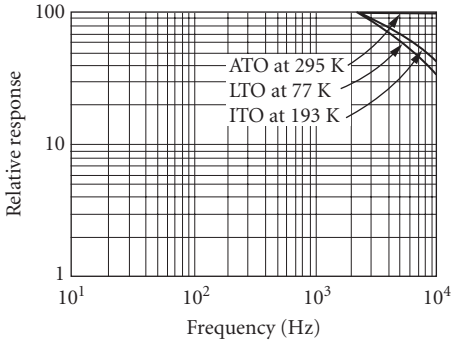

FIGURE 154 Example of signal versus frequency for PbSe detectors (ATO, ITO and LTO). (*Santa Barbara Research Center.*)

Recommended circuit: Standard photoconductor.

Operating temperature: 77 to 300 K.

Manufacturers: Cal-Sensors, Edmund Optics, Electro-Optical Systems, Hamamatsu

InSb Historically, indium antimonide material has been used for at least four different radiation detector types, two of which, the photoconductive and photoelectromagnetic types, are no longer widely used. We discuss here the intrinsic photovoltaic device. [The very far infrared bolometer (InSb bolometer) was previously discussed in Sec. 24.7.

At 77 K, InSb photodiodes offer background limited sensitivity at medium-to-high background flux conditions in the 1- to 5.5-μm spectral range. At lower temperatures, they provide sensitive detectors at low background flux levels such as in astronomy applications, but with a slightly shortened long-wavelength cutoff. Operation is possible up to as much as 145 K, but because the spectral

response increases with increasing temperature, the detector impedance drops rapidly leading to significant thermal noise.

Sensitivity: Spectral response out to 5.5 μm at 77 K (see Fig. 155). D^* 1×10^{11} Jones, increases with reduced background flux (narrow field of view and/or cold filtering) as illustrated in Fig. 156.

Quantum efficiency: ~ 60–70 percent without antireflection coating. >90 percent with antireflection coating.

Noise: Background current limited over wide range of background flux at 77 K (see Fig. 157).

Time constant: <1 μs.

Responsivity: 3 A/W at 5 μm without antireflection coating.

Noise equivalent power (*NEP*): Frequency dependence is shown in Fig. 158 for three detector sizes.

Capacitance: Typically 0.05 F/cm^2.

Impedance: Top-grade detectors have 1–5 × 10^6 Ωcm^2 R_0A product at 77 K, at zero bias, and without background flux.

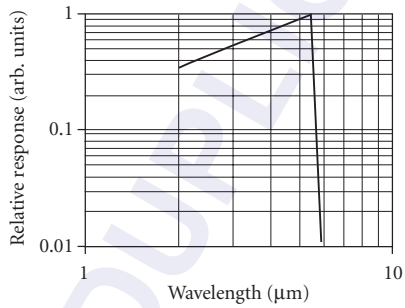

FIGURE 155 Relative spectral response per watt of an InSb photodiode without antireflection coating. the direct bandgap results in a sharp spectral cutoff. (*Santa Barbara Research Center.*)

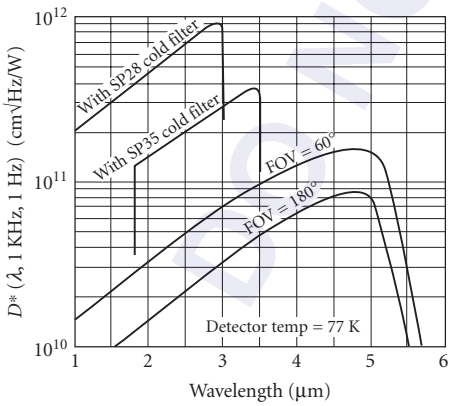

FIGURE 156 D^* as a function of wavelength for an InSb detector operating at 77 K. (*Teledyne Judson Technologies, 2008.*)

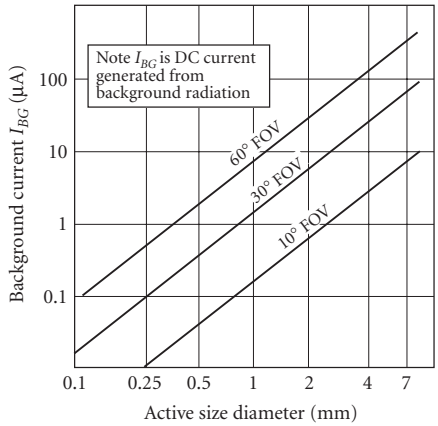

FIGURE 157 Background current as a function of photodiode area for InSb detectors operating at 77 K, shown at three values of the detector field of view. (*Teledyne Judson Technologies, 2008.*)

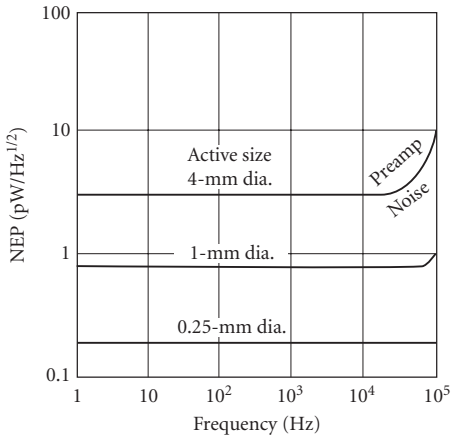

FIGURE 158 NEP as a function of frequency for three sizes of InSb photodiodes. (*Teledyne Judson Technologies, 2008.*)

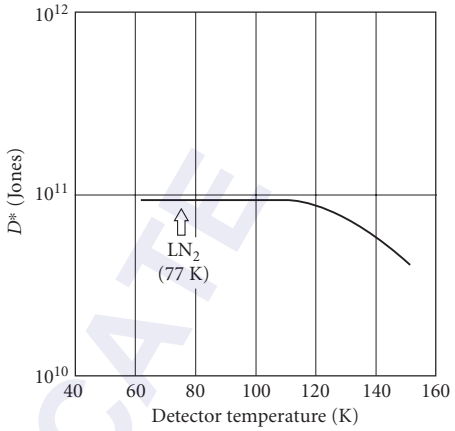

FIGURE 159 InSb photodiode D^* as a function of operating temperature between 77 K and 150 K, for a 2π (180°) FOV. (*Teledyne Judson Technologies, 2008.*)

Sensitive area: 0.04 × 0.04-mm square to 1 × 5-mm rectangle; 0.25 to 10-mm diameter.

Operating temperature: Normally 77 K; InSb can be used up to approximately 145 K (see Fig. 159).

Linearity: Linear to ~1-mW/cm^2 flux.

Sensitivity profile: ±15 percent or better.

Stability: Devices from some vendors are subject to "flashing," where exposure to visible or UV flux causes a change in the insulating surface charge thereby causing a change in the diode impedance. The detector typically recovers at room temperature.

Recommended circuit: Same as for Si and Ge photodiodes; zero or reverse bias in combination with a load resistor and low-noise preamplifier. Low-impedance load resistor can be used for obtaining fast response, with consequences of reduced sensitivity.

Manufacturers: L3 Cincinnati Electronics, Edinburgh Instruments, New England Photoconductor, Teledyne Judson Technologies, Electro-Optical Systems, Hamamatsu, Infrared Associates.

Ge:Au Gold-doped germanium detectors are relatively fast single-crystal p-type impurity-doped photoconductors for the 2- to 9-μm region. Although not the most sensitive detector anywhere in its range of spectral sensitivity, Ge:Au offers respectable sensitivity over a broad spectral region using liquid nitrogen cooling. Sensitivity can be improved by a factor of 2.5 by operating at T <65 K (pumped liquid nitrogen or other cryogen). At these temperatures, Ge:Au becomes background limited.

Sensitivity: See Figs. 160 to 163.

Quantum efficiency: Dependent on wavelength, detector geometry (absorption thickness), antireflection coating, and enclosure (integration chamber can increase absorption). $D_{\lambda pk}/D^*_{500\ K} = 2.7$ (see Fig. 164).

Noise: See Fig. 165.

Time constant: <50 ns with full D^* [shorter response times (<2 ns) can be tailored by heavy concentration of compensating (n-type) dopant and suitable bias circuit (see circuit discussion to follow). Heavy compensation increases resistance, and hence the incoherent signal-to-noise ratio becomes limited by the thermal noise of the load (typically a factor of 2 degradation in the signal-to-noise ratio). Quantum efficiency, however, is not significantly altered, so that a high compensation concentration does not hurt the coherent-detection signal-to-noise ratio].

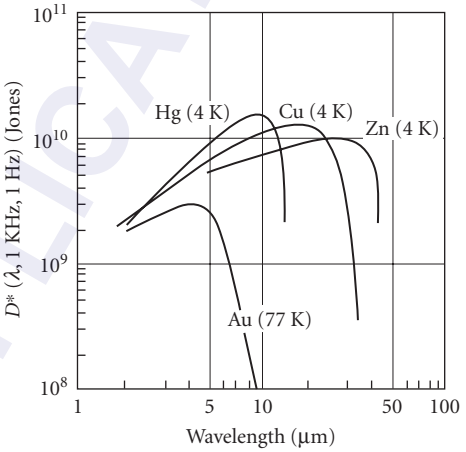

FIGURE 161 D^* as a function of wavelength for extrinsic germanium detectors doped with Au, Hg, Cu, and Zn, for a 300-K 2π (180°) FOV background flux. (*EG&G Judson, Infrared Detectors, 1994.*)

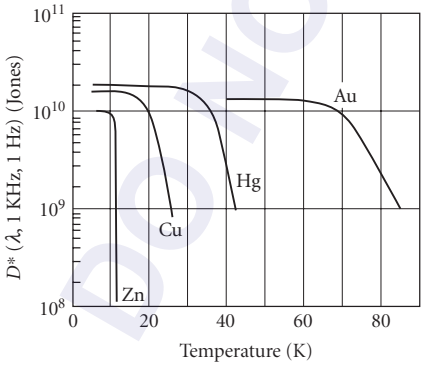

FIGURE 162 D^* as a function of operating temperature for extrinsic germanium detectors doped with Au, Hg, Cu, and Zn for a 300-K 2π (180°) FOV background flux. (*EG&G Judson, Infrared Detectors, 1994.*)

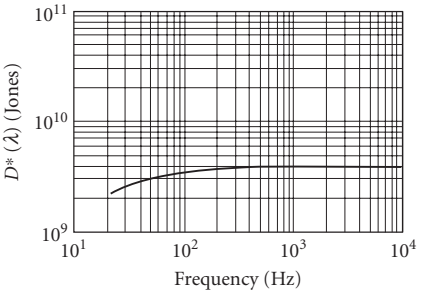

FIGURE 163 Typical D^* versus frequency (T = 77 K). (*Santa Barbara Research Center.*)

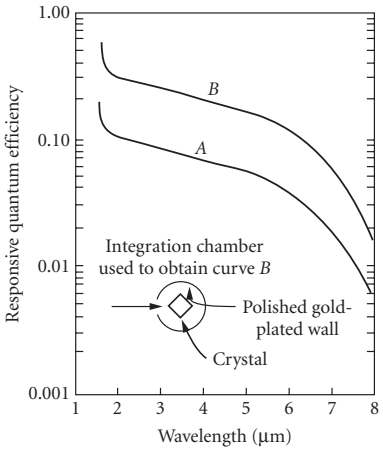

FIGURE 164 Quantum efficiency versus λ for Ge:Au (T = 78 K). (*Santa Barbara Research Center, internal report.*)

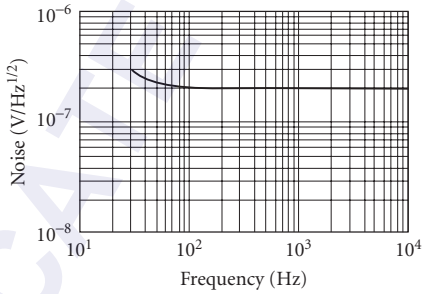

FIGURE 165 Typical noise spectrum for Ge:Au (T = 77 K, A = 1 × 1 mm). (*Santa Barbara Research Center.*)

Responsivity: Dependent upon bias and geometry, typical values are 0.1 to 0.2 A/W at 77 K. Multiply by detector resistance to get V/W.

Dark resistance: Varies with background flux and effective quantum efficiency (see previous quantum efficiency discussion), range may be 20 kΩ to 5 MΩ, or much greater under very low background flux conditions if adequately cooled to limit thermally activated conductivity. (Also see previous time-constant discussion.)

Capacitance: Depends on device geometry and mounting, typically <1 pF.

Sensitive area: 1 to 5-mm diameter standard.

Operating temperature: < 85 K (normally 77 K, but see Fig. 162).

Recommended circuit: Standard photoconductive. See Fig. 166.

Manufacturers: No suppliers are presently known.

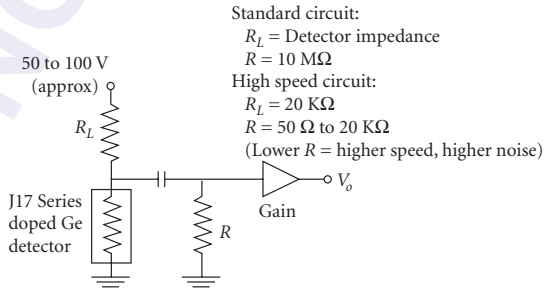

FIGURE 166 Basic operating circuit for extrinsic germanium detectors doped with Au, Hg, Cu, and Zn, for a 300-K 2π (180°) FOV high background flux. If the detector is operated in very low background flux conditions, the detector impedance can become very high. Cooled JFET ($T > \approx 50$ K) or PMOS buffer amplifiers can be helpful in impedance matching under these conditions. (*EG&G Judson, Infrared Detectors, 1994.*)

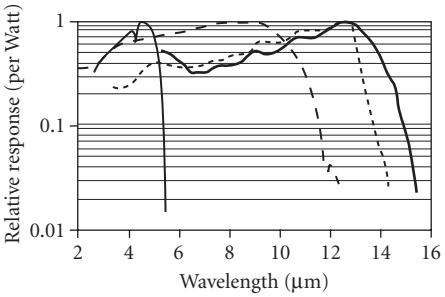

FIGURE 167 Relative spectral response per watt at 80 K for photoconductive HgCdTe detectors with antireflection coating. The curves are normalized to unity at peak value. The spectral cutoff can be adjusted by varying the ratio of HgTe to CdTe in the alloy. (*Santa Barbara Research Center.*)

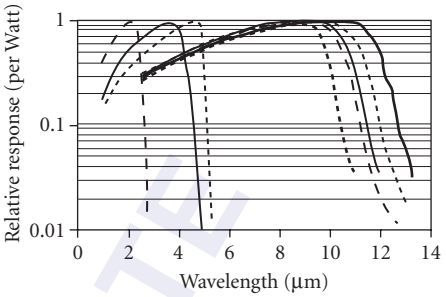

FIGURE 168 Relative spectral response per watt at 80 K for photovoltaic HgCdTe detectors without antireflection coating. The curves are normalized to unity at peak value. The spectral cutoff can be adjusted by varying the ratio of HgTe to CdTe in the alloy. (*Santa Barbara Research Center.*)

HgCdTe, HgZnTe, HgMnTe, etc. Mercury cadmium telluride is a direct-bandgap compound alloy semiconductor, made of chemical group II and VI elements, whose peak sensitivity at a particular temperature can be adjusted from 1 to 30 μm by varying the ratio of HgTe to CdTe (see Figs. 167 and 168). In addition to HgCdTe, other combinations of chemical groups II and VI elements can be used to produce similar variable spectral cutoff compound alloys, including HgZnTe, HgMnTe, HgCdZnTe, etc. For almost all purposes, HgCdTe will be as good as any other II-VI alloy detector, so we will speak here about it exclusively, but provide some data from the other alloys noted above. Both photoconductive (PC) and photovoltaic (PV) HgCdTe detectors are available for background-limited, high-speed, intrinsic photon detection in the SWIR, MWIR, and LWIR regions. Photoconductive devices with VLWIR response out to 25 μm are also available. HgCdTe detectors can be used at room temperature, with TE cooling, and at 77 K and lower temperatures. Sensitivity generally increases with cooling, depending upon the spectral cutoff and background flux. MWIR, LWIR, and VLWIR spectral range devices are generally operated at 77 K or lower temperature for maximum sensitivity, depending upon the background flux. The PC mode is advantageous when cooling is limited, since the thermal noise of a photoconductor increases less rapidly than a photodiode as the temperature is raised. Photoconductive devices with response out to 25 μm can be usefully operated at liquid nitrogen temperature and are popular for IR spectroscopy for this reason.

HgCdTe photoconductors are fabricated from thin (≈10-μm) single-crystal slices or epitaxial layers with metal contacts at each end of the element (see Fig. 8). They are low-impedance devices with 15 to 2000 Ω/square, depending upon the alloy composition, carrier concentration, operating temperature, background flux, and surface treatment. Photoconductor time constants at 77 K may be ≈ 2 μs for devices having a 12-μm cutoff, with longer time constants for shorter cutoffs, and shorter time constants for higher operating temperatures. In the case of small detector elements, the time constant may be reduced with increasing bias voltage because photoexcited carriers will be transported to the electrical contacts where they recombine. The spectral noise characteristics of PC HgCdTe typically exhibit $1/f$ noise out to a range of 50 Hz to 1 kHz or more, the value depending upon the detector quality, long-wavelength response, operating temperature, and background flux. White noise levels range from less than 1 nV/√Hz (where preamplifier noise may then dominate), up to 20 nV/√Hz, depending upon detector quality, size, geometry, applied bias, temperature, and alloy composition. Photoconductive HgCdTe detectors are typically antireflection coated with a quarter-wave ZnS film, giving a peak quantum efficiency in the range of 85 to 90 percent, although this figure is only indirectly measured because the PC gain can be much greater than unity. Without antireflection coating, the quantum efficiency is typically 70 percent, limited by the optical index of ≈ 4.

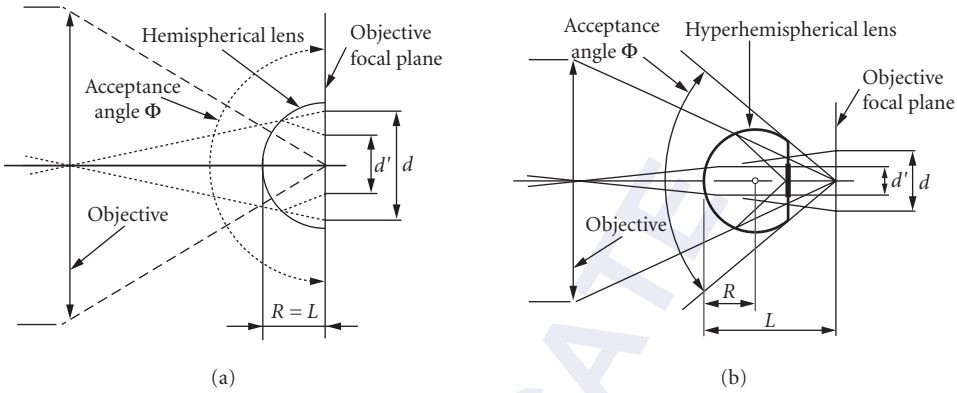

FIGURE 169 Schematic of an optically immersed HgCdZnTe detector with (*a*) hemispherical lens and (*b*) hyperhemispherical lens. Dimensions are summarized in Table 5. (*Vigo Systems.*)

TABLE 5 Summary of the Dimensions Depicted in Fig. 169, and Their Impact on D^* (Vigo Systems)

Parameter	Hemisphere	Hyperhemisphere
Distance, L	$L = R$	$L = R(n + 1)$
d/d'	n	n^2
$D^*_{imm}/D^*_{non\text{-}imm}$	n	n^2
Acceptance angle, Φ	$\Phi = 180°$	$\Phi = 2 \arcsin(1/n)$
F/#	0.5	1.55

n = index of refraction (approx. 3.3 for GaAs and 2.7 for CdTe)

A class of HgCdTe detectors is offered for detection at TE-cooled and room temperature which are optically "immersed" with a hemispherical or hyperhemispherical lens of Ge, CdTe, GaAs, or other high-index material (see Fig. 169 and Table 5). The lens increases the effective area of the detector without increasing the detector noise, provided the noise is dominated by thermal rather than photon noise as is the case for minimal cooling. The lens must be in intimate contact with the detector surface (<<1 μm spacing) to avoid total internal reflection of off-axis rays at the lens-detector interface. Immersed detectors offer up to a factor of n^2 (where n is the optical index) increased detector signal, which can mean an increase in D^* by the same factor for a thermal-noise-limited device. Operation of LWIR PC detectors at TE-cooled and room temperature is generally accompanied by increased $1/f$ noise which dominates out to higher frequencies.

Photovoltaic HgCdTe detectors ideally offer $\sqrt{2}$ higher D^* than detectors operating in the PC mode. Diodes are made in both n^+p and p^+n polarities, depending upon the manufacturer's capabilities. The R_0A product of HgCdTe photodiodes varies significantly with temperature, spectral cutoff, and device quality. It also varies with the amount of background flux incident on the device. The R_0A product defines the maximum D^* in the limit of reduced background flux (see Fig. 170 and Fig. 19). In addition to theoretically higher D^*, high-quality PV HgCdTe detectors have lower $1/f$ noise than PC HgCdTe devices, with $1/f$ knee frequencies as low as 1 Hz or less. However, the noise of PV detectors increases more rapidly with increasing temperature than for PC detectors, making photodiodes less attractive for applications where cooling is limited. Photodiodes of high quality are more difficult to make than good photoconductors and can be expected to warrant a premium price. Antireflection coating is available from some diode producers, but is not routinely offered.

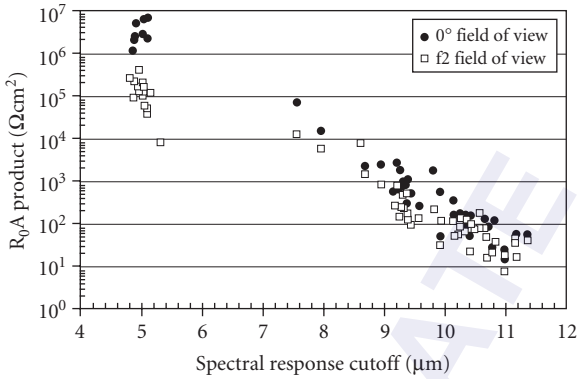

FIGURE 170 R_0A product "trendline" for small (25 × 25 to 100 × 100 μm) HgCdTe photodiodes at 77 K. Data is shown for devices with zero background flux (0° FOV) and with an F/2 field of view (29°) of a 300-K background. For 5-μm spectral cutoff material, the R_0A product is higher at 0° FOV by about an order of magnitude, compared with an F/2 background. At 10 μm, there is less of a difference between the two background conditions. Note that the R_0A product will generally be somewhat lower for larger area diodes.

Both PC and PV HgCdTe detectors are useful for infrared heterodyne detection. When sufficient local oscillator power is available, detector cooling becomes less important, since photon noise can dominate thermal noise at comparatively higher temperatures. Other things being equal, the photovoltaic detector has √2 sensitivity (signal-to-noise voltage) advantage over the photoconductor. For 10.6-μm heterodyne detection, 0.1 × 0.1-mm HgCdTe *pin* photodiodes with sensitivity near the quantum limit of ≈ 2×10^{-20} W/ Hz are available with bandwidths up to several gigahertz. Ordinary photodiodes of the same area have bandwidths of several hundred megahertz. Photoconductors make better 10.6-μm heterodyne detectors when cooling is limited to TE-cooled temperatures of 180 K up to room temperature. At 180 K, TE-cooled photoconductors offer bandwidths of 50 to 100 MHz and heterodyne NEPs of 1 to 2×10^{-19} W/Hz. At room temperature, the NEP at 10.6 μm is limited to about 1×10^{-16} W/Hz. Immersion does not improve the performance of minimally cooled heterodyne detectors, since optical gain is already provided by the local oscillator.

Photoconductive HgCdTe

Sensitivity: Adjustable by varying alloy composition (see Figs. 167, 171 to 174).

Dark resistance: 15 to 2000 Ω/sq depending upon temperature, spectral cutoff, and surface passivation.

Responsivity: Varies with spectral cutoff, temperature, detector resistance, element length, and bias voltage or power. See Eq. (21) and Fig. 175 for detector elements with 50 × 50-μm dimensions.

Noise: *1/f* noise is dominant at frequencies below 50 to 1000 Hz for LWIR detectors at 77 K (greater for LWIR at room temperature or TE-cooled). Generation-recombination (thermal or photon) white noise is present beyond the *1/f* region at a level of less than 10^{-9} V/√Hz to 2×10^{-8} V/√Hz, depending upon spectral cutoff, background flux, responsivity, bias, and operating temperature. Noise and signal rolloff at high frequency is determined by the time constant. See Fig. 176 for an example of the noise spectrum of an LWIR detector at 77 K.

Operating temperature: 77 K and below to 300 K and above for short spectral cutoffs and/or with significant D^* reduction for operation at higher temperatures. Detector immersion can increase D^* at elevated temperatures where thermal noise is dominate.

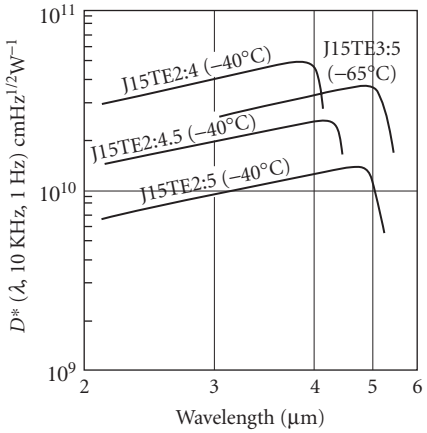

FIGURE 171 Typical D^* as a function of wavelength for a variety of MWIR HgCdTe photoconductors with thermoelectric cooling. (*Teledyne Judson Technologies.*)

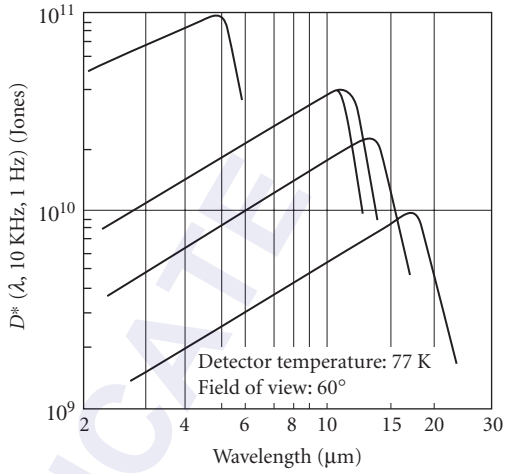

FIGURE 172 Typical D^* as a function of wavelength for a variety of LWIR and VLWIR HgCdTe photoconductors at 77 K. (*Teledyne Judson Technologies.*)

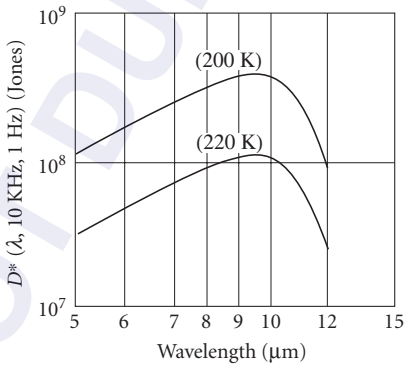

FIGURE 173 Typical D^* as a function of wavelength for LWIR HgCdTe photoconductors at 200 and 220 K. These units are cooled with three- or four-stage thermoelectric coolers. (*Teledyne Judson Technologies.*)

Linearity: At 77 K linearity begins to degrade at photon flux levels above ~ 10^{-3} W/cm^2. At 200 K linearity begins to degrade at photon flux levels above ~1 W/cm^2.

Sensitive area: 0. 025 to 4-mm linear dimensions.

Quantum efficiency: Typically >70 percent, 85 to 90 percent with antireflection coating.

Capacitance: Low, limited by mounting configuration.

Time constant: 1–2 μs for LWIR at 77 K (see Fig. 176), depends on spectral cutoff, temperature, doping, and bias.

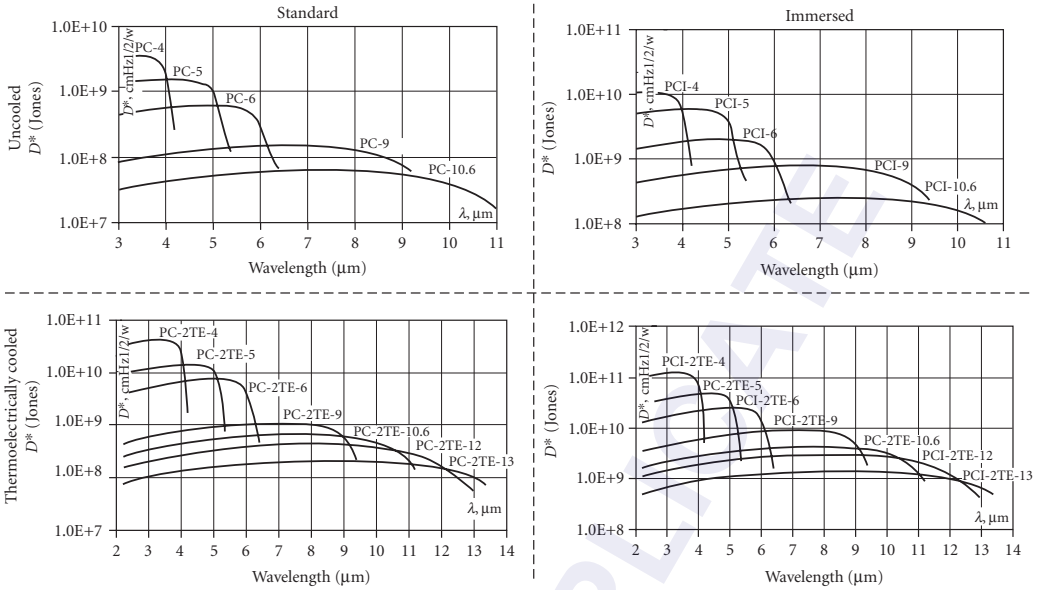

FIGURE 174 D^* for photoconductive HgCdTe detectors as a function of wavelength: *upper left*—ambient temperature operation; *upper right*—ambient temperature operation and immersed; *lower left*—thermoelectrically cooled; *lower right*—thermoelectrically cooled and immersed. (*Vigo Systems.*)

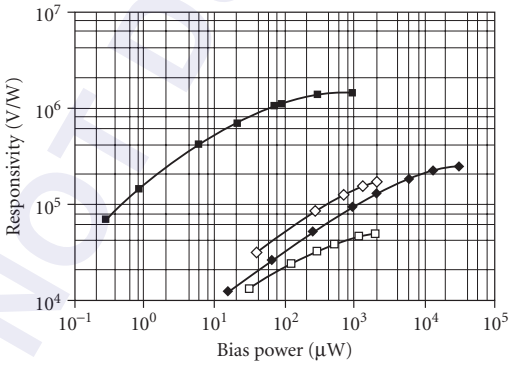

FIGURE 175 Range of peak responsivities for 12-μm cutoff HgCdTe photoconductors at 80 K. These devices have nominal dimensions of 50 × 50 μm, and resistance of 50 to 150 Ω/square. (*Santa Barbara Research Center.*)

Circuit: Standard photoconductive.

Manufacturers: Belov Technology, Boston Electronics, Hamamatsu, Infrared Associates, Kolmar Technologies, Oriel, Teledyne Judson Technologies, Vigo Systems.

Photovoltaic HgCdTe

Sensitivity: Adjustable by varying alloy composition (see Figs. 168, 170, 177, and 178). Also compare Fig. 170 with Fig. 19 for an estimate of the extent to which D^* may increase (up to the R_0A or shunt resistance limit) as the background flux is reduced.

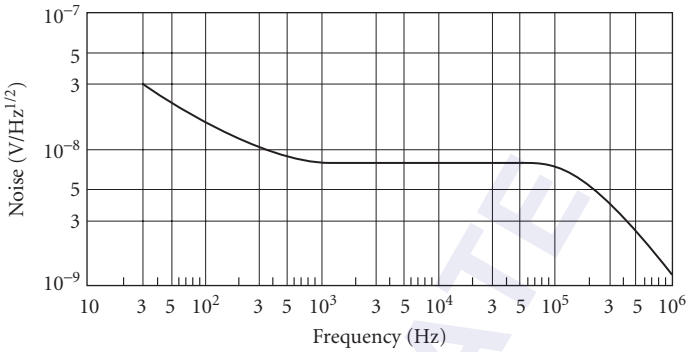

FIGURE 176 Variation of noise with frequency for photoconductive HgCdTe at 77 K. (*GEC Marconi Infrared Ltd.*)

Time constant: Depends on diode capacitance (area); 10 to 20 ns without bias; 0.5 to 3 ns with reverse bias (some trade-off of sensitivity). Low-capacitance *pin* devices with response out to several gigahertz (0.05 to 0.2-ns time constant) are also available for 10.6-μm CO_2 laser heterodyne detection.

Resistance: Refer to Fig. 170 for the R_0A product at zero bias corresponding to the detector cutoff wavelength (this figure shows very high quality diode impedances) and divide by the diode area. Large-area diodes will have somewhat lower R_0A product than shown in this figure. R_0A varies somewhat with background flux as can be noted from Fig. 170.

Operating temperature: Depends on spectral cutoff; 77 K and lower for LWIR and VLWIR detectors, up to room temperature for SWIR devices. Optical immersion and/or TE cooling will boost the performance for all spectral ranges compared with operation at ambient temperature—see Fig. 178.

Noise: High-quality devices may have flat noise response from 1 Hz out to the high-frequency limit of the time constant. $1/f$ noise may be present in lower quality devices and will increase with reverse bias.

Quantum efficiency: >50 percent (60–75 percent typical) without antireflection coating. Higher with antireflection coating.

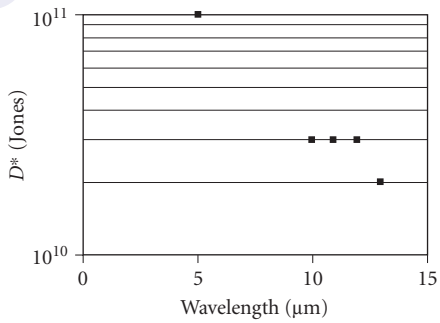

FIGURE 177 D^* specifications for small (50 × 50 to 250 × 250 μm) HgCdTe photodiodes at 77 K as a function of spectral cutoff. Data is shown for devices with 60° FOV background flux. (*Fermionics, Mercury Cadmium Telluride MWIR and LWIR Detector Series.*)

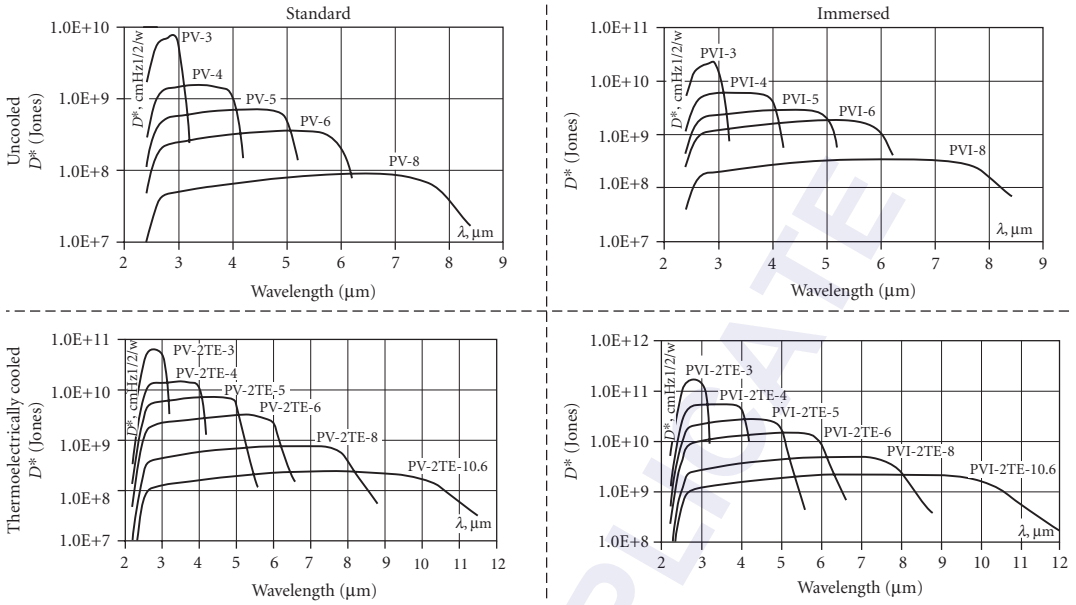

FIGURE 178 D^* for photovoltaic HgCdTe detectors as a function of wavelength: *upper left*—ambient temperature operation; *upper right*—ambient temperature operation and immersed; *lower left*—thermoelectrically cooled; *lower right*—thermoelectrically cooled and immersed. (*Vigo Systems.*)

Sensitive area: 0.0 to 0.25-mm square, 0.5- and 1-mm diameter.

Capacitance: Depends on junction doping, area, and applied bias (very slightly dependent on spectral cutoff). For standard *pn* junction devices at zero bias and 10^{15} cm^{-3} doping, capacitance is approximately 3×10^4 pF/cm. Significantly lower for *pin* junction devices.

Circuit: Standard photovoltaic circuits, reverse-bias operation to enhance speed and zero bias to maximize D^*.

Manufacturers: Boston Electronics, Kolmar Technologies, Oriel, Raytheon Vision Systems, Vigo Systems.

PbSnTe PbSnTe offers an alternative semiconductor alloy system based upon the IV-VI chemical groups to the II-VI (HgCdMnTeSe) groups previously described for fabricating variable spectral cut-off detectors. Only photovoltaic detectors are available in PbSnTe. This technology has an advantage in the ease of material growth and in the fabrication of good quality photodiode junctions. It has a disadvantage in the very high dielectric constant of the material, combined with relatively high doping concentrations giving high-capacitance (comparatively slow) detectors. For low-frequency applications this is not a disadvantage.

Sensitivity: $D^*_{\text{peak}} > 10^{10}$ Jones (see Fig. 179).

Time constant: >50 ns.

Sensitive area: 1×1 mm.

Operating temperature: 77 K.

Circuit: Standard photovoltaic.

Manufacturers: No suppliers are presently known.

Ge:Hg Mercury-doped germanium detectors are fast single-crystal impurity-doped photoconductors, sensitive out to 14 m. Ge:Hg is especially well suited for detection through the 8- to 13-μm

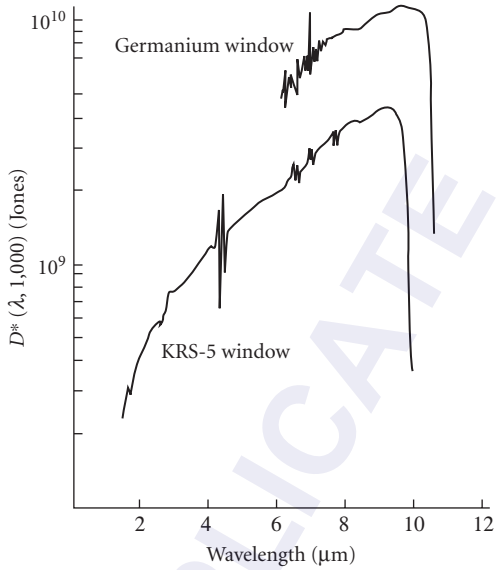

FIGURE 179 Photovoltaic PbSnTe D^* versus wavelength at 77 K and 60° FOV. (*Barnes Engineering Co.*)

atmospheric window and for detection of near-ambient sources. Unfortunately, its operating temperature must be kept less than 40 K, where it becomes 300-K background limited.

Sensitivity: See Figs. 161, 162, 180, and 181.

Quantum efficiency: 25 to 30 percent.

Noise: See Figs. 182 and 183.

Time constant: 100 ns with 50-Ω load for $T < 28$ K and electric fields < 30 V/cm. (Compensated material is available with ~5-ns time constant with a 50-Ω load. Responsivity then is reduced by 5–10× and detectivity is reduced by 2.)

Responsivity: Depends on concentration of compensating impurities, bias, area, and background flux See Figs. 183 to 185, ~10^5 V/W.

Dark resistance: Depends on area and FOV: ~100 kΩ for 180° FOV (see Fig. 186).

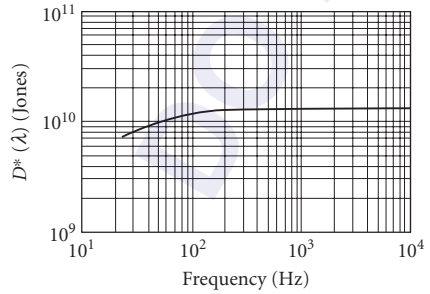

FIGURE 180 Typical D^* versus frequency at 30 K for Ge:Hg; 1 × 1-mm area; essentially constant with temperature. (*Santa Barbara Research Center.*)

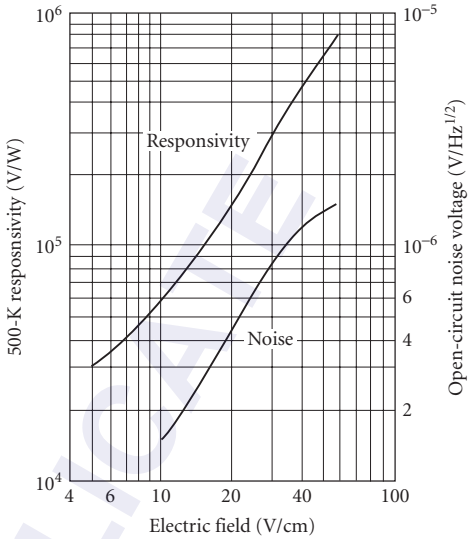

FIGURE 183 Open-circuit responsivity and noise voltage versus electric field for Ge:Hg; $T = 5$ K, 90° FOV; 300-K background; 6×10^{-4} cm^{-4} area; Irtran II window. (*Reprinted by permission of Texas Instruments.*)

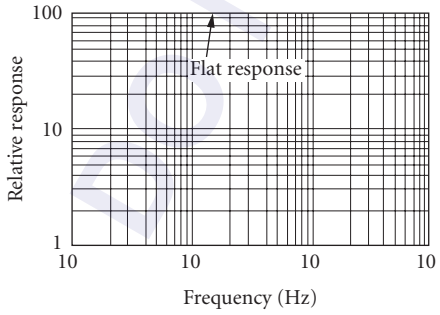

FIGURE 184 Ge:Hg typical relative response versus frequency; $T = 30$ K. (*Santa Barbara Research Center.*)

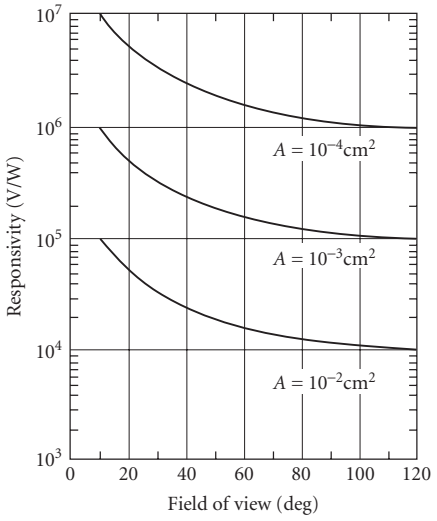

FIGURE 185 Open-circuit responsivity versus FOV for Ge:Hg at 5 K for various detector areas; 300-K background; 500-K blackbody source. (*Reprinted by permission of Texas Instruments.*)

Capacitance: < 1 pF.

Sensitive area: 1 to 5-mm diameter.

Operating temperature: See Fig. 162.

Linearity: 10^{-3} to 10^{-8} W (size dependent).

Sensitivity profile: ±15 percent.

Recommended circuit: Standard photoconductive (see Ge:Au). See Fig. 187 for current-voltage characteristics.

Manufacturer: No suppliers are presently known.

Si:Ga Gallium in silicon forms an acceptor level with a binding energy of ~72 meV which is the basis of an infrared detector with spectral response out to approximately 17 μm, as shown in Fig. 188. The exact spectral cutoff and quantum efficiency will vary slightly with the gallium doping concentration. Gallium-doped silicon requires cooling to 20 K or lower for optimum performance. Background-limited performance associated with a quantum efficiency of about 15 percent is achievable over a wide range of background flux levels, provided the operating temperature is low enough to reduce thermal noise below the photon noise level.

Sensitivity: D^* is given by $D^* = 1.1 \times 10^{10} \times \sqrt{(A\lambda\eta)}/\sqrt{Q}$ (Jones); where A is detector area, λ is the wavelength in micrometers, η is the quantum efficiency, and Q is the background flux in watts.

Responsivity: 0.9 A/W.

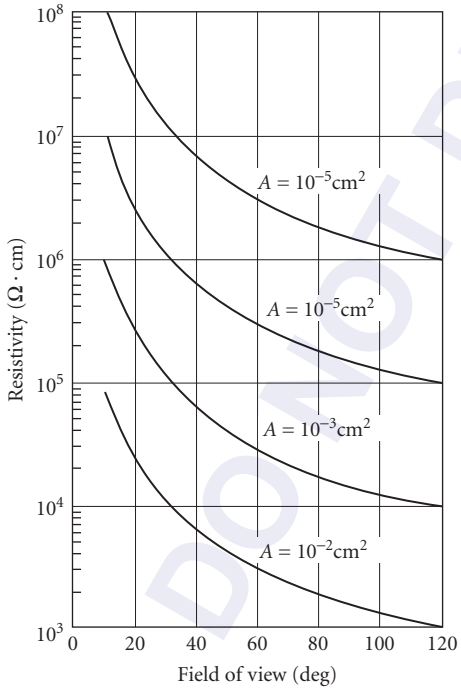

FIGURE 186 Open-circuit resistivity versus FOV for Ge:Hg at 5 K for various detector areas; 300-K background; 500-K blackbody source. (*Reprinted by permission of Texas Instruments.*)

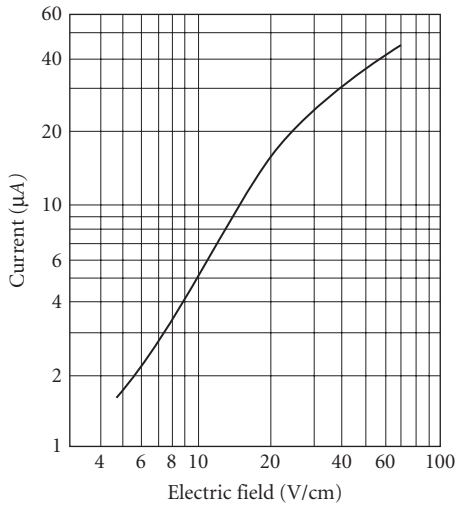

FIGURE 187 Ge:Hg bias current versus electric field; 90° FOV; T = 5 K, 300-K background; 6 × 10^{-4} cm^{-4} area; Irtran II window. (*Reprinted by permission of Texas Instruments.*)

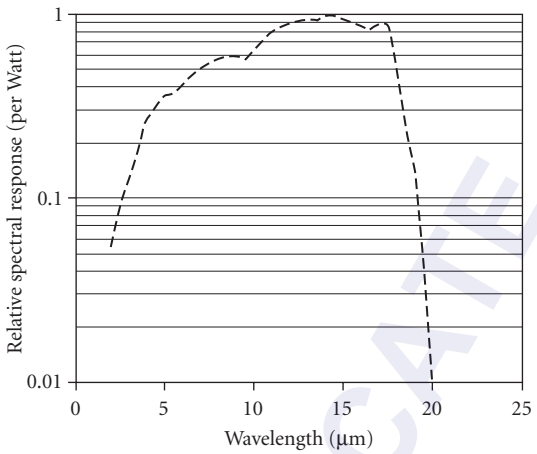

FIGURE 188 Relative spectral response per watt of Si:Ga as a function of wavelength. Data is normalized to unity at the peak response.

Time constant: <1 μs.

Resistance: Depends on background flux and detector bias (similar to Ge:Hg, see Fig. 186).

Capacitance: <1 pF (limited by mounting configuration).

Sensitive area: 0.2 to 2-mm square.

Operating temperature: <20 K.

Recommended circuit: Standard photoconductive.

Manufacturer: Infrared Laboratories.

Si:B Boron in silicon forms an acceptor level with a binding energy of ~45 meV which is the basis of this infrared detector with spectral response out to approximately 30 μm. The exact spectral cutoff and quantum efficiency will vary slightly with the boron-doping concentration. Boron-doped silicon requires cooling to about 15 K or lower for optimum performance. Background-limited performance associated with a quantum efficiency of about 10 percent is achievable over a wide range of background flux levels, provided the operating temperature is low enough to reduce thermal noise below the photon noise level.

Sensitivity: D^* is given by $D^* = 1.1 \times 10^{10} \times \sqrt{(A\lambda\eta)}/\sqrt{Q}$ (Jones); where A is detector area, λ is the wavelength in micrometers, η is the quantum efficiency, and Q is the background flux in watts.

Responsivity: 2 A/W.

Time constant: <1 μs.

Resistance: Depends on background flux and detector bias (similar to Ge:Hg, see Fig. 186).

Capacitance: <1 pF (limited by mounting configuration).

Sensitive area: 0.2 to 2-mm square.

Operating temperature: <15 K.

Recommended circuit: Standard photoconductive (see Ge:Au).

Manufacturer: Infrared Laboratories.

Ge:Cu Copper-doped germanium detectors are fast, single-crystal, impurity-doped photoconductors, with high sensitivity in the broad region 2 to 30 μm. Operating temperature must be maintained below 20 K (ideally <14 K). Ge:Cu is then 300-K background-limited, and response time <50 ns.

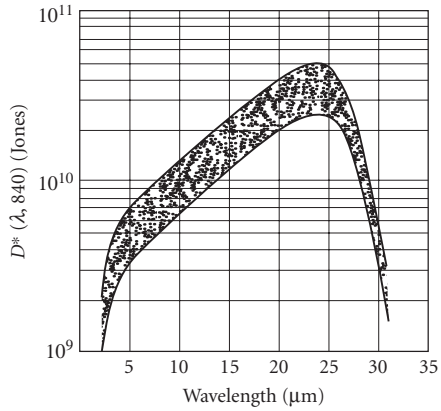

FIGURE 189 Range of spectral detectivities for Ge:Cu; 60° FOV. (*Santa Barbara Research Center.*)

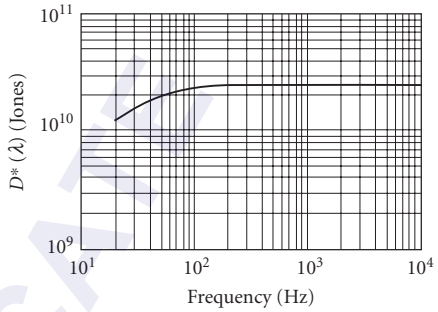

FIGURE 190 Typical D^* vs. frequency for Ge:Cu at 4.2 K. (*Santa Barbara Research Center.*)

Sensitivity: See Figs 161, 162, 189, and 190.

Noise: See Figs. 191 and 192.

Time constant: ~100 ns (can be doped to be faster, ~5 ns). (See discussion of time constant under Ge:Au).

Responsivity: 10^5 V/W (see Figs. 192 to 194).

Dark resistance: Depends on FOV (~100 kΩ for 180° FOV).

Capacitance: <1 pF.

Sensitive area: 1 to 5-mm diameter.

Operating temperature: See Figs. 162 and 194.

Linearity: 10^{-3}–10^{-8} W/cm^2 (depends on size).

Sensitivity profile: ±15 percent.

Stability: Stable in all ambient storage environments tested.

Recommended circuit: See Figs. 166 and 195.

Manufacturer: No suppliers are presently known.

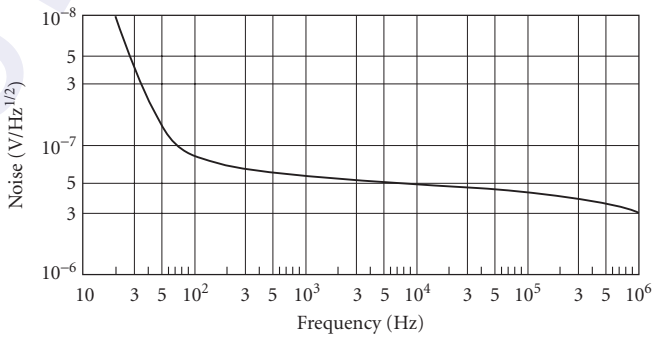

FIGURE 191 Typical noise frequency spectrum for Ge:Cu. (*GEC Marconi Infra Red Ltd.*)

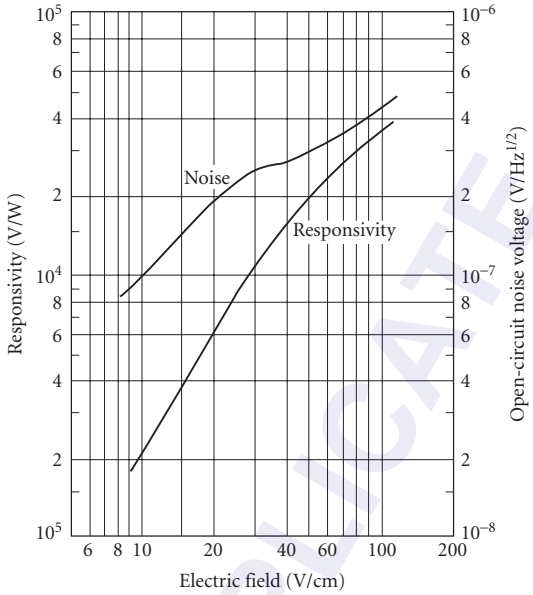

FIGURE 192 Typical noise and responsivity versus biasing field for Ge:Cu; 5 K, 60° FOV; 300-K background, A = 10^{-2} cm^2, 500-K blackbody. (*Reprinted by permission of Texas Instruments.*)

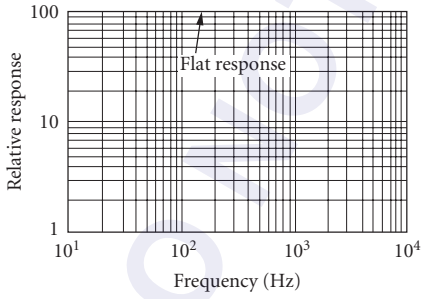

FIGURE 193 Relative response versus frequency for Ge:Cu at 4.2 K. (*Santa Barbara Research Center.*)

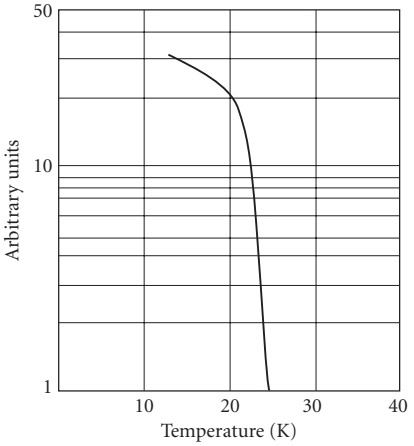

FIGURE 194 Relative responsivity versus temperature for Ge:Cu.

Ge:Zn Very similar to Ge:Cu except that cutoff wavelength moves out to 42 μm and operating temperature should be <10 K. A relatively low field breakdown limits the responsivity.

Sensitivity: See Figs 161, 162, and 196.

Noise: See Fig. 197 and 198.

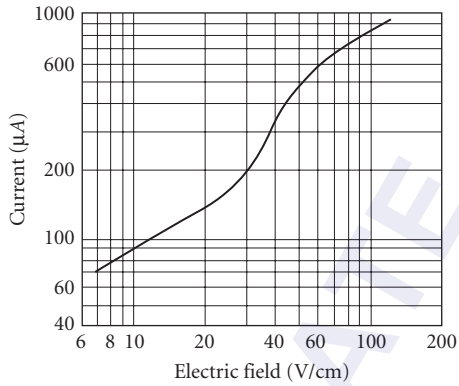

FIGURE 195 Typical current-voltage curve for Ge:Cu, 60° FOV; 300-K background: A = 10^{-2} cm^{-2}. (*Reprinted by permission of Texas Instruments.*)

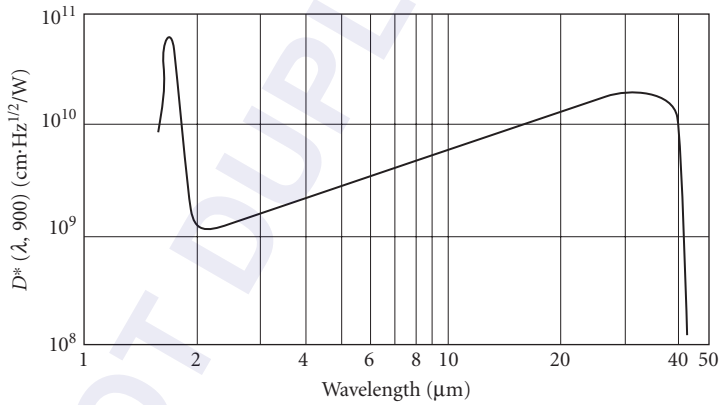

FIGURE 196 D^* versus wavelength for Ge:Zn.

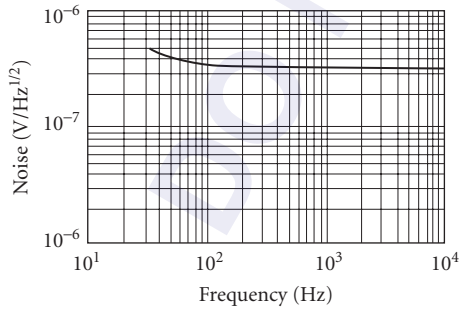

FIGURE 197 Typical noise-frequency spectrum for Ge:Zn at 4.2 K; $A = 1 \times 1$ mm. (*Santa Barbara Research Center.*)

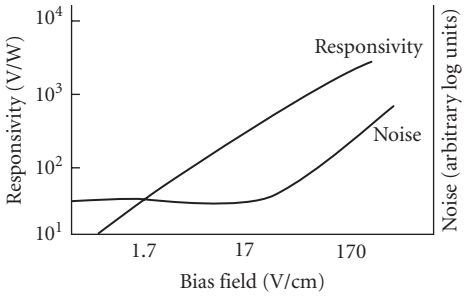

FIGURE 198 Signal and noise for Ge:Zn.

Responsivity: 10^3 V/W (see Fig. 198).

Time constant: <50 ns. (See discussion of time constant under Ge:Au.)

Dark resistance: 0.5 to 5 MΩ/ sq (60°-FOV ambient background).

Capacitance: <1 pF (limited by mounting configuration).

Sensitive area: 1-, 2-, 3-, and 5-mm diameters.

Operating temperature: <10 K.

Recommended circuit: Standard photoconductive.

Manufacturer: No suppliers are presently known.

Ge:Ga The elements of B, Al, Ga, In, and Tl from chemical group III form shallow acceptor states (~10 meV) in germanium which are the basis of infrared detectors with spectral response out to approximately 120 μm. Currently, gallium-doped germanium is commercially available, but germanium doped with other group III elements (Ge:B, Ge:Al, Ge:In, Ge:Tl) will give similar detector performance. The small binding energies associated with this detector require cooling to liquid helium temperatures (4.2 K) or lower for optimum performance. Background-limited performance associated with a quantum efficiency of about 7 percent is achievable over a wide range of background flux levels, provided the operating temperature is low enough to reduce thermal noise below the photon noise level.

Sensitivity: D^* is given by $D^* = 1.1 \times 10^{10} \times \sqrt{(A\lambda\eta)}/\sqrt{Q}$ (Jones); where A is detector area, λ is the wavelength in μm, η is the quantum efficiency, and Q is the background flux in watts.

Responsivity: 4 A/W.

Time constant: <1 μs.

Resistance: Depends on background flux and detector bias.

Capacitance: <1 pF (limited by mounting configuration).

Sensitive area: 0.5-, 1-, and 2-mm square.

Operating temperature: <4.2 K, best below 3 K.

Recommended circuit: Standard photoconductive.

Manufacturer: Infrared Laboratories.

Photographic In this paragraph we present only the spectral sensitivity of some typical photographic emulsions. See Chap. 29, "Photographic Films," for a more extensive coverage.

The term spectral sensitivity generally has a different meaning when applied to photographic detectors than it does when applied to the other detectors described in this chapter. It comes closer to responsivity than to minimum detectable power or energy.* In Fig. 199 sensitivity is the reciprocal of exposure, expressed in ergs per centimeter, required to produce

$$\text{Density} = \log \frac{1}{\text{transmittance}} = 0.3$$

above gross fog in the emulsion when processed as recommended.

Manufacturers: AGFA, Eastman Kodak, Fuji, Polaroid.

*Work is in progress to evaluate photographic materials in terms of minimum detectable energy, a concept involving the average number of photons necessary to produce a change in density (signal) equal to that of the fog-density fluctuations (noise); see Refs. 10, 26, 27, and 28.

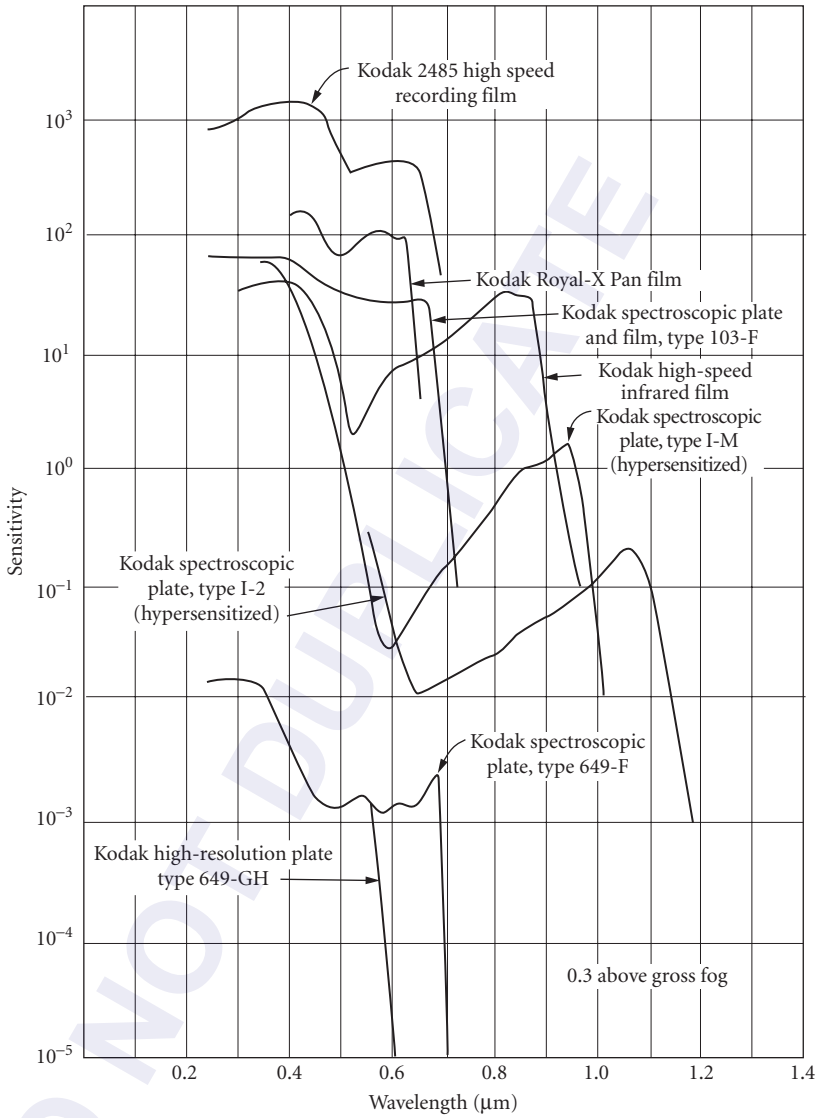

FIGURE 199 Sensitivity versus λ for typical photographic emulsions. (*Eastman Kodak.*)

25.1 GLOSSARY

A	photodetector active area
A_0	incident photon flux
B	bandwidth of the photodetector
C	capacitance of the photodetector
D^*	detectivity
E	applied electric field
E_a	activation energy
E_g	bandgap of the semiconductor
E_i	impurity energy state
f	frequency
I_{diff}	diffusion current
$I_{g\text{-}r}$	generation-recombination current
IR_0	unity gain current
IR_1	reverse current generated by avalanche action
I_{tun}	tunneling current
k	Boltzmann's constant
L	distance traveled by a charge carrier
M	photocurrent gain
m	effective mass of a electron
N_A	acceptor impurity concentration on p side
N_D	donor impurity concentration on n side
n	refractive index of the AR coating
q	electron charge
R	sum of the detector series resistance and load resistance

R_o detector shunt impedance
T temperature in kelvin
t_n transit time of electrons
t_p transit time of holes
t_r transit time of charge carriers (holes or electrons)
V applied reverse bias in volts
V_B breakdown voltage
V_{bi} built-in potential of a *p-n* junction
W depletion width of a *p-n* junction
α absorption coefficient of the photodetector's absorption layer
ε_s semiconductor permittivity
η quantum efficiency of photodetector
θ tunneling constant
λ wavelength of incident photons (nm)
λ_{co} detector cutoff wavelength (10 percent of peak response, nm)
μ mobility of charge carriers (holes or electrons)
μ_n mobility of electrons
μ_p mobility of holes

25.2 INTRODUCTION

The approach of this chapter is descriptive and tutorial rather than encyclopedic. It is assumed that the reader is primarily interested in an overview of how things work. Among the many excellent references to be consulted for further details are Sze's book,[1] and the article by Forrest.[2] For the latest in photodetector developments, consult recent proceedings of the Society of Photo-optical and Instrumentation Engineers (SPIE) conference or the IEEE Optical Fiber Conference.

A photodetector is a solid-state sensor that converts light energy into electrical energy. According to Isaac Newton, light energy consists of small packets or bundles of particles called *photons.* Albert Einstein, who won a Nobel prize for the discovery of the photoelectric effect, showed that when these photons strike a metal they can excite electrons in it. The minimum photoenergy required to generate (excite) an electron is defined as the *work function* and the number of electrons generated is proportional to the intensity of the light. The semiconductor photodetectors are made from different semiconductor materials such as silicon, germanium, indium gallium arsenide, indium antimonide, and mercury cadmium telluride, to name a few. Each material has a characteristic bandgap energy E_g which determines its light-absorbing capabilities. Light is a form of electromagnetic radiation comprised of different wavelengths (λ). The range of light spectrum is split approximately as ultraviolet (0–400 nm), visible (400–1000 nm), near infrared (1000–3000 nm), medium infrared (3000–6000 nm), far infrared (6000–40,000 nm), extreme infrared (40,000–100,000 nm). The equation between bandgap energy E_g and cutoff wavelength (λ_c) is

$$\lambda_c = \frac{1.24 \times 10^3 \text{ nm}}{E_g(\text{eV})} \tag{1}$$

The smaller the bandgap (eV), the farther the photodetector "sees" into the infrared. Table 1 lists some prominent photodetector materials, their bandgaps, and cutoff wavelengths λ_c at room temperature (300 K).

Photodetectors find various applications in fiber-optic communications (800–1600 nm), spectroscopy (400–6000 nm), laser range finding (400–10,600 nm), photon counting (400–1800 nm),

TABLE 1 Important Photodetector Materials

Type	E_g(eV)	λ_c(nm)	Band
Silicon	1.12	1100	Visible
Gallium arsenide	1.42	875	Visible
Germanium	0.66	1800	Near-infrared
Indium gallium arsenide*	0.73–0.47	1700–2600	Near-infrared
Indium arsenide	0.36	3400	Near-infrared
Indium antimonide	0.17	5700	Medium-infrared
Mercury cadmium	0.7–0.1	1700–12500	Near-to-far-infrared

*The alloy composition of indium gallium arsenide and mercury cadmium telluride can be changed to alter the bandgap E_g.

and satellite imaging (200–1200 nm), to name only a few topics. We will discuss three kinds of photodetectors: (1) Photoconductors, (2) *p-i-n* photodetectors (including avalanche diodes), and (3) photogates. Frequently, such detectors need to have high sensitivity, low noise, and high reliability. For fiber-optic applications, the frequency response and the cost can be a critical issue, whereas for infrared applications, many times it is the area of the photodetector. Large area (1 in diameter), high-sensitivity silicon avalanche photodetectors compete with conventional photomultiplier tubes for low light sensing applications in the visible. They offer the advantage of compact size and more rugged construction. We also discuss reliability issues concerning photodetectors and take notice of a few novel photodetector structures.

25.3 PRINCIPLE OF OPERATION

When an electron in the valence band receives external energy in the form of light, the electron may overcome the nuclear attraction and become a "free electron." When light energy creates this transformation, it is termed *photonic excitation* (see Fig. 1*a*). The range of energies acquired by these free electrons is termed the *conduction band.* The energy difference between the bottom of this conduction band and the top of the valence band is termed the *energy bandgap* E_g and represents the minimum energy of light that the material can absorb.

However, under the influence of even a small external electric field, the free electrons can "drift" in a specific direction. This is the fundamental principle of a photodetector. Figure 2 shows the three kinds of photodetectors discussed in this chapter. A brief explanation of each kind follows.

All photodetectors can be characterized by their quantum efficiency, detectivity (sensitivity), and response time.[1] Quantum efficiency (QE) is perhaps the most fundamental property, as it determines just how efficiently the device converts incoming photons into conduction electrons.

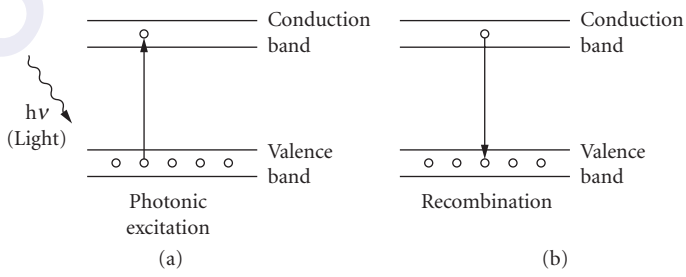

FIGURE 1 Photonic excitation and recombination in a semiconductor.

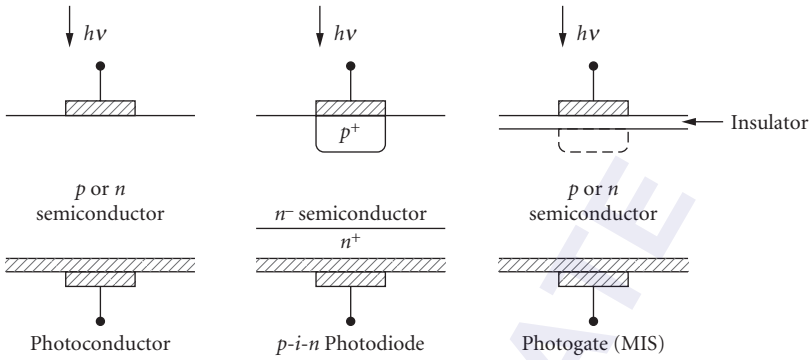

FIGURE 2 Types of photodetectors.

Usually expressed in percentage, quantum efficiency can range from under 1 percent for PtSi Schottky barrier infrared detectors to well over 90 percent for InGaAs *p-i-n* fiber-optic photodetectors. Responsivity (R) is a related term expressed in amps/watt, which determines how much photocurrent is produced by optical power of a given wavelength. Detectivity measures how *sensitive* a detector is; that is, not only its light conversion efficiency, but also its ability to detect low-level light signals. It is limited by the various noise currents (shot, 1/*f*, etc.) introduced by the detector. Finally, response time describes how rapidly a detector can respond to a changing light signal. This ranges from milliseconds for certain types of PbS photoconductors to picoseconds for GaAs-like metal-insulator-semiconductor detectors.

These three parameters are frequently traded off. A large-area detector captures more light signal and thus might have greater detectivity. However, its larger capacitance would slow down the device. Similarly, response time in *p-i-n* detectors can be improved by thinning the absorbing region of the detector. However, this in turn cuts down quantum efficiency by reducing the total number of photons absorbed.

Photoconductor

A photoconductor, as the name implies, is a device whose conductivity increases with illumination. It acts as an open switch under dark (or no illumination) and as a closed switch under illumination. The simple equivalent electric circuit is shown in Fig. 3. This basic principle of a photoconductor finds numerous applications in relays and control circuits. An ideal switch should have low resistance in the closed position and, therefore, a pair of ohmic (not-rectifying) contacts are formed to the photoconductor. These ohmic contacts form the electrodes and usually have contact resistance of less than 10 ohms.

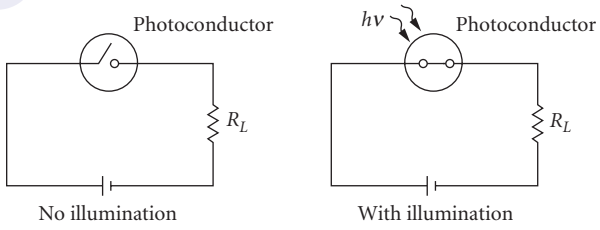

FIGURE 3 Equivalent circuit diagram of a photoconductor.

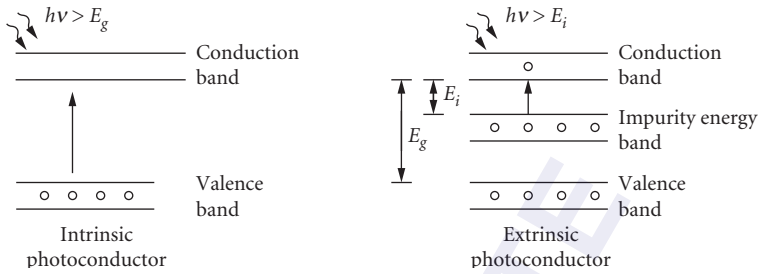

FIGURE 4 Functional diagram of an intrinsic and extrinsic photoconductor.

Types of Photoconductors The two principle photoconductors are (1) intrinsic and (2) extrinsic. In an intrinsic device there is no external impurity atom. However, when an external impurity (dopant) is added to a material, it is termed *extrinsic.* This impurity atom occupies an energy state between the valence band and the conduction band. The functional difference between the intrinsic and extrinsic photoconductor is seen in Fig. 4. For an intrinsic device, the photo excitation ($h\nu$) needs to have energy greater than the bandgap energy E_g and its cutoff wavelength λ_c is given by Eq. (1). But, for an extrinsic one, the photon excitation ($h\nu$) should exceed the impurity energy state E_i and its cutoff wavelength λ_{co} is

$$\lambda_{co} = \frac{1.24 \times 10^3 \text{ nm}}{E_i(\text{eV})} \tag{2}$$

For intrinsic photoconductors, it is extremely difficult to achieve bandgap energies E_g less than 0.1 eV (refer to Table 1). This limits its capability to see in the far infrared and extreme infrared (13,000–100,000 nm) and beyond. This is overcome by extrinsic devices whose E_i value is less than 0.1 eV and is normally done by doping germanium or silicon. However, the extrinsic photoconductor suffers from very low absorption coefficients and, hence, poor quantum efficiencies. Also, since ambient thermal energy can excite carriers, they have to be cooled to liquid nitrogen temperature (77 K) and below, whereas most intrinsic photoconductors can operate at room temperature (300 K).

Photo Gain The sensitivity of a photoconductor is determined by its gain. Photo gain is defined as the ratio of the output signal to the input optical signal. When photons impinge on a photoconductor, they generate electron-hole pairs and, under the influence of external fields, they are attracted toward the anode and cathode. A typical photoconductor is illustrated in Fig. 5 with L being the thickness of the active layer. The transit time (t_r) required for a charge carrier to travel a distance L is given by

$$t_r = \frac{L^2}{\mu V} \tag{3}$$

where V = applied voltage bias and μ = charge mobility.

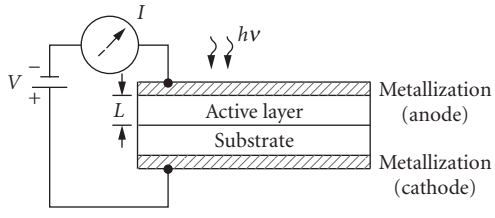

FIGURE 5 A typical photoconductor.

The mobility of electrons μ_n and that of holes μ_p is different, with μ_n being usually far higher than μ_p. This causes a difference in the transit time of electrons and holes. Hence, photon-generated electrons are swept away more quickly than holes which result in a positive charge in the active layer. To maintain the charge neutrality, new electrons are supplied by the external voltage source. Therefore, for one incident photon, more than one electron is circulated in the electric circuit. This results in an "effective gain." Thus, photoconductor gain can be defined as the ratio of slower transit time t_p to faster transit time t_n.

$$M = \frac{t_p}{t_n} \qquad \text{or} \qquad \frac{\mu_n}{\mu_p} \tag{4}$$

The slower the transit time, the higher the gain; however, the bandwidth of the device is reduced. Hence, high-gain photoconductors will result in slow devices and vice versa. Such "high-gain, slow devices" can be best utilized for imaging applications.[3] For high-speed optical communication applications in the 1000- to 1700-nm spectrum, InGaAs is the material of choice due to its high mobility. Several reports have been published on high-speed InGaAs photoconductors that find practical applications in optical receivers.[4–9] (Also see Chap. 26, "High-Speed Photodetectors," by John Bowers and Yih G. Wey.)

p-i-n Photodiode

Unlike photoconductors, a photodiode has a *p-n* junction, usually formed by diffusion or epitaxy. In a photoconductor, metal contacts are made to either *n*- or *p*-type material. However, a photodiode consists of both *n*- and *p*-type materials across which a natural electric field is generated. This field is known as the *built-in potential* V_{bi} and its value depends on the bandgap of its material. A silicon *p-n* junction has V_{bi} of 0.7 V whereas in germanium it is 0.3 V. The higher the bandgap E_g, the larger the built-in potential V_{bi}. An important physical phenomenon called *depletion* occurs when a *p*-type semiconductor is merged with an *n*-type semiconductor. After an initial exchange of charge, a potential is built up to prevent further flow of charge. This built-in field creates the depletion width *W*, which is a region free of any charge carriers and is given by[10]

$$W = \sqrt{\frac{2\varepsilon_s(N_A + N_D)}{q(N_A N_D)}(V_{\text{bi}} - V)} \tag{5}$$

where N_A and N_D are impurity concentrations of *p* side and *n* side, respectively, *q* is the electron charge, V_{bi} is the built-in potential, and ε_s is the semiconductor permittivity, *V* is the applied bias and is negative for reverse-bias operation. As seen from Eq. (5), under reverse bias the depletion width *W* increases causing a decrease in the capacitance of the photodiode. A *p-i-n* photodiode is similar to a parallel plate capacitor with the anode-cathode being the two plates and the depletion width *W* being the separating medium. A typical InGaAs *p-i-n* photodiode is shown in Fig. 6 and its capacitance is given by[1]

$$C = \frac{\varepsilon_s A}{W} \tag{6}$$

where ε_s is the semiconductor permittivity and *A* is the active area of the photodiode. From first principles, a decrease in capacitance improves the bandwidth *B* of the photodetector according to

$$B = \frac{0.35}{2.2RC} \tag{7}$$

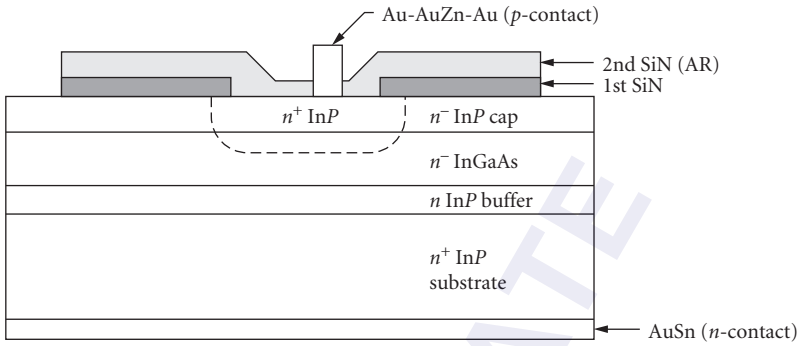

FIGURE 6 A typical InGaAs *p-i-n* photodiode.

where, R is the sum of the detector series resistance and load resistance. For a detailed analysis on high-speed photodetectors, see Chap. 26 by Bowers and Wey.

Dark Current For applications ranging from optical communications (III-V compound semiconductors) to infrared sensing (Si, Ge, III-IV, and II-IV compound semiconductors), a *p-i-n* photodiode must have high sensitivity and low noise. These are largely determined by the dark currents originating in the device. Several authors have published papers on dark currents in InGaAs[11–13] and HgCdTe.[14,15] The three major components of dark current are (1) diffusion current, (2) generation-recombination current, and (3) tunneling current.

Diffusion current In the nondepleted region of the photodiode, electron-hole pairs are formed by the ambient temperature. These thermally generated carriers diffuse toward the depletion region and produce the diffusion current.

$$I_{\text{diff}} \propto e^{-E_g/kT} \tag{8}$$

where E_g is the bandgap of the photodiode material, k is Boltzmann's constant, and T is the ambient temperature in kelvin. It is clear from Eq. (8) that the diffusion current is higher in a low-bandgap material. Therefore, InSb ($E_g = 0.17$ eV) has far higher diffusion current than silicon ($E_g = 1.12$ eV) and in fact this makes InSb almost useless at room temperature. To overcome this excessive diffusion current, InSb photodiodes are cooled to liquid nitrogen temperature (77 K).

Generation-recombination current The current generated in the depletion region of the photodiode is called the *generation-recombination current*. When impurity trap levels are present within the forbidden gap E_g, trapped carriers can be elevated to the conduction band with less energy than for diffusion current. This "trap-assisted" current is given by

$$I_{g-r} \propto \sqrt{(V_{\text{bi}} - V)}\, e^{-E_g/2kT} \tag{9}$$

From Eq. (5), the depletion width W is proportional to $V_{\text{bi}} - V$. Hence,

$$I_{g-r} \propto W e^{-E_g/2kT} \tag{10}$$

Generation-recombination current is proportional to the volume of the depletion width and, hence, is reverse-bias-dependent, whereas the diffusion current in Eq. (8) is bias-independent. For high-bandgap semiconductors with bandgaps above 1.0 eV (e.g., silicon), the generation current

usually dominates over the diffusion current at room temperature. However, for low-bandgap material such as indium antimonide, the diffusion current is dominant over generation current at room temperature.

Tunneling current When the electric field in a reverse-biased *p-n* junction exceeds 10^5 V/cm, a valence band electron can jump to the conduction band due to the quantum mechanical effect[10] called *tunneling* which occurs at high field and with geometrically narrow energy barriers. The tunneling current is given by

$$I_{\text{tun}} \propto EV \exp\left(\frac{-\theta\sqrt{m}}{E} E_g^{3/2}\right) \tag{11}$$

where E is the applied electric field, m is the effective mass of an electron, and θ is a dimensionless constant whose value depends on the tunneling barrier height. Higher doping levels at the *p-n* junction lead to a narrower depletion width which causes higher electric fields, thus increasing the amount of tunneling current. Low-bandgap photodiodes exhibit much more tunneling than do higher-bandgap diodes. Tunneling shows a weak dependence on temperature, the only minor change being caused by the temperature dependence of the bandgap E_g. This leads to a *decreasing* breakdown voltage with an increasing temperature as opposed to an *increasing* breakdown voltage exhibited by the avalanche effect.

Quantum Efficiency, Responsivity, and Absorption Coefficient Quantum efficiency η is defined as the ratio of electron-hole pairs generated for each incident photon. In a nonavalanche *p-i-n* photodiode, quantum efficiency is less than unity. Responsivity R is a measured quantity in amps/watt or volts/watt and is related to quantum efficiency by

$$\eta = \frac{(1240)R}{\lambda} \tag{12}$$

where λ is the wavelength in nm of incident photons and R is the responsivity in amps/watt. The value of η is determined by the absorption coefficient α of the semiconductor material and the penetration distance x in the absorbing layer. The light flux A at a distance x with the absorption layer is

$$A = A_0 e^{-\alpha x} \tag{13}$$

where, A_0 is the incident photon flux and α is a strong function of wavelength λ. Figure 7 shows its typical values for a 1-μm-thick undoped $In_xGa_{1-x}As$, $0 < x < 0.25$.[16] For optimized η, the reflectivity at the semiconductor surface has to be minimized. Hence, an antirefiection (AR) coating of proper thickness is deposited on the photodiode surface. For single-layer AR coatings, the proper "quarter-wave" thickness (L) of the AR coating is

$$L = \frac{\lambda}{4n} \tag{14}$$

where n is its refractive index. With good AR coatings, InGaAs photodiodes can achieve quantum efficiencies above 95 percent at 1300 to 1500 nm. For the visible region, silicon photodiodes show high η (90 percent) in the 800-nm range, and the mid-infrared InSb has a typical η of 80 percent at 5000 nm.

Avalanche Photodiodes Avalanche photodiodes (APDs) will be briefly discussed here. For a detailed treatment, see Chap. 26, "High-Speed Photodetectors," by Bowers and Wey. An avalanche photodiode is a *p-i-n* diode with a net efficiency or gain greater than unity. This is obtained through the process of "impact ionization" by operating the photodiode at a sufficiently high reverse bias. The typical operating voltage for an InGaAs APD is 75 V, while that for silicon can be as high as 400 V. The

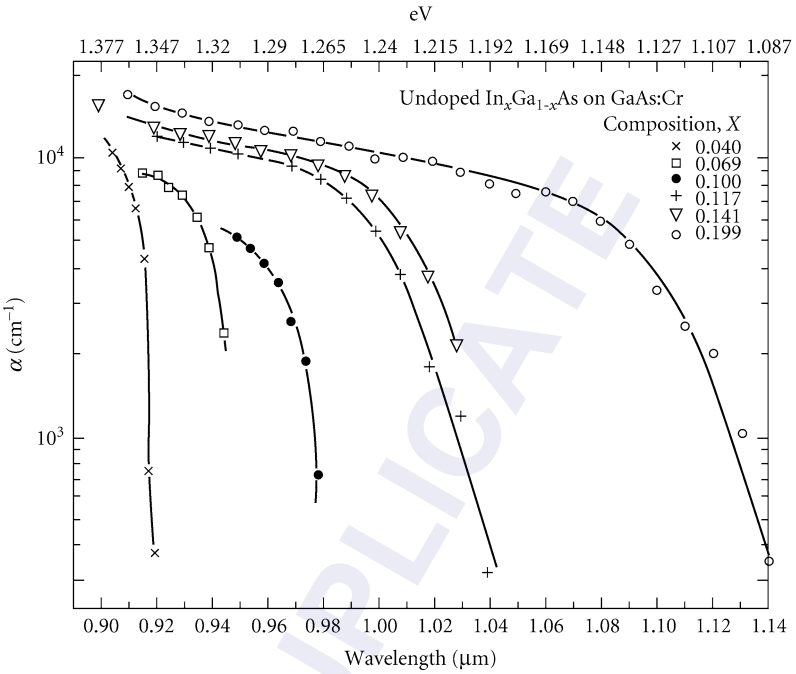

FIGURE 7 Absorption coefficients for 1-μm-thick undoped $In_xGa_{1-x}As$, $0< x < 0.25$.[16]

impact ionization process is described in Fig. 8. Under the influence of a high electric field (>5× 10^5 V/cm), electron *A* gains sufficient kinetic energy to strike atom *B* with a tremendous force and knock out an electron hole pair *B′*-*B″*. *A* is called the "parent" and *B′*-*B″* the "child" charge carriers. The child electron *B″* moves through a critical distance *S* and acquires enough kinetic energy to create its own child particles *D′*-*D″*. The sum effect of the impact ionization of a number of electrons is termed *avalanche multiplication.* Because of this avalanche action, the gain in an APD exceeds unity, reaching useful values above 10 for InGaAs and several hundred for silicon before the multiplied noise begins to exceed the multiplied signal. A solid-state APD is a fast device with gain-bandwidth products than can exceed 20 GHz.[17,18] In spite of high operating bias, an APD can be designed for low noise operation[19] and used for numerous applications such as photon-counting, laser pulse detection,[20] and fiber-optic communication. The gain or avalanche multiplication *M* of an APD is given by

$$M = \frac{IR_1}{IR_0} \tag{15}$$

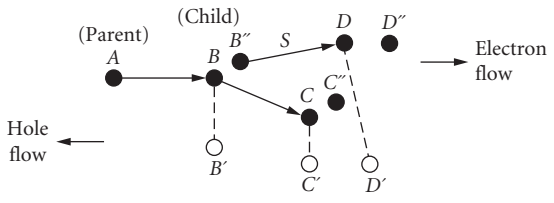

FIGURE 8 Impact ionization process.

where IR_1 is the reverse current generated by avalanche action and IR_0 is the unity gain current. At voltage breakdown of the APD, the multiplication factor M tends to infinity. An empirical relation between the multiplication factor M and reverse bias V is given by[21,22]

$$M = \frac{1}{1-(V/V_B)^n} \tag{16}$$

where V is the applied reverse bias and V_B is the breakdown voltage. The factor n varies between 3 and 6, depending on the semiconductor material and its substrate type. Typical gains are on the order of 10 to 20 for germanium and InGaAs APDs, and above 100 for silicon APDs. Due to their lower noise, InGaAs and silicon APDs have better sensitivity than their germanium counterparts.

Extended Wavelength (1000–3000 nm) Photodetectors

Detector materials used for the 1000 to 3000 nm spectrum include InSb, InAs, PbS, HgCdTe, and recently InGaAs. PbS is an inexpensive, reasonably sensitive detector that can operate at relatively high temperatures, even at room temperature. Its major drawback is its slow (typically milliseconds) response time. InAs has higher sensitivity over the 1000 to 3500 nm spectrum and fast response time, but must be cooled thermoelectrically (to 230 K) or cryogenically (to 77 K). InSb has similar properties out to 5500 nm but must definitely be cryogenically cooled. HgCdTe has high sensitivity and speed and it can be operated at room temperature. Indium gallium arsenide was originally developed for fiber-optic applications out to 1.7 μm (using $In_{0.53}Ga_{0.47}As$) but it can be used out to 2500 nm by increasing its indium content to $In_{0.8}Ga_{0.2}As$. InGaAs appears to be the *best* detector material for high-temperature operation in the 1000 to 3000 nm spectrum. It has a 10 to 100 times advantage in shunt resistance at room temperature compared to HgCdTe—the previously used material for this wavelength.

Table 2 contains a summary of the data. It is difficult to find data at exactly the same cutoff wavelengths and temperature with the same area device. R_0A was determined (in cases where it was given as such) by simply multiplying two numbers, where, R_0 is the shunt impedance of the detector, and A is the active area of the photodetector.

Photogate (Metal-Insulator-Semiconductor Detector)

The advent of silicon charge-coupled devices (CCDs) has revolutionized the television industry and introduced one of the most popular consumer items to millions of people around the world—the CCD camcorder. From the sandy shores of Hawaii to the ski slopes of Colorado, people have captured

TABLE 2 Comparison of R_0A Values in HgCdTe and InGaAs (Ω-cm^2)

	$R_0A(T)$	
λ_{co} (nm)	HgCdTe	InGaAs
1400	4×10^4 (292 K)	2.5×10^5 (300 K)
	7×10^6 (230 K)	1.3×10^8 (220 K)
1700	2×10^2 (300 K)	2.5×10^5 (300 K)
	2×10^5 (220 K)	1.3×10^8 (220 K)
2100	7×10^1 (300 K)	2.5×10^3 (300 K)
	7×10^3 (220 K)	6.5×10^5 (220 K)
2500	1×10^1 (300 K)	1.3×10^2 (300 K)
	1×10^3 (210 K)	1.0×10^5 (210 K)

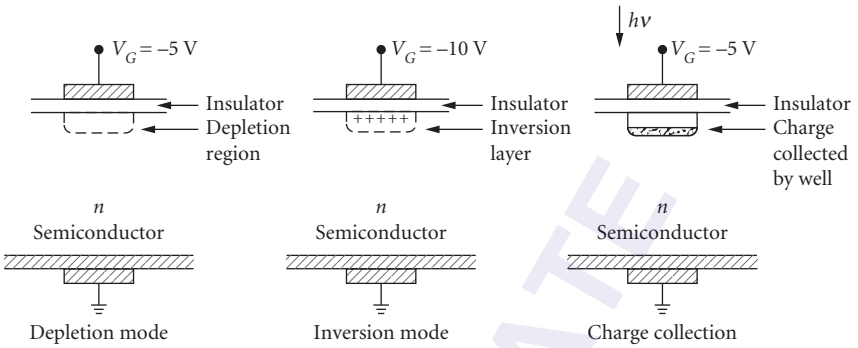

FIGURE 9 Schematic diagram of a photogate.

life's best moments with a CCD camcorder. With its superior imaging quality and noise performance of a few electrons per pixel (<20), a CCD has diverse uses from space imaging to chemical analysis spectroscopy. A CCD is a matrix of metal oxide semiconductor (MOS) devices operated in the "depletion" mode. Each individual MOS device is called a *photogate* and its schematic diagram is shown in Fig. 9. Consider an *n*-type semiconductor with a negative potential applied to its gate. It repels the negatively charged electrons and create a depletion layer. As the negative potential on the gate is increased, the volume of the depletion region increases further into the bulk. However, the surface potential at the semiconductor-insulator interface also becomes more negative. Finally, with increased gate bias, the surface potential becomes sufficiently high to attract minority carriers (holes). This creates a positive charge at the semiconductor-insulator interface and is termed the *inversion layer*. In a MOS transistor, the inversion layer forms a conducting channel between the source and the drain, and the gate bias needed to achieve inversion is termed the *threshold voltage*. Usually a photogate is operated in depletion at a gate bias lower than the threshold voltage. When incident photons create hole-electron pairs, the minority carriers drift away to the depletion region and the volume of the depletion region shrinks. The total amount of charge that a photogate can collect is defined as its *well capacity*. The total well capacity is decided by the gate bias, the insulator thickness, the area of the electrodes, and the background doping of the semiconductor. Numerous such photogates with proper clocking sequence form a CCD imaging array. For in-depth understanding of CCDs, we refer to Chap. 32 "Visible Array Detectors," by Timothy J. Tredwell.

25.4 APPLICATIONS

The main commercial uses of photodetectors include optical communications and infrared sensing. Although these applications often overlap, optical communication typically involves transmitting data over an optical fiber at higher rates. The format is increasingly digital (telecommunications and data links) at rates from 1 Mbit/s to over 2 Gbit/s.

However, one growing application is cable TV where analog data rates from 1 to over 1000 MHz are most often found. Infrared sensing mostly involves nonfiber applications at sub-MHz analog rates. The property to be detected is usually the amplitude (in watts) and wavelength of the incoming radiation. In digital applications, the wavelength and individual pulse amplitude are relatively fixed, and successful communication occurs simply by distinguishing when the pulse is "on" or "off." Although very weak pulses must sometimes be detected, the actual amplitude of the pulse is irrelevant. The ultimate "resolving power" of the detector is when a weak pulse can no longer be distinguished from background noise, i.e., when the incoming signal strength S equals the background

noise strength N or when the signal-to-noise ratio $S/N = 1$. Thus, the strengths of individual pulses are unimportant as long as the presence of a pulse can be detected. Information is conveyed by the timing sequence of the pulses rather than by the amplitude of the individual pulse. Analog applications, on the other hand, depend critically on the frequency content and amplitude of the transmitted signal. In an AM cable TV transmission system, the detector must be able to linearly reproduce the incoming optical signal as an electrical current of the same frequency content and amplitude, and to minimize intermodulation and harmonic distortion that is invariably produced in the detection of an AM signal.

Infrared applications often involve spectroscopy whereby the detected electrical signal depends on both the optical wavelength and strength of the incoming infrared signal. Thus, the detector must be carefully calibrated in terms of "responsivity" (electrical amps/optical watt) versus wavelength in order to accurately identify the nature of the incoming signal. Identification of gases (e.g., methane, which absorbs light near 1650 nm) depends on these properties. Other "infrared" applications include spectroscopy, remote sensing from satellite, and general laboratory detection. Not *all* infrared applications are analog, however. One notable digital application is LIDAR (Light detection and ranging), which essentially is a form of laser radar. High-intensity light pulses are emitted into the atmosphere (or a gas) which absorbs, scatters, and reemits the laser pulse. The character of the light pulses detected near the source can be used to determine the nature of the gas particles that interact with the light: the absorbing wavelength, the gas density (velocity), and the amount present. Applications include remote pollution monitoring and "windshear detection," whereby the presence of abrupt changes in wind velocity can be instantly detected at distances of several miles. This application[23] has been demonstrated with laser wavelengths of 2060 and 10,600 nm for use on an aircraft. The 2060-nm system works better in severe storms and does not require a cryogenically cooled detector (as does the 10,600-nm system).

One important noise source in infrared applications is the so-called $1/f$ noise which becomes noticeable at frequencies below 10 MHz. Although poorly understood, this noise is thought to originate at heterointerfaces such as semiconductor-metal contacts and heteroepitaxial interfaces. Photodiode arrays are often used to detect low-light-level signals of a few hundred photons, and they must integrate the signal for 1 second or more. However, with longer integration times, $1/f$ noise may become noticeable and can degrade the S/N ratio and thus, impose an upper limit on the effectiveness of longer integration times. Limiting $1/f$ noise becomes critical for numerous infrared sensing applications and research indicates that surface depletion width at the semiconductor-insulator interface to be a major source of $1/f$ noise in the InGaAs photodiodes.[24]

One important area for detectors is the array configuration used both for spectroscopy (linear) and imaging (two-dimensional). Linear arrays are used in the so-called multichannel analyzers whereby the detector is placed behind a fixed grating and the instrument functions as "motionless" or "instant" spectrometer with each pixel corresponding to a narrow band of wavelengths. The resolution of the instrument is determined by the number and spacing of pixels, so *narrow* pixel geometries are needed along one direction whereas *tall* pixel geometries are needed along the perpendicular direction to enhance the light collection.

One "mixed" infrared/fiber-optic application is the use of large-area (typically 3 mm diameter) detectors for optical power meters: the optical equivalent of a voltmeter which accurately measures the amount of optical power in watts or dBm (number of decibels above or below 1 mW contained in an incoming beam). The large area ensures large collection efficiency. The most important parameter here is the responsivity and the uniformity of response across the detector.

A "figure-of-merit" for infrared detectors is D^* (D-star), whereby detectors of differing area can be compared. It is related to the noise equivalent power (NEP) in watts, the lowest power a detector can detect at a signal-to-noise ratio of 1 as

$$D^*(\lambda, f, B) = (AB)^{1/2}/\text{NEP} \tag{17}$$

where A is the detector area. The optical bandwidth B (often taken to be 1 Hz), frequency of signal modulation f, and operating wavelength λ must be stated.

25.5 RELIABILITY

In today's global economy of severe competitiveness, new product development and innovation are incomplete without quality assurance and reliability. Reliability is the assurance that a device will perform its stated functions for a certain period of time under stated conditions, and considerable research has been done to improve the reliability of photodetectors.[25–28] The two major industrial standards for testing semiconductor device reliability are (1) test methods and procedures for microelectronics (MIL. STD. 883C), and (2) Bellcore technical advisory (TA-TSY-00468). The former standard is generic to the semiconductor industry, while the latter is specifically developed for fiber-optic optoelectronic devices.

The tests performed under MIL. STD. 883C comprise the following major groups: (1) *environmental tests,* e.g., moisture resistance, burn-in, seal, dew point, thermal shock, (2) *mechanical tests,* e.g., constant acceleration, mechanical shock, vibration, solderability, and bond strength, and (3) *electrical tests,* e.g., breakdown voltage, transition time measurements, input currents, terminal capacitance, and electrostatic discharge (ESD) sensitivity classification. Under the Bellcore Technical Advisory, each photodetector lot undergoes visual inspection, optical and electrical characterization, and screening. Visual inspection removes any photodiodes with faulty wire bonds or cracks in the glass window or in the insulating films. Table 3 lists the electrical and optical testing performed on every photodiode. After testing, all the devices are sent for screening (burn-in), e.g., some $In_{0.53}Ga_{0.47}As$ photodiodes are burned-in at 200°C for 20 hours at −20 V reverse bias to weed out any infant mortality.

Photodetector Life Test (Accelerated Aging)

To predict the lifetime or *mean-time-to-failure* (MTTF), accelerated aging tests are carried out on groups of diodes at several elevated temperatures. For example, the MTTF for 300 μm diameter InGaAs photodiodes was determined on groups of 20 screened devices at elevated temperatures of 200, 230, and 250°C. The failure criterion was a 25 percent increase in the room temperature dark current value.[28,29] The total lifetest extended over a time period of several years, and every week the samples were cooled to room temperature to check their dark current. Failed devices were removed from the sample population and the remaining good ones put back at the elevated temperature.

From the temperature-dependence of the data, it was observed that the failure mechanism is thermally activated. The Arrhenius relationship calculates the activation energy E_a for thermally activated failure[29] as

$$\mathrm{MTTF(T)} = Ce^{(E_a/kT)} \tag{18}$$

where, C is a constant, k is Boltzmann's constant (8.63×10^5 eV/K), and T is the temperature in kelvin. Figure 10 shows the MTTF for three batches of 300 μm diameter $In_{0.53}Ga_{0.47}As/InP$ photodiodes. Using least-squares fit to the data, the calculated activation energy E_a is 1.31 eV with a correlation coefficient r^2 of 0.99. From Eq. (18) and an experimentally determined activation energy

TABLE 3 Electrical and Optical Testing of Photodetectors

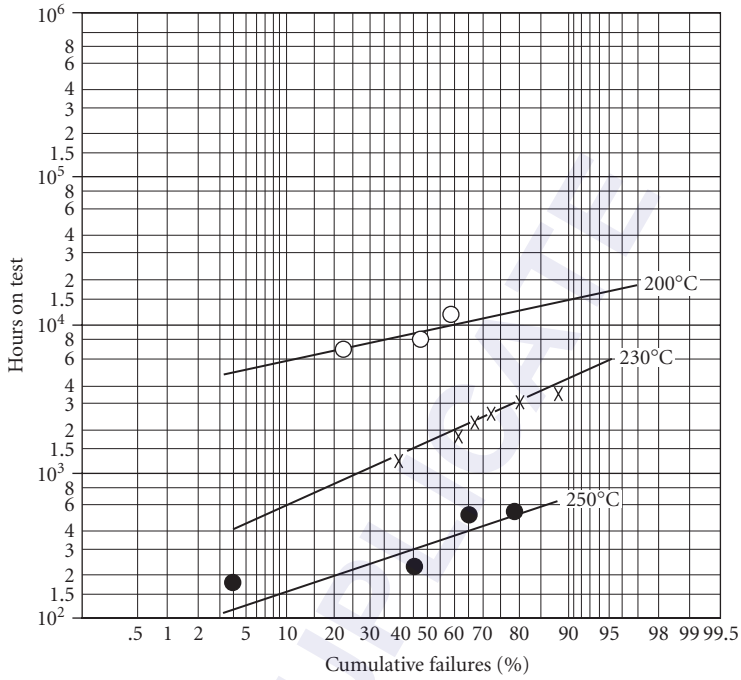

FIGURE 10 Time versus cumulative percent failure of InGaAs diodes at 200, 230, and 250°C lifetest.

of 1.31 eV, the MTTF at 25°C is calculated to be 1.34×10^{14} hours. Such a "geological" lifetime may seem to be an overkill, even for the electronics industry. However, when thousands of these devices are working together in a single system (e.g., telephones), the net MTTF of all these devices chained together may be on the order of only a few years. Thus, continuing improvements in reliability must be an ongoing process. Reliability in most photodetectors is determined by a number of factors including: (1) material quality, (2) processing procedures, (3) planar technology versus mesa technology, and (4) amount of leakage current. Poor material quality can introduce crystal defects such as vacancies and dislocations which can increase the dark current. Higher dark current has been directly linked to lower MTTF.[28] Device processing is probably the most crucial item in photodetector reliability. The dielectric (typically silicon nitride) used in planar detector processing serves as a diffusion mask in *p-n*-junction formation and a passivant (termination) for the junction so produced. Any surface states or impurities introduced here can directly increase leakage current and degrade reliability.

An important milestone in detector reliability was the changeover mesa to planar structures.[2,30] Just as the transistors in the 1950s were first made in mesa form, so were the optical photodetectors of the 1980s, due to their simplicity and ease of fabrication. However, in both cases, reliability issues forced the introduction of the more complex planar structure. A sketch of a mesa and planar photodiode is illustrated in Fig. 11. A mesa photodiode typically is formed by wet chemical etching of an epitaxially grown *p-n* crystal structure, while in a planar process, a *p-n* junction is formed by diffusing a suitable *p* or *n* dopant in an *n*- or *p*-type crystal. It has been shown a planar structure to be more reliable than a mesa one[30] because a *p-n* junction is never exposed to ambient conditions in a well-designed planar process. Exposure of the *p-n* junction can cause surface corrosion leading to increased leakage current and, in effect, poorer reliability.[31]

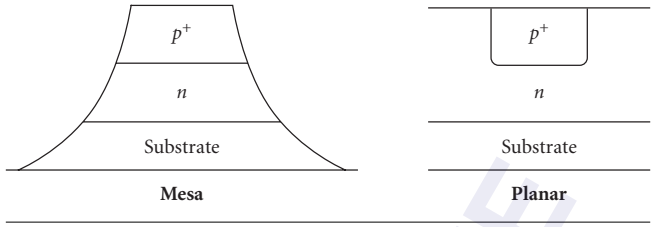

FIGURE 11 Sketch of a mesa and planar photodetector.

25.6 FUTURE PHOTODETECTORS

A lateral *p-i-n* photodiode and a quantum well infrared photodetector (QWIP) have been developed with better characteristics compared to the photodetector structures. A long wavelength QWIP in the 8000- to 12000-nm band[32–35] has posed a severe challenge to the present favorite mercury cadmium telluride photodetectors, while a medium wavelength QWIP in the 3000- to 5000-nm band[36] may compete with indium antimonide and platinum silicide photodetectors. A QWIP made from GaAs/AlGaAs heterosystems promises to have higher detectivity (D^*), higher yield due to well-established 3-in wafer GaAs technology, and easier monolithic integration with circuit electronics. A lateral *p-i-n* diode, as the name implies, has charge carrier flow in a lateral direction compared to the vertical direction in a conventional (vertical) photodiode structure. Because of its process compatibility and simple fabrication, a lateral *p-i-n* photodiode can be suitably integrated on an optoelectronic integrated circuit (OEIC) chip[37,38] having numerous field-effect transistors. An OEIC has a lower noise floor due to the reduced stray capacitances and inductances compared to that of hybrid detector-amplifier packages and finds applications in high-speed digital data communication.

Lateral p-i-n Photodetector

The vertical *p-i-n* structure in Fig. 6 has high sensitivity, low noise, low capacitance, better reliability, and an easy manufacturing process. However, such a vertical structure is nonplanar and therefore harder to integrate on an OEIC. The nonplanarity is also an issue with lasers and LEDs, and optical integration demands surface-emitting LEDs and lasers (SLEDs and SLASERs) over the conventional edge-emitting sources (ELED and ELASER). The cross section of an AlGaAs/GaAs lateral *p-i-n* photodiode is shown in Fig. 12.

The higher-bandgap AlGaAs layer acts as a surface barrier, reducing the leakage currents. The low-bandgap GaAs layer absorbs the incoming light, and the generated carriers flow to the W-Zn

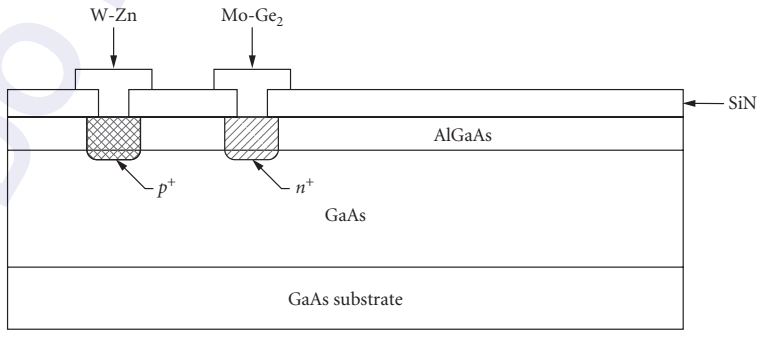

FIGURE 12 Cross section of an AlGaAs/GaAs lateral *p-i-n* photodiode.[38]

and Mo-Ge_2 ohmic contacts which act as the *p* and *n* regions, respectively. The diffusion of zinc and germanium in the ohmic contacts forms a compositionally graded barrier at the AlGaAs/GaAs interface, rather than an abrupt interface. This smooth barrier helps the lateral *p-i-n* photodiode to have better speed than a lateral metal-semiconductor-metal photodetector. A comfortable spacing of 3 to 5 μm between the *p* and *n* regions gives high quantum efficiency and low capacitance, thus providing all the desirable properties of a vertical *p-i-n* structure and yet being easier to integrate.

Quantum Well Infrared Photodetector

Quantum well infrared photodetectors (QWIPs) offer *long* wavelength (5000–10,000 nm) infrared detection by using materials whose bandgap normally allows them only to absorb light in the *short* wavelength (~10,000 nm) region, e.g., GaAs/AlGaAs. The use of thin (<500 Å) layers allows the absorbing wavelength to be controlled by material *geometry* rather than its *chemistry*.[39]

Before discussing the QWIPs, we take the liberty of explaining a few basic terms and concepts of quantum physics. Superlattices or quantum well structures consist of a stack of ultrathin semiconductor layers normally 50 to 500 Å in thickness. Molecular beam epitaxy (MBE) techniques are frequently employed to grow these structures because their characteristically slow growth rate of a few Angstroms per seconds which helps achieve abrupt heterointerfaces. Two semiconductors of different compositions, when stacked together, form a heterointerface. Type III-V compound semiconductors such as AlGaAs/GaAs and InAlAs/InGaAs are the best candidates for growing quantum well structures, as they can be easily doped and their alloy composition readily changed to form semiconductor layers of different bandgaps. Tailoring the bandgap can alter the heterobarriers, creating exciting device results. When quantum well layers have thicknesses less than the electron mean free path (typically 50 to 100 Å), electron and holes cannot have their normal three-dimensional motion. This restricts carriers to move in two dimensions in the plane of the layer.[2,39] Because of this quantized motion, a new band of discrete energy levels is generated. Carriers no longer obey Boltzmann's statistics[1] and optical absorption becomes more complicated than the conventional band-to-band absorption given by Eq. (1). The absorption of light energy by a quantum well structure can cause an electron to jump from "multiple valence subbands" to "multiple conduction subbands," thereby enabling it to absorb light wavelengths not decided by the *material* properties (bandgap) of the semiconductor layers alone, but by its *geometrical* properties as well.

In QWIPs, the light energy transfers an electron in a bound state to an excited state in the continuum.[40] Figure 13 shows an AlGaAs/GaAs quantum well structure with *L* being the width of the

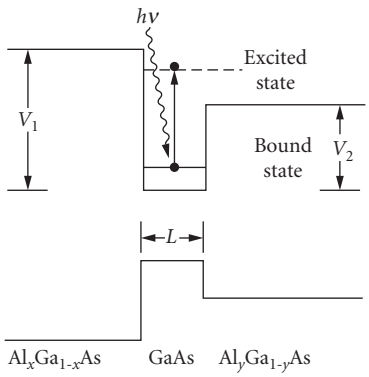

FIGURE 13 Infrared detection with an AlGaAs/GaAs quantum well.[40]

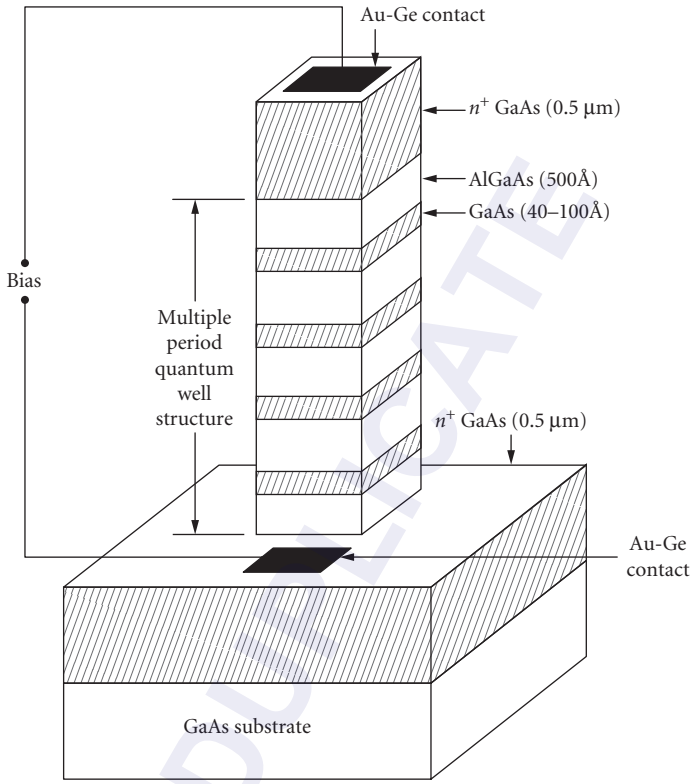

FIGURE 14 Multiple period AlGaAs/GaAs quantum well infrared photodetectors.

well and V_1, V_2 being the barrier heights. The electron excited by the IR radiation is swept out of the doped GaAs well by applying an external electrical field. By controlling the barrier heights V_1,V_2, and quantum well width L, the spectral response of a QWIP can be changed for the desired IR window of 3000 to 5000 or 8000 to 12,000 nm.[40] A multiple period quantum well infrared photodetector is illustrated in Fig. 14.[34] The n^+-doped (2×10^{18} cm^{-3}) GaAs quantum wells are 40 to 100 Å and the undoped AlGaAs barriers are of 500 Å thickness. The multiple period stack is sandwiched between two n^+ GaAs-doped contacts. This photodetector has exhibited a blackbody D^* of 1×10^{10} cm/(Hz/W)$^{1/2}$ at 68 K for a cutoff wavelength of 10,700 nm. InGaAs/AlInAs superlattices have exhibited blackbody D^* of 2×10^{10} cm/(Hz/W)$^{1/2}$ at 120 K with peak responsivity at 4000 nm.[36]

In summary, QWIPs have high detectivity, good uniformity, high yield, multiple spectral windows, and intrinsic radiation hardness for numerous imaging and spectroscopy applications.[41]

Santa Barbara, California

26.1 GLOSSARY

A	area
A^{**}	modified effective Richardson constant
$A_e(A_h)$	electron (hole) ionization parameters
B	bit rate
C_J	junction capacitance
C_P	pad capacitance
$D_e(D_h)$	diffusion coefficient for electrons (holes)
$\mathbf{E}$	electric field
$e_n(e_p)$	emission functions for electrons (holes)
F	frequency response
f	frequency
$f_{3\text{dB}}$	3-dB bandwidth
G	photoconductor gain
H	transfer function
h	Plank's constant
I_d	dark current
I_{dm}	multiplied dark current
I_{du}	unmultiplied dark current
I_{ph}	photocurrent
i	current
$\langle i_{\text{na}}^2 \rangle$	amplifier noise power
J	current density
J_{DIFF}	diffusion component of current density
J_{DRIFT}	drift component of current density

$J_e(J_h)$	electron (hole) component of current density
k	ratio of electron to hole ionization coefficient
k_b	Boltzmann constant
L	absorption layer thickness
$L_e(L_h)$	diffusion length for electrons (holes)
L_s	series inductance
M	multiplication factor
$M_n(M_p)$	electron (hole) initiated multiplication factor
m	electron mass
$n(p)$	electron (hole) density
P	input optical flux
q	electron charge
R	reflectivity
R_L	load resistance
R_s	series resistance
$R_1(R_2)$	reflectivity of the surface (substrate) mirror in a resonant detector
T	temperature
t	time
$t_e(t_h)$	transit time for electrons (holes)
V_B	breakdown voltage
V_j	junction voltage
v_e, v_h	electron and hole velocities
W	thickness of the depleted region
x	position
α	absorption coefficient
α_{FC}	free carrier absorption inside the absorption layer
$\alpha_{\mathrm{FC}x}$	free carrier absorption outside the absorption layer
α_{IB}	interband absorption
α_i	electron ionization rate
α_s	scattering loss
β	propagation constant in a waveguide photodetector
β_i	hole ionization rate
Γ	confinement factor
ε	permittivity
η	quantum efficiency
κ	coupling coefficient to the waveguide of a waveguide detector
λ	wavelength
$\mu_e(\mu_h)$	mobility for electrons (holes)
ν	optical frequency
σ	charge density
σ_d	noise current spectral density
τ_e, τ_h	trapping time at a heterojunction for electrons (holes)
τ_{tr}	transit time
$\phi_{bc}(\phi_{bv})$	barrier height for the conduction band (valence band)
ω	angular frequency

26.2 INTRODUCTION

High-speed photodetectors are required for telecommunications systems, for high-capacity local area networks, and for instrumentation. Many different detector structures and materials are required to cover this range of applications. Silicon is one of the most commonly used detector materials for wavelengths from 0.4 to 1.0 μm, while Ge photodetectors are used at longer wavelengths up to 1.8 μm. Silicon and germanium have indirect bandgaps at these wavelengths, which result in relatively small bandwidth-efficiency products. Consequently, for high-speed applications, direct bandgap semiconductors such as III-V materials are more important and are the focus of this chapter. $Ga_{0.47}In_{0.53}As$ with a cutoff wavelength of 1.65 μm is especially useful for telecommunication photodetectors at 1.3 and 1.55 μm. GaAs has a cutoff wavelength around 0.9 μm and is ideal for visible and near-infrared applications.

This chapter will focus on the physics and technology of high-speed photodetectors. The next section discusses the different structures that are possible. Later sections discuss some specific results and motivations for particular structures. The primary limitations to detector speed are discussed, followed by a description of specific photodetector systems. To supplement this chapter, the reader should refer to excellent chapters and articles written specifically about photodetectors,[1] photoconductors,[2] pin detectors,[3] avalanche photodetectors,[4] phototransistors,[5] and receivers.[6,7]

26.3 PHOTODETECTOR STRUCTURES

Many photodetector structures have been demonstrated and many more structures are possible. In this section, we classify the different possible structures and identify a few of the trade-offs. The optimum structure for a given application depends on the required bandwidth, efficiency, saturation power, linearity, ease of integration, and leakage current.

There are four common types of photodetectors: (1) photovoltaic detectors, (2) photoconductive detectors, (3) avalanche photodetectors (APD), and (4) phototransistors. Photovoltaic detectors have blocking contacts and operate under reverse bias. The blocking contact can be a reverse-biased *p-n* junction or a Schottky contact. The photoconductive detector has identical, nonblocking contacts such as two *n*+ regions in an undoped sample. The avalanche photodetector has a similar configuration to a photovoltaic detector except that it has a high-field region that causes avalanching and results in gain in the detector. Improvements to the basic APD design include separate avalanche and gain regions (SAM APDs), and staircase APDs to increase the ratio of electron to hole (or hole to electron) multiplication rate. Phototransistors are three-terminal devices which have an integrated electronic gain region.

The second criterion is the contact type and configuration. The photogenerated carriers may be collected by means of (1) a vertical current collector, often a *p-n* or Schottky junction, (2) an interdigitated metal-semiconductor-metal (MSM) structure, or (3) a laterally grown or etched structure. These options are illustrated in Fig. 1*a*. PIN junctions are usually formed during the growth steps and tend to have low leakage current and high reliability.[8,9] Schottky junctions are simple to fabricate, but tend to have a large leakage current on narrow-gap semiconductors, such as InGaAs. MSM structures have the advantage of lower capacitance for a given cross-sectional area, but often have longer transit times, limited by the lithography capabilities possible in production. Experimental demonstrations with very fine lines (50 nm) have yielded high-speed devices with good quantum efficiencies. MSM detectors tend to be photoconductive detectors, but one could lower the capacitance for a given area of a PIN detector by using an interdigitated MSM structure with *p* and *n* regions under alternating metal fingers.

The third important aspect of photodetector design is the orientation of the light with respect to the wafer and the current collection region (Fig. 1*b*). Most commercial photodetectors are vertically illuminated and the device area is 10 μm in diameter or larger, which allows simple, high-yield packaging with single-mode optical fibers, or easy alignment to external bulk optics. The problem with this configuration is that the absorbing layer must be thin for a high-speed detector to keep

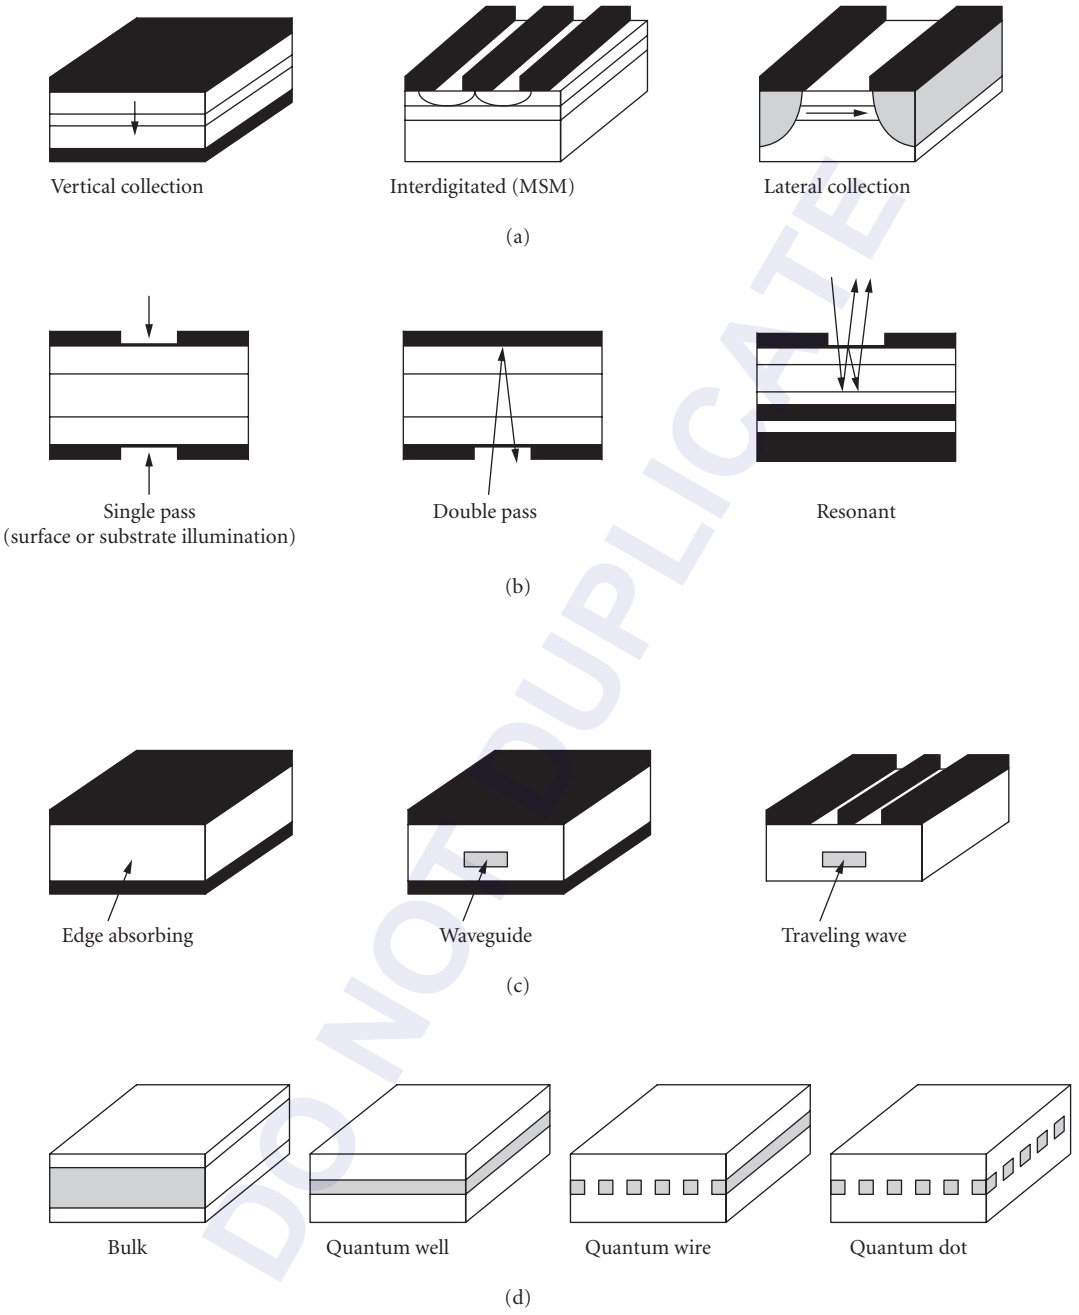

FIGURE 1 Schematic drawings of different types of photodetectors: (*a*) electrical configuration; (*b*) optical configuration—vertical illumination; (*c*) optical configuration—horizontal illumination; and (*d*) absorbing material.

the transit time of photogenerated carriers short. Consequently, the quantum efficiency is low, and single-pass vertically illuminated photodetectors tend to have bandwidth efficiency products around 30 GHz.[3] Bandwidth efficiency products are discussed in greater detail in Sec. 26.5. The bandwidth efficiency product can be increased by allowing two passes by reflecting the light off a metal layer or dielectric mirror.[10] Making a resonant cavity with multiple reflections at particular wavelengths should allow bandwidth efficiency products in excess of 100 GHz.[11–13] As will be seen below, essentially 100 percent quantum efficiency is possible with bandwidths up to 20 GHz, so there is no need for resonant detectors unless the required bandwidth is above 20 GHz or wavelength selectivity is needed as in a wavelength division multiplexed (WDM) system.

The other class of optical inputs are horizontally illuminated photodetectors (Fig. 1*c*). The simplest configuration is an edge-illuminated detector. The primary problem with an edge-illuminated detector is that the light is not guided. Diffraction of the incident light causes absorption to occur outside of the high-field region, and slow diffusion tails in the impulse response occur. A solution to this problem is the waveguide detector, where an optical waveguide confines the light to the high-field absorption region.[14–16] The waveguide efficiency product of this structure can be 100 to 200 GHz. However, it is limited by the capacitance of the structure, particularly if thin intrinsic layers are used for ultrahigh-speed devices. A solution to the capacitance limitation is a traveling wave photodetector where the incoming optical beam is velocity matched with the generated microwave signal.[17,18] The bandwidth efficiency product is then limited only by loss on the electrical transmission lines, and bandwidth efficiency products of hundreds of GHz are possible. Traveling wave detectors and, to a lesser extent, waveguide detectors have the important advantage that the volume of the light absorption can be quite large and, consequently, these detectors have much higher saturation powers.[19] Velocity matching in these structures requires quite narrow waveguides. Wu and Itoh[20] have suggested separating the parts of the optical waveguide with microwave delay lines to achieve velocity matching.

The fourth issue is the type of absorbing material (Fig. 1*d*) (1) bulk; (2) quantum well; (3) quantum wire; (4) quantum dot; (5 to 7) strained quantum well, wire, or dot; (8) *n-p-i-i* structure. The vast majority of commercial and experimental detectors use bulk material. However, quantum well detectors[21] are becoming increasingly important in photonic integrated circuits (PICs) because the absorbing quantum well material is also used in other parts of the PIC such as the laser. Quantum wire photodetectors[22] have potential advantages in terms of higher-bandwidth-efficiency products, but uniform quantum wires are rather difficult to fabricate. Quantum dot detectors have even higher peak absorption coefficients and more wavelength selectivity, but will probably have problems with slow impulse responses due to trapping of the carriers by the heterojunction. In other quantum-confined detectors, the carriers can be extracted along the quantum wire or well, and this problem can be avoided.[22]

The final classification is by means of the lifetime of the material. Conventional detectors have material lifetimes of typically 1 ns and achieve speed by using high field for rapid carrier collection. A second approach is to use low temperature (LT) grown material which has a very short lifetime, perhaps as low as 1 ps. A third approach is to damage the material by means of ion implantation. The final approach is to grow or diffuse in traps into the material such as iron[23] or gold.

If we combine these classifications, we find that 2600 types of photodetectors are possible, and additional subgroups such as superlattice APDs or SAGM APDs increase the total even further. In reality, about 100 types of detectors have been demonstrated. One of the points of this section is that improvements in one type of detector, such as adding a resonant cavity to a PIN detector, can be applied to other types of detectors, such as adding a resonant cavity to an APD. In the following section, we discuss in more detail some of the real limitations to the speed of a detector, and then apply this knowledge to a few important types of detectors.

26.4 SPEED LIMITATIONS

Generally speaking, the bandwidths of most photodetectors are limited by the following factors: (1) carrier transit time, (2) RC time constant, (3) diffusion current, (4) carrier trapping at heterojunctions, and (5) packaging. These limiting factors will be discussed in turn with specific application to *p-i-n* photodiodes.

Carrier Transit Time

In response to light absorbed in a material, the photogenerated carriers in the active region will travel across the high-field region and then be collected by the electrodes. As an example, Fig. 2*a* shows the *p-i-n* structure with a photogenerated electron-hole charge sheet of density σ. In response to the electric field, the electron will travel to the right and the hole to the left. This induces a

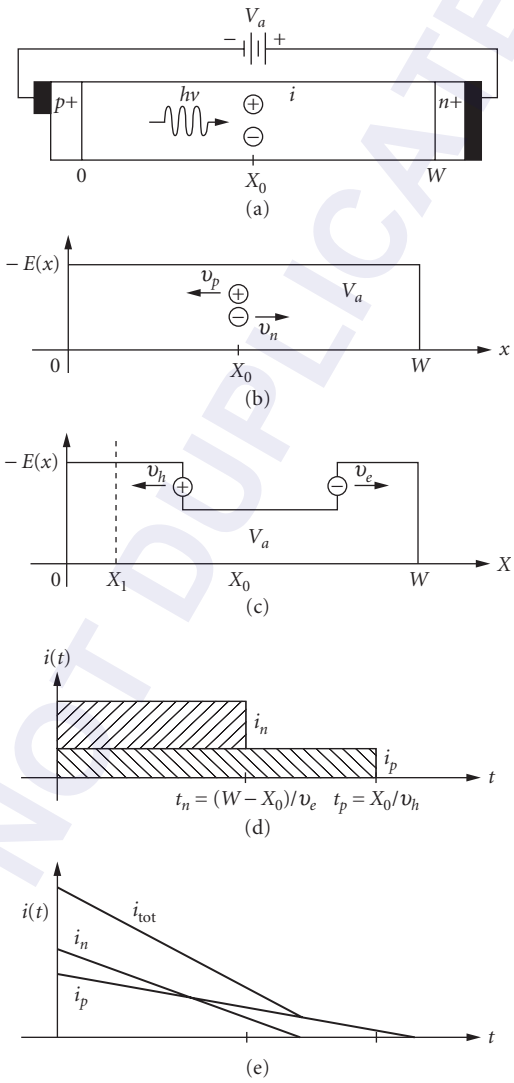

FIGURE 2 (*a*) Biased *p-i-n* structure. (*b*) Electrical field at the time when the electron-hole pairs are generated. (*c*) The perturbed electrical field due to the separated electron-hole pair. (*d*) The photocurrent due to single electron-hole pair. (*e*) The total photocurrent due to uniform illumination across the photodiode.

displacement current and reduces the internal electric field (Fig. 2*b* and *c*), which is the cause of saturation in photodetectors. From Gauss's law the difference in the electric field at the position of electron or hole is

$$\Delta E = \frac{q\sigma}{\varepsilon} \tag{1}$$

where q is the electron charge, and ε is the permittivity. Due to the constant total voltage across the depletion region, the reduced electric field between the electron and hole will be compensated by the increased electric field outside. The rate of change of the electric field at the position $X = X_1$ is

$$\frac{\partial E}{\partial t} = -\frac{(\upsilon_e + \upsilon_h)\Delta E}{W} \tag{2}$$

where υ_e and υ_h are the saturation velocities for electrons and holes, respectively. The assumption of saturation velocities is valid at high fields. The displacement current is hence given by

$$i(t) = -\varepsilon A\frac{\partial E}{\partial t} = \frac{qA\upsilon_e\sigma}{W} + \frac{q\upsilon_h\sigma A}{W} \tag{3}$$

The current consists of two components due to the electron and hole currents. The electron current lasts for a time duration of $(W - X_0)/\upsilon_e$ and hole current of X_0/υ_h. This is shown in Fig. 2*d*. Here, we note that if the fast carrier (i.e., electron) travels a longer distance, then we have a shorter pulse. The total electron and hole currents are given by

$$i_e(t) = \frac{q\upsilon_e A}{W}\int_0^w n(x, t)dx \tag{4}$$

$$i_h(t) = \frac{q\upsilon_h A}{W}\int_0^w p(x, t)dx \tag{5}$$

where $n(x, t)$ and $p(x, t)$ represent the electron and hole densities in the depletion region. The total current is the sum of Eqs. (4) and (5).

RC Time Constant

The RC time constant is determined by the equivalent circuit parameters of photodiode. For example, the intrinsic response of the *p-i-n* diode can be modeled as a current source in parallel with a junction capacitor. The diode series resistance, parasitic capacitance, and load impedance form the external circuit. Figure 3 shows the equivalent circuit of the *p-i-n* photodiode. The junction capacitance is defined by the edge of the depletion region (or space charge region). The series resistance is due to the ohmic contacts and bulk resistances. In addition, the parasitic capacitance depends on the metallization

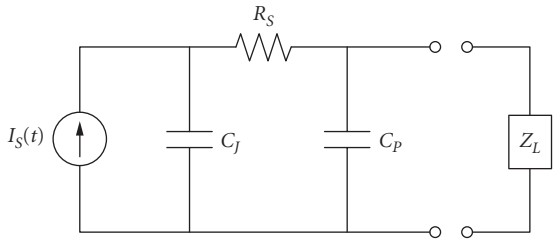

FIGURE 3 Equivalent circuit of a photodiode.

geometry. If the diode series resistance is R_s and a load resistance R_L is used to terminate the device, then the electrical 3-dB bandwidth can be approximated as

$$f_{3\text{dB}} = \frac{1}{2\pi(C_J + C_P)(R_L + R_S)} \tag{6}$$

If the photodiode is bonded by a section of gold wire, additional series inductance will be included in the load impedance. The 3-dB bandwidth due to parasitics in this case is then given in Ref. 3.

Diffusion Current

Diffusion current is important in detectors in which significant absorption occurs in regions outside the high-field region. This effect is reduced to some extent by recombination in these highly doped contact layers. Those carriers within about one diffusion length of the depletion region will have a chance to diffuse into the active region. This diffusion current will contribute a slow tail to the detector impulse response (Fig. 4). The electron diffusion current at the edge of the depletion region is given by

$$J_e = qD_e \frac{\partial n}{\partial x} = qD_e \frac{\Delta n}{L_e} \tag{7a}$$

and

$$J_h = -qD_h \frac{\partial p}{\partial x} = qD_h \frac{\Delta p}{L_h} \tag{7b}$$

where $D_e(D_h)$ and $L_e(L_h)$ are the diffusion coefficient and diffusion length, respectively, for electrons (holes). The diffusion process is a relatively slow process compared with the drift process. Assuming the photocarrier density is n, with the Einstein relation and Eq. (7*a*), the electron diffusion current can be written as

$$J_{\text{DIFF}} = qn\mu_e \left(\frac{kT/q}{L_e} \right) \tag{8}$$

and the drift current term for electron can be written as

$$J_{\text{DRIF}} = qn\mu_e \mathbf{E} \tag{9}$$

where μ_e is the electron mobility and $\mathbf{E}$ is the electric field. For most devices the electric field inside the depletion region is an order of magnitude larger than $(kT/q)L_e$. For example, the hole diffusion

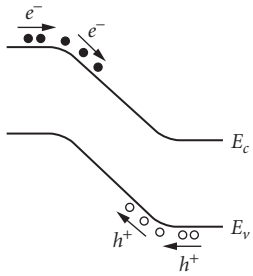

FIGURE 4 The origins of diffusion current.

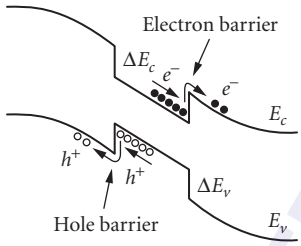

FIGURE 5 Heterostructure carrier trapping effect.

length for GaAs is typically around 10 μm and electric field is very often over 10 kV/cm. However, the diffusion-current terms could last as long as the carrier lifetime and the charge content in the tail can be as large as the drift component due to the slow diffusion times. For high-speed detectors, the diffusion-current problem can be eliminated with a double-heterostructure design that limits the absorbing regions to the high-field intrinsic regions.[24]

Carrier Trapping

Heterojunctions in photodetectors cause carrier trapping of electrons at conduction band discontinuities and trapping of holes at valence band discontinuities (Fig. 5). Hole trapping is a significant problem in long-wavelength photodetectors because of the large valence band discontinuity at the InP/InGaAs heterojunction. Usually, the emission rate is approximated by thermionic emission. If the interface deep-level recombination rate is significant, the total emission rate will be the sum of the two emission rates. The emission functions for electrons and holes are given by

$$e_n(t) = (1/\tau_e)\exp(-t/\tau_e)u(t) \tag{10a}$$

$$e_p(t) = (1/\tau_h)\exp(-t/\tau_h)u(t) \tag{10b}$$

where τ_e (τ_h) represents the emission time constant for electron (hole) and $u(t)$ is the step function. The rates of thermionic emission of trapped carrier are related to the Schottky barrier height due to the bandgap discontinuity:

$$1/\tau_e = B\exp(-\phi_{be}/kT) \tag{11}$$

where B is a constant and ϕ_{bc} is the barrier height for the conduction band. The response of the carrier-trap current in time domain is often obtained by convolving an intrinsic current source with the emission function. Since the applied bias will reduce the barrier height, sufficient device bias therefore will increase the emission rate. In order to reduce the barrier height, superlattice or compositional grading is often added at the heterointerface.[24]

Packaging

The external connections to the photodetector often limit the detector performance. Another problem is that the photodiode is a high impedance load and the device has a reflection coefficient close to unity. One solution to this problem is to integrate a matching resistor with the device.[24] This can usually be added using the lower contact layer without adding any additional mask or process steps. Figure 6 shows a Smith chart plot of the impedance of a typical photodetector along with the impedance of a device with an integrated matching resistor. A good match up to 40 GHz

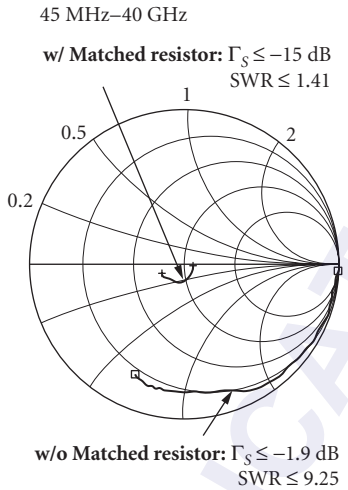

FIGURE 6 Smith chart of the impedance of typical photodiodes and photodiodes with integrated matching resistors.

is achieved. The disadvantage of a load resistor is the reduction in effective quantum efficiency by a factor of two since half of the photocurrent goes through the matching resistor. However, since the load resistance is now one-half, the RC time constant is also cut in half. Bandwidths in excess of 100 GHz have been achieved with quite large devices (7×7 μm^2) in this way. A second problem with very high speed devices is the difficulty in building external bias circuits without resonances in the millimeter range. The necessary bias capacitor and load resistor can be integrated with *p-i-n* photodetector without adding any additional mask or process steps by using a large-area *p-i-n* region as the capacitor and using the lower contact layer as the series resistor.[23] A photograph of the device is shown in Fig. 7 along with the device performance. In this case, bandwidths in excess of 100 GHz were achieved.

Optical fiber alignment and packaging are now quite standard. Simplified alignment by means of holes etched in the substrate of back-illuminated photodiodes may allow passive alignment of optical fibers. The photodetectors must be antireflection coated to reduce the reflection to air or optical epoxy. Single dielectric layers are typically used to minimize the reflection at one wavelength. Braun et al.[25] have achieved minimum reflectivity at multiple wavelengths with one dielectric layer by using one of the semiconductor layers in a multiple antireflectivity design.

26.5 *P-I-N* PHOTODETECTORS

Vertically Illuminated *p-i-n* Photodiode

In order to increase the frequency response of the vertically illuminated *p-i-n* photodiode, the efficiency is always sacrificed. As the active layer thickness is reduced, the transit time decreases, and the optical absorption decreases, and there is a trade-off between the efficiency and speed. The external quantum efficiency for a surface-illuminated *p-i-n* diode is given by

$$\eta = (1-R) \times (1-e^{-\alpha L}) \tag{12}$$

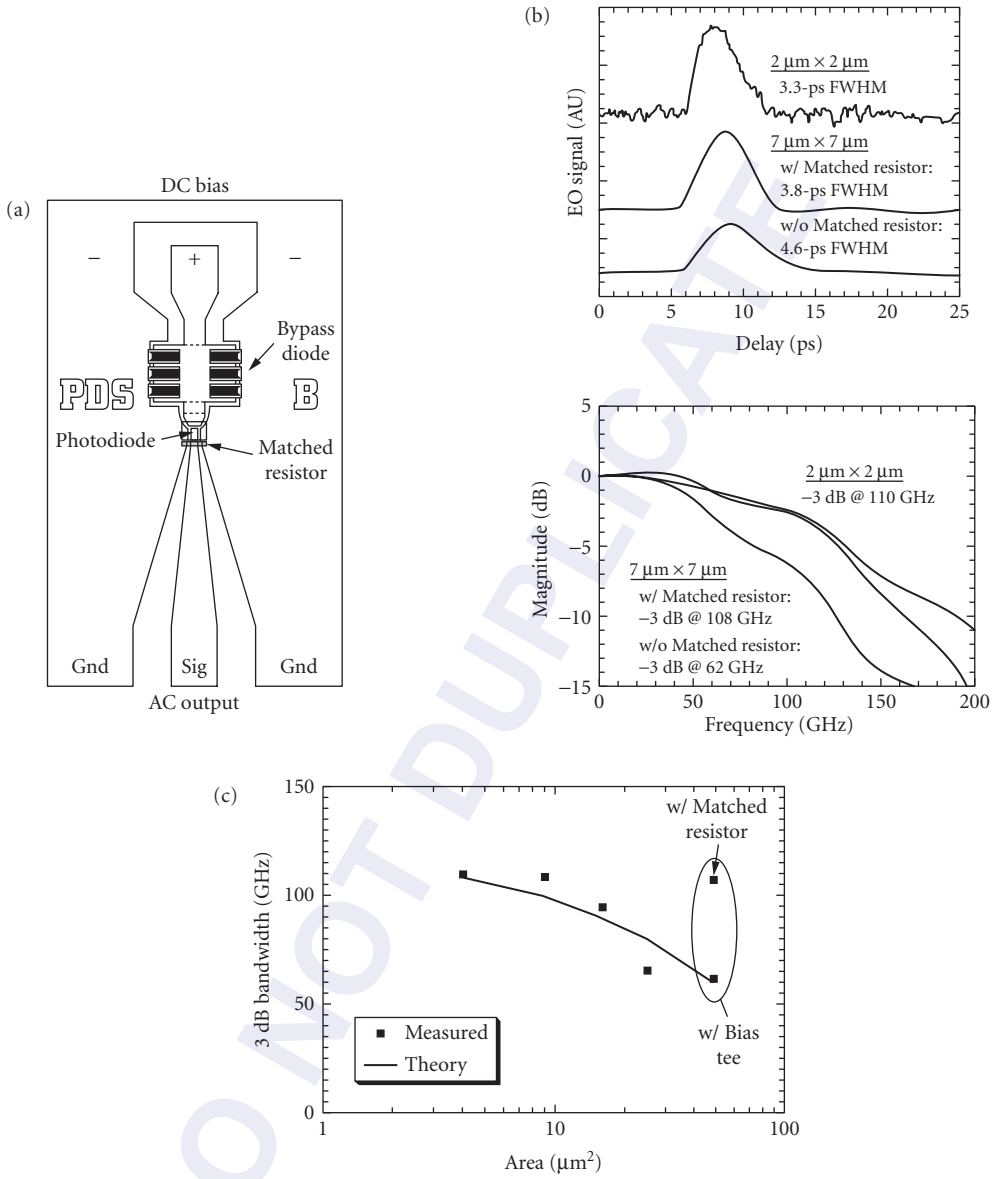

FIGURE 7 (*a*) Schematic diagram of a *p-i-n* photodiode with integrated matching resistor and bias circuit. (*b*) Impulse response of a 2 × 2 μm pin detector compared to 7 × 7 μm detectors with and without matching resistors. (*After Ref. 24.*) (*c*) Dependence of measured bandwidth on detector area and comparison to the theory presented in the text.

where R is the surface reflection, α is the absorption coefficient, and L is the active layer thickness. Since the absorption coefficient is a function of wavelength $\alpha = \alpha(\lambda)$, usually α decreases as λ increases. Thus, the diode intrinsic response is wavelength dependent. We can easily see the effect of light absorption on the transit-time-limited bandwidth by comparing the transit-time response[3,25] for two limiting cases for $\alpha L \to 0$ and $\alpha L \to \infty$ when $t_e = t_h = \tau_r$. The transit-time frequency response for a uniformly illuminated detector is

$$\left|F(\omega)_{\alpha L\to 0}\right| = \frac{2}{\omega\tau_{\text{tr}}}\left[1 + \frac{\sin^2\left(\dfrac{\omega\tau_{\text{tr}}}{2}\right)}{\left(\dfrac{\omega\tau_{\text{tr}}}{2}\right)} - 2\frac{\sin(\omega\tau_{\text{tr}})}{(\omega\tau_{\text{tr}})}\right]^{1/2} \tag{13}$$

For electron-hole pairs generated near the p side of the intrinsic region, electrons travel across the i region, and the frequency response is given by

$$\left|F(\omega)_{\alpha L\to\infty}\right| = \left|\frac{\sin\left(\dfrac{\omega\tau_{\text{tr}}}{2}\right)}{\left(\dfrac{\omega\tau_{\text{tr}}}{2}\right)}\right| \tag{14}$$

For these two limits, the transit-time-limited bandwidths are $f_{3\text{dB}(\alpha L=0)} = 0.45/\tau_{\text{tr}}$ and $f_{3\text{dB}(\alpha L=\infty)} = 0.55/\tau_{\text{tr}}$, respectively. For long-wavelength high-speed p-i-n diodes, the absorption layer is often very thin so that $1 - \exp(-\alpha L) \approx \alpha L$. The bandwidth efficiency product for transit-time-limited p-i-n diode is given by[3]

$$\eta f_{3\text{dB}} = 0.45\alpha v_s \tag{15}$$

Figure 8 shows the calculated 3-dB bandwidth for GaInAs/InP p-i-n diodes on the device area versus thickness plane for wavelength $\lambda = 1.3$ μm. The horizontal axis is the active layer thickness (which

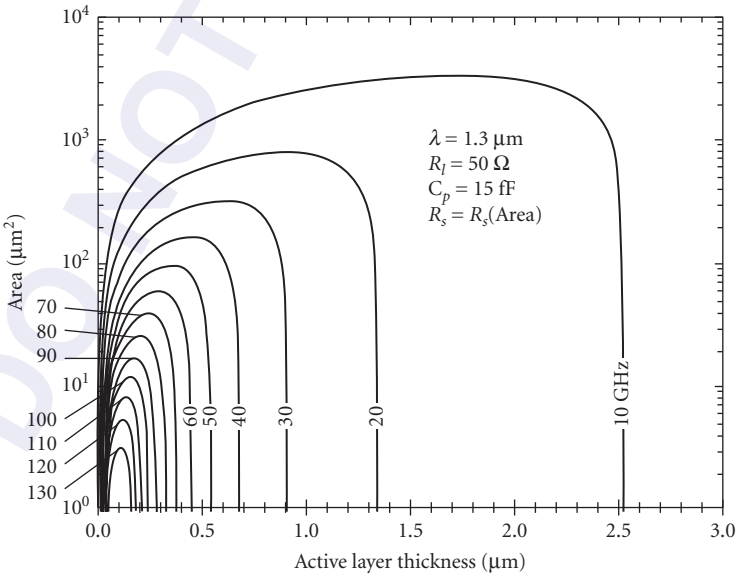

FIGURE 8 Calculated 3-dB bandwidth contours for a GaInAs pin vertically illuminated photodiode.

corresponds to the quantum efficiency) and the vertical axis is the device area. As we can see, when the device active layer thickness decreases, the quantum efficiency of *p-i-n* diode also decreases due to the insufficient light absorption in the active layer. The capacitance decreases as the device area decreases. Optimization of the device bandwidth is reached when transit-time-limited bandwidth approximately equals the RC limited bandwidth.

To minimize the bonding-pad capacitance, a semi-insulating substrate and thick polyimide layer are often used. Sometimes the series inductance of the bond wire is used to resonate the parasitic capacitance, and this results in a slightly peaked response with an increased 3-dB corner frequency. The electrical transfer function with series inductance is given by

$$H(\omega)=\frac{R_L}{[1-\omega^2(R_S R_L C_J C_P + L_S(C_J+C_P))]-j[\omega(R_L(C_J+C_P)+R_S C_J)-\omega^3 R_S C_J C_P L_S]} \tag{16}$$

where L_S is the series inductance.

To achieve high detector bandwidth, *double heterostructure* InP/GaInAs/InP *p-i-n* photodiodes have been fabricated to reduce the diffusion-current problem. However, carrier trapping can limit the impulse response. This effect can be characterized by the emission function $e_{e,h}(t)=(1/\tau_{e,h})\exp(-t/\tau_{e,h})$ where $\tau_{e,h}$ is emission time for electron (hole). The current-source response due to the electron and hole trapping at the heterointerfaces for *p*-side illumination is given by

$$\frac{i_s(\omega)}{i_s(0)}=\frac{1}{(1-e^{-\alpha L})}\left\{\left(\frac{1-e^{-j\omega t_e}}{j\omega t_e}-e^{-\alpha L}\frac{1-e^{-\alpha L}e^{-j\omega t_e}}{j\omega t_e-\alpha L}\right)\left(\frac{1}{1+j\omega\tau_e}\right)\right.$$
$$\left.+\left(\frac{1-e^{-\alpha L}e^{-j\omega t_h}}{j\omega t_e+\alpha L}-e^{-\alpha L}\frac{1-e^{-j\omega t_h}}{j\omega t_h}\right)\left(\frac{1}{1+j\omega\tau_h}\right)\right\} \tag{17}$$

and for *n*-side illumination is given by

$$\frac{i_s(\omega)}{i_s(0)}=\frac{1}{(1-e^{-\alpha L})}\left\{\left(\frac{1-e^{-\alpha L}e^{-j\omega t_e}}{j\omega t_e+\alpha L}-e^{-\alpha L}\frac{1-e^{-j\omega t_e}}{j\omega t_e}\right)\left(\frac{1}{1+j\omega\tau_e}\right)\right.$$
$$\left.+\left(\frac{1-e^{-j\omega t_h}}{j\omega t_h}-e^{-\alpha L}\frac{1-e^{-\alpha L}e^{-j\omega t_h}}{j\omega t_h-\alpha L}\right)\left(\frac{1}{1+j\omega\tau_h}\right)\right\} \tag{18}$$

where $\tau_{e,h}$ is the electron (hole) transit time. Other than the original *p-i-n* diode response, the extra terms $1/(1+j\omega\tau_{e,h})$ are due to the trapping effect. For InGaAs/InP heterostructure *p-i-n* diodes, the valence band offset is larger than the conduction offset and the hole effective mass is much larger than the electron effective mass. Thus, hole trapping is worse than the electron trapping in an InGaAs/InP *p-i-n* diode.

Waveguide *p-i-n* Photodiode

The main advantages of waveguide detectors are the very thin depletion region resulting in a very short transit time and the long absorption region resulting in a high bandwidth photodetector with a high saturation power (Fig. 1*c*). Due to the thin intrinsic layer, it can often operate at zero bias.[27] The absorption length of a waveguide detector is usually *designed to be long enough* (>5 μm) to ensure full absorption. The waveguide structure design (Fig. 9) is often required to have low coupling loss due to modal mismatch and reasonable effective absorption coefficient. The external quantum efficiency of a waveguide *p-i-n* detector is[28,29]

$$\eta=\kappa(1-R)\frac{\Gamma\alpha_{1B}}{\alpha}(1-e^{\alpha L}) \tag{19}$$

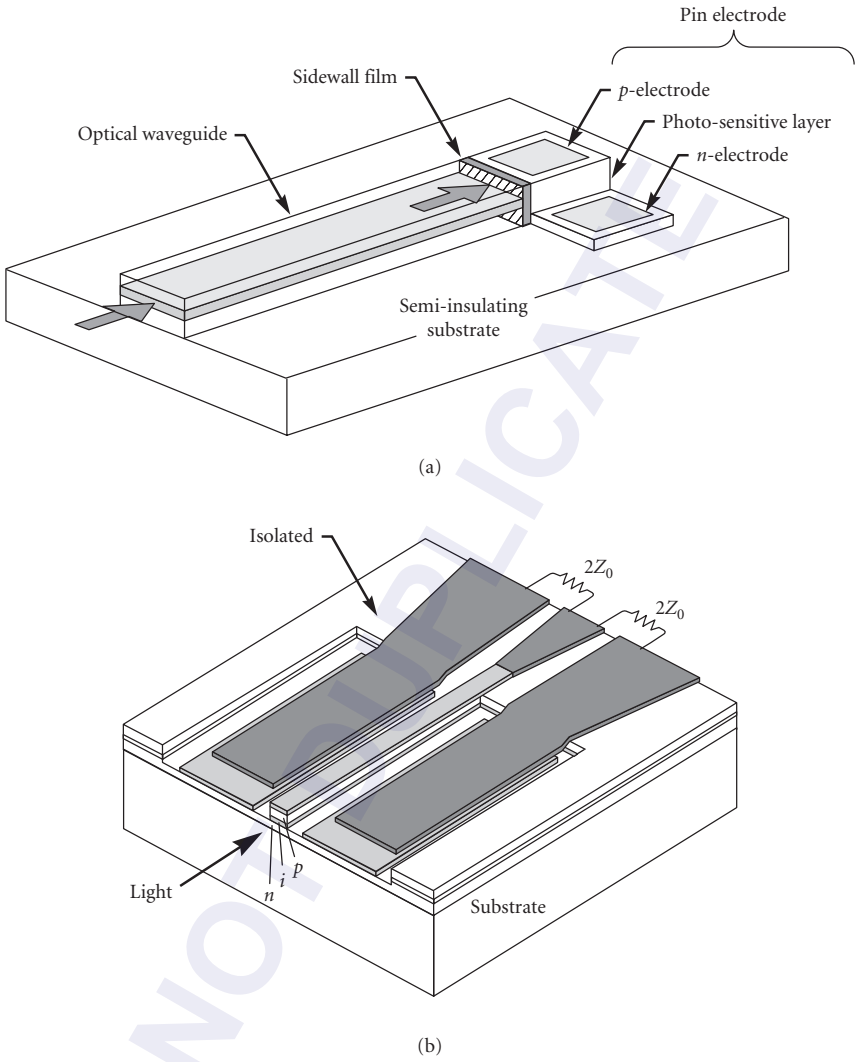

FIGURE 9 Schematic diagram of (*a*) a waveguide photodetector (*after Ref. 14*) and (*b*) a traveling wave photodetector (*after Ref. 17*).

where κ is the coupling efficiency due to the modal mismatch, Γ is the mode confinement factor, α_{IB} is the interband absorption. The loss coefficient α is given by

$$\alpha = \Gamma\alpha_{\mathrm{IB}} + \Gamma\alpha_{\mathrm{FC}} + (1-\Gamma)\alpha_{\mathrm{FCx}} + \alpha_s \tag{20}$$

where α_{FC}, α_{FCx} are the free carrier absorption loss inside and outside the absorption layer, α_s is the scattering loss. Kato et al.[14] reported an InGaAs waveguide *p-i-n* diode with bandwidth of 40 GHz. The detector quantum efficiency is 44 percent at 1.55-μm wavelength. The coupling loss estimated by an overlap integral was 2.1 dB. To reduce the coupling loss, it is important to have a good design of the layer structure to reduce modal mismatch and to coat the facet with an antireflecting (AR) film.

Resonant *p-i-n* Photodiode

A resonant detector utilizes the multiple passes in a Fabry-Perot resonator to achieve high quantum efficiency with thin absorbing layers (Fig. 1*b*). Since the speed of light is about three orders of magnitude faster than the carrier velocities, the quantum efficiency can be increased without significant pulse broadening due to the effective optical transit time.

The schematic diagram of a resonant cavity-enhanced photodetector is shown in Fig. 10. The efficiency of the resonant detector is given by

$$\eta = \left[\frac{(1+R_2 e^{-\alpha d})}{1-2\sqrt{R_1 R_2}\, e^{-\alpha d}\cos(2\beta L+\phi_1+\phi_2)+R_1 R_2 e^{-2\alpha d}} \right] \times (1-R_1)\times(1-e^{-\alpha d}) \tag{21}$$

where R_1, R_2 are mirror reflectivities, ϕ_1, ϕ_2 are mirror phase shifts, $\beta = 2\pi/n\lambda$ is the propagation constant, and d is the thickness of active region. The quantum efficiency has its maximum when $2\beta L+\phi_1+\phi_2 = 2m\pi$ (m=1, 2, 3, ...) and the quantum efficiency is then

$$\eta = \left[\frac{(1+R_2 e^{-\alpha d})}{(1-\sqrt{R_1 R_2}\, e^{-\alpha d})^2} \right] \times (1-R_1)\times(1-e^{-\alpha d}) \tag{22}$$

Figure 11 shows the calculated resonant quantum efficiency versus normalized absorption coefficient αd.[11] High quantum efficiency is possible even from thin absorption layers.

However, in terms of the fabrication, the material growth, and the structure design, building a high-speed resonant photodetector is not a simple task. The required low resistance and low capacitance with incorporated mirror structure is difficult to achieve due to the significant resistance of the multiple heterojunction mirror stack.

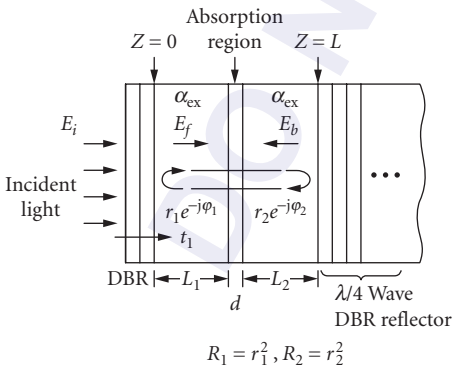

FIGURE 10 Schematic diagram of a resonant photodetector. (*After Ref. 13.*)

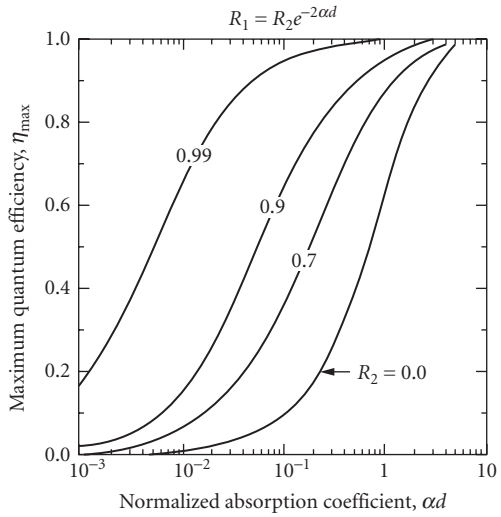

FIGURE 11 Dependence of quantum efficiency on mirror design in a resonant photodetector. (*After Ref. 13.*)

26.6 SCHOTTKY PHOTODIODE

Schottky photodiodes[30–32] are especially attractive for integration with FETs and III-V integrated circuits because of their simple material structure and easy fabrication. Figure 12 shows the Schottky barrier structure. For front-illuminated devices, the metal is very thin so that the light can penetrate the metal with very little loss. The *J-V* characteristic of a Schottky diode is given by[33]

$$J = J_0\left[\exp\left(\frac{qV}{k_B T}\right) - 1\right] \tag{23}$$

where

$$J_0 = A^{**}T^2 \exp\left(-\frac{q\Phi_b}{k_B T}\right) \tag{24}$$

and ϕ_b is the barrier height and A^{**} is the modified effective Richardson constant.[34]

The dynamics of photogenerated carriers in a Schottky diode are similar to those of a *p-i-n* diode (Fig. 2). The dynamics of both electrons and hole must be included in the analysis of a Schottky photodiode, resulting in expressions for the Schottky diode response given in Eqs. (13) to (18) with the exception that there is no diffusion current from the metal layer. The equivalent circuit of a Schottky diode is the same as that of a *p-i-n* diode.

In high-speed applications, GaAs Schottky diodes in the short-wavelength region with bandwidths over 200 GHz have been reported.[36] These devices can be combined with FETs or sampling diodes.[35,36] Figure 13 shows an integrated Schottky photodiode with a diode sampling circuit. A pair of short voltage pulses are generated by the nonlinear transmission line and a differentiator. The short voltage pulses are used to control the sampling capacitors to measure the photodiode signal. The sampled signal is then passed through a low-pass filter to extract the equivalent time domain waveform. Impulse responses of under 2 ps have been demonstrated in this way.[36]

In the long-wavelength region, GaInAs Schottky diodes experience high dark current problems due to the relatively low Schottky barrier height at the metal/GaInAs interface.[37] An InP or quaternary layer is usually added at the interface in order to increase the Schottky barrier height.[38] A graded bandgap layer (e.g., GaInAsP) is then needed at the GaInAs/InP interface to reduce hole trapping.

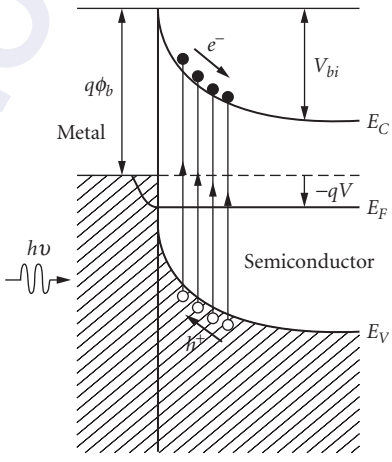

FIGURE 12 Schematic diagram of a Schottky barrier photodiode.

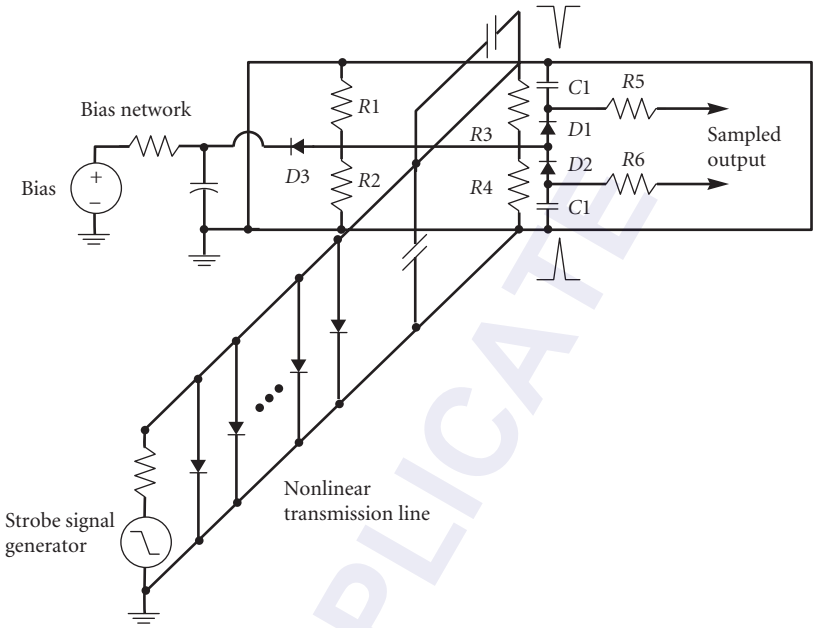

FIGURE 13 Integrated Schottky photodiode and sampling circuit. (*After Ref. 35.*)

26.7 AVALANCHE PHOTODETECTORS

High-speed avalanche photodetectors (APDs) are widely used in fiber communication. APDs with gain-bandwidth (GB) products in excess of 100 GHz have been reported.[39–43] In long-wavelength applications, InGaAs/InP APDs are better than Ge APDs due to their lower dark current and lower multiplication noise. The Ge APD also has a limited spectral response at 1.55-μm wavelength. The maximum achievable GB product of InGaAs/InP APDs is predicted to be around 140 GHz,[44] while the gain-bandwidth product of Si APDs in the near-infrared region can have GB products of over 200 GHz.[45] InGaAs/InAlAs superlattice avalanche photodiodes have a lower ionization ratio ($k = 0.2$)[46] than bulk avalanche photodiodes, and lower noise and higher gain-bandwidth product can be achieved.

High-speed GaInAs/InP APDs make use of separated absorption and multiplication layers (SAM APD). Figure 14 shows the simplified one-dimensional APD structure. The narrow bandgap *n*-GaInAs layer absorbs the incident light. The layer is usually thick (>1 μm) to ensure high quantum efficiency. The electric field in the absorption layer is high enough for carriers to travel at saturated velocities, yet is below the field where significant avalanching occurs and the tunneling current is negligible. The wide bandgap InP multiplication layer is thin (a few tenths of a micron) to have shorter multiplication buildup time.[47,48] The bias is applied to the fully depleted absorption layer in order to obtain effective carrier collection efficiency and, at the same time, electric field in the multiplication region must be high enough to achieve avalanche gain. A guard ring is usually added to prevent premature avalanche breakdown (or microplasma) at the corner of the diffusion edge. To reduce the hole pileup effect, a graded bandgap layer (e.g., superlattice or compositional grading) is often added at the heterointerface between the absorption layer and multiplication layer. This is the so-called separated absorption, grading, multiplication avalanche photodiode (SAGM APD).

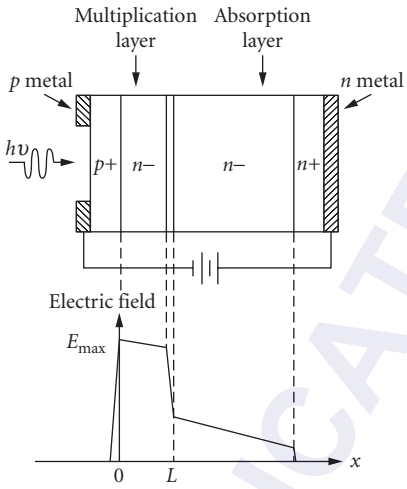

FIGURE 14 Schematic diagram of a SAGM APD.

The multiplication process in APDs can be described by the electron and hole ionization coefficients α_i and β_i. The field dependencies of ionization coefficients for electrons and holes are given by

$$\alpha_i(x) = A_e \exp(-B_e/E(x)) \tag{25a}$$

$$\beta_i(x) = A_h \exp(-B_h/E(x)) \tag{25b}$$

where $A_{e,h}$ and $B_{e,h}$ are constant parameters.[49] Since the electric field is generally position-dependent, the ionization coefficients are also position-dependent. With Eq. (25*a*, *b*) and the electric field distribution, the position-dependence of ionization coefficients can be derived. The multiplied photocurrent in the avalanche region ($0 \le x \le W$) including injected electron current density $J_n(0)$, injected hole current density $J_p(0)$, and photo-generation of electron-hole pairs $g(x)$ was derived by Lee et al.[50] The total photocurrent density is given by

$$J = \frac{J_p(w)\exp\left[-\int_0^w(\alpha_i-\beta_i)dx\right] + J_n(0) + q\int_0^w g(x)\exp\left[-\int_0^x(\alpha_i-\beta)dx'\right]dx}{1-\int_0^w \alpha_i \exp\left[-\int_0^w(\alpha_i-\beta_i)dx'\right]dx} \tag{26}$$

The electron-initiated and hole-initiated multiplication factors, M_n and M_p, can be obtained by putting $J_p(w) = g(x) = 0$ and $J_n(0) = g(x) = 0$, respectively in Eq. (26):

$$M_n = \frac{J}{J_n(0)} = \frac{1}{1-\int_0^w \alpha_i \exp\left[-\int_0^w(\alpha_i-\beta_i)dx'\right]dx} \tag{27a}$$

$$M_p = \frac{J}{J_p(w)} = \frac{\exp\left[-\int_0^w(\alpha_i-\beta_i)dx\right]}{1-\int_0^w \alpha_i \exp\left[-\int_0^w(\alpha_i-\beta_i)dx'\right]dx} \tag{27b}$$

The bandwidth of an APD is limited by the device RC time constant when the multiplication gain M is low (i.e., $M < \alpha_i/\beta_i$). As the multiplication gain increases above the ratio of the electron and hole ionization coefficients (i.e., $M > \alpha_i/\beta_i$), the avalanche buildup time becomes the dominant limitation on 3-dB bandwidth and the product of the multiplication gain and 3-dB bandwidth reaches a constant. The multiplication factor M as a function of frequency was derived by Emmons[51] and is given by

$$M(\omega) \approx \frac{M_o}{\left\{1+\omega^2 M_0^2 \tau_1^2\right\}^{1/2}}, \qquad M_o > \alpha_i/\beta_i \tag{28a}$$

$$\tau_1 \approx N(\alpha_i/\beta_i)\tau \tag{28b}$$

where τ_1 is the effective transit time, τ is the multiplication-region transit time, and $N(\beta_i/\alpha_i)$ is a number changing between 1/3 and 2 as β_i/α_i varies from 1 to 10^{-3}. The dc multiplication factor M_o is given by Miller:[52]

$$M_o = \frac{1}{1-(V_j/V_B)^n} \tag{29}$$

where V_B is the breakdown voltage, V_j is the junction voltage, and n is an empirical factor ($n < 1$).

The total APD dark current consists of two components. I_{du} is the unmultiplied current which is mainly due to the surface leakage current. I_{dm} is the bulk dark current experiencing the multiplication process. The total dark current is expressed by

$$I_d = I_{\text{du}} + MI_{\text{dm}} \tag{30}$$

where M is the avalanche gain. The noise current spectral density due to the dark current is given by

$$\sigma_d^2 = 2qI_{\text{du}} + 2qI_{\text{dm}}M^2F(M) \tag{31}$$

where $F(M)$ is the avalanche excess noise factor derived by McIntyre.[53] Excess noise factors for electron-initiated or hole-initiated multiplication are given by

$$F(M) = F_e(M) = [kM + (1-k)(2-1/M)] \tag{32a}$$

$$F(M) = F_h(M) = \left[\frac{1}{k}M + \left(1-\frac{1}{k}\right)(2-1/M)\right] \tag{32b}$$

where k is the ratio of the ionization coefficient of holes to electrons ($k = \beta_i/\alpha_i$), and k is assumed to be a constant independent of the position. Figure 15 shows the sensitivity of an APD receiver as a function of k_{eff} which is obtained by weighting the ionization rates over the electric field profile. From Fig. 15 we can see that the smaller the k factor is, the smaller the noise factor is and the better the receiver sensitivity is. Ge APDs have k values close to unity (0.7 to 1.0). GaInAs/InP APDs using an InP multiplication region have $1/k$ values from 0.3 to 0.5. Silicon is an excellent APD material since its k value is 0.02. Therefore, a Si APD has an excellent low dark current noise density and is predominantly used at short wavelengths compared with Ge APDs and GaInAs/InP APDs which are used at longer wavelengths.

In optical receiver applications,[54,55] the photodetector is used with a low-noise amplifier. The dark current noise power is given by

$$\left\langle i_{\text{nd}}^2 \right\rangle = 2qI_{\text{du}}BI_2 + 2qI_{\text{dm}}M^2F(M)BI_2 \tag{33}$$

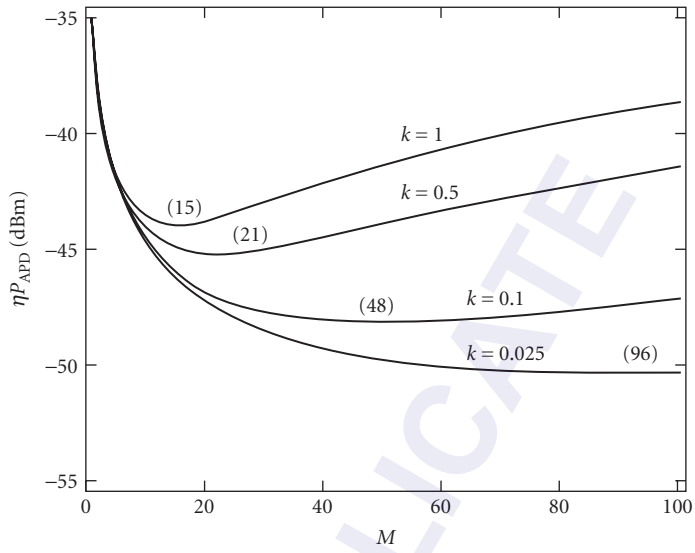

FIGURE 15 Dependence of APD receiver sensitivity on β/α in SAGM APDs. (*After Ref.* 7.)

where B is the receiver bit rate and I_2 is a parameter depending on the input optical pulse shape. The receiver sensitivity penalty[56] is given in terms of parameter ε_N.

$$\eta\overline{P} = (1+\varepsilon_N)\eta\overline{P}_o \tag{34}$$

where $\eta\overline{P}_o$ is the sensitivity with zero dark current. For example, $\varepsilon_N = 0.023$ for a 0.1-dB penalty. The maximum allowable dark current for a given sensitivity for a *p-i-n* FET receiver is

$$I_{du} = \frac{\varepsilon_N(2+\varepsilon_N)}{2qBI_2}\langle i_{na}^2\rangle \tag{35}$$

where $\langle i_{na}^2\rangle$ is the amplifier noise power and is proportional to B^3 above 100 MBits/s. Therefore, the maximum allowable dark current is proportional to B^2. For APD receivers, the maximum allowable dark current I_{dm} as a function of bit rate can be approximated by assuming that the sensitivity penalty is within 1 or 2 dB and optimum gain is constant. In Fig. 16, as we can see, the dark current is proportional to B at lower bit rates and $B^{1.25}$ at higher bit rates. So, as the bit rate increases, the maximum allowable dark current increases.

26.8 PHOTOCONDUCTORS

High-speed photoconductors[57–62] have become more important not only because of their simplicity in fabrication and ease of integration with MESFET amplifiers but also because of their useful applications for photodetector and photoconductor sampling gates. Usually the photoconducting film has a high density of defects with the trap energy levels deep within the bandgap to shorten the material lifetime and the detector impulse response. The characteristics of the photoconductive films include (1) high resistivity due to the fact that Fermi level is pinned at the midgap, (2) enhanced optical absorption for photon energy below the bandgap due to the introduction of new bandgap states, and (3) easy fabrication of ohmic contacts possibly due to the enhancement of tunneling through the narrow Schottky barrier with a pinned Fermi level.

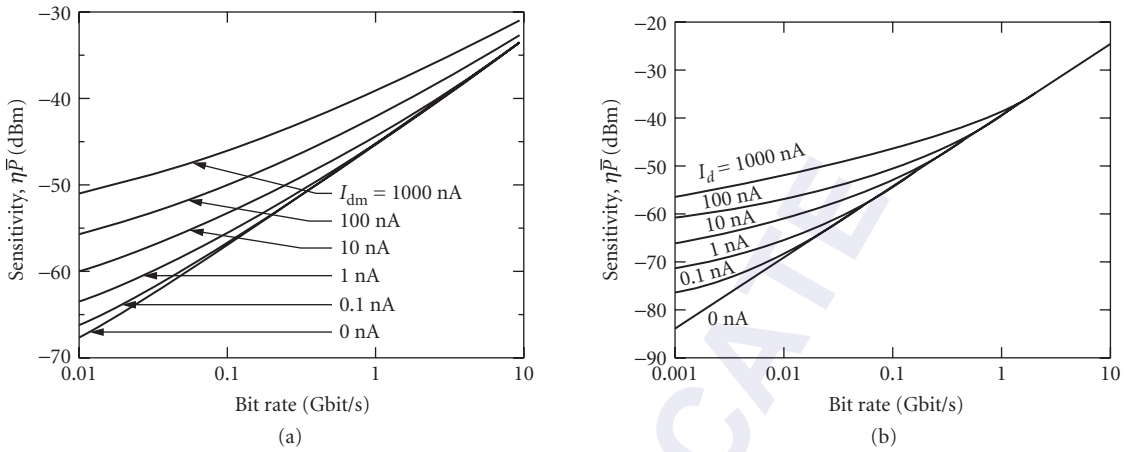

FIGURE 16 Dependence of receiver sensitivity on dark current for an (*a*) SAGM APD and (*b*) PIN detector, each with a GaAs FET preamplifier. (*After Ref. 6.*)

Figure 17 shows a typical photoconductor on a microstrip line structure. The photoconductive film is formed on top of a semi-insulating substrate. A microstrip transmission line consists of microstrip electrodes on top and ground plane on bottom. Under a steady-state illumination, the photogenerated carrier will experience high electrical field and travel to the electrodes. The photocurrent is

$$I_{\text{ph}} = \frac{q\eta GP}{h\nu} \tag{36}$$

where η is the external quantum efficiency, G is the photoconductor gain, and P is optical input flux. The photoconductor gain G is given by

$$G = \frac{\tau}{\tau_{\text{tr}}} \tag{37}$$

which is the ratio of carrier lifetime τ to the carrier transit time τ_{tr}. The frequency response of a photoconductive detector is plotted in Fig. 18 for different material lifetimes. In a detector without damage sites, the gain can be quite large at low frequencies. We can see from this figure how the

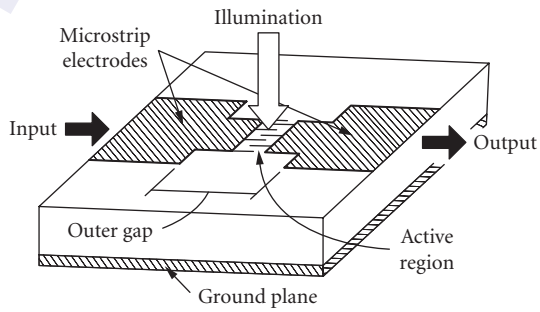

FIGURE 17 Schematic diagram of a high-speed photoconductor.

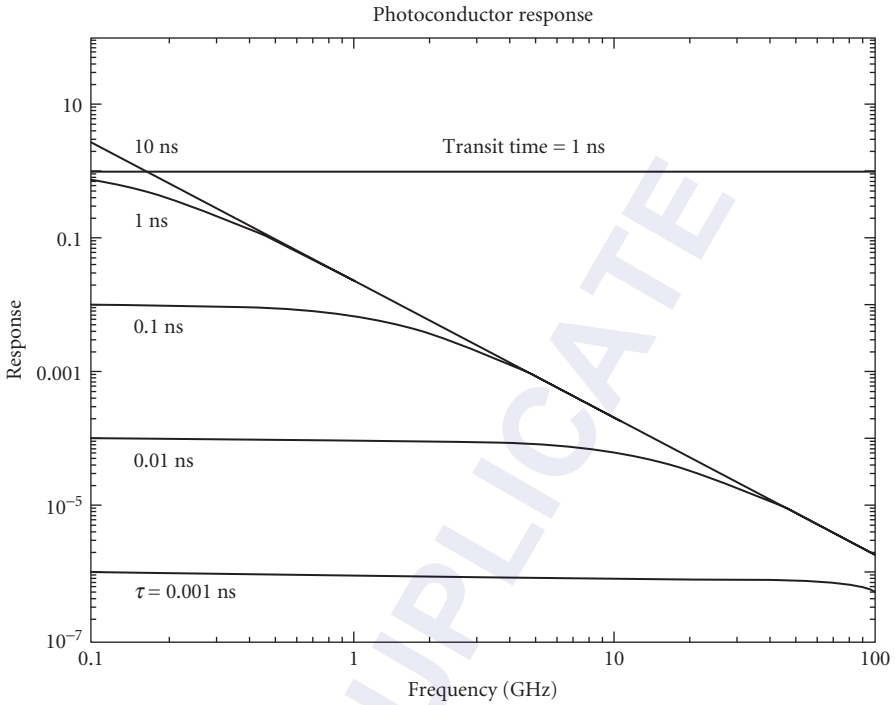

FIGURE 18 Frequency response of a photoconductor.

increased bandwidth is achieved at the expense of quantum efficiency. Using smaller finger separations, higher quantum efficiency can be achieved for a particular bandwidth.

The standard microstrip line configuration has reflection problems in the thickness direction of the substrate and the dispersion characteristics of a microstrip line is worse than that of a coplanar stripline.[57] Coplanar striplines with "sliding-contact" excitation can have zero capacitance to first order.[58] The photoconductor using coplanar stripline has been very successful in generating short electrical pulses. To measure the short electric pulse, several techniques can be used such as photoconductor sampling or electro-optic sampling. Both of the above techniques can provide subpicosecond resolution. The coplanar strip line configuration with sliding contact and sampling gate is shown in Fig. 19*a*. The equivalent circuit is shown in Fig. 19*b*.[58] The infinite capacitances represent that the line extends without end in both directions. The generated electrical signal due to the time-varying resistance $R_s(t)$ is

$$V_{\text{out}}(t) = V_b \frac{Z_o}{Z_o + R_s(t) + R_c} \tag{38}$$

where R_c is the contact resistance. If the excitation intensity is sufficiently low to keep $R_s(t) >> Z_o$, then

$$V_{\text{out}}(t) = V_b \frac{Z_o}{R_s(t) + R_c} \tag{39}$$

The photoconductor resistance $R_s(t)$ can be related to the photoexcited electron-hole pair density $n(t)$:[59]

$$R_s(t) = \frac{L}{qn(t)(\mu_e + \mu_e)wd_e} \tag{40}$$

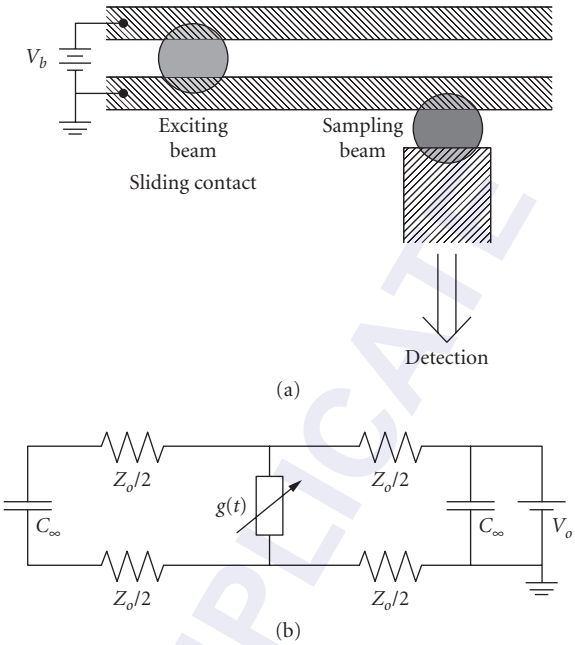

FIGURE 19 (*a*) Coplanar circuit layout of a photoconductor with sliding contact and (*b*) Equivalent circuit.

where L is the gap width, w is the width of photoconductive volume and d_e is the effective absorption length. When the pulse width is of the same order of magnitude as carrier lifetime and much shorter than the carrier transit time across the switch gap, the electron-hole pair density is given by

$$n(t) = e^{-t/\tau} \int_0^t e^{t/\tau} \frac{\eta P_o(t)(1-R)}{h\nu w d_e} dt \tag{41}$$

Here, we notice that the carrier density is an exponential decay function, so $G(t) = 1/R_s(t)$ is also an exponential decaying function with a time constant τ. This can be explained as a result of the convolution of the laser pulse with an exponential function with carrier life time τ.

The low temperature (LT) grown GaAs[60] can have both high carrier mobility and subpicosecond carrier lifetime when being compared with that of the ion-implanted photoconductor.[61] The dislocation density in LT GaAs is about the same as that in GaAs epitaxial layer grown at normal substrate temperatures such that the LT GaAs has a mobility as high as that of the bulk material. The resistivity of the LT GaAs is greater than that of semi-insulating GaAs ($>10^{17}$ Ω-cm) due to its high deep-level concentration. The LT GaAs photoconductive-gap switch in a coplanar strip transmission line configuration has obtained a 1.6-ps (FWHM) response with a 3-dB bandwidth of 220 GHz. Chen et al.[62] reported a high-speed photodetector utilizing LT GaAs MSM photoconductor. To achieve reasonable quantum efficiency and high-speed response, the optimum design requires carrier transit time approximately equal to carrier lifetime. With this requirement, the carriers not collected fast enough by the electrodes will be consumed by recombination. The response of a 0.2-μm finger and space MSM photodetector was measured by electro-optic sampling system. A 1.2 ps (FWHM) response with a 3-dB bandwidth of 350 GHz is obtained.

26.9 SUMMARY

Photodetector performance has steadily improved over the past decade. High-speed detectors are now available at a variety of wavelengths from 1.65 to 0.4 μm. MSM photoconductors have demonstrated the shortest impulse responses of under a picosecond. For applications that require high speed and high efficiency, the best results have been obtained using two passes through a *p-i-n* photodetector (30 percent quantum efficiency with 110-GHz bandwidth). Many applications require a high saturation power, and waveguide photodetectors have achieved the best results (20-GHz bandwidth with 0.5-A/W responsivity and 10-mW saturation power). Traveling wave photodetectors appear to offer the ultimate results in high-speed, high-responsivity, high-saturation power detectors. The combination of high-speed photodetectors with optical amplifiers is resulting in superb sensitivity of all bit rates, but requires the fabrication of high-speed photodetectors with at least 10-dBm saturation power.

An increasing amount of attention is being paid to integrating high-speed photodetectors with electronic and photonic circuits. Integration with electronic circuits increases the performance by eliminating the parasitics and limited bandwidth of bonding pads, wires, and connectors. Integration with optical waveguides decreases the optical loss associated with coupling from one device to another and reduces the packaging cost. Integration of photodetectors with optical amplifiers and wavelength tuning elements is a particularly important research direction.

SIGNAL DETECTION AND ANALYSIS

John R. Willison

Stanford Research Systems, Inc.
Sunnyvale, California

27.1 GLOSSARY

A	dimensionless material constant for $1/f$ noise
C	capacitance (farads)
I	current (amps)
$I_{\text{shot noise}}$	shot noise current (amps)
k	Boltzmann's constant
q	electron charge (Coulombs)
R	resistance (ohms)
S/N	signal-to-noise ratio
T	temperature (Kelvin)
$V_{\text{Johnson, rms}}$	RMS Johnson noise voltage (V)
Δf	bandwidth (Hz)

27.2 INTRODUCTION

Many optical systems require a quantitative measurement of light. Applications range from the very simple, such as a light meter using a photocell and a d'Arsenval movement, to the complex, such as the measurement of a fluorescence lifetime using time-resolved photon counting.

Often, the signal of interest is obscured by noise. The noise may be fundamental to the process: photons are discrete quanta governed by Poisson statistics which gives rise to shot noise. Or, the noise may be from more mundane sources, such as microphonics, thermal emf's, or inductive pickup.

This chapter describes methods for making useful measurements of weak optical signals, even in the presence of large interfering sources. The chapter will emphasize the electronic aspects of the problem. Important details of optical systems and detectors used in signal recovery are covered in Chap. 24, "Photodetectors," by Paul R. Norton; Chap. 25, "Photodetection," by Abhay M.

Joshi and Gregory H. Olsen; and Chap. 26, "High-Speed Photodetectors," by John E. Bowers and Yih G. Wey in this volume.

27.3 PROTOTYPE EXPERIMENT

Figure 1 details the elements of a typical measurement situation. We wish to measure light from the source of interest. This light may be obscured by light from background sources. The intensity of the source of interest, and the relative intensity of the interfering background, will determine whether some or all of the techniques shown in Fig. 1 should be used.

Optics

An optical system is designed to pass photons from the source of interest and reject photons from background sources. The optical system may use spatial focusing, wavelength, or polarization selection to preferentially deliver photons from the source of interest to the detector.

There are many trade-offs to consider when designing an optical system. For example, if the source is nearly monochromatic and the background is broadband, then a monochrometer may be used to improve the signal-to-background ratio of the light reaching the detector. However, if the source of interest is an extended isotropic emitter, then a monochrometer with narrow slits and high *f*-number will dramatically reduce the number of signal photons from the source which can be passed to the detector. In this case, the noise of the detector and amplifiers which follow the optical system may dominate the overall signal-to-noise ratio (*S*/*N*).

Photodetectors

There are many types of nonimaging photodetectors. Key criteria to select a photodetector for a particular application include sensitivity for the wavelength of interest, gain, noise, and speed. Important details of many detector types are given in other chapters in the *Handbook*. Operational details (such as bias circuits) of photomultipliers which are specific to boxcar integration and photon counting are discussed in Sec. 27.5.

Amplifiers

In many applications, the output of the detector must be amplified or converted from a current to a voltage before the signal may be analyzed. Selection criteria for amplifiers include type (voltage or transconductance), gain, bandwidth, and noise.

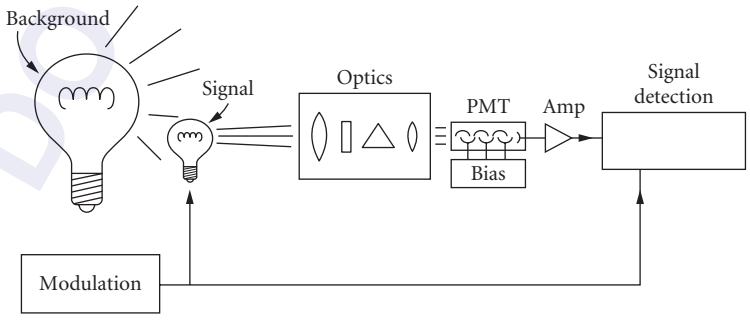

FIGURE 1 Prototypical optical measurement.

Signal Analysis

There are two broad categories of signal analysis, depending on whether or not the source is modulated. Modulating the source allows the signal to be distinguished from the background. Often, source modulation is inherent to the measurement. For example, when a pulsed laser is used to induce a fluorescence, the signal of interest is present only after the laser fires. Other times, the modulation is "arranged," as when a cw source is chopped. Sometimes the source cannot be modulated or the source is so dominant over the background that modulation is unnecessary.

27.4 NOISE SOURCES

An understanding of noise sources in a measurement is critical to achieving signal-to-noise performance near theoretical limits. The quality of a measurement may be substantially degraded by a trivial error. For example, a poor choice of termination resistance for a photodetector may increase current noise by several orders of magnitude.[1]

Shot Noise

Light and electrical charge are quantized, and so the number of photons or electrons which pass a point during a period of time are subject to statistical fluctuations. If the signal mean is M photons, its standard deviation (noise) will be $\sqrt{M}$, hence the $S/N = M/\sqrt{M} = \sqrt{M}$. The mean M may be increased if the rate is higher or the integration time is longer. Short integration times or small signal levels will yield poor S/N values. Figure 2 shows the S/N, which may be expected as a function of current level and integration time for a shot-noise limited signal.

"Integration time" is a convenient parameter when using time-domain signal recovery techniques. "Bandwidth" is a better choice when using frequency-domain techniques. The rms noise current in the bandwidth Δf Hz due to a "constant" current, I amps, is given by

$$I_{\text{shot noise}} = \sqrt{(2qI\,\Delta f)} \tag{1}$$

where $q = 1.6 \times 10^{-19}$ C

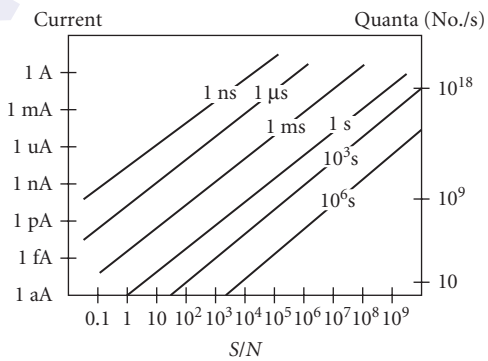

FIGURE 2 Signal-to-noise versus flux and measurement time.

Johnson Noise

The electrons which allow current conduction in a resistor are subject to random motion which increases with temperature. This fluctuation of electron density will generate a noise voltage at the terminals of the resistor. The rms value of this noise voltage for a resistor of R ohms, at a temperature of T Kelvin, in a bandwidth of Δf Hz is given by

$$V_{\text{Johnson,rms}} = \sqrt{(4kTR\Delta f)} \tag{2}$$

where k is Boltzmann's constant. The noise voltage in a 1-Hz bandwidth is given by

$$V_{\text{Johnson,rms}}(\text{per}\sqrt{\text{Hz}}) = 0.13\,\text{nV} \times \sqrt{(R(\text{ohms}))} \tag{3}$$

Since the Johnson noise voltage increases with resistance, large-value series resistors should be avoided in voltage amplifiers. For example, a 1-kΩ resistor has a Johnson voltage of about 4.1 nV/$\sqrt{\text{Hz}}$. If detected with a 100-MHz bandwidth, the resistor will show a noise of 41-μV rms, which has a peak-to-peak value of about 200 μV.

When a resistor is used to terminate a current source, or as a feedback element in a current-to-voltage converter, it will contribute a noise current equal to the Johnson noise voltage divided by the resistance. Here, the noise current in a 1-Hz bandwidth is given by

$$I_{\text{Johnson,rms}}(\text{per}\sqrt{\text{Hz}}) = 130\ \text{pA}/\sqrt{R(\text{ohms})} \tag{4}$$

As the Johnson noise current increases as R decreases, small-value resistors should be avoided when terminating current sources. Unfortunately, small terminating resistors are required to maintain a wide frequency response. If a 1-kΩ resistor is used to terminate a current source, the resistor will contribute a noise current of about 4.1 pA/$\sqrt{\text{Hz}}$, which is about 1000× worse than the noise current of an ordinary FET input operational amplifier.

1/*f* Noise

The voltage across a resistor carrying a constant current will fluctuate because the resistance of the material used in the resistor varies. The magnitude of the resistance fluctuation depends on the material used: carbon composition resistors are the worst, metal film resistors are better, and wire wound resistors provide the lowest 1/f noise. The rms value of this noise source for a resistance of R ohms, at a frequency of f Hz, in a bandwidth of Δf Hz is given by

$$V_{1/f,\text{rms}} = IR \times \sqrt{(A\Delta f/f)} \tag{5}$$

where the dimensionless constant A has a value of about 10^{-11} for carbon. In a measurement in which the signal is the voltage across the resistor (IR), the $S/N = 3\times10^5\sqrt{(f/\Delta f)}$. Often, this noise is a troublesome source of low-frequency noise in voltage amplifiers.

Nonessential Noise Sources

There are many discrete noise sources which must be avoided in order to make reliable low-level light measurements. Figure 3 shows a simplified noise spectrum on log-log scales. The key features in this noise spectra are frequencies worth avoiding: diurnal drifts (often seen via input offset drifts with temperature), low frequency (1/f) noise, power line frequencies and their harmonics, switching power supply and crt display frequencies, commercial broadcast stations

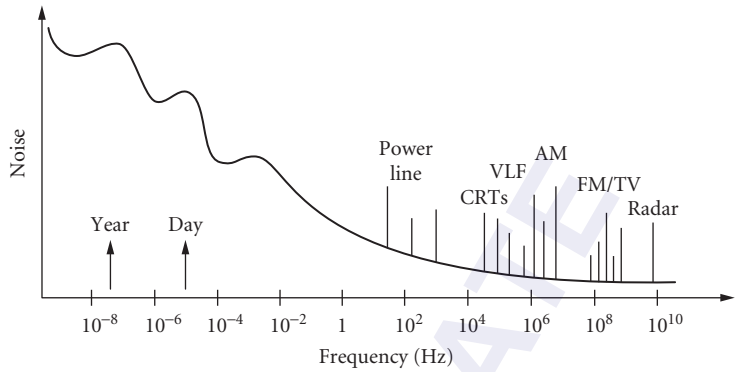

FIGURE 3 Simplified noise spectrum.

(AM, FM, VHF, and UHF TV), special services (cellular telephones, pagers, etc.), microwave ovens and communications, to RADAR and beyond.

Your best alternatives for avoiding these noise sources are

1. Shield to reduce pickup.
2. Use differential inputs to reject common mode noise.
3. Bandwidth limit the amplifier to match expected signal.
4. Choose a quiet frequency for signal modulation when using a frequency-domain detection technique.
5. Trigger synchronously with interfering source when using a time-domain detection technique.

Common ways for extraneous signals to interfere with a measurement are illustrated in Fig. 4*a* to *f*.

Noise may be injected via a stray capacitance as in Fig. 4*a*. The stray capacitance has an impedance of $1/jwC$. Substantial currents may be injected into low-impedance systems (such as transconductance inputs), or large voltages may appear at the input to high-impedance systems.

Inductive pickup is illustrated in Fig. 4*b*. The current circulating in the loop on the left will produce a magnetic field which in turn induces an emf in the loop on the right. Inductive noise pickup may be reduced by reducing the areas of the two loops (by using twisted pairs, for example), by increasing the distance between the two loops, or by shielding. Small skin depths at high frequencies allow nonmagnetic metals to be effective shields; however, high-mu materials must be used to shield from low frequency magnetic fields.

Resistive coupling, or a "ground loop," is shown in Fig. 4*c*. Here, the detector senses the output of the experiment plus the *IR* voltage drop from another circuit which passes current through the same ground plane. Cures for ground-loop pickup include grounding everything to the same point, using a heavier ground plane, providing separate ground return paths for large interfering currents, and using a differential connection between the signal source and amplifier.

Mechanical vibrations can create electrical signals (microphonics) as shown in Fig. 4*d*. Here, a coaxial cable is charged by a battery through a large resistance. The voltage on the cable is $V = Q/C$. Any deformation of the cable will modulate the cable's capacitance. If the period of vibration which causes the deformation is short compared to the *RC* time constant then the stored charge on the cable, *Q*, will remain constant. In this case, a 1-ppm modulation of the cable capacitance will generate an ac signal with an amplitude of 1 ppm of the dc bias on the cable, which may be larger than the signal of interest.

The case of magnetic microphonics is illustrated in Fig. 4*e*. Here, a dc magnetic field (the earth's field or the field from a permanent magnet in a latching relay, for example) induces an emf in the signal path when the magnetic flux through the detection loop is modulated by mechanical motion.

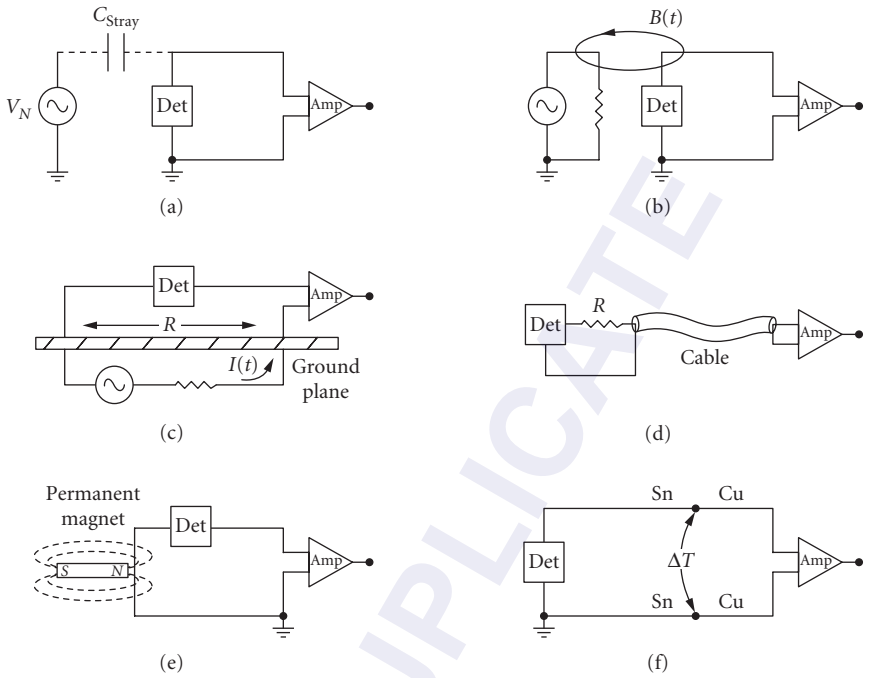

FIGURE 4 Coupling of noise sources.

Unwanted thermocouple junctions are an important source of offset and drift. As shown in Fig. 4*f,* two thermocouple junctions are formed when a signal is connected to an amplifier. For typical interconnect materials (copper, tin) one sees about 10 μV/°C of offset. These extraneous junctions occur throughout instruments and systems: their impact may be eliminated by making ac measurements.

27.5 APPLICATIONS USING PHOTOMULTIPLIERS

Photomultiplier tubes (PMTs) are used for detection of light from about 200 to 900 nm. Windowless PMTs can be used from the near UV through the x-ray region, and may also be used as particle detectors. Their low noise, high gain, wide bandwidth, and large dynamic range have placed them in many applications. They are the only detectors which may be recommended for low-noise photon counting applications.[2,3]

In this chapter, we are primarily concerned with the electrical characteristics of PMTs. Understanding these characteristics is important if we are to realize the many desirable features of these devices.

A schematic representation of a PMT, together with a typical bias circuit, is shown in Fig. 5. While the concepts depicted here are common to all PMTs, the particulars of biasing and termination will change between PMT types and applications. PMTs have a photocathode, several dynodes (6 to 14), and an anode. They are usually operated from a negative high voltage, with the cathode at the most negative potential, each successive dynode at a less negative potential, and the anode near ground. An incident photon may eject a single photoelectron from the photocathode which will strike the first dynode with an energy of a few hundred volts. A few (2– to 5) electrons will be ejected from the first dynode by the impact of the photoelectron: these electrons will in turn strike

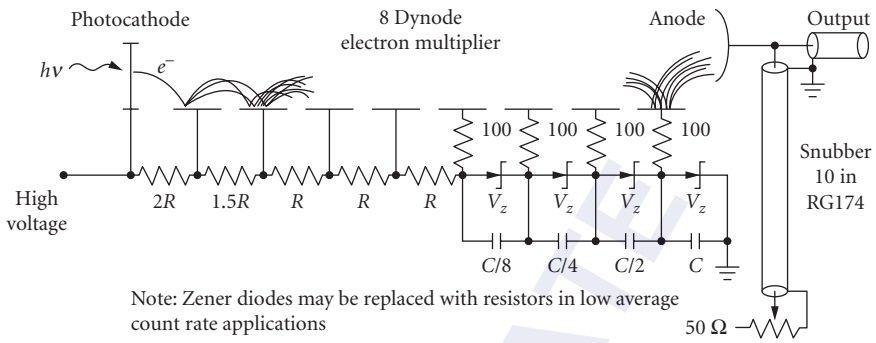

FIGURE 5 PMT base for photon counting or fast integration.

the second dynode, ejecting more electrons. The process continues at each dynode until all of the electrons are collected by the anode.

Quantum Efficiency

The quantum efficiency (QE) of a PMT is a measure of the probability that a photon will eject a photoelectron at the photocathode. The QE depends on the type of material used in the cathode and the wavelength of light. QEs may be as high as 10 to 30 percent at their peak wavelength. The cathode material will also affect the dark count rate from the PMT: a cathode with good red sensitivity may have a high dark count rate.

Gain

A PMT's gain depends on the number of dynodes, the dynode material, and voltage between the dynodes. PMT gains range from 10^3 to 10^7. The anode output from the PMT will typically go to an electronic amplifier. To avoid having the system noise be dominated by the amplifier's noise, the PMT should be operated with enough gain so that the dark current times the gain is larger than the amplifier's input current noise.

Bandwidth

The frequency response, speed, rise time, and pulse-pair resolution of PMTs depend on the structure of the dynode multiplier chain. The leading edges of the anode output have transition times from 2 to 20 ns. Trailing edges are usually about three times slower. Much faster PMTs, with rise times on order 100 ps, use microchannel plate multipliers.

When using gated integrators to measure PMT outputs, the pulse width of the anode signal should be less than the gate width so that timing information is not lost. For photon counting, the pulse width should be smaller than the pulse-pair resolution of the counter/discriminator to avoid saturation effects. When using lock-in amplifiers, pulse width is usually not important, since the slowest PMTs will have bandwidths well above the modulation frequency.

Pulse Height

In pulsed experiments, the criterion for a detectable signal often depends on the electrical noise environment of the laboratory and the noise of the preamplifier. In laboratories with Q-switched lasers or pulsed discharges, it is difficult to reduce the noise on any coaxial cable below a few millivolts.

A good, wide bandwidth preamplifier will have about 1.5 nV/$\sqrt{\text{Hz}}$, or about 25-μV rms over a 300-MHz bandwidth. Peak noise will be about 2.5 times the rms noise, so it is important that the PMT provide pulses of greater than 1-mV amplitude.

Use manufacturer's specifications for the current gain and rise time to estimate the pulse amplitude from the PMT:

$$\text{Amplitude (mV)} = 4 \times \text{gain (millions)/rise time (ns)} \tag{6}$$

This formula assumes that the electrons will enter a 50-Ω load in a square pulse whose duration is twice the rise time. (Since the rise time will be limited by the bandwidth of the preamplifier, use the larger of the amplifier or PMT rise times in this formula.)

If the PMT anode is connected via a 50-Ω cable to a large load resistance, then the pulse shape may be modeled by the lumped parameters of the cable capacitance (about 100 pF/meter for RG-58) and the termination resistance. All of the charge in the pulse is deposited on the cable capacitance in a few nanoseconds. The voltage on the load will be $V = Q/C$ where C = cable capacitance. This voltage will decay exponentially with a time constant of RC where R is the load resistance in ohms. In this case, the pulse height will be

$$\text{Amplitude (mV)} = 160 \times \text{gain (millions)/cable } C \text{ (pF)} \tag{7}$$

The current gain of a PMT is a strong function of the high voltage applied to the PMT. Very often, PMTs will be operated well above the high voltage recommended by the manufacturer, and thus substantially higher current gains (10× to 100× above specs). There are usually no detrimental effects to the PMT as long as the anode current is kept well below the rated value.

Dark Counts

PMTs are the quietest detectors available. The primary noise source is thermionic emission of electrons from the photocathode and from the first few dynodes of the electron multiplier. PMT housings which cool the PMT to about −20°C can dramatically reduce the dark counts (from a few kHz to a few Hz). The residual counts arise from radioactive decays of materials inside the PMT and from cosmic rays.

PMTs which are specifically designed for photon counting will specify their noise in terms of the rate of output pulses whose amplitudes exceed some fraction of a pulse from a single photon. More often, the noise is specified as an anode dark current. Assuming the primary source of dark current is thermionic emission from the photocathode, the dark count rate is given by

$$\text{Dark count (kHz)} = 6 \times \text{dark current (nA)/gain (millions)} \tag{8}$$

PMT Base Design

PMT bases which are designed for general-purpose applications are not appropriate for photon counting or fast-gated integrator applications (gates < 10 to 20 ns). General-purpose bases will not allow high count rates, and often cause problems such as double counting and poor plateau characteristics. A PMT base with the proper high-voltage taper, bypassing, snubbing, and shielding is required for good time resolution and best photon counting performance.

Dynode Biasing A PMT base provides bias voltages to the PMTs photocathode and dynodes from a single, negative, high-voltage power supply. The simplest design consists of a resistive voltage divider. In this configuration the voltage between each dynode, and thus the current gain at each dynode, is the same. Typical current gains are three to five, so there will typically be four electrons leaving the first dynode, with a variance of about two electrons. This large relative variance (due to the small

number of ejected electrons) gives rise to large variations in the pulse height of the detected signal. Since statistical fluctuations in pulse height are dominated by the low gain of the first few stages of the multiplier chain, increasing the gain of these stages will reduce pulse-height variations and so improve the pulse-height distribution. This is important for both photon counting and analog detection. To increase the gain of the first few stages, the resistor values in the bias chain are increased to increase the voltage in the front end of the multiplier chain. The resistor values are tapered slowly so that the electrostatic focusing of electrons in the multiplier chain is not adversely affected.[4]

Current for the electron multiplier is provided by the bias network. Current drawn from the bias network will cause the dynode potentials to change, thus changing the tube gain. This problem is of special concern in lifetime measurements. The shape of exponential decay curves will be changed if the tube gain varies with count rate. To be certain that this is not a problem, lifetime measurements should be repeated at reduced intensity. The problem of gain variation with count rate is avoided if the current in the bias network is about 20 times the output current from the PMT's anode.

There are a few other methods to avoid this problem which do not require high bias currents. These methods depend on the fact that the majority of the output current is drawn from the last few dynodes of the multiplier:

1. Replace the last few resistors in the bias chain with Zener diodes. As long as there is some reverse current through a Zener, the voltage across the diodes is nearly constant. This will prevent the voltage on these stages from dropping as the output current is increased.
2. Use external power supplies for the last few dynodes in the multiplier chain. This approach dissipates the least amount of electrical power since the majority of the output current comes from lower-voltage power supplies. However, it is the most difficult to implement.
3. If the average count rate is low, but the peak count rate is high, then bypass capacitors on the last few stages may be used to prevent the dynode voltage from dropping (use 20× the average output current for the chain current). For a voltage drop of less than 1 percent, the stored charge on the last bypass capacitor should be 100 × the charge output during the peak count rate. For example, the charge output during a 1-ms burst of a 100-MHz count rate, each with an amplitude of 10 mV into 50 Ω and a pulse width of 5 ns, is 0.1 μC. If the voltage on the last dynode is 200 Vdc, then the bypass capacitor for the last dynode should have a value given by

$$C = 100Q/V = 100 \times 0.15C/200V = 0.05\,\mu\text{F} \tag{9}$$

The current from higher dynodes is smaller so the capacitors bypassing these stages may be smaller. Only the final four or five dynodes need to be bypassed, usually with a capacitor which has half the capacitance of the following stage. To reduce the voltage requirement for these capacitors, they are usually connected in series.

Bypassing the dynodes of a PMT may cause high-frequency ringing of the anode output signal. This can cause multiple counts for a single photon or poor time resolution in a gated integrator. The problem is significantly reduced by using small resistors between the dynodes and the bypass capacitors.

Snubbing Snubbing refers to the practice of adding a network to the anode of the PMT to improve the shape of the output pulse for photon counting or fast-gated integrator applications. This "network" is usually a short piece of 50-Ω coax cable which is terminated into a resistor of less than 50 Ω. The snubber will delay, invert, and sum a small portion of the anode signal to itself. Snubbing should not be used when using a lock-in amplifier since the current conversion gain of a 50-Q resistor is very small.

There are four important reasons for using a snubber network:

1. Without some dc resistive path between the anode and ground, anode dark current will charge the signal cable to a few hundred volts (last dynode potential). When the signal cable is connected to an amplifier, the stored charge on the cable may damage the front end of the instrument. PMT bases without a snubber network should include a 100-MΩ resistor between the anode and ground to protect the instruments.

2. The leading edge of the output current pulse is often much faster than the trailing edge. A snubber network may be used to sharply increase the speed of the trailing edge, greatly improving the pulse pair resolution of the PMT. This is especially important in photon counting applications.
3. Ringing (with a few nanoseconds period) is very common on PMT outputs. A snubber network may be used to cancel these rings which can cause multiple counts from a single photon.
4. The snubber network will help to reverse terminate reflections from the input to the preamplifier.

The round-trip time in the snubber cable may be adjusted so that the reflected signal cancels anode signal ringing. This is done by using a cable length with a round-trip time equal to the period of the anode ringing.

Cathode Shielding Head-on PMTs have a semitransparent photocathode which is operated at negative high voltage. Use care so that no objects near ground potential contact the PMT near the photocathode.

Magnetic Shielding Electron trajectories inside the PMT will be affected by magnetic fields. A field strength of a few gauss can dramatically reduce the gain of a PMT. A magnetic shield made of a high permeability material should be used to shield the PMT.

PMT Base Summary

1. Taper voltage divider for higher gain in the first stages.
2. Bypass last few dynodes in pulsed applications.
3. Use a snubber circuit to shape the output pulse for photon counting or fast-gated integration.
4. Shield the tube from electrostatic and magnetic fields.

27.6 AMPLIFIERS

Several considerations are involved in choosing the correct amplifier for a particular application. Often, these considerations are not independent, and compromises will be necessary. The best choice for an amplifier depends on the electrical characteristics of the detector, and on the desired gain, bandwidth, and noise performance of the system.

Voltage Amplifiers

High Bandwidth Photon counting and fast-gated integration require amplifiers with wide bandwidth. A 350-MHz bandwidth is required to preserve a 1-ns rise time. The input impedance to these amplifiers is usually 50 Ω in order to terminate coaxial cables into their characteristic impedance. When PMTs (which are current sources) are connected to those amplifiers, the 50-Ω input impedance serves as the current-to-voltage converter for the PMT anode signal. Unfortunately, the small termination resistance and wide bandwidth yield a lot of current noise.[5]

High Input Impedance It is important to choose an amplifier with a very high input impedance and low-input bias current when amplifying a signal from a source with a large equivalent resistance. Commercial amplifiers designed for such applications typically have a 100-MΩ input impedance. This large input impedance will minimize attenuation of the input signal and reduce the Johnson noise current drawn through the source resistance, which can be an important noise source. Field effect transistors (FETs) are used in these amplifiers to reduce the input bias current to the amplifiers. Shot noise on the input bias current can be an important noise component, and temperature drift of the input bias current is a source of drift in dc measurements.[6]

The bandwidth of a high-input impedance amplifier is often determined by the *RC* time constant of the source, cable, and termination resistance. For example, a PMT with 1 meter of RG-58 coax (about 100 pF) terminated into a 1-MΩ resistor will have a bandwidth of about 1600 Hz. A smaller resistance would improve the bandwidth, but increase the Johnson noise current.

Moderate Input Impedance Bipolar transistors offer an input noise voltage which may be several times smaller than the FET inputs of high-input impedance amplifiers, as low as 1 nV/$\sqrt{\text{Hz}}$. Bipolar transistors have larger input bias currents, hence larger shot noise current, and so should be used only with low-impedance (<1 kΩ) sources.

Transformer Inputs When ac signals from very low source impedances are to be measured, transformer coupling offers very quiet inputs. The transformer is used to step up the input voltage by its turns-ratio. The transformer's secondary is connected to the input of a bipolar transistor amplifier.

Low Offset Drift Conventional bipolar and FET input amplifiers exhibit input offset drifts on the order of 5 μV/C. In the case where the detector signal is a small dc voltage, such as from a bolometer, this offset drift may be the dominant noise source. A different amplifier configuration, chopper-stabilized amplifiers, essentially measure their input offsets and subtract the measured offset from the signal. A similar approach is used to "autozero" the offset on the input to sensitive voltmeters. Chopper-stabilized amplifiers exhibit very low input offsets with virtually no input offset drift.

Differential The use of "true-differential" or "instrumentation" amplifiers is advised to provide common mode rejection to interfering noise, or to overcome the difference in grounds between the voltage source and the amplifier. This amplifier configuration amplifies the difference between two inputs, unlike a single-ended amplifier, which amplifies the difference between the signal input and the amplifier ground. In high-frequency applications, where good differential amplifiers are not available or are difficult to use, common mode choke may be used to isolate disparate grounds.

Transconductance Amplifiers

When the detector is a current source (or has a large equivalent resistance) then a transconductance amplifier should be considered. These amplifiers (current-to-voltage converters) offer the potential of lower noise and wider bandwidth than a termination resistor and a voltage amplifier; however, some care is required in their application.[7]

A typical transconductance amplifier configuration is shown in Fig. 6. An FET input op amp would be used for its low-input bias current. (Op amps with input bias currents as low as 50 fA are readily available.) The detector is a current source, I_o. Assuming an ideal op amp, the transconductance gain is $A = V_{\text{out}}/I_{\text{in}} = R_f$, and the input impedance of the circuit is R_{in} to the op amp's virtual null. (R_{in} allows negative feedback, which would have been phase shifted and attenuated by the

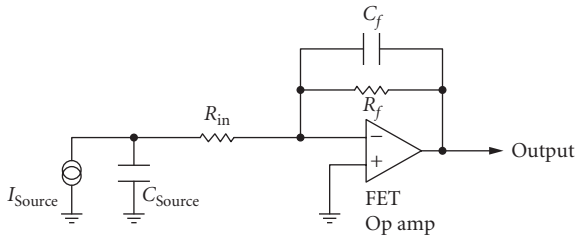

FIGURE 6 Typical transconductance amplifier.

source capacitance at high frequencies, to assure stability.) Commercial transconductance amplifiers use *R*s' as large as 10 MΩ, with R_{in}'s, which are typically R_f/1000. A low-input impedance will ensure that current from the source will not accumulate on the input capacitance.

This widely used configuration has several important limitations which will degrade its gain, bandwidth, and noise performance. The overall performance of the circuit depends critically on the source capacitance, including that of the cable connecting the source to the amplifier input. Limitations include:

1. The "virtual null" at the inverting input to the op amp is approximately R_f/A_v where A_v is the op amp's open loop gain at the frequency of interest. While op amps have very high gain at frequencies below 10 Hz (typically a few million), these devices have gains of only a few hundred at 1 kHz. With an R_f of 1 GΩ, the virtual null has an impedance of 5 MΩ at 1 kHz, hardly a virtual null. If the impedance of the source capacitance is less than the input impedance, then most of the ac input current will go to charging this capacitance, thereby reducing the gain.
2. The configuration provides high gain for the voltage noise at the noninverting input of the op amp. At high frequencies, where the impedance of the source capacitance is small compared to R_{in}, the voltage gain for noise at the noninverting input is R_f/R_{in}, typically about 1000. As FET input op amps with very low bias currents tend to have high-input-voltage noise, this term can dominate the noise performance of the design.
3. Large R_f's are desired to reduce the Johnson noise current; however, large R_f's degrade the bandwidth. If low values of R_f are used, the Johnson noise current can dominate the noise performance of the design.
4. To maintain a flat frequency response, the size of the feedback capacitance must be adjusted to compensate for different source capacitances.

As many undesirable characteristics of the transconductance amplifier can be traced to the source capacitance, a system may benefit from integrating the amplifier into the detector, thereby eliminating interconnect capacitance. This approach is followed in many applications, from microphones to CCD imagers.

27.7 SIGNAL ANALYSIS

Unmodulated Sources

For unmodulated sources, a strip-chart recorder, voltmeter, *A*/*D* converter, or oscilloscope may be used to measure the output of the amplifier or detector. In the case of low-light-level measurement, continuous photon counting would be the method of choice.

A variety of problems are avoided by modulating the signal source. When making dc measurements, the signal must compete with large low-frequency noise sources. However, when the source is modulated, the signal may be measured at the modulation frequency, away from these large noise sources.

Modulated Sources

When the source is modulated, one may choose from gated integration, boxcar averaging, transient digitizers, lock-in amplifiers, spectrum analyzers, gated photon counters, or multichannel scalers.

Gated Integration A measurement of the integral of a signal during a period of time can be made with a gated integrator. Commercial devices allow gates from about 100 ps to several milliseconds. A gated integrator is typically used in a pulsed laser measurement. The device can provide shot-by-shot data which is often recorded by a computer via an *A*/*D* converter. The gated integrator is

recommended in situations where the signal has a very low duty cycle, low pulse repetition rate, and high instantaneous count rates.[8]

The noise bandwidth of the gated integrator depends on the gate width: short gates will have wide bandwidths, and so will be noisy. This would suggest that longer gates would be preferred; however, the signal of interest may be very short-lived, and using a gate which is much wider than the signal will not improve the *S*/*N*.

The gated integrator also behaves as a filter: the output of the gated integrator is proportional to the average of the input signal during the gate, so frequency components of the input signal which have an integral number of cycles during the gate will average to zero. This characteristic may be used to "notch out" specific interfering signals.

It is often desirable to make gated integration measurements synchronously with an interfering source. (This is the case with time-domain signal detection techniques, and not the case with frequency-domain techniques such as lock-in detection.) For example, by locking the pulse repetition rate to the power-line frequency (or to any submultiple of this frequency) the integral of the line interference during the short gate will be the same from shot to shot, which will appear as a fixed offset at the output of the gated integrator.

Boxcar Averaging Shot-by-shot data from a gated integrator may be averaged to improve the *S*/*N*. Commercial boxcar averagers provide linear or exponential averaging. The averaged output from the boxcar may be recorded by a computer or used to drive a strip-chart recorder. Figure 7 shows a gated integrator with an exponential averaging circuit.

Lock-In Amplifiers Phase-sensitive synchronous detection is a powerful technique for the recovery of small signals which may be obscured by interference that is much larger than the signal of interest. In a typical application, a cw laser which induces the signal of interest will be modulated by an optical chopper. The lock-in amplifier is used to measure the amplitude and phase of the signal of interest relative to a reference output from the chopper.[9]

Figure 8 shows a simplified block diagram for a lock-in amplifier. The input signal is ac-coupled to an amplifier whose output is mixed (multiplied by) the output of a phase-locked loop which is locked to the reference input. The operation of the mixer may be understood through the trigonometric identity

$$\cos(\omega_1 t+\Phi)*\cos(\omega_2 t)=\frac{1}{2}\{\cos[(\omega_1+\omega_2)t+\Phi]+\cos[(\omega_1-\omega_2)t+\Phi]\} \tag{10}$$

When $\omega_1 = \omega_2$ there is a dc component of the mixer output, cos Φ. The output of the mixer is passed through a low-pass filter to remove the sum frequency component. The time constant of the filter is selected to reduce the equivalent noise bandwidth: selecting longer time constants will improve the *S*/*N* at the expense of longer response times.

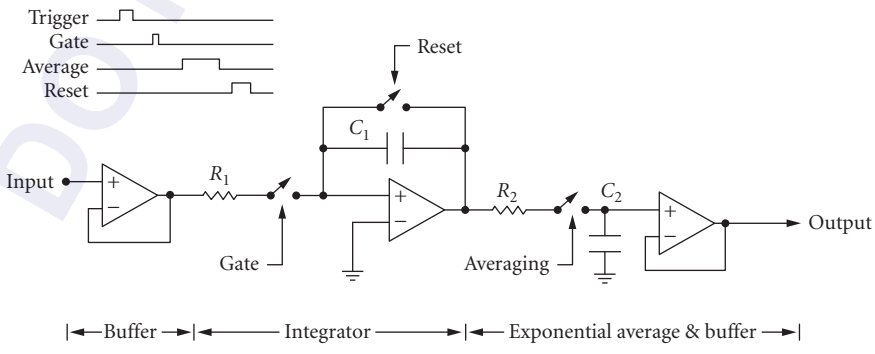

FIGURE 7 Gated integrator and exponential averager.

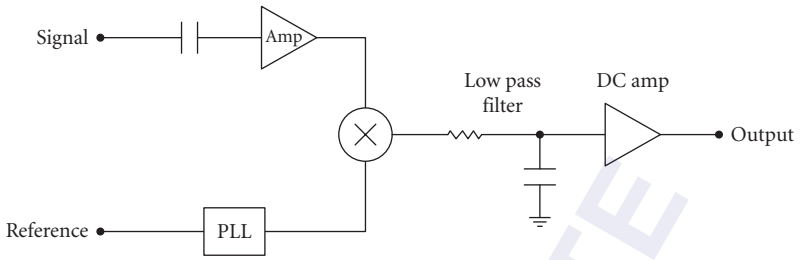

FIGURE 8 Lock-in amplifier block diagram.

The simplified block diagram shown in Fig. 8 is for a "single-phase" lock-in amplifier, which measures the component of the signal at one set phase with respect to the reference. A dual-phase lock-in has another channel which measures the component of the signal at 90° relative to the first channel, which allows simultaneous measurement of the amplitude and phase of the signal.

Digital signal processing (DSP) techniques are rapidly replacing the older analog techniques for the synchronous detection of the signal. In these instruments, the input signal is digitized by a fast, high-resolution *A*/*D* converter, and the signal's amplitude and phase are determined by high-speed computations in a digital signal processor. To maintain the 100-kHz bandwidth of the analog designs, the DSP designs must complete a quarter million 16-bit *A*/*D* conversions and 20 million multiply-and-accumulate operations each second. Many artifacts of the analog designs are eliminated by the DSP approach; for example, the output drift and dynamic range of the instruments are dramatically improved.[10]

Photon Counting Photon counting techniques offer several advantages in the measurement of light: very high sensitivity (count rates as low as 1 per minute can be a usable signal level), large dynamic range (signal levels as high as 100 MHz can be counted, allowing a 195-dB dynamic range), discrimination against low-level noise (analog noise below the discriminator thresholds will not be counted), and ability to operate over widely varying duty cycles.[11]

Key elements of a photon counting system include a high-gain PMT operated with sufficiently high voltage so that a single photoelectron will generate an anode pulse of several millivolts into a 50-Ω load, a fast discriminator to generate logic pulses from anode signals which exceed a set threshold, and fast-gated counters to integrate the counts.

Transient Photon Counting In situations where the time evolution of a light signal must be measured (LIDAR, lifetime measurements, chemical kinetics, etc.) transient photon counters allow the entire signal to be recorded for each event. In these instruments, the discriminated photon pulses are summed into different bins depending on their timing with respect to a trigger pulse. Commercial instruments offer 5-ns resolution with zero dead-time between bins. The time records from many events may be summed together in order to improve the *S*/*N*.[12]

Choosing the "Best" Technique Which instrument is best suited for detecting signals from a photomultiplier tube? The answer is based on many factors, including the signal intensity, the signal's time and frequency distribution, the various noise sources and their time-dependence and frequency distribution.

In general, the choice between boxcar averaging (gated integration) and lock-in detection (phase-sensitive detection) is based on the time behavior of the signal. If the signal is fixed in frequency and has a 50 percent duty cycle, lock-in detection is best suited. This type of experiment commonly uses an optical chopper to modulate the signal at some low frequency. Signal photons occur at random times during the "open" phase of the chopper. The lock-in detects the average difference between the signal during the "open" phase and the background during the "closed" phase.

To use a boxcar averager in the same experiment would require the use of very long, 50 percent duty cycle gates since the photons can arrive anywhere during the "open" phase. Since the gated integrator is collecting noise during this entire gate, the signal is easily swamped by the noise. To correct for this, baseline subtraction can be used where an equal gate is used to measure the background during the "closed" phase of the chopper and subtracted from the "open" signal. This is then identical to lock-in detection. However, lock-in amplifiers are much better suited to this, especially at low frequencies (long gates) and low signal intensities.

If the signal is confined to a very short amount of time, then gated integration is usually the best choice for signal recovery. A typical experiment might be a pulsed laser excitation where the signal lasts for only a short time (100 ps to 1 μs) at a repetition rate of up to 10 kHz. The duty cycle of the signal is much less than 50 percent. By using a narrow gate to detect signal only when it is present, noise which occurs at all other times is rejected. If a longer gate is used, no more signal is measured but the detected noise will increase. Thus, a 50 percent duty cycle gate would not recover the signal well and lock-in detection is not suitable.

Photon counting can be used in either the lock-in or the gated mode. Using a photon counter is usually required at very low signal intensities or when the use of a pulse height discriminator to reject noise results in an improved *S*/*N*. If the evolution of a weak light signal is to be measured, a transient photon counter or multichannel scaler can greatly reduce the time required to make a measurement.

28.1 GLOSSARY

DTGS	deuterated triglycine sulfate
p	pyroelectric coefficient
R_e	electrical resistance
R_{th}	thermal resistance
$\Re$	responsivity
S	Seebeck coefficient
TGS	triglycine sulfate
Z	figure of merit
τ_e	electrical time constant
τ_{th}	thermal time constant

28.2 THERMAL DETECTOR ELEMENTS[1]

Introduction

Thermal detectors (transducers) of optical radiation are generally considered to be those devices that absorb the radiation, increase their own temperature, and provide a resultant electrical signal. There are several types, divided according to the physical mechanism that converts the temperature change to a resultant electrical one. The oldest are bolometers and thermocouples. The bolometer changes its electrical resistance as a result of the temperature increase; the thermocouple changes its contact potential difference. There are several different types of bolometers, including thermistor, semiconducting, superconducting, carbon, and metallic. They may also be subdivided according to whether they operate at room or cryogenic temperature. Thermocouples vary according to the materials that are joined, and are sometimes connected in series to generate thermopiles.

Pyroelectric detectors make use of the property of a change in the internal polarization as a function of the change in temperature, the pyroelectric effect. Golay cells and certain variations make use of the expansion of a gas with temperature. All of these detectors are governed by the fundamental equation of heat absorption in the material. Many reviews and two books of collected reprints[2] provide additional information.

Thermal Circuit Theory

In the absence of joulean heating of the detector element, the spectrum of the temperature difference $d\Delta\tilde{T}$ is given in terms of the spectrum of the absorbed power $\tilde{P}$ (the power is *P)*

$$d\Delta\tilde{T} = \frac{\epsilon\tilde{P}}{G(1+i\omega\tau)} \tag{1}$$

where G is the thermal conductance, given by the product of the thermal conductivity times the cross-sectional area of the path to the heat sink and divided by the length of the path to that heat sink. The time constant τ is the product of the thermal resistance and the heat capacitance. The thermal resistance is the reciprocal of the thermal conductance, while the thermal capacitance is the thermal capacity times the mass of the detector. In the absence of joulean heating, this is a simple, single time constant thermal circuit, for which the change in temperature is given by

$$d\tilde{T} = \frac{\epsilon\tilde{P}}{G(1+i\omega\tau)} \tag{2}$$

The absorbed power is equal to the incident power times the absorptance α of the material:

$$\tilde{P} = \epsilon\tilde{P}_i \tag{3}$$

The absorptance α is usually written as ϵ (which is legitimate according to Kirchhoff's law) since α is also used for the relative temperature coefficient of resistance (some writers use η).

$$\alpha = \frac{1}{R}\frac{dR}{dT} \tag{4}$$

As radiation is absorbed, part of the heat is conducted to the sink. Some of it gives rise to an increase in temperature. Some is reradiated, but this is usually quite small and is ignored here. The dc responsivity of a thermal detector is proportional to the emissivity and to the thermal resistance. The greater proportion of radiation that is absorbed, the greater will be the responsivity. The less heat that is conducted to the sink, the greater will be the temperature rise. The time constant is a true thermal time constant, the product of thermal resistance and capacitance. The greater the heat capacitance, the more heat necessary for a given temperature increase, and the less heat conducted to the sink, the more available for temperature increase. A high absorptance is accomplished by the use of a black coating, and a sufficient amount of it. Thus, there is a direct conflict between high speed and high responsivity.

The Ideal Thermal Detector[3–6]

The ideal thermal detector has a noise that is associated only with the thermal fluctuations of the heat loss to the heat sink, and this coupling is purely radiative. Then the noise equivalent power (NEP) is given by

$$\text{NEP} = \sqrt{16A\sigma kT^5/\epsilon} \tag{5}$$

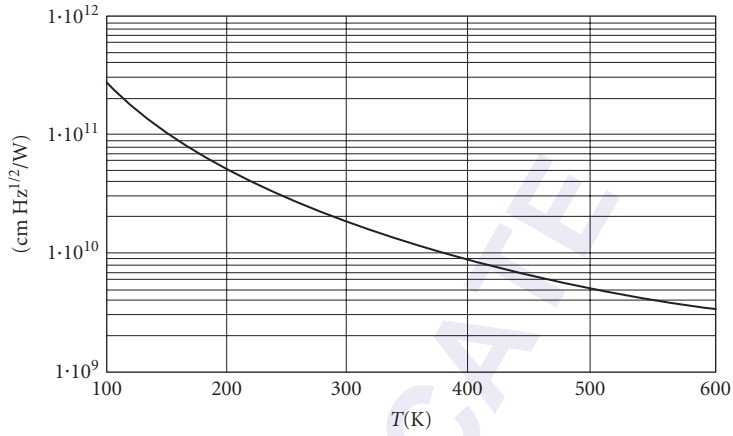

FIGURE 1 Theoretical specific detectivity for ideal thermal detectors.

where it is assumed that the detector is irradiated by a hemisphere of blackbody radiation at the same temperature T as the detector. The corresponding specific detectivity, assuming that the signal varies as the area and the noise as its square root, is

$$D^* = \frac{\epsilon^{1/2}}{4\sqrt{\sigma k T^5}} \tag{6}$$

where the detector and background are at the same temperature.

For circumstances in which the detector is in a cooled chamber, the total radiation from the sources at various temperatures must be calculated. Figure 1 shows the specific detectivity of a background limited ideal thermal detector as a function of the temperature of the surround.

No detector is ideal, and every one will be limited by the signal loss due to incomplete absorption at the surface and any transmission losses by the optical system that puts the radiation on the detector. The detector will also have noise that arises from its conductive coupling to the heat sink, and probably Johnson noise as well. The conductive mean square power fluctuation is given by

$$\langle P^2 \rangle = 4kT^2G \tag{7}$$

The Johnson noise power density is $4kT$. Therefore, the total mean square power fluctuation is given by

$$\langle P^2 \rangle = 4kT[GT + 4\epsilon A\sigma T^4 + 1] \tag{8}$$

Bolometers

Most single-element bolometers are connected in a voltage divider network, as shown in Fig. 2. A stable voltage supply is used to develop a current and consequent voltage drop across the two resistors. One is the detector, while the other should be a matching element to eliminate signals arising from a change in the ambient temperature. It should match the detector in both resistance and in the

temperature coefficient of resistance. Usually another, but blinded, detector is used. The expression for power conservation is

$$C\frac{d\Delta T}{dt}+G\Delta T=\frac{d(i^2R)}{dt}\Delta T+P$$
$$C\frac{d\Delta T}{dt}+G\Delta T=\frac{V^2(R_1-R)}{(R_1+R)^3}\frac{dR}{dT}\Delta T+P \tag{9}$$
$$C\frac{d\Delta T}{dt}+\left[G-\frac{V^2R\alpha}{(R_1+R)^2}\frac{(R_1-R)}{(R_1+R)}\right]\Delta T=P$$

The solution to this is a transient that has an RC time constant, where R is the reciprocal of the bracketed term, and C is the thermal capacitance, and the same steady-state term given above. The transient decays as long as G is greater than the rest of the bracket, but the detector burns up if not. This is still another reason for matching the resistances. The dc responsivity is a function of the construction parameters, including the path to the sink, the bias voltage, and the relative change of resistance with temperature. The different bolometers are divided according to how their resistances change with temperature. (R_1 and R represent slightly different values of R_D.)

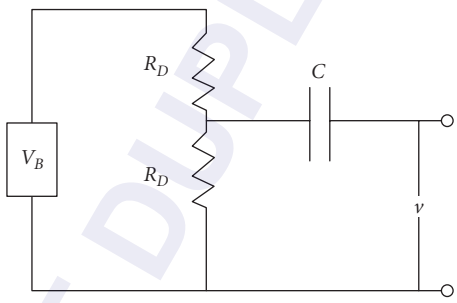

FIGURE 2 Balanced voltage divider circuit for a thermal detector.

Metal Bolometers These have a linear change in resistance with temperature that may be expressed as

$$R=R_0[1+\gamma(T-T_0)] \tag{10}$$

Therefore the thermal coefficient is

$$\alpha=\frac{\gamma}{1+\gamma(T-T_0)} \tag{11}$$

This coefficient always decreases with temperature, and burnout does not occur. The coefficient is approximately equal to the inverse of the temperature, and is therefore never very high.

Semiconductor Bolometers These have an exponential change of resistance with temperature, given by

$$R=R_0e^{\beta/T} \tag{12}$$

so that

$$\alpha=-\beta/T^2 \tag{13}$$

The value of β depends upon the particular material. These detectors can burn out. Two basic types exist: (1) those that are used at low temperatures and (2) those that are used at about room temperature.

The most used low-temperature bolometer[7] is germanium in a bath of liquid helium. Pure germanium is transparent in the infrared, but with enough compensated doping it becomes a good conductor with a high-temperature coefficient of resistance.[8] Typical concentrations are about 10^{16}cm^{-3} of gallium and 10^{15} of indium. Even these are not sufficient at wavelengths shorter than 10 μm since the free-carrier absorption is proportional to wavelength. In such a case a black coating is sometimes used. Improvements have been made since Low's first work.[9–11]

Superconducting Bolometers These make use of the extremely large thermal coefficient of resistance at the transition temperature.[12–14] Originally they needed to be controlled very carefully, or a small change in ambient conditions (on the order of 0.01 K) could cause an apparent signal of appreciable magnitude. A more recent version[15] incorporates an evaporated thin film on an anodized aluminum block that is coupled to a helium bath by a brass rod. The detector has a time constant of about 3 μs due to this high thermal conductance and a good NEP of about 10^{-13} WHz$^{-1/2}$. It still must be controlled to about 10^{-5} K, and this is accomplished with a heater current and control circuit.

Recently developed materials not only have high-temperature transition points but also have more gradual transitions, and provide a better compromise between good responsivity and the requirement for exquisite control.[16]

Carbon Bolometers These are a form of semiconductor bolometers that have been largely superseded by germanium bolometers. They are made of small slabs of carbon resistor material, connected to a metal heat sink by way of a thin mylar film. Although their responsivities are comparable to germanium bolometers, their noise is several orders of magnitude higher.[17]

Thermocouples and Thermopiles[18,19]

A *thermocouple* is made by simply joining two dissimilar conductors. A good pair has a large relative Seebeck coefficient and gives rise to a potential difference. The materials also have large electrical conductivities and small thermal ones, so there is little voltage drop across the length and a small thermal gradient. Although there are many different couples (many are not even used for radiation detection), those most often used for this application are bismuth telluride, copper, and constantan. The expression for the responsivity is given in terms of the relative Seebeck coefficient S_{12} (the difference in the voltage change with temperature between the two materials) and the expression derived above for the thermal circuit

$$\Re = \frac{S\epsilon}{G(1+i\omega\tau)} \tag{14}$$

Good materials are those that have a large Seebeck coefficient, a high electrical conductivity, and a small thermal conductivity, and the figure of merit is often defined as

$$Z_{12} = \frac{S_{12}^2}{\left[\sqrt{G_1/\sigma_1} + \sqrt{G_2/\sigma_2}\right]^2} \tag{15}$$

Thermopiles are arrays of thermocouples connected in series. They are manufactured in two ways. Some are carefully wound wires with junctions aligned in the desired pattern, while others are evaporated with the pattern determined by masking operations. Most of the "bulk" thermopiles are wrapped on appropriate mandrels to obtain rigidity. Both kinds are obtainable in a variety of sizes

and patterns that correspond to such things as spectrometer slits, centering annuli, and staggered arrays for moderate-sensitivity thermal imaging.

The Golay Cell[20]

This detector is used mostly for laboratory operations, as it is slow and fragile, although it has high sensitivity. It is a gas-filled chamber that has a thin membrane at one end and a blackened detector area at the other. Light on the blackened surface causes the increase in temperature; this is transferred to the gas which therefore expands. The membrane bulges, and the amount of the bulge is sensed by some sort of optical lever[21] or even change in capacity of an electrical element.[22] Other versions do not use a blackened surface, but allow the radiation to interact with the gas directly, in which case they are spectral detectors that are "tuned" to the absorption spectrum of the gas.[23]

Pyroelectric Detectors[24]

Some crystals which do not have a center of symmetry experience an electric field along a crystal axis. This internal electric field results from an alignment of electric dipoles (known as polarization), and is related to the crystal temperature. In these ferroelectric crystals, this results in a charge being generated and stored on plates connected to the crystal. Polarization disappears above the so-called Curie temperature that is characteristic of each material. Thus, below the Curie temperature, a change in temperature results in a current. The equation for the response of a pyroelectric detector is

$$\Re = \frac{\omega p A_d \epsilon R_e R_{\text{th}}}{(1+i\omega\tau_{\text{th}})(1+i\omega\tau_e)} \tag{16}$$

where ω is the radian frequency, p is the pyroelectric coefficient, A_d is the detector area, R_e is the electrical resistance, R_{th} is the thermal resistance, τ_{th} is the thermal time constant, and τ_e is the electrical time constant. The relation is shown in Fig. 3, where the responsivity is plotted as a function of frequency. In the low-frequency region the responsivity rises directly as the frequency. This is a result of the ac operation of a pyroelectric. At the (radian) frequency that is the reciprocal of the slower (usually the thermal) time constant, the response levels off. This is the product of the ac rise and the thermal rolloff. Then, when the frequency corresponding to the shorter time constant is reached, the response rolls off.

Type II pyroelectric detectors work on a slightly different mechanism, which is still not fully understood. The electrodes are on the sensing surface of the detector and parallel to the polar axis. In these crystals, the temperature change is not uniform at the onset of radiation and the primary

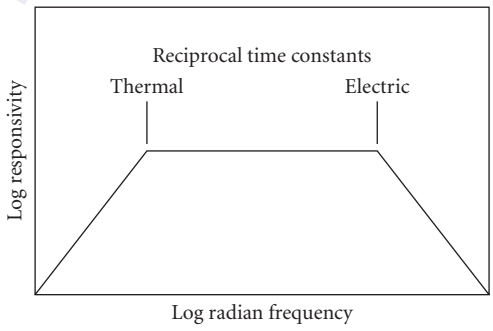

FIGURE 3 Responsivity asymptotes versus frequency.

TABLE 1 General Properties of Thermal Detectors

Type	Operating Temperature (K)	$D^* \times 10^8$ ($cmHz^{1/2}W^{-1}$)	NEP $\times 10^{-10}$ ($WHz^{-1/2}$)	Time Constant (m)	Size (mm^2)
Silicon bolometer	1.6		3×10^{-5}	8	0.25–0.70
Metal bolometer	2–4	1		10	
Thermistor bolometer	300	1–6		1–8	0.01–10
Germanium bolometer	2–4		0.005	0.4	1.5
Carbon bolometer	2–4		0.03	10	20
Superconducting bolometer (NbN)	15		0.2	0.5	5×0.25
Thermocouples	300		2–10	10–40	0.1×1 to 0.3×3
Thermopiles	300			3.3–10	1–100
Pyroelectrics	300	2–5		10–100†	2×2
Golay cell	300	10	0.6	10–30	10

†Shorter values can be obtained at the expense of NEP (for laser detection).

and secondary pyroelectric effects take place, thereby generating a body electric charge distribution.[25] Materials most often used for these detectors are TGS (triglycine sulfate), DTGS (deuterated TGS), Li_2SO_4, $LiNbO_3$, $LiTaO_3$, and PLZT (lead lanthanum zirconate titanate). TGS is the most used for specialized sensor systems, but has a relatively low Curie point. For higher-temperature operation, usually $LiTaO_3$ or PLZT is used in the general laboratory environment.

The two advantages of the pyreoelectric detector over the other thermal detectors, bolometers, and thermopiles, are its responsivity and its capability of rapid response. The response time and responsivity are traded by choice of the load resistor in the circuit. For instance, with a 100-MΩ load the time constant can be 1 ms and the responsivity 100 V/W, but with a 1-MΩ load the values would be 10 μs and 1 V/W.

Summary of Elemental Thermal Detector Properties

Although the user should contact suppliers for detailed information, this section provides overall property information about thermal detectors. There are several cautions about summary data. Most detectors can be tailored to have somewhat different properties. Improvements have often been made since the publication of these results. Not all parameters are available in all combinations. Table 1 does, however, give the general flavor of the performance of different thermal detectors.

28.3 ARRAYS

Introduction

As pointed out earlier, thermal detector response is governed by the thermal response time, which is the ratio of the pixel heat capacity C to the thermal conductance G of the heat leakage mechanism. High pixel responsivity is associated with high thermal isolation, i.e., low thermal conductance. Thermal detector design is driven by the thermal isolation structure. It is the structure which determines the extent to which the pixel performance can approach the temperature fluctuation noise limit and, ultimately, the background fluctuation noise limit. Given the value of G associated

with the heat loss mechanism, the pixel heat capacity must be designed appropriately to attain the required thermal response time. Response times in the millisecond range are compatible with high thermal isolation; response times in the microsecond range are not. Thus, two-dimensional arrays of thermal detectors which operate at TV frame rates (30 Hz in the United States) are under development for applications in thermal imagers.

Noise Equivalent Temperature Difference

Whereas elemental detectors are usually described by such figures of merit as NEP and D^*, arrays have been described by a noise equivalent temperature difference (NETD) associated with their use in a camera under certain specific conditions. It is defined as the change in temperature of a blackbody which fills the field of view of a pixel of an infrared imaging system that gives rise to a change of unity in the signal-to-noise ratio at the output of the system. The measurement of the NETD should, however, be with the flooding of several pixels to avoid fringing effects and with an SNR (signal-to-noise ratio) well above 1 to obtain good accuracy. The pixel is defined as the subtense of a single element of the array. The NETD can be written in several different forms. Perhaps the simplest is

$$\text{NETD} = \frac{\sqrt{A_d B}}{D^*(dP_d/dT)} \tag{17}$$

where D^* is the specific detectivity, A_d is the area of a single pixel, B is the system bandwidth and (dP_d/dT) represents the change in power on the detector element per unit change in temperature in the spectral band under consideration. This form does not include the system noise, which is often included by the manufacturers in their calculations. In Eq. (17) the change in power with respect to temperature is

$$\frac{dP_d}{dT} = \frac{A_d \tau_o}{4FN^2} \int_{\lambda_1}^{\lambda_2} \frac{dM}{dT} d\lambda \tag{18}$$

where τ_o is the optics transmission, FN is the focal ratio (defined as the effective focal length divided by the entrance pupil diameter), and M is the radiant emittance of the source. This is almost the definition of the specific detectivity. The NETD can also be written in terms of the responsivity $\Re$, since the detectivity and responsivity are related in the following way:

$$D^* = \frac{\sqrt{A_d B}}{P} \frac{V_S}{V_N} = \sqrt{A_d B} \frac{\Re}{V_N} \tag{19}$$

where V_S is the signal voltage at the sensor and V_N is the rms noise voltage of a pixel in the bandwidth B. Therefore

$$\text{NETD} = \frac{V_N}{\Re(\partial P_d/\partial T)_{\lambda_1 - \lambda_2}} \tag{20}$$

The power on the detector is related to the power on the aperture by the optical transmission τ_o. The expression can also be formulated in terms of the source radiance, L

$$\text{NETD} = \frac{4FN^2\sqrt{B}}{D^* \tau_a \tau_o \pi D \Delta\theta (\partial L/\partial T)_{\lambda_2 - \lambda_1}} \tag{21}$$

where D is the diameter of the aperture, $\Delta\theta$ is the angular subtense of a pixel, L is the source radiance, and τ_a is the atmospheric transmission. One last form can be generated by recognizing that, for an isotropic radiator, the radiance is the radiant emittance divided by π:

$$\text{NETD} = \frac{4FN^2V_N}{A_D\tau_a\tau_o\Re(T_S)(\partial M/\partial T)} \tag{22}$$

In this form of the expression for NETD, it is not necessary that the noise be white, nor is it necessary that the noise not include system noise. Whether or not system noise is included should be clearly stated.

Theoretical Limits

Figure 4 illustrates the theoretical limits of thermal arrays having the parameters shown and operating at 300 and 85 K as a function of thermal conductance. The performance of real thermal arrays with those parameters lies on or above the sloping line. As the conductance G is reduced (better thermal isolation), the noise equivalent temperature difference NETD is reduced (improves) until the background limit is reached, when radiant power exchange between the array and the background becomes the dominant heat transfer mechanism. Reducing the detector temperature to 85 K appropriate to a bolometer operating at the transition edge of the high-temperature superconductor $YBa_2Cu_3O_{7-x}$ (YBCO) reduces the NETD by $\sqrt{2}$ and allows the limit to be reached with less thermal isolation (higher G value).

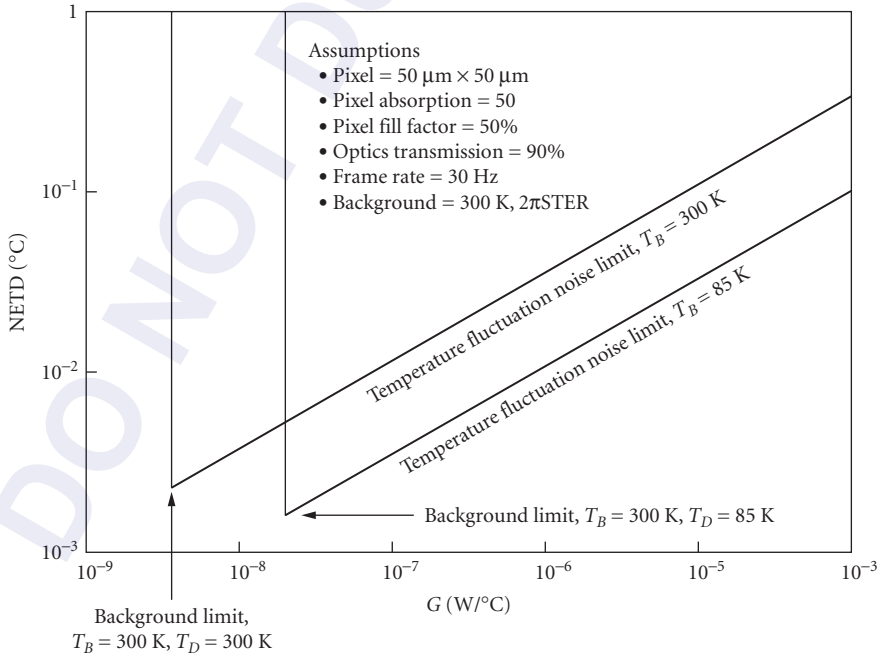

FIGURE 4 Temperature fluctuation noise limit and background fluctuation noise limit of uncooled and cryogenic thermal detector arrays.

Arrays fall into two categories: monolithic and hybrid. Monolithic arrays are prepared on a single substrate, e.g., silicon, upon which the detecting material is deposited in the form of a thin film which is subsequently processed into an array. Hybrid arrays are prepared in two parts: (1) the readout electronics arrays, usually in silicon, and (2) the detecting material array, usually in wafer form which is thinned by lapping, etching, and polishing. These two arrays are mated by a technique such as flip-chip bonding. Here the interconnection at each pixel must have a sufficiently high electrical conductivity, yet a sufficiently low thermal conductivity—a difficult requirement. If array cost considerations are important, then the monolithic approach, especially in silicon, is the more desirable.

Resistive Bolometer Arrays

The development of resistive bolometric arrays has proceeded along two paths: uncooled arrays and cryogenic arrays. Large, uncooled bolometric arrays have been developed at Honeywell by a team lead by R. A. Wood.[26,27] Silicon microstructure technology is employed to produce the arrays, a process resembling the fabrication of integrated circuits. Twelve arrays are prepared on a 4-in-diameter silicon wafer. Each monolithic array consists of 240×336 pixels; each pixel is 50×50 μm. The detecting material is a thin film of vanadium oxide. A Si_3N_4 membrane having a thermal conductance of 1×10^{-7} WC^{-1} supports the vanadium oxide at each pixel, as shown in Fig. 5. Bipolar transistors implanted in the silicon substrate act as pixel switches for the matrix-addressed array. The response is optimized for the 8- to 14-μm spectral interval. The thermal response time is adjusted for a 30-Hz frame rate. Each pixel is addressed once per frame by a 5-μs pulse. A thermoelectric stabilizer maintains the array at ambient temperature. Other than a one-shot shutter, the camera has no moving parts.

The measured NETD of the camera with F/1 optics at 300 K is 0.04 K. Given the G value of 1×10^{-7} WK^{-1} it can be seen from Fig. 4 that the array is within a factor of 4 of the temperature fluctuation noise limit. Furthermore, the pixel thermal isolation is so complete that there is no measurable thermal spreading among the pixels.

Linear resistive bolometric arrays of the high-temperature superconductor YBCO on silicon microstructures have been prepared by Johnson et al.,[28] also of Honeywell. A two-dimensional array is under development.[29] The monolithic arrays operate at the transition edge from 70 to 90 K. As was true for the uncooled arrays, the superconducting ones employed a silicon nitride membrane to support the thin film and provide thermal isolation. Excess noise at the contacts limited the performance

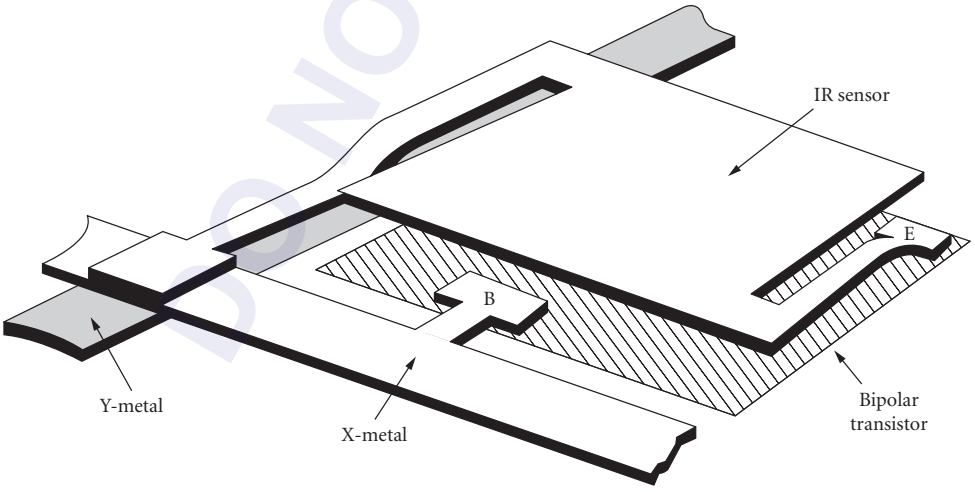

FIGURE 5 Monolithic silicon microbolometer.[26,27] (© *1992 IEEE.*)

of the 12-element linear array. With no excess noise, the calculated NETD[29] of a 240 × 336 array with 50 μm pixels and F/1 optics would be 0.002 K, which is near the 300 K background limit, as shown in Fig. 4.

Pyroelectric Hybrid Arrays

Linear and two-dimensional pyroelectric uncooled arrays have been under development for more than two decades.[20–32] The arrays employ hybrid construction, in which a bulk pyroelectric ceramic material such as lithium tantalate or lead zirconate is mechanically thinned, etched, and polished, then bump-bonded to a silicon substrate containing readout electronics,[33] as shown in Fig. 6. Reticulation is usually employed to prevent lateral heat conduction through the pyroelectric material. The theoretical system NETD of a two-dimensional uncooled array with F/1 optics is estimated to be 0.1 K.[33] Two-dimensional uncooled arrays operating in the 8- to 14-μm region having 100 × 100 pixels, each 100 × 100 μm, are available commercially.[34] Their NETD (with F/1 speed) is 0.35 K. A two-dimensional pyroelectric monolithic array employing a thin film of lead titanate on a silicon microstructure is under development.[35]

Ferroelectric bolometer arrays, also known as field-enhanced pyroelectric arrays, have been developed by Texas Instruments.[36,37] Operation depends upon the temperature dependence of the spontaneous polarization and dielectric permittivity in a ferroelectric ceramic near the Curie temperature. Barium strontium titanate (BST), the selected material, has its composition (barium-to-strontium ratio) adjusted during preparation so the Curie point is 22°C. A thermoelectric stabilizer is employed to hold the BST near 22°C such that the absorbed infrared radiation changes the temperature and thus the dielectric properties. The effect is similar to the pyroelectric effect; however, a voltage is applied to enhance the signal. Construction of this array is naturally similar to that of the pyroelectric array, described above, as shown in Fig. 7. Reticulation of the ceramic is frequently applied to these arrays as well. A radiation chopper is required as both the pyroelectric and ferroelectric effects depend upon the change in temperature. The Texas Instruments BST array,

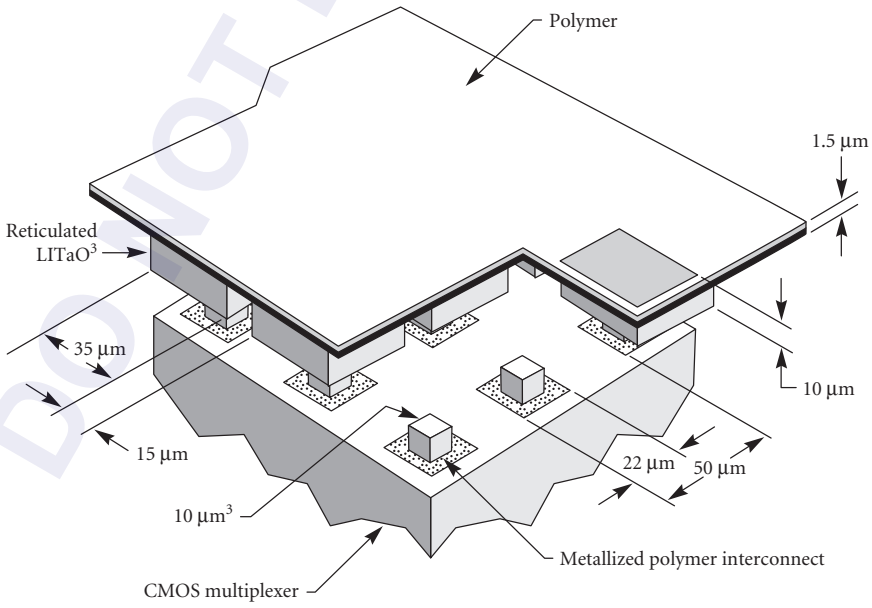

FIGURE 6 Hybrid pyroelectric array structure.[33]

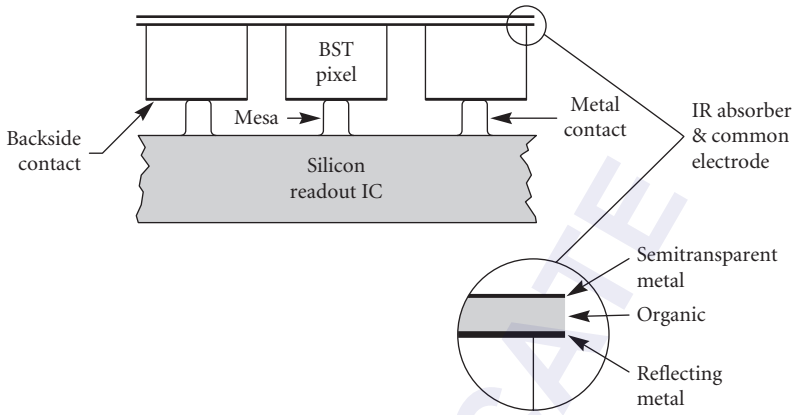

FIGURE 7 Ferroelectric bolometer hybrid array.[36,37]

incorporating 80,000 pixels, each about 50 × 50 μm, which are matrix addressed, has an NETD of less than 0.1°C (with F/1 optics).

Thermoelectric Arrays

Thermoelectric arrays prepared by silicon micromachining have been described by Choi and Wise.[38] Series-connected, thin-film thermocouples, i.e., a thermopile, are prepared on a silicon microstructure, the "hot" junctions (receiving the thermal radiation) on a silicon nitride/silicon dioxide membrane and the "cold" shield junctions on the surrounding silicon substrate. Both 64- and 96-pixel microthermopile linear arrays in silicon microstructures have been prepared by Honeywell,[39] each microthermopile consisting of several nickel iron/chromium thermocouples connected in series, as shown in Fig. 8. The "hot" junctions are deposited on silicon nitride membranes, whereas the "cold" junctions are on the silicon substrates. A camera incorporating the linear array has been employed to image moving targets such as automobiles. With an F/0.73 lens, the measured NETD is 0.10°C.

Since the first publication of this *Handbook*, many advances have been made in these arrays. The suppliers have improved sensitivity somewhat but have increased the number of pixels and decreased their size. The reader should check with the manufacturers for the latest information.

29.1 GLOSSARY

A	area of microdensitometer sampling aperture
a	projective grain area
D	optical transmission density
D_R	reflection density
DQE	detective quantum efficiency
$d(\mu)$	diameter of microdensitometer sampling aperture stated in micrometers
E	irradiance/illuminance (depending on context)
$\mathcal{G}$	Selwyn granularity coefficient
g	absorbance
H	exposure
IC	information capacity
M	modulation
M_e	angular magnification
m	lateral magnification
NEQ	noise equivalent quanta
$P(\lambda)$	spectral power in densitometer beam
Q'	effective Callier coefficient
q	exposure stated in quanta/unit area
R	reflectance
S	photographic speed
$S(\lambda)$	spectral sensitivity
S/N	signal-to-noise ratio of the image
T	transmittance
$T(\nu)$	modulation transfer factor at spatial frequency ν

t	duration of exposure
WS(ν)	value of Wiener (or power) spectrum for spatial frequency ν
γ	slope of D-log H curve
ν	spatial frequency
$\rho(\lambda)$	spectral response of densitometer
$\sigma(D)$	standard deviation of density values observed when density is measured with a suitable sampling aperture at many places on the surface
$\sigma(T)$	standard deviation of transmittance
$\phi(\tau)$	Autocorrelation function of granular structure

29.2 STRUCTURE OF SILVER HALIDE PHOTOGRAPHIC LAYERS

The purpose of this chapter is to review the operating characteristics of silver halide photographic layers. Descriptions of the properties of other light-sensitive materials, such as photoresists, can be found in Ref. 4.

Silver-halide-based photographic layers consist of a suspension of individual crystals of silver halide, called *grains*, dispersed in gelatin and coated on a suitable "support" or "base." The suspension is termed an *emulsion* in the field. The grains are composed of AgCl, AgClBr, AgBr, or AgBrI, the listing being in order of increasing sensitivity. Grain size ranges from less than 0.1 μm ("Lippmann" emulsions) to 2 to 3 μm, depending on the intended use of the coating. The number of grains per square centimeter of coating surface is usually very large, of the order of 10^6 to 10^8 grains/cm^2. The weights of silver and gelatin coated per unit area of support vary depending on intended use; usually both fall in the range 1 to 10 g/m^2. The silver-to-gel ratio may also vary depending on intended use. Typically, the emulsion may be about 30 to 40 percent silver by weight, but some special-purpose materials, such as films to record Schumann-wavelength-region radiation, contain very little gelatin.

For modern materials, both the emulsion and the coating structure can be very complex. The emulsion layer is much more than silver halide in gelatin, containing additional agents such as hardeners, antifoggants, fungicides, surfactants, static control agents, etc. Likewise, the coating structure may be very complex. Even some black-and-white materials consist of layers of two different emulsions coated one over the other and a thin, clear layer of gelatin is often coated over the emulsion(s) to provide some mechanical protection. In the case of color films, as many as 15 layers may be superimposed, some of them of the order of 1 μm thick. The thickness of the complete coating varies from about 3 μm to about 25 μm in normal films.

Commercially available emulsions are coated on a variety of glass, plastic (film), and paper supports (or "bases"). Glass is used for mechanical rigidity, spatial stability, or surface flatness.

Two different types of plastic are available commercially as film supports: cellulose acetate and polyethylene terephthalate (trade names "Cronar," "Estar," and "Mylar"). Of the two types, Mylar is superior in strength, flexibility, and spatial stability. However, the material is birefringent and its physical properties may be different in orthogonal directions. Also, these directions may not be aligned with the length or width of the sample. The anisotropic properties arise from the method of manufacture. Although not as tough as Mylar, cellulose acetate is, of course, fully adequate for most purposes. Also, this material is isotropic and easier to slit and perforate. Typical supports for roll films are around 4 mils (102 μm) thick, and for sheet films, 7 mils (178 μm), and other thicknesses are available. Most films are also coated on the back side of the support. The "backing" may be a layer of clear gelatin applied for anticurl protection, or of gelatin dyed with a dye that bleaches during processing, and provides both anticurl and antihalation protection. Lubricants and antistatic agents may also be coated, either on the front or back of the film. Properties of supports are discussed in Ref. 1.

29.3 GRAINS

The grain is the radiation-sensing element of the film or plate. It is a face-centered cubic crystal, with imperfections in the structure. For the most part, the grains act as independent receptors. In general, the larger grains are faster. The properties of the individual grains are controlled by the precipitation conditions and the after-precipitation treatment. Details of these matters are proprietary, but some discussion is given in Refs. 2 and 3. From the user's standpoint, the important fact is that when the grain is exposed to sufficient radiation it forms a "latent-image speck" and becomes *developable* by a solid-state process called the "Gurney-Mott mechanism." An excellent review of grains and their properties is given by Sturmer and Marchetti in chap. 3 of Ref. 4.

29.4 PROCESSING

The exposed halide layer is converted to a usable image by the chemical processes of development and fixation.

Development consists of reducing exposed crystals from silver halide to metallic silver, and a developing agent is an alkaline solution of mild reducer that reduces the grains having latent image specks, while not attacking the unexposed grains. Generally, once development starts the entire grain is reduced if the material is allowed to remain in the developer solution. Also, in most cases adjacent grains will not be affected, although developers can be formulated that will cause adjacent grains to be reduced ("infectious developers"). The number of quanta that must be absorbed by a grain to become developable is relatively small, of the order 4 to 40, while the developed grain contains on the order of 10^6 atoms. The quantum yield of the process is thus very high, accounting for the speed of silver-based materials.

The remainder of the process consists essentially of removing the undeveloped halide crystals which are still light-sensitive. The "fixer" is usually an acid solution of sodium thiosulfate $Na_2S_2O_3$, called "hypo" by photographers. The fixing bath usually serves as a gelatin hardener also. The thiosulfate reacts with the halide of the undeveloped grains to form soluble silver complexes, which can then be washed out of the emulsion layer. It is worth noting that proper washing is essential for permanent images. Additional treatments to promote permanence are available. Processing is discussed in detail in Refs. 2, 3, and 5, and image permanence in Ref. 6.

The exposed and processed silver halide layer thus consists of an array of grains of metallic silver, dispersed in a gelatin matrix. In color films, the silver is removed, and the "grains" are tiny spheres of dyed gelatin (color materials will be discussed below). Either type of grain acts as an absorber; in addition, the metallic silver grains act as scatterers. The transmittance or reflectance of the layer is thus reduced and, from the user's standpoint, this change constitutes the response of the layer.

29.5 EXPOSURE

From fundamental considerations it is apparent that the dimensions of exposure must be energy per unit area. Exposure H is defined by

$$H = Et \tag{1}$$

where t is the time for which the radiation is allowed to act on the photosensitive layer, and therefore E must be the irradiance on the layer. The symbol H is used here for exposure in accordance with international standards, but it should be noted that in many publications, especially older ones, E is used for exposure and I for irradiance, so that the defining expression for exposure becomes $E = It$.

Strictly speaking, H and E in Eq. (1) should be in radiometric units. However, photographic exposures are customarily stated not in radiometric but in photometric units. This is done mostly

for historical reasons; the English scientists Hurter and Driffield, who pioneered photographic sensitometry in 1891, measured the incident flux in their experiments in lumen per square meter, or lux. Their unit of exposure was thus the lux-second (old term, meter-candle-second). Strictly speaking, of course, weighting the incident flux by the relative visibility function is wrong or at least unnecessary, but in practice it works well enough because in most cases the photographer wishes to record what he or she sees, i.e., the visible spectrum. Conversion between radiometric and photometric units is discussed by Altman, Grum, and Nelson.[7]

Also, it should be noted that equal values of the exposure product (Et) may produce different outputs on the developed film because of a number of *exposure effects* which are described in the literature.[8] A complete review of radiometry and photometry is given in Chap. 34 in this volume of the *Handbook*.

29.6 OPTICAL DENSITY

As noted above, the result of exposure and processing is a change in the transmittance or reflectance of the layer. However, in photography, the response is usually measured in terms of the *optical density*, hereafter called the "density" in this chapter. For films (transmitting samples), density is defined by

$$D = -\log T = \log 1/T \tag{2}$$

where T is the transmittance. (Note: throughout this chapter, "log" indicates the base-10 logarithm.) For either silver grains or color grains, the *random dot* model of density predicts that

$$D = 0.434nag \tag{3}$$

where n = the number of grains per unit area of surface
a = the average projective grain area
g = the absorbance of the grain

Absorbance in turn is defined as $g = 1 - (T + R)$ where T and R are the transmittance and reflectance of the grain. For silver grains, the absorbance is taken as unity. The above expression, sometimes known as "Nutting's law," is based on a geometric approach, and does not take into account any scattering by the grains. However, of course, opaque silver particles on a clear background will act as scatterers, and in fact multiple scattering usually occurs in developed silver layers. This produces an increase in the density of such layers by a factor of 2 to 3 times from that predicted by Nutting's law. For color films, the refractive index of the gelatin in the dyed spheres is only negligibly different from that of the surround so that such layers are not scatterers. Even in the case of silver films, however, Nutting's law provides a useful model. Since for a given population of grains a and g will remain effectively constant, the law states that density should vary as the number of grains per unit area of surface. This fact is easily verified with a microscope.

Transmission Density

Transmission density is measured in a densitometer. It is worth noting that the device actually measures the transmittance of the sample and then displays the negative log of the result. In a normal or *macro* densitometer the sampling aperture area A is typically 1 mm^2 or more in size. When A is small, say, 0.1 mm^2 or less, the device becomes a *micro* densitometer. Microdensitometers present special problems and will be discussed below.

Because the scattered light may not reach the sensor of the densitometer when silver layers are measured, it is necessary to specify the angular subtenses of both the incident (influx) and emergent (efflux) beams at the sample. Clearly, if scattered light is lost to the sensor, the indicated density of the sample will *increase*. Four types of transmission density are described in an ISO standard,[9] of

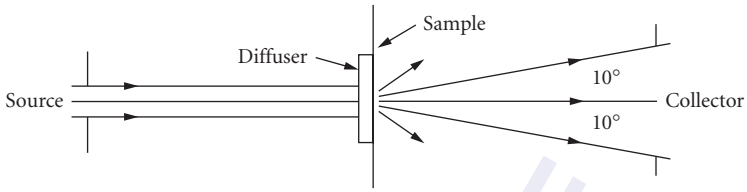

FIGURE 1 Optical system for measuring ISO/ANSI diffuse density with a 20° collection angle. (*Reprinted courtesy Eastman Kodak Co. © Eastman Kodak Co.*)

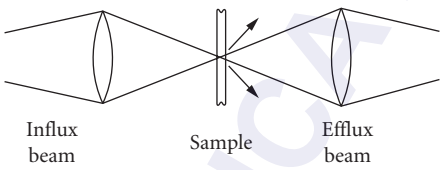

FIGURE 2 Optical conditions for projection density measurement.

which two are principally important to the user. The first of these is *diffuse density*, which is diagrammed in Fig. 1. As can be seen, a collimated incident beam illuminates an opal glass diffuser. The emulsion side of the sample is placed in contact with this diffuser, and the flux contained within a cone angle of ±10° is collected and evaluated by the sensor. The reverse of this arrangement yields the same density values and is also permitted by the standard. This is the type of density normally measured in practice. Physically, it corresponds to the conditions of contact printing.

The other case that is important in practice is projection density, which is diagrammed in Fig. 2. This case simulates the use of the layer in an optical system. As the figure shows, light is lost to the efflux system in projection density, the exact amount depending on the numerical aperture of the optics involved and the scattering characteristics of the sample. Thus, the projection density of a silver film is usually greater than the diffuse density. The effective Callier coefficient Q' may be defined by

$$Q' = \frac{\text{project density}}{\text{diffuse density}} \tag{4}$$

This factor can be measured experimentally. For silver films and *f*/2 optics, $Q' \approx 1.3$; for color films $Q' \approx 1.0$.

Nonneutral (Color) Density

In many cases, silver densities can be treated as neutrals. For dye densities, i.e., color films, measured density depends on the spectral characteristics of both the dye and the densitometer. The spectral response of the instrument is given by

$$\rho_\lambda = P_\lambda S_\lambda F_\lambda \tag{5}$$

where ρ_λ = the response at wavelength λ
P_λ = the power in the densitometer beam at λ
S_λ = the spectral sensitivity of the sensor at λ
F_λ = the transmittance of the densitometer optics at λ, specifically including any filters placed in the densitometer beam

The measured density of a nonneutral layer is then

$$D = \log\left[\frac{\int_{\lambda_1}^{\lambda_2} \rho_\lambda d\lambda}{\int_{\lambda_1}^{\lambda_2} \rho_\lambda T_\lambda d\lambda}\right] \tag{6}$$

where T_λ is the transmittance of the layer at wavelength λ, and the wavelength limits are set by the distributions. The response ρ_λ of the system is adjusted to be equal to that of the readout device with which the film is to be used.

Thus, for example, if the sample is to be viewed by an observer, ρ_λ is made equal to the visibility function, and the resulting measurement is called visual density, etc. Instrument responses have been standardized for sensitometry of color films.[10]

Reflection Density

When the emulsion is coated on paper the density is measured by reflection. Reflection density is then defined by

$$D_R = -\log R \tag{7}$$

where R is reflectance, measured under suitable geometric conditions. The measurement of reflection density is also described in the standards literature.[11]

29.7 THE D-LOG H CURVE

In routine sensitometry, samples receive a series of exposures varying by some constant factor, such as ×2 or $\times\sqrt{2}$. After processing, the measured densities are plotted against the common logarithm of the exposures that produced them. The resulting curve is known as the "D-log H curve," or the "H & D" curve (after Hurter and Driffield, the previously mentioned pioneers in the field). A typical D-log H curve is shown in Fig. 3.

As shown, the curve is divided into three regions, known as the "toe," "straight-line portion," and "shoulder," respectively. The fact that an appreciable straight-line portion is found in many cases is

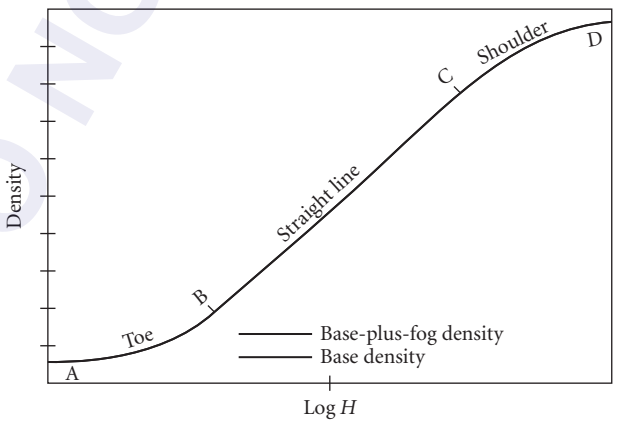

FIGURE 3 Typical D-log H curve for a negative photographic material. (*Reprinted courtesy Eastman Kodak Co. © Eastman Kodak Co.*)

not an indication that the film is a linear responder in this region because, of course, both axes of the plot are logarithmic. It is worth noting here that the equation of the straight-line portion of this curve can be written

$$D = \gamma(\log H - \log C) \tag{8}$$

where γ is the slope of the straight-line portion and C is the exposure at the point where the extrapolated straight line cuts the exposure axis. Taking antilogarithms, Eq. (8) becomes

$$T = \left(\frac{H}{C}\right)^{-\gamma} \tag{8a}$$

If $\gamma = -1$, $T = (1/C)H$, and for this special case, the system becomes linear over the exposure range corresponding to the straight-line portion. A negative value of γ indicates a *positive* image.

A number of useful performance parameters for films are taken from their D-log H curves, as follows.

1. *Fog:* For most films, a certain number of grains will be reduced even though they have received no exposure at all, or insufficient exposure to form a latent image speck. The resulting density is called *fog*. Since it is not exposure-related, and since it tends to veil any information recorded in the toe, excessive fog is very undesirable. For many purposes, the fog density plus the density of the support are subtracted from the gross density to give the value of the net density resulting from the exposure. More complicated formulas for correcting the film's response for fog grains have been proposed, but are rarely used.
2. *Gamma:* Traditionally, the slope of the straight-line portion of the D-log H curve is called the "gamma." Gamma is a crude measure of the contrast with which the original object is reproduced; it would be a good measure of this contrast if the object were in fact recorded entirely on the straight-line portion of the response curve. However, for many purposes, notably pictorial photography, an appreciable part of the toe is used. This fact led Niederpruem, Nelson, and Yule to propose the use of an average gradient that included part of the toe as a measure of the contrast of the reproduction.[12] This quantity is called the *contrast index*. Since it includes part of the toe, contrast index is less than gamma. Since information is often recorded in the toe, it is convenient to generalize the meaning of γ to refer to the gradient anywhere along the D-log H curve, and this is done in this chapter. Note that in this case, the traditional gamma is the maximum value the gradient attains.
3. *Latitude:* Latitude can be defined as the log exposure range between the point in the toe and the point in the shoulder between which the gradient is equal to or greater than the minimum value required for acceptable recording. Clearly, the latitude of the film must be at least equal to the log exposure range of the object for proper recording. In many practical cases the film's latitude easily exceeds the required range. Note that the latitude is determined in part by the maximum density that the film can produce.
4. *Speed:* Speed is defined by the general expression

$$S = \frac{K}{H_{\text{ref}}} \tag{9}$$

where K is a proportionality factor and H_{ref} is the exposure required to produce some desired effect. Since the desired effect varies depending on the type of film and the application, H_{ref} also varies. Also, H_{ref} can be stated in either radiometric or photometric units. If H_{ref} is given in radiometric units, the proportionality factor K is set to unity, and the resulting values are termed "radiometric speeds." Although radiometric speeds are the fundamental speed values, they are rarely used in practice because, as previously noted, exposures are usually given in photometric units. In this case, the factor K takes on different values that depend not only on H_{ref}, but also on the characteristics of the exposure meter, which is standardized.[13] Varying the factor K allows a single meter to be used with

all kinds of films and applications, which is a practical necessity. Thus, for example, the photometric speed (usually simply the "speed") of black-and-white pictorial films is evaluated from

$$S = \frac{0.8}{H_{0.1}} \tag{9a}$$

where $H_{0.1}$ is the exposure in lux-seconds required to produce a density of 0.1 above the densities of the base plus fog in a specified process. This density level has been shown empirically to be predictive of excellent tone reproduction quality in the print. Similarly, for color slide films

$$S = \frac{10}{H_m} \tag{10}$$

where H_m is the exposure to reach a specified position on the film's D-log H curve. Again, H_m was established empirically. The above two examples show how the two factors involved in determining a photometric or practical speed can vary. A number of other speeds have been defined and are described in the literature.[14]

Variation of Sensitometry with Processing

The rate of reduction of the exposed photographic grain depends on the characteristics of the grain itself, the formulation of the developer, and its temperature. In general, the reaction is allowed to continue until substantially all exposed grains have been reduced, and ended before fog becomes excessive. Many modern films are hardened and able to withstand processing temperatures up to, say, 40°C. Development times are often chosen on the basis of convenience and usually run in the order of 5 to 10 minutes in nonmachine processing. As development time and/or temperature are increased, the amount of density generated naturally increases. Thus for a given film a whole family of response curves can be produced, as shown in Fig. 4. As development time is lengthened, gamma and contrast index also increase. Typical behavior of these parameters is shown in the inset of Fig. 4.

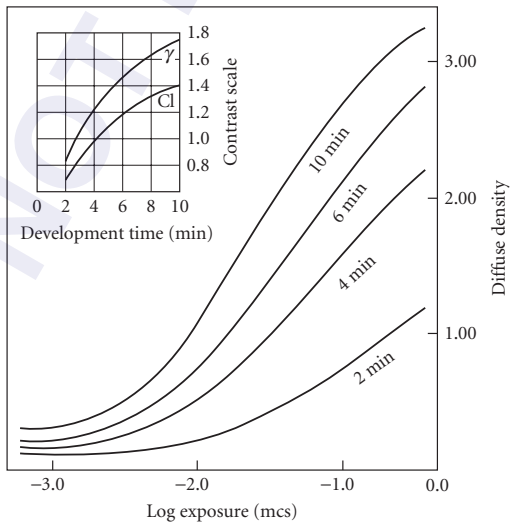

FIGURE 4 A family of characteristic curves for development times as shown, with corresponding plots of contrast index and gamma, mcs or the meter-candle second, as stated on p. 29.6, is the old term for lux-second or lxs. (*Reprinted courtesy Eastman Kodak Co. © Eastman Kodak Co.*)

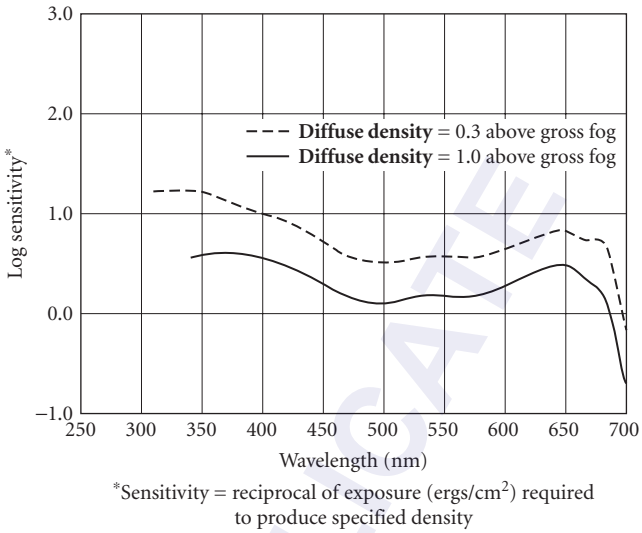

FIGURE 5 Spectral sensitivity curves for a modern negative material sensitized to about 690 nm. (*Reprinted courtesy Eastman Kodak Co. © Eastman Kodak Co.*)

29.8 SPECTRAL SENSITIVITY

The spectral absorption of the silver halide grain extends only to about 500 nm, and thus the inherent sensitivity of the grain is limited to regions shorter than that limit. However, it was discovered by Vogel in 1873 that sensitivity could be extended to longer wavelengths by dyeing the grains, and over the years the effective sensitivity range was extended into the infrared. Presently, materials are available usefully sensitized out to about 1.2 μm, but it should be noted that IR materials tend to have poor shelf life, and may require special handling. For our purposes, we may say that the sensitizing dye absorbs the incident energy in the required spectral region and transfers the energy to the grain in a manner that produces the required latent-image speck. The mechanisms are discussed in Ref. 3, chap. 10.

The spectral sensitivity of a photographic layer is usually specified by a family of curves showing log $(1/H_D)$ vs λ, where H_D is the exposure in ergs/cm^2 of wavelength λ required to produce some stated density. Spectral sensitivity values are thus radiometric speeds. Typical curves are shown in Fig. 5. In practical work, three broad classes of sensitization are recognized, which are called "color-blind" (or blue-sensitive), orthochromatic (additionally sensitized to green), and panchromatic (additionally sensitized to green and red). Most modern general-purpose materials are panchromatic.

In general, the shape of the spectral sensitivity curve follows that of the spectral absorption of the layer. It should also be noted that the gradient of the D-log H curve will be affected by the absorption of the layer. Gamma may therefore vary as a function of wavelength, and is generally somewhat lower in the blue and UV regions of the spectrum. This means that if the material is being used as a radiometer, it must be calibrated at the wavelength(s) of interest.

29.9 RECIPROCITY FAILURE

It was noted above that the exact response of a photographic layer may change due to exposure effects. Of these, the phenomenon of *reciprocity failure* is the most important in practical photography.

By definition [Eq. (1)] exposure is simply the product of the irradiance and time, and nothing in this definition specifies the magnitude of either factor. However, the developed *density* resulting from a given calculated exposure is often found to depend on the *rate* at which the radiation is supplied, all other factors being held constant. Broadly speaking, exposure times of about 0.01 to 1.0 second are most efficient in producing density, the exact values depending on the film involved. Times much outside the above range tend to produce lower density for the same calculated exposure. The emulsion-maker has some ways of minimizing the effect, and usually attempts to optimize the response for the exposure times expected to be used with the material. Reciprocity failure is discussed in detail in Ref. 3, chap. 4, sec. II.

The loss of efficiency for short-time and correspondingly high-irradiance exposures is termed "high-intensity reciprocity failure," and that for long exposure times (low irradiances) is termed "low-intensity reciprocity failure." The Gurney-Mott mechanism explains both types of failure well. Note also that the names are misnomers; the terms should, of course, be high and low *irradiance*.

Only limited data are available, but the gradient of the D-log H curve tends to decrease as exposure times are shortened. An example is shown in data published by Hercher and Ruff.[15] Limited data also indicate that the speed loss due to high-intensity failure stabilizes for times shorter than about 10^{-5} second.[16] Essentially, the amount of reciprocity failure is independent of exposing wavelength.[17] This is to be expected.

Reciprocity failure may be a considerable problem for photographers working in specialized time domains, such as oscilloscope photography or astronomy. Astronomers have been able to devise user treatments for minimizing low-intensity failure.[18] For the practical photographer, reciprocity failure sometimes appears as a problem in color photography. If the RF of the three sensor layers differs, the resulting picture may be "out of balance," i.e., grays may reproduce as slightly tinted. This is very undesirable, and correction filter recommendations are published for some films for various exposure times.

29.10 DEVELOPMENT EFFECTS

Besides exposure effects the final density distribution in the developed image may be affected by "development effects" arising from chemical phenomena during development. Various names such as "border effect," "fringe effect," "Eberhard effect," etc., are applied to these phenomena; what we shall here term "edge effect" may be important in practice.

Consider a sheet of black-and-white film developing in a tray, and assume for purposes of discussion that there is no motion of the developer. Since developing agent must be oxidized as halide is reduced, and since the by-products of this reaction may themselves be development inhibitors, it can be seen that local variations of developer activity will be produced in the tray, with the activity decreasing as density increases. Agitation of the solution in the tray reduces the local variations, but usually does not eliminate them entirely, because it is the developer that has diffused into the gelatin matrix that is actually reacting. Now an "edge" is a boundary between high- and low-density areas, as shown in Fig. 6. Because of the local exhaustion and the diffusion phenomena, the variation of developer activity within the layer will be as shown by the dotted line in the figure. The result is that the developed density near the edge on the low-density side tends to decrease, and on the high-density side tends to increase, as also shown in the figure. In other words, the density distribution at the edge is changed; this actually occurs to some degree in much practical work and has interesting consequences, as will be discussed below.

The local exhaustion of the developer may also be important in color films where development in one layer (see below) may affect the response of an adjacent layer. In color photography, the phenomenon is called "interimage effect."

29.11 COLOR PHOTOGRAPHY

Color photography has been extensively reviewed by Kapecki and Rodgers.[19] With one exception at the time of writing, all commercially available color films employ subtractive color reproduction. The exception is an instant film for color slides marketed by Polaroid Corporation, which employs

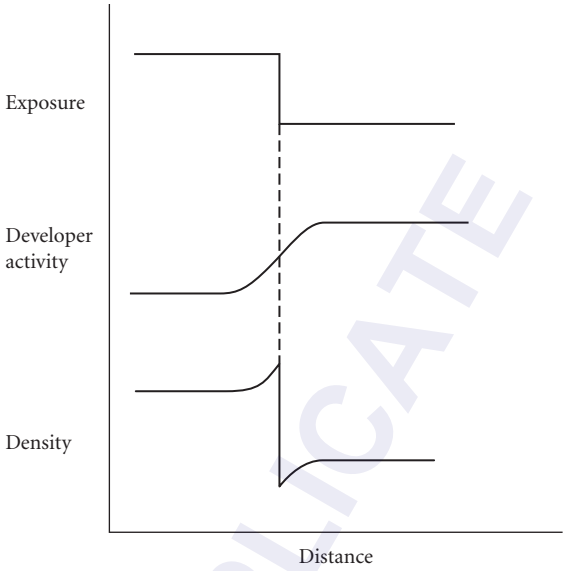

FIGURE 6 Distributions of developer activity and density resulting from a step-function input in the presence of edge effect.

additive color. The mechanism involves a reseau of very fine red, green, and blue stripes, which provide the color separation during the taking of the photograph, and also the color when the (reversed) image is projected.[20]

The basic structure of most other color films is similar to that shown in Fig. 7. The incoming light first encounters a nonspectrally-sensitized emulsion layer, which records the blue-light elements of the scene. The next layer is a yellow, or minus-blue filter, the purpose of which is to prevent any blue light from reaching the other two emulsion layers. This yellow filter is usually composed of "Carey Lea," or colloidal silver dispersed in gelatin. Such sols are yellow. The reason for using Carey Lea silver is that all metallic silver is removed from the film during processing anyway, and the necessary removal of the filter layer is thus accomplished automatically.

Moving downward in the stack, the next layer is an ortho-sensitized emulsion. Since any blue light has been blocked by the yellow filter, this layer records the green-light elements of the scene. The final layer in the stack is sensitized to red light but not to green light and this layer serves to record the red elements of the scene. Modern films usually contain many more than the four layers indicated here, but the operating principles of the film can be discussed in terms of such a "tripack." In accordance with the principles of subtractive color reproduction, the images in the three separation

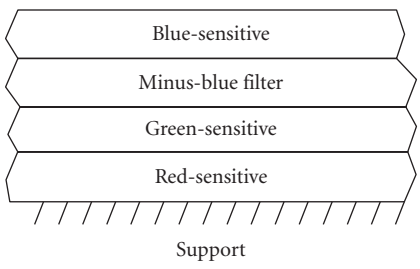

FIGURE 7 Schematic tripack structure of a color film.

records are then converted to yellow, magenta, and cyan dyes, respectively, and the final image is composed of these dyes, without the developed silver, which is either removed chemically or left behind, depending on the exact material.

Within this broad framework, films can be separated into two classes: chromogenic and nonchromogenic. In the former class, the dyes are not coated in the film, but are formed during the processing by a reaction called "coupling." In coupling, the by-products of the halide reduction reaction serve as components for a second reaction in which dye is formed; the amount of dye thus increases as density increases. The components of the dye-forming reaction (i.e., other than the development by-products) may be present in the developing solution (Eastman Kodak Co., "Kodachrome") or, more generally, coated within the various layers (Kodacolor, Polaroid "One Film," Agfachrome, Fujicolor, etc.). After the required dyes are formed, the developed silver is removed by a chemical process termed "bleaching."

The advantage of incorporating the couplers in the various layers of the tripack is simpler processing, but because of the additional material in the layers, such films tend to be not as sharp as the nonincorporated-coupler types. Chromogenic color films are available both as slide materials, in which the film undergoes a reversal process,[21] and as color negative—color print materials in which a dye negative is formed and then printed onto a color paper whose structure is fundamentally similar to that of the films.

The principal example of the nonchromogenic film is the Polaroid Instant Color Film. In this film the yellow, magenta, and cyan dyes are actually coated in the structure, along with the blue, green, and red-sensitive emulsions. When development takes place in a given layer, the corresponding dye is immobilized. The dye that has *not* been immobilized in the three layers migrates to a "receiver" layer, where it is mordanted. Since the amount of dye that migrates *decreases* as the original density *increases*, the result is a positive color image formed in the receiver. The material has been described in more detail in a paper by Land,[22] and also in chap. 6 of Ref. 4.

The image in a color film thus essentially consists of three superimposed dye images. Typical spectrophotometric curves for dyes formed by coupling reactions are shown in Fig. 8. The density of any one of these dye layers taken by itself is known as an *analytical* density. Note, however, that all the dyes show some "unwanted" absorption—that is, absorption in spectral regions other than the specific region that the dye is supposed to control. Thus the total density of the layer at any wavelength is the sum of the contributions of all three dyes; this type of density is known as "integral density." The integral density curve is also shown in Fig. 8.

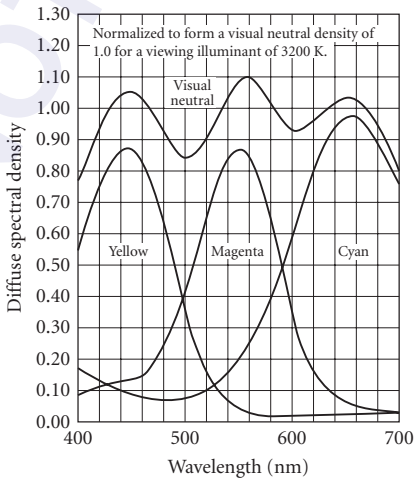

FIGURE 8 Spectral dye density curves for a color film. (*Reprinted courtesy Eastman Kodak Co. © Eastman Kodak Co.*)

The reproduction of color by photographic systems has been discussed by Hunt[23] and many others.[24] In general, exact colorimetric reproduction is not achieved, but for most purposes the reproduction of the hues and luminances in the original scene is satisfactory. Evans,[25] in fact, observes that under the right conditions the "magnitude of the reproduction errors that can be tolerated is astonishing." One aspect that is critical for many workers, especially expert photographers, is the ability of the system to produce good "balance," i.e., to reproduce a neutral as a neutral. This requirement is so important that one of the types of density that is measured for dye layers is the *equivalent neutral density* (END) which is defined as the visual neutral density that a dye layer would produce if combined with the correct amounts of the other two dyes (whatever those correct amounts may be). When the ENDs of the three layers are equal, the system is in balance, and color-film sensitometry is therefore often done in terms of ENDs. Further discussion of color sensitometry and densitometry may be found in Ref. 3, chap. 18.

29.12 MICRODENSITOMETERS

As indicated above, a microdensitometer is a densitometer designed to measure the density of a small area. The sampling apertures are typically slits which may be as narrow as 1 to 2 μm in nominal width. The sample is scanned over the aperture, creating a record of density as a function of position on the sample surface, i.e., distance.

In practical instruments, the small sampling aperture dimensions are achieved by projecting an enlarged image of the film onto a physical aperture. The optical system produces some effects not encountered in macrodensitometers, as follows:

1. In general, microdensitometers measure projection, or semispecular, density. As already noted, projection density is higher than diffuse density for silver layers, and the exact value of the effective Callier coefficient Q' depends in part on the numerical aperture of the optical system. Thus two microdensitometers fitted with optics of different NAs may give different density values for the same sample. Furthermore, macrodensity data are usually in terms of diffuse density, so that data from the microdensitometer should be corrected if intercomparisons are to be made. The effective Callier coefficient for the specific optics-sample combination is easily determined by measuring suitable areas of sample both in the microdensitometer and a macrodensitometer, and taking the ratios of the values.
2. The presence of stray light in the system tends to lower the measured density. This problem is especially troublesome in microdensitometry because of the types of images that are often encountered. Thus, for example, when an interface between clear and dense areas—that is, an edge—is scanned, stray light will distort the record in the manner shown in Fig. 9. If the image is that of a star or spectroscopic line, this behavior results in an artifically low density reading. It is very important to control stray light as completely as possible in microdensitometry.

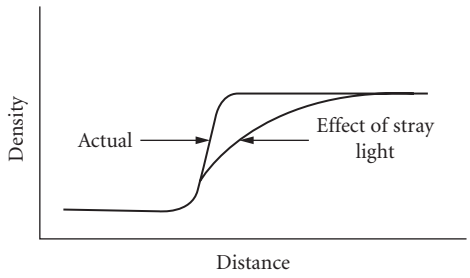

FIGURE 9 Effect of stray light in the microdensitometer on the apparent density distribution at an edge.

3. One feature of the usual microdensitometer optical system, installed for control of stray light, is the "preaperture," a field stop that limits the area of the sample that is illuminated. Because of this preaperture, and the optical system, a normal microdensitometer is a partially coherent system. This means that the instrument may respond to path-length differences in the sample as well as to density differences. This is undesirable since in practice it is the density differences that carry the information. Partial coherence in microdensitometers has been studied by Thompson and by Swing among others, and the results are summarized by Dainty and Shaw.[26] It has been shown that the coherence effects can be minimized by satisfying two conditions. In the first condition, the width W of the preslit

$$W \geq \frac{4\lambda}{NA_{\text{in}}} \tag{11a}$$

The second condition is

$$\frac{NA_{\text{in}}}{NA_{\text{eff}}} = 1 + \frac{\nu_s}{\nu_o} \tag{11b}$$

where λ = the wavelength of the light
NA_{in} = numerical aperture of the influx optics
NA_{eff} = numerical aperture of the efflux optics
ν_s = maximum spatial frequency in the sample
ν_o = spatial frequency cutoff of the scanning objective

If, for example $\nu_o = 3\nu_s$, then $NA_{\text{in}}/NA_{\text{eff}} \geq 1.3$. A microdensitometer arranged to minimize coherence problems is called a *linear* microdensitometer. Note that the two conditions above conflict with conditions commonly adopted to control stray light.

29.13 PERFORMANCE OF PHOTOGRAPHIC SYSTEMS

The following discussion of performance is limited to those aspects which are properties of the system, and excludes such aspects as the skill of the photographer, etc. Of those aspects, which we may term "technical" quality parameters, the most important is *tone reproduction*. The subject is divided into two areas: subjective tone reproduction and objective tone reproduction. Subjective tone reproduction is concerned with the relation between the brightness sensations produced in the observer's mind when the scene is viewed and when the picture is viewed. Since the sensation of brightness depends markedly on the viewing conditions and the observer's state of adaptation, the subjective tone reproduction of a given picture is not constant, and this aspect of the general subject is not often measured in the photographic laboratory. It is discussed by Kowalski.[27] Objective tone reproduction is concerned with the reproduction of the luminance and luminance differences of the scene as luminances in the final output. Tone reproduction studies apply equally well to projected images, prints, transparencies, and video images, but a negative-print system is usually assumed for discussion. It is easy to show that the log luminance of a print area, $\log L_p = C - D_p$, where C is a constant determined by the illuminance on the print and D_p is the density of the print area. Thus tone reproduction curves are usually plotted in the form of the print density versus the log luminance of the corresponding scene element (Fig. 10). Although both the scene luminances and the print densities are fixed quantities, the viewer's reaction still depends on the illumination level at which the picture is seen.

It has been shown empirically that for paper prints viewed under typical "room lighting conditions," the preferred tone reproduction curve is the solid line in Fig. 10. Perfect objective tone reproduction, defined as the case where $\Delta D_p = -\Delta \log L_{sc}$ for all scene luminance levels, would be

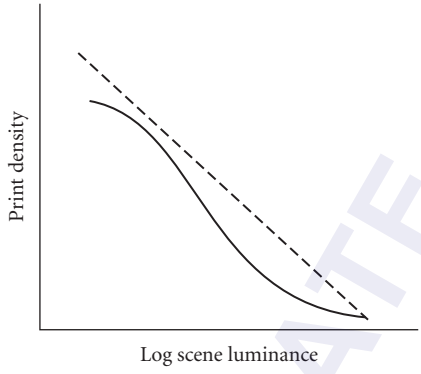

FIGURE 10 Preferred tone reproduction for viewing under typical room lighting conditions.

the dotted line in the figure. Thus under typical room lighting conditions viewers prefer a reproduction that has somewhat more contrast and less density than the "perfect" result. This preference will, however, change with illumination and stray light levels.

The exact shape of the tone reproduction curve obtained with a given system depends on the shape of the negative and positive D-log H curves, and also on the stray-light characteristic of the camera system. (Excessive stray light in the camera can be very deleterious to tone reproduction quality.) Using a graphic method devised by Jones and described by Nelson and others,[28] the effect of the D-log H curves and the stray light on the tone reproduction can be studied.

29.14 IMAGE STRUCTURE

The other two technical quality parameters of a photographic system are its sharpness and graininess, to use the most familiar terms for these properties. These properties are often lumped together under the general term "image structure." Actually, in photoscience the term sharp*ness* and grain*iness* are reserved for the subjective aspects of the phemomena, and measurement of these properties requires psychometric testing. Since such testing is expensive and time-consuming, objective correlates of both properties have been defined, and methods for measurement have been established. The objective correlate of sharpness is termed *acutance*, and of graininess is termed *granularity*. Image structure data for various kinds of materials are given in Table 1, along with speed and contrast values.

29.15 ACUTANCE

The original proposal for measuring acutance was made by Higgins and Jones[29] in 1952. It involved calculating a value from a microdensitometer trace of a test edge. However, the visual processes that occur when an observer views an edge are complex, and the straightforward calculation proposed by Higgins and Jones fails to predict the sensation of sharpness produced by some edge distributions. At about the same time, the optical transfer function (OTF) and related concepts began to be widely used in optics, and these were soon applied to photographic materials also.

The concepts of the point and line spread functions are essentially identical in optics and photoscience; in the photographic layer the smearing of the point (or line) input is caused by diffraction around the grains, refraction through them, and reflection from them. These phenomena are usually

TABLE 1 Performance Data for Types of Materials[a]

Type	SPD[b]	γ	Gran.[c]	ν_{50}[d]

[a]Data are as of early 1993 and were obtained from publications of the manufacturers listed in Sec. 29.21. They are presented as published. Note that products are frequently changed or improved.

[b]Speeds are calculated in different ways for various classes of product. The values given are suitable for use with standard exposure meters.

[c]Values represent 1000× the standard deviation of the diffuse density, measured at an average density of 1.0 using a 48-μm circular aperture. The exact granularity of a print depends on the characteristics of the print material and the printer as well as the granularity of the negative.

[d]Values show the spatial frequency at which the modulation transfer function is 50 percent.

[e]MTF values apply to the final print.

[f]Negative sign arises from the definition of gamma for the case of a positive image.

lumped together and termed "scattering," and have been treated by Gasper and dePalma.[30] Likewise, the concept of the optical transfer function, or the Fourier transform of the LSF, is basically the same in optics and photography. However, three important differences should be noted for the photographic case. (1) The emulsion is isotropic, so that the PSF and LSF are always symmetrical, and the complex OTF reduces to the modulation transfer function (MTF) only. (2) Unlike lenses, photographic layers are stationary, but are generally nonlinear. Therefore, all data and calculations must be in terms of *exposure* or allied quantities. When the calculations are complete, the results are converted to density via the D-log H curve. (3) The presence of edge effects tends to raise the MTF curve, so that for low frequencies the measured response values are often found to be greater than 100 percent. The subject is treated in detail by Dainty and Shaw.[31] Typical MTF curves for a film, showing the overshoot, are given in Fig. 11. Data for MTF curves of various types of films are also given in Table 1. The value given shows the spatial frequency for which the transfer factor drops to 50 percent.

The chain relating the MTF curve to image sharpness is the same as in optics: a high MTF curve transforms to a narrow spread function, and this in turn indicates an abrupt transition of exposure—and therefore density—across the edge. Thus MTF response values greater than unity, although mathematically anomalous, indicate improved image sharpness, and this is found to be the case in practice. As a matter of fact, edge effects are often introduced deliberately to improve sharpness. This is done either by adding suitable compounds to the coating itself, or by adjusting the developer formulation. The process is similar to the electronic "crispening" often used in television.

An index of sharpness can be computed from the MTF data by a procedure first suggested by Crane and later modified by Gendron.[32] These workers were interested mainly in films, but they recognized that the film is one component of a system; e.g., a color slide system involves a camera lens, the film (and process), a projector lens, the screen, and the observer's eye. The MTF of the system is then the cascaded MTFs of these components. Gendron suggested that the area under the cascaded MTF be taken as the stimulus that produced the sensation of sharpness. A formula was proposed

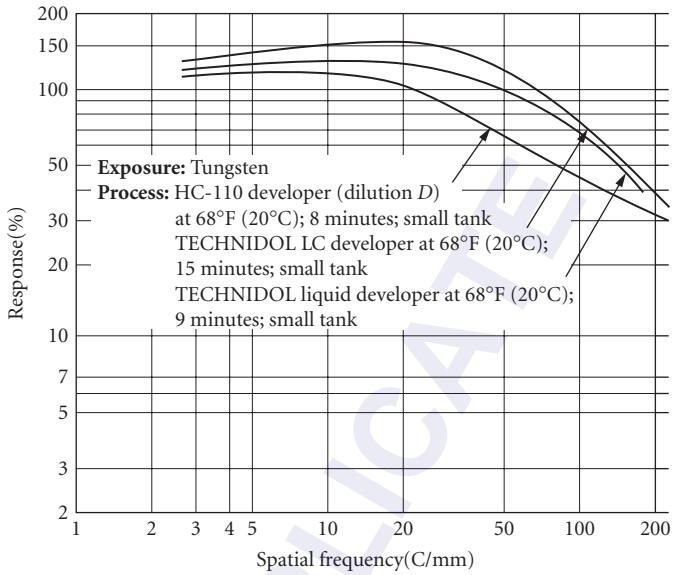

FIGURE 11 Modulation transfer functions of Kodak Technical Pan Film for three conditions of development. Note that the response at low frequencies exceeds 100 percent. (*Reprinted courtesy Eastman Kodak Co. © Eastman Kodak Co.*)

that produced a sharpness index scaled to 100. This index, now called CMT-Acutance (to distinguish it from the original Higgins-Jones acutance) has been found to correlate well with subjective data, and is used in the industry. Note that the treatment above has been simplified for the sake of brevity; details are available in Gendron's paper.

29.16 GRAININESS

The granular nature of the photographic image is one of its most significant characteristics. It may appear to the observer as an unpleasant roughness in what should be uniform areas, but it may also interfere with extracting information from the image. In the former case it is an aesthetic problem; in the latter case the structure is equivalent to noise in a communications channel. In either case it is desirable to measure the phenomenon objectively and in engineering terms.

The procedure now used for making these objective measurements was proposed by Selwyn in 1935.[33] He postulated that if the density of a uniformly exposed and processed layer were measured at many places using a suitable sampling aperture, the population of density values so obtained would be approximately gaussianly distributed around the mean. This being so, the variability for a given mean density is completely described by the standard deviation of the values. This quantity is termed the *rms-granularity*, $\sigma(D)$, and has indeed been shown to correlate with the subjective graininess.[34] It might be noted that calculating the standard deviation of the density is mathematically improper, since the underlying transmittance values are being multiplied. To avoid this problem the rms-granularity is formally defined by

$$\sigma(D)=\frac{0.434\sigma(T)}{\bar{T}} \tag{12}$$

where T is transmittance. However, it can be shown that when $\sigma(T)$ is small compared to $\bar{T}$, the error involved in calculating directly in density is small, and this is often done in practice.

Selwyn also showed that the measured value of $\sigma(D)$ depended upon A, the area of the sampling aperture. The product $\sigma(D)A^{1/2}$ may be termed the *Selwyn coefficient G;* for black-and-white films exposed to light, Selwyn showed that it should be constant, and this relation is called "Selwyn's law." Thus $\sigma(D)A^{1/2}$ is a measure of sample graininess no matter what the size of the sampling aperture. Unfortunately, the Selwyn coefficient does not remain constant with changes of aperture size for very important classes of samples. Selwyn's law may fail for prints and enlargements, black-and-white or color, for many color materials even if not enlarged, and also for radiographs, especially screened radiographs. For such materials $\sigma(D)$ still increases as A decreases, but not at a rate sufficient to keep the Selwyn coefficient constant, and it (the coefficient) is therefore not useful as an objective measure of graininess.

Stultz and Zweig[35] found that they obtained good correlation between $\sigma(D)$ and the sensation of graininess when the sampling aperture was selected in accordance with the rule

$$d(\mu)\cdot M_\theta \approx 515 \tag{13}$$

where $d(\mu)$ is the diameter of the sampling aperture in μm, and M_θ is the angular magnification[36] at which the photograph is seen by the viewer. M_θ is readily calculated from the relation

$$M_\theta = \frac{m}{4V} \tag{13a}$$

where m is the ordinary lateral magnification between the film image and the image presented to the viewer, and V is the viewing distance in meters.

An American standard[37] exists for the measurement of rms-granularity. This standard specifies that samples be scanned with a 48-μm-diameter aperture; for such an aperture, rms-granularity values for commercial films range from about 0.003 to 0.050 at an average density of 1.0. In practice, these values are often multiplied ×1000 to eliminate the decimals. It is worth noting that, experimentally, the measurement of rms-granularity is subject to many sources of error, such as sample artifacts. The standard discusses sources of error and procedures for minimizing them, and is recommended reading for those who must measure granularity.

While in practice rms-granularity serves well as an objective correlate of graininess, the situation is complicated by the fact that there are two broadly different types of granular pattern. Silver grains are small, opaque, and in nearly all cases are situated randomly and independently in the coating. The granular structure in an enlargement, however, is composed of clusters of print-stock grains that reproduce the exposure pattern coming from the enlarged negative grains. This type of granular pattern tends to be large and soft-edged compared to the pattern arising from the primary grains. The patterns found in such samples as color films and screened radiographs are generally similar to those found in enlargements. Microdensitometer traces of these two structures are illustrated in Fig. 12. A little thought will show that the two patterns shown in the figure might have the same mean and standard deviation, and yet the two patterns look entirely different. When different types of patterns are involved, the rms-granularity above is not a sufficient descriptor. The work by Bartleson which showed the correlation between graininess and rms-granularity was done with color negative films having similar granular structures.

As discussed by Dainty and Shaw,[38] further objective analysis of granular patterns may be carried out in terms of the *autocorrelation function*:

$$\phi(\tau) = \lim_{x\to\infty} \frac{1}{2x} \int_{-x}^{+x} \delta(x)\delta(x+\tau)dx \tag{14}$$

where $\delta(x) = D_x - \bar{D}$
Dx = the density reading at point x on the sample
$\bar{D}$ = mean density
$\delta(x + \tau) = D_{x+\tau} - \bar{D}$
τ = a small increment of distance

Note carefully that for the sake of simplicity it has been assumed that the sample is scanned by a very long, narrow slit, so that the autocorrelation function reduces to a one-dimensional function.

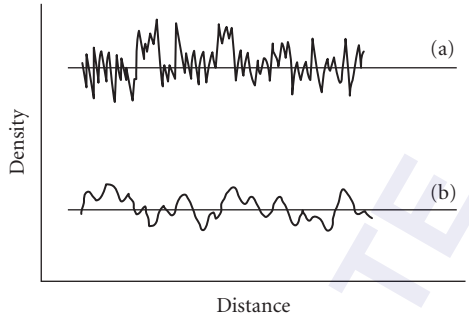

FIGURE 12 Microdensitometer traces of (*a*) primary silver grains and (*b*) granular structure of a print.

If the sample is scanned by a small circular aperture it will be two-dimensional. The use of a slit is common in practice. For the case where $\tau = 0$, we have

$$\phi(0) = \lim_{x\to\infty} \frac{1}{2x} \int_{-x}^{+x} [\delta(x)]^2 dx = \sigma^2 \tag{15}$$

Let $\phi(\tau)$ be calculated for several different values of τ, including values smaller than the slit width. Since when $\tau < w$ the slit will contain some of the same grains at points x and $x + \tau$, correlation is observed. If there is no spatial correlation in the actual sample, $\phi(\tau) \to 0$ for $\tau > w$. Positive values of $\phi(\tau)$ for $\tau > w$ are an indication of spatial correlation in the sample; that is, large-scale grain.

In practice, it is convenient to carry out the analysis of large-scale patterns in the spatial frequency domain. The Wiener-Khintchin theorem states that what is called the "Wiener spectrum" or *power spectrum of the granularity* distribution is the Fourier transform of the autocorrelation function; that is,

$$\mathrm{WS}(\nu) = \int_{-\infty}^{\infty} \phi(\tau) e^{i2\pi\nu\tau} d\tau \tag{16}$$

and also

$$\phi(\tau) = \int_{-\infty}^{\infty} \mathrm{WS}(\nu) e^{-i2\pi\nu\tau} d\nu \tag{16a}$$

where ν = spatial frequency.

In practice, an approximation of the Wiener spectrum is usually obtained by a direct Fourier transform of the granularity trace itself according to the expression

$$\mathrm{WS}(\nu) = \lim_{x\to\infty} \frac{1}{2x} \overline{\left| \int_{-x}^{x} \delta(x) e^{i2\pi\nu x} dx \right|^2} \tag{17}$$

where $\delta(x)$ has the same meaning as before, and the horizontal bar indicates that the average value of several different runs should be taken in order to provide a reasonable value for the approximation.

Returning to the definition of the autocorrelation function [Eq. (14)] it can be seen that the measured values of $\delta(x)$ and $\delta(x + \tau)$ are each actually the true values convolved with the slit response. By the convolution theorem of Fourier transforms, this means that in frequency space

$$\mathrm{WS}(\nu)_{\text{measured}} = \mathrm{WS}(\nu)_{\text{true}} x T(\nu)^2 \tag{18}$$

where $T(\nu)$ is the modulation transfer factor of the measuring system at spatial frequency ν. If $T(\nu)^2$ is divided out of $\mathrm{WS}(\nu)_{\mathrm{measured}}$ the underlying net value $\mathrm{WS}(\nu)$ is obtained. When this is done for black-and-white film samples exposed to light, the underlying spectrum is found to be flat. For the kinds of samples for which Selwyn's law fails, on the other hand, the net Wiener spectrum is found to contain excess low-frequency power and lack high frequencies. Finally, by the properties of Fourier transforms, the area under the Wiener spectrum curve is the zero-value of the autocorrelation function. But by Eq. (15) this zero-value equals σ^2 for the sample, so that the area under the WS curve gives the rms-granularity of the sample. This can also be seen intuitively, since the value of the WS at special frequency ν is simply the noise power of σ^2 in a spatial frequency band $\nu \pm \Delta\nu/2$.

Doerner[39] has shown that the rms-granularity of a negative can be tracked through a printer system in terms of the Wiener spectrum of the negative and the modulation transfer function of the printer system (which includes the MTF of the print stock itself). Doerner's expression is

$$\mathrm{WS}(\nu)_p = \mathrm{WS}(\nu)_n \gamma_p^2 A(\nu)_{\mathrm{syst}}^2 + \mathrm{WS}(\nu)_{\mathrm{ps}} \tag{19}$$

where n and p indicate negative and print respectively, "ps" the print stock itself, and the other symbols have their previous meanings. The granularity/graininess of a print thus depends on the contrast of the print stock and the spatial frequency response of the printer system as well as on the graininess of the negative.

29.17 SHARPNESS AND GRAININESS CONSIDERED TOGETHER

In the foregoing discussion, we have considered the sharpness and graininess aspects of the picture separately. But real photographs frequently suffer from less-than-optimum sharpness and graininess *both*. Bartleson[40] has studied the subjective quality of such photographs. He concluded that quality was not a linear combination of sharpness and graininess. Instead, ". . . quality tends to be determined primarily by the poorer of the two attributes. . . . If graininess is high, the print will likely be low in quality regardless of how sharp it may be or, conversely, if sharpness is low, so also will quality be low regardless of how grainy the print appears. . . ."

Bartleson's results are of interest in assessing the quality of electronic images, since, at least at the time of writing, such images exhibit low graininess, but also low sharpness. On the basis of Bartleson's work, such images would be judged to be of low subjective quality. In a comparison of electronic and film imagery published in 1990, Ikenoue and Tabei[41] rated the quality of the former as poor because of the sharpness level.

29.18 SIGNAL-TO-NOISE RATIO AND DETECTIVE QUANTUM EFFICIENCY

Since the information in a photograph is normally carried by the density variation, we may usefully define the output signal-to-noise ratio of the photography by

$$\mathrm{S/N}_{\mathrm{out}} = \frac{\Delta\bar{D}}{\sigma} = \frac{\gamma}{\sigma} \cdot \Delta \log H \tag{20}$$

where $\Delta\bar{D}$ is the mean density difference between an element to be detected and its surround, and σ is the rms-granularity of the surround. By Selwyn's law, $\sigma(D)$ varies as the area of the sampling

aperture changes; it is convenient here to take the sampling aperture area A as equal to the area of the image element. Furthermore, for ΔH sufficiently small we may write

$$S/N_{out} = 0.434 \frac{\gamma}{\sigma} \cdot \frac{\Delta H}{H} \tag{21}$$

Note that γ/σ is a property of the film; it is termed the *detectivity*. $\Delta H/H$, on the other hand, is a property of the object; in fact, it is the object contrast. Practical tests have shown that S/N_{out} should be 4 to 5 if the element is to be detected against its surround, and 8 to 10 if it is to be recognized.[42]

In 1946, Albert Rose of RCA published a paper[43] in which he discussed the performances of the TV pickup tube, the photographic layer, and the human eye on a unified basis. His approach was to compare their performances with that of an "ideal device," that is, a radiation detector whose performance was limited only by the quantum nature of the incoming radiation. Such a perfect detector would report the arrival of every incoming quantum, and add no noise to the signal.

In 1958, R. Clark Jones of Polaroid expanded Rose's work with specific application to photographic layers.[44] Jones proposed the term *detective quantum efficiency* (DQE) for Rose's performance indicator, and defined it by the expression

$$DQE = \left[\frac{S/N_{out}}{S/N_{ideal}}\right]^2 = \left[\frac{S/N_{out}}{S/N_{max}}\right]^2 = \left[\frac{S/N_{out}}{S/N_{in}}\right]^2 \tag{22}$$

where S/N_{out} is the signal-to-noise ratio produced by the actual device, and S/N ideal is the ratio that would be produced by the ideal device, given the same input. By the definition of the ideal device, $S/N_{ideal} = S/N_{max} = S/N_{in}$, where S/N_{in} is the signal-to-noise ratio in the input, and is due to the quantum nature of the input. The ratio is squared to make the DQE compatible with various other concepts.

It is easy to derive an expression for the S/N ratio of the input; when this is combined with Eq. (21) the result is

$$DQE = \left[\frac{0.434\gamma}{\mathcal{G}}\right]^2 \cdot \frac{1}{q} \tag{23}$$

where $\mathcal{G}$ is the Selwyn coefficient and q is the average exposure received by the image in *quanta per unit area*. Since $(1/q)$ is the radiometric speed of the film, it can be seen that the DQE is a performance parameter that combines the gain (gamma), noise, and speed of the layer. As written, the DQE does not involve the sharpness aspect, but this can be included also.[45]

Since Eq. (23) involves standard photographic parameters, it is readily evaluated for a given material. When this is done, it is found that the DQE of typical materials is on the order of 1 to 3 percent, peaking sharply at low densities in the case of black-and-white films. Note that DQE can be calculated for any sensor for which S/N_{out} can be derived. It is interesting to compare the 1 to 3 percent values given above with those of other sensors. Thus, for example, Jones gives a value of 1 percent for the human eye, and 6 percent for an image orthicon tube. On the other hand, a suitable photographic layer recording electrons may approach 100 percent DQE, and a value of 30 percent has been reported for a screened x-ray film.[46] DQE has also served as a useful approach to considering silver halide mechanisms; see, for example, a paper by Bird, Jones, and Ames that appeared in *Applied Optics* in 1969.[47]

Another figure of merit allied to DQE is the *noise equivalent quanta* (NEQ) which is defined as the number of quanta that a perfect detector would need to produce a record having the same S/N ratio as the system under consideration. It can be shown that

$$q' = DQE \times q \tag{24}$$

where q is again the number of quanta/unit area used by the real system, and q' the NEQ of a unit area of image.

29.19 RESOLVING POWER

The basic procedure used to measure photographic resolving power follows that used in optics. An American Standard exists.[48] The standard provides for a suitable test object to be reduced optically onto the material to be tested. (Strictly speaking, the test thus determines the resolution of the lens-film combination, but the resolution capability of the lenses specified is high compared to that of the film.) The developed image is then studied in a microscope to determine the highest spatial frequency in which the observer is "reasonably confident" that the structure of the test pattern can still be detected. Thus, as in optics, the "last resolved" image is a threshold image. However, unlike the optical case, the limit is set not only by the progressive decrease in image modulation as spatial frequency increases, but also by the granular nature of the image.

If an exposure series of the test pattern is made, it is found that the spatial frequency of the limiting pattern goes through a maximum. It is customary to report the spatial frequency limit for the optimum exposure as the resolving power of the film.

Photographic resolving power is now not much measured, but it retains some interest as an example of a signal-to-noise ratio phenomenon. Consider the modulation in the various triplet images in the pattern. By definition,

$$M = \frac{H_{\max} - H_{\min}}{H_{\max} + H_{\min}} = \frac{\Delta H}{2\bar{H}} \tag{25}$$

and from Eq. (21),

$$\Delta D = 0.868\,\gamma M \tag{26}$$

so that ΔD within the pattern varies as the modulation, which in turn decreases as the spatial frequency increases. Furthermore, the area of each of the triplets in the pattern (assuming the ISO pattern configuration) $= 2.5^2\lambda^2 = 2.5^2/\nu^2$. Assuming that Selwyn's law holds, it follows that $\sigma = \mathcal{G}/A^{1/2} = 0.4\,\mathcal{G}\nu = C\nu$, where we have lumped the constants. As the spatial frequency increases, the S/N of the triplet decreases because ΔD decreases and the effective rms-granularity increases. The resolving power limit comes at the spatial frequency where the S/N ratio drops to the limit required for resolution. Such a system has been analyzed by Schade.[49]

29.20 INFORMATION CAPACITY

The information capacity, or number of bits per unit area that can be stored on a photographic layer, depends on the size of the point spread function, which determines the smallest element that can be recorded, and on the granularity, which determines the number of gray levels that can be reliably distinguished. The exact capacity level for a given material depends on the acceptable error rate; for one set of fairly stringent conditions, Altman and Zweig[50] reported levels up to 160×10^6 bits/cm^2. Jones[51] has published an expression giving the information capacity of films as

$$IC = \frac{1}{2}\int\int_0^\infty \log_2\left(1 + \frac{S(\nu_x, \nu_y)}{N(\nu_x, \nu_y)}\right) d\nu_x d\nu_y \tag{27}$$

where S and N are the spectral distributions of power in the system's signal and noise. For a given spatial frequency, the signal power is given by

$$S = \mathrm{WS}_i(\nu)\mathrm{MTF}^2(\nu) \tag{28}$$

where $\mathrm{WS}_i(\nu)$ is the value of the Wiener spectrum of the input at ν and $\mathrm{MTF}(\nu)$ is the value of the film's MTF at that frequency. The information capacity thus depends on the frequency response and noise of the system, as would be expected. The matter is discussed by Dainty and Shaw.[52]

PHOTOGRAPHIC MATERIALS

John D. Baloga

Imaging Materials and Media
Eastman Kodak Company
Rochester, New York

30.1 INTRODUCTION

Photographic materials are optical devices. Their fabrication and technical understanding encompass the field of optics in the broadest sense. Light propagation, absorption, scattering, and reflection must be controlled and used efficiently within thin multilayer coatings containing tiny light-detecting silver halide crystals and chemistry. Many subdisciplines within classical optics, solid-state theory, and photochemistry describe these processes.

In Chap. 20 of Ref. 1, Altman sweeps broadly through the basic concepts and properties of photographic materials. His brief, high-level descriptions are still generally valid for today's photographic products, and the reader will profit by reviewing that summary. This chapter focuses more sharply on four fundamental photographic technologies intimately related to the broad field of optics, then gives an overview of photographic materials available today.

Section 30.2 discusses the optical properties of multilayer color photographic films and papers. This section outlines the basic structure of the device and describes the principal function of each layer. Light absorption, reflection, scattering, and diffraction properties are discussed in the context of providing minimum optical distortion to the final image.

Silver halide light detection crystals are solid-state devices described by quantum solid-state photophysics and chemistry in addition to crystallography. These devices absorb light to create an electron-hole pair. Delocalization of the electron in the conduction band of the crystal, trapping, reduction of interstitial silver ions, nucleation and growth of clusters of silver atoms, and reversible regression of these phenomena must be controlled and optimized to produce the most sensitive light detectors that also possess long-term stability.

Section 30.3 describes the basic photophysics of silver halides according to our best understanding today. It outlines the solid-state properties most important to image detection and amplification. Surface chemical treatment and internal doping are discussed in the context of providing silver halide emulsions having the highest sensitivity to light.

A color photographic image is formed by high-extinction and high-saturation dyes structurally designed by chemists to optimize their color, permanence, and other useful characteristics. Their properties in both the ground state and photoexcited states are important to color and stability.

Section 30.4 briefly outlines the photochemistry of photographic image dyes. Excited-state properties are described that are important to the photostability of these dyes for image permanence.

Color science guides us to optimize all factors in photographic materials conspiring to render an accurate and pleasing image. These include spectral discrimination during the light detection phase and color correction to compensate for imperfect spectral detection and imperfect image dyes.

Section 30.5 sketches the photophysics and color science of photographic spectral sensitizers with an aim toward describing how modern photographic films sense the world in color nearly as the human eye sees it.

Today there exists a large diversity of photographic films. In addition to different manufacturers' brands, films differ by speed, type, color attributes, format, and a multitude of other factors. This can be confusing. And what are the differences between a consumer film bought in a drugstore and a more expensive professional film?

Section 30.6 gives an overview of the different types of films available today. Differences between high- and low-speed films are described with an understanding of the origins of these differences. Consumer films are compared to professional films and some of the special needs of each type of customer are described. Some general guidelines are offered for film choices among color reversal films, black-and-white films, and color negative films.

In addition to Chap. 20 in Ref. 1, several other texts contain useful information about photographic materials. Kapecki and Rodgers[2] offer a highly lucid and digestible sketch of basic color photographic film technology. Besides Chap. 20 in Ref. 1, this is a good place for the technically astute but nonpractitioner to gain a high level understanding of basic color photography. The technically detailed treatise by James[3] is perhaps the best single comprehensive source containing the science and technology of the photographic system outside photographic manufacturers' internal proprietary libraries. Hunt[4] provides a good comprehensive treatise on all aspects of color science and additionally gives a good technical review of color photographic materials. Chapter 6 in Ref. 1 contains a useful overview of the theory of light-scattering by particles, Chap. 9 contains a good overview of optical properties of solids, and Chap. 26 on colorimetry provides a good introduction to the basic concepts in that field.

30.2 THE OPTICS OF PHOTOGRAPHIC FILMS AND PAPERS

Introduction

Color photographic materials incorporate design factors that optimize their performance across all features deemed important to customers who use the product. These materials are complex in composition and structure. Color films typically contain over 12 distinct optically and chemically interacting layers. Some of the newest professional color reversal films contain up to 20 distinct layers.* Each layer contributes a unique and important function to the film's final performance. Careful design and arrangement of the film's various layers ultimately determine how well the film satisfies the user's needs.

One very important customer performance feature is film *acutance,* a measure of the film's ability to clearly record small detail and render sharp edges. Because images recorded on color film are frequently enlarged, image structure attributes such as acutance are very important. Magnifications such as those used to place the image on a printed page challenge the film's ability to clearly record fine detail.

The ability of a photographic material to record fine detail and sharp edges is controlled by two factors. The first includes light scatter, diffraction, and reflections during the exposure step. These are collectively called *optical* effects. This factor dominates the film's ability to record fine detail and sharp edges and is therefore critical to the film's design.

*Fujichrome Velvia 50 RVP professional film.

Chemical adjacency effects collectively known as *Eberhard effects* (see Chap. 21 in Ref. 3) are the second factor. In today's color and black-and-white film products these are present during film development and are caused by accumulating development by-products such as iodide ions or inhibitors released by development inhibitor–releasing (DIR) chemicals that restrain further silver development in exposed regions of the image, leading to a chemical unsharp mask effect (pp. 274 and 365 of Ref. 4). These chemical signals also give rise to the film's interlayer interimage effects (HE; see p. 278 of Ref. 4) used for color correction. Film sharpness and HE are strongly related.

This section describes multilayer factors that contribute to light scatter, reflection, diffraction, and absorption in photographic materials. Factors that influence the nonoptical part of film acutance, such as Eberhard effects, were briefly reviewed by Altman.[1] More information about these processes can be found in references cited therein.

Structure of Color Films

Color film structures contain image-recording layers, interlayers, and protective overcoat layers. These layers suspend emulsions and chemistry in a hardened gelatin binder coated over a polyacetate or polyester support. Figure 1 shows the principal layers in a color multilayer film structure.

The overcoat and ultraviolet (UV) protective layers contain lubricants; plastic beads 1 to 5 μm in size called *matte* to impart surface roughness that prevents sticking when the film is stored in roll form; UV-light-absorbing materials; and other ingredients that improve the film's handling characteristics and protect the underlying light-sensitive layers from damage during use and from exposure to invisible UV light. Ultraviolet light is harmful for two reasons: it will expose silver halide emulsions, thereby rendering an image from light invisible to humans, and it promotes photodecomposition of image dyes, leading to dye fade over time (p. 977 of Ref. 2). Visible light exposure must first pass through these overcoats, but they typically do little harm to acutance as they contain nothing that seriously scatters visible light.

The blue-light-sensitive yellow dye imaging layers appear next. Silver halides, with the exception of AgCl—used primarily in color papers—have an intrinsic blue sensitivity even when spectrally sensitized to green or red light. Putting the blue-light-sensitive layers on top avoids incorrect

exposure leading to color contamination because a blue-light-absorbent yellow filter layer, located beneath the blue-sensitive imaging layers, absorbs all blue light that has passed completely through the blue-sensitive layers.

A collection of layers adjacent to one another that contain silver halide sensitized to a common spectral band is called a *color record.* Color records in films are always split into two or three separate layers. This arrangement puts the highest-sensitivity emulsion in the upper (fast) layer, where it gets maximum light exposure for photographic speed, and places low-sensitivity emulsions into the lower layer (or layers), where they provide exposure latitude and contrast control.

One or more interlayers separate the yellow record from the green-light-sensitive magenta record. These upper interlayers filter blue light to avoid blue light exposure color contaminating the red- and green-sensitive emulsion layers below. This behavior is called *punch through* in the trade. These interlayers also contain oxidized developer scavengers to eliminate image dye contamination between color records caused by oxidized color developer formed in one color record diffusing into a different color record to form dye.

The traditional yellow filter material is Carey Lea silver (CLS), a finely dispersed colloidal form of metallic silver, which removes most of the blue light at wavelengths less than 500 nm. The light absorption characteristics of this finely dispersed metallic silver are accounted for by Mie theory.[5] Unfortunately this material also filters out some green and red light, thus requiring additional sensitivity from the emulsions below. Bleaching and fixing steps in the film's normal processing remove the yellow CLS from the developed image.

Some films incorporate a yellow filter dye in place of CLS. Early examples contained yellow dyes attached to a polymer mordant in the interlayer. A *mordant* is a polymer that contains charged sites, usually cationic, that binds an ionized anionic dye by electrostatic forces. These dyes are removed during subsequent processing steps. Although these materials are free from red and green light absorption, it is a challenge to make them high in blue light extinction to avoid excessive chemical loads in the interlayer with consequent thickening.

Most recently, solid-particle yellow filter dyes[6] are seeing more use in modern films. These solid dyes are sized to minimize light scatter in the visible region of the spectrum and their absorption of blue light is very strong. They can be made with very sharp spectral cuts and are exceptionally well suited as photographic filter dyes. In some films solid-particle magenta filter dyes[7] are also used in the interlayers below the magenta imaging layers. Solid-particle filter dyes are solubilized and removed or chemically bleached colorless during the film's normal development process.

Because the human visual system responds most sensitively to magenta dye density, the green-light-sensitive image recording layers are positioned just below the upper interlayers, as close as practical to the source light exposure side of the film. This minimizes green light spread caused when green light passes through the turbid yellow record emulsions. It gives the maximum practical film acutance to the magenta dye record.

A lower set of interlayers separates the magenta record from the red-light-sensitive cyan dye record. These lower interlayers give the same type of protection against light and chemical contamination as do the upper interlayers. The magenta filter dye is absent in some films because red-light-sensitive emulsions are not as sensitive to green light exposure as to blue light exposure.

Located beneath the cyan record, just above the plastic film support, are antihalation undercoat (AHU) layers. The black absorber contained in this bottom layer absorbs all light that has passed completely through all imaging layers, thereby preventing its reflection off the gel-plastic and plastic-air interfaces back into the imaging layers. These harmful reflections cause a serious type of light spread called *halation,* which is most noticeable as a halo around bright objects in the photographic image.

The opacity required in the AHU is usually obtained by using predeveloped black filamentary silver, called *gray gel,* which is bleached and removed during the normal photographic processing steps. Alternatively, in many motion picture films a layer of finely divided carbon suspended in gelatin (*rem jet*) is coated on the reverse side of the film. When placed in this position the layer is called an *AHU pelloid.* It is physically removed by scrubbing just before the film is developed. The newest motion picture films incorporate a black solid-particle AHU filter dye that is solubilized and removed during normal development of the film and does not require a separate scrubbing step.

The overall thickness of a film plays an important role in minimizing harmful effects from light scatter. Because color films are structured with the yellow record closest to the light exposure source, it is especially important to minimize thickness of all film layers in the yellow record and below it, because light scattered in the yellow record progressively spreads as it passes to lower layers. The cyan record shows the strongest dependence on film thickness because red light passes through both yellow and magenta record emulsions en route to the cyan record. Because both emulsions often contribute to red light scatter, the cyan record suffers a stronger loss in acutance with film thickness.

Structure of Color Papers

The optical properties of photographic paper merit special consideration because these materials are coated in very simple structures on a highly reflective white Baryta-coated paper support. *Baryta* is an efficient diffuse reflector consisting of barium sulfate powder suspended in gelatin that produces isotropically distributed reflected light with little absorption.

Photographic papers generally contain about seven layers. On top are the overcoat and UV protective layers, which serve the same functions as previously described for film.

The imaging layers in color papers contain silver chloride emulsions for fast-acting development, which is important to the industry for rapid throughput and productivity. Generally only one layer is coated per color record, in contrast to films, which typically contain two or three layers per color record. The order of the color records in photographic papers differs from that in films due mainly to properties of the white Baryta reflective layer.

Because color paper is photographically slow, exposure times on the order of seconds are common. Most light from these exposures reflects turbidly off the Baryta layer. The imaging layers getting the sharpest and least turbid image are those closest to the reflective Baryta where light spread is least, not those closest to the top of the multilayer as is the case with film.

In addition, the Baryta layer as coated is not smooth. Its roughness translates into the adjacent layer, causing nonuniformities in that layer. Because the human visual system is most forgiving of physical imperfections in yellow dye, the yellow color record must be placed adjacent to the Baryta to take the brunt of these imperfections.

The magenta color record is placed in the middle of the color paper multilayer, as close to the Baryta layer as possible, since sharpness in the final image is most clearly rendered by magenta dye. This leaves the cyan record nearest to the top of the structure, just below the protective overcoats.

The magenta color record in the middle of the multilayer structure is spaced apart from the other two color records by interlayers containing oxidized developer scavengers to prevent cross-record color contamination, just as in films. However, no filter dyes are needed in color paper because silver chloride emulsions have no native sensitivity to light in the visible spectrum.

Light Scatter by Silver Halide Crystals

Because they consist of tiny particles, silver halide emulsions scatter light. Scattering by cubic and cubo-octahedral emulsions at visible wavelengths is most intense when the emulsion dimension ranges from 0.3 to 0.8 μm, roughly comparable to the wavelengths of visible light. This type of scattering is well characterized by Mie[8] theory and has been applied to silver halides.[9] We are often compelled to use emulsions having these dimensions in order to achieve photographic speed.

For photographic emulsions of normal grain size and concentration in gelatin layers of normal thickness, multiple scattering predominates. This problem falls within the realm of radiative transfer theory. Pitts[10] has given a rigorous development of radiative transfer theory to the problem of light scattering and absorption in photographic emulsions. A second approach that has received serious attention is the Monte Carlo technique.[11] DePalma and Gasper[12] were able to obtain good agreement between their modulation transfer functions (MTFs) determined by a Monte Carlo calculation and experimentally measured MTFs for a silver halide emulsion layer coated at various thicknesses.

Scattering by yellow record emulsions is especially harmful because red and green light must first pass through this record en route to the magenta and cyan records below. All other things being equal, the amount of light scattered by an emulsion layer increases in proportion to the total amount of silver halide coated in the layer.

Color films are constructed with low-scattering yellow record emulsions whenever possible. The amount of silver halide coated in the yellow record is held to a minimum consistent with the need to achieve the film's target sensitometric scale in yellow dye.

High-dye-yield yellow couplers[13] having high coupling efficiency are very useful in achieving silver halide mass reductions in the yellow record of color reversal films. These provide high yellow dye densities per unit silver halide mass, thereby reducing the amount of silver halide needed to achieve target sensitometry. Some upper-scale (high-density) increase in granularity often results from using these couplers in a film's fast yellow layer, but the benefits of reduced red and green light scatter overcome this penalty, especially because the human visual system is insensitive to yellow dye granularity.

Tabular emulsion grains offer a way to achieve typical photographic speeds using large-dimension emulsions, typically 1.0 to 3.0 μm in diameter, although smaller- and larger-diameter crystals are sometimes used. These do not scatter light as strongly at high angles from normal incidence with respect to the plane of the film as do cubic or octahedral emulsions having comparable photographic speeds. However, diffraction at the edges and reflections off the crystal faces can become a detrimental factor with these emulsions.

Silver halide tabular crystals orient themselves to lie flat in the plane of the gelatin layer. This happens because shear stress during coating of the liquid layer stretches the layer along a direction parallel to the support and also because the water-swollen thick layer compresses flat against the support after it dries by a ratio of roughly 20:1.

Reflections can become especially harmful with tabular emulsion morphologies since light reflecting from the upper and lower faces of the crystal interferes, leading to resonances in reflected light. The most strongly reflected wavelengths depend on the thickness of the tabular crystal. The thickness at which there is a maximum reflectance occurs at fractional multiples of the wavelength[14] given by:

$$t = \frac{\left(m + \frac{1}{2}\right)\lambda}{2n}$$

where t is the thickness of the tabular crystal, λ is the wavelength of light, n is the refractive index of the crystal, and m is an integer.

In an extreme case, tabular emulsions act like partial mirrors reflecting light from grain to grain over a substantial distance from its point of origin. This is called *light piping* by analogy with light traveling through an optical fiber (see Fig. 2). It is especially serious in the cyan record, where red light often enters at angles with respect to perpendicular incidence caused by scattering in upper layers.

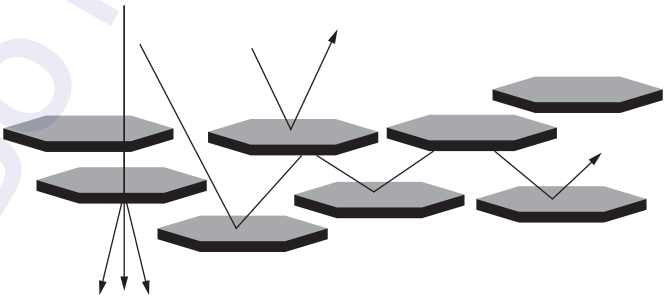

FIGURE 2 Light undergoes reflection, diffraction, and multiple reflections that may lead to light piping in film layers containing tabular silver halide crystals.

Another cause of light piping is the presence of small-grain emulsion contaminants within a tabular grain population. A highly turbid contaminant emulsion, even if present in small amounts, can scatter light at sufficient angles to induce severe light piping through the tabular grain matrix. Modern emulsion science takes great pains to produce tabular emulsions free from highly scattering contaminants.

Gasper[15] treated the problem of scattering from thin tabular silver halide crystals in a uniform gelatin layer. For very thin and large-diameter tabular silver bromide crystals (thickness <0.06 μm, diameter >1.0 μm) light at normal incidence is scattered almost equally in the forward and backward hemispheres. As the grain thickness increases there appears increasing bias for forward scatter in a narrow cone. The efficiencies for scatter and absorption were found to be independent of grain diameter for crystal diameters larger than ~1.0 μm. For such crystals, the backscatter and absorption efficiencies are approximately equal to the specular reflectance and absorption of a semiinfinite slab of the same material and thickness.

But the forward scattering efficiency does not approximate the specular transmittance of the semiinfinite slab as a result of interference between the directly scattered forward field and the mutually coherent unscattered field, a process analogous to diffraction that does not occur for the semiinfinite slab with no edge. The specific turbidity depends on grain thickness, but not diameter for diameter >1.0 μm.

A light-absorbing dye is sometimes added to a film to reduce the mean free path of scattered and reflected light leading to an acutance improvement. This improvement happens at the expense of photographic speed, since light absorbed by the dye is not available to expose the silver halide emulsions. However, the trade-off is sometimes favorable if serious light piping is encountered.

Light-absorbing interlayers between color records are sometimes used in color films to help eliminate the harmful effects of reflected light. For example, some films have a magenta filter dye interlayer between the magenta and cyan records. In addition to its usefulness in reducing light punchthrough (green light passing through the magenta record to expose the red-sensitized layers), this filter layer helps eliminate harmful reflections of green light off cyan record tabular emulsions, which bounce back into the magenta record. These reflections, although potentially useful for improving photographic green speed, can be harmful to magenta record acutance.

30.3 THE PHOTOPHYSICS OF SILVER HALIDE LIGHT DETECTORS

Chapter 20 in Ref. 1 gave a very brief sketch of the general characteristics of silver halide crystals used for light detection and amplification in photographic materials. These crystals, commonly termed *emulsions,* are randomly dispersed in gelatin binder layers in photographic films and papers. For photographic applications the most commonly used halide types are AgCl, AgBr, and mixed halide solid solutions of $AgCl_xI_y$ and $AgBr_xI_y$. In addition, pure phases of AgCl and AgI are sometimes grown epitaxially on AgBr crystals to impart special sensitivity and development properties.

Upon exposure to light, silver halide crystals form a latent image (LI) composed of clusters of three to hundreds of photoreduced silver atoms either within the interior or most usefully on the surface of the crystal where access by aqueous developing agents is easiest.* Higher light exposures result in larger numbers of silver atoms per latent image cluster on average in addition to exposing a larger number of crystals on average.

The detection of light by a silver halide crystal, subsequent conversion to an electron hole pair, and ultimate reduction of silver ions to metallic silver atoms is in essence a solid-state photophysical process. The application of solid-state theory to the photographic process began with Mott and

*Some specialized developing agents can etch into the silver halide crystal to develop the internal latent image (LI), but the most commonly used color negative and color paper developers have little capability to do this. They are primarily surface-developing agents. The color reversal black-and-white developer can develop slightly subsurface LI in color reversal emulsions.

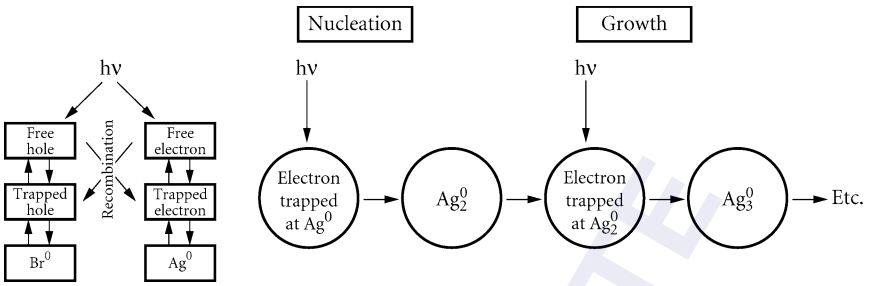

FIGURE 3 Diagram showing the basic features of the nucleation and growth mechanism for formation of a developable latent image site by light exposure of a silver halide crystal.

Gurney[16] and was extended by Seitz.[17] Additional reviews were published[18–20] as our understanding of these processes grew.

According to the nucleation and growth mechanism,[18] the photographic LI forms through a series of reversible electronic and ionic events (see Fig. 3). An electron is generated in the conduction band either by direct band gap photoexcitation of the crystal in its intrinsic spectral absorption region or by injection from a photoexcited spectral sensitizing dye on the crystal's surface. As this mobile electron travels through the crystal it becomes shallowly and transiently trapped at lattice imperfections carrying a positive charge. The ionized donor may be an interstitial silver ion or a surface defect. The kinked edge of a surface terrace, having a formal charge of +1/2 is one such site.

The electron may sample many such traps before becoming more permanently trapped at a preferred site. Trapping of the electron occurs in less than 0.1 ns at room temperature.[21] The shallowly trapped electron orbits about the trapping site in a large radius. At this stage the formal charge of the trap site becomes −1/2 and adjacent surface lattice ions relax, thereby increasing the depth of the trap.[22] In octahedral AgBr emulsions this shallow-deep transition occurs within 10 ns at room temperature.[21]

The negative charge formally associated with the trapped electron attracts a mobile interstitial Ag^+ ion, which the trapped electron reduces to an Ag^0 atom. The site's charge reverts to +1/2. A second photoelectron is then trapped at the site and reacts with a second interstitial Ag^+ ion to form Ag_2^0 and so on as additional photons strike the crystal. Frenkel defect concentrations—interior plus surface—in the range of $10^{14}/cm^3$ have been reported for AgBr crystals.[19] Latent image formation depends critically upon the existence of partially charged defects on the surface of the crystal.

Because the single-atom Ag^0 state is metastable and the Ag_2^0 state is not usefully detectable from gross fog by developing solutions (Chap. 4 of Ref. 3), a minimum of three photons must strike the crystal to form a detectable LI site, the second photon within the lifetime of the metastable trapped Ag^0 atom.* The transient existence of one or two silver atom sites has not been directly observed but is strongly inferred by indirect evidence.[20]

The highest photoefficiencies are achieved after silver halide emulsions are heated with aqueous sulfur and gold salts to produce Ag_2S and AgSAu species on the surface of the crystal.[22] Most of the evidence for sulfur sensitization suggests these sites improve electron trapping, perhaps by making trapping lifetimes longer at preexisting kink sites. Gold sensitization accomplishes at least two things: it reduces the size of the latent image center needed to catalyze development and it stabilizes silver atoms formed during the exposure process (Chap. 5 of Ref. 3).

Ideally only a single latent image site forms per exposed silver halide crystal. If more sites nucleate on a crystal, these can compete for subsequent photoelectrons, leading to losses in efficiency related to LI dispersity. One remarkable aspect of this process is that despite the large number of

*A metastable silver atom may dissociate back into an electron-hole pair, and the electron can migrate to another trapping site to form a new silver atom. This may happen many times in principle. The second electron must encounter the silver atom before electron-hole recombination or other irreversible electron loss takes place.

kink sites and chemically sensitized sites on a given crystal, in the most efficient silver halide emulsions only a single LI center forms per grain. The shallow-deep transition that occurs after the initial electron trapping selects one preferred defect out of the plethora of other possibilities for subsequent electron trapping.

The two predominant crystal faces that occur on photographically useful silver halide grains are [100] and [111]. Both surfaces have a negative charge[23] ranging from −0.1 to −0.3 V. A subsurface space charge layer rich in interstitial Ag+ ions compensates for the charged surface.[24] The [100] surfaces are flat with steps containing jogs that are either positively or negatively charged kink sites. The positive kinks on the surface form shallow electron traps.

In contrast, the [111] surface is not well characterized and is believed to be sensitive to surface treatment. Calculations of surface energies suggest that several arrangements may coexist, including microfaceted [100] planes and half layers of all silver or all halide ions in arrangements with hexagonal symmetry.[24,25]

All silver halides absorb light in the near-UV region of the spectrum. The absorption edge extends to longer wavelengths from AgCl to AgBr to AgI. AgCl and AgBr have indirect band gap energies of 3.29 and 2.70 eV, respectively.[19] Absorption of light produces electrons in a conduction band whose minimum lies at the zone center and holes in the valence band whose maximum is at an L point. Carriers produced at excess energy rapidly thermalize at room temperature since electron mobility is limited by phonon scattering.

Electron mobility in AgBr is about 60 cm^2/Vs at room temperature.[19] In AgCl the hole mobility is low, but in AgBr it is substantial—only about a factor of 30 lower than electron mobility.[20] Carriers generated by exposure will explore the crystal in a random walk as they scatter off phonons and transiently trap at charged defects. It is expected that electrons can fully sample a 1-μm crystal within less than 1 μs.

In most commercial photographic materials today, only about 25 percent to 50 percent of the electrons injected into the crystal's conduction band contribute to a developable LI site. The rest are wasted through electron-hole recombination, formation of internal LI that is inaccessible to the developing agent, or formation of multiple nucleation sites termed *dispersity.* The deliberate addition of dopants that act as shallow electron traps reduces the time electrons spend in the free carrier state and thereby limits their propensity to recombine with trapped holes.

Polyvalent transition metal ions are frequently doped into silver halide crystals to limit reciprocity effects, control contrast, and reduce electron hole recombination inefficiencies.[26] They act as electron or hole traps and are introduced into the crystal from aqueous hexa-coordinated complexes during precipitation. They generally substitute for $(AgX_6)^{5-}$ lattice fragments. Complexes of Ru and Ir have been especially useful. Because the dopant's carrier-trapping properties depend on the metal ion's valence state and the steriochemistry of its ligand shell, there are many opportunities to design dopants with specific characteristics. Dopants incorporating Os form deep electron traps in AgCl emulsions with an excess site charge of +3. An effective electron residence lifetime of 550 seconds has been measured for these dopants at room temperature.[20] They are used to control contrast at high-exposure regions in photographic papers.

Quantum sensitivity is a measure of the average number of photons absorbed per grain to produce developability in 50 percent of an emulsion population's grains (Chap. 4 in Ref. 27). This microscopic parameter provides a measure of the photoefficiency of a given emulsion; the lower the quantum sensitivity value, the more efficient the emulsion. The quantum sensitivity measurement gives a cumulative measure of latent image formation, detection, and amplification stages of the imaging chain.

Quantum sensitivity has been measured for many emulsions. The most efficient emulsions specially treated by hydrogen hypersensitization yield a quantum sensitivity of about three photons per grain.[28] Although hydrogen hypersensitization is not useful for general commercial films because it produces emulsions very unstable toward gross fog, this sensitivity represents an ambitious goal for practical emulsions used in commercial photographic products. The most efficient practical photographic emulsions reported to date have a quantum sensitivity of about five to six photons per grain.[29] The better commercial photographic products in today's market contain emulsions having quantum sensitivities in the range of 10 to 20 photons per grain.

30.4 THE STABILITY OF PHOTOGRAPHIC IMAGE DYES TOWARD LIGHT FADE

Introduction

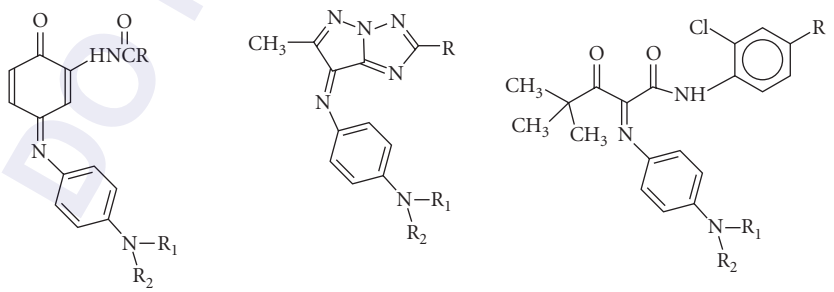
Azomethine dyes are formed in most photographic products by reaction between colorless couplers and oxidized *p*-phenylenediamine developing agents to form high-saturation yellow, magenta, and cyan dyes (Chap. 12 in Ref. 3). Typical examples are shown in Fig. 4. The diamine structural element common to all three dyes comes from the developing agent, where R_1 and R_2 represent alkyl groups. The R group extending from the coupler side of the chromophore represents a lipophilic ballast, which keeps the dye localized in an oil phase droplet. In some dyes it also has hue-shifting properties.

Heat, humidity, and light influence the stability of these dyes in photographic films and papers.[30] Heat and humidity promote thermal chemical reactions that lead to dye density loss. Photochemical processes cause dyes to fade if the image is displayed for extended periods of time. Ultraviolet radiation is especially harmful to a dye's stability, which is partly why UV absorbers are coated in the protective overcoat layers of a color film or paper.

Stability toward light is especially important for color papers, where the image may be displayed for viewing over many years. It is less important in color negative film, which is generally stored in the dark and where small changes in dye density can often be compensated for when a print is made. Light stability is somewhat important for color reversal (slide and transparency) film, since a slide is projected through a bright illuminant, but projection and other display times are short compared to values for color papers. A similar situation exists for movie projection films, where each frame gets a short burst of high-intensity light but the cumulative exposure is low.

Evaluation of the stability of dyes toward light is difficult because the time scale of the photochemical reactions, by design, is very slow or inefficient. The quantum yields of photochemical fading of photographic dyes, defined as the fraction of photoexcited dyes that fade, are on the order of 10^{-7} or smaller.[2,31] Accelerated testing using high-intensity illumination can sometimes give misleading results if the underlying photochemical reactions change with light intensity (p. 266 in Ref. 4).

Given that dyes fade slowly over time, it is best if all three photographic dyes fade at a common rate, thereby preserving the color balance of the image (p. 267 in Ref. 4). This rarely happens. The perceived light stability of color photographic materials is limited by the least stable dye. Historically, this has often been the magenta dye, whose gradual fade casts a highly objectionable green tint to a picture containing this dye. This is most noticeable in images containing memory colors, such as neutral grays and skin tones.



Cyan dye Magenta dye Yellow dye

FIGURE 4 Typical examples of azomethine dyes used in photographic materials.

Photochemistry of Azomethine Dyes

Upon absorption of a photon, a dye becomes reversibly excited to the singlet state. For azomethine dyes, the lifetime of the excited state is estimated to be on the order of picoseconds.[32–39] Similarly, the lifetime of the triplet state of azomethine dyes, which is expected to form rapidly by intersystem crossing from the singlet excited state, has been estimated to be in the nanosecond range.[36] The short lifetime of these species seems to be at the basis of the observed low quantum yields of photochemical fading of azomethine dyes.

The nature of the initial elementary reactions involving excited or triplet states of dyes is not well understood. For some magenta dyes, the fading mechanism was reported to be photooxidative.[37] Cyan dye light fade appears to involve both reductive and oxidative steps[38] following photoexcitation of the dye.

Singlet oxygen has been traditionally postulated to be involved in the oxidative pathway.[39] This high-energy species can, in principle, be formed by energy transfer between a triplet dye and molecular oxygen, and can subsequently induce dye destruction, although reaction with singlet oxygen does not always lead to decomposition.[40]

$Dye + h\nu \rightarrow {}^1Dye^*$	Formation of an excited state by light absorption
${}^1Dye^* \rightarrow {}^3Dye$	Formation of triplet state by intersystem crossing
${}^3Dye + \rightarrow {}^3O_2 \rightarrow Dye + {}^1O_2$	Formation of singlet oxygen
${}^1O_2 + Dye \rightarrow$ Chemical reaction	Dye fade by singlet oxygen

Studies of the photophysical properties of photographic dyes, however, have shown that in general, azomethine dyes are good quenchers of singlet oxygen.[41] This implies that the formation of singlet oxygen by the triplet state of the dyes should be inefficient. An alternative feasible role for molecular oxygen in dye fade involves electron transfer mechanisms.

${}^1Dye^* + O_2 \rightarrow Dye^+ + O_2^-$	(Radical formation) $\Rightarrow$ subsequent reactions leading to dye destruction
${}^3Dye + O_2 \rightarrow Dye^+ + O_2^-$	(Radical formation) $\Rightarrow$ subsequent reactions leading to dye destruction

The chemistry of dye fade may also be started by electron transfer between excited or triplet dye and a dye molecule in its ground state.

${}^1Dye^* + Dye \rightarrow Dye^+ + Dye^-$	(Radical formation) $\Rightarrow$ subsequent reactions leading to dye destruction
${}^3Dye + Dye \rightarrow Dye^+ + Dye^-$	(Radical formation) $\Rightarrow$ subsequent reactions leading to dye destruction

Excited State Properties

The few papers that have been published about excited singlet-state properties of azomethine dyes have mainly focused on pyrazolotriazole magenta dyes.[32–35] These dyes have fluorescence quantum yields on the order of 10^{-4} at room temperature, but increase to ~1 in rigid organic glasses at 77 K.[40] The fluorescence quantum yield is the fraction of photoexcited molecules that emit a quantum of light by fluorescence from an excited state to the ground state having the same multiplicity (usually singlet to singlet). The results at room temperature imply singlet-state lifetimes of only a few picoseconds.[40]

Room-temperature flash photolysis has identified a very short-lived fluorescent state plus a longer-lived nonfluorescent transient believed to be an excited singlet state whose structure is twisted compared to the ground state. This is consistent with the temperature-dependent results that allow rapid conformational change to the nonfluorescent singlet species at room temperature,

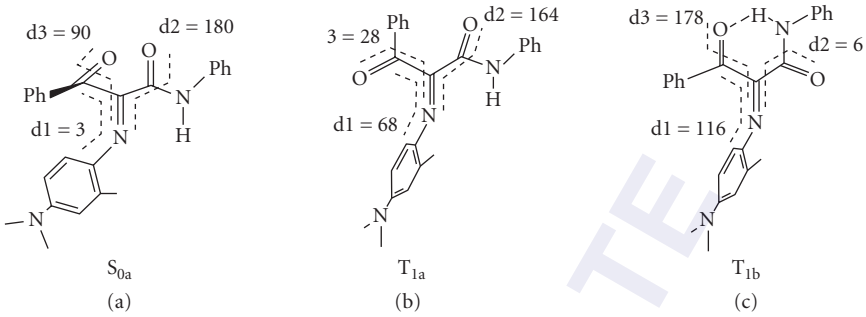


FIGURE 5 (*a*) Ground state conformation and (*b* and *c*) two conformations of the lowest triplet state.

in addition to intersystem crossing to the triplet excited state. But this conformational change is presumably restrained in a cold organic glass matrix, thereby allowing the excited singlet state time to fluoresce back to the ground state.

Investigation of the triplet states of azomethine dyes has proven difficult, and there are no definitive reports of direct observation of the triplet states. There are no reliable reports of phosphorescence from the triplet state of these dyes, although they have been studied by flash photolysis.[32–35,41–45] Using indirect energy transfer methods, triplet lifetimes have been estimated to be less than 10 ns.[36] Similar studies[43] gave triplet energies of 166 to 208 kJ mol^{-1} for yellow dyes, 90 to 120 kJ mol^{-1} for magenta dyes, and about 90 kJ mol^{-1} for cyan dyes.

Computational studies have been carried out recently on the ground and lowest triplet states of yellow azomethine dyes.[45] Consistent with crystallographic studies,[46,47*] the calculated lowest-energy ground state conformation S_0 is calculated to have the azomethine C═N bond coplanar with the anilide C═O carbonyl, but perpendicular to the C═O carbonyl of the ketone. The energy of the vertical transition triplet state having this conformation is quite high, calculated to be 230 kJ mol^{-1} above the ground state. Energy minimization on the lowest triplet energy surface starting with the geometry of S_0 results in a relaxation energy of 100 kJ mol^{-1} and leads to T_{1a}, characterized by a substantial twist around the C═N bond and by increased planarity of the keto carbonyl with the azomethine plane. These conformational changes offer an efficient mechanism for stabilizing the lowest triplet state in these dyes. A second triplet conformer T_{1b} with an energy 25 kJ mol^{-1} below T_{1a} was also calculated (see Fig. 5).

The low energy values calculated for T_{1a} and T_{1b} relative to S_{0a} (130 and 105 kJ mol^{-1}, respectively) have led to a new interpretation of the reported results[43] of energy transfer to S_{0a}. Using the nonvertical energy transfer model of Balzani,[48] it is shown that observed rates of energy transfer to S_{0a} can be consistent with formation of two distinct triplet states: one corresponding to a higher-energy excited triplet state (T_2) 167 kJ mol^{-1} above S_{0a}, and the second corresponding to one conformation of the lowest triplet state (T_1) with an energy of 96 kJ mol^{-1} above S_{0a}, in good agreement with the calculated T_{1b} configuration. The large structural differences between S_{0a} and the conformers of T_1 can explain the lack of phosphorescence in this system.

Light Stabilization Methods

Stabilization methods focus on elimination of key reactants (such as oxygen by various barrier methods), scavenging of reactive intermediates such as free radicals transiently formed during photodecomposition, elimination of ultraviolet light by UV absorbers, or quenching of photoexcited species in the reaction sequence.

*Other unpublished structures exhibiting the same conformation of S_{0a} have been solved at Kodak.

Stabilizer molecules[49] have been added to photographic couplers to improve the stability of their dyes toward light fade. Although the exact mode by which these stabilizers operate has not been disclosed, it is probable that some quench the photoexcited state of the dyes, thereby preventing further reaction leading to fading; some scavenge the radicals formed during decomposition steps; and some may scavenge singlet oxygen.

Polymeric materials added to coupler dispersions also stabilize dyes. These materials are reported to improve thermal dye decomposition[50] by physically separating reactive components in a semirigid matrix or at least decreasing the mobility of reactive components within that matrix. They may provide benefits for light stability of some dyes by a similar mechanism.

Photographic dyes sometimes form associated complexes or microcrystalline aggregates (p. 322 of Ref. 4). These have been postulated to either improve light stability by electronic-to-thermal (phonon) quenching of excited states, or to degrade light stability by concentrating the dye to provide more available dye molecules for reaction with light-induced radicals. Both postulates may be correct depending upon the particular dyes.

Modern photographic dyes have vastly improved light stabilities over dyes of the past. For example, the magenta dye light stability of color paper dyes has improved by about two orders of magnitude between 1942 and the present time.[51] New classes of dyes[52,53] have proved especially resistant to light fade and have made memories captured by photographic materials truly archival.

30.5 PHOTOGRAPHIC SPECTRAL SENSITIZERS

Introduction

Spectral sensitizing dyes are essential to the practice of color photography. In 1873, Vogel[54] discovered that certain organic dyes, when adsorbed to silver halide crystals, extend their light sensitivity to wavelengths beyond their intrinsic ultraviolet-blue sensitivity. Since then, many thousands of dyes have been identified as silver halide spectral sensitizers having various degrees of utility, and dyes exist for selective sensitization in all regions of the visible and near-infrared spectrum. These dyes provide the red, green, and blue color discrimination needed for color photography.

The most widely used spectral sensitizing dyes in photography are known as *cyanine dyes.* One example is shown in Fig. 6. These structures are generally planar molecules as shown.

A good photographic spectral sensitizing dye must adsorb strongly to the surface of the silver halide crystal. The best photographic dyes usually self-assemble into aggregates on the crystal's surface. Aggregated dyes may be considered partially ordered two-dimensional dye crystals.[55] Blue-shifted aggregates are termed *H-aggregates,* while red-shifted ones, which generally show spectral narrowing and exitonic behavior, are termed *J-aggregates.* Dyes that form J-aggregates are generally most useful as silver halide spectral sensitizers.

A good sensitizing dye absorbs light of the desired spectral range with high efficiency and converts that light into a latent image site on the silver halide surface. The relative quantum efficiency[56] of sensitization is defined as the number of quanta absorbed at 400 nm in the AgX intrinsic absorption region to produce a specified developed density, divided by the number of like quanta absorbed only by dye within its absorption band. For the best photographic sensitizing dyes this number is only slightly less than unity.

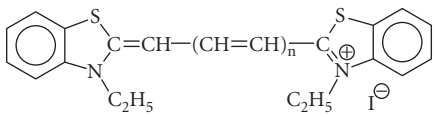

FIGURE 6 Typical cyanine spectral sensitizing dye used in photographic materials.

Adsorption isotherms for J-aggregated cyanine dyes on AgX follow Langmuir behavior with a saturation coverage that indicates closely packed structures.[57] The site area per molecule derived from the Langmuir isotherms implies dye adsorption along its long axis with heterocyclic rings perpendicular to the surface. Recent scanning tunneling microscope work[58,59] has convincingly detailed the molecular arrangement within these aggregates, confirming general expectations.

The Photophysics of Spectral Sensitizers on Silver Halide Surfaces

Sensitizing dyes transfer an electron from the dye's excited singlet state to the conduction band of AgX. Evidence for this charge injection comes from extensive correlations of sensitization with the electrochemical redox properties of the dyes.[22,60,61] In the adsorbed state a good sensitizing dye has an ionization potential smaller than that of the silver halide being sensitized. This allows the energy of the dye excited state to lie at or above the silver halide conduction band even though the energy of the photon absorbed by the dye is less than the AgX band gap. Dye ionization potentials are generally well correlated with their electrochemical oxidation potentials.

The triplet energy level of a typical cyanine dye lies about 0.4 to 0.5 eV (about 35 to 50 kJ mol^{-1}) below the radiationally excited singlet level.[62] In most cases, this triplet state seems to have little effect on spectral sensitization at room temperature, although it may influence sensitization in special cases.[63]

Electron transfer takes place by tunneling from the excited-state dye to the silver halide conduction band. Simple calculations verify that penetration of the potential barrier will compete favorably with de-excitation of the dye by fluorescence emission (p. 253 of Ref. 3). The interaction time between an excited spectral sensitizer and silver bromide appears to occur between 10^{-13} and 10^{-10} (p. 237 of Ref. 3). Factors favoring irreversible flow of electrons from dye to silver halide are delocalization within the conduction band, the negative space charge layer on the surface of the crystal, trapping by remote sites on the silver halide surface, and irreversible trapping to form a latent image.

Free electrons from dye sensitization appear in the silver halide conduction band having the same mobility and lifetime as those formed by intrinsic absorption. These electrons participate in latent image formation by the usual mechanism.

After electron transfer, the oxidized dye radical cation becomes the hole left behind. Because there is evidence that a single dye molecule may function repeatedly,[64] the dye cation "hole" must be reduced again. This can occur by electron tunneling from an occupied site on the crystal's surface, whose energy level is favorable for that process. A bromide ion at a kink is one such site. This leaves a trapped hole on the crystal surface that may be thermally liberated to migrate through the crystal. This hole can lead to conduction band photoelectron loss by recombination. A supersensitizer molecule (discussed later) may also trap the hole.

The formation of the J-aggregate exciton band has significant effects on the excited-state dynamics of the dye. There is the possibility of coherent delocalization of the exciton over several molecules in the aggregate.[65] The exciton is mobile and can sample over 100 molecules within its lifetime.[66] This mobility means that the exciton is sensitive to quenching by traps within the aggregate structure. The overall yield of sensitization generally increases to maximum, then decreases somewhat as the aggregate size increases. Optimum sensitizations usually occur below surface monolayer coverage.

Sometimes the spectral sensitivity of a dye is increased by addition of a second substance. If the added sensitivity exceeds the sum of both sensitizers individually, the increase is super-additive and the second substance is called a *supersensitizer*. Maximum efficiency of a supersensitizer often occurs in the ratio of about 1:20 where the supersensitizer is the dilute component.

The supersensitizer may increase the spectral absorption of the sensitizer by inducing or intensifying formation of a J-aggregate. In some cases these changes are caused by a mutual increase in adsorption to the grain surface, as when the sensitizer and supersensitizer are ions of opposite charge.[67] However, the most important supersensitizers appear to increase the fundamental efficiency of spectral sensitization as measured by the relative quantum yield.

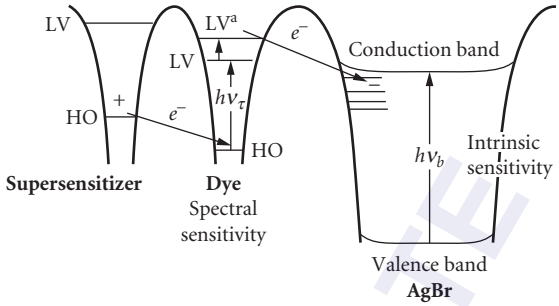

FIGURE 7 Simplified energy level diagram for a spectral sensitizer dye plus a supersensitizer dye adsorbed to a silver bromide surface.

The low concentration of supersensitizer relative to sensitizer suggests trapping of an exciton moving through the quasicrystalline array of J-aggregated sensitizer molecules. One hypothesis is that the supersensitizer molecule traps the exiton, providing a site for facile electron transfer into the silver halide.[68]

Gilman and coworkers[69–72] proposed that the supersensitization of J-aggregating dyes takes place via hole trapping by the supersensitizer molecules. The exciton moving through the aggregate may be self-trapped at a site adjacent to a supersensitizer molecule. By hypothesis, the highest occupied (HO) electron energy level of the supersensitizer is higher than that of the partially empty HO level of the excited sensitizer molecule. An electron transfers from the supersensitizer to the sensitizer molecule. The sensitizer is reduced to an electron-rich, anion-free radical while the supersensitizer is oxidized to an electron-deficient cation radical of lower energy than the original hole, thereby localizing the hole on the supersensitizer (see Fig. 7).

Following electron transfer from the supersensitizer, the electron-rich free radical anion left on the sensitizer will possess an occupied electron level of higher energy than the excited level of the parent sensitizer. The reduction process thereby raises the level of the excited electron with respect to the conduction band of AgX, with a consequent increase in probability of electron tunneling into the silver halide conduction band.

The various proposed mechanisms of supersensitization are not mutually exclusive. Exciton trapping and hole trapping may operate together. Underlying all mechanisms are the roles of exciton migration throughout the aggregate, its interruption at or near the supersensitizer site, and a more facile transfer of the electron into the AgX conduction band at that localized state.

Spectral sensitizing dyes, especially at high surface coverage, desensitize silver halides in competition with their sensitization ability. Red spectral sensitizers generally desensitize more than green or blue spectral sensitizers do. Desensitization can be thought of as reversible sensitization. For example, a mobile conduction band electron can be trapped by a dye molecule to form a dye radical anion[73] or by reduction of a hole trapped on the dye.[63,74–76] Under normal conditions of film use (not in a vacuum), a dye radical anion may transfer the excess electron irreversibly to an O_2 molecule with formation of an O_2^-anion. Either postulate leads to irreversible loss of the photoelectron and consequent inefficiency in latent image formation.

Color Science of Photographic Spectral Sensitizers

Human vision responds to light in the range of 400 to 700 nm. The human eye is known to contain two types of light-sensitive cells termed *rods* and *cones,* so named because of their approximate shapes. Cones are the sensors for color vision. There is strong evidence for three types of cones sometimes termed long (L), middle (M), and short (S) wavelength receptors (Chap. 1 in Ref. 1). The normalized spectral responses of the human eye receptors (Chap. 26, Table 5 in Ref. 1) are

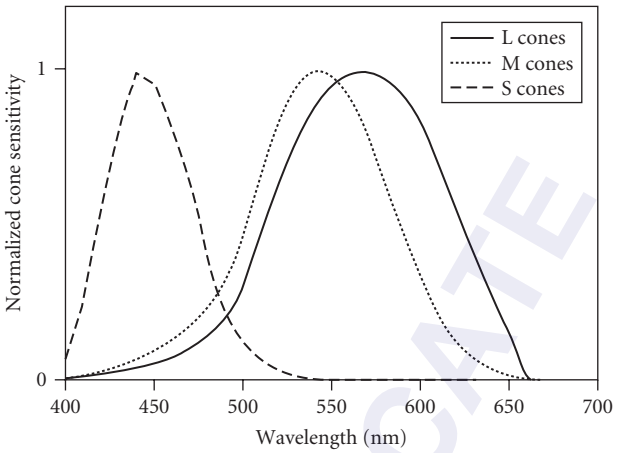

FIGURE 8 Normalized spectral sensitivity of the human eye.

shown in Fig. 8. The ability of humans to distinguish differences in spectral wavelength is believed to rely on difference signals created in the retina and optic nerve and interpreted by the brain from responses to light by the three cone detectors (Chap. 9 in Ref. 4).

The human eye's red sensitivity function peaks at around 570 nm and possesses little sensitivity at wavelengths longer than 650 nm. Also, there exists considerable overlap between red and green sensitivity functions, and to a lesser extent overlap between blue and green and blue and red sensitivity functions. This overlap in sensitivity functions, combined with signal processing in the retina, optic nerve, and brain, allows us to distinguish subtle color differences while simultaneously appreciating rich color saturation.

Photographic films cannot do this. The complex signal processing needed to interpret closely overlapping spectral sensitivity functions is not possible in a photographic material (Chap. 9 in Ref. 4). Some relief from this constraint might be anticipated by considering Maxwell's principle.[77]

Maxwell's principle states that any visual color can be reproduced by an appropriate combination of three independent color stimuli called *primaries.* The amount of each primary per wavelength needed to reproduce all spectral colors defines three color-matching functions (Chap. 6 in Ref. 1) for those primaries. If there exists a set of color-matching functions that minimize overlap between spectral regions, a photographic film with spectral sensitivity like that set of color-matching functions and imaging with the corresponding primary dyes would faithfully reproduce colors.

The cyan, magenta, and yellow dye primaries used in photographic materials lead to theoretical color-matching functions (Chap. 19-II in Ref. 3; Ref. 78)* having more separation than human visual sensitivity, but possessing negative lobes as shown in Fig. 9. This is impossible to achieve in practical photographic films (Chap. 9 in Ref. 4), although the negative feedback from HE effects provides an imperfect approximation. Approximate color-matching functions have been proposed[80] that contain no negative lobes. But these possess a very short red sensitivity having a high degree of overlap with the green sensitivity, similar to that of the human eye.

It is therefore not possible to build a perfect photographic material possessing the simultaneous ability to distinguish subtle color differences, especially in the blue-green and orange spectral regions, and to render high-saturation colors. Compromises are necessary.

*The theoretical color-matching functions were calculated using the analysis described in Ref. 78, Eq. (9a–c) for block dyes having trichromatic coefficients in Table II, and using the Judd-Vos modified XYZ color matching functions in Chap. 26, Table 2 of Ref. 1.

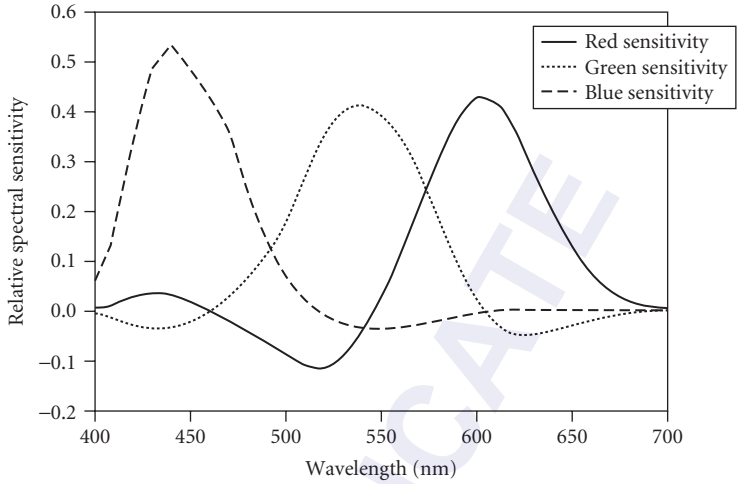

FIGURE 9 Spectral sensitivity for idealized photographic dyes. Note the large negative lobe around 525 nm.

Most photographic materials intended to image colors at high saturation possess spectral sensitivities having small overlap, and in particular possess a red spectral sensitivity centered at considerably longer wavelengths than called for by theoretical color-matching functions. This allows clean spectral detection and rendering among saturated colors but sacrifices color accuracy.

For example, certain *anomalous reflection colors* such as the blue of the lobelia flower possess a sharp increase in spectral reflectance in the long red region not seen by the human eye but detected strongly by a photographic film's spectral sensitivity (see Fig. 10). This produces a serious color

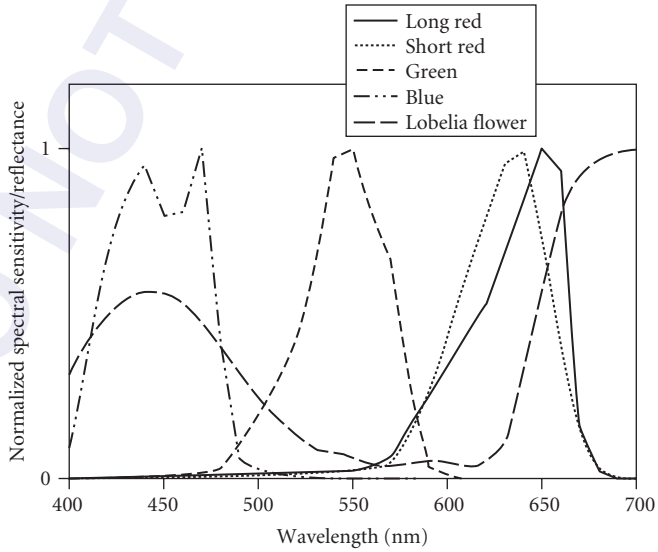

FIGURE 10 Spectral sensitivity for a real photographic film plus reflectance of the lobelia flower.

accuracy error (the flower photographs pink, not blue).[80] Among other such colors are certain green fabric dyes that image brown or gray. To correct for these hue errors, a special color reversal film was made whose general characteristic involves a short red spectral sensitivity.* This film does a considerably better job of eliminating the most serious hue errors, but unfortunately does not possess high color saturation. It is important in catalogue and other industries where accurate color reproduction is of paramount importance, but most consumers prefer saturated colors.

More recently, color negative films possessing short red spectral sensitivities combined with powerful development inhibitor anchimeric releasing (DIAR) color correction chemistry and masking coupler technology have produced films† simultaneously having high color saturation plus accurate color reproduction, at least toward anomalous reflection colors. In addition, these films render improved color accuracy under mixed daylight plus (red-rich) incandescent lighting conditions. These films maintain the high color saturation capability important to consumers but also provide more accurate color hues—although they are not perfect.

A new type of color negative film has been described[81] that possesses a fourth color record whose function approximates the large negative lobe in the theoretical red color-matching function of photographic dyes. Several embodiments have been described and are employed in modern films. The most practical utilizes a fourth color record containing silver halide emulsions sensitive to short green light plus a magenta DIR color correction coupler.‡

In simple terms, this special color record responds to short green light in the negative lobe region by releasing a development inhibitor that travels into the red-sensitive cyan color record, thereby reducing cyan dye in response to short green light, an effect opposite to that of normal red light exposure. This film's advantages reside in its ability to more accurately record colors in the blue-green spectral region, plus improved color accuracy under certain fluorescent lights that have a pronounced blue-green emission component.

Modern films are moving toward shorter-wavelength red spectral sensitivity. This allows improved color accuracy by shifting the red spectral sensitivity closer to that of the human eye. In addition, films have been designed to crudely approximate the principal negative lobe in the theoretical red color-matching function for photographic dye primaries, thereby producing a more accurate rendition of certain blue-green colors. Although not perfect, these techniques allow modern photographic films to record the world of color in all its richness and subtleties nearly as we ourselves see it.

30.6 GENERAL CHARACTERISTICS OF PHOTOGRAPHIC FILMS

Today there is available a large variety of films including different film speeds, types, and sizes. Many films are offered in both professional and consumer categories. This section describes some general characteristics of films as they relate to film speed and type. Some unique characteristics of professional films are contrasted to consumer films. Finally, color reversal, black-and-white, and color negative films are compared in more detail.

Low-Speed Films Compared to High-Speed Films

Higher granularity, higher sensitivity to ambient background radiation, and higher sensitivity to x rays are fundamental penalties that come with higher photographic speed. High-speed films often suffer additional penalties compared to their lower-speed counterparts, but these additional penalties

*Kodak Ektachrome 100 Film, EPN—a color reversal professional film.

†Kodak Gold 100, Kodak Gold 200, and Kodak Max 400 color negative films.

‡Fuji Reala 100 Film; Fuji Superia 200 and 400 film; Fuji Nexia 200 and 400 film; and Fuji 160 NPL, NPS, and NC professional films. These are all color negative films.

are not intrinsic. They represent conscious choices made by the manufacturer nearly always traceable to the desire to minimize granularity.

As one example, 400-speed color slide film generally has lower color saturation than its 100-speed counterpart. The reduced color saturation comes as a result of lower interlayer interimage effects (IIE) caused by higher iodide content in the mixed silver bromo-iodide crystals, which, in turn, is needed to achieve higher speeds from a smaller sized crystal and is ultimately done to reduce the photographic granularity penalty.

Photographic Speed and Photographic Granularity To understand the intrinsic connection between photographic speed and photographic granularity, recall that light quanta striking a flat surface follow Poisson statistics (Chap. 1 of Ref. 27). Therefore, a uniform light exposure given to a photographic film delivers photon hits Poisson-distributed across the plane of the film. Silver halide crystals are on the order of 1 μm^2 in projected area. On average in a film exposure (the product of the intensity of the radiation and the duration) appropriate for an EI100-speed film, the most sensitive silver halide crystals receive:*

E_q(red light; 650 nm)	~48 photons per square micrometer
E_q(green light; 550 nm)	~40 photons per square micrometer
E_q(blue light; 450 nm)	~33 photons per square micrometer

Because the most efficient practical photographic emulsions to date have a quantum sensitivity of about five photons per grain,[29] these approximate numbers suggest there is enough light (on average) striking a film during an EI100-speed film exposure to form latent image on efficient 1-μm^2 silver halide grains. But an EI800-speed exposure at three stops down begins to push the limits of modern emulsion efficiency at five green photons per square micron.

Silver halide crystals within the film are light collectors. Just as large-area mirrors in telescopes collect more photons and are more sensitive detectors of starlight than smaller mirrors, all other things being equal, larger silver halide crystals likewise collect more photons to become more sensitive light detectors.

Strong correlates exist between silver halide surface area and photographic speed. Photographic speed often linearly follows the average surface area of the silver halide crystal population (p. 969 of Ref. 2): speed $\sim \bar{a}$.

According to the well-known Siedentopf formula (p. 60 in Ref. 27), the root-mean-square photographic granularity at density D is given by $G \sim D\hat{a}$. In this formula, the symbol â represents the average cross-sectional area of the image particle projected onto the film plane. To a good approximation, this is proportional (not necessarily linear) to the mass of developed silver regardless of whether the image particle is a dye cloud or silver deposit.

These considerations demonstrate the intrinsic and well-known correlation between photographic speed and photographic granularity. For a given crystal morphology, as the size of the silver halide crystal increases, both surface area and mass increase, leading to a speed plus granularity increase.

At a fundamental level, to lower the granularity of a higher-speed photographic film the sensitivity to light of the silver halide crystals must improve. Then smaller silver halide crystals can be used to attain speed. Factors that contribute to this problem were discussed in Sec. 30.2.

In general, larger silver halide crystals suffer more inefficiencies in the latent-image-forming process because latent-image dispersity, electron-hole recombination, and other irreversible photon waste processes become more problematic as the grain size increases (p. 993 in Ref. 2). Overcoming these inefficiencies at all speeds, but especially at high photographic speeds, is a major challenge of modern photographic science.

Photographic Speed and Sensitivity to High-Energy Radiation High-energy subatomic particles induce developable latent image formation in photographic films. The process by which high-energy

*Analysis based on a typical EI100-speed color reversal film where the exposure falls near the photographically fastest, most sensitive part of the sensitometric curve. This analysis is described on p. 47 of Ref. 27.

charged particles produce latent image usually involves energy transfer to valence band electrons by inelastic scattering. Some of these scattered electrons are promoted into the silver halide conduction band and go on to produce latent image by the usual processes. Higher-speed films are more sensitive to this radiation because their larger silver halide crystals are hit (on average) more frequently and more collisions occur by passage through a larger crystal than through a smaller crystal.

Photographic films are slowly exposed by ambient background radiation (Chap. 23 in Ref. 3) caused by cosmic rays; ubiquitous stone and masonry building materials, which contain trace amounts of radioactive elements; and other low-level radiation sources. These radiation sources emit various types of charged and uncharged high-energy particles and photons including alpha particles, neutrons, γ rays, β particles, muons, and others. This results in a shorter ambient shelf life for very-high-speed films unless special storage precautions are taken.

Photographic emulsions are also sensitive to x rays. The formation of latent image silver by x rays (and γ rays) is due to the action of high-energy electrons emitted during the absorption or inelastic scattering of the electromagnetic radiation by matter (Chap. 23 in Ref. 3). These electrons may enter the conduction band of silver halide and proceed to latent image formation in the usual way. If the primary emitted electron is of sufficiently high energy, it may create secondary electrons of lower energy by inelastic scattering with other electrons. These secondary electrons enter the conduction band.

High-speed films have more sensitivity to x rays than do low-speed films. Some airline travelers ask airport security agents to hand-check their film rather than allowing it to pass through the baggage x-ray scanner. This precaution is prudent for higher-speed film because airport x-ray machines have become stronger emitters recently, especially at airports with special security concerns.

Despite the higher price, inherent penalties, and willful compromises that characterize high-speed films, they offer access to more picture space under low-light conditions. Among the advantages a high-speed film offers are the following:

1. Pictures under low light where flash is not permitted, such as theaters and museums.
2. Pictures under low light using slower lenses such as zoom and telephoto lenses.
3. Pictures under low light when the subject lies beyond the reach of flash.
4. Pictures under low light taken in rapid sequence without waiting for a flash to recharge.
5. Pictures under low light when flash disturbs the subject, as in some nature photography.
6. Pictures of people without flash. Flash is responsible for a major defect known as *redeye,* caused when light from a flash reflects off the retina of the eye.
7. Pictures using a stopped-down camera aperture for improved depth of field, so objects over a wider range of distance from the camera are imaged in focus.
8. Reduced dependence on flash for longer battery life.
9. Low-cost one-time-use cameras (OTUCs) when flash units are not needed.
10. Ability to freeze action using a rapid shutter speed.

For these and other reasons, a high-speed film may be the best choice for many film applications despite its shortcomings compared to lower-speed alternatives.

Professional Film Compared to Amateur Film

Most film manufacturers offer film in a professional category and an amateur (sometimes called *consumer*) category. These differ in many respects.

Consumer film is targeted for the needs of the amateur snap shooter. Drugstores, supermarkets, department stores, and other outlets frequented by nonprofessional photographers sell this film. Because most amateurs are price conscious, discount brands of film are available having some performance compromises that may not be important to some consumers.

To keep the price low, manufacturing tolerances for consumer film performance attributes are wider than those for professional film. In a well-manufactured film these departures from performance

aims are small enough to go unnoticed by most average consumers but large enough to be objectionable to highly discerning professionals.

People want pleasing color in their pictures that renders the main subject attractive to the eye. For most amateurs this means saturated colors enhanced to some extent beyond their true appearance in the original scene. However, this preference is highly selective since over-saturated skin tones are objectionable. Other *memory colors*—those that we recognize and know what they should be, such as green grass and blue sky—must also be rendered carefully to produce the most pleasing color appearance (Chap. 5 in Ref. 4). The best consumer films accommodate these color preferences.

Exposures on a roll of consumer film are sometimes stored for long times. It is not unusual for amateurs to take pictures spanning two successive Christmas seasons on the same roll of film. Thus, latent image stability under a wide range of temperature and humidity conditions is very important to a good consumer film. On the other hand professional photographers develop their film promptly, making this requirement far less demanding in a professional film.

Most amateurs are not skilled photographers. It is advantageous for consumer film to be easy to use and provide good-looking pictures under a wide variety of conditions. Consumer film incorporates more tolerance toward over- and underexposures.

Film for amateurs is offered in three standard formats. The most common format is the 35-mm cassette. Consumer cameras that accept this film have become compact, lightweight, and fully automatic. The camera senses the film speed through the DX coding on the film cassette and adjusts its shutter, aperture, and flash accordingly. Autofocus, autorewind, and automatic film advance are standard on these cameras, making the picture-taking experience essentially point and shoot.

The new Advanced Photo System (APS) takes ease of use several steps further by incorporating simple drop-in film loading and a choice of three popular print aspect ratios from panoramic to standard size prints. A magnetic coating on the film records digital data whose use and advantages are just beginning to emerge.

The third format is 110 film. Although not as popular as 35-mm and APS, it is often found in inexpensive cameras for gift packages. Film for this format comes in a cartridge for easy drop-in loading into the camera.

Professional photographers demand more performance from their film than do typical amateurs. These people shoot pictures for a living. Their competitive advantage lies in their ability to combine technical skill and detailed knowledge of their film medium with an artistic eye for light, composition, and the color of their subject.

Film consistency is very important to professionals, and they pay a premium for very tight manufacturing tolerances on color balance, tone scale, exposure reciprocity, and other properties. They buy their film from professional dealers, catalogues, and in some cases directly from the manufacturer. Professionals may buy the same emulsion number in large quantity, then pretest the film and store it in a freezer to lock in its performance qualities. Their detailed knowledge about how the film responds to subtleties of light, color, filtration, and other characteristics contributes to their competitive advantage.

Professional film use ranges from controlled studio lighting conditions to harsh and variable field conditions. This leads to a variety of professional films designed for particular needs. Some photographers image scenes under incandescent lighting conditions in certain studio applications, movie sets, and news events where the lights are balanced for television cameras. These photographers need a tungsten-balanced film designed for proper color rendition when the light is rich in red component, but deficient in blue compared to standard daylight.

Catalogue photographers demand films that image colors as they appear to the eye in the original scene. Their images are destined for catalogues and advertisement media that must display the true colors of the fabric. This differs from the wants of most amateurs, who prefer enhanced color saturation.

Some professional photographers use high color saturation for artistic effect and visual impact. These photographers choose film with oversaturated color qualities. They may supplement this film by using controlled light, makeup on models, lens gels, or other filtration techniques to control the color in the image.

Professional portrait photographers need film that gives highly pleasing skin tones. Their films typically image at moderate to low color saturation to soften facial skin blotches and marks that most people possess but don't want to see in their portraits. In addition, portrait film features highly

controlled upper and lower tone scale to capture the subtle texture and detail in dark suits and white wedding dresses and the sparkle in jewelry.

Professional photographers image scenes on a variety of film sizes ranging from standard 35-mm size to 120-size, and larger 4 × 5 to 8 × 10 sheet-film formats that require special cameras. Unlike cameras made for amateurs, most professional cameras are fully controllable and adjustable by the user. They include motor drives to advance the film rapidly to capture rapid sequence events. Professional photographers often take many pictures to ensure that the best shot has been captured.

Many specialty films are made for professional use. For example, some films are sensitized to record electromagnetic radiation in the infrared, which is invisible to the human eye. Note that these films are not thermal detectors. Infrared films are generally *false colored,* with the infrared-sensitized record producing red color in the final image, the red-light-sensitized record producing green color, and the green/blue-sensitized record producing blue color. Other professional films are designed primarily for lab use, such as duplicating film used to copy images from an original capture film.

Some film applications are important to a professional but are of no consequence to most amateurs. For example, professionals may knowingly underexpose their film and request *push processing,* whereby the film is held in the developing solution longer than normal. This brings up an underexposed image by rendering its midtone densities in the normal range, although some loss in shadow detail is inevitable. This is often done with color transparency film exposed under low-ambient-light conditions in the field. Professional films for this application are designed to provide invariant color balance not only under normal process times but also under a variety of longer (and shorter) processing times.

Multipop is another professional technique whereby film is exposed to successive flashes or *pops.* Sometimes the photographer moves the camera between pops for artistic effect. The best professional films are designed to record a latent image that remains nearly invariant toward this type of exposure.

Consumer film is made for amateur photographers and suits their needs well. Professional film comes in a wide variety of types to fit the varied needs of highly discerning professional photographers who demand the highest quality, specialized features, and tightest manufacturing tolerances—and are willing to pay a premium price for it.

Color Reversal Film

Color reversal films, sometimes called *color transparency* or *color slide* films, are sold in professional and amateur categories. This film is popular among amateurs in Europe and a few other parts of the world but has largely been replaced by color negative film among amateurs in North America. However, it is still very popular among advanced amateurs, who favor it for the artistic control this one-stage photographic system offers them, the ease of proofing and editing a large number of images, and the ability for large-audience presentations of their photographic work. Because the image is viewed by transmitted light, high amounts of image dye in these films can project intense colors on the screen in a dark auditorium for a very striking color impact.

Color reversal film is the medium of choice for most professional commercial photographers. It offers them the ability to quickly proof and select their most favored images from a large array of pictures viewed simultaneously on a light table. The colors are more intense compared to a reflection print, providing maximum color impact to the client. And professional digital scanners have been optimized for color reversal images, making it convenient to digitally manipulate color reversal images and transcribe them to the printed page. Today's professional imaging chain infrastructure has been built around color reversal film, although digital camera image capture is making inroads, especially for low-quality and low-cost applications.

Large-format color reversal film, from 120 size to large sheet formats, is often shot by professionals seeking the highest-quality images destined for the printed page. A larger image needs little or no magnification in final use and avoids the deterioration in sharpness and grain that comes from enlarging smaller images. Additionally, art directors and other clients find it easier to proof larger images for content and artistic appeal.

EI400-speed color reversal films generally possess low color saturation, low acutance, high grain, and high contrast compared to lower-speed color reversal films. The high contrast can lead to some loss in highlight and shadow detail in the final image. Except for very low-light situations, EI100 is

the most popular speed for a color reversal film. It offers the ultrahigh image quality professionals and advanced amateurs demand.

Modern professional color reversal films maintain good color balance under push processing conditions. They also perform very well under a variety of exposure conditions including multipop exposures and very long exposure times.

When professional photographers believe nonstandard push or pull process times are needed, they may request a "clip test" (sometimes also called a "snip test") whereby some images are cut from the roll of film and processed. Adjustments to the remainder of the roll are based on these preprocessed images. Some photographers anticipate a clip test by deliberately shooting sacrificial images at the beginning of a roll.

Professional color reversal films can be segregated into newer modern films and older *legacy films.* Modern films contain the most advanced technology and are popular choices among all photographers. Legacy films are popular among many professional photographers who have come to know these films' performance characteristics in detail after many years of experience using them.

Legacy films continue to enjoy significant sales because the huge body of personal technical and artistic knowledge about a film accumulated by a professional photographer over the years contributes to his or her competitive advantage. This inertia is a formidable barrier to change to a new, improved, but different film whose detailed characteristics must be learned.

In some cases, the improved features found in modern films are not important to a particular professional need. For example, a large 4 × 5 sheet film probably needs little or no enlargement, so the poorer grain and sharpness of a legacy film may be quite satisfactory for the intended application. The detailed knowledge the professional has about how the legacy film behaves in regard to light and color may outweigh the image structure benefits in a modern film. Also, all films possess a unique tone scale and color palette. A professional may favor some subtle and unique feature in the legacy film's attributes.

Kodachrome is a special class of color reversal legacy films. Unlike all other types of color reversal films, this film contains no dye-forming incorporated couplers. The dyes are imbibed into the film during processing so the film's layers are coated very thin. This results in outstanding image sharpness. Moreover, many photographers prefer Kodachrome's color palette for some applications.

Kodachrome dyes are noted for their image permanence. Images on Kodachrome film have retained their colors over many decades of storage, making this film attractive to amateurs and professionals alike who want to preserve their pictures. However, modern incorporated coupler color reversal films also have considerably improved dark storage image stability compared to their predecessors.

Table 1 lists some color reversal films available today. This is not a comprehensive list. Most film manufacturers improve films over time, and portfolios change frequently.

TABLE 1 Color Reversal Capture Films

Modern Films	Legacy Films	Kodachrome Films	Tungsten Films
Kodak Ektachrome 100VS (very saturated color)	Fuji Velvia 50 RVP (very saturated color)	Kodachrome 25 PKM	Kodak Ektachrome 64T EPY
Kodak Ektachrome E100S (standard color, good skin tones)	Kodak Ektachrome 64 EPR (standard color)	Kodachrome 64 PKR	Fujichrome 64T RTP
Fuji Astia 100 RAP (standard color, good skin tones)	Kodak Ektachrome 100 Plus EPP (standard color)	Kodachrome 200 PKL	Agfachrome 64T
Fuji Provia 100 RDPII (standard color)	Kodak Ektachrome 100 EPN (accurate color)		Kodak Ektachrome 160T EPT
Agfachrome 100 (standard color)	Kodak Ektachrome 200 EPD (lower color saturation)		Kodak Eltachrome 320T EPJ
Kodak Ektachrome E200 (can push 3 stops)	Agfachrome 200		
	Kodak Ektachrome 400 EPL		
	Fuji Provia 400		
	Agfachrome 400		

Unless a photographer has some particular reason for choosing a legacy color reversal film, the modern films are generally a better overall choice. More detailed information about these films' uses and characteristics can be found in the film manufacturers' Web pages on the Internet.

Black-and-White Film

Black-and-white (B&W) films and papers are sold through professional product supply chains. Color films and papers have largely displaced B&W for amateur use, with the exception of advanced amateurs who occasionally shoot it for artistic expression.

The image on a B&W film or print is composed of black metallic silver. This image has archival stability under proper storage conditions and is quite stable even under uncontrolled storage. Many remarkable and historically important B&W images exist that date from 50 to over 100 years ago. This is remarkable considering the primitive state of the technology and haphazard storage conditions.

Pioneer nature photographer Ansel Adams reprinted many of his stored negatives long after he stopped capturing images in the field. This artistic genius recreated new expressions in prints from scenes captured many years earlier in his career because his negatives were well preserved.

Ansel Adams worked with B&W film and paper. Many photographic artists work in B&W when color would distract from the artistic expression they wish to convey. For example, many portraits are imaged in B&W.

B&W films pleasingly image an extended range of tones from bright light to deep shadow. They are panchromatically sensitized to render colors into grayscale tones. A B&W film's tone scale is among its most important characteristics.

Photographers manipulate the contrast of a B&W image by push- or pull-processing the negative (varying the length of time in the developer solution) or by printing the negative onto a select contrast paper. Paper contrast grades are indexed from 1 through 5, with the higher index giving higher contrast to the print. Multigrade paper is also available whereby the contrast in the paper is changed by light filtration at the enlarger.

It is generally best to capture the most desired contrast on the negative because highlight or shadow information lost on the negative cannot be recovered at any later printing stage. Paper grades are designed for pleasing artistic effect, not for highlight or shadow recovery.

Legacy films are very important products in B&W photography. Although typically a bit grainier and less sharp than modern B&W films, their tone scale characteristics, process robustness, and overall image rendition have stood the test of time and are especially favored by many photographers. Besides, the B&W photographic market is small so improvements to this line of films occur far less frequently than do improvements to color films.

Unlike the case with color films, which are designed for a single process, a photographer may choose among several developers for B&W films. Kodak Professional T-Max developer is a good choice for the relatively modern Kodak T-Max B&W film line. Kodak developer D-76 is also very popular and will render an image with slightly less grain and slightly less speed. It is a popular choice for legacy films. Kodak Microdol-X developer is formulated to give very low grain at the expense of noticeable speed loss. Kodak developer HC110 is popular for home darkrooms because of its low cost and ease of use, but it renders a grainier image compared to other developers. Other manufacturers, notably Ilford Ltd., carry similar types of B&W developers.

A new type of B&W film has emerged that is developed in a standard color negative process. This incorporated-coupler 400-speed film forms a black-and-white image from chemical dyes instead of metallic silver. Among its advantages are very fine grain at normal exposures in the commonly available color negative process. Its shortcomings are the inability to control contrast on the negative by push or pull processing and its objectionable high grain when underexposed compared to a comparably underexposed 400-speed legacy film. And many photographers prefer the tone scale characteristics found in standard B&W films.

Table 2 lists some B&W films available today. This is not a comprehensive list. Modern films generally feature improved grain and sharpness compared to legacy films. However, the legacy films are favorite choices among many photographers because of their forgiving process insensitivity, the

TABLE 2 Black and White Films

Modern Films	Legacy Films	Specialty Films
Kodak T-Max 100 Professional (fine grain, high sharpness)	Ilford Pan F Plus 50	Kodak Technical Pan 25 (fine grain and very high sharpness)
Ilford Delta 100 Pro (fine grain, high sharpness)	Kodak Plus-X 125	Kodak IR (infrared sensitive)
Kodak T-Max 400 Professional (finer grain compared to legacy films)	Ilford FP4 Plus 125	Ilford SFX 200 (extended long red sensitivity but not IR)
Ilford Delta 400 Pro (finer grain compared to legacy films)	Kodak Tri-X 400	Ilford Chromogenic 400 (incorporated couplers, color negative process)
Fuji Neopan 400 (finer grain compared to legacy films)	Ilford HP5 Plus 400	Kodak Professional T400 CN (incorporated couplers, color negative process)
Kodak T-Max P3200 Professional (push process to high speed, high grain)		
Ilford Delta P3200 Pro (push process to high speed, high grain)		

experience factor of knowing their detailed behavior under many conditions, and the characteristic look of their images. More detailed information about these films' uses and characteristics can be found in the film manufacturers' Web pages on the Internet.

Color Negative Film

Today's color negative film market is highly segmented. It can be most broadly divided into consumer films and professional films. The consumer line is further segmented into 35-mm film, 110 format film (a minor segment whose image size is 17 × 13 mm), single-use cameras, and the new Advanced Photo System (APS). Each segment serves the needs of amateur photographers in different ways. The basic films are common across segments, with the main difference being camera type.

Consumer color negative film is a highly competitive market with many film and camera manufacturers offering products. In general, films for this marketplace offer bright color saturation that is most pleasing to amateurs. The higher-speed films show progressively more grain than do the lower-speed films. The highest-speed films are less often used when enlargement becomes significant, such as in APS and 110 format, but are prevalent in single-use cameras.

Consumer 35-mm Films Films in 35-mm format form the core of all consumer color negative products. These same basic films are also found in single-use cameras, 110 format cameras, and APS cameras. Film speeds include 100, 200, 400, and 800. All manufacturers offer films at 100, 200, and 400 speed, but only a few offer films at speeds of 800 and above.

The 400-speed film is most popular for indoor shots under low light and flash conditions. Lower-speed films are most often used outdoors when light is plentiful.

The best consumer films feature technology for optimized color rendition including the high color saturation pleasing to most consumers, plus accurate spectral sensitization for realistic color rendition under mixed lighting conditions of daylight plus fluorescent and incandescent light, which is often present inside homes. Technology used for accurate spectral sensitization was briefly described for Fujicolor Superia and Kodak Gold films in Sec. 30.5.

Kodak consumer films segment into Kodak Gold and Kodak Royal Gold films. Kodak Gold consumer films emphasize colorfulness, while Kodak Royal Gold films emphasize fine grain and high sharpness.

Films made in 110 format generally fall into the 100- to 200-speed range because the enlargement factors needed to make standard-size prints place a premium on fine grain and high sharpness.

Single-Use Cameras The single-use camera marketplace is extremely competitive because of the high popularity of this film and camera system among amateurs. These low-cost units can be bought at all consumer outlets and are especially popular at amusement parks, theme parks, zoos, and similar family attractions. After the film is exposed, the photographer returns the entire film plus camera unit for processing. Prints and negatives are returned to the customer while the camera body is returned to the manufacturer, repaired as needed, reloaded with film, and repackaged for sale again. These camera units are recycled numerous times from all over the world.

Single-use cameras come in a variety of styles including a waterproof underwater system, low-cost models with no flash, regular flash models, an APS style offering different picture sizes, and a panoramic style. Single-use cameras typically contain 800-speed film, except for APS and panoramic models, which usually contain 400-speed film due to enlargement demands for finer grain.

***Advanced Photo System* (*APS*)** APS is the newest entry into consumer picture taking. The size of the image on the negative is 29 × 17 mm, about 60 percent of the image size of standard 35-mm film (image size 36 × 24 mm). This puts a premium on fine grain and high sharpness for any film used in this system. Not all film manufacturers offer it. Speeds offered are 100, 200, and 400, with the higher speeds being the most popular.

Some manufacturers offer a B&W film in APS format. The film used is the incorporated-coupler 400-speed film that forms a black-and-white image from chemical dyes and is developed in a standard color negative process.

The APS camera system features simple drop-in cassette loading. Unlike the 35-mm cassette, the APS cassette contains no film leader to thread into the camera. When loaded, the camera advances the film out of the cassette and automatically spools it into the camera, making this operation mistake-proof. Three popular print sizes are available; panoramic, classic, and high-definition television (HDTV) formats. These print sizes differ in their width dimension.

A thin, nearly transparent magnetic layer is coated on the APS film's plastic support. Digital information recorded on this layer, including exposure format for proper print size plus exposure date and time, can be printed on the back of each print. Higher-end cameras offer prerecorded titles—for example, "Happy Birthday"—that can be selected from a menu and placed on the back of each print. Additional capabilities are beginning to emerge that take more advantage of this magnetic layer and the digital information it may contain.

The APS system offers easy mid-roll change on higher-end cameras. With this feature, the last exposed frame is magnetically indexed so the camera "remembers" its position on the film roll. A user may rewind an unfinished cassette to replace it with a different cassette (different film speed, for example). The original cassette may be reloaded into the camera at a later time. The camera will automatically advance the film to the next available unexposed frame.

Markings on the cassette indicate whether the roll is unexposed, partially exposed, fully exposed, or developed. There is no uncertainty about whether a cassette has been exposed or not. Unlike the 35-mm system, where the negatives are returned as cut film, the negatives in the APS system are rewound into the cassette and returned to the customer for compact storage. An index print is given to the customer with each processed roll so that each numbered frame in the cassette can be seen at a glance when reprints are needed.

Compact film scanners are available to digitize pictures directly from an APS cassette or 35-mm cut negatives. These digitized images can be uploaded into a computer for the full range of digital manipulations offered by modern photo software. Pictures can be sent over the Internet, or prints can be made on inkjet printers. For the best photo-quality prints, special photographic ink cartridge assemblies are available with most inkjet printers to print onto special high-gloss photographic-quality paper.

Table 3 summarizes in alphabetical order many brands of 35-mm consumer film available today worldwide. Some of these same basic films appear in single-use cameras, APS format, and 110 format, although not all manufacturers listed offer these formats. This is not a comprehensive list. Because this market is highly competitive, new films emerge quickly to replace existing films. It is not unusual for a manufacturer's entire line of consumer films to change within three years. More detailed information about these films' uses and characteristics can be found in the film manufacturers' Web pages on the Internet.

Konica Color Centuria	100	200	400	800	
Polaroid One Film	100	200	400		

Professional Color Negative Film Professional color negative film divides roughly into portrait and wedding film and commercial and photojournalism film. Portrait and wedding films feature excellent skin tones plus good neutral whites, blacks, and grays. These films also incorporate accurate spectral sensitization technology for color accuracy and excellent results under mixed lighting conditions. The contrast in these films is about 10 percent lower than in most consumer color negative films for softer, more pleasing skin tones, and its tone scale captures highlight and shadow detail very well.

The most popular professional format is 120 size, although 35-mm and sheet sizes are also available. Kodak offers natural color (NC) and vivid color (VC) versions of Professional Portra film, with the vivid color having a 10 percent contrast increase for colorfulness and a sharper look. The natural color version is most pleasing for pictures having large areas of skin tones, as in head and shoulder portraits.

Commercial films emphasize low grain and high sharpness. These films offer color and contrast similar to those of consumer films. Film speeds of 400 and above are especially popular for photojournalist applications, and the most popular format is 35 mm. These films are often push processed.

Table 4 summarizes in alphabetical order many brands of professional color negative film available today worldwide. This is not a comprehensive list. Because this market is highly competitive, new films emerge quickly to replace existing films. More detailed information about these films' uses and characteristics can be found in the film manufacturers' Web pages on the Internet.

Silver halide photographic products have enjoyed steady progress during the past century. This chapter has described most of the technology that led to modern films. Most noteworthy among these advances are

1. Efficient light management in multilayer photographic materials has reduced harmful optical effects that caused sharpness loss and has optimized beneficial optical effects that lead to efficient light absorption.
2. Proprietary design of silver halide crystal morphology, internally structured halide types, transition metal dopants to manage the electron-hole pair, and improved chemical surface treatments has optimized the efficiency of latent image formation.

TABLE 4 Professional Color Negative Films

Manufacturer and Brand Name (Commercial Film)					
Agfacolor Optima II Prestige	100	200	400		
Fujicolor Press			400	800	
Kodak Professional Ektapress	PJ100		PJ400	PJ800	
Konica Impresa	100	200			3200 SRG
Manufacturer and Brand Name (Portrait Film)					
Agfacolor Portrait		160 XPS			
Fujicolor		160 NPS	400 NPH	800 NHGII	
Kodak Professional Portra		160 NC	400 NC		Pro 1000
		160 VC	400 VC		
Konica Color Professional		160			

3. Transition metal dopants and development-modifying chemistry have improved process robustness, push processing, and exposure time latitude.
4. New spectral sensitizers combined with powerful chemical color correction methods have led to accurate and pleasing color reproduction.
5. New image dyes have provided rich color saturation and vastly improved image permanence.
6. New film and camera systems for consumers have made the picture-taking experience easier and more reliable than ever before.

Photographic manufacturers continue to invest research and product development resources in their silver halide photographic products. Although digital electronic imaging options continue to emerge, consumers and professionals can expect a constant stream of improved silver halide photographic products for many years to come.

31.1 GLOSSARY

B_s	phosphor screen brightness, photometric units
CCDs	charge-coupled devices
CIDs	charge-injection devices
E_i	image plane illuminance, lux
E_s	scene illuminance, lux
e	electronic charge, coulombs
FO	fiberoptic
FOV	field-of-view, degrees
fc	illuminance, photometric, foot candles = lm/ft^2
f_N	spatial Nyquist frequency, cycle/mm
f_{lto}	limiting resolution at fiberoptic taper output
F_{si}	input window signal flux
ftL	luminance, photometric (brightness), foot Lamberts = lm/ft^2
G_m	VMCP electron gain, e/e
HVPS	high-voltage power supply
II	image intensifier
LLL	low-light-level
lx	illuminance, photometric, lux = lm/m^2
M_{fot}	magnification of fiberoptic taper
MCP	microchannel plate
MTF	modulation transfer function, 0 to 1.0
N_{essa}	number of stored SSA electrons per input photoelectron, e/photon
N_f	total number of frames, #
N_p	number of photoelectrons, #

$N_{ps}(\lambda)$	number of photons per second, photon/s
PDAs	photodiode arrays
P	phosphor screen efficiency, photon/eV
$P_p(\lambda)$	radiometric power spectral distribution, W
QLI	quantum limited imaging
Q_{ssa}	stored SSA charge per input photoelectron from the photocathode, C
R_s	scene reflectance, ratio
R_{sn}	signal-to-noise ratio, ratio
$S(\lambda)$	absolute spectral sensitivity, mA/W
$S(f)$	squarewave response versus frequency, cycles/mm
SIT	silicon-intensifier-target vidicon
SNR	signal-to-noise ratio
sb	luminance, photometric (brightness), stilbs = cd/cm^2
SSA	silicon self-scanned array
T_f	filter transmission, 0 to 1.0
T_{fot}	transmission of fiberoptic taper, 0 to 1.0
T_n	lens T-number = $FN/\sqrt{\tau_0}$
T_{ssa}	transmission of fiberoptic window on the SSA, 0 to 1.0
V_a	phosphor screen, actual applied voltage, V
V_d	phosphor screen, "dead-voltage," V
V_m	VMCP applied potential, V
V_s	MCP-to-screen applied potential, V
$Y(\lambda)$	quantum yield (electrons/photon), percent
Y_k	quantum yield, photoelectrons/photon
Y_{ssa}	SSA quantum yield, e/photon
τ_e	the exposure period, s
τ_i	CCD charge integration period, s
τ_o	lens transmission, 0 to 1.0
Φ_p	photon flux density, photon/m^2/s

31.2 INTRODUCTION

It is appropriate to begin our discussion of image tube intensified (II) electronic imaging with a brief review of natural illumination levels. Figure 1 illustrates several features of natural illumination in the range from full sunlight to overcast night sky conditions. Various radiometric and photometric illuminance scales are shown in this figure. Present silicon self-scanned array (SSA) TV cameras, having frame rates of 1/30 to 1/25 s, operate down to about 0.5 lx minimum illumination.

The generic term *self-scanned array* is used here to denote any one of several types of silicon solid-state sensors available today which are designed for optical input. Among these are charge-coupled devices (CCDs), charge-injection devices (CIDs), and photodiode arrays (PDAs). Vol. II, Chaps. 32, "Visible Array Detectors," and 33, "Infrared Detector Arrays," contain detailed information on these types of optical imaging detectors. Specially designed low-light-level (LLL) TV cameras making use of some type of image intensifier must be used for lower exposures, i.e., lower illumination and/or shorter exposures.

The fundamental reason for using an II SSA camera instead of a conventional SSA camera is that low-exposure applications require the low-noise optical image amplification provided by an II

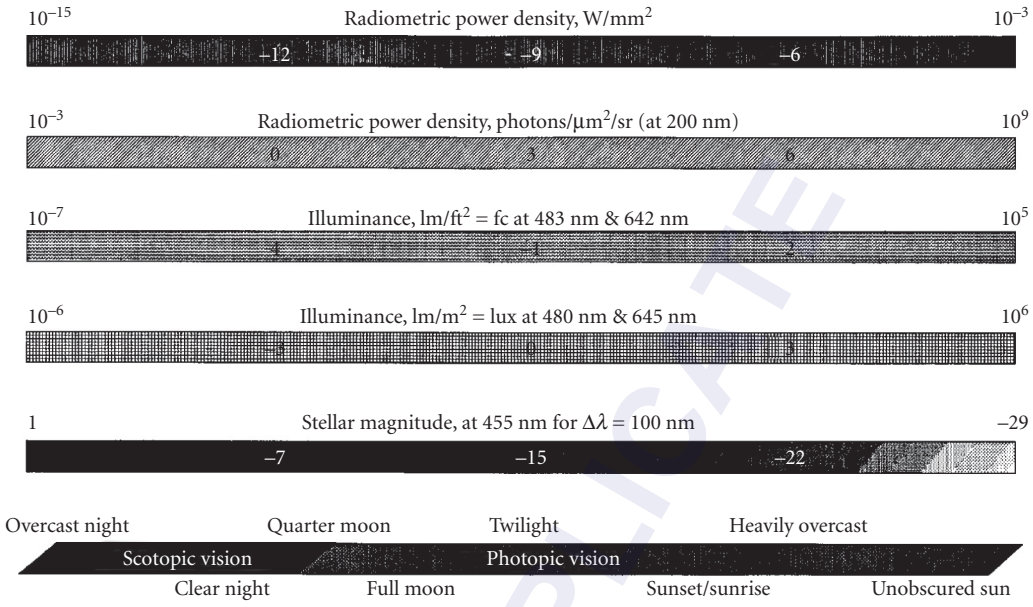

FIGURE 1 Various optical illumination ranges.

to produce a good signal-to-noise ratio from the SSA camera. Other important applications arise because of the ability to electronically shutter IIs as fast as 1 ns or less and the higher sensitivity of IIs in certain spectral regions. The following sections deal with the optical interface between the object and the II SSA, microchannel plate proximity-focused IIs, and II SSA detector assemblies. By using auto-iris lenses and controlling both the electronic gain and gating conditions of the II, II SSA cameras can provide an interscene dynamic range covering the full range of twelve orders of magnitude shown in Fig. 1. Several applications for II SSAs are discussed later in the chapter under "Applications."

31.3 THE OPTICAL INTERFACE

It is necessary to begin our analysis of II SSA cameras with a brief discussion of the various ways to quantify optical input and exposure. Two fundamental systems are used to specify input illumination: radiometric and photometric. These systems are briefly described, and the fundamentals of optical image transfer are discussed. Detailed aspects of radiometry, photometry, and optical image transfer are discussed in Vol. II, Chap. 34, "Radiometry and Photometry" and Vol. I, Chap. 4, "Transfer Function Techniques." However, enough information is presented in this chapter to allow the reader to properly design, analyze, and apply II SSA imaging technology for a wide variety of practical applications.

Quantum Limited Imaging Conditions

Quantum limited imaging (QLI) conditions exist in a wide variety of applications. An obvious one is that of LLL TV imaging at standard frame rates, i.e., 33-ms exposure periods, under nighttime illumination conditions. For example, under full moonlight input faceplate illumination conditions,

only ~1000 photons enter a $10 \times 10\ \mu m^2$ image pixel in a 33-ms frame period. Assuming a quantum yield of 10 percent, an average of only 100 electrons is generated, and the maximum SNR achievable in each pixel and each frame is only $\sqrt{100} = 10$. Alternatively, under full unobscured sunlight input faceplate illumination conditions, an electronically gated camera with gatewidth limited exposure period of 10 ns produces a total of (1E9 photons/ μm^2/s) (10 $\lambda \times 10\ \mu m^2$)(10 ns) = 1000 photons, or the same SNR as for the LLL operating conditions noted above. These are both clearly QLI operating conditions. II SSA camera technology is used to obtain useful performance in both of these types of applications. Without the use of an II, a bare SSA does not meet the requirements for useful SNR under these conditions.

Radiometry

The unit of light flux in the radiometric system is the watt. The watt can be used anywhere in the optical spectrum to give the number of photons per second (N_{ps}) as a function of wavelength (λ). Since the photon energy $E_p(\lambda)$ is

$$E_p = \frac{hc}{\lambda} \tag{1}$$

where h is Planck's constant and c is the velocity of light in vacuum, the radiometric power $P_p(\lambda)$, in watts, is given by

$$P_p(\lambda) = \left(\frac{hc}{\lambda}\right) \cdot N_{ps}(\lambda) \tag{2}$$

or

$$P_p(\lambda) = (2 \cdot 10^{-25}) \cdot \frac{N_{ps}(\lambda)}{\lambda} \tag{3}$$

where N_{ps} is the number of photons per second. Alternatively, the photon rate is given by

$$N_{ps}(\lambda) = (5 \times 10^{24}) \lambda P_p(\lambda) \quad \text{photons/s} \tag{4}$$

For example, one milliwatt of 633-nm radiation from an He-Ne laser is equivalent to (5E24)(633E − 9) (1E − 3) = 3.2E15 photons/s.

Radiometric flux density, in W/m^2, represents a photon rate per unit area, and radiometric exposure per unit area is the product of the flux density times the exposure period. The active surface of a photoelectronic detector produces a current density in response to an optical flux density input, while a total signal charge is produced per unit area in the same detector during a given exposure period.

Rose[1] has shown that all types of optical detectors, e.g., photographic, electronic, or the eye, are subject to the same fundamental limits in terms of signal-to-noise ratio (R_{sn}), optical input, and exposure period. In summary, the noise in a measured signal of N_p photoelectrons during a fixed exposure period is $\sqrt{N_p}$, so that

$$R_{sn} = \sqrt{N_p} \tag{5}$$

The brightness (B_s) of a scene that produces this signal in a square pixel of dimensions ($y \cdot y$), as a result of the optical transfer and conversion from the source to the detector, possibly through a medium that absorbs, scatters, and focuses photons, is

$$B_s = \frac{C \cdot N_p}{y^2} \tag{6}$$

where C is a constant. In terms of signal-to-noise ratio,

$$B_s = \frac{C \cdot R_{sn}^2}{y^2} \tag{7}$$

Thus, for twice the signal-to-noise ratio, the scene brightness must be increased four times, or the throughput of the optical system must be quadrupled, etc. Also, if the pixel size is reduced by a factor of two, the same changes in scene brightness or optical throughput must be made in order to maintain the same signal-to-noise ratio. Under QLI conditions, higher resolution necessarily requires more input flux density for equal signal-to-noise ratio, and higher resolution inherently implies less sensitivity. The Rose limit should be used often as a proof check on design and performance estimates of LLL and other QLI imaging systems.

As an example, assume a simple imaging situation such as a single pixel, e.g., a star in the nighttime sky, and an II SSA camera having an objective lens of diameter D_o. Also assume that the starlight is filtered, to observe only a narrow wavelength band, and that the photon flux density from the star is Φ_p (photon/m^2/s). The number of photoelectrons produced at the photocathode of the II SSA detector (N_p) is given by

$$N_p = \Phi_p \cdot T_f \cdot \left(\frac{\pi D_o^2}{4}\right) \cdot \tau_o \cdot Y_k \cdot \tau_c \tag{8}$$

where T_f is the filter transmission, τ_o is the lens transmission, Y_k is the quantum yield of the window/photocathode assembly in the II SSA camera, and τ_e is the exposure period. Note that the II SSA camera parameters which determine the rate of production of signal photoelectrons are filter transmission, lens diameter, quantum yield, and exposure period. The key one is of course the lens diameter, and not lens f-number, for this kind of imaging; it is important, however, for extended sources such as terrestrial scenes.

Photometry and the Camera Lens

A lens on the II SSA camera is used to image a scene onto the input window/photocathode assembly of the II SSA. The relationship between the scene (E_s) and II SSA image plane (E_i) illuminances in lux (lx) is

$$E_i = \frac{\pi \cdot E_s \cdot R_s \cdot \tau_o}{(4 \cdot \mathrm{FN}^2 \cdot (m+1)^2)} \tag{9}$$

where R_s is the scene reflectance, τ_o is the optical transmission of the lens, FN is the lens f-number, and m is the scene-to-image magnification. If E_s is in foot-lamberts, then the π is dropped and E_i is in footcandles.

Alternatively, Eq. (9) becomes

$$E_i = \frac{E_s \cdot R_s}{(4 \cdot T_n^2 \cdot (m+1)^2)} \tag{10}$$

using the T-number of the lens, where

$$T_n = \frac{FN}{\sqrt{\tau_o}} \tag{11}$$

The sensitivity of an II is usually given in two forms, i.e., "white-light" luminous sensitivity, in units of μA/lm, and absolute spectral sensitivity, in units of A/W as a function of wavelength, as discussed later in the section "Input Window/Photocathode Assemblies" in Sec. 31.4.

Example: A scene having an average reflectance of 50 percent receives LLL "full-moon" illumination of 1.0E − 2 fc. If a lens having a T-number of 3.0 is used, and the scene is at a distance of 100 m

from a lens with a focal length of 30 mm, what is the input illumination at the II SSA? Since the distance to the scene is much longer than the focal length of the lens, the magnification is much smaller than unity and m can be neglected. Thus,

$$E_i = \frac{E_s R_s}{(4 \cdot T_n^2)} \tag{12}$$

For the given values, the input illumination at the II SSA is bound to be E_i = (1.0E − 2 fc) $(0.50)/(4(3.0)^2)$ = 1.4E − 4 fc.

General Considerations

It is of prime importance in any optoelectronic system to couple the maximum amount of signal input light into the primary detector surface, e.g., the window/photocathode assembly of an II SSA. In order to achieve the maximum signal-to-noise ratio, the modulation transfer function of the input optic and the spectral sensitivity of the II SSA must be carefully chosen. As shown in Fig. 2, the spectral sensitivity of a silicon SSA is much different than that of a Gen-3 image intensifier tube.

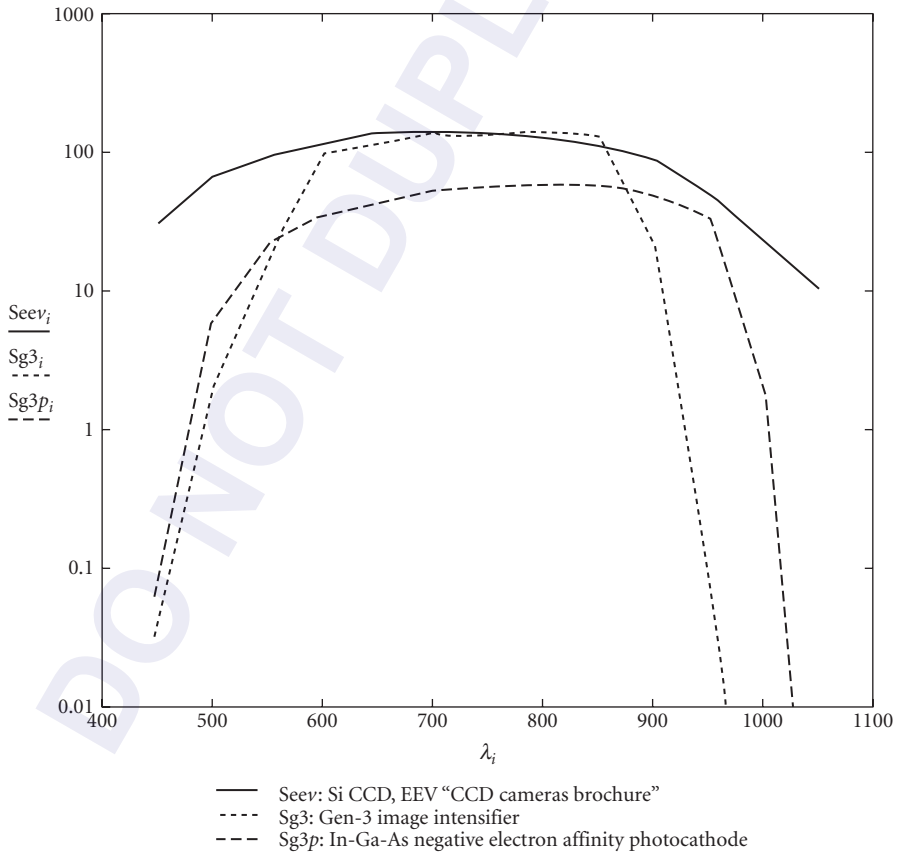

FIGURE 2 Absolute spectral sensitivity S (mA/W) versus wavelength λ (nm) of a frame-transfer type of CCD, a gen-III image intensifier, and an II having an In-Ga-As negative electron affinity photocathode.

Thus, an optimized objective lens design for a CCD will be much different than that for an II SSA. The dynamic range characteristics are also very different, since IIs will handle seven orders-of-magnitude interscene dynamic range, using a combination of II gain control and electronic duty-cycle gating, while SSAs will only provide about two orders of magnitude.[2]

Several factors must be considered if the overall system resolution and sensitivity are to be optimized. For example, the spectral responses of many optical input SSAs and/or lenses used in commercial cameras have been modified by using filters to reduce the red and near-ir responses to give more natural flesh tones. In an II SSA the filter may have little effect if the filter is on the SSA. The filter should not be used in the objective lens for the II SSA since a major portion of the signal will be filtered out. If a color SSA is to be used in an intensified system using relay lens coupling, sacrifice of both sensitivity and resolution will result. This is due to the matrix color filter used in these SSA chip designs. Most of the signal will go into green bandpass filter elements, and very little will go into the blue and red elements. The color matrix filter is usually bonded to the surface of the SSA chip; thus these SSA types are not used for fiberoptically coupled II SSAs.

The ideal objective lens design for an II SSA needs to be optically corrected over the spectral range of sensitivity of the II and the spectral range of interest. For special-purpose photosensitivity covering portions of the uv, blue, or near-ir spectral regions, appropriate adjustments must be made in the lens design. Although they may be adequate for many applications, it is very seldom that a commercial CCTV lens is optimized for nighttime illumination, or other LLL or QLI conditions.

Another very important part of an optimized II SSA camera design is to make the proper choice of II and SSA formats. This subject is discussed in detail later under "Fiberoptic-Coupled II/SSAs," under Sec. 31.5. The input of the II SSA system is the II, and the most likely choice will be one with an 18-mm active diameter, since the widest choice of II features is available in this size. Image intensifiers are also available having 25- and 12-mm active diameters, but these are generally more expensive. Regarding the SSA standard format sizes, the standard commercial TV formats are named by a longtime carryover from the days when vidicons were used extensively. Thus 2/3-, 1/2-, and 1/3-in format sizes originally referred to the diameters of the vidicon envelope and not the actual image format.

31.4 IMAGE INTENSIFIERS

An image intensifier (II) module, when properly coupled to an SSA camera, produces a low-light-level electronic imaging capability that is extremely useful across a broad range of application areas, including spectral analysis, medical imaging, military cameras, nighttime surveillance, high-speed optical framing cameras, and astronomy. An immediate advantage of using an II is that its absolute spectral sensitivity can be chosen from a wide variety of window/photocathode combinations to yield higher sensitivity than that of a silicon SSA. Since recently developed IIs are very small, owing to the use of microchannel plate (MCP) electron multipliers, the small size of a solid-state SSA camera is not severely compromised. In summary, advantages of using MCP IIs are

- Long life
- Low power consumption
- Small size and mass
- Rugged
- Very low image distortion
- Linear operation
- Wide dynamic range
- High-speed electronic gating, e.g., a few nanoseconds or less

An image intensifier can be thought of as an active optical element which transforms an optical image from one intensity level to another, amplifying the entire image at one time, i.e., all pixels are

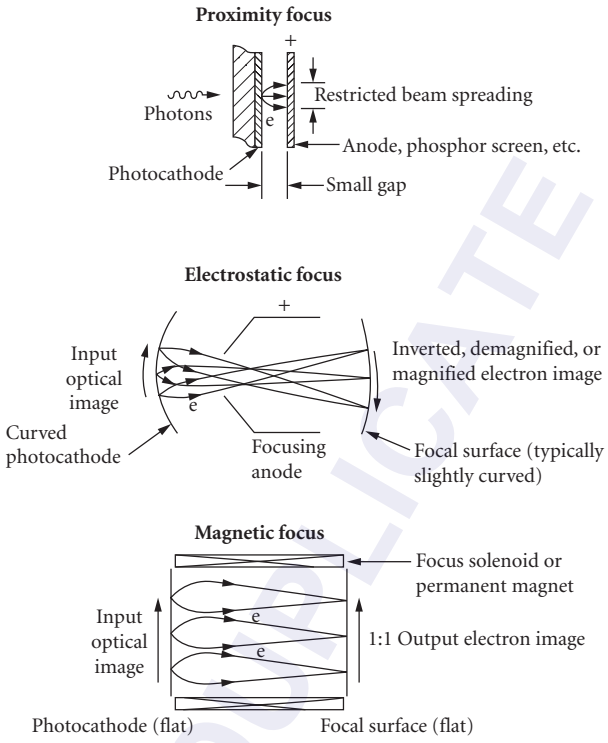

FIGURE 3 Electron lenses.

amplified in parallel and relatively independent of each other. In most cases, the resultant output image is more intense than that of the input image. The level of image amplification depends on the composite efficiency of all the conversion steps of the process involved in the image intensification operation and the basic definition of amplification. The term *image intensifier* is generally used to refer to a device that transforms visible and near-visible light into brighter visible images. Devices which convert nonvisible radiation, e.g., uv or ir, into visible images are generally referred to as *image converters*. For simplicity we refer to both types of image amplifiers/converters as "IIs" in this chapter.

Three general families of IIs exist, shown schematically in Fig. 3, that are based upon the three kinds of electron lenses used to extract the signal electrons from the photocathode, namely,

- Proximity focus IIs
- Electrostatic focus IIs
- Magnetic focus IIs

The first image tubes used a "proximity-focus" electron lens.[3] Having inherently low gain and resolution, the proximity-focus lens was dropped in favor of electrostatic focus and magnetic focus IIs. The so-called Generation-0 and Generation-1 image tubes made for the U.S. Army used electrostatically focused IIs. The input end of the silicon-intensifier-target (SIT) vidicon also made use of electrostatic focusing. Magnetic focusing was used extensively in the old TV camera tubes, e.g., image orthicons, image isocons, and vidicons, and also for large-active-area and high-resolution IIs for specialized military and scientific markets.

With the development of the MCP, which was achieved for the U.S. Army's Generation-2 types of night-vision devices, it became practical to use a proximity-focused electron lens again to meet the

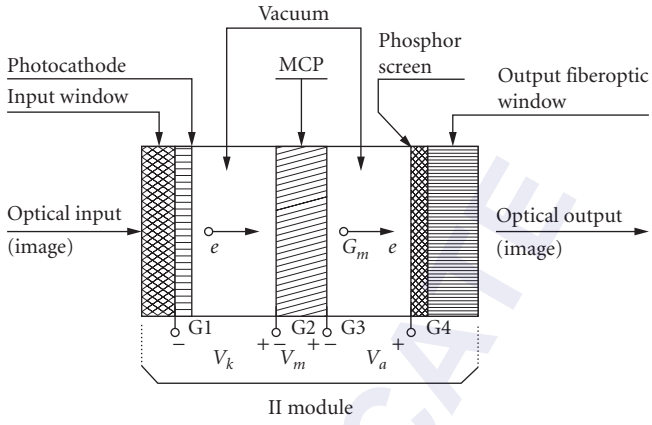

FIGURE 4 Schematic design of a proximity-focused MCP image intensifier tube module.

needs for extremely small and low-mass IIs. These "Gen-2" tubes are being used extensively for military night-vision applications, e.g., night-vision goggles for helicopter pilots, individual soldier helmet mounted night-vision goggles, etc. The most recently developed "Gen-3" IIs have higher sensitivity and limiting resolution characteristics than Gen-2 IIs, and they are used in similar night-vision systems.

Both the Gen-2 and Gen-3 types of IIs are available for use as low-noise, low-light-level amplifiers in II SSA cameras. In addition, by choosing special input window/photocathode combinations outside the military needs for Gen-2 and Gen-3 devices, a very wide range of II SSA spectral sensitivities can be achieved, well beyond silicon's range. For II SSA camera applications, we will focus our attention exclusively on the use of proximity-focused MCP IIs because of their relative advantages over other types of IIs.

The basic components of a proximity-focused MCP II are shown schematically in Fig. 4. This type of II contains an input window, a photocathode, a microchannel plate, a phosphor screen, and an output window. The *photocathode* on the vacuum side of the *input window* converts the input optical image into an electronic image at the vacuum surface of the photocathode in the II. The *microchannel plate* (MCP) is used to amplify the electron image pixel-by-pixel. The amplified electron image at the output surface of the MCP is reconverted to a visible image using the *phosphor screen* on the vacuum side of the *output window.* This complete process results in an output image which can be as much as 20,000 to 50,000 times brighter than what the unaided eye can perceive. The input window can be either plain transparent glass, e.g., Corning type 7056, fiberoptic, sapphire, fused-silica, or virtually any optical window material that is compatible with the high-vacuum requirements of the II. The output window can be glass, but it is usually fiberoptic, with the fibers going straight through or twisted 180° for image inversion in a short distance.

A block diagram of a generalized high-voltage power supply (HVPS) used to operate the II is given in Fig. 5. For dc operation, the basic HVPS provides the following typical voltages:

$V_k = 200$ V
$V_m = 800$ V for an MCP
($V_m = 1600$ V for a VMCP)
($V_m = 2400$ V for a ZMCP)
$V_a = 6000$ V

For high-speed electronic gating of the II, the photocathode is normally gated off by holding the G1 electrode a few volts positive with respect to the G2 electrode. Then, to gate the tube on and off

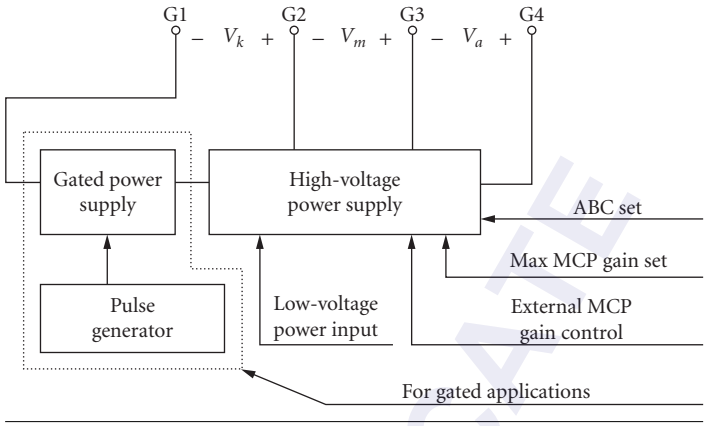

FIGURE 5 MCP image intensifier high-voltage supply.

for a short period, a pulse generator is used to control the output of the gated power supply to the normal gated on condition, i.e., $V_k = 200$ V with the polarity as shown in Fig. 5.

The dc HVPSs for IIs draw very little power, and they can be operated continuously using two AA cells, e.g., 3-V input voltage, for about 2 days. These dc HVPSs are available in small flat-packs or wraparound versions. Gated HVPSs, excluding the pulse generator, are generally at least two times larger than their dc counterparts.

In operation, an input image is focused onto the input window/photocathode assembly, producing a free-electron image pattern which is accelerated across the cathode-to-MCP gap by an applied bias voltage V_k. Electrons arriving at the MCP are swept into the channels, causing secondary electron emission gain due to the potential V_m applied across the MCP input and output electrodes. Finally, the amplified electron image emerging from the output end of the MCP is accelerated by the voltage V_a applied across the MCP-to-phosphor screen gap so that they strike an aluminized phosphor screen on a glass or FO output window with an energy of about 6 keV. This energy is sufficient to produce an output image which is many times brighter than the input image. The brightness gain of the MCP II is proportional to the product of the window/photocathode sensitivity to the input light, the gain of the MCP, and the conversion efficiency of the phosphor-screen/output-window assembly. Each of these key components and/or assemblies is discussed in more detail in the following sections of this section.

Input Window/Photocathode Assemblies

The optical spectral range of sensitivity of an II, or the II SSA that it is used in, is determined by the combination of the optical transmission properties of the window and the spectral sensitivity of the photocathode. In practice, a photocathode is formed on the input window in a high-vacuum system to produce the window/photocathode assembly as shown in Fig. 6. This assembly is then vacuum-sealed onto the II body assembly, and the finished II is then removed from the vacuum system. This type of photocathode processing is called *remote processing* (RP), because the alkali metal generators, antimony sources, and/or other materials used to form the photocathode are located outside of the vacuum II tube. Since there is no room for these photocathode material generators, remote processing must be used for MCP IIs. Also, IIs made using remote processing are found to have significantly less spurious dark current emission than the older Gen-0 and Gen-1 types of IIs having internally processed photocathodes.

The short wavelength cutoff of a window/photocathode assembly is determined by the optical transmission characteristic of the window, i.e., its thickness and material composition. The absolute

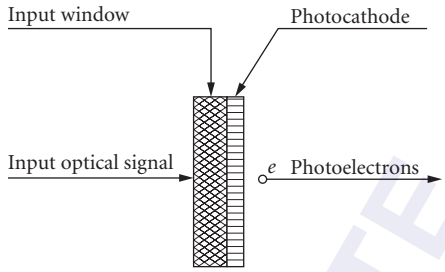

FIGURE 6 Input window/photocathode assembly.

spectral sensitivity of the photocathode determines the midrange and long wavelength cutoff characteristics of the assembly. Photocathode materials having longer wavelength cutoffs also have lower bandgap energies and generally higher thermionic emission than photocathodes with shorter wavelength cutoffs.

The spectral quantum efficiencies of various window/photocathode combinations are shown in Fig. 7 for comparison. Useful spectral bands range from the uv to the near-ir, depending upon the particular combination chosen. This figure shows the spectral sensitivity advantages that can be achieved with II SSAs. Other advantages are discussed throughout this chapter.

Note that the window/photocathode spectral quantum efficiency $[Y(\lambda)]$ curves given in Fig. 7 represent the ratio of the average number of photoelectrons produced per input photon as a function of wavelength λ. Alternatively, window/photocathode response can be specified in terms of

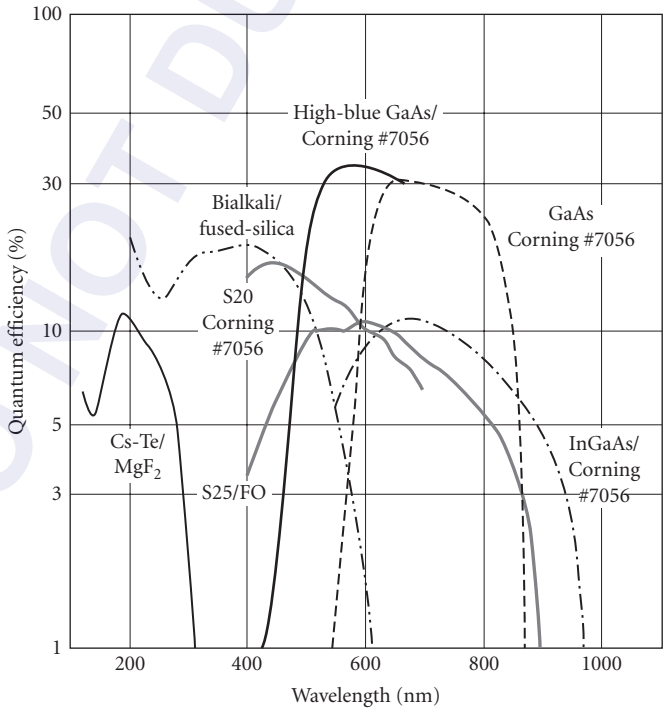

FIGURE 7 Window/cathode spectral quantum efficiencies.

absolute spectral sensitivity [$S(\lambda)$], or defined as the ratio of photocathode current per watt incident as a function of wavelength. These two parameters are related by the convenient equation

$$Y(\lambda) = \frac{124 \cdot S(\lambda)}{\lambda} \tag{13}$$

where Y is the quantum yield in percent, S is the absolute sensitivity in mA/W, and λ is the wavelength in nm.

Microchannel Plates

The development of the microchannel plate (MCP) was a revolutionary step in the art of making IIs. Although developed for and used in modern military passive night-vision systems, MCP IIs are being used today in nearly all II SSA cameras.

An MCP is shown schematically in Fig. 8. Microchannel plates are close-packed-hexagonal arrays of channel electron multipliers. With a voltage V_m applied across its input and output electrodes, the MCP produces a low-noise gain G_m, e.g., a small electron current (I_{in}) from a photocathode produces an output current $G_m I_{in}$. In addition to its function as a low-noise current amplifier, the MCP retains the current density pattern or "electron image" from its input to output electrodes. It is also possible to operate two MCPs (VCMP) or three MCPs (ZMCP) in face-to-face contact to achieve electron gains as high as about 1E7 e/e in an II tube, as shown in Fig. 9. Other general characteristics of these types of MCP assemblies are also given in Fig. 9.

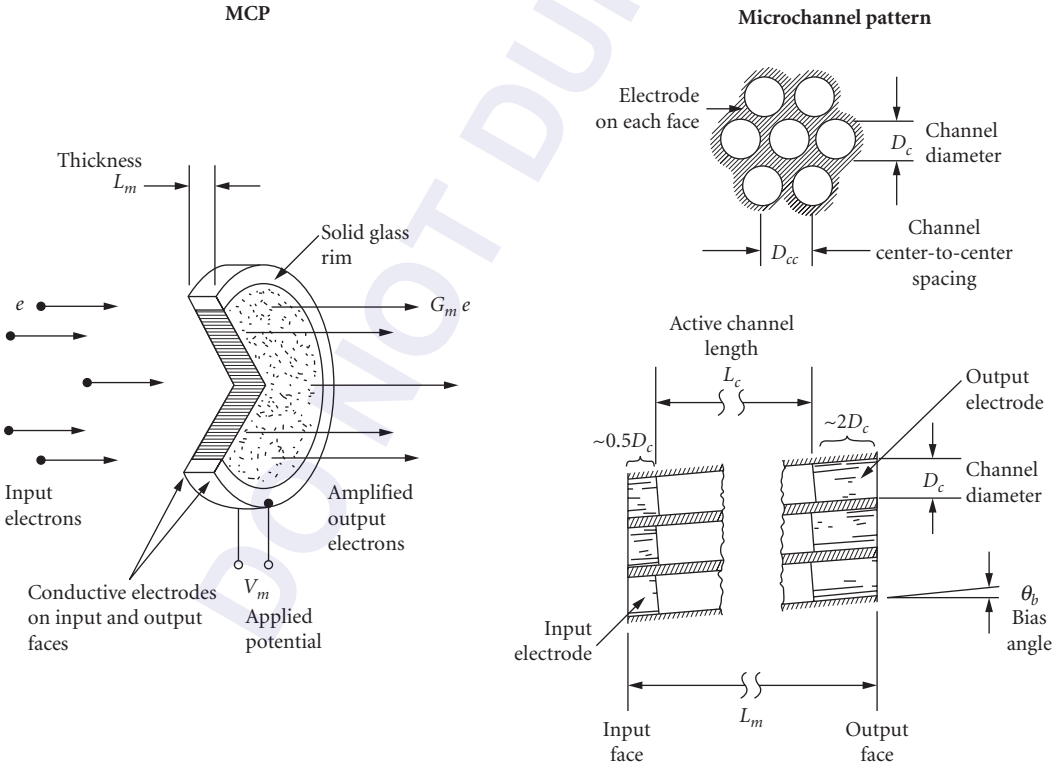

FIGURE 8 MCP parameters.

MCP:	V_m max (kV)	G_m max (e/e)	Pulse height distribution (% FWHM)	Relative limiting resolution (units)
	1.0	1E3	Negative exponential	1.00
VMCP:				
	2.0	1E5	120	0.71
ZMCP:				
	3.0	1E7	80	0.50

FIGURE 9 General characteristics of MCPs, VMCPs, and ZMCPs.

The approximate limiting spatial resolutions of MCPs depend upon the channel center-to-center spacings, as follows:

Channel Diameter (μm)	Channel Center-to-Center Spacing (μm)	Approximate Limiting Resolution (lp/mm)
4	6	83
6	8	63
8	10	50
10	12	42
12	15	33

As shown in Fig. 8, MCPs are made to have channel axes that make a "bias angle" (θ_b) with respect to the normal to its input and output faces. This bias angle improves electron gain and reduces noise factor by reducing "boresighting" of electrons into the channels. The MCP bias current or "strip current" (I_s) that results from the voltage applied to the MCP sets an upper limit to the maximum linear dynamic range of the MCP. Generally, when the output current density of the MCP is in excess of about 10 percent of the strip current density, the MCP ceases to remain a linear amplifier. Conventional MCPs have strip current densities of about 1 μA/cm^2, and recent high-output-technology MCPs (HOT MCPs)[4] have become available that have strip current densities as high as about 40 μA/cm^2. Electron-gain characteristics of MCP assemblies are given approximately by the equation and associated parameters shown in Table 1.

TABLE 1 MCP Gain Equation and Gain Parameters

$$G_m(V_m) = \left(\frac{V_m}{V_c}\right)^g$$

Type	V_c(V)	g (units)	(L_m/D_c) (units)
MCP	350	8.5	40
MCP	530	13	60
VMCP	700	17	80
ZMCP	1050	25	120

Power noise factors for conventional MCPs, used in Gen-2 IIs, and "filmed-MCPs," used in Gen-3 IIs, are approximately 2.0 and 3.5, respectively. Detailed information on MCP gain, noise factors, and other parameters are given by Eberhardt.[5] Note that MCP gain is a strong function of the channel length-to-diameter ratio. The parameter V_c in the gain equation is the "crossover" voltage for the channel, i.e., it is the MCP applied voltage at which the gain is exactly unity.

Phosphor Screens

Output spectral and temporal characteristics of a wide variety of screens are given in an Electronic Industries Association publication.[6] The phosphor materials covered in this publication are listed in Table 2. Both the old "P-type" and the new two-letter phosphor designations are given in this table. Any of these phosphor screen materials can be used in proximity-focused MCP IIs. However, one very commonly used phosphor is the type KA (P20) because it has a high conversion efficiency, its output spectral distribution matches the sensitivity of a silicon SSA reasonably well, it is fast enough for conventional 1/30-s frame times, it has high resolution, and it is typically used in direct-view night-vision IIs.

The three main components of an aluminized phosphor-screen/output-window assembly, of the type used in a proximity focused MCP II, are shown schematically in Fig. 10. An aluminum film electrode is deposited on the electron input side of the phosphor to accelerate the MCP output to high energy, e.g., about 6 keV, and to increase the conversion efficiency of the assembly by reflecting light toward the output window. The phosphor itself is deposited on the glass or fiberoptic output window.

Decay times, or persistence, and relative output spectral distributions for a variety of phosphor types are given in Fig. 11. Key phosphor assembly parameters that should be accounted for in the design of MCP II SSAs are MCP-to-phosphor applied potential (V_a), effective "dead-voltage" resulting from electron transmission losses in the aluminum film, phosphor screen energy input-to-output conversion efficiency, optical transmission of the glass or fiberoptic window, sine-wave MTF of the assembly, phosphor persistence, and output spectral distribution.

Before specifying the use of a particular phosphor, the operational requirements of the II SSA camera should be reviewed. The phosphor persistence should be short compared to the SSA frame

time to minimize image smear due to rapidly moving objects. Also, the absolute conversion efficiency of the phosphor assembly and its relative output spectral distribution should be spectrally matched[7] to the sensitivity of the SSA for maximum coupling efficiency.

Typical absolute spectral response characteristics, i.e., the phosphor spectral efficiency (radiated watts per nanometer per watt excitation) as a function of wavelength, of aluminized phosphor screens are given in Ref. 7. The associated phosphor screen efficiencies are also given in this reference in three different ways:

- Typical quantum yield factor: photons out per eV input
- Typical absolute efficiency: radiated watts per watt excitation
- Typical luminous equivalent: radiated lumens per radiated watt

For example, a type KA(P20) aluminized phosphor-screen/glass window assembly is found to have its peak output at 560 nm and a typical quantum yield factor of 0.063 photons/eV. Thus, an electron which leaves the MCP and strikes the assembly with 6 keV of energy, and for a "dead-voltage" of 3 kV, approximately (6 − 3) keV × 0.063 photons/eV = 190 photons will be produced at the output.

Proximity-Focused MCP IIs

By combining the image transfer and conversion properties of the three major proximity-focused MCP II assemblies discussed earlier, i.e.,

- Input window/photocathode
- Microchannel plate
- Phosphor screen/output window

the operational characteristics of the II itself, as shown in Fig. 4, can be determined.

For example, consider an II CCD application for a space-based astronomical telescope that requires more than 10 percent quantum yield at 200 nm, but minimum sensitivity beyond 300 nm. It is desired that the top end of the dynamic range be at an input window signal flux (F_{si}) of 1000 photon/pixel/s at 250 nm. Let the CCD have a 1-in vidicon format, i.e., an active area of 11.9×8.9 mm^2, with 325 vertical columns and 244 horizontal rows of pixels. The limiting resolution of even a dual-MCP (VMCP) image tube has a limiting resolution that is significantly higher than the horizontal pixel spatial Nyquist frequency (f_N) in the CCD, so that the pixel size at the input to the II will be essentially the same as that of the CCD. Let us rough-in an II design by making the following additional assumptions:

MCP-to-phosphor applied potential (V_a)	6000 V
Phosphor screen type	KA (P20)
Phosphor screen/window-quantum yield (P_q)	0.06 photon/eV
Phosphor screen dead voltage (V_d)	3000 V
CCD charge integration period (τ_i)	33 ms
CCD pixel full-well charge	1 pC = 6.3*E*6 e

An II with an 18-mm active diameter can be used, since the diagonal of the CCD active area is 14.9 mm. From Fig. 7, the MgF_2/Cs-Te window/photocathode assembly will be chosen, having a quantum yield (Y_k) of 0.12 at 200 nm, to meet the spectral sensitivity requirements.

Let's now proceed to estimate the required gain of the MCP structure, decide what kind of an MCP structure to use, and determine its operating point. A first-order estimate of the stored pixel charge (Q_{ccd}) for the given input signal flux density is

$$Q_{ccd} = F_{si} \cdot Y_k \cdot G_m \cdot (V_a - V_d) \cdot P_q \cdot Y_{ccd} \cdot \tau_i \tag{14}$$

Since

$$F_{si} = 1000 \text{ photon/pixel/s}$$
$$Y_k = 0.10 \text{ e/photon}$$
$$Y_{ccd} = 0.3 \text{ e/photon}$$

it is found that $Q_{ccd} = G_m$ (178 e/pixel). Setting this charge equal to the full-well pixel charge gives G_m = 6.3E6 e/pixel/(178 e/pixel) = 3.5E4 e/e. This MCP assembly gain is easily satisfied by using a VMCP. From Table 1, it is found that the gain of a VMCP is given approximately by $G_m = (V_m/700)^{17}$ = 3.5E4 e/e. Solving for V_m gives V_m = 1300 V.

Thus, a first-order estimate for the general requirements to be placed in the II to do the job is as follows:

Active diameter	18 mm
Quality area	(11.9 × 8.9 mm)
Input window/photocathode	Fused-Silica/Cs-Te
MCP assembly	VMCP
Aluminized phosphor screen assembly	KA/FO window

Coupling this II to the specified FO input window CCD, e.g., by using a suitable optical cement, will meet the specified objective. Other parameters like the dark count rate per pixel as a function of temperature, the DQE of the II CCD, cosmetic, uniformity of sensitivity, and other specifications will have to be considered as well before completing the design.

Recent "Generations" of MCP IIs The most impressive improvement in direct-view night-vision devices has come with the advent of Gen-3 technology. The improvement, which is most apparent at very low light levels, is mainly due to the use of GaAs as the photocathode material. At higher light levels, e.g., half-moon to full-moon conditions, the Gen-2+ gives somewhat better performance. Key to the detection of objects under LLL conditions is the efficiency of the photocathode; the Gen-3 sensitivity is typically a factor of 3 higher. Also, the spectral response of Gen-3 matches better to the night sky spectral illumination. This equates to being able to see at almost one decade lower scene illumination with Gen-3. A summary of proximity-focused MCP image intensifier general characteristics is given in Table 3.

TABLE 3 Summary of Proximity-Focused MCP Image Intensifier General Characteristics

Minimum Active Diameter (mm)	Input Window Material*	Spectral Sensitivity Range (nm)	MCP Assembly Type	Temperature Rating		Output Window Material	Minimum Limiting Resolution (lp/mm)	Technology Type
				Storage (°C)	Operating (°C)			
11.3	FS	160–850	MCP	−55, +65	−20, +40	FO	25	Gen-2

Gen-3	GaAs, InGaAs	Wide selection

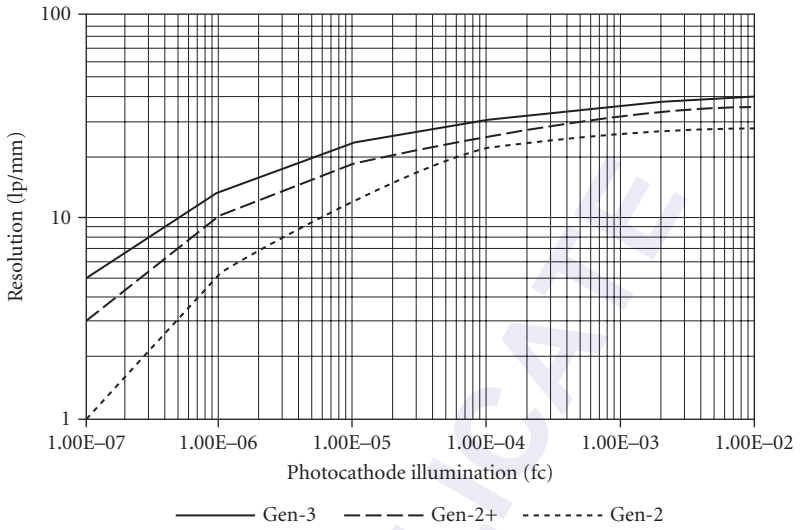

FIGURE 12 Image intensifier tube resolution curves.

For systems design work, it is useful to know the approximate characteristics of the three most recent generations in terms of II resolution versus photocathode illumination. The resolution transfer curves shown in Fig. 12 give the II resolution, observable by the eye, as a function of input illumination for Gen-2, Gen-2+, and Gen-3 IIs. These curves do not include system optics degradations, except in the sense that a human observer made the resolution measurements using a 10-power eyepiece in viewing the output image of the II.

Improved Performance Gen-2 IIs Recent enhancements in the dynamic range performance of Gen-2 IIs for direct-view applications have been made which also benefit II SSA camera performance. Improvement goals were to increase both the usable output brightness and the LLL gain of Gen-2 IIs. Night-vision devices are normally used at light levels ranging from full moon to just below quarter-moon, or in dark city environments with ample scattered light. It is important to have good contrast over as wide a light-level range as possible. To get this extended dynamic range, the gain should be held nearly constant to as high a level as possible, for improved contrast at the high-light levels. Any gain improvement should be attained with little or no increase in noise, to ensure good performance at the minimum light levels. Reducing the objective lens *f*-number as low as possible also improves system performance and gain. However, *f*-number reduction by itself may create problems in the system dynamic range if the II and its power supply assembly is not appropriately adjusted to match the optical throughput.

Figure 13 shows the extended dynamic range of a Gen-2+ II and power supply assembly, as compared to the typical MIL-SPEC Gen-2 assembly. Increasing the gain in a standard Gen-2 assembly by increasing the gain control voltage, i.e., the MCP voltage, will not give the same benefits as the Gen-2+. Ideally, a change of one unit in input brightness should result in a proportional output brightness change. The increased near-linear gain range up to higher-output light levels in the Gen-2+ improves the contrast at the higher levels. Brightness limiting begins reducing the gain to hold the output brightness constant after the automatic brightness control (ABC) limit of the power supply is reached. The increased gain of the Gen-2+ improves the performance at the lowest-light levels as well.

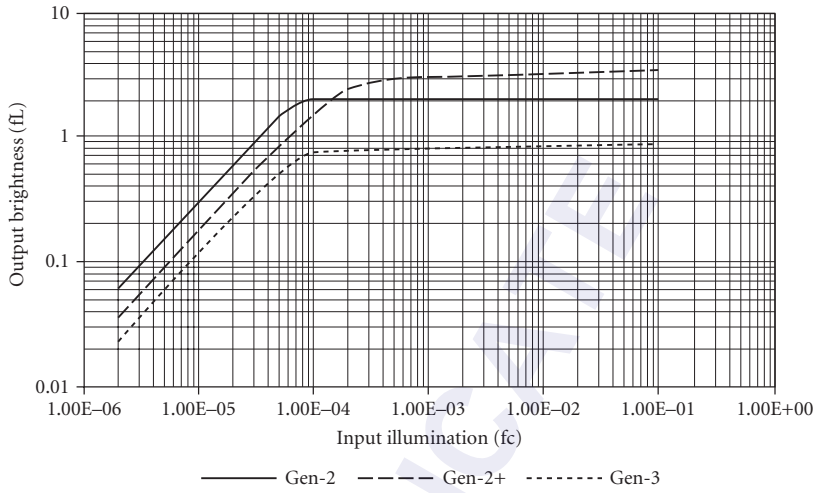

FIGURE 13 Output versus input transfer characteristics of Gen-2, Gen-2+, and Gen-3 II/power supply assemblies.

31.5 IMAGE INTENSIFIED SELF-SCANNED ARRAYS

There are several reasons to consider using an II SSA instead of an SSA alone. One obvious reason is to achieve LLL sensitivity. Figure 14 shows the limiting resolution versus faceplate illumination characteristic of CID camera operating in the unintensified and intensified modes.[8] It is seen that

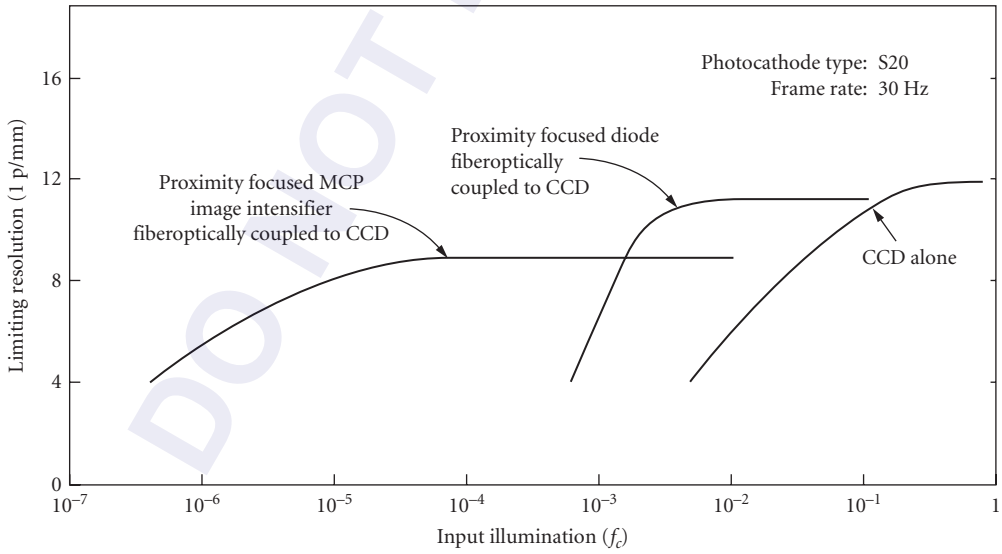

FIGURE 14 Resolution versus input illumination characteristics of a conventional optical input CCD camera and the same camera fiberoptically coupled to an MCP image intensifier tube. (*From Ref. 8.*)

LLL sensitivity is achieved by coupling the CID to an image intensifier tube, albeit at the expense of reduced high-light resolution. Other reasons for using an II SSA are

- High-speed electronic gating, down to a few nanoseconds, for framing cameras, LADAR, smoke and fog penetration
- Improved spectral sensitivity
- Use in a TV camera system that operates automatically under lighting conditions ranging from nighttime to full daylight conditions.
- High-sensitivity and high-speed-gated optical multichannel analyzers (OMAs)

Fiberoptic-Coupled II/SSAs

Figure 15 shows a schematic design of a fiberoptically (FO) coupled II SSA assembly. These designs are modular, since an II module is optically coupled to an SSA module. Virtually any type of image tube can be optically coupled to an SSA. The fiberoptically coupled design shown in Fig. 15 requires the use of an II having a fiberoptic output window and an SSA having an SSA input window. A fiberoptic taper, instead of a simple unity magnification FO window, is also generally required to efficiently couple the output of the II into the SSA, and this is shown in Fig. 15 as a separate module. The various fiberoptic modules are joined at interfaces 1, 2, and 3, using optical cement, optical grease, immersion oil, or "air." For the highest-resolution image transfer across these interfaces, it is necessary that the gap length at each interface be kept short, and the numerical aperture of the fiberoptic windows should be kept as low as possible, consistent with the SNR and gain requirements. It has been shown[9] that the first interface can be eliminated by making the fiberoptic taper part of the II and depositing the phosphor screen directly onto it, and interface 3 can also be eliminated by coupling the fiberoptic taper directly to the SSA. The properties of the image transfer and conversion components shown in Fig. 15 can be used to estimate the overall performance characteristics of the fiberoptically coupled II SSA camera.

The terminology used to define SSA image format sizes derives from the earlier vidicon camera tube technology. The mass, volume, and power requirements of vidicon cameras are much larger than SSA cameras. Vidicons also have image distortion and gamma characteristics which must be accounted for, whereas SSAs and II SSSAs using proximity-focused IIs are nearly distortion-free with

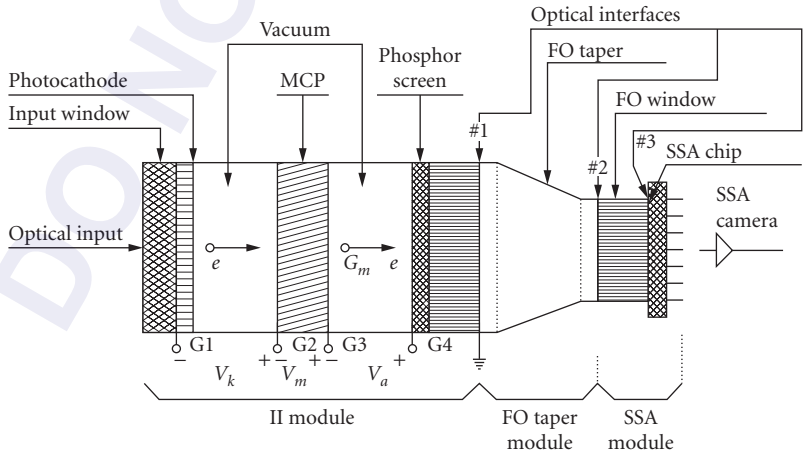

FIGURE 15 Schematic design of fiberoptically coupled II SSA assembly.

FIGURE 16*b* Typical dimensions for image intensifies and SSAs using 3:4 format.

The present limiting resolution range of MCP IIs is 36 to 51 lp/mm. In an II SSA, the resolution of the II should be matched, in some sense, to that of the SSA. For example, it is unwise to use a low-resolution II and fiberoptic lens combination with a much higher resolution CCD.

Lens-Coupled II SSAs

Figure 17 is a schematic design for a lens-coupled II SSA assembly. The differences between this design and the fiberoptic-coupled II SSA design described earlier are that the output window of the II can be either fiberoptic or glass, and a lens is used instead of an FO taper to couple the output optical image from the II directly into a conventional optical input SSA, i.e., no FO window is required at the SSA. Although the lens-coupling efficiency is lower, its image distortion and resolution performance is superior to the FO-coupled design. Also, the chance for possible adverse rf interference at the sensitive input to the SSA camera from the II high-voltage power supply is less than for the lens-coupled design.

Parameters to Specify Typical parameters to specify for an MCP II SSA detector assembly, using either fiberoptic or lens-coupling, are as follows:

- Sensitivity
  White-light (2856 K) (μA/lm)
  Spectral sensitivity (mA/W versus nm)
  Sensitivity (mA/W at specified wavelength)
- EBI (lm/cm^2 at 23°C)
- MCP applied potential for 10 K fL/fc luminous gain (V)
- Horizontal resolution at specified input illumination (TVL)
- Shades-of-gray (units)
- Cosmetic properties
  Uniformity (percent)
  Bright spots (number allowable in format zone) Dark spots (number allowable in format zone)
- Burn-in (procedure)

Electron-Bombarded SSA

Since the early work by Abraham et al.[10] which showed the feasibility of achieving useful electron gain by electron bombardment (EB) of a silicon diode in a photomultiplier tube, several attempts have been made to achieve similar operation using an SSA specially designed for EB input, instead of optical input. The charge gain (G_{eb}) resulting from the electron bombardment is given by

$$G_{eb} = \frac{(V_a - V_d)}{3.6} \tag{15}$$

where V_a is the acceleration voltage and V_d is the "dead-voltage" of the EBSSA. It was quickly found that successful CCD operation could not be obtained by simply bombarding the normal optical input side of the chip with electrons, because interface states soon form which prevent readout of the chip and other problems. By thinning a CCD chip to 10 to 15 μm from the "backside" and operating in a backside EB-mode, useful performance is achieved. In this way, 100 percent of the silicon chip is sensitive to incident photoelectrons, and it becomes technically feasible to make EBSSA cameras.

Proximity Focused EBSSAs *A* proximity-focused EBSSA is shown schematically in Fig. 18. In this design, the input light enters the window/photocathode assembly to generate the signal photoelectrons which are accelerated to about 10-keV energy and bombard the thinned backside of the EBSSA. Note that no MCP, no MCP-to-screen gap, no phosphor screen/output window assembly, and no fiberoptic or lens coupling is used to transfer the electronic image to the SSA for readout. Thus, higher limiting resolution is attainable. Also, the power noise factor associated with the EBSSA gain process is lower than that of MCP devices, and image lag is eliminated because no phosphor is used. Early work on proximity-focused EBDDs was done by Barton et al.,[11] Williams,[12] and Cuny et al.[13] By 1979, a 100 × 160 pixel TI CCD was used in this type of detector and put into a miniature TV camera. With an acceleration voltage of V_a = 15 kV, an electron gain of 2000 was achieved, along with a Nyquist limited resolution of 20 lp/mm. Recent advances have brought this technology closer

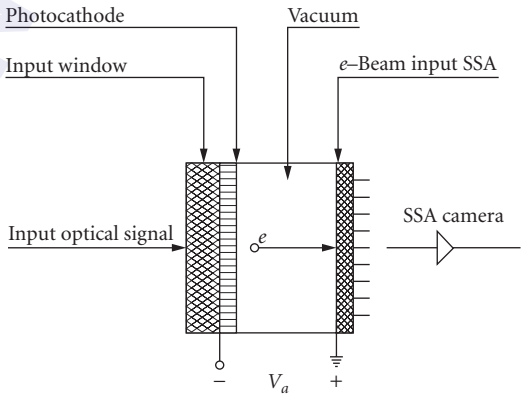

FIGURE 18 Electron bombarded SSA (EBSSA).

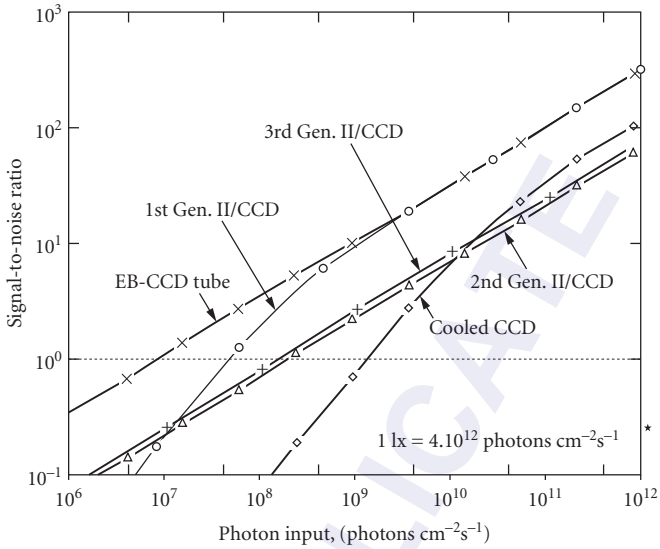

FIGURE 19 Comparison of the signal-to-noise ratio of various optoelectronic imagers versus the photon input. (*From Ref. 14.*)

to extensive usage possibilities. Richard et al.[14] have compared the SNR characteristics of an EB CCD tube, various other types of II CCDs, and bare CCDs. Their results are shown in Fig. 19.

In order to achieve its full performance capabilities, the energy of the bombarding electrons must be absorbed by the active silicon SSA material, photoelectrons must not be lost, the exposure of the EBSSA to high-energy electrons should not cause a life problem, and it must be possible to read out the stored charge pattern in the SSA. It is found that recombination phenomena at the EB-input face can be reduced with a p^+ passivation layer, e.g., by using 3E17 cm^{-3} boron doping, which reduces back-diffusion of signal electrons, front-diffusion of "dark" charges from the rear face, reduced diffusion length, separation of holes and electrons by the built-in electric field, and higher surface conductivity, thus better voltage stability, at the rear face.

Internally processed (IP) and remotely processed (RP) or "transfer" photocathodes have been used in EBSSAs. It is generally found that the internal processing produces consistently higher-background and spurious noise problems due to field emission from tube body parts and the photocathode. Both types of photocathode processes have yielded long-life EBCCD detectors.

Proven applications to date for EBSSA detectors:

- Photon-counting wavefront sensor (adaptive optics), European Space Organization 3.6-m telescope at La Silla, Chile
- NASA, Goddard Space Flight Center, Oblique Imaging EB CCD uv sensitive camera

Advantages of EBSSA cameras over MCP II-based II-SSAs:

- No image lag
- Higher resolution
- Single photoelectron detection per frame per pixel
- Higher DQE

Digital II SSA Cameras Consider a photon-counting imaging detector consisting of an MCP image intensifier tube (II) that is fiberoptically coupled to a silicon solid-state self-scanned array

(SSA) chip in a TV camera. Incoming photons at wavelength λ pass through the input window of the II and produce an average quantum yield of Y_k photoelectrons per photon at the photocathode. The resulting photoelectrons (e) are accelerated into the MCP electron multiplier assembly. Amplified output electrons from this low-noise electron multiplier are accelerated into an aluminized phosphor screen on the output window of the II. The number of output photons from the II per photoelectron is proportional to the electron gain in the MCP (G_m), the effective electron bombardment energy at the phosphor screen (εV_s), and finally the electron-input to photon-output conversion efficiency (P) at the phosphor screen. As discussed earlier the optical transmission of the input window and the actual quantum yield of the photocathode are usually factored together in the average quantum yield parameter Y_k, and the optical transmission of the output window is also normally factored together with the actual conversion efficiency of the phosphor screen in the screen efficiency parameter P.

The output photon pulse from the II, resulting from the single detected input photon, is coupled into the SSA via the fiberoptic taper, which matches the output size of the II to the size of the SSA, and a fiberoptic window on the SSA. This photon pulse is then converted to an electron signal charge packet (Q_{ssa}) at the SSA. The number of electrons stored per pixel in the SSA depends upon the area of the photon pulse at the SSA, the spatial distribution of photons in this pulse, and the area per pixel in the SSA. Thus, in addition to the above II factors, the stored charge in the SSA per photoelectron is also proportional to the optical transmissions of the FO taper (T_{fot}) and SSA window (T_{ssa}), and the quantum yield of the SSA (Y_{ssa}).

By using two or three conventional MCPs in cascade, i.e., VMCPs or ZMCPs, the gain can be made so large that it completely overrides any normal room-temperature thermal dark current in an SSA at a conventional RS-170 rate. In this photon-counting mode of operation, a charge signal above a preset threshold value is looked for. When it is found in a given pixel, a "1" is stored in memory for that pixel's address, "Os" are stored in pixel addresses where this condition is not met, and the entire frame is read out. By reading out a total of N_f frames, the dynamic range can be made as high as N_f if the dark count rate is negligible. Thus, photon-counting imaging can achieve a very large dynamic range.

Another advantage of photon-counting imaging is that the image resolution can also be made very high by centroiding the detected charge packets in the SSA. Since the performance of a centroiding camera depends upon the signal-processing algorithm, this will not be analyzed here. Instead, the reader is referred to several references in which centroiding is discussed.[15]

Let us next calculate the stored charge and number of stored electrons in a photon-counting II SSA per photoelectron. Assume that a proximity-focused VMCP II is coupled to the SSA with a fiberoptic taper. For our analysis, some typical values will be used for the operating voltage and gain of a VMCP: the acceleration voltage between the VMCP and the phosphor screen, the efficiency of an aluminized type KA (P20) phosphor screen, the optical transmissions of a fiberoptic taper and an SSA fiberoptic window, and the quantum yield of an SSA.

Definitions for the parameters that will be used are summarized as follows:

Q_{ssa}	stored SSA charge per input photoelectron from the photocathode
Y_k	photocathode quantum yield, e/photon
G_m	VMCP electron gain, e/e
V_m	VMCP applied potential, V
V_s	MCP-to-screen applied potential, V
V_d	phosphor screen "dead-voltage"
P	phosphor screen efficiency, photon/eV
T_{fot}	transmission of fiberoptic taper
T_{ssa}	transmission of fiberoptic window on the SSA
Y_{ssa}	quantum yield of SSA, e/photon
e	electron charge, 1.6E–19 C
N_{essa}	number of stored SSA electrons per input photoelectron

Using these definitions, the general equation for the charge stored in the SSA per input photoelectron is given by Eq. (16).

$$Q_{\text{ssa}} = e \cdot G_m \cdot (V_s - V_d) \cdot P \cdot T_{\text{fot}} \cdot T_{\text{ssa}} \cdot Y_{\text{ssa}} \tag{16}$$

Thus, Q_{ssa} is given by the product of the VMCP gain, the effective electron bombardment energy at the aluminized phosphor screen, the conversion efficiency of the phosphor screen assembly, the transmissions of the FO taper and the SSA's FO window, and finally the quantum yield of the SSA.

For

$$V_m = 1380 \text{ V}$$

the VMCP electron gain is

$$G_m(V_m) = \left(\frac{V_m}{700\ V}\right)^{17}$$

$$G_m(V_m) = 1 \times 10^5$$

By using the following values for the additional parameters

$V_s = 5500$ V
$V_d = 2500$ V
$P = 0.06$ photon/eV
$T_{\text{fot}} = 0.6$
$T_{\text{ssa}} = 0.8$
$Y_{\text{ssa}} = 0.5$ e/photon

it is found that the stored charge per photoelectron is

$$Q_{\text{ssa}} = 7 \times 10^{-13} \text{C}$$

and that the number of electrons stored in the SSA per input photoelectron is

$$N_{\text{essa}} = Q_{\text{ssa}} / \text{e}$$

$$N_{\text{essa}} = 4 \times 10^6 \text{ electrons}$$

Since the full-well or saturation charge for an SSA pixel in on the order of 1 pC, this VMCP II/SSA assembly is seen to qualify as a photon-counting imaging detector.

Modulation Transfer Function and Limiting Resolution The modulation transfer function (MTF) of an II SSA camera is determined by a convolution of the individual MTFs of the camera lens, II, II-to-SSA-coupling fiberoptic or lens, fiberoptic-to-fiberoptic interfaces, fiberoptic-to-SSA interface, SSA, etc. There are several ways to determine the MTF of an existing II SSA camera.

For example, the II SSA camera can be focused on a spatial frequency burst pattern, i.e., a periodic pattern of black and white bars in which the spatial frequency of the bars increases in one direction. Alignment of the pattern's bars with pixel columns and readout of the modulation of the spatial pattern in the pixel row direction gives the squarewave MTF of the camera $S(f)$, where f is the spatial frequency in cycles/mm. Conversion of this square-wave MTF to a sine-wave MTF is accomplished by using the Fourier transform at a given frequency:

$$T(f) = \left(\frac{\pi}{4}\right) \cdot \left(S(f) + \frac{S(3f)}{3} - \frac{S(5f)}{5} + \frac{S(7f)}{7} + \cdots\right) \tag{17}$$

By calculating several values of $T(f)$ from the known square-wave function, the sine-wave MTF can be determined and used for camera system optical image transfer analysis. The limiting resolution is often taken to be the spatial frequency value for this sine-wave MTF at which the modulation drops to a few percent.

Also, to use the above example as an illustration, the MTF of an II SSA is a function of the direction in which the spatial frequency burst pattern is aligned. Self-scanned array pixels are not generally square, and the distances between centers of pixels in the horizontal and vertical directions are not generally the same. Thus, the corresponding MTFs in the horizontal and vertical directions are different, and the MTF is a function of the angle that the burst pattern makes with the rows and columns of pixels.

A convenient specification of the spatial frequency response of an SSA or an II SSA camera is the Nyquist frequency (f_N), defined to be the reciprocal of twice the distance between the pixels. For example, if an SSA has rows of pixels spaced on 20-μm center-to-center, then the horizontal Nyquist spatial frequency is

$$f_{N,h} = \frac{1}{(2.(0.02\text{ mm}))} = 25\text{ cycles/mm}$$

Assuming an II limiting resolution (f_{II}) of 32 cycle/mm, and assuming that the MTFs are gaussian, then an estimated value for the limiting resolution of the II SSA camera is

$$\left(\frac{1}{f_{\text{cam}}^2}\right) = \left(\frac{1}{f_{11}^2}\right) + \left(\frac{1}{f_{\text{ssa}}^2}\right) \tag{18}$$

or

$$f_{\text{cam}} = \frac{f_{\text{II}} \cdot f_{\text{ssa}}}{\sqrt{(f_{\text{II}}^2) + (f_{\text{ssa}}^2)}} \tag{19}$$

For the values used in this example, $f_{\text{cam}} = 20$ cycle/mm. Although this gaussian estimate is convenient to use, a more exact estimate can be made by multiplying the various component sine-wave MTFs to find the II SSA camera's MTF, and from this its limiting resolution can also be found.

For example, actual MTF measurements[9] on an II SSA camera, having a proximity-focused 18-mm active diameter MCP II fiberoptically coupled to a CCD with an $m = 8$ mm/18 mm = 0.44 magnification taper, showed that the MTF of the CCD, referred to the II input, is given by $T_{\text{CCD}}(f) = \exp - (f/9.0)^{1.4}$, where f is the spatial frequency in cycles/mm. The Nyquist frequency of the CCD was $f_N = 20$ cycle/mm, and the MTF of the complete camera was found to be $T_{\text{II SSA}}(f) = \exp - (f/6.3)^{1.1}$, both referred to the II input.

31.6 APPLICATIONS

In time, it is expected that most of the quantum-limited and LLL TV applications will use some form of II SSA camera, instead of an intensified vidicon-based camera. A few of the major application areas for II SSA cameras are highlighted in this section.

Optical Multichannel Analyzers

Optical multichannel analyzers (OMAs) are instruments used to measure optical radiation in linear patterns, e.g., spectra or two-dimensional images. Photographic film, single-channel photomultiplier tubes, and TV camera tubes, e.g., vidicons, have been replaced by SSAs, e.g., CCDs, and II SSAs, e.g., image tube intensified CCDs or photodiode arrays (PDAs). Four distinct application areas exist for OMAs using II SSA detectors:[16]

Application	Detector*	Time
	Type	Resolution
Spectroscopy	IILPDA	50 ms
Time-resolved pulsed laser spectroscopy	GIILPDA	<5 ns
Time-resolved pulsed laser imaging spectroscopy	GIISSCCD	<5 ns/spectrum
Time-resolved imaging	GIISSCCD	<5 ns/spectrum

*IILPDA = image intensified photodiode array; GIILPDA = gated image intensified photodiode array; GIISSCCD = gated image intensified charge-coupled device.

In each of these types of systems, the incoming radiation is converted to charge packets that are stored in each pixel of the SSA. Each line and/or field of pixels is read out by a suitable camera electronics, and the pixel charge values are stored in a computer for subsequent processing and analysis. The sensitivity of the II is chosen for best performance over the range of wavelengths being investigated. The dynamic range of OMAs can be as high as 18 bits. In comparison with the older single-element scanning system, modern II SSA-based OMAs acquire spectra up to 1000 times faster and/or with higher SNR during a given measuring period. Three common OMA applications are Raman spectroscopy, multiple input spectroscopy, and small-angle light scattering.

Range Gating and LADAR

Range gating is becoming increasingly important because the required technology now exists at an affordable cost and the signal-to-noise ratio improvement is much higher than nongated conventional TV imaging. A gated laser sends out a laser pulse of only a few nanoseconds duration while the II SSA camera is gated off. No reflection from scattering or reflection in the medium between the camera and the object is allowed to be registered in the II SSA camera.[17] The II SSA camera is gated on only at the moment when the light packet from the object returns to the camera and, after exposing for the duration of the outgoing pulse, it is returned to a gated-off condition. By repeating this process and controlling the image-storing conditions, high-contrast images having high signal-to-noise ratios can be achieved. Another obvious advantage of the range-gated system is that the time-of-flight between pulse output and receipt gives the range to the object being viewed, thus leading to the realization of a *la*ser *d*etection *a*nd *r*anging (LADAR) system.

Microchannel plate image tubes offer high-speed gating and spectral response advantages to LADAR systems. They can be electronically gated to a few nanoseconds, i.e., providing distance resolutions of a few feet for LADAR systems. Present MCP IIs offer the user a broad range of spectral sensitivity, including near-ir imaging at 1060 nm, so that powerful and efficient lasers may be used for optimum LADAR system performance. Also, the ruggedness, extremely small size, and low power drain characteristics of II SSA cameras make them very attractive for LADAR applications for spacecraft and unmanned autonomous vehicles.

Day/Night Cameras

Full day-night interscene dynamic range capability, while maintaining a high signal-to-noise ratio, is achievable using an II SSA camera in conjunction with an auto-iris camera lens.[18] The principle of operation of this type of camera can be described as follows. Assume that operation begins at the lowest light level to be encountered. The MCP voltage in the II is set to operate with high SNR for the camera lens, an auto-iris lens, set to its lowest *f*-number. As the light level is increased, the system operates over two orders-of-magnitude dynamic range. For four orders-of-magnitude higher light level inputs, the f-setting of the auto-iris lens is increased by a feedback circuit, driven by the peak-to-peak video output signal from the SSA camera. The effective exposure of the SSA is next automatically reduced as the light level increases by four-and-one-half orders-of-magnitude, again to

maintain a high SNR, by duty-cycle gating the MCP II. Finally, another two-and-one-half orders-of-magnitude in input light level are accommodated by reducing the gain of the MCP, i.e., by reducing its applied operating potential. The total interscene dynamic range achievable with this type of automatically controlled day/night camera is 13 orders-of-magnitude. In addition to its wide dynamic range capability, this type of camera is also able to make rapid narrow-band spectral samples across a wide spectral range, e.g., from the uv to the near-ir.

Mosaic II SSA Cameras

For very high amounts of image information throughput, multiple SSAs are used to read out large area IIs. For example, a 75-mm active diameter MCP II can be coupled fiberoptically to four individual SSA cameras. The fiberoptic couplers are made to butt against each other at the output of the II, and their output ends are optically coupled to the SSAs. Parallel readout of the SSAs is then accomplished, giving the advantage of high-resolution readout without the disadvantage of having to use a wide bandwidth video electronic system or lower frame rates.

One such II SSA camera is designed for x-ray radiology image input.[19] The x-ray input image is converted to a visible light image at a scintillator screen that is in optical contact with the 6-in-diameter fiberoptic window. This scintillator/window assembly is, in turn, coupled to the input of a 6-in-diameter proximity-focused diode II, i.e., without an MCP, for modest light gain and good image quality. Six fiberoptic tapers in a 2×3 matrix couple the images from the six adjacent output sections of the II to six CCD cameras which operate in parallel to continuously read out the converted x-ray image.

Other Applications

Other applications for II SSA cameras are the following:

- Semiconductor circuit inspection
- Astronomical observations
- X-ray imaging
- Coronary angiography
- Mammography
- Nondestructive testing
- Multispectral video systems

Active Imaging Active imaging is becoming increasingly important because the required technology now exists at an affordable cost and the signal-to-noise ratio improvement is much higher than nonactive conventional TV imaging. Two types of active imaging presently exist, i.e., "line-scanned" and "range-gated."

In a line-scanned imaging system, a narrow beam from a cw laser is raster-scanned across the object to be viewed, and the resulting reflected light is collected by a lens and detector assembly which receives and measures light from the illuminated field-of-view (FOV). Large FOV scenes can be scanned in a short period of time, which is a major advantage of this system. The signal from the detector is finally processed by a video electronics system and displayed, for direct viewing, or image processed as required. Limiting-resolution is set by the beam diameter achievable at the object. Thus systems operating in space; atmospheric and underwater environments have significantly different limiting-resolution characteristics.

In a range-gated type of system, a gated laser sends out a laser pulse of only a few nanoseconds duration while the TV camera is gated off. No reflection from scattering or reflection in the medium between the camera and the object is allowed to be registered in the TV camera. The TV camera is

gated on only at the moment when the light packet from the object returns to the camera and, after exposing for the duration of the outgoing pulse, the TV camera is returned to a gated-off condition. By repeating this process and controlling the image-storing conditions, high-contrast images having high signal-to-noise ratios can be achieved.

Another obvious advantage of the range-gated system is that the time of flight between pulse output and receipt gives the range to the object viewed, thus leading to the realization of a laser detection and ranging (LADAR) system. MicroChannel plate image tubes offer high-speed gating and spectral response advantages to LADAR systems. They can be electronically gated to a few nanoseconds, i.e., distance resolutions of a few feet, and in some parts of the optical spectrum they offer high sensitivity.

32.1 GLOSSARY

A	area of the pixel
C_{FD}	total capacitance of the floating diffusion in a CCD output
C_g	gate capacitance per unit area
C_r	readout line capacitance
J_D	total dark current per unit area
J_s	surface generation current
$L_{\mathbf{e}}$	diffusion length of electrons in silicon
L_p	diffusion length of holes in silicon
N_A	p-type dopant concentration in silicon
N_D	n-type dopant concentration in silicon
$N_{\mathbf{e}}$	total number of electrons collected in a pixel
$N(0)$	number of photons entering the silicon
$N(x)$	number of photons remaining a distance x below the surface
n_i	intrinsic carrier concentration in silicon
$P(x)$	probability that an electron-hole pair generated a distance x from the surface will be collected before recombination
q	electron charge
S_o	surface recombination velocity
T_{int}	integration time of light in an image sensor
$T(\lambda)$	transmission of light
V_{bi}	built-in voltage for a silicon pn junction
$W(V)$	width of the depletion layer at a given bias voltage in the MOS capacitor or junction-photodiode
$\alpha(\lambda)$	absorption coefficient of light

ε_s silicon dielectric constant
μ_e electron mobility in silicon
μ_p hole mobility in silicon
τ_o depletion-layer lifetime
τ_p minority carrier hole lifetime in silicon
Φ_s electrostatic potential at the silicon-silicon dioxide, also called surface potential

32.2 INTRODUCTION

Since the invention of the image sensor in 1964, solid state image sensors have advanced in resolution, sensitivity, and image quality to the point where they have replaced other methods of converting visible light to electronic signals in nearly all imaging applications. There are two types of image sensors: *area image sensors,* which are used in cameras, and *linear sensors,* which are used in scanning applications. Cameras using area image sensors dominate the camcorder, video and broadcast, machine vision, scientific, and medical fields. Area image sensors for camcorder applications are typically 400,000 picture elements in resolution, 60 dB in dynamic range, and have noise levels of a few tens of electrons. Area image sensors for scientific applications may have resolutions of over six million elements, dynamic ranges exceeding 80 dB, and noise levels approaching a single electron. Scanners employing linear solid-state image sensors dominate facsimile, document scanner, digital copier, and film scanner applications. Linear sensors range from 2000-element monochrome arrays with 40 dB of dynamic range used in facsimile applications to 8000 or more element trilinear arrays with 80 dB of dynamic range for high-performance color scanning applications.

The steps involved in image sensing consist of (1) converting the incoming photons to charge at picture element (pixel), and (2) transferring that charge to an output amplifier and converting the charge to a voltage or current signal which can be sensed by circuits external to the sensor. The image-sensing elements are described first, followed by readout elements. Sensor architectures for area and linear sensors are described next.

32.3 IMAGE SENSING ELEMENTS

There are four basic types of structures which are used for image sensing: the junction photodiode, the photocapacitor, the pinned (p^+np) photodiode, and the photoconductor.* The first three are generally fabricated in single-crystal silicon as part of the image sensor; the photoconductor is usually fabricated from amorphous silicon deposited over the image sensor. The photoconversion process begins with the absorption of a photon in silicon resulting in the generation of a single electron-hole pair. The absorption of light at a particular wavelength is given by

$$N(x, \lambda) = N(0)e^{-\alpha(\lambda)x} \tag{1}$$

where $N(x)$ is the number of photons remaining at a distance x below the surface, $N(0)$ is the number of photons entering, and $\alpha(\lambda)$ is the absorption coefficient.[1,2] The absorption coefficient is shown in Fig. 1 as a function of wavelength λ for single-crystal silicon, doped polycrystalline silicon, and hydrogenated amorphous silicon. The absorption depth is defined as the inverse of the absorption coefficient $[d(\lambda) = 1/\alpha(\lambda)]$. In single-crystal silicon, the absorption depth is 0.4 μm in the blue (450 nm), 1.5 μm

*For some scientific applications in which high quantum efficiency and fill factor are essential, the silicon wafer is thinned to 10 μm or less in thickness and illuminated from the backside. The frontside contains an area charge coupled device, which is used to collect the photogenerated carriers.

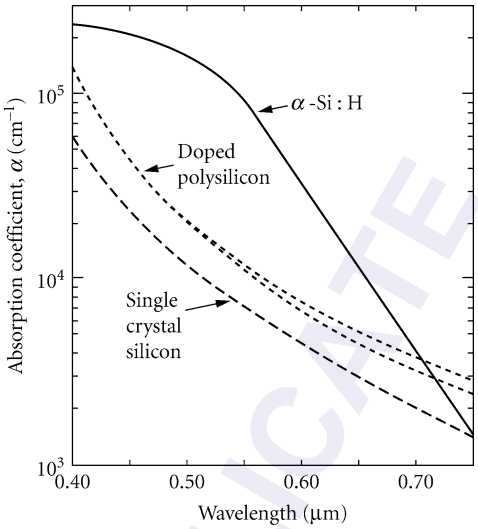

FIGURE 1 Absorption coefficient for light in single-crystal silicon, heavily doped polycrystalline silicon, and hydrogenated amorphous silicon as a function of wavelength.

in the green (550 nm), and 3.0 μm in the red (640 nm). In the infrared, the absorption depth increases to 10.5 μm at 800 nm. Beyond 1100 nm, the absorption is virtually zero because the photon energy is less than the 1.1-eV silicon bandgap.

Junction Photodiode

The junction photodiode is one of the most common image-sensing elements. The physical structure and band diagram of the junction photodiode are shown in Fig. 2*a* for a *p*-type substrate. The *n*-type region is formed by ion implantation or diffusion of phosphorous or arsenic to a depth of 2000 to 10,000 Å into the *p*-type silicon. The *n*-type dopant region is usually graded, with the highest concentration at the surface. The gradient in *n*-type dopant concentration results in a gradient in electrostatic potential which accelerates photogenerated carriers (holes in the *n*-type region) away from the surface. This reduces loss of photogenerated carriers to surface recombination. The photodiode is typically operated with a reverse bias V of 1 to 5 V. A depletion layer is formed between the *n*-and *p-type* regions.* The width of the depletion layer $W(V)$ for an abrupt $n + p$ junction is given by

$$W(V)=\sqrt{\frac{2\varepsilon_s(V+V_{\text{bi}})}{\text{q}N_A}} \tag{2}$$

where q is the electronic charge, ε_s is the silicon dielectric constant, N_A is the *p*-type dopant concentration, and V_{bi} is the built-in voltage given by

$$V_{\text{bi}}=\frac{kT}{\text{q}}\ln\frac{N_A}{n_i} \tag{3}$$

*For a detailed review of the device physics of junction diodes and MOS capacitors, see Sze, *Physics of Semiconductor Devices,* Wiley, New York, 1969.

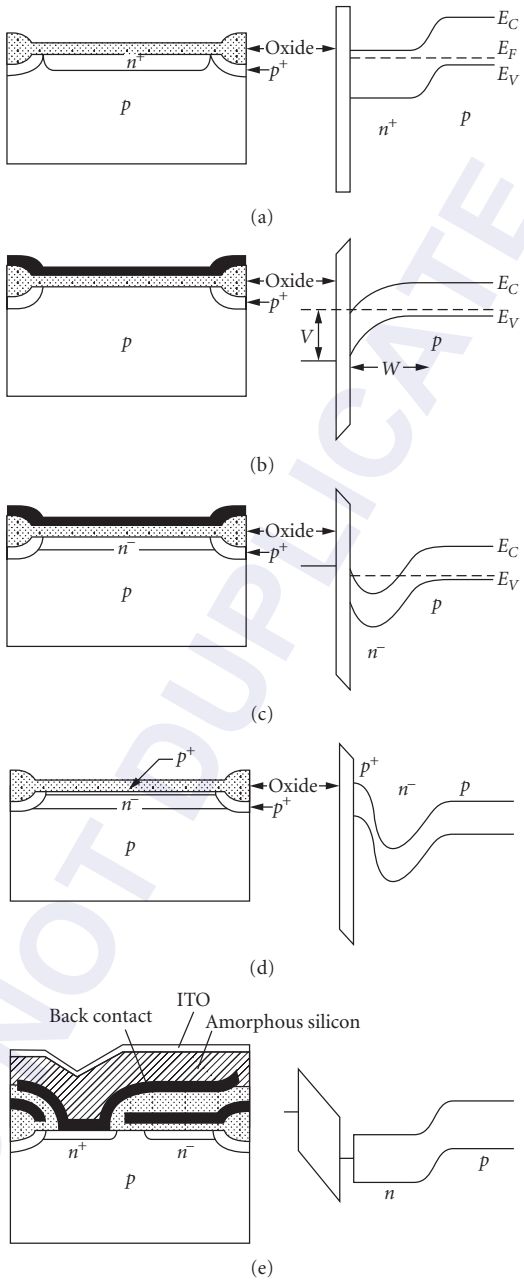

FIGURE 2 Cross-sectional diagrams and band diagrams for (*a*) junction photodiode; (*b*) surface-channel MOS capacitor; (*c*) buried-channel MOS capacitor; (*d*) pinned or hole-accumulated diode; and (*e*) amorphous silicon photoconductor.

where n_i is the intrinsic carrier concentration. For silicon doped at 1×10^{16} cm^{-3}, the depletion width at 5-V reverse bias is 0.8 μm.

If the diode is illuminated, some of the photons will be absorbed in the *n*-region, some in the depletion layer, and the remainder in the *p*-type substrate. The quantum efficiency $\eta(\lambda)$ is the ratio of the charge collected to the number of photons incident on the diode (i.e., 100-percent quantum efficiency refers to one electron-hole pair collected for every incident photon). The quantum efficiency depends on three factors: transmission $T(\lambda)$ of light through the overlying layers into silicon, absorption of light in silicon, and the probability $P(x)$ that an electron-hole pair generated a distance x from the surface will be collected before recombination:

$$\eta(\lambda) = T(\lambda) \int_{x=0}^{x=\infty} (1 - e^{-\alpha(\lambda)x}) P(x) dx \tag{4}$$

The transmission of light through the overlying layers into the silicon can be calculated using standard multilayer interference models.

The collection of the photogenerated charge takes place by two processes: drift and diffusion. Drift is the movement of electrons and holes due to an electric field. Even for small electric fields, the transport of carriers by drift will dominate diffusion. This is the case in the depletion region. Outside the depletion region, such as in the *p*-type substrate, there is no electric field, and carrier transport occurs by diffusion. For example, a photon absorbed in the *p*-type region will excite an electron from the valence band to the conduction band. The electron will move in a three-dimensional random walk until it recombines or encounters the edge of the depletion region, where it is swept across the junction by the electric field. The probability that an electron at a distance x' from the junction can diffuse to the junction before recombining is given by

$$P(x') = e^{-x'/L_e} \quad \text{where} \quad L_e = \sqrt{\frac{KT}{q} \mu_e \tau_e} \tag{5}$$

in which L_e is the diffusion length, μ_e is the electron mobility, and τ_e is the electron lifetime (typically ~1 μs). For a 1-μs lifetime, the electron diffusion length in *p*-type silicon is 50 μm. Electrons generated from photons absorbed at less than the diffusion length from the junction have a high probability of collection.*† Similarly, photons absorbed in the *n*-type layer create electron-hole pairs. The holes must travel by diffusion to the junction in order to be collected. The probability that a hole a distance x' from the junction can diffuse to the junction is given by

$$P(x') = e^{-x'/L_p} \quad \text{where} \quad L_p = \sqrt{\frac{KT}{q} \mu_p \tau_p} \tag{6}$$

in which L_p is the diffusion length, μ_p is the hole mobility, and τ_p is the hole lifetime. For a 1-μs lifetime, the hole diffusion length in *n*-type silicon is 30 μm. Since the *n*-type region in an $n + p$ junction is less than 1 μm thick, the holes have no difficulty diffusing through the *n*-type region to the junction unless the *n*-type region is so heavily damaged or so heavily doped that the hole lifetime is

*In image sensors, the collection of photogenerated carriers can be complicated by a variety of factors. The doping concentration may not be uniform on either the *n*- or *p*-sides. On the *n*-side, the dopant concentration is designed to decrease from the surface to the junction, building in a potential gradient for holes away from the surface and toward the junction, preventing surface recombination. On the *p*-side, the dopant concentration may not be uniform owing to the use of epitaxial layers or wells diffused into silicon. Additionally, the carrier lifetime may not be uniform. Impurity gettering, a process used in many image sensors to remove metallic contaminants will leave a region of crystalline defects in the silicon starting 20 to 50 μm beneath the silicon surface. The defects result in a very short electron lifetime in this region. Finally, diffusion takes place in three dimensions; a carrier absorbed beneath a given pixel in an array will diffuse laterally by the same amount it diffuses vertically. This can cause it to be collected in adjacent pixels.

†See, for example, Lavine et al., "Steady State Photocarrier Collection in Silicon Imaging Devices," *IEEE Transactions on Electron Devices* **ED-30:**1123–1133 (Sept. 1983).

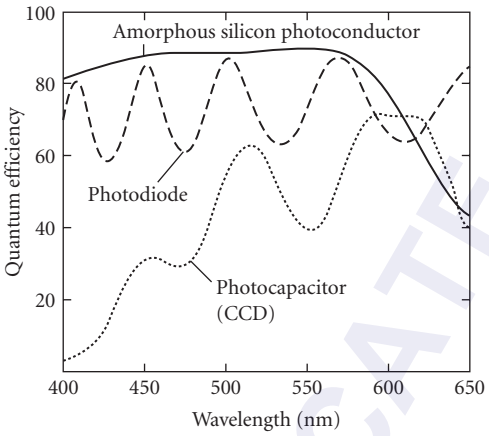

FIGURE 3 Quantum efficiency as a function of wavelength for photocapacitor, photodiode, and amorphous silicon photoconductor.

very short. More typically, loss of quantum efficiency on the *n*-side results from recombination at the surface.

The quantum efficiency of a junction photodiode is illustrated as a function of wavelength in Fig. 3. In the ultraviolet, the light is absorbed very near the surface and some of the photogenerated charge can be lost to surface recombination. In the 420- to 700-nm region, most of the light is absorbed close to the junction and is easily collected. The structure in the quantum efficiency illustrated in Fig. 3 results from the multilayer reflections of light in the oxide layer which overlies the photodiodes used in image sensors. The positions of the minima and maxima depend on the thicknesses and indices of refraction of the layers overlying the silicon. Beyond 800 nm, some of the photons are absorbed sufficiently deep in silicon that the carriers recombine before they can diffuse to the junction; this results in a decrease in quantum efficiency at longer wavelengths.

In most image sensing applications, the junction diode at each picture element is used not only to collect the photogenerated carriers but also to store the carriers until they can be read out. In an imaging array, each photodiode would be reset to a reverse bias V, by a MOS gate. The capacitance of the diode of area A for an abrupt $n + p$ junction is given by $C(V) = \varepsilon_s A/[W(V)]$ where $W(V)$ is the depletion width.

When a photogenerated carrier is collected by the junction, it is stored on the junction until it is read out. Storage of a carrier will cause the voltage on the junction to decrease by $q/C(V)$. When the photogenerated charge is removed from the junction during readout, the junction voltage is restored to its original value.

If so much photogenerated charge is stored on the photodiode that the voltage drops to zero before the charge can be read out, additional charge cannot be collected and will diffuse into the *p*-type substrate. This condition is referred to as *saturation*. The diffusion of excess charge into neighboring photosites is called *blooming*.

One of the difficulties encountered in using the junction photodiode in image sensor applications is *image lag*. The combination of the capacitance of the photodiode and the channel resistance of the MOS transfer gate used to read out the diode give rise to a time constant for transferring the photogenerated charge from the diode to the readout structure. As a result, not all the charge can be completely drained from the diode during the short reset times typically used in imaging applications. The remaining charge is drained in successive readouts, causing an afterimage. This effect is called image lag.[3]

MOS Capacitor

The MOS capacitor consists of the silicon substrate (taken to be *p*-type in this section), a thin layer of silicon dioxide (typically 200 to 1000 Å thick), and an electrode (typically polycrystalline silicon doped heavily *n*-type with phosphorous). The physical structure and the band diagrams of the surface channel MOS capacitor are shown in Fig. 2*b* for a *p*-type substrate. If the gate of the MOS capacitor is biased positive, a depletion layer is created in the *p*-type silicon substrate. The depth of the depletion layer depends on the substrate doping, gate voltage, and oxide thickness. The calculation of the depth of the depletion layer is somewhat more complex than the photodiode* and depends on the electrostatic potential at the surface, called the surface potential Φ_s. For values typical of image sensors ($N_A = 1 \times 10^{15}$, 5-V gate bias, 500-Å oxide thickness) the depletion layer is 2.4 μm deep. On the edges of the photocapacitor (see Fig. 2*b*) is a heavily doped *p*-type region overlaid by a thick (2000- to 5000-Å) oxide layer. This is called the field or *channel stop* region. Because of the heavier *p*-type doping, the field is not depleted by the voltage on the gate. The channel stops confine the electrons to the channel region.

If the MOS capacitor is illuminated, a fraction of the light will be reflected, a fraction will be absorbed in the polysilicon, and the rest will be transmitted into the silicon substrate. The absorption coefficient of heavily doped polysilicon is shown as a function of wavelength in Fig. 1. The absorption coefficient is 4×10^4 cm^{-1} at 450 nm and 1.2×10^4 cm^{-1} at 550 nm. For a 3000-Å-thick polysilicon electrode, less than 30 percent of the blue light and less than 70 percent of the green light is transmitted through the polysilicon. The photons entering the silicon are absorbed, either in the depletion layer of the MOS capacitor or in the undepleted *p*-type silicon beneath the depletion layer. Those photogenerated electrons created in the undepleted *p*-type region move by diffusion until they are captured by the depletion layer or they recombine. The electrons are held at the silicon-SiO_2 interface, where they remain until they are read out. The quantum efficiency as a function of wavelength is illustrated in Fig. 3. The efficiency is low in the blue owing to absorption in the polysilicon. The structure in the quantum efficiency as a function of wavelength is due to multilayer interference in the polysilicon-oxide-silicon stack.

Charge is stored in the MOS capacitor at the silicon-silicon dioxide interface as a layer of sheet-charge only a few hundred angstroms thick. As more photogenerated charge is added, the surface potential decreases. If sufficient photogenerated charge is added, the surface potential becomes zero and no additional charge can be stored. This condition is saturation.

The capacitance per unit area on which photogenerated charge is stored is the parallel capacitance of the oxide and the depletion layer:

$$C^{-1} = \left(\frac{t_{ox}}{\varepsilon_{ox}} + \frac{W(\Phi_s)}{\varepsilon_{si}} \right) \tag{7}$$

where the depletion width $W(\Phi_s)$ is give by

$$W(\Phi_s) = \sqrt{\frac{2\varepsilon_{si}\Phi_s}{qN_A}} \tag{8}$$

in nearly all cases, the oxide capacitance is the dominant term. As a result, the storage capacity of the MOS capacitor is significantly larger than the junction diode in which the charge is stored only on the depletion capacitance.

A variant of the surface-channel photocapacitor is the buried-channel photocapacitor. The structure and band diagram are shown in Fig. 2*c*. In this device, a lightly-doped *n*-type region is diffused or implanted into the silicon surface early in the fabrication process. This *n*-type region is sufficiently lightly doped that it is fully depleted. The *n*-type dopant in the buried channel results in

*To determine the depletion depth, the surface potential Φ_s must be calculated which depends on the voltage on the gate of the MOS capacitor, the oxide thickness, substrate doping, and weakly on temperature. See reference on p. 32.3.

a band diagram with a potential minimum, or well, for electrons just below the surface.* This well is separated from the surface by a few thousand angstroms in distance and about 1 V in potential. When the buried-channel photocapacitor is illuminated, the electrons collect in the buried channel and do not contact the surface. The primary purpose of the buried channel is to prevent electrons from being trapped by interface states at the silicon-silicon dioxide interface.

The photocapacitor has several advantages over the junction photodiode. These include higher storage capacity per unit area, zero lag readout, and generally lower dark current. The principal disadvantage is the low quantum efficiency in the blue. In some applications, a transparent electrode, such as indium-tin-oxide (ITO) may be substituted to improve the blue response.[4] ITO has very low absorption over the visible (420 to 750 nm) and can be deposited sufficiently conductive for use as a gate electrode in an image sensor.

Another approach to achieving high quantum efficiency is the thinned backside-illuminated charge-coupled device (CCD). In this approach, the CCD (which is an array of MOS capacitors) is fabricated on the frontside of a silicon wafer. The wafer is then thinned from the backside to 10 μm or less in thickness. The backside is passivated to prevent surface recombination. Photons entering the backside are absorbed in silicon beneath the MOS capacitors (usually buried channel). The photogenerated carriers diffuse to the capacitors, where they are held until they are read out. This device has quantum efficiency similar to the photodiode in the visible. However, because the silicon is thin, some of the photons at wavelengths beyond 700 nm will not be absorbed and so the quantum efficiency falls off beyond 700 nm. Owing to their extreme complexity in process and their extremely fragile design, backside-illuminated image sensors are limited to special scientific applications, especially astronomy.

Pinned Photodiode

The third type of photosensitive element is the pinned (p^+np) photodiode.[5] This is sometimes called the *hole accumulation diode,* or HAD. This element combines the best features of the photodiode and photocapacitor, offering the high blue response of the photodiode with the high charge capacity, zero lag, and low dark current of the buried-channel photocapacitor. The pinned photodiode consists of a very shallow (<2000 Å) P^+ layer overlying an n-type buried-channel region. The structure and band diagrams are shown in Fig. 2*d.* The p^+ surface layer, which contacts the p^+ channel stop region on the sides, holds the electrostatic potential at the surface at 0 V. When the photodiode is illuminated, the photogenerated electrons are held in the n-type buried-channel region just below the surface.

The quantum efficiency of the pinned photodiode is nearly identical to that of the photodiode shown in Fig. 2. Because there is no overlying polysilicon electrode, the blue response is very high, similar to that of the photodiode. Because the buried-channel region can be completely emptied, the pinned photodiode does not have the lag of a normal junction (n^+p or p^+n) photodiode. The pinned photodiode has been the most widely used image-sensing element in interline area CCDs used for camcorders and for industrial and medical cameras. The pinned photodiode is also used in some linear image sensors, particularly where low image lag is critical.

Photoconductor

The last type of photosensitive device is the photoconductor. The most common material for the photoconductor is hydrogenated amorphous silicon, although other material systems have been explored. Amorphous silicon photoconductors have been used for two types of image sensors: area image

*For a review of the calculation of electrostatic potential and charge capacity of buried-channel MOS capacitors and charge-coupled devices, see B. C. Burkey, G. Lubberts, E. A. Trabka, and T. J. Tredwell, *IEEE Transactions on Electron Devices* **ED-31**(4):423 (April 1984).

sensors, where it is deposited on top of an area array to improve fill factor (i.e., the proportion of the picture element which is photosensitive), and contact linear sensors, where it is deposited on large ceramic or glass substrates to fabricate very long line or linear arrays.

The structure of an amorphous silicon photoconductor on a CCD image sensor and the corresponding band diagrams are shown in Fig. 2*e*. The hydrogenated amorphous silicon photoconductor consists of a back electrode, an undoped amorphous silicon layer approximately 1 μm thick, and a transparent top electrode.[6] Additional doped amorphous silicon or silicon nitride layers may be added to the amorphous silicon front or back surfaces to improve performance. Photons absorbed in the amorphous silicon generate electron-hole pairs. Photogenerated electrons and holes are quickly swept to the back and front electrodes, respectively, because of the high electric field in the photoconductor. When the amorphous silicon is used as part of an area image sensor, the electrons on the back electrode can be transferred into the readout element; when used as part of a contact linear array, the voltage change can be amplified and read out through a multiplexer.

The quantum efficiency of an amorphous silicon photoconductor is shown in Fig. 3. Owing to the wider bandgap of the amorphous silicon, photons of wavelength greater than about 650 nm are not absorbed. The advantage of the amorphous silicon is the high quantum efficiency across the visible wavelengths and the ability to fabricate devices either on top of area CCDs for higher fill factor or to process on glass or ceramic for very large linear sensors. The disadvantages include charge trapping at defects in the amorphous silicon and low carrier mobility, both of which lead to field-dependent nonlinear response and image lag when used in an image sensor. Improvements in material and device technology have mitigated many of these disadvantages at the expense of process and device complexity.[7]

Antiblooming in Charge-Sensing Elements

Blooming in image sensors occurs when the charge generated in an image-sensing element exceeds its capacity. If no method is provided to remove this excess charge, it will be injected either onto the readout element (CCD or MOS readout line) or into the substrate. If the excess charge is injected onto the readout element, it will usually appear as a bright line in the image. If it is injected into the substrate, the charge can diffuse in a circular pattern and be collected by neighboring elements.

There are two basic types of antiblooming circuits: lateral and vertical.[8,*] In lateral antiblooming, illustrated in Fig. 4*a* and *b,* a MOS antiblooming gate and an antiblooming drain are provided adjacent to each image-sensing element. Excess charge on the sensing element overflows the antiblooming gate onto the antiblooming drain. The antiblooming drains of all elements on the array are connected and the current sunk in a bias supply.

In a vertical antiblooming structure, illustrated in Fig. 4*c* and *d* for a pinned photodiode sensing element, the image-sensing element is fabricated in a shallow, lightly doped *p*-well. A large (10- to 30-V) bias is applied to the *n*-type silicon substrate, causing the *p*-well underneath the photodiode to become completely depleted. Once the charge on the diode exceeds its capacity, the excess charge flows over the saddle-point in the *p*-well, under the diode, and into the substrate. The substrate is connected to a bias supply which sinks the blooming current. The vertical antiblooming structure has the advantage of requiring no additional silicon area, so that antiblooming is achieved with no reduction in fill factor. Lateral antiblooming, on the other hand, requires additional silicon area in each pixel, thereby reducing fill factor. The vertical antiblooming has the disadvantage of lower quantum efficiency at wavelengths longer than about 500 nm. Because any light absorbed below the photodiode or photocapacitor is drained into the substrate, the quantum efficiency of photodiodes or photocapacitors with vertical antiblooming is reduced.

*Other types of antiblooming are occasionally used in image-sensing arrays. One of these is charge pumping, in which a MOS gate is repeatedly clocked in order to cause excess charge held underneath it to recombine at interface states at the silicon-silicon dioxide interface. In charge pumping, the MOS gate is pulsed sufficiently negative to cause accumulation, resulting in the interface stated filling with holes. When the gate is pulsed out of accumulation, excess electrons can recombine with the holes.

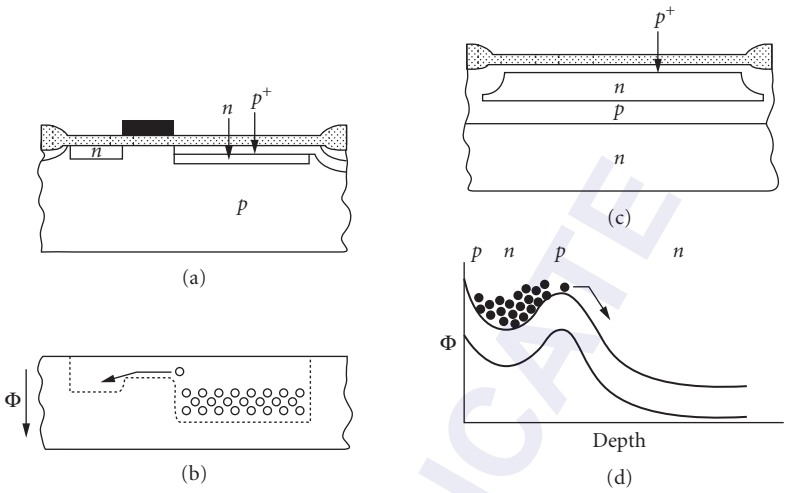

FIGURE 4 Antiblooming methods for image sensors: (*a*) cross section of lateral antiblooming structure; (*b*) illustration of electrostatic potential and charge overflow in lateral antiblooming; (*c*) cross section of vertical antiblooming structure; and (*d*) band diagram and illustration of charge overflow in vertical antiblooming.

Dark Current in Photosensing Elements

Signal in photosensing elements is the result of collection of electron-hole pairs generated by the absorption of light. However, charge is generated at each photosensing element even in the absence of light. This generation is called dark current and is a result of thermal generation of electron-hole pairs. The thermal generation occurs at defects, such as impurities or crystalline defects, in the bulk of silicon and at surface states at the silicon-silicon dioxide interface.

There are four sources of dark current: (1) diffusion current, which is the thermal generation of carriers in the undepleted *n*- and *p*-type regions; (2) depletion layer generation current, which occurs in the depletion layer of a diode or MOS capacitor; (3) surface generation current, which is the generation of electron-hole pairs at interface states at the Si-SiO_2 interface; and (4) leakage, which refers to generation at extended defects such as impurity clusters or stacking faults, particularly in the presence of a large electric field. These sources of dark current are illustrated for a photodiode and a photocapacitor in Fig. 5. The generation of the electron-hole pairs in both diffusion current and depletion-layer generation-recombination current occurs almost exclusively at impurity sites. Impurities with energy levels near midgap, such as gold, copper, and iron, are particularly effective in the thermal generation of charge. The depletion-layer generation current is given by*

$$J_g(V) = \frac{qn_i W(V)}{\tau_o} \tag{9}$$

where $W(V)$ is the width of the depletion layer at a given bias voltage in the MOS capacitor or junction-photodiode, n_i is the intrinsic carrier concentration, and τ_o is the depletion-layer lifetime, for carriers.

*The expressions here are for the generation current. The total current is the sum of the generation and recombination current given by

$$J_{gr}(V) = (qn_i W(V)/\tau_o)(e^{qV/2kT} - 1)$$

However, for diodes under 0.2 V or more of reverse bias ($qV/kT > 8$), such as would be the case in an image sensor, the recombination current is negligible.

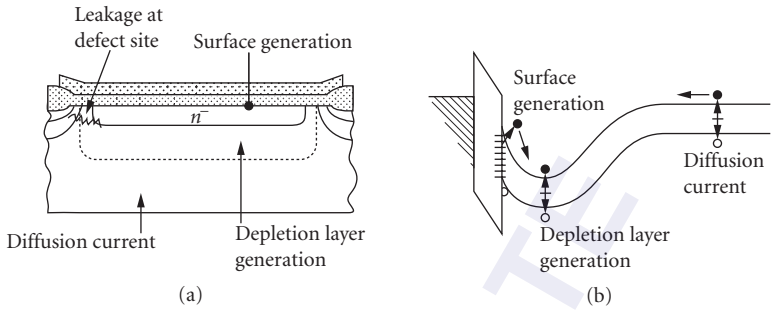

FIGURE 5 (*a*) Cross section of buried-channel MOS capacitor and (*b*) band diagram of buried-channel MOS capacitor illustrating mechanisms for dark current generation.

Typical values of τ_o in clean MOS processes would be 1 to 10 ms and values of J_{gr} would be 30 to 300 pA/cm^2.

The diffusion generation current for a *p*-type region is given by*

$$J_{\text{diff}} = \frac{q n_i^2 L_e}{N_a \tau_e} \tag{10}$$

Since the intrinsic carrier concentration n_i depends on temperature as $e^{-E_g/2kT}$, depletion-layer generation current and diffusion current will have different temperature dependences. Depletion-layer generation current will increase as $e^{-E_g/2kT}$, which corresponds to a doubling in dark current for every 9 to 11°C increase in temperature near room temperature. Diffusion current will increase as $e^{-E_g/2kT}$, which corresponds to a doubling every 4.5 to 5.5°C increase in temperature.

The surface generation current J_S occurs almost exclusively at regions where the depletion layer intersects the Si-SiO$_2$ interface, such as the surface region between the n^+- and *p*-regions around a photodiode or in the depleted surface under a MOS capacitor. It is given by

$$J_s = \frac{q n_i s_o}{2} \tag{11}$$

where s_o is the surface recombination velocity. A typical value of J_S for a MOS surface would be 100 pA/cm^2.[9,†] The surface generation depends on temperature in the same manner as the depletion-layer current. In very clean MOS processes (i.e., low concentration of metallic impurities in silicon), the surface current is often the largest component of the overall dark current.

Leakage current occurs at extended defects in silicon, such as impurity clusters and stacking faults, particularly when these defects are in a depletion layer and so are subject to a high electric field. While there is no single analytical expression for the current generated by an extended defect,

*The full expression for the diffusion current from the undepleted *p*-region in a diode is

$$J_{\text{diff}} = \frac{q n_i^2 L_e}{N_a \tau_e}(e^{qV/kt} - 1)$$

However, for reverse biases more than 0.2 V ($qV/kT > 8$), as would be the case in a photodiode in an image sensor, only the generation term is important.

†In calculating the total surface current, the current density J_s is multiplied by the area of the depleted surface. For a *pn* junction diode, this would be the area of depleted surface region around the diode between the *n*- and *p*-regions (i.e., approximately the junction perimeter times the depletion-layer width); for a MOS capacitor it would be the entire area under the MOS capacitor unless sufficient sheet charge of electrons had formed at the surface to invert the surface. The surface recombination velocity is given by $S_o = N_{st} \upsilon_{th} \sqrt{\sigma_n \sigma_p}$ where N_{st} is the density of surface states near midgap, υ_{th} is the thermal velocity (2.0×10^7 cm/s) and σ_n and σ_n are the electron and hole cross sections for midgap surface states. See reference on p. 32.3 for a complete explanation.

they are characterized by very high values of dark current ($\gg$1 nA/cm^2), a very strong dependence on the electric field, and, in regions of high electric field, only a very slight dependence on temperature. In an image sensor, they are visible as "bright spots" in a few isolated pixels against the otherwise low level of background thermal generation.[10]

Values for the dark current vary widely because of variation in the amount of impurities in the silicon; the dark current can range from 0.01 nA/cm^2 in very high quality image sensors to >10 nA/cm^2 in sensors with significant metallic contamination. The total number of electrons N_e collected in a pixel is

$$N_e = JAT_{int}/q \tag{12}$$

where J is the total dark current per unit area, A is the area of the pixel, and T_{int} is the integration time. For a 1/2-in format CCD such as would be used in a camcorder, typical values would be a dark current of 0.5 nA/cm^2, a pixel area of 100 μm^2, and an integration time of 1/30 second; the number of thermally generated electrons would be 105 electrons per pixel. Image sensors developed for scientific purposes might have a dark current 5 to 10 times lower at room temperature. These same devices might also be operated below room temperature to reduce the thermal generation to levels below one electron per pixel.

There are two types of noise associated with the charge generated by the dark current: shot noise and pattern noise. The shot noise due to the dark current is the square root of the number of dark electrons in a pixel. Pattern noise is due to pixel-to-pixel variations in the dark current and is often highly correlated between neighboring pixels. A numerical value for the dark pattern noise is typically obtained by using the standard deviation of the pixel values in the dark from a large region of an imager, where the values are obtained by averaging over many frames to eliminate shot noise and other temporal noise sources.*

32.4 READOUT ELEMENTS

The readout element transfers the charge from the image-sensing element (photodiode, photocapacitor, or photoconductor) to the output of the image sensor. In a linear sensor, the readout is only in one direction. In an area sensor, both x and y readout is required. There are two basic types of readout elements: charge-coupled devices, or CCDs, and x-y addressed photodiode arrays (typically called MOS arrays owing to the MOS transistors used in the addressing of the pixels). CCDs are by far the most widely used readout elements owing to their very low noise. Nearly all consumer camcorders, facsimile machines, scanners, copiers, and professional and scientific cameras utilize CCDs. Applications of MOS arrays are largely restricted to those where addressing of an individual pixel or subarray is required.

Charge-Coupled Device (CCD)

CCD Operation The CCD works by moving packets of charge physically at or near surface of silicon from the image-sensing element to an output, where the charge packet is converted into a voltage. The CCDs is formed by an array of overlapping MOS capacitors.[11–13] There are a number of different types of CCDs, including four-phase, three-phase, two-phase, virtual (single-) phase, and ripple-clocked CCDs. The number of phases refers to the number of separately clocked elements

*A histogram of the dark current values of the pixels is rarely gaussian. In most cases, it exhibits an extended tail at high dark current values due to pixels with crystalline defects. The histogram may also exhibit quantization due to pixels with integral number of impurities (i.e., 1, 2, or 3 gold atoms); the quantization may even be used as a signature of the impurity present. See, for example, McColgin et al., "Effects of Deliberate Metal Contamination on CCD Image Sensors," *Materials Research Society Symposium Proceedings,* **262:** 769 (1992) and "Dark Current Quantization in CCD Image Sensors," *Proc. 1992 International Electron Device Meeting,* Washington, D.C., 113–116 (1992).

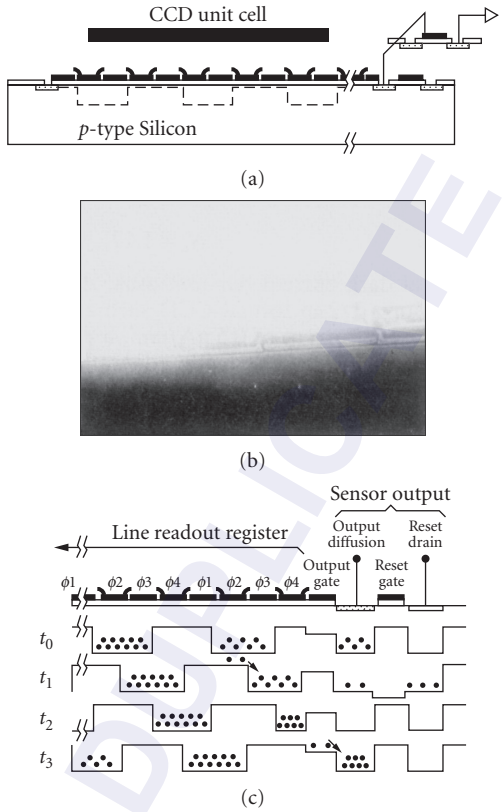

FIGURE 6 (*a*) Cross-sectional diagram of unit cell of a four-phase CCD; (*b*) scanning electron micrograph of a unit cell of a four-phase CCD; and (*c*) illustration of charge transfer along a four-phase CCD, showing both transfer along the register and at the sensor output.

within a single stage of the CCD. These are described later. For understanding the principle of charge transfer in a CCD, consider the four-phase CCD illustrated in Fig. 6*a*.

The four-phase CCD physically comprises a silicon substrate (assumed to be *p*-type for purposes of illustration), a gate oxide 300 to 1000 Å thick, and overlapping polysilicon electrodes 1000 to 5000 Å thick which have been heavily doped with phosphorus to lower their resistance. For a four-phase CCD, two levels of electrode are required. The first level is deposited, then defined photolithographically to form two phases ($\phi 1$ and $\phi 3$). A thin (500-Å) oxide is grown over the first level of polysilicon to insulate it from the second level. The second level of polysilicon is then deposited, doped with phosphorus, and defined to form the other two phases ($\phi 2$ and $\phi 4$). An electron micrograph of a four-phase CCD with six-micron long gates is shown in Fig. 6*b*.

The process of charge transfer in a four-phase CCD is illustrated in Fig. 6*c*. In order to hold a packet of electrons, two adjacent gates ($\phi 2$ and $\phi 3$, for example) would be held at a high positive potential (~+5 V) while the other two phases would be held at a low potential (~0 V). A depletion layer, or well, is formed under $\phi 2$ and $\phi 3$, allowing electrons to be held at or below the surface. The other two phases, $\phi 1$ and $\phi 4$, serve as potential barriers, keeping the charge packet under $\phi 2$ and $\phi 3$. To transfer the electrons through silicon, the electrode ahead of the charge packet ($\phi 4$) is clocked

positive and the electrode behind ($\phi 2$) is clocked negative. The electrons move along the silicon surface following the positive potential. This is repeated through all four phases, during which the charge packet is moved forward one pixel.

The CCD may be either surface-channel or buried-channel. In a surface-channel CCD (Figs. 2*b* and 6*a*) the electrons are held at the silicon surface. Surface-channel CCDs are rarely used owing to the trapping of electrons at interface states at the silicon surface. At the silicon-SiO_2 interface there is a density of states of about $1 \times 10^{10} cm^{-2}\ eV^{-1}$. These states can trap electrons from one charge packet and reemit the electrons into a later charge packet. This results in transfer efficiency. In the buried-channel CCD (Figs. 2*c* and 6*d*), a lightly doped *n*-type layer is formed in silicon. This *n*-type layer results in a potential well for electrons just below the surface rather than at the surface (Fig. 2*b*). As a result, the electrons remain separated from the interface and are not trapped by interface states. This results in the ability to transfer charge from one stage to another with very high efficiency. Virtually all CCDs for image-sensing applications utilize buried-channel CCDs. The clock voltages used to drive CCD gates typically swing by 5 to 8 V between high and low levels.

For buried-channel CCDs, transfer rates of up to 20 MPix/s can usually be achieved without special design considerations. Above this rate, special attention must be paid to optimizing the electric field along the direction of transfer to speed up charge transfer. Transfer rates exceeding 50 MPix/s have been achieved in optimized CCD designs.[14]

CCD Output At the output of the CCD is a circuit to convert the charge packets into a voltage signal. By far the most common type of output circuit is the floating diffusion with source follower amplifier. The floating diffusion output is shown schematically in Fig. 7*a* and a photograph of the end of a CCD shift register with the first stage of the amplifier is shown in Fig. 7*b*. The floating diffusion output consists of an output gate (OG), a floating diffusion, a reset gate (RG), and a reset drain. The floating diffusion is an n^+-type region between the output gate and the reset gate. The floating diffusion is connected to the gate of a source-follower amplifier. The output gate is held at a fixed dc voltage, creating a barrier potential over which the packet of electrons can be transferred onto the floating diffusion when the last phase of the CCD register is clocked to its low (~0 V) voltage.

The sequence of events in the CCD output is shown in Fig. 6*c*. As the charge packet is transferred along the CCD, it arrives at the last phase ($\phi 4$) before the output gate (time t_2 in Fig. 6c). When $\phi 4$ is clocked low (time t_3), the packet of electrons is transferred over the output gate onto the floating diffusion (time t_0). The voltage of the floating diffusion changes by an amount

$$V = N\mathrm{q}/C \tag{13}$$

where N is the number of electrons and C is the total capacitance of the floating diffusion itself, the interconnect to the source-follower amplifier and the input capacitance of the amplifier. In typical CCDs, this capacitance would be in the 10- to 50-fF range. Because this capacitance is so small, there is a large change in voltage for a small change in charge. The charge-to-voltage conversion is an important parameter in CCD design; for a 10-fF capacitance the charge-to-voltage conversion is 16 μV/electron. After the change in voltage has been sensed by the amplifier, the charge packet must be removed from the floating diffusion before the next packet arrives. This is achieved by clocking the reset gate positive (time t_1 in Fig. 6*c*), allowing the charge packet to flow from the floating diffusion to the reset drain. The reset drain is held at a constant positive voltage, typically ~10 V. The reset drain is then turned off and the floating diffusion is prepared to accept the next packet of electrons.

The change in voltage from the floating diffusion is typically buffered on-chip by a source-follower (Fig. 7*c*). A two-stage source follower is most often used. The first stage utilizes very small-dimensioned FET transistors in order to minimize the input capacitance. The second uses much larger FET transistors in order to achieve sufficient drive current to overcome off-chip capacitances such as package and lead capacitances on the circuit board. The source-follower amplifier is typically designed to have a bandwidth on the order of ten times the CCD pixel rate. For high-pixel-rate applications (>10 MPix/s), three-stage source-follower amplifiers are employed.

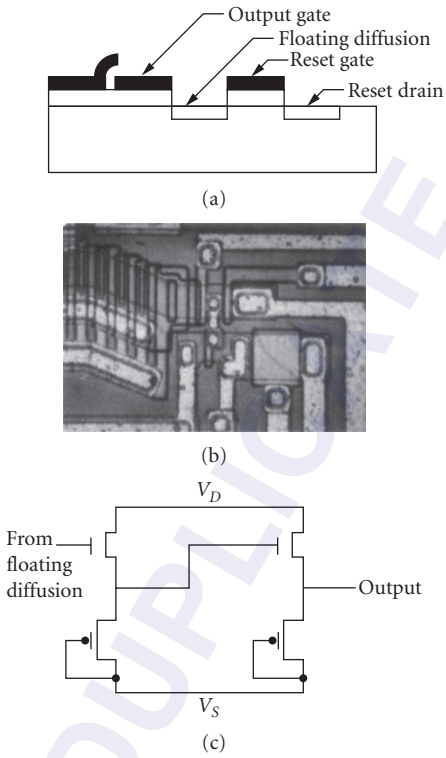

FIGURE 7 (*a*) Cross section of the floating diffusion output for a CCD; (*b*) photomicrograph of a floating diffusion output including the first stage of the source-follower amplifier; and (*c*) two-stage source-follower amplifier with on-chip loads.

For special purpose applications, such as CCD signal processing, nondestructive readout is required. Floating gate output amplifiers are used in these applications. These amplifiers are similar to the floating diffusion except that the floating diffusion is replaced by a MOS gate which is connected to the MOS amplifier. Other outputs, such as buried-channel JFET structures, have seen limited use in very low noise applications.[15]

Types of CCDs In addition to the four-phase CCD described here, there are a number of other types of CCD shift registers, including three-phase, two-phase, and virtual phase. The different types are illustrated in Fig. 8. The four-phase CCD (Fig. 8*a*) was described previously. The three-phase (Fig. 8*b*) consists of three different layers of polysilicon electrodes. The charge is normally held under one of the three; during transfer, the gate ahead of the charge packet is clocked positive and the gate holding the charge is clocked negative in order to transfer the charge one gate ahead. The three-phase CCD has the advantage of a shorter unit cell than the four-phase but at the expense of additional processing complexity (i.e., a third polysilicon layer).

In the two-phase CCD, each phase has a barrier and a well region. The barrier is formed by doping the barrier region slightly less *n*-type than the well region, making the electrostatic potential in the barrier region a few volts lower than the well region for the same gate voltage. Electrons will flow over the barrier region and be held in the well region. There are two methods of fabricating a two-phase CCD. In the first method (Fig. 8*c*), two separate gates are used for each phase; one gate receives

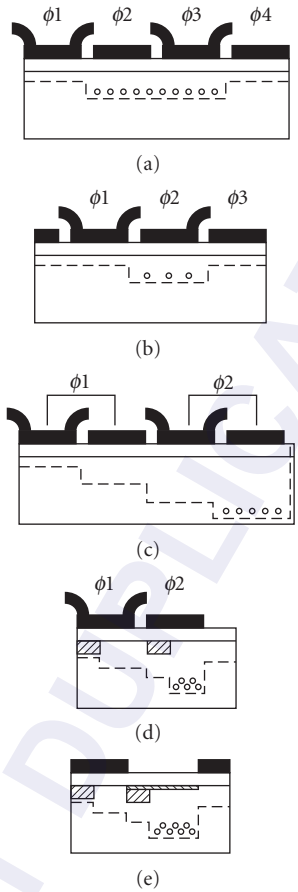

FIGURE 8 Types of CCD registers: (*a*) four-phase; (*b*) three-phase; (*c*) pseudo-two-phase; (*d*) true two-phase; and (*e*) virtual phase. In the pseudo-two-phase CCD, each phase consists of two polysilicon gates, one of which is offset in potential from the other by an implanted threshold adjustment. In the true two-phase CCD, each phase consists of a single polysilicon gate in which the implanted threshold-adjust region is formed underneath a portion of the gate.

a threshold-adjust ion implantation in order to create the barrier region. The two gates, however, are connected and thus driven at the same voltage. In the other method (Fig. 8*d*), the barrier and well regions are created under a single polysilicon gate. The two-phase CCD is very commonly used for three reasons. First, it requires only two clocks ($\phi 1$ and $\phi 2$), simplifying drive circuitry. Second, the clocks are complementary. This reduces clock feedthrough. Third, the two-phase has a higher horizontal density, especially the two-phase with barrier and well regions under the same gate.

The virtual phase CCD[16,17] (Fig. 8*e*) consists of one gate with both barrier and well regions within it and a second region, the virtual phase, in which a shallow high-dose ion implantation is used to create a heavily doped surface region which pins the surface potential at 0 V. The virtual phase has both barrier and well regions within it and acts the same as a polysilicon gate held at a constant voltage. Charge is first transferred from the clocked phase into the virtual phase, then the charge is transferred from the virtual phase into the next clocked phase. The virtual phase CCD has a number of advantages, including higher quantum efficiency than two-polysilicon-level area CCD sensors and simpler clocking. The disadvantages of the virtual phase include the need for larger voltage

swings on the single-clock and high-clock feedthrough into the output due to the lack of complementary clocks.

CCD Characteristics The four major performance parameters of a CCD shift register and output amplifier are charge-handling capacity, charge-transfer efficiency, charge-to-voltage conversion ratio, and noise. The charge capacity is the number of electrons which can be held and transferred in the CCD shift register. As charge is added to a shift register, a point is reached at which excess charge cannot be held; the excess charge either overflows into adjacent pixels or overflows into the bulk beneath the CCD or, in the case of a buried-channel CCD, overflows the barrier to the $Si\text{-}SiO_2$ surface. The charge capacity is a function of the device design, device layout, and CCD process. Figure 9*a* shows the electrostatic potential and charge distribution in a buried-channel CCD at three levels of charge: approximately one-quarter of saturation, at saturation, and beyond saturation. Below saturation, the electrons fill the center of the buried channel in the region of largest potential, separated from the surface by approximately 0.2 μm in distance and about 500 mV in potential. As more charge is added, the electron distribution spreads toward the surface and the potential barrier to the surface drops. Beyond saturation, the electrons contact the surface directly, resulting in charge-transfer inefficiency and blooming to neighboring pixels. The charge capacity of most CCD shift registers is of the order 1×10^{12} electrons/cm^2 of area in which the charge is held. In most CCD cells, the charge is held in only a fraction of the total cell area both along and across the CCD register. Typically, area CCD image sensors are designed with CCD charge capacities in the range of 50,000 to 200,000 electrons. Linear CCD image sensors, because of the larger amount of silicon area available for the CCD shift register, often are designed for 100,000 to 1,000,000 electrons.

The second major performance parameter for CCD shift registers is charge transfer efficiency. The transfer of charge from one stage to the next is neither instantaneous nor complete, limiting both transfer rate and the total number of stages in the CCD. There are two intrinsic mechanisms governing charge transfer: drift and diffusion. Drift is the movement of charge in the presence of an electric field. There are two origins of the electric field seen by an electron during charge transfer:

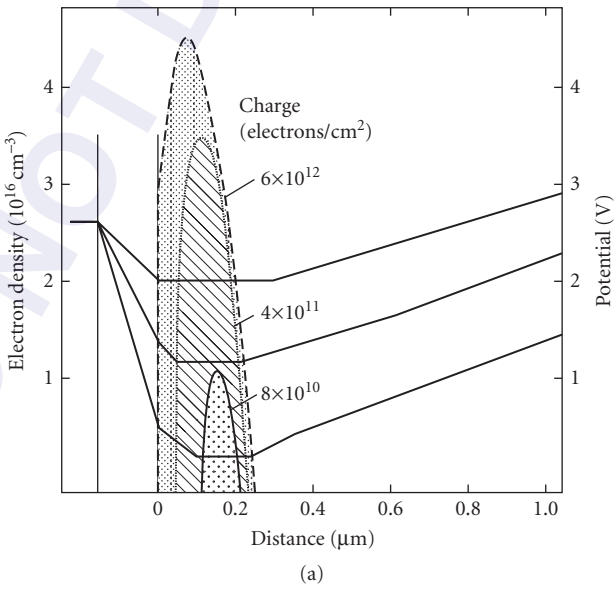

FIGURE 9 (*a*) Charge distribution and electrostatic potential as a function of distance from the surface for a buried-channel CCD for three levels of charge density.

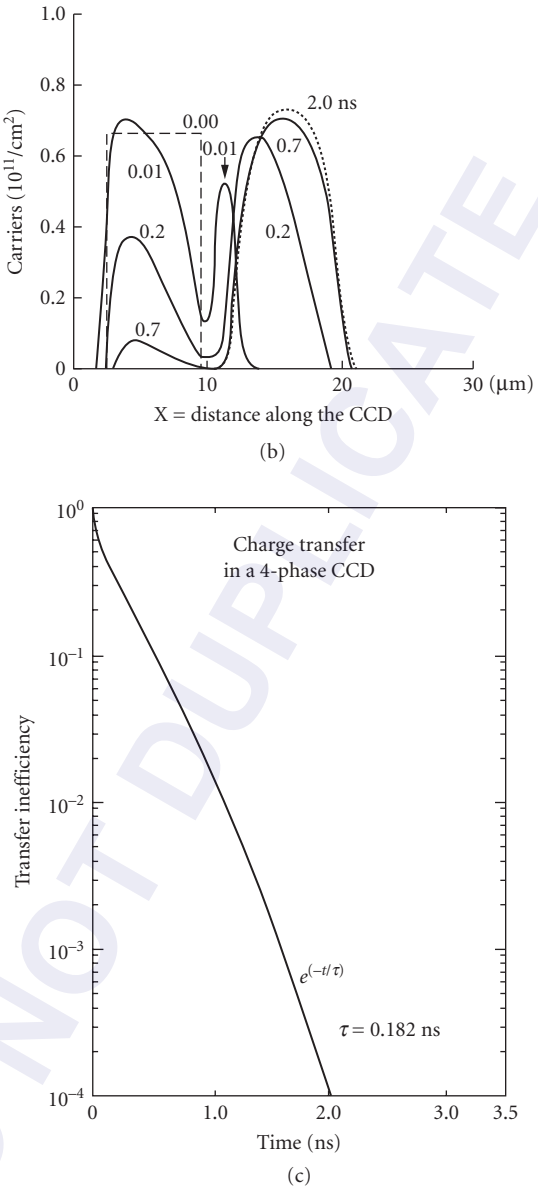

FIGURE 9 (*b*) Charge density as a function of distance along a CCD for various times following the beginning of charge transfer from one 8-μm stage to another and (*c*) charge transfer inefficiency as a function of time from the start of charge transfer for the same example. (*Continued*)

the self-induced field resulting from the other electrons under the gate and the externally induced or fringing field. During the early stages of charge transfer, the self-induced field is large and is the dominant factor. After the charge concentration under the gate has decreased to a low value, the remainder of the charge transfer will be governed either by diffusion or by drift due to externally induced or fringing fields.

For a surface-channel CCD, the self-induced fields can be estimated from the formula:

$$E = -\frac{q}{C}\frac{dN}{dx} \tag{14}$$

where C is the gate capacitance per unit area and $N(x)$ is the density of electrons as a function of distance x from the edge of the electrode. In the early stages of charge transfer, both N and dN/dx are large. As the transfer proceeds, both N and dN/dx become small and the charge transfer is governed by fringing fields and diffusion.

Fringing fields are due to the two-dimensional nature of the electrostatic potential. If the charge is being transferred from gate 1 to 2, the potential will change smoothly between the two gates. The effect of the potential from one gate will typically extend 1 to 3 μm into a neighboring gate. The charge within the range of the fringing field will move by drift to the neighboring gate. Charge out of the range of the fringing fields will move by diffusion.

Figure 9*b* shows an example of charge transfer calculated for charge transfer from one 8-μm-long CCD gate into an adjacent gate. The charge density is shown as a function of distance along the CCD at several times after the start of charge transfer. At the start of the transfer, all the charge is under the first gate. At 0.01 ns into the transfer, the charge has moved from the edge of the first gate into the second gate, as a result of self-induced drift. By 0.2 ns, approximately half the charge has been transferred. By 0.7 ns, over 90 percent of the charge has moved into the second gate, leaving a residual in the first. At this point, the self-induced drift is sufficiently small that drift due to fringing fields and diffusion are the dominant mechanisms. Figure 9*c* shows the charge transfer inefficiency as a function of time for this example. Two slopes are evident in the transfer inefficiency. In the first 0.5 ns, the charge is transferred rapidly owing to the self-induced drift. For times longer than 0.7 ns, the transfer is due to fringing fields in this example.

For CCDs with longer gates or lower fringing fields than the example above, the final ~10 percent of the charge must transfer by diffusion. Charge transfer by diffusion follows an exponential time dependence.

$$N(t) = N(0)e^{-t/\tau_{\text{diff}}} \tag{15}$$

where, the time constant τ_{diff} for diffusion is

$$\tau_{\text{diff}} = \frac{4L_g^2}{\pi^2 D} \tag{16}$$

Here, L_g is one gate length and $D = KT\mu_e/q$.

For electrons at room temperature, D = 25.8 cm^2/s. For an 8-μm long gate, the diffusion time constant is ~10 ns. To achieve a transfer inefficiency below 2×10^{-5} per transfer, 11 time-constants, or 110 ns in this example, are required. For this reason CCDs are typically designed with gate lengths shorter than ~8 μm and to build-in fringing fields.

In the simplest case for very low levels of transfer inefficiency, the total transfer inefficiency in a CCD register is the product of the number of stages N in the register and the transfer inefficiency per stage. Each stage will require two or more transfers. Virtual phase and two-phase require two transfers per stage, three-phase requires three transfers, and four-phase requires four transfers. The inefficiency per stage, however, will likely depend in a complicated manner on the amount of charge in the charge packet, the amount of charge in preceding charge packets, the voltages, and frequency of operation. The charge in the preceding packets will affect the filling of both bulk and interface traps.

In addition to the intrinsic sources of transfer inefficiency, there are a variety of extrinsic sources. These include surface and bulk traps and potential wells and barriers. The traps and the potential obstacles hold back an amount of charge from a charge packet. The charge is reemitted to later charge packets. The inefficiency due to traps depends on whether the traps have been filled by preceding charge packets and the emission time constants of the traps, and so is not modeled in a simple manner.

The intrinsic sources of noise in CCD shift registers include dark current and output amplifier noise. In addition, other sources of noise not intrinsic to the CCD itself include noise due to clock feedthrough from the CCD clocks to the output signal and noise in external electronics. The generation of dark current in CCD shift registers is the same as described at the end of Sec. 32.3 for photosensing elements. Associated with the dark current are both shot noise and pattern noise. The magnitude of the pattern noise in a CCD shift register is reduced over that of a single element since the charge packet averages the dark current over many pixels as it is transferred to the output.

The noise associated with the CCD output consists of the Johnson or thermal noise, the $1/f$ noise of the output amplifier, and the kTC noise associated with resetting the floating diffusion. The kTC noise is due to uncertainty in the amount of charge remaining on the floating diffusion following reset owing to thermal fluctuations in the reset gate. The rms noise σ_n in the number of electrons caused by kTC noise is given by

$$\sigma_n = \sqrt{\frac{kT}{q} C_{FD}} \tag{17}$$

where C_{FD} is one total floating diffusion capacitance. For a 10-fF floating diffusion capacitance, the rms noise is ~40 electrons.

The kTC noise may be eliminated entirely by use of a signal-processing technique called correlated double sampling (CDS). In correlated double sampling, the output level is sampled before the charge packet is transferred onto the floating diffusion and again after transfer of the charge packet (times t_2 and t_0 respectively in Fig. 6*c*). The two values are subtracted either by an analog circuit or by digital subtraction. Any uncertainty in the voltage level of the floating diffusion following reset is subtracted and thus the kTC noise eliminated. The output amplifier low-frequency noise, called $1/f$ noise because of the inverse frequency ($1/f$) shape of the noise power spectrum, is also reduced but not eliminated by correlated double sampling. The total noise of a CCD output amplifier is in the range of 7 to 40 rms electrons per pixel depending on the amplifier design and the operating speed. Values of a single rms electron or less have been obtained for very slow pixel rates under cooled conditions.[18]

MOS Readout

The other major category of readout structures is the MOS readout. The individual light-sensing elements (photodiodes, photocapacitors, or photoconductors) at each pixel are connected to a readout line by means of a transfer gate. Each pixel along the readout line is addressed separately by addressing circuitry. When a particular pixel is addressed, the transfer gate is turned on and the charge transferred from the pixel to the readout line. An amplifier at the end of the readout line senses the change in voltage or current resulting from the charge transfer.

Typically, the pixels would be addressed serially along the line. The first pixel would be addressed, causing the charge from the image-sensing element to be transferred onto the readout line. The voltage change or current would be sensed, the readout line reset to its original voltage if necessary, and the next pixel addressed. This is different from a CCD. In the CCD, charge from all pixels is transferred into the CCD register simultaneously. Individual pixels or groups of pixels cannot easily be addressed in a random fashion by the CCD, but this random addressing can be accomplished readily by the MOS readout.

There are several types of MOS readout devices. These include the CID,[19] the AMI,[20] and the CMD[21] in addition to the normal MOS array. The CID has no readout line. Each pixel consists of two overlapping gates, one controlled by a row address and the other by a column address.[11] When neither a row nor a column of a particular pixel is being addressed, the photogenerated charge is held under both gates and can be transferred between them. When a row of a pixel is addressed, the charge transfers onto the column gate. Then both row and column are addressed, the charge is injected into the substrate, and the current sensed. The CID is not widely used in visible imaging applications because the charge conversion sensitivity is very poor and noise very high compared to the CCD or the other MOS architectures.

In the amplified MOS imager (AMI), the image-sensing element at each pixel consists of a phototransistor rather than a simple photodiode. The photogenerated charge is stored on the gate of the MOS transistor.[19] When a particular pixel is addressed, the photogenerated charge modulates the transistor current. This current amplification at each pixel helps to overcome many of the noise and speed limitations of conventional MOS arrays.

MOS readout differs in an important way from CCD readout. In MOS readout, the charge is transferred from a single pixel onto a readout line and the change in voltage or current in the readout line is sensed. In a CCD, the charge packets are kept intact while being transferred physically to a low-capacitance output. The lower sensitivity of a simple MOS array can be illustrated as follows. The change in voltage on the readout line is given by $V = Nq/C$ where N is the number of electrons, and C is the readout line capacitance. Because the readout line covers the full length of the array, its capacitance is in the picofarad range (typically 2 to 10 pF depending on design and process). This compares to the 10-fF capacitance for the CCD output. As a result, the voltage swings on the readout line are very small (16 nV/electron for a 10-pF readout line capacitance). This leads to a high sensitivity to clock noise due to capacitive feedthrough of the row and column address clocks onto the readout line. The feedthrough may be many times larger than the signal in most MOS sensors. Once the charge has been transferred onto the readout line, it is sensed either by a current-sensitive amplifier or by a voltage-sensitive amplifier, followed by a reset of the readout line to its original voltage.

CCD readout has the advantages of very high sensitivity and low noise. However, CCD readouts are limited in charge-handling capacity, while MOS readouts are capable of carrying very large amounts of charge and so are not as limited on the high end of the dynamic range. However, because the MOS readout line has much higher capacitance than the CCD, the sensitivity is lower and the noise is higher. Another difference is in the readout architecture. The CCD readout is essentially serial and not suited to random readout or partial-array readout. The MOS array, however, can be addressed in a manner similar to a memory, making it well-suited to pixel or partial-array addressing.

32.5 SENSOR ARCHITECTURES

Solid-state image sensors are classified into two basic groupings: linear and area. Linear sensors include single-line arrays, multilinear arrays for color scanning, and time delay and integrate (TDI) arrays for low-light-level scanning. Area sensor architectures include the frame transfer CCD, the interline transfer CCD, and various forms of MOS *x-y* addressed arrays.

Linear Image Sensor Arrays

Linear sensors are used almost exclusively in scanning systems for scanning documents, film, and three-dimensional still objects. There are two basic classes of scanning systems: contact scanners and reduction scanners. These are illustrated in Figs. 10*a* and *b*. In reduction scanners (Fig. 10*a*), the sensor is smaller than the document to be scanned; lenses are used to image the document onto the sensor. In contact scanners (Fig. 10*b*), the sensor is the same width as the item to be scanned, usually a document. Relay optics is used between the sensor and the document. Selfoc lenses (Fig. 10*c* and *d*) and roof-mirror-lens arrays are the two types of relay optics used most frequently.

There are three basic architectures for linear sensing arrays: MOS line arrays, CCD linear and multilinear sensors, and time-delay and integrate (TDI) sensors. These architectures are illustrated in Fig. 11. The MOS array is used most often in contact scanning applications where material or processing problems make CCD arrays impractical. These applications include arrays fabricated from polysilicon or amorphous silicon on nonsilicon substrates, arrays covering large distances, or arrays requiring special processing (such as logarithmic amplification) at each pixel. The CCD linear and multilinear arrays are used most often in reduction scanning where wide dynamic range

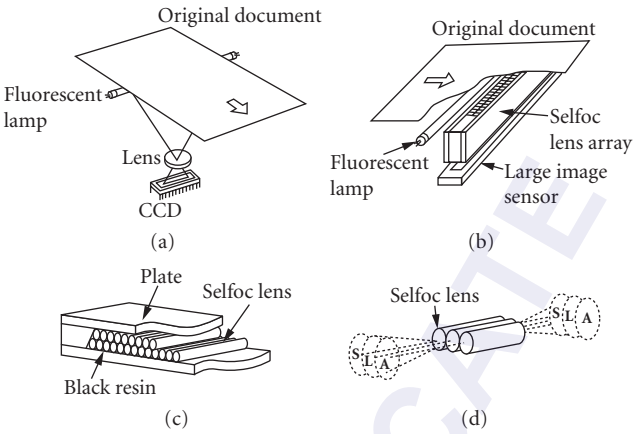

FIGURE 10 (*a*) Reduction document scanner using linear image sensor, in which the image on the page is reduced by a lens onto the line array; (*b*) contact document scanner in which the length of the image sensor is the same as the document width and one-to-one relay optics is used to transfer the image from the document to the array; (*c*) diagram of a selfoc lens array used as transfer optics between document and array in a contact scanner; and (*d*) operation of a selfoc lens array.

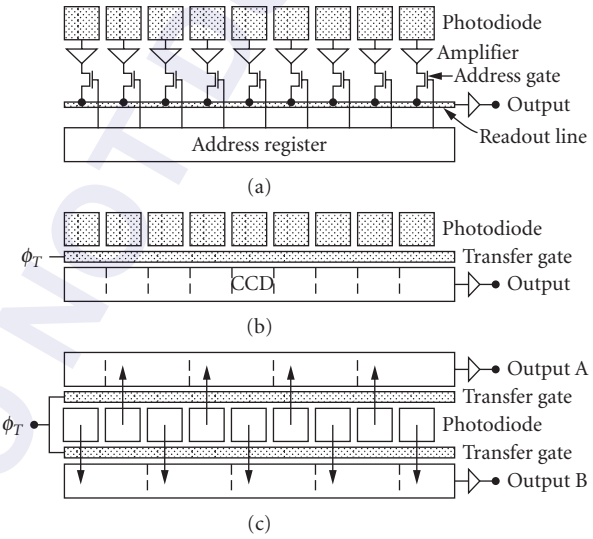

FIGURE 11 Architectures for linear image sensors: (*a*) MOS line array consisting of photodiodes, preamplifier, MOS switches addressed by an address register, and a readout line with amplifier; (*b*) linear CCD image sensor consisting of photo-diodes, transfer gate, and CCD readout; and (*c*) linear CCD image sensor with two CCD output registers, one for the odd diodes and the other for the even diodes, for higher horizontal pitch.

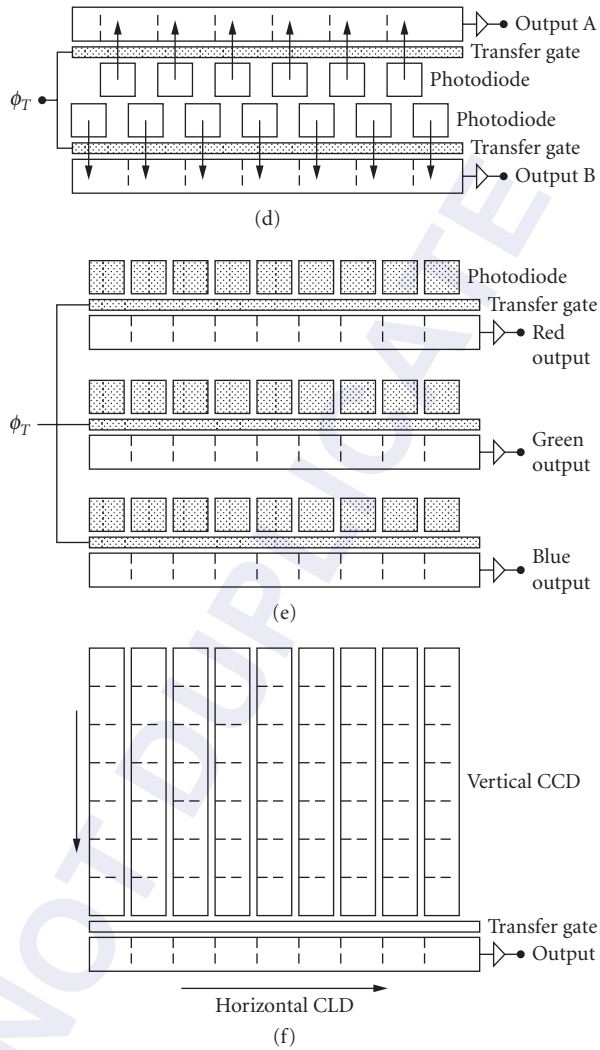

FIGURE 11 (*d*) Staggered linear CCD image sensor with two rows of photodiodes offset by one-half pixel to increase horizontal sampling; (*e*) trilinear CCD in which three CCDs are fabricated on the same silicon die, each with its own color filter; and (*f*) time-delay and integrate (TDI) array, in which the charge in the vertical registers is clocked in phase with the motion of the scene or document being imaged in order to increase signal-to-noise. (*Continued*)

and small pixel size are required. However, contact arrays are also often realized by butting multiple CCD arrays end-to-end. TDI arrays are used in very low-light-level scanning applications where integration over many lines is required to achieve adequate signal-to-noise ratio.

The MOS linear array (Fig. 11*a*) consists of individual photosensing elements, an amplifier, an address switch, and a readout line and amplifier. The photosensing element is usually a photodiode,

although photoconductors are used in contact scanning arrays fabricated from amorphous silicon. Since the charge generated in the diode is generally very small (in the hundreds to thousands of electrons), a simple amplifier is usually placed at each pixel to drive the high-capacitance readout line. The use of amplification at each pixel can allow some signal-processing functions, such as logarithmic amplification, clipping, triggering and latching, etc., to be performed at the pixel. A MOS switch placed after the amplifier allows each pixel to be addressed in sequence; the switch is driven by an address register. At the end of the readout line is an amplifier which may buffer and/or amplify the signal. The MOS array has the advantage of process simplicity and the ability to perform signal processing at each pixel; it has the disadvantage of low signal level (because of the large readout line capacitance) and pattern noise introduced by feedthrough from the switching transistor.

The linear CCD image sensor is the most often used architecture for scanning applications owing to its low noise, high sensitivity, wide dynamic range, and small pixel pitch. Figure 11*b* shows the simplest type of linear CCD, in which a single row of photodiodes is connected to a single CCD register via a transfer gate. In operation, the signal is integrated on the image-sensing element (generally a photodiode) for a line time. The horizontal CCD is then stopped, the transfer gate opened, and the charge transferred from all the photodiodes simultaneously to the CCD. The transfer time is typically a few microseconds. The transfer gate is then closed, integration resumed for the next line, and the CCD clocked to read out the charge packets. Many arrays also feature antiblooming for situations where the light level may not be controlled, as well as electronic shuttering, which allows an integration time on the photodiodes to be less than the readout time of the CCD.

For linear-sensing applications requiring a higher pixel density, a double-sided readout is often used (Fig. 11*c*). In this architecture, a CCD array is placed on either side of the line of photodiodes and charge transfer from the diodes alternates between the top and bottom CCDs. This architecture uses lower horizontal clock rates and a higher pixel pitch, since the diode pitch can usually be made smaller than the CCD pitch. The charge packets from the two arrays may be multiplexed into one output if desired. The disadvantage of this architecture is the slight differences between even and odd pixels, due to slight differences in the two outputs (or slight differences due to multiplexing the two registers).

Another architecture which is used to further decrease the sampling pitch is the staggered linear array (Fig. 11*d*). In the staggered array, two rows of photodiodes are offset by a half pixel. The two rows are read out by CCD arrays. The first array is delayed (usually in a digital line store) and then combined with the second to form a double-density scan.

Multilinear arrays (Fig. 11*d*) have been developed for color scanning applications. In this architecture, several (usually three) linear arrays are combined on the same silicon die separated by a distance equivalent to an integral number of scan lines. Color filters (either integral or in close proximity) are aligned over the arrays. External digital line delays are used to realign the three arrays. Separate electronic shuttering may be provided for each array in order to adjust for differences in intensity in each of the bands.

The third major class of line arrays is time-delay and integrate, or TDI, arrays.[22,23] The TDI architecture is shown in Fig. 11*f*. TDI arrays are used when inadequate signal-to-noise ratio from a single-line array requires averaging over multiple lines. Applications for TDI arrays include high-speed document scanners and space-based imaging systems. Instead of a single row of photodiodes, the TDI array utilizes CCD stages in the vertical dimension which are clocked synchronously with the movement of the document to be scanned. The signal level in a TDI array increases linearly with the number of stages. The noise level, however, increases most as the square root of the number of stages.

Area Image Sensor Arrays

There are three major classes of area image sensor architectures: MOS diode arrays, frame-transfer CCDs, and interline-transfer CCDs. Within each there are a number of variations. CCDs have come to dominate the majority of applications owing to their higher sensitivity. However, MOS arrays are still used for specialized applications where addressability or high readout rate is important.

TABLE 1 Image Area Dimensions and Pixel Dimensions for Various Format Image Sensors

The format name is given in inches based on historic image tube formats. The pixel dimensions are based on a 484 × 768 *pixel array.*

Optical format	1 in	2/3 in	1/2 in	1/3 in	1/4 in
Active area (4:3 aspect ratio)					
Height (mm)	9.6	6.6	4.8	3.3	2.4
Width (mm)	12.8	8.8	6.4	4.4	3.2
Diagonal (mm)	16	11	8	5.5	4
Pixel dimensions (484 lines × 768 pixels)					
Height (μm)	19.8	13.6	9.9	6.8	4.9
Width (μm)	16.7	11.5	8.3	5.7	4.2

Historically, the physical dimensions of the active imaging areas of CCD arrays for consumer and commercial applications are specified by the size of the vidicon tube which it replaces. The common format sizes include 1/4, 1/3, 1/2, and 1 in. In most cases, the aspect ratio is 4:3, reflecting the television standard. Table 1 lists the formats and the corresponding dimensions of the imaging area of the array.

The standards for the number of vertical lines in arrays for consumer and professional video are usually based on the corresponding television standards, including NTSC, PAL, and the various HDTV standards. NTSC has 484 active lines, PAL has 575, the Japanese HDTV standard has 1035, and the European HDTV standard has 1150. In all cases the lines are interlaced; i.e., odd lines are read out in one field and even lines in the next. Historically, for sensors for NTSC television, the number of pixels horizontally in a line has been associated with multiples of the color subcarrier frequency; common horizontal pixel counts include 384, 576, and 768. Sensors for the Japanese HDTV standard typically have 1920 horizontal pixels. The pixels are rectangular rather than square. Table 1 lists approximate pixel dimensions in micrometers for a few common formats for a 484(V) × 768(H) pixel image sensor.

For industrial, scientific, graphics electronic photography, digital television, and multimedia applications, however, the nonsquare pixels and interlaced readout of sensors based on television standards are significant disadvantages. Image sensors designed for these industrial and commercial applications typically have square pixels and progressive scan readout. In interlaced NTSC readout, for example, the first field consists of lines 1, 3, 5 ⋯ 483 and is read out in the first 1/60 second of a frame. The second field consists of lines 2, 4, 6 ⋯ 484 and is read out in the second 1/60 second of a frame. The resulting temporal and spatial displacement between the two fields is undesirable for these applications. In addition, digital compression of interlaced scan moving images, especially with motion estimation, is difficult and also introduces artifacts.

In progressive scan readout each line is read out sequentially. There is no even or odd field, only a single frame. As a result there are no temporal and spatial sampling displacement differences. However, for a given resolution and frame rate, the readout rate of a progressive scan image sensor is double that of an interlaced scan. In addition, for these applications, the number of pixels is often based on powers of 2: such as 512 × 512 or 1024 × 1024—facilitating memory mapping and image processing.

MOS Area Array Image Sensors The architecture of MOS area arrays is illustrated in Fig. 12.[24] It consists of the imaging array, vertical and horizontal address registers, and output amplifiers. The pixel of a MOS array consists of an image-sensing element (photodiode, photocapacitor, phototransistor, or photoconductor), a row-address gate, and a vertical readout line. The row-address gate is bussed horizontally across the array and is driven from a row-address register on the side(s) of the array. At the start of a line, a single row is addressed, causing the charge from all the photodiodes in

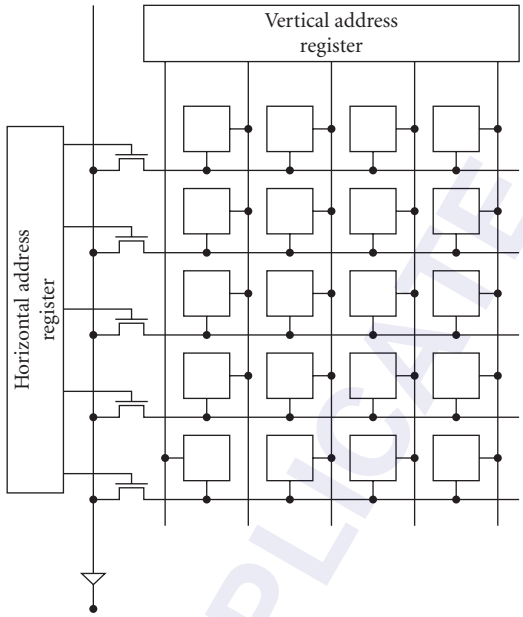

FIGURE 12 MOS photodiode array, consisting of vertical and horizontal address registers and readout line.

a row to be transferred onto the vertical readout line. Horizontal address gates are placed at the bottom of the vertical readout line. Buffer amplifiers to drive the horizontal readout line may also be placed at the end of the vertical readout line. The horizontal address register then serially addresses each vertical readout line, sequentially turning on the horizontal address gates. After the horizontal addressing is completed, the readout lines may be reset and precharged and the next row addressed.

There is a wide range of variations on this basic architecture. An example is the charge modulation device, or CMD,[25,26] array in which a phototransistor is placed at each pixel site in order to achieve amplification and to achieve high currents to drive the capacitance of the vertical and horizontal readout lines. Other examples include arrays with sophisticated charge collection circuits at the end of each vertical readout line.

Frame Transfer CCD Image Sensors CCD area arrays fall into two categories: frame transfer and interline transfer. The simplest form of frame transfer CCD is the full-frame type, shown in Fig. 13*a*. A photograph of a few pixels of a frame transfer CCD is shown in Fig. 14*a*. The array consists of a single image area composed of vertical CCDs and a single horizontal register with an output amplifier at its end. In this architecture, the pixel consists of a single stage of a vertical CCD. This type of device requires an external shutter. When the shutter is opened, the entire surface of the sensor is exposed and the charge is collected in the CCD potential wells at each pixel. After the shutter is closed, the sensor is read out a row at a time by clocking a row of the vertical register into the horizontal register, then clocking the horizontal register to read out the row through the output amplifier. For higher readout rates dual horizontal CCDs are used in parallel. The full-frame CCD has the advantage of progressive scan readout high fill factor, very low noise, and wide dynamic range. However, it requires an external shutter. It is most often used in still electronic photography, scientific, industrial, and graphics applications.

For motion imaging applications, a shutter is not practical. In order to overcome the need for a shutter, frame transfer CCDs incorporate a storage area in addition to imaging area. For interlaced video applications, this storage area is sufficiently large to hold a field (242 lines in NTSC television).

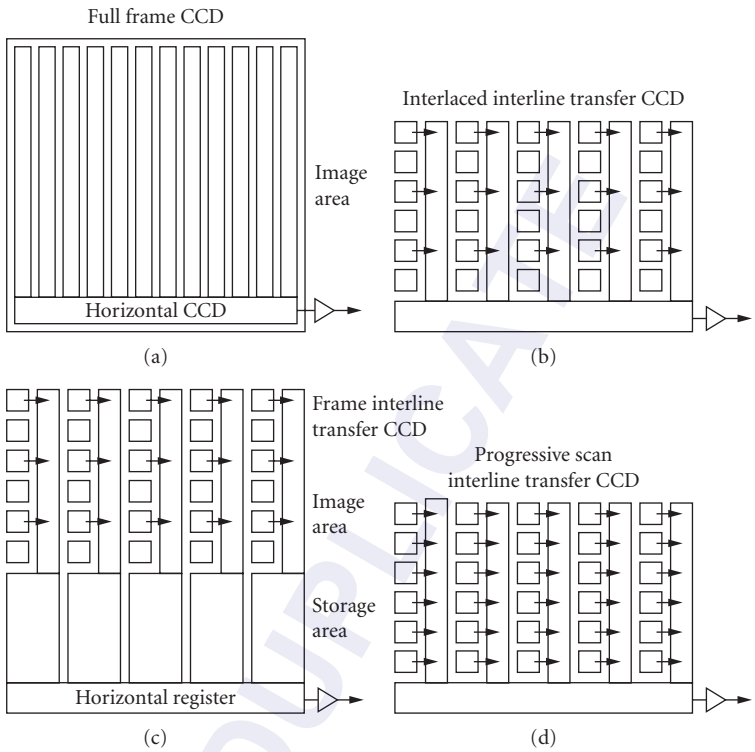

FIGURE 13 (*a*) Architecture of full-frame CCD; (*b*) architecture of interlaced interline transfer CCD; (*c*) architecture of frame interline transfer CCD, in which a storage area is provided to reduce smear during readout; and (*d*) progressive scan interline transfer CCD, in which every photodiode is read out into the vertical CCD simultaneously.

The image area consists of vertical CCDs. For interlaced NTSC video, there are 242 pixels vertically in the image area. Interlace is achieved by changing the gates under which integration is performed in the even and odd fields. For example, for a four-phase CCD, integration would be performed under phases 1 and 2 in one field and 3 and 4 in another, effectively shifting the sampling area by half a pixel in each field. The storage area consists also of 242 pixels vertically. The device operation is as follows. The image area integrates for a field time and the photogenerated charge held in the vertical CCDs. The vertical CCDs are then clocked in order to rapidly transfer the charge from the image area into the storage area. Because the sensor is still under illumination, this transfer time must be much shorter than the integration time. This transfer typically requires 0.2 to 0.5 ms. The storage area is then read out a row at a time by transferring a row into the horizontal register and clocking this register. While this readout is occurring, the image area is integrating the next field. The most significant disadvantage of frame transfer CCDs is the image smear caused by illumination during the transfer from the image to the storage area. This smear can be on the order of 3 percent.

In both frame transfer and full-frame devices, the light must pass through the polysilicon electrodes before being absorbed in silicon. Owing to the high absorption of short wavelengths in the polysilicon, the quantum efficiency in the blue is only about 20 percent and in the green is about 50 percent. Figure 14*b* shows the quantum efficiency for a full-frame image sensor with polysilicon gates. Three approaches have been used to improve the efficiency: the virtual phase CCD, transparent electrodes, and backside illumination. In the virtual phase CCD (see "Types of

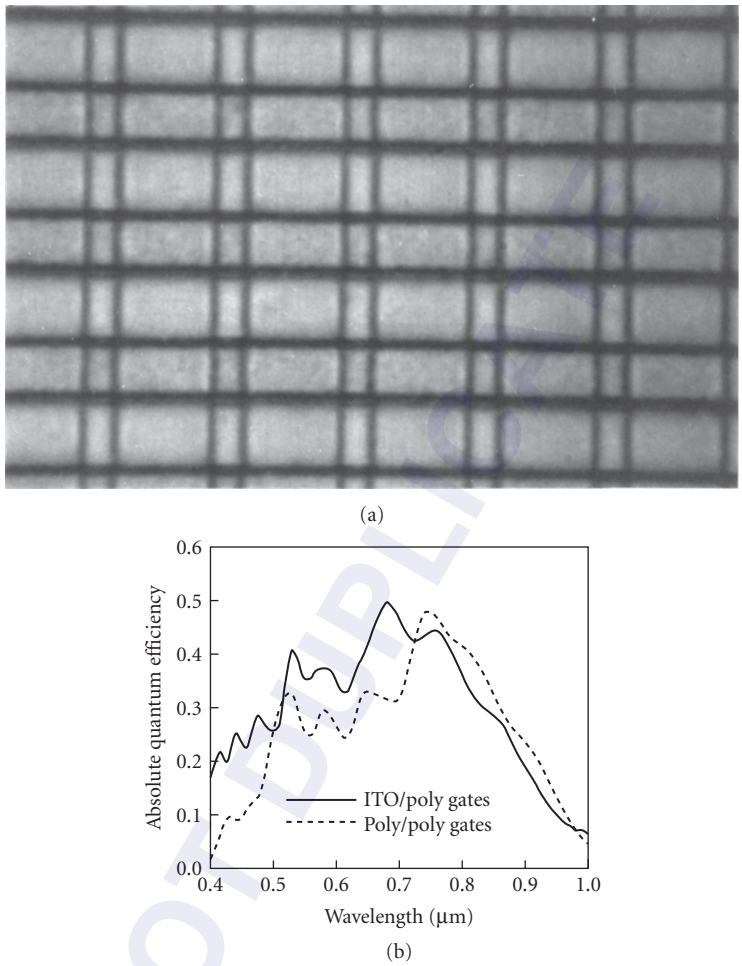

FIGURE 14 (*a*) Photograph of a few pixels in the image area of a full-frame CCD and (*b*) quantum efficiency as a function of wavelength for a full-frame CCD with polysilicon and with transparent indium-tin-oxide electrodes.

CCDs" in Sec. 32.4), the second polysilicon electrode is replaced with a very shallow highly doped p^+ layer, very similar to the pinned photodiode (Fig. 2*d*). Since there is no electrode over this phase to absorb the light, higher quantum efficiency is achieved, particularly at wavelengths less than 500 nm. Backside illumination provides nearly unity quantum efficiency but requires that the sensor be thinned to less than 10 μm. Owing to its cost, backside thinning is employed only in sensors for very specialized scientific or aerospace applications. Indium-tin-oxide, or ITO, is the most commonly used transparent electrode.[27] Usually it is substituted for the second level of polysilicon. Figure 14*b* also shows the quantum efficiency of a full-frame device in which ITO has been substituted for one of the polysilicon gates.

Interline Transfer CCD Image Sensors The interline transfer CCD is fundamentally different from the frame-transfer CCD in that, in addition to the vertical CCD, the pixel also contains a separate image-sensing element (photodiode, pinned photodiode, photocapacitor, or photoconductor) and a

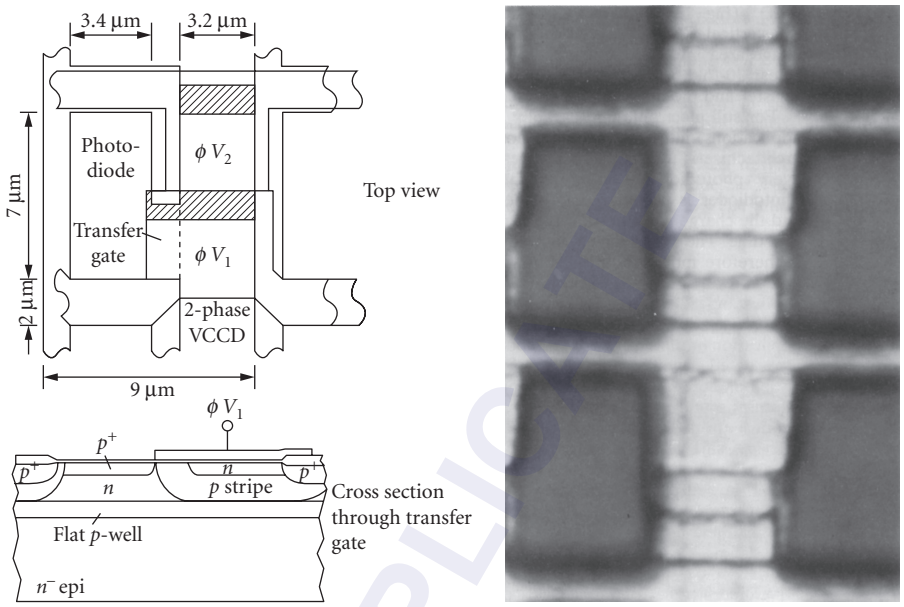

FIGURE 15 (*a*) Diagram of a pixel of an interline transfer CCD and (*b*) photograph of a pixel from an interline transfer CCD.

transfer region between the photodiode and the vertical CCD. Interline CCDs with photodiodes for sensing elements are considered first. Figure 13*b* illustrates the architecture of an interline transfer CCD and Fig. 15 illustrates a pixel of the CCD. The CCD and the transfer region between the diode and CCD are covered with a light shield (typically aluminum, although metal silicides are also used). The light shield prevents any light from entering the vertical CCD registers, allowing them to be read out while the sensor is illuminated. When the sensor is illuminated, the photogenerated charge is held on the photodiode. During the vertical retrace interval at the end of a field, the photogenerated charge is transferred into the vertical CCD by clocking the CCD gate over the transfer region. Once the charge has been transferred from the diodes into the vertical CCDs, the diodes resume integrating and the vertical CCDs are clocked in order to transfer a row at a time from the image area into the horizontal CCD.

For consumer and most commercial applications, interlaced interline CCDs are used to be consistent with television standards. In interlaced interline CCDs there is one vertical CCD stage for every two photodiodes. During the retrace time before the first field the charge from the odd rows of photodiodes is transferred into the vertical CCDs; the charge is then transferred out a row at a time into the horizontal CCD. During the retrace time before the second field the charge from the even rows of photodiodes is transferred into the vertical CCDs; once again, the charge is transferred out a row at a time into the horizontal CCD. In NTSC television the fields are approximately 1/60 second long; in PAL the field time is 1/50 second.

Because the vertical CCDs in an interline CCD are covered by a light shield, very little stray light is absorbed in the CCD. However, due to light scattering under the lightshield and lateral diffusion of photogenerated electrons, some charge can reach the vertical registers as they are read out during a field. This results in smear. For consumer applications the level of smear is not noticeable. However, for especially demanding applications such as television broadcast cameras, a field storage area is added to the bottom of the image area. This architecture is called the frame interline transfer, or FIT CCD[28] (Fig. 13*c*). Following transfer of the photogenerated charge from the diodes

into the vertical CCDs, the vertical CCDs are clocked to rapidly shift the charge from the image area into the storage area. This transfer typically takes less than 0.5 ms, reducing smear 30-fold. One line at a time is transferred from the storage area to the horizontal register and the readout.

For still electronic photography, scientific, computer-related, graphics and professional applications, interlaced video is not desirable. For these applications a progressive scan architecture is utilized. In a progressive scan interline CCD there is a full CCD stage for every photodiode.[28] Following integration, the photogenerated charge from all the photodiodes is transferred into the vertical CCDs. The photodiodes resume integration and the charge packets from the vertical registers are transferred into the horizontal a row at a time. The progressive scan interline CCD requires twice the vertical CCD density and is therefore more complicated to fabricate. However, progressive scan readout provides many advantages in image quality for both motion and still imaging.

Nearly all interline CCDs used in camcorder, broadcast camera, or commercial applications utilize vertical antiblooming in order to prevent blooming when the sensor is illuminated beyond saturation. A cross-section diagram of an interline CCD with vertical antiblooming is shown in Fig. 15*b*. The device illustrated uses a pinned photodiode photosensing element. The CCD is built on an *n*-type silicon substrate. A *p*-well is formed about 2 μm deep in the *n*-type silicon. An *n*-type buried-channel is then formed followed by a *p*+ surface layer. The *n*-type substrate is reverse biased with respect to the *p*-well. When the photodiode is illuminated above saturation, the excess electrons spill out of the *n*-type buried channel and into the substrate. Owing to the vertical overflow, however, photogenerated carriers from photons absorbed below the *p*-well are drawn into the substrate and are not collected by the diode. Thus the quantum efficiency of these devices falls rapidly at wavelengths beyond 550 nm. Figure 16 shows the quantum efficiency of an interline CCD with vertical antiblooming as a function of wavelength. The internal quantum efficiency of the photodiode is nearly 100 percent to about 550 nm, after which it decreases. However, since the photodiode only occupies about 20 percent of the pixel, and this aperture is typically reduced further by the light shield in order to eliminate optical scattering into the vertical CCD, the actual efficiency of the device is only about 15 percent. The photoresponse is linear at low signal levels but becomes nonlinear at charge levels near saturation.[29]

Two major approaches are used to improve the fill factor (and therefore the quantum efficiency) of interline CCDs. One uses microlens arrays to focus the light incident on a pixel onto the photodiode and the other a vertical integration of image sensors with amorphous silicon photoconductors to achieve a high fill factor. Figure 17 shows a microlens array on top of an interline CCD.[30] The

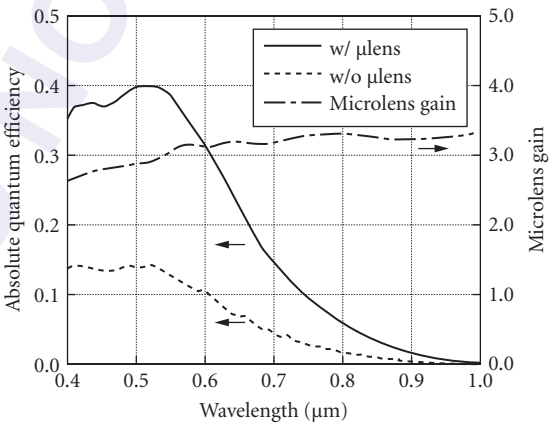

FIGURE 16 Quantum efficiency as a function of wavelength for an interline transfer CCD with and without microlens array.

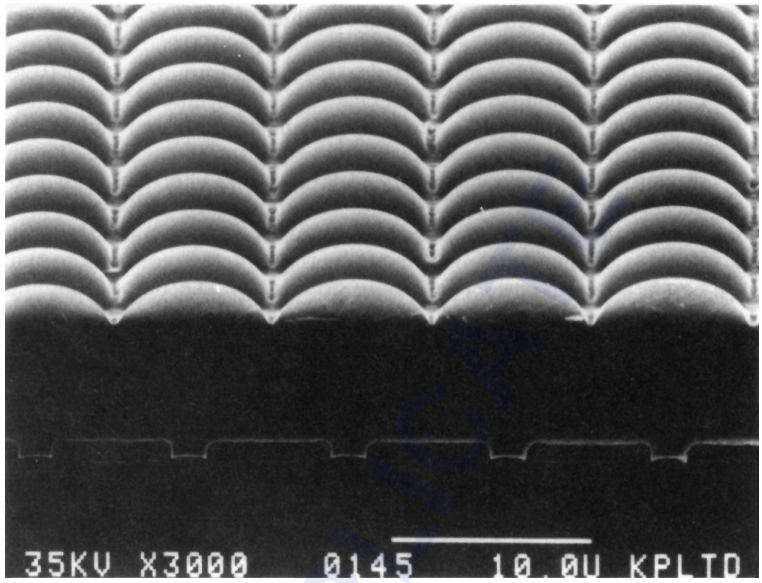

FIGURE 17 Scanning electron micrograph of microlens array on top of an interline transfer CCD.

lenses are formed by coating a spacer layer on the wafer of CCD devices followed by a lens-forming layer. The lens-forming layer is patterned and then reflowed to form the lens arrays. The quantum efficiency of an interline CCD with and without a microlens array is shown in Fig. 18. A 3-fold improvement in quantum efficiency is achieved because light from nearly the entire pixel area is focused onto the photodiode.

The structure of the photoconductor and its band diagram in the second approach[7] are illustrated in Fig. 2*e*. The amorphous silicon is about 1 μm thick; owing to its high absorption coefficient in the visible, it can achieve nearly 100 percent internal quantum efficiency. The back contact of the

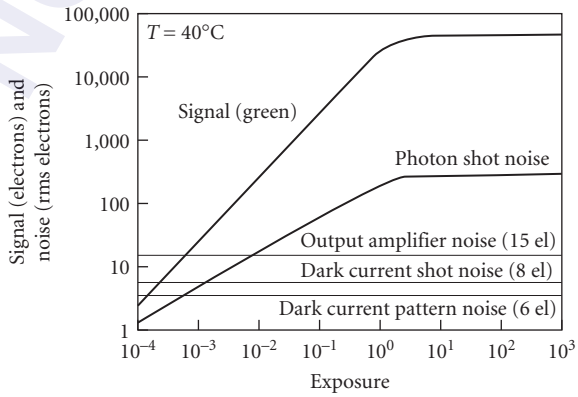

FIGURE 18 Quantum efficiency of interline CCD with and without microlens array.

photoconductor contacts the diode in the interline CCD. Light absorbed in the amorphous silicon generates electron-hole pairs. The amorphous silicon is biased such as to create a high field which sweeps out the electrons to the back contact, where they can be stored on the diode until they are transferred into the CCD. Because the photoconductor is fabricated on top of the CCD pixel, it can have nearly 100 percent fill factor. In addition, because of the wide bandgap of the amorphous silicon, its dark current (due to thermal generation of carriers) is often lower than the single-crystal silicon. However, the amorphous silicon photocon ductors suffer difficulties related to charge trapping. Owing to impurities and dangling or strained bonds, there is a high density of traps in amorphous silicon. These can trap charge carriers and reemit them at a later time, causing image lag. Because the trapping and detrapping is field-dependent, it can also result in nonlinear response.

CCD Performance In all CCDs, both interline and frame transfer, the signal output is linear with the illumination except at levels approaching saturation. This linear response is in marked contrast to image tubes, which exhibit highly nonlinear response. For interline CCDs, the total charge capacity ranges from 100,000 electrons for larger cells (such as the 13.6(V) × 11.6(H)-μm cell typical for a 2/3-in format) to 20,000 electrons or less for smaller cells (such as the 6.8 × 5.8-μm cell in a 1/3-in format 484 × 768-pixel CCD).

The principal noise sources in both interline and full-frame image sensors are dark current pattern and shot noises and output amplifier noise. To illustrate the contributions, CCDs have dark current levels at 40°C of less than 1 nA/cm^2. For a 2/3-in format sensor, this would correspond to about 320 electrons per pixel dark level. The corresponding shot noise would be 18-rms electrons and the pattern noise would typically be at a similar level. However, because of the nonrandom nature of pattern noise, its appearance is considerably more noticeable. The output amplifier noise would also be at about the 15-rms electron level. Thus, the overall noise for this example would be in the 30-electron range and the dynamic range would be over 2000 for a charge capacity of 90,000 electrons. For scientific applications where the sensor can be cooled and the readout performed at a lower frequency, noise levels less than 5 electrons can be achieved and even subelectron noise has been reported.[18]

Color Imaging

Silicon based CCDs are monochrome in nature. That is, they have no natural ability to determine the varying amounts of red, green, and blue (RGB) illumination presented to the photodetectors. There are three techniques to extract color information.

1. *Color Sequential* (Fig. 19)—A color image can be created using a CCD by taking three successive exposures while switching in optical filters having the desired RGB transmittances. This approach is normally used only to provide still images of stationary scenes. The resulting image is then reconstructed off-chip. The advantage to this technique is that resolution of each color can remain that of the CCD itself. The disadvantage is that three exposures are required, reducing frame times by more than a factor of three. Color misregistration can also occur due to subject or camera motion. The filter switching assembly also adds to the mechanical complexity of the system.
2. *Three-Chip Color* (Fig. 19)—Three-chip color systems use an optical system to split the scene into three separate color images. A dichroic prism beam splitter is normally used to provide RGB images. Color images can then be detected by synchronizing the outputs of the three CCDs. The disadvantage to such a system is that the optical complexity is very high and registration between sensors is difficult.
3. *Integral Color Filter Arrays* (*CFA*) (Fig. 19)—Instead of performing the color filtering off-chip, filters of the appropriate characteristics can be fabricated above individual photosites.[31,32] This approach can be performed during device fabrication using dyed (e.g., cyan, magenta, yellow) photoresists in various patterns. The major problem with this approach is that each pixel is sensitive to only one color. Off-chip processing is required to "fill in" the missing color information between pixels.[33,34]

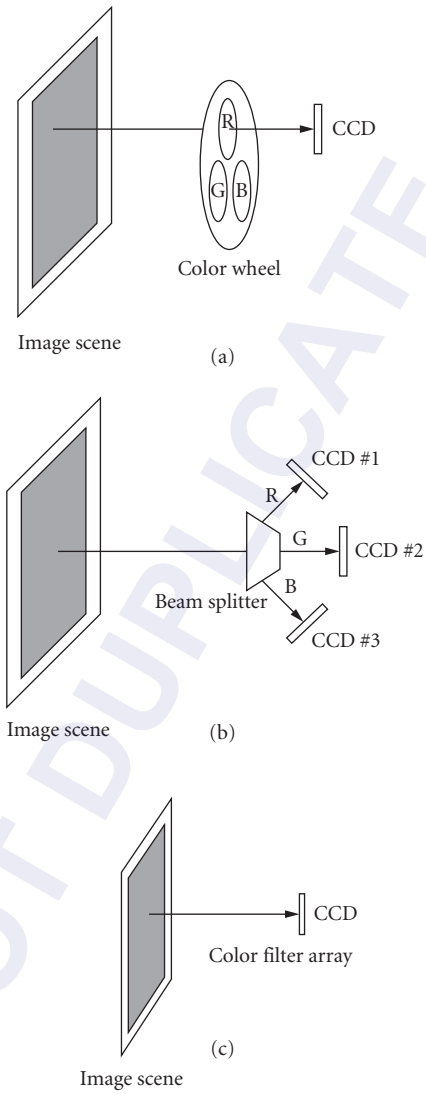

FIGURE 19 Methods of color separation in cameras with area image sensors: (*a*) color sequential using a color wheel; (*b*) a prism with dichroic beam splitters and three image sensors; and (*c*) single-chip image sensor with integral color filter array.

In order to minimize size, weight, and cost, most consumer color camcorders use a CCD sensor with an integral CFA. The photosites are covered with individual color filters—for example, a red, green, and blue striped filter, or a green, magenta, cyan, and yellow mosaic filter. Some popular CFA patterns are shown in Fig. 20. Because each photosite can sense only one color, the color sampling is not coincident. For example, a blue pixel might be seeing a white line, while nearby red and green pixels are seeing a dark line in the scene. As a result, high-frequency luminance edges can be aliased into bright color bands. These color bands depend not only on the color filter pattern used, but also

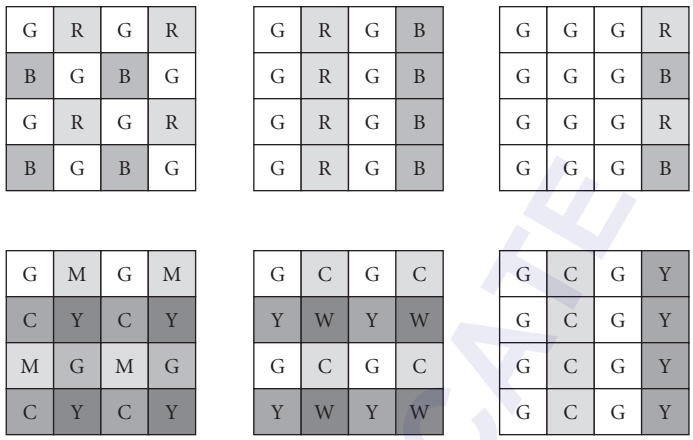

FIGURE 20 Common color filter array patterns where, R = Red, G = Green, B = Blue, Y = Yellow, M = Magenta, C = Cyan, and W = White.

on the optical prefilter and CFA interpolation algorithm. The color bands are caused by aliasing, which is a property of any sampled system. Aliasing occurs when the frequency of the input signal is greater than the Nyquist limit of one-half the sampling frequency. If the input frequency is well below the Nyquist limit, there are many samples per cycle. This allows the input to be reconstructed perfectly, if a proper reconstruction filter is used. When the input frequency is greater than the Nyquist limit, there are less than two samples per cycle. The sample values now define a new curve, which has a frequency lower than the input frequency. In effect, the high frequency takes on the alias of a lower frequency. Aliasing is a particular problem with color sensors, since the sampling phase is different for the different color photosites. Therefore, the aliased signal has different phases for different colors. This creates the color bands.

The color aliasing is reduced by using an optical anti-aliasing or "blur" filter, positioned in front of the color CCD sensor.[35] Blur filters are typically made of birefringent quartz, with the crystal axis oriented at a 45° angle, as shown in Fig. 21. In this orientation, the birefringent quartz exhibits the double refraction effect. An unpolarized input ray emerges as two polarized output rays, labelled *o*- and *e*-rays. The output ray separation is proportional to the filter's thickness, T. A 1.5-mm-thick plate will give a separation of about 9 μm. Figure 21 shows a simple "two-spot" filter. More complex filters use three or more pieces of quartz cemented in a stack.

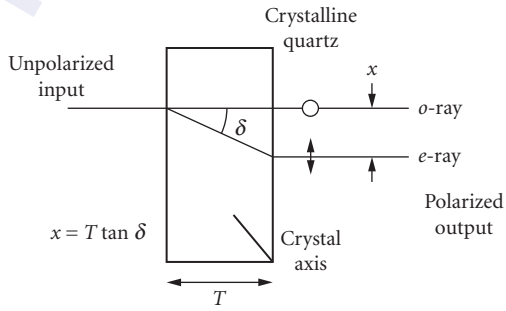

FIGURE 21 Birefringent blur filter used to reduce aliasing in single-chip color image sensors.

33.1 GLOSSARY

A_{det}	detector area
A_I	gate modulation current gain (ratio of integration capacitor current to load current
A_V	amplifier voltage gain
C_{amp}	amplifier capacitance
C_{det}	detector capacitance
C_{FIS}	fill-and-spill gate capacitance for a Tompsett type CCD input
C_{fb}	CTIA feedback or Miller capacitance
C_{gd}	FET gate-drain overlap capacitance
C_{gs}	FET gate-source capacitance
C_L	CTIA band-limiting load capacitance
C_{out}	sense node capacitance at the CCD output
C_T	effective feedback (transcapacitance) or integration capacitance for a capacitive transimpedance amplifier
$C_{T\lambda}$	spectral photon contrast
cte	charge transfer efficiency
$D^*_{\lambda pk}$	peak detectivity (cm-Hz$^{1/2}$/W or Jones)
D^*_{bb}	blackbody detectivity (cm-Hz$^{1/2}$/W or Jones)
D^*_{th}	thermal detectivity (cm-Hz$^{1/2}$/W or Jones)
e^-	electron
E_g	detector energy gap
$f/\#$	conventional shorthand for the ratio of the focal length of a lens to its diameter
f_{chop}	chopper frequency

*Deceased.

f_{frame}	display frame rate
f_{knee}	frequency at which the 1/*f* noise intersects the broadband noise
f_s	spatial frequency (cycles/radian)
$g_{m,\text{ LOAD}}$	gate transconductance of the load FET in the gate-modulated input circuit
g_{m}	gate transconductance of a Field Effect Transistor
h	Planck's constant
I_D	FET drain current
I_{det}	detector current
I_{photo}	detector photocurrent
k	Boltzmann constant
K_{amp}	amplifier FET noise spectral density at 1 Hz
K_{det}	detector noise spectral density at 1 Hz
K_{FET}	FET noise spectral density at 1 Hz
L	length-to-width ratio of a bar chart (always set to 7)
MRT	minimum resolvable temperature (K)
MTF	modulation transfer function for the optics, detector, readout, the integration process, or the composite sensor
n	detector junction ideality or diffusion constant
$N_{\text{amp, 1/}f}$	number of noise carriers for one integration time due to amplifier FET 1/*f* noise
$N_{\text{amp, white}}$	number of noise carriers for one integration time due to amplifier FET white noise
N_c	number of photo-generated carriers integrated for one integration time
n_{det}	detector junction ideality or diffusion constant
NE ΔT	noise equivalent temperature difference (K)
n_{FET}	subthreshold FET ideality
N_{FPA}	composite (total) FPA noise in carriers
$N_{kTC,\text{ channel}}$	CTIA broadband channel noise in carriers
$N_{\text{load, white}}$	number of noise carriers for one integration time due to CTIA load FET white noise
N_{os}	display overscan ratio
N_{PHOTON}	shot noise of photon background in carriers
NSD	noise spectral density of a detector or field effect transistor; the 1/*f* noise is often specified by the NSD at a frequency of 1 Hz
N_{sf}	source follower noise
N_{ss}	serial scan ratio
q	electron charge in coulombs
Q_B	photon flux density (photons/cm^2-s) incident on a focal plane array
Q_D	charge detected in a focal plane array for one integration time
Q_{max}	maximum charge signal at saturation
R_{det}	detector resistance
R_{LOAD}	gate modulation load resistance
R_0	detector resistance at zero-bias resistance
R_0A	detector resistance-are product at zero-bias voltage
R_r	detector resistance in reverse-bias resistance
S/N	signal-to-noise ratio
SNR_T	target signal-to-noise ratio
S_V	readout conversion factor describing the ratio of output voltage to detected signal carriers
T	operating temperature

tce	thermal coefficient of expansion
TCR	thermal coefficient of resistance for bolometer detectors
T_D	time constant for correlated double sampling process normally set by Nyquist rate
t_{int}	integration time
U	residual nonuniformity
V_{br}	detector reverse-bias breakdown voltage, sometimes defined as the voltage where $R_r = R_0$
V_D	FET drain voltage
V_{det}	detector bias voltage
V_{DS}	FET grain-to-source voltage
V_G	FET gate voltage
υ_n	measured rms noise voltage
ΔA_I	gate modulation current gain nonuniformity
Δf	noise bandwidth (Hz)
ΔI_{photo}	differential photocurrent
ΔT	scene temperature difference creating differential photocurrent ΔI_{photo}
ΔV_S	signal voltage for differential photocurrent ΔI_{photo}
Δx	horizontal detector subtense (mradian)
Δy	vertical detector subtense (mradian)
η	detector quantum efficiency
η_{BLIP}	percentage of BLIP
$\eta_{\text{inj, DI}}$	injection efficiency of detector current into the source-modulated FET of the direct injection input circuit
η_{inj}	injection efficiency of detector current
η_{noise}	injection efficiency of DI circuit noise into integration capacitor
η_{pc}	quantum efficiency of photoconductive detector
η_{pv}	quantum efficiency of photovoltaic detector
λ_c	detector cutoff wavelength (50 percent of peak response, μm)
σ_{det}	noise spectral density of total detector noise including photon noise
$\sigma_{\text{input, ir}}$	noise spectral density of input-referred input circuit noise
σ_{LOAD}	noise spectral density of input-referred load noise
$\sigma_{\text{mux, ir}}$	noise spectral density of input-referred multiplexer noise
σ_{VT}	rms threshold voltage nonuniformity across an FPA
τ_{amp}	amplifier time constant (s)
τ_{eye}	eye integration time (s)
τ_o	optical transmission
ω	angular frequency (radians)
$\langle e_{\text{amp}} \rangle$	buffer amplifier noise for buffered direct injection circuit

33.2 INTRODUCTION

Infrared sensors have been available since the 1940s to detect, measure, and image the thermal radiation emitted by all objects. Due to advanced detector materials and microelectronics, large scanning and staring focal plane arrays (FPA) with few defects are now readily available in the short wavelength infrared (SWIR; 1 to 3 μm), medium wavelength infrared (MWIR; ≈3 to 5 μm), and long wavelength infrared (LWIR; ≈8 to 14 μm) spectral bands. We discuss in this chapter the disparate FPA technologies, including photon and thermal detectors, with emphasis on the emerging types.

IR sensor development has been driven largely by the military. Detector requirements for missile seekers and forward looking infrared (FLIR) sensors led to high-volume production of photoconductive (PC) HgCdTe arrays starting in the 1970s. Though each detector requires direct connection to external electronics for purposes of biasing, signal-to-noise ratio (SNR) enhancement via time delay integration (TDI), and signal output, the first-generation FPAs displaced the incumbent Pb-salt (PbS, PbSe) and Hg-doped germanium devices, and are currently being refined using custom analog signal processing,[1] laser-trimmed solid-state preamplifiers, etc.

Size and performance limitations of first-generation FLIRs necessitated development of self-multiplexed FPAs with on-chip signal processing. Second-generation thermal imaging systems use high-density FPAs with relatively few external connections. Having many detectors that integrate longer, low-noise multiplexing and on-chip TDI (in some scanning arrays), second-generation FPAs offer higher performance and design flexibility. Video artifacts are suppressed due to the departure from ac-coupling and interlaced raster scan, and external connections are minimized. Fabricated in monolithic and hybrid methodologies, many detector and readout types are used in two basic architectures (staring and scanning). In a monolithic FPA, the detector array and the multiplexing signal processor are integrated in a single substrate. The constituents are fabricated on separate substrates and interconnected in a hybrid FPA.

FPAs use either photon or thermal detectors. Photon detection is accomplished using intrinsic or extrinsic semiconductors and either photovoltaic (PV), photoconductive (PC), or metal insulator semiconductor (MIS) technologies. Thermal detection relies on capacitive (ferro- and pyroelectric) or resistive bolometers. In all cases, the detector signal is coupled into a multiplexer and read out in a video format.

Infrared Applications

Infrared FPAs are now being applied to a rapidly growing number of civilian, military, and scientific applications such as industrial robotics and thermography (e.g., electrical and mechanical fault detection), medical diagnosis, environmental and chemical process monitoring, Fourier transform IR spectroscopy and spectroradiometry, forensic drug analysis, microscopy, and astronomy. The combination of high sensitivity and passive operation is also leading to many commercial uses. The passive monitoring provided by the addition of infrared detection to gas chromatography-mass spectroscopy (GC-MS), for example, yields positive chemical compound and isomer detection without sample alteration. Fusing IR data with standard GC-MS aids in the rapid discrimination of the closely related compounds stemming from drug synthesis. Near-IR (0.7 to 0.1 μm) and SWIR spectroscopy and fluorescence are very interesting near-term commercial applications since they pave the way for high-performance FPAs in the photochemical, pharmaceutical, pulp and paper, biomedical, reference quantum counter, and materials research fields. Sensitive atomic and molecular spectroscopies (luminescence, absorpion, emission, and Raman) require FPAs having high quantum efficiency, low dark current, linear transimpedance, and low read noise.

Spectral Bands

The primary spectral bands for infrared imaging are 3 to 5 and 8 to 12 μm because atomspheric transmission is highest in these bands. These two bands, however, differ dramatically with respect to contrast, background signal, scene characteristics, atmospheric transmission under diverse weather conditions, and optical aperture constraints. System performance is a complex combination of these and the ideal system requires dual band operation. Factors favoring the MWIR include its higher contrast, superior clear-weather performance, higher transmissivity in high humidity, and higher resolution due to ~3 × smaller optical diffraction. Factors favoring the LWIR include much-reduced background clutter (solar glint and high-temperature countermeasures including fires and flares have much-reduced emission), better performance in fog, dust, and winter haze, and higher immunity to atmospheric turbulence. A final factor favoring the LWIR, higher

S/N ratio due to the greater radiance levels, is currently moot because of technology limitations. Due to space constraints and the breadth of sensor applicability, we focus on target/background metrics in this section.

The signal collected by a visible detector has higher daytime contrast than either IR band because it is mainly radiation from high-temperature sources that is subsequently reflected off earth-based (ambient temperature; ≈290 K) objects. The high-temperature sources are both solar (including the sun, moon, and stars) and synthetic. Since the photon flux from high- and low-temperature sources differs greatly at visible wavelengths from day to night, scene contrasts of up to 100 percent ensue.

Reflected solar radiation has less influence as the wavelength increases to a few microns since the background radiation increases rapidly and the contrast decreases. In the SWIR band, for example, the photon flux density from the earth is comparable to visible room light (10^{13} photons/cm^2-s). The MWIR band (~10^{15} photon flux density) has lower, yet still dynamic, daytime contrast, and can still be photon-starved in cold weather or at night.

The net contribution from reflected solar radiation is even lower at longer wavelengths. In the LWIR band, the background flux is equivalent to bright sunlight (≈10^{17} photons/cm^2-s). This band thus has even lower contrast and much less background clutter, but the "scene" and target/background metrics are similar day and night. Clear-weather performance is relatively constant.

Depending on environmental conditions, however, IR sensors operating in either band must discern direct emission from objects having temperatures very near the average background temperature (290 K) in the presence of the large background and degraded atmospheric transmissivity. Under conditions of uniform thermal soak, such as at diurnal equilibrium, the target signal stems from minute emissivity differences.

The spectral photon incidence for a full hemispheric surround is

$$Q = \tau_{cf} \int_{\lambda_1}^{\lambda_2} Q_\lambda(\lambda) d\lambda \tag{1}$$

if a zero-emissivity bandpass filter having in-band transmission τ_{cf}, cut-on wavelength λ_1, and cutoff wavelength λ_2 is used (zero emissivity obtained practically by cooling the spectral filter to a temperature where its self-radiation is negligible). The photon flux density, Q_B (photons/cm^2-s), incident on a focal plane array is

$$Q_B = \frac{1}{4(f/\#)^2 + 1} Q \tag{2}$$

where *f*/# is the conventional shorthand for the ratio of the focal length to the diameter (assumed circular) of the limiting aperture or lens. The cold shield *f*/# limits the background radiation to a field-of-view consistent with the warm optics to eliminate extraneous background flux and concomitant noise. The background flux in the LWIR band is approximately two orders of magnitude higher than in the MWIR.

The spectral photon contrast, $C_{T\lambda}$, is the ratio of the derivative of spectral photon incidence to the spectral photon incidence, has units K^{-1}, and is defined

$$C_{T\lambda} = \left(\frac{\partial Q}{\partial T} \frac{}{Q} \right) \tag{3}$$

Figure 1 is a plot of $C_{T\lambda}$ for several MWIR subbands (including 3.5 to 5, 3.5 to 4.1, and 4.5 to 5 μm) and the 8.0 to 12 μm LWIR spectral band. The contrast in the MWIR bands at 300 K is 3.5 to 4 percent compared to 1.6 percent for the LWIR band. While daytime MWIR contrast is even higher due to reflected sunlight, an LWIR FPA offers higher sensitivity if it has the larger capacity needed for storing the larger amounts of photogenerated (due to the higher background flux) and detector-generated carriers (due to the narrow bandgap). The photon contrast and the background flux are key parameters that determine thermal resolution as will be described later under "Performance Figures of Merit."

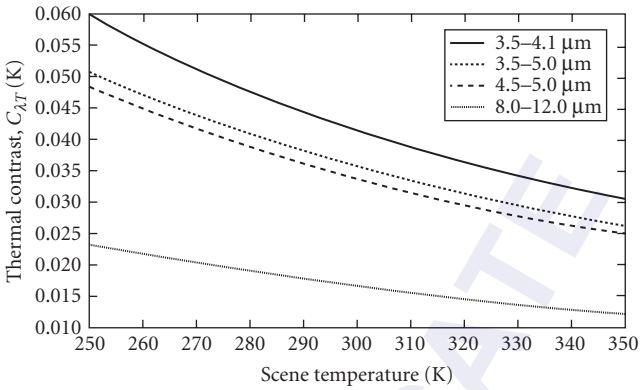

FIGURE 1 Spectral photon contrast in the MWIR and LWIR.

Scanning and Staring Arrays

The two basic types of FPA are scanning and staring. The simplest scanning device consists of a linear array as shown in Fig. 2*a*. An image is generated by scanning the scene across the strip. Since each detector scans the complete horizontal field-of-view (one video raster line) at standard video frame rates, each resolution element or pixel has a short integration time and the total detected charge can usually be accommodated.

A staring array (Fig. *2b*) is the two-dimensional extension of a scanning array. It is self-scanned electronically, can provide enhanced sensitivity, and is suitable for lightweight cameras. Each pixel

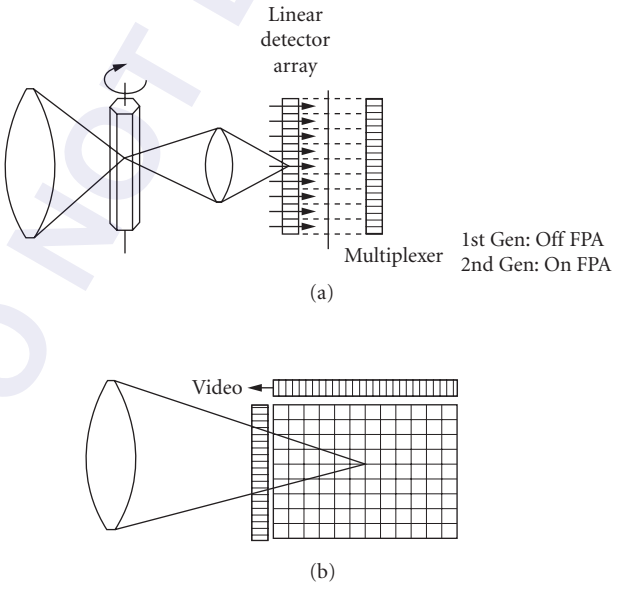

FIGURE 2 Scanning (*a*) and staring (*b*) focal plane arrays.

is a dedicated resolution element, but synchronized dithering of sparsely populated arrays is sometimes used to enhance the effective resolution, minimize spatial aliasing, and increase the effective number of pixels. Although theoretically charge can be integrated for the full frame time, the charge-handling capacity is inadequate at terrestrial LWIR backgrounds.

Detectors

Infrared detectors convert IR photons and energy to electrical signals. Many types are used in FPAs (as shown in Fig. 3[2]) including photon and thermal detectors that address diverse requirements spanning operating temperatures from 4 K to room temperature. Figure 4 compares the quantum efficiencies of several detector materials.

Intrinsic detectors[3] usually operate at higher temperatures than extrinsic devices, have higher quantum efficiencies, and dissipate less power. Backside-illuminated devices, consisting of an absorbing epitaxial layer on a transparent substrate, are used in hybrid FPAs and offer the advantages of nearly 100 percent active detector area, good mechanical support, and high quantum efficiency. The most popular intrinsic photovoltaics are HgCdTe and InSb. These detectors are characterized by their quantum efficiency (η), zero-bias resistance (R_0), reverse-bias resistance (R_r), junction ideality or diffusion constant n, excess noise (if any) versus bias, and reverse-bias breakdown voltage (V_{br}), which is sometimes defined as the voltage where $R_r = R_0$.

PtSi is a photovoltaic Schottky barrier detector (SBD) which is the most mature for large monolithic FPAs. IR detection is via internal photoemission over a Schottky barrier (0.21 to 0.23 eV). Characteristics include low (≈0.5 percent for broadband 3.5 to 5.0 μm) but very uniform quantum efficiency, high producibility that is limited only by the Si readout circuits, full compatibility with VLSI technology, and soft spectral response with peak below 2 μm and zero response just beyond 6 μm. Internal photoemission dark current requires cooling below 77 K.

HgCdTe is the most popular intrinsic photoconductor, and various linear arrays in several scanning formats are used worldwide in first-generation FLIRs. For reasons of producibility and cost, HgCdTe photoconductors have historically enjoyed a greater utilization than PV detectors despite the latter's higher quantum efficiency, higher D^* by a factor of $(2\eta_{pv}/\eta_{pc})^{1/2}$, and superior modulation transfer function (MTF). Nevertheless, not all photoconductors are good candidates for FPAs due to their low detector impedance. This includes the intrinsic materials InSb and HgCdTe.

The most popular photoconductive material system for area arrays is doped extrinsic silicon (Si: x; where x is In, As, Ga, Sb, etc.), which is made in either conventional or impurity band conduction [IBC or blocked impurity band (BIB)] technologies. Early monolithic arrays were doped-Si devices, due primarily to compatibility with the silicon readout. Extrinsic photoconductors must be made relatively thick (up to 30 mils; doping density of IBCs, however, minimizes this thickness requirement but does not eliminate it) because they have much lower photon capture cross section than intrinsic detectors. This factor adversely affects their MTF in systems having fast optics.

Historically, Si:Ga and Si:In were the first mosaic focal plane array PC detector materials because early monolithic approaches were compatible with these dopants. Nevertheless, problems in fabricating the detector contacts, early breakdown between the epitaxial layer and the detector material (double injection), and the need for elevated operating temperatures helped force the general move to monolithic PtSi and intrinsic hybrids.

The most advanced extrinsic photoconductors are IBC detectors using Si:As and Si:Ga.[4] These have reduced recombination noise (negating the √2 superiority in S/N that PV devices normally have) and longer spectral response than standard extrinsic devices due to the higher dopant levels. IBC detectors have a unique combination of PC and PV characteristics, including extremely high impedance, PV-like noise (reduced recombination noise since IBC detectors collect carriers both from the continuum and the "hopping" impurity band), linear photoconductive gain, high uniformity, and superb stability. The photo-sensitive layer in IBCs is heavily doped to achieve hopping-type conduction. A thin, lightly doped (10^{10}/cm^2) silicon layer blocks the hopping current before

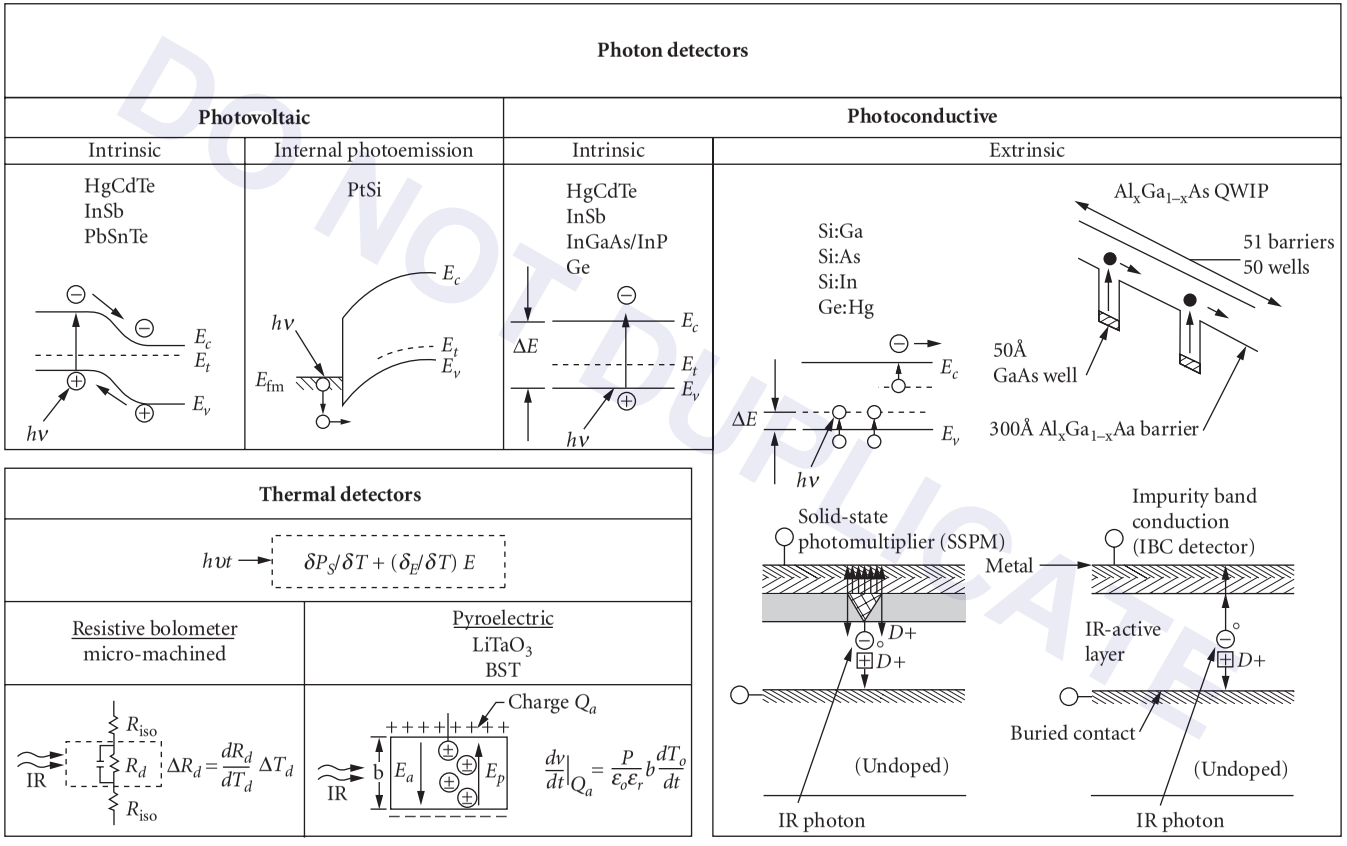

FIGURE 3 Photon and thermal detectors.

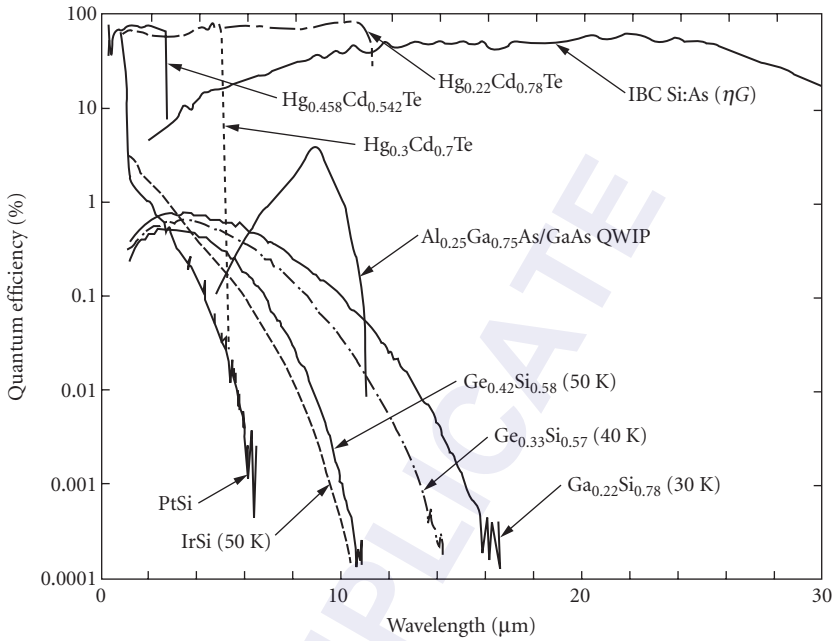

FIGURE 4 Quantum efficiency versus wavelength for several detector materials.

it reaches the device electrode to reduce noise. Specially doped IBCs (see cross-sectional views in Fig. 3) operate as solid-state photomultipliers (SSPM) and visible light photon counters (VLPC) in which photoexcited carriers are amplified by impact ionization of impurity-bound carriers.[5] The amplification allows counting of individual photons at low flux levels. Standard SSPMs respond from 0.4 to 28 μm.

An alternative custom tunable detector is the GaAs/AlGaAs quantum well infrared photodetector (QWIP). Various QWIP photoconductive[6] and photovoltaic[7] structures are being investigated as low-cost alternatives to II-VI LWIR detectors like HgCdTe. Infrared detection in the typical PC QWIP is via intersubband or bound-to-extended-state transitions within the multiple quantum well superlattice structure. Due to the polarization selection rules for transitions between the first and second quantum wells, the photon electric field must have a component parallel to the superlattice direction. Light absorption in *n*-type material is thus anisotropic with zero absorption at normal incidence. The QWIP detector's spectral response is narrowband, peaked about the absorption energy. The wavelength of peak response can be adjusted via quantum well parameters and can be made bias-dependent.

Various bolometers, both resistive and capacitive (pyroelectric), are also available. Bolometers sense incident radiation via energy absorption and concomitant change in device temperature in both cooled moderate-performance and uncooled lower-performance schemes. Much recent research, which was previously highly classified, has focused on both hybrid and monolithic uncooled arrays and has yielded significant improvements in the detectivity of both resistive and capacitive bolometer arrays. The resistive bolometers currently in development consist of a thin film of a temperature-sensitive resistive material film which is suspended above a silicon readout. The pixel support struts provide electrical interconnect and high thermal resistance to maximize pixel sensitivity. Recent work has focused on the micromachining necessary to fabricate mosaics with low thermal conductance using monolithic methodologies compatible with silicon.

Capacitive bolometers sense a change in elemental capacitance and require mechanical chopping to detect incident radiation. The most common are pyroelectric detectors. J. Cooper[8] suggested the use of pyroelectric detectors in 1962 as a possible solution for applications needing a low-cost IR FPA with acceptable performance. These devices have temperature-dependent spontaneous polarization. Ferroelectric detectors are pyroelectric detectors having reversible polarization. There are over a thousand pyroelectric crystals, including several popularly used in hybrid FPAs; e.g. lithium tantalate ($LiTaO_3$), triglycine sulfate (TGS), and barium strontium titanate[9] ($BaSrTiO_3$).

33.3 MONOLITHIC FPAs

A monolithic FPA consists of a detector array and the readout multiplexer integrated on the same substrate. The progress in the development of the monolithic FPAs in the last two decades has been strongly influenced by the rapid advances in the silicon VLSI technology. Therefore, the present monolithic FPAs can be divided into three categories reflecting their relationship to the silicon VLSI technology. The first category includes the "complete" monolithic FPAs in which the detector array and the readout multiplexer are integrated on the same silicon substrate using processing steps compatible with the silicon VLSI technology. They include the extrinsic Si FPAs reported initially in the 1970s,[10] FPAs with Schottky barrier,[11] heterojunction detector FPAs, and microbolometer FPAs.[12]

The second category will be referred to here as the "partial monolithic" FPAs. This group includes narrowband detector arrays of HgCdTe[13] and InSb[14] integrated on the same substrate only with the first level of multiplexing, such as the row and column readout from a two-dimensional detector array. In this case the multiplexing of the detected signal is completed by additional silicon IC chips usually packaged on the imager focal plane.

The third category represents "vertically integrated" photodiode (VIP) FPAs. These FPAs are functionally similar to hybrids in the sense that a silicon readout multiplexer is used with the narrowbandgap HgCdTe detectors. However, while in the hybrid FPA the completed HgCdTe detector array is typically connected by pressure contacts via indium bumps to the silicon multiplex pads; in the case of the vertically integrated FPAs, HgCdTe chips are attached to a silicon multiplexer wafer and then the fabrication of the HgCdTe photodiodes is completed including the deposition and the definition of the metal connections to the silicon readout multiplexer.

In the following sections we will review the detector readout structures, and the main monolithic FPA technologies. It should also be noted that most of the detector readout techniques and the architectures for the monolithic FPAs were originally introduced for visible silicon imagers. This heritage is reflected in the terminology used in the section.

Architectures

The most common structures for the photon detector readout and architectures of monolithic FPAs are illustrated schematically in Figs. 5 and 6.

MIS Photogate FPAs: CCD, CID, and CIM Most of the present monolithic FPAs use either MIS photogates or photodiodes as the photon detectors. Figure 5 illustrates a direct integration of the detected charge in the potential well of a MIS (photogate) detector for a charge coupled device (CCD) readout in (*a*), a charge injection device (CID) readout in (*b*), and a charge-integration matrix (CIM) readout in (c). The unique characteristic of the CCD readout is the complete transfer of charge from the integration well without readout noise. Also in a CCD FPA the detected charge, Q_D, can be transferred via potential wells along the surface of the semiconductor that are induced by clock voltages but isolated from the electrical pickup until it is detected by a low-capacitance (low kTC noise) on-chip amplifier. However, because of the relatively large charge transfer losses ($\sim 10^{-3}$ per transfer) and a limited charge-handling capacity, the use of nonsilicon CCD readout has

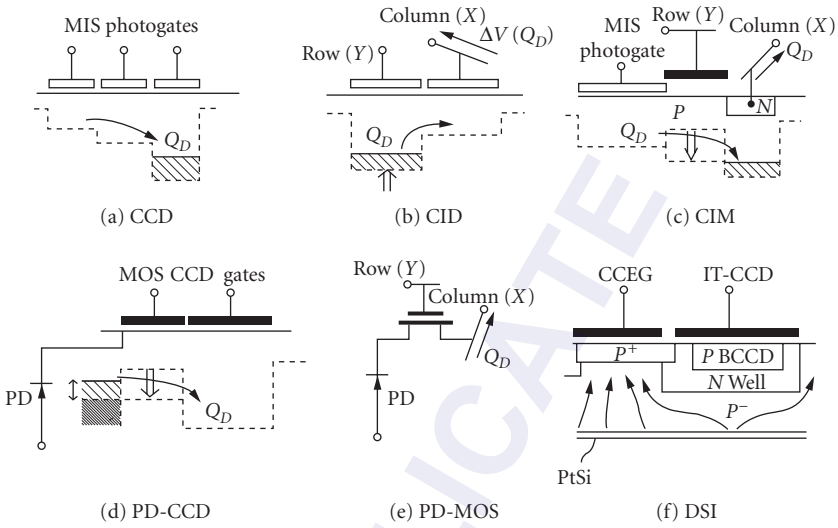

FIGURE 5 Photodetector readout structures.

been limited mainly to HgCdTe TDI FPAs. Such TDI imager is shown in Fig. 6*a* as a frame transfer (FT) type CCD area imager performing a function of a line sensor with the effective optical integration time increased by the number of TDI elements (CCD stages) in the column CCD registers. In this imager the transfer of the detected charge signal between CCD wells of the vertical register is adjusted to coincide with the mechanical motion of the image.

In the FT-CCD TDI FPA, the vertical registers perform the functions of charge detection and integration as well as transfer. The detected image is transferred one line at a time from the parallel vertical registers to the serial output registers. From there it is transferred at high clock rate to produce the output video. Similar TDI operation can also be produced by the interline-transfer (IT) CCD architecture shown in Fig. 6*e*. However, in the case of IT-CCD readout, the conversion of infrared radiation into charge signal photodetection is performed by photodiodes.

In the CID readout, see Fig. 5*b*, the detected charge signal is transferred back and forth between the potential wells of the MIS photogates for nondestructive X-Y addressable readout, $\Delta V(Q_D)$, that is available at a column (or a row) electrode due to the displacement current induced by the transfer of the detected charge signal, Q_D. At the end of the optical integration time, the detected charge is injected into the substrate by driving both MIS capacitors into accumulation.

CID FPAs with column readout for single-output-port and parallel-row readout are illustrated schematically in Fig. 6*b* and *c*, respectively. Another example of a parallel readout is the CIM FPA shown in Fig. 6*d*. The parallel readout of CID and CIM FPAs is used to overcome the inherent limitation on charge-handling capacity of these monolithic FPAs by allowing a short optical integration time with fast frame readout and off-chip charge integration by supporting silicon ICs.

Silicon FPAs: IT-CCD, CSD, and MOS FPAs The monolithic FPAs fabricated on silicon substrate take advantage of well-developed silicon VLSI process technology. Therefore, silicon (E_g = 1.1 eV), which is transparent to infrared radiation having wavelength longer than 1.0 μm, is often used to produce monolithic CCD and MOS FPAs with infrared detectors that can be formed on silicon substrate. In the 1970s there was great interest in the development of monolithic silicon FPAs with extrinsic Si:In and Si:Ga photoconductors. However, since the early 1980s most progress was reported on monolithic FPAs with Schottky-barrier photodiodes, GeSi/Si heterojunction photodiodes, vertically integrated photodiodes, and resistive microbolometers. With the exception of the

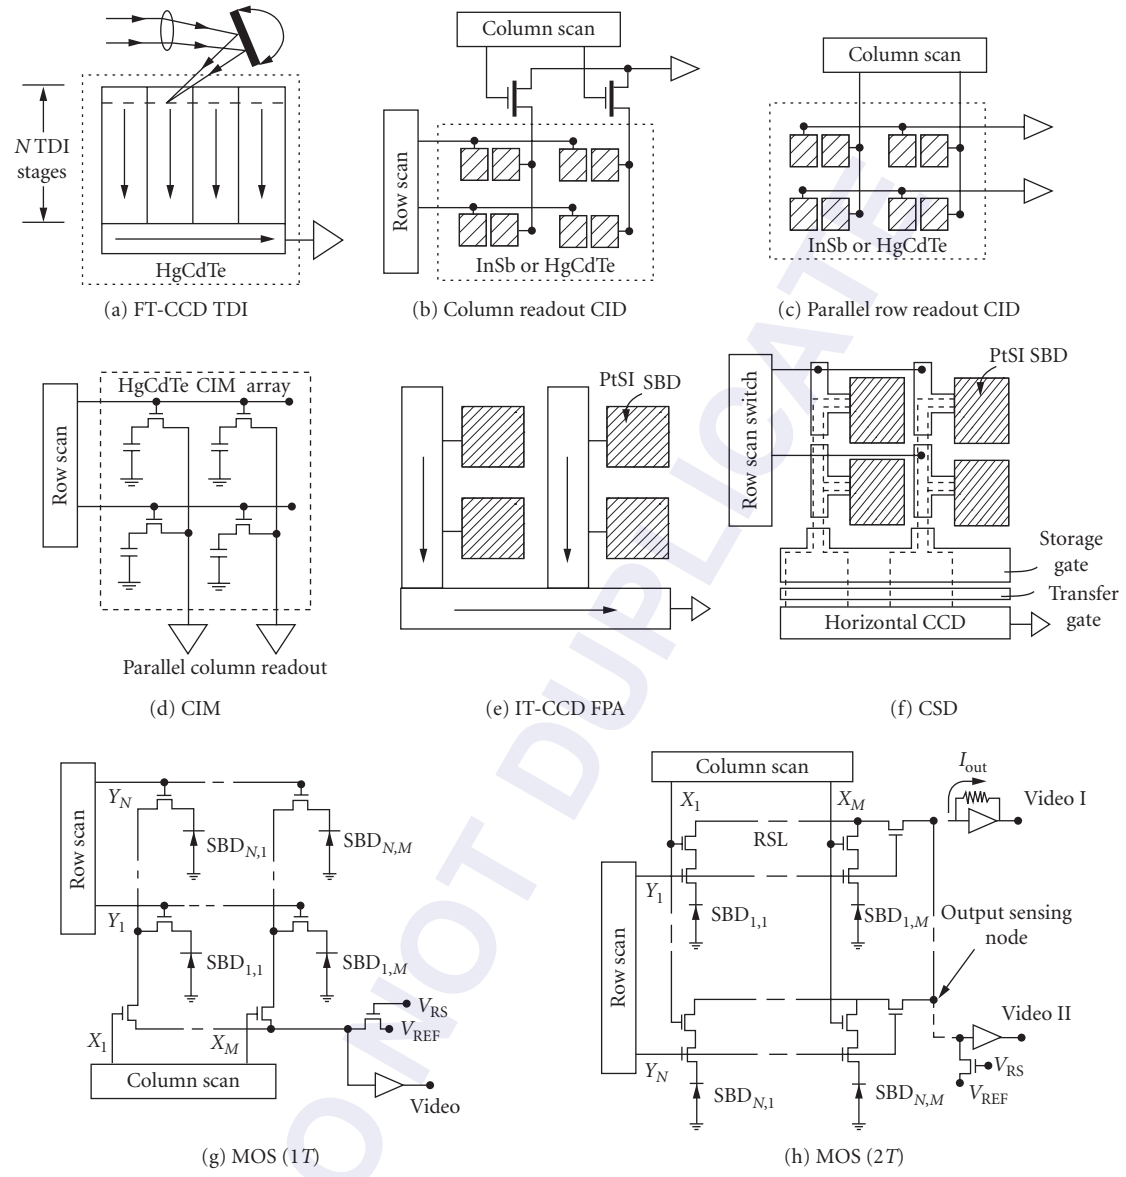

FIGURE 6 Monolithic FPA architectures.

resistive microbolometers, in the form of thin-film semiconductor photoresistors formed on micromachined silicon structures, all of the above infrared detectors can be considered to be photodiodes and can be read out either by IT-CCD or MOS monolithic multiplexer.

The photodiode (PD) CCD readout, see Fig. 5*d,* is normally organized as the interline-transfer (IT) CCD staring FPA, shown in Fig. 6*e.* The IT-CCD readout has been used mostly for PtSi Schottky-barrier detectors (SBDS). The operation of this FPA consists of direct integration of the detected charge signal on the capacitance of the photodiode. At the end of the optical integration time, a frame readout is initiated by a parallel transfer of the detected charge from the photodiodes to the

parallel vertical CCD registers. From there the detected image moves by parallel transfers one line at a time into the horizontal output register for a high-clock-rate serial readout.

The design of the Schottky-barrier IT-CCD FPA involves a trade-off between fill factor (representing the ratio of the active detector area to the pixel area) and maximum saturation charge signal (Q_{mix}). This trade-off can be improved by the charge sweep device (CSD) architecture, shown in Fig. 6*f*, that has also been used as a monolithic readout multiplexer for PtSi and IrSi SBDs.

In CSD FPA the maximum charge signal is limited only by the SBD capacitance since its operation is based on transferring the detected charge signal from one horizontal line corresponding to one or two rows of SBDs (depending on the type of the interlacing used) into minimum geometry vertical CCD registers. During the serial readout of the previous horizontal line, the charge signal is swept into a potential well under the storage gate by low-voltage parallel clocking of the vertical registers. Then, during the horizontal blanking time, the line charge signal is transferred in parallel to the horizontal CCD register for serial readout during the next horizontal line time.

The main advantage of the silicon CCD multiplexer is relatively low readout noise, from a few electrons to the order of several tens of electrons (depending on video rate, sense capacitance, and CCD technology), so that a shot-noise-limited operation can be achieved at relatively low signal levels. But as the operating temperature is lowered below 60 K, the charge transfer losses of buried-channel CCDs (BCCDs) become excessive due to the freeze-out of the BCCD implant. Therefore, detectors requiring operation at 40 K or lower are more compatible with MOS readout device technology.

Photodiode (PD) MOS readout (see Fig. 5*e)* represents another approach to construction of an *X-Y* addressable silicon multiplexer. These types of monolithic MOS multiplexers used for readout of PtSi SBDs are illustrated in Fig. 6*g* and *h.*

A single-output-port FPA with one MOSFET switch per detector, MOS (1T), is shown in Fig. 6*g*. During FPA readout, the vertical scan switch transfers the detected charge signal from one row of detectors to the column lines. Then the column lines are sequentially connected by MOSFET switches to the output sense line under the control of the horizontal scan switch. The main limitation of the MOS (IT) FPA is a relatively high readout noise (on the order of 100 electrons/pixel) due to sensing of small charge signals on large-capacitance column lines. This readout noise can be decreased with a row readout MOS (2T) FPA having two MOSFET switches per detector. In this case, low readout noise can be achieved using current sensing, it is limited by the noise of the amplifier, and for voltage sensing it can be reduced by correlated double sampling (CDS).[15] A readout noise of 300 rms electrons/pixel was achieved at Sarnoff for a 640 × 480 low-noise PtSi MOS (2T) FPA designed with row buffers and 8:1 multiplexing of the output lines;[16] 2T MOS FPA read noise of 60e^- was later achieved by reading via capacitive transimpedance amplifier column buffers in 0.5 μm CMOS technology.[17]

An alternative form of the MOS (IT) FPA architecture is an MOS FPA with parallel column readout for fast frame operation. This silicon VIP FPA, resembling CIM architecture in Fig. 6*d,* can be used with HgCdTe vertically integrated PV detectors.

Direct-Charge-Injection Silicon FPAs All of the silicon monolithic FPAs thus far described use separately defined detectors. A direct-charge-injection type monolithic silicon FPA with a single detector surface is a PtSi direct Schottky injection (DSI) imager that is made on thinned silicon substrate having a CCD or MOS readout on one side and PtSi SBD charge-detecting surface on the other side.[18] A cross-sectional area of one pixel of this FPA for IT-CCD readout is shown in Fig. 5*f*. In the operation of this imager, the *p*-type buried-channel CCD formed in an *n*-well removes charge from a P^+ charge-collecting electrode that in turn depletes a high-resistivity *p*-type substrate. Holes injected from the PtSi SBD surface into the *p*-type substrate drift through the depleted *p*-type substrate to the P^+ charge-collecting electrode. The advantages of the DSI FPA include 100 percent fill factor, a large maximum charge due to the large capacitance between the charge collecting electrode and the overlapping gate, and that the detecting surface does not have to be defined. A 128 × 128 IT-CCD PtSi DSI FPA was demonstrated;[19] however, the same basic structure could also be used with other internal photoemission surfaces such as IrSb or Ge:Si.

Microbolometer FPAs A microbolometer FPA for uncooled applications consists of thin-film semiconductor photoresistors micromachined on a silicon substrate. The uncooled IR FPA is fabricated as an array of microbridges with a thermoresistive element in each microbridge. The

resistive microbolometers have high thermal coefficient of resistance (TCR) and low thermal conductance between the absorbing area and the readout circuit which multiplexes the IR signal. As each pixel absorbs IR radiation, the microbridge elemental resistance changes accordingly with its temperature.

Metal films have traditionally been used to make the best bolometer detectors because of their low $1/f$ noise. These latest devices use semiconductor films of 500 Å thickness having TCR of 2 percent per °C. The spacing between the microbridge and the substrate is selected to maximize the pixel absorption in the 8- to 14-μm wavelength range. Standard photolithographic techniques pattern the thin film to form detectors for individual pixels. The thin film TCR varies over an array by ±1 percent, and produces responsivity of 70,000 V/W in response to 300 K radiation. This has been sufficient to yield 0.1°C NE ΔT with an $f/1$ lens. Potential low-cost arrays at prices similar to that of present large IC memories are possible with this technology.

Scanning and Staring Monolithic FPAs

In an earlier section we have reviewed the available architectures for the construction of two-dimensional scanning TDI, scanning, and staring FPAs. The same basic readout techniques, however, are also used for line-sensing imagers with photodiodes and MIS photogate detectors. For example, a line-scanning FPA corresponds to a vertical column CCD with the associated photodiodes of an IT-CCD, a column readout CID, a MOS (IT) FPA with only one row of detectors. However, since the design of a staring FPA is constrained by the size of the pixels, there is more space available for the readout multiplexer of a line of detectors. Therefore, design of the monolithic silicon multiplexer for a line detector array may also resemble the complexity of silicon multiplexer for hybrid FPAs.

33.4 HYBRID FPAs

Hybrid FPAs are made by interconnecting, via either direct or indirect means, a detector array to a multiplexing readout. Several approaches are pursued in both two- and three-dimensional configurations. Hybrids are typically made by either epoxying detector material to a processed silicon wafer (or readout) and subsequently forming the detectors and electrical interconnects by, for example, ion-milling; by mating a fully processed detector array to a readout to form a "two-dimensional" hybrid;[20] or by mating a fully processed detector array to a stack of signal processors to form a three-dimensional stack (*Z*-hybrid or "3D-IC"). The detector is usually mounted on top of the multiplexer and infrared radiation impinges on the backside of the detector array. Indium columns typically provide electrical and, often in conjunction with various epoxies, mechanical interconnect.

Hybrid methodology allows independent optimization of the detector array and the readout. Silicon is the preferred readout material due to performance and the leveraging of the continuous improvements funded by commercial markets. Diverse state-of-the-art processes and lithography are hence available at a fraction of their original development cost.

Thermal expansion match In a hybrid FPA, the detector array is attached to a multiplexer which can be of a different material. In cooling the device from room temperature to operating temperature, mechanical strain builds up in the hybrid due to the differing coefficients of thermal expansion. Hybrid integrity requires detector material that has minimum thermal expansion mismatch with silicon. Based on this criterion, the III-V and II-VI detectors are favored over Pb-salts. Silicon-based detectors are matched perfectly to the readout; these include doped-Si and PtSi. The issue of hybrid reliability has prompted the fabrication of II-VI detectors on alternative substrates to mitigate the mismatch. HgCdTe, for example, is being grown on sapphire (PACE-I),[21] GaAs (liftoff techniques are available for substrate thinning or removal), and silicon in addition to the lattice-matched Cd(Zn)Te substrates. Detector growth techniques[22] include liquid phase epitaxy and vapor phase epitaxy (VPE). The latter includes metal organic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE).

Hybrid Readout

Hybrid readouts perform the functions of detector interface, signal processing, and video multiplexing.[23] The hybrid FPA readout technologies include

- Surface channel charge coupled device (SCCD)
- Buried channel charge coupled device (BCCD)
- *x-y* addressed switch-FET (SWIFET) or direct readout (DRO) FET arrays
- Combination of MOSFET and CCD (MOS/CCD)
- Charge-injection device (CID)

Early hybrid readouts were either CIDs[24] or CCDs, and the latter are still popular for silicon monolithics. However, *x-y* arrays of addressed MOSFET switches are superior for most hybrids for reasons of yield, design flexibility, simplified interface, and direct leveraging of Moore's Law for ongoing improvements and cost reduction. The move to the FET-based, direct readouts is key to the dramatic improvements in staring array producibility and is a consequence of the spin-off benefits from the silicon memory markets. DROs are fabricated with high yield and are fully compatible with advanced processes that are available at captive and commercial foundries. We will thus focus our discussion on these families. Though not extensively, CCDs are still sometimes used in hybrid FPAs.[25]

Nonsilicon readouts Readouts have been developed in Ge, GaAs, InSb, and HgCdTe. The readout technologies include monolithic CCD, charge-injection device (CID), charge-injection matrix (CIM), enhancement/depletion (E/D) MESFET (GaAs), complementary heterostructure FET (C-HFET; GaAs),[26] and JFET (GaAs and Ge). The CCD, CID, and CIM readout technologies generally use MIS detectors for monolithic photon detection and signal processing.

The CID and CIM devices rely on accumulation of photogenerated charge within the depletion layer of a MIS capacitor that is formed using a variety of passivants (including CVD and photo-SiO_2, anodic SiO_2, and ZnS). A single charge transfer operation then senses the accumulated charge. Device clocking and signal readout in the CIDs and CIMs relies on support chips adjacent to the monolithic IR FPA. Thus, while the FPA is monolithic, the FPA assembly is actually a multichip hybrid.

CCDs have been demonstrated in HgCdTe and GaAs.[27] The *n*-channel technology is preferred in both materials for reasons of carrier mobility and device topology. In HgCdTe, for example, *n*-MOSFETs with CVD SiO_2 gate dielectric have parametrics that are in good agreement with basic silicon MOSFET models. Fairly elaborate circuits have been demonstrated on CCD readouts, e.g., an on-chip output amplifier containing a correlated double sampler (CDS).

GaAs has emerged as a material that is very competitive for niche applications including IR FPAs. Since GaAs has very small thermal expansion mismatch with many IR detector materials including HgCdTe and InSb, large hybrids are possible, and VPE detector growth capability suggests future development of composite monolithic FPAs. The heterostructure (H-)MESFET and C-HFET technologies are particularly interesting for IR FPAs because low $1/f$ noise has been demonstrated; noise spectral densities at 1 Hz of as low as 0.5 $\mu V/\sqrt{Hz}$ for *p*-HIGFET and 2 $\mu V/\sqrt{Hz}$ for the enhancement H-MESFET[28] at 77 K have been achieved. The H-MESFET has the advantage of greater fabrication maturity (16 K SRAM and 64×2 readout demonstrated), but the C-HFET offers lower power dissipation.

Direct Readout Architectures The DRO multiplexer consists of an array of FET switches. The basic multiplexer has several source follower stages that are separated at the cell, row, and column levels by MOSFET switches which are enabled and disabled to perform pixel access, reset, and multiplexing. The signal voltage from each pixel is thus direct-coupled through the cascaded source follower architecture as shown, for example, in Fig. 7. Shift registers generate the various clock signals; a minimum of externally supplied clocks is required. Since CMOS logic circuitry is used, the clock levels do not require precise adjustment for optimum performance. The simple architecture also gives high functional yield even in readout materials less mature than silicon.

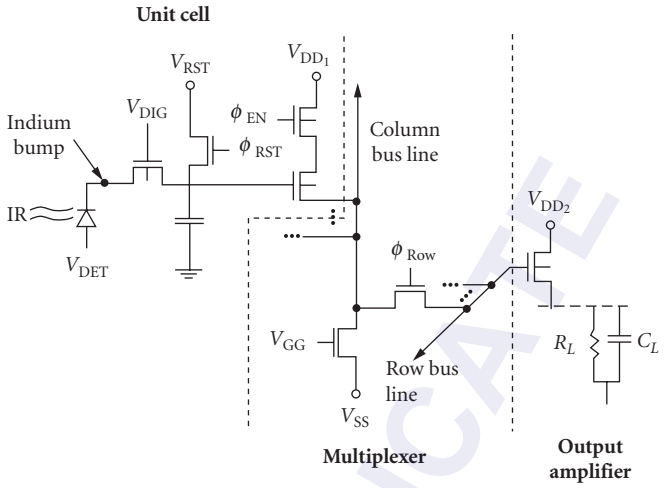

FIGURE 7 Direct readout schematic (shown with direct injection input).

Owing to the relatively low internal impedances beyond the input circuit, multiplexer noise is usually negligible. The inherent dynamic range is often >100 dB and the FPA dynamic range is limited only by the output-referred noise of the input circuit and the maximum signal excursion. The minimum read noise for DROs in imaging IR FPAs is typically capacitor reset noise. Correlated double samplers are thus used to suppress the reset noise for highest possible SNR at low integrated signal level.

In addition to excellent electrical characteristics, the DRO has excellent electro-optical properties including negligible MTF degradation and no blooming. Crosstalk in DRO-based FPAs is usually detector-limited since the readouts typically have low (<0.005 percent) electrical crosstalk. DROs also have higher immunity to clock feedthrough noise due to their smaller clock capacitances. Substrate charge pumping, which causes significant FET backgating[29] and transconductance degradation in SCCDs, is low in DROs.

X-Y addressing and clock generation Both static and dynamic shift registers are used to generate the clock signals needed for cell access, reset, and pixel multiplexing. Static registers offer robust operation and increased hardness to ionizing radiation in trade for increased FET count and preference for CMOS processes. Dynamic registers use fewer transistors in NMOS or PMOS processes, but require higher voltages, have lower maximum clocking rate, and must be carefully designed to avoid being affected by incident radiation.

Dynamic shift registers use internal bootstrapping to regenerate the voltage at each tap. The circuit techniques limit both the lowest and highest clock rates and require fine-tuning of the MOSFET design parameters for the specific operating frequency. More importantly, the high internal voltages stress conventional CMOS processes.

Electronically scanned staring FPAs The inability to integrate photogenerated charge for full staring frame times is often handled by integration time management. Since the photon background for the full 8- to 12-μm spectral band is over two orders of magnitude larger than the typical MWIR passband, and since the LWIR detector dark current is several orders of magnitude larger than similarly sized MWIR devices, LWIR FPA integration duty cycle can be quite poor. It is sometimes prudent to concede the limited duty cycle by electronically scanning the staring readout. Electronic scanning refers to a modified staring FPA architecture wherein the FPA is operated like a scanning FPA but without optomechanical means. Sensitivity is enhanced beyond that of a true scanning FPA by, for example, using multiple readout bus lines to allow integration times longer than one row time. The sharing reduces circuit multiplicity and frees unit cell real estate to share circuitry and

larger integration capacitance, and to use the otherwise parasitic bus capacitance to further increase capacity. More charge can thus be integrated even though the duty cycle is preset to 1/*N*, where *N* is the number of elements on each common bus.

Time delay integration scanning FPAs While no longer extensively used for staring readouts, SCCDs are used in scanning readouts to incorporate on-focal plane TDI since they have higher dynamic range than FET bucket brigades. Dynamic range >72 dB and as high as 90 dB are typically achieved with high TDI efficacy. Two architectures dominate. In one, the CCD is integrated adjacent to the input circuit in a contiguous unit cell. In the second, the input circuit is segregated from the CCD in a sidecar configuration. The latter offers superior cell-packing density and on-chip signal processing in trade for circuit complexity. Figure 8 shows the schematic circuit for a channel of a scanning readout having capacitive transimpedance amplifier input circuit (discussed earlier), common TDI channel bus, and fill-and-spill[30] input to a sidecar SCCD TDI. This scheme integrates CMOS and CCD processes for much on-chip signal processing in very fine orthoscan pitch.[31]

The readout conversion factor, i.e., volts out per electrons in, for the sidecar CTIA scheme is

$$S_V = \frac{\Delta V}{e^-} = \frac{C_{\text{F/S}}}{C_T} A_{V_1} A_{V_2} \frac{q}{C_{\text{out}}} \tag{4}$$

where $C_{\text{F/S}}$ is the fill-and-spill gate capacitance, C_T is the integration/feedback capacitance, A_{Vx} characterizes the various source follower gains, and C_{out} is the sense node capacitance at the CCD output. The ratio of $C_{\text{F/S}}$ to C_T sets a charge gain that allows design-tailoring for managing dynamic range or lowering input-referred noise. High charge-gain yields read noise that is limited by the input circuit and not by the transfer noise[32] of the high-carrier-capacity SCCD.

MOSFET bucket brigades are also used as TDI registers since simpler, all-MOS designs and processes can be used. Advantages include compatibility with standard MOS and CMOS, and capability for external clocking using specific CMOS-compatible clock levels. The latter potential advantage is mitigated in the sidecar TDI scheme by appropriately sizing the SCCD registers and the charge gain to yield the desired CCD clock levels, for example. Disadvantages include higher TDI register noise due to kTC noise being added at each transfer and limited signal excursion.

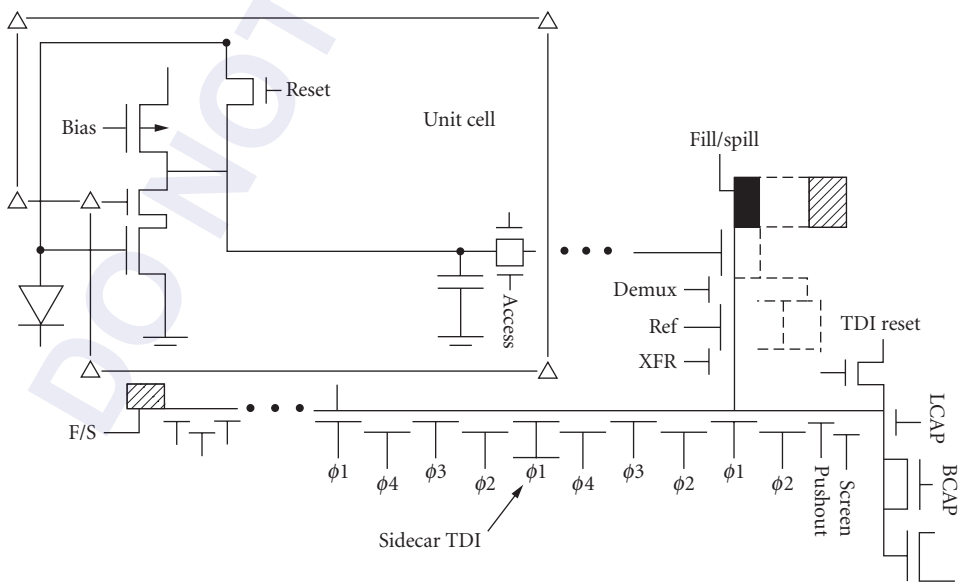

FIGURE 8 Sidecar TDI with capacitive transimpedance amplifier input circuit.

Output circuits Output circuitry is usually kept to a minimum to minimize power dissipation. Circuit design thus tends to focus on the trades between voltage-mode and current-mode output amplifiers, although on-chip signal processing is now at system-on-chip (SoC) level of sophistication, including low-speed A/D conversion, switched-capacitor filtering,[33] and on-chip nonuniformity correction. Voltage-mode outputs offer better S/N performance across a wider range in backgrounds for a given readout transimpedance. Current-mode outputs offer wider bandwidth and better drive capability at higher clock frequencies.

Detector Interface: Input Circuit After the incoming photon flux is converted into a signal by the detector, it is coupled into the readout via a detector interface circuit.[34] Signal input is optical in a monolithic FPA, so signal conditioning is limited. In hybrid FPAs and some composite material monolithics, the signal is injected electrically into the readout. The simplest input schemes offering the highest mosaic densities include direct detector integration (DDI) and direct injection (DI). More complex schemes trade simplicity for input impedance reduction [buffered direct injection (BDI) and capacitive transimpedance amplification (CTIA)], background suppression (e.g., gate modulation), or ultralow read noise with high speed (CTIA). We briefly describe the more popular schemes and their performance. Listed in Table 1 are approximate performance-describing equations for comparing the circuits schematically shown in Fig. 9.

Direct detector integration Direct detector integration (Fig. 9*a*), also referred to as source follower per detector (SFD), is used at low backgrounds and long frame times (frame rates typically ≤15 Hz in large staring arrays). Photocurrent is stored directly on the detector capacitance, thus requiring the detector to be heavily reverse-biased to maximize dynamic range. The changing detector voltage modulates the gate of a source follower whose drive FET is in the cell and whose current source is common to all the detectors in a column or row. The limited cell area constrains the source followers' drive capability and thus the bandwidth.

The DDI unit cell typically consists of the drive FET, cell enable transistor(s), and reset transistor(s). A detector site is read out by strobing the appropriate row clock, thus enabling the output source follower. The DDI circuit is capable of read noise as low as a few electrons per pixel.

Direct injection Direct injection (Fig. 9*b)* is perhaps the most widely used input circuit due to its simplicity and high performance. The detector directly modulates the source of a MOSFET. The direct coupling requires that detectors with *p*-on-*n* polarity, as is the case with InSb and most photovoltaic LWIR detectors, interface *p*-type FETs (and vice versa) for carrier collection in the integration capacitor. In surface channel CCDs, the input transistor's drain is virtual, as formed by a fully enhanced well, and often doubles as the integration capacitor.

Practical considerations, including limited charge-handling capacity, constrain the DI input to operation with high-impedance MWIR or limited cutoff ($\lambda_c \leq 9.5\ \mu m$) LWIR detectors. The associated background photocurrent for the applications where direct injection can be used mandates that the DI FET operate subthreshold.[35] The subthreshold gate transconductance, g_m, is independent of FET geometry:[36]

$$g_m = \left(\frac{\partial I_D}{\partial V_G}\right)\bigg|_{V_{DS}=\text{constant}} = \frac{q\left\{\eta_{\text{inj}}\left\{I_{\text{photo}} + \dfrac{V_{\text{det}}}{R_{\text{det}}} - I_{\text{det}_0}\left(e^{(qV_{\text{det}}/n\text{det}kT)} - 1\right)\right\}\right)}{nkT} \approx \frac{qI_D}{nkT} \tag{5}$$

The injection efficiency, η_{inj}, of detector current into the DI FET is

$$\eta_{\text{inj, DI}} = \frac{g_m R_{\text{det}}}{1 + g_m R_{\text{det}}}\left[\frac{1}{1 + \dfrac{j\omega C_{\text{det}} R_{\text{det}}}{+ g_m R_{\text{det}}}}\right] \tag{6}$$

where R_{det} and C_{det} are the detectors' dynamic resistance and capacitance, respectively. Poor DI circuit bandwidth occurs at low-photon backgrounds due to low g_m.

TABLE 1 Focal Plane Array Performance

Input Circuit	Percentage of BLIP	Detector Noise	Input-Referred Circuit Noise	Input-Referred MUX Noise	Transimpedance
Direct Detector Integration	$\dfrac{(\eta A_{\text{det}} Q_B \tau_{\text{int}})^{1/2}}{\left[\eta A_{\text{det}} Q_B \tau_{\text{int}} + \dfrac{2kT\tau_{\text{int}}}{qR_{\text{det}}} + N_{\text{rf}}^2 + \dfrac{2kT\tau_{\text{int}}}{qR_{\text{int}}}\right]}$	$I_{\text{det}}^2 = \left[\dfrac{4KT}{R_{\text{det}}} + 2qI_{\text{det}}\right]\Delta f + \int^{\Delta f}\left(\dfrac{K_{\text{det}}}{f}\right)df$	$N_{sf} \approx \dfrac{\sqrt{2}}{S_V}\left[\int^{\Delta f} V_n^2(f)\dfrac{(1-\cos 2\pi ft)}{[1+(2\pi f T_D)]}df\right]^{1/2}$ $S_V = \left(\dfrac{C_{\text{det}} A_V}{q}\right)^{-1}$	$\sigma_{\text{mux,ir}}^2 = \dfrac{1}{A_v^2} kTC_{\text{bus}}\Delta f$	$\left(\dfrac{t_{\text{int}}}{C_{\text{det}}}\right)A_v$

Gate Modulation (FET Load)	$\dfrac{(2qI_{\text{photo}}\Delta f)^{1/2}}{(\sigma_{\text{det}}^2 + \sigma_{\text{load}}^2 + \sigma_{\text{input,ir}}^2 + \sigma_{\text{mux,ir}}^2)^{1/2}}$		$\sigma_{\text{input,ir}}^2 = \int^{\Delta f}\left[\dfrac{1}{A_I^2}\left(2qI_{\text{input}} + \dfrac{K_{\text{FET,input}}}{f^\alpha}\right)\right]df$	$\sigma_{\text{mux,ir}}^2 = \dfrac{1}{A_{\text{inj}}^2} kTC_{\text{input}}\Delta f$	$\left(\dfrac{A_I t_{\text{int}}}{C_{\text{int}}}\right)A_v$
Capacitive Trans-impedance Amplifier	$\dfrac{\eta A_{\text{det}} Q_B \tau_{\text{int}}}{\left[\eta A_{\text{det}} Q_B \tau_{\text{int}} + \dfrac{2kT\tau_{\text{int}}}{qR_{\text{det}}} + N_{\text{amp},1/f}^2 + N_{\text{amp,white}}^2 + N_{\text{load,white}}^2\right]}$		$N_{\text{amp},1/f} \approx \dfrac{C_{\text{det}} K_{\text{amp}}\sqrt{2}}{q}\left[\ln\dfrac{5\tau_{\text{int}}}{\tau_{\text{amp}}}\right]$ $N_{\text{amp,white}} \approx \dfrac{C_{\text{det}}}{q}\sqrt{\dfrac{8}{3}\dfrac{kT}{g_m \tau_{\text{amp}}\pi}}$ $N_{\text{load,white}} \approx \dfrac{C_{\text{det}}}{qA_{v,\text{amp}}A_v^2}\sqrt{\dfrac{2kT}{C_L}}$	$I_{\text{mux,ir}}^2 = kTC_{\text{input}}\Delta f$	$Z_T = \dfrac{\tau_{\text{int}}}{C_T}A_{v,\text{sf}}$ $C_T = \dfrac{\left[\begin{matrix}(C_{\text{gd}} + C_{\text{gs}} + C_{\text{det}}) \\ +A_v(C_{\text{fb}} + C_{\text{gd}})\end{matrix}\right]}{A_v}$

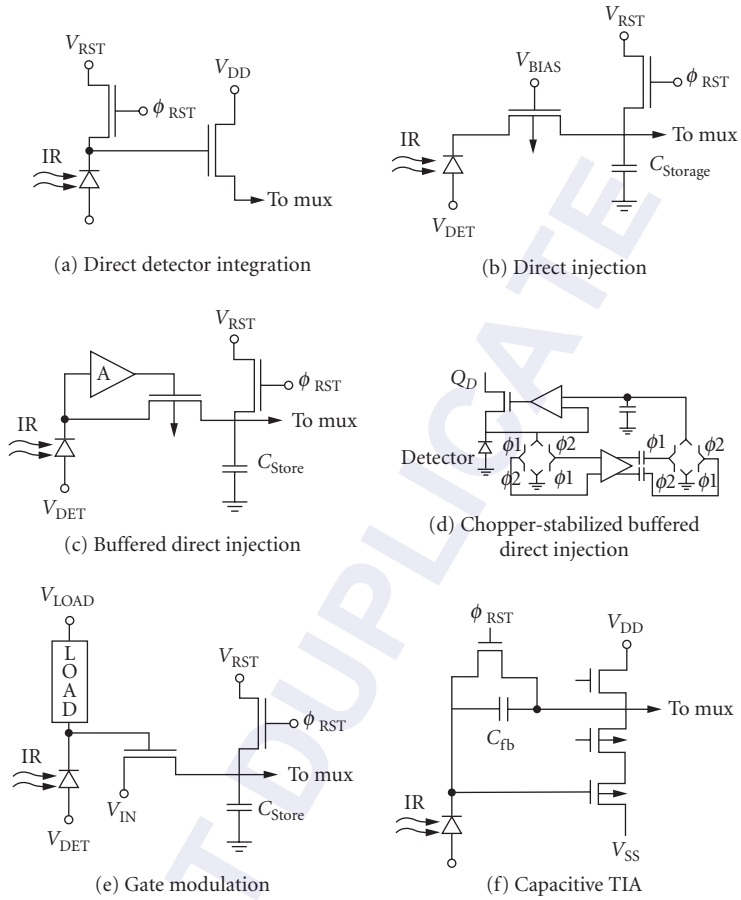

FIGURE 9 Hybrid FPA detector interface circuits.

The injection efficiency varies across an FPA due to FET threshold, detector bias, and detector resistance nonuniformity. Changes in detector current create detector bias shifts since the input impedance is relatively high. In extreme cases a large offset in threshold gives rise to excess detector leakage current and $1/f$ noise, in addition to fixed pattern noise. The peak-to-peak threshold voltage nonuniformity spans the range from ≈1 mV for silicon p-MOSFETs to over 125 mV for some GaAs-based readouts.

Depending upon the interface to the multiplexing bus, the noise-limiting capacitance, C_{input}, is approximately the integration capacitance or the combined integration and bus capacitance. Some direct-injection cells are thus buffered with a source follower (see Fig. 7). Omitting the source follower reduces the readout transimpedance (due to charge splitting between the integration capacitor and thus bus line capacitance) in trade for larger integration capacitance since more unit-cell real estate is available.

Increasing the pixel density has required a continuing reduction in cell pitch. Figure 10 plots the charge-handling capacity as functions of cell pitch and minimum gate length for representative DI designs using the various minimum feature lengths. Also plotted is the maximum capacity assuming the cell is composed entirely of integration capacitor (225 $\text{Å}iO_2$). A 27-μm DI cell, fabricated in 1.25-μm CMOS, thus had similar cell capacity as an earlier 60-μm DI cell in 3-μm CMOS. Limitations on cell real estate, operating voltage, and the available capacitor dielectrics nevertheless

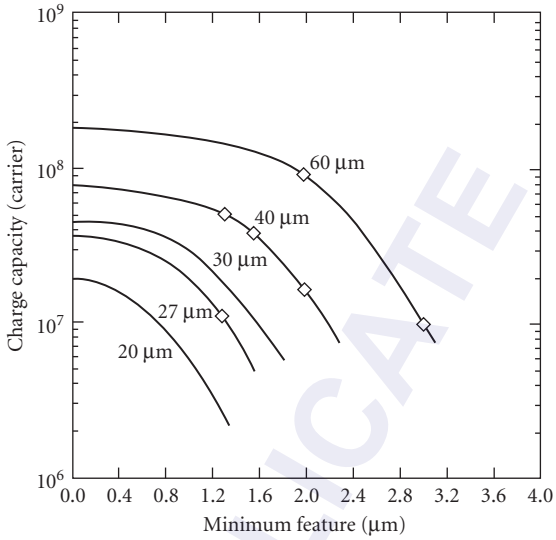

FIGURE 10 Direct injection charge-handling capacity versus cell pitch for standard CMOS processes.

dictate maximum integration times that are often shorter than the total frame time. This duty cycling equates to degradation in detective quantum efficiency.

Buffered direct injection A significant advantage of the source-coupled input is MOSFET noise suppression. This suppression is implied in the η_{BLIP} expression shown in Table 1. When injection efficiency is poor, however, MOSFET noise becomes a serious problem along with bandwidth. These deficiencies are ameliorated via buffered direct injection (BDI),[37] wherein a feedback amplifier with open-loop gain $-A_v$ (Fig. 9*c*) is added to the DI circuit. The buffering increases injection efficiency to near-unity, increases bandwidth by orders of magnitude, and suppresses the DI FET noise.

BDI has injection efficiency

$$\eta_{inj} \cong \frac{g_m R_{det}(1+A_V}{1+g_m R_{det}(1+A_v)+j\omega R_{det}[(1+A_v)C_{amp}+C_{det}]} \tag{7}$$

where C_{amp} is the Miller capacitance of the amplifier. Circuit bandwidth is maximized by lowering the amplifiers' Miller capacitance to provide detector-limited frequency response that is lower than that possible with DI by the factor $(1 + A_V)$.

The noise margin of the BDI circuit is superior to DI, even though two additional noise sources associated with the feedback amplifier are added. The dominant circuit noise stems from the drive FET in the amplifier. The noise power for frequencies less than $1/(2\pi R_{det}C_{det})$ is directly proportional to the detector impedance. Amplifier noise is hence a critical issue with low impedance (<1 MΩ) detectors including long wavelength photovoltaics operating at temperatures above 80 K.

Chopper-stabilized buffered direct injection The buffered direct injection circuit has high $1/f$ noise with low-impedance detectors. While the MOSFET $1/f$ noise can be suppressed somewhat by reverse-biasing the detectors to the point of highest resistance, detector $1/f$ noise may then dominate. Other approaches include enlarging MOSFET gate area, using MOS input transistors in the lateral bipolar mode, or using elaborate circuit techniques such as autozeroing and chopper stabilization. Chopper stabilization is useful if circuit real estate is available, as in a scanning readout. Figure 9*d* shows a block diagram schematic circuit of chopper-stabilized BDI.

Chopper stabilization refers to the process of commutating the integrating detector node between the inverting and noninverting inputs of an operational amplifier having open-loop gain, A_V. This chopping process shifts the amplifier's operating frequency to higher frequencies where the amplifier's noise is governed by white noise, not 1/*f* noise. At chopping frequencies $f_{chop} >> f_K$, the equivalent low-frequency input noise of the chopper amplifier is equal to the original amplifier white-noise component.[38] The amplifier's output signal is subsequently demodulated and filtered to remove the chopping frequency and harmonics. This scheme also reduces the input offset nonuniformity by the reciprocal of the open-loop gain, thereby generating uniform detector bias. Disadvantages include high circuit complexity and the possibility of generating excess detector noise via clock feedthrough-induced excitation of traps, particularly with narrow bandgap photovoltaic detectors.

Gate modulation Signal processing can be incorporated in a small unit cell by using a gate-modulated input structure (c.f. MOSFET load gate modulation in Fig. 9*e*).[39] The use of an MOSFET as an active load device, for example, provides dynamic range management via automatic gain control and user-adjustable background pedestal offset since the detector current passes through a load device with resistance R_{LOAD} The differential gate voltage applied to the input FET varies for a change in photocurrent, ΔI_{photo}, as

$$\Delta V_G = R_{LOAD} \eta_{inj,DI} \Delta I_{photo} \tag{8}$$

The current injected into the integration capacitor is

$$I_{input} = g_m R_{LOAD} \eta_{inj,DI} \Delta I_{photo} \tag{9}$$

The ratio of I_{input} to I_{photo} is the current gain, A_I, which is

$$A_I = \frac{g_m}{g_{m,LOAD}} \eta_{inj,DI} \tag{10}$$

The current gain can self-adjust by orders of magnitude depending on the total detector current. Input-referred read noise of tens of electrons has thus been achieved with high-impedance SWIR detectors at low-photon backgrounds. The same circuit has also been used at LWIR backgrounds with LWIR detectors having adequate impedance for good injection efficiency.

The current gain expression suggests a potential shortcoming for imaging applications since the transfer characteristic is nonlinear, particularly when the currents in the load and input FETs differ drastically. In conjunction with tight specifications for threshold uniformity, pixel functionality can be decreased, dynamic range degraded, and imagery dominated by spatial noise. The rms fractional gain nonuniformity (when operating subthreshold) of the circuit is approximately

$$\frac{\Delta A_I}{A_I} = \frac{q\sigma_{VT}}{n_{FET} kT} \tag{11}$$

where σ_{VT} is the rms threshsold nonuniformity. At 80 K, state-of-the-art σ_{VT} of 0.5 mV for a 128 × 128 FPA, and $n = 1$, the minimum rms nonuniformity is ≈7 percent.

Capacitive transimpedance amplifier (CTIA) Many CTIAs have been successfully demonstrated. The most popular approach uses a simple CMOS inverter[40] for feedback amplification (Fig. 9*f*). Others use a more elaborate differential amplifier. The two schemes differ considerably with respect to open-loop voltage gain, bandwidth, power dissipation, and cell real estate. The CMOS inverter-based CTIA is more attractive for high-density arrays. The latter is sometimes preferred for scanning or *Z*-hybrid applications where real estate is available primarily to minimize power dissipation.[41]

In either case, photocurrent is integrated directly onto the feedback capacitor of the transimpedance amplifier. The minimum feedback capacitance is set by the amplifier's Miller capacitance and defines the maximum circuit transimpedance. Since the Miller capacitance can be made very small (<5 fF), the resulting high transimpedance yields excellent margin with respect to

downstream system noise. The transimpedance degrades when the circuit is coupled to large detector capacitances, so reducing pixel size serves to minimize read noise and the circuits' attractiveness will continue to increase in the future.

The CTIA allows extremely small currents to be integrated with high efficiency and tightly regulated detector bias. The amplifier open-loop gain, $A_{V,\,\mathrm{amp}}$, ranges from as low as on the order of ten to higher than several thousand for noncascoded inverters, and many thousands for cascoded inverter and differential amplifier designs. The basic operating principle is to apply the detector output to the inverting input of a high-gain CMOS differential amplifier operated with capacitive feedback. The feedback capacitor is reset at the detector sampling rate. The noise equivalent input voltage of the amplifier is referred to the detector impedance, just as in other circuits.

The CTIA's broadband channel noise sets a lower limit on the minimum achievable read noise, is the total amplifier white noise, and can be approximated for condition of large open-loop gain by

$$N^2_{kTC,\mathrm{channel}} = \frac{kTC_{\mathrm{fb}}}{q^2}\left[\frac{C_{\mathrm{det}}+C_{\mathrm{fb}}}{C_L+\dfrac{C_{\mathrm{fb}}C_{\mathrm{det}}}{C_{\mathrm{fb}}+C_{\mathrm{det}}}}\right] \tag{12}$$

where C_{fb} is the feedback capacitance including the Miller capacitance and integration capacitance and C_L is the output load capacitance. This expression provides an intuitive formula for minimizing noise: detector capacitance must be low (i.e., minimize detector shunting capacitance which reduces closed-loop gain) and output capacitance high (i.e., limit bandwidth). Of the three amplifier noise sources listed in Table 1, amplifier $1/f$ noise is often largest. For this reason, the CMOS inverter-based CTIA has best performance with *p*-on-*n* detectors and *p*-MOSFET amplifier FET due to the lower $1/f$ noise.

33.5 PERFORMANCE: FIGURES OF MERIT

In the early days of infrared technology, detectors were characterized by the noise equivalent power (NEP) in a 1-Hz bandwidth. This was a good specification for single detectors, since their performance is usually amplifier limited. The need to compare detector technologies for application to different geometries and the introduction of FPAs having high-performance on-board amplifiers and small parasitics necessitated normalization to the square root of the detector area for comparing S/N. R. C. Jones[42] thus introduced detectivity (D^*), which is simply the reciprocal of the normalized NEP and has units cm-√Hz/W (or Jones).

While D^* is well-suited for specifying infrared detector performance, it can be misleading to the uninitiated since the D^* is highest at low background. An LWIR FPA operating at high background with background-limited performance (BLIP) S/N can have a D^* that is numerically lower than for a SWIR detector having poor S/N relative to the theoretical limit. Several figures of merit that have hence proliferated include other ways of specifying detectivity: e.g., thermal D^* (D^*_{th}), blackbody $D^*(D^*_{\mathrm{bb}})$, peak D^* ($D^*_{\lambda,\mathrm{pk}}$), percentage of BLIP (%BLIP or η_{BLIP}), and noise equivalent temperature difference (NEΔT). Since the final output is an image, however, the ultimate figure of merit is how well objects of varying size are detected and resolved in the displayed image. The minimum resolvable temperature (MRT) is thus a key benchmark. These are briefly discussed in this section.

Detectivity (D^*)

D^* is the S/N ratio normalized to the electrical bandwidth and detector area. In conjunction with the optics area and the electrical bandwidth, it facilitates system sensitivity estimation. However, D^* can be meaningless unless the test conditions, including magnitude and spectral distribution of the flux source (e.g., blackbody temperature), detector field-of-view, chopping frequency (lock-in amplifier),

background temperature, and wavelength at which the measurement applies. D^* is thus often quoted as "blackbody," since the spectral responsivity is the integral of the signal and background characteristics convolved with the spectral response of the detector. D^*_{bb} specifications are often quantified for a given sensor having predefined scene temperature, filter bandpass, and cold shield *f*/# using a generalized expression.

Peak detectivity is sometimes preferred by detector engineers specializing in photon detectors. The background-limited peak detectivity for a photovoltaic detector is

$$D^*_{\lambda pk} = \sqrt{\frac{\eta}{2Q_B}} \frac{\lambda_{pk}}{hc} \tag{13}$$

and refers to measurement at the wavelength of maximum spectral responsivity. For detector-limited scenarios, such as at higher operating temperatures or longer wavelengths (e.g., $\lambda_c > 12$ μm at operating temperature less than 78 K or $\lambda_c > 4.4$ μm at >195 K), the peak detectivity is limited by the detector and not the photon shot noise. In these cases the maximum detector-limited peak D^* in the absence of excess bias-induced noise (both 1/*f* and shot noise) is

$$D^*_{\lambda pk} = \frac{\eta q}{2} \sqrt{\frac{R_0 A}{kT}} \frac{\lambda}{hc} \tag{14}$$

The R_0A product of a detector thus describes detector quality even though other parameters may actually be more relevant for FPA operation.

Percentage of BLIP

Whereas D^* compares the performance of dissimilar detectors, FPA designers often need to quantify an FPA's performance relative to the theoretical limit at a specific operating background. Percentage of BLIP, η_{BLIP}, is one such parameter and is simply the ratio of photon noise to composite FPA noise

$$\eta_{BLIP} = \left(\frac{N^2_{PHOTON}}{N^2_{PHOTON} + N^2_{FPA}} \right)^{1/2} \tag{15}$$

NEΔT

The NEΔT of a detector represents the temperature change, for incident radiation, that gives an output signal equal to the rms noise level. While normally thought of as a system parameter, detector NEΔT and system NEΔT are the same except for system losses (conservation of radiance). NEΔT is defined:

$$\text{NE}\,\Delta T = \upsilon_n \left(\frac{\partial T}{\partial Q} \right) \Big/ \left(\frac{\partial V_s}{\partial Q} \right) = \upsilon_n \frac{\Delta T}{\Delta V_s} \tag{16}$$

where υ_n is the rms noise and ΔV_S is the signal measured for the temperature difference ΔT. It can be shown that

$$\text{NE}\,\Delta T = \left(\tau_o C_{T\lambda} \eta_{BLIP} \sqrt{N_c} \right)^{-1} \tag{16a}$$

where τ_o is the optics transmission, $C_{T\lambda}$ is the thermal contrast from Fig. 1, and N_c is the number of photogenerated carriers integrated for one integration time, t_{int}:

$$N_c = \eta A_{det} t_{int} Q_B \tag{16b}$$

The distinction between an integration time and the FPA's frame time must be noted. It is often impossible at high backgrounds to handle the large amount of carriers generated over frame times compatible with standard video frame rates. The impact on system D^* is often not included in the FPA specifications provided by FPA manufacturers. This practice is appropriate for the user to assess relative detector quality, but must be coupled with usable FPA duty cycle, read noise, and excess noise to give a clear picture of FPA utility. Off-FPA frame integration can be used to attain a level of sensor sensitivity that is commensurate with the detector-limited D^* and not the charge-handling-limited D^*.

The inability to handle a large amount of charge nevertheless is a reason why the debate as to whether LWIR or MWIR operation is superior is still heated. While the LWIR band should offer order-of-magnitude higher sensitivity, staring readout limitations often reduce LWIR imager sensitivity to below that of competing MWIR cameras. However, submicron photolithography, alternative dielectrics, and refinements in readout architectures are ameliorating this shortfall and LWIR FPAs having sensitivity superior to MWIR counterparts are available. Figure 11 shows the effect on high quantum efficiency FPA performance and compares the results to PtSi at TV-type frame rate. The figure illustrates BLIP and measured NE ΔTs versus background temperature for several spectral bands assuming a 640 × 480 DI readout multiplexer (27-μm pixel pitch and ≈1-μm-minimum

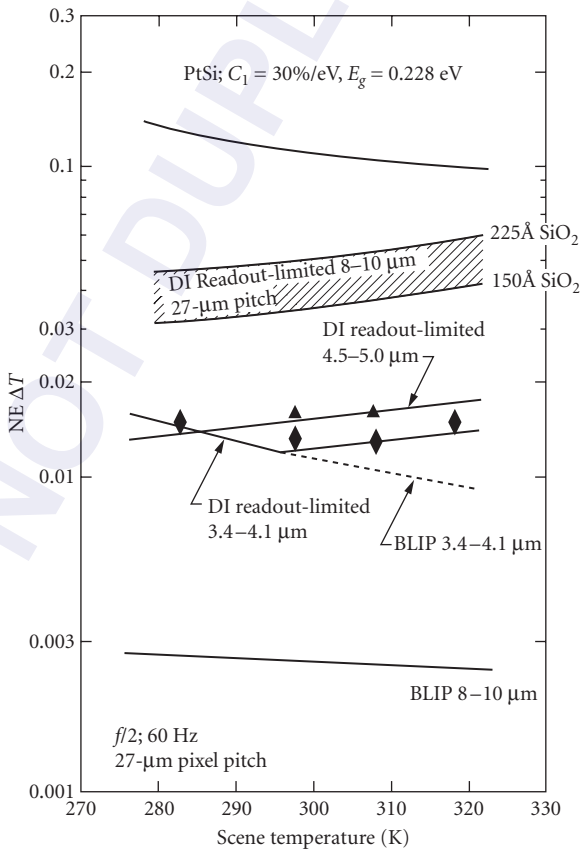

FIGURE 11 NE ΔT versus background temperature for several prominent spectral bands.

feature) is hybridized to high-quantum-efficiency MWIR and LWIR detectors. Though the device has large charge-handling capacity, there is large shortfall in the predicted LWIR FPA performance relative to the BLIP limit. The measured MWIR FPA performance values, as shown by the data points, are in good agreement with the predicted trends.

Spatial noise Estimation of IR sensor performance must include a treatment of spatial noise that occurs when FPA nonuniformities cannot be compensated correctly. This requires consideration of cell-to-cell response variations. Mooney et al.[43] comprehensively discussed the origin of spatial noise. The total noise determining the sensitivity of a staring array is the composite of the temporal noise and the spatial noise. The spatial noise is the residual nonuniformity U after application of nonuniformity compensation, multiplied by the signal electrons N. Photon noise, equal to $\sqrt{N}$, is the dominant temporal noise source for the high infrared background signals for which spatial noise is significant (except for TE-cooled or uncooled sensors). The total noise equivalent temperature difference is

$$\text{Total NE}\,\Delta T = \frac{\sqrt{N+U^2N^2}}{\dfrac{\partial N}{\partial T}} = \frac{\sqrt{1/N+U^2}}{\dfrac{1}{N}\dfrac{\partial N}{\partial T}} \tag{17}$$

where $\partial N/\partial T$ is the signal change for a 1 K source temperature change. The denominator, $(\partial N/\partial T)/N$, is the fractional signal change for a 1 K source temperature change. This is the relative scene contrast due to $C_{T\lambda}$ and the FPA's transimpedance.

The dependence of the total NEΔT on residual nonuniformity is plotted in Fig. 12 for 300 K scene temperature, two sets of operating conditions, and three representative detectors: LWIR HgCdTe, MWIR HgCdTe, and PtSi. Operating case A maximizes the detected signal with f/1.4 optics, 30-Hz frame rate, and 3.4 to 5.0-μm passband. Operating case B minimizes the solar influence by shifting the passband to 4.2 to 5.0 μm and trades off signal for the advantages of lighter, less expensive optics (f/2.0) at 60-Hz frame rate. Implicit in the calculations are charge-handling capacities of 30 million e^- for MWIR HgCdTe, 100 million e^- for LWIR HgCdTe, and 1 million for PtSi. The sensitivity at the lowest nonuniformities is independent of nonuniformity and limited by the

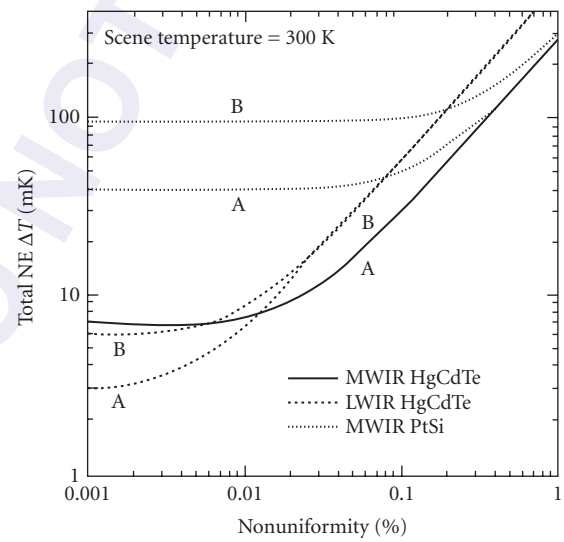

FIGURE 12 Total NEΔT versus nonuniformity at 300 K scene temperature.

shot noise of the detected signal. The LWIR sensitivity advantage is achieved only at nonuniformities less than 0.01 percent, which is comparable to that achieved with buffered input circuits. At the reported direct-injection MWIR HgCdTe residual nonuniformity of 0.01 to 0.02 percent, the total NEΔT is about 0.007 K, which is comparable to the MWIR BLIP limit. At the reported PtSi residual nonuniformity of 0.05 percent with direct detector integration, total NEΔT is higher at 0.04K, but exceeds the BLIP limit for the lower quantum efficiency detectors.

Minimum Resolvable Temperature

The minimum resolvable temperature (MRT) is often the preferred figure of merit for imaging infrared sensors. MRT is a function of spatial resolution and is defined as the signal-to-noise ratio required for an observer to resolve a series of standard four-bar targets. While many models exist due to the influence of human psycho-optic response, a representative formula[44] is

$$\mathrm{MRT}(f_s, T_{\mathrm{SCENE}}) = \frac{2\mathrm{SNR}_T \mathrm{NE}\,\Delta T(T_{\mathrm{SCENE}})}{\mathrm{MRT}(f_s)} \left[\frac{f_S^2 \Delta x \Delta y}{L \tau_{\mathrm{eye}} f_{\mathrm{frame}} N_{\mathrm{OS}} N_{\mathrm{SS}}} \right]^{1/2} \tag{18}$$

where f_s is the spatial frequency in cycles/radian, a target signal-to-noise ratio (SNR_T) of five is usually assumed, the MTF describes the overall modulation transfer function including the optics, detector, readout, and the integration process, Δx and Δy are the respective detector subtenses in mRad, τ_{eye} is the eye integration time, f_{frame} is the display frame rate, N_{OS} is the overscan ratio, N_{SS} is the serial scan ratio, and L is the length-to-width ratio of a bar chart (always set to 7). While the MRT of systems with temporal noise-limited sensitivity can be adequately modeled using the temporal NEΔT, scan noise in scanned system and fixed pattern noise in staring cameras requires that the MRT formulation be appropriately modified.

Shown in Fig. 13 are BLIP (for 70 percent quantum efficiency) MRT curves at 300 K background temperature for narrow-field-of-view (high-resolution) sensors in the MWIR and LWIR spectral bands. Two LWIR curves are included to show the impact of matching the diffraction-limited blur

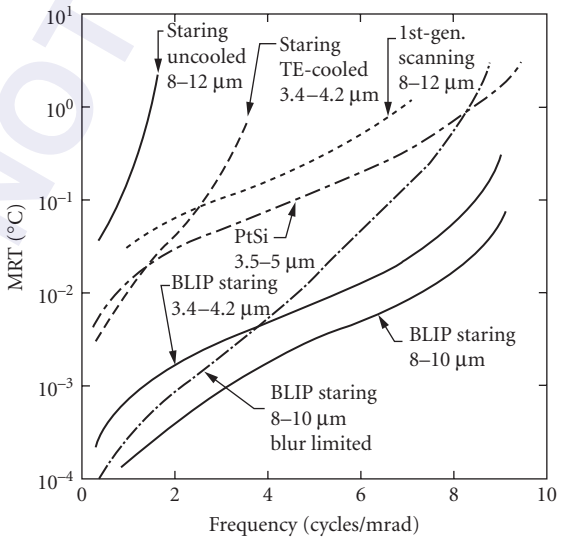

FIGURE 13 BLIP MRT for representative staring FPA configurations in the various bands.

to the pixel pitch versus 2× oversampling of the blur. The latter case commonly arises, for example, when the LWIR FPA is miniaturized to minimize die size for enhancing yield and, for hybrid FPAs, alleviating thermal expansion mismatch. Also included for comparison are representative curves for first-generation scanning, staring uncooled, staring TE-cooled and staring PtSi sensors assuming 0.1, 0.1, 0.05, and 0.1 K NEΔTs, respectively. Theoretically, the staring MWIR sensors have order of magnitude better sensitivity while the staring LWIR bands have two orders of magnitude better sensitivity than the first-generation sensor. In practice, due to charge-handling limitations, an LWIR sensor has only slightly better MRT than the MWIR sensor. The uncooled sensor is useful for short-range applications such as a driver's aid in modern automobiles; the TE-cooled sensor provides longer range than the uncooled, but less than the high-density PtSi-based cameras.

33.6 CURRENT STATUS AND FUTURE TRENDS

Status

After over three decades of ongoing development, today's second-generation infrared focal plane arrays have typically 1000 times more pixels and up to 10 times higher sensitivity than first-generation devices. FPA format is consequently now set by application need, rather than a technological barrier. Nevertheless, there is ongoing motivation for fully achieving theoretically limited performance, especially at elevated operating temperatures. Development is hence continuing in the form of third-generation FPA technology. While specifications for third-generation FPAs encompass a broad range of needs, common objectives require overcoming recurring practical limits with respect to sensitivity, frame rate, power dissipation, multispectral capability, and cost. The common methodology going forward, regardless of specific mission requirements, is to dramatically increase on-FPA functionality via system-on-chip integration. While second-generation technology was largely driven by defense-oriented R&D funding, it is likely that third-generation technology will more directly leverage emerging commercial foundry capability for 3D-IC assembly; this emerging commercial interest in 3D-IC integration should dramatically lower infrared FPA cost while further improving FPA performance.

Figure 14 summarizes the typical performance of the most prominent detector technologies. The figure, a plot of the D^*_{th} (300 K, 0° field-of-view) versus operating temperature, clearly shows the performance advantage that the intrinsic photovoltaics have over the other technologies. Thermal detectivity is used here to compare the various technologies for equivalent NEΔT irrespective of wavelength. While the extrinsic silicon detectors offer very high sensitivity, high producibility, and very long cutoff wavelengths, the very low operating temperature is often prohibitive. Also shown is the relatively low and slightly misleading detectivity of PtSi, which is offset by its

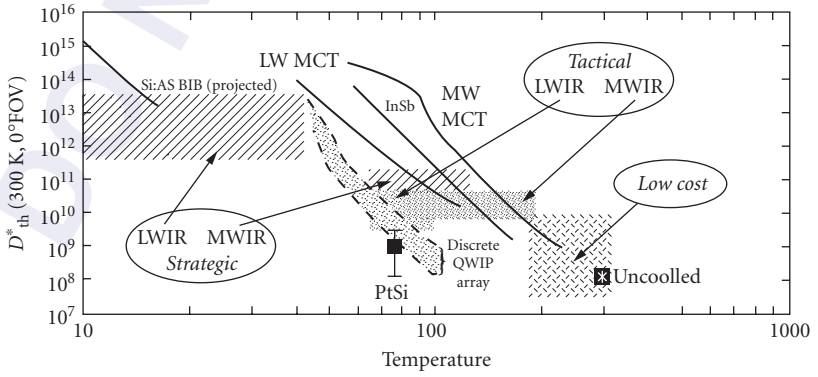

FIGURE 14 Comparison of photon detector D^*_{th} (300 K, 0°) for varous IR technologies for equivalent NEΔT.

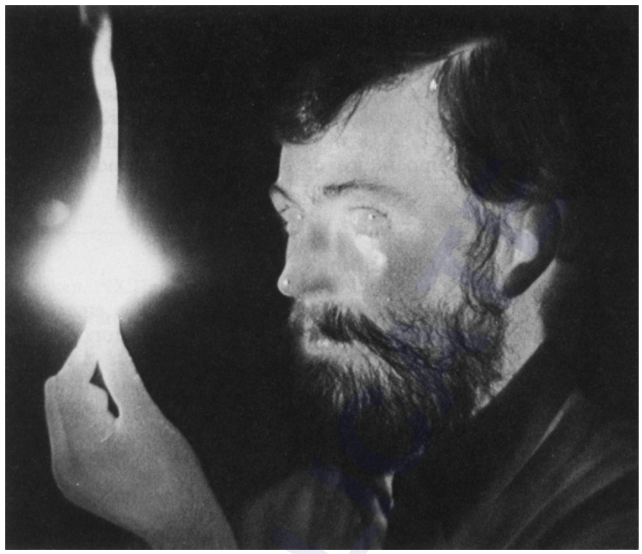

FIGURE 15 Thermal image of a man holding a match detected by the 640 × 480 MOS imager. (*Courtesy of Sarnoff*).

excellent array uniformity (i.e., array performance is commensurate with best diode performance). Thermal imaging achieved with a Sarnoff 640 × 480 PtSi FPA is shown in Fig. 15, an image free of the artifacts often plaguing competing detector technologies. Table 2 further summarizes the characteristics of monolithic and hybrid PtSi FPAs with IR-CCD, CSD, and MOS silicon multiplexers developed at the peak of PtSi FPA interest. In addition to the pixel size and fill factor, this table also shows the process design rules, maximum charge signal, Q_{max}, the reported noise equivalent temperature (NE ΔT) for operation with specific *f*/# optics, the associated company, and the pertinent references for that era.

TABLE 2 Representative Staring PtSi FPAs

Type of FPA	Pixel Size (μm^2)	Fill Factor	Design Rules (μm)	$Q_{max} \times 10^6$ (e^-/p)	NEΔT (K)	*f*/#	Year	Company	References

640 × 488 hybrid 4-point	20 × 20	80	2.0	0.75	0.1	2.0	1991		55

Similar in performance at cryogenic temperatures, InSb and HgCdTe have comparable array size and pixel yield at MWIR cutoff wavelengths. Wavelength tunability and high radiative efficiency, however, have often made HgCdTe the preferred material because the widest possible bandgap semiconductor can be configured and thus the highest possible operating temperature achieved for a given set of operating conditions. The associated cooling and system power requirements can thus be optimally distributed.

FPA costs are currently very similar for all the second-generation FPA technologies. Though it is often argued that FPA cost for IR cameras will be irrelevant once it reaches a certain minimum production volume, nevertheless the key determinants as to which FPA technology becomes ubiquitous in the coming decade are availability and cost.

Future Trends and Technology Directions

The 1980s saw the maturation of PtSi and the emergence of HgCdTe and InSb as producible MWIR detector materials. Many indicators pointed to the 1990s being the decade that IR FPA technology would enter the consumer marketplace, but penetration did not actually occur until a decade later. Figure 16 shows the chronological development of IR FPAs including monolithic and hybrid technologies. Specifically compared is the development of various hybrids (primarily MWIR) to PtSi, the pace-setting technology with respect to array size. The hybrid FPA data includes Pb-salt, HgCdTe, InSb, and PtSi devices. This database suggests that monolithic PtSi led all other technologies with respect to array size by about 2 years and clearly shows the thermal mismatch barrier confronted by hybrid FPA developers in the mid-1980s.

In addition to further increases in pixel density to $>10^{16}$ pixels, several trends are clear. Future arrays will have much more on-chip signal processing, need less cooling, have higher sensitivity (particularly intrinsic LWIR FPAs), and offer multispectral capability. If the full performance potential of the uncooled technologies is realized, either the microbolometer arrays or, less likely, the pyroelectric arrays will capture the low-cost markets. It is not unreasonable that the uncooled arrays may obsolete "low-cost" PtSi, QWIP, and HIP FPAs, and render the intrinsic TE-cooled developments inconsequential. To improve hybrid reliability, alternative detector substrate materials including silicon along with alternative readout materials will become sufficiently mature to begin monolithic integration of the intrinsic materials with highest radiative performance. True optoelectronic FPAs consisting of IR sensors with optical output capability may be developed for reducing

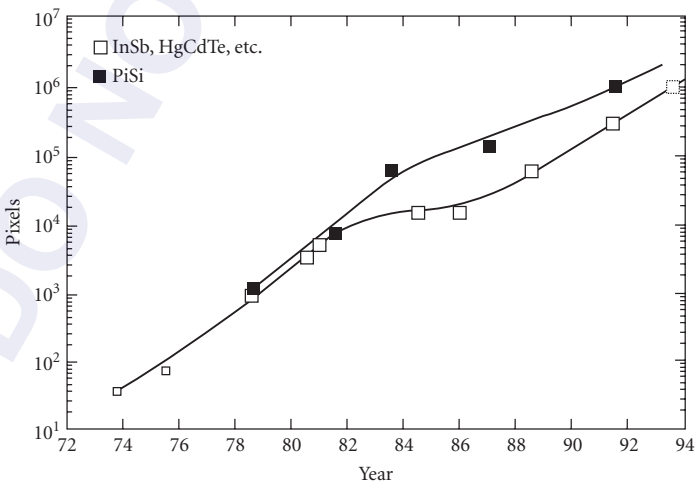

FIGURE 16 Chronological development of IR FPAs.

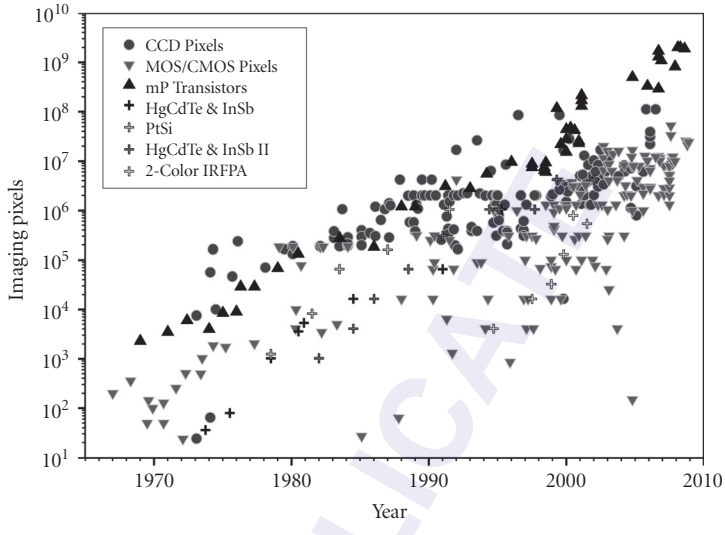

FIGURE 17 Integrated Circuit Chronology.

thermal loading and improving immunity to noise pickup. Availability of inexpensive, commercial devices is imminent along with the development of IR neural networks for additional signal processing capability.

In conclusion, it is likely instructive to compare the development of infrared sensors with both visible imaging sensors and other commercial integrated circuits, including semiconductor memory and microprocessors. All these products commonly share the benefits derived from Moore's law.[56] Fig. 17 is such a chronology showing notable devices of all types. Early infrared devices tended to develop at a pace only a few years behind the overlying trend known as Moore's law. Multicolor sensors initially developed at a rapid pace since the infrastructure was already in place. All infrared devices lag visible sensor development, which is driven by consumer demand. The largest visible sensors now boast about 100 million pixels; these foreshadow the size of upcoming infrared sensors once reliability issues and packaging costs are fully contained.

34.1 GLOSSARY

A	area
A_1, A_2, A_s, A_d	area of surface 1, surface 2, a source, a detector, respectively
A_r	area of an image on the retina of a human eye
A_p	area of the pupil of a human eye
A_{in}, A_{out}, A_{sph}	area of an input port, output port, and sphere surface, respectively
b	distance from optic axis
c	the speed of light in a vacuum
C_e	photon-to-electron conversion efficiency, i.e., quantum efficiency of a photodetector
D	diameter
dA	infinitesimal element of area
dA_1, dA_2, dA_s, dA_d	infinitesimal element of area of surface 1, surface 2, a source, a detector, respectively
dL_λ	infinitesimal change in radiance per wavelength interval
dT	infinitesimal change in temperature
$d\Phi_{12}$	infinitesimal amount of radiant power transferred from point 1 to point 2
$d\lambda$	infinitesimal wavelength interval
$d\nu$	infinitesimal frequency interval
$d\Omega$	infinitesimal change in solid angle
E	irradiance, the incident radiant power per the projected area of a surface
E_v	illuminance, the photometric equivalent of irradiance
E_r	average illuminance in an image on the retina of a human eye
E_T	retinal illuminance in units of trolands
$E_T(\lambda)$	photopic retinal illuminance from a monochromatic source in trolands

$E'_T(\lambda)$	scotoptic retinal illuminance from a monochromatic source in trolands
$E_{r\lambda}$	retinal spectral irradiance in absolute units: W $nm^{-1}m^{-2}$
f	focal length
$f\#$	F-number
g	fraction of light lost through the input and output ports of an averaging sphere
h	Planck's constant
h_s, h_d	object (source) height, image (detector) height
I	radiant intensity, the emitted or reflected radiant power per solid angle
i	photoinduced current from a radiation detector
I_v	luminous intensity, the photometric equivalent of radiant intensity
k	Boltzmann's constant
K_m	luminous efficacy (i.e., lumen-to-watt conversion factor) for photopic vision
K'_m	luminous efficacy for scotopic vision
K_{ab}	nonlinearity correction factor for a photodetector
L	radiance, the radiant power per projected area and solid angle
L_{12}	radiance from point 1 into the direction of point 2
L_a, L_b	radiance in medium a, in medium b
L_e	radiance within the human eye
L_λ	radiance per wavelength interval
L_ν	radiance per frequency interval
L_v	luminance, the photometric equivalent of radiance
$L_v(\lambda)$	luminance of a monochromatic light source
M	exitance, the emitted or reflected radiant power per the projected area of a source
m	mean value
N	photon flux, the number of photons per second
n	index of refraction
n_a, n_b	index of refraction in medium a, in medium b
n_e	index of refraction of the ocular medium of the human eye
n_s, n_d	index of refraction in the object (i.e., source) region, in the image (i.e., detector) region
N_λ	photon flux per wavelength interval
N_ν	photon flux per frequency interval
$N_{E\lambda}$	photon flux irradiance on the retina of a human eye
Q	radiant energy
Q_λ	radiant energy per wavelength interval
Q_ν	radiant energy per frequency interval
R	responsivity of a photodetector, i.e., electrical signal out per radiant signal in
r	radius
r_s, r_d, r_{sph}	radius of a source, detector, sphere, respectively
$R(\lambda)$	spectral (i.e., per wavelength interval) responsivity of a photodetector
s	distance
s_{12}	length of the light ray between points 1 and 2
s_{sd}	length of the light ray between points on the source and detector
s_{pr}	distance from the pupil to the retina in a human eye

T	absolute temperature
t	time
U	photon dose, the total number of photons
$V(\lambda)$	spectral luminous efficiency function (i.e., peak normalized human visual spectral responsivity) for photopic vision
$V'(\lambda)$	spectral luminous efficiency function for scotopic vision
w	width
x_i	the ith sample in a set of measurements
α	absorptance, fraction of light absorbed
β_a, β_b	angle of incidence or refraction
γ	absorption coefficient of a solute
δ	angle of rotation between crossed polarizers
ε	emittance of a blackbody simulator
E	étendue
η	total number of sample measurements
θ_s, θ_d	angle between the light ray and the normal to a point on the surface of a source, of a detector
θ_1, θ_2	angle between the light ray and the normal to a surface at point 1, at point 2
κ	concentration of a solute
λ	wavelength
ν	frequency
ρ	fraction of light scattered or reflected
σ	standard deviation
σ_m	standard deviation of the mean
τ	transmittance, radiant signal out per radiant signal into a material
$\tau(\lambda)$	spectral (i.e., per wavelength interval) transmittance
$\tau_e(\lambda)$	spectral transmittance of the ocular medium of the human eye
Φ	radiant power or equivalently radiant flux
ϕ	half angle subtended by a cone
$\Phi_{\text{in}}, \Phi_{\text{out}}$	incoming radiant power, outgoing radiant power
Φ_r	luminous flux at the retina of the human eye
$\Phi\lambda$	radiant power per wavelength interval
Φ_ν	radiant power per frequency interval
Φ_ν	photopic luminous flux, radiant power by photopic detectable human vision
Φ'_ν	scotopic luminous flux, radiant power detectable by scotopic human vision
Ω	solid angle, a portion of the area on the surface a sphere per of the square of the sphere radius
Ω_a, Ω_b	solid angle in medium a, in medium b

34.2 INTRODUCTION

Radiometry is the measurement of the energy content of electromagnetic radiation fields and the determination of how this energy is transferred from a source, through a medium, and to a detector. The results of a radiometric measurement are usually obtained in units of power, i.e., in watts. However, the result may also be expressed as photon flux (photons per second) or in units of energy

(joules) or dose (photons). The measurement of the effect of the medium on the transfer of radiation, i.e., the absorption, reflection, or scatter, is usually called *spectrophotometry* and will not be covered here. Rather, the assumption is made here that the radiant power is transferred through a lossless medium.

Traditional radiometry assumes that the propagation of the radiation field can be treated using the laws of geometrical optics. That is, the radiant energy is assumed to be transported along the direction of a ray and interference or diffraction effects can be ignored. In those situations where interference or diffraction effects are significant, the flow of energy will be in directions other than along those of the geometrical rays. In such cases, the effect of interference or diffraction can often be treated as a correction to the result obtained using geometrical optics. This assumption is equivalent to assuming that the energy flow is via an incoherent radiation field. This assumption is widely applicable since most radiation sources are to a large degree incoherent. For a completely rigorous treatment of radiant energy flow, the degree of coherence of the radiation must be considered via a formalism based on the theory of electromagnetism as derived from Maxwell's equations.[1,2] This complexity is not necessary for most of the problems encountered in radiometry.

In common practice, radiometry is divided according to regions of the spectrum in which different measurement techniques are used. Thus, vacuum ultraviolet radiometry, intermediate-infrared radiometry, far-infrared radiometry, and microwave radiometry are considered separate fields, and all are distinguished from radiometry in the visible and near-visible optical spectral region.

The reader should note that there is considerable confusion regarding the nomenclatures of the various radiometries. The terminology for radiometry that we have inherited is dictated not only by its historical origin,[3] but also by that of related fields of study. By the late 1700s, techniques were developed to measure light using the human eye as a null detector in comparisons of sources. At about the same time, radiant heating effects were studied with liquid-in-glass thermometers and actinic (i.e., chemical) effects of solar radiation were studied by the photoinduced decomposition of silver compounds into metallic silver. The discovery of infrared radiation in 1800 and ultraviolet radiation in 1801 stimulated a great deal of effort to study the properties of these radiations. However, the only practical detectors of ultraviolet radiation at that time were the actinic effects—for infrared radiation it was thermometers and for visible radiation it was human vision. Thus actinometry, radiometry, and photometry became synonymous with studies in the ultraviolet, infrared, and visible spectral regions. Seemingly independent fields of study evolved and even today there is confusion because the experimental methods and terminology developed for one field are often inappropriately applied to another. Vestiges of the confusion over what constitutes photometry and radiometry are to be found in many places. The problems encountered are not simply semantic, since the confusion can often lead to substantial measurement error.

As science progressed, radiometry was in the mainstream of physics for a short time at the end of the nineteenth century, contributing the absolute measurement base that led to Planck's radiation law and the discovery of the quantum nature of radiation. During this period, actinic effects, which were difficult to quantify, became part of the emerging field of photochemistry. In spite of the impossibility of performing an absolute physical measurement using the human eye, it was photometry, however, that grew to dominate the terminology and technology of radiant energy measurement practice in this period. At the beginning of the nineteenth century, the reason photometry was dominant was that the most precise (not absolute) studies of radiation transfer relied on the human eye. By the end of the nineteenth century, the growth of industries such as electric lighting and photography became the economic stimulus for technological developments in radiation transfer metrology and supported the dominance of photometry. Precise photometric measurements using instrumentation in which the human eye was the detector continued into the last half of the twentieth century. The fact that among the seven internationally accepted base units of physical measurement there remains one unit related to human physiology—the candela—is an indication of the continuing economic importance of photometry.

Presently, the recommended practice is to limit the term photometry to the measurement of the ability of electromagnetic radiation to produce a visual sensation in a physically realizable manner, that is, via a defined simulation of human vision.[4–5] Radiometry, on the other hand, is used to describe the measurement of radiant energy independent of its effect on a particular detector.

Actinometry is used to denote measurement of photon flux (photons per second) or dose (total number of photons) independent of the subsequent photophysical, photochemical, or photobiological process. Actinometry is a term that is not extensively used, but there are current examples where measurement of the "actinic effect of radiation" is an occasion to produce a new terminology for a specific photoprocess, such as for the Caucasian human skin reddening effect commonly known as sunburn. We do not attempt here to catalog the many different terminologies used in photometry and radiometry, instead the most generally useful definitions are introduced where appropriate.

This chapter begins with a discussion of the basic concepts of the geometry of radiation transfer and photon flux measurement. This is followed by several approximate methods for solving simple radiation transfer problems. Next is a discussion of radiometric calibrations and the methods whereby an absolute radiant power or photon flux measurement is obtained. The discussion of photometry that follows is restricted to measurements employing physical detectors rather than those involving a human observer. Because many esoteric terms are still in use to describe photometric measurements, the ones most likely to be encountered are listed and defined in the section on photometry.

It is not the intention that this chapter be a comprehensive listing or a review of the extensive literature on radiometry and photometry; only selected literature citations are made where appropriate. Rather, it is hoped that the reader will be sufficiently introduced to the conceptual basis of these fields to enable an understanding of other available material. There are many texts on general radiometry. Some of the recent books on radiometry are listed in the reference section.[6–10] In addition, the subject of radiometry or photometry is often presented as a subset of another field of study and can therefore be found in a variety of texts. Several of these texts are also listed in the reference section.[11–14] Finally , the reader will also find material related to radiometry, photometry, colorimetry, and spectrophotometry in Chaps. 34 to 40 in this volume and Chap. 10, "Colorimetry" in Vol. III.

34.3 RADIOMETRIC DEFINITIONS AND BASIC CONCEPTS

Radiant Power and Energy

For a steadily emitting source, that is a radiation source with a continuous and stable output, radiometric measurement usually implies measurement of the power of the source. For a flashing or single-pulse source, radiometric measurement implies a measurement of the energy of the source.

Radiometric measurements are traditionally measurements of thermal power or energy. However, because of the quantum nature of most photophysical, photochemical, and photobiological effects, in many applications it is not the measurement of the thermal power in the radiation beam but measurement of the number of photons that would provide the most physically meaningful result. The fact that most radiometric measurements are in terms of watts and joules is due to the history of the field. The reader should examine the particular application to determine if a measurement in terms of photon dose or photon flux would not be more meaningful and provide insight for the interpretation of the experiment. (See section on "Actinometry" later in this chapter.)

Radiant Energy Radiant energy is the energy emitted, transferred, or received in the form of electromagnetic radiation.
Symbol: Q Unit: joule (J)

Radiant Power Radiant power or radiant flux is the power (energy per unit time t) emitted, transferred, or received in the form of electromagnetic radiation.
Symbol: Φ *Unit:* watt (W)

$$\Phi = \frac{dQ}{dt} \tag{1}$$

Geometrical Concepts

The generally accepted terminology and basic definitions for describing the geometry of radiation transfer are presented below. More extensive discussions of each of these definitions and concepts can be found in the references.[4–14]

The concepts of irradiance, intensity, and radiance involve the density of the radiant power (or energy) over area, solid angle, and area times solid angle, respectively.

In situations where the density or distribution of the radiation on a surface is the required quantity, then it is the irradiance that must be measured. An example of where an irradiance measurement would be required is the exposure of a photosensitive surface such as the photoresists used in integrated circuit manufacture. The irradiance distribution over the surface determines the local degree of exposure of the photoresist. A nonuniform irradiance distribution will result in overexposure and/or underexposure of regions across the piece and results in a defect in manufacture.

In an optical system where the amount of radiation transfer through the system is important, then it is the radiance that must be measured. The amount of radiation passing through the optical system is determined by the area of the source from which the radiation was emitted and the field of view of the optic, also known as the solid angle or collection angle. Radiance is often thought of as a property of a source, but the radiance at a detector is also a useful concept.

Both irradiance and radiance are defined for infinitesimal areas and solid angles. However, in practice, measurements are performed with finite area detectors and optics with finite fields of view. Therefore all measurements are in fact measurement of average irradiance and average radiance.

Irradiance and radiance must be defined over a projected area in order to account for the effect of area change with angle of incidence This is easily seen from the observation that the amount of a viewed area diminishes as it is tilted with respect to the viewer. Specifically, the view of the area falls off as the cosine of the angle between the normal to the surface and the line of sight. This effect is sometimes called the *cosine law of emission* or the *cosine law of irradiation*.

Intensity is a term that is part of our common language and often a point of confusion in radiometry. Strictly speaking, intensity is definable only for a source that is a point. An average intensity is not a measurable quantity since the source must by definition be an infinitesimal point. All intensity measurements are an approximation, since a true point source is physically impossible to produce. It is an extrapolation of a series of measurements that is the approximation of the intensity. An accurate intensity measurement is one that is made at a very large distance and, consequently, with a very small signal at the detector and an unfavorable signal-to-noise ratio. Historically speaking, however, intensity is an important concept in photometry and, to a much lesser extent, it has some application in radiometry. Intensity is a property of a source, not a detector.

Irradiance Irradiance is the ratio of the radiant power incident on an infinitesimal element of a surface to the projected area of that element, dA_d, whose normal is at an angle θ_d to the direction of the radiation.
Symbol: E Unit: watt/meter^2 (W m^{-2})

$$E = \frac{d\Phi}{\cos\theta_d dA_d} \tag{2}$$

Exitance The accepted convention makes a distinction between the irradiance, the surface density of the radiation incident on a radiation detector (denoted by the subscript d), and the exitance, the surface density of the radiation leaving the surface of a radiation source (denoted by the subscript s).

Exitance is the ratio of the radiant power leaving an infinitesimal element of a source to the projected area of that element of area dA_s whose normal is at an angle θ_s to the direction of the radiation.
Symbol: M Unit: watt/meter^2 (W m^{-2})

$$M = \frac{d\Phi}{\cos\theta_s dA_s} \tag{3}$$

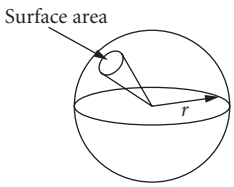

FIGURE 1 The solid angle at the center of the sphere is the surface area enclosed in the base of the cone divided by the square of the sphere radius.

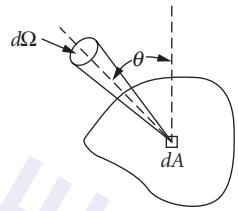

FIGURE 2 The radiance at the infinitesimal area dA is the radiant flux divided by the solid angle times the projection of the area dA onto the direction of the flux.

Intensity Radiant intensity (often simply "intensity") is the ratio of the radiant power leaving a source to an element of solid angle $d\Omega$ propagated in the given direction.
Symbol: I Unit: watt/steradian (W sr^{-1})

$$I = \frac{d\Phi}{d\Omega} \tag{4}$$

Note that in the field of physical optics, the word *intensity* refers to the magnitude of the Poynting vector and thus more closely corresponds to irradiance in radiometric nomenclature.

Solid Angle The solid angle is the ratio of a portion of the area on the surface of a sphere to the square of the radius r of the sphere. This is illustrated in Fig. 1.
Symbol: Ω *Unit:* steradian (sr)

$$d\Omega = \frac{dA}{r^2} \tag{5}$$

It follows from the definition that the solid angle subtended by a cone of half angle ϕ, the apex of which is at the center of the sphere, is given by

$$\Omega = 2\pi(1-\cos\phi) = 4\pi\sin^2\frac{\phi}{2} \tag{6}$$

Radiance Radiance, shown in Fig. 2, is the ratio of the radiant power, at an angle θ_s to the normal of the surface element, to the infinitesimal elements of both projected area and solid angle. Radiance can be defined either at a point on the surface of either a source or a detector, or at any point on the path of a ray of radiation.
Symbol: L Unit: watt/steradian $meter^2$ (W $sr^{-1}m^{-2}$)

$$L = \frac{d\Phi}{\cos\theta_s dA_s d\Omega} \tag{7}$$

Radiance plays a special role in radiometry because it is the propagation of the radiance that is conserved in a lossless optical system; see "Radiance Conservation Theorem, Homogeneous Medium." Radiance was often referred to as the brightness or the specific intensity, but this terminology is no longer recommended.

Spectral Dependence of Radiometric Quantities

Polychromatic Radiation Definitions For polychromatic radiation, the spectral distribution of radiant power (or radiant energy) is denoted as either radiant power (energy) per wavelength interval or radiant power (energy) per frequency interval.

Symbol: $\Phi_\lambda(Q_\lambda)$ *Unit:* watt/nanometer (W nm^{-1}); joule/nanometer (J nm^{-1});
or
Symbol: $\Phi_\nu(Q_\nu)$ *Unit:* watt/hertz (W Hz^{-1}); joule/hertz (J Hz^{-1})

It follows that $\Phi_\lambda d\lambda$ is the radiant power in the wavelength interval λ to $\lambda + d\lambda$, and $\phi_\nu\, d\nu$ is the radiant power in the frequency interval ν to $\nu + d\nu$. The total radiant power over the entire spectrum is therefore

$$\Phi = \int_0^\infty \Phi_\lambda d\lambda \tag{8a}$$

or

$$\Phi = \int_0^\infty \Phi_\nu d\nu \tag{8b}$$

If λ is the wavelength in the medium corresponding to the frequency ν, and since $\nu = c/n\lambda$, where c is the speed of light in a vacuum and n is the index of refraction of the medium, then

$$d\nu = -\frac{c}{n\lambda^2} d\lambda \tag{9}$$

and

$$\lambda \Phi_\lambda = \nu \Phi_\nu \tag{10}$$

Since the wavelength changes with the index of refraction of the medium, it is becoming more common to use the vacuum wavelength, $\lambda = c/\nu$. It is particularly important in high-accuracy applications to state explicitly whether or not the vacuum wavelength is being used.

Spectral versions of the other radiometric quantities, i.e., radiant energy, radiance, etc., are defined similarly.

Polychromatic Radiation Calculations As an example of the application of the concept of the spectral dependence of a radiometric quantity, consider the calculation of the response of a radiometer consisting of a detector and a spectral filter. The spectral responsivity of a detector $R(\lambda)$ is the ratio of the output signal to the radiant input at each wavelength λ. The output is usually an electrical signal, such as a photocurrent i, and the input is a radiometric quantity, such as radiant power. The spectral transmittance of a filter $\tau(\lambda)$ is the ratio of the output radiant quantity to the input radiant quantity at each wavelength λ. For a spectral radiant power Φ_λ, the photocurrent i of the radiometer is

$$i = \int_0^\infty R(\lambda)\tau(\lambda)\Phi_\lambda d\lambda \tag{11}$$

In practice, either the responsivity of the detector or the transmittance of the filter are nonzero only within a limited spectral range. The integral need be evaluated only within the wavelength limits where the integrand is nonzero.

Photometry

The radiation transfer concepts, i.e., geometrical principles, of photometry are the same as those for radiometry. The exception is that the spectral responsivity of the detector, the human eye, is specifically defined. Photometric quantities are related to radiometric quantities via the spectral efficiency functions defined for the photopic and scotopic CIE Standard Observer. The generally accepted values of the photopic and scotopic human eye response function are represented in the "Photometry" section in Table 2.

Luminous Flux The photometric equivalent of radiant power is luminous flux, and the unit that is equivalent to the watt is the lumen. Luminous flux is spectral radiant flux weighted by the appropriate eye response function. The definition of luminous flux for the photopic CIE Standard Observer is

Symbol: Φ_v *Unit:* lumen (lm)

$$\Phi_v = K_m \int \Phi_\lambda V(\lambda) d\lambda \tag{12}$$

where $V(\lambda)$ is the spectral luminous efficiency function and K_m is the luminous efficacy for photopic vision. The spectral luminous efficacy is defined near the maximum, λ_m = 555 nm, of the photopic efficiency function to be approximately 683 lm W^{-1}.

Definitions of the Density of Luminous Flux

Illuminance Illuminance is the photometric equivalent of irradiance; that is, illuminance is the luminous flux per unit area.
Symbol: E_v *Unit:* lumen/meter^2 (1m m^{-2})

$$E_v = \frac{d\Phi_v}{\cos\theta_d dA_d} = \frac{d[K_m \int \Phi_\lambda V(\lambda) d\lambda]}{\cos\theta_d dA_d} \tag{13}$$

Luminous intensity Luminous intensity is the photometric equivalent of radiant intensity. Luminous intensity is the luminous flux per solid angle. For historical reasons, the unit of luminous intensity, the candela—not the lumen—is defined as the base unit for photometry. However, the units for luminous intensity can either be presented as candelas or lumens/steradian.
Symbol: I_v *Unit:* candela or lumen/steradian (cd or lm sr^{-1})

$$I_v = \frac{d\Phi_v}{d\Omega} = \frac{d[K_m \int \Phi_\lambda V(\lambda) d\lambda]}{d\Omega} \tag{14}$$

Luminance Luminance is the photometric equivalent of radiance. Luminance is the luminous flux per unit area per unit solid angle.
Symbol: L_v *Unit:* candela/meter^2 (cdm^{-2})

$$L_v = \frac{d\Phi_v}{\cos\theta_s dA_s d\Omega} = \frac{d[K_m \int \Phi_\lambda V(\lambda) d\lambda]}{\cos\theta_s dA_s d\Omega} \tag{15}$$

Actinometry

Radiant Flux to Photon Flux Conversion Actinometric measurement practice closely follows that of general radiometry except that the quantum nature of light rather than its thermal effect is emphasized. In actinometry, the amount of electromagnetic radiation being transferred is measured in units of photons per second (photon flux). The energy of a single photon is

$$Q = h\nu \tag{16}$$

where ν is the frequency of the radiation and h is Planck's constant, 6.6261×10^{-34} J s. For monochromatic radiant power Φ_λ, measured as watts and wavelength λ, measured as nanometers, the number of photons per second N_λ in the monochromatic radiant beam is

$$N_\lambda = 5.0341 \times 10^{15} n\lambda\Phi_\lambda \tag{17}$$

Photon Dose and the Einstein Dose is the total number of photons impinging on a sample. For a monochromatic beam of radiant power Φ_λ that irradiates a sample for a time t seconds, the dose U measured as Einsteins is

$$U = 8.3593 \times 10^{-9} n\lambda\Phi_\lambda t \tag{18}$$

The Einstein is a unit of energy used in photochemistry. An Einstein is the amount of energy in one mole (Avogadro's number, 6.0221×10^{23}) of photons.

TABLE 1 Radiation Transfer Terminology, Spectral Relationships

	Radiometric	Photometric	Actinometric
Base quantity:	Radiant power (also radiant flux)	Luminous flux	Photon flux
Units:	Watts/nanometer	Lumens	Photons/second
Conversion:	—	[W/nm] $K_m V(\lambda)$	[W/nm] λ $(hc)^{-1}$
Surface density:	Irradiance	Illuminance	Photon flux irradiance
Solid angle density:	Radiant intensity	Luminous intensity	Photon flux intensity
Solid angle and surface density:	Radiance	Luminance	Photon flux radiance

Conversions between Radiometry, Photometry, and Actinometry

Conversions between radiometric, photometric, and actinometric units is not simply one of determining the correct multiplicative constant to apply. As seen previously, the conversion between radiant power and photon flux requires that the spectral character of the radiation be known. It was also shown that, for radiometric to photometric conversions, the spectral distribution of the radiation must be known. Furthermore, there is an added complication for photometry where one must also specify the radiant power level in order to determine which CIE Standard Observer function is appropriate. Table 1, which summarizes the spectral radiation transfer terminology, may be helpful to guide the reader in determining the relationship between radiometric, photometric, and actinometric concepts. In Table 1, the power level is assumed to be high enough to restrict the photometric measurements to the range of the photopic eye response function.

Basic Concepts of Radiant Power Transfer

Radiance Conservation Theorem, Homogeneous Medium In a lossless, homogeneous isotropic medium, for a perfect optical system (i.e., having no aberrations) and ignoring interference and diffraction effects, the radiance is conserved along a ray through the optical system. In other words, the spectral radiance at the image always equals the spectral radiance at the source.

It follows from Eq. (7), the definition of radiance, that for a surface A_1 with radiance L_{12} in the direction of a second surface A_2 with radiance L_{21} in the direction to a first surface, and joined by a light ray of length s_{12}, the net radiant power exchange between elemental areas on each surface is given by

$$\Delta\Phi = d\Phi_{12} - d\Phi_{21} = \frac{(L_{12} - L_{21})\cos\theta_1 \cos\theta_2 dA_1 dA_2}{s_{12}^2} \tag{19}$$

where θ_1 and θ_2 are the angles between the ray s_{12} and the normals to the surfaces A_1 and A_2, respectively. The transfer of radiant power and the terminology used in this discussion is depicted in Fig. 3.

The total amount of radiation transferred between the two surfaces is given by the integral over both areas as follows:

$$\Phi = \iint \frac{(L_{12} - L_{21})\cos\theta_1 \cos\theta_2}{s_{12}^2} dA_1 dA_2 \tag{20}$$

This is the generalized radiant power transfer equation for net exchange between two sources. In the specialized case of a source and receiver, the radiant power emitted by a receiver is zero by definition. In this case, the term L_{21} in Eq. (20) is zero.

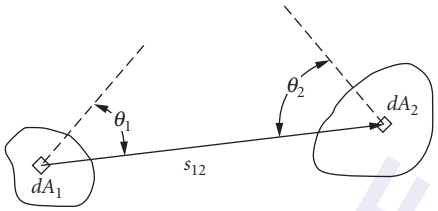

FIGURE 3 The radiant flux transferred between the infinitesimal areas dA_1 to dA_2.

Refractive Index Changes In the case of a boundary between two homogeneous isotropic media having indices of refraction n_a and n_b, the angles of incidence and refraction at the interface β_a and β_b are related by Snell's law. If the direction of the light ray is oblique to the boundary between n_a and n_b, the solid angle change at the boundary will be

$$d\Omega_a = \frac{n_b^2 \cos\beta_b}{n_a^2 \cos\beta_a} d\Omega_b \tag{21}$$

Therefore the radiance change across the boundary will be

$$\frac{L_a}{n_a^2} = \frac{L_b}{n_b^2} \tag{22}$$

This result is obtained directly by substituting the optical path for the distance in Eq. (19) and considering that the radiance transferred across the boundary between the two media is unchanged. Optical path is the distance within the medium times the index of refraction of the medium.

In the case of an optical system having two or more indices of refraction, the radiance conservation theorem is more precisely stated as: In a lossless, homogeneous isotropic medium, for a perfect optical system (i.e., having no aberrations) and ignoring interference and diffraction effects, at a boundary between two media having different indices of refraction the radiance divided by the square of the refractive index is conserved along a ray through the optical system.

Radiative Transfer through Absorbing Media For radiation transmitted through an absorbing and/or scattering medium, the radiance is not conserved. This is not only because of the loss due to the absorption and/or scattering but the medium could also emit radiation. The emitted light will be due to thermal emission (see the discussion on blackbody radiation later in this chapter). In some cases, the medium may also be fluorescent. Fluorescence is the absorption of radiant energy at one wavelength with subsequent emission at a different wavelength.

Historically, the study of radiative transfer through absorbing and/or scattering media dealt with the properties of stellar atmospheres. Presently, there is considerable interest in radiative transfer measurements of the earth and its atmosphere using instruments on board satellites or aircraft. An accurate measure of the amount of reflected sunlight (approximately 400 to 2500 nm) or the thermally emitted infrared (wavelengths >2500 nm) requires correction for the absorption, scattering, and, in the infrared, the emission of radiation by the atmosphere. This specialized topic will not be considered here. Detailed discussion is available in the references.[15–17]

34.4 RADIANT TRANSFER APPROXIMATIONS

The solution to the generalized radiant power transfer equation is typically quite complex. However, there are several useful approximations that in some instances can be employed to obtain an estimate of the solution of Eq. (20). We shall consider the simpler case of a source and a detector rather

then the net radiant power exchange between two sources, since this is the situation commonly encountered in an optical system. In this case, Eq. (20) becomes

$$\Phi = \iint \frac{L \cos\theta_s \cos\theta_d}{s_{sd}^2} dA_s dA_d \tag{23}$$

where the subscripts s and d denote the source and detector, respectively. Here it is assumed the detector behaves as if it were a simple aperture. That is, it responds equally to radiation at any point across its surface and from any direction. Such a detector is often referred to as a cosine corrected detector. Of course, deviations from ideal detection behavior within the spatial and angular range of the calculation reduces the accuracy of the calculation.

Point-to-point Approximation: Inverse Square Law

The simplest approximations are obtained by assuming radiant flux transfer between a point source emitting uniformly in all directions and a point detector. The inverse square law is an approximation that follows directly from the definitions of intensity, solid angle, and irradiance, Eqs. (2), (4), and (5), respectively. The irradiance (at an infinitesimal area whose normal is along the direction of the light ray) times the square of the distance from a point source equals the intensity of the source

$$I = \frac{\Phi}{A} s^2 = Es^2 \tag{24}$$

The relationship between the uniformly emitted radiance and the intensity of a point source is obtained similarly from Eqs. (4) and (7):

$$L = \frac{I}{A_s} \tag{25}$$

These point-to-point relationships are perhaps most important as a test of the accuracy of a radiation transfer calculation at the limit as the areas approach zero.

Lambertian Approximation: Uniformly Radiant Areas

Lambertian Sources A very useful concept for the approximation of radiant power transfer is that of a source having a radiance that is uniform across its surface and uniformly emits in all directions from its surface. Such a uniform source is commonly referred to as a lambertian source.

For the case of a lambertian source, Eq. (23) becomes

$$\Phi = L \iint \frac{\cos\theta_s \cos\theta_d}{s_{sd}^2} dA_s dA_d \tag{26}$$

Configuration factor The double integral in Eq. (26) has been given a number of different names: configuration factor, radiation interaction factor, and projected solid angle. There is no generally accepted terminology for this concept, although configuration factor appears most frequently. Analytical solutions to the double integral have been found for a variety of different shapes of source and receiver. Tabulations of these exact solutions to the integral in Eq. (26) are usually found in texts on thermal engineering,[18,19] under the heading of radiant heat transfer or configuration factor.

Radiation transfer between complex shapes can often be determined by using various combinations of configuration factors. This technique is often referred to as configuration factor algebra.[18] The surfaces are treated as pieces, each with a calculable configuration factor, and the separate configuration factors are combined to obtain the effective configuration factor for the complete surface.

Étendue The double integral in Eq. (26) is often used as a means to characterize the flux-transmitting capability of an optical system in a way that is taken to be independent of the radiant properties of the source. Here the double integral is written as being over area and solid angle:

$$\Phi = L\iint \cos\theta_d dA_s d\Omega \tag{27}$$

In this case, the surface of the lambertian source is assumed perpendicular to the optic axis and to lie in the entrance window of the optical system. The solid angle is measured from a point on the source to the entrance pupil. The étendue E of an optical system of refractive index n is defined as

$$E = n^2 \iint \cos\theta_d dA_s d\Omega \tag{28}$$

Equation (28) is sometimes referred to as the throughput of an optical system.

Total flux into a hemisphere The total amount of radiation emitted from a lambertian source of area dA_s into the hemisphere centered at dA_s (or received by a hemispherical, uniform detector centered at dA_s) is obtained from integrating Eq. (26) over the area A_d. Note that the ray s_{sd} is everywhere normal to the surface of the hemisphere; i.e., $\cos\theta_d = 1$.

$$\Phi = L\pi \int dA_s \tag{29}$$

Using Eq. (3), the definition of the exitance, the radiance at each point on the surface of the source is

$$L = \frac{M}{\pi} \tag{30}$$

Because of the relationship expressed in Eq. (30), Eq. (26) is often written in terms of the exitance.

$$\Phi = M\pi \iint \frac{\cos\theta_s \cos\theta_d}{s_{sd}^2} dA_s dA_d \tag{31}$$

In this case, the factor π is considered to be part of the configuration factor. Note again that there is no generally accepted definition of the configuration factor.

Radiation transfer between a circular source and detector The particular case of radiation transfer between circular apertures, the centers of which are located along the same optical axis as shown in Fig. 4, is a configuration common to many optical systems and is therefore illustrated here. The

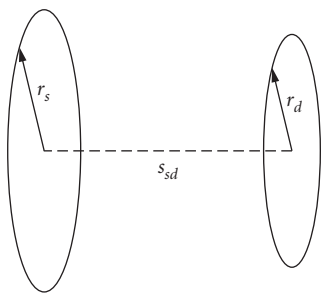

FIGURE 4 Radiant flux transfer between two circular apertures normal and concentric to the axis joining them.

radius of the source (or first aperture) is r_s, the detector (second aperture) radius is r_d, and the distance between the centers is s_{sd}. The exact solution of the integral in Eq. (26) yields

$$\Phi = \frac{2L(\pi r_s r_d)^2}{r_s^2 + r_d^2 + s_{sd}^2 + [(r_s^2 + r_d^2 + s_{sd}^2)^2 - 4r_s^2 r_d^2]^{1/2}} \tag{32}$$

This result can be approximated for the case where the sum of the squares of the distance and radii is large compared to the product of the radii, that is, $(r_s^2 + r_d^2 + s_{sd}^2) >> 2r_s r_d$ so that Eq. (32) reduces to

$$\Phi \cong \frac{L(\pi r_s r_d)^2}{r_s^2 + r_d^2 + s_{sd}^2} \tag{33}$$

From this expression the irradiance at the detector can be obtained

$$E = \frac{\Phi}{A_d} \cong \frac{LA_s}{r_s^2 + r_d^2 + s_{sd}^2} \cong \frac{LA_s}{s_{sd}^2} \tag{34}$$

where A_s is the area of the lambertian disk and A_d is the detector area. The approximation at the extreme right is obtained by assuming that the radii are completely negligible with respect to the distance. This is the same result that would be obtained from a point-to-point approximation.

Off-axis irradiance: cosine-to-the-fourth approximation Equation (34) describes the irradiance from a small lambertian disk to a detector on the ray axis and where both surfaces are perpendicular to the ray. If the detector is moved off-axis by a distance b as depicted in Fig. 5, the ray from A_s to A_d will then be at an angle with respect to the normal at both surfaces as follows

$$\theta_s = \theta_d = \theta = \tan^{-1}\left(\frac{b}{s_{sd}}\right) \tag{35}$$

The projected areas are then ($A_s \cos\theta$) and ($A_d \cos\theta$). In addition, the distance from the source to the detector increases by the factor ($1/\cos\theta$). The radiant power at a distance b away from the axis therefore decreases by the fourth power of the cosine of the angle formed between the normal to the surface and the ray.

$$\Phi \cong \frac{LA_sA_d}{s_{sd}^2}\cos^4\theta \tag{36}$$

Since the radiance is conserved for propagation in a lossless optical system, Eq. (36) also approximates the radiant power from an off-axis region of a large lambertian source received at a small detector. The approximate total radiant power received at the detector would then be the sum of the radiant power contributed by each region of the source.

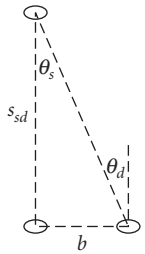

FIGURE 5 illustration of the cosine-fourth effect on irradiance, displacement of the receiving surface by a distance b.

Spherical lambertian source In order to compute the radiant power at a point at a distance s_{sd} from the center of a spherical lambertian source of radius r_{sph}, it is not necessary to explicitly solve the integrals in the radiation transfer equation. The solution is readily obtained from the symmetry of the lambertian sphere. Using the relationship between the exitance and radiance of a lambertian source [Eq. (30)], the total radiation power emitted by the source is obtained from the product of the surface area of the source times the exitance.

$$\Phi = 4\pi^2 r_{sph}^2 L \tag{37}$$

The radiant power is isotropically emitted. Therefore, the irradiance at any point on an enclosing sphere of radius s_{sd} is the total radiant power divided by the area of the enclosing sphere.

$$E = \frac{\pi r_{sph}^2 L}{s_{sd}^2} \tag{38}$$

Note that the irradiance from a spherical lambertian source follows the inverse square law at all distances from the surface of the sphere. The intensity of a spherical lambertian source is

$$I = \pi r_{sph}^2 L \tag{39}$$

Radiant Flux Transfer through a Lambertian Reflecting Sphere A lambertian reflector is a surface that uniformly scatters a fraction ρ of the radiation incident upon it.

$$L = \frac{\rho E}{\pi} \tag{40}$$

where E is the irradiance.

A spherical enclosure whose interior is coated with a material that approximates a lambertian reflector is a widely used tool in radiometry and photometry.[20] Such spheres are used either for averaging a nonuniform radiant power distribution (averaging sphere) or for measuring the total amount of radiant power emitted from a source (integrating sphere).

The sphere has the useful property whereby the solid angle subtended by any one section of the wall times the projected area is constant over all other points on the inside surface of the sphere. Therefore, if radiation falling on any point within the sphere is uniformly reflected, the reflected radiation will be uniformly distributed, i.e., produce uniform irradiance, throughout the interior. This result follows directly from the symmetry of the sphere.

Consider a sphere of radius r_{sph} and the radiant power transfer between two points on the inner surface. The normals to the two points are radii of the sphere and form an isosceles triangle when taken with the ray joining the points. Therefore, the angles between the ray and the normals to each point are equal. From Eq. (26)

$$\Phi = L \iint \frac{\cos^2 \theta}{s_{sd}^2} dA_s dA_d \tag{41}$$

The length of the ray joining the points is $2r_{sph} \cos \theta$. The irradiance is therefore

$$E = \frac{\Phi}{A_d} = \frac{LA_s}{4r_{sph}^2} \tag{42}$$

which is independent of the angle θ. If Φ_{in} is the radiant power entering the sphere, the irradiance at any point on the sphere after a single reflection will be

$$E = \frac{\rho \Phi_{in}}{4\pi r_{sph}^2} \tag{43}$$

A fraction ρ of the flux will be reflected and again uniformly distributed over the sphere. After multiple reflections the irradiance at any point on the wall of the sphere is

$$E = \frac{(\rho + \rho^2 + \rho^3 + \cdots)\Phi_{in}}{4\pi r_{sph}^2} = \frac{\rho \Phi_{in}}{(1-\rho)A_{sph}} \tag{44}$$

where A_{sph} is the surface area of the sphere. The flux Φ_{out} exiting the sphere through a port of area A_{out} is

$$\Phi_{out} = \frac{\rho \Phi_{in} A_{out}}{(1-\rho)A_{sph}} \tag{45}$$

In Eq. (45) it is assumed that the loss of radiation at the entrance and exit ports is negligible and does not affect the symmetry of the radiation distribution.

The effect of the radiation lost through the entrance and exit ports is approximated as follows. After the first reflection, the fraction of radiation lost in each subsequent reflection is equal to the combined areas of the ports divided by the sphere area. Therefore the fraction reflected within the sphere is

$$g = 1 - \frac{A_{in} + A_{out}}{A_{sph}} \tag{46}$$

Using this in Eq. (44) yields

$$\Phi_{out} = \frac{\rho \Phi_{in} A_{out}}{(1-\rho g)A_{sph}} \tag{47}$$

Since the sphere is approximately a lambertian source, the radiance at the exit port is

$$L = \frac{\rho \Phi_{in}}{(1-\rho g)\pi A_{sph}} \tag{48}$$

Radiometric Effect of Stops and Vignetting

Refer to Fig. 6 for an illustration of these definitions. The *aperture stop* of an optical system is an aperture near the entrance to the optical system that determines the size of the bundle of rays leaving the source that can enter the optical system.

The *field stop* is an aperture within the optical system that determines the maximum angle of the rays that pass through the aperture stop that can reach the detector. The position and area of the field stop determines the field of view of the optical system. The field stop limits the extent of the source that is represented in its image at the detector.

The image of the aperture stop in object space, i.e., in the region of the source, is the *entrance pupil*. The image of the aperture stop in image space, i.e., in the region of the detector, is the *exit pupil*. Light rays that pass through the center of the aperture stop also pass through the centers of the images of the aperture stop at the entrance and exit pupils. Since all of the light entering the optical system must pass through the aperture stop, all of the light reaching the detector appears to pass through the exit pupil.

The field stop defines the solid angle within the optical system, the system field of view. When viewed from the image, the field stop of an optical system takes on the radiance of the object being imaged. This is a useful radiometric concept since a complex optical system can often be approximated as an exit pupil having the same radiance as the object being imaged (modified by the system transmission losses). The direction in which the radiation in the image appears to be emitted is,

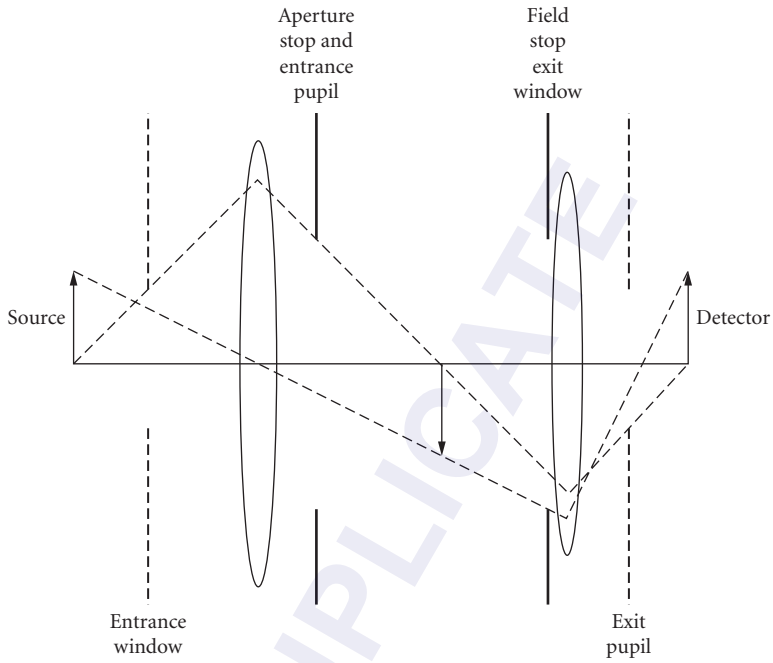

FIGURE 6 Schematic showing the relative positions of the stops, pupils, and windows in a simple optical system.

of course, limited by the aperture at the field stop. A word of caution: if the object is small, its image will be limited by diffraction effects and its radiance will depart even further from the extended source (large area) approximations used here.

The *entrance window* is the image of the field stop at the source and the *exit window* is the image of the field stop at the detector. If the field stop coincides with the detector, i.e., the detector is in the image plane of the optical system, then the entrance window will correspond with the object plane on the source. If the field stop does not coincide with the image plane at the detector, then because of parallax, different portions of the source will be visible from different points within the exit pupil. This condition, known as *vignetting*, causes a decrease in the irradiance at the off-axis points on the detector or image plane.

Approximate Radiance at an Image

Aplanatic Optical Systems Except for rays that lie on the optic axis, the radiance of an image must be based on a knowledge of the image quality since any aberrations introduced by the optical system divert some of the off-axis rays away from the image.

Consider a well-corrected optical system that is assumed to be aplanatic for the source and image points. That is, the optical system obeys Abbe's sine condition which is

$$n_s h_s \sin\theta_s = n_d h_d \sin\theta_d \tag{49}$$

where n_s and n_d are the refractive indices of the object (source) and image (detector) spaces, h_s and h_d are the object and image heights, and θ_s and θ_d are the angles between the off-axis rays and the

optic axis in object and image space. From Eq. (27) the flux radiated by a small lambertian source of area A_s into the solid angle of the optical system is

$$\Phi \cong 2\pi L A_s \int_0^{\theta_s} \cos\theta \sin\theta d\theta = \pi L A_s \sin^2\theta_s \tag{50}$$

The differential of the solid angle is obtained from Eq. (6). Since Φ is the radiant flux at the image and A_d is the area of the image, the irradiance at the image is

$$E = \frac{\Phi}{A_d} = \frac{\pi L A_s}{A_d} \sin^2\theta_s \tag{51}$$

If h_s and h_d are the radii of circular elements A_s and A_d, then according to Abbe's sine condition

$$\frac{A_s}{A_d} = \frac{n_d^2 \sin^2\theta_d}{n_s^2 \sin^2\theta_s} \tag{52}$$

The irradiance at the image is

$$E = \frac{\pi L n_d^2}{n_s^2} \sin^2\theta_d \tag{53}$$

Numerical Aperture and F-number The quantity $n_d \sin\theta_d$ in Eq. (53) is called the *numerical aperture* of the imaging system. The irradiance of the image is proportional to the square of the numerical aperture. Geometrically speaking, the image irradiance increases with the angle of the cone of light converging on the image.

Another approximate measure of the image irradiance of an optical system is the *F*-number, *f*# (sometimes called the focal ratio) defined by the ratio of focal length (in the image space) *f* to the diameter *D* of the entrance pupil. For a source at a very large distance

$$f\# = \frac{f}{D} = \frac{1}{2\tan\theta_d} \cong \frac{1}{2\sin\theta_d} \tag{54}$$

The approximate image irradiance expressed in terms of the *F*-number is

$$E \cong \pi L \left(\frac{n_d}{2 n_s f\#} \right)^2 \tag{55}$$

34.5 ABSOLUTE MEASUREMENTS

An absolute measurement, often referred to as an absolute calibration, is a measurement that is based upon, i.e., derived from, one of the internationally recognized units of physical measurement. These units are known as the SI units (Système International d'Unitès[21]). The absolute SI base units are the meter, second, kilogram, kelvin, ampere, candela, and mole. The definitions of the SI units, the methods for their realization, or their physical embodiment are a matter of international agreement under the terms of the 1875 Treaty of the Meter. A convenient method (but often not a sufficient condition) for achieving absolute accuracy is to obtain traceability to one of the SI units via a calibration transfer standard issued by one of the national standards laboratories. The United States standards laboratory is the National Institute of Standards and Technology (NIST, formerly the National Bureau of Standards).

A relative measurement is one that is not required to be traceable to one of the SI units. Relative measurements are usually obtained as the ratio of two measurements. An example of a relative

measurement is the determination of the transmittance of an optical material wherein the ratio of the output radiant power to the input radiant power is measured; the measurement result is independent of SI units.

Absolute Accuracy and Traceability

Establishment of legal traceability to an SI unit requires that one obtain legally correct documentation, i.e., certification, of the device that serves as the calibration transfer standard and sometimes of the particular measurement process in which the device is to be used. Certification of legal traceability within each nation is obtained from the national standards laboratory of that nation. Often another nation's standards laboratory can be used to establish legal traceability, provided that there exists the legal framework for mutual recognition of the legality of each other's standards.

In order to establish accurate traceability to an SI unit, one needs to determine the total accumulated error arising from: (1) the realization of the base SI unit; (2) if applicable, the derivation of an associated measurement quantity; (3) if applicable, scaling to a higher or lower value; and (4,5...) transfer of the calibration from one device to another. The last entries must include the instability of the calibration transfer devices; the others may or may not involve a transfer device.

Legal traceability to SI units does not guarantee accurate traceability and vice versa. In order to obtain accurate traceability, it is not necessary to prove traceability to a national standards laboratory. Instead, the measurement must trace back to one of the SI units. However, it is usually convenient to establish accurate traceability via one of the national standards laboratories. The degree of convenience and accuracy will depend upon the accuracy of the measurement method and type of calibration transfer device available from the particular national standards laboratory.

Although relative measurements do not require traceability to one of the SI base units often to satisfy legal requirements traceability to a national standards laboratory may be necessary.

Types of Errors, Uncertainty Estimates, and Error Propagation

It is almost pointless to state a value for an absolute or relative measurement without an estimate of the uncertainty and the degree of confidence to be placed in the uncertainty estimate. Verification of the accuracy and the confidence limits is not only desirable but is often a legal requirement.

The accuracy and the uncertainty of a measurement are synonymous. The usual terminology is that a measurement is "accurate to within $\pm x$" or "uncertain to within $\pm x$", where x is either a fraction (percent) of the measured value or an interval within which the true value is known to within some degree of confidence. The degree of confidence in the uncertainty estimate is the confidence interval or σ-level.

Errors are classified as type A errors, also known as random errors, and type B, or systematic errors. Type A errors are the variations due to the effects of uncontrolled variables. The magnitude of these effects is usually small and successive measurements form a random sequence. Type B errors are not detectable as variations since they do not change for successive measurements with a given apparatus and measurement method. Type B errors arise because of differences between the ideal behavior embodied in fundamental laws of physics and real behavior embodied in an experimental simulation of the ideal. A type B error could also be a function of the quantity being measured; for example, in a blackbody radiance standard using the freezing point of a metal and its defined temperature instead of the true absolute temperature.

Type A errors are estimated using standard statistical methods. If the distribution of the measurements is known (e.g., either Gaussian, which is often called a normal distribution, or Poisson), then one uses the formalism appropriate to the distribution. Unless enough data is obtained to establish that the distribution is not Guassian, it is usual to assume a gaussian distribution. A brief discussion of Gaussian statistical concepts and terminology is given here to guide the reader in interpreting or determining the uncertainty in a radiometric or photometric calibration. A thorough discussion of these topics is available via the web from NIST.[22]

The mean value m, the standard deviation σ, and the standard deviation of the mean σ_m, of a set of measurement x_i, are estimated for a small sample from a gaussian distribution of measurements as follows:

$$m = \sum_i \frac{x_i}{\eta} \tag{56}$$

$$\sigma^2 = \frac{\sum (x_i - m)^2}{\eta - 1} \tag{57}$$

$$\sigma_m = \frac{\sigma}{\sqrt{\eta}} \tag{58}$$

where $i = 1$ to η, and η is the total number of measurements.

The standard deviation is an estimate of the spread of the individual measurements within a sample, and it approaches a constant value as η is increased.

The standard deviation of the mean is an estimate of the spread of the values of the mean that would be obtained from several different sets of sample measurements. The standard deviation of the mean decreases as the number of samples in a set increases, since the estimate of the mean approaches the true mean for an infinite data set. The standard deviation of the mean is used in the estimate of the confidence interval assigned to the reported value of the mean.

The degree of confidence to which a reported value of the mean is valid is known as the *confidence interval* (CI). If it is assumed that a very large set of measurements has been sampled, then the CI is often given in terms of the number of standard deviations of the mean (one-σ level, two-σ level, etc.) within which the type A error of a reported value is known.

The CI is the probability that the mean from a normal distribution will be within the estimated uncertainty. That is, for a z-percent confidence interval, z-percent of the measurements will fall inside and $(100 - z)$ percent will fall outside of the uncertainty estimate. For small measurement samples from a gaussian distribution, Student's t-distribution is used to estimate the CI. Tables of Student's t-distribution along with discussions concerning its use are presented in most statistics textbooks. For large sets of measurements, a one-σ level corresponds approximately to a 68-percent CI, a two-σ level to a 95-percent CI, and a three-σ level to a 99.7-percent CI.

The reader is cautioned about using the σ level designation to describe the CI for a small sample of measurements. As an example of the small versus large sample difference, consider two data sets, one consisting of three samples and the other ten. Using a Student's t-distribution to estimate the CI for the three sample set, the one-σ, two-σ, and three-σ levels correspond to CIs of 61 percent, 86 percent, and 94 percent, respectively. For the ten-sample set, the respective CIs are 66 percent, 93 percent, and 99 percent. It can be quite misleading to state only the σ level of the uncertainty estimate without an indication of the size of the measurement set from which it was drawn. In order to avoid misleading accuracy statements, it is recommended that, instead of simply reporting the σ level, either the estimated CI be reported or the standard deviation of the mean be reported along with the number of measurement samples obtained.

Type B error estimates are either educated guesses of the magnitude of the difference between the real and the ideal or they are the result of an auxiliary measurement. If an appropriate auxiliary experiment can be devised to measure a systematic or type B error, then it need no longer be considered an error. The result obtained from the auxiliary measurement can usually be used as a correction factor. If a correction factor is applied, then the uncertainty is reduced to the uncertainty associated with the auxiliary experiment.

Most of the effort in high-accuracy radiometry and photometry is devoted to reducing type B errors. The first rule for reducing type B errors is to ensure that the experiment closely simulates the ideal. The second rule is that the differences between real and ideal should be investigated and that a correction be applied. Unlike type A errors for which an objective theory exists, the educated guess for a type B error is often subjective. For type B errors, neither a confidence interval nor a σ level is objectively quantifiable.

Error propagation, error accumulation, or a combined uncertainty analysis is the summation of all the type A and type B uncertainties that contribute to the final measurement in the chain. Because type A errors are truly random, they are uncorrelated and the accumulated type A error is obtained from the square-root of the sum of the squares (also known as root-sum-square, RSS) of the several type A error estimates. Type B uncertainties, however, may be either correlated or uncorrelated. If they are uncorrelated, the total uncertainty is the RSS of the several estimates. Type B uncertainties that are correlated must be arithmetically summed in a way that accounts for their correlation. Therefore, it is usually desirable to partition type B uncertainties so that they are uncorrelated.

Absolute Sources

Planckian or Blackbody Radiator A blackbody, or planckian, radiator is a thermal radiation source with a predictable absolute radiance output. An ideal blackbody is a uniform, i.e., lambertian, source of radiant power having a predictable distribution over area, solid angle, and wavelength. It is used as a standard radiance source from which the other radiometric quantities, e.g., irradiance, intensity, etc., can be derived.

Blackbody simulators are in widespread use not only at national standards laboratories but also in many other industrial, academic, and government laboratories. Blackbody simulators are commercially available from a number of manufacturers and cover a wide range of temperatures and levels of accuracy. Because they are in such widespread use as absolute standard sources for a variety of radiometric applications, particularly in the infrared, they are discussed here in some detail. Furthermore, since many practical sources of radiation can be approximated as a thermal radiation source, a blackbody function is often used in developing the radiometric model of an optical system.

An ideal blackbody is a completely enclosed volume containing a radiation field which is in thermal equilibrium with the isothermal walls of the enclosure that is at a known absolute temperature. The radiation in equilibrium with the walls does not depend upon the shape or constitution of the walls provided that the cavity dimensions are much larger than the wavelengths involved in the spectrum of the radiation.

Since the radiometric properties of a blackbody source are completely determined by its temperature, the SI base unit traceability for blackbody-based radiometry is to the kelvin. Because of recent improvements in the accuracy of absolute detector-based measurements thermodynamic temperatures are obtained by radiometric detector methods. [23]

Since the radiation field and the walls are in equilibrium, the energy in the radiation field is determined by the temperature of the walls. The relationship between the absolute temperature T and the spectral radiance L_λ is given by Planck's law:

$$L_\lambda = \frac{2hc^2}{n^2\lambda^5}[e^{(hc/n\lambda kT)} - 1]^{-1} \tag{59}$$

Here h is Planck's constant, c is the speed of light in a vacuum, k is Boltzmann's constant, λ is the wavelength, and n is the index of refraction of the medium. Incorporating the values of the constants in this equation yields,

Spectral radiance units: W m^{-2} sr^{-1} μm^{-1}

$$L_\lambda = \frac{1.1910\times10^{8}}{n^2\lambda^5}[e^{(1.4388\times10^{4}/n\lambda T)} - 1]^{-1} \tag{60}$$

It follows that the peak of the spectrum of a blackbody is determined by its temperature (Wein displacement law).

$$n\lambda_{\max}T = 2898\,\mu\text{mK} \tag{61}$$

It is often useful to measure blackbody spectral radiance in units of photons per second N_λ. The form of Planck's law in this case is

Spectral radiance units: photons s^{-1} m^{-2} sr^{-1} μm^{-1}

$$N_\lambda = \frac{2c}{n\lambda^4}[e^{(hc/n\lambda kT)} - 1]^{-1} \tag{62}$$

The peak of this curve is not at the same wavelength as in the case of radiance measured in units of power. Wein's displacement law for blackbody radiance measured in photons per second is

$$n\lambda_{\max} T = 3670\,\mu\text{mK} \tag{63}$$

In other applications, the spectral distribution of the blackbody radiation may be required in units of photons per second per frequency interval (symbol: N_ν). This form of Planck's law is
Spectral radiance units: photons s^{-1} m^{-2} sr^{-1} Hz^{-1}

$$N_\nu = \frac{2n^2\nu^2}{c^2}[e^{(h\nu/kT)} - 1]^{-1} \tag{64}$$

and that of Wein's displacement law is

$$\frac{T}{\nu_{\max}} = 1.701 \times 10^{-11}\,\text{KHz}^{-1} \tag{65}$$

Planck's law integrated over all wavelengths (or frequencies) leads to the Stefan-Boltzmann law which describes the temperature dependence of the total radiance of a blackbody. For blackbody radiance measured as radiant power, the Stefan-Boltzmann law is
Radiance units: W m^{-2} sr^{-1}

$$L = 1.8047 \times 10^{-8} n^2 T^4 \tag{66}$$

Equation (66) is the usual form of the Stefan-Boltzmann law; however, it can also be derived for blackbody radiance measured as photon flux.
Radiance units: photons s^{-1} m^{-2} sr^{-1}

$$N = 4.8390 \times 10^{14} n^2 T^3 \tag{67}$$

The preceding expressions are valid provided that the cavity dimensions are much larger than the wavelengths involved in the spectrum of the radiation. The restriction imposed by the cavity dimension may lead to significant errors in very high accuracy radiometry or very long wavelength radiometry. For example, in a cube 1 mm on a side and at a wavelength of 1 μm, the approximate correction to Planck's equation is only 3×10^{-7}; however, if the measurement is made within a 1-nm bandwidth or less, the root mean square fluctuation of the signal is about 2×10^{-3} which may not be negligible. Recent work describes how well the Planck and Stefan-Boltzmann equations describe the radiation in small cavities and at long wavelengths.[24–26]

Blackbody Simulators An ideal blackbody, being completely enclosed, does not radiate into its surrounds and therefore cannot serve as an absolute radiometric source. A blackbody simulator is a device that does emit radiation but only approximates the conditions under which Planck's law is valid. In general, a blackbody simulator is an enclosure at some fixed temperature with a hole in it through which some of the radiation is emitted. Some low-accuracy blackbody simulators are fabricated as a flat surface held at a fixed temperature.

A blackbody simulator can be used as an absolute source provided that the type B errors introduced by the deviations from the ideal Planck's-law conditions are evaluated and the appropriate corrections are applied. In a blackbody simulator there are three sources of type B error: inaccurate surface temperature, nonequilibrium between the radiant surface and the radiation field due to openings in the enclosure, and nonuniformity in the temperature of the radiant surface.

Calculation of the effect of a temperature error on the spectral radiance is obtained from the derivative of Planck's law with respect to temperature.

$$\frac{dL_\lambda}{L_\lambda} = \frac{hc}{n\lambda kT}[1 - e^{-(hc/n\lambda kT)}]^{-1}\frac{dT}{T} \tag{68}$$

Since the radiation field is in equilibrium with the surface of the cavity, it is the absolute temperature of the surface that must be measured. It is usually impractical to have the thermometer located on the emitting surface and it is the temperature within the wall that is measured. The difference between the temperature within the wall and the surface must therefore be measured, or calculated from a thermal model, and the correction applied.

The error due to nonequilibrium occurs because a practical radiation source cannot be a completely closed cavity. The correction factor for the effect on the radiance due to the escaped radiation is obtained from application of Kirchhoff's law. Simply stated, Kirchhoff's law states that the absorptive power of a material is equal to its emissive power. According to the principle of detailed balancing, for a body to be in equilibrium in a radiation field, the absorption of radiation by a given element of the surface for a particular wavelength, state of polarization, and in a particular direction and solid angle must equal the emission of that same radiation. If this were not true, the body would either emit more than it absorbs or vice versa, it would not be in equilibrium with the radiation, and it would either heat up or cool off.

Radiation impinging upon a body is either reflected, transmitted, or absorbed. The fraction of the incident radiation that is reflected ρ (reflectance), plus the fraction absorbed α (absorptance), plus the fraction transmitted τ (transmittance), is equal to one.

$$1 = \rho + \alpha + \tau \tag{69}$$

From Kirchhoff's law for a surface in radiative equilibrium, the fraction of absorbed radiation equals the fraction emitted ε (emittance or emissivity). Therefore, the sum of the reflectance, transmittance, and emittance must also be equal to one. If the body is opaque, the transmittance is zero and the emittance is just equal to one minus the reflectance.

$$\varepsilon = 1 - \rho \tag{70}$$

For a body not in an enclosed volume to be in equilibrium with a radiation field, it must absorb all the radiation impinging upon it, because any radiation lost through reflection will upset the equilibrium. An emittance less than one is the measure of the departure from a perfect absorber and, therefore, it is a measure of the radiance change due to the departure from closed-cavity equilibrium. In general, cavities with an emittance nearly equal to unity are those for which the size of the hole is very small in comparison to the size of the cavity.

Temperature nonuniformity modifies the radiant flux over the whole cavity in much the same way as the presence of a hole in that it is a departure from equilibrium. Radiation loss from the region of the cavity near the hole is typically larger than from other regions and this loss produces a temperature change near the hole and a nonuniformity along the cavity wall. In addition, the temperature nonuniformity is another source of uncertainty in the absolute temperature. In practice, the limiting factor in the accuracy of a high-emittance blackbody simulator is typically the nonuniformity of the temperature.

Accurate calculation of the emittance of a cavity radiator requires a detailed knowledge of the geometry of the cavity and the viewing system. This is a radiance transfer calculation and, in order to perform it accurately, one must know the angular emitting or reflecting properties of the cavity surface. The regions that contribute most to the accuracy of the calculation are those that radiate directly out the hole into the direction of the solid angle of the optical detection system.

There are many methods of calculating the emittance. The most popular are based upon the assumption of uniform emission that is independent of direction, i.e., lambertian emission. One can calculate the spectral emittance and temperature of each element along the cavity wall and sum the contribution from each element to the cavity radiance. Extensive discussion of the diffuse emittance and temperature nonuniformity calculation methods can be found elsewhere.[27–31]

Instead of calculating the emittance of a cavity directly, the problem may be transformed into one of calculating the absorptance for a ray incident from the direction in which the emittance is required.[32–34] The quantity to be calculated in this case is that fraction of the radiation entering the hole from a particular direction which is subsequently reflected out of the hole into a hemisphere.

Real surfaces are not perfectly diffuse reflectors and often have a higher reflectance in the specular direction. A perfect specularly reflecting surface is at the other extreme for calculating the emittance of a blackbody simulator. In some applications, a specular black surface might perform better than a diffusely reflecting one, particularly if the viewing geometry is highly directional and well known. The calculation of the emittance of a cavity made from a perfectly specular reflector is obtained in terms of the number of reflections undergone by an incident ray before it leaves the cavity.[35]

One can reduce the error due to temperature nonuniformity by reducing the emittance of those regions along the cavity wall that do not contribute radiation directly to that emitted from the cavity.[36] That is, by fabricating the "hidden" portions of the cavity wall from a specular, highly reflecting material and by proper orientation of these surfaces, the highly reflecting surfaces absorb almost none of the radiation but reflect it back to the highly absorbing surfaces. Since the highly reflective surfaces absorb and emit very little radiation, their temperature will have a minimal effect on the equilibrium within the cavity.

In high-accuracy applications, it is preferable to measure rather than calculate the emittance of the blackbody cavity. This can be done either by comparison of the radiance of the device under test to that of a higher-quality blackbody simulator (emittance closer to unity) or by a direct measurement of the reflectance of the cavity.[37] Accurate measurement of thermal nonuniformity by measurement of the variations in the radiance from different regions within the cavity is made difficult by the fact that radiance variations depend not only on the local temperature but also upon the emittance of the region.

Synchrotron Radiation *A* synchrotron is an electronic radiation source that if well-characterized has a predictable absolute radiance output. A synchrotron source is a very nonuniform, i.e., highly directional and highly polarized, radiance standard in contrast to a blackbody which is uniform and unpolarized. However, like a blackbody, a synchrotron has a predictable spectral output and it is useful as a standard radiance source from which the other radiometric quantities, e.g., irradiance, intensity, etc., can be derived.

Classical electrodynamic theory predicts that an accelerated charged particle will emit radiation. A synchrotron is a type of electron accelerator where the electron beam is accelerated in a closed loop and synchrotron radiation is the radiation emitted by the electrons undergoing acceleration. The development of these and other charged particle accelerators led to closer experimental and theoretical scrutiny of the radiation emitted by an accelerated charged particle. These studies culminated in Schwinger's complete theoretical prediction, including relativistic effects, of the spectral and angular distribution of the radiation emitted by a beam in a particle accelerator.[38] The accuracy of Schwinger's predictions have been verified in numerous experimental studies.[39–41]

Schwinger's theoretical model of the absolute amount of radiation emitted by an accelerated charged particle is analogous to the Planck equation for blackbody sources in that both predict the behavior of an idealized radiation source. Particle accelerators, when compared to even the most elaborate blackbodies, are, however, far more expensive. Furthermore, in order to accurately predict the spectral radiance of the beam in a particle accelerator, much detailed information is required of the type not found for most accelerators. Accurately predictable radiometric synchrotron sources are consequently found only in a few laboratories throughout the world.

The magnitude of the radiant power output from a synchrotron source is proportional to the number of electrons in the beam and their velocity, i.e., the number of electrons per second or current and their energy. Therefore, synchrotron radiometry is traceable to the SI unit of electricity, the ampere.

Because absolute synchrotron sources are so rare, a detailed discussion of Schwinger's model of synchrotron radiation and the various sources of uncertainty will not be presented here. It is generally useful, however, to know some of the characteristics of synchrotron radiation. For example, the radiance from a synchrotron beam is highly polarized and very nonuniform: radiant power is almost entirely in the direction of the electron velocity vector and tangent to the electron beam. The peak of the synchrotron radiation spectrum varies from the vacuum ultraviolet to the soft x-ray region depending upon the energy in the beam. Higher-energy beams have a shorter wavelength peak: 1-GeV

peaks near 10 nm, 6-GeV peaks near 0.1 nm. Radiant power decreases to longer wavelengths by very roughly two decades for every decade increase of wavelength, so that for the typical radiometric-quality synchrotron source, there is usually sufficient energy to perform accurate radiometric measurements in the visible for intercomparison to other radiometric standards.[41]

Absolute Detectors

Electrical Substitution Radiometers An electrical substitution radiometer, often called an electrically calibrated detector, is a device for measuring absolute radiant power by comparison to electrical power.[8] As a radiant power standard, an electrical substitution radiometer can be used as the basis for the derivation of the other radiometric quantities (irradiance, radiance, or intensity) by determining the geometrical distribution (either area and/or solid angle) of the radiation.[42–48] Since an electrical substitution radiometer measures the spectrally total radiant power, it is used primarily for the measurement of monochromatic sources or those with a known relative spectral distribution.

An electrical substitution radiometer consists of a thermal detector (i.e., a thermometer) that has a radiation-absorbing surface and an electrical heater within the surface, or the heater is in good thermal contact with the surface. When the device is irradiated, the thermometer senses the temperature of the radiantly heated surface. The radiation source is then blocked and the power to the electrical heater adjusted to reproduce the temperature of the radiantly heated surface. The electrical power to the heater is measured and equated to the radiant power on the surface. The absolute base for this measurement is the electrical power measurement which is traceable to the SI ampere. In order for the measurement to be accurate, differences between the radiant and electrical heating modes must be evaluated and the appropriate corrections applied.

Electrical substitution radiometers predate the planckian radiator as an absolute radiometric standard.[49–50] They were the devices used to quantify the radiant power output of the experimental blackbody simulators studied at the end of the nineteenth century. Electrical substitution radiometers are in widespread use today and are commercially available in a variety of forms that can be classified either as to the type of thermometer, the type of radiant power absorber, or the temperature at which the device operates.

Early electrical substitution radiometers operated at ambient temperature and used either a thermocouple, a thermopile, or a bolometer as the detector. Thermopile- and bolometer-based radiometers are presently used in a variety of applications. They have been refined over the years to produce devices of either greater accuracy, sensitivity, and/or faster response time. Thermopile-based, ambient temperature electrical substitution radiometers used for radiant power (and laser power, see later discussion) measurements at about the 1-mW level at several national standards laboratories have estimated uncertainties reported to be within ±0.1 percent.[51–53] Electrical substitution radiometers have also been used for very high-accuracy absolute radiant power measurements of the total solar irradiance both at the surface of the earth,[51,53] and above its atmosphere.[52] The type of high-accuracy radiometer used at various national standards laboratories is a custom-built device and is not commercially available in general. On the other hand, electrical substitution radiometers for solar and laser power measurements at a variety of accuracy levels are available commercially.

An ambient temperature electrical substitution radiometer based on a pyroelectric as the thermal detector was developed in the 1970s.[54,55] A pyroelectric detector is a capacitor containing a dielectric with a temperature-sensitive spontaneous electrical polarization; a change in temperature results in a change in polarization. Small and rapid changes of polarization are readily detectable, making the pyroelectric a sensitive and fast thermal detector. It is most useful as a detector of a pulsed or chopped radiant power signal. During the period when the radiant power signal is blocked, electrical power can be introduced to a heater in the absorptive surface of the radiometer. As in the method for a thermopile- or bolometer-based electrical substitution radiometer, the electrical power is adjusted to equal the heating produced by the radiant power signal. Chopping can be done at a reasonable frequency, hence the electrical heating can be adjusted to achieve a balance in a comparatively short time. Because the radiant-to-electrical heating balance is more rapidly obtained, a pyroelectric radiometer is often more convenient to use than a thermopile radiometer. Pyroelectric

electrical substitution radiometers are generally more sensitive but are usually less accurate than the room temperature thermopile or bolometer electrical substitution radiometers.

Electrical substitution radiometers are further distinguished by two types of radiant power absorber configurations: a flat surface coated with a highly absorbing material or a cavity-shaped, light-trapping detector. Cavity-shaped radiometers are usually more accurate over a greater spectral range than flat-surface radiometers. However, a flat-surface receiver can usually be fabricated with less thermal mass than a cavity-shaped receiver and therefore may have greater sensitivity and/or a faster response time.

Electrical substitution radiometers are further distinguished by the temperature at which the electrical-to-radiant-power comparison is performed. In the last two decades there have been significant advancements[56,57] made in instruments that perform the radiant-to-electrical comparison at a temperature near to that of liquid helium (4.2 K). Such devices are known as cryogenic electrical substitution radiometers or electrically calibrated cryogenic detectors and they are commercially available. Cryogenic electrical substitution radiometers are presently the most accurate absolute radiometric devices; the uncertainty of some measurements of radiant power has been estimated to be within ±0.005 percent.[47]

Sources of Error in Electrical Substitution Radiometers The relative significance of each of the possible sources of error and the derived correction factor depends upon the type of radiometer being used and the particular measurement application. It is possible to determine the total error occurring in equating radiant to electrical power and thence the accuracy of the traceability to the absolute electrical SI unit of measurement. Most manufacturers provide extensive characterization of their instruments. In such cases, the traceability to SI units is independent of radiometric standards such as blackbodies, hence electrical substitution radiometers are sometimes called absolute detectors. A commercially produced electrical substitution radiometer is capable of far greater accuracy (within ±0.01 percent for the cryogenic instruments) than any of the typical radiometric transfer devices available from a national standards laboratory. Hence, establishing traceability through a radiometric standard from a national standards laboratory is almost pointless for a cryogenic electrical substitution radiometer.

The sources of error in an electrical substitution radiometer can be divided into three categories: errors in traceability to the absolute base unit, errors due to differences in the radiant-versus-electrical heating modes of operation, and errors arising in a particular application. The major error sources common to all electrical substitution radiometers as well as some of the less common are briefly described here. An extensive listing and description of all of these errors is given in Ref. 8, Chap. 1.

Electrical power measurement accuracy is first determined by the accuracy of the voltage and resistance standards (or voltmeter and resistance meter) used to measure voltage and current. Electrical power measurement accuracy within ±0.01 percent is readily achievable and if needed it can be improved by an order of magnitude or better. Additional error is possible due to improper electrical measurement procedures such as those giving rise to ground-loops (improper connection to earth).

Differences between electrical-versus-radiant heating appear as differences in radiative, conductive, or convective losses. Most of these differences can be measured and a correction factor applied to optimize accuracy. The most obvious example is probably that of the radiative loss due to reflection from the receiver surface. Less obvious perhaps is the effect due to extraneous heating in the portion of the electrical conductors outside the region defined by the voltage sensing leads.

Differences between electrical heating and radiant heating may also arise due to spatial nonuniformity of the thermal sensor and/or differences in the heat conduction paths in the electrical-versus-radiant heating modes. These effects are specific to the materials and design of each radiometer. The electrical heater is typically buried within the device, whereas radiant heating occurs at the surface, so that the thermal conductivity paths to the sensor may be very different. Also, the distribution of the radiant power across the receiver is usually quite different compared to the distribution of the electrical heating. A detailed thermal analysis is required to create a design which minimizes these effects, but for optimum accuracy, the measurement of the magnitude of the nonuniformity effects is required to test the thermal model. Nonuniformity can be measured either by placing small auxiliary electrical heaters in various locations or by radiative heating of the receiver in several regions by moving a small spot of light across the device.

It should be noted that the thermal conduction path differences may also be dependent upon the environment in which the radiometer is to be operated. For example, atmospheric-pressure-dependent differences between the electrical-to-radiant power correction factor have been detected for many radiometers. These differences are, of course, greatest for a device for which the correction factors have been characterized in a normal atmosphere and which is then used in a vacuum.

Application-dependent errors arise from a variety of sources. Some examples are window transmission losses if a window is used, the accuracy of the aperture area and diffraction corrections are critical for measurements of irradiance; and, if a very intense source such as the sum is measured, heating of the instrument case and the body of the aperture could be an important correction factor. The last effect might also be very sensitive to atmospheric pressure changes.

Photoionization Devices Another type of absolute detector is a photoionization detector which can be used for absolute photon flux, i.e., radiant power, measurements of high-energy photon beams. Since a photoionization detector is a radiant power standard like the electrical substitution radiometer, it can in principle be used as the basis for the derivation of the other radiometric quantities (irradiance, radiance, or intensity) by determining the geometrical distribution (either area and/or solid angle) of the radiation.

A photoionization detector is a low-pressure gas-filled chamber through which a beam of high-energy (vacuum ultraviolet) photons is passed between electrically charged plates, the electrodes. The photons absorbed by the gas, if of sufficient energy, ionize the gas and enable a current to pass between the electrodes. The ion current is proportional to the number of photons absorbed times the photoionization yield of the gas and is, therefore, proportional to the photon flux.

The photoionization yield is the number of electrons produced per photon absorbed. If the photon is of sufficiently high energy, the photoionization yield is 100 percent for an atomic gas. The permanent atomic gases are the rare gases: helium, neon, argon, krypton, and xenon. Their photoionization yields have been measured relative to each other and shown to be 100 percent over specific wavelength ranges.[58,59] If an ionization chamber is constructed properly and filled with the appropriate gas so that all of the radiation is absorbed, then the number of photons per second incident on the gas is simply equal to the ion current produced. If instead of measuring the ion current one were to measure each pulse produced by a photon absorption, then one would have a photon counter.

Carefully constructed ion current measurement devices have been used as absolute detectors from 25 to 102.2 nm and photon counters from 0.2 to 30 nm. Careful construction implies that all possible systematic error sources have either been eliminated or can be estimated, with an appropriate correction applied. Because of the difficulty in producing accurate and well-characterized devices, ion chambers and high-energy photon counters are not claimed to be high-accuracy radiometric devices. Furthermore, they are limited to applications in vacuum ultraviolet radiometry and are consequently of restricted interest.

Predictable Quantum Efficiency Devices A useful and quite economical type of absolute detector is a predictable quantum efficiency (PQE) device using high-quality silicon photodiodes. Quantum efficiency is the photon fiux-to-photocurrent conversion efficiency. Because there have been many technological advancements made in the production of solid-state electronics, it is now possible to obtain very high quality silicon photodiodes whose performance is extremely close to that of the theoretical model.[60,61] The technique for predicting the quantum efficiency of a silicon photodiode is also known as the self-calibration of a silicon photodiode.[62,63] It is a relatively new absolute radiometric technique, quite simple to implement and of very high accuracy.[64,65]

Conversion of a detector calibration from spectral responsivity $R(\lambda)$, in units of A/W, to quantum efficiency, i.e., photon-to-electron conversion efficiency, is as follows:

$$C_e = 1239.85 \frac{R(\lambda)}{\lambda} \tag{71}$$

where λ is the in-vacuum wavelength in nm and C_e is in units of electrons per photon.

As in the case of the other absolute detectors discussed previously, a PQE device is used for absolute photon flux, i.e., radiant power, measurements. It can also be used as the basis for the derivation

of the other radiometric quantities such as irradiance, radiance, or intensity. The extension to other radiometric measurements is by the determination of the geometrical distribution (area and/or solid angle) of the radiation. Also, like other absolute detectors, it measures spectrally total flux (within its spectral response range) and is therefore used primarily for the measurement of monochromatic sources or those with a known relative spectral distribution.

In a solid-state photodiode, the process for the conversion of a photon to an electronic charge is as follows. Photons not lost through reflection or by absorption in a coating at the front surface are absorbed in the semiconductor—if the photon is of high enough energy. To be absorbed, the photon energy must be greater than the band gap; the band gap for silicon is 1.11 eV (equivalent wavelength, 1.12 μm). In silicon, the absorption of a photon causes a promotion of a charge carried to the conduction band. Absorption of very high energy photons will create charge carriers with sufficient energy to promote a second, third, or possibly more charge carriers into the conduction band by collision processes. However, for silicon, the photon energy throughout the visible spectral range is insufficient for such impact ionization processes to occur. Therefore, in the visible to near-ir spectral region (about 400 to 950 nm), one absorbed photon produces one electron in the conduction band of silicon.

In a photodiode, impurity atoms diffused into a portion of the semiconductor material create an electric field. The internal electric field causes the newly created charge carriers to separate, eventually promoting the flow of an electron in an external measurement circuit. The efficiency with which the charge carriers are collected depends upon the region of the photodiode in which they are created. In the electric field region of a high-quality silicon photodiode, this collection efficiency has been demonstrated to approach 100 percent to within about 0.01 percent. Outside the field region, the collection efficiency can be determined by simple electrical bias measurements.

For the spectral regions in which the collection efficiency is 100 percent, the only loss in the photon-to-electron conversion process is due to reflection from the front surface of the detector. Several silicon photodiodes can be positioned to more effectively collect the radiation, acting as a light trap.[66,67] If the radiation reflected from the first photodiode is directed to a second photodiode, then onto a third photodiode, etc., almost all the radiation will be collected in a small number of reflections. The photocurrents from all of the photodiodes are then summed and the total current (electrons per second) will be nearly equal, within 0.1 percent or less, to the photon flux (photons per second).

The more common type of silicon photodiode is the pn-type (positive charge impurity diffused into negative charge impurity starting material). High-quality pn-type detectors have their high collection efficiency in the long wavelength visible to near-ir spectral region. On the other hand, np-type silicon photodiodes have high collection efficiency in the short wavelength spectral region. At this time, the silicon photodiodes with the highest quantum efficiency (closest to ideal behavior) in the blue spectral region are the np-type devices, while nearly ideal red region performance is obtained with pn-type devices. The predictable quantum efficiency technique for silicon photodiodes has been demonstrated[64–67] to be absolutely accurate to within ±0.1 percent from about 400 nm to 900 nm.

A disadvantage of the light-trap geometry is the limited collection angle (field of view) of the device. Light-trap silicon photodiode devices are now commercially available using large area devices and a compact light-trap configuration that maximizes the field of view.

An np-type silicon photodiode trap detector optimized for short-wavelength performance and a pn-type silicon photodiode trap detector optimized for long-wavelength performance can be used as an almost ideal radiometric standard. The pair covers the 400- to 900-nm spectral range, has direct absolute SI base unit traceability via convenient electrical standards, and they are sufficiently independent to be meaningfully cross-checked to verify absolute accuracy and long-term stability. These detectors are not only useful radiometric standards by themselves but can be used with various source standards to either verify the absolute accuracy or to correct for the instabilities in the source standards.

The concept of a PQE light-trapping device is extendable to other high-quality photodiodes. Very recently, InGaAs devices with nearly 100-percent collection efficiency in the 1000- to 1600-nm spectral range have been developed. A light-trapping device employing these new detectors is now commercially available.

Calibration Transfer Devices

The discussion to this point focused on absolute radiometric measurements using methods that in themselves can be made traceable to absolute SI units. It is often more convenient (and sometimes required by contractual agreements) to obtain a device that has been calibrated in radiometric units at one of the national standards laboratories. Specific information as to the type and availability of various calibration transfer devices and calibration services may be obtained by directly contacting any of the national standards laboratories in the world. The products and services offered by the various standards laboratories cover a range of applications and accuracies, and differ from country to country.

Radiometric calibration transfer devices are either sources or detectors. The calibration transfer sources are either incandescent, tungsten filament lamps, deuterium lamps, or argon arc discharge sources.[68–70] Generally, calibration transfer detectors are photodiodes of silicon, germanium, or indium gallium arsenide. The most prevalent calibration transfer sources are incandescent lamps and the typical calibration transfer detector is a silicon photodiode.[71]

The commonly available spectral radiance calibration transfer devices that span the 250- to 5000-nm region are typically tungsten strip filament lamps. Lamps calibrated in the 250- to 2500-nm region by a national standards laboratory are available. Lamps calibrated in the 2.5- to 5-μm region by comparison to a blackbody are commercially available. These devices are calibrated within specific geometrical constraints: the area on the filament, and the direction and solid angle of observation. The calibration is reported at discrete wavelengths, for a specified setting of the current through the filament and the ambient laboratory temperature. The optimum stability of spectral radiance is obtained with vacuum rather than gas-filled lamps, and with temperature controlled, i.e., water-cooled electrodes. Vacuum lamps cannot be operated at high filament temeratures and consequently do not have sufficient uv output. Gas-filled lamps cover a broader spectral and dynamic range and are the more commonly available calibration transfer device.

The commonly available spectral irradiance calibration transfer devices that span the 250- to 2500-nm region are tungsten coiled filament lamps. These are usually gas-filled lamps that have a halogen additive to prolong filament life and enable higher-temperature operation. Lamps calibrated in the 250- to 2500-nm region by a national standards laboratory are available. These devices are calibrated within the specific geometrical constraints of the distance and the direction with respect to a location on the lamp base or the filament. The calibration is reported at discrete wavelengths, for a specified setting of the current through the filament and the ambient laboratory temperature. Because the filament is operated at a higher temperature, the spectral irradiance lamps are usually less stable than the radiance lamps.

The drift of an incandescent lamp's radiance or irradiance output is not reliably predictable. It is for this reason that the calibration is most reliably maintained not by an individual lamp but by a group of lamps. The lamps are periodically intercompared and the average radiance (irradiance) of the group is considered to be the calibration value. The calculated differences between the group average and the individual lamps is used as a measure of the performance of the individual lamp. Lamps that have drifted too far from the mean are either recalibrated or replaced.

Spectral radiance and irradiance calibration transfer devices for the vacuum to near-uv (from about 160 to 400 nm) are typically available as deuterium lamps.

The commonly available calibrated transfer detectors for the 250- to 1100-nm spectral region are silicon photodiodes and for the 1000- to 1700-nm region, they are either germanium or indium gallium arsenide photodiodes. The calibration is reported at discrete wavelengths in absolute responsivity units (A/W) or irradiance response units (A cm^2/W). In the first case, the calibration of the detector is performed with its active area underfilled, while in the second case, it is overfilled. If the detector is fitted with a precision aperture and if its spatial response is acceptably uniform, then the area of the aperture can be used to calculate the calibration in either units. The conditions under which the device was calibrated should be reported. The critical parameters are the location and size of the region within the active area in which it was calibrated, the radiant power in the calibration beam (alternately the photocurrent), and the temperature at which the calibration was performed. The direction in which the device was calibrated is usually assumed to be normal to its surface and

the irradiation geometry is usually that from a nearly collimated beam. Significant departures from normal incidence or near collimation should be noted.

Lasers

Power and Energy Measurement Lasers are highly coherent sources and the previous discussion of radiometry has been limited to the radiometry of incoherent sources. Nevertheless, the absolute power (or energy) in a laser beam can be determined to a very high degree of accuracy (within ±0.01 percent in some cases) using some of the detector standards discussed here. The most accurate laser power measurements are made with cryogenic and room temperature electrical substitution radiometers and with predictable quantum efficiency devices. In order to measure the laser power (energy) it is necessary to ensure that all the radiation is impinging on the sensitive area of the detector and, if the absolute detector characterization was obtained at a different power (energy) level, that the detector is operating in a linear fashion. For pulsed lasers, the peak power may substantially exceed the dynamic range of the detector's linear performance. (A discussion of detector linearity is presented later in this chapter.) Furthermore, caution should be exercised to ensure that the detector not be damaged by the high photon flux levels achieved with many lasers.

In addition to ensuring that the detector intercept all of the laser beam, it is necessary to determine that all coherence effects have been eliminated (or minimized and corrected).[72,73] The predominant effects of coherence are, first, interference effects at windows or beam splitters in the system optics and, second, diffraction effects at aperture edges. The use of wedged windows will minimize interference effects, and proper placement of apertures or the use of specially designed apertures[74] will minimize diffraction effects.

Lasers as a Radiometric Characterization Tool It should be noted that lasers, particularly the cw (continuous wave) variety, are particularly useful as characterization tools in a radiometric laboratory. Some of their applications are instrument response uniformity mapping, detector-to-detector spectral calibration transfer, polarization sensitivity, linearity verifications, and both diffuse and specular reflectance measurements.

Lasers are highly polarized and collimated sources of radiation. It is usually simple to construct an optical system as required for each measurement using mostly plane and spherical mirrors and to control scattered light with baffles and apertures. Lasers are high-power sources so that the signal-to-noise levels obtained are very good. If the power level is excessive it can usually be easily attenuated. Also, care must be taken to avoid local saturation of a detector at the peak of a laser's typical gaussian beam profile. They are highly monochromatic so that spectral purity, i.e., out-of-band radiation, is not usually a problem. However, in very high accuracy, within <0.1 percent, measurements, lasing from weaker lines may be significant and additional spectral blocking filters could be required.

Lasers are not particularly stable radiation sources. This problem is overcome by putting a beam splitter and stable detector into the optical system near the location of the measurement. The detector either serves to monitor the laser beam power and thereby supplies a correction factor to compensate for the instability, or its output is used to actively stabilize the laser.[43] In the latter case, an electronically controllable attenuator, such as an electro-optical, acousto-optical, or a liquid crystal system, is used to continuously adjust the power in the laser beam at the beam splitter. Feedback stabilization systems for cw lasers, both the electro-optical and liquid crystal type, are commercially available. For the highest-accuracy measurements, i.e., optimum signal-to-noise ratios, it is necessary both to actively stablize the laser source and also to monitor the beam power close to the measurement in order to correct for the residual system drifts.

Various Type B Error Sources

Offset Subtraction One common error source, which is often simply an oversight, is the incorrect (or sometimes neglected) adjustment of an instrument reading for electronic and radiometric offsets.

This is often called the dark signal or dark current correction since it is obtained by shutting off the radiation source and reading the resulting signal. The shuttered condition needs to be close to radiant zero, at least within less than the expected accuracy of the measurement.

A dark signal reading is usually easy to achieve in the visible and near-visible spectral regions. However, in the long-wavelength infrared a zero radiance source is one that is at a temperature of ideally 0 K. Often an acceptably cold shutter is not easily obtained so that the radiance, i.e., temperature, of the "zero" reference source must be known in order to determine the true instrument offset.

Scattered Radiation and Size of Source Effect An error associated with the offset correction is that of scattered radiation from regions outside the intended optical path of the measurement system. Often, by judicial placement of the shutter, the principal light path can be blocked while the scattered light is not. In this case, the dark signal measurement includes the scattered light which is then subtracted from the measurement of the unshuttered signal. It is not possible to formulate a general scattered light elimination method so that each radiometric measurement system needs to be evaluated on an individual basis. The effects of scattered radiation can often be significantly reduced by using an optical chopper, properly placed, and lock-in amplifier system to read the output of the photodetector.

No optical element will produce a perfect image and there will be an error due to geometrically introduced stray light. Sharp edges between bright and dark regions will be blurred by aberrations, instrument fabrication errors, scattering due to roughness and contamination of the optical surfaces, and scattered light from baffles and stops within the instrument enclosure. Diffraction effects will also introduce stray light. Light originating from the source will be scattered out of the region of the image and light from the area surrounding the source will be scattered into the image. The error resulting from scattering at the objective lens or mirror is related to the size of the source since the scattering is proportional to the irradiance of the objective element. Thus, the error introduced by the lack of image quality is commonly referred to as the size-of-source effect.

The effect of the aberrations on the radiant power both into and out of an image can, in principle, be calculated. The diffraction-related error can also be calculated in some situations.[73–75] However, the effect due to scattering is very difficult to model accurately and usually will have to be measured. In addition, the amount of scattering can be expected to change in time due to contamination of the optics, baffles, and stops. It is often more practical to measure the size of source effect and determine a correction factor for the elimination of this systematic error.

There are two different methods for measuring the size-of-source effect. The first method measures the response of the instrument as the size of the source is increased from the area imaged to the total area of the source. In the second method, a dark target of the same size as the image is placed at the imaged region on the source, and the surrounding area is illuminated. The second method has the advantage in that the effect being measured is the error signal above zero, whereas in the first method a small change in a large signal is being sought. In either case, the total error signal is measured; it includes aberrations, diffraction, and scattering effects.

Polarization Effects These are often significant perturbations of radiant power transfer due to properties of the radiation field other than its geometry. One such possible error is that due to the polarization state of the radiation field. The signal from a photodetector that is polarization-sensitive will be dependent upon the relative orientation of the polarization state of the radiation with respect to the detector orientation. Examples of polarization-dependent systems are grating monochromators and radiation transfer through a scattering medium or at a reflecting surface. In principle, the polarization state of the radiation field may be included in the geometrical transfer equation as a discrete transformation that occurs at each boundary or as a continuous transformation occurring as a function of position in the medium. Often it is sufficient to perform a calibration at two orthogonal rotational positions of the instrument or its polarization-sensitive components. However, it is recommended that other measurements at rotations intermediate between the two orthogonal measurements be included to test if the maximum and minimum polarization sensitivities have been sampled. The average of the maximum and minimum polarization measurements is then the calibration factor of the instrument for a nonpolarized radiation source.

Detector Nonlinearity

Nonlinearity measurement by superposition of sources Another possibly significant error source is photodetector and/or the electronic signal processing system nonlinearity. If the calibration and subsequent measurements are performed at the same radiant power level, then nonlinearity errors are avoided. Often conditions require that the measurements be performed over a range of power levels. In general, a separate measurement is required either to verify the linearity of the photodetector (and/or the electronics) or to deduce the form of the nonlinearity function in order to apply the appropriate correction.[72,76–78]

The typical form of a nonlinearity appears as a saturation of the photoelectronic process at high irradiance levels. At low radiant flux levels what often appears to be a nonlinearity may be the result of failing to apply a dark signal or offset correction. There are, of course, other effects that will appear as a nonlinearity of the photodetector and/or electronics.[79]

Either the linearity of the detector and electronics can be directly verified by experiment or it can be determined by comparison to a photodetector/electronics system of verified linear performance. It is useful to note that several types of silicon photodiodes using a transimpedance or current amplifier have been demonstrated to be linear within ±0.1 percent over up to eight decades for most of its principal spectral range.[78]

The fundamental experimental method for determining the dynamic range behavior of a photodetector is the superposition-of-sources method.[76–78] The principle of the method is as follows. If a photodetector/electronics system is linear, then the arithmetic sum of the individual signals obtained from different radiant power sources should equal the signal obtained when all the sources irradiate the photodetector at the same time. There are many variations of the multiple source linearity measurement method using combinations of apertures or beam splitters. A note of caution: Interference effects must be avoided when combining beams split from the same source or when combining highly coherent sources such as lasers.

The difference between the arithmetic sum and the measured signal from the combined sources is used as the nonlinearity correction factor. Consider the superposition of two sources having approximately equal radiant powers ϕ_a and ϕ_b, which when combined have a radiant power of $\phi_{(a+b)}$. The signals from the photodetector when irradiated by the individual and combined sources is i_a, i_b, and $i_{(a+b)}$. The following equation would be equal to unity for a linear detector:

$$K_{ab} = \frac{i_{(a+b)}}{i_a + i_b} \tag{72}$$

For a calibration performed at the radiant power level ϕ_a (or ϕ_b), the detector responsivity is R and

$$i_a = R\phi_a \tag{73}$$

For a measurements at the higher radiant power level $\phi_{(a+b)}$,

$$i_{(a+b)} = K_{ab} R \phi_{(a+b)} \tag{74}$$

Scaling up to much higher radiant power levels (or down to lower levels) requires repeated application of the superposition-of-sources method. For example, in order to scale up to the next higher radiant power level, the source outputs from the first level are increased to match the second level (e.g., by using larger apertures). The increased source outputs are then combined to reach a third level and a new correction factor calculated. The process is repeated to cover the entire dynamic range of a photodetector/electronics system in factor-of-two steps.

Note that when type B errors, such as the interference effects noted above, are eliminated, the accumulated uncertainty in the source superposition method is the accumulated imprecision of the individual measurements.

Various nonlinearity measurement methods Other techniques for determining the dynamic range behavior of a photodetector are derivable from predictable attenuation techniques.[72] One such method is based upon chopping the radiation signal using apertures of known area in a rotating disk. This is often referred to as Talbot's law: the average radiant power from a source viewed through the

apertures of a rotating disk is given by the product of the radiant power of the source and the transmittance of the disk. The transmittance of the disk is the ratio of the open area to the blocked area of the disk. The accuracy of this technique depends upon the accuracy with which the areas are known and may also be limited by the time dependence of the photodetector and/or electronics.

Another predictable attenuation technique is based upon the transmittance obtained when rotating, i.e., crossing two polarizers.

$$\tau = \tau_0 \cos^4 \delta \tag{75}$$

Here δ is the angle of rotation between the linear polarization directions of the two polarizers and τ_0 is the transmittance at $\delta = 0°$. This technique, of course, assumes ideal polarizers that completely extinguish the transmitted beam at $\delta = 90°$, and its accuracy is limited by polarization efficiency of the polarizers.

A third predictable attenuation technique is the application of Beer's law which states that the transmittance of a solution is proportional to the concentration κ of the solute

$$\tau = e^{-\gamma\kappa} \tag{76}$$

Here γ is the absorption coefficient of the solute. The accuracy of this technique depends upon the solubility of the solute and the absence of chemical interference, i.e., concentration-dependent chemical reactions.

Time-dependent Error For measurements of pulsed or repeatedly chopped sources of radiation, the temporal response of the detector could introduce a time-dependent error. A photodetector that has a response that is slow compared to the source's pulse width or the chopping frequency will not have reached its peak signal during the short time interval. Time-dependent error is avoided by determining if the detector's frequency response is suitable before undertaking the calibration and measurement of pulsed or chopped radiation sources.

Nonuniformity The nonuniformity of the distribution of radiation over an image or within the area sampled in an irradiance or radiance measurement may lead to an error if the response of the instrument is nonuniform over this area. The calibration factor for a nonuniform instrument will be different for differing distributions of radiation. The size of the error will depend upon the relative magnitudes of the source and instrument nonuniformities and it is a very difficult error to correct. This type of error is usually minimized either by measuring only sources that are uniform or by ensuring that the instrument response is uniform. It is usually easier to ensure that the instrument response is uniform.

Nonideal Aperture For very high-accuracy radiometric calibrations, the error due to the effect of the land on an aperture must be correctly taken into account. An ideal aperture is one that has an infinitesimally thin edge that intercepts the radiation beam. In practice an aperture will have a surface of finite thickness at its edge. This surface is referred to as the land; see Fig. 7. The effective

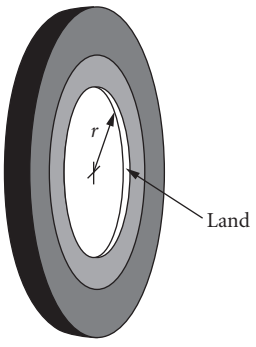

FIGURE 7 The nonideal aperture showing the location of the land.

radius of the aperture will be slightly reduced by vignetting caused by the land on its edge, assuming that the vignetting is small compared to the aperture radius and that all the radiation reflected by the land eventually falls on the detector (i.e., the land has a highly reflective surface). The effective radius of the aperture r' is

$$r' = r\left[1 - \frac{(1-\rho)w}{s}\right] \tag{77}$$

Here ρ is the reflectance, s is the distance between this aperture and the mirror or lens (or other aperture), and w is the width of the land.

Spectral Errors

Wavelength error In those cases where a spectrally selective element, such as a monochromator or a filter, is included in the radiometric instrument, spectral errors must be taken into account.[44] The first type of error is called the wavelength error and is due to misassignment of the wavelength of the spectrum of the filter or the monochromator in the instrument. That is, either the monochromator used to calibrate the filter transmission or the monochromator within the radiometric instrument has an error in its wavelength setting. This error is eliminated by calibration of the monochromator wavelength setting using one or more atomic emission lines from either a discharge lamp (usually a mercury and/or a rare gas lamp) or one of the many spectra of the elements available as a hollow cathode lamp. The wavelengths of most atomic emission lines are known with an accuracy that exceeds the requirements of radiometric calibrations.

A special note regarding the wavelength error and the use of interference filters in a radiometric instrument. The typical angular sensitivity of an interference filter is 0.1 nm per angular degree of rotation. If the transmission of the interference filter is measured in a collimated beam and then used in a convergent beam there will be an error due to the angularly dependent shift in the spectral shape of the transmission. For an accurate radiometric instrument it is important to measure interference filter transmission in nearly the same geometry as it will be used. Furthermore, the temperature coefficient of the transmission of an interference filter is about 0.2 nm K^{-1}. Therefore, it is also important in subsequent measurements to ensure that the filter remains at the same temperature as that used during the calibration.

It should also be noted that in order to accurately determine the spectral transmission of a monochromator it is necessary to completely fill the aperture of the dispersing element in the monochromator. This usually means that the field of view of the monochromator must be filled by the beam from the spectral calibration instrument.
