TABLE 13 Elastic Stiffness Constants for Selected Single Crystal Metals

			Elastic stiffness (GN/m^2)		
Cubic Metals[93]			C_{11}	C_{44}	C_{12}
Aluminum			108.0	28.3	62.0
Chromium			346.0	100.0	66.0
Copper			169.0	75.3	122.0
Germanium			129.0	67.1	48.0
Gold			190.0	42.3	161.0
Iron			230.0	117.0	135.0
Molybdenum			459.0	111.0	168.0
Nickel			247.0	122.0	153.0
Silicon			165.0	79.2	64.0
Silicon carbide94			352.0	233.0	140.0
Silver			123.0	45.3	92.0
Tantalum			262.0	82.6	156.0
Tungsten			517.0	157.0	203.0
Hexagonal Metals	C_{11}	C_{33}	C_{44}	C_{12}	C_{13}
Beryllium[95]	288.8	354.2	154.9	21.1	4.7
Magnesium[93]	22.0	19.7	60.9	−7.8	−5.0
Silicon carbide[94]	500.0	521.0	168.0	98.0	

Elastic Properties The principal elastic stiffnesses C_{ij} of single crystals of some materials are given in Table 13. The three moduli and Poisson's ratio for polycrystalline materials are given in Table 14. These properties vary little with temperature, increasing temperature causing a gradual decrease in the moduli.

TABLE 14 Elastic Moduli and Poisson's Ratio for Selected Polycrystalline Materials

Materials	Young's Modulus (GN/m^2)	Shear Modulus (GN/m^2)	Bulk Modulus (GN/m^2)	Poisson's Ratio	Reference
Aluminum: 5086-O	71.0	26.4		0.33	84
Aluminum: 6061-T6	68.9	25.9		0.33	84
Beryllium: I-701-H	315.4	148.4	115.0	0.043	96
Copper	129.8	48.3	137.8	0.343	97
Germanium	79.9	29.6		0.32	97
Gold	78.5	26.0	171.0	0.42	97
Invar 36	144.0	57.2	99.4	0.259	97
Iron	211.4	81.6	169.8	0.293	97
Molybdenum	324.8	125.6	261.2	0.293	97
Nickel	199.5	76.0	177.3	0.312	97
Platinum	170.0	60.9	276.0	0.39	97
Silicon	113.0	39.7		0.42	97
Silicon carbide: CVD	461.0			0.21	80
Silicon carbide: reaction sintered	413.0			0.24	88
Silver	82.7	30.3	103.6	0.367	97
Stainless steel: 304	193.0	77.0		0.27	97
Stainless steel: 416	215.0	83.9	166.0	0.283	97
Stainless steel: 430	200.0	80.0		0.27	97
Tantalum	185.7	62.2	196.3	0.342	97
Tungsten	411.0	160.6	311.0	0.28	97

TABLE 15 Strength and Fracture Properties for Selected Materials

Material	Yield Strength (MN/m^2)	Microyield Strength (MN/m^2)	Elongation (in 50 mm) %	Fracture Toughness ($MN\ m^{-3/2}$)	Flexural Strength (MN/m^2)	Hardness*	Reference
Aluminum: 5086-O	115.0	40.0	22.0	>25.0	—	55 HRB	84
Aluminum: 6061-T6	276.0	160.0	15.0	<25.0	—	95 HRB	84
Beryllium: I-70-H	276.0	30.0	4.0	12.0	—	80 HRB	84,85
Copper	195.0	12.0	42.0	—	—	10 HRB	84
Germanium	—	—	—	1.0	110.0	800 HK	84
Gold	125.0	—	30.0	—	—	30 HK	84
Invar 36	276.0	37.0	35.0	—	—	70 HRB	86
Molybdenum	600.0	—	40.0	—	—	150 HK	84
Nickel	148.0	—	47.0	—	—	109 HRB	84
Platinum	150.0	—	35.0	—	—	40 HK	84
Silicon	—	—	—	1.0	207.0	1150 HK	84
Silicon carbide: CVD	—	—	—	3.0	595.0	2500 HK	80
Silicon carbide: reaction sintered	—	—	—	2.0	290.0	2326 HK	88
Silver	130.0	—	47.0	—	—	32 HK	84
Stainless steel: 304	241.0	—	60.0	—	—	80 HRB	89
Stainless steel: 416	950.0	—	12.0	—	—	41 HRC	89
Stainless steel: 430	380.0	—	25.0	—	—	86 HRB	89
Tantalum	220.0	—	30.0	—	—	120 HK	84
Tungsten	780.0	—	2.0	—	—	350 HK	84

*HK = Knoop (kg/mm^2); HRB = Rockwell B; HRC = Rockwell C.

Strength and Fracture Properties The properties of tensile yield (at 0.2 percent offset), microyield strength, ductility (expressed as percent elongation in 50 mm), fracture toughness, flexural strength, and mechanical hardness are listed in Table 15. Most of these properties vary with temperature: strength and hardness decreasing, and fracture toughness and ductility increasing with temperature.

5.1 GLOSSARY

A	power absorption
$\mathbf{B}$	magnetic field
c	velocity of light
$\mathbf{D}$	displacement field
d	film thickness
$\mathbf{E}$	applied electric field
E_c	energy, conduction band
E_{ex}	exciton binding energy
E_g	energy band gap
E_H	hydrogen atom ionization energy = 13.6 eV
$\mathbf{E}$	electric field

$\mathbf{E}_n^{\pm}$	Landau level energy
E_v	energy, valence band
e_I	ionic charge
g^*	effective g-factor
$\mathbf{K}$	phonon wave vector
k	extinction coefficient
k_B	Boltzmann's constant
$\mathbf{k}$	electron/hole wave vector
$L_{\pm}$	coupled LO phonon — plasmon frequency
m_e^*	electron effective mass
m_h^*	hole effective mass
m_i	ionic mass
m_i'	reduced ionic mass
m_{imp}	impurity ion mass
m_l^*	longitudinal effective mass
m_o	electron rest mass
m_r	electron-hole reduced mass
m_t^*	transverse effective mass
N	volume density
n	refractive index (real part)
$\tilde{n} = (n + ik)$	complex index of refraction
$\mathbf{P}$	polarization field
$\mathbf{q}$	photon wave vector
R	power reflection
R_y	effective Rydberg
S	oscillator strength
T	power transmission
T	temperature
V	Verdet coefficient
α	absorption coefficient
α_{AD}	absorption coefficient, allowed-direct transitions
α_{AI}	absorption coefficient, allowed-indirect transitions
δ	skin depth or penetration depth
γ	phenomenological damping parameter
Δ	spin-orbit splitting energy
Γ	Brillouin zone center
ε	dielectric function
$\varepsilon_{\text{fc}}(\omega)$	free-carrier dielectric function
$\varepsilon_{\text{imp}}(\omega)$	impurity dielectric function
$\varepsilon_{\text{int}}(\omega)$	intrinsic dielectric function
$\varepsilon_{\text{lat}}(\omega)$	lattice dielectric function
$\varepsilon(0)$	static dielectric constant
ε_0	free-space permittivity
ε_1	Real (ε)
ε_2	Im (ε)

ε_∞ high-frequency limit of dielectric function
η impurity ion charge
λ wavelength
λ_c cut-off wavelength

σ conductivity
τ scattering time
φ work function
χ susceptibility
$\chi^{(n)}$ induced nonlinear susceptibility
Ω phonon frequency
ω angular frequency
ω_c cyclotron resonance frequency
ω_{LO} longitudinal optical phonon frequency
ω_p free-carrier plasma frequency
ω_{pv} valence band plasma frequency
ω_{TO} transverse optical phonon frequency

5.2 INTRODUCTION

Rapid advances in semiconductor manufacturing and associated technologies have increased the need for optical characterization techniques for materials analysis and in situ monitoring/control applications. Optical measurements have many unique and attractive features for studying and characterizing semiconductor properties: (1) they are contactless, nondestructive, and compatible with any transparent ambient including high-vacuum environments; (2) they are capable of remote sensing, and hence are useful for in situ analysis on growth and processing systems; (3) the high lateral resolution inherent in optical systems may be harnessed to obtain spatial maps of important properties of the semiconductor wafers or devices; (4) combined with the submonolayer sensitivity of a technique such as ellipsometry, optical measurements lead to unsurpassed analytical details; (5) the resolution in time obtainable using short laser pulses allows ultrafast phenomena to be investigated; (6) the use of multichannel detection and high-speed computers can be harnessed for extremely rapid data acquisition and reduction which is crucial for real-time monitoring applications such as in in situ sensing; (7) they provide information that complements transport analyses of impurity or defect and electrical behavior; (8) they possess the ability to provide long-range, crystal-like properties and hence support and complement chemical and elemental analyses; and (9) finally, most optical techniques are "table-top" procedures that can be implemented by semiconductor device manufacturers at a reasonable cost. All optical measurements of semiconductors rely on a fundamental understanding of their optical properties. In this chapter, a broad overview of the optical properties of semiconductors is given, along with numerous specific examples.

The optical properties of a semiconductor can be defined as any property that involves the interaction between electromagnetic radiation or light and the semiconductor, including absorption, diffraction, polarization, reflection, refraction, and scattering effects. The electromagnetic spectrum is an important vehicle for giving an overview of the types of measurements and physical processes characteristic of various regions of interest involving the optical properties of semiconductors. The electromagnetic spectrum accessible for studies by optical radiation is depicted in Fig. 1, where both the photon wavelengths and photon energies, as well as the common designations for

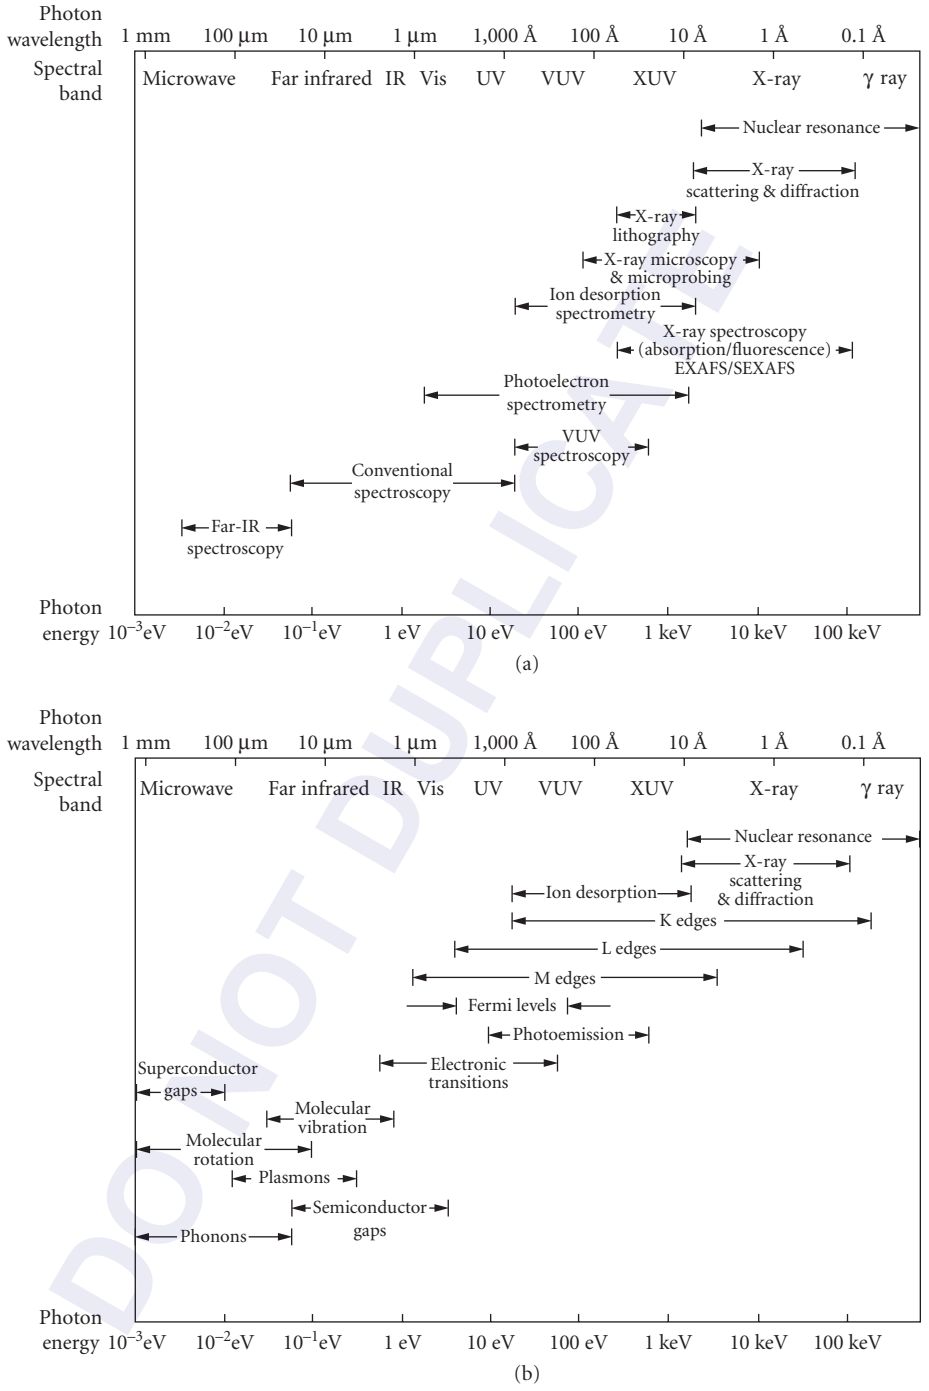

FIGURE 1 The electromagnetic spectrum comprising the optical and adjacent regions of interest: (*a*) characterization techniques using optical spectroscopy and synchrotron radiation and (*b*) molecular, atomic, and electronic processes characteristic in various parts of the electromagnetic spectrum plotted as a function of photon energy.[1]

the spectral bands, are given.[1] Figure 1*a* shows the various techniques and spectroscopies and their spectral regions of applicability. Molecular, atomic, and electronic processes characteristic of various parts of the spectrum are shown in Fig. 1*b.* The high-energy x-ray, photoelectron, and ion desorption processes are important to show because they overlap the region of vacuum ultraviolet (VUV) spectroscopy. The ultraviolet (UV) region of the spectrum has often been divided into three rough regions: (1) the near-UV, between 2000 and 4500 Å; (2) the VUV, 2000 Å down to about 400 Å; and (3) the region below 400 Å covering the range of soft x-rays, 400 to 10 Å.[2] The spectrum thus covers a broad frequency range which is limited at the high-frequency end by the condition that $\lambda >> a$, where λ is the wavelength of the light wave in the material and a is the interatomic distance. This limits the optical range to somewhere in the soft x-ray region. Technical difficulties become severe in the ultraviolet region (less than 100 nm wavelength, or greater than 12.3 eV photon energies), and synchrotron radiation produced by accelerators can be utilized effectively for ultraviolet and x-ray spectroscopy without the limitations of conventional laboratory sources. A lower limit of the optical frequency range might correspond to wavelengths of about 1 mm (photon energy of 1.23×10^{-3} eV). This effectively excludes the microwave and radio-frequency ranges from being discussed in a chapter on the optical properties of semiconductors.

From the macroscopic viewpoint, the interaction of matter with electromagnetic radiation is described by Maxwell's equations. The optical properties of matter are introduced into these equations as the constants characterizing the medium such as the dielectric constant, magnetic permeability, and electrical conductivity. (They are not actually "constants" since they vary with frequency.) From our optical viewpoint, we choose to describe the solid by the complex dielectric constant or complex dielectric function $\varepsilon(\omega)$. This dielectric constant is a function of the space and time variables and should be considered as a response function or linear integral operator. The complex index of refractive index $\tilde{n}$ is the complex square root of the dielectric function. Its real and imaginary parts are the refractive index n and the extinction coefficient k.

There are a number of methods for determining the optical constants of a semiconductor as a function of wavelength. Some of the most common techniques are as follows:

1. Measure the reflectivity at normal incidence *or* the transmission of a thin slab of known thickness over a wide wavelength range and use a Kramers-Kronig dispersion relation.
2. Measure the transmission of a thin slab of known thickness *and* the absolute reflectivity at normal incidence for a uniform bulk isotropic thin slab of known thickness with smooth surfaces (front and back).
3. Use a polarimetric method like ellipsometry which involves finding the ratio of reflectivities for polarizations perpendicular and parallel to the plane of incidence at a nonnormal incidence together with the difference of phase shifts upon reflection. With recent advancements in the availability of commercial ellipsometers, this is the most common method in use today.
4. Use detailed computer modeling and fitting of reflection, transmission, and/or ellipsometric measurements over a sufficiently large energy range. This method can also be applied in many circumstances to obtain the optical constants of anisotropic materials or thin films.
5. Calculate the band structure of a crystalline material using ab initio methods employing the local density approximation (LDA) with GW corrections (to correct the bandgap error usually found in LDA calculations). Integrate this band structure to determine the joint density of states weighted with the probability of optical transitions by the dipole operator matrix elements. If this technique is used, the Bethe-Salpeter equations need to be solved to take into account many-body excitonic effects (electron-hole interactions). Due to recent advances in computer technology, the accuracy of this method approaches the accuracy of measurements, especially if large samples with high quality cannot be obtained.

These optical constants describe an electromagnetic wave in the medium of propagation; the refractive index n gives the phase shift of the wave, and the extinction coefficient k gives the attenuation of the wave. In practice, one often uses the absorption coefficient α instead of k because of Beer's law formalism describing the absorption.

The field of optical spectroscopy is a very important area of science and technology since most of our knowledge about the structure of atoms, molecules, and solids is based upon spectroscopic investigations. For example, studies of the line spectra of atoms in the late 1800s and early 1900s revolutionized our understanding of the atomic structure by elucidating the nature of their electronic energy levels. Similarly for the case of semiconductors, optical spectroscopy has proven essential to acquiring a systematic and fundamental understanding of the nature of semiconductors. Since the early 1950s, detailed knowledge about the various eigenstates present in semiconductors has emerged including energy bands, excitonic levels, impurity and defect levels, densities of states, energy-level widths (lifetimes), symmetries, and changes in these conditions with temperature, pressure, magnetic field, electric field, etc. One of the purposes of this chapter is to review and summarize the major optical measurement techniques that have been used to investigate the optical properties of semiconductors related to these features. Specific attention is paid to the types of information that can be extracted from such measurements of the optical properties.

Most optical properties of semiconductors are integrally related to the particular nature of their electronic and vibrational structures.[3] These electronic and vibrational dispersion relations are in turn related to the type of crystallographic structure, the particular atoms, and their bonding. The full symmetry of the space groups is also essential in determining the structure of the energy bands and vibrational modes. Group theory makes it possible to classify energy eigenstates, determine essential degeneracies, derive selection rules, and reduce the order of the secular determinants which must be diagonalized in order to compute approximate eigenvalues. Often, experimental measurements must be carried out to provide quantitative numbers for these eigenvalues. A full understanding of the optical properties of semiconductors is thus deeply rooted in the foundations of modern solid-state physics. In writing this chapter, the authors have assumed that the readers are familiar with some aspects of solid-state physics such as can be obtained from an advanced undergraduate course.

Most semiconductors have a diamond, zincblende, wurtzite, or rock-salt crystal structure. Elements and binary compounds, which average four valence electrons per atom, preferentially form tetrahedral bonds. A tetrahedral lattice site in a compound AB is one in which each atom A is surrounded symmetrically by four nearest neighboring B atoms. The most important lattices with a tetrahedral arrangement are the diamond, zincblende, and wurtzite lattices. In the diamond structure, all atoms are identical, whereas the zincblende structure contains two different atoms. The wurtzite structure is in the hexagonal crystal class, whereas the diamond and zincblende structures are cubic. Other lattices exist which are distorted forms of these, and many lattices have no relation to the tetrahedral structures.

Band structure calculations show that only the valence band states are important for predicting the following crystal ground-state properties: charge density, Compton profile, compressibility, cohesive energy, lattice parameter, x-ray emission spectra, and hole effective masses. In contrast, both the valence band and conduction band states are important for predicting the following properties: optical dielectric constant or refractive index, optical absorption spectrum, and electron effective masses. Further complexities arise because of the many-body nature of the particle interactions which necessitates understanding excitons, electron-hole droplets, polarons, polaritons, etc.

The optical properties of semiconductors cover a wide range of phenomena which are impossible to do justice to in just one short chapter in this *Handbook*. We have thus chosen to present an extensive, systematic overview of the field, with as many details given as possible. The definitions of the various optical properties, the figures chosen, the tables presented, and the references given all help to orient the reader to appreciate various principles and measurements that form the foundations of the optical properties of semiconductors.

The optical properties of semiconductors are often subdivided into those that are electronic and those that are vibrational (lattice related) in nature. The electronic properties concern processes involving the electronic states of the semiconductor, while the lattice properties involve vibrations of the lattice (absorption and creation of phonons). Lattice properties are of considerable interest for heat dissipation, electronic transport, and lifetimes (broadenings) of electronic states, but it is the electronic properties which receive the most attention in semiconductors

because of the technological importance of their practical applications. Modern-day semiconductor optoelectronic technologies include lasers, light-emitting diodes, photodetectors, optical amplifiers, modulators, switches, etc., all of which exploit specific aspects of the electronic optical properties.

Almost all of the transitions that contribute to the optical properties of semiconductors can be described as one-electron transitions. Most of these transitions conserve the crystal momentum and thus measure the vertical energy differences between the conduction and valence bands. In the one-electron approximation, each valence electron is considered as a single particle, moving in a potential which is the sum of the core potentials and a self-consistent Hartree potential of the other valence electrons.

The phenomena usually studied to obtain information on the optical properties of semiconductors are (1) absorption, (2) reflection or ellipsometry, (3) photoconductivity, (4) emission, (5) light scattering, and (6) modulation techniques. Most of the early information on the optical properties of semiconductors was obtained from measurements of photoconductivity, but these measurements can be complicated by carrier trapping, making interpretation of the results sometimes difficult. Thus, most quantitative measurements are of the type (1), (2), (4), or (5). For example, the most direct way of obtaining information about the energy gaps between band extrema and about impurity levels is by measuring the optical absorption over a wide range of wavelengths. This information can also be obtained by (2) and (4).

The transient nature of the optical properties of semiconductors is important to establish because it gives insight to the various relaxation processes that occur after optical excitation. Because of the basic limitations of semiconductor devices on speed and operational capacity, ultrafast studies have become an extremely important research topic to pursue. The push to extend the technologies in the optoelectronic and telecommunication fields has also led to an explosion in the development and rise of ultrafast laser pulses to probe many of the optical properties of semiconductors: electrons, holes, optical phonons, acoustic phonons, plasmons, magnons, excitons, and the various coupled modes (polaritons, polarons, excitonic molecules, etc.). The time scale for many of these excitations is measured in femtoseconds (10^{-15}) or picoseconds (10^{-12}). Direct time measurements on ultrafast time scales provide basic information on the mechanisms, interactions, and dynamics related to the various optical properties. Some of the processes that have been investigated are the carrier lifetime, the formation time of excitons, the cooling and thermalization rates of hot carriers, the lifetime of phonons, the screening of optical-phonon-carrier interactions, the dynamics of ballistic transport, the mechanism of laser annealing, dephasing processes of electrons and excitons, optical Stark effect, etc. It is not possible in this short review chapter to cover these ultrafast optical properties of semiconductors. We refer the reader to the many fine review articles and books devoted to this field.[4,5]

The advent of the growth of artificially structured materials by epitaxial methods such as molecular beam epitaxy (MBE) has made possible the development of a new class of materials and heterojunctions with unique electronic and optical properties. Most prominent among these are heterojunction quantum wells and superlattices. The field of microstructural physics has thus been one of the most active areas of research in the past decades. The novel properties of nanostructures fabricated from ultrathin layers of semiconductors of thicknesses <100 Å stem from microscopic quantum mechanical effects. The simplest case to visualize is that of a particle confined in a box which displays distinct quantum energy states, the equivalent of which are electrons and holes confined to a thin layer of a material such as GaAs sandwiched between two thick layers of AlAs. The new energy states produced by the confinement of the charges in the artificially produced potential well can be manipulated, by tailoring the size and shape of the well, to produce a wide variety of effects that are not present in conventional semiconductors. Microstructures formed from alternating thin layers of two semiconductors are called superlattices. They also lead to novel electronic and optical behaviors, most notable of which are large anisotropic properties. The ability to "engineer" the behavior of these nanostructures has led to an explosion of research and applications that is too large to be dealt with in this short review. The reader is referred to several review articles on their optical behavior.[6,7]

5.3 OPTICAL PROPERTIES

Background

The interaction of the semiconductor with electromagnetic radiation can be described, in the semiclassical regime, using response functions such as ε and χ which are defined in the following section. The task of the description is then reduced to that of building a suitable model of χ and ε that takes into account the knowledge of the physical characteristics of the semiconductor and the experimentally observed optical behavior. One example of a particularly simple and elegant, yet surprisingly accurate and successful, model of ε for most semiconductors is the linear-chain description of lattice vibrations.[8] This model treats the optical phonons (i.e., the vibrations that have an associated dipole moment) as damped simple harmonic motions. Even though the crystal is made up of $\approx 10^{23}$ atoms, such a description with only a few resonant frequencies and phenomenological terms, such as the damping and the ionic charge, accurately accounts for the optical behavior in the far-infrared region. The details of the model are discussed in the following section "Optical/Dielectric Response." Such simple models are very useful and illuminating, but they are applicable only in a limited number of cases, and hence such a description is incomplete.

A complete and accurate description will require a self-consistent quantum mechanical approach that accounts for the microscopic details of the interaction of the incident photon with the specimen and a summation over all possible interactions subject to relevant thermodynamical and statistical mechanical constraints. For example, the absorption of light near the fundamental gap can be described by the process of photon absorption resulting in the excitation of a valence band electron to the conduction band. In order to obtain the total absorption at a given energy, a summation has to be performed over all the possible states that can participate, such as from multiple valence bands. Many-body effects (the Coulomb attraction between the photoexcited electron and hole) also need to be considered for an accurate description. Thermodynamic considerations such as the population of the initial and final states have to be taken into consideration in the calculation as well. Hence, a detailed knowledge of the specimen and the photon-specimen interaction can, in principle, lead to a satisfactory description.

Optical/Dielectric Response

Optical Constants and the Dielectric Function In the linear regime for an isotropic solid, the dielectric function ε and the susceptibility χ are defined by the following relations:[9]

$$\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P} \tag{1}$$

$$\mathbf{D} = \varepsilon_0 (\mathbf{1} + \chi)\mathbf{E} \tag{2}$$

$$\mathbf{D} = \varepsilon \mathbf{E} = (\varepsilon_1 + i\varepsilon_2)\mathbf{E} \tag{3}$$

where **E**, **D**, and **P** are the free-space electric field, the displacement field, and the polarization field inside the semiconductor; ε_0 is the permittivity of free space; and ε and χ are dimensionless quantities, each of which can completely describe the optical properties of semiconductors. The refractive index $\tilde{n}$ of the material is related to ε as shown below:

$$\tilde{n} = \sqrt{\varepsilon} = n + ik \tag{4}$$

The real and imaginary parts of the refractive index, n and k, which are also referred to as the optical constants, embody the linear optical property of the material. The presence of k, the imaginary component, denotes absorption of optical energy by the semiconductor. Its relationship to the absorption Coefficient is discussed in the following section. "Reflection, Transmission, and Absorption coefficients." In the spectral regions where absorptive processes are weak or absent, as in the case of the sub-bandgap range, k is very small, whereas in regions of strong absorption, the magnitude of k is large. The optical constants for a large number of semiconductors may be found in Refs. 10 and 11. The variation in the real part n is usually much smaller. For example, in GaAs, at room temperature, in the visible and near-visible region extending from 1.4 to 6 eV, k varies from $<10^{-3}$ at 1.41 eV which is just below the gap, to a maximum of 4.1 at 4.94 eV.[12] In comparison, n remains nearly constant in the near-gap region extending from 3.61 at 1.4 eV to 3.8 at 1.9 eV, with the maximum and minimum values of 1.26 at 6 eV and 5.1 at 2.88 eV, respectively. The real and imaginary components are related by causal relationships that are also discussed in the following sections.

Reflection, Transmission, and Absorption Coefficients The reflection and transmission from a surface at normal incidence are given by

$$\tilde{r} = \frac{(\tilde{n}-1)}{(\tilde{n}+1)} = |\tilde{r}| \cdot \exp(i\theta) \tag{5}$$

$$R = |\tilde{r}^2| \tag{6}$$

$$T = (1-R) \tag{7}$$

where $\tilde{r}$ is the complex (Fresnel) reflection coefficient (consisting of a magnitude and a phase θ) and R and T are the reflectance and transmission, describing the ratio of the reflected and transmitted intensity relative to the incident intensity. For a thin slab, in free space, with thickness d and complex refractive index $\tilde{n}$, the appropriate expressions are:[13]

$$\tilde{r} = \frac{\tilde{r}_1 + \tilde{r}_2 \cdot \exp(i4\pi\tilde{n}d/\lambda)}{1 + \tilde{r}_1 \cdot \tilde{r}_2 \cdot \exp(i4\pi\tilde{n}d/\lambda)} \tag{8}$$

where $\tilde{r}_1$ and $\tilde{r}_2$ are the Fresnel reflection coefficients at the first and second interfaces, respectively, and λ is the free-space wavelength.

For most cases of optical absorption, the energy absorbed is proportional to the thickness of the specimen. The variation of intensity inside the absorptive medium is given by the following relationship:

$$I(x) = I(0) \cdot \exp(-\alpha \cdot x) \tag{9}$$

and the absorption coefficient α is related to the optical constants by

$$\alpha = 4\pi k/\lambda \tag{10}$$

Here we note that α (measured in cm^{-1}) describes the attenuation of the radiation intensity rather than that of the electric field.

In spectral regions of intense absorption, all the energy that enters the medium is absorbed. The only part of the incident energy that remains is that which is reflected at the surface. In such a case, it is useful to define a characteristic "skin" thickness that is subject to an appreciable density of optical energy. A convenient form used widely is simply the inverse of α; that is, $1/\alpha$. This skin depth (or penetration length) is usually denoted by δ:

$$\delta = \frac{1}{\alpha} \tag{11}$$

The skin depths in semiconductors range from >100 nm near the bandgap to <5 nm at the higher energies of ≈6 eV.

Kramers-Kronig Relationships A general relationship exists for linear systems between the real and imaginary parts of a response function as shown in the following:

$$\varepsilon_1(\omega) = 1 + \frac{2}{\pi} P \int_0^\infty \frac{\omega' \varepsilon_2(\omega')}{\omega'^2 - \omega^2} d\omega' \tag{12}$$

$$\varepsilon_2(\omega) = -\frac{2\omega}{\pi} P \int_0^\infty \frac{\varepsilon_1(\omega') d\omega'}{\omega'^2 - \omega^2} + \frac{\sigma_0}{\varepsilon_0 \cdot \omega} \tag{13}$$

where σ_0 is the dc conductivity.

$$n(\omega) = 1 + \frac{2}{\pi} P \int_0^\infty \frac{\omega' k(\omega')}{\omega'^2 - \omega^2} d\omega' \tag{14}$$

$$k(\omega) = -\frac{2}{\pi} P \int_0^\infty \frac{\mathrm{n}(\omega')}{\omega'^2 - \omega^2} d\omega' \tag{15}$$

where P denotes the principal part of the integral. These are referred to as the Kramers-Kronig dispersion relationships.[14,15] An expression of practical utility is one in which the experimentally measured reflectance R at normal incidence is explicitly displayed as shown:

$$\theta(\omega) = -\frac{\omega}{\pi} P \int_0^\infty \frac{\mathrm{I}n\,(R(\omega'))\, d\omega}{\omega'^2 - \omega^2} \tag{16}$$

This is useful since it shows that if R is known for all frequencies, the phase θ of the Fresnel reflection coefficient can be deduced, and hence a complete determination of both n and k can be accomplished. In practice, R can be measured only over a limited energy range, but approximate extrapolations can be made to establish reasonable values of n and k.

The measurement of the reflectivity over a large energy range spanning the infrared to the vacuum ultraviolet, 0.5 to 12 eV range, followed by a Kramers-Kronig analysis, used to be the main method of establishing n and k.[16] However, the advances in spectroscopic ellipsometry in the past 20 years have made this obsolete in all but the highest energy region. A Kramers-Kronig analysis of reflectance data also has experimental difficulties related to surface roughness and native oxides, which are more easily corrected with ellipsometry than with reflectivity measurements. The Kramers-Kronig relations are still important today, since they place consistency conditions on optical constants determined from ellipsometry.

Above 12 eV, the higher energy reflectance is dominated by the valence band plasma edge ω_{PV} and, hence, takes the following forms for $\varepsilon(\omega)$, $\tilde{n}(\omega)$, and $R(\omega)$:

$$\tilde{n} = \sqrt{\varepsilon}(\omega) \approx -\frac{1}{2} \cdot \left(\frac{\omega_{PV}^2}{\omega^2} \right) \tag{17}$$

$$R(\omega) = \frac{(n(\omega)-1)}{(n(\omega)+1)} = \frac{1}{16} \cdot \left(\frac{\omega_{PV}^4}{\omega^4} \right) \tag{18}$$

Sum Rules Having realized the interrelationships between the real and imaginary parts of the response functions, one may extend them further using a knowledge of the physical properties of the semiconductor to arrive at specific equations, commonly referred to as sum rules.[14,15] These equations are useful in cross-checking calculations and measurements for internal consistency or reducing the computational effort. Some of the often-used relations are shown below:

$$\int_0^\infty \omega \varepsilon_2(\omega) d\omega = \frac{\pi}{2} \omega_{PV}^2 \tag{19}$$

$$\int_0^\infty \omega \, \mathrm{Im}\left[\frac{-1}{\varepsilon(\omega)} \right] d\omega = \frac{\pi}{2} \omega_{PV}^2 \tag{20}$$

$$\int_0^\infty \omega k(\omega) \cdot d\omega = \frac{\pi}{4} \omega_{PV}^2 \tag{21}$$

$$\int_0^\infty [n(\omega) - 1] d\omega = 0 \tag{22}$$

where ω_{PV} is the valence band plasma frequency.

The dc static dielectric constant, $\varepsilon(0)$, may be expressed as

$$\varepsilon(0) = 1 + \frac{2}{\pi} \int_0^\infty \frac{\varepsilon_2(\omega)}{\omega} \cdot d\omega \tag{23}$$

The reader is referred to Refs. 14 and 15 for more details.

Linear Optical Properties

Overview The optical properties of semiconductors at low enough light levels are often referred to as linear properties in contrast to the nonlinear optical properties described later. There are many physical processes that control the amount of absorption or other optical properties of a semiconductor. In turn, these processes depend upon the wavelength of radiation, the specific properties of the individual semiconductor being studied, and other external parameters such as pressure, temperature, etc. Just as the electrical properties of a semiconductor can be controlled by purposely introducing impurity dopants (both *p* and *n* type) or affected by unwanted impurities or defects, so too are the optical properties affected by them. Thus, one can talk about *intrinsic* optical properties of semiconductors that depend upon their perfect crystalline nature and *extrinsic* properties that are introduced by impurities or defects. Many types of defects exist in real solids: point defects, macroscopic structural defects, etc. In this section we review and summarize intrinsic linear optical properties related to lattice effects, interband transitions, and free-carrier or intraband transitions. Impurity- and defect-related extrinsic optical properties are also covered in a separate section and in the discussion of lattice properties affected by them. Figure 2 schematically depicts

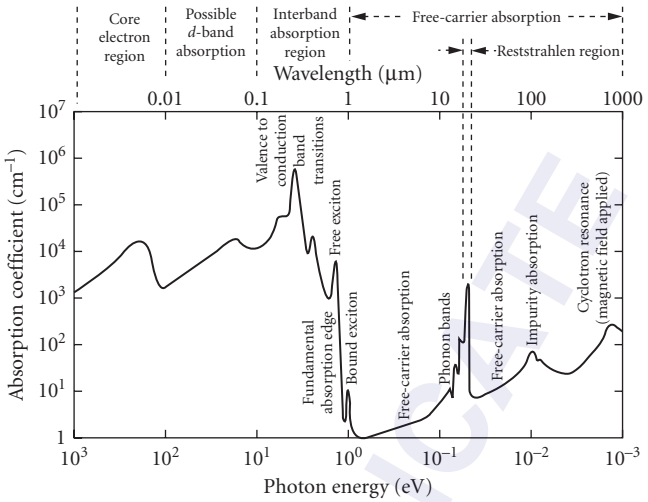

FIGURE 2 Absorption spectrum of a typical semiconductor showing a wide variety of optical processes.

various contributions to the absorption spectrum of a typical semiconductor as functions of wavelength (top axis) and photon energy (bottom axis). Data for a real semiconductor may show more structure than shown here. On the other hand, some of the structure shown may be reduced or not actually present in a particular semiconductor (e.g., impurity absorption, bound excitons, *d*-band absorption). Table 1 shows the classification of the optical responses of the semiconductor to light in various wavelength regions showing the typical origin of the response and how the measurements are usually carried out. At the longest wavelengths shown in Fig. 2, cyclotron resonance (CR) may occur for a semiconductor in a magnetic field, giving rise to an absorption peak corresponding to a transition of a few meV energy between Landau levels. Shallow impurities may give rise to additional absorption at low temperatures, and here a 10 meV ionization energy has been assumed. If the temperature was high enough so that $k_B T$ was greater than the ionization energy, the absorption peak would be washed out. At wavelengths between 5 and 50 μm, a new set of absorption peaks arises due to the vibrational modes of the lattice. In ionic crystals, the absorption coefficient in the reststrahlen region may reach 10^5 cm^{-1}, whereas in homopolar semiconductors like Si and Ge, only multiphonon features with lower absorption coefficients are present (around 5 to 50 cm^{-1}).

Models of the dielectric function The interaction of light with semiconductors can be completely described by the dielectric function, $\varepsilon(\omega)$. The dielectric function $\varepsilon(\omega)$ may be divided into independent parts to describe various physical mechanisms so long as the processes do not interact strongly with each other; this is an approximation, referred to as the adiabatic approximation which simplifies the task at hand considerably.[17] The major players that determine the optical behavior of an intrinsic semiconductor are the lattice, particularly in a nonelemental semiconductor; the free carriers (i.e., mobile electrons and holes) and the interband transitions between the energy states available to the electrons. These three mechanisms account for the intrinsic linear properties that lead to a dielectric function as shown:

$$\varepsilon_{\text{int}}(\omega) = \varepsilon_{\text{lat}}(\omega) + \varepsilon_{\text{fc}}(\omega) + \varepsilon_{\text{inter}}(\omega) \tag{24}$$

The addition of impurities and dopants that are critical to controlling the electronic properties leads to an additional contribution, and the total dielectric response may then be described as shown:

$$\varepsilon(\omega) = \varepsilon_{\text{int}}(\omega) + \varepsilon_{\text{imp}}(\omega) \tag{25}$$

TABLE 1 Classification by Wavelength of the Optical Responses for Common Semiconductors

Wavelength (nm)	Responses	Physical Origin	Application	Measurement Tech.
$\lambda > \lambda_{TO}$ Far-IR and micro wave region	Microwave *R* and *T* Plasma *R* and *T*	Free-carrier plasma	Detectors Switches	*R, T,* and *A** Microwave techniques Fourier Transform Spectrometry (FTS), FT-SE
$\lambda_{LO} < \lambda < \lambda_{TO}$ Reststrahlen region	Reststrahlen *R*	Optical phonons in ionic crystals	Absorbers Filters	*R, T,* and *A* FTS & Dispersion spectrometry (DS), FT-SE
$\lambda \sim \lambda_{LO}, \lambda_{TO}, \lambda_P$ Far-IR region	Far-IR *A*	Optical phonons, impurities (vibrational and electronic), free carriers, intervalence transitions	Absorbers Filters	*R, T,* and *A* FTS, DS, and FT-SE
$\lambda_{LO} > \lambda > \lambda_G$ Mid-IR region	Mid-IR *T* and *A*	Multiphonon, multiphoton transitions, impurities (vibrational and electronic), intervalence transitions excitons, Urbach tail	Detectors Switches Absorbers Filters	*R, T,* and *A* Ellipsometry FTS and DS
$\lambda < \lambda_G$ IR, visible, and UV	*R, T,* and *A*	Electronic interband transitions	Reflectors Detectors	Reflection Ellipsometry
$\lambda \sim \lambda_W$ UV, far-UV	Photoemission	Fermi energy to vacuum-level electronic transitions	Photocathodes Detectors	High-vacuum spectroscopy techniques, UV ellipsometry
$\lambda_W > \lambda > \geq a$	*R, T,* and *A*	Ionic-core transitions	Detectors	Soft x-ray and synchrotron-based analyses
	Diffraction	Photo—ionic-core interactions	X-ray optics and monochromators	X-ray techniques

**R*, *T*, and *A*—Reflection, transmission, and absorption. SE—Spectroscopic ellipsometry.
Note: P—Plasma; G—Energy gap; W—Work functions; *a*—lattice constant.
TO, LO—Transverse and longitudinal optical phonons.

Lattice Absorption

Phonons The dc static response of a semiconductor lattice devoid of free charges to an external electromagnetic field may be described by the single real quantity $\varepsilon(0)$. As the frequency of the electromagnetic radiation increases and approaches the characteristic vibrational frequencies associated with the lattice, strong interactions can occur and modify the dielectric function substantially. The main mechanism of the interaction is the coupling between the electromagnetic field with the oscillating dipoles associated with vibrations of an ionic lattice.[8] The interactions may be described, quite successfully, by treating the solid to be a collection of damped harmonic oscillators with a characteristic vibrational frequency ω_{TO} and damping constant γ. The resultant dielectric function may be written in the widely used CGS units as:

$$\varepsilon_{lat}(\omega) = \varepsilon(\infty) + \frac{S\omega_{TO}^2}{(\omega_{TO}^2 - \omega^2 - i\omega\gamma)} \tag{26}$$

where S is called the oscillator strength and may be related to the phenomenological ionic charge e_i, reduced mass m_i', and volume density N, through the equation

$$S\omega_{TO}^2 = \frac{4\pi N e_i^2}{m_i'} \tag{27}$$

In the high frequency limit of $\varepsilon(\omega)$, for $\omega >> \omega_{TO}$, (but well below the onset of interband absorption)

$$\varepsilon(\omega) \rightarrow \varepsilon_{\infty} \tag{28}$$

The relationship may be easily extended to accommodate more than one characteristic vibrational frequency by summing over all phonon modes *i*:

$$\varepsilon_{lat}(\omega) = \varepsilon_{\infty} + \sum_i \frac{S_i(\omega_{TO}^i)^2}{[(\omega_{TO}^i)^2 - \omega^2 - i\omega\gamma^i]} \tag{29}$$

It is worth noting some important physical implications and interrelations of the various parameters in Eq. (26).

For a lattice with no damping, it is obvious that $\varepsilon(\omega)$ displays a pole at ω_{TO} and a zero at a well-defined frequency, usually referred to by ω_{LO}. A simple but elegant and useful relationship exists between these parameters as shown by

$$\frac{\varepsilon(0)}{\varepsilon_{\infty}} = \left(\frac{\omega_{LO}}{\omega_{TO}}\right)^2 \tag{30}$$

which is known as the Lyddane-Sachs-Teller relation.[18]

The physical significance of ω_{TO} and ω_{LO} is that these are the transverse and longitudinal optical phonon frequencies with zero wave vector, **K**, supported by the crystal lattice. The optical vibrations are similar to standing waves on a string. The wave pattern, combined with the ionic charge distribution, leads to oscillating dipoles that can interact with the incident radiation and, hence, the name optical phonons. $\varepsilon(\omega)$ is negative for $\omega_{TO} \geq \omega \geq \omega_{LO}$, which implies no light propagation inside the crystal and, hence, total reflection of the incident light. The band of frequencies spanned by ω_{TO} and ω_{LO} is referred to as the reststrahlen band.

The reflectivity spectrum of AlSb[19] is shown in Fig. 3. It is representative of the behavior of most semiconductors. Note that the reflectivity is greater than 90 percent at ≈31 μm in the reststrahlen band spanned by the longitudinal and transverse optical phonons. The two asymptotic limits of the reflection tend to $[(\sqrt{\varepsilon}(0)-1)/(\sqrt{\varepsilon}(0)+1)]^2$ and $[(\sqrt{\varepsilon_{\infty}}-1)/(\sqrt{\varepsilon_{\infty}}+1)]^2$, respectively, compare Eqs. (5) and (6). The effects of the phonon damping are illustrated in Fig. 4.[20] For the ideal case with zero damping, the reflection in the reststrahlen band is 100 percent. Since absolute reflectance measurements are very difficult to carry out experimentally, the reststrahlen region is nowadays often investigated with infrared ellipsometry. Note that for the elemental semiconductors such as Si and Ge, the lack of a dipole moment associated with the optical vibrations of the lattice leads to the absence of any oscillator strength and hence no interaction with the radiation. The reflection spectrum will, therefore, show no change at or near the optical phonon frequencies. The optical phonon frequencies (ω_{LO} and ω_{TO}) and wavelengths and $\varepsilon(0)$ and ε_{∞} for the commonly known semiconductors are presented at the end of this chapter in Table 11. For elemental semiconductors, $\varepsilon(0) = \varepsilon_{\infty}$.

The optical phonons ω_{LO} and ω_{TO} are the frequencies of interest for describing the optical interactions with the lattice. In addition, the lattice is capable of supporting vibrational modes over a wide range of frequencies extending from 0 to $\omega_{LO}(\Gamma)$, the LO phonon frequency at the center of the Brillouin zone, Γ, as discussed by Cochran in Ref. 21. The vibrational modes can be subdivided into two major categories. The first are optical phonons that possess an oscillating dipole moment and therefore can interact with light. The second group is the acoustic phonons; that is, sound-like vibrations that do not possess a dipole moment and hence are not of primary importance in

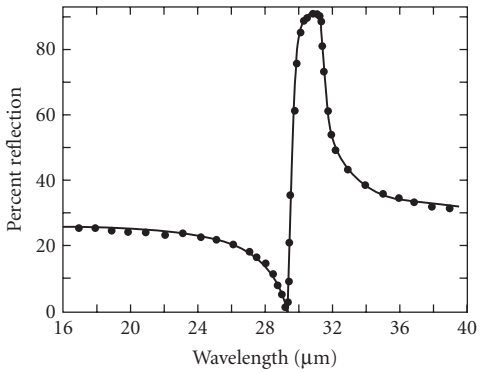

FIGURE 3 Reststrahlen reflection spectrum of AlSb.[19]

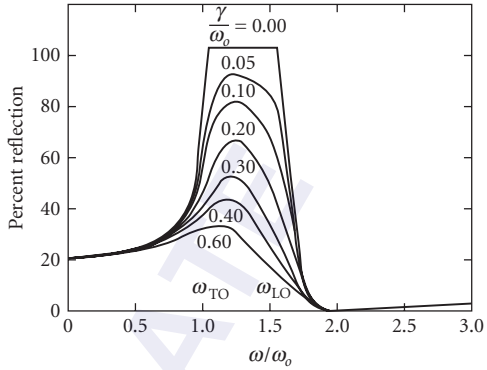

FIGURE 4 Reflection spectra of a damped oscillator for various values of the damping factor.[20]

determining the optical properties. For the optical band, only the $\mathbf{K} \approx 0$ modes are important since a strong interaction is precluded for other modes due to the large mismatch in the wave vectors associated with the light and vibrational disturbances.

The simple treatment so far, though very useful, is limited to the most obvious and strongest aspect of the interaction of light with the lattice. However, many weaker but important interaction mechanisms have not yet been accounted for. An attempt to produce a complete description starts with the consideration of the total number of atoms N that makes up the crystal. Each atom possesses three degrees of freedom, and hence one obtains $3N$ degrees of freedom for the crystal, a very large number of magnitude, $\approx 10^{24}$. The complexity of the description can be readily reduced when one realizes the severe restriction imposed by the internal symmetry of the crystal. The vibrational characteristics now break up into easily understandable normal modes with well-defined physical characteristics. The translational symmetry associated with the crystal makes it possible to assign a definite wave vector to each lattice mode. In addition, the phonons can be divided into two major classes: the optical vibrations, which we have already discussed, and the acoustic vibrations, which, as the name implies, are sound-like vibrations. The acoustic phonons for $|\mathbf{K}| \to 0$ are identical to the sound waves. Hence, specifying the type of phonon, energy, wave vector, and polarization uniquely describes each vibrational mode of the crystal. The conventional description of phonons is achieved by graphically displaying these properties in a frequency versus $\mathbf{K}$ plot, as shown in Fig. 5 for GaAs.[22]

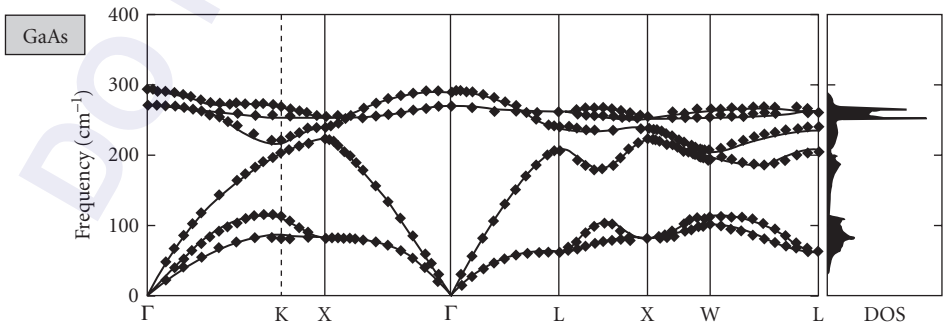

FIGURE 5 Phonon dispersion curves of GaAs. Experimental data are represented by symbols. Solid lines show the results of the calculation of Gianozzi et al.[22]

The energies of the phonons are plotted as a function of the wave vector along the high-symmetry directions for each acoustic and optical branch. It can be shown that the number of acoustic branches is always three, two of transverse polarization and one longitudinal, leaving $3p$-3 optical branches, where p is the number of atoms in the primitive cell. The majority of the most important semiconductors fall into the three cubic classes of crystals—namely, the diamond, zincblende, and the rock-salt structures that contain two atoms per primitive cell and hence possess three acoustic and three optical branches each.[23] However, more complicated structures with additional optical phonon branches can be found. The most important group among the second category is the wurtzite structure displayed by CdS, CdSe, GaN, InN, AlN, etc., which contains four atoms in the primitive cell and hence two additional sets of optical phonon branches.[23] The specific symmetry associated with the vibrational characteristics of each mode is used to distinguish them as well as their energies at the high-symmetry points in the phonon dispersion curves.

Multiphonon absorption It has already been pointed out that the interaction of light with phonons is restricted to those with $\mathbf{K} \approx 0$. This is true only when single-phonon interactions are considered in ideal crystals. Higher-order processes, such as multiphonon absorption, can activate phonons with $\mathbf{K} \neq 0$.[23,24] Symmetry considerations and their implication on the multiphonon absorption are discussed by Birman in Ref. 25. In multiphonon processes, the total momentum of the interacting phonons will be 0, but many modes with $\mathbf{K} \neq 0$ can participate in the interaction.

The energy and momentum conservation conditions may be expressed as follows:

$$\hbar\omega = \sum_i \hbar\Omega_i \tag{31}$$

$$\hbar\mathbf{q} = \sum_i \hbar\mathbf{K}_i \approx 0 \tag{32}$$

where $\hbar\omega$ is the energy of the absorbed photon, $\hbar\Omega_i$ is the energy of the phonons, and $\hbar\mathbf{q}$ and $\hbar\mathbf{K}_i$ are the corresponding momenta. Any number of phonons can participate in the process. However, the strength of interaction between the incident photon and the higher-order processes falls off rapidly with increasing order, making only the two- or three-phonon processes noteworthy in most semiconductors. The well-defined range that spans the phonon energies in most semiconductors, extending from 0 to the LO phonon energy at the center of the zone Γ, restricts the n-phonon process to a maximum energy of $n\hbar\omega_{LO}(\Gamma)$. Among the participating phonons, those with large values of $\mathbf{K}$ and those in the vicinity of the critical points are the most important owing to their larger populations. These factors are important in understanding the multiphonon absorption behavior, as we now discuss.[23,24]

Multiphonon processes may be subdivided into two major categories: (1) sum processes where multiple phonons are created, and (2) difference processes in which both phonon creation and annihilation occur with a net absorption in energy. The former process is more probable at higher-incident photon energies and the converse is true for the latter. The reduction of the equilibrium phonon population at low temperatures leads to a lower probability for the difference process, and hence it is highly temperature dependent.

The multiphonon interactions are governed by symmetry selection rules in addition to the energy and momentum conservation laws stated earlier. A list of the possible combination processes is presented in Table 2 for the diamond structure and Table 3 for the zincblende structure. Representative multiphonon absorption spectra are presented in Figs. 6 and 7 for Si[26] and GaAs.[27] The Si ω_{TO} and ω_{LO} frequency of ~522 cm^{-1} is indicated in the spectrum for reference. Note that the absence of a dipole moment implies that ω_{TO} and ω_{LO} are degenerate, and no first-order absorption is present. In contrast, for GaAs the very large absorption associated with the one-phonon absorption precludes the possibility of obtaining meaningful multiphonon absorption data in the reststrahlen band that spans the ~269 to 295 cm^{-1} (~34–37 meV) spectral region. The multiphonon spectra obtained from GaAs are displayed in Fig. 7*a* and *b*. The absorption associated with the multiphonon processes is much smaller than the single-phonon process. However, the rich structure displayed by the spectra is extremely useful in analyzing the lattice dynamics of the material. In

addition, in applications such as windows for high-power lasers, even the small absorption levels can lead to paths of catastrophic failure.

Impurity-related vibrational optical effects The role of impurities is of primary importance in the control of the electrical characteristics of semiconductors and hence their technological applications. This section outlines the main vibrational features of impurities and the resulting modification of the optical properties of these semiconductors. Impurities can either lead to additional vibrational modes over and beyond that supported by the unperturbed lattice or they can activate normally inactive vibrational modes.[28] The perturbation of the lattice by a substitutional impurity is a change in the mass of one of the constituents and a modification of the bonding forces in its vicinity. If the impurity is much lighter than the host atom it replaces, high-frequency vibrational modes above $\omega_{LO}(\Gamma)$, the maximum frequency supported by the unperturbed lattice, are introduced. These vibrational amplitudes are localized in the vicinity of the impurity and hence are known as local vibrational modes (LVM). For heavier impurities, the impurity-related vibrations can occur within the phonon band or in the gap between the acoustic and optical bands. These modes are referred to as resonant modes (RM) or gap modes (GM).[28]

The qualitative features of an impurity vibrational mode can be understood by considering a simple case of a substitutional impurity atom in a linear chain. The results of a numerical calculation of a 48-atom chain of GaP are presented in Figs. 8 and 9.[28] The highly localized character can be seen from Fig. 9. Note that the degree of localization reduces with increasing defect mass for a fixed bonding strength.

two naturally occurring isotopes of Ga. The fine structure in the spectrum helps identify the site occupied by C as belonging to the As sublattice. When accurate calibration curves are available, the concentration of the impurity can be determined from the integrated intensity of the LVM band. The LVM frequencies of a number of hosts and impurities are presented in Table 4.[28] The symmetry of the point group associated with the defect is T_d. The use of LVM in the study of complex defects, particularly those that involve hydrogen, has led to a wealth of microscopic information not easily attainable by any other means.[31]

The quantitative accuracy obtainable from LVM analysis may be illustrated by a simple harmonic model calculation. In such an approximation, the total integrated absorption over the entire band may be expressed as:[32]

$$\int \alpha d\omega = \frac{2\pi^2 N \eta^2}{n m_{\text{imp}} c} \tag{33}$$

where N is the volume density of the impurity and η and m_{imp} are the apparent charge and mass of the impurity ion; c is the velocity of light. n is the refractive index of the host crystal. η is an empirically derived parameter that is specific to each center, that is, a specific impurity at a specific lattice location. Once calibration curves are established, measurement of the intensity of absorption can be used to determine N. Figure 12 displays a calibration used to establish the density of interstitial oxygen.[33] Such analyses are routinely used in various segments of the electronic industry for materials characterization.

The effect of the impurities can alter the optical behavior in an indirect fashion as well. The presence of the impurity destroys translational symmetry in its vicinity and hence can lead to relaxation of the wave-vector conservation condition presented earlier in Eq. (32). Hence, the entire acoustic and optical band of phonons can be activated, leading to absorption bands that extend from zero frequency to the maximum $\omega_{\text{LO}}(\Gamma)$. The spectral distribution of the absorption will depend on the phonon density-of-states modulated by the effect of the induced dipole moment.[28] The latter is a consequence of the perturbation of the charge distribution by the impurity. The perturbation due to defects may be viewed in a qualitatively similar fashion. For instance, a vacancy may be described as an impurity with zero mass.

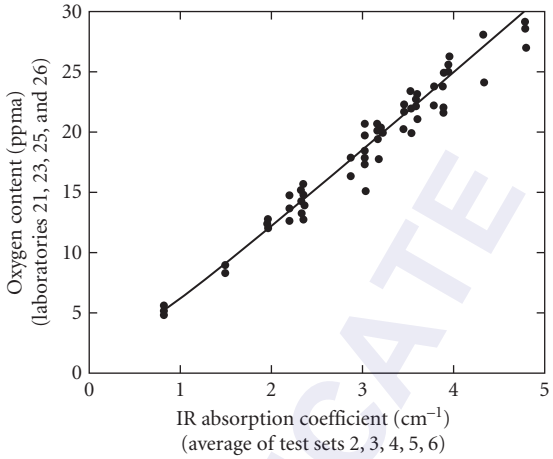

FIGURE 12 The absorption coefficient dependence on the concentration of interstitial oxygen in Si.[33]

Interband Absorption

Absorption near the fundamental edge The fundamental absorption edge is one of the most striking features of the absorption spectrum of a semiconductor. Within a small fraction of an electron volt at an energy about equal to the energy gap E_g of the material, the semiconductor changes from being practically transparent to completely opaque—the absorption coefficient changing by a factor of 10^4 or more. This increased absorption is caused by transitions of electrons from the valence band to the conduction band. This characteristic optical property is clearly illustrated in Fig. 13, which shows the transmission versus wavelength for a number of major semiconductors.[34] At the lower wavelengths, the transmission approaches zero which defines a cutoff wavelength λ_c for each material. For example, $\lambda_c \approx 7.1$ μm for InSb; $\lambda_c \approx 4.2$ μm, PbTe; $\lambda_c \approx 3.5$ μm, InAs; $\lambda_c \approx 1.8$ μm, GaSb and Ge; $\lambda_c \approx 1$ μm, Si; and $\lambda_c \approx 0.7$ μm for CdS. At much longer wavelengths than the edge at λ_c, lattice and free-carrier absorption become appreciable and the transmission drops. Studies of the fundamental absorption edge thus give values for the energy gap and information about the states just above the edge in the conduction band and below it in the valence band. Properties of these states are important to know since they are responsible for electrical conduction. Details of the band structure near the band extrema can be determined from the position and shape of the absorption edge and from its temperature, magnetic field, pressure, impurity concentration, and other parameters' dependence. Finally, this fundamental gap

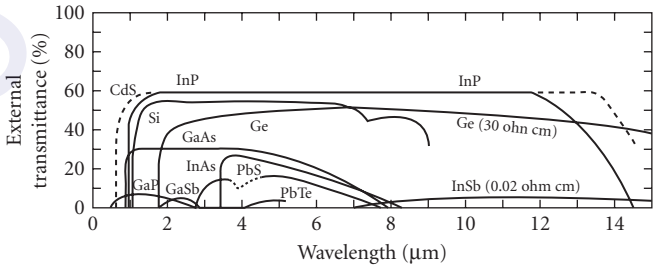

FIGURE 13 The transmission of CdS, InP, Si, Ge, GaAs, GaP, GaSb, InAs, InSb, PbTe, and PbS.[34]

region is important because usually it is only near the energy gap that phenomena such as excitons (both free and bound), electron-hole drops, donor-acceptor pairs, etc., are seen.

Interband transitions near the fundamental absorption edge are classified as (1) direct or vertical or (2) indirect or nonvertical. The momentum of light ($\hbar q = \hbar n\omega/c$) is negligible compared to the momentum of a **k**-vector state at the edge of the Brillouin zone. Thus, because of momentum conservation, electrons with a given wave vector in a band can only make transitions to states in a higher band having essentially the same wave vector. Such transitions are called vertical transitions. A nonvertical transition can take place, but only with the assistance of phonons or other entities which help preserve momentum.

Direct transitions The interband absorption coefficient depends upon the band structure and photon energy $\hbar\omega$. Use of quantum mechanics and, in particular, time-dependent perturbation theory becomes necessary.[35] For a nonzero momentum (dipole) matrix element, a simple model gives for allowed direct transitions

$$\alpha_{AD} = C_{AD}(\hbar\omega - E_g)^{1/2} \tag{34}$$

The coefficient C_{AD} involves constants, valence and conduction band effective masses, matrix elements, and only a slight dependence on photon energy. The absorption strengths of direct-gap semiconductors are related to their density of states and the momentum matrix element that couples the bands of interest. Many semiconductors such as AlAs, AlP, GaAs, InSb, CdS, ZnTe, and others have allowed direct transitions; many complex oxides, such as Cu_2O, SiO_2, and rutile, have forbidden direct absorption.

Figure 14 shows the spectral variation of the absorption coefficient for pure InSb at a temperature of 5 K compared to various theoretical predictions.[36] We note the extremely sharp absorption edge which is fit best by the $(\hbar\omega - E_g)^{1/2}$ dependence near the edge. However, a big deviation from the experimental data occurs at higher photon energies. Consideration of two more details allows a better

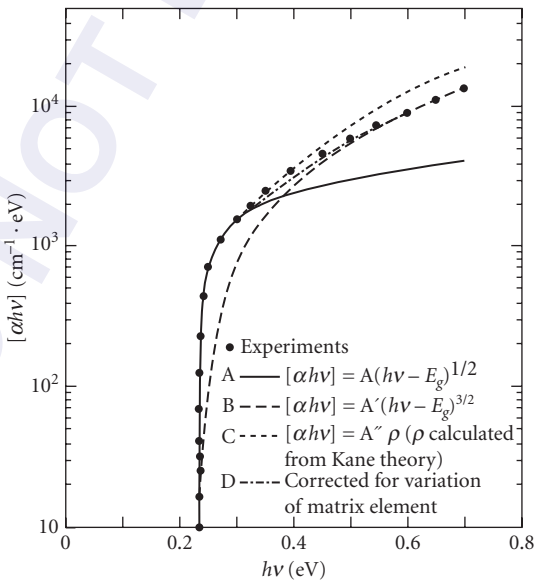

FIGURE 14 Theoretical fit to the experimental absorption edge of InSb at ≈5 K.[36]

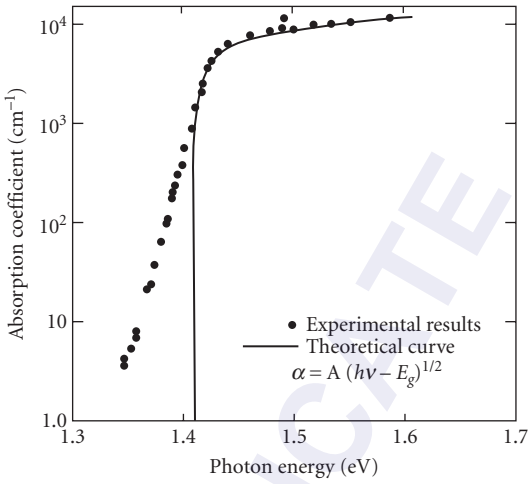

FIGURE 15 Absorption edge of GaAs at room temperature.[38]

fit: (1) use of a more complicated band model from Kane[37] which predicts a more rapidly increasing density of states than for the simple bands, and (2) taking into account a decrease in the optical matrix element at the higher photon energies because of the **k**-dependence of the wave functions. The calculated curves in Fig. 14 were arbitrarily shifted so that they look like a better fit than they are. The actual calculated absorption is a factor of about 15 too low at high energies. This discrepancy was attributed to the neglect of exciton effects which can greatly affect the absorption as discussed later. Modern calculations (including the Bethe-Salpeter corrections for many-body effects to the local density approximation) have much better accuracy in describing the optical absorption due to excitons.

Figure 15 shows the absorption behavior of GaAs at room temperature compared with calculations based on Kane's theory.[38] Below about 10^3 cm^{-1}, the absorption decreases much more slowly than predicted and absorption is even present for energies below E_g. In practice, there seems to exist an exponentially increasing absorption edge rule (called Urbach's rule) in most direct transition materials which is found to correlate reasonably well with transitions involving band tails. These band tails seem to be related to disorder, such as doping effects, phonon-assisted transitions, and the broadening of electronic states due to electron-phonon interactions.

Indirect transitions Semiconductors such as GaP, Ge, and Si have indirect gaps where the maximum valence band energy and minimum conduction band energy do not occur at the same **k** value. In this case, the electron cannot make a direct transition from the top of the valence band to the bottom of the conduction band because this would violate conservation of momentum. Such a transition can still take place but as a two-step process requiring the cooperation of another particle and which can then be described by second-order perturbation theory. The particle most frequently involved is an intervalley phonon of energy $\hbar\Omega_K$ which can be either generated or absorbed in the transition. (In some cases, elastic scattering processes due to impurity atoms or dislocations must be considered; they are less frequent than the phonon interactions in high-purity crystals.) The photon supplies the needed energy, while the phonon supplies the required momentum. The transition probability depends not only on the density of states and the electron-phonon matrix elements as in the direct case, but also on the electron-phonon interaction which is temperature dependent.

Calculations of the indirect-gap absorption coefficient give for the allowed indirect transitions

$$\alpha_{\mathrm{AI}} = C_{\mathrm{AI}}^{(\mathrm{abs})}(\hbar\omega + \hbar\Omega_q - E_g)^2 + C_{\mathrm{AI}}^{(\mathrm{em})}(\hbar\omega - \hbar\Omega_q - E_g)^2 \tag{35}$$

where the superscripts (abs) and (em) refer to phonon absorption and emission, respectively. This expression is only nonzero when the quantities in parentheses are positive, that is, when $\hbar\omega \pm \hbar\Omega q > E_g$. We note that the phonon energies are usually small (≤ 0.05 eV) compared to the photon energy of about 1 eV and thus for the case of allowed indirect transitions with phonon absorption

$$\alpha_{AI} \approx C_{AI}^{(abs)}(\hbar\omega - E_g)^2 \tag{36}$$

Thus the absorption increases as the second power of $(\hbar\omega - E_g)$, much faster than the half-power dependence of the direct transition as seen in Eq. (34).

Figure 16 shows the variation of the absorption coefficient of GaP with photon energy at room temperature near the indirect edge.[39] A reasonable fit to the experimental data of Spitzer et al.[40] is obtained indicating that, for GaP, allowed indirect transitions dominate. Further complications arise because there can be more than one type of phonon emitted or absorbed in the absorption process. Transverse acoustic (TA), longitudinal acoustic (LA), transverse optic (TO), and longitudinal optic (LO) phonons can be involved as shown in the absorption edge data of GaP, as seen in Fig. 17.[41] The phonon energies deduced from these types of experimental absorption edge studies agree with those found from neutron scattering.

Both indirect and direct absorption edge data for Ge are shown in Fig. 18, while the analysis of the 300 K data is plotted in part *b*.[42] At the lowest energies, α rises due to the onset of indirect absorption as seen by the $\alpha^{1/2}$ dependence on photon energy. At higher energies, a sharper rise is found where direct transitions occur at the zone center and an α^2 dependence on energy is then seen. Note the large shifts of E_g with temperature for both the direct and indirect gaps. Also, the direct-gap absorption is much stronger than that of the indirect-gap absorption.

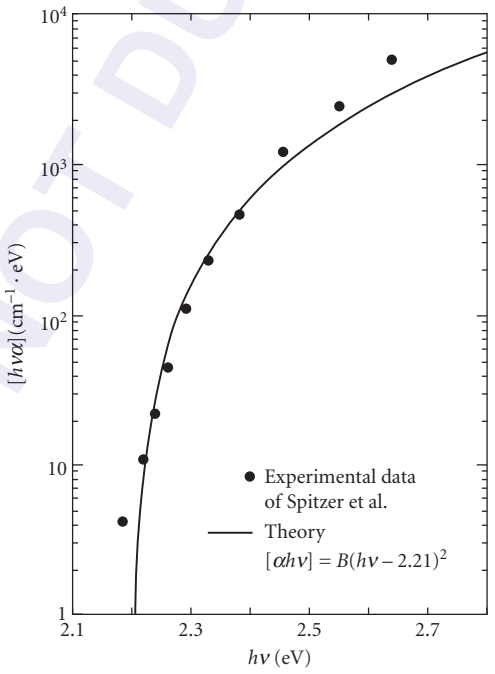

FIGURE 16 Comparison of the experimental data at room temperature for the absorption edge of GaP with the theory for an indirect edge.[39]

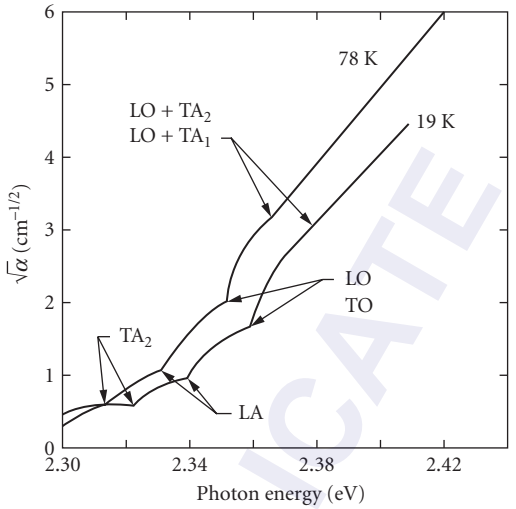

FIGURE 17 Absorption spectra at the edge of GaP, showing thresholds associated with the emission of each of several different phonons.[41]

Excitons Among the various optical properties of semiconductors, the subject of excitons has one of the dominant places because of their remarkable and diverse properties. Studies of exciton properties represent one of the most important aspects of scientific research among various solid-state properties. According to Cho,[43] there are a number of reasons for this: (1) excitonic phenomena are quite common to all the nonmetallic solids—semiconductors, ionic crystals, rare gas crystals, molecular crystals, etc.; (2) the optical spectra often consist of sharp structure, which allows a detailed theoretical analysis; (3) theories are not so simple as to be understood by a simple application of atomic theory or the Bloch band scheme, but still can be represented by a quasi-hydrogen-like level scheme; (4) sample quality and experimental techniques have continually been improved

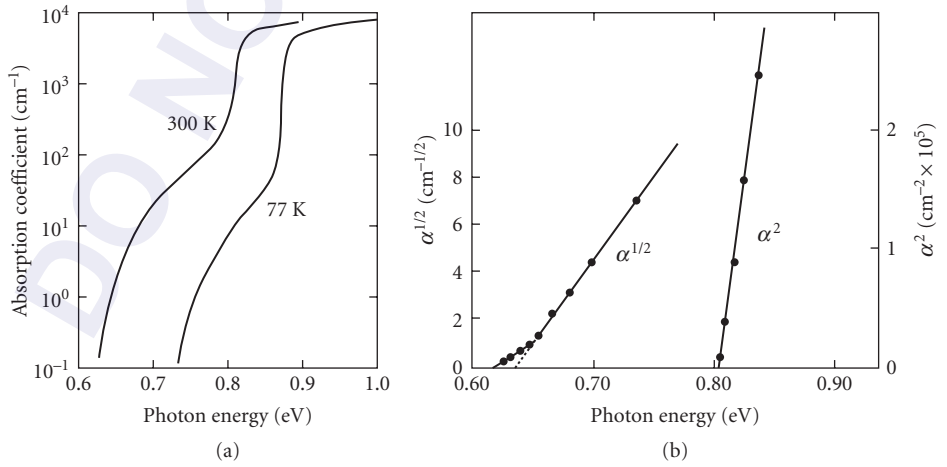

FIGURE 18 (*a*) α vs. $\hbar\omega$ for Ge and (*b*) the analysis of the 300 K experimental data.[42]

TABLE 5 A Glossary of the Main Species of Excitons[44]

Exciton	In essence, an electron and hole moving with a correlated motion as an electron-hole pair
Wannier exciton	Electron and hole both move in extended orbits; energy levels related to hydrogen-atom levels by scaling, using effective masses and dielectric constant; occurs in covalent solids such as silicon
Frenkel exciton	Electron and hole both move in compact orbits, usually essentially localized on adjacent ions; seen in ionic solids, such as KCl, in absorption
Self-trapped exciton	One or both carriers localized by the lattice distortion they cause; observed in ionic solids, such as KCl, in emission
Bound exciton	Only a useful idea when a defect merely prevents translational motion of an exciton and does not otherwise cause significant perturbation
Core exciton	Lowest-energy electronic excitation from a core state, leaving an unoccupied core orbital (e.g., the 1 s level of a heavy atom) and an electron in the conduction band whose motion is correlated with that of the core hole
Excitonic molecule	Complex involving two holes and two electrons
Multiple bound excitons	Complex of many holes and a similar number of electrons, apparently localized near impurities; some controversy exists, but up to six pairs of localized carriers have been suggested
Exciton gas	High concentration of electrons and holes in which each electron remains strongly associated with one of the holes (as insulating phase)
Electron-hole drops	High concentration of electrons and holes in which the motions are plasma-like (a metallic phase), not strongly correlated as in excitons

with subsequent experiments proving existing theories and giving rise to new ones; and (5) the exciton is an elementary excitation of nonmetallic solids, a quantum of electronic polarization. It has a two-particle (electron and hole) nature having many degrees of freedom, and, along with the variety of energy-band structures, this leads to a lot of different properties from material to material or from experiment to experiment. Table 5 gives a definition of the major types of excitons in a glossary obtained from Hayes and Stoneham.[44] Many examples exist in the literature involving work on excitons in semiconductors to understand their nature and to determine their properties. Besides the references cited in this chapter, the authors refer the reader to the more detailed work presented in Refs. 45 and 46.

An electron, excited from the valence band to a higher energy state in the conduction band, can still be bound by the Coulomb attraction to the hole that the electron leaves in the valence band. This neutral bound-electron hole pair is called an exciton which can move throughout the crystal. Excitons are most easily observed at energies just below E_g using optical absorption or photoluminescence measurements. There are two models used for describing excitons in solids, named after Frenkel and Wannier. In a solid consisting of weakly interacting atoms, Frenkel considered excitons as described by excitations of a single atom or molecule.[47] An excited electron describes an orbit of atomic dimensions around an atom with a vacant valence state. The empty valence state acts as a mobile hole since the excitation can move from one atom to another. These tightly bound excitons are similar to an ordinary excited state of the atom, except that the excitation can propagate through the solid. The radius of the Frenkel exciton is on the order of the lattice constant. Frenkel excitons are useful to describe optical properties of solids like alkali halides and organic phosphors.

Wannier (or also called Mott-Wannier) excitons are also electrons and holes bound by Coulomb attraction.[48,49] In contrast to the Frenkel exciton, the electron and hole are separated by many lattice spacings producing a weakly bound exciton which is remarkably similar to a hydrogen-atom-like system. Since the electron and hole are, on the average, several unit cells apart, their Coulomb interaction is screened by the average macroscopic dielectric constant, ε_∞, and electron and hole effective masses can be used. Their potential energy $-e^2/\varepsilon_\infty r$ is just that of the hydrogen atom (except for ε_∞). The binding energy of the free exciton (relative to a free electron and free hole) is then given by the hydrogen-atom-like discrete energy levels plus a kinetic energy term due to the motion of the exciton:

$$E_{\text{ex}} = \frac{R_y}{n^2} - \frac{\hbar^2 k^2}{2(m_e^* + m_h^*)} \tag{37}$$

$$R_y = \left(\frac{m_r}{\varepsilon_\infty^2}\right)\left(\frac{e^4}{2\hbar^2}\right) = \left(\frac{m_r}{m_H \varepsilon_\infty^2}\right) E_H \tag{38}$$

where

$$m_r = \left(\frac{1}{m_e^*} + \frac{1}{m_h^*}\right)^{-1} \tag{39}$$

is the reduced mass of the exciton, m_H is the reduced mass of the hydrogen atom, n is the principal quantum number (1, 2, . . ., ∞), E_H is the ionization energy of the hydrogen atom (13.6 eV), and R_y is the effective Rydberg energy. The lowest energy absorption transition of the semiconductor is thus $E_g - E_{\text{ex}}$. As an example, consider CdS where $m_e^* \approx 0.21\ m_o$, $m_h^* \approx 0.64\ m_o$, and $\varepsilon_\infty \approx 8.9$; here $m_r \approx 0.158 m_o$ and $R \approx 27$ meV. The Bohr radius for the $n = 1$ ground state is about 30 Å.

A series of excitonic energy levels thus exists just below the conduction band whose values increase parabolically with **k** and whose separation is controlled by *n.* Excitons are unstable with respect to radiative recombination whereby an electron recombines with a hole in the valence band, with the emission of a photon or phonons. These excitonic levels are shown in Figs. 19 and 20. For

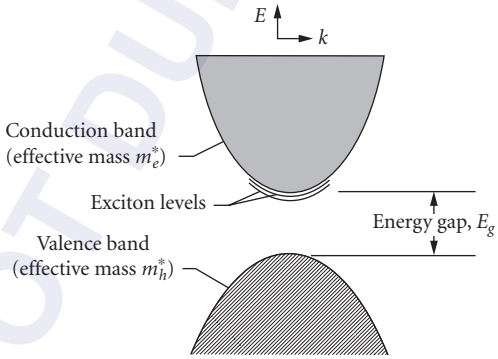

FIGURE 19 Exciton levels in relation to the conduction-band edge, for a simple band structure with both conduction and valence band edges at near $k = 0$.

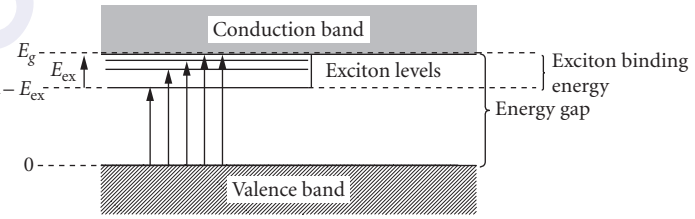

FIGURE 20 Energy levels of a free exciton created in a direct process. Optical transitions from the top of the valence band are shown by the arrows; the longest arrow corresponds to the energy gap.

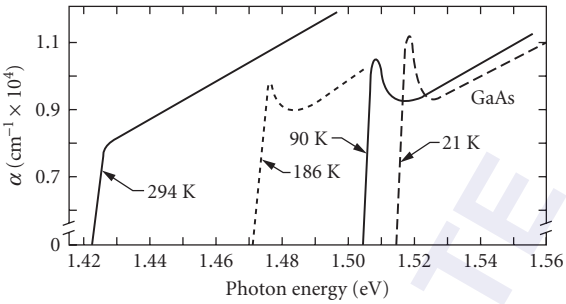

FIGURE 21 Observed exciton absorption spectra in GaAs at various temperatures between 21 and 294 K. Note the decrease in the band edge with increasing temperatures.[50]

many semiconductors only a single peak is observed, as shown in Fig. 21 for GaAs.[50] However, even though only one line is observed, the exciton states make a sizable contribution to the magnitude of the absorption near and above the edge. At room temperatures, the exciton peak can be completely missing since the binding energy is readily supplied by phonons. In semiconductors with large enough carrier concentrations, no excitons exist because free carriers tend to shield the electron-hole interaction. Neutral impurities can also cause a broadening of the exciton lines and, at large enough concentrations, cause their disappearance.

Extremely sharp exciton states can often be seen as shown in Fig. 22, which shows the absorption spectrum of a very thin, very pure epitaxial crystal of GaAs.[51] The $n = 1$, 2, and 3 excitons are clearly

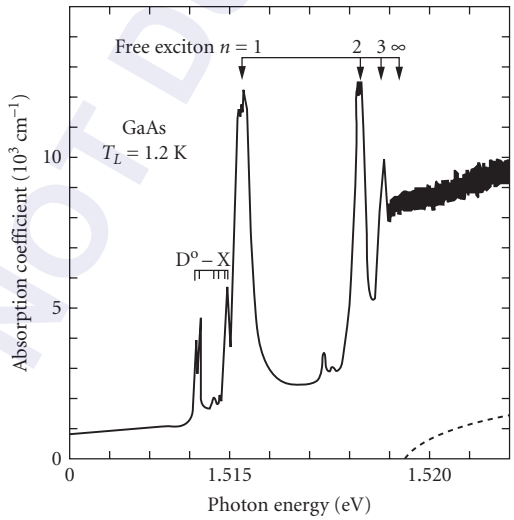

FIGURE 22 Absorption spectrum at 1.2 K of ultrapure GaAs near the band edge. The $n = 1$, 2, 3 free exciton peaks are shown; also the bandgap E_g, determined by extrapolation to $n = \infty$, and impurity lines (D_oX) from the excitons bound to $\approx 10^{15}$ cm^{-3} donors. (The rise at high energy is due to substrate absorption.) The dashed line shows the $(E - E_g)$ behavior expected in the absence of electron-hole interaction (the absolute magnitude is chosen to fit the absorption far from the band edge).[51]

seen followed by excited states with $n > 3$ leading smoothly into the continuum. The dashed line, calculated neglecting the effects of excitons, illustrates how important exciton effects are in understanding the optical properties of semiconductors and confirms the qualitative picture of exciton absorption.

Excitons in direct-gap semiconductors such as GaAs are called direct excitons. For indirect-gap semiconductors like Si or GaP, the absorption edge is determined by the influence of indirect excitons as revealed by the shape of the absorption. Such indirect-exciton transitions have been observed in several materials including Ge, Si, diamond, GaP, and SiC.

Real semiconductor crystals contain impurities and defects which also can affect the optical properties related to excitonic features, in addition to their causing impurity/defect absorption. A bound exciton (or bound-exciton complex) is formed by binding a free exciton to a chemical impurity atom (ion), complex, or a host lattice defect. The binding energy of the exciton to the defect or impurity is generally weak compared to the free-exciton binding energy. These bound excitons are extrinsic properties of the semiconductor; the centers to which the free excitons are bound can be either neutral donors or acceptors or ionized donors or acceptors. They are observed as sharp-line (width ≈ 0.1 meV) optical transitions in both absorption and photoluminescence spectra. The absorption or emission energies of these bound-exciton transitions always appear below those of the corresponding free-exciton transitions. Bound excitons are very commonly observed because semiconductors contain significant quantities of impurities or defects which produce the required binding. These complexes are also of practical interest because they characterize the impurities often used to control the electrical properties of semiconductors as well as being able to promote radiative recombination near the band gap. Bound excitons exhibit a polarization dependence similar to the free-exciton states from which they originated.

At higher densities of free excitons and low temperatures, they can form an electron-hole droplet by condensing into a "liquid" phase. This condensed phase occurs for electron-hole concentrations of about 2×10^{17} cm^{-3} and can be thought of as an electron-hole plasma with a binding energy of several meV with respect to the free excitons.[52]

Polaritons Interesting optical effects arise when one considers explicitly the influence of longitudinal and transverse optical phonons on a transverse electromagnetic wave propagating through the semiconductor. This influence can be taken into account via the dielectric function of the medium. Dispersion curves that arise do not conform either to the photon or to the phonon. The coupling between the photon and phonon becomes so strong that neither can continue to be regarded as an independent elementary excitation, but as a photon-phonon mixture! This mixture can be regarded as a single quantity which can be interpreted as a new elementary excitation, the *polariton.*[53] Similar couplings exist between an exciton and the photon. It is an important consideration for interpreting some optical processes involving Raman and luminescence measurements.

High-energy transitions above the fundamental edge The optical properties of most semiconductors have been thoroughly investigated throughout the visible and ultraviolet regions where transitions above the fundamental gap energy give rise to properties strongly dependent upon photon energy. This regime is dominated by optical absorption and reflection of a photon arising from both valence and core electron transitions from the ground state of the system into various bound, autoionizing, continuum, or other excited states. The sum of all excitations—both bound (nonionizing) and ionizing—gives the total absorption coefficient and the complex dielectric constant at each photon energy $h\nu$. Photoemission or photoelectron spectroscopy measurements in this high-energy regime provide an alternative to ultraviolet spectroscopy for providing detailed information on the semiconductor. (See the electromagnetic spectrum in Fig. 1 in the Introduction for a reminder that photoemission measurements overlap UV measurements.) Electrons may be ejected from the semiconductor by high-energy photons as shown in Fig. 23.[54] Their kinetic energies are measured and analyzed to obtain information about the initial electron states. Ionizing excitations involve electron excitations into unbound states above the vacuum level. These excitations result in photoemissions depicted for the two valence bands and the core level shown. For photoemission involving one-electron excitations (usually dominant), binding energies E_B of valence and core levels are given directly by the measured kinetic energies E (from $N(E)$ in the figure and energy conservation):

$$E_B = h\nu - E - \phi \tag{40}$$

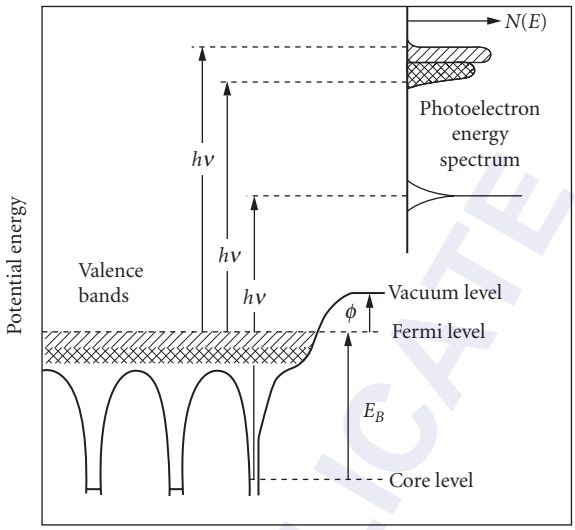

FIGURE 23 A schematic energy-level diagram showing photoemission from the valence bands and a core level in a solid.[54]

Here φ is the work function (usually about 2 to 5 eV for most clean solids) which is known or easily measured. X-ray photoemission spectroscopy (XPS) is usually used to study core states and ultraviolet photoemission spectroscopy (UPS) to study valence band states. Photoemission techniques are also used for the study of surface states. Synchrotron radiation provides an intense source of light over a large spectral region. By measuring the angular distribution of the emitted UPS electrons, a direct determination of the E versus k relation for the valence band of GaAs can be made.

There are several regions of importance that must be considered in describing the optical properties of this high-energy region. Figure 24 shows the regions for InSb that are representative of the results for other semiconductors.[55] InSb is a narrow gap material with a direct bandgap of 0.17 eV at room temperature, so what is shown is at much greater energies than E_g. Sharp structure associated with transitions from the valence band to higher levels in the conduction band characterize the first region that extends to about 8 to 10 eV. This behavior is also characteristic for group-IV and other III-V compound semiconductors, see Fig. 25 which displays the imaginary part of the dielectric function for Si and GaAs. To show how this type of optical spectra can be interpreted in terms of the materials energy band structure, consider Fig. 26 which shows the spectral features of ε_2 for Ge in *a* and the calculated energy bands for Ge in *b*.[57,58] Electronic transitions can take place between filled and empty bands subject to conservation of energy and wave vector. The initial and final electron wave vectors are essentially equal, and only vertical transitions between points separated in energy by $\hbar\omega = E_c(k) - E_v(k)$ are allowed.

The intensity of the absorption is proportional to the number of initial and final states and usually peaks when the conduction and valence bands are parallel in k-space. This condition is expressed by

$$\nabla_k [E_c(k) - E_v(k)] = 0 \tag{41}$$

Places in k-space where this is true are called critical points or Van Hove singularities. The experimental peaks can be sharp as shown in Fig. 26*a* because interband transitions in very pure crystals are not appreciably broadened by damping, and thus the lineshapes are determined primarily by the density of states, especially at low temperature. At room temperature, the broadening is dominated by electron-phonon scattering. Much information is available from the data if a good theory is used.

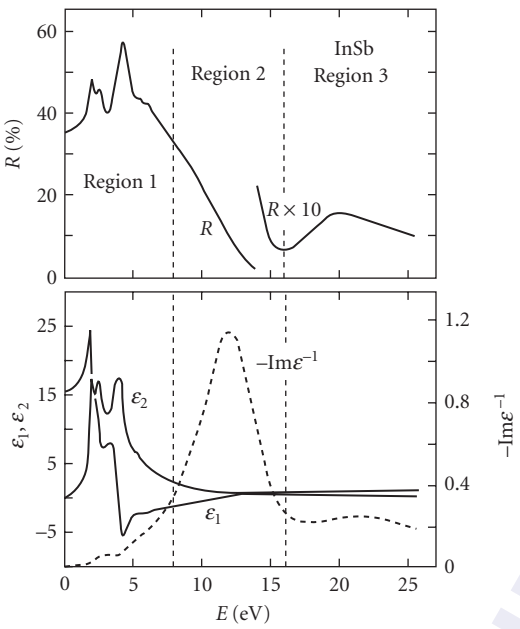

FIGURE 24 The spectral dependence of the reflectance R, the real and imaginary parts of the dielectric constant ε_1 and ε_2, and the energy-loss function $-Im(\varepsilon^{-1})$ for InSb.[55,56]

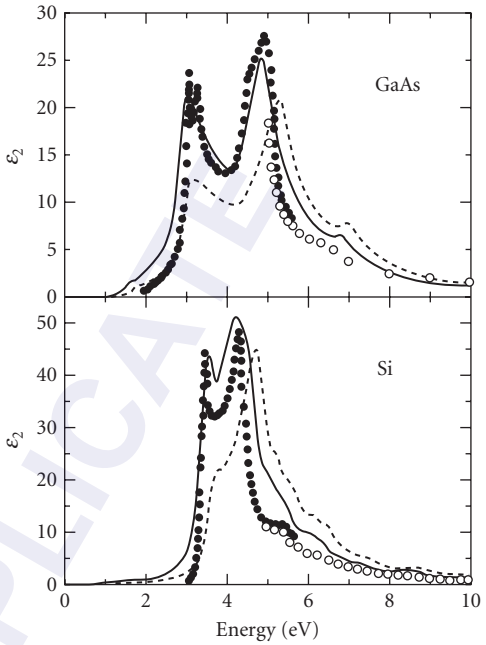

FIGURE 25 Imaginary part of the dielectric function for GaAs and Si. The symbols show experimental results. The dashed line is the result of a calculation based on the local-density approximation with GW corrections. The calculation shown by the solid line also takes into account excitonic effects using the Bethe-Salpeter equations.[59]

Figure 26*b* shows pseudopotential energy-band calculations that show the special points and special lines in the Brillouin zone that give rise to the data shown in *a.* Band structure calculations using the local density approximation (see Fig. 26) are unable to predict the correct location of the peaks in the dielectric function. In general, the calculated gap is lower than the experimentally observed one (see Fig. 26). Considerable improvement to the accuracy of the excited states is possible when employing GW corrections to the band structure. While these corrections give an accurate band structure (Fig. 25, dashed line), they still ignore the excitonic interactions between the electron and hole participating in the interband transition and thus underestimate the magnitude of the absorption. Quite recently, a number of groups have been successful in considering excitonic Coulomb effects in their calculations using the Bethe-Salpeter equations. Modern calculations of the band structure and the dielectric function are almost as accurate as the best experimental methods, see Fig. 25.[59]

The second region in Fig. 24 extends to about 16 eV and shows a rapid decrease of reflectance due to the excitation of collective plasma oscillations of the valence electrons. The behavior in this second "metallic" region is typical of the behavior of certain metals in the ultraviolet. One can think of the valence electrons as being essentially unbound and able to perform collective oscillations. Sharp maxima in the function $-Im\ \varepsilon^{-1}$, which describes the energy loss of fast electrons traversing the material, have been frequently associated with the existence of plasma oscillations.

In the third region, the onset of additional optical absorption is indicated by the rise in reflectance. This structure is identified with transitions between filled *d* bands below the valence band and empty conduction band states. As shown in Fig. 27, the structure in region three is present in other III-V compounds, but is absent in Si which does not have a *d*-band transition in this region.[60]

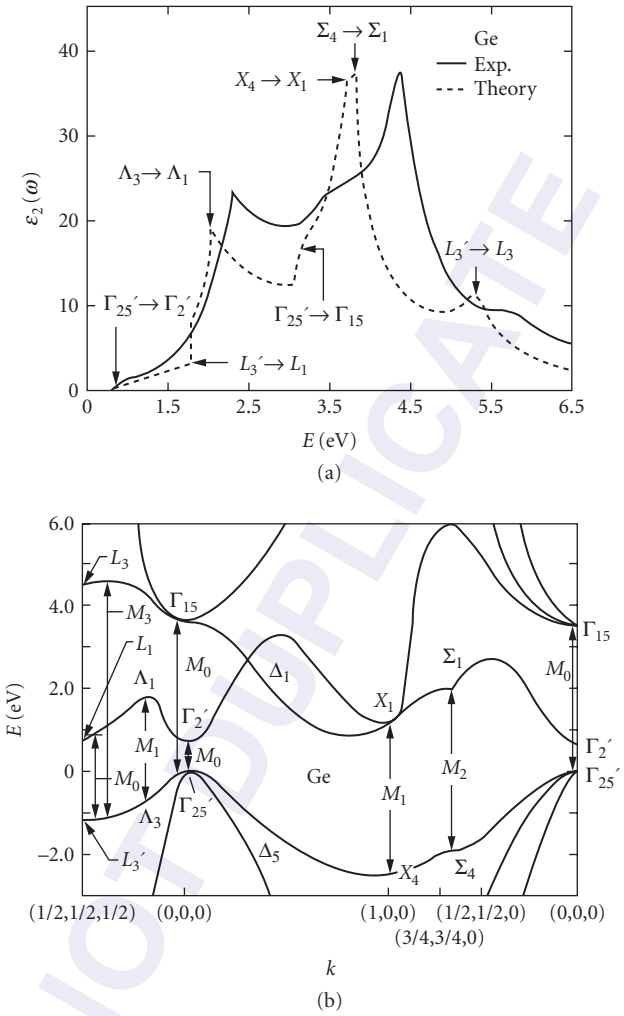

FIGURE 26 (*a*) Spectral features of ε_2 for Ge; (*b*) the calculated pseudopotential energy bands for Ge along some of the principal axes.[57,58]

Other structure at higher photon energies is observed for Si as shown in Fig. 28 which shows the imaginary part of the dielectric constant of Si from 1 to 1000 eV.[56,61] The large peaks on the left are due to excitations of valence electrons, whereas the peaks on the right are caused by excitation of core electrons from L shell states. K shell electrons are excited at energies beyond the right edge of the graph (beyond 1000 eV).

Elemental and compound semiconductors can often be mixed to form mixed-crystal alloys, such as $Al_{1-x}Ga_xAs$ or $Si_{1-x}Ge_x$. The former alloy is used for optoelectronic applications (e.g., CD players), while the latter is found in high-end microprocessors or cellular telephones. The vibrational spectra of such alloys show multimode behavior (i.e., Si-Si, Ge-Ge, and Si-Ge vibrations in $Si_{1-x}Ge_x$ alloys) with phonon mode energies depending on the masses of the atoms. In the visible and UV spectral range, on the other hand, the peaks in the dielectric function given by the energy of the critical

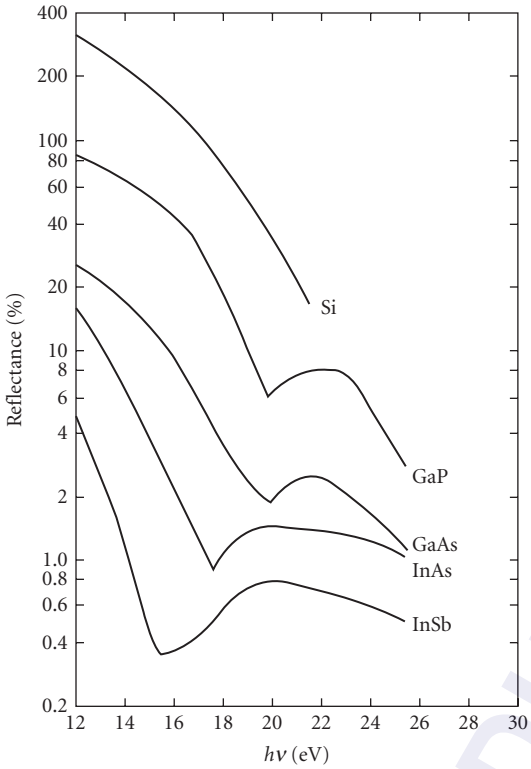

FIGURE 27 Reflectance of several semiconductors at intermediate energies. Starting from 12 eV the reflectance decreases, representing the exhaustion of bonding → antibonding oscillator strength at energies greater than $2E_g$. The rise in reflectivity in the 15 to 20 eV range in the Ga and In compounds is caused by excitation of electrons from Ga cores (3d states) or In cores (4d states). The ordinate should be multiplied by 2 for InSb, 1 for InAs, 1/2 for GaAs, 1/4 for GaP, and 1/10 for Si.[60]

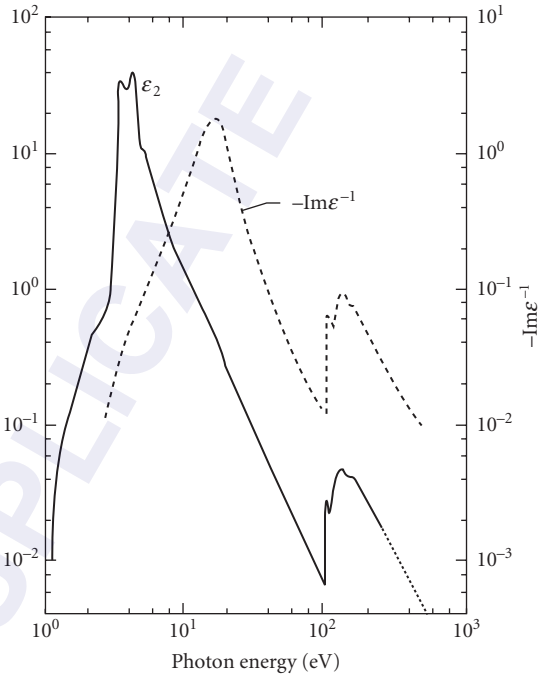

FIGURE 28 Imaginary part of the dielectric function for Si from 1 to 1000 eV.[2] (From reflectivity measurements of H.R. Philipp and H. Ehrenreich, Ref. 60, out to 20 eV and from transmission measurements of C. Gahwiller and F. C. Brown, Ref. 61, from 40 eV to 200 eV.)

points shift roughly linear with composition as shown in Fig. 29. The dielectric function of such alloys is known with very high accuracy (often also as a function of strain) and used in the production of modern microelectronic circuits to measure thickness and composition of semiconductor alloy films.[62,63]

Free Carriers

Plasmons Semiconductors, in addition to a crystal lattice that may be ionic, may contain free charges as well.

The free-carrier contribution to the dielectric function is given by Maxwell's equation in CGS (Centimeter, Gram, Second) system of units

$$\varepsilon_{\mathrm{fc}}(\omega) = -i\frac{4\pi\sigma}{\omega} \tag{42}$$

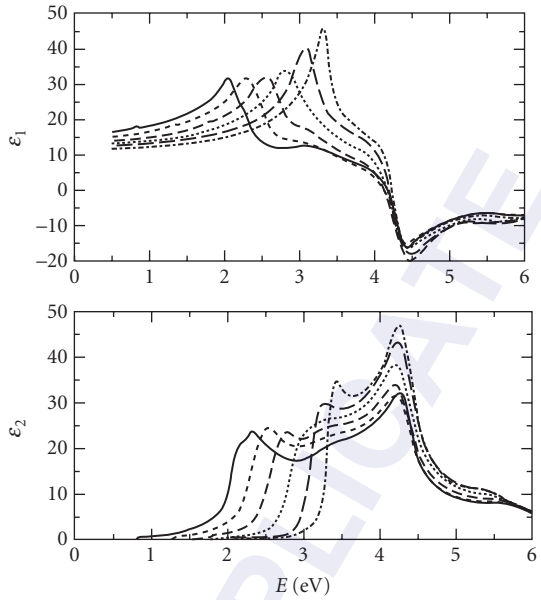

FIGURE 29 Real and imaginary parts of the dielectric function of $Si_{1-x}Ge_x$ alloys (bulk polycrystals) for x from 0 to 1 in steps of 0.2. Ge and Si are shown by the solid and long-dashed lines, respectively. The E_1 peak shifts from near 2 eV in Ge to about 3.4 eV in Si. Thin-film effects and strain modify these values in epitaxial films.[62]

The task of establishing the functional form of $\varepsilon(\omega)$ hence reduces to one of determining the conductivity at the appropriate optical frequencies.

The response of a charge to an externally applied field may be described by classical methods, assuming a damping or resistive force to the charge that is proportional to the velocity of the charge. This simplification is known as the Drude approximation,[64] and it leads to the following relationship:

$$\sigma = \frac{Ne^2\tau}{m^*}\frac{1}{(1-i\omega\tau)} \tag{43}$$

and is related to the dc conductivity by the relationship:

$$\sigma(0) = Ne^2\tau/m^* \tag{44}$$

where N is the free-carrier density, $1/\tau$ is the constant of proportionality for the damping force, and τ is a measure of the electron-electron collision time. Now,

$$\varepsilon_{fc}(\omega) = -\frac{i\omega_p^2\varepsilon_\infty}{\omega\left(\omega + \dfrac{i}{\tau}\right)} \tag{45}$$

ω_p is the plasma frequency that describes oscillations of the plasma, that is, the delocalized charge cloud

$$\omega_p^2 = \frac{4\pi N e^2}{m^* \varepsilon_\infty} \tag{46}$$

against the fixed crystal lattice.

In an ideal plasma with no damping, the $\varepsilon(\omega)$ reduces to

$$\varepsilon(\omega) = 1 - \frac{\omega_p^2}{\omega^2} \tag{47}$$

$\varepsilon(\omega)$ is negative for $\omega < \omega_p$, which leads to total reflection and, hence, the term plasma reflectivity.

The phenomenon of optical reflection from a plasma reflection and the relationship to the free-carrier density are illustrated in Fig. 30 using the far-infrared reflection spectrum from a series of PbTe samples with hole densities extending from 3.5×10^{18} cm^{-3} to 4.8×10^{19} cm^{-3}.[65] The plasma frequency increases with increasing carrier density as described by Eq. (46).

Coupled plasmon-phonon behavior Most semiconductor samples contain free carriers and phonons, and the frequencies of both are comparable. Hence, a complete description of the far-infrared optical properties has to take both into account. This can be achieved readily using Eq. (45) to describe the free carriers. The combined $\varepsilon(\omega)$ may then be expressed as

$$\varepsilon(\omega) = \varepsilon_\infty + \frac{S\omega_{\mathrm{TO}}^2}{\omega_{\mathrm{TO}}^2 - \omega^2 - i\omega\gamma} - \frac{i\omega_p^2 \varepsilon_\infty}{\omega(\omega + i/\tau)} \tag{48}$$

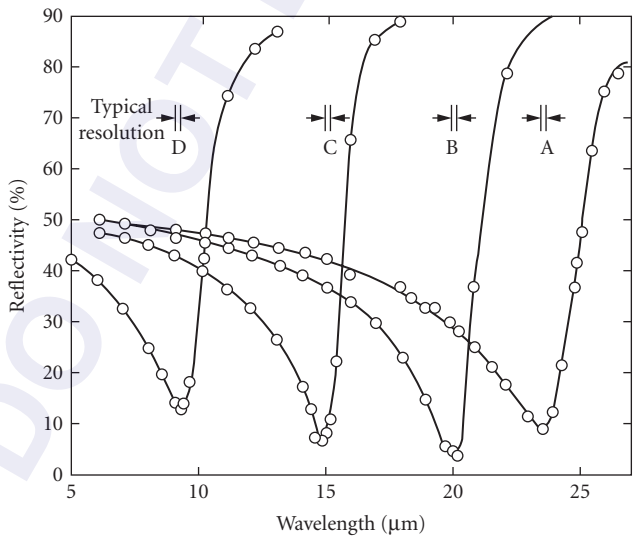

FIGURE 30 Reflectivity at 81 K and normal incidence of variously doped samples of *p*-type PbTe, showing the plasma resonance. Hole concentrations: A, 3.5×10^{18} cm^{-3}; B, 5.7×10^{18} cm^{-3}; C, 1.5×10^{19}; D, 4.8×10^{19} cm^{-3}.[65]

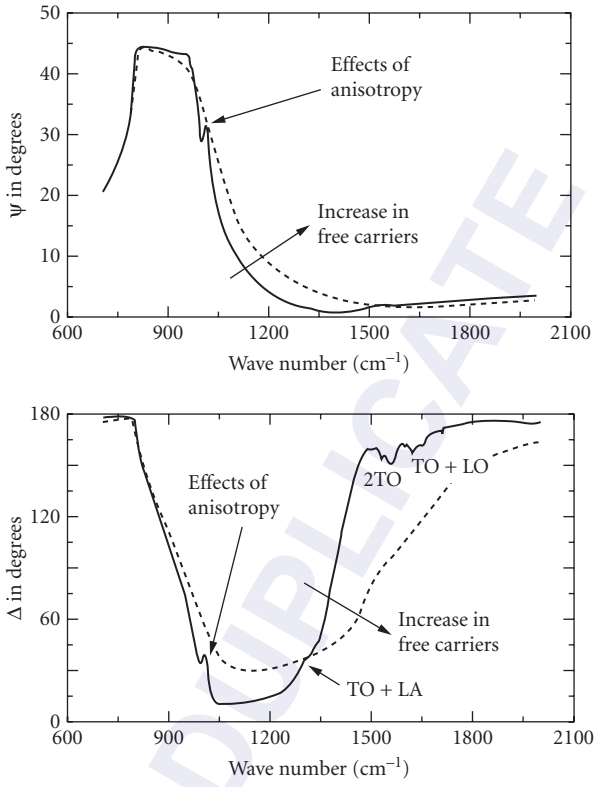

FIGURE 31 Mid-infrared ellipsometry spectra for 4H SiC. The reststrahlen band in the phonon absorption region (near 900 cm^{-1}) is affected by free carriers and the crystal anisotropy. Two-phonon absorption is also visible.[66]

A good example of the accurate description of the far-infrared behavior of a semiconductor is presented in Fig. 31.[66] The ellipsometric angles Ψ (related to reflectivity) and Δ (related to the polarization phase shift) of 4H SiC in the vicinity of the reststrahlen band (phonon absorption near 900 cm^{-1}) are affected by the free-carrier effects and the anisotropy of the crystal. All the major features in the complicated spectrum can be well described using the simple oscillatory models described.

The coexistence of phonons and plasmons leads to a coupling between the two participants.[67] Of particular interest are the coupled plasmon-LO phonon modes denoted by L_+ and L_- that are exhibited as minimas in the reflection spectra. As explained earlier, the LO phonon frequencies occur at the zeros of the dielectric function $\varepsilon(\omega)$. In the presence of plasmons, the zeros are shifted to the coupled mode frequencies L_+ and L_-. These frequencies can be determined directly for the case of no damping for both the phonon and the plasmon as shown below:

$$L_{\pm} = \frac{1}{2}\{(\omega_{LO}^2 + \omega_p^2) \pm [(\omega_{LO}^2 - \omega_p^2)^2 + 4\omega_{LO}^2\omega_p^2(1-\varepsilon_\infty/\varepsilon(0)]^{1/2}\} \tag{49}$$

Note that the presence of the plasmon introduces an additional low frequency zero at L_-. The relationship of the L_+ and L_- frequencies with the carrier density is presented in Fig. 32.[69] The existence of the coupled modes were predicted by Varga[67] and later observed using Raman scattering[68,69] and far-infrared reflectivity.[70]

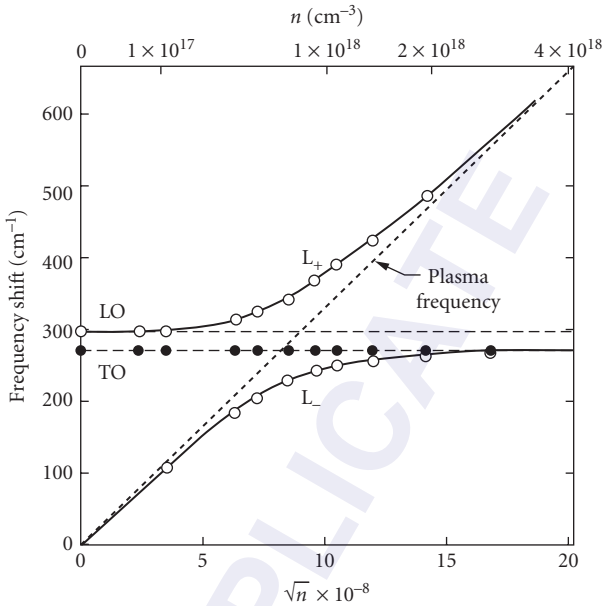

FIGURE 32 The solid curves labeled L_+ and L_- give the calculated frequencies of the coupled longitudinal plasmon-phonon modes, and the measured frequencies are denoted by the open circles.[69]

Impurity and Defect Absorption The extended electronic states, excitons, lattice vibrations, and free carriers discussed thus far are all intrinsic to the pure and perfect crystal. In practice, real-life specimens contain imperfections and impurities. The characteristic optical properties associated with impurities and defects are the subject of discussion in this section. Two representative examples of the most widely observed effects, namely, shallow levels and deep levels in the forbidden gap, are considered in the following discussion.

Some of the effects due to impurities are considered in other parts of this chapter: impurity-related vibrational effects were considered under "Lattice"; excitons bound to impurity states were discussed under "Excitons"; and impurity-related effects in magneto-optical behavior are dealt with under "Magnetic-Optical Properties." In addition to these effects, optical absorption due to electronic transitions between impurity-related electronic levels may also be observed in semiconductors.

The presence of impurities in a semiconductor matrix leads to both a perturbation of the intrinsic electronic quantum states and the introduction of new states, particularly in the forbidden energy gap. The major classes of electronic levels are the shallow levels that form the acceptor and donor states and lie close to the valence and conduction band extremes, respectively, and those that occur deep in the forbidden gap. The former are well known and are critical in controlling the electrical behavior of the crystal, and the latter are less well known but are, nevertheless, important in determining the sub-bandgap optical behavior.

Direct transitions from the shallow levels to the closest band extrema can be observed in the far-infrared transmission spectra of many semiconductors. An elegant example of this property is illustrated with the spectrum obtained from a high-purity Si wafer[71] as displayed in Fig. 33. Sharp, well-resolved absorption features from electronic transitions due to B, P, As, and Al are present, as are additional features perhaps from unidentified impurities. Note that both acceptors and donor bands are observable due to the highly nonequilibrium state in which the specimen was maintained through the use of intense photoexcitation.

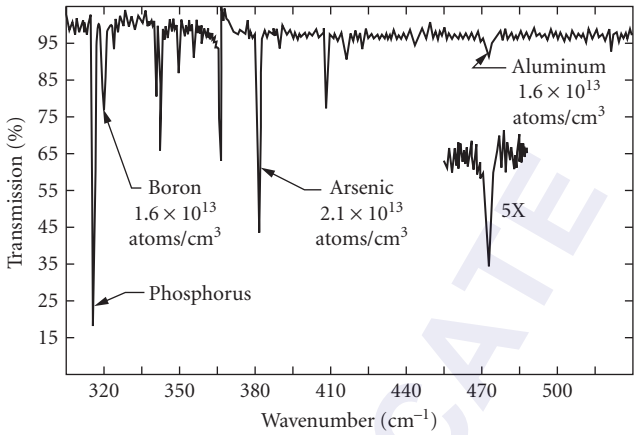

FIGURE 33 Total impurity spectrum of a 265-Ω-cm *n*-type Si sample obtained by the simultaneous illumination method. The input power to the illumination source was about 50 W.[71]

Electronic transitions from impurity- and defect-related levels deep in the forbidden gap can significantly alter the sub-bandgap behavior. One of the best known examples of this is the native defect level known as EL2 in GaAs. The level occurs 0.75 eV below the conduction band extremum, and, when present, it can completely dominate the subband gap absorption. The absorption spectrum recorded from a GaAs sample containing EL2 is presented in Fig. 34.[72] The onset of the absorption at 0.75 eV is due to transitions to the conduction band extremum at the direct gap, and the features at 1.2 and 1.4 eV are due to transitions to higher-lying extrema.[72] The figure also shows two spectra that exhibit the well-known photoquenching effect associated with EL2. When the specimen is subjected to intense white light radiation, the EL2 absorption is quenched, leaving only the band-to-band transitions with an onset at E_g which occurs at ≈1.5 eV at 10 K.

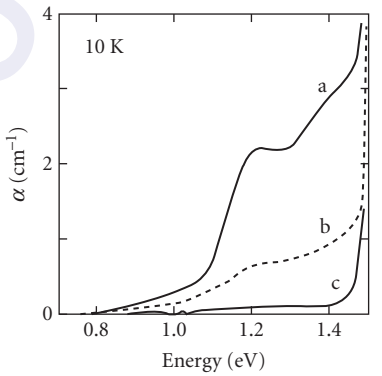

FIGURE 34 EL2 optical absorption spectra recorded at 10 K in the same undoped semi-insulating GaAs material. Curve a: after cooling in the dark; curves b and c: after white light illumination for 1 min and 10 min, respectively.[72]

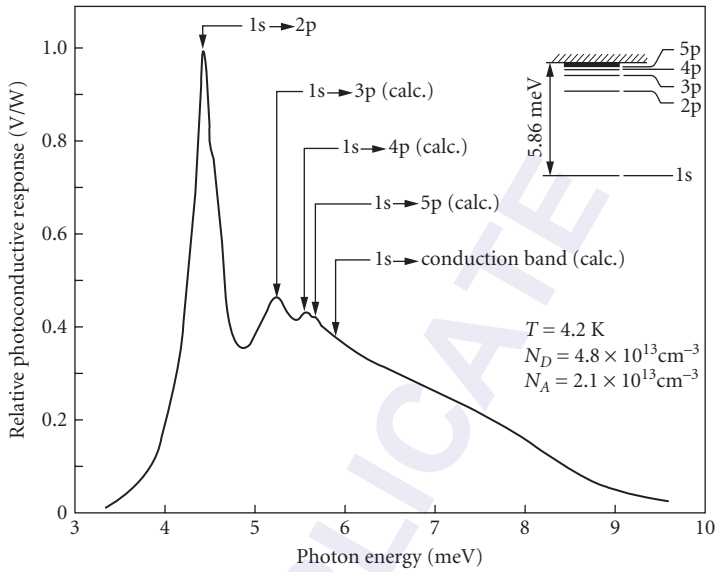

FIGURE 35 Far-infrared photoconductivity spectrum of a high-purity GaAs sample showing the measured transition energies and those calculated from the hydrogenic model using the (1s → 2p) transition energy. The hydrogenic energy level diagram is shown in the inset.[73]

Optical measurements of shallow impurities in semiconductors have been carried out by absorption (transmission) and photoconductivity techniques. The photoconductivity method is a particularly powerful tool for studying the properties of shallow impurity states, especially in samples which are too pure or too thin for precise absorption measurements. In most cases, this type of photoconductivity can only be observed in a specific temperature range, usually at liquid helium temperatures. Figure 35 shows the photoconductivity response of a high-purity GaAs sample with specific transition energies that correspond to hydrogenic-like transitions.[73] If the excited states of the impurity were really bound states, electrons in these states could not contribute to the conductivity of the sample, and the excited state absorption would not result in peaks in the photoconductivity spectrum. However, there have been several suggestions as to how the electrons that are excited from the ground state to higher bound excited states can contribute to the sample's conductivity. First, if the excited state is broadened significantly by interactions with neighboring ionized donor and acceptor states, it is essentially unbound or merged with the conduction band. Other mechanisms for impurity excited-state photoconductivity all involve the subsequent transfer of the electron into the conduction band after its excitation to the excited state by the absorption of a photon. Mechanisms that have been considered for this transfer include (1) impact ionization of the electrons in the excited state by energetic free electrons, (2) thermal ionization by the absorption of one or more phonons, (3) photoionization by the absorption of a second photon, and (4) field-induced tunneling from the excited state into the conduction band. All of these mechanisms are difficult to describe theoretically.

Magneto-Optical Properties

Background Phenomena occurring as a result of the interaction of electromagnetic radiation with solids situated in a magnetic field are called magneto-optical (MO) phenomena. Studies of MO phenomena began in 1845 when Michael Faraday observed that the plane of vibration of polarized light rotated as it propagated through a block of glass in a strong magnetic field. By the 1920s, most

MO effects were fairly well understood in terms of the classical dynamics of an electron in a magnetic field. However, when semiconductors were first investigated in the early 1950s, a quantum mechanical interpretation of the MO data in terms of the energy-band structure was found to be necessary. MO spectroscopy was developed in the 1950s and 1960s as a powerful tool for characterizing the fundamental electronic properties of semiconductors. Cyclotron resonance experiments using microwaves, interband studies using broadband visible and infrared sources, and finally lasers were used to characterize the symmetry of band structures, as well as properties such as energy gaps, effective masses, and other band parameters. The two major limitations of the classical theory are that no effects depending on the density of states are predicted and no effects of electron spin are included.

Table 6 presents an overview of the typical types of magneto-optical phenomena observed in semiconductors and the information that can be determined from the experimental measurements. Four classes of MO phenomena can be distinguished: those arising from (1) interband effects, (2) excitonic effects, (3) intraband or free-carrier effects, and (4) impurity magnetoabsorption effects. Further clarification can then be made by determining whether the effect is absorptive or dispersive, resonant or nonresonant, and upon the relative orientation of the magnetic field to the direction of propagation of the electromagnetic radiation and its polarization components. Resonant experiments usually provide more detailed information about the band structure of a semiconductor and often are easier to interpret. There is thus a wide variety of effects as shown which can give different types of information about the crystal's energy-band structure, excitonic properties, and impurity levels. Before summarizing and discussing each of these magneto-optical effects, it is necessary to briefly describe the effects of a magnetic field on the energy-band structure of a semiconductor.

Effect of a Magnetic Field on the Energy Bands Magneto-optical experiments must be analyzed with specific energy-band models in order to extract the related band parameters and to emphasize the underlying physical concepts with a minimum of mathematical complexity. Most often, one deals with only the highest valence bands and the lowest conduction bands near the forbidden energy-gap region. If simple parabolic bands are assumed, a fairly complete analysis of the MO experiments is usually possible, including both the resonant transition frequencies and their line shapes. On the other hand, if more complicated energy bands (e.g., degenerate, nonparabolic) are needed to describe the solid, the detailed analysis of a particular experiment can be complicated.

The effect of a magnetic field on a free electron of mass m^* was determined in 1930 by Landau, who solved the Schroedinger equation. The free electrons experience a transverse Lorentz force which causes them to travel in orbits perpendicular to the magnetic field. The resulting energy eigenvalues corresponding to the transverse components of the wave vector are quantized in terms of harmonic oscillator states of frequency ω_c, while a plane-wave description characterizes the motion along the magnetic field. The allowed energy levels, referred to as Landau levels, are given by

$$E_n^{\pm} = \left(n + \frac{1}{2}\right)\hbar\omega_c + \frac{\hbar^2 k_z^2}{2m^*} \pm \frac{1}{2} g^* \mu_B B \tag{50}$$

where n is the Landau level number (0, 1, 2, . . .), ω_c (the cyclotron frequency) is equal to eB/m_c^*, and m_c^* is the cyclotron effective mass. The middle term represents the energy of an electron moving along the direction of the **B** field in the z direction; it is not quantized. The first term represents the quantized energy of motion in a plane perpendicular to the field. The last term represents the effect of the electron's spin; g^* is the effective spectroscopic g-factor or spin-splitting factor and

$$\mu_B = e\hbar/2m_o = 5.77 \times 10^{-2}\, me\,\mathrm{V/T} \tag{51}$$

is the Bohr magneton. The g-factor in a semiconductor has values quite different from the usual value of two found for atomic systems (e.g., for narrow-energy gaps and a strong spin-orbit interaction, g^* can be large and negative).

TABLE 6 Magneto-Optical Phenomena and Typical Information Obtainable

Magneto-Optical Effect	Some Information or Properties Obtainable
Interband effects	
In transmission	
Band-to-band magnetoabsorption	Energy gaps, effective masses, g-factors, higher band parameters
Faraday rotation (resonant and nonresonant)	Energy gaps, effective masses
Faraday ellipticity (nonresonant)	Relaxation times
Voigt effect (resonant and nonresonant)	Effective masses
Cross-field magnetoabsorption	
In reflection	
Magnetoreflection	Studies of very deep levels or where absorption is high, similar information as in transmission magnetoabsorption
Kerr rotation	
Kerr ellipticity	
Magneto-excitonic effects	
In transmission, reflection, and photoconductivity	Diamagnetic and Zeeman shifts and splittings; energy gap; effective reduced-mass tensor; effective Rydberg; anisotropy parameter; dielectric tensor components; effective g-factors; effective masses; quality of materials, structures, alloys and interfaces
Intraband or free-carrier effects	
In transmission	
Cyclotron resonance (resonant)	Effective masses, relaxation times, nonparabolicity
Combined resonance	Same information as cyclotron resonance plus *g*-factors
Spin resonance	*g*-factors
Phonon-assisted cyclotron resonance harmonics	Same information as cyclotron resonance plusphonon information
Faraday rotation (resonant and nonresonant)	Carrier concentration, effective masses; use for impure materials, flexible, can be used at high temperature
Faraday ellipticity (nonresonant)	
Voigt effect (nonresonant)	
Interference fringe shift (nonresonant)	
Oscillatory variation of the Shubnikov-de Haas type	Carrier concentration
In reflection	
Magnetoplasma reflection	Effective masses, carrier concentration
Magnetoplasma rotation (Kerr effect)	
Magnetoplasma ellipticity	
Impurity magneto-absorption	
Zeeman and diamagnetic effect-type behavior of impurities	Hydrogenic impurity information, binding energy, effective masses, effective Rydberg, central cell corrections, static dielectric constant; both impurity and Landau level information; impurity information as above plus Landau-level information related to effective masses and *g*-factors
Photoionization behavior (transitions from ground state of impurity to Landau levels)	

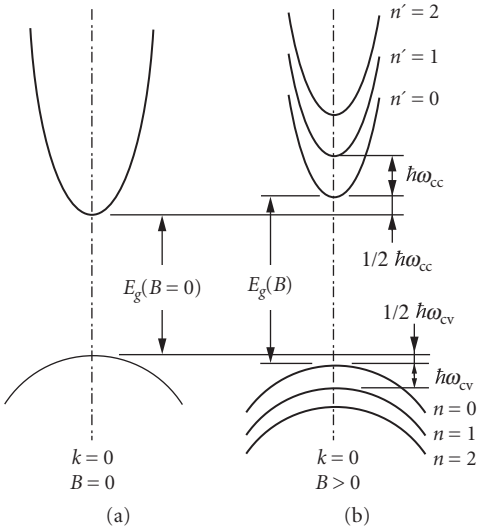

FIGURE 36 Landau levels for simple bands.

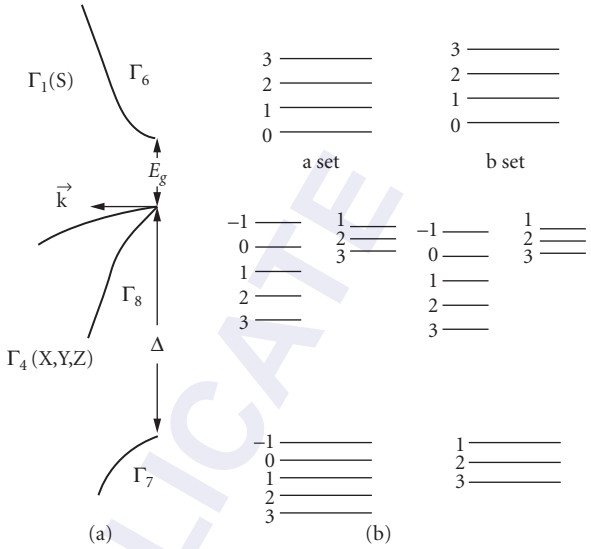

FIGURE 37 (*a*) Zincblende semiconductor energy bands (**H** = 0) and (*b*) in an applied magnetic field **H**.[74]

Figure 36 shows schematically the effect of a magnetic field on a simple parabolic direct gap extrema at $k = 0$. The quasi-continuous parabolic behavior of the nondegenerate conduction and valence bands at $\mathbf{B} = 0$ (shown in *a*) is modified by the application of a magnetic field into Landau levels as shown in *b*. Each Landau level is designated by an integer $n = 0, 1, 2, 3, \ldots$. Finally, in Fig. 37, the Landau effects are shown schematically for zincblende energy bands when both spin and valence band degeneracy are taken into account for both $\mathbf{B} = 0$ (*a*) and $\mathbf{B} \neq 0$ (*b*).[74] With spin included, the valence band splits into the Γ_8 and Γ_7 bands with spin-orbit splitting energy Δ. The quantization of the bands into Landau levels is illustrated in the right-hand side of the figure. The Pidgeon and Brown[75] model has been successfully used to describe the magnetic field situation in many semiconductors, since it includes both the quantum effects resulting from the partial degeneracy of the p-like bands and the nonparabolic nature of the energy bands. The *a*-set levels are spin-up states, and the *b*-set, the spin-down states. These large changes in the **E** versus *k* relations of the bands when a magnetic field is applied also means large changes in the density of states which become periodic with a series of peaks at energies corresponding to the bottom of each Landau level. This oscillatory variation in the density of states is important for understanding the various oscillatory phenomena in a magnetic field and is a key advantage of using magnetic fields to study semiconductors.

Interband Magneto-Optical Effects Interband transitions in a magnetic field connect Landau-level states in the valence band to corresponding states in the conduction band. Thus, they yield direct information concerning energy gaps, effective masses, effective g-factors, and higher band parameters. The strongest allowed transitions are those that are proportional to the interband matrix element $p = -(i\hbar/m_o)\langle s|p_j|x_j\rangle$, where $j = x, y, z$.

This matrix element directly connects the p-like valence band (x, y, z) which is triply degenerate with the s-like conduction band through the momentum operator p_j. The transition energies can be calculated directly from a knowledge of the selection rules and use of an energy-band model. The selection rules are given by[76]

$$\sigma_L: a(n) \rightarrow a(n-1), b(n) \rightarrow b(n-1)$$
$$\sigma_R: a(n) \rightarrow a(n+1), b(n) \rightarrow b(n+1)$$
$$\pi: a(n) \rightarrow b(n+1), b(n) \rightarrow a(n-1)$$

where σ_L, σ_R, and π are left circular, right circular, and linear ($\mathbf{e} \parallel \mathbf{B}$) polarizations. As discussed earlier, a and b denote the spin-up and spin-down states, and n the Landau-level number. Often, sharp optical transitions between the Landau levels are observed, providing highly accurate information about the fundamental band parameters such as the energy gap E_g, effective masses of the electrons and holes, higher band parameters, etc.

InSb is a material in which interband effects have been studied very extensively; thus, it is a good representative example. Even though it is a narrow-gap semiconductor and thus has a small exciton binding energy, Weiler[77] has shown that excitonic corrections must be made to properly interpret the magnetic-field-dependent data. This shall be discussed in more detail in the next section. The band models discussed earlier predict that there is an increase in the energy of the absorption edge with magnetic field because of the zero point energy $1/2\hbar\omega_c$ of the lowest conduction band. At larger photon energies, transmission minima (absorption maxima) which are dependent upon magnetic field are observed. By plotting the photon energy positions of the transmission minima against magnetic field, converging, almost linear plots are obtained as shown in Fig. 38.[75] Extrapolation of the lines to zero field gives an accurate value for the energy gap. Use of a band model and specific transition assignments further allow the determination of other important band parameters, such as effective masses and g-factors.

Magnetoreflection Besides the changes in absorption brought about by the magnetic field, there are changes in the refractive index. Since the reflectivity depends upon both the real and imaginary

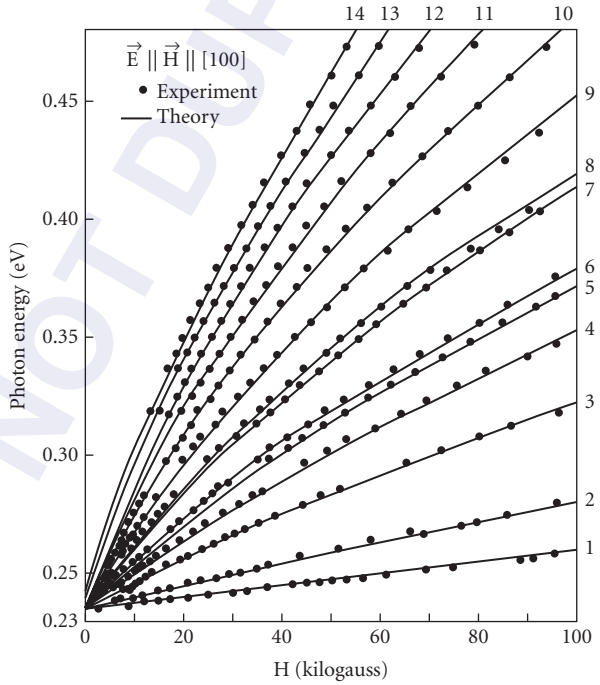

FIGURE 38 Energy values of transmission minima versus magnetic field for electron transitions between Landau levels of valence and conduction bands in InSb. Plot of the photon energy of the principal transmission minima as a function of magnetic field for $\mathbf{E} \parallel \mathbf{H} \parallel [100]$. The solid lines represent the best theoretical fit to the experimental data. The numeral next to each line identifies the quantum assignment.[75]

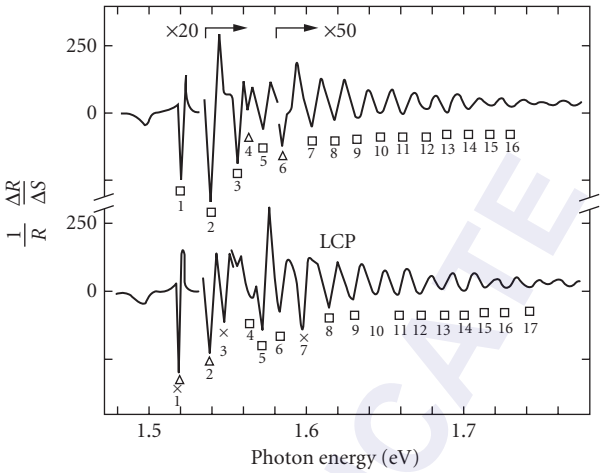

FIGURE 39 Stress-modulated magnetoreflectance spectra for the fundamental edge in epitaxially grown high-purity ⟨211⟩ GaAs at $T \approx 30$ K, with $\Delta\mathbf{S} = 5 \times 10^{-5}$, observed in the Faraday configuration with magnetic field $\mathbf{H}\|\ [11\bar{2}]$ and $H = 88.6$ kG. The number directly below each prominent transition refers to the identification of the transitions, Δ, LHa; ×, LHb; □, HH(AV).[78]

parts of the index, clearly it is affected by the field. Interband transitions are often observed in reflection because of the high absorption coefficients. In addition, modulation spectroscopy techniques, in which a parameter such as stress, electric field, wavelength, magnetic field, etc. is periodically varied and the signal synchronously detected, provide several orders of magnitude enhancement in the sensitivity for observing resonant transitions. This is especially important for the observation of higher energy transitions lying far away from the energy of the fundamental gap. Figure 39[78] shows the stress-modulated magnetoreflectance spectra for the fundamental edge region, the interpretation of which must involve the effect of excitons on the transitions. Quantitative information about the split-off valence to conduction band edge in GaAs is also obtainable from magnetoreflection.[79]

Faraday rotation A plane-polarized wave can be decomposed into two circularly polarized waves. The rotation of the plane of polarization of light as it propagates through the semiconductor in a direction parallel to an applied magnetic field is called the Faraday effect, or Faraday rotation. The amount of rotation is usually given by the empirical law $\ominus = V\mathbf{B}l$, where $\ominus$ is the angle of rotation, V is the Verdet coefficient, $\mathbf{B}$ is the magnetic field value, and l is the thickness. The Verdet coefficient is temperature, wavelength, and sometimes field dependent. The Faraday effect can then be understood in terms of space anisotropy effects introduced by the magnetic field upon the right and left circularly polarized components. The refractive indices and propagation constants are different for each sense of polarization, and a rotation of the plane of polarization of the linearly polarized wave is observed. The sense of rotation depends on the direction of the magnetic field. Consequently, if the beam is reflected back and forth through the sample, the Faraday rotation is progressively increased. When measurements are thus made, care must be taken to avoid errors caused by multiple reflections. Faraday rotation may also be considered as birefringence of circularly polarized light.

If absorption is present, then the absorption coefficient will also be different for each sense of circular polarization, and the emerging beam will be elliptically polarized. Faraday ellipticity specifies the ratio of the axes of the ellipse.

Faraday rotation can be observed in the Faraday configuration with the light beam propagating longitudinally along the $\mathbf{B}$-field direction. Light propagating transverse to the field direction is

designated as the Voigt configuration. Two cases must be distinguished—the incident beam may be polarized so that its **E** field is either parallel or perpendicular to **B**. The Voigt effect is birefringence induced by the magnetic field and arises from the difference between the parallel and perpendicular indices of refraction in the transverse configuration. It is usually observed by inclining the incident plane-polarized radiation with the electric vector at 45° to the direction of **B**. The components resolved parallel and perpendicular to **B** then have different phase velocities and recombine at the end of the sample to give emerging radiation which is elliptically polarized. Measurements of this ellipticity then determine the Voigt effect.

The interband Faraday effect is a large effect and is therefore useful for characterizing semiconductors. For frequencies smaller than the frequency corresponding to the energy gap, the interband Faraday effect arises from the dispersion associated with the interband magnetoabsorption. In this region, it has been used to determine energy gaps and their pressure and temperature dependence. Since the beam propagates through the crystal in a transparent region of the spectrum, it may be attractive to use in certain applications. For example, in GaAs,[80] at long wavelengths the Faraday effect has a positive rotation, while near the gap the Verdet coefficient becomes negative. For frequencies equal to or larger than the frequency corresponding to the energy gap, the Faraday rotation is dominated by the nearest magneto-optical transition. Oscillatory behavior, like that seen in the magnetoabsorption, is also often observed.

Diluted magnetic semiconductors (DMS) are a class of materials that have attracted considerable scientific attention. Any known semiconductor with a fraction of its constituent ions replaced by some species of magnetic ions (i.e., ions bearing a net magnetic moment) can be defined as a member of this group. The majority of DMS studied so far have involved Mn^{+2} ions embedded in various II–VI hosts. The optical properties of DMS are controlled by the interaction between the localized magnetic moments of Mn^{+2} and the conduction and/or valence band electrons (referred to as the sp-d interaction), which results in features unique to DMS. The best known (and quite spectacular) of these are the huge Faraday rotations of the visible and near-infrared light in wide-gap DMS. The origin of the large rotations is the sp-d exchange interaction which makes the band structure much more sensitive to the strength of external magnetic fields than in ordinary semiconductors. Figure 40 shows the Faraday effect in $Cd_{1-x}Mn_xSe(x = 0.25)$ at $T = 5$ K.[81] Each successive peak represents an additional Faraday rotation of 180°.

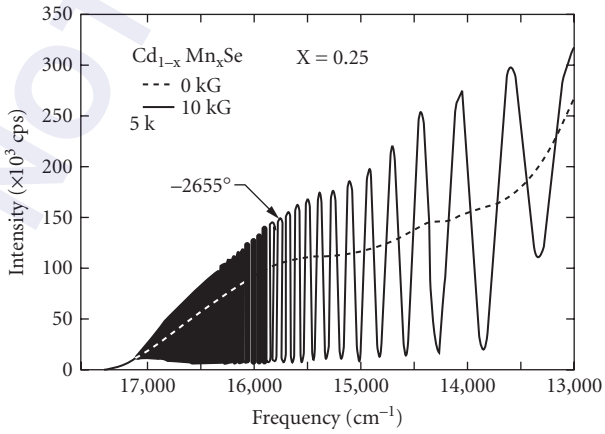

FIGURE 40 Faraday effect in $Cd_{1-x}Mn_xSe$ ($x = 0.25$), $T = 5$ K. The dashed line represents the transmission of light as a function of its frequency for a 3-mm-thick sample located between two polaroids with their axes at 45° and at zero magnetic field. The light propagates along the optic axis, $\hat{c}$. The oscillations occur when a 10-kG magnetic field is applied along $\hat{c}$.[81]

Excitonic magneto-optical effects As described earlier, a free exciton consists of an electron and hole bound together electrostatically. When the pair has an energy less than that of the energy gap, they orbit around each other. If the orbital radius is large compared with the lattice constant, they can be approximately treated as two point charges having effective masses and being bound together by a Coulomb potential that gives rise to a hydrogen-atom-like behavior. In the presence of a magnetic field, excitons give rise to Zeeman and diamagnetic effects analogous to those in atomic spectra. Fine structure can occur due to motions other than the simple orbiting of an electron and hole—the carriers can have intrinsic motion, motion around an atom, spin motion, and motion of the complete exciton through the lattice. Some of these motions may even be coupled together.

Bound excitons (or bound-exciton complexes) or impurity-exciton complexes are extrinsic properties of materials. Bound excitons are observed as sharp-line optical transitions in both photoluminescence and absorption. The bound exciton is formed by binding a free exciton to a chemical impurity atom (or ion), a complex, or a host lattice defect. The binding energy of the exciton to the impurity or defect is generally smaller than the free-exciton binding energy. The resulting complex is molecular-like (hydrogen-molecule-like), and bound excitons have many spectral properties analogous to those of simple diatomic molecules.

The application of a magnetic field to samples where excitonic features are observed in the absorption spectra results in line splittings, energy shifts, and changes in linewidths. These arise from diamagnetic and Zeeman effects just as in atomic or molecular spectroscopy. The treatment of the problem of an exciton in a magnetic field in zincblende-type structures is difficult due to the complexity of the degenerate valence band. Often a practical solution is adopted that corrects the interband model calculations for exciton binding energies that are different for each Landau level. Elliott and Loudon showed that the absorption spectrum has a peak corresponding to the lowest $N = 0$ hydrogen-like bound state of the free exciton, which occurs below the free interband transition by the exciton binding energy E_B.[82] Weiler suggests that for transitions to the conduction band Landau level n, the exciton binding energy E_B can be approximated by[74]

$$E_B(n) \approx 1.6R[\gamma_B/(2n+1)]^{1/3} \tag{52}$$

where R is the effective Rydberg,

$$R = R_o \mu/m_o \varepsilon(0) \tag{53}$$

$R_o = 13.6$ eV, $\varepsilon(0)$ is the static-dielectric constant, μ is the reduced effective mass for the transition, and γ_B is the reduced magnetic field

$$\gamma_B = m_o S/2\mu R \tag{54}$$

and

$$S = \hbar eB/m_o \tag{55}$$

Thus after calculating the interband transition energy for a particular conduction band Landau level n, one subtracts the above binding energy to correct for exciton effects.

Nondegenerate semiconductors, in particular, materials belonging to the wurtzite crystal structure, have been extensively studied both with and without a magnetic field. Exciton states in CdS have been studied by high-resolution two-photon spectroscopy in a magnetic field using a fixed near-infrared beam and a tunable visible dye laser.[83,84] Figure 41 shows the photoconductive response versus total photon energy near the A-exciton region.[83] The two-photon transitions involve P states, and both 2P and 3P states are clearly seen. As the field is increased, both Zeeman splittings and diamagnetic shifts occur. Figure 42 shows both experimental and theoretical transition energies versus **B** field.[83] Excellent agreement is obtained by using variational calculations that have been successfully used to describe impurity atoms in a magnetic field.

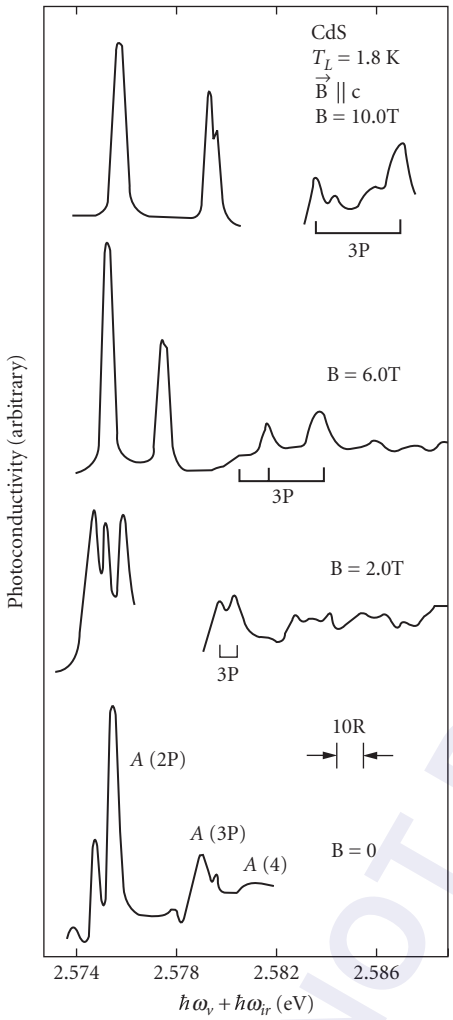

FIGURE 41 Photoconductivity vs. total photon energy $\hbar\omega_v + \hbar\omega_{ir}$ near the A-exciton region in CdS platelets for various magnetic fields. The magnetic field was parallel to the hexagonal *c* axis in a Voigt configuration with *E* perpendicular to *c* for the two photons at a lattice temperature of T_L = 1.8 K. The instrumental resolution *R* = 0.1 meV is narrower than the intrinsic linewidths.[83]

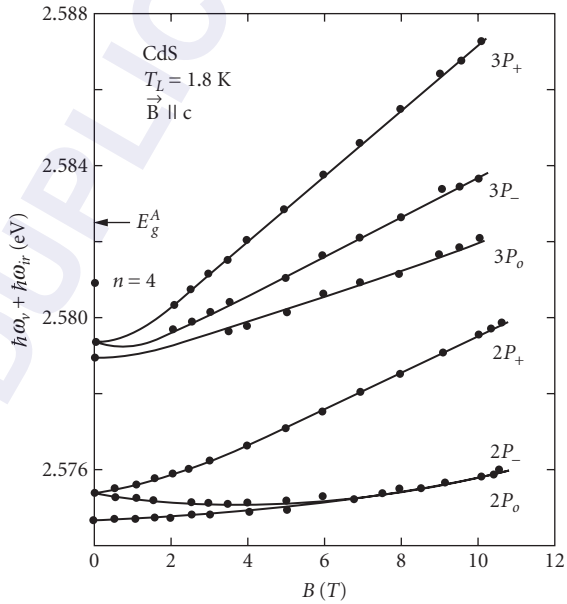

FIGURE 42 Peak positions, in total photon energy $\hbar\omega_v + \hbar\omega_{ir}$ for the 2*P* and 3*P* *A* excitons in CdS platelets as a function of applied **B** field. The solid points were determined experimentally, and the solid curves are theoretically obtained from variational calculations of the diamagnetic shifts along with use of the experimental *g*-factors.[83]

Intraband or Free-Carrier Effects

Cyclotron resonance Cyclotron resonance absorption of free carriers is the simplest and most fundamental magneto-optical effect and provides a direct determination of carrier effective masses. Classically, it is a simple phenomenon—charged particles move in circular orbits (in planes perpendicular to the direction of the magnetic field) whose radii increase as energy is absorbed from the applied electric fields at infrared or microwave frequencies. After a time τ, a collision takes place and

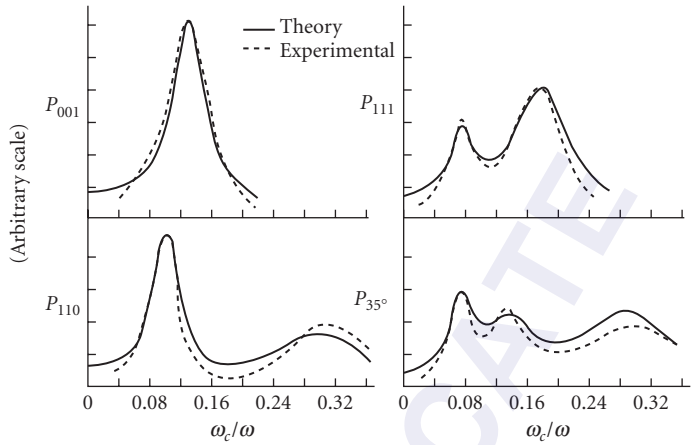

FIGURE 43 Microwave absorption in intrinsic *n*-type Ge at 4.2 K for four different directions of **B** in the (110) plane as a function of the magnetic field. $P_{35°}$ represents the absorption with **B** at 35° to the [001] axis.[88]

the absorption process begins again. From the resonance relation $\omega_c = e\mathbf{B}/m^*$, extensive and explicit information about the effective masses and the shape of energy surfaces near the band extrema can be obtained. Excellent reviews of cyclotron resonance have been previously published by McCombe and Wagner[85,86] and Kobori et al.[87]

A classical example of the explicit band structure information that can be obtained from cyclotron resonance experiments is given for Ge. Figure 43 shows the microwave absorption for *n*-type germanium at 4.2 K for four different **B**-field directions, each peak corresponding to a specific electron effective mass.[88] Figure 44 shows the orientation dependence of the effective masses obtained from the cyclotron resonance experiments which demonstrates that there is a set of crystallographically equivalent ellipsoids oriented along all ⟨111⟩ directions in the Brillouin zone.[89] Figure 45 shows the band structure of Ge that these measurements helped to establish[90]: *a* illustrates the conduction band minima along the ⟨111⟩ direction at the zone edge and *b,* the eight half-prolate ellipsoids of revolution or four full ellipsoids. The longitudinal and transverse masses are $m_l^* = 1.6m_o$ and $m_t^* = 0.082m_o$, respectively. Both holes and electrons could be studied by using light to excite extra carriers. This illustrates the use of cyclotron resonance methods to obtain band structure information. Since that time, numerous experiments have been carried out to measure effective mass values for carriers in various materials.

The beginning of modern magneto-optics in which "optical" as opposed to "microwave" techniques were used, began in 1956 with the use of infrared frequencies at high magnetic fields. Far-infrared lasers are extremely important for modern-day measurements of cyclotron resonance as seen in Fig. 46 for *n*-type InSb.[91] At low temperatures, only the lowest CR transition C_1 (0^+ to 1^+) is seen. Raising the temperature populates the higher-lying Landau levels, and other CR transitions are seen at different fields because of the nonparabolicity of the conduction band which gives rise to an energy-dependent effective mass. At 13 K, a second transition C_2 (0^- to 1^-) is seen and at 92 K, C_3 (1^+ to 2^+). The low field feature denoted by *I* is called impurity cyclotron resonance because, although it is a neutral donor excitation, its appearance resembles that of the regular CR magnetoabsorption. It results from neutral donors exhibiting a Zeeman transition ($1s \rightarrow 2p+$), the transition energy of which is much larger than the ionization energy. The *I* signal gradually disappears as the temperature increases because the donors become ionized.

Cyclotron resonance also serves as a valuable tool for materials characterization through making use of the cyclotron resonance linewidth and intensity. Resonance linewidths can differ considerably from sample to sample. This difference in linewidth is attributed to differences in impurity content, with the higher-purity samples having the narrowest linewidths and largest intensities. Figure 47 shows the electron CR signals for both *n*-type and *p*-type GaAs crystals with low compensation.[87]

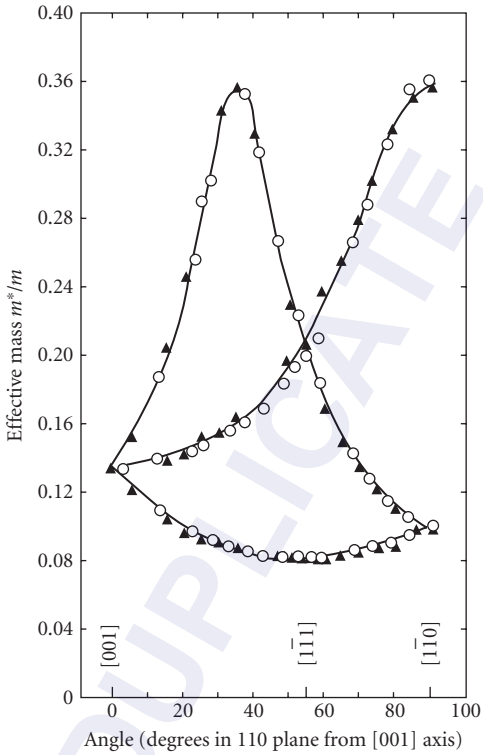

FIGURE 44 Effective mass of electrons in Ge at 4 K for magnetic field directions in a (110) plane.[89]

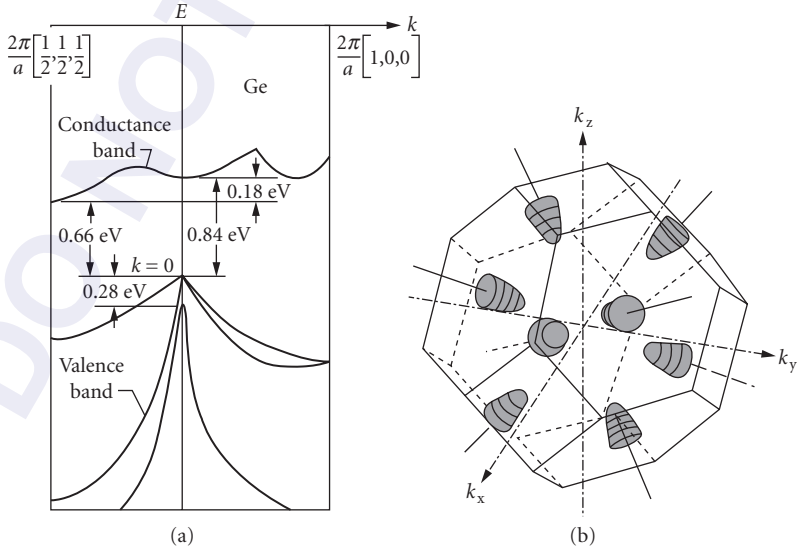

FIGURE 45 (*a*) Band structure of Ge plotted along the [100] and [111] directions and (*b*) ellipsoidal energy surface corresponding to primary valleys along the ⟨111⟩ directions.[90]

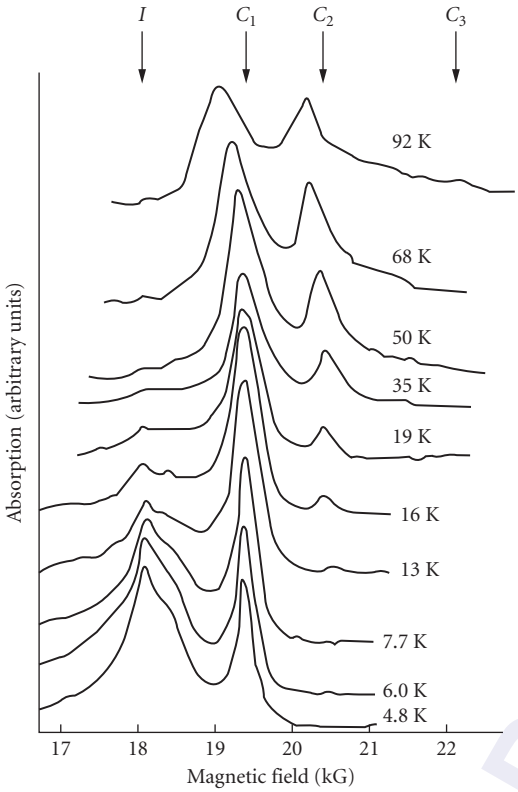

FIGURE 46 Thermal equilibrium resonance traces in *n*-type InSb at various temperatures. At 4.8 K, only the lowest cyclotron transition $C_1(0^+ \rightarrow 1^+)$ and impurity cyclotron resonance *I* (ICR) are visible. On raising the temperature, the signal *I* disappears on complete ionization of donors, while the second and third cyclotron transitions $C_2(0^- \rightarrow 1^-)$ and $C_3(1^+ \rightarrow 2^+)$ start to show up.[91]

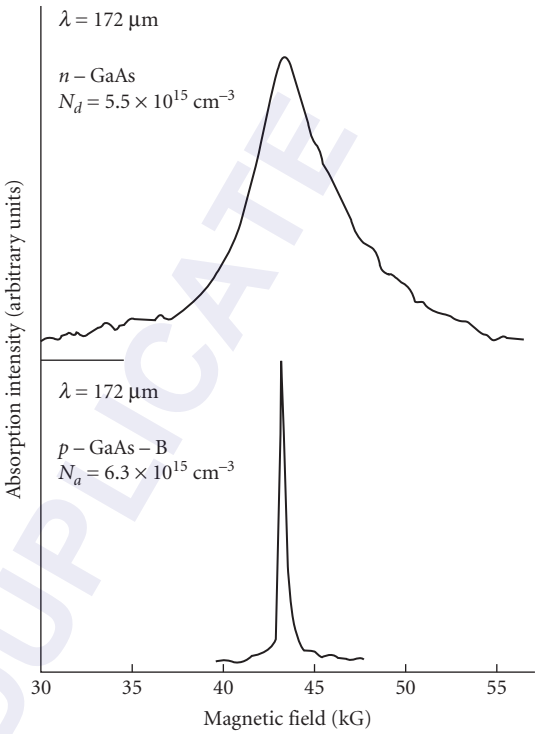

FIGURE 47 Difference in electron cyclotron resonance linewidth between *n*- and *p*-type GaAs crystals, having the same order of donor or acceptor concentrations.[87]

The observed large difference in linewidths is primarily considered to reflect the difference in the electron-donor and electron-acceptor scattering rates.

An electron placed in the conduction band of a polar insulator or semiconductor surrounds itself with an induced lattice-polarization charge. The particle called a polaron consists of the electron with its surrounding lattice-polarization charge. The term *magnetopolaron* is also often referred to as a polaron in a magnetic field. Landau-level energies of these magnetopolarons are shifted relative to those predicted for band electrons. These energy shifts give rise to polaron effects that are most clearly evident in optical experiments such as cyclotron resonance. The review by Larsen provides an annotated guide to the literature on polaron effects in cyclotron resonance.[92]

Free-carrier Faraday rotation and other effects Observation of free-carrier rotation was first reported in 1958. It is best understood as the differential dispersion of the cyclotron resonance absorption, and, as such, it is an accurate method for determining carrier effective masses. It can be measured off resonance and detected under conditions which preclude the actual observations of cyclotron resonance absorption. Cyclotron resonance is a more explicit technique which enables carriers of different mass to be determined by measuring different resonant frequencies. The Faraday effect is an easier and

more flexible technique, but is less explicit, since the dispersion involves the integral of all CR absorption. Also, it is unable to detect any anisotropy of the effective mass in a cubic crystal.

Other free-carrier effects are ellipticity associated with the Faraday rotation, the Voigt effect, and the magnetoplasma effect on the reflectivity minimum.

Impurity magnetoabsorption Impurity states forming shallow levels (i.e., those levels separated from the nearest band by an energy much less than the gap E_g) can be described by the effective mass approximation. This simple model for impurities is that of the hydrogen atom with an electron which has an effective mass m^* and the nuclear charge reduced to e/ε_∞, by the high-frequency dielectric constant of the crystal. This hydrogen-atom-like model leads to a series of energy levels leading up to a photoionization continuum commencing at an energy such that the electron (hole) is excited into the conduction (or valence) band.

The effect of a magnetic field on impurity levels and the related optical transitions is one of the most important tools for the study of the electronic states in semiconductors. The reason for this is that a magnetic field removes all degeneracies including the Kramers' degeneracy due to time reversal. It can produce new quantization rules, and it is a strong perturbation which is not screened like the Coulomb interactions.

For donor states with an isotropic conduction band minimum, as in GaAs or InSb, the hamiltonian acquires terms which are linear (Zeeman term) and quadratic (diamagnetic) in magnetic field. In this case, perturbation theory is appropriate to use until one considers transitions to very high quantum numbers or very high fields. Often complicated variational procedures must be used for accurate solutions. In the high field limit where $\hbar\omega_c/R >> 1$ or for high energies, the impurity level quantum numbers do not provide a proper classification, and, instead, the states should be related to the continuum Landau levels. The effect of a magnetic field on acceptor impurity states is more complicated because of band degeneracy and of spin-orbit coupling. Also for acceptors, one can be in the high field limit at relatively small values of the field for shallow levels and for excited states.

High-resolution photoconductivity measurements in high-purity GaAs indicate that the behavior of shallow donors in GaAs deviates from that predicted by the simple hydrogenic model. Figure 48

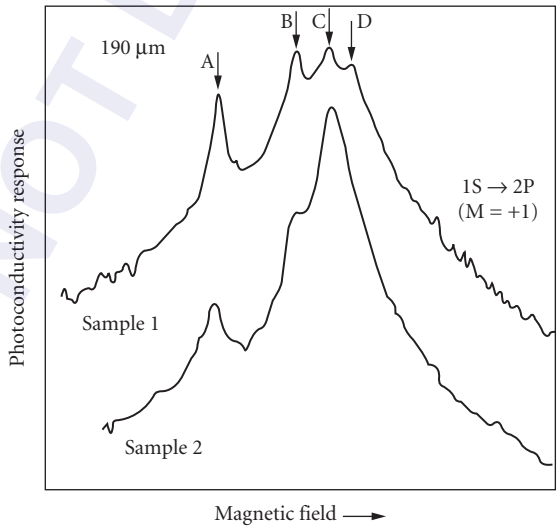

FIGURE 48 The photoconductivity due to the (1s → 2p, $m = +1$) transition as a function of magnetic field for two different samples when excited by 190 μm laser radiation. For sample 1, $N_D = 2.0 \times 10^{14}$ cm^{-3}, $N_A = 4.0 \times 10^{13}$ cm^{-3}, and $\mu_{77K} = 153{,}000$ cm^2/V·s. For sample 2, $N_D = 4.3 \times 10^{13}$ cm^{-3}, $N_A = 2.5 \times 10^{+13}$ cm^{-3}, and $\mu_{77K} = 180{,}000$ cm^2/V·s.[93]

shows that, under high resolution, the single (1s → 2p) transition observed at lower resolution actually consists of several different unresolved transitions.[93] The photoconductive response is shown for two different high-purity GaAs samples. The magnetic field range shown covers about 1 kG at around 15 kG. The different transitions labeled A, B, C, and D each correspond to a different donor species, and variation of the amplitude of these transitions in different samples results from the different relative concentrations of the particular donor species. Thus, the use of magnetic fields in studying the absorption properties of shallow impurities provides an analytical method of characterizing impurities. Because of the central-cell corrections (chemical shifts), different impurities of the same type (donor or acceptors) can be distinguished and identified by back-doping experiments.

Semiconductor Nanostructures: Low Dimensional Systems Development of growth techniques such as molecular beam epitaxy and metal organic chemical vapor deposition have made possible the precise growth of high-quality, layered, semiconductor heterostructures. Various sequences of thin film layers can be grown to form quantum wells, wires, and dots as well as superlattices and heterojunctions. In these low dimensional systems, the quantization effect of the magnetic field is significantly enhanced, leading to a wealth of new ways to characterize these structures. We refer the readers to recent books that review these systems.[94,95]

Nonlinear Optical Properties of Semiconductors

Background The study and characterization of nonlinear optical properties of semiconductors are increasingly important topics for research and development, with new effects being discovered and useful nonlinear optical devices being constructed. The underlying cause of these nonlinear optical effects lies in the interaction of electromagnetic radiation with matter. Each nonlinear optical process may be thought to consist of the intense light first inducing a nonlinear response in a medium and then the medium in reacting, modifying the optical fields in a nonlinear way. There is a wide variety of nonlinear optical phenomena in semiconductors, leading to many papers on the subject of nonlinear properties. It is thus not possible here to do justice to this field. We refer the reader to Chap. 10, "Nonlinear Optics."[96] Here, we give a brief overview of the nonlinear optical processes starting from Maxwell's equations and describe and categorize some important second- and third-order nonlinear processes and properties.

Theoretical Overview of Nonlinear Optical Processes and Properties

Maxwell's equations and polarization power series expansion All electromagnetic phenomena are governed by Maxwell's equations for the electric and magnetic fields **E** (**r**, *t*) and **B** (**r**, *t*) or by the resulting wave equations

$$\left[\nabla\cdot\nabla+\frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right]\mathbf{E}(\mathbf{r},t)=\frac{-4\pi}{c^2}\frac{\partial^2}{\partial t^2}\mathbf{P}(\mathbf{r},t)$$
$$\nabla\cdot\mathbf{E}(\mathbf{r},t)=-4\pi\nabla\cdot\mathbf{P}(\mathbf{r},t) \tag{56}$$

Here, **P** is the generalized electric polarization which includes not only the electric dipole part but all the multiple contributions. In general, **P** is a function of **E** which describes fully the response of the medium to the field. It is often known as the constitutive equation since all optical phenomena would be predictable and easily understood from it and its solution for the resulting set of Maxwell's equations with appropriate boundary conditions. Unfortunately, this equation is almost never possible to solve exactly, and physically reasonable approximations must be resorted to for progress to occur.

Most nonlinear optical properties can be described in terms of a power series expansion for the induced polarization. (This assumes that **E** is sufficiently weak.) Since lasers are most often used to observe nonlinear optical effects, one usually deals with the interaction of several monochromatic or quasi-monochromatic field components, and **E** and **P** can be expanded into their Fourier components as

$$\mathbf{E}(\mathbf{r},t)=\sum_i \mathbf{E}(\mathbf{q}_i,\omega_i),\quad \mathbf{P}(\mathbf{r},t)=\sum_i \mathbf{P}(\mathbf{q}_i,\omega_i) \tag{57}$$

where

$$\mathbf{E}(\mathbf{q}_i\,\omega_i)=\mathbf{E}(\omega_i)\exp(i\mathbf{q}_i\cdot\mathbf{r}-i\omega_i t)+\text{c.c.} \tag{58}$$

The induced polarization is usually written as

$$\mathbf{P}(\mathbf{q}_i,\omega_i)=\chi^{(1)}(\mathbf{q}_i,\omega_i)\cdot\mathbf{E}(\mathbf{q}_i,\omega_i)+\sum_{j,k}\chi^{(2)}(\mathbf{q}_i=\mathbf{q}_i+\mathbf{q}_k,\omega_i=\omega_j+\omega_k):\mathbf{E}(\mathbf{q}_j,\omega_j)\mathbf{E}(\mathbf{q}_k,\omega_k)$$
$$+\sum_{j,k,l}\chi^{(3)}(\mathbf{q}_i=\mathbf{q}_j+\mathbf{q}_k+\mathbf{q}_l,\omega_i=\omega_j+\omega_k+\omega_l):\mathbf{E}(\mathbf{q}_j,\omega_j)\mathbf{E}(\mathbf{q}_k,\omega_k)\mathbf{E}(\mathbf{q}_l,\omega_l)+\cdots \tag{59}$$

It is, however, sometimes more convenient to use $\mathbf{E}(\mathbf{r}, t)$ and $\mathbf{P}(\mathbf{r}, t)$ directly instead of their Fourier components, especially when dealing with transient nonlinear phenomena.

In the electric dipole approximation, $\chi^{(n)}(\mathbf{r}, t)$ is independent of **r**, or $\chi^{(n)}$ $(\mathbf{k}, \omega)$ is independent of **q**, and the equations become simpler to write and to work with. These $\chi^{(n)}$ are the susceptibilities, with $\chi^{(1)}$ = linear electric dipole susceptibility and $\chi^{(2)}$ ($\chi^{(3)}$) = nonlinear second-order (third-order) susceptibility tensor. Both absorptive and refractive effects can be described in terms of these complex electric susceptibilities, which have real and imaginary parts for each tensor element. These linear and nonlinear susceptibilities characterize the optical properties of the medium and are related to the microscopic structure of the medium. Knowledge of $\chi^{(n)}$ allows, at least in principle, to predict the *n*th-order nonlinear optical effects from Maxwell's equations. Consequently, much effort (both experimentally and theoretically) has gone into determining the $\chi^{(n)}$.

The definitions of the nonlinear susceptibilities in the literature vary and have led to some confusion. Shen reviews these definitions and the reasons for the confusion.[97] In addition to some intrinsic symmetries, the susceptibilities must obey crystallographic symmetry requirements. The spatial symmetry of the nonlinear medium imposes restrictions upon the form of the various $\chi^{(n)}$ tensors. Butcher has determined the structure of the second- and third-order tensors for all crystals.[98] One important consequence is that, for media with inversion symmetry, $\chi^{(2)} \equiv 0$, and thus $\chi^{(3)}$ represents the lowest-order nonlinearity in the electric-dipole approximation. Of the 12 nonzero elements, only 3 are independent. These susceptibility tensors must transform into themselves under the point group symmetry operations of the medium.

It is often convenient to discuss the various optical processes which might occur in terms of whether they are active or passive. Passive processes involve energy or frequency conservation, and the material medium acts basically as a catalyst. The susceptibilities are predominantly real for passive processes. Of course, as resonances are approached, susceptibilities become complex and may even become totally imaginary. These passive nonlinear optical phenomena are listed in Table 7.[99] Active nonlinear optical phenomena are listed in Table 8.[99] In general, energy is exchanged between the radiation and the material only for the active processes. We also note that second-order effects are always passive.

Second-order nonlinear optical properties Most existing nonlinear optical devices are based upon second-order nonlinear optical effects that are quite well understood. Here, we assume the presence of only three quasi-monochromatic fields

$$\mathbf{E}=\mathbf{E}(\omega_1)+\mathbf{E}(\omega_2)+\mathbf{E}(\omega_3) \tag{60}$$

TABLE 7 Passive Nonlinear Optical Phenomena[99]

Frequencies of Incident Fields	Frequencies of Fields Generated by the Polarization of the Medium	Susceptibility	Process (Acronym)
ω_1	No polarization	$0(\varepsilon = 1)$	Vacuum propagation (VP)
ω_1	ω_1	$\chi^{(1)}(\omega_1; \omega_1)$	Linear dispersion (LD)
ω_1, ω_2	$\omega_3[\omega_3 = \omega_1 + \omega_2]$	$\chi^{(2)}(\omega_3; \omega_1, \omega_2)$	Sum mixing (SM)
ω_1	$\omega_3[\omega_3 = 2\omega_1]$	$\chi^{(2)}(\omega_3; \omega_1, \omega_1)$	Second-harmonic generation (SHG)
$\omega_1, 0$	ω_1	$\chi^{(2)}(\omega_1; \omega_1, 0)$	Electro-optic linear Kerr effect (EOLKE)
ω_1	$\omega_2, \omega_3[\omega_1 = \omega_2 + \omega_3]$	$\chi^{(2)}(\omega_2; -\omega_3, \omega_1)$	Difference-frequency mixing (DFM)
ω_1	$\omega_2[\omega_1 = 2\omega_2]$	$\chi^{(2)}(\omega_2; -\omega_2, \omega_1)$	Degenerate difference-frequency (DDF)
ω_1	0	$\chi^{(2)}(0; -\omega_1, \omega_1)$	Inverse electro-optic effect (IEOE)
$\omega_1, \omega_2, \omega_3$	$\omega_4[\omega_4 = \omega_1 + \omega_2 + \omega_3]$	$\chi^{(3)}(\omega_4; \omega_1, \omega_1, \omega_1)$	Third-harmonic generation (THG)
ω_1, ω_2	$\omega_3, \omega_4[\omega_1 + \omega_2 = \omega_3 + \omega_4]$	$\chi^{(3)}(\omega_3; -\omega_4, \omega_1, \omega_2)$ $\chi^{(3)}(\omega_4; -\omega_3, \omega_1, \omega_2)$	Four-wave difference-frequency mixing processes (FWDFMP)
ω_1	$\omega_2, \omega_3, \omega_4[\omega_1 = \omega_2 + \omega_3 + \omega_4]$	$\chi^{(3)}(\omega_2; -\omega_3, -\omega_4, \omega_1)$	
ω_1	ω_1	$\chi^{(3)}(\omega_1; \omega_1, -\omega_1, \omega_1)$	Intensity-dependent refractive index (IDRI)
$\omega_1, 0$	ω_1	$\chi^{(3)}(\omega_1; 0, 0, \omega_1)$	Quadratic Kerr effect (QKE)

$\omega = 0$ indicates the presence of a uniform electric field.

and

$$\omega_1 = |\omega_2 \mp \omega_3| \tag{61}$$

Thus, Eq. (56) can be decomposed into three sets of equations for each $\mathbf{E}(\omega_i)$. They are then nonlinearity coupled with one another through the polarizations

$$\mathbf{P}(\omega_1) = \chi^{(1)}(\omega_1) \cdot \mathbf{E}(\omega_1) + \chi^{(2)}(\omega_1 = |\omega_2 \pm \omega_3|) : \mathbf{E}(\omega_2)\mathbf{E}(\omega_3) \tag{62}$$

The second-order nonlinear processes are then described by the solutions of the coupled-wave equations with the proper boundary conditions. $\chi^{(2)} = 0$ for materials with a center of inversion. The coefficient $\chi^{(2)}$ is a third-rank tensor. Some second-order processes include sum- and difference-frequency mixing, the electro-optic linear Kerr effect, the inverse electro-optic effect, parametric amplification and oscillation, and second-harmonic generation. The past emphasis has been

TABLE 8 Active Nonlinear Optical Phenomena[99]

Susceptibility	Process
$\chi^{(1)}(\omega_1; \omega_1)$	Linear absorption ($\omega_1 \approx \omega_{10}$)
$\chi^{(3)}(\omega_2; \omega_1, -\omega_1, \omega_2)$	Raman scattering ($\omega_2 \approx \omega_1 \mp \omega_{10}$)
$\chi^{(3)}(\omega_1; \omega_1, -\omega_1, \omega_1)$	Two-photon absorption ($2\omega_1 \approx \omega_{10}$) or Saturable absorption ($\omega_1 \approx \omega_{10}$)
$\chi^{(5)}(\omega_2; \omega_1, \omega_1, -\omega_1, -\omega_1, \omega_2)$	Hyper-Raman scattering ($\omega_2 \approx 2\omega_1 \mp \omega_{10}$)

on finding new nonlinear crystals with a large $\chi^{(2)}$. Semiconductor crystals have received much attention: III-V compounds like GaAs and InSb, II-VI compounds like ZnS and CdSe, I-III-VI compounds like $AgGaS_2$ and $CuInS_2$, and II-IV-V compounds like $CdSiAs_2$ and $ZnGeP_2$.

In most applications of second-order nonlinear optical effects, it is important to achieve phase-matching conditions

$$\Delta\mathbf{q} = \mathbf{q}_1 - \mathbf{q}_2 - \mathbf{q}_3 = 0 \tag{63}$$

where $\mathbf{q}_i$ is the wave vector of $\mathbf{E}(\omega_i)$. This ensures an efficient energy conversion between the pump field(s) and the signal field.

The intensity of the electric field of a laser can produce photons at multiples of the frequency of the probing light signal (ω_0). Second harmonic generation has been widely used to characterize interfaces between silicon and thin dielectric films as well as thin metal films.[100] There are two sources of second harmonic light at the interface between dielectric films and centro-symmetric crystals such as silicon. One is due to the weak electric quadrupole contribution, and the second is due to a surface dipole contribution.[101,102] The dipole contribution is stronger than the second harmonic signal from the quadrupole one. The detailed crystalline symmetry along the probe beam direction results in a rotational dependence to the quadrupole signal. The surface dipole contribution is strongly affected by chemical changes in the interface making it an ideal means of characterizing subtle process-induced changes in the dielectric film stack used for transistor applications.[101] The second harmonic intensity, *I*, from a *p*- or *s*-polarized probe and a *p*- or *s*-polarized SHG signal for the Si(100) crystal face are

$$I_{PP}(2\omega) = |a_{PP}^{(0)} + a_{PP}^{(4)} \cos(4\Phi)|^2$$

$$I_{PS}(2\omega) = |a_{PS}^{(4)} \sin(4\Phi)|^2$$

$$I_{SP}(2\omega) = |a_{SP}^{(0)} + a_{SP}^{(4)} \cos(4\Phi)|^2$$

$$I_{SS}(2\omega) = |a_{SS}^{(4)} \sin(4\Phi)|^2$$

Here, the *a* coefficients are due to either a surface dipole contribution $a^{(0)}$ or a bulk quadrupole $a^{(4)}$ contribution. Φ is the angle between the $[0\bar{1}0]$ crystal axis and the projection of the wave vector of the second harmonic light on the surface. The SHG signal is also strongly influenced by electric fields present in the sample. Changes in the electric field due to trapped charge in hafnium oxide have been characterized using the changes in $a^{(0)}$ due to annealing temperature.[101] Both the phase and amplitude of the second harmonic signal from Si(100) surfaces have been measured by SHG.[102]

Third-order nonlinear optical properties In materials with inversion symmetry, third-order processes are the dominant nonlinearity. These processes are described by a fourth-rank nonlinear susceptibility tensor $\chi^{(3)}$ whose contribution to the polarization is given according to Eq. (59) by

$$\mathbf{P}(\omega_i) = \sum_{j,k,l} \omega^{(3)}(\omega_i = \omega_j + \omega_k + \omega_l) : \mathbf{E}(\omega_j)\mathbf{E}(\omega_k)\mathbf{E}(\omega_l) \tag{64}$$

In general, this nonlinearity will provide a coupling between four electromagnetic waves. Depending on whether the susceptibility tensor elements are real or imaginary and on whether some of the frequencies are identical or different, a large variety of physical phenomena can be understood and accounted for: third-harmonic generation, two-photon absorption, saturable absorption, intensity-dependent index of refraction, stimulated Raman effect, anti-Stokes generation, stimulated Raleigh scattering, modulation of the index of refraction, and self-focusing of light. We concentrate on discussing only a few of the most pertinent cases of interest.

Third-harmonic generation Here, the output frequency $\omega_4 = \omega_1 + \omega_2 + \omega_3 = 3\omega_1$, since $\omega_1 = \omega_2 = \omega_3$. The polarization at the frequency ω_4 will generate radiation at the third-harmonic frequency. The quantum process responsible for the harmonic generation may be described as a scattering process in which three quanta at the fundamental frequency are annihilated and one quantum at the third-harmonic frequency is created. The system remains in the ground state, although three virtually excited states are involved in the scattering process. Since the phases are important, the process is actually an interference between many four-photon scattering processes.

Two-photon absorption Here, for example, $\omega_1 = -\omega_2 = \omega_3 = \omega_4$ and $\Delta\mathbf{k} = 0$, and the nonlinear polarization has components described by

$$\mathbf{P}(\omega_4) = \chi^{(3)}(\omega_4 = +\omega_1 - \omega_2 + \omega_3) : \mathbf{E}(\omega_1)\mathbf{E}^*(\omega_2)\mathbf{E}(\omega_3) \tag{65}$$

The nonlinear susceptibility $\chi^{(3)}$ is purely imaginary, but positive. One can define an absorption coefficient proportional to the intensity itself. In the important case of resonance, the sum of two frequencies of the exciting field is approximately equal to a transition frequency of the medium, $\omega_{ab} = 2\omega_1$, where $\hbar\omega_{ab}$ is the energy difference between two levels $|a\rangle$ and $|b\rangle$ with the same parity.

The TPA coefficient can be expressed in terms of a third-order nonlinear susceptibility tensor by solving the wave equation using the slowly varying amplitude approximation. The explicit expression for β is related to the imaginary part of the third-order electric dipole susceptibility tensor which depends upon the crystal class and laser electric field direction, for example, in crystals with $\bar{4}3$ m symmetry (e.g., $Hg_{1-x}Cd_x$ Te, GaAs, InSb, etc.) and the electric field along the [001] direction,[103]

$$\beta = \frac{32\pi^2\omega}{n^2c^2}\left[3\,\mathrm{Im}\,\chi^{(3)}_{1111}(-\omega,\omega,\omega,-\omega)\right] \tag{66}$$

where the convention used is that of Maker and Terhune (1965).[104]

Since $\chi^{(3)}$ is a second-rank tensor, there are, in general, nine terms contributing to β with magnitudes which vary with orientation. However, in most systems the symmetry is such that there are relations between some of the terms. For example, in crystals with $\bar{4}3$ m symmetry, there are three possible values of χ for each β, and for crystals with m3m symmetry, there are four possible values. These can, in general, be measured by using both linearly and circularly polarized light. It is not always possible to sort out all the different TPA spectra simply by changing the sample orientation or the light polarization because of the competing process of absorption by second-harmonic-produced light.

5.4 MEASUREMENT TECHNIQUES

Overview

The ability to measure the optical response of a semiconductor specimen precisely under well-controlled environmental conditions is of obvious importance in the determination of the optical properties of semiconductors. The significant resolution with which optical spectra can be measured makes it possible to perform precise determinations of the intrinsic properties such as the energy separation between electronic states, lattice vibration frequencies, as well as extrinsic properties due to impurities. The wealth of information that can be obtained and the direct relevance to device-related issues has led to much effort being expended in developing techniques and apparatus to perform a wide range of measurements. This chapter reviews the most widely used procedures and optical components employed in these investigations.

Optical studies, except in rare instances, are contactless and noninvasive. These attractive features have led to widespread use of the techniques in both scientific analyses and, more recently,

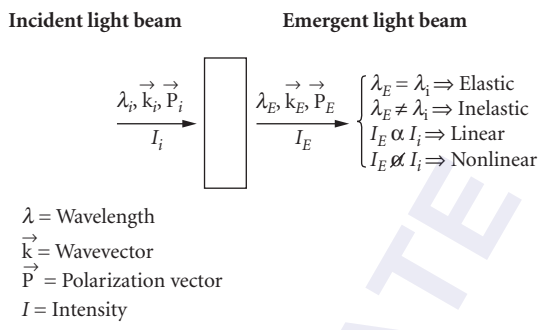

FIGURE 49 Schematic of interaction of light with semiconductors showing the linear, nonlinear, elastic, and inelastic processes.

in manufacturing environments. Specific procedures and experimental apparatus and variations of them are too numerous to be dealt with in this brief chapter. The motivation here is, therefore, to set forth the essentials and dwell on the major aspects of each technique covered, as well as to provide some references which contain more details than could be given here.

The essence of spectroscopic investigations is to determine the interaction of a light beam, with a well-defined wavelength, intensity, polarization, and direction, with a semiconductor specimen, in most cases from the point of view of the light beam. Figure 49 schematically displays this light-specimen interaction. Upon interacting, both the specimen and the light beam will change, and the experimental task is to precisely measure the change in the properties of the light beam. The changes may be classified into the linear and nonlinear regimes based on whether or not the response of the specimen is linear with respect to the incident power. The interactions may be elastic or inelastic; the light beam may also undergo a change in all aspects except its wavelength or photon energy in the former, and the wavelength can also be modified in the latter. These terms arise from the elastic or inelastic interaction of the photon with the specimen where the incident photon energy is preserved or modified in the process. The incident light beam may be reflected, scattered, and transmitted by the specimen. In addition to these processes, a properly excited specimen may emit light as well. The last process, known as luminescence, may also be exploited to gain an insight into the physical behavior of the material.

The linear, elastic regime covers most of the procedures used to elucidate the equilibrium properties related to the optical constants, n and k, introduced previously. The techniques used are comprised of reflection and transmission spectroscopies where the energy reflection R and transmission T of the specimen are studied as function of the wavelength, polarization, and angle of incidence. The net energy absorption A may be determined from R and T as follows: $A = (1 - R - T)$.

As discussed earlier, a complete knowledge of R or T over a large range of energies is required to determine both n and k. Such a task is usually difficult. A more convenient and accurate procedure is to measure the change in polarization properties of an obliquely incident plane-polarized light beam after it interacts with the specimen. This procedure, called ellipsometry, uses the polarization change of the incident beam in the material to extract n and k as well as the thickness of each layer of a multilayer structure.[105,106] The underlying principles and a more detailed discussion follow.

The nonlinear and inelastic spectroscopic procedures have been popular since the advent of lasers. The very large power densities achievable using lasers over the wide range of energies extending from the far-infrared (FIR) to the UV have driven the rapid developments in this field. At high excitation powers, the absorption of light energy can become superlinear due to the presence of higher-order interactions as discussed previously. Exploitation of these specific interactions as a means of gaining information regarding the specimen is the content of nonlinear spectroscopic techniques. On the other hand, the high degree of wavelength purity and coherence offered by lasers is exploited to perform inelastic spectroscopic analyses such as Raman[107] and Brillouin[107] spectroscopies. The crux of these techniques is to project a high-power highly coherent laser beam onto a

specimen and observe the scattered part of the intensity. The scattered part will be dominated by light with the same wavelength as the incident laser beam; that is, the elastic part, but a small part, usually $<10^{-8}$ of the original intensity, can be observed with well-defined frequency shifts. These additional frequency bands, similar to the sidebands that arise as a consequence of intensity modulation, can be analyzed to provide crucial information regarding the specimen. For instance, optical phonons can interact with the incoming laser photon and energy-shift it by an amount equal to a multiple of the phonon energy. Hence, an analysis of the frequency-shifted bands in the Raman spectrum can be used to establish phonon energies. The major task of Raman spectroscopy is to isolate the very weak frequency-shifted component in the scattered beam.[107]

Light emission is important for both spectroscopic analysis and device applications and, hence, has commanded a large amount of attention.[108,109] Any excited semiconductor will emit light as a means of relaxing to its equilibrium state. Under proper excitation, such as with above-bandgap radiation, the light emission can be made quite intense and can then be easily recorded and subjected to spectroscopic analyses. Within the specimen, the above-bandgap photoexcitation leads to a transition of the electron from a valence band to the conduction band, followed by a rapid process of thermalization whereby the excited electron and hole reach their respective band extrema and recombine from there radiatively; that is, by emitting the potential energy in the form of a photon. The photoexcited free electrons and holes may also form an exciton, or interact with the impurity states in the forbidden band, or both. The final recombination can be mediated by a large number of such intermediate processes, and, hence, the luminescence spectra can display a very rich and complicated structure. The most important aspect of the luminescence spectrum is the fact that nearly all the interactions involve impurity and defect states in the forbidden band. Add to this the rapid thermalization and large self-absorption effects for emission of light with energies greater than the gap, and luminescence is almost entirely a sub-bandgap tool dominated by the impurities and defects present in the semiconductor.

The major categories of spectroscopic procedures are grouped by the energy range of photons used. The commonality of the instrumentation for a given wavelength range accounts for this categorization. The lowest energy region in the FIR spans the phonon energies and a variety of other possible excitations such as plasmons (free-carrier oscillations), magnons, and impurity-related electronic and vibrational excitations. The energy-bandgap of semiconductors ranges from 0 for HgTe to >5 eV[110] in diamond and can hence occur anywhere from the far-infrared to the vacuum ultraviolet. For two of the most important electronic materials, namely Si and GaAs, the gaps occur in the near-infrared at 0. 8 and 1.5 eV,[110] respectively. Hence, the mid- and near-infrared investigations have largely been confined to the study of impurity states within the forbidden gap. The electronic band transitions dominate the higher energies.

Instrumentation

The major components of a spectroscopic system are schematically displayed in Fig. 50. Light from the broadband source enters a monochromator fitted with a dispersion element that separates the various wavelength components and allows a chosen narrow spectral band of light to interact with the specimen. A detector converts the intensity information in the beam to an electrical or digital signal that can then be recorded by a computer or other recording device and then analyzed. Passive components such as lenses and mirrors, filters, polarizers, light pipes, and optical fibers, etc., that are needed to tailor the behavior of the system also form an integral part of the experimental apparatus. A short discussion of each of the major components follows.

Sources

Broadband The ideal broadband source should emit light with sufficient intensity in the wavelength band of interest, possess a stable output and exhibit a minimum amount of noise, and display a slowly varying spectral character; that is, the source should not possess intense spectral features that will interfere with the measurement procedure.[111] All these characteristics can be

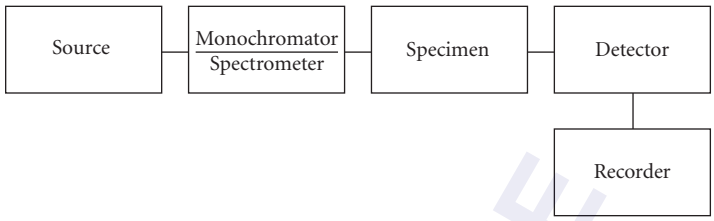

FIGURE 50 Schematic of a spectroscopic measurement apparatus.

satisfied by blackbodies, and, if blackbodies with high enough temperatures can be fabricated, they would be ideal sources for any wavelength region. However, this is not possible since the operating temperatures required to obtain workable energy densities in the ultraviolet are extremely large. Hence, blackbody sources are usually restricted to wavelengths in the red-yellow region starting at ≈500 nm or larger and ending at ≈2000 μm in the FIR. The incandescent lamp with a hot filament is the best known BB source. Gas emission lamps such as high-pressure arc lamps and low-pressure discharge lamps are useful in the visible and ultraviolet region. Their main feature is the ability to produce a large intensity in the upper energy regions. However, the inherent atomic processes and associated line spectra that are present make using these somewhat complicated. Care should be exercised to avoid wavelength regions where intense spectroscopic features arise from the discharge medium. The unavoidable electronic activity in the discharge media can also be a source of noise.

Laser Laser sources are required in applications where large intensities are essential, as in the studies of nonlinear optical phenomena using Raman scattering or photoluminescence techniques. Lasers are currently available from the UV to the FIR, and often both cw and pulsed operations are possible.[112] The argon and krypton ion lasers with emissions in the visible and near-infrared regions, the Nd:YAG with a 1.06 μm emission, and the CO_2 laser with emission in the 9.2 to 10.8 μm range have been the workhorses for a wide variety of semiconductor investigations.

Since efficient laser operation requires a set of excitable electronic or vibrational levels properly arranged to produce population inversion and sufficient amplification, intense laser emission is usually confined to specific wavelengths. However, the use of optically excited dye lasers and tunable solid-state lasers such as the Ti:sapphire lasers can be used to fill the wavelength regions in between most of the visible and near-infrared regions.

The semiconductor lasers that are currently available extend in wavelength from the red to the far-infrared. The III-V alloy-based double heterostructure lasers, fabricated from $Al_x Ga_{1-x} As$ and $In_{1-x}Ga_xAs$, are particularly efficient in the near-infrared region. The IV–VI alloy-based lasers, fabricated from $Pb_{1-x}Sn_xTe$, operate at considerably longer wavelengths of ≈10 μm; a small range of emission wavelength tunability has been achieved based on the change of the band gap with the temperature. The intense interest in the development of blue-green laser emission is now having substantial influence.

Spectrometers and Monochromators

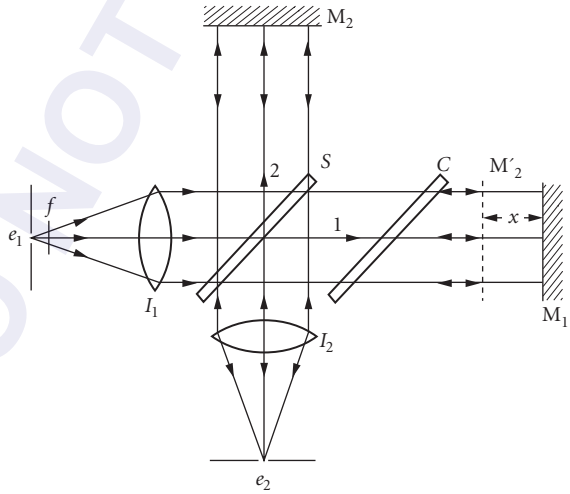
Dispersion spectrometers The monochromator or the spectrometer is the heart of the spectroscopic apparatus, and the dispersion element that analyzes the light is the main component of the monochromator.[113] The simplest and best known dispersion unit is the transparent prism. The physical mechanism that leads to the dispersion is the inherent dispersion in the optical refractive index n of the prism material over the wavelength range of interest. Prism-based monochromators work very well and are still employed. They possess a large throughput; that is, they transmit a large fraction of the incident intensity but suffer from limited resolution since the degree of dispersion is restricted by the characteristics of the prism material.

The most widely used dispersion element is the diffraction grating which is a collection of finely spaced grooves or slits. Diffraction from the multiple slits leads to a dispersive action. The dispersion is given by the following relationship: $n\lambda = d \sin(\theta)$.

The fact that the degree of dispersion can be controlled by the slit spacing reduces the complexity of design and fabrication when compared to the prism. Gratings have a drawback in that they display multiple orders, and hence the throughput at any given order is likely to be very high. Blazing (i.e., control of the shape of the groove) can be used to increase energy in a given band in a particular order to reduce this shortcoming. Both transmission and reflection gratings can be fabricated as well as concave gratings that both disperse and focus the light beam. The major manufacturing flaw in grating fabrication that used mechanical devices was that groove spacing was not well controlled and hence the flawed grating led to the appearance of spectroscopic artifacts that were called "ghosts." The advent of holographic grating fabrication procedures has eliminated these difficulties.

Fourier-transform spectrometers An alternate method for performing spectroscopic measurements is the use of Michelson's interferometer.[114] Figure 51 displays the layout of the interferometer. The approach in this procedure is to divide the white-light beam from the source into two wavefronts, introduce a path difference x between the two, recombine them, and record the interference-modulated intensity as a function of x. The recorded intensity variation $\mathbf{B}(x)$ is known as the interferogram, and a Fourier transformation of $I(x)$ will yield the spectral distribution of the white light. Experimentally, this is achieved as shown in Fig. 51. The incident beam from the source is collimated by lens l_1, split into two wavefronts by the beam splitter S. The two wave fronts are directed to a movable mirror, M_1, and a fixed mirror, M_2. The reflected beams are combined at the detector where the intensity is recorded as a function of x, the path difference between M_1 and M_2. The spectrum $\mathbf{B}(\omega)$ is related to $I(x)$ by the following relationship:

$$\mathbf{B}(\omega) = \int_0^\infty [I(x) - I(\infty)] \cos(2\pi\omega x) dx \tag{67}$$



$$B(\omega) = \int_O^\infty [I(x) - I(\infty)] \cos(2\pi\omega x)\, dx$$

FIGURE 51 Schematic of the Fourier-transform interferometer.

This procedure of measuring the spectra is referred to as Fourier-transform spectroscopy and contains two major advantages: the throughput advantage and the multiplex advantage, both of which greatly add to the ultimate signal-to-noise ratios that can be achieved as compared to measurements performed with grating spectrometers under comparable conditions of illumination and recording times. The throughput advantage arises from the fact that improved resolution is not achieved at the expense of reducing slits and reduced throughput, and the multiplex advantage is a consequence of the fact that all wavelength channels are observed all the time as opposed to a one-channel-at-a-time measurement constriction in the dispersion-based instruments.

These significant advantages come with a price. The much larger signal intensities are likely to be seen by the detector and place stringent conditions on the detector performance in its dynamic range and linearity. Less-than-optimum performance may lead to significant distortions in the transformed spectrum that are not intuitively evident. The FT spectrometer was used first in the far-infrared, soon after the advent of high-speed computers that were capable of performing the Fourier transformations. However, the advances in the technology of designing and fabricating complicated optical elements and computer hardware have contributed greatly to the advancement of the field, and FT spectrometers are now available that cover a wide spectral region extending from FIR to the VUV.

Detectors The photomultiplier (PMT)[115] is a widely used light detector that is a vacuum-tube-based device that uses a photoemitter followed by a large ($>10^5$) amplification stage so that very low signal levels can be detected. The wavelength band that the detector responds to is determined by the photocathode and window characteristics. Photomultipliers are particularly useful when low-light-level detection is needed as in Raman spectroscopy, but their use is largely confined to the visible and near-infrared as a consequence of the limitation in obtaining photoemitters for lower energies. Use of fluorescent phosphors can extend the upper working region of the PMTs to the VUV and beyond. Since they are vacuum-based devices, they are fragile and have to be handled with care.

Solid-state detectors[115] which are almost entirely fabricated from semiconductors have advanced to a state where, in many applications, they are preferable to PMTs. The simplest semiconductor detector is the photoconductor (PC), where absorption of an above-band-gap photon leads to an increase in conductivity. Semiconducting PC detectors are, therefore, sensitive to any radiation with an energy larger than the bandgap. Since the bandgap of semiconductors extends all the way from 0 in HgTe to >5 eV in diamond,[110] detectors that function over a very large energy range can be fabricated. Photovoltaic detectors, as the name implies, employ the photovoltaic effect in a p-n junction and can also detect above-bandgap radiation.

The explosive growth in semiconductor technology that has led to large-scale integration has benefited spectroscopic experimenters directly in the field of detectors. Imaging devices such as the CCD (charge-coupled device) array have been incorporated in spectroscopy. The array detectors combined with a dispersion spectrometer can be used for observing multiple channels simultaneously. This has led to an advantage similar to the multiplex advantage in the Fourier spectrometer. In addition, the low noise levels present in these detectors, particularly when they are cooled, have had a large impact on high-sensitivity spectroscopic analysis. Commercially available CCDs are fabricated and, hence, have a lower energy limit of 0.8 eV, the bandgap of Si. However, some linear and 2D arrays, fabricated from InSb and HgCdTe, with longer wavelength response are also available.

Major Optical Techniques

Advances in semiconductor physics have relied on measuring fundamental material and device properties, measuring the quality of the material, and accurately determining the details of thin films, quantum wells, and other microstructures that control or affect device performance. Properties that need to be determined therefore include basic band structure properties such as energy gaps, the presence and concentration of impurities and defects, alloy parameters, layer thicknesses, homogeneity, and uniformity. A very practical review, "Optical Characterization in Microelectronics Manufacturing" describes in detail six techniques: ellipsometry, infrared spectroscopy, microscopy, modulation spectroscopy, photoluminescence, and Raman scattering.[116] The

discussion of each technique indicates the basic semiconductor quantities measured, gives the scientific basis of the technique, and indicates how the measurement is made. Illustrative examples from the literature are discussed in detail, showing applications to important semiconductor materials.

Much of the basic physics concerning the optical functions of silicon and related materials has been known since the 1950s. Jellison has reviewed the understanding of the physics of optical measurements in the interest of providing the background required for understanding the many optical techniques.[117] The practical value of spectroscopic ellipsometry in gate dielectric metrology for the semiconductor industry is well known and has been documented by Clive Hayzelden.[118] Finally, we point out that there are important applications in real-time monitoring of film growth, etching, and surface modification using spectroscopic ellipsometry measurements with monolayer precision.[119]

Reflection and Transmission/Absorption Measurements of the power reflection, transmission, and absorption, R, T, and A, respectively, are the simplest and most direct methods of spectroscopic analyses of semiconductor materials. The measurements are simple to perform so long as satisfactory spectroscopic apparatus is available in the wavelength region of interest. The major drawback is the less-than-satisfactory absolute accuracies with which the measurements can be performed.

The measurements are usually conducted at near-normal incidence for convenience; normal incidence measurements are difficult to perform and oblique incidence measurements are difficult to analyze. Once the major elements of the spectroscopic system— namely, the source, monochromator, and detector—have been chosen, the R measurements are obtained by directing the light beam on the specimen and measuring the incident and reflected intensities with the detector. The experimental R is determined by ratioing the incident and reflected power, I_0, and I_R, respectively.

$$R = \frac{I_R}{I_0} \tag{68}$$

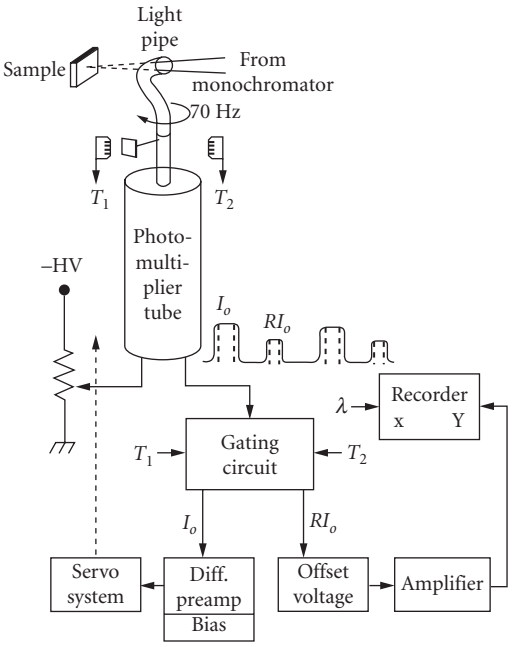
The spectral behavior of the measurement apparatus will not affect the final result so long as they remain fixed during the observation of I_0 and I_R. A change in the source intensity or the response of the detector will be reflected in the measurement. Since the measurement conditions cannot be identical in the two measurements, this is an unavoidable source of error.

Several arrangements have been attempted to minimize such an error. The most direct approach is to hold the optical path fixed and instead of measuring I_0 and I_R; one measures I_{REF}, and I_R, where I_{REF} is the reflected intensity from a well-calibrated reference surface. A ratio of these two measurements leads to the following relationship:

$$\frac{I_R}{I_{\text{REF}}} = \frac{R}{R_{\text{REF}}} \tag{69}$$

A knowledge of R_{REF}, the known reflectivity of the reference surface, may then be used to extract R. This procedure works well and has been employed widely in the infrared region, where reference surfaces from metal mirrors with ≈100 percent reflectivity and stable blackbody sources are available. For the visible and higher-energy regions that use gas lamp sources that tend to be not as stable as blackbody sources, the reference method is not satisfactory. The procedure used to overcome the short-term variations in the lamp intensity was to perform the ratioing at each measurement wavelength. Such a "real-time" ratioing arrangement used a dynamical arrangement with a rotating optical element that directed the light beam alternately to the reference and the sample. Many such configurations were used, and a good example of a particularly ingenious arrangement is presented in Fig. 52. The essence of this rotating light pipe reflectometer[120] was the rotating light pipe that sampled the incident and reflected beam alternately at a frequency of ≈70 Hz, a frequency large enough to remove any errors due to variations in the lamp intensity.

The use of reflectometers for the spectroscopic analysis of semiconductors in the visible and near-visible regions has been limited since the advent of the spectroscopic ellipsometer. However, they are still used at higher energies and in applications where their simplicity makes them attractive, for example, to monitor thin films in semiconductor device fabrication.



Schematic diagram of the system

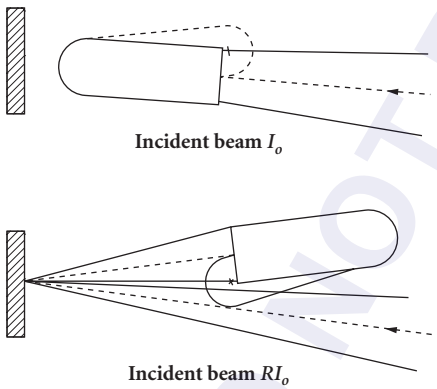


FIGURE 52 Schematic diagram of the rotating light pipe reflectometer and expanded top view showing the geometry of the sample and bent light pipe.[120]

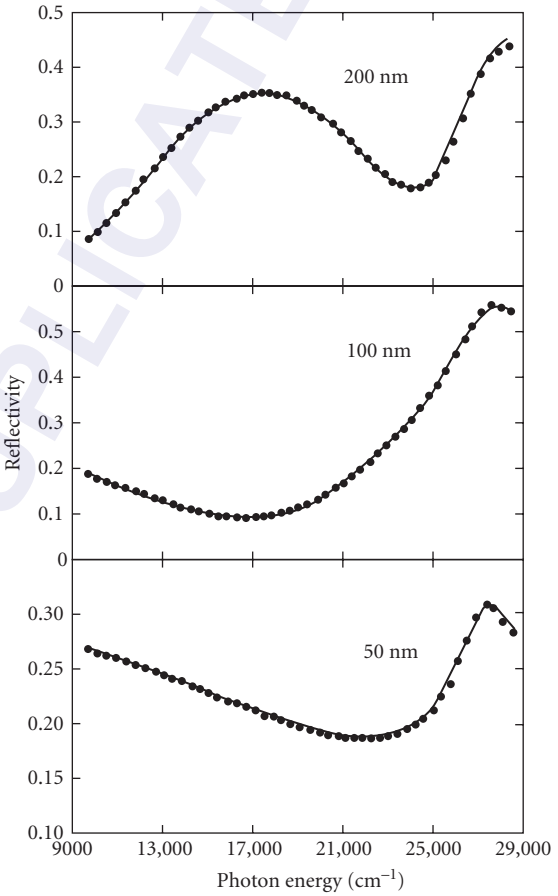

FIGURE 53 Measured (points) and calculated (line) optical reflectivity spectra of silicon dioxide films on silicon.[121]

Recent advances in optics have pushed the energy range of commercial reflectometers to just beyond 10 eV (120 nm) and ellipsometers to just beyond 8 eV (150 nm). Reflectometers and ellipsometers are both currently used for measurement of dielectric film thickness during the manufacture of integrated circuits and other semiconducting multilayer film measurements. The reflectivity spectrum obtained from three SiO_2 films on Si is presented in Fig. 53.[121] The results of the computer fit are also displayed. The thicknesses determined from the reflection analyses agree to within ≈0.5 percent of the values obtained from ellipsometric values. As illustrated in the figure, the change in the spectral shape from the 200-nm-thick film to 100 nm is much greater than that between the

100- and the 50-nm films which points to reducing sensitivity to film thickness determination as the films get thinner. The ultra-precise measurement of film thickness for dielectric films less than 2 nm in thickness requires use of ellipsometry.

The techniques used to measure the transmission spectra are almost identical to those used for reflection except that nature provides a perfect reference, namely, the absence of the sample in the beam. The sample-in/sample-out reference intensity ratioing works satisfactorily. Since transmission measurements are mainly confined to energies below the forbidden gap and hence lower energies covered by blackbody sources, the difficulties faced by high-energy reflectivity analysis have not been as keenly felt.

The absorption of energy of a specimen may be determined from a knowledge of R and T. The most important absorption mechanism is that associated with the electronic transitions discussed previously. The absorption edge spectra for a number of semiconductors were reproduced in Fig. 13. The sub-bandgap region has been studied extensively using absorption spectroscopy where the spectra are dominated by impurity-related effects. The absorption from the electronic transitions associated with a number of impurities in Si was presented earlier in Fig. 33. The impurity-related vibrational features and the lattice phonon bands can be observed as discussed under the section, "Lattice." The collective charge carrier oscillations and impurity to band-type transitions may also be observed in this region.

Modulation Spectroscopy A very useful variation of the reflection and transmission analysis is the use of modulation techniques that produce a periodic perturbation of a property of the specimen or the light beam and detect in-phase changes in R and T. The schematic diagram of a measurement apparatus is presented in Fig. 54.[122] The capacity of lock-in amplifiers for very large amplifications of $> 10^5$ with a concomitant reduction in broadband noise is the heart of the procedure. Modulations in R and T, namely, ΔR and ΔT, of 10^{-5} can be easily detected. This means the modulating perturbation can be quite small and accessible in routine experimental systems. In the simplest cases, the modulation response of a specimen to a property x may be expressed as follows:

$$\Delta R = \frac{dR}{dx} \cdot \Delta x \tag{70}$$

where Δx is the intensity of modulation. The modulated property may be internal to the specimen, such as the temperature and pressure, or external, such as the wavelength or polarization of the probe. The most attractive feature, from a measurement point of view, is the fact that modulation

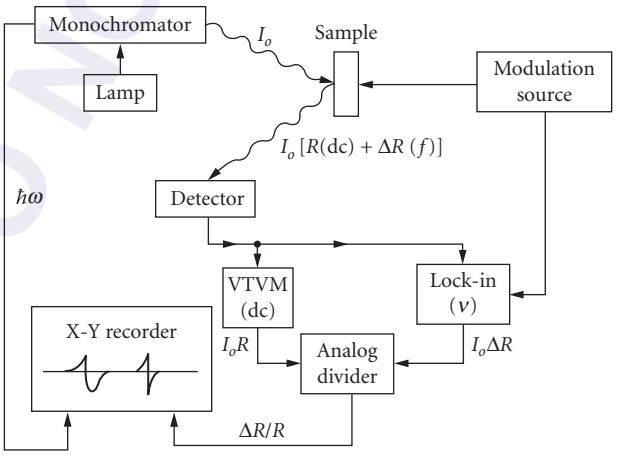

FIGURE 54 Block diagram of a typical modulation spectrometer.[122]

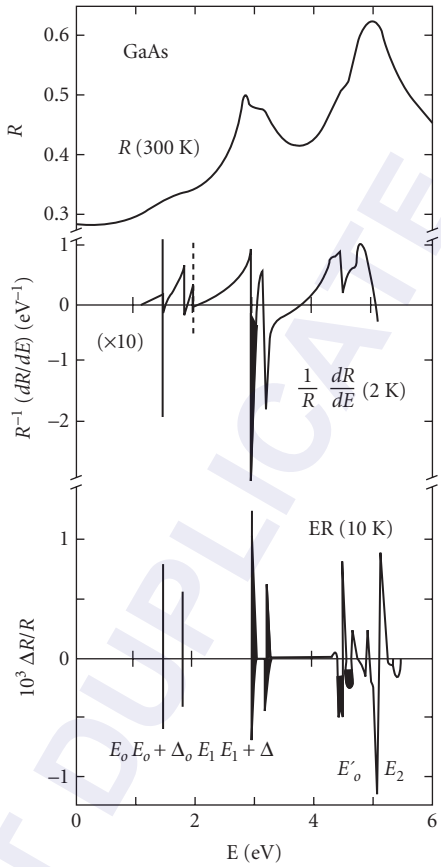

FIGURE 55 A comparison of three types of spectra from 0 to 6 eV for a typical semiconductor, GaAs. *Top:* reflectance *R*; *middle*: energy-derivative reflectance; and *bottom*: low-field electroreflectance.[123]

spectra are derivative-like and hence suppress slowly varying background structure and emphasize features in the vicinity of the critical points in the electronic band structure. Figure 55 presents a comparison of the reflective spectrum of GaAs in the 0 to 6 eV region and a wavelength-modulated spectrum and an electric-field-modulated spectrum.[123] Note the narrow linewidths and larger signal-to-noise ratios in both the WMR (wavelength modulation reflectance) and ER (electroreflectance) spectra. For instance, the $E_0 + \Delta_0$, indistinguishable in *R*, is clearly observable in both WMR and ER. These techniques are crucial in providing accurate values of the interband transition energies, which result in a better understanding of the electronic band structure of a material.

A variety of modulation procedures, underlying mechanisms, measured specimen properties, and other salient features are presented in Table 9.[123] The techniques are broadly classified as internal or external modulation to signify if the perturbation is intrinsic to the measurement approach, as in the case of WMR, or is external, as in the case of ER where an externally applied electric-field modulation is needed at the specimen surface. Temperature, stress, and magnetic-field modulation are included for completion. Compositional modulation that compares two nearly identical alloy samples is less frequently used to investigate semiconductors. Spectroscopic ellipsometry, to be discussed later, may

TABLE 9 Characteristics of Some Commonly Used Modulation Techniques[123]

Technique	Name	Type	Variable	Sample Parameters Affected	Lineshape Type	Principal Parameters Measured	Principal Advantages	Disadvantages
Wavelength modulation: energy derivative reflectance	Internal	Scalar	Wavelength λ; energy $\hbar\omega$	—	1st derivative	E_g, γ	Universal applicability; minimal sample preparation; fast, convenient	Measurement system can generate intrinsic structure, not easy to eliminate
Spectroscopic ellipsometry	Internal	Scalar	Wavelength λ; energy $\hbar\omega$	—	Absolute	Dielectric function	As energy derivative reflectance but on ε_1, ε_2 directly	Strongly influenced by surface preparation and thin films
Composition modulation	Internal	Scalar	Sample compared to control sample	—	Complicated	Doping, alloying effects	Obtains differences for parameters impossible to vary cyclically	Two samples/beam motion involved; alignment and surface preparation critical
Thermomodulation	External	Scalar	Temperature T	Threshold E_g; broadening parameters γ	1st derivative	E_g, γ, dE_g/dT, $d\gamma/dT$	Wide applicability; identifies Fermi-level transitions in metals	Slow response (1–40 Hz); broad spectra
Hydrostatic pressure	External	Scalar	Pressure P	Threshold E_g	1st derivative	Deformation potentials		Cannot be modulated; must be used in conjunction with another technique
Light modulation (photoreflectance) (photovoltage)	External	Scalar or tensor	Intensity I of secondary beam	Carrier concentration or surface electric field	Complicated	E_g	Convenient; minimal sample preparation required	Effect on material usually not well-defined
Uniaxial stress	External	Tensor	Stress X	Threshold E_g; matrix elements	1st derivative	E_g, γ symmetries; deformation potentials	Symmetry determination	Difficult to modulate; limited to high fracture/yield stress materials
Electric field	External	Tensor	Field **E**	Electron energy $E(k)$ oscillations	3rd derivative (low) Franz-Keldysh symmetries (high)	E_g, γ Effective masses in VUV; impurity concentrations	Very high resolution; only high-resolution technique usable	Requires certain resistivity ranges
Magnetic field	External	Tensor	Field **H**	Election energy levels	Landau levels	E_g, effective masses	Extremely high resolution	Advantages realized only for lower conduction band minima

also be considered to be a polarization-modulation technique. Modulation techniques are useful in yielding crystal properties such as the electronic transition energies as well as information regarding the perturbation mechanism such as the electro-optic or magneto-optic effects.

A widely used and very useful form of a modulation technique for the study of semiconductors is the electric-field-modulated reflection spectroscopy, referred to as electroreflectance. The basis of the procedure is the electric-field-induced changes in the optical response.

The electric-field-induced perturbations can be treated in detail by considering the effects of the applied potential on the electronic band structure. For relatively weak fields (i.e., for field strengths not large enough to modify the band structure significantly), the major perturbation mechanism may be considered to be the acceleration of the electron to a successive set of momentum states. The perturbation to $\varepsilon(E, \mathbf{E})$, for such a simple case may be expressed as:[123]

$$\Delta\varepsilon = \frac{(\hbar\Omega)^3}{3E^2}\frac{\partial^3}{\partial E^3}[E^2 \cdot \varepsilon(E)] \tag{71}$$

where E is the energy and

$$(\hbar\Omega)^3 = (e^2\mathbf{E}^2\hbar^2)/(8\mu_{||}) \tag{72}$$

e is the electronic charge, and $\mu_{||}$ the effective mass parallel to **E**.

When the field is large, the electroreflectance spectra display oscillatory structure, known as Franz-Keldysh oscillations, and $\Delta R/R$ has a more complicated functional form that can be found in Ref. 124.

In practical terms, the oscillations may be analyzed to determine $\hbar\Omega$ and, hence, the strength of the electric field that causes the perturbation.

A particularly attractive and widely used form of electroreflectance is the contactless form of electric-field-modulated reflectivity known as photoreflectance (PR).[125] In this procedure, one uses the electric-field modulation produced near the surface of the specimen by a chopped laser beam to modulate the reflectivity of a weak probe beam. PR is observable when there is band bending at the surface of the semiconductor such as that observed in damaged oxide layers on silicon.[126,127]

The sharp features in the PR spectrum associated with the critical points in the electronic density of states including the direct gap E_g may be employed to determine the transition's energies accurately. The information obtained using ER and PR was instrumental in leading to a detailed understanding of the band structure of semiconductors. The variation of the critical point energies with alloy composition has been used to understand the electronic behavior as well as characterize semiconductor alloys.[128] Similar studies have been used extensively in the study of microstructures, where PR is particularly useful since it allows the observation of the gap as well as several additional higher-energy transitions as shown in Fig. 56.[129] Distinct transition from both the well and the barrier region can be observed, and, hence, a complete picture of the microstructure can be obtained. The electric-field-induced Franz-Keldysh oscillations in the ER and PR line shapes have been used to establish the electric field strengths,[124,130] and, more recently, a similar technique has been used to measure the electric field strength in the surface region of GaAs and the effects of passivation[130] as shown in Fig. 57. The electric field strength can be determined from the slope of the inset in Fig. 57. Since PR measurements can be performed at room temperature with minimal sample preparation, it is attractive for routine characterization. Commercial PR spectrometers are now available for use in semiconductor fabrication. Several excellent reviews of the applications of PR are available. A compilation of activity may be found in the Proceedings of the 1990 International Conference on Modulation Spectroscopy[131] and the review by Glembocki and Shanabrook,[132] and the reader is referred to them for more details. A more recent reference is the third International Workshop on Modulation Spectroscopy of Semiconductor Structures, July 3–5, 2008, Wrocław, Poland.

Ellipsometry The reflection and transmission measurements discussed in the previous section consider the ratio of the incident to the reflected or transmitted optical power and hence ignore

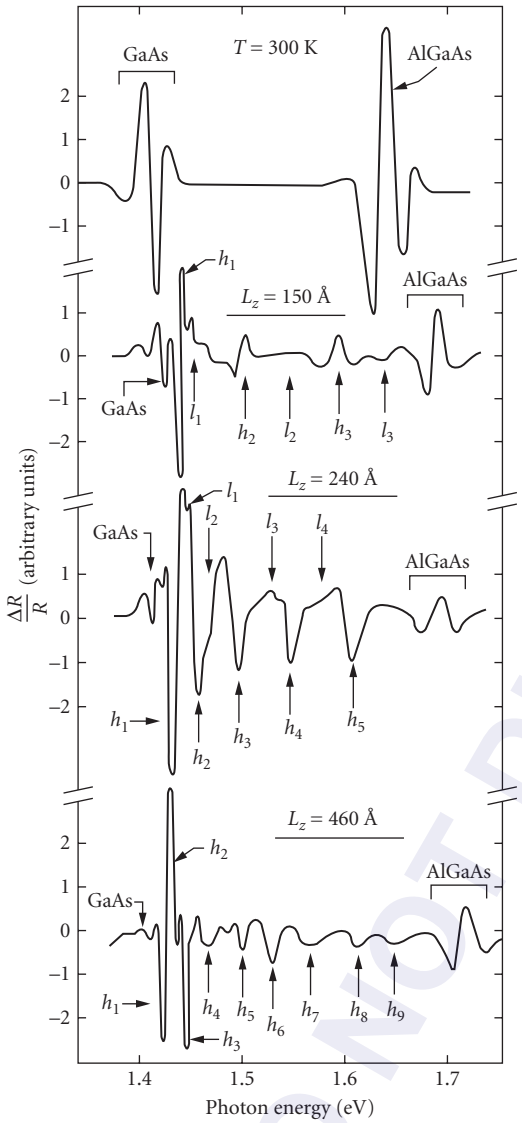

FIGURE 56 Room-temperature PR spectra for an undoped GaAs/Al_xGa_{1-x} As heterojunction and three multiple quantum-well samples with $x \approx 0.2$, L_z is the well thickness, and arrows labeled h_1, h_2, . . . (l_1, l_2, . . .) correspond to calculated values of interband transitions involving heavy (light) hole valence bands.[129]

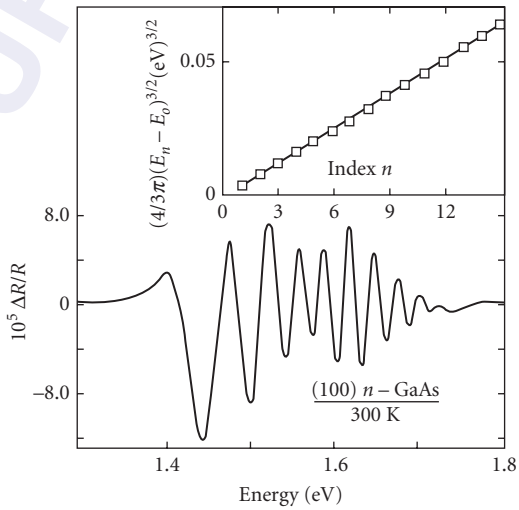

FIGURE 57 Photoreflectance spectrum at room temperature with I_{pump} = 3 μW/cm² and I_{probe} = 2 μW/cm². The inset shows a plot of $(4/3\pi)(E_n - E_o)^{3/2}$ as a function of index n. The slope of the line in the inset yields the electrical field strength.[130]

any information carried by the phase change suffered by the incident beam. A complete description of the reflection or transmission process will have to include the phase information as well. Ellipsometry attempts to obtain part of the phase information by measuring the phase difference, introduced upon reflection, between the normal components of obliquely incident plane-polarized

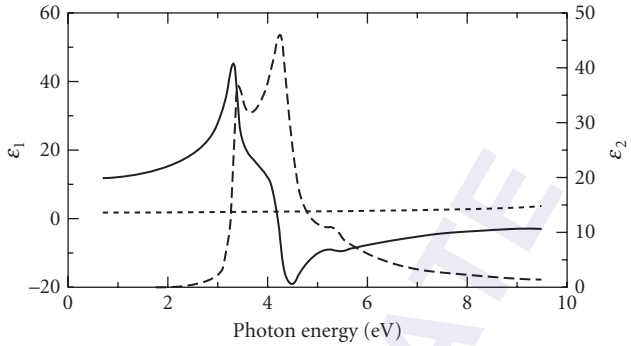

FIGURE 58 Real (solid) and imaginary (dashed) parts of the dielectric function of Si determined using VUV spectroscopic ellipsometry. For comparison, the real part of the dielectric function of SiO_2 is given by the short-dashed line.[138]

light. Even though the absolute phase suffered by each component is not measured, the phase difference may be measured easily as an ellipticity in the polarization state of the reflected light, hence, the name ellipsometry. Recent developments in ellipsometry as well as handbooks covering practical applications can be found in Refs. 133, 134, 135, 136, and 137.

The intrinsic sensitivity of ellipsometry may be illustrated by considering a thin film with thickness d, refractive index n, and measurement wavelength λ. The phase change in the reflected component can be measured to a precision of 0.001° in ellipsometers which translates to a sensitivity of approximately $10^{-4}\lambda$ in thickness. Such extraordinary precision may be used for the study of submonolayer films or as a real-time monitor for measuring very small changes in materials' properties. With recent advances in instrumentation, the lower wavelength limit has been extended to below 135 nm (9.5 eV). As an example, Figure 58 shows the dielectric functions of Si and SiO_2 between 0.7 eV and 9.5 eV. Due to the extended spectral limit into the VUV, ellipsometry has become attractive to study wide-bandgap semiconductors, insulators, oxides, and very thin films.[138]

Recent extensions of ellipsometry to long wavelength now permit investigation of lattice vibrations (phonons) and free-charge carriers (plasmons) in complex semiconductor layer structures.[139] The infrared dielectric function is sensitive to strain, composition, and ordering. Furthermore, concentration, mobility, and effective mass parameters can be determined from far-infrared magneto-optic generalized ellipsometry measurements.[140–143.] Even the sign of the free-charge carrier can be determined, just as in an electrical Hall effect measurement. Finally, magneto-optic generalized ellipsometry has even been extended into the terahertz frequency domain using an intense terahertz synchrotron source at wavelengths from approximately 30 to 270 cm^{-1} (0.9–8.1 THz).[144] Even Landau transitions could be seen in a two-dimensionally confined electron system in a grapheme sample.

Luminescence The process of luminescence, as described earlier, occurs in a suitably excited specimen. It is a mechanism through which the excited specimen relaxes to the equilibrium state.[108,109] Hence, unlike reflection and transmission spectroscopies, luminescence procedures concentrate on the relaxation of the specimen and often lead to complementary information. For instance, impurities in semiconductors (particularly at low concentrations) are impossible to detect through reflection and more difficult to detect by absorption than by luminescence. Luminescence spectroscopy is thus an important part of the analysis of the optical behavior of semiconductors.[108] Moreover, since one of the main applications of semiconductors is in the arena of light emitters including lasers, the study of luminescence provides direct access to device optoelectronic information.

Luminescence processes may be induced by excitations that produce free electron-hole (e-h) pairs that may recombine across the bandgap or through defect- and impurity-related intermediate steps and emit a photon. The excitations employed most often are (1) an incident intense above-bandgap radiation such as from a laser source, (2) an incident electron beam, (3) electrical injection of electrons and/or holes through an appropriate contact, and (4) thermal excitation. These procedures are known as photoluminescence (PL), cathodoluminescence (CL),[145] electroluminescence (EL),[146] and thermoluminescence (TL), respectively. The most widely used technique for the analysis of semiconductor materials is PL. Cathodoluminescence measurements are usually conducted in a scanning electron microscope (SEM). The SEM electron beam can be focused to a spot size 1000 Å and can be scanned over the area of the sample. Hence, much work has been performed in CL imaging of wafers where one can obtain not only spectroscopic information but also spatial details. Electroluminescence is the most difficult to obtain because of the complexity of producing appropriate contacts. However, in terms of application, EL is the most important since a light emitter has to be able to produce light in an efficient manner under electrical excitation. Thermoluminescence is a technique used with insulators and wide-gap materials and is not widely employed in the analysis of the commercially important materials such as GaAs and Si. The principles of luminescence and the optical information regarding the semiconductor that can be obtained are discussed in the next section using PL.

Photoluminescence Luminescence processes may be excited using an above-bandgap-beam of light that leads to the creation of an electron-hole pair that may recombine across the gap and emit a photon with energy equal to the gap E_g. This process is schematically displayed in Fig. 59.[109] Two

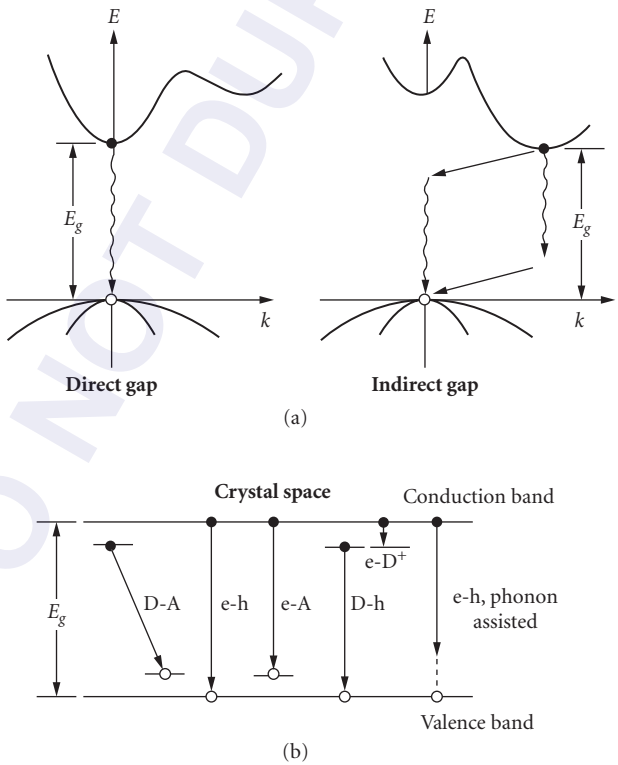

FIGURE 59 Schematic of photoexcitation and relaxation in semiconductors.[109]

possibilities are shown: namely, the direct-gap and the indirect-gap semiconductors. The recombination will be direct in the former and will have to involve an additional participant, mostly a phonon, to conserve momentum in the latter. This is the simplest possible recombination mechanism. Several additional routes exist for the relaxation that involves impurities. The photoexcited charges may recombine with ionized acceptors (A) and donors (D) with or without involving a phonon. The process may also be more complicated where, for example, an electron may be trapped by an ionized donor which may subsequently recombine with a hole at a neutral acceptor, leading to a donor-acceptor pair (DAP) transition. In addition, recombination may also occur through the annihilation of excitons considered further in this section.

Excitons, as discussed earlier, are hydrogen-like two-particle electron-hole combinations that are not included in the one-electron energy band description of the solid. The strong Coulomb interaction between the electron and the hole leads to the excitonic coupling.

As the excitation intensity increases, so does the population of the excitons. Higher-order interactions can occur between excitons and entities, such as biexcitons, and may be observed. Under intense excitation, the electrons and holes form a liquid state known as the electron-hole liquid. The presence of impurities and defects can also significantly alter the nature of the luminescence spectra, in particular the excitonic behavior. The electric field in the vicinity of the impurity can trap and localize excitons. Such an interaction leads to bound excitons; the binding energy of the bound exciton E_{BE} will, in addition to E_{ex} given in Eq. (37), contain a localization part as shown:

$$E_{BE} = E_{ex} + \delta \tag{73}$$

The impurity potential that confines an exciton to a given center depends on both the impurity and its local environment. Hence, the impurity-bound excitonic features can be very rich and informative. A detailed knowledge of the PL excitonic spectrum may be used to identify both the chemical species and its environment, as is demonstrated later on. The observed luminescent photon energy at low temperatures may be written as

$$E = E_g - E_{BE} \tag{74}$$

Transitions from a free electron or hole to a neutral acceptor or donor, respectively, will occur at the following energies:

$$E = E_g - E_{ion} \tag{75}$$

where E_{ion} is the relevant ionization energy. A complete description of the free-to-bound transition will have to take into account both the dispersion of the band in the vicinity of the minima and the population distribution. For the donor-to-acceptor transition, an additional electrostatic energy term $e^2/\varepsilon(0)r_{sep}$ will have to be accounted for as shown:

$$E = E_g - (E_A + E_D) + \frac{e^2}{\varepsilon(0)} r_{sep} \tag{76}$$

where r_{sep} is the distance that separates the two participating centers. The last term is needed to account for the electrostatic energy of the final ionized state of both centers. All of the transitions discussed may occur with phonon participation, and hence the emission energies should be reduced by the quantum of the energy of the phonon; multiple phonons may also be involved in more complex spectra.

The measurement of PL is, in most cases, routine and straightforward, which partly accounts for its popularity as a materials characterization technique. The laser provides the excitation and the

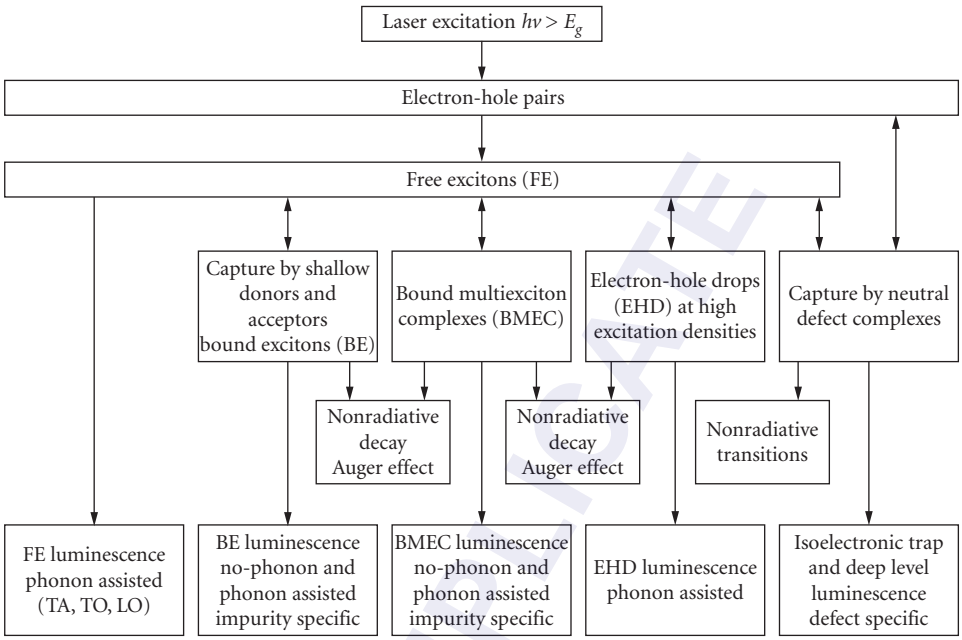

FIGURE 60 Luminescence decay processes stimulated by above-bandgap photoexcitation in high-purity Si.[147]

dispersive spectrometer along with a sensitive detector, the detection. The sample should be cooled to ≈5 K so that the temperature-induced broadening is kept to a minimum and the population of the processes with a small activation energy, such as the excitons, is sufficiently high to perform accurate measurements. Photoluminescence measurements may also be performed using Fourier transform (FT) spectrometers. The main advantage is the extraordinary resolution that can be achieved with the FT systems.

The extension of PL into a tool with quantitative accuracy, particularly in very high-purity Si, has demonstrated the versatility of the analysis.[147] The paths of luminescence decay in high-purity Si are schematically presented in Fig. 60. The first step in the excitation process is the creation of electron-hole pairs, which subsequently can undergo a wide variety of processes before recombination. Figure 60 represents the possible intermediate states that eventually lead to radiative recombinations. A typical spectrum obtained from a sample containing 1.3×10^{13} cm^{-3} B, 1.8×10^{12} cm^{-3} P, and 3×10^{11} cm^{-3}, As is presented in Fig. 61.[147] The spectrum displays both the no-phonon (NP) component (shown as an inset) and TA, TO, and LO phonon-assisted features for the free exciton (FE) and the impurity-related bound exciton features. The measurement was performed at 4.2 K. Since B is an acceptor and P and As are donors in Si, electrical transport analyses are not sufficient to fully analyze the impurities. In contrast, all three impurities can be unambiguously identified using PL. In addition, when dependable calibration curves are available, the concentration of each species can also be established. A representative calibration curve is presented in Fig. 62 for the impurities B, Al, and P.[147] Note that quantitative measurements can be performed down to 10^{12} cm^{-3} for all three impurities. In the case of B, in ultrapure samples, measurements can be performed to levels as low as ~10^{10} cm^{-3}.

Next, we turn our attention to GaAs, which is a direct-bandgap material and hence exhibits efficient luminescence. Figure 63*a* displays a representative spectrum from a high-quality MOCVD-grown sample doped with C and Zn measured using an FT spectrometer.[148] The spectra shown are intense, sharp, and well-resolved near the band edge, with excitonic features appearing slightly below

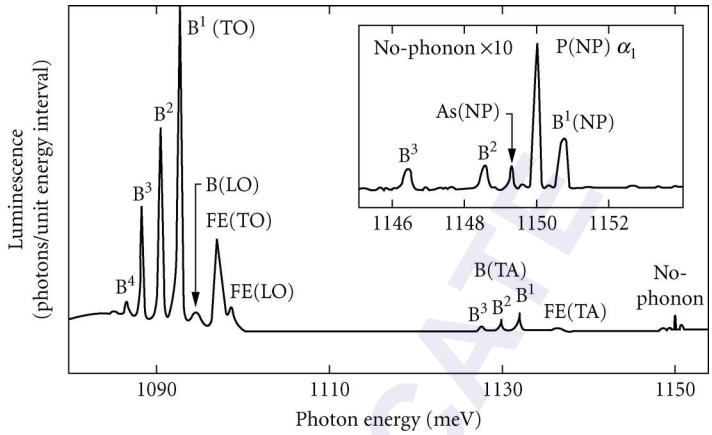

FIGURE 61 Photoluminescence spectrum from a Si sample doped with 1.3×10^{13} cm^{-3} B, contaminated with 1.8×10^{12} cm^{-3} P, and 3×10^{11} cm^{-3} As.[147]

the band gap of ≈1.519 eV at 4.2 K. The near-edge features, labeled (A^0, X) and (D^0, X), are due to excitons bound to neutral donors and acceptors, and the deeper-lying features are the free-to-bound transition to the C acceptor, (e, C^0) and the donor-acceptor-pair transitions, (D^0, Zn^0), and (D^0, C^0), to the Zn and C centers, respectively. An expanded high-resolution version of the same spectrum, in the vicinity of (A^0, X) region, is displayed in Fig. 63*b*.[148] Note the impressive resolution obtainable in the FT system and the clear resolution of the excited states associated with the bound exciton.

The use of PL techniques may be extended deeper in the infrared region as well. Deep levels associated with impurities such as Fe, Cr, and Ag in GaAs are known to produce luminescence bands at ~0.35, ~0.6, and ~1.2 eV.[149] The narrow-gap semiconductors such as InAs, InSb, and HgCdTe luminesce in the 100 to 200 meV region farther into the infrared region. An example of the PL spectra observed from $Hg_{0.78}Cd_{0.22}$ Te narrow-gap alloy[150] is displayed in Fig. 64. The spectra, in comparison to those presented earlier, are rather featureless due to the fact that the effective masses in the

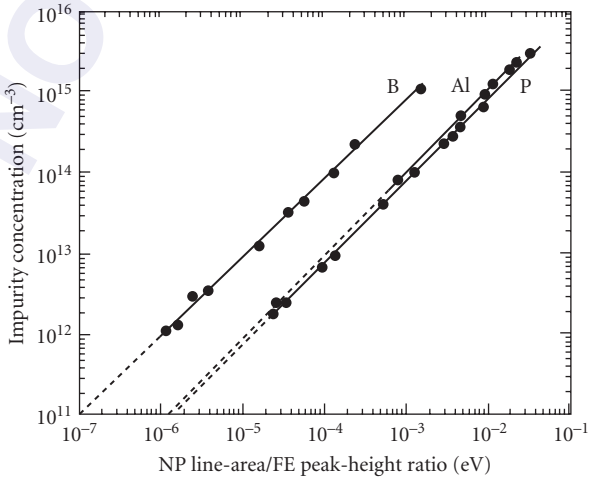

FIGURE 62 Calibration of the photoluminescence technique for measuring B, P, and Al concentrations in Si.[147]

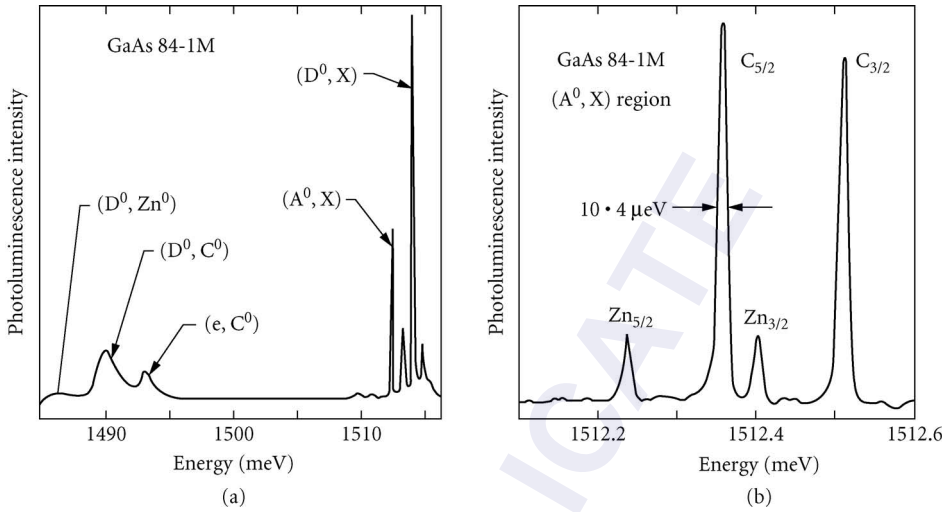

FIGURE 63 (*a*) Representative PL spectrum from MOCVD-grown GaAs.[148] (*b*) High-resolution, near-band edge spectrum of the same sample as in (*a*).[148]

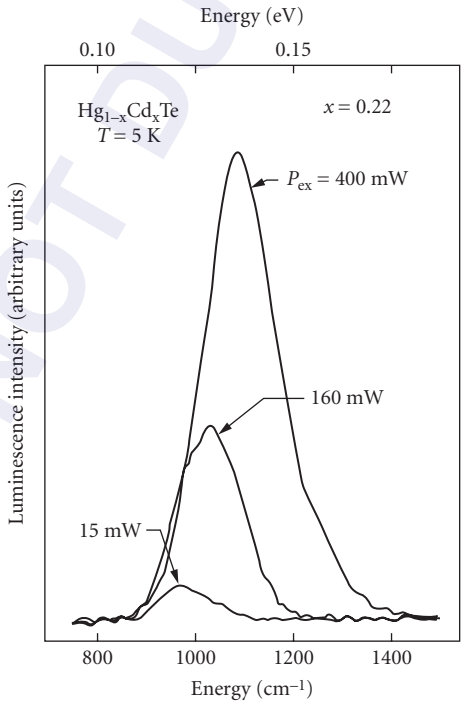

FIGURE 64 Luminescence spectra from $Hg_{0.78}$– $Cd_{0.22}Te$ measured at 6 K for different 1.06 μm excitation power.[150]

narrow-gap semiconductors tend to be small, and hence the excitonic binding energies are small as well. Therefore, sharp, well-resolved spectra are not normally observed. The observation of luminescence is much more difficult in narrow-gap semiconductors.

The luminescence processes described provide information on the relaxation mechanisms and hence are heavily weighted toward transitions that involve only the first excited state and the final ground state of a system. A complete study of a recombination process, for instance the FE, requires information regarding the higher excited states. This can be achieved by a variation of the PL procedure known as photoluminescence excitation (PLE) spectroscopy. The crux of this technique is to concentrate on the PL response with respect to the excitation wavelength and thereby to determine the excitation resonances. Since the resonances occur when the excitation photon energy matches the excited energies, information regarding the excited states may be elucidated. The principle is illustrated with Fig. 65, where an attempt is made to determine the process that the photoexcited electron-hole pair undergoes before the formation of a free exciton in high-purity CdTe.[151] The spectrometer was set to the FE energy of 1.596 eV, and the excitation photon energy was scanned from 1.6 to ~1.8 eV. The excitation wavelength may be scanned using a dye laser as shown in Fig. 65. Two PLE spectra obtained at 1.8 and 20.6 K are displayed in Fig. 65. The strong oscillatory behavior, with spacing of 21 meV, demonstrates a cascade process through intermediate states separated by the LO phonon energy of 21 meV. This study illustrates the importance of the LO phonon in the electron-hole relaxation process and yields information regarding electronic states that lie above the conduction band extremum, involving the hot electron behavior.

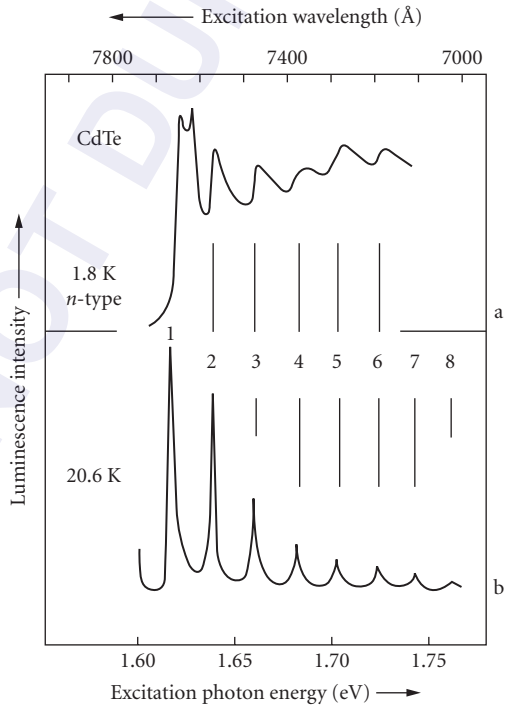

FIGURE 65 Excitation spectra of exciton luminescence of the emission line at 1.596 eV in the energy region higher than the bandgap of CdTe: (*a*) a pure *n*-type sample at 1.8 K and (*b*) the sample at 20.6 K.[151]

Inelastic Light Scattering (Raman and Brillouin) The elastic interaction of the incident photon with the specimen implies a process where the energy or wavelength of the photon is preserved. For instance, reflection and transmission spectroscopies involve the measurement of the fraction of the incident beam that is reflected or transmitted with no change in the incident wavelength. The vast majority of the incident photons undergo only elastic interactions, but a tiny fraction, of the order of ~10^{-8}, are subjected to inelastic scattering. Inelastic interactions, though very few, are extremely important as probes of the properties of the specimen. The advent of high-powered coherent laser sources and sensitive detectors has made the measurement of the scattered spectra straightforward, leading to an explosive growth in the last 20 years. Several excellent reviews may be found in the five volumes on light scattering, edited by Cardona and Guntherodt.[152] A good introduction to the procedure and theory may be found in Ref. 153.

The experimental procedure involves projecting a high-power laser beam onto a specimen, collecting the back-scattered light, and performing a spectrum analysis and detection. Multiple-dispersion stages are needed for improved resolution and filtering out of the unwanted elastically scattered beam. A typical set of spectra measured from GaAs[68] is presented in Fig. 66. The axes for the spectra are the detected intensity and the frequency shift suffered by the incident light. The intense peak at 0 cm^{-1} is the elastically scattered peak. The spectrum at the room temperature of ~300 K displays both the frequency up-shifted and down-shifted components labeled as Stokes and anti-Stokes features corresponding to the TO phonon interaction; these correspond to microscopic processes where the incident photon loses or gains energy due to TO phonon emission or absorption, respectively. At lower temperatures, additional features labeled L_+ and L_- appear near the TO peak as well as a broad feature in the 0 to 100 cm^{-1} region. These features originate from charge carriers and were discussed in earlier sections.

The inelastic scattering techniques are usually divided into two categories, namely, Brillouin and Raman scattering. The former covers low frequencies extending from 0 to ~10 cm^{-1}, while the latter spans the higher frequencies. The low-frequency Brillouin scattering measurements provide access to information on properties of acoustic phonons, spin waves, etc., and involve the use of specialized spectrometers needed to remove the very intense elastic peak.[154] The position of the elastic peak is taken to be the reference zero position, and the scattered spectrum is measured with respect to the zero position; that is, the spectrum is recorded as a function of the frequency shift and not the absolute frequency. Raman scattering is, in general, easier to perform and more informative for the study of semiconductors and hence is emphasized in this section.

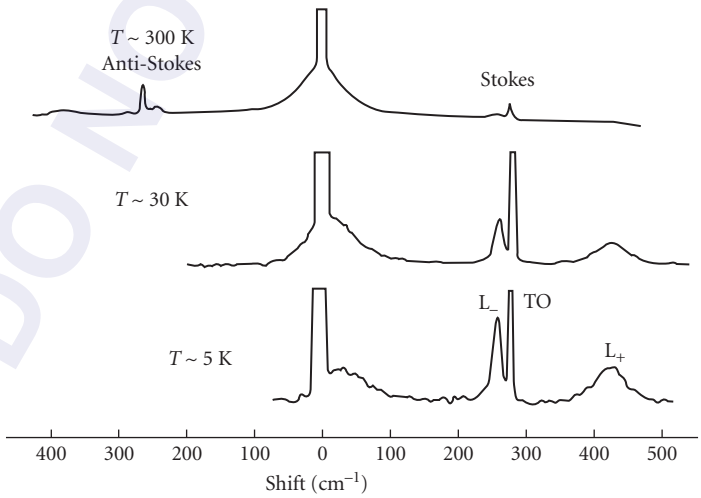

FIGURE 66 Typical Raman spectrum in GaAs, with $n = 1.4 \times 10^{18}$ cm^{-3}, at 300, 30, and 5 K showing the lineshape change with temperature.[69]

The techniques reviewed so far all involve first-order interactions that provide direct information regarding the electronic, vibrational, and impurity-related behavior of semiconductors. In contrast, inelastic light scattering such as Raman and Brillouin scattering involves the electron-phonon or other quasi-particle interactions and hence can provide additional information regarding these interactions. In addition, since inelastic scattering involves a higher-order interaction, processes that are inactive in first-order may be investigated. For instance, the optical phonons in Si do not possess a dipole moment and therefore do not interact with infrared radiation but can be clearly observed in Raman scattering.

The response of the specimen may be expressed, through the susceptibility χ.[155] However, the presence of the inelastic interactions will give rise to additional contributions. Consider the example of lattice vibrations and their influence on χ in the visible-frequency range. Since the lattice vibrational frequencies correspond to far-infrared light frequencies, no direct contribution is expected. However, the lattice vibrations can influence χ even in the visible-frequency range in an indirect fashion by a small amount. The influence of this interaction may be expressed as follows:

$$\chi = \chi_0 + \sum_i \frac{\partial \chi}{\partial u_i} \cdot \mathbf{u}_i + \sum_{i,j} \frac{\partial^2 \chi}{\partial u_i \partial u_j} \mathbf{u}_i \mathbf{u}_j + \cdots \tag{77}$$

where $\mathbf{u}_i$ and $\mathbf{u}_j$ are the displacements associated with the normal modes of lattice vibrations or phonons. The first term contains the elastic term, and the second and third terms denote the second- and third-order inelastic interactions with the phonons. Note that the form of χ shown here differs from that used previously in nonlinear optics because it is expressed explicitly in terms of the phonon coordinates. Assuming sinusoidal oscillations for the incident radiation $\mathbf{E}$ and the phonons $\mathbf{u}_j$, the polarization induced in the specimen may be expressed as follows:

$$\mathbf{P} = \chi_o \mathbf{E}_o \exp(i\omega_o t) + \sum_i \chi' u_{io} \exp\{i(\omega_o \pm \omega_i)t\} + \sum_{ij} \chi'' u_{io} u_{jo} \exp\{i(\omega_o \pm \omega_i \pm \omega_j)\}t \tag{78}$$

The source of the inelastically scattered or frequency-shifted components is immediately apparent.

The scattered intensity, assuming only second-order interactions, is usually expressed in terms of a differential cross section; that is, scattered energy per unit time in the solid angle $d\Omega$ as follows:

$$\frac{d\sigma}{d\Omega} = V^2 \left(\frac{\omega_s}{c}\right)^4 \hat{\mathbf{e}}_i \chi' \hat{\mathbf{e}}_s \begin{cases} n_j & \text{Stokes} \\ (n_j + 1) & \text{Anti-Stokes} \end{cases} \tag{79}$$

where $\hat{\mathbf{e}}_i$ and $\hat{\mathbf{e}}_s$ denote the polarization state of the scattered and incident light, ω_s the frequency of the scattered beam, and V the scattering volume.

χ' and χ'' are Raman tensors whose symmetry properties may be calculated from a knowledge of the structure of the crystals.[156] The notation used to express the combination of incident and scattered beam directions and polarizations is as follows: $a(b, c)d$, where a and d denote the incident and scattered directions, and b and c denote the respective polarizations. Using the cubic crystal axes x, y, and z, the selection rules may be expressed as follows.

Back scattering from (100) surface:

TO—disallowed for any combination of incident and scattered beam configurations

LO—allowed only for crossed polarizations; that is, $z(x, y)\,\bar{z}$ and $z(y, x)\,\bar{z}$, where $\bar{z}$ is the opposite direction to z.

Similar selection rules may be derived for other orientations and crystal structures.

A microscopic description of the scattering event considers quantum mechanical details using perturbation theory. The incident photon with frequency ω_i and wave vector $\mathbf{k}_i$ produces a transition from the initial state i to a virtual state b where the incident photon is annihilated, followed by a transition to the final state f, accompanied by the emission of the "scattered" photon with frequency and wave vector $\boldsymbol{\omega}_s$ and $\mathbf{q}_s$, respectively. The entire process is part of a complete quantum mechanical event and will be governed by momentum, energy, and symmetry conservation rules shown as

$$\begin{aligned} \hbar\omega_i &= \hbar\boldsymbol{\omega}_s \pm \hbar\Omega \\ \hbar\mathbf{q}_i &= \hbar\mathbf{q}_s \pm \hbar\mathbf{K} \end{aligned} \tag{80}$$

where Ω and $\mathbf{K}$ denote the frequency and wave vector of the participating phonon. The exact forms of the scattering cross section will depend on the details of the interactions and are reviewed in Ref. 153.

One of the most powerful aspects of Raman scattering is the ability to perform resonance excitation. When the incident photon energy or the scattered photon energy matches an intrinsic excitation energy, a substantial increase in the scattered intensity is observed. This ability to resonate has been used for both an understanding of the details of the scattering process and applications in which the source of the scattering can be selected. For instance, the study of a particular impurity in a large matrix may be conducted by tuning the resonance to match that of the impurity. Examples of resonance studies are discussed in the following sections.

The power and versatility of Raman scattering to probe many important properties of semiconductors have been exploited for a wide variety of characterizations. Figure 67 schematically displays

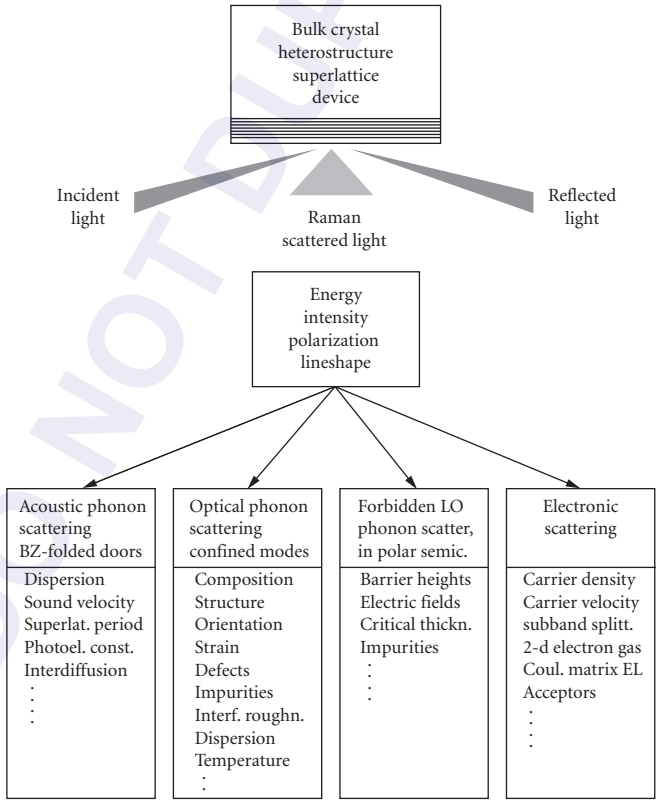

FIGURE 67 Schematics of inelastic light scattering and information which can be extracted from such measurements.[157]

the broad areas where Raman scattering has been employed.[157] The study of materials, devices, and microstructural properties include chemical, structural, and electronic properties. The developments in microscopic measurements and analysis have opened up new applications as well. The measurement of the temperature in a spot ≈1 μm in diameter is one such example that is discussed in the following sections.

The most dominant Raman-scattering mechanism in semiconductors is that due to phonons—in particular, the optical phonons at the center of the Brillouin zone—namely, TO (Γ) and LO (Γ). Even though a semiconductor crystal can support a variety of vibrations, the momentum conservation requirements restrict the interaction of the incident photon to only the TO (Γ) and LO (Γ). The position and shape of the spectra contain important information regarding the structural state of the material: the presence of strain will be reflected as shifts in the line position; degraded crystal quality due to multiple grains and concomitant distributed strain will lead to a broadening of the lineshape. The effects of crystal damage on the Raman spectrum as a result of ion implantation in GaAs is displayed in Fig. 68.[158] Note the large increase in the linewidth of the LO (Γ) feature. In addition, a series of new structures, not present in the undamaged sample, can also be observed. These have been interpreted to be the result of relaxing the momentum conservation laws and hence the activation of phonon-scattering processes not normally allowed in a good crystal. A simple interpretation of the broadening of the LO lineshape was provided using a phonon confinement model, where the LO phonon is described as being confined to small damage-free regions. The shift

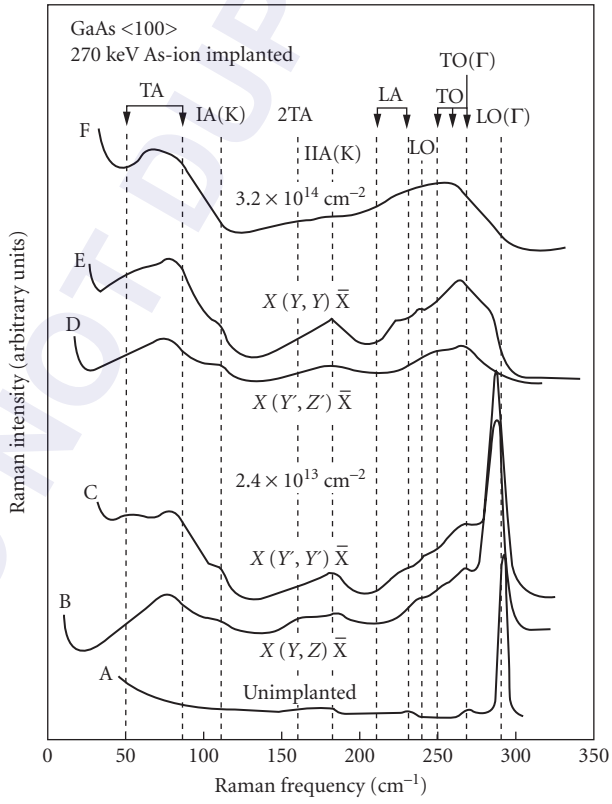

FIGURE 68 Raman spectra of ⟨100⟩ GaAs before implantation (A), implanted to a fluence of 2.4×10^{13} cm^{-2} for various polarization configurations (B, C, D, and E) and a fluence of 3.2×10^{14} cm^{-2} (F).[158]

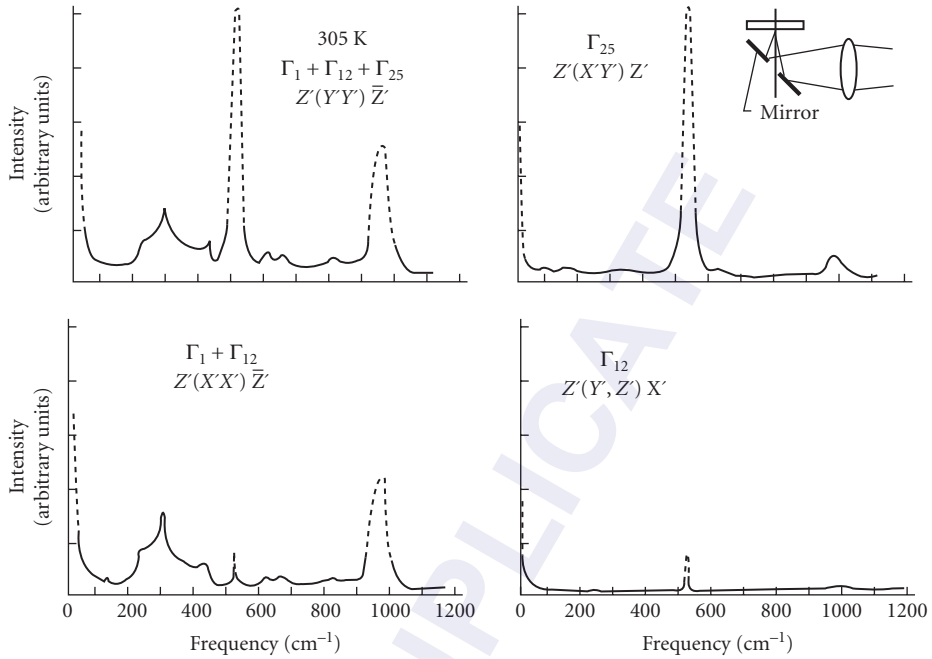

FIGURE 69 The Raman spectra of Si at room temperature showing the multiphonon contributions. The polarization configuration and the representations which were possible contributors to the spectra are shown for each of the four spectra.[159]

in the position of the LO peak and the full-width-at-half-maximum were related to the diameter of the undamaged region. The information obtained is useful in characterizing lattice damage, amorphous materials, and degrees of recovery during annealing.

As explained earlier, Raman processes can involve higher-order interactions that involve more than one phonon. Hence, multiphonon scattering can be performed, and information complementary to that discussed in the section entitled "Lattice" on the infrared absorption properties can be obtained. The Raman spectra obtained from Si[159] are displayed in Fig. 69. The spectra were recorded at room temperature where $X' = (100)$, $Y' = (011)$, and $Z' = (0\bar{1}1)$. The irreducible representation of the phonons involved is also noted in the figure. Note the strong peak at ~522 cm^{-1} which is due to the degenerate TO(Γ)/LO(Γ) phonons that are not observable in infrared absorption measurements. Additional bands present in the 200 to 400 cm^{-1} and the 600 to 1000 cm^{-1} range are due to multiphonon scattering processes. The ability to employ polarization selection rules has been used effectively to isolate the symmetry character of the underlying vibrational features and can be used to eventually identify the source of the various features. Such studies are useful both in understanding the optical behavior of Si and in illuminating the lattice dynamical properties of the material.

In crystals that contain a substantial number of free carriers, the incident photon can scatter off collective charge oscillations, known as plasmons, as discussed earlier. The Raman spectra measured from three GaAs samples[160] with electron densities ranging from 1.95×10^{18} to 6.75×10^{18} cm^{-3} are presented in Fig. 70. The observed features in addition to the LO phonon peak at ~293 cm^{-1} are due to the coupled LO phonon-plasmon features, also discussed earlier. The variation of the L_+ mode frequencies with the carrier density may be calculated and compared to measurements, as was shown in Fig. 32. The shape of the L_+ and the L_- features can be used to deduce the mobility of the carriers as well. The uniqueness of the Raman results is that they can be employed to study the behavior of carriers near the

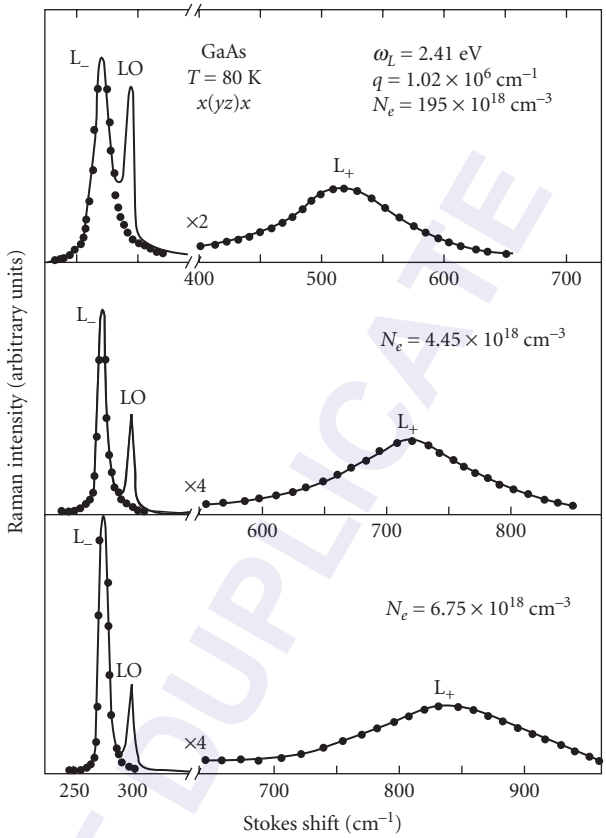

FIGURE 70 Raman spectra of three different *n*-GaAs samples obtained in backscattering geometry from (100) surfaces showing the coupled plasmon-LO phonon modes.[160]

surface. Since the incident laser light with a photon energy of ~2.5 eV penetrates only 1000 Å into the sample, the Raman results represent only the behavior of this near-surface region.

The single-particle nature of the free carriers can also be probed by Raman scattering.[69] The mechanism responsible for the interaction is the scattering of the carriers from inside the Fermi-surface to momentum states that lie outside, the total change in momentum being equal to that imparted by the photons. The integrated effect in the case of the spherical Fermi-surface in GaAs is displayed in Fig. 71. The Fermi wave vector is denoted by $\mathbf{p}_F$ and that of the electron is $\mathbf{p}$. The wave-vector change as a result of the scattering is $\mathbf{q}$. Two cases of small and large $\mathbf{q}$ and the resultant single-particle spectrum at 0 K are shown. The net effect in the first case will be a linear increase followed by a rapid fall, and, when $\mathbf{q}$ is large, the spectrum displays a band-like behavior as shown. The single-particle spectrum measured from a sample of *n*-GaAs[161] is presented in Fig. 72. The measurements were performed using the 6471 Å line of the Kr^+ laser at 10 K. The ability to probe the Fermi sphere directly, using a spectroscopic technique, can lead to valuable insights into the electronic distributions that are complementary to those obtained from transport studies that usually provide only information regarding integrated effects of all the carriers.

The effect of resonance enhancement, as mentioned earlier, is one of the most powerful features of Raman scattering. The effect can be illustrated with the variation of the scattering intensity of the

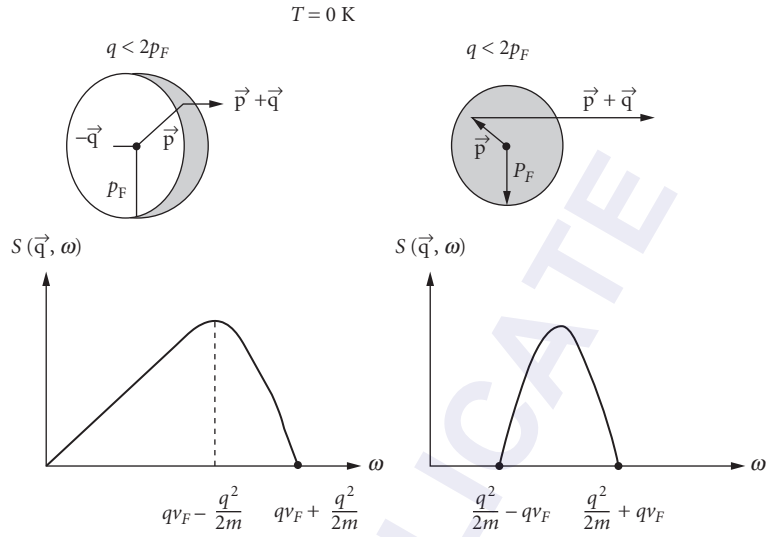

FIGURE 71 Single-particle excitation spectrum at 0 K.[69]

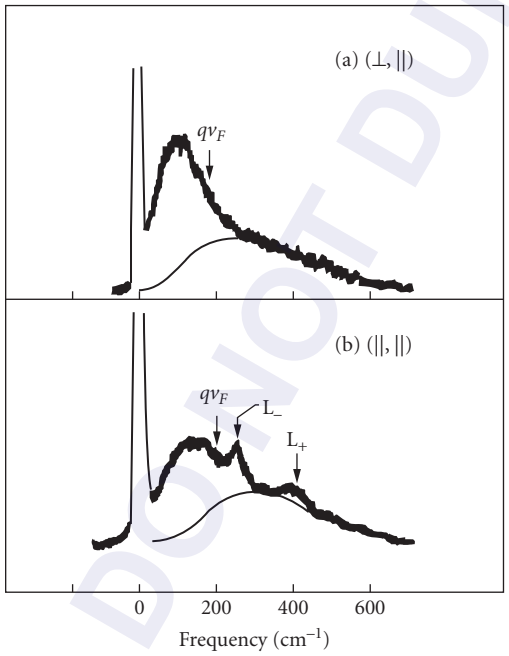

FIGURE 72 Single-particle spectra and coupled LO phonon-plasmon modes ($L_{\pm}$) for *n*-GaAs, $n = 1.3 \times 10^{18}$ cm^{-3}. Temperature: 10 K. Excitation: 6471 Å. The interband transition energy from the split-off valence band to the Fermi level is very close to the laser photon energy. Estimated luminescence background is shown by the dashed line.[161]

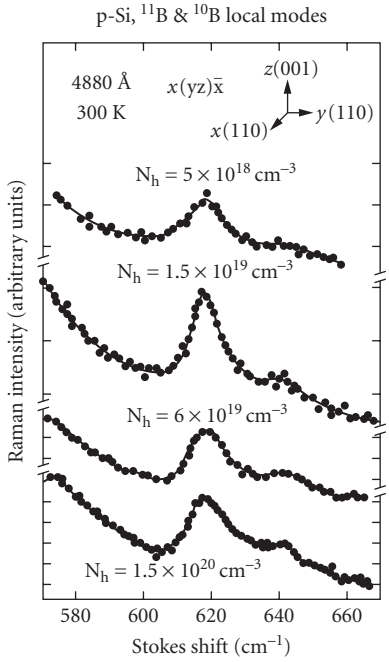

FIGURE 73 Scattering by local modes of boron (isotopes B^{10} and B^{11}) in *p*-type silicon.[163]

optical phonons in CdS with the incident photon energy as discussed in Ref. 162. An order-of-magnitude enhancement was observed as the excitation energy approached the energy gap at ~2.6 eV for all the observed phonon modes. In addition, the TO modes both displayed a reduction before a large enhancement as E_g was approached. The reduction was interpreted as the result of a destructive interference between the resonant and nonresonant terms that contribute to the scattering cross section. Resonance Raman-scattering studies can therefore shed light on the microscopic details of the scattering process.

The application of Raman scattering to the localized vibration due to impurities is illustrated in Fig. 73 which presents the data obtained from B-doped Si.[163] In most cases, the density of the impurities needs to be quite high to be observable in Raman scattering. However, rapid advances in the measurement procedures may improve the sensitivities. Direct measurement of the electronic transitions related to dopant ions can also be observed in Raman scattering. A good example is the electronic interbound state transitions from three donors in GaP.[164] The normally symmetric, threefold degenerate 1S state of the donor, split into a $1S(A_1)$ singlet and a 1S(E) doublet due to the interaction with the conduction band valleys in the indirect-gap GaP was clearly observed as well-resolved peaks.[164] The Raman spectra are sensitive to the impurity electronic states and provide a tool to probe them as well.

The authors express their deep appreciation for the help rendered by Erik Secula in preparing the manuscript.

5.6 SUMMARY AND CONCLUSIONS

An overview of the optical properties of semiconductors has been presented in this chapter. These properties form the foundation for understanding and utilizing the wide variety of optical devices manufactured today. A number of materials can be used together with electronic circuits to generate, detect, and manipulate light signals leading to the field of optoelectronics. Semiconductor materials are becoming increasingly important for use in optoelectronic devices: devices can be made very small, leading to a high degree of compactness and compatibility with other electronic and optical functions; they are robust and highly reliable; they are highly efficient as light-generating sources with internal efficiencies sometimes approaching 100 percent; they are capable of large power dissipation, of very high frequency performance, and can access an enormous range of wavelengths; and performances can be tuned over wavelength, frequency, and efficiency.[165] Table 10 lists some of the most important materials and their applications for optoelectronics.[165]

In conclusion, Table 11 presents some of the important parameters for the most common semiconductors that determine the optical behavior of each material. The forbidden-energy gap and higher-energy critical point energies are listed along with optical phonon energies, dielectric constants, refractive index at energies below the energy gap, and free exciton binding energy. Closely related transport parameters such as the charge carrier effective masses and the mobilities are also included for completion. The reader is referred to Palik's compilation in Refs. 10 and 11 for refractive indices for several semiconductors over a wide range of energies. Additional information may also be obtained from many comprehensive collections of physical parameters such as those presented in the Landolt and Bornstein Tables,[166–169] which are now available on the Internet.[170] A more concise semiconductor data handbook was recently published by O. Madelung, and much of the data, figures, references, and more detailed information were shifted to an accompanying CD-ROM.[171]

TABLE 10 Some Important Semiconductor Materials and Applications for Optoelectronics[165]

Material	Type	Substrate	Devices	Wavelength Range (μm)	Applications
Si	IV	Si	Detectors, solar cells	0.5–1	Solar energy conversion, e.g., watches, calculators, heating, cooling, detectors
SiC	IV	SiC	Blue LEDs	0.4	Displays, optical disk memories, etc.
Ge	IV	Ge	Detectors	1–1.8	Spectroscopy
GaAs	III–V	GaAs	LEDs, lasers, detectors, solar cells, imagers, intensifiers, electro-optic modulators, optoisolators	0.85	Remote control TV, etc., video disk players, range-finding, solar energy conversion, optical fiber communication systems (local networks), image intensifiers
AlGaAs	III–V	GaAs	LEDs, lasers, solar cells, imagers	0.67–0.98	
GaInP	III–V	GaAs	Visible lasers, LEDs	0.5–0.7	Displays, control, compact disk players, laser printers/scanners, optical disk memories, laser medical equipment
GaAlInP	III–V	GaAs	Visible lasers, LEDs	0.5–0.7	
GaP	III–V	GaP	Visible LEDs	0.5–0.7	
GaAsP	III–V	GaP	Visible LEDs, optoisolators	0.5–0.7	
InP	III–V	InP	Solar cells	0.9	Space solar cells
InGaAs	III–V	InP	Detectors	1–1.67	Optical fiber communications (long-haul and local loop)
InGaAsP	III–V	InP	Lasers, LEDs	1–1.6	
InAlAs	III–V	InP	Lasers, detectors	1–2.5	
InAlGaAs	III–V	InP	Lasers, detectors	1–2.5	
GaSb/GaAlSb	III–V	GaSb	Detectors, lasers	2–3.5	Imaging
GaAlInN	III–V	Quartz, GaN, AlN	IR to UV source and detector	0.25–0.7	Displays, optical disk memories, bio detectors, solar cells, photochemistry, traffic lights, etc.
CdHgTe	II–VI	CdTe	IR detectors	3–5 and 8–12	Infrared imaging, night vision sights, missile seekers, and many other military applications
ZnSe	II–VI	ZnSe	Short LED, lasers	0.4–0.6	Commercial applications (R&D stage only)
ZnS	II–VI	ZnS	Short LED, lasers	0.4–0.6	
Pb compounds	IV–VI	Pb Compounds	IR lasers, detectors	3–30	Spectroscopy, pollution monitoring

Breault Research Organization, Inc.
Tucson, Arizona

6.1 INTRODUCTION

Optical instruments and telescopes rely on black baffle and vane surfaces to minimize the effect of stray light on overall system performance. For well-designed and well-baffled systems, the black surfaces chosen for the baffles and vanes can play a significant role in reducing the stray light on the detector.[1–8] In space-borne systems, a large number of black surfaces play an important role. An excellent and comprehensive review of infrared surfaces is given by Persky.[9] Additional infrared measurements of materials are given by Miller[10] and Persky and Szczesniak.[11] Black surfaces are also used extensively in solar collector applications. Excellent reviews of spectrally selective surfaces for heating and cooling applications are found in Hahn and Seraphim[12] and in Granqvist[13]. In many solar applications, high solar absorptance is desired along with low thermal emittance.[14] In general, surfaces for solar applications will not be addressed in this chapter.

Black coatings are also used in radiometric detectors.[15] Because the surface needed is often small, these surfaces may be even more specialized than the black coatings used for stray light reduction in optical instruments. This chapter will concentrate on the selection and characterization of black surfaces chosen for stray light suppression and suitable for application to relatively large areas of an optical system or optical test bed. Some examples of these uses are seen in Table 1.

The optical system designer has a wide repertoire of baffle surfaces from which to choose. Summaries of optical properties of materials were given by Wolfe,[16] Pompea et al.,[4] and McCall et al.[17] Reviews of materials by McCall[18] and Smith and Howitt[19] emphasized the ultraviolet/visible and infrared properties, respectively. A number of company databases of scattering data are available, including one using the same instrument (for bidirectional scatter distribution function or BSDF measurements at 0.5145 μm) for approximately 15,000 data runs![20] Large amounts of BSDF data are at Breault Research Organization and a BSDF database format has been proposed by Klicker et al.[21] An organized effort to create specialized databases of optical properties of surfaces applicable to both ground- and space-based instruments has been undertaken and is proving to have great utility.[22]

The choices of optical black surfaces are usually first narrowed by the nature of the application, the substrates available or possible, the wavelength or bandpasses of interest, the angles at which the surfaces must be nonreflective, and a host of system issues and environmental factors.[5] As the system performance requirements have become more stringent, an array of surfaces has become available to meet these requirements. Many paints (e.g., Chemglaze Z306, SolarChem) (Table 2); anodized surfaces (e.g., Martin Black, Infrablack, Tiodize) (Table 3); etched, electrodeposited, and

plasma-sprayed metal surfaces (Table 4) are now available to meet quite specific optical and system performance and environmental requirements.

New classes of surfaces are also being developed to give selected performance at specific angles and wavelengths. Other materials are being developed for applications where "hardened" laser-resistant or radiation-resistant materials are needed. A third area where much development is currently taking place is in the area of materials that are able to withstand severe and unusual forms of environmental exposure for long periods.

The surface morphology of a "black" or diffusely scattering surface is only one determinant of its complex optical properties. However, for many surfaces, surface roughness plays a most significant role. This can be illustrated in Figs. 1 to 8, scanning electron micrographs of some important black or diffuse surfaces. The size and shapes of the surface features provide a valuable indication of how light will be absorbed and scattered or diffracted by such a surface. The creation and design of new

surfaces will be touched upon later, in the section on design techniques for creating new surfaces for specific applications.

This chapter gives a summary of the materials used in a variety of optical systems (with an emphasis on those that are currently available) and describes their optical and material properties so that the optical designer can begin the material selection process. As such, it is rather an extreme condensation of the data available. However, even the data presented here cannot be considered very definitive. There are a number of reasons for inconsistencies and ambiguities in the data presented. First, many of these surfaces and the processes that create them are evolving, and improving continuously. Even though the actual surface may change, the name may not. Thus, optical measurements of the same named surface that are separated by several years may not be consistent, even if the measurement techniques are consistent.

A second cause of inconsistency among data sets comes from the remeasurement of "archival"samples. When new measurement techniques or improved instruments become available, or the needs of a program demand new measurements, archival samples are retrieved and remeasured. Sometimes these archival samples may not have been stored properly and may not be in pristine or original condition. Other times, these samples may never have been archival in quality. They may have been marketing samples made without specific quality control and distributed widely. These measurements still enter the body of literature with the reader usually unaware of the important circumstances. For robust samples, poor storage may be of little importance. For more exotic materials (e.g., specialized baffles for space applications) that must be handled carefully, lack of proper handling can be of great importance. In this latter case, the measurements made on these degraded surfaces may not be representative.

Wolfe [88] compares the theory and experiments for bidirectional reflectance distribution function (BRDF) measurements of microrough surfaces. The BRDF of a surface is very useful in understanding the optical performance of a surface and is defined as the ratio of scattered radiance [W/(cm^{2}sr)] to surface irradiance (W/cm^2). Its units are inverse steradians. Radiance is used in the definition of BRDF in order to make the BRDF independent of the parameters of the measuring instrument, such as the detector aperture and distance to the detector. BRDF measurements can be made by a variety of instruments and can be made for any number of wavelengths. For example, BRDF measurements of surfaces have been made in vacuum ultraviolet to far-infrared wavelengths. However, the most common BRDF measurements that are made on black surfaces are probably made at convenient laser wavelengths of 0.6328 and 10.6 μm. It is important to keep in mind that these measurements may be of less predictive value if the system is operating at a substantially different wavelengths than where the measurements were made.

To make a BRDF measurement requires a light source, a sample mounted and illuminated by that source from a variety of angles, a detector to measure the scatter from the sample, and the computer/electronics package to accurately record the detection of the scattered light as a function of angle of incidence and detection angle.

While the optical properties of surfaces can be described or characterized through the use of specular and diffuse reflectance measurements, the use of BRDF measurements are very useful in characterizing both highly specular and highly diffuse surfaces and provide an excellent way to characterize the optical properties of any surface. The BRDF can be used to describe the angle-dependent optical scatter from any surfaces. The angular distribution of scatter can be used, in conjunction with computer modeling to calculate if the scatter from a black surface will be a limiting factor in the resolution or noise level of an optical system. BRDF measurements of surfaces are also used in computer graphics visualization programs to illustrate what a surface may look like under various illumination conditions. For some types of black surfaces, the angular distribution of scatter can be used to calculate a variety of surface parameters (e.g., surface roughness) if certain assumptions about the surface can be made. For opaque black surfaces, appropriate BRDF measurements in the wavelengths, angles, polarizations, and so on of interest have proven to be one of the best overall descriptors of the optical properties of the surface.

Measurements of optical quantities such as the BRDF, that are by definition measurement-device-independent, can also show large variations.[89,90] No attempt has been made in this chapter to reconcile measurement discrepancies; indeed, no attempt to even identify the areas where conflicting data

occur is made. This would be a herculean task, but more importantly, it is probably unnecessary. The variations in the measurement process ensure that the optical description of black surfaces is still an order-of-magnitude science, or, at best, a half-an-order-of-magnitude science. Optical practitioners should use their own safety factor or better yet, have their own measurements made.[5,17]

6.2 SELECTION PROCESS FOR BLACK BAFFLE SURFACES IN OPTICAL SYSTEMS

The selection of black surfaces is a systems issue; it must be addressed early and consider all aspects of system design and performance. It must also be examined from a total system performance perspective. Cost and schedule considerations have important effects on the decision and need to be taken seriously. A baffle structure that cannot be built with surfaces that cannot be coated is not a desirable state of affairs!

Similarly, proper financial and schedule support must be present. Black surfaces need to be taken as seriously as any other optical components, such as mirror surfaces or the thin films that act as filters. They deserve serious treatment in their design, fabrication, procurement, and testing. They are not last-minute design decisions or items to be created at the last minute. Since the baffle design and choice of surfaces often sets the final system performance (especially in infrared systems), it makes little sense to expend great energy and money to optimize other more traditional system components while ignoring stray light design and the surfaces so important in the design.

Figures 9 and 10 are a comparison of two processes that could lead to the selection of surfaces for an application. Figure 9 shows a process where design activities are done sequentially. In this process, stray light issues (including black surface issues) are left to the end of the program. In practice, with limited budgets, stray light and other fundamental system engineering issues are often not addressed at all in this process, or are addressed only at stages in the program where the system design is frozen, or cannot be changed without great expense. At this stage, when fundamental problems are found, they often have severe performance, budget, and schedule penalties. That many stray light and black surface problems are rectified (with severe penalties to schedule and budget) at late stages in programs attests to the overall importance of black surfaces to the ultimate success of a system.

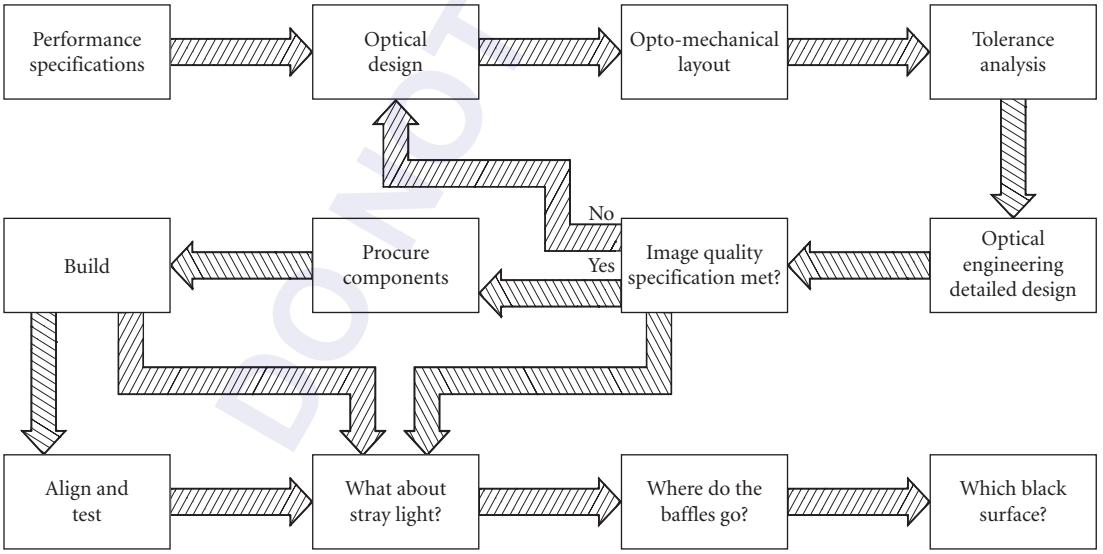

FIGURE 9 When selection of black surfaces is left to the end of a program, serious risks to the program are likely. (*From Pompea and McCall.*[5])

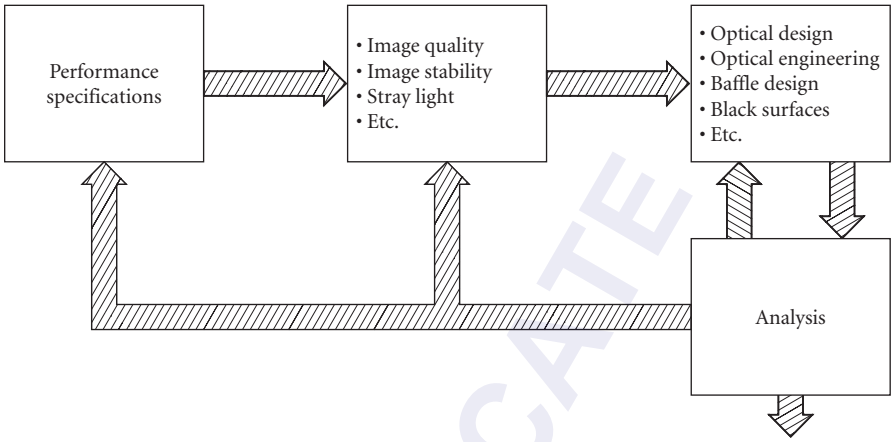

FIGURE 10 The most effective context for black surface selection is near the beginning of the program. This flowchart illustrates the early phase of a system-oriented design process. (*From Pompea and McCall.*[5])

In an integrated systems engineering or concurrent engineering environment, illustrated in Fig. 10, the selection process begins early. There are many iterations of the design in the early stages, and close work among designers of different disciplines is essential. The level of detail increases with time, but no fundamental issues are decided without addressing their implication for the system and for each subsystem. This process is far superior to the one in the first flowchart, in which the surface selection process is treated as a trivial one and one waits until the end of the program to evaluate candidate surfaces. A review of general aspects of selection with emphasis on the system level issues inherent in the selection process is given by Pompea and McCall,[5] McCall et al.,[17] and Pompea.[91]

Once it has been decided to use black surfaces in an optical system, a whole host of system-level issues must be addressed to determine an appropriate coating or coatings. The high-level items include (1) purpose and position of the surface in the instrument, (2) wavelength(s) and waveband(s) of interest, (3) general robustness of the surface, (4) nature of the installation process, (5) environment of the optical system, (6) availability, (7) cost, (8) substrate, and (9) other mission or system requirements.

For systems that operate over a wide wavelength range, the selection process may be difficult because data may not be available over the entire wavelength range of interest. For example, the next generation of infrared and submillimeter telescopes are being designed for wavelengths between about 10 and 800 μm. Baffle coatings must be adequate over this entire wavelength range.

The position of the coating in the system and its function at that location is a critical item. For positions where the incident radiation is nearly normal to the surface, the optical considerations become less critical, since the reflectance at near-normal incidence does not vary as significantly at this angle for the most often used surfaces. Also, the BRDF is usually at its lowest value. There is a wealth of data at these near-normal incident angles.[4]

The corollary is that if surfaces must be used close to grazing incidence, the optical properties become extremely important to understand (and quantify for system predictions) just as the amount of data becomes vanishingly small.[6] Although there is sufficient optical data on specular reflections from specular surfaces, there is relatively little information on specular reflections from diffuse surfaces, let alone BRDFs at large angles of incidence. For these reasons, optical designers try to use lambertian-like surfaces at near to normal incidence light paths as possible.

The robustness of the surface in its environment is a complex subject. Some specific areas that will be addressed here are the atomic oxygen environment of low earth orbit, outgassing in the vacuum of space, and particle generation by surfaces. The practical considerations of expense, schedule, ease of

cleaning, exportability, and availability of specialized surfaces all play important roles. For a unique space instrument, there are different manufacturing considerations than for a large-volume production process. The installation process is often overlooked. It often plays a key role in the successful use of many surfaces.

Exposed spacecraft surfaces often must not contribute to spacecraft charging problems. Some nonconductive surfaces support the buildup of charges that can create large electrical potentials between spacecraft components, or the spacecraft and the plasma and subsequent damage may result. This is particularly important in the region near a detector, which is often very charge-sensitive. Surfaces such as Martin Black do not support charges in excess of 200 V, since the coating can leak charge to the aluminum substrate. Textured metallic coatings, as a general rule, do not have surface charging problems. Some paints as well (e.g., Aeroglaze Z307) are designed to be conductive. Table 5 describes several surfaces used for thermal control in space craft. Some of these surfaces are designed to be conductive, to avoid charging effects. For space applications where charge buildup is not critical, nonconductive surfaces may be used.

Other considerations are the ability of a surface to withstand vibration, acceleration, elevated temperatures, thermal cycling, chemical attack (including atomic oxygen), solar and nuclear radiation, micrometeoroids, and moisture.

For the coating of baffle and (particularly) vane surfaces in ground-based telescopes, a further consideration may often be important. The baffle and vane surfaces in telescopes often have a large view angle or geometrical configuration factor (GCF) with the sky. This is particularly true for telescopes that operate without an enclosure or with a very large slit or opening to the night sky. In this case, the black baffle and vane surfaces must not radiatively couple strongly to the night sky. If there is a substantial view to the sky, and the emissivity of the surface is high, it will cool below the air temperature. This can create temperature-induced "seeing" effects which degrade image quality. The requirement that a surface be strongly absorbing of visible light, yet a poor emitter in the infrared is often a difficult one to meet. Table 6 gives the absorptivity and emissivity of some widely used surfaces.

In many laboratory or instrument applications, the use of one of a few standard black coatings or surfaces (such as the now unavailable 3M Black Velvet 101-C10) was entirely adequate to achieve the necessary performance of the optical system. In these applications, if the stray light performance was inadequate, it usually indicated that the stray light design, not the choice of black surface, was in error. The explanation was that the ignorance of some of the principles of stray light design could produce system performance five orders of magnitude worse than a poor choice of surfaces. The visibility of surfaces from the detector and the paths from those surfaces to the front of the instrument (not the optical properties or blackness of the surface) largely determine the total system performance. In stray light terminology, the GCF (geometrical configuration factor of surfaces) is more important than the BRDF (bidirectional scatter characteristics of surfaces).

6.3 THE CREATION OF BLACK SURFACES FOR SPECIFIC APPLICATIONS

The optical properties in the visible (e.g., BRDF at 0.6328 μm) at near-normal incidence between painted black surfaces and more specialized high-performance black surfaces usually do not differ by more than a factor of 10. For infrared and ultraviolet wavelengths, the performance of more specialized surfaces is far superior to many paints by a much larger factor. The optical designer must take care not to overspecify the optical performance properties required for a baffle surface. The lowest reflectance surface is not necessary for all applications. On the other hand, the choice of low-performance coatings has important consequences.

Some systems have been designed with an excessive number of vanes on their baffles. In these cases, the baffle system is probably too heavy, costs more than necessary to manufacture, and the excessive number of vane edges may be introducing extra diffraction effects that degrade the performance. The advantage of the high-performance coatings often lies not only in their optical properties, but in the considerable experience of their manufacturers in working on baffle systems, the reliability and consistency in the application process, and the superior documentation of the optical performance characteristics. The environmental resistance of the high-performance coatings is generally much better and much better documented than paints that are used for a wide variety of applications.

Black Surfaces as Optical Design Elements

The systems approach to the choice of black surfaces in optical systems that has been stressed here has led to the rule of thumb in stray light design that the choice of a black surface's optical properties should not be the first design issue considered. If the performance of the preliminary design is inadequate, the designer should look at the design carefully, rather than look for a better black surface to boost the performance. A flaw in the general system design is probably more responsible for the performance than the "blackness" of surfaces.

One reason for this approach is that the choice of a different black surface may not improve the performance, if the surface is used in the system in certain ways (e.g., grazing incidence). An important equalizing factor among many black surfaces is that they become highly specular when used at angles significantly different from normal incidence. This optical performance characteristic makes it critical for the baffle designer to conceptualize the paths and ranges of angles that are required, and to avoid using a surface where its performance is requried at grazing incidence or close to it. The writing of scatter specifications is discussed by Stover,[93] and Breault[2] discusses sources of BRDF data and facilities where BRDF measurements are routinely made.

Black surfaces can be contaminated and their absorbing or diffuse structure can be destroyed by improper handling. This can lead to a significant degradation in their optical properties. A margin of safety should always be included in the performance estimates.

Many specific high-performance applications today require that black surfaces must become critical design elements that are used with only small "safety" factors. First, all of the principles of stray light design are used. If the required performance is barely achievable without optimizing the choice of black surfaces, then considerable attention must be paid to the choice of surfaces. Sometimes, designers must often use several black surfaces in an instrument or telescope; each particular black surface is used where its performance is optimal. In the past few years, a variety of black surfaces have become available to supplement the old standbys such as 3M Black Velvet (the mainstay of laboratories 10 years ago), and Chemglaze Z306 (now called Aeroglaze Z306) and Martin Black (the standard bearers for space instruments in the 1980s). Since the applications for these blacks are so specific, we refer to them as *designer blacks.* This term refers not only to new classes of surfaces that have been developed, but also to the creativity of optical and material scientists in modifying existing surfaces to create special properties for specific applications.

This new array of designer optical blacks can still be subdivided into the traditional categories of specular blacks and diffuse (lambertian) blacks. Glossy or specular black surfaces have been used for vane cavities and their use is reviewed by Freniere[94] and Freniere and Skelton.[61] The approach is to reflect unwanted radiation out of the system or to attenuate it while tightly controlling its reflected direction. The use of specular baffles (reflective black or shiny) requires considerable care to avoid sending specular beams further into the instrument at some particular narrow angles.[59,95] The increasing sophistication of stray light analysis programs makes this analysis much more complete. The most widely used specular black surfaces are Chemglaze Z302 and a paint formerly called Cat-a-lac Glossy Black, now available from Akzo as 463-3-8.

The lambertian black surface is often the most desirable type of surface to use in baffled telescopes and instruments. However, there is no *true* lambertian black, though several are extremely close for a near-normal angle of incidence. All diffuse blacks have larger BRDFs at large angles of incidence. Furthermore, these black surfaces can be further categorized by the wavelengths where they absorb best, the general categories being the ultraviolet, visible, near-infrared, middle-infrared, and far-infrared. They can also be distinguished by their degree of resistance to the atomic oxygen found in low earth orbit, their resilience under laser illumination, and their performance at narrow laser wavelengths or specific angles of incidence. The method of manufacture and the performance of these specialized surfaces may be proprietary or classified. Even if the general qualities of these surfaces that perform in these areas are known, the full range of test results on them often are not readily available.

Design Techniques for Creating Black Surfaces

Four general tools are available to the black surface designer to tailor the optical properties. Many highly absorbing surfaces use several of these effects to good advantage. The first tool is to use absorbing compounds in the surface. Examples of this are the organic black dye, which is a good visible absorber, in the Martin Black anodized surface and the carbon black particles found in many paints. Similarly, for the infrared paints, the addition of silicon carbide particles provides good absorption near 12 μm. The addition of compounds may create quite different properties at visible and infrared wavelengths; a visual observation of blackness is no guarantee of its infrared properties. The converse is also true. Titanium dioxide is a good infrared absorber, but is very reflective in the visible region. "Black," therefore, means absorptive in the wavelength region being discussed.

The addition of large (relative to the wavelength of interest) cavities, craters, or fissures in the surface can aid in the absorption process by requiring the radiation to make multiple reflections within the material before it leaves the surface. The same effect is achieved by growing large angular projections from a flat substrate. Each reflection allows more of the radiation to be absorbed. For example, a surface with a reflectivity of 15 percent (a rather poor black) becomes a very good black if the light can scatter or reflect three times within the surface before it exits. After three internal reflections, the 15 percent reflectivity black has become a $(0.15)^3$ or 0.34 percent reflective surface. The NBS Black and Ball Black surfaces are good examples of this; they are shiny electroless nickel surfaces until etched. After etching, the surface is filled with a plethora of microscopic, cavities that absorb enough light to create a surface that is black to the eye.

Black appliqués can also be used to create rough absorbing surfaces.[96] These surfaces can be "tuned" for different wavelengths or for maximum absorptance at certain angles of incidence. This can be done by angling fibers or surface structure to provide cavities that are oriented normal to the angle of incidence. These materials have low reflectance at a variety of incident angles.[96–98]

Aerogels can also be used to create very black surfaces. Aerogels are highly porous materials nanometer-scale structures that can be synthesized through the removal of the pore-filling liquid. Of particular interest are carbon aerogels consist of 10-nm-sized particles, which are amorphous, connected in an interconnected network with approximately 10- to 50-nm pores and a pore volume of over 80 percent. Since carbon has inherent absorption in the infrared, this innately rough surface can have extremely low reflectivities over a broad wavelength range (e.g., 2 to 14 μm).[99]

The third phenomenon is the use of scattering from the surface structure, from particles in the surface coating, or from the substrate to diffuse the incoming beam over a hemispherical solid angle. Even without any absorption, this dilution factor can be very important in destroying specular paths, particularly in the far-infrared, where broad wavelength absorption is difficult. For an introduction to surface roughness and scattering phenomena, see Refs. 33, 46, 93, and 100. An in-depth, very readable, treatment of scattering by small particles is given by Bohren and Huffman.[101]

The fourth phenomenon is based on optical interference of light in thin films. A black optical thin-film multilayer structure can significantly enhance, through optical interference, the amount of absorption of light in a multilayer structure over that of intrinsic absorption alone.[87] The black layer system technology has been used successfully in a range of applications.[84–87,102,103] Optical thin films provide tremendous design flexibility. The reflectance, absorptance, and transmittance can be tailored as a function of angle and wavelength. Black multilayers may have a higher cost per unit of surface area, are generally limited to small surfaces, and have a strong angular sensitivity. This last characteristic can be used to great advantage for specialized applications. The films (especially those deposited by ion-beam process) are durable and are suitable for space use.

There is no ideal black surface. For good absorption across a wide wavelength band (e.g., 0.5 to 20 μm), the surface might be excessively thicker than is needed for a narrowband application. Even a "perfect" absorbing surface has disadvantages associated with higher emissivity (e.g., the surface radiates to the detector). In practice, even specular surfaces can be acceptable as black baffle surfaces under the right circumstances, although they are much more difficult to use. By design, they must direct the energy out of the system or in a direction that is not harmful to the system performance.[95,104,105] Their alignment is critical and there are caveats for their use.[59] The "blackest" surface is not necessarily the best for a specific application.

In some other applications, a combination of low absorptance and high emittance are desirable. High emittance-low absorptance coatings are possible using a combination of techniques or surfaces. For example, a potassium silicate binder with zinc oxide or zinc orthotitanate particles can be applied to an anodized aluminum surface. In this case, the absorptance is less than 0.16 and the emittance is about 0.92.[106]

6.4 ENVIRONMENTAL DEGRADATION OF BLACK SURFACES

Contamination control for terrestrial and spaceborne sensors is a very rapidly developing and important area. A good introduction to the field with extensive references is given in Refs. 2, 107 to 109. A good review of contamination assessment techniques given by Heaney[110] and Nahm et al.[111] discusses scattering from contaminated surfaces. The prevention, detection, and removal of contamination should be important considerations early in the design of the sensor.

Three areas of great interest for spaceborne sensors are the effects of atomic oxygen, outgassing effects, and particle generation by surfaces. A large number of other effects can also influence the performance of surfaces or of the systems where those surfaces are installed over short or long periods. These include adhesion of coatings, radiation effects on coatings, thermal cycling effects, vacuum ultraviolet effects, and electrostatic charging effects, to name a few. It would be helpful if each new coating developed could be tested by a suite of tests relevant to the area of concern, similar to what was done in cryomechanical tests of Ames 24E2 infrared black coating.[34] All too often, the tests are done on different formulations at different labs and with different degrees of care. This makes it extremely difficult for the optical designer to have the data necessary to make good decisions.

The surface contamination of a black surface as well as aging effects can affect its optical properties. However, the effect of contaminants from black surfaces on mirror scatter in the optical system is much more pronounced. Williams and Lockie[112] use the BRDF as the sensitive parameter to judge the effects of dust, hydrocarbon oil, acrylic, and peelable coating residue on low-scatter mirror surfaces. Young[113] describes the effect of particle scatter on mirrors. Shepard et al.[71] have suggested that scattering properties of black baffle surfaces may be temperature-dependent. This may be a result of chemical changes in the surface or in changes to the surface as absorbed molecules are released at increased temperatures. Further work should be done at the temperatures of interest.

A large number of studies have been done to describe the behavior of black baffle surfaces to intense exposure to high-powered lasers and radiation, where damage to the surface is widespread. Accurate results can often be obtained using other vehicles to deliver energy into the surface. For example, rapid pulsed, low-energy electron beam irradiation of optical surfaces is described by Murray and Johnson[114] as a cost effective way to test for radiation hardness. Black baffle surfaces are vulnerable even at low fluences because of their great absorptivity. The damage mechanisms are not well understood. Many of the damage mechanisms are related to the thermal shocks produced by rapid heating of a surface of thin layers on different materials. The destruction of surfaces not only reduces the ability of the surface to absorb stray radiation, but often also creates a contaminating cloud of particles that can greatly affect the optical system.

Atomic Oxygen Effects

Spacecraft surfaces on the early space-shuttle flights showed significant weight loss and aging effects. For example, on STS-1 the forward bulkhead camera blanket was milky yellow after the flight and the white paints on the suttle exhibited exposure-related degradation effects. On later flights, surfaces such as Kapton showed significant mass losses. These effects were attributed to the interaction of the surfaces with the atomic oxygen present in low earth orbit.[115] The atomic oxygen attacks the binder materials in paints, thus removing mass, and causes glossy surfaces to become more lambertian.[116] Carbon particles are released when the binder is removed. The weight loss is due both to chemical processes and to erosional (kinetic energy) processes.

A second problem is that many surfaces have a glow associated with them when exposed to the atomic oxygen. Both of these phenomena undermine the effectiveness of baffle surfaces on space instruments. The effect of exposure to atomic oxygen on anodized black surfaces (Martin Black and Enhanced Martin Black) has been measured and simulations of atomic oxygen exposure on Chemglaze (now called Aeroglaze) Z306 paint has been done with a plasma etch chamber.[64]

These tests showed that a carbon-black-based paint could be significantly degraded by atomic oxygen over time while anodized surfaces exhibited only small changes in their surface morphologies or in their visible and near-infrared reflectances. The graying of some smooth painted black surfaces is somewhat compensated for by an etching process that roughens these surfaces. If the exposure times are short, the etching action of the atomic oxygen may even improve the scattering properties of paints. However, removed material may show up on optical surfaces, degrading the optical performance, and it should be obvious that long exposure times would remove too much of the coating.

In general, however, the optical properties of surfaces degrade during longer exposure times and at higher atomic oxygen flux levels. Experiments in space on the long duration exposure facility (LDEF) have indicated how the properties of materials change after nearly six years of exposure to atomic oxygen. For Chemglaze (now called Aeroglaze) Z306 paint, for example, this exposure has led to a loss of the binder material[117] and to loss of pigment. Some ion-textured surfaces were also flown as part of this experiment and showed high stability in the space environment.[79] The effects of space exposure on infrared baffle coatings were described by Blue and Perkowitz[118] who showed that long-term exposure decreased the reflectance of these surfaces.

Outgassing

For space applications, the amount of outgassed material and its composition are of great importance. One of the primary dangers is that the outgassed products may form a film with undesirable properties on optical components. This hazard of space exposure is particularly relevant for cooled systems. For cryogenic systems, the continued outgassing of materials as they break down after long exposure to the space environment becomes an additional source of contamination on optical surfaces. Outgassing is also of concern for severe environments on the ground, though the correlation between vacuum testing and a behavior of black surfaces under severe heat in air is not well understood. For the context of this chapter, only vacuum outgassing measures will be considered. In either case, the condensation of volatile materials on optical components can lead to catastrophic system failure.

The two primary measures or tests of outgassing are the *total mass loss* (TML) and the percent *collected volatile condensable materials* (CVCM). An American Society for Testing and Materials (ASTM) Standard Test Method was developed for this purpose and is called E 595-77/84. Several NASA publications give values for TML and CVCM (Ref. 119 gives the most extensive listing; see also Ref. 120). For example, measurements at Goddard Space Flight Center of Chemglaze (now Aeroglaze) Z306 black urethane paint give a TML of 0.92 percent and a CVCM of 0.03 percent. Wood et al. shows the near-infrared absorption due to the outgassing products of Aeroglaze Z306 black paint. For the paint, the total mass loss was 2.07 percent. Ames[28] reports outgassing problems with Aeroglaze Z306 if exposed to temperatures greater than 40°C after a room temperature cure. However, many potential space material outgassing problems with this and other surfaces can be avoided completely with proper bakeout procedures. In 1993, a low volatile version of Z306 was being developed.

A third measure of outgassing relates to the water content of the material or surface. The *water vapor regained* (WVR) is a measure of the amount of water readsorbed/reabsorbed in 24 hours, while the sample is exposed to 25°C and 50 percent relative humidity (for extensive listings, see Ref. 119). This determination is done after the vacuum tests for TML and CVCM.

Particle Generation

Materials for space use must be able to withstand launch vibration without generating an excessive number of particles. This is not simply a coating or surface problem—it is a dynamics and substrate problem as well. The details of the baffle design and assembly play an important role in the generation

of particles. If a baffle surface is grossly distorted by the launch vibration, the adhesion of the black surface should not be blamed for the failure; the baffle design failed. A common source of particle generation is abrasion between coated baffle surfaces. For severe vibration environments and for fragile surfaces, special considerations are necessary.[70] Similarly, surfaces must be able to withstand thermal cycling without producing particles. As painted materials outgas and their composition is altered, particles in the paint can become dislodged.

Materials used in baffles can also get dusty or contaminated by exposure to outgassing products from the spacecraft. For an accessible ground-based black surface, normal cleaning procedures appropriate to the surface may be used, if they do not damage the texture or optical properties of the surface. For a baffle system already in space, the cleaning procedures developed to clean mirrors in situ may apply. These techniques include laser cleaning, plasma or ion cleaning, and jet snow cleaning (see, e.g., Ref. 121, and other papers in Ref. 109).

Baffle Material for Extreme Environments

One important form of degradation for earth-based materials involves the exposure of the surface to the elements of temperature cycling, sunlight, humidity, and other factors of its operating environment. This combination is a severe test of many surfaces. Unfortunately, there is very little data published on the environmental degradation of black surfaces that are exposed to the outdoor environment, or to high temperatures, such as might be found in a closed automobile in the summer. Often, a black surface that is very ordinary in its optical properties is chosen for use in an extreme environment. The reason is that it was the first surface that did not peel or fade significantly.

Space-based surfaces must withstand severe launch vibrations, temperature extremes, collisions with space debris and micrometeoroids, and exposure to ultraviolet radiation. Military missions have also added the requirement that these materials be hardened against nuclear or laser threats. For example, these baffle surfaces and their associated optics must still perform after exposure to high-power lasers.

In the simplest sense, these black surfaces must be able to either selectively reject laser radiation (a difficult requirement) or be able to absorb significant amounts of energy and not degrade. Most of the coatings have been developed for application to substrates, which can survive high temperatures, such as molybdenum, beryllium, tungsten, carbon/carbon, and titanium, because of their ability to withstand high flux densities of laser light. Generally, painted surfaces are completely inadequate. Even anodized surfaces on aluminum may not be adequate at these flux densities.

6.5 OPTICAL CHARACTERIZATION OF BLACK SURFACES

The baffle designer must be concerned about the optical properties of black surfaces over a large range of wavelengths and angles of incidence. Wolfe[16] summarizes the relevant design data. Performance measurements, such as measurements of the specular reflectance and total hemispherical reflectance over a range of wavelengths are now supplemented by a more complete characterization of these optical surfaces: the bidirectional reflectance distribution function (BRDF).[122] BRDF has units of inverse steradians and is usually measured at several discrete wavelengths, which are easily generated by the most common lasers. In particular, measurements at the HeNe laser wavelengths of 0.6328 μm and at the CO_2 wavelength of 10.6 μm are particularly valuable for visible and infrared applications. There is a notable shortage of BRDF data in the ultraviolet, from 1 to 4 μm, and for far-infrared wavelengths.

BRDF measurements at the same wavelength have the additional advantage that they are directly comparable. As Smith and Wolfe[123] point out, the directional reflectivity of a surface is convolved with the instrument function (a weighted mean of the detector solid angle), a unique characteristic of each reflectometer. An approximate deconvolution of the instrument function can be easily

performed by dividing the measured reflectance by the projected measurements, which are instrument independent as mentioned in ASTM Standard E12.09. However, simple specular reflectance measurements and spectra made on different instruments must first be divided by the projected detector solid angle before being compared. Several studies[89,90] have detailed the variation between BRDF measurements made in different laboratories. With the advent of the ASTM standard, greater congruence among BRDF measurements in the future is probable.

Because of the value of BRDF measurements in comparing the scattering characteristics of surfaces, a large set of BRDF data of black baffle materials that have traditionally been used in optical devices of all types, as well as the scattering functions of some new materials are presented in this chapter. These measurements may be compared to previous measurements made on other instruments.[67]

The specular and total hemispherical reflectance data thus become most valuable in describing some general characteristics of a surface over a wide wavelength range, while the BRDF data at a wavelength of particular interest allow the designer to characterize the angular scattering of the surface for angles of incidence of interest and for view angles from the detector. The total integrated scatter also is extremely useful for surface roughness determination.[93]

This chapter provides the optical designer a useful summary of data. Sufficient data are presented to allow a determination of which surfaces might be appropriate for a given task. The data generally can be divided into two forms, the first being specular and hemispherical reflectance data over a wavelength range. These data allow the designer to choose a surface with the right basic properties over the wavelength range of interest. BRDF measurement provides a second form of data. The data are usually presented for a few characteristic angles of incidence (5°, 30°, 45°, and 60° are the most common) at each wavelength. These BRDF measurements are particularly useful as input to optical modeling or stray light modeling programs.

In stray light analysis programs such as APART,[124] ASAP,[125] and GUERAP,[126] as well as many other modeling programs, it is the mathematical value of the bidirectional reflectance distribution function that is used by the program models. In these programs, a library of BRDF functions for the most common surfaces is available for use by the analyst. For surfaces that do not explicitly have a BRDF associated with them in the code, the BRDF values can be input.

In most baffle designs, surfaces are used at angles not represented by the available BRDF measurements. Some surfaces are even used at angles close to grazing incidence where few measurements have been made. For these areas, the data available for the models are very limited, and often generous extrapolations are needed. A smooth transition between measurements at different angles or at very large angles of incidence, or from one wavelength to another is often assumed. The more unusual or nonrandom the surface, the more these assumptions or extrapolations should be questioned. Examples of how BRDF measurements are made and used in system designs and analysis are found in, for example, Refs. 3, 43, and 127 to 130.

Black surfaces are also used in radiators used for the thermal control of spacecraft. The hemispherical reflectivity can provide a general indication of the optical properties for a thermal analysis. The normal emittance at room temperature is also an important quantity for spacecraft design. Table 7 gives the hemispherical reflectance and normal emittance of some surfaces. Radiatively cooled surfaces are important for space infrared telescopes and, if designed properly, can provide a reliable means of reducing background radiation. Because of on-orbit degradation, the radiators must be sized for the appropriate performance at the end of the mission.

For these applications, the absorptivity and emissivity of surfaces as a function of wavelength and temperature must be well understood. Thus, room temperature measurements of normal emittance may not be very useful if the surface is to be used at cryogenic temperatures. Stierwalt[41,132] has contributed greatly to the measurement of far-infrared emissivity of black materials. Clarke and Larkin[133] describe measurements on a number of black surfaces suitable for radiometry detectors where a low reflectance is needed, independent of wavelength. For opaque surfaces, the spectral emittance at a given wavelength is equal to the spectral absorptance, which is equal to one minus the spectral reflectance.

These parameters are very sensitive to coating thickness and may change with exposure to ultraviolet radiation from the sun, with damage from solar electron and proton radiation, damage from space debris and micrometeoroids, and with outgassing. In practice, the solar absorptance is measured

TABLE 7 Hemispherical Reflectance and Emittance of Some Common Spacecraft Surfaces

Surface	Thickness	Hemispherical reflectance at 546 nm (incidence angle, degrees) 20	40	60	70	80	Normal Emittance (300 K)

by obtaining the reflectance from 0.3 to 2.4 μm, the region containing 95 percent of the sun's energy. The normal emittance is determined using an infrared spectrophotometer over the wavelength range 5 to 35 μm, where close to 90 percent of the energy of a 300 K blackbody is emitted (see Table 6). While these measurements are useful for design of radiators that operate near room temperature, further measurements are required in order to predict a surface's thermal emittance at lower operating temperature.

6.6 SURFACES FOR ULTRAVIOLET AND FAR-INFRARED APPLICATIONS

Many surfaces are multipurpose and are useful for a variety of wavelengths. Before discussing the properties of these surfaces, it may be instructive to look at several surfaces that are used for ultraviolet and far-infrared applications. In these wavelength regions, the performance of black surfaces is often critical to the performance of the optical instrument.

Black Surfaces for Ultraviolet Applications

For space telescopes or instruments operating in the ultraviolet, surfaces such as Martin Black have been used successfully. However, very few measurements of candidate baffle material have been made at wavelengths less than 0.3 μm (300 nm) and even fewer have been made at shorter ultraviolet wavelengths. Jelinsky and Jelinsky[40] studied the performance characteristics of a variety of surfaces and surface treatments for use on baffle materials in the Extreme Ultraviolet Explorer. They determined some scattering characteristics of several materials at 30.4, 58.4, and 121.6 nm.

Heaney[131] has made some pioneering bidirectional measurements at 15°, 45°, 75°, and 85° at 58.4 nm (584 Å) of candiate baffle materials for space instrument applications. Interestingly, two of his samples are "bare" aluminum with no applied coating. The natural oxide present on uncoated aluminum samples is strongly absorbing at this wavelength and, by itself, reduces the reflectances to below 5 percent at near-normal incidence. The baffle surface candidates are described here and their optical properties are presented in the figures.

Roughened aluminum: Aluminum 6061 alloy, sheet finish, sandblasted to an unspecified degree of surface roughness. Uncoated (Fig. 11).

Gold iridite: Aluminum with a chromate surface coating produced in a room temperature chemical conversion process (Fig. 12).

Black nickel: Aluminum with a black nickel surface that was produced in an electroplating process with NiS and ZnS (Fig. 13).

Copper black: An aluminum substrate coated with approximately 80 to 100 nanometers of evaporated Cu to provide a conductive layer and then overcoated with an evaporated Cu black deposited at a chamber pressure in the 10^{-3} torr range (Fig. 14).

Black paint: An aluminum substrate painted with a carbon-loaded black silicone paint (NSB69-82) (Fig. 15).

Aluminum, grooved and blazed: An aluminum plate, 6061 alloy, with grooves cut at a blaze angle of about 20°, with a period of 1.1 mm, a depth of 0.4 mm, and otherwise uncoated (Figs. 16, 17, and 18).

Surfaces for Far-Infrared (>30 μm) Use

In the far-infrared wavebands, many surfaces such as paints, which have good visible absorptance, lose their absorbing and scattering characteristics. Although measurements have only been made at wavelengths longer than 15 μm on a few surfaces, the data suggest that most surfaces do not

perform well as "blacks" for long wavelength operation.[41,133] Smith[32] points out that many coatings become transparent at longer wavelength and the substrate roughness enters strongly into the scattering characteristics. An example of this is Infrablack, a rough anodized surface that was previously described. The approach has been carried further in Ames 24E.[134] A number of approaches and surfaces have been developed to create effective surfaces at these wavelengths.

A model has been constructed[33] to describe the effect of coating roughness and thickness on the specular reflectance. Smith and Howitt[19] survey materials for infrared opaque coatings (2 to 700 μm). They highlight the value of silicon carbide and carbon black for far-infrared absorption. Smith [32,33,39,46,57,72,134–137] provides much of the reference work in this area.

The optical properties of the several infrared coatings and surfaces are given in Figs. 19 to 24. For applications in laboratories and in calibration facilities, surfaces like velvet, commando cloth, and even neoprene may be used. The long-wavelength measurements on these surfaces are given in Figs. 25 to 32. The long-wavelength coatings may be grouped into a few basic categories discussed here. As this area is one of rapid development for space infrared telescopes and space radiators, there will likely be many new approaches in the next few years.

Multiple-Layer Approach For reducing the far-infrared reflectance of baffles, a technique of using antireflection surfaces composed of multiple layers with a different refractive index in each layer was discussed by Grammar et al.[55] For such a coating to be effective, it must match the optical constants of free space with the large constants of the baffle substrate.

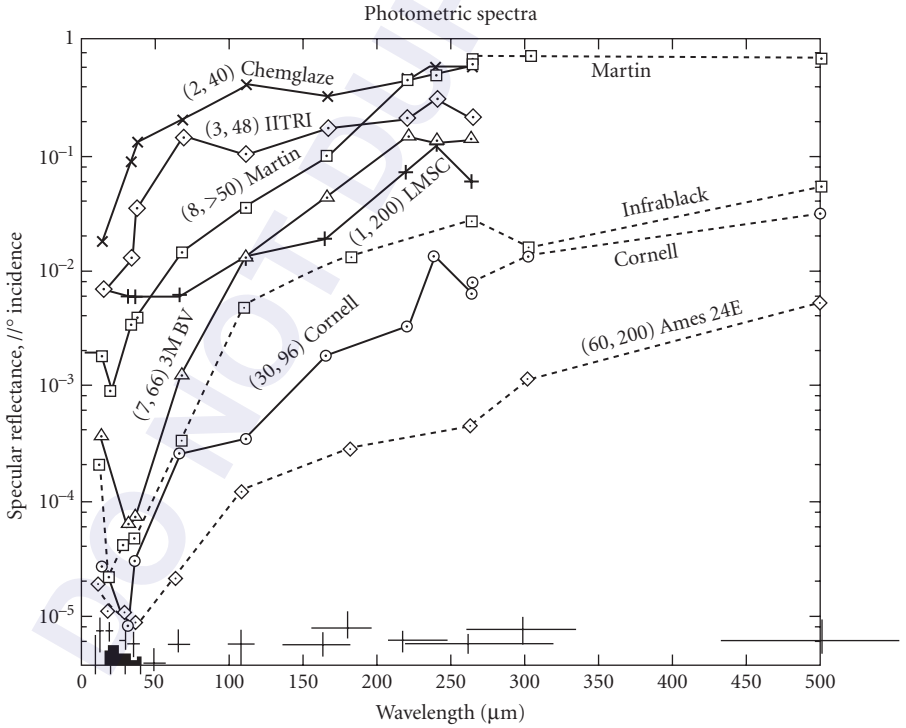

FIGURE 19 Specular reflectance spectra of eight black coatings. Measurements of coating roughness and thickness in micrometers are shown in parentheses before the name of each coating. Filter passbands are shown by horizontal error bars. The absorption bands of amorphous silicates are indicated by the solid histogram in lower left end of the graph. (*From Smith.*[32,33,46])

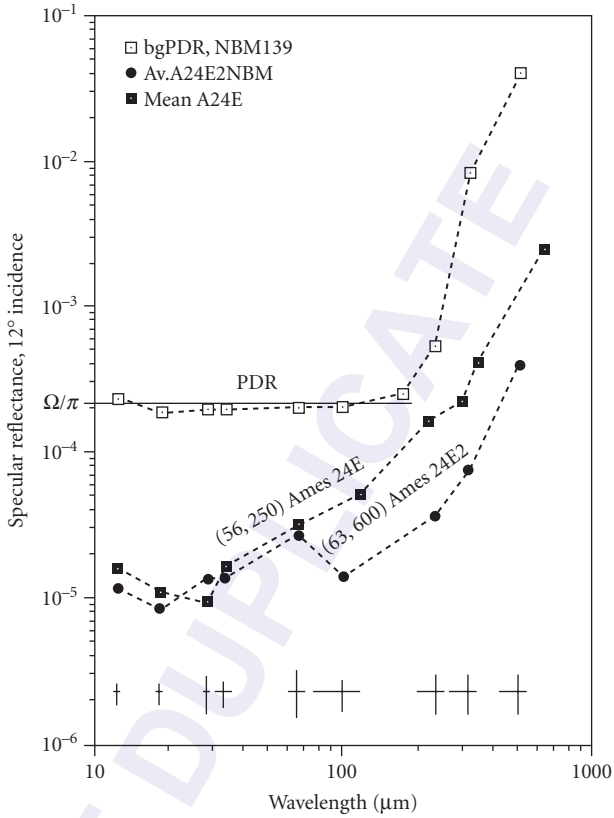

FIGURE 20 Specular reflectance spectra of PDR surface and two infrared black coatings. Dashed lines connect data points of a set, and the solid line indicates the theoretical value of reflectance for a perfect lambertian surface. The coating roughness and thickness are given in parentheses, and filter passbands are indicated by horizontal error bars. (*From Smith.*[136,137])

Teflon Overcoat A polytetrafluoroethylene (Teflon) spray-on lubricant was used as an antireflection overcoat for opaque baffle surfaces in the far-infrared and submillimeter by Smith.[50] A thick Teflon overcoat created by spraying Teflon Wet Lubricant reduced the specular reflectance at millimeter and infrared wavelengths by a factor of two. The refractive index of the coating plays a more significant role than the thickness.

Cornell Black Houck[49] created a far-infrared black paint based on adding large particles of grit (silicon carbide #80 and #180 grit) to 3M Black Velvet Nextel 101-C10. This paint could be repeatedly cycled to cryogenic temperatures with no flaking or peeling. The far-infrared properties of Cornell Black are described by Smith.[32,33] Since this 3M paint is no longer available, Cornell Black is not now generally used. The ECP-2200 (now called MH2200) replacement for 3M Black Velvet was studied by Smith and Howitt[19] in an effort to create a paint similar to Cornell Black. Houck[49] gives complete instructions for making the Cornell Black paint.

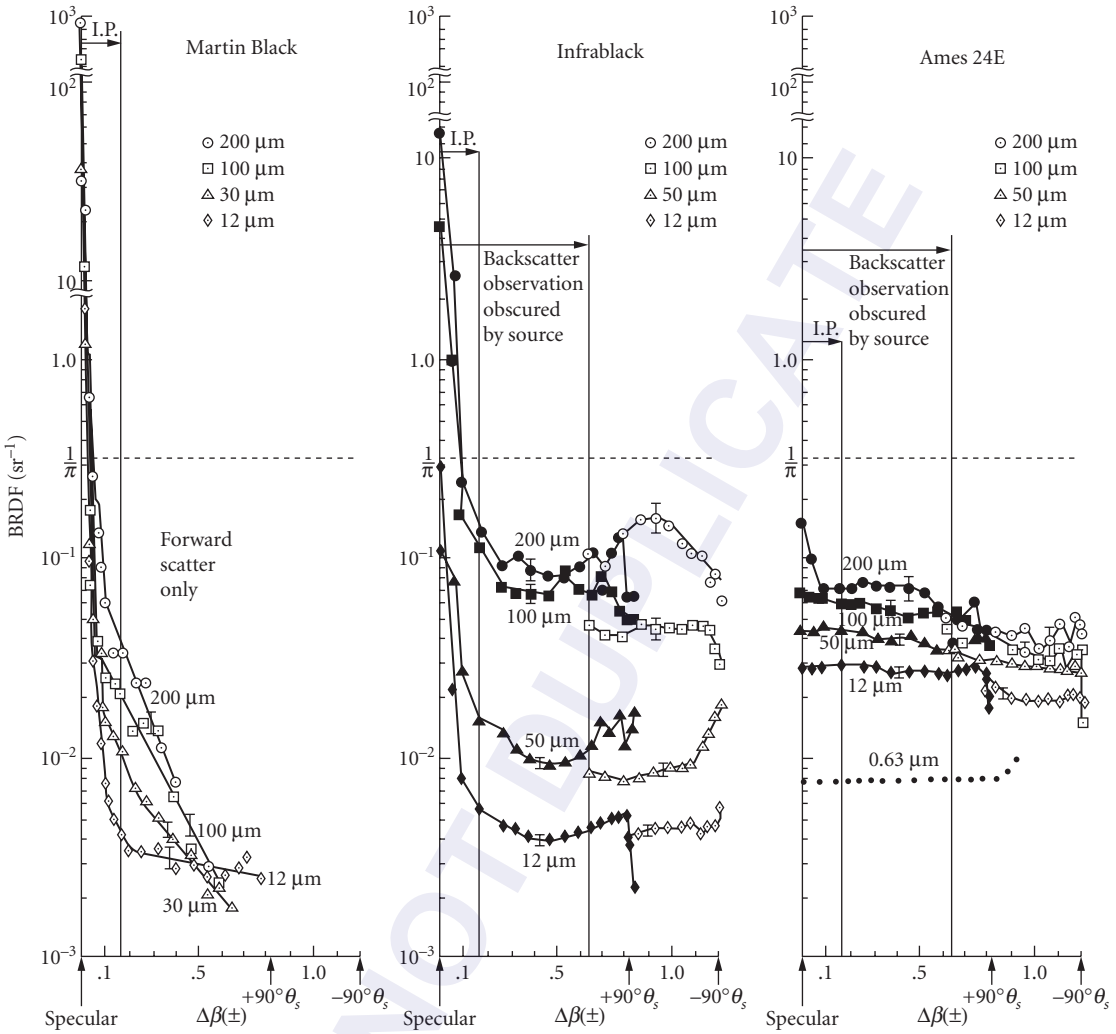

FIGURE 21 BRDFs of Martin Black, Infrablack, and Ames 24E. Note the different breaks in the ordinate scale of the Martin Black measurements used to compress its specular reflectance to fit the scale of the figure. Forward scatter data are solid symbols; backscatter data are open symbols. Forward and backscatter measurements at 0.6328 μm of Ames 24E are by D. Shepard of Martin Marietta (Denver) and are shown schematically by the dotted line in the right hand figure. (*From Smith.*[46]) Smith[137] recalibrated this data; the relative comparison of these coatings remained essentially unchanged.

Infrablack Infrablack is a black anodized surface generally applied to 6061 Aluminum.[31,64,138] It is highly suitable for space radiators, infrared baffles, and for applications where a high emissivity is desired. The specular reflectance of the Infrablack is conservatively one order of magnitude less than that of Martin Black across the spectral region from 12 to 500 μm. The reduced reflectance of Infrablack is attributed to a large increase in the roughness of its substrate prior to anodization. The diffuse reflectance characteristics of the Infrablack are different from Martin Black at the longer wavelengths. At 12 and 50 μm, the BRDF of Infrablack is considerably less than that of Ames 24E, while at 100 and 200 μm they are comparable.

Ames 24E and Ames 24E2 Ames 24E is a new coating developed at NASA's Ames Research Center.[46] The coating is a very rough, very thick, highly absorbing coating composed largely of SiC grit and carbon black, and has very low far-infrared reflectance.[46] BRDF measurements show that this surface is a model lambertian surface at a wavelength of 10.6 μm at near-normal incidence. Ames 24E is nearly lambertian at longer wavelengths, even at 200 μm.

Ames 24E2 is a formulation using ECP-2200, carbon black, silicone resin, and #80 silicon carbide grit. The coating was developed for far-infrared space telescopes and can pass severe cryogenic cycling and vibration tests.[34] The coating is considerably less reflective at 100 μm than Ames 24E and has excellent absorption out to about 500 μm. Smith[137] has also developed a highly lambertian, diffuse reflectance standard, which he calls PDR, for perfect diffuse reflector. It shows lambertian behavior from 10 to about 100 μm.

6.7 SURVEY OF SURFACES WITH OPTICAL DATA

A Note on Substrates and Types of Coatings

Many different substrates are employed for baffle and vane surfaces. In particular, for space or cryogenic use, the 6000 series of alloys of aluminum (particularly 6061) are popular. They represent the baseline by which other materials are judged. Titanium and graphite epoxy are also widely used, and beryllium and carbon fiber substrates are becoming more common. For high-temperature applications or for resistance to lasers, materials with high melting points such as nickel, molybdenum, and carbon/carbon are used.

The distinction between substrate and surface or surface coating is blurry. When paints or other coatings are applied to a substrate, the distinction between the two is very clear. However, many surfaces today involve an extensive alteration of the substrate before the "coating" is applied. They may chemically alter the substrate to create the surface coating, which is an integral part of the substrate. In these cases, the use of the word substrate only serves as a description of the material that must be altered to create the black surface.

The classification of surfaces by substrate and/or type of coating or surface treatment is only one of the many ways available. However, it is a very useful form of classification, and will be used here.

6.8 PAINTS

Paints are easy to apply and their availability and usually low price make them ideal for laboratory experiments and instruments. However, their high outgassing rates and, in some cases, the large number of particles that can be liberated from them compromise their use in space-based applications. However, there are many space-qualified paints that have been flown in space. Notable among them is Aeroglaze Z306, and the derivatives of this basic paint system that have been developed at Goddard Space Flight Center.

The way that paint may be applied can greatly affect the optical properties. The most obvious are the number of coats and the thickness; the substrate preparation also plays a critical role. Brown[27] describes the effects of number of coats on optical performance for three diffuse paints. The importance of developing a procedure for painting that incorporates the paint manufacturers' application recommendations cannot be overstated. This procedure must also include process control requirements, cleanliness requirements, application process and surface preparation requirements, safety requirements, quality assurance requirements, and storage shipping requirements, as McCall[18] describes in detail. A short description of a few of the more common paints is given here. Table 2 gives further reference data on these and other paints.

3M Paints and Their Current Derivatives

3M Nextel Black Velvet Several varieties of 3M Black Nextel paint from Minnesota Mining and Manufacturing Company have seen extensive use in ground-based instruments and were considered as standards for black coatings. These paints consisted of pigments with approximately 20 percent carbon black and 80 percent silicon dioxide. However, most of them are presently unavailable. Those that are available are manufactured under license by other companies. The optical properties of the original paint are given in Fig. 33.

The paint labeled 3M 101-C10 historically was one of the most widely used laboratory black paints; however, it is no longer made. Redspot Paint and Varnish (Evansville, Indiana) now makes a similar paint, but uses resin instead of glass microspheres, making it unsuitable for space applications according to Ames.[28] Two other paint varieties in the same line were 3M401-C10 and 3M3101 (see Figs. 34 and 35), apparently available from Red Spot Paint and Varnish.

The 3M Nextel Black Velvet was replaced by 3M SCS-2200 (3M Brand ECP-2200) (see Fig. 35). The optical differences between the original and its replacement are discussed by Willey et al.[42] Illinois Institute of Technology now produces the ECP-2200 under the name MH2200 (see following).

Nextel 2010 A sprayable Nextel 2010 Velvet paint is available from the German company Mankiewicz Gebr. & Co., Hamburg, and has been used on several ground-based astronomical instruments, where cryogenic cycling durability is important. The 2010 surface has an outgassing rate of 1.3×10^{-4} g/cm^2 at 84°F (29°C) in a 20-hour test at 10^{-5} to 10^{-6} torr. The solar alpha of this surface (from the company literature) is about 0.97 and the normal emittance is about 0.95.

The total emissivity of different black surfaces was investigated with regard to their being used as a total radiation standard in the temperature range –60 to +180°C by Lohrengel.[139] The investigations showed that the matte varnish Nextel Velvet Coating 2010 black with an emissivity of 0.951 was

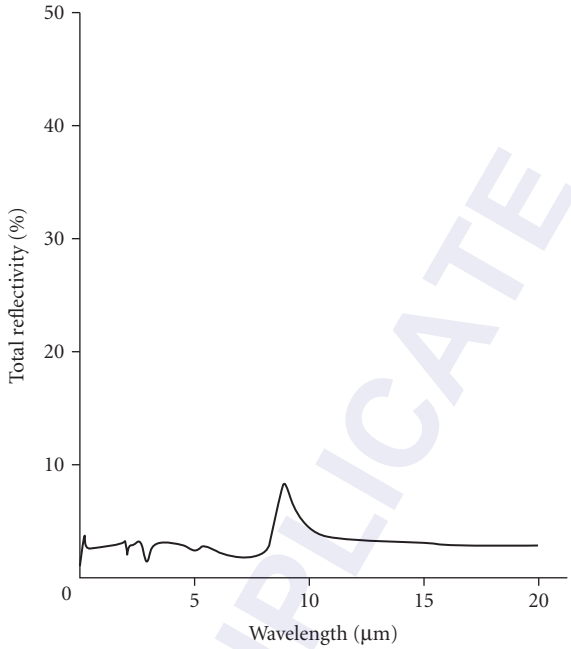

FIGURE 33 Total hemispherical reflectivity of 3M Nextel Black Velvet. (*From Willey et al.*[42])

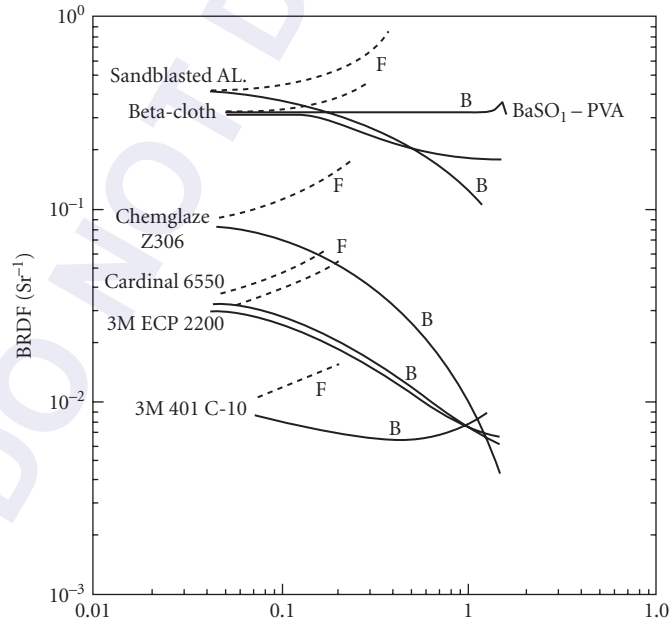

FIGURE 34 Comparison of BRDF profiles at an angle of 45° and 633-nm wavelength. (*From Viehmann and Predmore.*[35])

(*From Viehmann and Predmore.*[35])

best suited for these purposes. Additional changes to the surface (sprinkling of Cu globules, etching) could be made to increase the total emissivity by a further 0.007 or 0.016, respectively. The present availability of this paint from U.S. manufacturers is unknown.

Nextel Brand Suede Coating Series 3101-C10 C-10 is the black variety of this paint, available from Red Spot (see references). It is a low-gloss paint, with reasonable abrasion resistance (see Fig. 36). It has a soft-cushioned feel and suedelike appearance and was used on office equipment, furniture, and electronic equipment housings. The manufacturer recommends it for interior use only.

MH 2200 MH2200 (formerly ECP-2200, which was derived from the original 3M Nextel Black Velvet) is a one-part, flat black, nonselective solar absorber coating designed for high-temperature service (Fig. 37). When applied to aluminum substrates, the coating integrity and its "solar absorption" of 0.96 are unaffected by temperatures to about 500°C. The coating is 43 percent solids in xylene and is intended for nonwear applications. ECP-2200 is available from IIT Research Institute. It is touted as the substitute for 3M Nextel Black, but does not have the low BRDF at visible wavelengths of its former relative. It has a normal emittance of 0.95 at 10.6 μm and an absorptance of 0.96 over the wavelength range of 0.35 to 2.15 μm. Its emittance is 0.86 on an aluminum substrate (normal emittance at 75°F from 2 to 25 μm).

Aeroglaze Z Series Aeroglaze (formerly Chemglaze) Z306 diffuse black paints are part of the Z line of single-package, moisture-curing, ASTM Type II, oil-free polyurethanes.[24] This paint has excellent chemical, solvent, and (if used with a primer) salt-spray resistance. This is a popular paint for aerospace

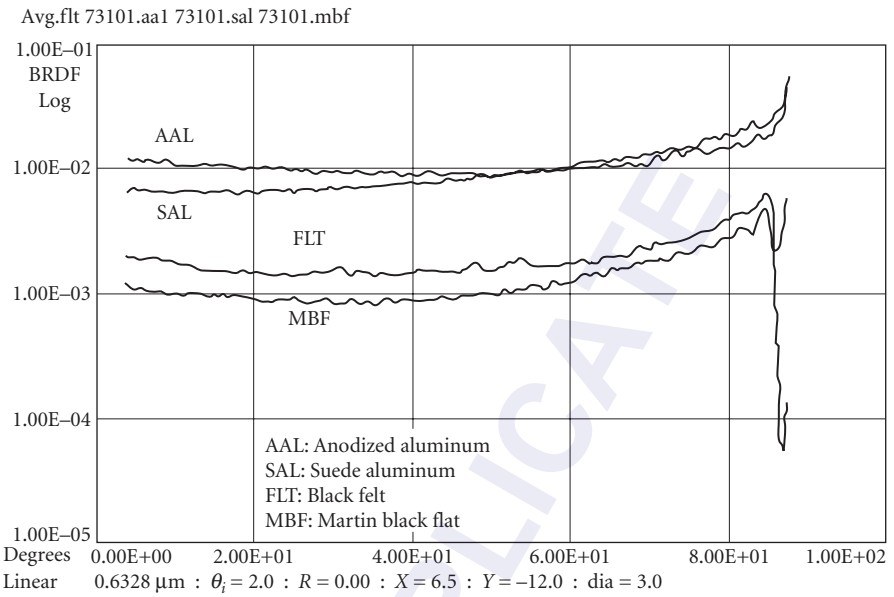

FIGURE 36 BRDF data for anodized aluminum, 3M Nextel Suede paint, black felt, and an aluminum flat with Martin Black wavelength is 633 nm, at near normal incidence. (*From Cady et al.*[66])

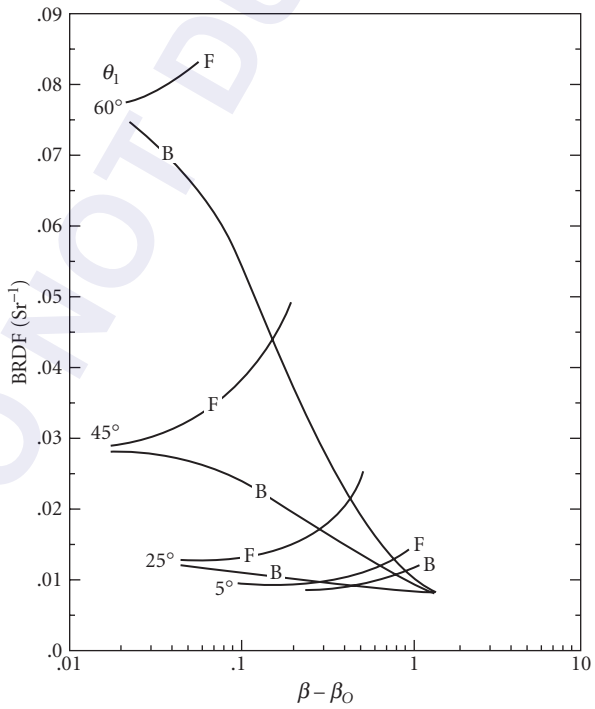

FIGURE 37 BRDF profiles of 3M ECP-2200 black paint 6550 at 633 nm. (*From Viehmann and Predmore.*[35])

use, especially after the discontinuation of 3M's 401-C10 Black Velvet Nextel.[28] For space use, the Aeroglaze 9924 and Aeroglaze 9929 primers are recommended. The optical properties are given in Figs. 34 and 38 to 43.

A low volatile version of the paint is being developed. In a version developed at Goddard Space Flight Center (based on the Z306)[44] glass microballoons are added to reduce the specular component, though the particles may be a source of particulate contamination. Other versions were developed at Goddard based on the Z004 paint. Goddard Black is a generic term for several paints of composition and optical properties different from Z306. This name is often incorrectly applied to the modified Z306 described here.

Akzo Nobel Paints Three paints sold formerly under the label Cat-a-lac are now known as Akzo 463-3-8 (formerly Cat-a-lac 463-3-8 diffuse black), 443-3-8 (formerly Cat-a-lac 443-3-8) (see Figs. 34 and 43 to 46) and 443-3-17 (formerly called Sikkens 443-3-17). The Bostic name is also formerly associated with these same paints. The 463-3-8 is the most diffuse of the three blacks, and the other two are considered "glossy." It is an epoxy-based system with low outgassing and low reflectance.

Cardinal Black From Cardinal Industrial Finishes. Optical data are given in Fig. 47.

Cat-a-lac Black (Former Name) This is an epoxy system with low outgassing and low reflectance. It is now manufactured by Sikkens Aerospace Finishes (see Akzo in the tables for address) and is described here.

DeSoto Black The PRC DeSoto Black is a flat black paint most suitable for the range 0.2 to 2.5 μm. It has a reflectance of between 2 and 3 percent over this range. Its emissivity is 0.960 compared to a 300 K blackbody, while its absorptivity over the solar spectrum is 0.924. DeSoto Black can meet outgassing requirements for space applications when vacuum baked. The weight loss is typically below 0.5 percent and the volatile condensable material is below 0.5 percent, similar to 3M Black Velvet.[140] A BRDF curve is given in Fig. 35.

Floquil: Black for Lens Edges Lewis et al.[141] discuss experiments to find low-scatter blackening components for refractive elements. With index of refraction matching, gains of several magnitudes in lower BRDF can be achieved over other edge-blackening techniques. The paint Floquil (Polly S Corporation) has been used as an edge-blackening compound and is discussed by Lewis. Smith and Howitt[19] give a specular reflectance curve for Floquil in the infrared from 20 to 200 μm.

Parson's Black Prior to 1970, Parson's Black was a standard black reference.

SolarChem SolarChem is a black paint with excellent visible absorbing properties and has been suggested as a replacement for the unavailable 3M Nextel Black. The visible BRDF of SolarChem has a flat profile at near-normal angles of incidence (Fig. 48), while the 10.6-μm BRDF of SolarChem shows quite a different shape.[88] The surface is highly specular at 10.6 μm.

Anodized Processes

Anodized processes can produce fine black surfaces. The condition of the substrate plays an important role in the overall scattering properties of the surfaces. A common technique is to sandblast (vapor hone) the surface before anodization. Many varieties of grit may be used and each will produce a different kind of surface treatment. Sometimes, small pieces of grit can become embedded in the surface and this may affect the anodizing process. The BRDF of sandblasted aluminum surfaces are given in Figs. 49 and 50. Table 3 gives reference data on anodized surfaces.

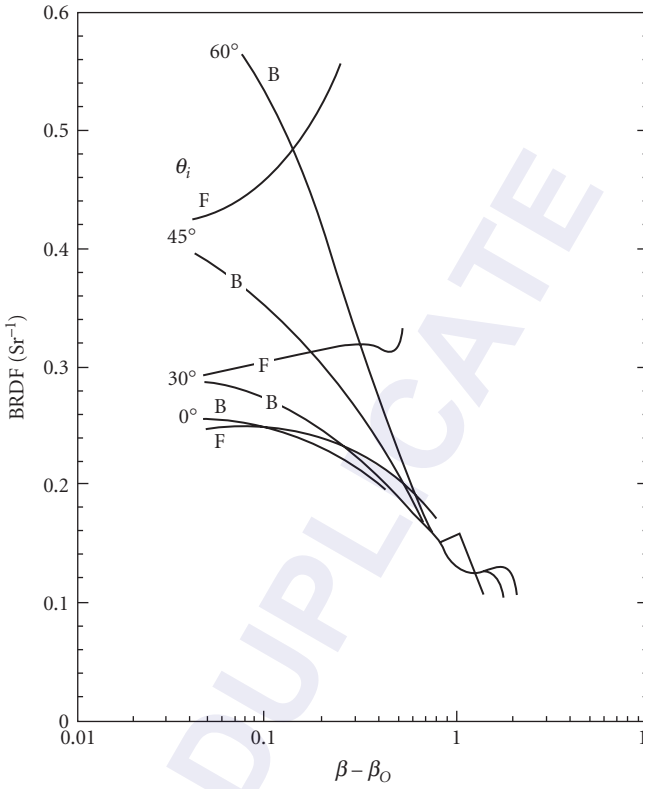

FIGURE 50 Forward (F) and back (B) scatter profiles of sandblasted aluminum. Wavelength of 633 nm. (*From Viehmann and Predmore*.[35])

Martin Black Martin Black is an anodized aluminum surface that is made microrough by a special anodization process developed by Lockheed Martin, Denver.[142,143] It is made black from the inclusion of an aniline dye that is sealed into the surface. It was developed for the Skylab program and has been used on a wide variety of space instruments operating at vacuum ultraviolet to far-infrared wavelengths. The surface is rough, and scattering at several fundamentally different scale lengths occurs.

Special care in handling surfaces of this class is needed since the surface morphology consists of pyramids extending from the surface, and these features are easily crushed. The surface is still quite black, however, even if some surface damage occurs. The surface morphology works well for space applications as it does not support electrical potentials higher than 200 V, is not affected by temperatures as high as 450°C, by hard vacuum, or by ultraviolet radiation. It also has very low outgassing rates and will not delaminate even under severe environmental conditions.[144] It passes NASA SP-R-0022A specifications for outgassing.

The surface is also highly resistant to chemical attack by atomic oxygen prevalent in low earth orbit.[64] BRDF measurements of Martin Black show its lambertian character at 0.6328 and 10.6 μm. The reflectance spectrum shows significant reflectances at about 2.5 and 5 μm; at other wavelengths, the reflectance is low. The optical data are given in Figs. 36, 51, and 52.

Enhanced Martin Black Enhanced Martin Black is similar in its properties to Martin Black, but was created to provide an even more durable surface for long exposure to atomic oxygen in low earth orbit. Experiments aboard the space shuttle confirm this superiority in the shuttle orbit environment.[64] The

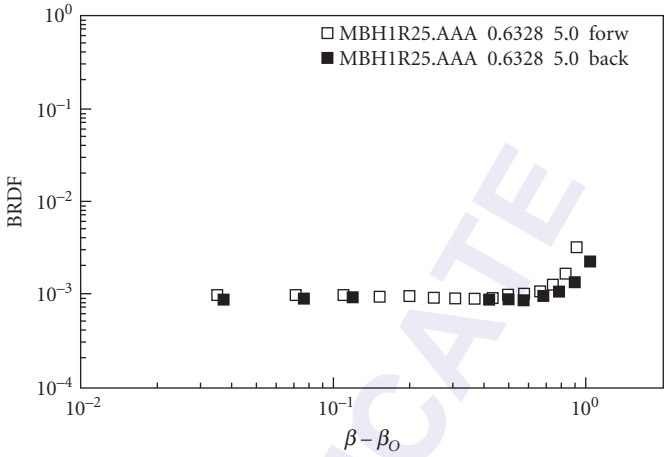

FIGURE 51 Visible (0.6328 μm) BRDF of Martin Black at 5° angle of incidence. (*From Pompea et al.*[4])

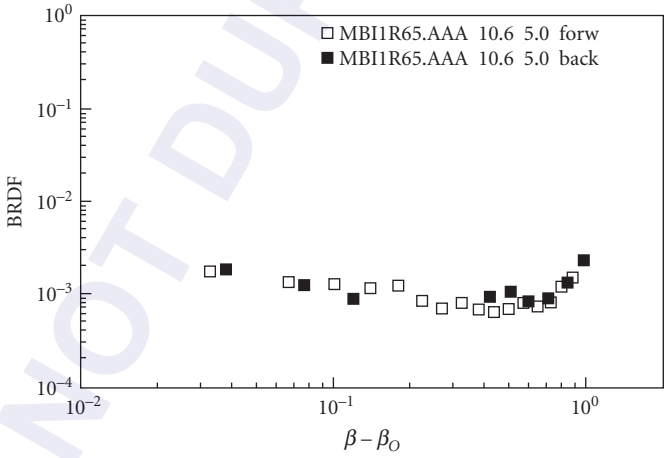

FIGURE 52 Infrared (10.6 μm) BRDF of Martin Black at 5° angle of incidence. (*From Pompea et al.*[4])

process refinements also reduced the near- and middle-infrared reflectances from about 40 percent at 2.3 μm to about 25 percent and from about 15 percent at 5.5 μm to about 3.5 percent, while maintaining an absorption of about 99.6 percent in the visible region.

Posttreated Martin Black Another variation of the Martin Black surface is designed for near-infrared applications. Posttreated Martin Black uses hydrogen fluoride to further reduce the near-infrared reflectance peak and eliminate the middle-infrared reflectance peak of Martin Black. The area under the 2.3-μm peak of Martin Black has been reduced by about two-thirds and the 5.8-μm peak of Martin Black has been eliminated.

Infrablack Infrablack is another anodized surface from Martin Marietta, which relies upon a very rough substrate to produce a diffusing and absorbing surface for wavelengths up to 750 μm.[138,145] It was developed for the next generation of far-infrared NASA telescopes. It has also been used in experiments to measure the Stefan-Boltzmann constant where a "blackbody" surface with very high emissivity was needed. This type of surface can also be used in space radiators where high emissivity is beneficial. Like other anodized surfaces in this class, the Infrablack surface is fragile and care in handling is needed to avoid crushing the surface structure. As with Martin Black, even a mistreated or crushed surface will still be significantly more light absorbing than most other black surfaces. Infrablack can be tuned for maximum absorption between 100 and 500 μm. The BRDF in the visible and infrared for Infrablack is similar to Martin Black and Enhanced Martin Black; all exhibit relatively lambertian behavior in the visible at near-normal angles of incidence (Figs. 53 and 54).

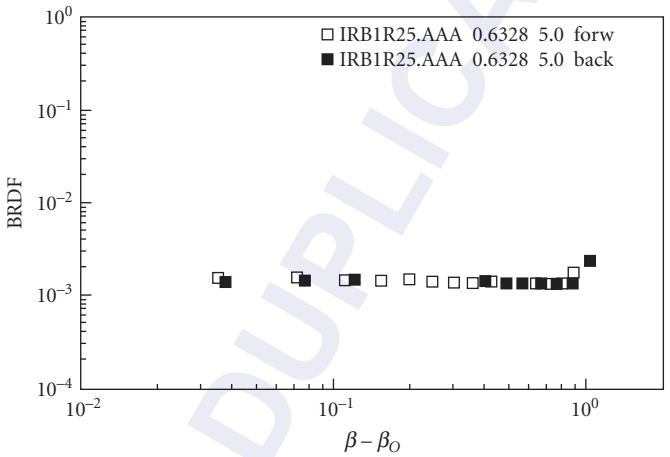

FIGURE 53 Visible (0.6328 μm) BRDF of Infrablack at 5° angle of incidence. (*From Pompea et al.*[4])

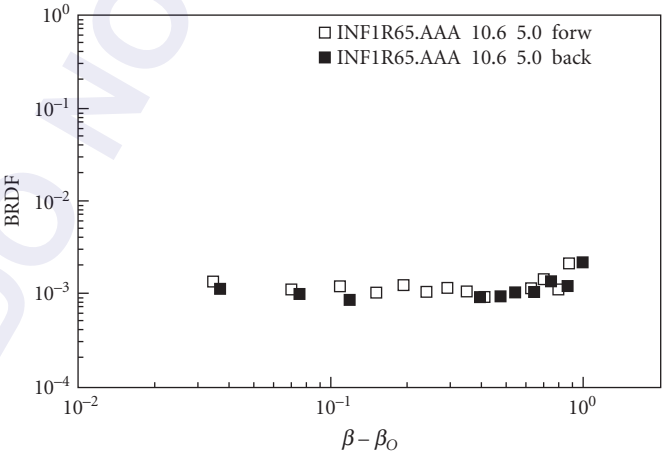

FIGURE 54 Infrared (10.6 μm) BRDF of Infrablack at 5° angle of incidence. (*From Pompea et al.*[4])

DEEP SPACE BLACK DEEP SPACE BLACK (N-Science/Advanced Surface Technologies, Arvada, Colorado) shares many if not most characteristics of Martin Optical Black, a similar specialized anodization process. Like Martin Black it is extremely absorptive over a wide range of wavelengths from ultraviolet to the infrared and is best used on 6061 aluminum. The surface has good mechanical stablility. The surface can be fine tuned for better performance in the near-infrared (1 to 5 μm) and for maximal durability in the low-earth orbit space environment. The total hemispherical reflectance in the 0.4- to 0.7-μm range is 0.37 and 0.78 percent in the 0.4- to 1.0-μm range. Like Martin Black, the surface does not support an electrical potential greater than 200 V and is robust under vibration and cryogenic cooling. When cryogenically cooled the surface has an emissivity in the far-infrared region (7 to 120 μm) of 0.985 or better.

This surface is used in controlling stray light or as black surface with high emissivity in a variety of optical systems such as detector cold shields and assemblies, detector calibration sources and blackbody cavities, thermal control and radiator surfaces, and spacecraft applications such as star trackers and cameras. DEEP SPACE BLACK is available in three variations:

DEEP SPACE BLACK-VIS: DSB-VIS is optimized for performance in the visible wavelength regime.

DEEP SPACE BLACK-Full Spectrum Basic: DSB-FSB is optimized to provide best performance over the largest wavelength regime possible. DEEP SPACE BLACK-Full Spectrum Enhanced: DSB-FSE is a special variant of DSB-FSB that has a more robust finish with the same outstanding optical characteristics of the FSB. DSB-FSE provides a somewhat improved optical performance in the near- and middle-IR. The performance in the visible region of the spectrum is maintained. This product is more suited to spacecraft applications, including those applications concerned with LEO environments.

Tiodize V-E17 Surface The Tiodize process is an electrolytic-conversion hard coating of titanium using an all-alkaline, room-temperature bath. It produces an antigall coating with good optical properties. The process can be used on all forms of titanium and its alloys and has been used in a wide variety of space vehicles and aircraft. The Ultra V-E17 coating is a black organic coating which changes the absorptivity and emissivity of titanium (0.62 and 0.89, respectively) to 0.89 and 0.91, respectively. The emittances were determined from a 25-point integration between 4.8 and 26.2 μm. The absorptance was determined by a 19-point integration between 0.32 and 2.1 μm. The surface has a total mass loss (TML) of 0.91 percent and no detectable volatile condensable material (VCM) in tests run at Ford Aerospace.[146] Its interaction with atomic oxygen is unknown.

TRU-Color Diffuse Black An electrolytic coloring process from Reynolds Aluminum.

Hughes Airborne Optical Adjunct Coating A cleanable specular black for use at 1 to 10 μm.

Etching of Electroless Nickel

The etching of electroless nickel provides a black coating useful for many applications. Some reference data on several electroless nickel processes are presented in Table 4. Kodama et al.[147] developed optical absorbing black films of etched nickel-phosphorus alloy deposited on substrates using an electroless plating process. Results of varying the plating and etching bath components and conditions were studied. They produced an optical absorber with a spectral reflectance of about 0.1 to 0.2 percent in the wavelength range of 488 to 1550 nm. The absorber showed substantial immunity to degradation in two accelerated-aging environments: 2000 hours in a dry-heat environment at 100°C, and 2000 hours in a damp-heat environment at 85°C and 85 percent relative humidity.

NBS Black This is a blackened electroless nickel surface developed for use as a solar collector at the National Bureau of Standards (now NIST) in Gaithersberg, MD.[75,76,148] It consists of an electroless nickel-phosphorous coating that can be plated onto a wide variety of substrates such as metals, glass, ceramics, and plastics. This coating is subsequently etched using nitric acid, creating conically shaped holes into the surface, which act as light traps.

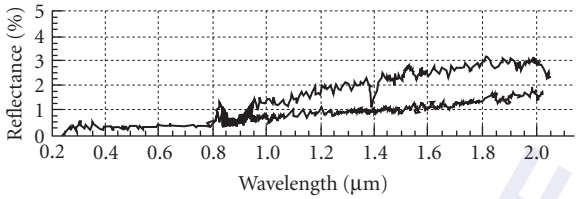

FIGURE 55 Total integrated scatter of NBS Black. The substrates are magnesium AZ31B-F (upper curve) and magnesium ZK60A-T5. Substrate is silica sandblasted. $\alpha = 0.978$. $\varepsilon = 0.697$. (*From Geikas.*[65])

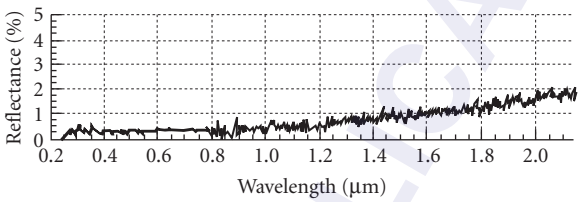

FIGURE 56 Diffuse scatter of NBS Black. The substrates are magnesium AZ31B-F and magnesium ZK60A-T5. The plots are overlaid and are virtually identical. Substrate is silica sandblasted. $\alpha = 0.978$. $\varepsilon = 0.697$. (*From Geikas.*[65])

The specular reflectance is less than 1 percent over the range of 0.32 to 2.4 μm, making it an extremely black coating (Figs. 55 and 56). As this surface finish was developed for solar collectors, the surface has a high value for absorptivity (0.978), but a low value for room-temperature emissivity (about 0.5). The surface is moderately durable as the surface's relief consists of conical holes into the surface. The NBS Black process has been modified resulting in the next surface, which has greater infrared absorption.

Ball Black Ball Black is an optical black surface produced with modifications to the techniques just described—the selective etching on an electroless nickel surface to produce a multiplicity of conical light traps in the surface.[29,65] The surface appears intensely black to the eye. The surface, however, is still an unaltered nickel-phosphorous deposit with the same chemical properties as the unetched surface, which was shiny. Ball Black can be plated on aluminum, beryllium, copper, stainless steel, invar, polycarbonate and ABS plastics, titanium, and some magnesium alloys. Since this process involves only deposition and etching of a metallic material, problems with outgassing or volatization of the surface in a vacuum are minimal.

The surface is able to withstand rapid changes in temperature, with immersion into boiling water after being at liquid nitrogen temperature. The surface is sensitive to handling, though less so than surfaces like Martin Black. Small blemishes in the surface can be restored by re-etching without replating. The solar absorptivity can be made to vary between 0.71 and 0.995 and its room-temperature emissivity can be tailored to values between 0.35 and 0.94 by changes in the etching parameters. The directional reflectance increases by less than a factor of two from 1.5 to 12 μm. It has a BRDF of about 6×10^{-2} at normal incidence at 0.6328 μm. See Figs. 57 and 58 for optical data.

Plasma-Sprayed Surfaces

Boron Black Martin Marietta Boron Black is a surface that is black in the visible (solar absorptivity between 0.89 and 0.97, and emissivity of at least 0.86) and black in the infrared[149] (Fig. 59). Boron

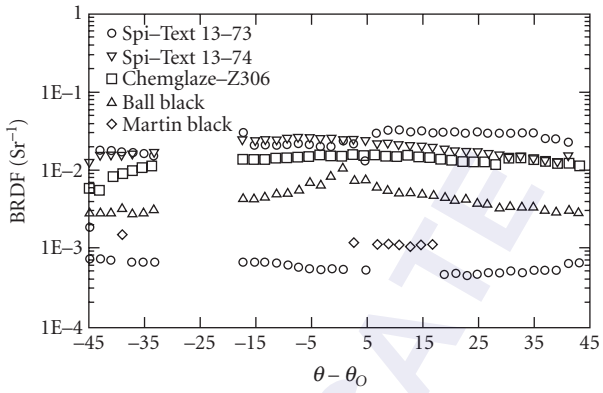

FIGURE 57 BRDF measurements at 0.6328 μm of textured metal surfaces from Spire Corporation and Chemglaze Z306 paint, Ball Black electroless nickel coating, and Martin Black anodized coating. (*From Lompado et al.*[29])

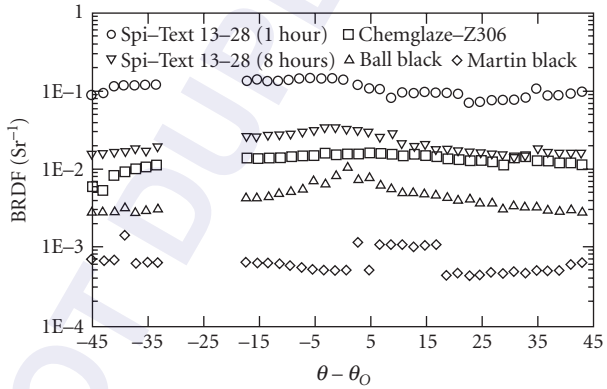

FIGURE 58 BRDF measurements at 0.6328 μm of two textured metal surfaces from Spire Corporation and Chemglaze Z306 paint, Ball Black electroless nickel coating, and Martin Black anodized coating. (*From Lompado et al.*[29])

Black is a plasma-sprayed surface and can probably be applied to most metallic substrates. It has been applied to molybdenum, nickel, and titanium substrates. It offers a low-atomic-number surface with good optical properties and the ease of a plasma-spray deposition. The infrared BRDFs show a profile characteristic of a surface with lambertian profiles at near-normal angles of incidence.

Boron Carbide This is a Martin Marietta proprietary process. The boron carbide surface is applied to a titanium substrate. A 10- to 15-μm layer of B_4C is applied in a proprietary plasma-spraying process. BRDF measurements at 30° angle of incidence at two wavelengths illustrate that this surface is more lambertian in the visible.

Beryllium Surfaces Porous surfaces or those with steep-walled features which can trap radiation have been developed using plasma-sprayed beryllium and sputter-deposited beryllium by workers at Oak Ridge[82,150,151] and at Spire Corp.[152] who are developing baffles that can operate in severe environments.

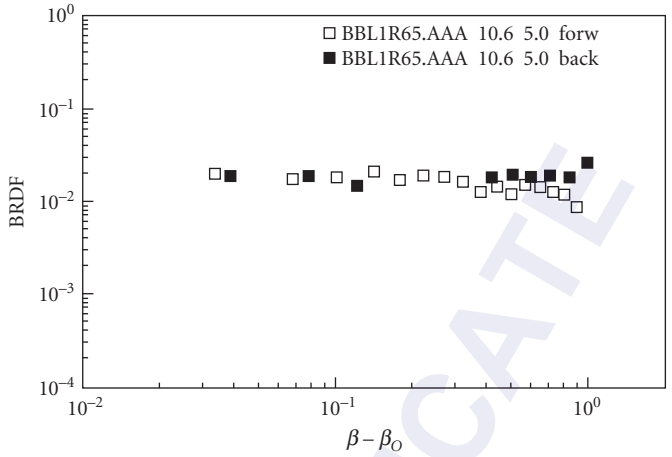

FIGURE 59 Infrared (10.6 μm) BRDF of Boron Black Black at 5° angle of incidence. (*From Pompea et al.*[4])

Plasma-sprayed beryllium samples appear visually rough with a matte gray finish. The specular reflectance is approximately constant at about 1.6 percent from 2 to 50 μm, while the BRDF is lambertian in character at near-normal angles of incidence with a value of about 5×10^{-2} sr^{-1}, equivalent to a total hemispherical reflectance of about 15 percent.

Beryllium surfaces with varying thicknesses and columnar grain sizes can also be created by low-temperature magnetron sputtering. The surfaces can then be chemically etched to enhance their absorptive properties. These surfaces exhibit less than 2 percent specular reflectance at near-infrared wavelengths. Very thick surfaces (350 μm) exhibit specular reflectances of less than 0.5 percent up to 50 μm wavelength.

A sputtered coating of Be on a Be surface can be made more absorptive through exposure to an oxygen plasma to form a layer of BeO on the surface of the coating.[29] Optical data are presented in Figs. 57, 58, 60, and 61.

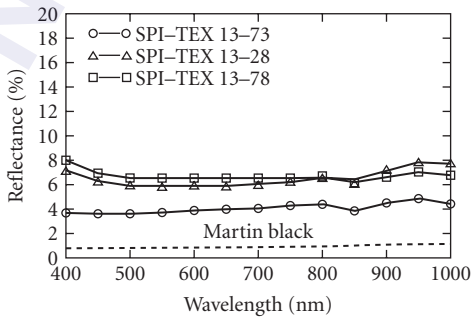

FIGURE 60 Total hemispherical reflectance in the visible bandpass for textured baffle materials from Spire Corp. The 13–73 surface is a textured aluminum surface. (*From Spire.*[81])

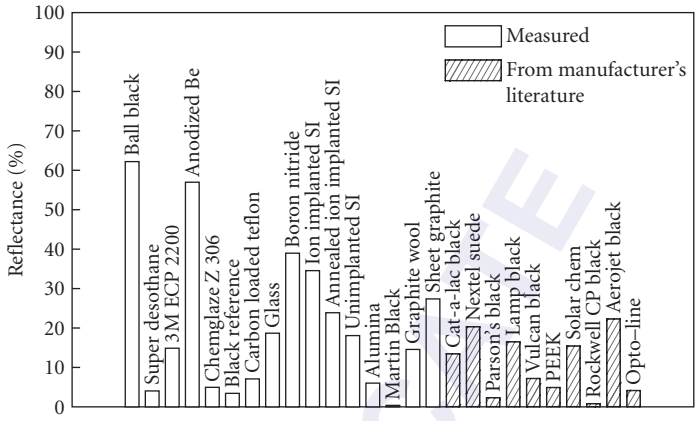

FIGURE 61 Total hemispherical reflectance data for baffle materials at 10.6 μm. The shaded measurements are from the manufacturer's literature and have not been independently verified. (*From Johnson.*[153])

Ion Beam-Sputtered Surfaces

Ion beam-sputtering processes can roughen surfaces of a large variety of compositions. An excellent review is by Banks in Cuomo et al.[77] (see also Ref. 78). A variety of sputtering processes can create rough features of various geometries that decrease specular reflections and create a black-appearing surface from a light-appearing substrate. Since the roughness is integral to the surface, these surfaces often have desirable environmental resistance to atomic oxygen. However, these surfaces also have tremendous surface area for trapping of contaminants and thus a potential for large outgassing rates if preventative steps are not taken. These surfaces are expensive to make in large areas, though they are becoming less expensive as coating facilities are built to harness this technology. They do have tremendous potential as diffuse baffle surfaces and as high-emittance surfaces for high-temperature space radiators.[154,155] They are also cleanable and very durable.

Lompado et al.[29] and Blatchley et al.[83] describe several textured aluminum surfaces and give plots of their total hemispherical reflectance in the 0.4- to 1.0-μm range, as well as BRDF plots at 0.6328 and 10.6 μm (Fig. 60).

Electrodeposited Surfaces

Refer to Table 4 for further reference data on these surfaces.

Black Cobalt Black cobalt is a patented surface developed at Martin Marietta[156] which appears black in the visible, with a solar absorptivity of at least 0.96 and emissivity of at least 0.6. It is applied by an electrodeposition process to a substrate of nickel, molybdenum, or titanium; other substrates are also expected to work. It can be used at higher temperatures than anodized aluminum surfaces such as Martin Black. It is stable against loss of absorptivity at temperatures greater than 450°C for prolonged periods. The surface is not a lambertian surface at 10.6 μm (Fig. 62).

Black Chrome A black chrome surface developed for aerospace use[157] is black in the visible and is created by an electroplating process on a conducting substrate. Many metallic substrates can be used and samples on molybdenum, nickel, and titanium have been made. The preferred substrates are titanium and molybdenum. The coating process involves electrodeposition using chromium and chromium oxides. The visible BRDF is flat (Fig. 63), while the infrared profile shows the surface to

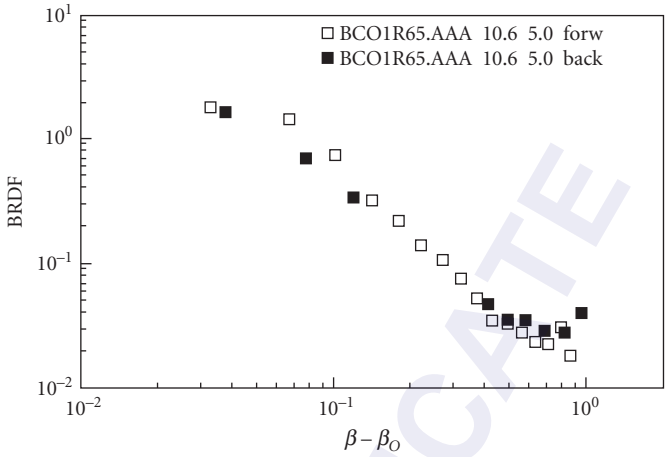

FIGURE 62 Infrared (10.6 μm) BRDF of Black Cobalt at 5° angle of incidence. (*From Pompea et al.*[4])

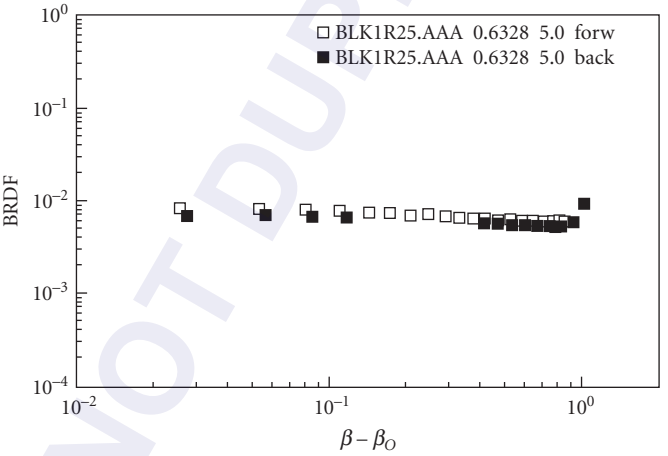

FIGURE 63 Visible (0.6328 μm) BRDF of Black Chrome at 5° angle of incidence. (*From Pompea et al.*[4])

be largely specular in its scattering profile. The solar absorptivity is at least 0.95 and the emissivity can be tailored in the range of 0.4 to 0.8. The surface has excellent adhesion to the substrate.

Orlando Black Optical Coating A dendritic surface is produced by the electrodeposition of copper in a proprietary copper-plating formulation (Janeczko[158]). The dendritic structure is then oxidized to form smaller structures superimposed on the larger ones. The surface has excellent broadband absorption properties from 0.4 to 14 μm and good absorptance at nonnormal angles of incidence (Fig. 64). It may be suitable for use at shorter wavelengths. The surface is usable in vacuum environments as well as a thermal reference in FLIR systems. A wide variety of materials can be coated including ABS plastic, nylon, Ultem, Noryl, fiberglass-reinforced epoxy, glass, stainless steel, copper, brass, nickel, aluminum, gold, and beryllium oxide. Dimensional allowances must be made for the thickness of the finish (approximately 0.001 in).

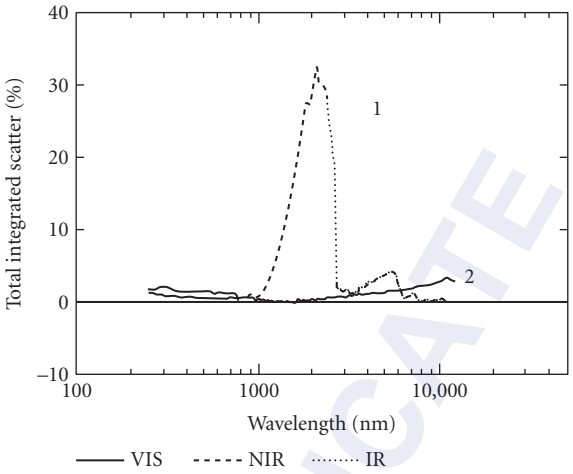

FIGURE 64 Total integrated scatter measurement of (1) and (2) Orlando Black commercially available anodized aluminum. (*From Janeczko*.[158])

Other Specialty Surfaces

Refer to Table 4 for further data on some of these surfaces.

Acktar Black Coatings (Acktar Ltd., Kiryat-Gat, Israel) Aktar makes a number of black coatings including Nano Black, Magic Black, Vacuum Black, Fractal Black, Ultra Black, and Metal Velvet. These inorganic coatings each have a wide range of working temperatures, very low outgassing (CVCM) in the 0.001 percent range and RML in the 0.167 percent range. Additionally the coatings have excellent adhesion to aluminum, copper, stainless steel, invar, kovar, glass, ceramics, polyimide, nickel, magnesium, titanium and other metals. There are options to make the coatings electrically conductive or nonconductive. The company also makes high emissivity foils.

Carbon Nanotubes and Nanostructured Materials Carbon nanotube arrays can also be used to create ultrablack surfaces. These surfaces are not yet practical for many applications but may have utility in specialized areas. For example, Yang et al.[159] have demonstrated that low-density vertically aligned carbon nanotube arrays can be engineered to have an extremely low index of refraction. The nanoscale surface roughness of the arrays contributes to an ultralow diffuse reflectance of 1×10^{-7}; an order-of-magnitude lower compared to commercial low-reflectance standard carbon. The nanotube arrays can have an integrated total reflectance of 0.045 percent making it among the darkest materials ever fabricated.

Vorobyev and Guo[160] and Paivasaari et al.[161] have also showed that laser ablation and altering of metallic surfaces can lead to greatly enhance optical absorptance.

Nanostructuring alone can enhance the absorptance by a factor of about three or more. The physical mechanism of the increased absorption is due to several effects including nanostructural, microstructural, and macrostructural surface modifications. The value of femtosecond laser ablation techniques using high fluences with a large number of applied pulses in reducing surface reflectivity may be applicable for a wide variety of metallic surfaces. Currently the process is time consuming for large area surfaces.

DURACON (American IMEX Corporation, Monroe, CT) *DURACON* is another high emissivity (>0.98 over the 0.55- to 1.8-μm range; >0.95 over the 2- to 20-μm wavelength range) durable black coating used in applications that cover a variety of wavelengths, especially the middle-infrared. It has

good thermal diffusivity and the interesting property that its conductivity can be tailored from low resistivity (less than 700 Ω cm) to nearly an insulating surface. Thus, it can be used in environments where electrostatic discharge may be damaging to dielectric and insulating surfaces. It has good adherence and can be used on ceramic, glass, composite, plastic, and metal surfaces. It is durable to handling, unlike some anodized surfaces with surface structures that can be damaged by abrasion or direct compression. It also has very good ability to withstand wind shear at high Mach numbers and to withstand thermal cycling to 1000°F.

The surface can be applied by brush on, spray, or dip coating and any damaged areas can be repaired using a brushed on application of a fresh layer. The product is reported to be ready for normal regular use in 2 hours after this repair.

Electrically Conductive Black Paint Birnbaum et al.[51] developed an electrically conductive, flat black paint for space use in places such as Jupiter's radiation belts where spacecraft charging effects can be important. Its small resistivity prevents the buildup of charge on the surface. It has a visual reflectance of less than 5 percent and other desirable optical properties.

Epner laser black (Brooklyn, New York) This makes a well-known coating used in a variety of application. Laser Black is a multilayer metallic oxide that has a microdendritic structure susceptible to crushing. This inorganic coating does not outgas and when vibrated ultrasonically in acetone shows no flaking or chipping. It has good durability at cryogenic temperatures and can be applied to any metallic substrate and most plastics. It requires a deposition of copper approximately 10 to 12 μm thick. Laser Black is used in cold shields for micro-bolometers and in baffles.

Ebanol C This specialty cupric oxide coating can be applied per MIL-C-14550 undercoat and MIL-F-495 processes: immersion in a zincate bath followed by a high cyanide, low copper bath, and copper strike and dip in an Ebanol C solution.[9]

High-Resistvity Coatings Strimer et al.[162] describe a number of black surfaces with high electrical resistivity for visible and infrared applications.

Sputtered and CVD Surfaces Carbon, quartz, and silicon surfaces have been modified by sputtering or by chemical vapor deposition[163–165] to create surfaces that are black over the wavelength range of 1 to 15 μm. The textured surfaces are produced by sputtering with a low-energy (e.g., 500 eV) broadbeam ion source while adding impurities to the surface. The results from sputtering with this seeding process are structures in the form of cones, pyramids, and ridges. The exact nature of the surfaces created depends on the substrate temperature, ion and impurity fluxes, and the impurity species. The reflectivity of one modified silicon surface was below 1 percent throughout 1- to 25-μm wavelength range.

Silicon Carbide A silicon carbide surface for high-temperature applications was developed at Martin Marietta for application to a carbon-carbon substrate. It is applied to a hot substrate by a chemical vapor deposition process. The visible BRDF is flat, while the infrared profiles show the surface's specular nature at the longer wavelength.[4]

IBM Black (Tungsten Hexafluoride) This is a surface being produced at Martin Marietta, Orlando, using a process licensed from IBM. Any material that can tolerate 400°C can be used as a substrate for this process which involves vapor deposition of tungsten. The surface has dendritic structures that form light-absorbing traps. The surface looks like a collection of obelisks, does not outgas, and is rugged to the touch. Optical properties and an SEM photograph of the surface are given by Willey et al.[42] The surface is very black in the 1- to 2-μm wavelength range.

ZO-MOD BLACK ZO-MOD BLACK (ZYP Coatings, Oak Ridge, Tenn.) is a high-emissivity coating applied like paint to ceramic porous and fibrous structures. On heating, a hard abrasion- and chemical-resistant, calcia-stabilized zirconium oxide coating is formed. The coating has high emissivity. The coating has been used inside of ceramic furnaces.

Gold Black Gold blacks are fragile surfaces made by evaporating gold in a low-pressure atmosphere of helium or nitrogen. The surface has good visible light absorption. The preparation and optical properties of gold blacks are given by Harris and McGinnies,[166] Blevin and Brown,[167] and Zaeschmar and Nedoluha.[168]

Flame-Sprayed Aluminum Flame-sprayed aluminum is a very durable and very rough surface that has uses as an infrared diffuse reflectance standard. The parameters of the flame-spray process must be tightly controlled to create a similar surface each time.

Black Glass Black glass is available from Schott Glass Technologies, Duryea, Pa., in a glass called UG1, which is an ionically colored glass. Star Instruments, Flagstaff, Ariz., produces a glossy black glass called LOX8. It is a low-expansion copper glass with a coefficient of expansion of about 30 times lower than Pyrex.

Black Kapton The optical properties of Black Kapton are given in Fig. 65.

Other Surfaces Some other data is given for specular metallic anodized baffle surfaces (Fig. 66). This kind of basic treatment is adequate for some applications. The BRDF of Beta cloth is given in Fig. 67. Figure 68 shows the potential of various structured carbon surfaces to be highly absorbing over a wide range of angles. These kind of surfaces have great potential for the future.

6.9 CONCLUSIONS

Black surfaces are used as optical elements in a variety of ways. There is a great choice of surfaces available, but the selection of the appropriate surface is often problematical. The consequences of choosing the wrong surface are often quite severe.

For the selection process to be most effective, it must be done as early as possible. While the optical data on surfaces is relatively extensive, the data are often inconsistent or are not available for the particular wavelength of interest. The creation of large databases of optical and material properties is a great aid to the optical designer and materials consultant. Of great concern for space materials is the lack of very long term environmental test data. The synergistic effect of a number of degrading influences (e.g., solar ultraviolet, charging effects, atomic oxygen) is unknown for many interesting and potentially effective space materials. The use of specialized surfaces that can be tailored for very specific applications is an emerging trend and is likely to continue.

When black surfaces are used effectively in optical systems, the performance of the system can be greatly enhanced. However, when other approaches to stray light control are not implemented, even the "blackest" possible surfaces cannot establish the desired system performance. This cruel fact is a persuasive basis for an integration of black surface selection into the general stray light design studies, which today are nearly mandatory for the design of high-performance optical devices.

6.10 ACKNOWLEDGMENTS

The National Optical Astronomy Observatory is operated by the Association of Universities for Research in Astronomy (AURA), Inc. under cooperative agreement with the National Science Foundation. Special thanks to J. Heaney (NASA Goddard Space Flight Center), S. H. C. P. McCall (Stellar Optics

Laboratory, Inc.), and S. Smith (NASA Ames Research Center) for the use of their unpublished data. Thanks to R. Bonaminio (Lord Corp.), C. Bowers (Hughes Aircraft Co.), B. Banks (NASA Lewis Research Center), R. Harada (IIT Research Institute), D. Janeczko (Martin Marietta Corp.), A. Olson (Ball Aerospace), R. Seals (Oak Ridge National Laboratory), D. Shepard (Lockheed Martin), and S. Smith (NASA Ames Research Center) for providing data and photographs. Thanks also to J. Martin, L. Bergquist, F. Bartko, R. Culver, and S. Russak for support in the early stages of this work, and to D. Shepard, S. McCall, S. Smith, and W. Wolfe for helpful suggestions on this manuscript.

OPTICAL PROPERTIES OF FILMS AND COATINGS

Jerzy A. Dobrowolski

Institute for Microstructural Sciences
National Research Council of Canada
Ottawa, Ontario, Canada

7.1 INTRODUCTION

Scope of Chapter

In the broadest sense of the term, an optical filter is any device or material which is deliberately used to change the spectral-intensity distribution or the state of polarization of the electromagnetic radiation incident upon it. The change in the spectral intensity distribution may or may not depend on the wavelength. The filter may act in transmission, in reflection, or in both.

Filters can be based on many different physical phenomena, including absorption, refraction, interference, diffraction, scattering, and polarization. For a comprehensive review of this broader topic the interested reader is referred to the chapter entitled "Coatings and Filters" which appeared in the first edition of the *Handbook of Optics*.[1] This chapter deals only with filters that are based on absorption and interference of electromagnetic radiation in thin films. Optical thin-film coatings have numerous applications in many branches of science and technology and there are also many consumer products that use them. The spectral region covered in this chapter extends from about 0.003 to 300 μm (3 to 3×10^5 nm), although the main emphasis is on filters for the visible and adjacent spectral regions.

The discussion in this chapter is largely confined to generic thin-film filters, such as antireflection coatings, cutoff filters, narrowband transmission or rejection filters, reflectors, beam splitters, and so forth. Filters for very specific applications, such as filters for colorimeters and other scientific instruments, color correction filters, and architectural coatings, are, as a rule, not treated. Of the filters described, many are available commercially while others are only research laboratory prototypes. This review does not cover thin-film filters whose properties can be changed by external electric or magnetic fields, temperature, or illumination level.

In this introductory section some general considerations on the use of optical filters are presented. In the following sections, the theory of optical multilayers and the methods for their deposition and characterization are briefly discussed. These sections are useful for gaining a proper understanding of the operation, advantages, and limitations of optical coatings. The remaining sections then describe the properties of various generic thin-film filters.

For further information on this subject the interested reader is particularly encouraged to consult the books by Macleod,[2] Rancourt,[3] and Baumeister.[4]

General Theory of Filters

There are many different ways of describing the performance of optical coatings and filters. For example, transmission and reflection filters intended for visual applications are adequately described by a color name alone, or by reference to one of the several existing color systems (see Chap. 10, Vol. III). There also exist other specialized filter specifications for specific applications. However, the most complete information on the performance of a filter is provided by spectral transmittance, reflectance, absorptance, and optical density curves. This is the method adopted in this chapter.

Referring to Fig. 1, at a wavelength λ the spectral transmittance $T(\lambda)$ of a filter placed between two semi-infinite media is equal to the ratio of the light intensity of that wavelength transmitted $I_T(\lambda)$ by the filter to that incident $I_0(\lambda)$ upon it,

$$T(\lambda)=\frac{I_T(\lambda)}{I_0(\lambda)} \tag{1}$$

The spectral reflectance $R(\lambda)$ of a filter is defined in a similar way,

$$R(\lambda)=\frac{I_R(\lambda)}{I_0(\lambda)} \tag{2}$$

At non-normal incidence the component of the intensity perpendicular to the interface must be used in the above equations.[2] The relationship between the transmittance $T(\lambda)$ and the density $D(\lambda)$ of a filter is given by

$$D(\lambda)=\log\frac{1}{T(\lambda)} \tag{3}$$

In this chapter, transmittances and reflectances will be plotted using either linear or logarithmic scales. The logarithmic scale is particularly well suited whenever accurate information about the low transmission or reflection region is to be conveyed. However, this is done at the expense of detail at the high end of the scale. A variant, the decibel scale, equal to $-10D(\lambda)$, is frequently used in the telecommunications field. Wavelengths are normally specified in micrometers (μm) because this is the most convenient unit for the whole spectral range covered in this chapter. In the following discussions the dependence of the transmittance, reflectance, and absorptance on wavelength will be implicitly assumed.

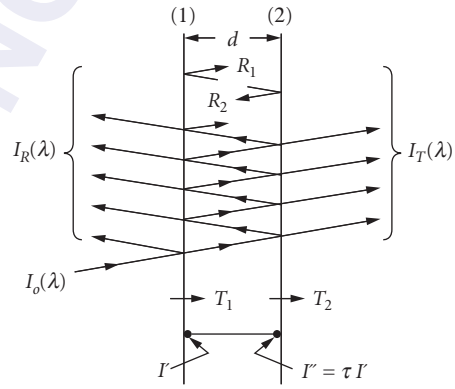

FIGURE 1 Specular transmission and reflection of light by a plane-parallel plate (see Sec. 7.1, subsection "General Theory of Filters").

Transmission and Reflection of Coatings on a Substrate

Many multilayer coatings are deposited onto a transparent or partially transparent substrate. Both the multilayer and the substrate contribute to the overall performance of the filter. For example, absorption in the substrate is frequently used to limit the transmission range of the filter. Reflectances at the filter interfaces need also to be considered. However, they can be reduced by antireflection coatings, or by cementing several components together.

In general, a filter can consist of multilayer coatings deposited onto one or both sides of a substrate. The overall transmittance T_{total} of a filter can be expressed in terms of the internal, or intrinsic transmittance τ of the substrate and the transmittances T_1, T_2 and internal reflectances R_1, R_2 of each surface of the substrate (Fig. 1).

The internal transmittance τ of a substrate is defined to be the ratio of the light intensity I'' just before reaching the second interface to the intensity I' just after entering the substrate (Fig. 1):

$$\tau = \frac{I''}{I'} \tag{4}$$

Expressions for the evaluation of the transmittance T and reflectance R of multilayer coatings are given in Sec. 7.2, subsection "Matrix Theory for the Analysis of Multilayer Systems."

Providing that the incident light is not coherent, there will be no interference between the beams reflected from the two surfaces of a substrate, even when the surfaces are plane parallel. A summation of all the partial reflections leads to the following expression for the overall spectral transmittance T_{total} of a filter:

$$T_{\text{total}} = \frac{T_1 T_2 \tau}{1 - R_1 R_2 \tau^2} \tag{5}$$

The reflection coefficients of uncoated interfaces can be calculated from Eq. (80), providing that the complex refractive indices of the substrate and of the medium are known. If all the materials in the filter are nonabsorbing, then

$$T_{\text{total}} = \frac{T_1 T_2}{1 - R_1 R_2} \tag{6}$$

If R_1 is small, an appropriate expression for T_{total} is

$$T_{\text{total}} \approx [1 - R_1(1 - R_2)]T_2 \tag{7}$$

However, this last approximation is not valid in general; some infrared substrate materials have high-reflection coefficients and in such cases Eq. (6) must be used.

Transmission Filters in Series and Parallel

To obtain a desired spectral transmittance it is frequently necessary to combine several filters. One common approach is to place several filters in series (Fig. 2*a*).

Because of the many different partial reflections that may take place between the various surfaces, precise formulas for the resulting transmittance are complicated.[5] Accurate calculations are best carried out using matrix methods.[6]

To a first approximation, the resultant transmittance T' of a filter system consisting of k individual filters placed in series is given by

$$T' \approx T_1' T_2' T_3' \cdots T_k' \tag{8}$$

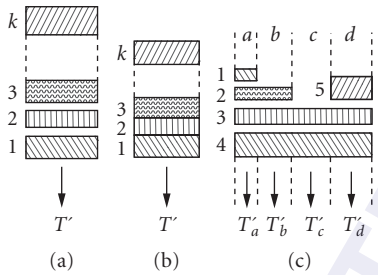

FIGURE 2 Transmission filters arranged in series and in parallel. The filters can be air-spaced (*a*), (*c*) or cemented (*b*).

Here T_i' is the total transmittance of filter *i*. This expression is valid only if the reflectances of the individual filters are small or if the interference filters are slightly inclined to one another and the optics are arranged in such a way that the detector sees only the direct beam.

Under other circumstances the use of this expression with interference filters can lead to serious errors. Consider two separate filters placed in series and let T_1', T_2', R_1' and R_2' correspond to the transmittances and reflectances of the two filters. If $T_1' = T_2' = R_1' = R_2' = 0.5$, then according to Eq. (8), the resulting transmittance will be $T' = 0.25$. For this simple case the precise expression can be derived from Eq. (5) and is given by

$$T' = \frac{T_1' T_2'}{1 - R_1' R_2'} \tag{9}$$

Evaluating this expression one obtains $T' = 0.33$. This is significantly different from the result obtained from the application of Eq. (8).

Some spectral transmittance curves cannot be easily designed by placing filters in series alone. For certain applications it is quite acceptable to place filters not only in series, but also in parallel.[7] This introduces areas as additional design parameters. Thus, for example, the effective spectral transmittance T' of the filter shown in Fig. 2*c* would be given by

$$T' = \left(\frac{a}{A} T_a' + \frac{b}{A} T_b' + \frac{c}{A} T_c' + \frac{d}{A} T_d' \right) \tag{10}$$

where

$$A = \text{overall area of filter},$$

$$a, b, c, d = \text{areas of the four zones},$$

$$T_a', T_b', T_c', T_d' = \text{transmittances of four zones}$$

The latter are given by

$$\begin{aligned} T_a' &= T_1' \cdot T_2' \cdot T_3' \cdot T_4' \\ T_b' &= T_1' \cdot T_2' \cdot T_3' \\ T_c' &= T_1' \cdot T_2' \\ Td' &= T_1' \cdot T_2' \cdot T_3' \cdot T_5' \end{aligned} \tag{11}$$

Great care must be exercised when using such filters. Because the spectral transmittance of each zone of the filter is different, errors will result unless the incident radiation illuminates the filter uniformly.

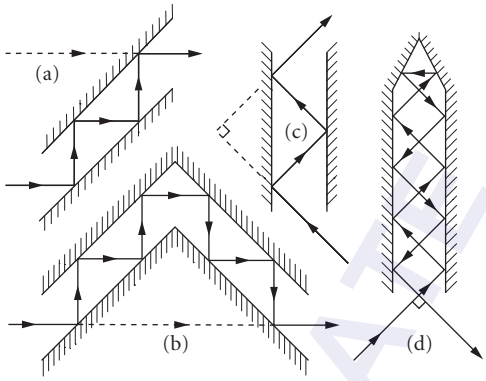

FIGURE 3 Various arrangements (*a*) to (*d*) for multiple-reflection filters.

Similar care must be used when employing the filtered radiation. One way proposed to alleviate these problems is to break the filter down into a large number of small, regular elements and to reassemble it in the form of a mosaic.[8]

Reflection Filters in Series

If radiation is reflected from k different filters, the resultant reflectance R' will be given by

$$R' = R'_1 \cdot R'_2 \cdot R'_3 \cdots R'_k \tag{12}$$

which is analogous to Eq. (8) for the resultant tansmittance of filters placed in series. Many of the considerations of that section also apply here. For instance, R' will be significant only at those wavelengths at which every one of the reflectors has a significant reflectance. Metal layers (Sec. 7.15, subsection "Reducing Reflection with a Thin Metal Film") and thin-film interference coatings can be used exclusively or in combination.

For the sake of convenience the number of different reflecting surfaces used is normally restricted. The outlines of some possible reflector arrangements given in Fig. 3 are self-explanatory. The arrangement shown in Fig. 3*b* does not deviate or displace an incident parallel beam. The number of reflections depends in each case on the lengths of the plates and on the angle of incidence of the beam. Other arrangements are possible.

Clearly, reflection filters placed in series require more space and are more complicated to use than transmission filters. But if in a given application these shortcomings can be accepted, multiple-reflection filters offer great advantages, which stem mainly from the nature of the reflectors available for their construction (see Sec. 7.16, subsection "Multiple Reflection Filters").

7.2 THEORY AND DESIGN OF OPTICAL THIN-FILM COATINGS

Design Approaches

A thin-film designer may be asked to design a multilayer coating in which the transmittance, reflectance, and/or absorptance values are specified at a number of wavelengths, angles, and polarizations of the incident light. The designer may be required to provide a coating with many other more

complicated properties, including integral quantities such as CIE color coordinates, solar absorptance, or emissivity.[9] The parameters that can be used to reach these goals are the number of layers in the multilayer, its overall thickness, the layer thicknesses and the refractive indices and extinction coefficients of the individual layers and of the surrounding media. Clearly, the more demanding the performance specifications, the more complex the resulting system. Many different methods have been developed for the design of multilayer coatings. For a good overview of this topic the interested reader is referred to the books by Macleod,[2] Knittl,[10] and by Furman and Tikhonravov.[11] Here only the most important methods will be mentioned.

Graphical vector methods provide the most understanding of the problem, but the necessary approximations limit them to the solution of problems in which the final reflectance is not too high. Admittance diagrams and similar chart methods do not suffer from this limitation, but they are best applied to problems in which the specifications are relatively simple.[12] Many problems can be solved using the known properties of periodic multilayer systems.[13] Analytical synthesis methods yield solutions to problems in which quite complex spectral transmittance or reflectance curves are specified.[14,15] However, solutions frequently obtained in this way call for the use of inhomogeneous layers that are often more difficult to deposit, or for homogeneous layers with optical constants that are outside the range of known materials. Numerical design methods are the most flexible of all because they can be applied to problems with very complex specifications requiring a large number of layers for their solution.[16,17] They are usually based on the matrix theory of optical multilayer systems and are particularly powerful for the solution of complicated spectral problems when combined with analytical methods.

Matrix Theory for the Analysis of Multilayer Systems

If electromagnetic radiation falls onto a structure consisting of thin films of several different materials, multiple reflections will take place within the structure. Depending on the light source and the layer thicknesses, the reflected beams may be coherent and interfere with one another. This optical interference can be used to design optical multilayer filters with widely varying spectral characteristics. In this section the basic equations for thin-film calculations are presented and some general properties of interference filters are listed. For a thorough discussion of this topic the reader is referred to the work of Macleod[2,18] and Thelen.[19]

Consider the thin-film system consisting of L layers shown in Fig. 4. The construction parameters comprise not only the refractive indices n_j and the thicknesses d_j of the layers $j = 1, 2, \ldots L$, but also

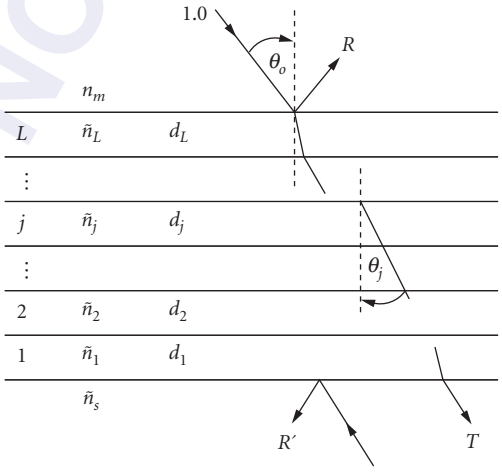

FIGURE 4 Construction parameters of a multilayer.

the refractive indices n_s and n_m of the substrate and the incident medium. The angle of incidence θ, the wavelength λ, and the plane of polarization of the incident radiation are the external variables of the system. It should perhaps be mentioned here that in some application areas it is more customary to use the grazing angle of incidence θ_g, where $\theta_g = 90 - \theta$.

The most general method of calculating the transmittance T and the reflectance R of a multilayer from the above quantities is based on a matrix formulation[20,21] of the boundary conditions at the film surfaces derived from Maxwell's equations.[21]

It can be shown that the amplitude reflection r and transmission t coefficients of a multilayer coating consisting of L layers bounded by semi-infinite media, for the general case of obliquely incident light, are given by

$$r = \frac{\eta_m E_m - H_m}{\eta_m E_m + H_m} \tag{13}$$

and

$$t = \frac{2\eta_m}{\eta_m E_m + H_m} \tag{14}$$

where

$$\begin{pmatrix} E_m \\ H_m \end{pmatrix} = \mathbf{M} \begin{pmatrix} 1 \\ \eta_s \end{pmatrix} \tag{15}$$

E_m and H_m are the electric and magnetic vectors, respectively, in the incident medium, and $\mathbf{M}$ is a product matrix given by

$$\mathbf{M} = \mathbf{M}_L \mathbf{M}_{L-1} \cdots \mathbf{M}_j \cdots \mathbf{M}_2 \mathbf{M}_1 \tag{16}$$

In the above equation $\mathbf{M}_j$ is a 2×2 matrix that represents the jth film of the system:

$$\mathbf{M}_j = \begin{pmatrix} m_{11} & im_{12} \\ im_{21} & m_{22} \end{pmatrix} = \begin{pmatrix} \cos\delta_j & \frac{i}{\eta_j}\sin\delta_j \\ i\eta_j \sin\delta_j & \cos\delta_j \end{pmatrix} \tag{17}$$

where

$$\delta_j = \frac{2\pi}{\lambda}(n_j d_j \cos\theta_j) \tag{18}$$

the quantity $n_j d_j \cos\theta_j$ is the *effective optical thickness* of the layer j for an angle of refraction θ_j. In Eqs. (13) to (17) η represents the admittance of the medium, substrate, or layer and is given by

$$\eta = \begin{Bmatrix} \frac{n}{\cos\theta} & p\text{-polarization} \\ n\cos\theta & s\text{-polarization} \end{Bmatrix} \tag{19}$$

depending on whether the incident radiation is polarized parallel (p) or perpendicular (s) to the plane of incidence. Clearly, for normal incidence of light, the value of the admittance is equal to the refractive index. The angle θ_j is related to the angle of incidence θ_0 by Snell's law

$$n_m \sin\theta_0 = n_j \sin\theta_j \tag{20}$$

The intensity transmittance and reflectance are

$$T=\frac{\eta_s}{\eta_m}|t|^2 \tag{21}$$

$$R=|r|^2 \tag{22}$$

and the phase changes on transmission and reflection, ϕ_T and ϕ_R, are given by

$$\phi_T=\arg t \tag{23}$$

$$\phi_R=\arg r \tag{24}$$

More often than not, multilayer coatings are specified in terms of T and R and the phase changes on reflection and transmission are usually not of direct interest to the users. Exceptions are reflectors for interferometers.[22] It has also been found that specifying certain values of φ_T, φ_r was useful in controlling the solution type obtained by some thin-film design methods.[23]

If the materials in a multilayer are all nonabsorbing, then $T + R = 1$. Should one or more materials absorb, then in the above equations the refractive indices of these materials must be replaced by their complex refractive indices $\tilde{n}$, defined by

$$\tilde{n}=n-ik \tag{25}$$

where k is the extinction coefficient of the material. Even though all the elements of the layer matrix for such a material are now complex, its determinant will still be unity. The absorptance of the multilayer is then calculated from

$$A=1-T-R \tag{26}$$

Certain important general conclusions about the properties of multilayer filters can be drawn from the above equations.

1. The properties of thin-film systems vary with angle of incidence [Eqs. (18), and (19)]. For some applications this is the major disadvantage of interference filters compared to absorption filters.
2. This variation depends on the polarization of the incident radiation [Eq. (19)]. The following equations define T and R for obliquely incident nonpolarized radiation:

$$T=\frac{1}{2}(T_p+T_s) \tag{27}$$

$$R=\frac{1}{2}(R_p+R_s) \tag{28}$$

   The dependnce of T and R on polarization has been used for the design of polarizers (see Chap. 13, Vol. I). However, like the angular variation, it is a disadvantage for most other applications. Many researchers have investigated ways of reducing these effects.[13,24–27]
3. Transmittance curves of nonabsorbing multilayers composed of layers whose optical thicknesses are all multiples of $\lambda/4$ show symmetry about λ_0 when plotted on a relative wavenumber scale λ_0/λ [Eqs. (17)and (18)].
4. A proportional change of all the thicknesses of a nonabsorbing multilayer results merely in a displacement of the transmittance curve on a wave-number scale [Eq. (18)]. Thus a thin-film design can be utilized in any part of the spectrum subject only to the limitations imposed by the dispersion of the optical constants of the materials used.
5. The reflectance and absorptance of a filter containing absorbing layers will depend, in general, on which side of the filter the radiation is incident (Fig. 5). However, the transmittance does not depend on the direction of the incident light.

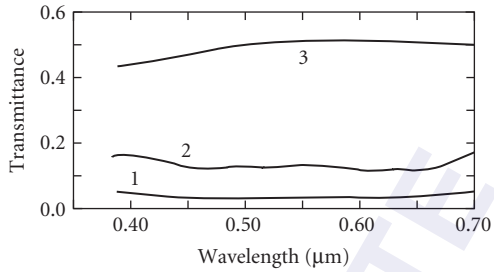

FIGURE 5 Spectral characteristics of a thin chromium alloy film on glass. Curve 1: transmittance; curves 2 and 3: reflectance from the glass and air sides, respectively. (*After Liberty Mirror.*[28])

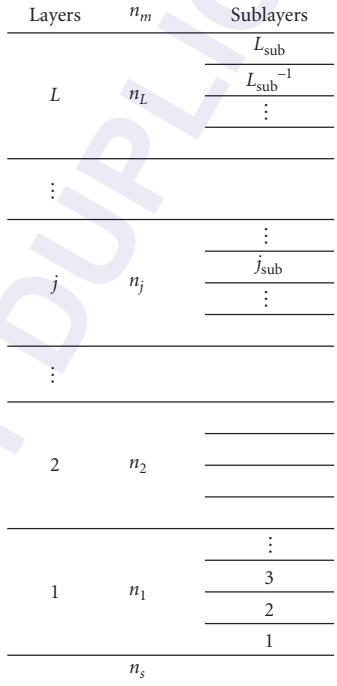

FIGURE 6 Subdivision of layers for the evaluation of the electric field within a multilayer (see Sec. 7.2, subsection "Matrix Theory for the Analysis of Multilayer Systems").

An important parameter is the electric field amplitude squared, $|E|^2$. The susceptibility of a multilayer to high-power laser damage is proportional to the highest value of this quantity within the multilayer. One way to evaluate E is to subdivide each layer of the system into L_{sub} sublayers (Fig. 6) and to evaluate the partial matrix products P_j,

$$\mathbf{P}_j = \begin{pmatrix} p_{11} & ip_{12} \\ ip_{21} & p_{22} \end{pmatrix} = \prod_{k=1}^{j} (\mathbf{S}_k) \tag{29}$$

for all L sublayers, where S_k is the matrix of the kth sublayer. Then, the electric field amplitude at a point j in the multilayer is given in terms of the elements of the total and partial product matrices by the following expression:[29]

$$E_j = \frac{4[p_{11}^2 + (n_s p_{12})^2]}{[m_{11} + (n_s m_{22}/n_m)]^2 + [(m_{21}/n_m) + n_s m_{12}]^2} \tag{30}$$

The analysis of optical thin-film systems [with computer programs based on Eqs. (13) to (30)] is relatively simple. The design of filters with any but the simplest spectral characteristics is a more complicated problem and one of the methods listed in Sec. 7.2, subsection "Design Approaches" must be used.

7.3 THIN-FILM MANUFACTURING CONSIDERATIONS

The optical, mechanical, and environmental properties of multilayer coatings depend on the materials used, on the deposition process and on the surface quality of the substrate.

There are many different methods for the deposition of thin films.[30–32] Some of the more common processes are reviewed below. The deposition methods and process parameters used affect the microstructure of the resulting layers. The films can be dense with an amorphous or a microcrystalline structure, or they may exhibit a columnar growth with considerable voids. The optical constants clearly depend on this microstructure and films of the same materials may sometimes have very different properties, depending on how they were deposited (see, for example, Ref. 33). The individual films in a multilayer may be under tensile or compressive stress and, unless materials and film thicknesses are selected to compensate for these stresses, the overall stress may be large enough to distort the substrate or cause the multilayer to break up. The mechanical properties of multilayer coatings also critically depend on the microstructure of the films. An excellent discussion of the effects of microstructure on the various properties of optical coatings has been given by Macleod.[18]

Optical Coating Materials

Many different materials have been used in the past for the construction of optical multilayer coatings. Some of the compounds used for the deposition of nonabsorbing layers for the ultraviolet, visible, and infrared parts of the spectrum are cryolite (1.35), LiF (1.37), MgF_2 (1.39), ThF_4 (1.52), CeF_3 (1.62), PbF_2 (1.73), ZnS (2.30), ZnSe (2.55), Si (3.5), Ge (4.20), Te (4.80), PbTe (5.50), and the oxides SiO_2 (1.48), Al_2O_3 (1.60), MgO (1.72), Y_2O_3 (1.82), Sc_2O_3 (1.86), SiO (1.95), HfO_2 (1.98), ZrO_2 (2.10), CeO_2 (2.20), Nb_2O_5 (2.20), Ta_2O_5 (2.10), and TiO_2 (2.45). The numbers in parenthesis represent the approximate refractive indices at the midpoints of the material transparency range. Some of the metals used in the same wavelength range for the deposition of reflecting or absorbing layers are Ag(0.12 - i3.45), Al(1.02 - i6.85), Au(0.31 - i2.88), Cu(0.83 - i2.60), Ni(1.80 - i3.33), Cr(3.18 - i4.41), Inconel(2.94 - i2.92), and Rh(2.00 - i5.11). The complex refractive indices of the metals given in the brackets correspond to a wavelength of 0.56 μm. The above values are approximate and are intended as a rough guide only. More extensive listings of coating materials are given, for example, by Macleod[2] and Costich.[34]

As already mentioned, the properties of multilayers depend on the materials used for their construction. For example, layers made of oxides are, as a rule, harder than those made of fluorides, sulphides, or semiconductors. They are therefore preferred for use on exposed surfaces. Semiconductor materials should be avoided in filters that are to be used over a wide range of temperatures because their optical constants can change significantly. Some metals are soft and easily damaged while others tarnish when exposed to the atmosphere. Such coatings require further protective coatings, or should be cemented between two transparent plates. Other materials require the precoating with adhesion layers to ensure a good bond to the substrate. For example, frequently a Ni adhesive layer is deposited onto glass before coating with Au.

Evaporation

Conventional (nonreactive) or reactive evaporation from resistance, induction or electron beam gun sources is a low energy process (~0.1 eV) and the resulting films frequently have a porous structure. The porosity may vary with the material, the substrate temperature, the residual pressure in the deposition chamber, the deposition rate and angle of incidence of the vapour on the substrate. Values of porosities ranging from 0 to 40 percent have been observed. On exposure to the atmosphere some of the voids in the film may adsorb water vapor. This increases the effective refractive index of the films and results in a shift of the spectral features of the multilayer towards longer wavelengths ("ageing"). This shift is partially reversible—by placing the filter in an inert atmosphere or in a vacuum, or on heating, some of the adsorbed water vapor can be removed. Unless it has been allowed for at the design stage, such ageing can render some filters useless.

The microstructure of the films can be significantly affected by bombarding the substrate during deposition with energetic ions from an auxilliary ion beam source.[35–37] The additional energy (~50 to 100 eV) results in denser films. Hence, coatings produced by *ion-assisted deposition* have higher refractive indices and exhibit less or no ageing on exposure to the atmosphere.

The *ion-plating* process can result in even denser coatings.[38–40] In this high deposition rate process the starting material must be a good conductor and is usually a metal. Argon and a reactive gas species are introduced into the chamber and, together with the evaporant, are ionized. The ions are then accelerated to the substrate with energies of the order of 10 to 50 eV. Transparent films with near-bulklike densities and low temperature variation of refractive index can be obtained by this process. For most materials the layers are glasslike and the interfaces remain smooth. This results in a lower scatter. *Plasma-ion-assisted deposition* is a process that also produces such good quality coatings, but it has the advantage over the ion-plating process that it does not require a conducting evaporant, so that fluorides and other nonconducting materials can be deposited with it. [41–43]

Conventionally evaporated thin films can be under compressive or tensile stresses. If not controlled, these stresses can distort the substrate or cause the multilayer to break up. The magnitudes of the stresses depend on the material and on the deposition conditions. It is often possible to select the materials and process parameters so that the stresses of the various layers counteract each other. In contrast, almost all ion-plated layers are under compressive stress. It is therefore more difficult to produce stress-compensated multilayers by this process.

Sputtering

Reactive or nonreactive DC, RF, AC, or pulsed magnetron sputtering are also used to deposit optical multilayer coatings. Very many varients of this process exist.[44] Most are significantly slower than evaporation and the targets can be quite expensive. Filters produced by magnetron sputtering may therefore also be more expensive. However, the process is stable, provides excellent control over the thicknesses of the layers and can be readily scaled to provide uniform coatings over large areas. Both metal and metal oxide layers can be produced. Sputtering is an energetic process and results in dense, bulklike layers that exhibit virtually no ageing.

In *ion-beam sputtering* an energetic beam of inert ions is aimed at a target made of the material that is to be deposited. Atoms or clusters of atoms of the material are dislodged from the target and land on the substrate with a high energy (about 10 to 200 eV). This is the slowest physical vapor thin-film deposition method described here and it cannot yet be readily scaled for the coating of large components. However, it yields the highest quality coatings. Many of the high reflectance coatings for laser gyros, in which no significant losses can be tolerated, are produced in this way.

Deposition from Solutions

In this procedure the substrate is either dipped in an organo-metallic solution and withdrawn at a very steady rate from it, or the solution is applied from a pipette onto a spinning substrate. The substrate is then placed in an oven to drive off the solvent. The thickness of the film depends on the

concentration of the solvent and on the rate of withdrawal or spinning. Other factors that influence the process are temperature and humidity, as well as the freshness of the solution. Although it yields quite porous films, this method is of interest because many of the layers produced in this way have a high laser damage threshold. The process has also been adapted for the coating of quite large area substrates with multilayer antireflection coatings for picture frame glass and for display windows.

Other Deposition Methods

Great strides have been made in the development of various *chemical vapor deposition methods* for the production of optical coatings.[45] These processes often take place in the presence of plasmas operating at microwave and/or radio frequencies. The advantage of this approach is that it is relatively easy to produce robust layers with intermediate optical constants through the use of appropriate mixtures of two or more reactant gases. However, most of the reactants used are toxic and their handling requires special care.

Atomic layer deposition is inherently a slow deposition process that is capable of depositing very precise, conformal layers onto irregular-shaped substrates. Recently it has been demonstrated that it can be a commercially viable process if large chambers that contain stacks of closely packed substrate holders are used for the simultaneous coating of hundreds of objects.[46]

Thickness Control during Deposition

The performance of many optical multilayers depends critically on the thicknesses of the individual layers. The control of the layer thicknesses during their formation is therefore very important. Many different methods exist for the monitoring of layer thicknesses. For very steady deposition processes, such as sputtering, simple timing can give good results. However, the most common techniques used are quartz crystal and optical monitoring. The former is very sensitive and can be used for thin and thick films, as well as transparent and opaque films. However, it is an indirect method and requires careful calibration. This is usually not a problem whenever layers of established coating materials are formed using a standard geometry and deposition conditions. Optical monitoring can be performed directly on the substrate, or indirectly on a witness glass. The quantities measured are usually T, R, or the ellipsometric parameters. One advantage of direct optical monitoring is that the parameters measured are usually closely related to the required performance. Furthermore, with optical monitoring, a real-time error determination and compensation is possible after the deposition of each layer, through the reoptimization of the remaining layers of the system.[47] With this method even quite complicated multilayer structures can be manufactured. This process is now used in many laboratories. Even better results should be possible in the future when the above process is combined with ion-beam etching to adjust the thicknesses of layers that exceed the intended value.[48]

7.4 MEASUREMENTS ON OPTICAL COATINGS

Optical Properties

Transmission, Reflection, and Absorption The most commonly used instrument for the measurement of the optical performance of thin-film coatings is the spectrophotometer. The wavelength dispersion of commercial instruments for the 0.185 to 80.0 μm spectral range is usually provided by prisms or by ruled or holographic gratings. Grazing incidence gratings, crystals, or multilayer coatings are used in the soft x-ray and extreme ultraviolet (XUV) spectral regions. Fourier transform spectrometers are capable of measurements from about 2 to 500 μm. A variety of attachments are available for the measurement of specular and diffuse reflectance. Absolute measurements of T and R that are accurate to within ±0.1 percent are difficult to make even in the visible part of the electromagnetic spectrum. Measurements at oblique angles of incidence are even more difficult.

Very small absorptions of single layers are normally measured with calorimeters.[49] The losses of high performance laser reflectors are obtained from measurements of the decay times of Fabry-Perot interferometer cavities formed from these mirrors.[50]

Roughness of the substrate and irregularities occuring within individual films and the layer interfaces give rise to light scattering in all directions.[51–53] For many applications it is important to minimize this scatter. Special instruments, called scatterometers, are used to measure the angular variation of the light scatter. Such data provides information about the substrate and multilayer.[54]

The transmittance, reflectance, and absorptance of some optical coatings are affected by exposure to atomic oxygen and by electron, proton, and ultraviolet irradiation. They also depend critically on the cleanliness of the components measured. In space contamination of optical components can also take place.[55,56]

Optical Constants A reliable knowledge of the optical constants of all the materials used in the construction of optical multilayer coatings is essential. There exist many different methods for their determination.[57] These include methods that are based on refractometry, photometric, and spectrophotometric measurements of *R* and/or *T,* polarimetry, singlewavelength or spectroscopic ellipsometry, various interferometric methods, attenuated total reflection, or on a combination of two or more of the above methods. Excellent monographs on the various methods will be found in Palik's *Handbook of Optical Constants of Solids*.[58,59] Some are suitable for measurements on bulk materials and the results are valid only for films produced by the more energetic deposition processes described above. The optical constants of porous films must be measured directly. They will depend on the deposition parameters and on the layer thickness, and may differ significantly from those of bulk materials.[60] Special methods have to be used for the determination of the optical constants in the x-ray, XUV, and sub-millimeter regions. The accurate measurement of very small, residual extinction coefficients of transparent coating materials is difficult. Generally it involves the use of laser calorimetry or the use of the film as a spacer layer in a bandpass filter. It is also very important to be able to measure the thickness of the film independently.

Laser Damage A measure of the ability of an optical component to withstand high laser irradiations is the laser damage threshold (LDT). There are several ways of defining this quantity. One frequently used definition is based on a plot of the percentage of components that are damaged when they are exposed to different laser fluences. The value of the fluence corresponding to the intersection of a mean curve through the experimental points with the ordinate is defined to be the LDT. It is thus the maximum fluence at which no damage is expected to the component.

Absorption is the main cause for laser damage. The incident radiation that is absorbed in the optical component will be converted into heat. If the thermal conductance of the optical component is too low, the temperature of the local hot spot on the mirror will rise to a value at which damage occurs. The damage will therefore depend on the thermal conduction of the materials of which the mirror blank is made. For example, some high reflectivity mirrors consist of coatings on Si or Cu substrates that are water-cooled during use.

Thermal conductivities of thin films are several orders of magnitude smaller than those of the corresponding bulk materials. (Exceptions to this are some fluoride layers.) This compounds the problem. To increase the LDT, the deposition methods are optimized to obtain thin films with more bulklike thermal conductivities.

Absorption damage usually initiates at defects and other imperfections. In the case of the substrate, it may occur at or below the surface, even when the substrate material is nonabsorbing. It is very important to avoid materials with color centers and subsurface damage and inclusions. The substrate surface must be very smooth and devoid of scratches, digs, and pores, otherwise polishing compounds and other contaminants can be trapped. It is imperative that the substrate be perfectly clean prior to coating. Electric fields associated with the above imperfections increase the absorption by an amount that is proportional to the refractive index of the material.

The coating materials used for the construction of high LDT multilayers must be very pure, with absorption edges far away from the wavelength of interest. As a rule, materials in thin-film form have

extinction coefficients that are orders of magnitude larger than those of the corresponding bulk materials. Currently the processes used to produce high LDT coatings include ion-beam sputtering, sol-gel deposition, and electron beam gun evaporation. To reduce the effects of the residual surface roughness, the thicknesses of the layers are often adjusted to shift the peaks of the electric field away from the layer boundaries.

The form that the damage takes depends to a large extent on the materials. Pitting of the coatings is probably due to the evaporation of the thin-film materials. Delamination may be due to poor adhesion of the layers to the substrate, to undue stresses in the films and/or to a poor match between the expansion coefficients of the layers and the substrate.

The LDT also depends on the laser pulse duration. For very short pulses (<10 ns) thermal conductance does not play a role in the process. For higher values, the LDT is proportional to the square root of the pulse duration. For high repetition rates the LDT depends on the repetition rate. To achieve a long life (10,000 or 100,000 pulses) in an industrial environment, the laser should be operated at a fraction (say, 1/4 or 1/10) of the nominal LDT. In CW lasers it is not the LDT, but the power handling capability that is of essence. Long before damage takes place, the heating can cause a distortion of the surface that, in turn, can result in loss of power and in mode and focussing problems.

The development of high LDT of laser coatings is so important, that conferences have been held in Boulder, Colorado, on this topic every year since 1970. For more detail the reader is referred to the proceedings of these conferences,[61] as well as to an article written by Ristau.[62] There exists also a draft international standard on this topic. An increasing number of thin-film vendors include in their catalogues LDT information on all or some of their products. Independent LDT test services are provided by several commercial companies and publically funded institutions.

Mechanical Properties

Optical multilayer coatings are frequently required to operate under severe mechanical and environmental conditions. Quite frequently meeting these requirements is more difficult than to achieve the necessary optical performance. A number of standards deal with the substrate and coating quality (MIL-0-13830B), the adhesion of coatings (MIL-M-13508C, MIL C 48497), their abrasion resistance (MIL-C-675A, MIL C 675C, MIL-C-14806-A, MIL C 48497), hardness (MIL-M-13508C), and resistance to humidity (MIL-C-675A, MIL-C-14806-A, MIL-810-C, MIL C 48497), salt solution (MIL-C-675-A) and salt spray (MIL-M-13508-C, MIL-C-14806-A). Most of these standards are reprinted in Rancourt's book.[3] Depending on the application, multilayer coatings may be required to meet one or more of the above standards. An overview of the subject of stresses and hardness of thin films on a substrate has been recently published by Baker and Nix.[63] Sapieha and her coworkers compared various mechanical properties of three commonly used oxide layers produced by different deposition processes.[64]

Analytical Analysis Methods

In addition to optical and mechanical measurements, multilayer coatings can be subjected to a number of analytical measurements. These include Auger electron spectroscopy, energy dispersive x-ray analysis, Rutherford backscattering, secondary ion mass spectrometry, transmission electron microscopy and x-ray photoelectron spectroscopy.[63,65] Some of these tests are destructive. However, when a multilayer coating is subjected to these tests, they yield fairly accurate information about the number of layers in a system, and on the composition, thickness, and structure of the individual layers.[66]

7.5 ANTIREFLECTION COATINGS

Effect of Surface Reflections on Performance of Optical Systems

The reflectance of an interface between two nonabsorbing media of refractive indices n_1 and n_2 is given by

$$R=\left[\frac{n_1-n_2}{n_1+n_2}\right]^2 \tag{31}$$

An expression for the total transmittance T_0 of a nonabsorbing plane-parallel plate that takes into account the effect of multiple internal reflections within the plate can be obtained from Eq. (9):

$$T_0=\frac{1-R}{1+R} \tag{32}$$

Of this light only a fraction $(1-R)^2$ passes through the plate without undergoing any reflections.

An expression for the transmission of a number of such plates placed in series is of interest. It helps to explain the effect of multiple reflections between the various plates on the performance of devices such as tripple glazings and photographic objectives. It can be shown[6] that the total transmittance T_{total} of m plates placed in series is given by

$$T_{\text{total}}=\frac{T_0}{m-T_0(m-1)} \tag{33}$$

The amount of light transmitted directly T_{direct}, is

$$T_{\text{direct}}=(1-R)^{2m} \tag{34}$$

The light T_{stray} that undergoes multiple reflections before transmission is responsible for spurious images and stray light in the image plane. It is given by

$$T_{\text{stray}}=T_{\text{total}}-T_{\text{direct}} \tag{35}$$

The variation of T_{direct} and T_{stray} with R, for several values of m, is shown in Fig. 7. The refractive indices of the plate material plotted against the upper x axis assume that the plates are in air.

It will be seen that even for a relatively small number of low-refractive-index plates the ratio $T_{\text{stray}}/T_{\text{direct}}$ becomes significant. This means that in an image-forming system under unfavorable conditions the stray light can completely obscure the image.[67] Second, even in nonimaging optical systems the loss of light $(1-T_{\text{direct}}-T_{\text{stray}})$ can become quite prohibitive.

Both these problems can be overcome by reducing the surface reflection through the application of suitable antireflection coatings to the plate boundaries. Since antireflection coatings with zero reflectance across the whole spectrum cannot be constructed, the spectral reflectance $R(\lambda)$ of antireflection coatings is usually chosen to minimise the integral

$$\int_{\lambda} R(\lambda)I(\lambda)S(\lambda)d\lambda \tag{36}$$

where $I(\lambda)$ and $S(\lambda)$ are the spectral-intensity distribution of the incident radiation and the spectral sensitivity of the detector, respectively. A low reflectance is thus needed only in the spectral region in

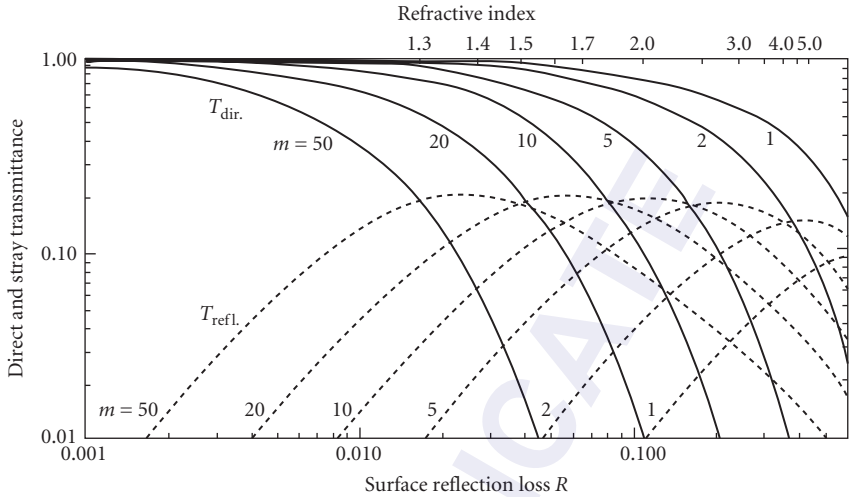

FIGURE 7 Transmittance of a system of m parallel plates of surface reflectances R for directly transmitted radiation T_{direct} and for radiation that suffers multiple reflections before transmission T_{stray}. The upper x axis is calibrated in terms of the refractive index of the plates for the special case when the plates are in air.

which $I(\lambda)S(\lambda)$ is significant. It should be emphasized here that in addition to this requirement, for most applications antireflection coatings must be mechanically very tough, withstand drastic climatic and thermal variations, and stand up to the usual lens-cleaning procedures. Some examples of improvements in the performance of image-forming and non-image-forming optical systems obtained through the use of antireflection coatings are given by Mussett and Thelen[67] and by Faber et al.[68]

Antireflection coatings can be based on homogeneous layers or on inhomogeneous coatings. One can further classify them into single layer, digital, or structured, and homogeneous multilayer or complex inhomogeneous layer coatings (Fig. 8*a* to *f*). Because of their industrial importance, antireflection coatings for the visible and infrared spectral regions have been the subject of much research and development. Two books have been written on this topic[69,70] and there exists a very extensive literature in scientific and technical journals. For a review of this literature and for a systematic discussion of antireflection coatings, the reader is referred to the excellent review articles by Cox and Hass[71] and by Mussett and Thelen.[67] A recent report on the present state of the art has been published in the Japanese language. In this section, only a brief summary will be given of the results obtained thus far, intended to aid in the selection of antireflection coatings for particular applications. The calculated data is presented on a logarithmic scale. The relative wavenumber scale facilitates the calculations of the width of the effective region of a coating in different parts of the spectrum.

Antireflection Coatings Made of Homogeneous Layers

The single homogeneous-layer antireflection coating (Fig. 8*a*) was the first antireflection coating and perhaps is still the most widely used. Theoretically it should be possible to obtain a zero reflectance at one wavelength with single dense films. However, because of a lack of suitable low-index coating materials, this cannot be realised in practice for substrates with indexes less than about 1.9. Nevertheless, even with the available materials a very useful reduction in reflection in a broad spectral region is obtained for all common glass types, the reflectance never rising above that of the uncoated surface (Fig. 9, curve 8). With the sol-gel method it is possible to produce homogeneous porous oxide and fluoride films with very low refractive indices.[72–75] Such films have excellent optical characteristics

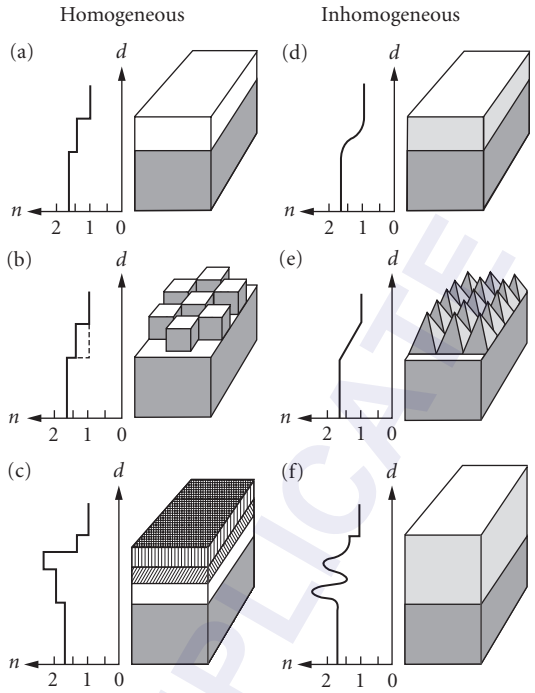

FIGURE 8 Structure and effective refractive index profiles of various types of antireflection coatings. (*a*), (*b*), (*c*) homogeneous single layer, digital and multilayer AR coatings and (*d*), (*e*), (*f*) simple inhomogeneous layer, structured and more complex inhomogeneous layer AR coatings.

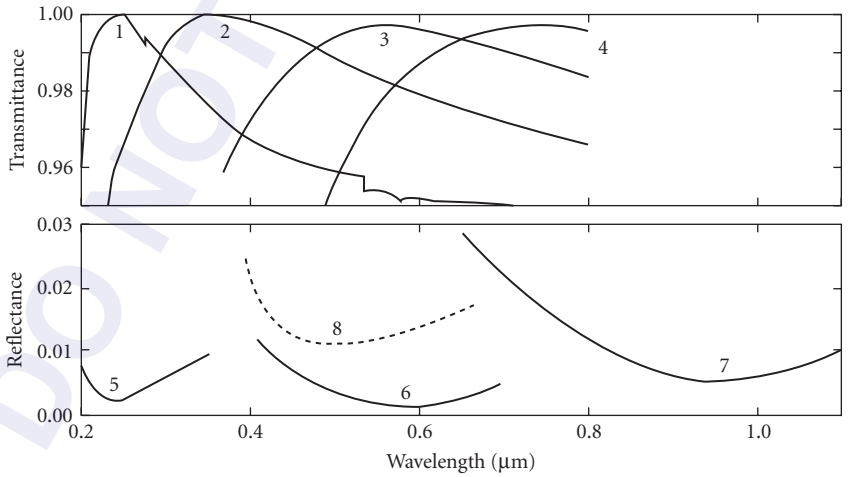

FIGURE 9 Performance of single layer porous homogeneous antireflection coatings on various substrate surfaces. Porous silica on fused silica (1, 3, 5); on glass (6); on KDP (7); SF_8 (4). Porous MgF_2 on fused silica (2). A conventional single layer antireflection coating on glass is shown for comparison (8). (*Curve 1 after Wilder;*[72] *curve 2 after Thomas;*[74] *curves 3 and 4 after Thomas;*[75] *curves 5–7 after O'Neill;*[73] *and curve 9 after Balzers.*[76])

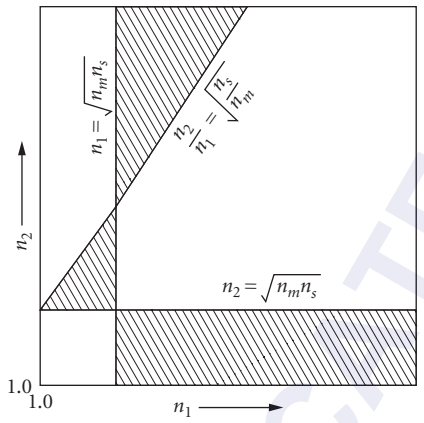

FIGURE 10 Refractive index combinations (*shaded areas*) of two-layer antireflection coatings with which a zero reflectance at one wavelength can be achieved.

(Fig. 9) and have laser damage thresholds that are considerably higher than those produced by conventional means. However, these gains are at the expense of mechanical strength and long-term stability. Low-refractive index coating materials can also be simulated by the deposition or etching of subwavelength structures (Fig. 8*b*, *e*). The effective refractive index depends on the volume fraction occupied by the structures.[77]

If more than one layer is used, all the degrees of freedom could be used to either (1) obtain a more complete antireflection in one particular spectral region; (2) increase the width of the spectral region over which the reflectance is generally low; or (3) obtain a coating in which the low reflectance is very uniform across the spectrum.[78,79] Vlasov has shown with the aid of a diagram of the type shown in Fig. 10 that even for a two-layer antireflection coating there exists a large number of refractive index combinations which will yield zero reflectance at one wavelength.[69] As the number of layers and the overall thickness of the antireflection coating increases, it becomes possible to find solutions for a particular problem that not only fully meet the most important above desirata and almost satisfy the others but are also based on the use of the mechanically most satisfactory coating materials.

The conditions that are satisfied by the refractive indexes and thicknesses of various types of antireflection coatings are given in Table 1. In a few cases where they are very complicated, reference is made to a paper in which they are set out in full. The calculated transmittance curves of antireflection-coated surfaces of glass (Fig. 11*a* to *c*), quartz (Fig. 11*d*), germanium (Fig. 11*e* and *f*), silicon (Fig. 11*g*), and other infrared materials (Fig. 11*h*) utilize refractive indexes that for the most part correspond to real coating materials, and hence the curves represent realistic solutions rather than the theoretically best possible ones. The actual refractive indices used in the calculations (and optical thicknesses where they do not correspond to a multiple of $\lambda/4$) are given in Table 1.

Figure 11*a* shows the performance of several antireflection coatings on glass for applications which require the highest possible efficiency for a limited wavelength region. Of these the coating 2.1 has probably found the greatest acceptance. A typical measured performance curve for such a coating is shown in Fig. 12. Antireflection coatings with a low reflectance in a broad spectral region are shown in Fig. 11*b* and Fig. 13. Coatings of the type 3.4 probably find the widest application in practice. The performance of commercial coatings for quartz substrates are shown in Fig. 14.

Solutions listed in Table 1 presume that coating materials with the required refractive indices exist. This is frequently not the case and the thin-film designer must seek solutions based on available coating materials. For example, Furman[89] gives a series of practical two-, three-, and four-layer solutions for 10 different values of the substrate index ranging between 1.5 and 4.0, while Stolov provides[90] seven-layer solutions for 10 values of n_s, $1.46 \le n_s \le 1.82$.

Willey has given a useful empirical expression which relates the average reflectance R_{avg} in the visible and near-infrared spectral region $\lambda_{min} \le \lambda \le \lambda_{max}$ to the overall optical thickness $\Sigma(nd)$ of an antireflection coating composed of layers of refractive indices n_M, n_H and a single, outermost layer of index n_L:[91]

$$R_{avg} = 0.01\left[\frac{\lambda_{max}}{\lambda_{min}}(n_L - 1)\right]^{3.4}\left(\frac{\lambda_{max}}{\Sigma(nd)}\right)^{0.63}[(1.2 - \Delta n)^2 + 0.42] \tag{37}$$

The above expression is valid for the following parameter values:

$$1.5 \le \frac{\lambda_{max}}{\lambda_{min}} \le 3.0 \quad 1.17 \le n_L \le 1.46 \quad 1.38 \le n_M, n_H \le 2.58$$
$$1.0 \le \frac{\Sigma(nd)}{\lambda_{max}} \le 3.0 \quad 0.4 \le \Delta n = n_H - n_M \le 1.2 \tag{38}$$

A method for the design of optimum or near-optimum two-material antireflection coatings for a given substrate, coating materials, and overall thickness has recently been described.[92]

Since for some applications the color introduced into an optical system by antireflection coatings is of paramount importance, it has been the subject of many studies.[93–96] One way to avoid the problem is to utilise coatings that are particularly achromatic (Fig. 11*c*). Thus, for example, 50 surfaces coated with antireflection coating 4.4 would have a transmittance of 78 $\pm$ 3 percent across the whole visible spectrum. Nevertheless, of the coatings shown in Fig. 11*c* only the single-layer antireflection coating is being used extensively. Antireflection coatings can also be used to correct the residual color of lens systems.[97]

Often transmittance rather than reflectance measurements are performed to evaluate antireflection coatings. In general, it is incorrect to assume that $T = 1 - R$. For instance, the transmission of antireflection-coated infrared materials depends not only on the efficiency of the antireflection coating but

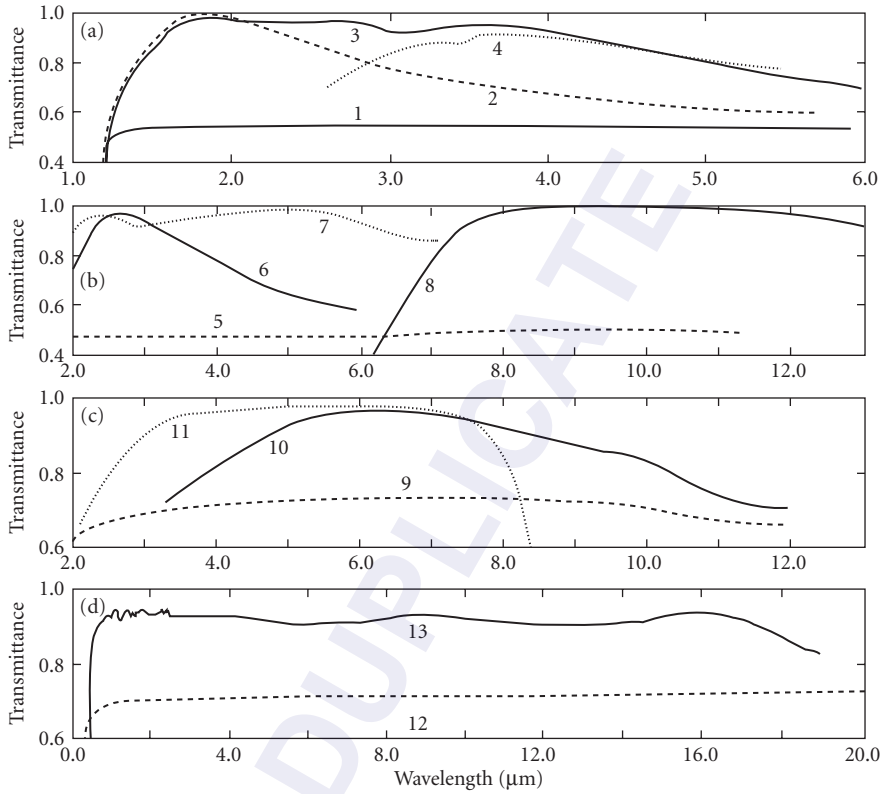

FIGURE 15 Transmittance of plates of infrared materials antireflection-coated on both sides. (*a*) Silicon. also on the thickness and temperature of the material. This is because of the finite scatter and absorption in such materials and because of the dependence, in some cases, of the latter on temperature. The measured spectral transmittances of three common antireflection-coated infrared materials at room temperature are shown in Fig. 15. Curves for other materials are given by Cox and Hass.[71]

Inhomogeneous and Structured Antireflection Coatings

The interface between two media with refractive indices n_1 and n_2 can be antireflection coated over a very broad spectral region by the application of a transition layer with an index that changes continuously from n_1 to n_2 (Fig. 8*d*). Many different refractive index profiles have been investigated in the past.[100–103] Although some of these profiles are more effective than others, all reduce the reflectance to a fraction of a percent over the spectral region in which the coatings are transparent and do not

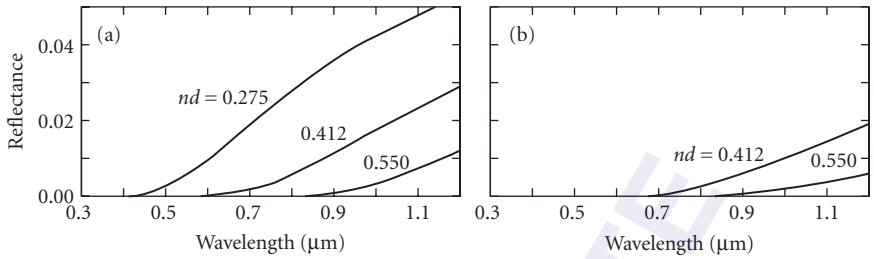

FIGURE 16 Calculated reflectances of the interfaces between two media antireflection-coated with inhomogeneous layers of indicated thicknesses and (complex) refractive indexes that vary smoothly, from the index of one medium to that of the other. (*a*) Two nonabsorbing media of indexes 1.52 and 2.36. (*b*) Glass-chromium interface with refractive indexes 1.52 and 2.26 – *i*0.43, respectively. (*After Anders and Eichinger.*[107])

scatter excessively, and for which the optical thickness of the layer is at least one half wavelength (Fig. 16*a*). A further advantage of inhomogeneous antireflection coatings is that they are not sensitive to the angle of incidence.[104] Processes used for the production of inhomogeneous antireflection coatings include various additive, subtractive, additive/subtractive, and replication methods. Excellent reviews of this topic exist.[105, 106]

In the additive method relatively dense inhomogeneous layers of varying compositions of two or more compounds are formed on the substrate by physical or chemical deposition processes. Such coatings are mechanically more durable than any other described in this section. However, because of a lack of coating materials with refractive indexes lower than about 1.35, solid inhomogeneous layers are not very suitable for the antireflection coating of air-glass interfaces. The several different inhomogeneous antireflection coatings of this type described in the past do not offer any special advantages over those composed of homogeneous layers.[70,108,109] The situation is different in the case of high-index materials (Fig. 17). An even lower reflectance can be achieved by ending the inhomogeneous layer

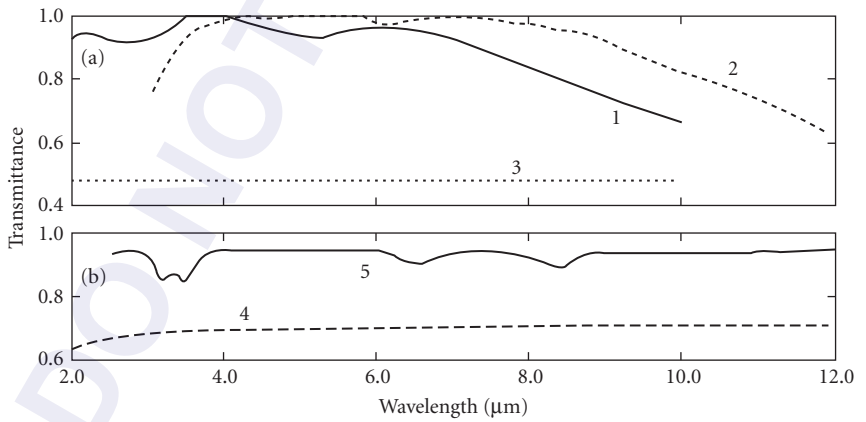

FIGURE 17 (*a*) Measured transmittance of a germanium plate coated on both sides with inhomogeneous antireflection coatings. Curve 1: 1.2-μm-thick film with an index that changes gradually from that of Ge to that of MgF_2 (*after Jacobsson*[110]); curve 2: 1.76-μm-thick film with an index that varies from 4.0 to 1.5, overcoated with a 0.74-μm-thick homogeneous MgF_2 layer (*after Scheuerman*[111]); and curve 3: transmittance of an uncoated plate. (*b*) Measured transmittance of a TBI-5 plate. Curve 4: uncoated and curve 5: coated on both sides with ten 2.5-μm-thick homogeneous layers with refractive indexes that vary between 1.3 and 2.29 and that are obtained through the evaporation of suitable NaF-CdTe mixtures. (*After Kuznetsov and Perveyev.*[112])

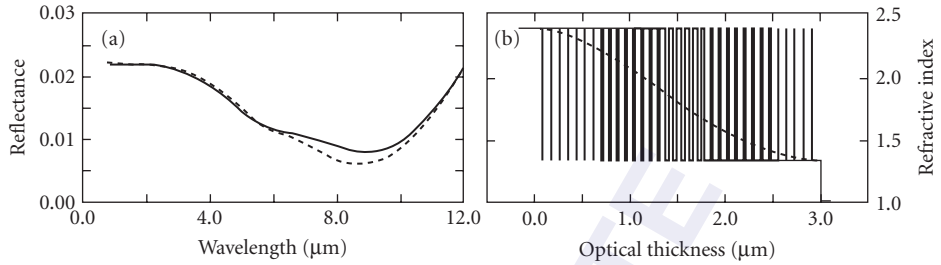

FIGURE 18 Calculated performances (*a*) and refractive index profiles (*b*) of an inhomogeneous layer coating and its two-material equivalent. (*After Southwell.*[116])

when its index is equal to the square of that of the lowest-index coating material available. It is then possible to complete the coating by depositing an additional homogeneous quarter-wave-thick layer of that material (Fig. 17*a*).

A dense inhomogeneous layer can be approximated by a series of homogeneous layers of gradually decreasing refractive indexes (curve 10.1, Fig. 11*f*).[113,114] Such layers can be prepared by evaporating a series of appropriate mixtures of two coating materials or, without mixing, by using the Herpin equivalent-index concept[115] to simulate intermediate refractive indexes. An even more practical solution is to replace the inhomogeneous layer by a series of thin homogeneous layers of two materials only (Fig. 18).[116]

In another additive process a refractive index variation down to a value of 1.0 is achieved by depositing onto the substrate microspheres of transparent oxides or fluorides which form pyramid-like clumps (Fig. 8*e*).[117] If losses due to scattering are to be low, the average lateral size of the features of this structure must be a small fraction of the shortest wavelength for which the coating is to be effective. A reflectance of 0.3 percent can be achieved, but the films are fragile.

The subtractive methods are attractive because they do not require expensive deposition equipment. The surface to be antireflection coated is leached and/or etched to form a porous transition layer in which the index varies with thickness. Not all optical materials can be treated in this way. However, special phase-separable glasses have been developed that lend themselves well to this process.[118–121] Fairly durable antireflection coatings with a reflectance of less than 0.5 percent for the 0.35 to 2.5 μm spectral region have been produced in this way (Fig. 19*a*). Some other materials, such as Lexan, Mylar, and CR-39 plastic, require an ion implantation pretreatment before the etching can be applied.[101,122]

In the technologically important additive/subtractive method, a single glasslike film is first deposited by a sol-gel process onto the surface that is to be antireflection coated. The composition of the film is such that, after phase separation, it can be readily leached and/or etched to form a porous microstructure with a controlled refractive index gradient.[123,126] This eliminates the need for the use of expensive phase separation glass components. Such coatings have reflectances as low as 0.13 percent and a laser damage threshold that is 4 times higher than that of coatings produced by conventional physical vapor deposition techniques (Fig. 19*b*).[127] Variants of this process exist.

Microstructured surfaces can also be produced in polymeric and similar materials by a replication process from a suitable cast. Average reflectances in the visible of the order of 0.3 percent have been reported for surfaces treated in this way (Fig. 19*c*).[124]

Recently there has been a renewed interest in antireflection coatings in which the variable porosities of leached or etched layers are simulated by dense regular shaped structures formed by photochemical or mechanical means. Clapham and coworkers appear to have been the first to demonstrate such devices.[128] They applied a photoresist to a surface, exposed it to two orthogonal sets of ultraviolet interference fringes, and then developed it to form a regular array of protuberances that could be optionally enlarged by additional ion-beam etching. Such surfaces can reduce the reflectance to less than 0.3 percent in the visible part of the spectrum (Fig. 19*d*).[125] The theory of such structures has been investigated by several workers[129,130] and devices for wavelengths extending into the micrometer

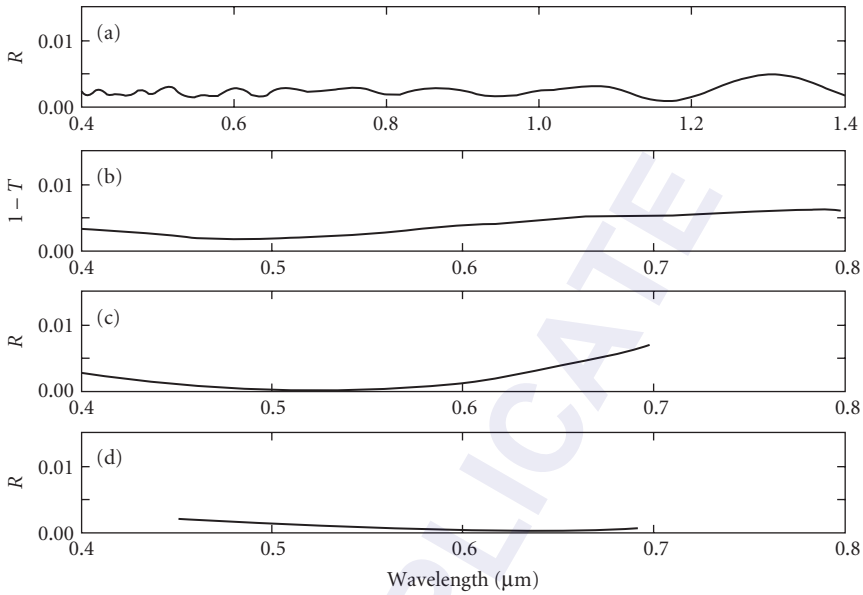

FIGURE 19 Measured performance of various broadband inhomogeneous antireflection coatings. (*a*) Subtractive process—leached and etched phase separation glass (*after Asahara*[120]); (*b*) additive/subtractive process—leached and etched phase-seperable film deposited onto fused silica (*after Yoldas*[123]); (*c*) replication process on a cellulose acetate butyrate surface (*after Maffitt*[124]); and (*d*) structured antireflection coating in photoresist (*after Wilson*[125]).

and sub-millimeter region have been fabricated.[77,121] Efficient laboratory prototype AR coatings produced by the glancing angle deposition process have been demonstrated by Kennedy and Brett.[131]

Universal AR Coatings

The idea of a universal AR coating which would reduce the reflectances of a range of substrates with different refractive indices has been first proposed by Vvedenski et al.[132] Such an AR coating could simplify operations in a coating shop, because all substrates, regardless of the glass that they were made of, could be coated in one deposition run. The prize that one pays for this convenience is that the performance of an AR coating consisting of the same number of layers, but designed for one substrate only will be significantly better.

In Fig. 20 are shown the results obtained for two AR coatings of this type consisting of 11, 17 layers each (rows a, b, respectively). The coatings were designed to simultaneously reduce the reflectances of substrates of index 1.48, 1.55, 1.60, 1.65, 1.73, and 1.75. In column 1 the reflectances of the uncoated and of the coated substrates are shown. Also indicated are the average reflectances of all the coated substrates. The refractive index profiles of the six systems for the different substrate materials shown in a2, b2 differ only in the substrate refractive indices. Increasing the number of layers in the universal AR coatings shown in this figure will result in a diminishing return in the performance. Several papers on this topic have been published by Yeuch-Yeong Liou.[134]

Antireflection Coating of Absorbing and Amplifying Media

Antireflection coatings for glasses and semiconductors in regions of weak absorption, and for present-day laser materials in which k_1, the imaginary part of the complex refractive index [Eq. (25)] is small and negative, differ little from those described above.[135]

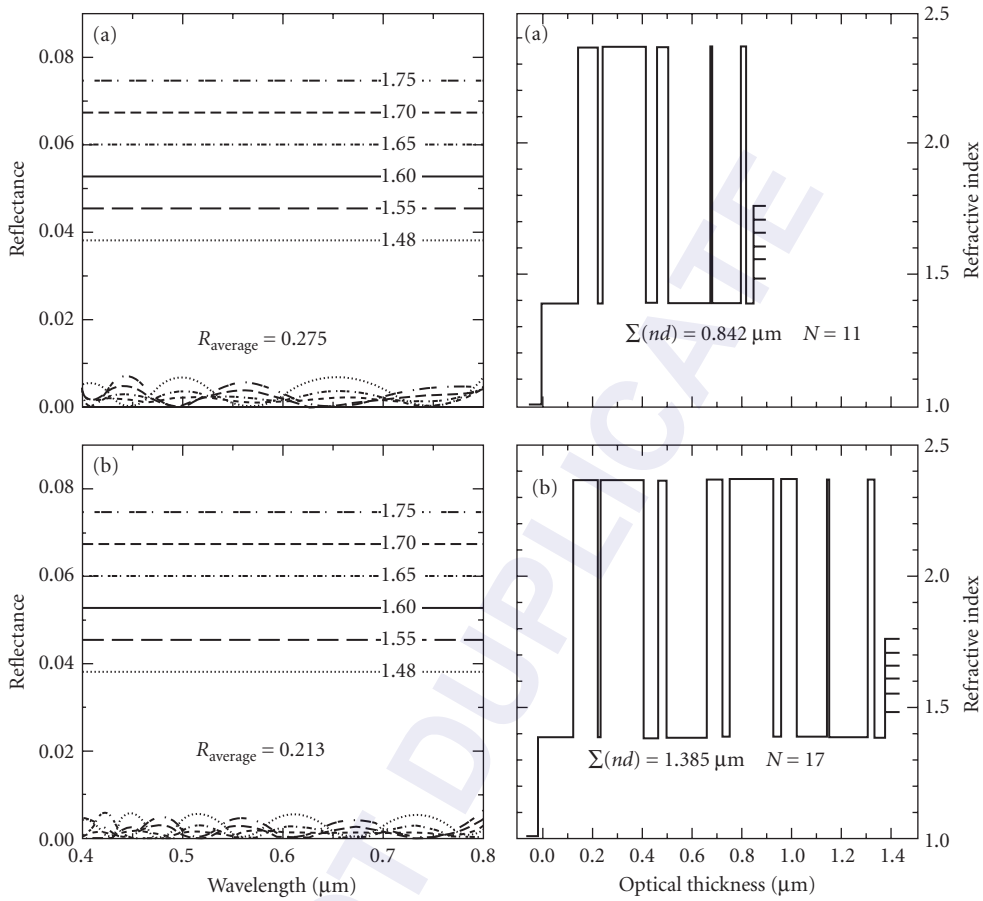

FIGURE 20 Universal AR coatings for substrates with refractive indices 1.48, 1.55, 1.60, 1.65, 1.70, and 1.75. Rows *a*, *b* depict solutions based on 11, 17 layers. Column 1 depicts the reflectances of the substrates before and after the application of the AR coating. In column 2 are shown the refractive index profiles of the solutions. (*After Dobrowolski and Sullivan.*[133])

The reduction of the reflectance of opaque materials for architectural, decorative and technical purposes leads to a corresponding increase in the absorption.[136,137] This can be utilised to improve the efficiency of radiation detectors and to control the solar-absorptance and thermal-emittance characteristics of surfaces (see, for example, Ref. 138 and 139). A measured example of the reduction in the reflectance of a metal surface attainable with a homogeneous nonabsorbing layer is shown in Fig. 21.

Inhomogeneous transition layers whose refractive index and extinction coefficient change gradually from the values of one of the media to those of the other are also very effective.[107] The calculated reflectance of a glass-chromium interface coated in this way, useful for blackening of prism faces, lens edges, scales, and so on, is shown in Fig. 16*b*. Metal-air interfaces can be treated a little less effectively with single layers because of the lack of suitable low-index materials.

Antireflection Coating of Surfaces Carrying a Thin Film

For some applications it is necessary to deposit a certain film onto a glass surface. The objectionable reflectance that such a film would normally introduce can be avoided by incorporating it into an

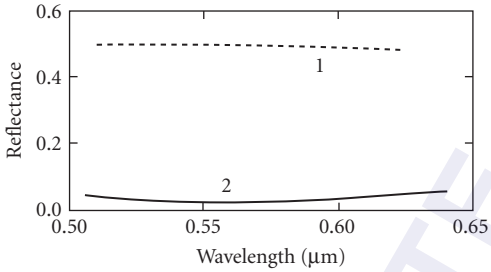

FIGURE 21 Antireflection coating of opaque metals. Curves 1 and 2: reflectance of chromium and of chromium with a ZnS layer. (*After Lupashko and Sklyarevskii.*[136]).

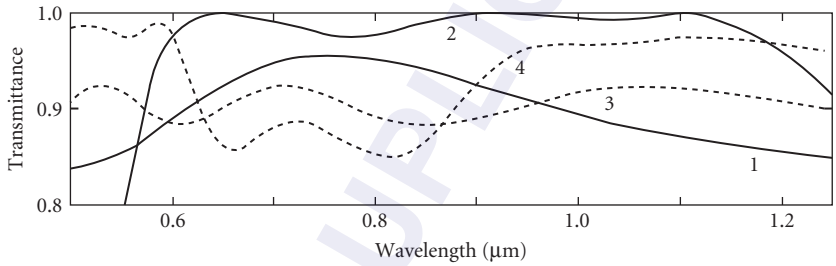

FIGURE 22 Calculated single-surface transmittance of antireflection coatings incorporating a conducting layer. Curves 1 and 2: glass of refractive index 1.755 coated with a 0.566-μm-thick SnO_2 layer before and after three dielectric layers were added to complete the antireflection coating and curves 3 and 4: as above except that the refractive index of the glass and the metric thickness of the SnO_2 film are 1.516 and 0.200 μm, respectively. (*After Veremey and Gorbunova.*[142])

antireflection coating. Thus, for example, Fig. 22 shows the calculated transmittances of two conducting layers before and after inclusion in antireflection coatings. The use of homogeneous and of inhomogeneous antireflection coatings with absorbing layers for opthalmic purposes is described by Katsube et al.[140] and Anders.[141]

Antireflection Coatings at Nonnormal Angle of Incidence

The calculated performances at 0°, 45°, and 60° incidence of the three commercially most important antireflection coatings and of a 10-layer coating for germanium are shown in Fig. 23. The deterioration with angle of incidence is particularly severe for the narrowband high-efficiency antireflection coating. Figure 23*d* suggests that the closer the design of an antireflection coating approximates an inhomogeneous transition layer (Sec. 7.5, subsection "Inhomogeneous and Structured Antireflection Coatings") the less angle-dependent is its performance.

To design an antireflection coating for one angle of incidence and one plane of polarization the effective thicknesses and refractive indexes [Eqs. (18) and (19)] of its layers should satisfy the relations set out in Table 1. In practice, small departures from those conditions are required to optimise the performance with good coating materials. Calculated curves for two sets of two- and three-layer coatings designed for use at 45° are shown in Fig. 24.

If the obliquely incident radiation is unpolarized, a compromise is necessary. The effective thicknesses are matched for the design angle, but the refractive-index conditions set out in Table 1

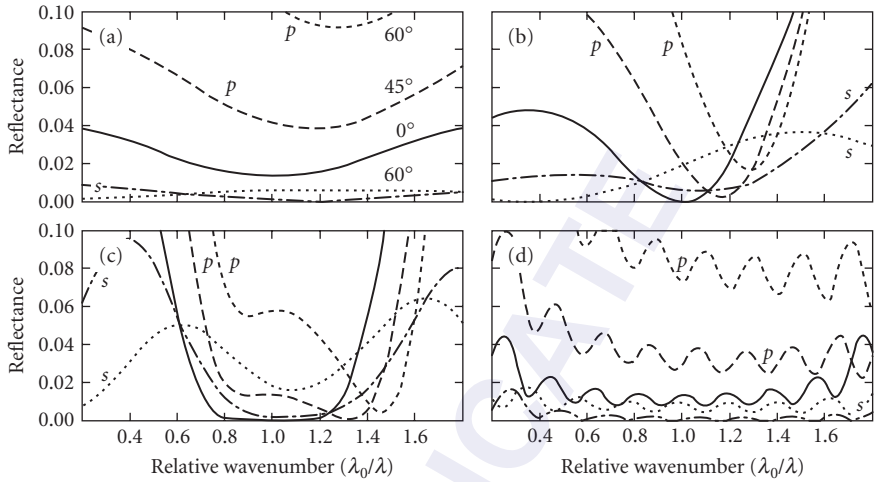

FIGURE 23 Calculated reflectance of (*a*) one-, (*b*) two-, (*c*) three-, and (*d*) 10-layer antireflection coatings (sytems 1.1, 2.1, 3.4, and 10.1 in Table 1) at angles of incidence of 0° (solid curve), 45° (dashed curve), and 60° (dotted curve) for light polarized parallel and perpendicular to the plane of incidence.

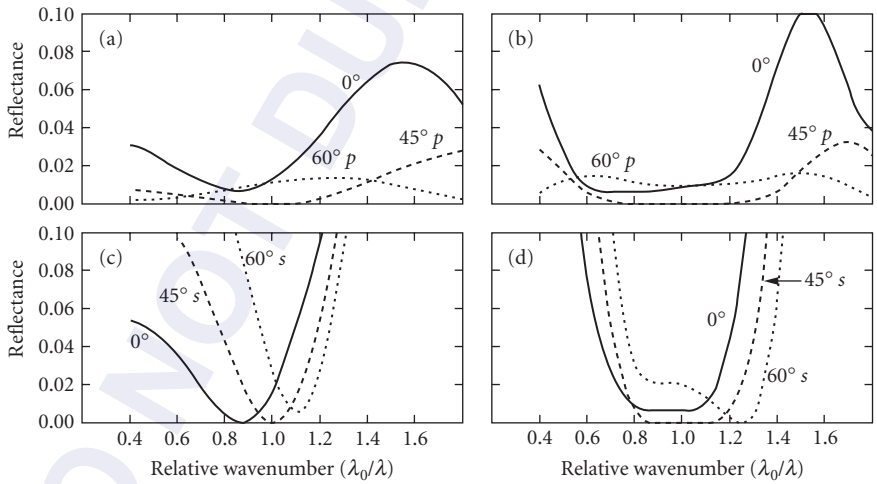

FIGURE 24 Calculated reflectance at 0° (solid curve), 45° (dashed curve), and 60° (dotted curve) of (*a*) and (*c*) two-layer and (*b*) and (*d*) three-layer antireflection coatings designed for light incident at 45° and polarized parallel or perpendicular to the plane of incidence. (*After Turbadar.*[143,144])

are satisfied for normal incidence since they cannot be satisfied for both polarizations at the same time (Fig. 25).

Achromatic antireflection coatings can be designed that are optimised for both polarizations at the same time or that are suitable for use over a range of angles of incidence (Fig. 26*b*).[24,145] But the problem becomes more difficult the greater the spectral and angular ranges required, especially if angles of incidence greater than 60° are involved.

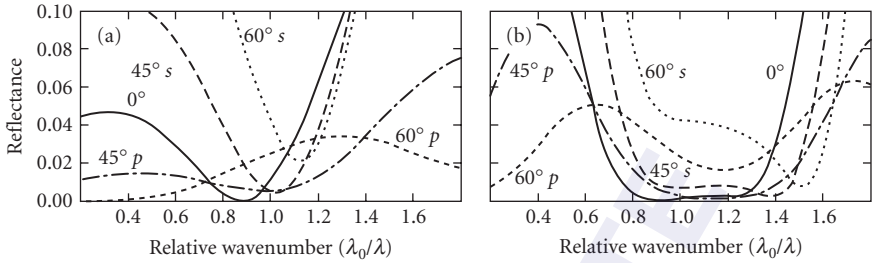

FIGURE 25 Calculated reflectance at 0° (solid curve), 45° (dashed curve), and 60° (dotted curve) of (*a*) two-layer and (*b*) three-layer antireflection coatings (systems 2.1 and 3.4 in Table 1) for use with unpolarized light, with the thicknesses of the layers optimized for an angle of incidence of 45°.

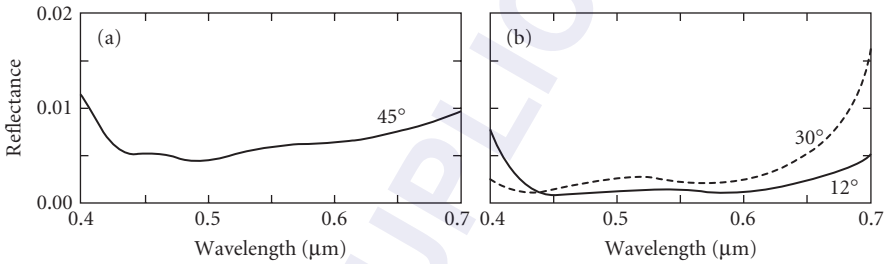

FIGURE 26 Average reflectances for unpolarized light of antireflection coatings designed (*a*) for 45° incidence and (*b*) for use with a convergent light cone of semi-angle of 30°. (*Optical Coating Laboratory.*[84])

In Fig. 27*a* is shown the variation with angle of incidence of the calculated average reflectance of a six-layer AR coating system for the He-Ne laser wavelength. The reflectance is less than 1 percent for all angles smaller than 60°, but only for a narrow wavelength region around the design wavelength. The performance was limited by the lowest available refractive index at the time.

It has been shown previously (Fig. 19) that, for normal incidence of light, the reflectance from an interface between two media with refractive indices n_s, n_m can be effectively removed over a broad spectral region by an inhomogeneous layer with a refractive index that changes gradually from n_s to n_m, providing that the optical thickness of this inhomogeneous layer is at least one half wavelength thick at the longest wavelength for which the reflectance is to be low. It has been shown numerically[151] and theoretically,[152] that this rule continues to hold for up to very high angles of incidence, providing that the *effective* optical thickness is at least one-half wavelength at the highest angle of interest. This means that broadband inhomogeneous layer AR coatings effective up to very high angles of incidence will be very thick. However, it is possible to transform such solutions to homogeneous layer systems with which, because of the additional thin-film interference effects, similar performances can be obtained with a small number of layers and much smaller overall optical thicknesses. Such solutions still call for the use of at least one layer with a refractive index that is very close to the medium index, n_m. Such solutions can be readily implemented for glass/glass interfaces (Fig. 27*c*). The angular measurements shown in this diagram were obtained with a laser light source, but the AR region was quite broad. When the medium is air and a maximum angle of incidence is 85° is stipulated, a refractive index of the outermost layer should be of the order of 1.02. In the infrared part of the spectrum there are a number of Reststrahlen materials with a refractive index that falls below unity. The measured average spectral reflectance for a number of angles of incidence of an AR coating based on such a material is shown in Fig. 27*b*. The antireflection region is narrow because the refractive index of the outermost layer has the required value only in a narrow wavelength band. In the visible part of the spectrum such indices can only be achieved with very porous or structured layers. Ways of producing such layers are

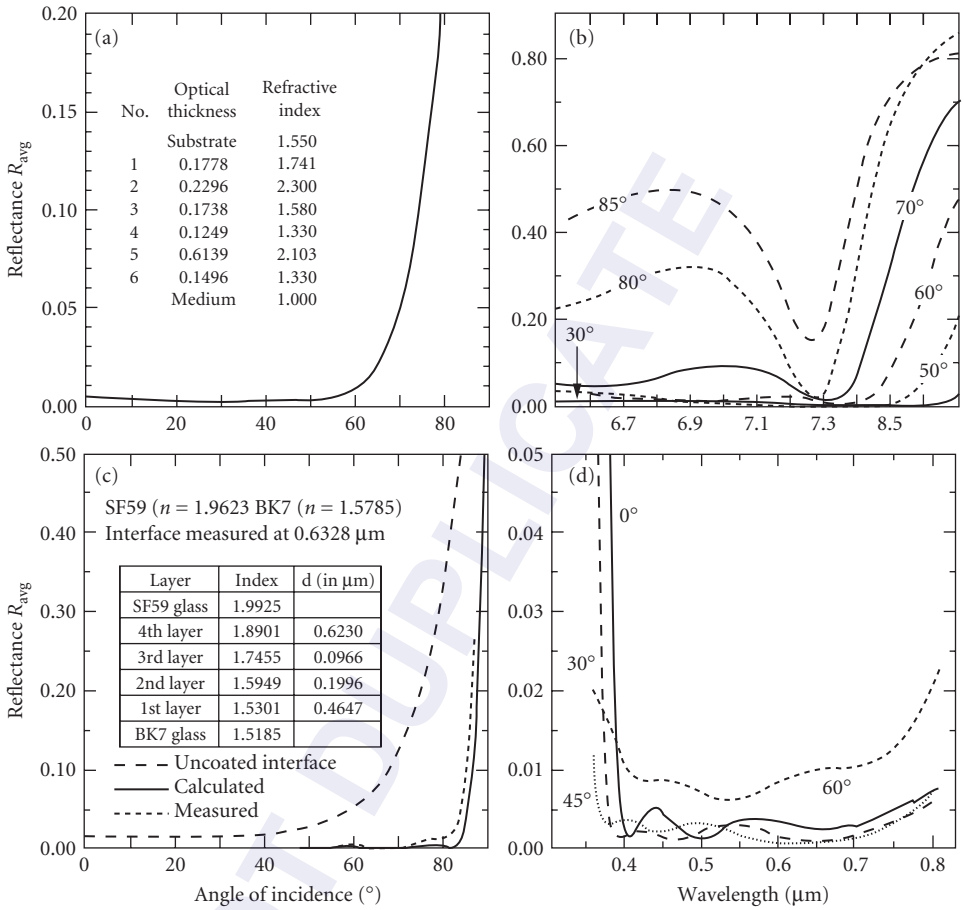

FIGURE 27 Wide angle AR coatings. (*a*) Calculated average reflectance of a conventional AR coating for the He-Ne laser wavelength for angles of incidence up to 60° (*after Dobrowolski et al.*[146,147]); (*b*) measured average reflectance of a Si/air interface for angles of incidence up to 85° with an AR coating based on the use of a Reststrahlen material (*after Dobrowolski et al.*[148]); (*c*) measured average reflectance of a glass/glass interface for angles of incidence up to 85° (*after Ma et al.*[149]); and (*d*) predicted performance of a hybrid wide-band AR coating for angles of incidence up to 60° (*after Schulz et al.*[150]).

being investigated at many laboratories. The predicted average reflectance of a hybrid AR coating consisting of seven solid thin films and an outermost structured layer is shown in Fig. 27*d*. It is expected to be less than 1 percent over a broad spectral region for all angles of incidence smaller than 60°. This will be a huge improvement over the performance of the coating depicted in Fig. 27*a*.

The design of antireflection coatings for very high angles of incidence has been considered by Monga.[153,154]

Nonoptical Properties of Antireflection Coatings

Antireflection coatings, in addition to optical specifications, often have to satisfy additional, nonoptical requirements. One such requirement may be to provide scratch resistance to soft, plastic surfaces. In Fig. 28*a* is shown the measured reflectance of an AR coating produced by Schulz et al. for

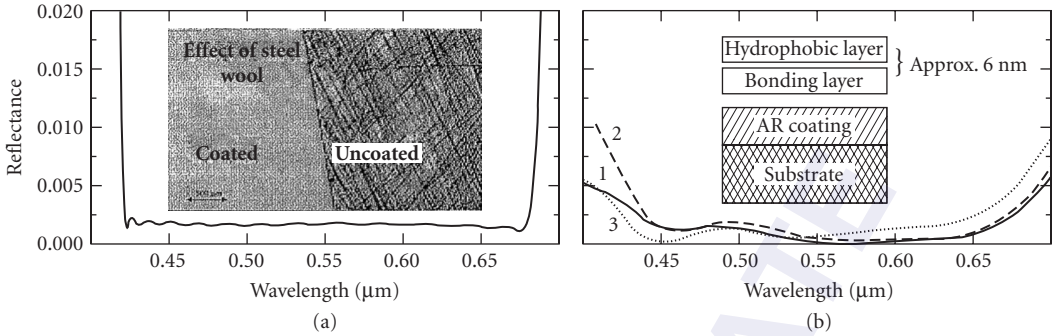

FIGURE 28 Nonoptical properties of antireflection coatings. (*a*) Measured reflectance of a 27-layer, 3-μm-thick SiO_2/Ta_2O_5 AR coating. The insert illustrates the effect of steel wool on the coated and uncoated portions of the substrate (*after Schulz et al.*[43]). (*b*) Performance of a water- and dust-repellent AR coating. Curves 1 and 2 are the calculated and measured reflectances. Curve 3 is the performance after cleaning the coating with acetone (*after Bruynnghe et al.*[155]).

a PMMA surface.[43] It consists of 27 layers of SiO_2 and Ta_2O_5, with an overall metric thickness of of over 3 μm, of which most corresponds to SiO_2. The inset shows, that the AR coating provides good protection from abrasion. Bruynooghe et al. describe an AR coating which repels water, oil, and dust (Fig. 28*b*).[155] This coating consists of a more or less conventional AR coating onto which is deposited a bilayer coating, the first part of which provides for good adhesion to the AR coating, and the second, the required hydrophobic properties. The total thickness of the bilayer is 0.006 μm.

7.6 TWO-MATERIAL PERIODIC MULTILAYERS THEORY

Nonabsorbing $[AB]^N$ and $[AB]^NA$ Multilayer Types

Let a periodic multilayer be composed of N periods AB, where A, B represent layers of refractive indexes n_A, n_B and optical thicknesses n_Ad_A, n_Bd_B. The most general representation of the complete multilayer is

$$\underset{1}{AB}\cdot\underset{2}{AB}\cdot\underset{3}{AB}\cdots\underset{N}{AB}=[AB]^N \tag{39}$$

In practice it is customary to write $[HL]^N$ or $[LH]^N$, depending on whether n_A is greater or less than n_B, respectively. The spectral-reflectance curve of the multilayer $[AB]^N$ will lie within a pair of envelopes which, at normal incidence, depend only on n_Ad_A, n_Bd_B, n_A, n_B, n_s, and n_m.[156,157] For $n_s = n_m$ the lower of the envelopes becomes $R = 0$. The envelopes contain high-reflectance zones within which the reflectance at each wavelength increases monotonically with the number of periods, approaching 1.0 as N tends to infinity (Fig. 29). Outside these high-reflectance zones the curves exhibit subsidiary maxima and minima whose number depends on n_Ad_A/n_Bd_B and which increases with N. The first-order high-reflectance zone occurs at a wavelength λ_1 given by

$$n_Ad_A+n_Bd_B=\frac{\lambda_1}{2} \tag{40}$$

and subsequent zones occur at wavelengths λ_q ($\lambda_1 > \lambda_2 > \lambda_3 \ldots$) given by

$$N(n_Ad_A+n_Bd_B)=q\frac{\lambda_q}{2} \qquad q=2,3,4\cdots \tag{41}$$

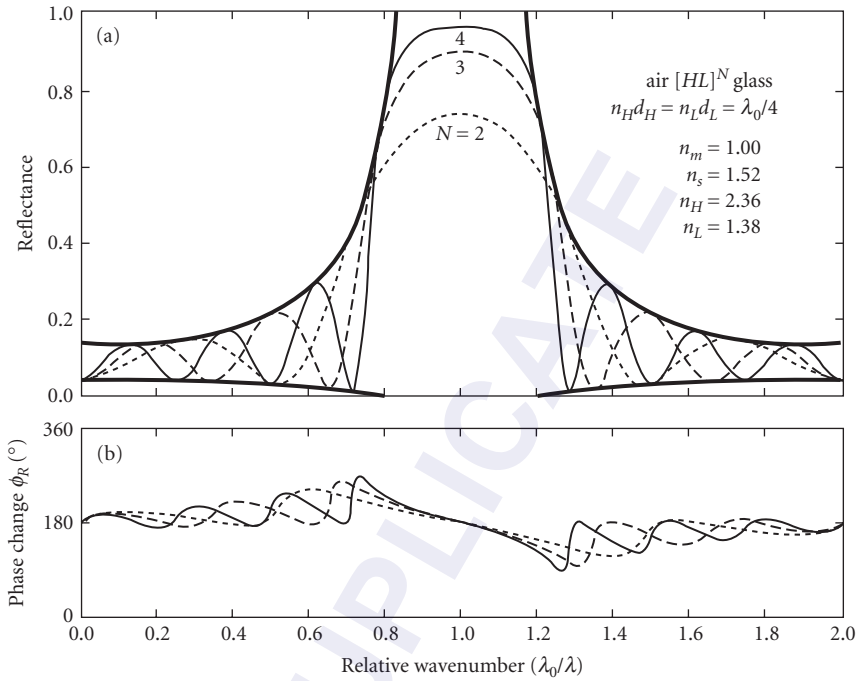

FIGURE 29 (*a*) Calculated reflectance and (*b*) phase change on reflection of periodic multilayers of the type $[HLH]^N$. *H* and *L* stand for high- and low-refractive-index layers of quarter-wave thickness at $\lambda_0 = 1.0$ μm. The heavy lines are the envelopes of the reflectance curves.

providing that at these wavelengths

$$n_A d_A, n_B d_B \neq p\frac{\lambda_q}{2} \qquad p = 1,2,3\cdots \tag{42}$$

It is thus possible, by choosing suitable thickness ratios, to arrange for or to suppress high-reflectance zones in several spectral regions at the same time. This is useful in the design of broadband reflectors (Sec. 7.7, "Rejection Filters"), cutoff filters and hot- and cold mirrors (Sec. 7.8), laser reflectors, and so on. Typical curves for thickness ratios 1:1 and 2:1 are given in Fig. 30. Plotted on a λ_0/λ scale, they show symmetry about all wavelengths λ for which $n_A d_A$ and $n_B d_B$ are both equal to some integral multiple of $\lambda/4$.

Maximum Reflectance For a given refractive index ratio (n_A/n_B) and number of periods *N* the highest reflectance occurs whenever $n_A d_A$, $n_B d_B$ are each equal to an odd multiple of $\lambda/4$. It is given by

$$R_{\max} = \left[\frac{n_m/n_s - (n_A/n_B)^{2N}}{n_m/n_s + (n_A/n_B)^{2N}}\right]^2 \tag{43}$$

Intermediate reflectances are obtained for the related symmetrical multilayers $[AB]^N A$:

$$R_{\max} = \left[\frac{n_m n_s/n_A^2 - (n_A/n_B)^{2N}}{n_m n_s/n_A^2 + (n_A/n_B)^{2N}}\right]^2 \tag{44}$$

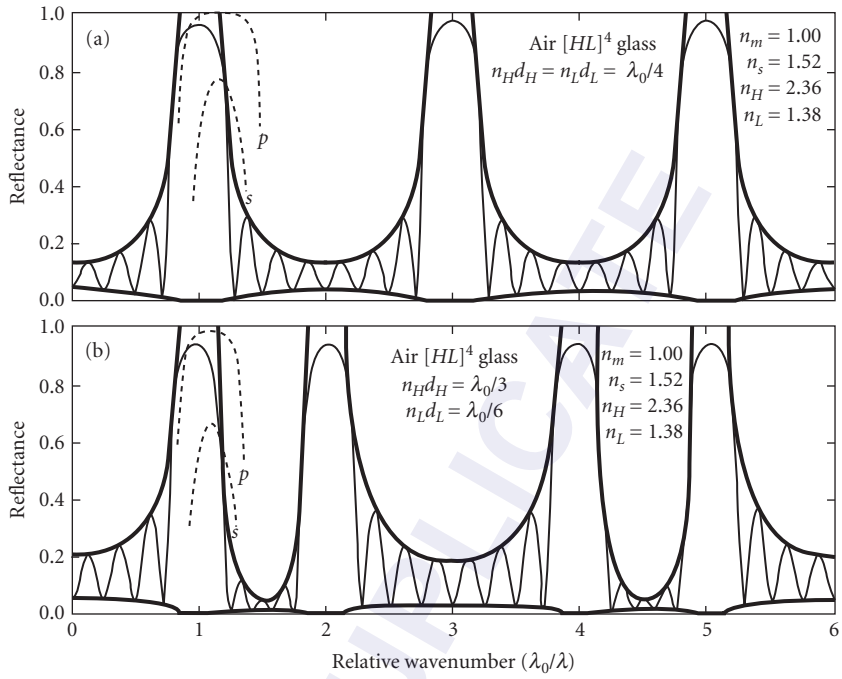

FIGURE 30 Calculated reflectance curves of periodic multilayers with (*a*) 1:1 and (*b*) 2:1 thickness ratios. The dotted curves represent the reflectance of polarized radiation incident at an angle of 60°.

Results for a number of such cases are given in Fig. 31. Intermediate reflectances can be obtained by changing the refractive index of any of the layers in the stack.

Explicit expressions for *R* for other thicknesses are complicated.

Phase Change on Reflection The dispersion of the phase change on reflection from periodic all-dielectric multilayers is much greater than that of metal reflectors. Unless corrected for, it will lead to errors in some metrological and interferometric applications. Like reflectance, it varies rapidly outside the high-reflection zone (Fig. 29*b*). Within the high-reflectance zone it changes almost linearly with wavenumber and is 180° at $\lambda_0/\lambda = 1$. The slope of this portion of the graph increases and approaches a limiting value as *N* tends to infinity. The limiting value (in degrees per unit wavelength) is given by

$$\left[\frac{d\phi}{d\lambda}\right]_\lambda = \left\{ \begin{array}{ll} \dfrac{180 n_m}{\lambda_0 (n_H - n_L)} & \text{for } n_H \\ \dfrac{180 n_H n_L}{\lambda_0 n_m (n_H - n_L)} & \text{for } n_L \end{array} \right\} \tag{45}$$

depending on whether the light is first incident on a high- (n_H) or low- (n_L) refractive index layer.[158] The above values should be multiplied by 3, 5, . . . in stacks composed of $3\lambda/4$, $5\lambda/4$, . . . layers.

Böhme has shown that, by changing the refractive index of one of the layers in a quarter-wave stack, it is possible to obtain a zero value of the phase change on reflection ϕ at λ_0.[159]

	n_m	n_s	n_L	n_H
◆	1.46	1.46	1.38	1.46
■	1.00	1.46	1.42	1.70

FIGURE 31 Transmittance at the reflection maximum of quarterwave stacks composed of MgF_2 and SiO_2 in the visible region (◆), MgF_2 and MgO in the ultraviolet (■). MgF_2 and ZnS in the visible region (▲), and ZnS and PbTe in the infrared (●).

Periodic Multilayers of the $[(0.5A)B(0.5A)]^N$ Type

The construction of such multilayers differs from that of the type $[AB]^NA$ discussed above by having outermost layers of only half the thickness of the remaining layers.[115] The position and width of the high-reflection zones are the same in both cases, but in coatings of the $[(0.5A)B(0.5A)]^N$ type it is possible to reduce the height of the subsidiary maxima on either one or the other side of the main reflectance maximum if $n_A t_A = n_B t_B$. Kard et al. describe the optimum choice of all the construction parameters (N, n_A, n_B, n_s, n_m) of such a coating.[160] If the refractive indices n_s, and n_m of the surrounding media must be chosen on some other basis, then for maximum improvement of the short- and long-wavelength transmission the refractive indexes n_A and n_B, of the coating materials must satisfy

$$n_s n_m = \frac{n_A^3}{n_B} \tag{46}$$

or

$$n_s n_m = n_A n_B \tag{47}$$

respectively. Estimates of the maximum reflectance for larger values of N can be obtained from Fig. 31. Multilayers of this type are of importance in the design of cutoff filters (Sec. 7.8), and are illustrated in Fig. 32, which should be compared with the curves of Fig. 33.

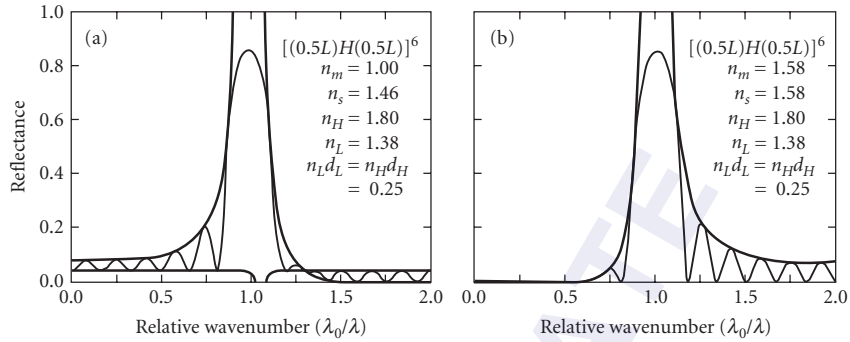

FIGURE 32 Calculated reflectance curves of two periodic multilayers with symmetrical periods of the type $[(0.5L)H(0.5L)]^6$ in which the subsidiary reflectance maxima on (*a*) the short- and (*b*) the long-wavelength side of the high-reflectance zone are reduced.

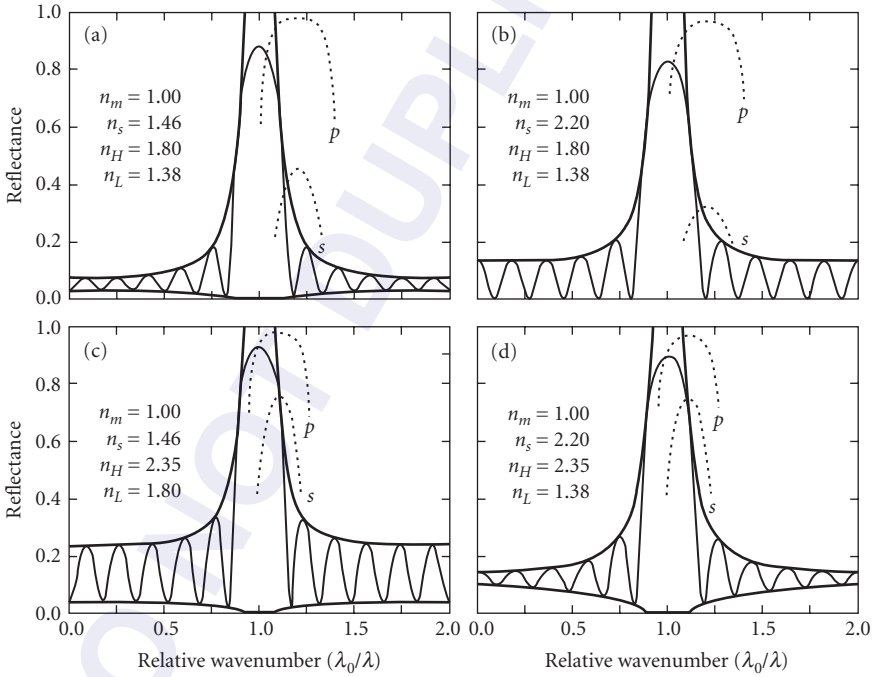

FIGURE 33 Calculated reflectance curves of two quarter-wave stacks of the type $H(LH)^N$ with different values of n_H and n_L but with the same ratio n_H/n_L, (rows 1, 2) deposited onto two different substrate materials (columns 1 and 2). The dotted curves represent the reflectances for light incident at 60°.

Width of the High-Reflectance Zone

For a given value of (n_A/n_B), the width $\Delta\lambda_R/\lambda$ of the high-reflectance zone is greatest when $n_A d_A = n_B d_B = \lambda/4$, and it is then given by

$$\frac{\Delta\lambda_R}{\lambda} = \frac{4}{\pi}\sin^{-1}\left(\frac{1-n_A/n_B}{1+n_A/n_B}\right) \tag{48}$$

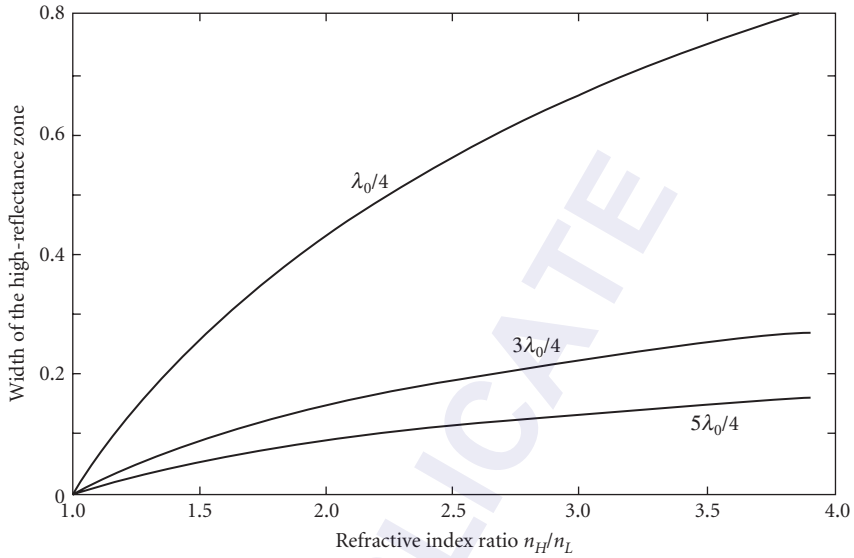

FIGURE 34 Calculated widths of high-reflectance zones of two-material periodic stacks of layers of optical thicknesses $\lambda_0/4$, $3\lambda_0/4$, and $5\lambda_0/4$ for different refractive index ratios.

This width is reduced by a factor of $2N–1$ if Nth-order quarter-wavelength layers are used. Graphs of the widths of the high-reflectance zones versus refractive index ratio for $\lambda_0/4$, $3\lambda_0/4$, and $5\lambda_0/4$ layer stacks are given in Fig. 34. Periodic multilayers with equal refractive index ratios have high-reflectance zones of equal widths, but their reflectance curves will not be the same unless the refractive indexes of the surrounding media are also increased by the same ratio (Fig. 33).

Periodic Multilayers of the $[xH\cdot(1 - x)L]^N\cdot xH$ Type

As already stated in Sec.7.6, subsection "Periodic Multilayers of the $[(0.5A)B\ (0.5\ A)^N$ Type" it is not necessary for the optical thicknesses of the layers of a periodic multilayer reflector to be equal to a quarter wave. A multilayer system of the type $[xH\cdot(1 - x)L]^N\cdot xH$, where H, L correspond to quarter-wave layers of a high- and low-refractive index and where $0 < x < 1.0$, will have a high reflectance, providing that the number of periods N is high enough.[161–164] However, the smaller the value of x, the narrower the width of the high reflectance zone. Given two coating materials, it is thus possible to independently select the reflectance and the width of the rejection region. Figure 35*a*, and *b* shows the relationship between R_{max}, $\Delta\lambda_R/\lambda$ and x , N for values of n_H, n_L, corresponding to the refractive indices of ZnS and polyethylene at about 200 μm.

Angular Sensitivity

For some applications it is important to reduce the angular variation of the reflectance curve. This can be done by using materials with high refractive indexes (Fig. 33) (see also Sec. 7.8, subsection "Angle-of-Incidence Effects"). Another way is to use periods in which the high-index film is thicker than the low-index film (Fig. 30*b* and Fig. 60*a*).

Multilayer Reflectors Made of Absorbing Materials

It is possible to achieve a high reflectance with multilayers of the $[AB]^NA$ type even when A, B correspond to absorbing materials. This is of particular interest for spectral regions for which no nonabsorbing coating materials exist. The optical thicknesses of the periods of such systems are still

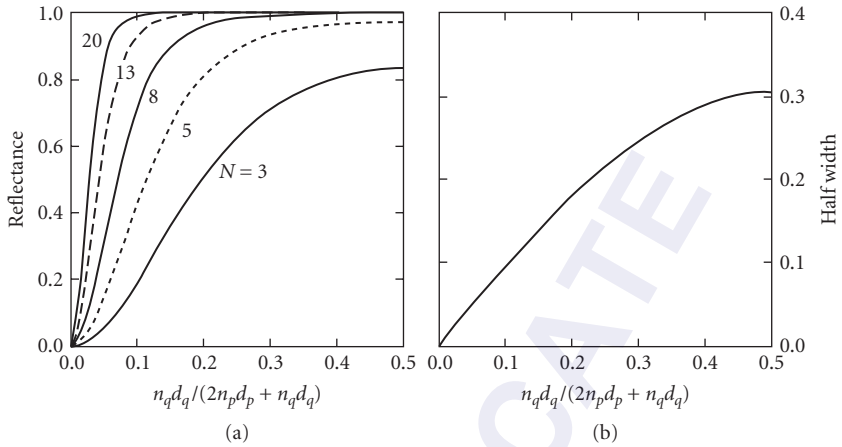

FIGURE 35 Width of the high reflectance zone (*a*) and maximum reflectance (*b*) of periodic multilayers of the type $[xH\cdot(1\text{-}x)L]^N x\cdot H$. The curves were evaluated for refractive indices $n_H = 2.4$ and $n_L = 1.51$. (*After Shao.*[165])

approximately equal to $\lambda/2$ but, for maximum reflectance, the individual thicknesses d_A, d_B may be quite different, depending on the number of periods N and on the optical constants of the materials used. Reflectors with $k_A > k_B$, have structures that are intermediate to those of quarter-wave stacks (with $k_A = k_B = 0$ and optical thicknesses of $\lambda/4$, in which constructive interference effects are maximized), and those of ideal Bragg crystals (with $k_A >> k_B$, and in which $d_A << d_B$ to minimize absorption losses).

In the extreme ultraviolet (XUV) and the soft x-ray regions ($n - 1$), k is much smaller than 1 for most coating materials.[165–167] To design a periodic multilayer with a high normal incidence reflectance for a given wavelength, it is first necessary to choose a material ($n_B - ik_B$) with the lowest possible extinction coefficient.[166,168] Next a second, chemically compatible material ($n_A - ik_A$) is selected with the lowest extinction coefficient that will maximize the normal incidence Fresnel reflection coefficient of the interface between the two materials given by

$$r_{BA} = \frac{(n_B - n_A) - i(k_B - k_A)}{(n_B + n_A) + (k_B + k_A)} \tag{49}$$

Vinogradov and Zeldovich use a factor β_{opt} to relate the metric thicknesses of the layers A and B that yield a maximum reflectance to the overall thickness d_{opt} of the period:[169]

$$d_A = \beta_{\text{opt}} \cdot d_{\text{opt}} \quad \text{and} \quad d_B = (1 - \beta_{\text{opt}}) \cdot d_{\text{opt}} \tag{50}$$

where β_{opt} is obtained by the solution of the equation

$$\tan(\pi\beta_{\text{opt}}) = \pi\left[\beta_{\text{opt}} + \frac{n_B k_B}{n_A k_A - n_B k_B}\right] \tag{51}$$

d_{opt} is approximately equal to $\lambda/2$, but Vinogradov and Zeldovich give a more accurate expression for this quantity, as well as for the limiting reflectance R and the number of periods N required to reach that value.[169]

7.7 MULTILAYER REFLECTORS—EXPERIMENTAL RESULTS

In the calculations of the data for Figs. 29 to 34, the dispersion of the optical constants of the materials was ignored, and it was assumed that the films were absorption and scatter free and that their thicknesses had precisely the required values. In practice, none of these assumptions is strictly valid, and hence there are departures from the calculated values. In general, the agreement is better within the high-reflectance zone than outside.

Reflectors for Interferometers, Lasers, etc.

The measured reflectances and transmittances of a number of quarter-wave reflectors suitable for use in Fabry-Perot interferometers are shown in Fig. 36. The transmission of a typical commercial laser reflector for $\lambda = 0.6328$ μm is shown in Fig. 37. The measured reflectances of a number of highly reflecting coatings for the infrared spectral region are shown in Fig. 38.

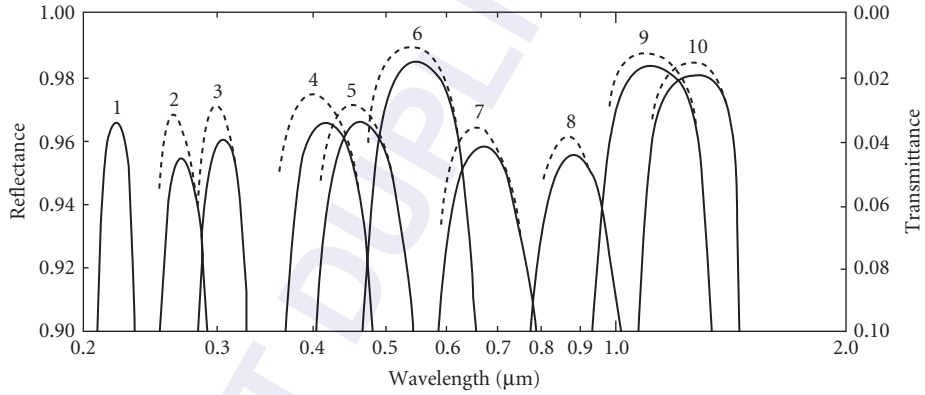

FIGURE 36 Measured spectral reflectance and transmittance curves of periodic all-dielectric reflectors of the type $[HL]^N H$ for the ultraviolet, visible, and near-infrared parts of the spectrum. Curve 1: 27 layers of MgO and MgF_2; curves 2 and 3: 11 and 13 layers of PbF_2 and cryolite, respectively; curves 4, 5, 7, and 8: 7 layers of ZnS and cryolite; curves 6, 9-, and 10: 9 layers of ZnS and cryolite. (*Curve 1 after Apfel*[170] *and curves 2 to 10 after Hefft et al.*[171])

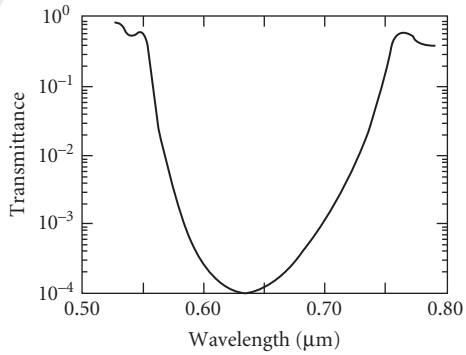

FIGURE 37 Measured spectral transmittance of a laser reflector. (*After Costich.*[172])

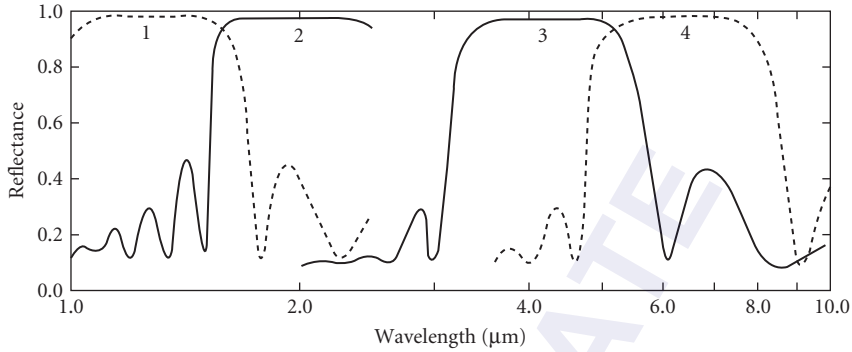

FIGURE 38 Measured spectral-reflectance curves of all-dielectric reflectors for the infrared made of stibnite and chiolite. Curves 1 and 2: multilayers of the type $[HL]^4H$ on glass; curves 3 and 4: type $[(0.5L)H(0.5L)]^4$ on barium fluoride. (*After Turner and Baumeister.*[173])

Both "soft" laser coatings that can be dissolved in weak acids and "hard" coatings that can be removed only through polishing are available commercially.

Effects of Imperfections

Thickness Errors Small errors in the thickness of the layers of a quarter-wave stack have only a very small effect on the reflectance and on the phase change on reflection of the multilayer within the high-reflectance zone but they do affect the performance outside the zone.[174,175] In fact, the effect may be quite serious: thickness variations can give rise to an apparent lack of flatness of the substrate surface.[176–178]

Dispersion The most noticeable effects of dispersion of the optical constants in quarter-wave stacks of a given multilayer type are the increase in the peak reflectance with decrease in wavelength (see Fig. 36) and the asymmetry of the maxima on either side of the main reflectance maximum.

Absorption The separation between the transmission and reflectance curves in Fig. 36 is mostly due to absorption. These losses can limit the usefulness of the reflectors for some applications. Thus, for example, in interference filters and Fabry-Perot interferometers they lead to a reduction in the peak transmissions and limit the attainable half widths. In optical information-storage devices they set a limit to the highest reflectance attainable. In lasers the losses counteract directly the gain in the laser medium. In addition, absorption within the layers is responsible for damage to laser reflectors (see also Sec. 7.4, subsection "Laser Damage").

If the two materials used for the construction of periodic quarter-wave stacks have small, but finite extinction coefficients, the resulting absorption at first reduces both the transmission and reflection coefficients.[156,176,179,180] With an increase in the reflectance of a multilayer of the $[HL]^NH$ type the absorption occurs more and more at the expense of the reflection coefficient, approaching a limiting value of

$$A = -\delta R = \frac{2\pi n_m}{n_H^2 - n_L^2}(k_H + k_L) \tag{52}$$

that is independent of the number of layers.[2] The corresponding expression for a multilayer $[HL]^N$ in which a low refractive index faces the incident medium is

$$A = -\delta R = \frac{2\pi(n_L^2 k_H + n_H^2 k_L)}{n_m(n_H^2 - n_L^2)} \tag{53}$$

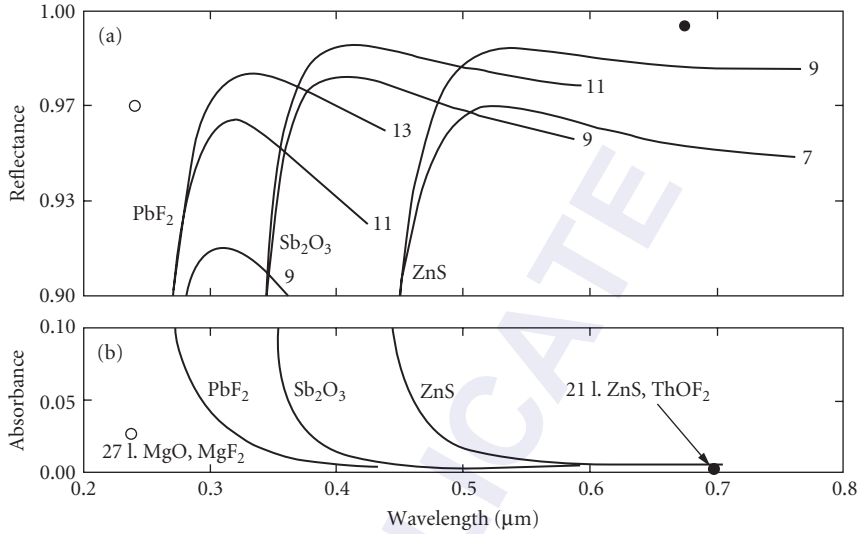

FIGURE 39 Variation with wavelength of the observed peak reflectance of 7-, 9-, 11-, and 13-layer quarter-wave stacks made of PbF_2, Sb_2O_3, or ZnS with cryolite as the low-index material (*a*). The lower curves indicate the limiting value of the absorbance with these materials (*b*). (*After Honcia and Krebs.*[181] *Results obtained by Apfel*[170] (o) *and Behrndt and Doughty*[182] (•) *with other materials are included for comparison.*)

Figure 39 shows the spectral variation of experimentally determined maximum reflectances and limiting losses of various quarter-wave multilayer reflectors.

The absorption in periodic multilayers composed of materials having finite extinction coefficients can be reduced below the values given by Eqs. (52) and (53) if a structure of the $[xH\cdot(1–x)L]^N\cdot xH$ type is used.[163]

Surface and Interface Imperfections In thin-film calculations it is usually assumed that substrate surfaces and interfaces between the layers are smooth and that the layers are homogeneous. In practice, substrate surfaces and interfaces have a certain roughness and, at times, thin uniform or inhomogeneous interface layers formed between the boundaries of two layers as a result of oxidation, chemical interactions, or interdiffusion of the two coating materials. The interface layers, as a rule, are different at the *AB* and *BA* boundaries and are typically 0.0003 or 0.0010 μm thick. These and other imperfections of the layer system result in reduced reflection and/or in scatter. If ignored in the model used to represent the multilayer, they add to the discrepancies that are observed between the calculated and experimental data.

Scattering losses are particularly significant at shorter wavelengths. For this reason there have been many theoretical and experimental investigations of scattering of surfaces and thin films. Investigations have shown that when scatter does occur, most of the light is scattered in directions that are close to that of the specularly reflected light.[156,183] The experimental results for a typical mirror are shown in Fig. 40.

Very low loss reflectors Mirrors with very low losses are required for use in laser cavities and in ring lasers. Mirrors with a combined loss *L* (= transmission + absorption + scatter) of the order of 5×10^{-5} are commercially available. With special manufacturing techniques practically loss-free reflectors can now be made.

A 41 quarter-wave stack made of Ta_2O_5 and SiO_2 layers with a combined loss of $L = 1.6 \geq 10^{-6}$, corresponding to a reflectance of 0.9999984 at 0.633 μm, has been reported.[185] The absorption and scatter losses were estimated to be of the order of $1.1 \geq 10^{-6}$. The essential starting point for the manufacture of such coatings are superpolished substrates with a surface roughness of 0.5 Å rms or

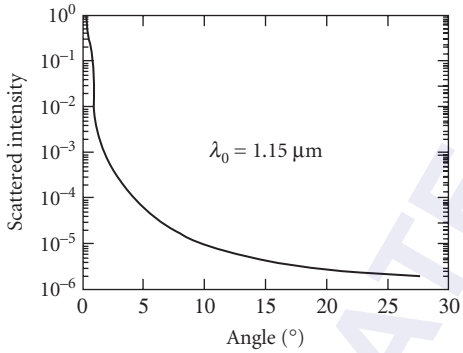

FIGURE 40 Measured intensity of the scattered radiation as a function of the angle away from the direction of specular reflection. (*After Blazey.*[184])

less. The layers were deposited by reactive ion-beam sputtering from high purity oxide targets in a cryogenically pumped, fully automated deposition system.[186]

An even greater challenge will be the requirements of reflecting coatings for Michelson interferometers for the detection of gravitational waves.[185,187] For this application, not only must the absorption and scattering losses be less than 0.5 and 2 ppm, but in addition, to reduce the thermal noise arising from mechanical loss in the coatings, it will be necessary to match the thermal expansion coefficient and the Young's modulus of the coating materials to those of the substrates.

Multilayers for the soft x-ray and XUV regions The effect of roughness and of interface layers is particularly important in soft x-ray and XUV multilayers because the dimensions of these defects are comparable to the thicknesses of the individual layers and of the wavelength.[165,166,168] For this reason much attention has been focused on the proper modeling of such coatings. Many workers use several very thin layers and the matrix method outlined in Sec. 7.2, subsection "Matrix Theory for the Analysis of Multilayer Systems" to model the effects of roughness and interface layers.[188,189] Others make use of the following recursive formula for the amplitude reflectance r_j of the first j layers of the system:

$$r_j = \frac{r_{j-1} + r_{BA}\exp(2i\delta_j)}{1 + r_{j-1}r_{BA}\exp(2i\delta_j)} \tag{54}$$

Here δ_j is the effective optical thickness of the jth layer [Eq. (18)], r_{j-1} is the amplitude reflectance of the first $(j-1)$ layers and r_{BA} is the amplitude reflectance of the interface between the jth and $(j+1)$th layers. In this approach, if the Fresnel amplitude reflection coefficient r_{BA} is replaced by

$$r_{BA}\exp\left\{-\frac{1}{2}\left[\frac{4\pi}{\lambda_0}\sigma\,\Re\mathrm{e}(\tilde{n}\cos\tilde{\theta}_0)\right]^2\right\} \tag{55}$$

the combined effect of roughness and of interface layers σ can be allowed for.[190] In the hard x-ray region, where $n \approx 1$, $k \approx 0$ for all materials, the exponential term in the above expression reduces to the so-called Debye-Waller factor DW,

$$\mathrm{DW} = \exp\left[-\frac{1}{2}\left(\frac{4\pi}{\lambda_0}\sigma\cos\theta_j\right)^2\right] \tag{56}$$

The calculated reflectance of a XUV mirror, with and without the effect of surface imperfections is shown in Fig. 41. These significant reflection losses can be reduced through interface engineering—a

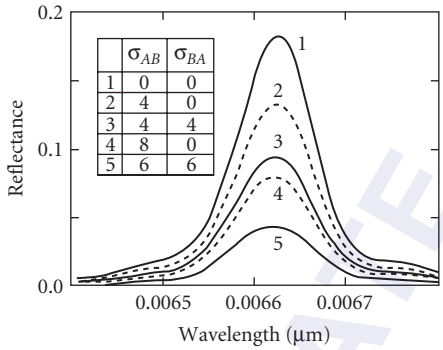

FIGURE 41 Calculated reflectances of 64-period x-ray mirrors with different imperfections σ (in Å) at the ReW-C and C-ReW interfaces. (*Afer Spiller.*[191])

process in which interdiffusion or oxidation is inhibited by the deposition at the interfaces of thin barrier layers of materials such as C or B_4C.[192]

Narrowband Reflection Coatings

Narrowband rejection (or notch, or minus) filters transmit freely all the radiation incident upon them except in one narrow spectral region in which the radiation is either wholly or partially reflected.[193] Lord Rayleigh observed a corresponding natural phenomenon in potassium chlorate crystals.[194] Subsequent experimentors reported crystals with rejection bands varying between 0.001 and 0.038 μm in width and reflectances between 33 and 99.9 percent.[195–197] But, unfortunately, at present the size of the crystals that can be grown is insufficient, and the position and width of the rejection region cannot be controlled. The same comments can be made about coextruded polymer films made of the thermoplastic materials polypropylene ($n = 1.49$) and polycarbonate ($n = 1.59$).[198,199] With thin films the above limitations can be overcome, but until recently it has been difficult to achieve the extremely narrow widths and high rejections observed in the crystals.

A quarter-wave stack of the type $[AB]^N A$ has been suggested as a model for the construction of such filters (see, for example, Refs. 196 and 200). It follows from Figs. 31 and 34 that the closer the refractive index ratio n_A/n_B is to unity, the narrower the width of the reflectance zone and the more layers required to achieve a certain rejection. Shown in Fig. 42*a* is (1 – the measured reflectance) of a multilayer consisting of 760 layers that was produced by a plasma chemical deposition technique.[201] Unfortunately, that method could only deposit such coatings on the inside of a tube. To reduce the number of layers, films with higher n_A/n_B ratios could be utilized and the width reduced by using layers with thicknesses that are odd multiples of a quarter wavelength. But this can be done only at the expense of bringing the adjacent higher- and lower-order reflection peaks closer. Resonant reflectors are an extreme example of this. However, recent progress in the manufacture of multilayer systems (see Sec. 7.12) has made it possible to produce notch filters for Raman spectroscopy at any wavelength in the visible or near-infrared that exceed the reported performance of the naturally occurring crystals. Fig. 42*b* shows the measured transmittance and optical density of a filter that has a 0.020-μm-wide rejection region and a very high transmittance with only a 1 to 2 percent ripple in the wavelength range $0.6 < \lambda < 1.00$ μm. The optical density at $\lambda = 0.75$ is 6.0. The filter consists of 714 layers and it has a metric thickness of 51 μm.[202] The measured width of the notch of the filter shown in Fig. 42*c* is about 0.024 μm and it has an optical density of 5.9 at $\lambda = 1.064$ μm, as measured with a laser. The second surface of this filter was not antireflection coated, and so the transmittance is a little lower, but the high transmittance extends from 0.4 to 1.09 μm. The metric thickness of this filter is 122.2 μm and it consists of 4410 layers.[203]

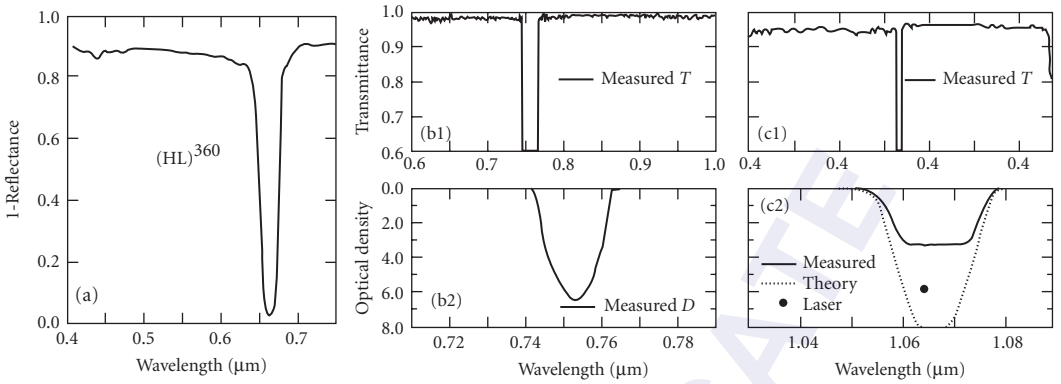

FIGURE 42 Narrow band rejection filters. (*a*) Measured value of (1 – reflectance) of a 760-layer quarterwave stack produced by chemical vapor deposition using materials with refractive indices of 1.575, 1.585 (*after Edmonds et al.*[201]); (*b*) measured reflectance and optical density a 714-layer, 51-μm-thick filter (*after Iridian Spectral Technologies*[202]); and (*c*) measured reflectance and optical density a 4410-layer, 122.2-μm-thick filter (*after JDSU*[203]).

Resonant Reflectors

In the past, even "hard" evaporated coatings could not survive the power densities present in some high-power lasers. To overcome this problem, resonant reflectors were used.[204–207] They consisted of one or more accurately air-spaced plane-parallel plates of thicknesses of the order of millimeters made of a tough, high-optical-quality material. Because of the long coherence length of the laser radiation incident upon them, interference takes place in the same way as in thin films. Resonant reflectors may be regarded as being quarter-wave reflectors of enormously high order of interference, and all the equations given in Sec. 7.6 apply.

Resonant reflectors made of quartz and sapphire are commercially available. Since the refractive index of quartz is lower than that of sapphire, a larger number of plates is required to attain the same reflectance. On the other hand, quartz is much cheaper and is less temperature sensitive. The calculated reflectance of one-, two-, three-, and four-plate sapphire resonant reflectors are shown in Fig. 43. In another development diffusion-doped quartz plates are used in the construction of resonant

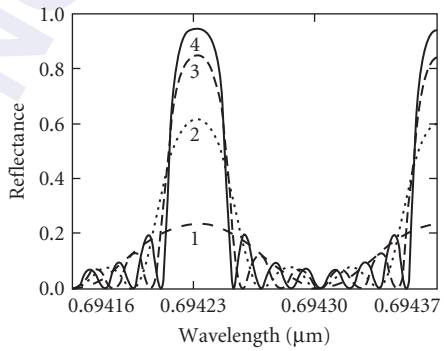

FIGURE 43 Calculated spectral reflectance of resonant reflectors consisting of one, two, three, and four sapphire plates ($n = 1.7$). The optical thicknesses of the plates and of the air spaces between them were assumed to be 1.7 mm.

reflectors.[208] The doping process causes the refractive index of the plate to increase smoothly in a 0.5-μm region from that of quartz to about 2.0 at the surface. As a consequence fewer elements are needed to achieve a given reflectance.

All-Dielectric Broadband Reflectors

There are several ways of obtaining a coating with a broad high-reflection region should the width attainable with quarter-wave stacks be inadequate. For a broad region with a very high reflectance one can superimpose two quarter-wave stacks tuned to two different wavelengths. The widest continuous high-reflectance region is attained when materials with the highest available refractive-index ratios are used and the thicknesses of the layers are so chosen that the two high-reflectance zones are contiguous (see Fig. 44*c*). For an even broader region further quarter-wave stacks can be superimposed. If high-reflection regions overlap, special precautions must be taken to prevent the appearance of sharp reflectance minima in the high-reflectance region.[173] It is not easy to obtain a very uniform, moderately high reflectance in this way. Another approach is to deposit onto the substrate a series of alternating high- and low-refractive-index films of gradually increasing or decreasing thicknesses (Fig. 45). A broad high-reflection region can also be obtained with a multilayer in which the layers are different multiples of $\lambda/4$ of a selected wavelength (see Fig. 46). Finally, it has been suggested that multilayers with 10:1 high reflectance regions might be produced by depositing hundreds of layers of random thicknesses made of two materials that are nonabsorbing throughout the spectral range of interest.[209] As yet experimental data for this approach have not been presented.

If only a relatively small increase in the high-reflectance region is required, or if a uniform but only moderately high reflectance is required, the desired result can be achieved by modifying the thicknesses and refractive indexes of a quarter-wave stack using a computer refinement program or by the addition of achromatizing $\lambda/2$ layers. The measured performances of several such reflectors are shown in Figs. 47 and 48. Broadband reflectors with moderate and high reflectances for the ultraviolet spectral region have been reported by Korolev,[213] Sokolova,[214] and Stolov.[215] A boadband reflector for the XUV spectral region is shown in Fig. 57*b*.

Broadband Reflectors Effective over a Wide Range of Angles (Perfect Mirrors) At times it is required that the reflectance be high not only over a broad wavelength region, but also for a large range of angles of incidence. It was clear that if this is to be achieved, the superimposed periodic stacks (Fig. 44) must be contiguous at the highest angle required, and that they will therefore overlap at lower angles. This situation has been investigated at some length in a theoretical paper for visible reflectors effective for angles up to 50°.[220] Subsequently a number of workers outside the thin-film field rediscovered this possibility and described similar coatings working for all angles, which they called "perfect mirrors."[221–223]

Phase Change on Reflection from Broadband Reflectors The phase change on reflection from broadband reflectors varies even more rapidly with wavelength (Figs. 44 to 47) than that from quarter-wave stacks (Fig. 29).[224,225] In fact, the phase change can be so large, that it has been proposed for the construction of spacerless transmission interference filters (see Fig. 93*h*). But a high phase change on reflection can also be a disadvantage in certain metrological applications. Another consequence of this rapid variation is that, in the presence of systematic thickness variations in the layers, it can give an impression of a lack of flatness in the substrate.[178] Figures 47*d* and 48*a* represent designs of broadband reflectors in which an effort was made to reduce this effect.

Coatings for Ultrafast Optics

In all sections of this chapter, with the exception of this one, it is assumed that the intensity of the radiation that is falling onto a multilayer does not vary in time and that a steady state exists. However, there are applications in telecommunications, spectroscopy, and in other areas in which the use of very short pulses of light is a great advantage. But, for pulse durations shorter than 100 fs, the transient effects that can be ignored during steady-state operations become significant. In ultrafast optics the incident light can consist of very short Gaussian light pulses with a temporal bandwidth as short as 5 fs. Under these conditions the phase changes φ_R, φ_T of a multilayer on reflection or transmission, and their first and second derivatives with respect to ω, where $\omega = 2\pi c/\lambda$ and where c is the speed of light in a vacuum, become very important. The first and second derivatives of the phase changes, $-(d\phi/d\omega)$ and $-(d^2\phi/d\omega^2)$, are called the Group Delay (GD) and Group Delay Dispersion (GDD), respectively. Unless they are suitably controlled in a multilayer, the pulse length of the incident beam can be considerably broadened on reflection. In order to avoid this, the thicknesses of layer pairs in a coating are reduced in a systematic way, so that light of shorter wavelengths does not penetrate as deeply into the multilayer structure before a significant part of it is reflected. Such structures resemble those used in broadband reflectors (see, for example, Fig. 45) and are called by some "chirped multilayers." At times it is useful to use "double chirped" structures in which, in addition to a gradual reduction of the bilayer thickness, the relative thicknesses of the high and low refractive index layers

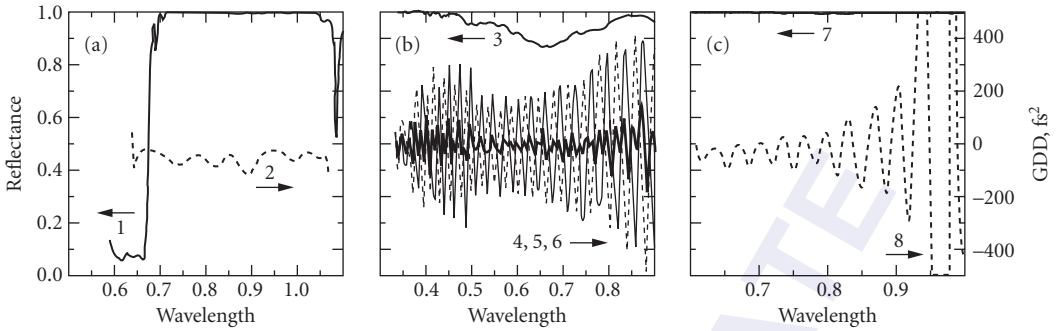

FIGURE 49 Measured reflectances R and the Group Delay Dispersions (GDD) of three different systems designed for femtosecond use. (*a*) Input coupler.[228] (*b*) The large fluctuations of the GDD values that occur in mirrors designed for a very wide spectral regions can be reduced by reflecting the light from a pair of mirrors designed to have oscillations that are complimentary. In this diagram, the dotted and thin solid curves correspond to the individual GDD curves; the heavy solid curve corresponds to the GDD after reflection from both mirrors.[229] (*c*) Dispersive mirror designed by the time-domain method.[230]

within each pair are also varied. Of course, more degrees of freedom to obtain the required performance are obtained if in the final calculations the thicknesses of all layers of the system are allowed to vary independently.

It has been shown that the temporal and spectral widths of the reflected pulses are related to one another though a Fourier transformation that uses a product of the complex spectrum of the incident pulse with the factor $r_i(\omega)\exp[\phi_i(\omega)]$ for the reflecting coating (see, for example, Refs. 226 and 227). In the numerical design of such coatings, *R*, GD, and GDD, or even the desired temporal pulse length, may need to be specified and they will depend on the particular problem on hand. A more detailed presentation of the design of such coatings is outside the scope of this chapter and the interested reader is referred to the reviews by MacLeod[2] and Tempea et al.[226]

Some of the multilayer reflector coating types that are required for ultrafast optics include input couplers (with a high *R* and a negative GDD and a high *T* in the gain and absorption region of the laser); output couplers (with a certain GDD and a rather low transmittance $0.05 < T < 0.3$ in a wide spectral range of the laser oscillator); chirped mirrors with very large bandwidths. The measured performance of three reflectings coatings for femtosecond applications are shown in Fig. 49.

It should be stated that this is currently a very fast moving field. Tunable dispersion compensators[202,231] for femtosecond use are currently employed.[232] Compressors and stretchers for nonlinear optics amplifiers with negative and positive GDD as large as of 2000 fs^2 are being developed.[233] In addition to reflectors, the design of beam splitters[234] and antireflection coatings[235] for ultrafast optics have also been discussed in the literature.

Rejection Filters

Minus Filters Minus filters are, in essence, multilayer reflectors in which the ripples in the transmission regions on either side of the high reflectance zone have been reduced or eliminated. Filters of this kind with various widths and attenuations find applications as correction filters.[236] Narrow minus filters with high attenuations have various scientific and technological uses, including protection of equipment and personnel from harmful laser radiation. Figure 50 shows the measured transmittances of a number of rejection filters of various widths and attenuations. Quite recently spectacular progress has been made in the deposition of narrowband rejection filters that find applications in Raman spectroscopy. The two commercial narrow band rejection filters shown in Fig. 42*b* and *c* consist of 713, 4410 layers each, have 0.02- and 0.025-μm-wide rejection regions and measured transmittances of less than 10^{-6} at the center of the notches.[202,203]

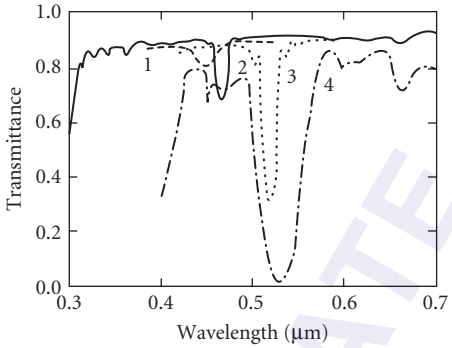

FIGURE 50 Measured spectral transmittances of several narrowband rejection filters. (*Curves 1 to 3 after Dobrowolski*[236] and *curve 4 after Optical Coating Laboratory.*[237])

Thelen has shown how to optimize the transmission on both sides of the rejection band of a minus filter simultaneously.[238] If the multilayer is surrounded on both sides by the same medium, it will be symmetrical and can be represented by $C[AB]^N AC$, $DAC[AB]^N ACAD$, . . . Here *A, B, C, D*, . . . are layers of quarter-wave optical thickness at the design wavelength and

$$n_m = n_s = n_A \tag{57}$$

The refractive indices n_C, n_D, . . . depend on n_A and n_B in a more complicated way. The larger the number of different materials used in the construction of these multilayers, the better the performance in the transmission region. Should the use of more than two coating materials not be convenient, it is a simple matter to find a two-material version of this solution. The above points are illustrated in Fig. 51.

Young[193] described two other design methods for narrowband rejection filters with improved transmission characteristics. The methods are based on analogies with antenna theory, and they yield nonperiodic equi-ripple designs in which all the layers either have equal thicknesses but different indexes or are made of two materials only but have many different thicknesses.

Should the simultaneous rejection of several wavelengths be required, it is possible to achieve this by depositing several minus filters on top of one another (Fig. 52).

Rugate Filters In inhomogeneous layers the refractive index varies continuously in the direction of the thickness of the layer.[100,240,241] If the refractive index varies in a periodic manner between two extreme values, it is possible to design a minus filter with a high transmission on either side of the rejection band (Fig. 53). Such periodic inhomogeneous layers are sometimes called rugate filters. The rejection wavelength corresponds to that wavelength for which the period of the index variation is equal to a half wavelength. The attenuation depends on the ratio of the highest to lowest refractive index in the design and on the number of periods. As in the multilayer minus filters, the width of the rejection region also depends on the refractive index ratio. Rugate filters do not have the higher-order reflection peaks that are characteristic of periodic multilayers and this is one reason for their attractiveness. Another reason—no sharp interfaces, less scatter, and better mechanical properties. However, they are more difficult to produce. If necessary, they can be approximated by a homogeneous multilayer system consisting of a few (three of four) materials.

As in the case of minus filters, it is possible to reject a number of wavelengths by depositing several rugate filters on top of each other. However, the combined overall thickness of the rugate filters will then be quite high. It is possible to find an inhomogeneous layer solution to this problem in which the refractive index profile is more complicated, but which requires a considerably thinner inhomogeneous layer (Fig. 54).[242]

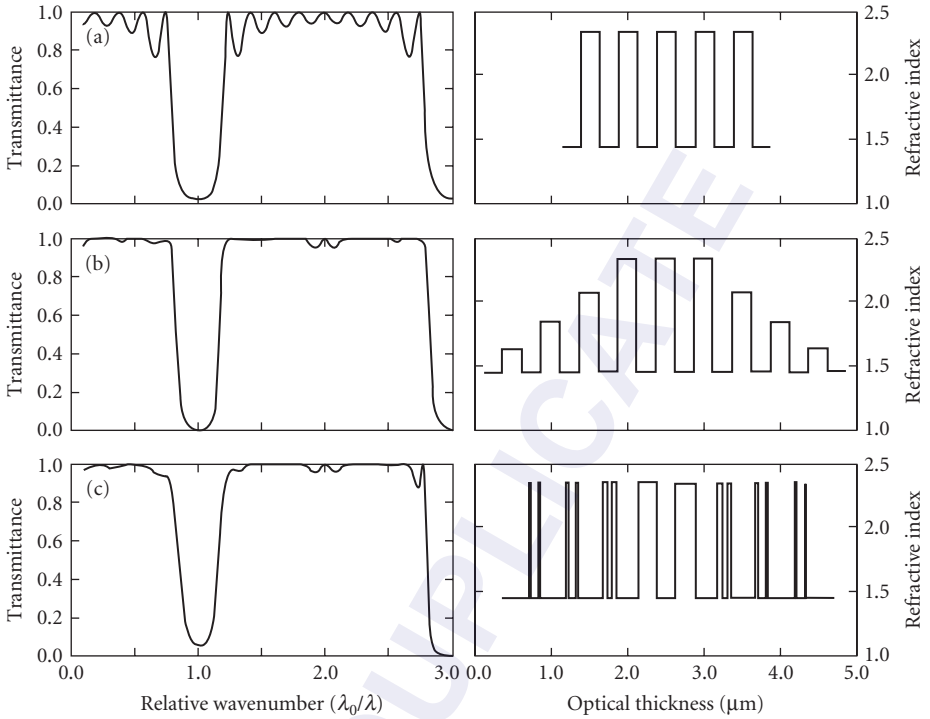

FIGURE 51 Suppression of ripples in the transmission region of rejection filters. Calculated spectral transmittance curves and refractive index profiles of a 9-layer quarter-wave stack (*a*); a 17-layer, 5 material minus filter (*b*); and a two material equivalent of the minus filter (*c*).

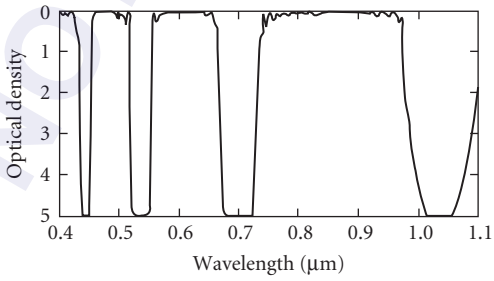

FIGURE 52 Transmission of laser goggles for the rejection of the ruby (0.694 μm) and the NdYag (0.532 and 1.064 μm) laser lines. (*After Omega Optical Inc.*[239])

In Lippmann-Bragg holographic mirrors the refractive index varies continuously in a direction perpendicular to the plane of the substrate. These devices behave like thin-film systems and have properties similar to those of rugate filters. Holographic edge and narrowband rejection filters are available commercially.[244,245]

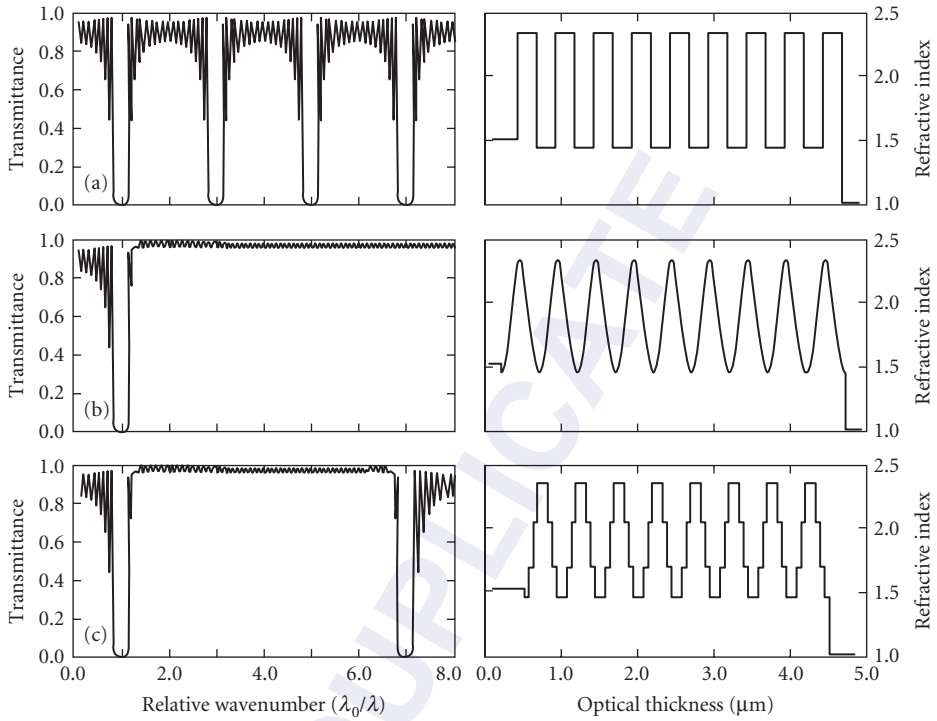

FIGURE 53 Suppression of higher order reflectance peaks in rejection filters. Calculated spectral transmittance curves and refractive index profiles of a 17-layer quarter-wave stack (*a*); a 9-period rugate filter (*b*); and a 49-layer four material design (*c*) by Thelen.[13]

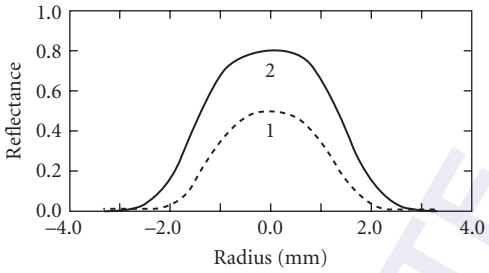

FIGURE 55 Experimental results for two super-Gaussian graded reflectivity mirrors for $\lambda = 1.064$ μm. Curve 1: three layer system with one layer of varying thickness, with $R_{max} = 0.5$ and $\omega = 1.92$ mm (*after Piegari*[250]) and curve 2: fully shaped mirror with $R_{max} = 0.85$ and $\omega = 1.90$ mm (*after Duplain*[248]).

Graded Reflectivity Mirrors

Mirrors in which the absorption or reflection varies radially have been proposed in the past for the control of modes and of edge diffraction effects in laser resonators.[246,247] In addition to meeting the reflectance specifications, graded reflectivity mirrors must have a sufficiently high laser damage threshold for use with high-power lasers. Graded reflectivity mirrors are produced by depositing thin films through a suitable mask. The substrate and the mask can be stationary, or one or both can rotate. A single shaped layer suffices for a maximum reflectance of intermediate values. For higher values the shaped layer can be inserted between a stack of layers of uniform thickness or, alternatively, all the layers can be deposited through the mask.[248,249] The experimentally measured reflections of two graded reflectivity mirrors are shown in Fig. 55.

Multilayer Reflectors for the Far-Infrared Region

Thin film-filters cannot be produced by conventional deposition techniques for wavelengths greater than about 80 μm because of a lack of low absorption coating materials that can be deposited in the form of thick, stable films. However, a hybrid process in which plastic sheets coated with relatively thin high refractive index materials are heat-bonded can be used to produce self-supporting optical multilayer filters.[251,252,164] As mentioned before (Sec. 7.6, subsection "Periodic Multilayers of the $[xH \cdot (1–x)\ L]^N \cdot xH$ Type"), periodic multilayers of unequal optical thickness can have a high reflectance, providing that the number of periods is high enough. The measured reflectance curves of two typical hybrid multilayer filters are shown in Fig. 56.

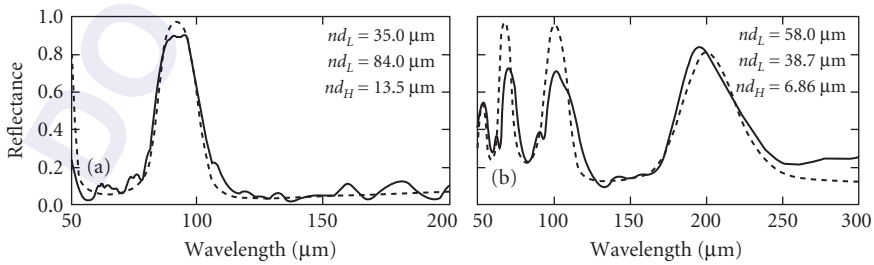

FIGURE 56 Measured and calculated performance of (*a*) L'(HL)^{16} and (*b*) L'(HL)^{16} reflectors made of ZnS and polyethylene of thicknesses indicated in the diagram. An instrumental resolution of 3 cm^{-1} was assumed in the calculations. (*After Shao.*[164])

Multilayer Reflectors for the Soft X-Ray and XUV Regions

There are two main obstacles to obtaining multilayers with a high normal incidence reflectance in the soft x-ray and in the XUV regions. First, at these wavelengths all materials absorb; this limits the number of layers that can contribute to the overall reflectance. Second, roughness and the interdiffusion and alloying of the materials degrade the individual interfaces; this reduces their contribution to the overall reflectance.[189]

XUV mirrors are normally produced from two chemically compatible materials by sputtering or by electron beam gun evaporation. As already discussed in Sec. 7.6, subsection "Multilayer Reflectors Made of Absorbing Materials" the XUV multilayers mirrors have a period of optical thickness $\lambda/2$. Within this period, the thickness of the less absorbing material is larger. This material usually has an absorption edge that is close to the design wavelength. Optical constants can vary widely in this region.[167] The second more absorbing material is therefore selected to maximize the Fresnel reflection coefficient of the interface.

Theoretically, the best results are obtained with pure elements. However, sometimes alloys are used because they result in multilayers with better interfaces. At other times, $MoSi_2$ might be used in place of Mo, or B_4C instead of C or B. Examples of some more commonly used material pairs for near-normal incidence reflectors are (a) Mo/Si for the 130 to 250 Å region; (b) Mo/Y for the 90 to 130 Å region; (c) W/B_4C, Ru/B_4C, Mo/B_4C, etc. for the 70 to 130 Å region; and (d) Co/C, W/C, Re/C, ReW/C, Ni/C, etc. for the 45 to 70 Å. In the above, the second material in each pair has the lower extinction coefficient. A much more complete review of this topic will be found in the review article by Windt et al.[253] Also, an up-to-date list of material pairs and the measured peak reflectances achieved with them will be found on Henke's website.[254]

There are many reasons why there are differences between the theoretical performance of a multilayer reflector and the reflectance measured on a synchrotron.[165,166] The highest near-normal reflectance achieved at 135 Å thus far is $R \approx 0.70$ for an interface-engineered Mo/Si multilayer.[255] The measured reflectances of other experimentally produced x-ray and XUV mirrors are shown in Fig. 57. Curve 8 in this diagram shows that, as in the visible part of the spectrum (Figs. 44 to 48), by departing from periodic multilayer systems, it is possible to produce reflectors in this spectral region that have a comparatively wide spectral region with a constant reflectance.

In the XUV and soft x-ray regions, the reflectances that can be achieved with near-normal angles of incidence are not sufficient. For some imaging applications it is necessary to resort to near-grazing incidence mirrors. In Sec. 7.16 the reflectances of some metals, compounds, and two- or three-layer combinations at high angles, as well as periodic and nonperiodic multilayer interference reflectors consisting of tens or even thousands of layers, are presented.

For more information on coatings for the XUV and soft x-ray region, the interested reader is referred to the review article by Yulin.[266]

7.8 CUTOFF, HEAT-CONTROL, AND SOLAR-CELL COVER FILTERS

Ideal cutoff filters would reject all the radiation below, and transmit all that above a certain wavelength, or vice versa. Real cutoff filters, of course, are not perfect and so, in addition to the cutoff wavelength, the slope of the transition region and the extent and average transmission values of the transmission and rejection regions must be specified. The tolerable departures of these quantities from the ideal values depend greatly on the application. Most all-dielectric cutoff filters are based on periodic multilayers, whose basic properties were described in Sec. 7.6.

Transmission in the Passband Region

The usual way of avoiding the secondary transmission minima in the transmission band of a quarter-wave stack is through the use of eighth-wave layers on both sides of the stack (Sec. 7.6, subsection "Periodic Multilayers of the $[(0.5A)\ B\ (0.5A)]^N$ Type").

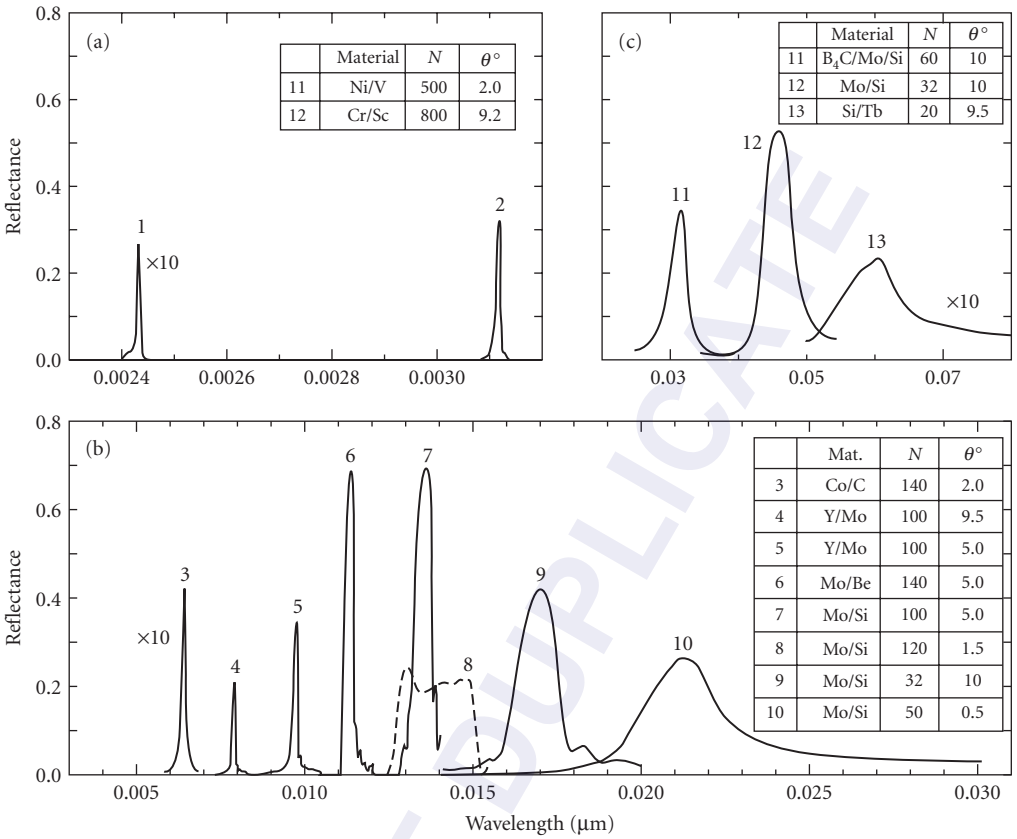

FIGURE 57 Measured reflectance curves of some representative multilayer x-ray mirrors for the (*a*) 0.0022 to 0.0032 μm; (*b*) 0.003 to 0.0029 μm; and (*c*) 0.03 to 0.08 μm spectral regions. The materials used, the number of layers N and the angles θ_0 at which the near-normal reflectance was measured are indicated in the tables. (*Curve 1 after Eriksson;*[256] *curve 2 after Gullikson;*[257] *curve 3 after Spiller;*[258] *curves 4 and 5 after Montcalm;*[259] *curve 6 after Skulina;*[260] *curve 7 after Bajt;*[255] *curves 8 and 12 after Kaiser;*[261] *curve 9 after Ravet;*[262] *curve 10 after Ceglio;*[263] *curve 11 after Gautier;*[264] *and curve 13 after Kjornrattanawanich.*[265])

Other, less frequently used methods of smoothing the transmission in the passband are the adjustment of the thicknesses of all the layers of a quarter-wave stack,[267] the use of homogeneous[268] and inhomogeneous[269] layers on either side of the stack; the choice of an optimum set of refractive index values for the substrate and films,[270] and the use of an equi-ripple design[193] in which thicknesses are kept constant but the refractive indices are varied.

The Width of the Transmission Region

For short-wavelength cutoff filters of the type described above, the transmission region is limited only by the transmission characteristics of the materials used for their construction. In long-wavelength cutoff filters the transmission regions can be limited by the appearance of higher-order reflectance maxima (Sec. 7.6, subsection "Nonabsorbeing $[AB]^N$ and $[AB]^NA$ multilayer Types"). Should this be a serious limitation, it is possible to suppress a number of adjacent reflectance maxima by using multilayers with periods composed of three or more different materials (Fig. 58).

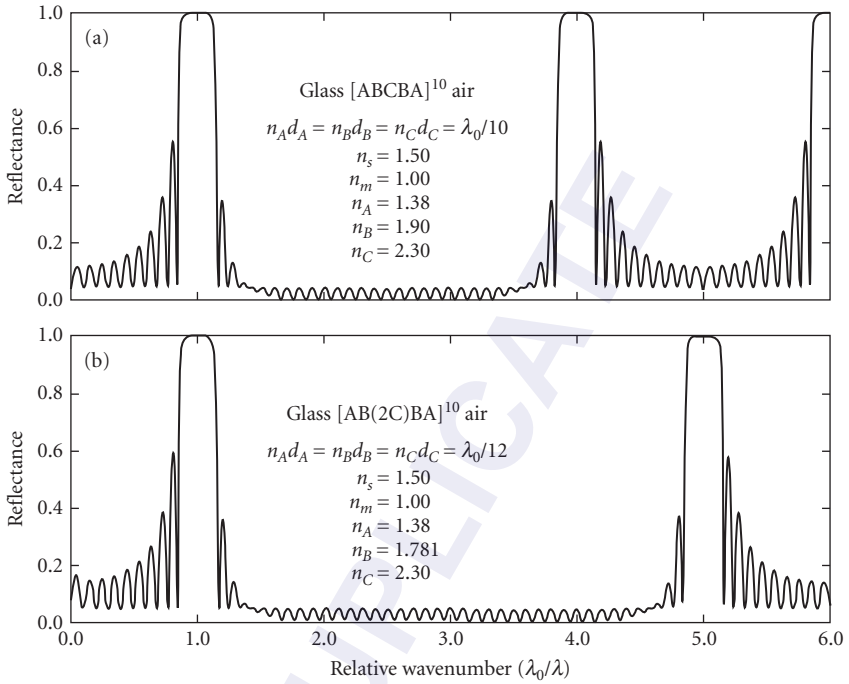

FIGURE 58 Calculated reflectances (*a*), (*b*) of two different of three-material periodic multilayers with suppressed higher-order reflectance maxima. (*After Thelen.*[271])

By using a period consisting of an inhomogeneous layer with a special refractive-index profile an even larger number of consecutive reflectance maxima can be suppressed (see also Fig. 53).[269] Figure 59 shows the measured results for two such experimental coatings in which reflectance maxima are suppressed at three and nine consecutive integer multiples of $1/\lambda_0$, a fact obscured in the case of the second filter by the absorption of the materials used.

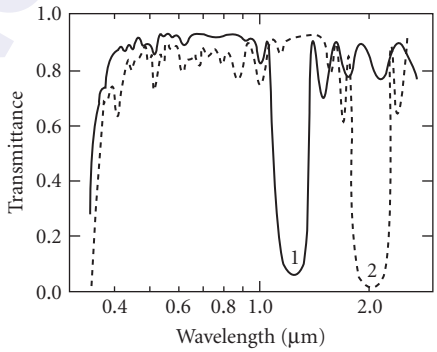

FIGURE 59 Measured transmittance of periodic multilayers in which higher-order reflectance maxima are suppressed through the use of periods that consist of an inhomogeneous layer. (*After Scheuerman.*[111])

Transmission in the Rejection Region

Figure 31 can be used for an estimate of the number of layers required to achieve a given transmission (Sec. 7.6, subsection "Maximum Reflectance"). Through the use of suitable substrate materials the transmittances throughout the rejection region can typically be below 0.01 and 0.1 percent for short- and long-wavelength cutoff filters, respectively. Rejection filters with higher rejections can be provided or, alternatively, two or more filters in series can be used if they are placed at a small angle to one another.

The Width of the Rejection Region

The width of the high-reflection region of $[(0.5A)B(0.5A)]^N$ coatings can be estimated from Fig. 34. There is no shortage of absorbing materials should it be necessary to extend the rejection region of shortwave cutoff filters. The number of suitable absorbing materials for long-wavelength cutoff filters is more restricted and often it is necessary to use thin films to extend the cutoff region. In addition to the superposition of two or more cutoff filters tuned to different wavelengths (Sec. 7.7, subsection "Rejection Filters") one can deposit such coatings onto different substrates or onto the opposite sides of the same substrate.[272] The resulting transmission will be governed by the considerations of Sec. 7.1, subsection "Transmission Filters in Series and Parallel."

Slope of the Cutoff

This quantity is defined in a number of ways. One common definition is

$$\left|\frac{\lambda_{0.8}-\lambda_{0.05}}{\lambda_{0.5}}\right|\times 100\% \tag{58}$$

where $\lambda_{0.8}$, $\lambda_{0.5}$ and $\lambda_{0.05}$ refer to the wavelengths at which the transmittances are 0.8, 0.5, and 0.05 of the maximum transmittance of the filter. Explicit formulas for the slope are complicated.[160] The slope increases with the number of periods and with the refractive index ratio. Slopes with values of the order of 5 percent are readily available in practice.

Angle-of-Incidence Effects

The edges of cutoff filters move toward shorter wavelengths as the angle of incidence is increased. The use of higher-index materials reduces the effect. Measured results for a cutoff filter in which the shift was reduced by using high-refractive-index layers that have 3 times the thickness of the low-index layers are shown in Fig. 60*a*. See also Sec. 7.9, subsection "Nonpolarizing Beam Splitters" on polarization independent color-selective beam splitters.

Experimental Results

The spectral transmittance curves of a number of commercially available short- and long-wavelength cutoff filters are shown in Figs. 61 and 62. High performance long- and short-wavelength cutoff filters are depicted in Figs. 63, 104, and 115. Similar filters for intermediate wavelengths can, of course, be constructed. It is also possible to construct edge filters in which the thicknesses of all the layers vary in proportion around the circumference of the substrate (see also Sec. 7.11, subsection "Linear and Circular Wedge Filters"). A tuning of the cutoff wavelength is thus possible.

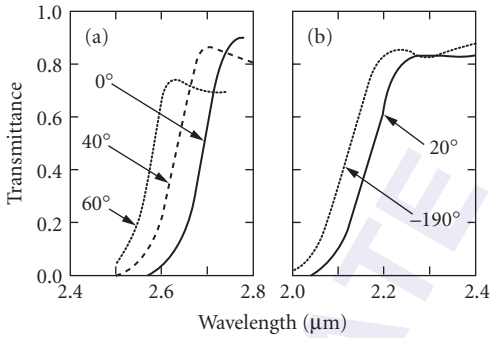

FIGURE 60 Effect of (*a*) angle of incidence and (*b*) temperature on the performance of cutoff filters. (*Optical Coating Laboratory.*[273])

Heat Reflectors, Cold Mirrors, and Infrared Suppressing Filters

Only 39 percent of the total radiation from carbon arcs and 13 percent from tungsten lamps operated at 3250 K represent visible light. Most of the remaining energy is infrared radiation, which is converted into heat on absorption. The use of heat reflectors and cold mirrors in film projectors,[278] in spot lamps for television and film studios,[279] and other optical instruments can lead to a very significant reduction of this unwanted heat.

Heat reflectors (also called hot mirrors) are special long-wavelength cutoff filters with a cutoff at 0.7 μm which transmit the visible radiation from 0.4 to 0.7 μm without disturbing the color balance. The width of the rejection region depends on the light source to be used and on whether a heat absorbing glass is also to be used. The spectral-transmittance curves of three typical commercial heat reflectors are shown in Fig. 64*a*. The measured spectral transmittance and reflectance curves of two heat-reflecting coatings not based on periodic multilayers are shown in Fig. 65.

Cold mirrors reflect as much as possible of the visible light incident upon them and transmit the remaining radiation. The reflectance curves of two commercial cold mirrors are shown in Fig. 64*b*.

Solar-Cell Covers

Solar-cell covers remove the incident solar energy that does not contribute to the electrical output of the cell and protect it from possible deterioration of its performance through the action of ultraviolet radiation.[283,284] The spectral transmittance of a blue-red solar-cell cover is shown in Fig. 64*b*. The earlier blue solar-cell covers (curve 2, Fig. 61) protected the cell only from the adverse effects of ultraviolet radiation.

(*After Turner.*[282])

Temperature Effects

Refractive indexes of optical materials increase almost linearly with increase in temperature thus causing cutoff edges to move toward longer wavelengths. In actual filters the fractional-wavelength shift varies between 3×10^{-3} and 10^{-4}/°C. Ion-plated films have a smaller temperature shift than films prepared by conventional e-beam evaporated layers.[285] Higher-index materials tend to be more temperature sensitive, thus making it difficult to construct filters that are insensitive both to angle of incidence and temperature changes.[286] The measured performance of a cutoff filter at two temperatures is shown in Fig. 60*b*.

Metal-Dielectric Reflection Cutoff Filters

It is possible to construct metal dielectric cutoff filters that act in reflected light (Fig. 66). Short-wavelength cutoff filters consist of an opaque metal layer and one or more additional layers. The light is removed through absorption within the absorbing layers of the system. The thicknesses of the individual layers are adjusted to maximize the absorption and width of the rejection region. Long-wavelength cutoff filters consist of all-dielectric multilayer reflectors superimposed

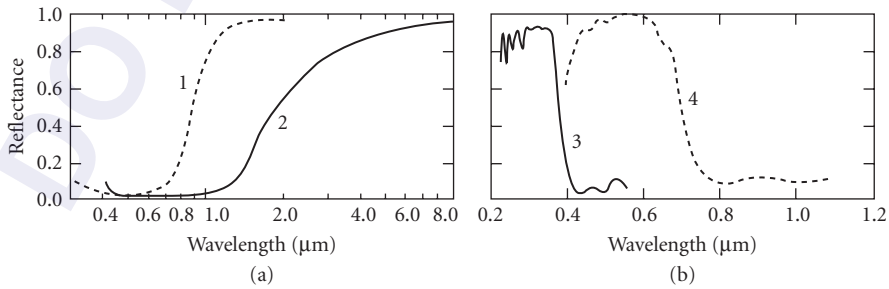

FIGURE 66 Short- and long-wavelength metal-dielectric reflection cutoff filters based on reflection. (*a*) Curves 1 and 2: three-layer coatings on aluminum (*after Drummeter and Hass*[138]) and (*b*) curves 4 and 5: multilayer reflecting coatings deposited onto black absorber coatings (*after Hoppert*[287]).

onto a black absorbing coating. A high attenuation of the unwanted radiation can be achieved by placing identical filters of either type in a multiple reflection arrangement of the kind depicted in Fig. 3.

Cutoff Filters Based on Absorption

All materials used in multilayer interference coatings possess short- and long-wavelength absorption edges. These can often be used to assist in the blocking of such filters. The admixture of small amounts of absorbing materials to an evaporant or organic coating solution is used at times to tune this absorption edge (Fig. 67*a* and *c*). For example, antireflection coatings containing such ultraviolet-absorbing materials can be used to protect works of art.[288]

A series of commercial short-wavelength cutoff filters for the infrared spectral region consisting of chemically deposited silver sulfide coatings on silver chloride substrates are also shown in Fig. 67*b*. These filters are quite delicate. When protected with a polystyrene layer, their transmittance is reduced and sharp absorption bands appear. The filters should not be used outdoors unless additionally protected, nor should they be exposed to ultraviolet radiation or temperatures in excess of 110°C.

The greatest advantage of cutoff filters based on absorption in thin films is their much smaller angular dependence.

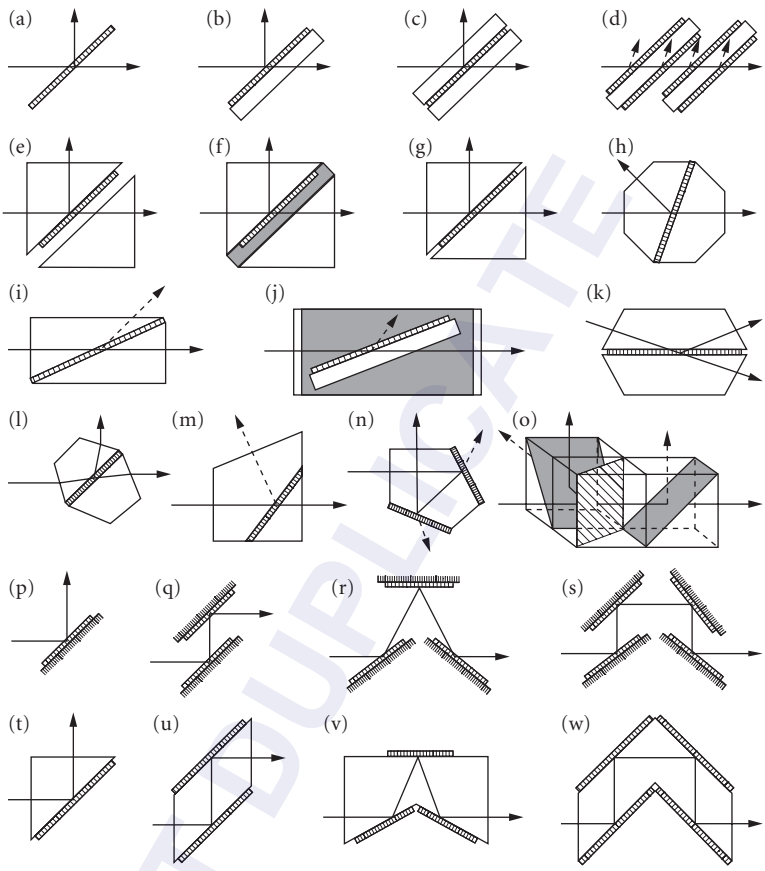

FIGURE 68 Schematic representations (*a* to *w*) of some arrangements for beam splitters, polarizers, phase retarders and multiple reflection devices. Thin films are represented in the diagrams by narrow shaded rectangles. Heavy lines ending in an arrow represent the path of the utilized radiation. Broken lines correspond to beams that are not used. The angles of incidence depend on the application.

7.9 BEAM SPLITTERS AND NEUTRAL FILTERS

Geometrical Considerations

Several different physical forms of beam splitters are illustrated in Fig. 68. The simplest beam splitter (Fig. 68*b*) consists of a coating on a transparent plane-parallel substrate. If the two derived beams are to traverse identical paths, a cemented beam splitter is used (Fig. 68*c*). The lateral displacement of the transmitted beam introduced by the above forms can be avoided with a beam splitting cube (Fig. 68*f*) To reduce the stray reflected light in the system, the free surfaces of the above beam splitters can be antireflection coated. Alternatively the coatings can be deposited onto an approximately 2-μm-thick nitrocellulose pellicle (Fig. 68*a*). The latter is an integral part of the multilayer and may introduce an interference pattern into the spectral reflectance and transmittance characteristics. Pellicle beam splitters are very light and yet quite sturdy.[111,291,292] They are, however, subject to vibrations

caused by air currents and acoustical waves. The mechanical design of rugged, environmentally stable mounts for the above types of beam splitters have been discussed by Heinrich et al., and Lipshutz.[293,294] Pellicles made of Mylar have been used at temperatures down to 4 K.[295]

In general, the transmission and reflection coefficients T and R will depend on the polarization of the incident radiation. The polarization effect can be reduced though the use of more complicated thin-film designs, but usually at the expense of other performance aspects. Achromatic or color-selective beam splitting arrangements have been described in which the two derived beams have intensities that are completely polarization-independent over a very wide spectral region.[296] They consist of three identical beam splitters arranged in such a way that each beam undergoes identical reflections and transmissions on passing through the system (Fig. 68*o*).

Achromatic Beam Splitters

These devices are introduced into an incident beam of radiation when it is desired to divide it into two beams of approximately equal relative spectral composition but propagating in two different directions.[297] In neutral beam splitters the quantity $0.5(R_p + R_s)_{\theta=45°}$ is always close to the reflectance at normal incidence, even though the individual R_p and R_s values may be quite different. The reflectance of absorbing, uncemented beam splitters depends also on the direction of incidence (Sec. 7.2, subsection "Matrix Theory for the Analysis of Multilayer Systems"). The optimum values of T and R depend on the application. For example, for a binocular eye piece on a nonpolarizing microscope the most important requirement is $T_p + T_s = R_p + R_s$ (Fig. 69*a*). For a vertical illuminator ($R_pT_p + R_sT_s$) should be a maximum (Fig. 69*b*). The condition for maximum fringe contrast in some interferometers requires that $R_{1,p}T_p = R_{2,p}T_p$ and $R_{1,s}T_s = R_{2,s}T_s$ (Fig. 69*c*). This is satisfied automatically by all nonabsorbing and by absorbing cemented beam splitters. The occasional requirement that the phase change on reflection be the same for radiation incident onto the beam splitter from opposite sides is automatically satisfied at the design wavelength by all-dielectric coatings composed of $\lambda/4$ layers, but not by uncemented metal beam splitters.[298]

For maximum efficiency with unpolarized radiation R_p, R_s, T_p, and T_s should all approach 0.5. However, such a coating will not necessarily exhibit the best ratio of the intensities of the directly transmitted or reflected radiation to that which first undergoes multiple reflections.[297] Often beam splitters are required that are uniform over a broad spectral region. Inconel films satisfy this requirement although about one-third of the incident radiation is lost through absorption (see also Sec. 7.9, subsection "Neutral Filters"). The design of achromatic all-dielectric beam splitters has been discussed by many workers.[299–304] Knittl considered the design of beam splitters in which both the reflectance and the phase change on reflection are achromatised.[305] The measured performance of several beam splitters is shown in Figs. 70 and 71.

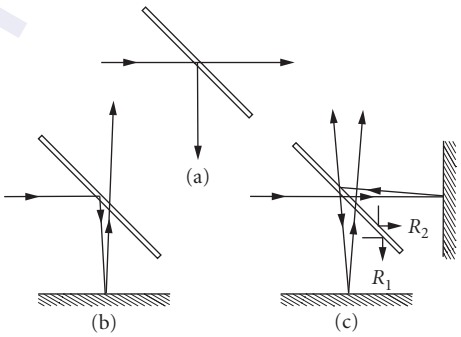

FIGURE 69 Three different ways [(*a*), (*b*), and (*c*)] of using beam splitters.

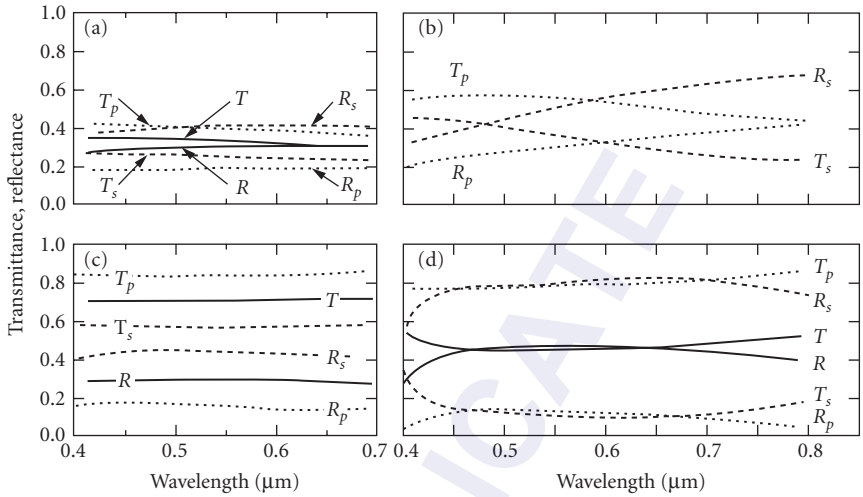

FIGURE 70 Measured spectral transmittance for polarized and unpolarized light of (*a*) Inconel- and (*c*) dielectric-coated beam-splitting plates (*Oriel*[306]) and of (*b*) silver- and (*d*) dielectric-coated beam-splitting cubes (*after Anders*[297]).

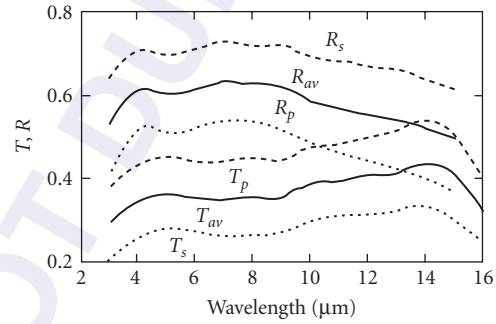

FIGURE 71 Measured performance of a 45° infrared beam splitter consisting of a suitably coated ZnSe plate. (*After Pellicori.*[307])

Beam splitters for the x-ray region described so far operate at close to normal incidence and are effective only over a very narrow range of wavelengths. They consist of multilayer reflecting stacks (see Secs. 7.6, subsection "Multilayer Reflectors Made of Absorbing Materials" and 7.7, subsection "Multilayer Reflectors for the Soft X-Ray and XUV Regions") deposited onto membranes or onto substrates that are thinned to enhance the transmitted component (Fig. 72).[308]

Nonpolarizing Beam Splitters For some applications it is important that the beam splitter introduce no polarization effects. Azzam has shown that, with the appropriate single layer on the face of a suitable high-refractive-index prism, it is possible to construct a polarization independent beam splitter.[309] This device is quite achromatic and, in addition, by changing the angle of incidence of the beam on the prism, the beam-splitting ratio can be tuned over a wide range of values (Fig. 73*a*). The principle of frustrated total internal reflection can also be used to design beam splitters that have a very good performance.[310,311] In these devices radiation is incident at a very oblique angle

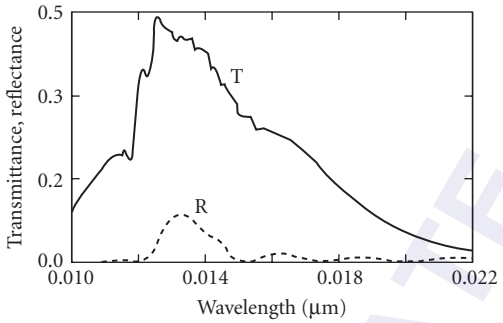

FIGURE 72 Measured performance of an x-ray beam splitter consisting of 11 pairs of Mo and Si layers on a 0.03-μm-thick Si_3N_4 membrane, operating at an angle of incidence of 0.5°. (*After Ceglio.*[263])

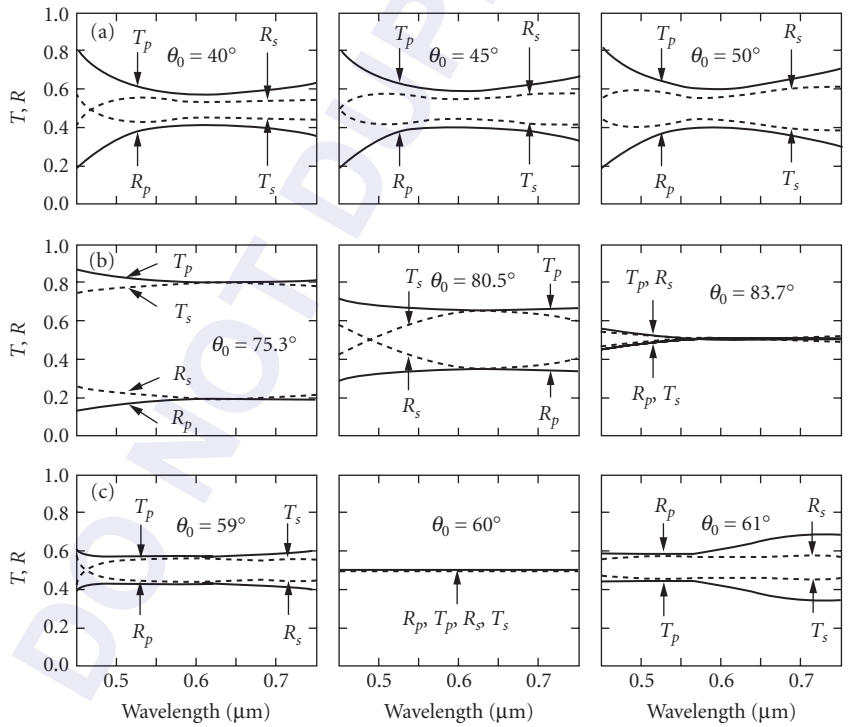

FIGURE 73 Calculated performance at three angles of incidence of beam splitters with an incident medium of air. (*a*) Beam splitter of the type glass $(HL)^2$ air, where $n_H = 2.35$, $n_L = 1.38$; (*b*) single layer ($n = 1.533$, $d = 0.1356$ μm) on a prism ($n_s = 2.35$) (*after Azzam*[309]); and (*c*) 15-layer frustrated total internal reflection beam splitter (*after Macleod*[311]). The last two systems are fairly polarization independent and yield different T/R ratios for different angles of incidence.

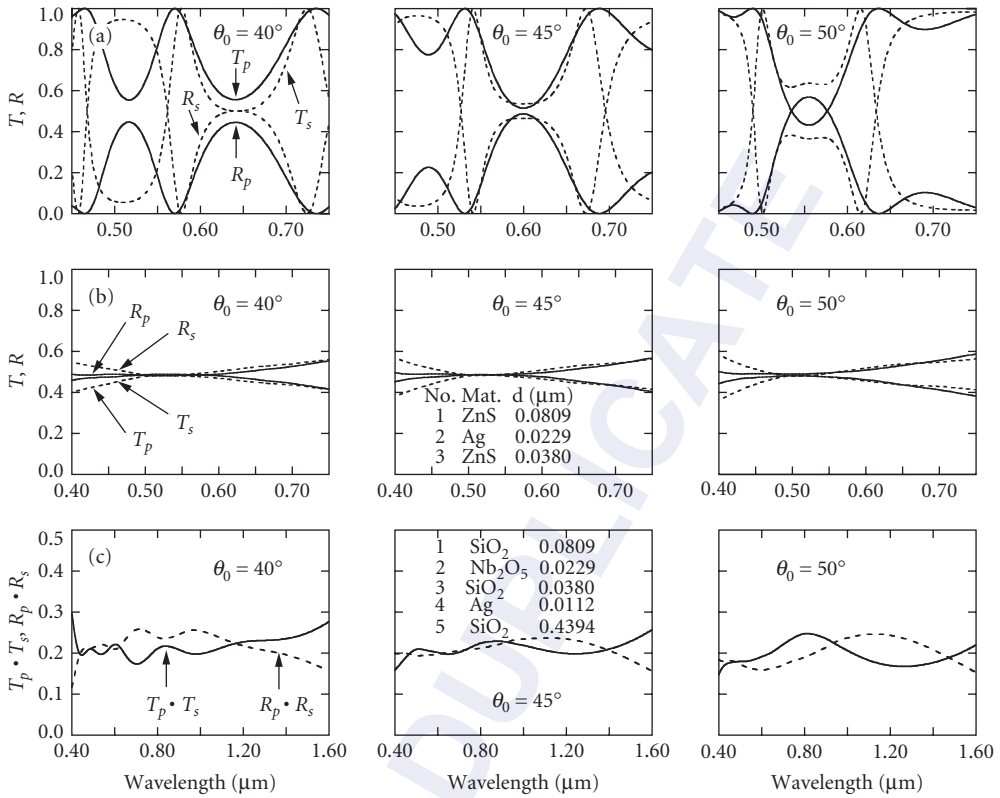

FIGURE 74 Calculated performance of polarization insensitive achromatic beam splitters consisting of layer systems cemented between glass prisms. (*a*) All-dielectric system of the type n_s $(LMHMHML)^2$, where $n_s = 1.52$, $n_L = 1.38$, $n_M = 1.63$, $n_H = 2.35$; the quarterwave layers are matched for 45° incidence. (*after Thelen*[13]); (*b*) three-layer metal/dielectric system (*after Chang*[322]); and (*c*) polarization independent beam splitting arrangement of the type of Figure 68*o* composed of three identical prisms (*after Ho*[296]).

onto an air gap or low-refractive-index films at the interface between two prisms (Fig. 68*e,* and *f*). Unfortunately, the performance of such systems is very sensitive to the angle of incidence (Fig. 73*c*).

In many applications it is important that the beam splitter be relatively insensitive to the angle of incidence. One way is to reduce the angle of incidence as much as possible (Fig. 68*h*).[312] However, in many cases a 45° angle of incidence is mandatory. Relatively polarization insensitive beam splitters based on dielectric-metal-dielectric layer systems embedded between two prisms have been described.[313,314] Much work has been done to find solutions based on dielectric layers only.[24,207,314–321] However, the improvement is frequently at the expense of the width of the spectral region over which the beam splitter is effective. Some typical results are shown in Figs. 74 and 75.

Simple angle- and polarization-insensitive mechanical solutions to the achromatic beamsplitting problem exist if the application can tolerate spacial or temporal beam sharing (Fig. 76).

Color-Selective Beam Splitters

For various technological applications a beam of light must be divided into several components of different color. All-dielectric color selective beam splitters (*dichroics*) are used for this purpose

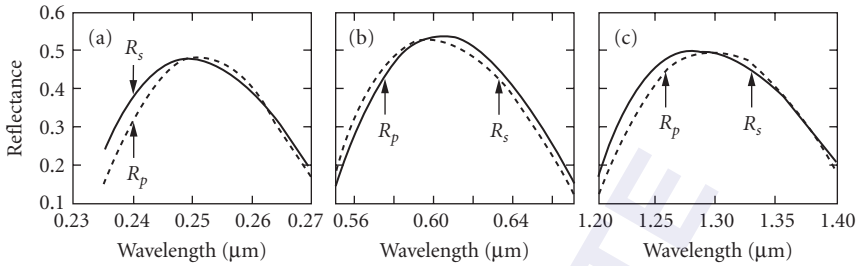

FIGURE 75 Measured performances (*a*) to (*c*) of polarization insensitive beam splitters of the type of Fig. 74*a* produced for three different spectral regions. (*After Konoplev.*[323])

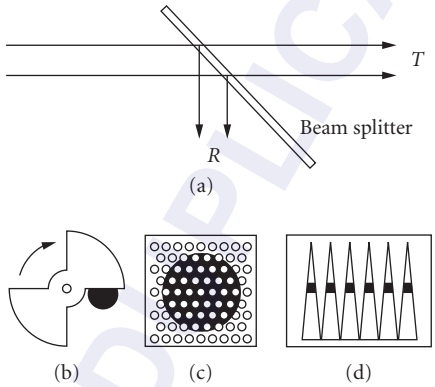

FIGURE 76 Achromatic and angle-insensitive mechanical beam splitting arrangements. (*a*) and (*b*) Rotating aluminized blade which alternatively transmits and reflects the incident radiation. (*c*) Stationary transparent plate with a polka-dot pattern in which either the circles or the backgroud (each of equal total area) are aluminized. (*d*) Aluminized saw-tooth pattern on a transparent substrate that can be displaced to reflect different fractions of the incident radiation that is collimated into a narrow beam.

because they are practically lossless and because their transition wavelengths can be selected at will. They are essentially cutoff filters (Sec. 7.8) usually designed for use at 45° incidence. Their spectral characteristics normally depend on the polarization of the incident radiation. The effect of this and of the variations in the angle of incidence and thickness of the coatings on the chromaticity coordinates of dichroic beam splitters for television cameras was investigated by Pohlack.[324] If necessary, the polarization of the derived beams can be reduced through the use of auxiliary normal incidence cutoff filters.[219] Typical transmittance curves of several color-selective beam splitters are shown in Fig. 77.

Nonpolarizing Edge and Bandpass Filters For more exacting applications, such as for use in multiplexers and demultiplexers, or for the separation of emission or absorption lines in atmospheric physics or Raman spectroscopy, it is possible to design and construct short- and long-wavelength color selective beam splitters in which the polarization splitting has been largely eliminated.[13,325] In the designs described the polarization splitting is usually removed for all angles smaller than the design angle, but the cutoff wavelength still shifts with the angle of incidence (Fig. 78). Some of the designs do not have a wide transmission region.

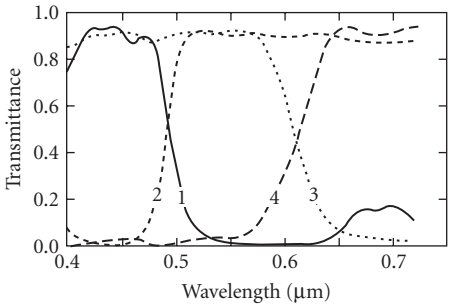

FIGURE 77 Measured spectral transmittance of four color-selective beam splitters. (*Optical Coating Laboratory.*[237])

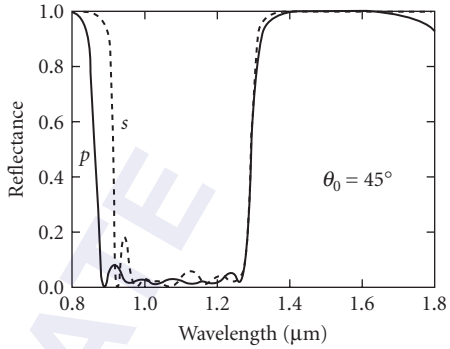

FIGURE 78 Calculated transmittance of a polarization independent color selective beam splitter for several angles of incidence. (*After Thelen.*[13])

Neutral Filters

These devices are used whenever the intensity of the incident radiation is to be reduced uniformly throughout an extended part of the spectrum. The radiation usually traverses neutral filters at or near-normal incidence. A number of absorbing glasses and gelatin filters are suitable for making neutral-density filters with densities of up to 5.0. However, their spectral transmission curves are not very uniform.

Evaporated films of metals such as aluminum, chromium, palladium, platinum, rhodium, tungsten, and alloys such as chromel, nichrome, and inconel have been used for a long time to produce filters with densities of up to 6.0. A disadvantage of such filters is their high specular reflection. At present inconel is commonly used for high-precision neutral-density filters. Chromium is favored when tough, unprotected coatings are required (Fig. 79). The operating range and neutrality depends on the substrate materials. The spectral-transmittance curves of neutral-density filters on magnesium fluoride, calcium fluoride, quartz , glass, sapphire, and germanium substates are shown in Fig. 80. Linear and circular metal-film neutral-density wedges and step filters are also available commercially.

At times there may be a need for a neutral attenuation that is not based on absorption. Sets of all-dielectric multilayer coating designs have been published with uniform transmission levels for the ultraviolet,[326] visible,[215,327] and near-infrared[328] parts of the spectrum (Fig. 81).

7.10 INTERFERENCE POLARIZERS AND POLARIZING BEAM SPLITTERS

The dependence of the optical properties of thin-film systems on the plane of polarization of obliquely incident radiation[24] (Sec. 7.2, subsection "Matrix Theory for the Analysis of Multilayers Systems") can be exploited to design interference polarizers and polarizing beam splitters with properties that augment those attainable by other means (Chap. 13, Vol. I). The main difference between a polarizer and a polarizing beam splitter is that in the former only one polarized beam is required, whereas in the latter both beams are to be utilized. A polarizing beam splitter can therefore also be used as a polarizer. The performance in transmission or reflection of both devices is usually characterized by their degree of polarization P, or by the extinction ratio ER, both of which are functions of the transmittance T and reflectance R for the desired and undesired polarizations:

$$\left\{\begin{array}{l} P=\dfrac{\left|T_{\text{desired}}-T_{\text{undesired}}\right|}{\left|T_{\text{desired}}+T_{\text{undesired}}\right|} \quad \text{or } P=\dfrac{\left|R_{\text{desired}}-R_{\text{undesired}}\right|}{\left|R_{\text{desired}}+R_{\text{undesired}}\right|} \\ \text{or by} \\ \text{ER}=\dfrac{T_{\text{desired}}}{T_{\text{undesired}}} \quad \text{or ER}=\dfrac{R_{\text{desired}}}{R_{\text{undesired}}} \end{array}\right\} \tag{59}$$

In a polarizing beam splitter a high degree of polarization is required in both beams and this is more difficult to achieve. Presently efficient interference polarizers and polarizing beam splitters can be constructed for the soft x-ray, ultraviolet, visible, and infrared spectral regions. Interference polarizers and polarizing beam splitters are of particular interest whenever large areas and low losses are required. Schematic representations of the geometries of some of the devices are given in Fig. 68.

Multicomponent Polarizers

It is always possible to find an angle of incidence at which a substrate coated with a film of quarter-wave effective thickness will reflect only *s*-polarized radiation which is polarized perpendicular to the plane of incidence.[333] This property can be used to construct efficient transmitting polarizers using far fewer plates than necessary in the conventional pile-of-plates polarizer of equal performance (Fig. 68*d*).[334] The calculated degree of polarization attainable with different numbers of plates is shown in Fig. 82 for a series of film indices and polarizing angles. Experimental results agree closely with the calculations. In polarizers of this type the variation of the degree of polarization is small over a wavelength span of 2:1 and for angular apertures of up to 10°.[333] Yet, because of its bulk, this type of polarizer is not frequently used. An exception is polarizers for the infrared, where it is more difficult to produce multilayers composed of many layers. Because of the high refractive indices available in that spectral region, it is possible to achieve a high degree of polarization even after a single transmission through a plate coated with one layer only.[335]

Several geometries of the reflection equivalent of the multiple plate polarizer exist (Fig. 68). The reflectors can consist of one or more dielectric layers deposited onto nonabsorbing parallel plates or prisms (Fig. 68 *t* to *w*). In other devices the substrates are made of metal, or are coated with an opaque metallic film (Fig. 68 *p* to *s*).[336] The angles of incidence on the various mirrors need not be the same. Polarizers of this type are particularly useful in the infrared[337] and vacuum ultraviolet (see subsection "Polarizers for the Extreme Ultraviolet and Soft X-Ray Regions") spectral regions. Interesting variants are polarizers that are based on total internal reflection or frustrated total internal reflection (Fig. 68 *m* and *n*).

Plate Polarizers

The number of coated plates in the transmission polarizers described above can be reduced without compromising the performance by depositing more than one high-refractive-index layer onto the surface

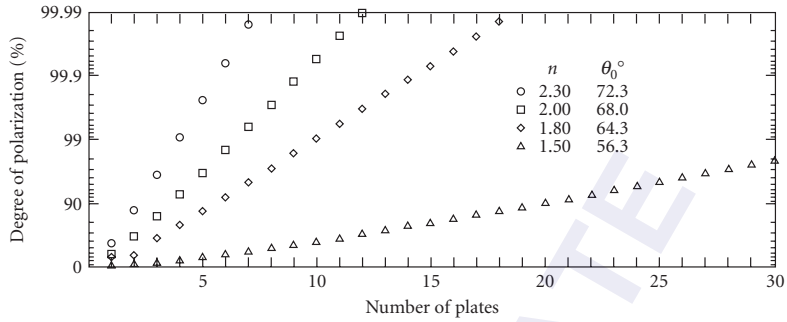

FIGURE 82 Calculated degree of polarization of different numbers of plates of refractive index 1.5 coated on both sides with films of different refractive indexes n. The films have effective optical thicknesses of a quarter wavelength at the appropriate polarizing angle θ.

of a plate and by spacing them with low-index films. In particular, it is possible to minimize the surface scatter, plate absorption, and lateral beam displacement by combining all the layers into one coating.

The most common solution for high-power laser applications are plate polarizers that are based on the polarization splitting that occurs at higher angles, for example, at the edges of quarter-wave stack reflectors (Fig. 68).[338] The plate on which the multilayer is deposited is held at Brewster's angle with respect to the incident light to avoid second surface reflections. Usually the long-wavelength edge of the reflector is used and the design is somewhat modified to remove the ripples in the transmission band of the *p*-polarized radiation (Fig. 83). The use of other multilayer structures, such as bandpass filters, for the construction of plate polarizers has also been proposed.[339] The wavelength range over which plate polarizers are effective is much smaller than that of polarizers based on a series of coated plates, but this is acceptable for most laser applications.

Other methods for the design of narrowband plate polarizers based on two or three coating materials have been described by Minkov,[340] Mahlein,[207] and Thelen.[341] However, these solutions require many layers and sometimes very oblique angles of incidence.

Embedded Polarizers and Polarizing Beam Splitters Based on Two Coating Materials

Polarizers and polarizing beam splitters effective over a wider spectral region are obtained when multilayer coatings of the type $[HL]^N H$ or $[(0.5H)L(0.5H)]^N$ are embedded between media of higher refractive index than air.[342] The higher the refractive index ratio of the two coating materials used, the fewer the number of layers needed to achieve a certain degree of polarization and the wider the spectral region over which the polarizer will be effective. However, a certain relationship between the refractive indexes of the materials and the angle of incidence must be satisfied.[343] The optical thicknesses of the quarterwave layers should be matched for the angle of incidence.

A particularly convenient polarizer with no lateral beam displacement results when the multilayer is embedded between two right-angled prisms, as shown in Fig. 68*i*.[344,345] MacNeille polarizers operate over

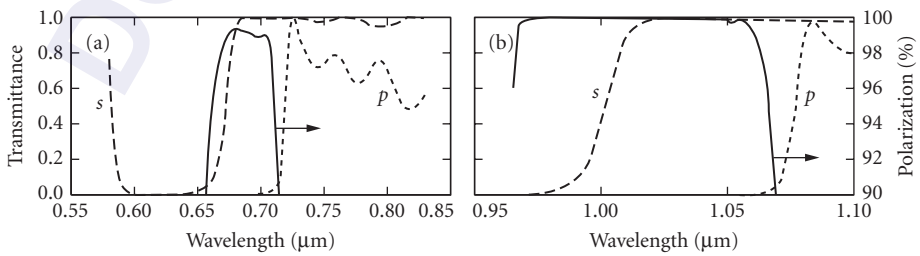

FIGURE 83 Measured performances (*a*), (*b*) of two plate polarizers. (*After TechOptics.*[86])

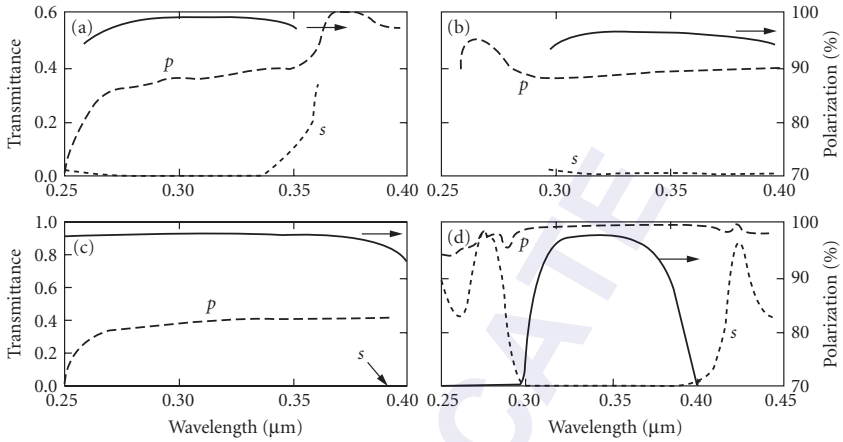

FIGURE 84 The measured degree of polarization P and transmittance of parallel and crossed MacNeille interference polarizers for the ultraviolet spectral region. (*c*) Represents the results obtained when the cemented polarizers shown in (*a*) and (*b*) are placed in series (*after Sokolova and Krylova*[346]); and (*d*) is the measured performance of an optically contacted polarizer with a high laser damage threshold (*after Wimperis*[347]).

a very broad range of wavelengths (Fig. 84*a* and *b*). For best results, the following relationship between the angle of incidence θ_p and the refractive indices of the prism and the layers should be satisfied:

$$n_p \sin\theta_p = \frac{n_L n_H}{\sqrt{n_L^2 + n_H^2}} \tag{60}$$

This expression is independent of the thicknesses of the layers and, were it not for the dispersion of the optical constants, the transmission for the p polarization would be 1.0 across the entire spectral region at the design angle θ_p. However, the dispersion of the high-index material as well as the limit of the index ratio n_L/n_H will tend to decrease the useful spectral range of the polarizer.[348] It is possible to select the V-number of the substrate material in order to decrease this disturbing effect. The rejection of the unwanted polarization will normally not be the same in both beams, although this can be achieved at the expense of the wavelength range.[349] If polarizers for an even wider spectral region are required, it is possible to extend the range by placing two polarizers in series (Fig. 84*c*), by using the technique of superposition of stacks with contiguous high-reflectance zones (Sec. 7.7, subsection "Rejection Filters") or of two periodic multilayers with thickness ratios of 1:1 and 1:2.[173] When both beams are used, the useful angular field of the MacNeille polarizer is of the order of ±2°. It is possible to increase it to ±10°, but again at the expense of narrowing the spectral range.[350]

When the MacNeille polarizer is to be used as a polarizing beam splitter, it is possible to design it for normal incidence of the beams onto the prism faces, or for a 90° deflection between the two beams (Fig. 68*l*).[349,351] However, it is more convenient to embed the multilayers between two 45° prisms. A higher-refractive-index prism material is required if (60) is to be satisfied[350] and the effective wavelength range will once again be reduced (Fig. 85).[352]

MacNeille polarizers and polarizing beam splitter cubes suffer from several disadvantages. The diameter of the light beam that can be used with the polarizer is limited by the size, cost, and availability of the prism material. The attainable degree of polarization is also affected by the residual birefringence in the glass prisms. Cemented polarizers cannot be used with high-power lasers because of the absorption of the glue. To overcome these difficulties a liquid prism polarizer has been proposed consisting of a multilayer on a quartz plate that is immersed in distilled water (Figs. 68*j* and 86).[353] Another way of avoiding the use of a cement is to optically contact the polarizer prisms (Figs. 68*g*, and 84*d*).[354] More frequently the layers are deposited onto the hypotenuse of one of two air-spaced prisms (Fig. 68*e*).[355] However, this arrangement is similar to a plate polarizer designed for use at 45° and so is its performance.

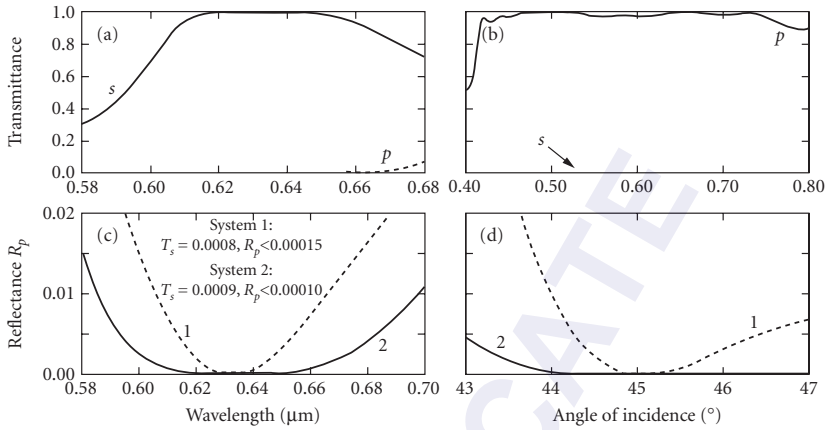

FIGURE 85 Measured performance of polarizing beam splitting cubes. (*a*) and (*b*) Measured spectral transmittance curves of two commercial devices (*after TechOptics*[86]). (*c*) and (*d*) Measured spectral and angular performance of two different systems (*after Netterfield*[352]).

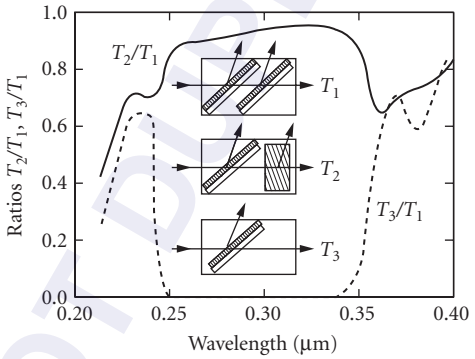

FIGURE 86 Measured spectral performance of two parallel and crossed coated plates forming a liquid prism McNeille polarizer for the ultraviolet part of the spectrum. The multilayers on both plates were identical and consisted of 13 alternate quarterwave layers of HfO_2 and SiO_2. (*After Dobrowolski.*[353])

Embedded Polarizing Beam Splitters Based on More than Two Coating Materials

By using coating materials with more than two refractive indices in the design of embedded polarizing beam splitters, it is possible to obtain devices that match the spectral region of a MacNeille polarizer while increasing its angular field. For example, a polarizing beam splitter has been described with a 72-layer 4-material design that has a ±6° angular field measured in air that is effective across the 0.4 to 0.7 μm wavelength range.[356]

Li Li Polarizing Beam Splitter

Li Li described the design of a new type of embedded beam splitter for the visible and infrared spectral regions, using a geometry that is depicted in Fig. 68*k*.[357] What distinguishes this device from the

polarizing beam splitters described in the previous sections is that it operates at angles greater than the critical angle and that it transmits *s*-polarized light and reflects *p*-polarized light, respectively. The calculated performances of these designs in both the transmitted and reflected beams exceed those of any previous devices. For example, one polarizing beam splitter (described in Ref. 357) that consists of 53 layers has a ±7.4° angular field measured in air in the 0.4 to 0.7 μm wavelength region.

However, because the Li Li polarizing beam splitters require the use of prisms of high refractive index for which there are no suitable optical cements, the two prisms must be optically contacted. The measured performance of prototypes produced in this manner was in good agreement with the calculated values.[358] The need for optical contacting, and the rather large size of the prisms, is the reason why the Li Li polarizing beam splitter is not yet widely used.

Metal-dielectric versions of the Li Li polarizer have been described that are simpler and consist of fewer layers, but they absorb some of the incident light.[359]

In Fig. 87*a* to *j* the calculated spectral and angular performances of a number of polarizers and polarizing beam splitters for the near-UV, visible, and near-IR spectral regions are compared. A theoretical comparison of the properties of the MacNeille, cube and plate polarizers for one wavelength has been given by Cojocaru.[360]

Polarizers for the Extreme Ultraviolet and Soft X-Ray Regions

Polarizers based on reflections from two or more single layer coated surfaces have been proposed for the vacuum ultraviolet[366–368] spectral region. The measured performances in the XUV region of two such polarizers that are based on three reflections are depicted in Fig. 88.

Polarizers for the soft x-ray region can also be based on the fact that the reflectance of an x-ray multilayer mirror at oblique angles is very different for radiation polarized parallel and perpendicular to the plane of incidence. Curve 3, Fig. 91 shows the reflectance of such a periodic Mo/B_4C multilayer with a very high degree of polarization.[370] Because the region of high reflection is very narrow, this type of polarizer essentially operates at one wavelength only.[371] However, if the radiation is reflected from two identical mirrors of this type (Fig. 68*q*), it is possible to construct a device with a reasonable throughput (>0.05) that can be tuned over a wide range of wavelengths without changing the direction of the emerging beam (Fig. 89).[372]

More recently multilayer polarizers effective over a broader range of wavelengths have been constructed. A few examples are shown in Fig. 90.[370,373–375] They are nonperiodic systems made of two suitable materials and they consist of between 60 and 300 layers. The one exception is curve 3 which corresponds to a periodic system and which is shown here for comparison purposes. It will be seen that the effectiveness over a broader range of wavelengths comes at the expense of a lower throughput, but it is also accompanied by a much wider angular field. This is of particular importance when the polarizers are to be used with imaging optics.

7.11 BANDPASS FILTERS

An ideal bandpass filter transmits all the incident radiation in one spectral region and rejects all the other radiation. Such a filter is completely described by the width of the transmission region and the wavelength at which it is centered. Practical filters are not perfect and require more parameters to adequately describe their performance. No uniform terminology has yet been developed for this purpose. Care should be taken when reading and writing specifications since often different terms are used to describe different types of filters, and sometimes quantities bearing the same name are defined differently.

The position of the transmission band is variously specified by the wavelength λ_{max} at which the maximum transmission occurs, the wavelength λ_0 about which the filter passband is symmetrical, or the spectral centre of gravity λ_c of the band. When specifying the tolerance on λ_0 it should be remembered that the peak of interference filters can be moved only toward shorter wavelengths by tilting (see Sec. 7.2, subsection "Matrix Theory for the Analysis of Multilayer System").

The peak transmittance T_0 may or may not take into account the absorption within the substrate and/or blocking filters used to remove the unwanted transmission of the interference filter away from the principal passband (Fig. 91).

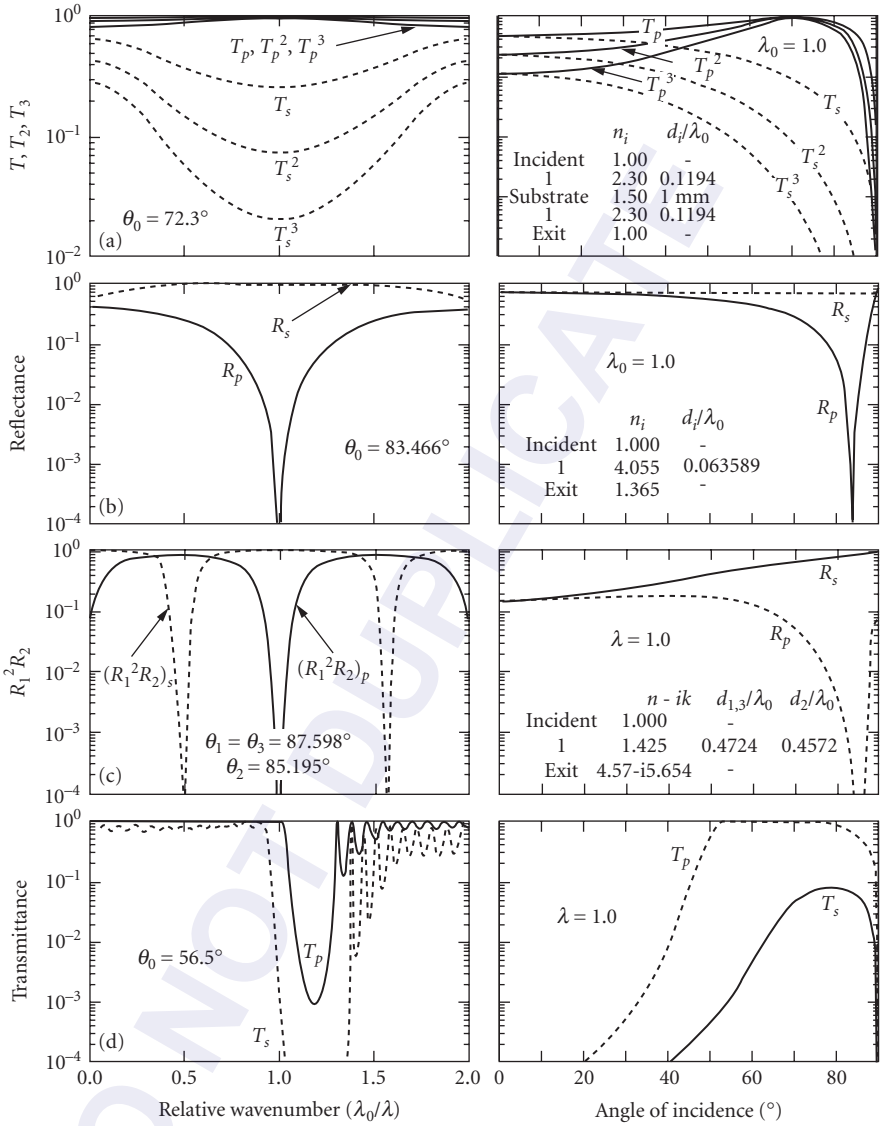

FIGURE 87 Calculated spectral and angular performance of several types of polarizers and polarizing beam splitters with an air incident medium (*a* to *d*) and embedded between identical prisms (*e* to *j*). Calculations assume that all nonmetals are absorption and dispersion free. The angles of incidence on the three mirrors (see Fig. 68*r*) are given in brackets. (*After Remneva et al.*[369])

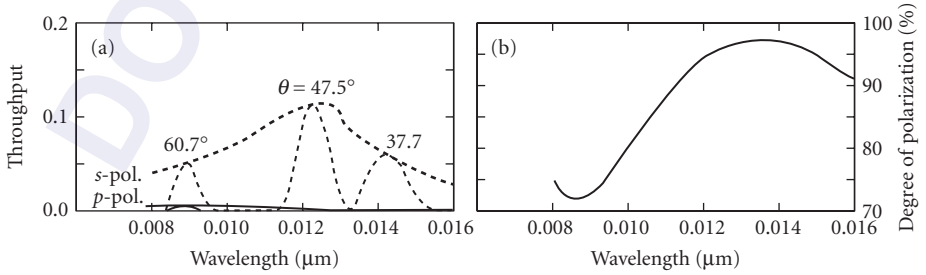

FIGURE 89 Measured throughput (*a*) and degree of polarization (*b*) of an x-ray polarizer consisting of two identical 21-layer Ru-C multilayers on Si substrates. The polarizer can be tuned to different wavelengths by changing the angle of incidence θ of the radiation on the two mirrors. (*After Yanagihara et al.*[372])

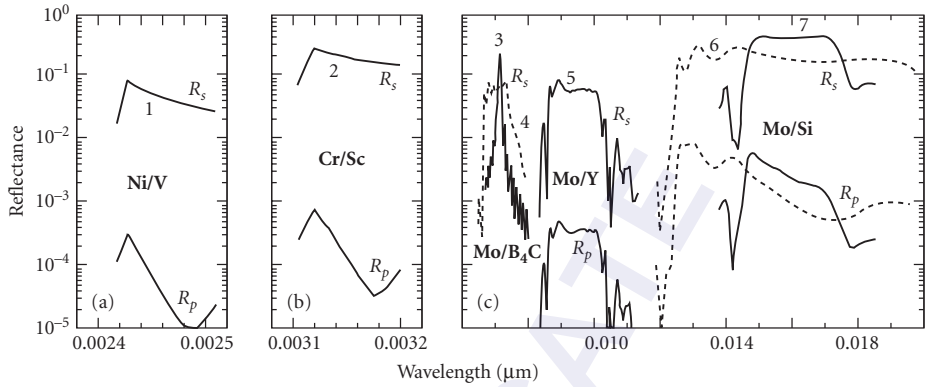

FIGURE 90 Measured spectral performances of two-material multilayer reflection thin-film polarizers for the soft x-ray (*a*, *b*) and extreme ultraviolet (*c*) spectral regions. In the diagrams the reflectances for *s*- and *p*-polarized radiation for each polarizer are plotted with the same line type. The materials of which the multilayers are made are indicated in the figures. The measurements were performed at the Brewster angle which, for all the systems, is close to 45°. (*Curves 1 and 2 after Eriksson*[256] *and curves 3 to 7 after Zhanshan Wang.*[370,374,375])

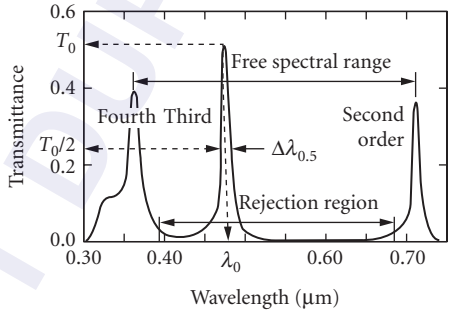

FIGURE 91 Definition of some of the terms used to describe the properties of narrow-bandpass filters (Sec. 7.11). The curve represents the measured transmittance of an unblocked second-order metal-dielectric interference filter of the Fabry-Perot type (Sec. 7.11, subsection "Filters with metallic reflecting coatings"). (*After Bausch & Lomb.*[275])

The half width (HW) $\Delta\lambda_{0.5}$ of the filter is the difference between the wavelengths at which the transmittance is a half of T_0. This quantity is also sometimes called the full width half maximum (FWHM). It is often expressed as a percentage of λ_0. The base width (BW) $\Delta\lambda_{0.01}$ is similarly defined. The ratio $\Delta\lambda_{0.01}/\Delta\lambda_{0.5}$, sometimes called the *shape factor*, indicates how "square" the transmission band is. Sometimes widths corresponding to other fractions of the transmittance are used to define it.

The minimum transmittance T_{min} of the filter does not take into account the effect of blocking filters. The quantity T_{min}/T_0 is called the *rejection ratio*.

In all-dielectric transmission-band filters the transmittance rises at some distance on either side of the transmission band. The distance over which the transmittance is low is called the *rejection region*. The distance between the two transmission maxima adjacent to the principal transmission band is called the *free spectral range*. Should either of the above two quantities be inadequate, auxiliary blocking filters might have to be provided.

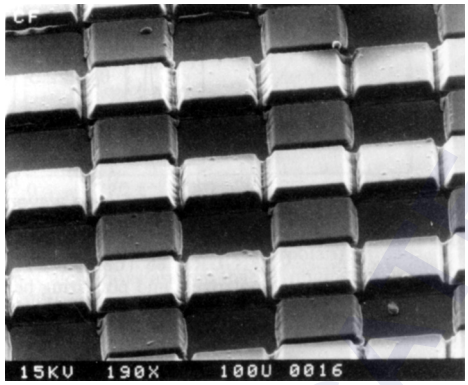

FIGURE 92 Four color checkerboard pattern for use with a 64 × 64 element focal plane HgCdTe detector array. The dimensions of each element are 100 × 100 μm. (*Reproduced with permission from Barr Associates.*[380])

The ultimate measure of the suitability of a bandpass filter with a blocked spectral transmittance $T(\lambda)$ for a particular application is the signal-to-noise ratio SN, defined in terms of the spectral energy distribution $I(\lambda)$ of the source and the spectral detectivity $D(\lambda)$ of the detector,

$$\mathrm{SN}=\frac{\int_{\lambda_1}^{\lambda_2} I(\lambda)T(\lambda)D(\lambda)d\lambda}{\int_0^{\lambda_1} I(\lambda)T(\lambda)D(\lambda)d\lambda+\int_{\lambda_2}^{\infty} I(\lambda)T(\lambda)D(\lambda)d\lambda} \tag{61}$$

where λ_1, λ_2 are the lower and upper limits of the transmission region of the filter. The SN ratio is sometimes expressed in terms of optical density.

Useful general reviews of bandpass filters exist.[376,377] Interference filters, and especially bandpass filters, are increasingly deposited in complicated millimeter and sub-millimeter patterns for use with display devices and detectors.[378,379] Very fine masks or photo-lithographic processes are required to produce such structures (Fig. 92).

Narrow- and Medium-Bandpass Filters (0.1 to 35 percent hw)

Even though the essential components of Fabry-Perot (FP) interference filters, that is, the spacer and the two reflectors that surround it, can take on many different forms (see Fig. 93), the filters are essentially low-order FP interferometers and hence the theory developed for the latter (see, for example, Born and Wolf[19]) applies in full.

The transmittance of a FP type filter, not allowing for absorption and multiple reflections within the substrate, is given by

$$T=\frac{T_R^2}{(1-R)^2+4R\sin^2\delta} \tag{62}$$

where

$$T_R=\sqrt{T_1T_2} \qquad R=\sqrt{R_1R_2} \tag{63}$$

T_1, R_1 and T_2, R_2 are the transmittances and reflectances of the first and second reflectors, respectively, as seen from within the spacer medium, and δ is given by

$$\delta=\frac{2\pi}{\lambda}nd\cos\theta+\phi \tag{64}$$

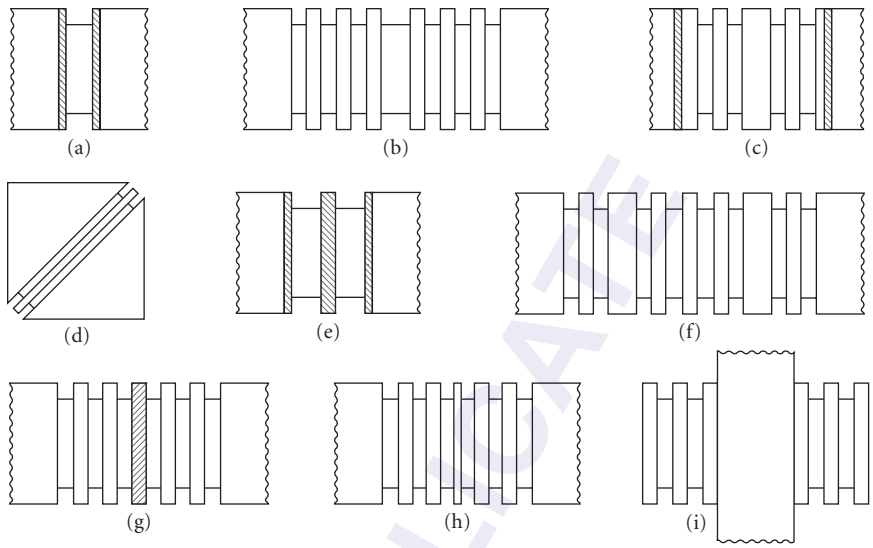

FIGURE 93 Schematic representations of various types of bandpass interference filters: (*a*) to (*c*) Fabry-Perot interference filters with metal, dielectric, and metal-dielectric reflectors; (*d*) frustrated-total-internal-reflection filter; (*e*) and (*f*) square-top multicavity filters with metal and dielectric reflectors; (*g*) induced-transmission filter; (*h*) phase-dispersion (spacerless) interference filter; and (*i*) Fabry-Perot filter with a mica or quartz spacer.

$$\phi = \frac{\phi_1 + \phi_2}{2} \tag{65}$$

n, d, and θ are the refractive index, thickness, and angle of refraction of the spacer, respectively, and ϕ_1 and ϕ_2 are the phase changes on reflection from the spacer side of the first and second reflectors at a wavelength λ. Maxima of T occur at wavelengths

$$\lambda_0 = \frac{2nd\cos\theta}{k - \phi/\pi} \qquad k = 0, 1, 2\ldots \tag{66}$$

and are given by

$$T_0 = \left(\frac{T_R}{1-R}\right)^2 = \left(\frac{1}{1 + A/T_R}\right)^2 \tag{67}$$

$A\ (= 1 - T_R - R)$ is the mean absorption of the reflectors. The minimum transmittance

$$T_{\min} = \left(\frac{T_R}{1+R}\right)^2 \tag{68}$$

occurs at

$$\lambda_{\min} = \frac{2nd\cos\theta}{k - \phi/\pi} \qquad k = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}\cdots \tag{69}$$

If T_R and R are essentially the same at λ_0 and $\lambda_{\min}$, the rejection ratio is given by

$$\frac{T_{\min}}{T_0} = \left(\frac{1-R}{1+R}\right)^2 \tag{70}$$

For $R > 0.7$ the half width of the transmission band (expressed as a percentage of λ_0) is given by

$$\frac{\Delta\lambda_{0.5}}{\lambda_0} \times 100 \approx \frac{1-R}{\sqrt{R}} \frac{100}{\frac{2\pi n d \cos\theta}{\lambda_0} - \lambda_0 \frac{\partial\phi}{\partial\lambda}} \tag{71}$$

For a given order of interference the half width and rejection ratio cannot be varied independently. The formula

$$T \approx \frac{T_0}{1+4[(\lambda-\lambda_0)/\Delta\lambda_{0.5}]^2} \tag{72}$$

valid for FP filters with small values of $\partial\phi/\partial\lambda$ in the neighbourhood of λ_0, represents a lorentzian line shape with $\Delta\lambda_{0.1} = 3\Delta\lambda_{0.5}$ and $\Delta\lambda_{0.01} = 10\Delta\lambda_{0.5}$. The shape factor of all FP-type interference filters is therefore of the order of 10.

Southwell has recently shown that a spacer in an interference filter need not consist of a single layer only, and that there are some advantages when it is partitioned into a number of layers.[381]

Fabry-Perot Interference Filters (0.1 to 10 percent hw)

Filters with metallic reflecting coatings This is the first interference bandpass filter ever made, and the simplest.[382] It consists of two partially transmitting, highly reflecting metal layers separated by a dielectric film and is symbolically represented by MDM (Fig. 93*a*). The best metallic reflectors currently available are aluminium and silver for the 0.125 to 0.34 μm and 0.34 to 3.0 μm spectral ranges, respectively. The measured spectral-transmittance curves of a number of typical filters are shown in Fig. 94.

The phase changes on reflection at the spacer-metal-reflector surface are finite and hence they affect the position of the transmission maxima [Eq. (66)]. But the dispersion of the phase change on reflection can be neglected, and so the half width depends only on the reflectance of the metal layers and the order of the spacer. Filters with half widths of 1 to 8 percent are common. Because the ratio A/T is not very small for metals, the maximum transmission is limited [Eq. (67)]. Maximum transmittances of 40 percent are relatively common. For filters with the narrower half widths, or for shorter wavelengths, transmittances of the order of 20 percent have to be accepted. This is much less than the transmittances of all-dielectric filters of comparable half widths. Nevertheless, filters of this type are useful because their transmittances remain low except at wavelengths at which the first- and

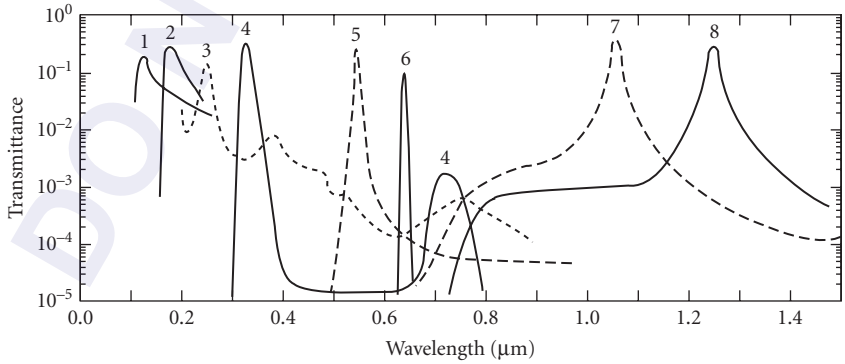

FIGURE 94 Measured transmittance of FP filters with metallic reflecting coatings. Curve 6 represents the transmission of two identical filters cemented together. (*Curve 1 after Harrison;*[383] *curve 2 after Bradley et al.;*[384] *curves 3 and 5 to 7 after Balzers;*[385] *curves 4 and 8 after Schott & Gen.*[386])

higher-order transmission maxima occur [Eq. (66)]. Blocking is thus easy. In particular, first-order filters usually do not require any blocking on the high-wavelength side—a difficult task at all times. The rejection of the filters is good, though not spectacular. If a better rejection is required and a lower transmittance can be tolerated, two identical filters may be cemented together (curve 6, Fig. 94). This is possible because of the finite absorption in the metal films. Alternatively, metal square-top filters (Sec. 7.11, subsection "Square-Top Multicavity Bandpass Filters") or filters with even more complicated structures (Sec. XI A 3) can be used.

Filters with all-dielectric reflectors Above 0.2 μm the metallic reflectors can be replaced by all-dielectric quarter-wave stacks (Sec. 7.6).[344] The symbolic representation of such a filter (Fig. 93*b*) is, for example, $[HL]^N 2mH[LH]^N$ or $H[LH]^N 2mL[HL]^N H$, H and L being quarter-wavelength layers of high and low refractive indices, respectively, m is the order of the spacer and N the number of full periods in the reflecting stacks. The phase change on reflection at the boundary between the spacer and such a reflector does not affect the position of λ_0 [Eq. (66)] but the dispersion of the phase change on reflection is finite, depends on the materials used, and for lower-order spacers, contributes very significantly to the reduction of the half width of the transmission band [Eq. (71)]. Expressions for the half width

$$\frac{\Delta\lambda_{0.5}}{\lambda_0}\times 100 = \frac{4n_0 n_L^{2N}(n_H - n_L)\times 100}{m\pi n_H^{2N+1}(n_H - n_L + n_L/m)} = \frac{4n_0 n_L^{2N-1}(n_H - n_L)\times 100}{m\pi n_H^{2N}(n_H - n_L + n_L/m)} \tag{73}$$

for high- and low-refractive-index spacers, respectively have been given by Macleod.[2]

By choosing a suitable combination of the reflectance and order of the spacer almost any half width between 0.1 and 5 percent can be achieved in the visible part of the spectrum while maintaining a useful rejection ratio.

The maximum transmittances of all-dielectric FP filters depart from unity because of the finite absorption, scattering, and errors in the thicknesses and refractive indexes of the films. In the central part of the visible spectrum maximum transmittances of 0.8 are normal for unblocked filters with a half width of 1 percent, although higher transmittances can be achieved. This figure is gradually reduced as λ_0 approaches 0.2 or 20 μm, and filters with narrower half widths become impracticable for lack of adequate transmittance.

The transmittance away from the transmission maximum is low only over the extent of the rejection region of the two materials used for the construction of the reflectors (Fig. 34), and additional blocking is often required on both the long- and the short-wavelength sides. This can result in a considerable lowering of the maximum transmittance of the blocked filter, a 30 to 40 percent loss being not uncommon for filters peaked in the ultraviolet or infrared spectral regions.

For those parts of the visible and infrared for which nonabsorbing mechanically robust coating materials abound, square-top interference filters (Sec. 7.11, subsection "Square-Top Multicavity Bandpass Filters") are often preferred because of their better shape factor and higher rejection ratio. All-dielectric FP filters are still attractive in the ultraviolet, where there is a lack of such materials and where thickness monitoring is difficult, and also in the far-infrared, where very thick layers are required.

The measured transmittance curves of a number of typical all-dielectric FP filters are shown later in Fig. 98. An additional curve on a smaller scale is given, whenever necessary, to show the transmittance away from the passband.

Filters with metal-dielectric reflectors In these filters the reflectors consist of metal layers whose reflectance has been enhanced through the addition of several dielectric layers (Sec. 7.14, subsection "Fabry-Perot Filters with Solid Spacers") (Fig. 93*c*).[387] The properties of such filters are intermediate to those described in the two previous sections.

Frustrated total internal reflection filters These are essentially FP filters in which the spacer layer is surrounded by two frustrated-total-reflection surfaces (Fig. 93*d*).[387,388] They have not found wide applications as bandpass filters because the finite absorption and scattering within the layers have prevented the theoretically expected high transmittance and small half widths from being realised and because the angular variation of the wavelength of the transmission peaks is very high.

Square-Top Multicavity Bandpass Filters (0.1 to 35 percent hw) A filter with a "squarer" shape that does not suffer from some of the disadvantages of the FP filters results when the basic FP structure is repeated two or more times.[158,389,390] Such filters may be based on metal[391] or all-dielectric[392,393] reflectors (Fig. 93*e* and *f*). Thus, for example, $[HL]^N 2H[LH]^N C[HL]^N 2H[LH]^N$ represents an all-dielectric square-top filter in which the FP structure $[HL]^N 2H[LH]^N$ is repeated twice. The quarter-wavelength layer *C* is called a *coupling* or *tie layer,* and the half-wavelength-thick spacer layers 2*H* are often called *cavities*. Small departures from the above model are made at times to improve the transmittance in the pass band or the angular properties of the filter.

The half widths of the narrower multicavity filters of the above type do not differ very significantly from those of the basic FP structure [Eq. (71)]. The shape factors decrease with an increase in the number of the cavities and do not seem to depend on the materials.[389] They are approximately 11, 3.5, 2.0, and 1.5 for one, two, three, and four cavities, respectively. The minimum transmittance in the rejection region is roughly that which could be obtained if the filter were composed entirely of $\lambda/4$ layers [Eq. (44)]. Unlike in the FP filter, the half width and rejection ratio can therefore be varied independently. These various points are illustrated in Fig. 95. The peak transmittance of multicavity square-top filters is less affected by the residual absorption in the layers than that of FP type filters. As in the case of their FP counterparts, metal-dielectric square-top filters can be cemented together to enhance the rejection (curve 5, Fig. 96).

The improvement in the performance of square-top bandpass filters over that of the FP type is such that despite their more critical and expensive production, most manufacturers regard them as their standard line of filters. The spectral-transmittance characteristics of typical commercially produced metal-dielectric and all-dielectric bandpass interference filters of different half widths are shown in Figs. 96 and Figs. 97 to 102, respectively. Filters with intermediate half widths and peak wavelengths can readily be obtained.

For very critical or special applications multicavity filters are designed and constructed with properties that exceed those shown in the above figures. For example, for the use in fiber-optic communications systems, multicavity filters are required in which the peak transmittance closely approaches unity. Various procedures for the design of such filters, including some that are based on the use of Chebyshev polynomials, have been described.[407,408] Special care has to be taken during the manufacture of the coatings to meet this requirement. Typical measured spectral transmittance

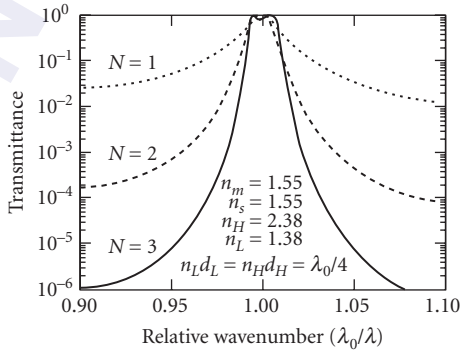

FIGURE 95 Calculated transmittance on a logarithmic scale of the bandpass filters: *air*-$[[(0.5H)L(0.5H)]^3 H[(0.5H)L(0.5H)]^3]^N$-*glass*, $N = 1$, 2, and 3.

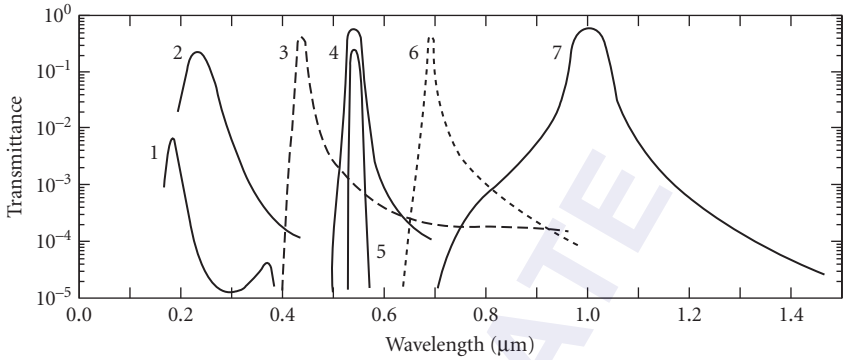

FIGURE 96 Measured transmittance of square-top bandpass filters with metallic reflecting coatings. Curve 5 corresponds to the transmission of two identical filters cemented together. (*Curves 1 and 2 after Schröder;*[394] *curves 3 and 6 after Balzers;*[385] *and curves 4, 5, and 7 after Schott & Gen.*[386])

curves are shown in Fig. 103. For other applications, such as fluourescence or Raman spectroscopy, the peak transmittance is not important, but signal-to-noise ratios of the order of 10^{-8} are required. This necessitates the use of many cavities (Fig. 104).

Induced-Transmission Filters The transmittance of a metal layer can be considerably enhanced by surrounding it with suitable multilayer structures (Fig. 93*g*). Thus, for example, it is possible to induce a transmittance of 65 percent at $\lambda = 0.25$ μm in a 0.03-μm-thick aluminum film which, when deposited directly onto a quartz substrate, would transmit only 2.5 percent of the same radiation.[410] The induced transmittance is highly wavelength-sensitive and can be used to construct bandpass filters containing one or more metal layers.[411–417] Induced-transmission filters combine the good long-wavelength attenuation properties of the more common types of metal/dielectric filters (Secs. 7.11, subsection "Filters with metallic reflecting coatings" and "Filters with all-dielectric reflectrors") with peak transmittances that are closer to those of all-dielectric filters. The performances of some experimentally produced induced-transmission filters are shown in Fig. 105.

Very Narrow Bandpass Filters (hw - 0.1 percent)

It follows from (71) that the half widths of interference filters can be reduced by increasing the reflectance of the reflectors, the order of interference of the spacer, or the dispersion of the phase change on reflection. All these approaches have been tried in the past.

Filters with Evaporated Spacers (hw > 0.03 percent) In narrowband filters of conventional construction both high reflectance and higher-order spacers are used. The manufacturing process is quite critical, and attention must be paid to details. The films have to be very uniform over the filter area, and they must not absorb or scatter. They must not age, or, alternatively, their aging must be capable of being accelerated or arrested. Monitoring must be precise, so that the peak occurs at or close to the desired wavelength.

Both FP and square-top filters of very narrow bandwidths can be made, the latter being preferable for most applications. The present limit on the half widths of this type of filter seems to be of the order of 0.03 percent.[419] The performance of two commercially produced filters of this type are shown in Fig. 97*a* and *b*.

Fabry-Perot Filters with Solid Spacers In practice the half width of interference filters cannot be reduced indefinitely by increasing the optical thickness of an evaporated spacer [Eq. (71)] because

when the latter exceeds about two wavelengths, it may become too rough to be useful.[396] A high-order filter can, however, be constructed by evaporating reflecting coatings on either side of a thin prefabricated spacer (Fig. 93*i*).

Mica Spacers (hw > 0.01 percent) Transmission bands in silvered mica were probably first observed by Wood[420], but the deliberate use of mica to construct filters came much later.[421–424] The construction of mica interference filters with transmittances of 30 to 80 percent per polarization for half widths of the order of 0.01 to 0.1 percent in the 0.45- to 2.0-μm wavelength region is relatively straightforward.[423] The position of the transmission peak can be located within a fraction of an angstrom, does not change with time, and can be sufficiently uniform over areas of 2 to 5 cm diameter. Because of the very high order of interference (70 to 700 orders) the spectral-free range is quite small, and auxiliary filtering is necessary for most applications. Unless the thickness of the mica is specially selected, the birefringence of mica will result in two mutually perpendicularly polarized sets of transmission bands, a fact that can be used to advantage in some applications. The spectral-transmittance curve of a fully blocked mica interference filter for H_α is shown in Fig. 97*c*.

Optically polished solid spacers (hw > 0.002 percent) It is possible to construct very narrow bandpass filters having thin fused-quartz spacers.[425–429] A good fused-quartz flat is coated with an all-dielectric reflector, and this coated surface is optically contacted to another flat.[397,430] The flat is then ground down and polished to form a spacer layer of the required thickness, and the second

reflector layers are applied to complete the filter. As in the mica filters, the position of the transmission band is very stable, and auxiliary blocking filters are needed because of the small spectral-free range. The transmittance of filters with silica spacers is higher than that of corresponding mica filters because fused quartz is highly transparent and is not birefringent. A typical unblocked filter with a clear aperture of 3.5 cm and a half width of 0.007 percent had a transmittance of 45 percent for nonpolarized light. An important advantage of filters with fused-silica spacers is that it has been found possible, by repeating the process described above, to construct square-top filters with rejection ratios of the order of 5×10^{-4} (Fig. 97*f*) and filters with half widths as low as 0.002 percent (Fig. 97*g*). However, such filters are very expensive.

Other materials can also been used to produce solid spacers by optical polishing. Germanium was used by Smith and Pidgeon[431] and by Costich[252] to produce very narrow bandpass filters for the infrared. Roche and Title used a substrate made of a combination of yttrium and thorium oxides to produce a filter with a hw = 0.004 percent at 3.3 μm.[432]

Plastic spacers (hw > 0.15 percent) Mylar has very smooth surfaces and areas can be selected that have a sufficiently uniform thickness to permit the use of this material as a solid spacer. Candille and Saurelle have used this material to produce narrow bandpass filters and obtained half widths of the order of 0.0008 μm.[433,434] In some of their designs a second, evaporated narrowband filter deposited onto one side of the solid spacer served to remove unwanted adjacent orders.

Phase-Dispersion Filters (hw > 0.1 percent) The dispersion of the phase change on reflection enters into (71) for the half width of FP filters. Typical values of this quantity at $\lambda = 0.5$ μm for a silver reflector, a nine-layer quarter-wave stack with $n_H/n_L = 1.75$, and for a broadband reflector are –0.5, –6.8, and –112.0, respectively.[224] As a result, the half widths of FP filters constructed with such reflectors should be reduced by factors of about 1.05, 2, and 20. In the last case the contribution of the spacer to the half width is negligible, and a spacerless design is possible (Fig. 93*h*).[435,436] Unfortunately, the expected reduction in half width has so far not been fully realised in practice, probably because of errors in the monitoring and lack of uniformity of the layers.[437]

Tunable filters (hw > 0.001 percent) These are usually air-spaced FP interferometers, often provided with elaborate automatic plate-parallelism and spacing control, which are more akin to spectrometers than to filters.[438,439] The position of the pass band can be tuned quite significantly by changing the separation between the reflector plates. This type of tuning, unlike the tuning of filters by tilting, does not affect the angular field or shape of the transmission band. Ramsey reviews the various problems associated with the construction and use of such instruments.[440,441]

An electrically tunable 0.005 percent half width interference filter with a lithium niobate spacer sandwiched between two conducting reflecting coatings has also been described (Fig. 106).

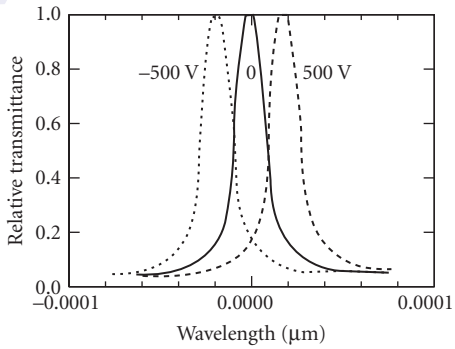

FIGURE 106 Performance of an electrically tunable narrow band filter with a lithium niobate spacer. (*After Burton.*[442])

Wide-Bandpass Filters

Filters with half widths ranging from 10 to 40 percent can be constructed using techniques described in Sec. 7.11. subsection "Square-Top Multicavity Bandpass Filters" (Figs. 101 and 102). Filters with wider transmission bands are usually obtained by combining short- and long-pass filters with cutoffs at the desired wavelengths. The cutoff filters may be all-dielectric (Figs. 61 and 62), glass or gelatine cutoff filters or antireflection-coated infrared materials. Some of the short- or long-pass filters may be regarded as being wide-bandpass filters in their own right. The cutoff filters may be combined into a single filter. Alternatively, it is possible to assemble a number of short- and long-wavelength cutoff filters into sets that make it possible to assemble wide-passband filters of different half widths and peak wavelengths. In this latter arrangement the cutoff positions of all-dielectric short- and long-pass filters can be tuned individually by tilting to coincide with the desired wavelengths. Another way of tuning the edges of the transmission band is to pass the radiation through a pair of circular wedge short- and long-wavelength cutoff filters placed in series.

Filters with very broad transmission bands are also obtained when a multilayer is formed from two suitably displaced long-wavelength cutoff filters separated by an appropriate matching layer (Fig. 107*a*).[443] Automatic computer programs can be used to design high-transmission broadband filters with a high rejection and a shape factor close to unity (Fig. 107*b*).[444]

Interference Filters with Multiple Peaks

For some applications filters with multiple peaks in one particular spectral region are required. The design of such filters has been considered by Pelletier et al.[447] Typical results are shown in Fig. 108. Filters with different peak separations, rejections and half widths are possible.

Linear and Circular Wedge Filters

If the thicknesses of all the layers of a bandpass filter vary in proportion across the surface of a substrate, the position of the transmission peak will vary in the same way (Sec. 7.2, subsection "Matrix Theory for the Analysis of Multilayers Systems"). Such wedge filters are as old as the interference filter itself and are available in versions in which the wavelength variation occurs along a straight line or a circle. The latter arrangement is particularly useful because it lends itself well to the construction of low cost, small and light weight rapid-scan monochromators of moderate resolution that are robust and environmentally stable.[448] Methods for the production of circular variable filters with a linear dependence of wavelength on angle and references to some of the previous work on wedge

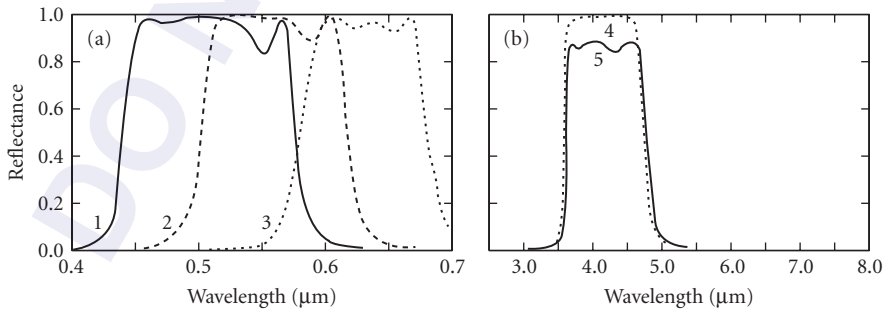

FIGURE 107 Broadband transmission filters: (*a*) calculated transmittance of three filters consisting essentially of two superimposed suitably tuned long-wavelength cutoff filter structures (*after McKenney and Turner*[445]) and (*b*) calculated (curve 4) and measured (curve 5) transmittances of a filter designed with an automatic synthesis program (*after Michael*[446]).

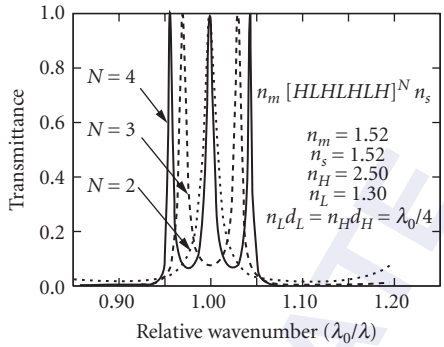

FIGURE 108 Calculated performance of interference filters with two and three closely spaced peaks of the type. glass $[HLHLHLH]^N$ glass for values of $N = 3, 4$. The refractive indices of the surrounding media n_m and of the layers n_H, n_L are 1.52 and 2.52, 1.30, respectively. (*After Pelletier and Macleod.*[447])

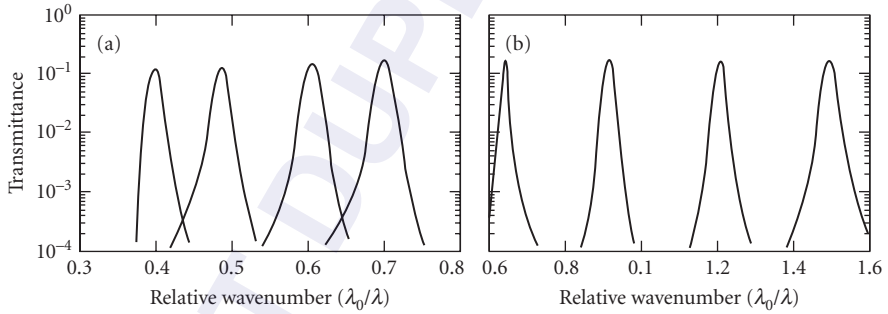

FIGURE 109 The transmission at different angular positions of two circular variable square-top filters for the (*a*) visible and (*b*) near-infrared spectral regions. (*After Mussett.*[456])

filters are given in several papers.[449–453] Circular variable square-top filters for the 0.24- to 0.4- and for the 0.4- to 25-μm spectral regions are described by Avilov and by Yen.[454,455] The maximum transmittances for fully blocked filters vary between 15 and 75 percent, depending on the spectral region and the half width of the filter. Rejection levels of 0.1 or 0.01 percent are possible. Typical transmission curves for several angular positions on two circular variable square-top filters are shown in Fig. 109. The ratio of the maximum to minimum wavelength available in one wheel varies between 1.11 and 16.[454] The angular width of the slit used in conjunction with a circular variable filter, expressed as a percentage of the angular size of the filter wedge, should not exceed the nominal half width of the filter (expressed in percent) if it is not to cause a marked reduction in the resolution.

Angular Properties of Bandpass Interference Filters

With the gradual increase of the angle of incidence the transmittance maximum of a typical bandpass filter moves toward shorter wavelengths (Fig. 110*a*). On further increase in the angle of incidence the maximum transmittance and the half width deteriorate; the transmission band becomes asymmetric and eventually splits up into *p*- and *s*-polarized components (Fig. 110*b*). The deterioration is more rapid for nonparallel radiation.

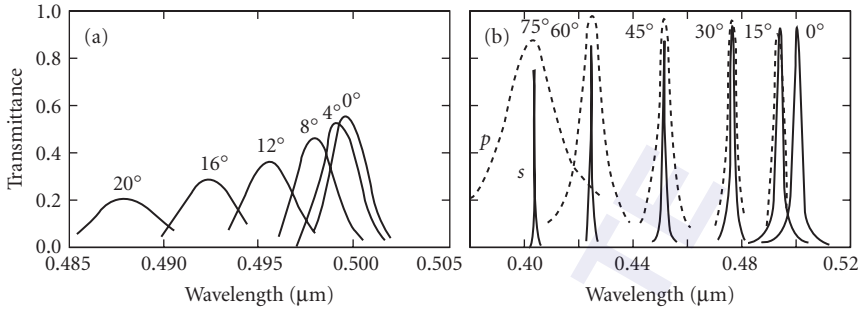

FIGURE 110 Angular properties of all-dielectric interference filters. (*a*) Measured variation with angle of incidence of the spectral transmittance of a typical commercial interference filter (*after Blifford*[403]) and (*b*) calculated transmittance of a filter in which the peaks of the two polarized transmission bands at nonnormal incidence coincide. The filter is of the type air-$[HL]^4(2A)[LH]^4$-glass, where $n_H t_H = n_L t_L = n_A t_A = \lambda/4$ and $n_s = 1.52$, $n_M = 1.00$, $n_H = 2.30$, $n_L = 1.38$, and $n_A = 1.825$.

Properties of Bandpass Filters for Angles of Incidence Less than 20° The behavior of bandpass filters for angles of incidence $\theta_0 \le 20°$ can be described quantitatively using the concept of an *effective index* μ^* of the filter. In terms of μ^* the transmittance T in the neighborhood of the transmission peak of any FP filter is given by Lissberger:[457]

$$T \approx \frac{T_0}{1+\left[\dfrac{2(\lambda-\lambda_0)}{\Delta\lambda_{0.5}}+\dfrac{\lambda_0}{\Delta\lambda_{0.5}}\dfrac{\theta_0^2}{\mu^{*2}}\right]^2} \tag{74}$$

$\Delta\lambda_{0.5}$ and T_0 are the half widths and the maximum transmittance (at λ_0) for normal incidence of the radiation. Formulas for μ^* in terms of the construction parameters have been found for the all-dielectric FP filter and the double-spacer filter[458,459] and for the metal-dielectric FP and induced-transmission filters.[460] The change in position of the transmission peak $(\delta\lambda)_0$, and the half width $(\Delta\lambda_{0.5})\theta$ at angle θ are

$$\left(\frac{\delta\lambda}{\lambda_0}\right)_\theta = -\frac{\theta_0^2}{2\mu^{*2}} \tag{75}$$

and

$$\frac{(\Delta\lambda_{0.5})_\theta}{\Delta\lambda_{0.5}} = \left[1+\left(\frac{\theta_0^2\lambda_0}{\mu^{*2}\Delta\lambda_{0.5}}\right)^2\right]^{1/2} \tag{76}$$

For convergent radiation of semiangle α the corresponding expressions are

$$\left(\frac{\delta\lambda}{\lambda_0}\right)_\alpha = -\frac{\alpha^2}{4\mu^{*2}} \tag{77}$$

$$\frac{(\Delta\lambda_{0.5})_\alpha}{\Delta\lambda_{0.5}} = \left[1+\left(\frac{\alpha^2\lambda_0}{2\mu^{*2}\Delta\lambda_{0.5}}\right)^2\right]^{1/2} \tag{78}$$

Linder and Lissberger discuss the requirements and design of filters for this case.[457,461]

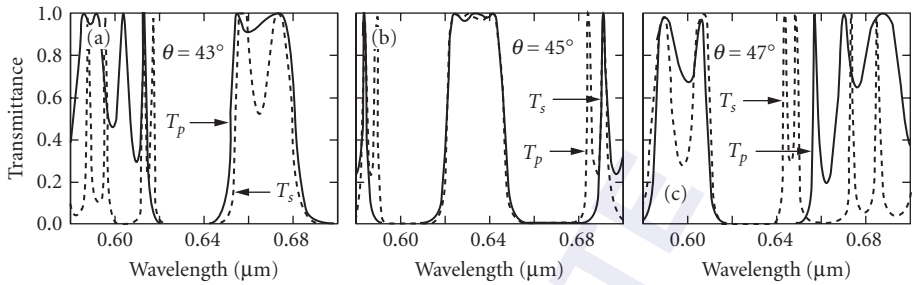

FIGURE 111 Performance at 43° (*a*), 45° (*b*), and 47° (*c*) of a multicavity bandpass filter designed to show no polarization splitting for light incident at 45°. (*After Baumeister.*[464])

Small tilts are commonly used to tune the peak of a filter to the desired wavelength even though they have an adverse effect on the angular field of the filter.

Bandpass Filters with Little or No Polarization Splitting It has been shown numerically for the phase-dispersion filter,[435] for the frustrated-total-reflection filter,[462] and for the metal-dielectric[24] and all-dielectric[463] FP filters that it is possible to arrange for the two polarized transmission bands, which may have different widths, to coincide at high angles of incidence (Fig. 110*b*). The narrow, symmetrical high-transmittance bands that result may be useful for some applications even though the position of the maximum is still displaced with angle. Baumeister has shown how to design multicavity filters with no polarization splitting at one angle of incidence (Fig. 111).[464]

Wide-Angle Bandpass Filters Figure 112 shows the variation with effective index μ^* of the angular field of FP filters, defined as being twice the angle of tilt necessary to reduce to $0.8T_0$ the transmittance of the filter for radiation of wavelength λ_0. To increase the angular field μ^* must be increased. Thus, for example, in an all-dielectric FP filter the expression for μ^* shows that $n_L < \mu^* < n_H$ and that with increasing spacer order μ^* approaches the refractive index of the spacer. The upper limits for μ^* for an all-dielectric FP filter in the ultraviolet, visible, and infrared parts of the spectrum are

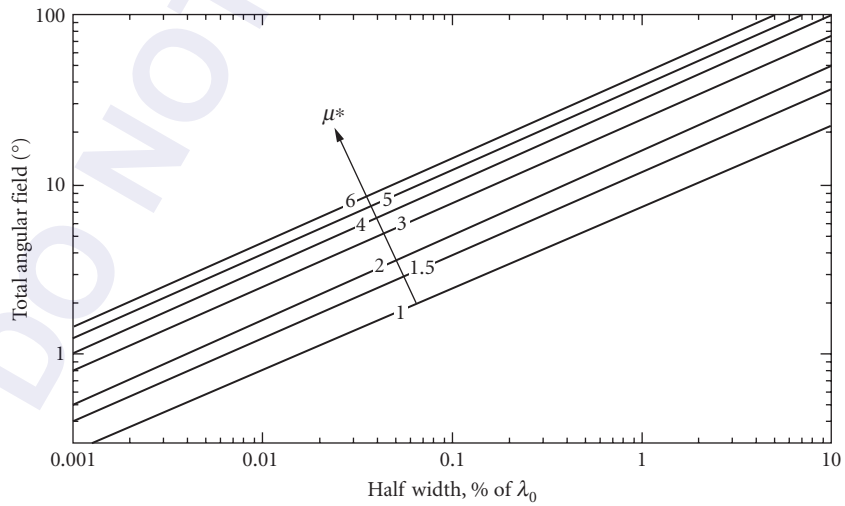

FIGURE 112 Angular field of FP filters as a function of the half width for different effective indexes μ^*.

of the order of 2.0, 2.35, and 5.0, respectively. Little can be done about the angular field of solid spacer filters (Sec. 7.11, subsection "Fabry-Perot Filters with Solid Spacers").

For metal-dielectric FP and for induced-transmission filters effective indexes μ^* of up to 3.2 and 2.0 have been reported.[460]

Wilmot and Schineller[465] and Schineller and Flam[466] have announced a filter consisting of a thin, plane-parallel fiber-optic face plate coated on both sides with all-dielectric mirrors. Since in such a filter the half width is determined only by the thickness of the plate and the reflectivity of the coatings, and since the field of view depends on the ratio of the wavelength to the fiber diameter, the two quantities are independent. The measured transmittance of a 15-Å-half-width, 6-mm-diameter filter composed of 1.5-μm-diameter fibers was 30 percent, and the shift in wavelength with angle of incidence was one-eighth that of a conventional filter.

Stability and Temperature Dependence of Bandpass Filters

The stability of the position of the transmission peak has been studied by many workers.[389,396,467–475] The observed changes (up to 1 percent of λ_0) seem to depend greatly on the materials and manufacturing conditions. In filters with evaporated spacers both irreversible changes, probably due to changes in the structure of the films, and reversible changes due to the absorption of water vapor, have been observed. Many manufacturers are now able to minimise these effects through the use of more stable materials, improved high energy deposition methods (see Sec. 7.3), or accelerated artificial ageing processes. No changes were observed in solid spacer filters (Sec. 7.11, subsection "Fabry-Perot filters with Solid Spacers").

Changes in the operating temperature normally do not significantly affect the half widths and peak transmittances of medium and wide bandpass interference filters (see, for example, Refs. 476 to 479). An exception are filters that contain semiconductors that start to absorb significantly on heating (e.g., germanium) or on cooling (PbTe).[480,481]

The position of the transmission peaks shift linearly toward longer wavelengths with an increase in temperature, the magnitude of the shift depending largely on the spacer material. The temperature coefficient, expressed as a percentage change in λ_0 per degree Celsius change in temperature, lies between 2×10^{-4} and 3×10^{-3} for filters with evaporated spacers for the 0.3- to 1.0-μm spectral region[403] and between 2×10^{-3} and 2×10^{-2} for the infrared spectral region.[389,237] It is of the order of 1×10^{-3} for filters with mica[423] and quartz[397] spacers. Unless temperature control is provided, under adverse conditions all the above temperature coefficients could lead to serious shifts of the transmission peaks of very narrow band filters (Sec. 7.11 subsection "Very Narrow Bandpass Filters"). The temperature control can take the form of an external constant-temperature enclosure, or it might be built in right into the filter. Eather and Reasoner[396] and Mark et al.[482] describe arrangements of the latter type in which two sensors embedded in the filters are used to control the current flowing through two transparent conducting coatings that surround the filter.

Deliberate changes in the temperature can be used for a fine tuning of the transmission wavelength without having an adverse effect on the angular field of the filter.

Bandpass Filters for the XUV and X-Ray Regions

The construction of good bandpass filters for the extreme ultraviolet is hampered by the lack of coating materials with suitable optical constants. However, certain metals in thin-film form can be used as rudimentary bandpass filters in the extreme ultraviolet. The primary process in these filters is absorption, although at times interference within the film may have to be considered to explain the spectral transmission characteristics fully.

The measured spectral transmittance of some of these materials are shown in Figs. 113 and 114. By increasing the thicknesses of the films higher rejection ratios could be obtained at the expense of peak transmissions, and vice versa. The transmittance of the most promising material, aluminum, would be higher if it were not for the formation of absorbing oxide layers.

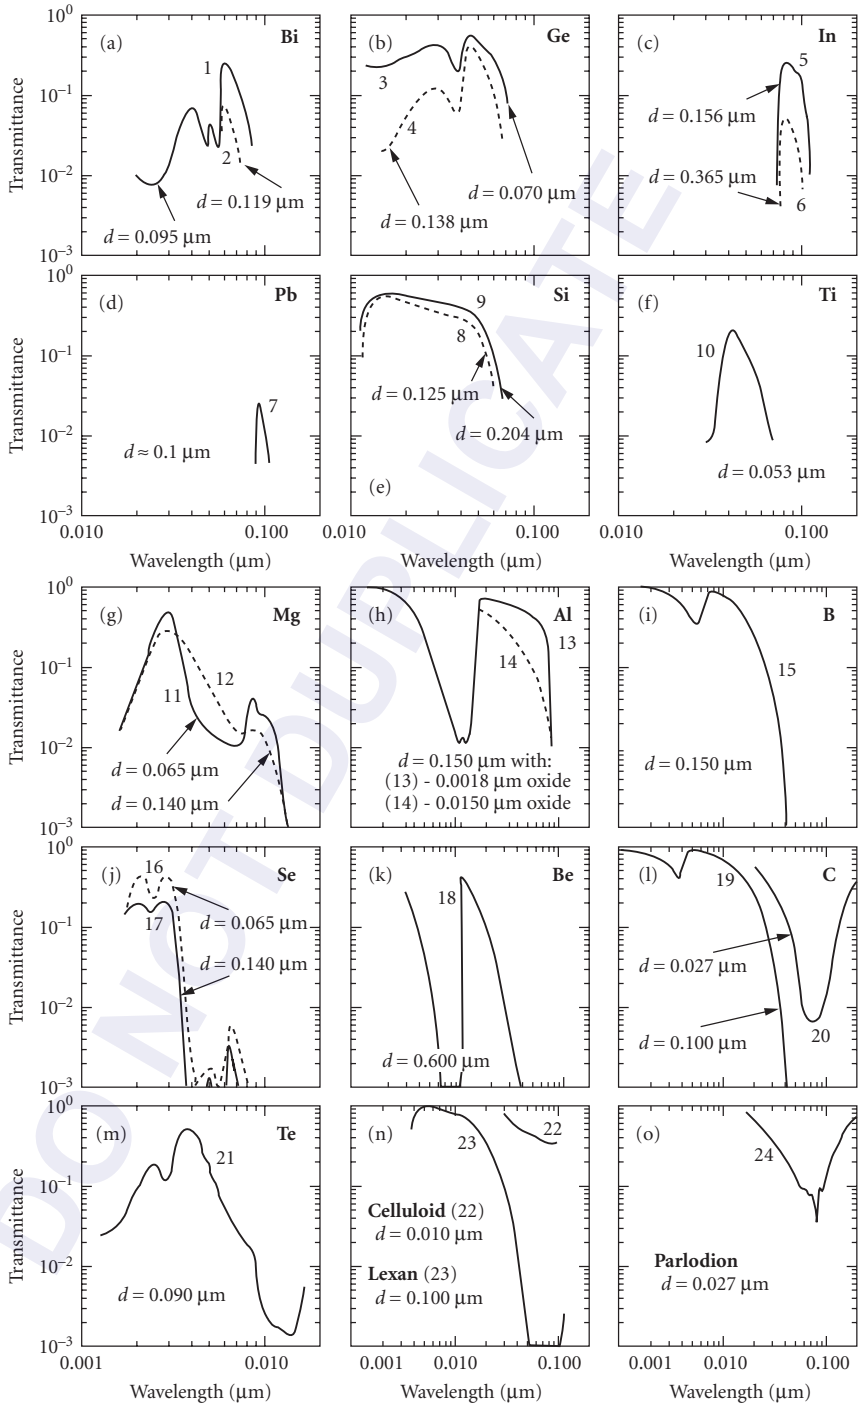

FIGURE 113 Measured extreme-ultraviolet and soft x-ray transmittances (*a*) to (*o*) of several self-supporting metal films of indicated thicknesses.

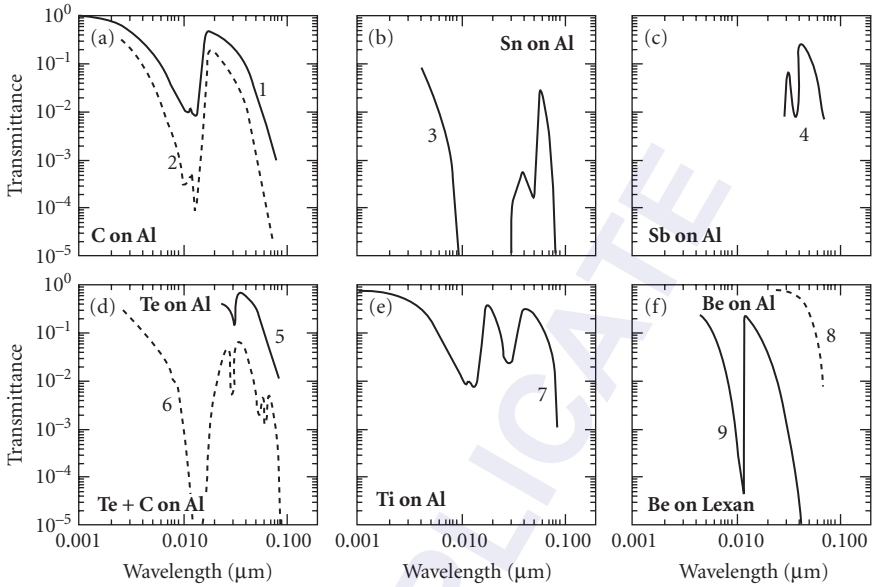

FIGURE 114 Measured extreme-ultraviolet and soft x-ray transmittances (*a*) to (*f*) of six metal films of indicated thicknesses deposited onto thin aluminum or plastic films.

Many of the layers are self-supporting (Fig. 113). Others must be deposited onto a suitable transparent substrate (Fig. 114). Thin aluminum films are sometimes used for this purpose. Other materials used in the past are Zapon (cellulose acetate); collodion, Parlodion, and Celluloid (cellulose nitrates); Mylar (polyethylene teraphtalate); and Formvar (polyvinyl formal) (Fig. 113*n* and *o*). Any residual absorption in the substrate contributes, of course, to the overall-transmission curve. The preparation of self-supporting thin films is described by Novikov and by Sorokin and Blank.[483,484] Because of their fragility such films are usually mounted on a very fine mesh screen.

Multilayer Fabry-Perot interference filters for the soft x-ray region have also been constructed.[485–487] However, thus far the only spectral measurements reported are nonnormal incidence reflection.[488] The finesse of the filters is low and the modulation of the reflectance curve depends on the thickness of the spacer. The devices are useful for measurement purposes.

7.12 HIGH PERFORMANCE OPTICAL MULTILAYER COATINGS

Advances in the design and the automation of the manufacture of optical multilayer coatings have made possible the routine production of filters with a performance that would have seemed impossible to achieve even fifteen years ago. For the visible and near-infrared parts of the spectrum materials and processes have been developed at a number of commercial and research facilities which permit them to deposit with high accuracy layer systems that consist of more than 4000 layers and with total metric thicknesses exceeding 100 μm. Currently the most common application areas for such coatings are in telecom systems (with filter sizes typically of the order of 1 mm) and in fluorescence and Raman spectroscopy (diameters between 10 and 25 mm). The filter specifications for these filters, as a rule, span such a range of transmittances, or have such sharp gradients, that to depict the results properly, it is usually necessary to present the data in at least two graphs. In this section representative examples will be given to illustrate the type of performance that can be currently achieved.

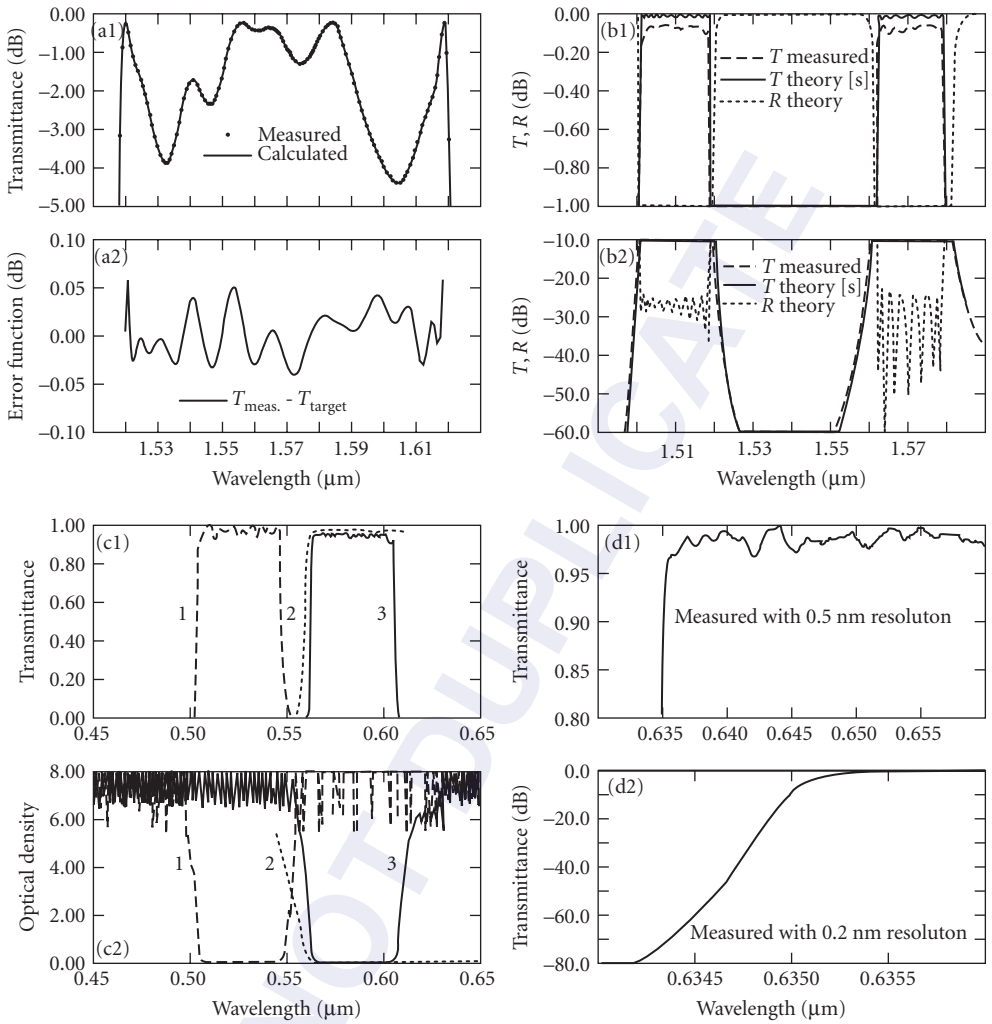

FIGURE 115 Measured data for some high performance optical filters. (*a*) A precise telecom gain flattening filter with an attenuation that is defined over four decades; (*b*) dual band filters with very high transmission and reflection regions, for adding or removing signals of certain wavelengths in fiber networks; (*c*) a set of three filters for fluorescence probe microscopy, having very high transmittances and sharp drop-offs; curves 1, 2, and 3 correspond to the transmittance curves of the excitation, beam splitting and emission filters; (*d*) Raman edge pass filter with an edge steepness of approx. 86 dB/nm. (*After Iridian Spectral Technologies.*[202])

In Fig. 115*a*1 is shown the calculated and measured performance of a 50-μm-thick gain-flattening filter for telecom applications in which the specified transmittance varies in the 1.530- to 1.625-μm spectral region between 0.0 and –4.0 dB. The difference between the target and measured transmittances is show in Fig. 115*a*2 and the peak-to-peak variation is <0.1 dB.

Figure 115*b*1 presents the measured transmittance of a dual band filter of the type that is used for adding or dropping signals of certain wavelengths from a fiber network. Also shown are the theoretical transmittance and reflectance. The main requirements for this application are that the transmittance be as high as possible with low ripple in the transmission bands and have low transmittance

between these bands. The filter shown consisted of more than 300 layers and had a total thickness of 65 μm. Figure 115*b*2 shows that the rejection between the two transmission peaks is indeed very high.

In Fig. 115*c* are shown the measured transmittance curves of the excitation and emission filters and the beam splitter required for fluorescence probe microscopy. For this application the filters must have very high transmittances and sharp drop-offs in order to maximize the signal-to-noise ratio. The emission and excitation filters were about 35 μm thick and consisted of more than 300 layers. The optical density outside the transmission regions are shown in Fig. 115*c*2. Some of these measurements are noise limited above an optical density 6.

In Fig. 115*d* is shown the measured transmittance of a steep cutoff filter for Raman spectroscopy. The filter consisted of about 500 layers and had a total thickness of about 40 μm. The ripple in the transmission region is only 4 percent. To appreciate the steepness of the cutoff (about 86 dB/nm) the region around the cutoff is plotted in Fig. 115*c*2 on an expanded wavelength scale.

Very advanced spectroscopic notch filters are shown in Fig. 42, one of these consisting of as many as 4410 layers. Of course, the processes used to produce the advance coatings described above are used today to produce better coatings with the simpler properties described in the earlier diagrams.

7.13 MULTILAYERS FOR TWO OR THREE SPECTRAL REGIONS

Increasingly there are applications, especially in laser science, in which the spectral transmission and/or reflection has to be controlled at two or more wavelengths.[34] The design and construction of such coatings is more difficult than that of systems for one wavelength region only, especially when the ratio of the wavelengths of interest is very large.

Multilayers for Two Spectral Regions

Costich was the first to specify the construction parameters of coatings having all possible combinations of low and high reflection behavior at wavelength ratios of 1.5-, 2.0-, and 3.0: 1.0.[489] His solutions were based on systems composed of quarter-wave layers or layers with other simple thickness relationships. Experimental results are in good agreement with the calculated values. The calculated performance of two coatings not shown before are given in Figs. 116 and 117 presents the performance of a number of commercially produced coatings of this type. Systems for other wavelength ratios and for combinations of other reflection values are possible.

Sometimes coatings are required in which the reflectance is controlled for wavelength ratios of 10:1 or more.[490,491] A systematic method for the design of such multilayers with different reflectance characteristics at the two wavelengths has been described.[492,493] The calculated performance of such coatings for the wavelengths of 0.6328 and 10.6 μm are shown in Fig. 118.

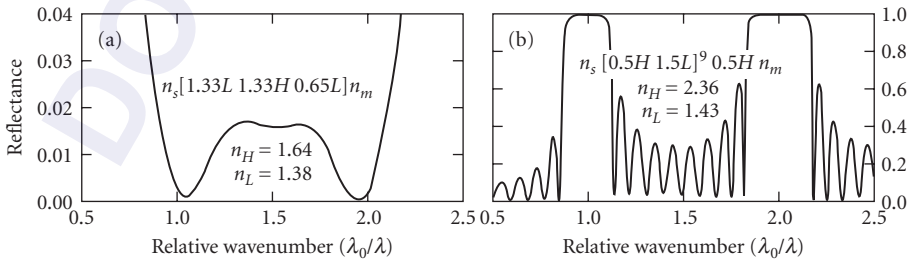

FIGURE 116 Calculated performance of a commercial antireflection coating (*a*) and a high reflectance coating (*b*) for wavenumbers 1.0 and 2.0 μm^{-1}. (*After Costich.*[34])

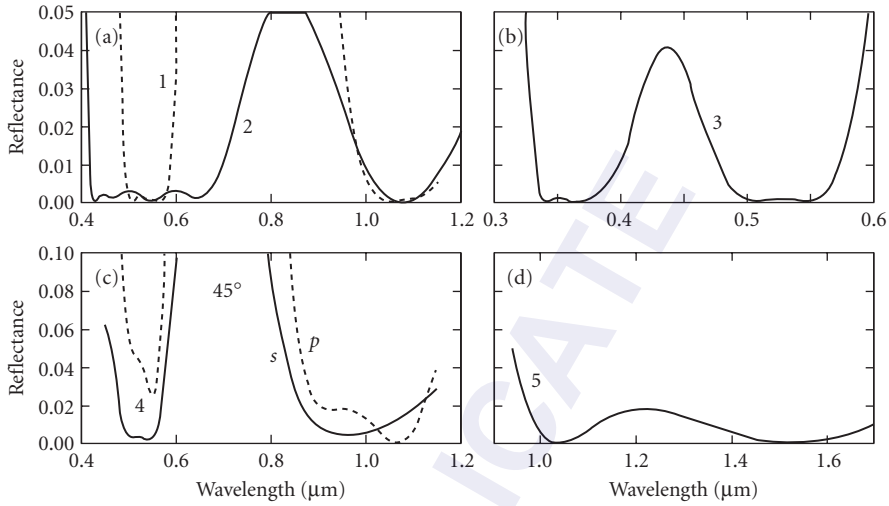

FIGURE 117 Measured reflectances (*a*) to (*d*) of some commercial two-wavelength antireflection coatings. (*Curves 1, 3, and 4 after TechOptics*[86] and *curves 2 and 5 after Thin Film Lab.*[85])

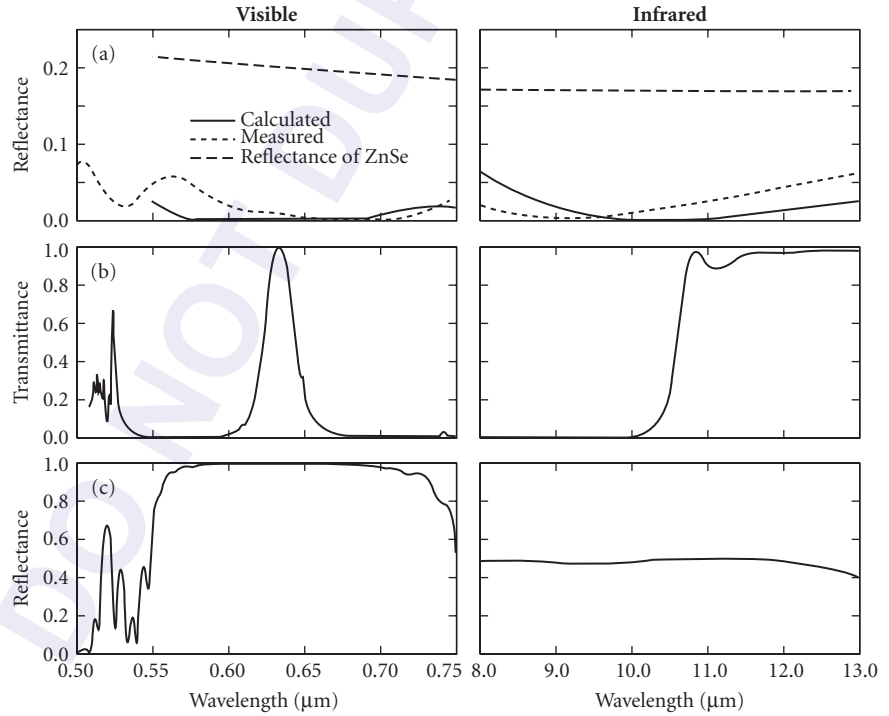

FIGURE 118 Calculated performance of three multilayer coatings (*a*), (*b*), and (*c*) designed for two widely separated spectral regions. Columns 1 and 2 represent the performance of the multilayers in the visible and in the infrared spectral regions, respectively. The experimental measurements for one coating are also shown. (*After Li.*[492,493])

Multilayers for Three Spectral Regions

For some laser applications the reflectance or transmittance has to be controlled at three or more wavelengths. Solutions to such problems can also be found. Costich has given designs for all possible combinations of low and high reflection for the important special case of a set of wavenumbers σ_0, $2\sigma_0$, and $3\sigma_0$.[489] The designs and performances of his solutions to this problem are shown in Fig. 119.

In principle, the method for the design of coatings for two widely separated spectral regions mentioned above can be extended to the design of coatings for three or more wavelengths. However, the number of layers required increases dramatically as the number of layers required for the longest wavelength region increases. Figure 120 shows the calculated performance of a coating that behaves like a high reflection coating, a beam splitter and an antireflection coating at 0.63, 2.52, and 10.6 μm, respectively.

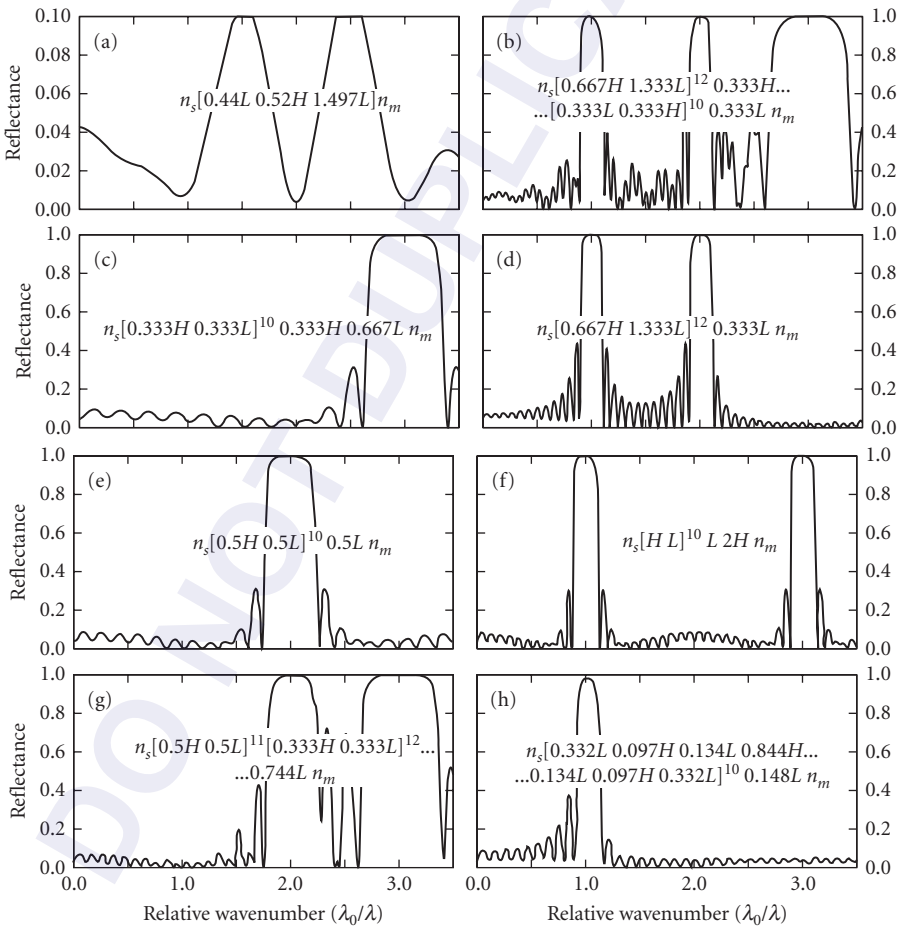

FIGURE 119 Calculated spectral reflectances of multilayer coatings on glass with various combinations of high and low reflectance at relative wavenumbers λ_0/λ 1.0, 2.0, and 3.0. In the designs *H, L* correspond to quarterwave layers at λ_0 = 1.0 μm. n_m, n_s, n_H, and n_L were assumed to be 1.00, 1.52, 1.95, and 1.43, except in (*a*) where n_H, n_L were 1.64, 1.38, respectively. (*After Costich.*[34])

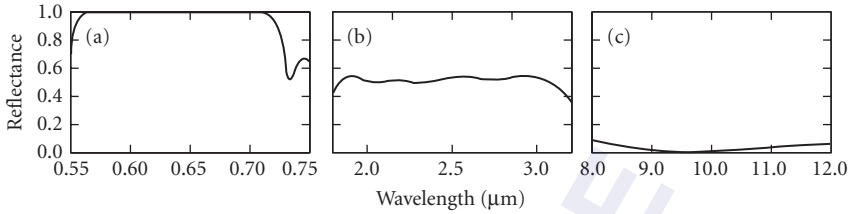

FIGURE 120 Calculated performance of a multilayer with different properties in three spectral regions. (*After Dobrowolski.*[494])

7.14 PHASE COATINGS

In some applications, in addition to transmittance or reflectance requirements, special phase relationships have to be satisfied. These may be specific phase changes on reflection ϕ_R or transmission ϕ_T for radiation incident at 0°. At other times it is required to displace or to deflect a beam without affecting its state of polarization. However, most frequently it is necessary to introduce a certain phase difference $(\phi_p - \phi_s)$ between *p*- and *s*-polarized light. Quarter-wave plates made of birefringent crystals are normally used to provide this phase difference.

Solutions to these and similar problems based on optical interference coatings can also be found. Porous films with an inclined columnar structure, formed in physical vapor deposition processes when the vapor is incident onto the substrate at an oblique angle, can also be birefringent.[495] Such films have been proposed for the construction of phase retardation plates for use with normal incidence of the radiation.[496] However, more frequently solutions are based on the difference between the effective indices η_p, η_s of thin films for obliquely incident radiation [Eq. (19)]. Azzam has shown that, when performance at one wavelength only is specified and when oblique angles of incidence are acceptable, elegant solutions to many of the problems can be found that are based on a single layer only.[335]

Phase retarding reflectors are commonly designed for use at 45°. Many layers are required when the radiation is incident from the air side. The performances of two multilayers of this type with different phase differences are shown in Fig. 121. The multilayers are optimized to maintain a constant phase difference in the vicinity of the design wavelength. Coatings with other phase differences and

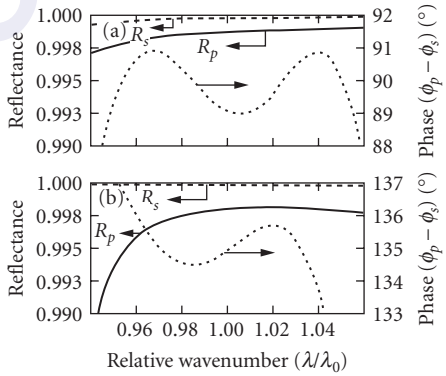

FIGURE 121 Calculated performance of two front surface 45° reflectors with different phase retardations. (*a*) 20 layers on a Ag substrate (*after Southwell*[499]) and (*b*) 22 layers on an Al substrate (*after Grishina*[500]).

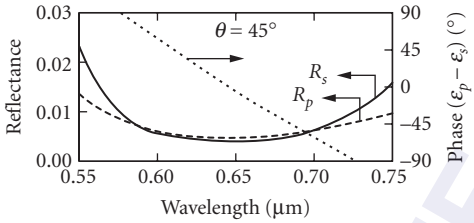

FIGURE 122 Antireflection coating on glass for use at 45° with zero phase retardation at $\lambda = 0.6471$ μm. (*After Thin Film Lab.*[85])

reflectances can also be constructed.[497,498] For example, an antireflection coating for 45° incidence in which the phase change is 180° is shown in Fig. 122.

When the radiation is incident on the layers from the substrate side, total internal reflection takes place.[501] The design of thin-film phase retarders based on this approach has also been examined by Apfel[502] and Azzam.[503] Total internal reflection phase retarders operate over broader spectral regions (Fig. 123) but their size is limited by the weight and homogeneity of the prism materials.

More complex phase retardation devices have been constructed in which the radiation is allowed to undergo 2, 3, or even 4 internal reflections.[342,506,507] The performance of some typical total internal reflection devices that are based on the configurations of Fig. 68*u, v, w* is shown in Fig. 124. For high-power laser beam delivery systems front surface reflectors are usually employed (Fig. 125).

In Fig. 126 are shown the phase changes on reflection of a set of four metal/dielectric interferometer mirrors, all with $R > 0.97$, for which the differences in the phase changes on reflection for adjacent members in the set were approximately 90° over an extended spectral region. Other requirements for phase changes or phase change differences can also be satisfied with thin films.

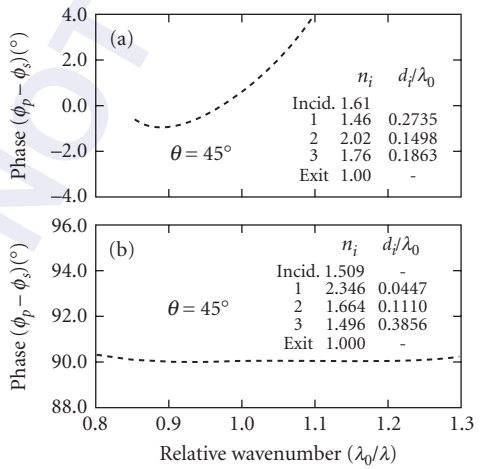

FIGURE 123 Phase retarders based on total internal reflection, consisting of 3 layers on glass and operating at an angle of incidence of 45°. (*a*) 0° phase retardation (*after Cojocaru*[504]) and (*b*) 90° phase retardation (*after Spiller*[505]).

7.15 INTERFERENCE FILTERS WITH LOW REFLECTION

Reducing Reflection with a Thin Metal Film

A suitable thin metal film deposited onto a glass surface can act as a very efficient achromatic antireflection coating for light incident from the glass side (Fig. 127). The reflectance for light incident from the air side is not reduced and the transmittance suffers as a result of the absorption within the film.[511] By combining such films with additional layers, attractive coloured sun glasses or architectural coatings are obtained.

Black Absorbers

Black absorbers efficiently absorb the radiation incident upon them in a specified spectral region. They are used, for example, to control radiant energy,[512] to remove stray light in optical systems, to enhance contrast in display devices[513] and to increase the signal-to-noise ratio in multiplexers.[514] Black absorber coatings are based on interference in thin film and generally consist of an opaque metal layer and one or more dielectric layers interspersed with partially transparent metal layers (Figs. 21 and 66*a*). They can be designed for first- and second-surface application (Fig. 128). Coatings of this type can also be designed for the ultraviolet and infrared spectral regions.[515]

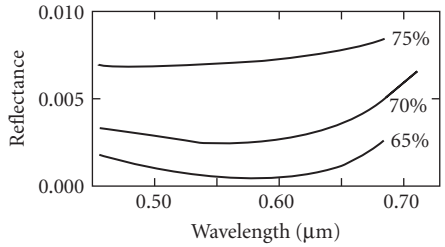

FIGURE 127 Spectral reflectance of thin chromium films on glass for light incident from the substrate side. The transmittance of the layers at $\lambda = 0.565$ μm is indicated. (*After Pohlack.*[511])

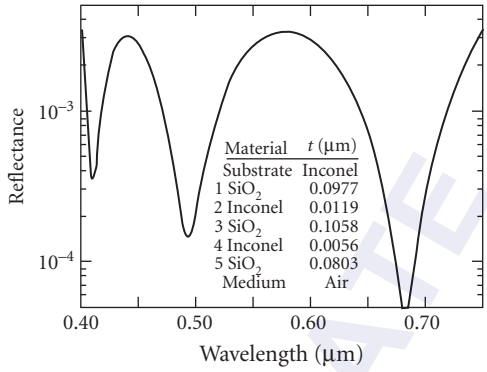

FIGURE 128 Calculated performance of a five layer metal/dielectric black absorber. (*After Dobrowolski.*[516])

Neutral Attenuators

Conventional metallic film attenuators described in Sec. 7.9, subsection "Neutral Filters" cannot readily be placed in series because multiple reflections between the components may result in unpredictable density values. However, by using metal and dielectric layer combinations of appropriate optical constants and thicknesses, it is possible to reduce the reflection of the metallic film from one or both sides of the substrate.[82,513–515,517,518] The experimental results for one such attenuator are given in Fig. 129*b*.

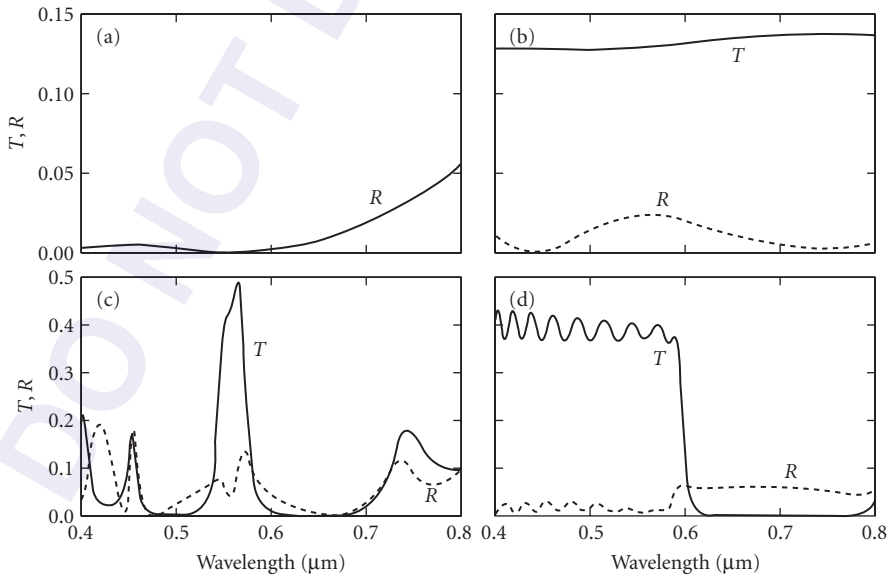

FIGURE 129 Measured performance of interference filters with reduced reflection: (*a*) black absorber; (*b*) neutral attenuator; (*c*) narrow bandpass filter; and (*d*) long-wavelength cutoff filter. (*After Dobrowolski*[519] *and Sullivan.*[520])

Other Interference Filters

It is possible, using a similar approach, to reduce the reflection of narrow bandpass filters, cutoff filters, and other filter types. In particular, low reflection narrowband interference filters for welding applications have been described by Jacobsson.[521] The experimental performance of a bandpass filter and of a long-wavelength cutoff filter are given in Fig. 129*c* and *d*. In both cases the luminous reflectance has been reduced by an order of magnitude over that of a conventional design. However, this is at the expense of the transmittance.

7.16 REFLECTION FILTERS AND COATINGS

Metallic Reflectors

The Fresnel reflection coefficient of an interface between two semi-infinite media of complex refractive indices $\tilde{n}_m$, $\tilde{n}_s$ for polarized radiation incident at nonnormal angle is given by

$$R=\left|\frac{\eta_s-\eta_m}{\eta_s+\eta_m}\right|^2 \tag{79}$$

where η_s, η_m are given by (19). When $\tilde{n}_m$, $\tilde{n}_s$ correspond to air, and the metal, respectively, and when the angle of incidence is zero, the above expression reduces to

$$R=\frac{(n_s-1)^2+k_s^2}{(n_s+1)^2+k_s^2} \tag{80}$$

If the substrate is opaque, the above represents the total energy reflected, the remaining energy being absorbed within the material.

Metal reflectors are most commonly made by vacuum deposition of the material onto a suitable glass or quartz substrate. Before deposition aluminum or beryllium mirror surfaces are sometimes first chemically plated with a nickel-phosphorus alloy (Kanigen process). Such deposits have excellent adhesion to the substrate and have a very hard surface that can be optically polished before coating.[522]

Visible, infrared, and ultraviolet spectral reflectancs of some of the more commonly used metals are shown in Figs. 130 and 131. Using Eq. (80) and the optical constants in Palik's handbook,[58,59] the

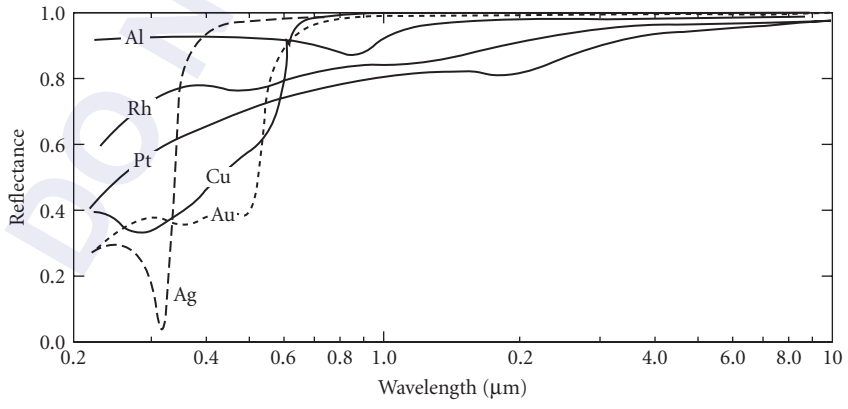

FIGURE 130 Reflectances of some metals. (*After Drummeter and Hass.*[138])

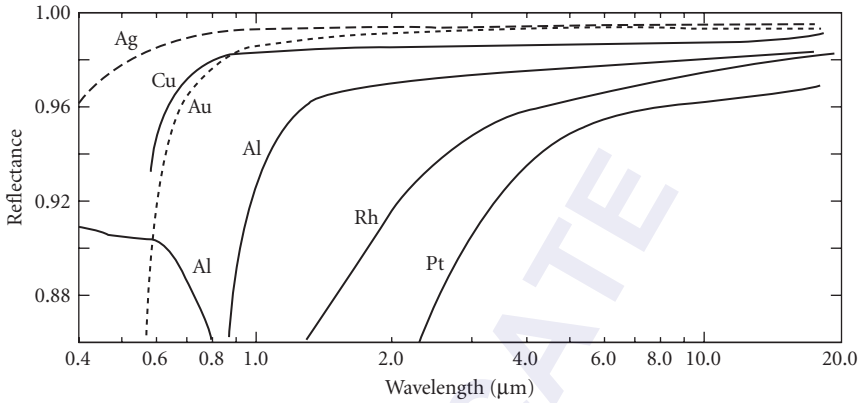

FIGURE 131 Visible and infrared reflectance of certain metals. (*Al after Bennett et al.*;[525] *Ag and Au after Bennett and Ashley*;[526] *Cu after Hass and Hadley*;[527] *Rh and Pt after Hass and Fowler.*) (*See Drummeter and Hass.*[138])

spectral reflectances for many additional metals can be calculated. Silver has the highest visible and infrared reflectance, and hence is used for interferometer mirrors and interference filters. Exposed silver films tarnish readily but they can be protected. Aluminum has the broadest high reflectance region of all metals and is commonly used in front-surface mirrors. It would reflect highly down to 0.1 μm were it not for the absorption below 0.18 μm of the thin oxide layer that starts to form seconds after deposition.[523,524] Some of the highest known reflectances in the ultraviolet are shown in Fig. 132.

Protective Coatings For many applications the thin aluminum oxide layer on an aluminum surface does not offer sufficient protection against abrasion and chemical attack, and therefore aluminum mirrors are often overcoated with single SiO_2 or of MgF_2 protective layers. Such mirrors can be repeatedly cleaned with water and even withstand boiling in saltwater.[534] Single protective layers reduce the reflectance (Fig. 133). If necessary this problem can be overcome by using protective coatings consisting of two or more layers (Fig. 134).

The deterioration of the ultraviolet reflectance of aluminum mirrors due to oxdiation can be partially avoided by covering the freshly deposited aluminum layer immediately with a suitable

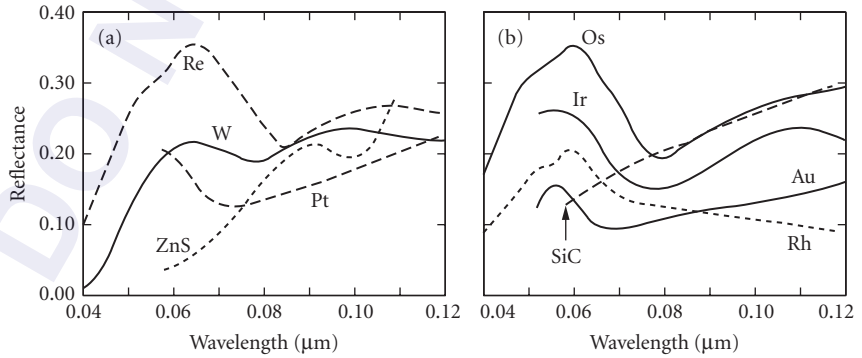

FIGURE 132 Measured ultraviolet reflectance of certain materials (*a*) and (*b*). (*Pt, Au, and ZnS after Hunter*;[528] *Ir after Hass et al.*;[529] *Rh after Cox et al.*;[530] *Re, and W after Cox et al*;[531] *Os after Cox et al.*;[532] *and SiC after Seely.*[533])

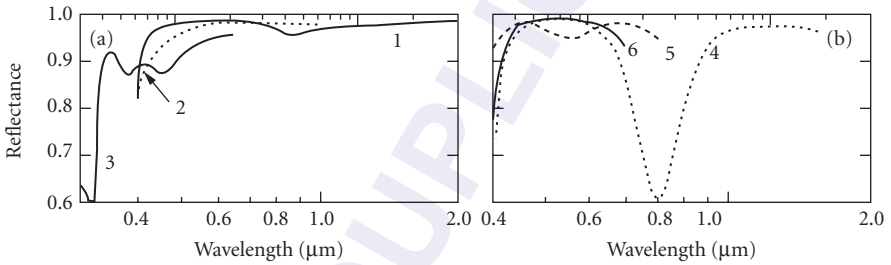

FIGURE 134 Reflectance of very durable overcoated metal mirrors. (*a*) Silver mirrors: curve 1: protected front-surface mirror (*after Denton*[535]); curve 2: enhanced reflection (*after Vvedenskii*[536]); curve 3: extended reflection (*after Song et al.*[537]). (*b*) Aluminum mirrors: curve 4: with four layers of MgF_2 and CeO_2 (*after Hass*[534]); curve 5: with four layers of SiO_2 and TiO_2 (*after AIRCO*[538]); and curve 6: with four layers MgF_2 and ZnS (*after Furman and Stolov*[539]).

coating of MgF_2 [540–542] or LiF. [540,543,544] The reflectances of such overcoated aluminum reflectors are shown in Fig. 135. Their variation with angle of incidence in the 0.03 to 0.16 μm spectral region is discussed by Hunter. [56]

The reflectance of unprotected and protected silver mirrors has been investigated by Burge et al.[545] Highly adherent and chemically stable mirrors with a reflectance in excess of 0.95 for wavelengths greater than 0.5 μm have been reported.[546,547]

The reflectance of protected metal mirrors at oblique angles of incidence in the infrared part of the spectrum can be seriously reduced at the short-wavelength side of the Reststrahlen peak of the material used for its protection.[548–551]

Enhancement of Reflection

By depositing a quarter-wave stack (Sec.7.6 subsections "Nonabsorbing $[AB]^N$ and $[AB]^N A$ Multilayer Types" and "Periodic Multilayers of the $[(0.5A)\ B\ (0.5A)]^N$ Type") onto the metal mirror its reflectance can be enhanced considerably.[387] The thickness of the first layer should be adjusted to compensate for the phase change on reflection at the metal surface.[552] The spectral-reflectance curve dips on either side of the high-reflection region whose width is governed by the considerations of Sec. 7.6, subsection "Width of the High-Reflectance Zone" and which can be somewhat enhanced by the use of a half-wave outermost layer (Fig. 134). The measured spectral characteristics of three metal-dielectric reflectors for the ultraviolet region are shown in Fig. 136.

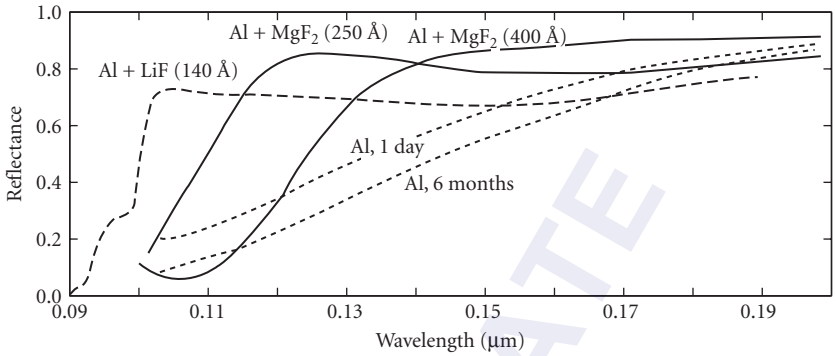

FIGURE 135 Measured spectral-reflectance curves of unprotected aluminum and aluminum overcoated with MgF_2 and LiF films of indicated thicknesses. (*Al + LiF coating after Cox et al.*[544] and *all other curves after Canfield et al.*[541])

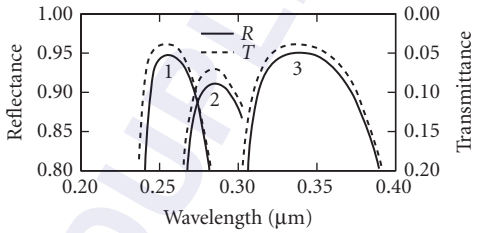

FIGURE 136 Enhanced ultraviolet reflectances of semitransparent aluminum films obtained through the addition of quarter-wave stacks. Curves 1 and 2: eleven layers of PbF and MgF_2 (*after Leś et al.*[553]); curve 3: nine layers of Sb_2O_5 and MgF_2 (*after Leś and Leś*[554]).

The reflectance of silver, although very high in the visible, falls of rapidly in the near-ultraviolet. Attempts to enhance the reflectance in that part of the spectrum and, at the same time, to protect the silver from tarnish, have been successfull (Fig. 134*a*).[537]

A different kind of reflection enhancement has been reported for the extreme ultraviolet. By depositing semi-transparent platinum films onto different substrates the opaque-film reflectances of 19.3 and 12.8 percent at 0.0584 and 0.0736 μm were increased by up to 2.8 and 3.8 percent, respectively.[555] For space applications suitably thick aluminum films on iridium are expected to yield reflectances as high as 40 and 52 percent at the same wavelengths (Fig. 137). Other proposed reflectance-increasing combinations can be found in Madden et al.[556]

Selective Metal-Dielectric Reflectors Several types of coatings that reflect highly in one spectral region, but not in another have been developed in the past for different applications. Hadley and Dennison presented the theory and experimental results of reflection interference filters for the isolation of narrow spectral regions (Fig. 138*a*).[558,559] Very narrow reflection filters have been described by Zheng (Fig. 138*b*).[560] High-infrared and low-visible reflectance coatings (Fig. 66) are used to control the temperature of satellites.[138] These coatings could also be used to remove visible light from infrared optical systems. Several reflectors designed to reduce stray visible light in ultraviolet systems are shown in Fig. 139.

(*b*) Calculated and experimental performance of a very narrow band near-infrared reflecting filter (*after Gamble*[563]).

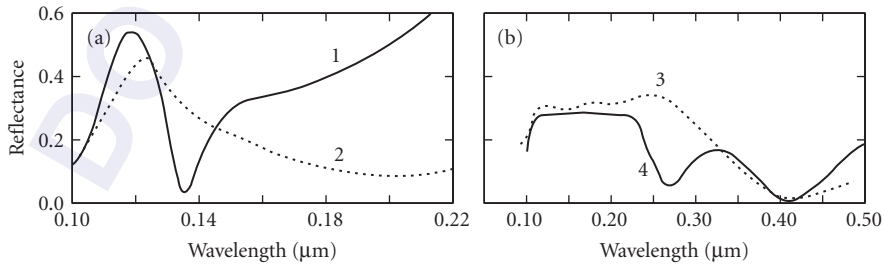

FIGURE 139 Measured performance of four multilayer selective ultraviolet reflectors for the control of stray radiation in the intermediate ultraviolet and visible spectral regions (*a*) and (*b*). (*Curve 1 after Hunter;*[528] *curve 2 after Berning et al.,*[564] *and curves 3 and 4 after Hass and Tousey.*[542])

Reflection at Angles Close to Grazing Incidence

At wavelengths much shorter than the ultraviolet, all materials have refractive indices that are close to unity and extinction coefficients that are rather small. It follows from Eq. (80) that normal incidence reflectances in that part of the spectrum are small. However, for angles of incidence greater than the critical angle θ_c,

$$\theta_c = \cos^{-1}[\sqrt{2(1-n_s)}] \tag{81}$$

total external reflection occurs resulting in high reflectances. Measured values of oblique angle reflection coefficients in the 0.0023 to 0.019 μm spectral region for a number of materials are given by Lukirskii et al.[565,566] and also on Henke's website.[254] Typical spectral reflectance curves of some elements are shown in Fig. 140*a* and *b*. An Al reflectance of 0.987 for an angle of incidence of 80° at 0.0584 μm has been reported by Newnam.[567] It has also been shown that two or three thin films on a suitable substrate can have a better performance than a single metal layer (Fig. 140*c*).[568] Higher reflectances can be achieved with periodic and nonperiodic multilayers designed for use at grazing incidence. For use in near-grazing incidence telescope optics for the soft x-ray region it may also be a requirement that, for a given wavelength, the reflectance stays constant over a small range of angles. Nonperiodic systems with such properties are sometimes called "supermirrors" and they can be composed of hundreds of layers. The performances of several such coatings are shown in Fig. 141.

Multiple-Reflection Filters

Metal and Metal-Dielectric Multiple-Reflection Filters Metals such as silver, copper, gold, and metal-dielectric coatings of the type shown in Fig. 64*a* used in a multiple-reflection arrangement should make low-wavelength cutoff filters with excellent rejection, sharp transition, and a long, unattenuated pass region far superior to those available with transmission filters.

Multiple-Reflection Filters Made of Thin-Film Interference Coatings Interference coatings for use in a multiple-reflection filter need not be deposited onto substrates that transmit well in the spectral region of interest, but they should be used at small angles of incidence if disturbing effects due to polarization are not to occur.[578] The following are examples of some of the difficult filtering problems that can be easily solved with multiple reflection filters composed of interference coatings, providing that there is space to use a multiple reflection arrangement.

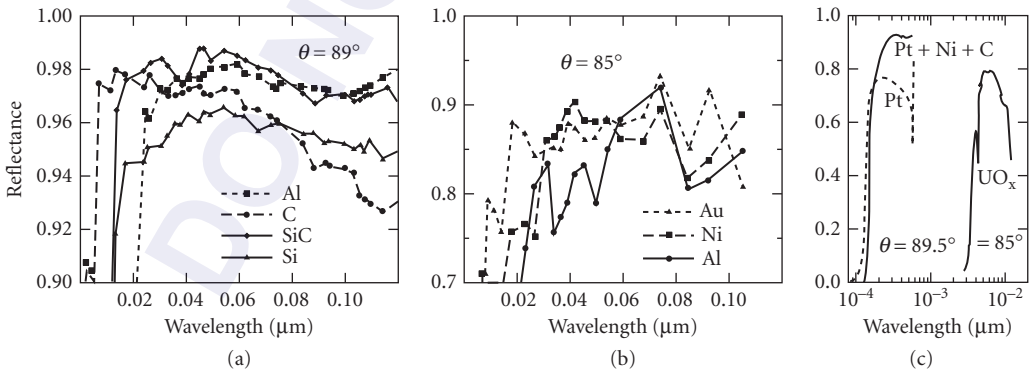

FIGURE 140 Measured XUV and x-ray reflectances of (*a*) Al, Si, C, and CVD SiC films (*after Windt et al*[569]); (*b*) Ni, Au, and Al films (*after Malina and Cash*[570]); and (*c*) uranium oxide (*after Sandberg et al*[571]) and a single Pt layer and a triple layer of Pt, Ni, and C (*after Tamura et al.*[568]). The angles of incidence are indicated in the diagrams.

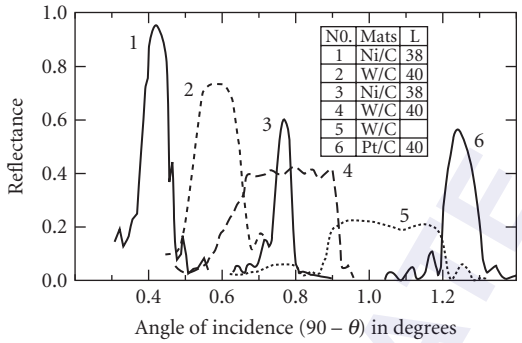

FIGURE 141 Measured reflectances of some mirrors operating at near-grazing angles of incidence for 8 keV (λ = 0.0001543 μm) radiation. The total number of layers and the materials used in their construction are indicated in the table. (*Curve 1 after Spiga;*[572] *curve 2 after Protopopov;*[573] *curve 3 after Citterio;*[574] *curve 4 after Protopopov;*[575] *curve 5 after Wang;*[576] *and curve 6 after Yamashita.*[577])

It is difficult to provide adequate blocking with transmission filters for narrow-bandpass filters of the type shown in Figs. 97 to 102 without considerably reducing the peak transmittance. This is done readily with a multiple-reflection filter composed of quarter-wave stacks of the same materials used for the construction of the bandpass filter and centered at the same wavelength (Fig. 142).

It should be possible to construct highly efficient short-pass filters with a very long and low rejection region by using broadband reflectors consisting of several contiguous stacks (Sec. 7.7, subsection "Rejection Filters").

The use of a narrowband transmission filter in a multiple reflection arrangement of the type shown in Fig. 3 results in a high attenuation narrowband rejection filter surrounded by regions of high transmission (Fig. 143). However, such devices must be used with well-collimated light.

The transmittance curves of three multiple-reflection bandpass filters are shown in Fig. 144*a* to *c*. By using a number of multiple reflection filters with sharp features it is possible to seperate signals

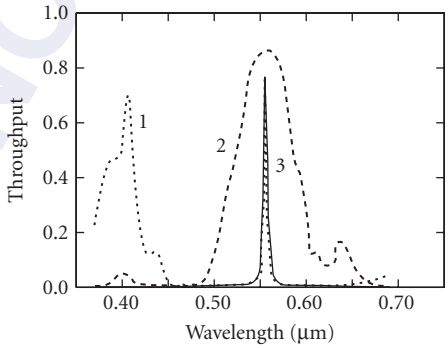

FIGURE 142 Blocking an all-dielectric narrowband interference filter with a multiple-reflection filter. (*a*) Eight reflections (solid curves) from identical quarter-wave stacks (dotted); (*b*) six reflections (solid) from each of two quarter-wave stacks (dotted, dashed) tuned to different wavelengths (*after Valeyev*[579]); and (*c*) commercial multiple-reflection interference filter (*Schott & Gen.*[580]).

transmitted by radiation of different, closely spaced wavelengths with a very low cross-talk and small insertion loss.[514]

Additional information on reflection coatings and filters will be found in the reviews by Hass et al. and by Lynch.[581,582]

7.17 SPECIAL PURPOSE COATINGS

Space considerations limit the detailed description of coatings and filters for specific applications. Absorbing multilayer coatings on glass for enhancing the visual appearance, thermal and illumination control, and as "one-way-mirrors" find applications in architecture and in the automotive

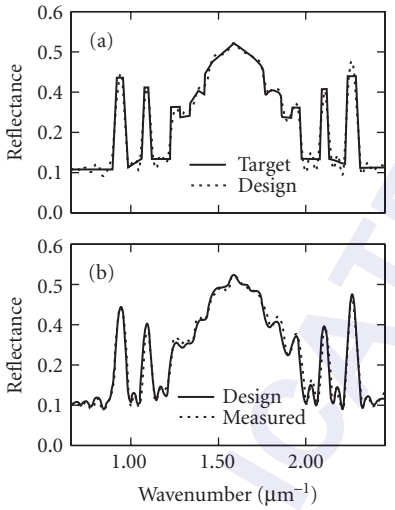

FIGURE 145 Calculated and experimentally measured reflectance of a filter that approximates the silhouette of the Taj Mahal. (*After Sullivan and Dobrowolski.*[583])

industry. They are also used in solar energy conversion and have been proposed for radiative cooling. Thin-film coatings are used in optical recording media and in optical multiplexers/demultiplexers. Bistable Fabry-Perot structures are proposed for use as light switches in optical computers. Special filters and coatings are used in colorimetry, radiometry, detectors, and in high contrast display devices. Consumer-oriented products include various kinds of decorative coatings, as well as coatings for the protection of documents and products from counterfeiting. There is no doubt that in the future even more applications will appear for optical multilayer coatings. Some of these will require very complex spectral charateristics. At the time of writing of the second edition of this *Handbook*, methods for the design and manufacture of such coatings have just been demonstrated (Fig. 145). Now much more complicated correction and gain flattening filters (Fig. 115*a*) are important components for the telecommunications industry and they are routinely produced by many companies and laboratories.

The author would like to acknowledge the help and encouragement of his colleagues, Brian T. Sullivan, Li Li, Claude Montcalm, Pierre Verly, Daniel Poitras, Jeffrey Wong, and Allan Waldorf.

8.1 GLOSSARY

$\underline{\mathbf{A}}$	vector field
$\underline{\mathbf{B}}$	magnetic induction
c	speed of light
$\underline{\mathbf{D}}$	displacement field
d_M	penetration depth of material
d_{TIR}	evanescent field depth for total internal reflection
$\underline{\mathbf{E}}$	electric field
$\mathscr{E}_g$	band gap energy
$\underline{\mathbf{E}}_{\mathrm{loc}}$	local electric field
$-e$	electronic charge
e_i^{ρ}	components of unit vectors of incident polarization
e_s^{ρ}	components of unit vectors of scattered polarization
f_j	oscillator strength
$\underline{\mathbf{G}}$	reciprocal lattice vector
$\mathbf{H}$	hamiltonian
$\underline{\mathbf{H}}$	magnetic field
I	irradiance
$\underline{\underline{\mathbf{I}}}$	unit tensor
$\underline{\mathbf{J}}_{\mathbf{c}}$	conduction current density
$\underline{\underline{\mathbf{K}}}$	dielectric constant or relative permittivity
$\underline{\mathbf{k}}$	electron wavevector
$\underline{\mathbf{M}}$	induced magnetization
m	electron mass
m^*	effective electron mass

$\mathbf{N}$	charge density
N_L	refractive index for left circularly polarized light
N_R	refractive index for right circularly polarized light
n	real part of refractive index
P	Kane momentum matrix element
$\underline{\mathbf{P}}$	induced dipole moment per unit volume
P_D	dielectric amplitude reflection polarization ratio
$\mathbf{p}_{j'j}$	momentum matrix element
P_M	metallic amplitude reflection polarization ratio
$P_{p\sigma,\mathbf{ij}}$	elasto-optic coefficients
$\mathbf{p}$	electron momentum
$\tilde{\mathbf{q}}$	complex photon wavevector
$\hat{\mathbf{q}}$	unit photon wavevector
R	reflectance
R_{ex}	exciton Rydberg
$\mathbf{P}_{\sigma,p}$	Raman scattering coefficient
r_p	field reflection amplitude for p-polarization
r_s	field reflection amplitude for s-polarization
$\underline{\mathbf{S}}$	Poynting vector
s_{ij}	components of lattice strain
S_R	Raman scattering efficiency
S_j	phonon oscillator strength
T	transmittance
t_p	field transmission amplitude for p-polarization
t_s	field transmission amplitude for s-polarization
V	volume of unit cell
$\mathbf{P}(\underline{r})$	periodic lattice potential
v	phase velocity
$\mathrm{W}(\omega)$	transition rate
Z	number of electrons per atom
α	absorption coefficient
β	two-photon absorption coefficient
Γ	damping constant
Δ_D	dielectric reflection polarization phase difference
Δ_M	metallic reflection polarization phase difference
Δ_S	specific rotary power
Δ_{SO}	spin-orbit splitting
δ	energy walk-off angle
$\underline{\underline{\varepsilon}}$	electrical permittivity
$\tilde{\varepsilon}$	complex permittivity
$\varepsilon(\infty)$	high frequency permittivity
$\varepsilon(0)$	static permittivity
ε_1	real part of permittivity
ε_2	imaginary part of permittivity
ε_o	electrical permittivity of vacuum

$\tilde{\eta}$	complex refractive index
$\bar{\theta}$	principal angle for metallic reflection
θ_{OA}	angle between optic axis and principal axis
θ_B	Brewster's angle
θ_C	total internal reflection critical angle
θ_{TIR}	phase change for total internal reflection
κ	imaginary part of refractive index
$\underline{\underline{\mu}}$	magnetic permeability
μ_o	magnetic permeability of vacuum
ξ	Hooke's law constant
$\hat{\xi}$	unit polarization vector
ρ_f	free charge density
ρ_p	band or polarization charge density
ρ_p	real field amplitude for p-polarization
ρ_s	real field amplitude for s-polarization
ρ_t	total charge density
$\tilde{\sigma}$	complex conductivity
$\underline{\underline{\sigma}}$	electrical conductivity
σ_1	real part of conductivity
σ_2	imaginary part of conductivity
τ	scattering or relaxation time
ϕ	scalar field
$\phi_{i'}$	ground state wavefunction
$\tilde{\chi}$	complex susceptibility
χ'	real part of susceptibility
χ''	imaginary part of susceptibility
$\underline{\underline{\chi}}_e$	electrical susceptibility
$\underline{\underline{\chi}}_m$	magnetic susceptibility
$\psi_{\underline{\mathbf{k}}}$	Bloch solution wavefunction
ω	photon frequency
ω_j	resonant oscillation frequency
ω_{LO}	longitudinal optical phonon frequency
ω_p	plasma frequency
ω_s	surface frequency
ω_{TO}	transverse optical phonon frequency

8.2 INTRODUCTION

This chapter describes the fundamental interactions of light with solids. The discussion is restricted to *intrinsic* optical properties. *Extrinsic* optical properties of solids are described in Chap. 10, "Optical Spectroscopy and Spectroscopic Lineshapes," by Brian Henderson in Vol. I. Basic formulas, definitions, and concepts are listed for reference and as a foundation for subsequent chapters of this *Handbook*. More detailed accounts of specific optical properties and particular types of solids are given in later chapters, that is, Chap. 7, "Optical Properties of Films and Coatings,"

by Jerzy A. Dobrowolski in this volume and Chap. 7, "Electro-Optic Modulators" by Georgeanne M. Purvinis and Theresa A. Maldonado in Vol. V. The reader is referred to the many texts which provide more elaborate discussions of the optical properties of solids.[1-13]

Electrical measurements distinguish three general types of solid by their conductivities, i.e., dielectrics, semiconductors, and metals. Optically, these three groups are characterized by different fundamental bandgap energies, $\mathscr{E}_g$. Although the boundaries are not sharply defined, an approximate distinction is given by metals, $\mathscr{E}_g \leq 0$, semiconductors, $0 < \mathscr{E}_g < 3$ eV, and dielectrics, $\mathscr{E}_g > 3$ eV. Solids may be found in single crystal, polycrystalline, and amorphous forms. Rudimentary theories of the optical properties of condensed matter are based on light interactions with perfect crystal lattices characterized by extended (nonlocal) electronic and vibrational energy states. These eigenstates are determined by the periodicity and symmetry of the lattice and the form of the Coulomb potential which arises from the interatomic bonding.

The principal absorption bands in condensed matter occur at photon energies corresponding to the frequencies of the lattice vibrations (phonons) in the infrared, and electronic transitions in the near infrared, visible, or ultraviolet. A quantum mechanical approach is generally required to describe electronic interactions but classical models often suffice for lattice vibrations. Although the mechanical properties of solids can vary enormously between single crystal and polycrystalline forms, the *fundamental* optical properties are similar, even if the crystallite size is smaller than a wavelength, since the optical interaction is microscopic. However, electronic energy levels and hence optical properties are fundamentally altered when one or more dimensions of a solid are reduced to the scale of the de-Broglie wavelength of the electrons. Modern crystal growth techniques allow fabrication of atomic precision epitaxial layers of different solid materials. Ultrathin layers with dimensions comparable with or smaller than the de-Broglie wavelength of an electron may form quantum wells, quantum wires, and quantum dots in which electronic energy levels are quantized. Amorphous solids have random atomic or molecular orientation on the distance scale of several nearest neighbors, but generally have well-defined bonding and local atomic order which determine the overall optical response.

8.3 PROPAGATION OF LIGHT IN SOLIDS

Dielectrics and semiconductors provide transparent spectral regions at radiation frequencies between the phonon vibration bands and the fundamental (electronic) absorption edge. Maxwell's equations successfully describe the propagation, reflection, refraction, and scattering of harmonic electromagnetic waves.

Maxwell's Equations

Four equations relate the macroscopically averaged electric field **E** and magnetic induction **B**, to the total charge density, ρ_t, (sum of the bound or polarization charge, ρ_p and the free charge, ρ_f), the conduction current density, $\mathbf{J}_c$, the induced dipole moment per unit volume, **P**, and the induced magnetization of the medium, **M**, (expressed in SI units),

$$\nabla \cdot \mathbf{E} = \frac{\rho_t}{\varepsilon_o} \tag{1}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{2}$$

$$\nabla \cdot \mathbf{B} = 0 \tag{3}$$

$$\nabla \times \mathbf{B} = \mu_o \left(\varepsilon_o \frac{\partial \mathbf{E}}{\partial t} + \frac{\partial \mathbf{P}}{\partial t} + \mathbf{J}_C + \nabla \times \mathbf{M} \right) \tag{4}$$

where $\varepsilon_o = 8.854 \times 10^{-12}$ F/m is the permittivity of vacuum, $\mu_o = 4\pi \times 10^{-7}$ H/m is the permeability of vacuum and c the speed of light in vacuum, $c = (\varepsilon_o \mu_o)^{-1/2}$. By defining a displacement field, **D**, and magnetic field, **H**, to account for the response of a medium

$$\mathbf{D} = \mathbf{P} + \varepsilon_o \mathbf{E} \tag{5}$$

$$\mathbf{H} = \frac{\mathbf{B}}{\mu_o} - \mathbf{M} \tag{6}$$

and using the relation between polarization and bound charge density,

$$-\nabla \cdot \mathbf{P} = \rho_p \tag{7}$$

Equations (1) and (4) may also be written in the form

$$\nabla \cdot \mathbf{D} = \rho_f \tag{8}$$

and

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} + \mathbf{J_c} \tag{9}$$

Vector **A** and scalar ϕ fields may be defined by

$$\mathbf{B} = \nabla \times \mathbf{A} \tag{10}$$

$$\mathbf{E} = -\nabla \varphi - \frac{\partial \mathbf{A}}{\partial t} \tag{11}$$

A convenient choice of gauge for the optical properties of solids is the Coulomb (or transverse) gauge

$$\nabla \cdot \mathbf{A} = 0 \tag{12}$$

which ensures that the vector potential **A** is transverse for plane electromagnetic waves, while the scalar potential represents any longitudinal current and satisfies Poisson's equation

$$\nabla^2 \varphi = -\frac{\rho_t}{\varepsilon_o} \tag{13}$$

Three constitutive relations describe the response of conduction and bound electrons to the electric and magnetic fields

$$\mathbf{J_c} = \underline{\underline{\sigma}} \mathbf{E} \tag{14}$$

$$\mathbf{D} = \mathbf{P} + \varepsilon_o \mathbf{E} = \underline{\underline{\varepsilon}} \mathbf{E} \tag{15}$$

$$\mathbf{B} = \mu_o (\mathbf{H} + \mathbf{M}) = \underline{\underline{\mu}} \mathbf{H} \tag{16}$$

where $\underline{\underline{\sigma}}$ is the electrical conductivity, $\underline{\underline{\varepsilon}}$ is the electrical permittivity, and $\underline{\underline{\mu}}$ is the magnetic permeability of the medium and are in general tensor quantities which may depend on field strengths. An alternative relation often used to define a dielectric constant (or relative permittivity), $\underline{\underline{\mathbf{K}}}$ is given by, $\mathbf{D} = \varepsilon_o \underline{\underline{\mathbf{K}}} \mathbf{E}$. In isotropic media using the approximation of linear responses to electric and magnetic fields, σ, ε, and μ are constant scalar quantities.

Electric, $\underline{\underline{\chi}}_e$, and magnetic, $\underline{\underline{\chi}}_m$, susceptibilities may be defined to relate the induced dipole moment, **P**, and magnetism, **M** to the field strengths **E** and **H**,

$$\mathbf{P} = \varepsilon_o \underline{\underline{\chi}}_e \mathbf{E} \tag{17}$$

$$\mathbf{M} = \varepsilon_o \underline{\underline{\chi}}_m \mathbf{H} \tag{18}$$

Thus,

$$\underline{\underline{\varepsilon}} = \underline{\underline{\varepsilon}}_o (\underline{\underline{\mathbf{I}}} + \underline{\underline{\chi}}_e) \tag{19}$$

and

$$\underline{\underline{\mu}} = \mu_o (\underline{\underline{\mathbf{I}}} + \underline{\underline{\chi}}_m) \tag{20}$$

where $\underline{\underline{\mathbf{I}}}$ is the unit tensor.

Wave Equations and Optical Constants

The general wave equation derived from Maxwell's equations is

$$\nabla^2 \mathbf{E} - \nabla(\nabla \cdot \mathbf{E}) - \varepsilon_o \mu_o \frac{\partial^2 \mathbf{E}}{\partial t^2} = \mu_o \left(\frac{\partial^2 \mathbf{P}}{\partial t^2} + \frac{\partial \mathbf{J_c}}{\partial t^2} + \nabla \times \frac{\partial \mathbf{M}}{\partial t} \right) \tag{21}$$

For dielectric, (nonconducting) solids

$$\nabla^2 \mathbf{E} = \mu \varepsilon \frac{\partial^2 \mathbf{E}}{\partial t^2} \tag{22}$$

The harmonic plane wave solution of the wave equation for monochromatic light at frequency, ω,

$$\mathbf{E} = \frac{1}{2} \mathbf{E}_o \exp i(\mathbf{q} \cdot \mathbf{r} - \omega t) + c.c. \tag{23}$$

in homogeneous ($\nabla \varepsilon = 0$), isotropic ($\nabla \cdot \mathbf{E} = 0$, $\mathbf{q} \cdot \mathbf{E} = 0$), nonmagnetic ($\mathbf{M} = 0$) solids results in a complex wavevector, $\tilde{\boldsymbol{q}}$,

$$\tilde{\boldsymbol{q}} = \frac{\omega}{c} \sqrt{\frac{\varepsilon}{\varepsilon_o} + i \frac{\sigma}{\varepsilon_o \omega}} \tag{24}$$

A complex refractive index, $\tilde{\eta}$, may be defined by

$$\tilde{\boldsymbol{q}} = \frac{\omega}{c} \tilde{\eta} \hat{\boldsymbol{q}} \tag{25}$$

where $\hat{\boldsymbol{q}}$ is a unit vector and

$$\tilde{\eta} = n + i\kappa \tag{26}$$

Introducing complex notation for the permittivity, $\tilde{\varepsilon} = \varepsilon_1 + i\varepsilon_2$, conductivity, $\tilde{\sigma} = \sigma_1 + i\sigma_2$, and susceptibility, $\tilde{\chi}_e = \chi_e' + i\chi_e''$, we may relate

$$\varepsilon_1 = \varepsilon = \varepsilon_o (1 + \chi_e') = \varepsilon_o (n^2 - \kappa^2) = -\frac{\sigma_2}{\omega} \tag{27}$$

and

$$\varepsilon_2 = \varepsilon_o \chi_e'' = 2\varepsilon_o n\kappa = \frac{\sigma}{\omega} = \frac{\sigma_1}{\omega} \tag{28}$$

Alternatively,

$$n = \left[\frac{1}{2\varepsilon_o}\left(\sqrt{\varepsilon_1^2 + \varepsilon_2^2} + \varepsilon_1\right)\right]^{1/2} \tag{29}$$

$$\kappa = \left[\frac{1}{2\varepsilon_o}\left(\sqrt{\varepsilon_1^2 + \varepsilon_2^2} - \varepsilon_1\right)\right]^{1/2} \tag{30}$$

The field will be modified locally by the induced dipoles. If there is no free charge, ρ_f, the local field, $\mathbf{E}_{\text{loc}}$, may be related to the external field $\mathbf{E}_i$ in isotropic solids using the Clausius-Mossotti equation which leads to the relation

$$\mathbf{E}_{\text{loc}} = \frac{n^2 + 2}{3}\mathbf{E}_i \tag{31}$$

Energy Flow

The direction and rate of flow of electromagnetic energy is described by the Poynting vector

$$\mathbf{S} = \frac{1}{\mu_o}\mathbf{E} \times \mathbf{H} \tag{32}$$

The average power per unit area, (irradiance, I), W/m^2, carried by a uniform plane wave is given by the time averaged magnitude of the Poynting vector

$$I = \langle \mathbf{S} \rangle = \frac{cn|\mathbf{E}_o|^2}{2} \tag{33}$$

The plane wave field in Eq. (23) may be rewritten for absorbing media using Eqs. (25) and (26)

$$\mathbf{E}(\mathbf{r}, t) = \frac{1}{2}\mathbf{E}_o(\mathbf{q}, \omega)\, \exp\left(-\frac{\omega}{c}\kappa\hat{\mathbf{q}} \cdot \mathbf{r}\right) \exp\left[i\left(\frac{\omega}{c}\mathbf{n}\hat{\mathbf{q}} \cdot \mathbf{r} - \omega t\right)\right] + c.c. \tag{34}$$

The decay of the propagating wave is characterized by the extinction coefficient κ. The attenuation of the wave may also be described by Beer's law

$$I = I_o \exp(-\alpha z) \tag{35}$$

where α is the absorption coefficient describing the attenuation of the irradiance, I, with distance, z. Thus,

$$\alpha = \frac{2\omega\kappa}{c} = \frac{4\pi\kappa}{\lambda} = \frac{\sigma_1}{\varepsilon_o cn} = \frac{\varepsilon_2 \omega}{\varepsilon_o cn} = \frac{\chi_e'' \omega}{cn} \tag{36}$$

The power absorbed per unit volume is given by

$$P_{\text{abs}} = \alpha I = \frac{\omega \chi_e''}{2} \left| \mathbf{E}_o \right|^2 \tag{37}$$

The second exponential in Eq. (34) is oscillatory and represents the phase velocity of the wave, $v = c/n$.

Anisotropic Crystals

Only amorphous solids and crystals possessing cubic symmetry are optically isotropic. In general, the speed of propagation of an electromagnetic wave in a crystal depends both on the direction of propagation and on the polarization of the light wave. The linear electric susceptibility and dielectric constant may be represented by tensors with components of $\underline{\underline{\chi}}_e$ given by

$$P_i = \varepsilon_o \chi_{ij} E_j \tag{38}$$

where i and j refer to coordinate axes. In an anisotropic crystal, $\mathbf{D} \perp \mathbf{B} \perp \mathbf{q}$ and $\mathbf{E} \perp \mathbf{H} \perp \mathbf{S}$, but **E** is not necessarily parallel to **D** and the direction of energy flow **S** is not necessarily in the same direction as the propagation direction **q**.

From energy arguments it can be shown that the susceptibility tensor is symmetric and it therefore follows that there always exists a set of coordinate axes which diagonalize the tensor. This coordinate system defines the principal axes. The number of nonzero elements for the susceptibility (or dielectric constant) is thus reduced to a maximum of three (for any crystal system at a given wavelength). Thus, the dielectric tensor defined by the direction of the electric field vector with respect to the principal axes has the form

$$\begin{bmatrix} \varepsilon_1 & 0 & 0 \\ 0 & \varepsilon_2 & 0 \\ 0 & 0 & \varepsilon_3 \end{bmatrix}$$

The principal indices of refraction are

$$n_i = \sqrt{1 + \chi_{ii}} = \sqrt{\varepsilon_i} \tag{39}$$

with the **E**-vector polarized along any principal axis, i.e., $\mathbf{E} \| \mathbf{D}$. This case is designated as an ordinary or **o**-ray in which the phase velocity is independent of propagation direction. An extraordinary or **e**-ray occurs when both **E** and **q** lie in a plane containing two principal axes with different n. An *optic axis* is defined by any propagation direction in which the phase velocity of the wave is independent of polarization.

Crystalline solids fall into three classes: (a) optically isotropic, (b) uniaxial, or (c) biaxial (see Table 1). All choices of orthogonal axes are principal axes and $\varepsilon_1 = \varepsilon_2 = \varepsilon_3$ in *isotropic* solids. For a *uniaxial* crystal, $\varepsilon_1 = \varepsilon_2 \neq \varepsilon_3$, a single optic axis exists for propagation in direction **3**. In this case, the ordinary refractive index, $n_o = n_1 = n_2$, is independent of the direction of polarization in the **1-2** plane. Any two orthogonal directions in this plane can be chosen as principal axes. For any other propagation direction, the polarization can be divided into an **o**-ray component in the **1-2** plane and a perpendicular **e**-ray component (see Fig. 1). The dependence of the **e**-ray refractive index with propagation direction is given by the ellipsoid,

$$n_j(\theta_i) = \frac{n_i n_j}{(n_i^2 \cos^2 \theta_i + n_j^2 \sin^2 \theta_i)^{1/2}} \tag{40}$$

TABLE 1 Crystalographic Point Groups and Optical Properties

		Point Group	Symbols

where θ_i is defined with respect to optic axis, $i = 3$, and $j = 1$ or 2. $\theta_i = 90°$ gives the refractive index $n_e = n_3$ when the light is polarized along axis **3**. The difference between n_o and n_e is the birefringence. Figure 1*a* illustrates the case of positive birefringence, $n_e > n_o$ and Fig. 1*b* negative birefringence, $n_e < n_o$. The energy walk-off angle, δ, (the angle between **S** and **q** or **D** and **E**) is given by

$$\tan\delta = \frac{n^2(\theta)}{2}\left[\frac{1}{n_3^2} - \frac{1}{n_1^2}\right]\sin 2\theta \tag{41}$$

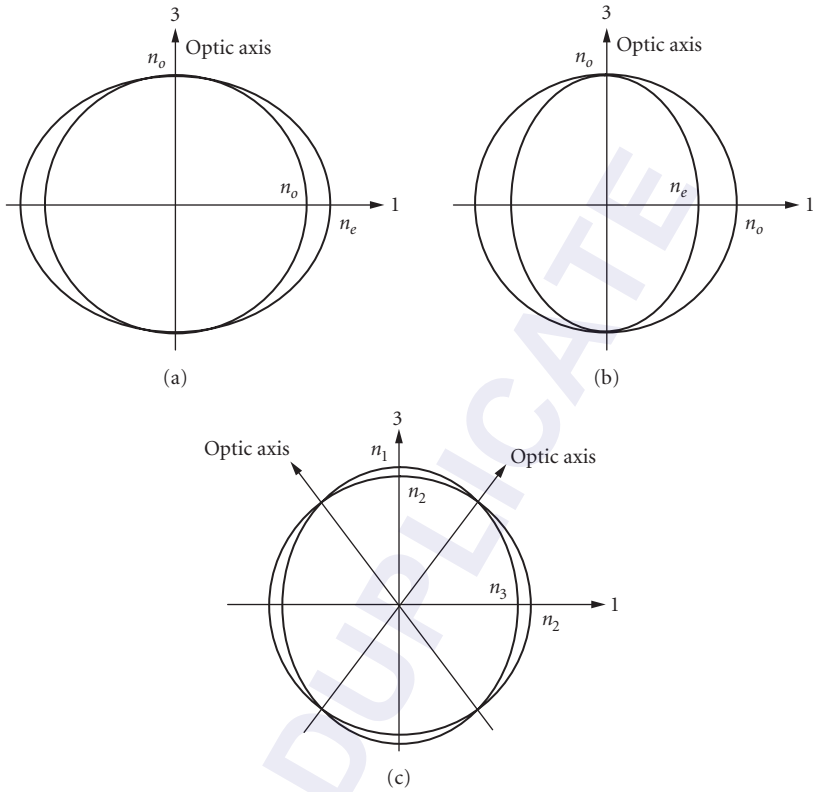

FIGURE 1 Illustration of directional dependence of refractive indices and optic axes in (*a*) a uniaxial, positive birefringent crystal, (*b*) a uniaxial, negative birefringent crystal, and (*c*) biaxial crystal.

In *biaxial* crystals, diagonalization of the dielectric tensor results in three independent coefficients, $\varepsilon_1 \neq \varepsilon_2 \neq \varepsilon_3 \neq \varepsilon_1$. For orthorhombic crystals, a single set of orthogonal principal axes is fixed for all wavelengths. However, in monoclinic structures only one principal axis is fixed. The direction of the other two axes rotates in the plane perpendicular to the fixed axis as the wavelength changes (retaining orthogonality). In triclinic crystals there are no fixed axes and orientation of the set of three principal axes varies with wavelength. Equation (40) provides the **e**-ray refractive index within planes containing two principal axes. Biaxial crystals possess two optic axes. Defining principal axes such that $n_1 > n_2 > n_3$, both optic axes lie in the **1-3** plane, at an angle θ_{OA} from axis **1**, as illustrated in Fig. 1*c*, where

$$\sin\theta_{OA} = \pm\frac{n_1}{n_2}\sqrt{\frac{n_2^{\,2} - n_3^{\,2}}{n_1^{\,2} - n_3^{\,2}}} \tag{42}$$

Crystals with certain point group symmetries (see Table 1) also exhibit optical activity, i.e., the ability to rotate the plane of linearly polarized light. An origin for this phenomenon, is the weak magnetic interaction $\nabla \times \mathbf{M}$ [see Eq. (21)], when it applies in a direction perpendicular to **P** (i.e. $\mathbf{M} \| \mathbf{P}$). The specific rotary power Δ_S, (angle of rotation of linearly polarized light per unit length) is given by

$$\Delta_S = \frac{\pi}{\lambda}(n_L - n_R) \tag{43}$$

where n_L and n_R are refractive indices for left and right circular polarization. Optical activity is often masked by birefringence; however, polarization rotation can be observed in optically active materials when the propagation is along the optic axis or when the birefringence is coincidentally zero in other directions. In the case of propagation along the optic axis of an optically active uniaxial crystal such as quartz, the susceptibility tensor may be written

$$\begin{bmatrix} \chi_{11} & i\chi_{12} & 0 \\ -i\chi_{12} & \chi_{11} & 0 \\ 0 & 0 & \chi_{33} \end{bmatrix}$$

and the rotary power is proportional to the imaginary part of the magnetic susceptibility, $\chi''_m = \chi_{12}$,

$$\Delta_S = \frac{\pi \chi_{12}}{n\lambda} \tag{44}$$

Crystals can exist in left- or right-handed versions. Other crystal symmetries, e.g., $\bar{4}$2m, can be optically active for propagation along the **2** and **3** axes, but rotation of the polarization is normally masked by the typically larger birefringence except at accidental degeneracies.

Interfaces

Applying boundary conditions at a plane interface between two media with different indices of refraction leads to the laws of reflection and refraction. Snell's law applies to all o-rays and relates the angle of incidence, θ_A in medium A and the angle of refraction, θ_B in medium B to the respective ordinary refractive indices n_A and n_B,

$$n_A \sin\theta_A = n_B \sin\theta_B \tag{45}$$

Extraordinary rays do not satisfy Snell's law. The propagation direction for the **e**-ray can be found graphically by equating the projections of the propagation vectors in the two media along the boundary plane. Double refraction of unpolarized light occurs in anisotropic crystals.

The field amplitude ratios of reflected and transmitted rays to the incident ray (r and t) in isotropic solids (and **o**-rays in anisotropic crystals) are given by the Fresnel relations. For s- (σ or TE) polarization (**E**-vector perpendicular to the plane of incidence) (see Fig. 2*a*) and p- (π or TM) polarization (**E**-vector parallel to the plane of incidence) (see Fig. 2*b*):

$$r_s = \frac{E_{\text{rs}}}{E_{\text{is}}} = \frac{n_A \cos\theta_A - \sqrt{n_B^2 - n_A^2 \sin^2\theta_A}}{n_A \cos\theta_A + \sqrt{n_B^2 - n_A^2 \sin^2\theta_A}} \tag{46}$$

$$r_p = \frac{E_{\text{rp}}}{E_{\text{ip}}} = \frac{n_B^2 \cos\theta_A - n_A \sqrt{n_B^2 - n_A^2 \sin^2\theta_A}}{n_B^2 \cos\theta_A + n_A \sqrt{n_B^2 - n_A^2 \sin^2\theta_A}} \tag{47}$$

$$t_s = \frac{E_{\text{ts}}}{E_{\text{is}}} = \frac{2n_A \cos\theta_A}{n_A \cos\theta_A + \sqrt{n_B^2 - n_A^2 \sin^2\theta_A}} \tag{48}$$

$$t_p = \frac{E_{\text{tp}}}{E_{\text{ip}}} = \frac{2n_A n_B \cos\theta_A}{n_B^2 \cos\theta_A + n_A \sqrt{n_B^2 - n_A^2 \sin^2\theta_A}} \tag{49}$$

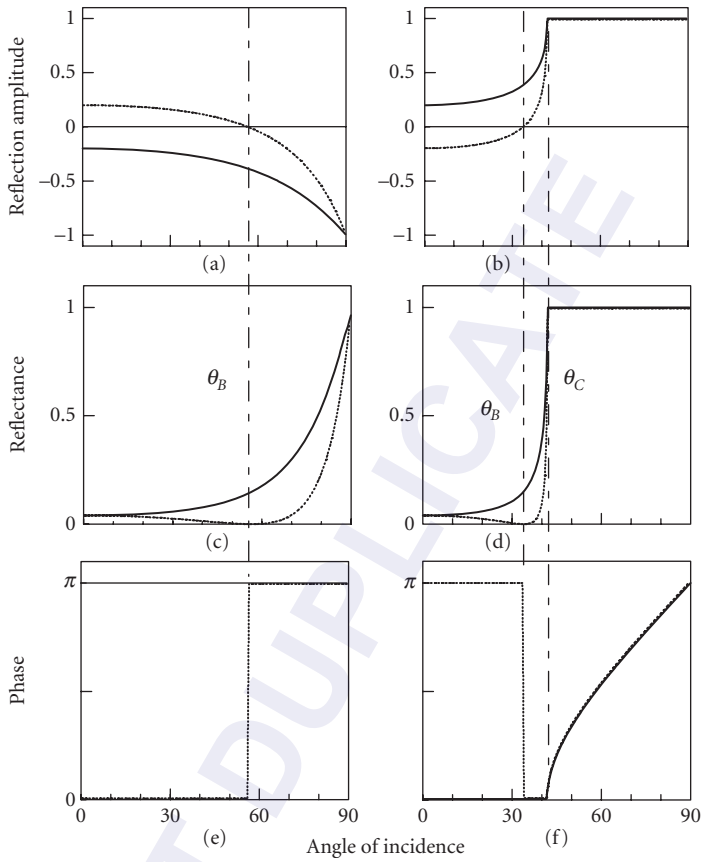

FIGURE 2 The electric field reflection amplitudes (*a*, *b*), energy reflectance (*c*, *d*), and phase change (*e*, *f*) for s- (solid lines) and p- (dashed lines) polarized light for external (*a*, *c*, *e*) and internal (*b*, *d*, *f*) reflection in the case $n_A = 1$, $n_B = 1.5$. θ_B is the polarizing or Brewster's angle and θ_C is the critical angle for total internal reflection.[2]

At normal incidence, the energy reflectance, R, (see Figs. 2*c* and *d*), and transmittance, T, are

$$R = \left|\frac{E_r}{E_i}\right|^2 = \left|\frac{n_B - n_A}{n_B + n_A}\right|^2 \tag{50}$$

$$T = \left|\frac{E_t}{E_i}\right|^2 = \frac{4n_A^2}{\left|n_A + n_B\right|^2} \tag{51}$$

The p-polarized reflectivity, Eq. (47), goes to zero at Brewster's angle under the condition

$$\theta_B = \tan^{-1}\left(\frac{n_A}{n_B}\right) \tag{52}$$

If $n_A > n_B$, total internal reflection (TIR) occurs when the angle of incidence exceeds a critical angle,

$$\theta_C = \sin^{-1}\left(\frac{n_A}{n_B}\right) \tag{53}$$

This critical angle may be different for s- and p-polarizations in anisotropic crystals. Under conditions of TIR, the evanescent wave amplitude drops to e^{-1} in a distance

$$d_{\text{TIR}} = \frac{c}{\omega}\left(n_A^2 \sin^2\theta_A - n_B^2\right)^{-1/2} \tag{54}$$

The phase changes on reflection for external and internal reflection from an interface with $n_A = 1.5$, $n_B = 1$ are plotted in Fig. 2*e* and *f*. Except under TIR conditions, the phase change is either 0 or π. The complex values predicted by Eqs. (46) and (47) for angles of incidence greater than the critical angle for TIR imply phase changes in the reflected light which are neither 0 nor π. The phase of the reflected light changes by π at Brewster's angle in p-polarization. The ratio of *s* to *p* reflectance, P_D, is shown in Fig. 3*a* and the phase difference, $\Delta_D = \phi_p - \phi_s$ in Fig. 3*b*. Under conditions of TIR, the phase change on reflection, ϕ_{TIR}, is given by

$$\tan\frac{\phi_{\text{TIR}}}{2} = \frac{\sqrt{\sin^2\theta_A - \sin^2\theta_C}}{\cos\theta_A} \tag{55}$$

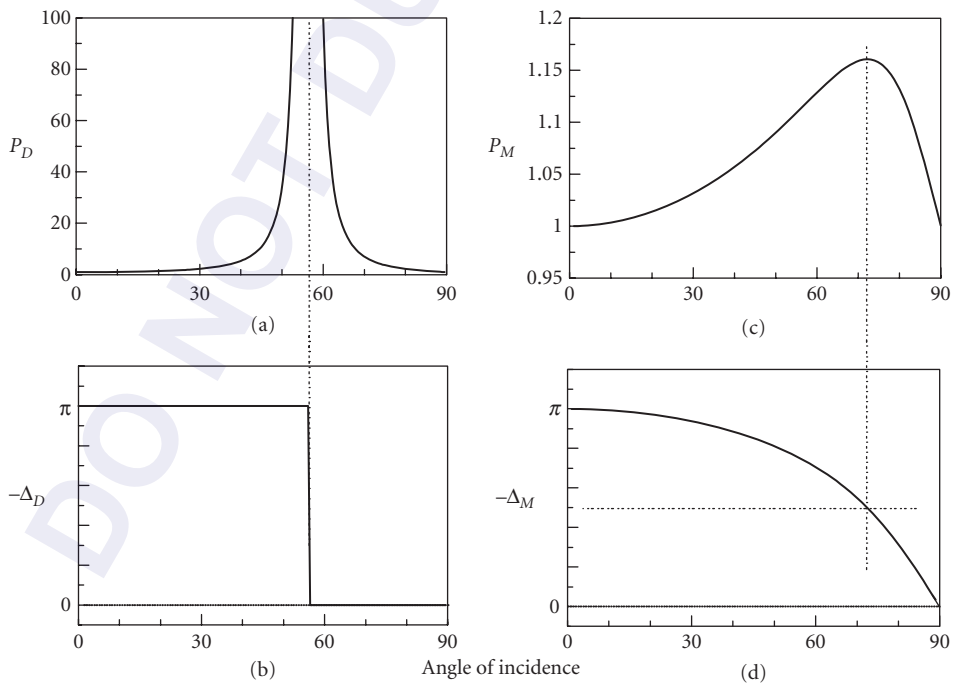

FIGURE 3 Typical polarization ratios, *P*, (*a, c*) and phase differences Δ, (*b, d*) for s- and p-polarizations at dielectric, D, and metallic, M, surfaces.[1]

8.4 DISPERSION RELATIONS

For most purposes, a classical approach is found to provide a sufficient description of dispersion of the refractive index within the transmission window of insulators, and for optical interactions with lattice vibrations and free electrons. However, the details of interband transitions in semiconductors and insulators and the effect of d-levels in transition metals requires a quantum model of dispersion close to these resonances.

Classical Model

The Lorentz model for dispersion of the optical constants of solids assumes an optical interaction via the polarization produced by a set of damped harmonic oscillators. The polarization **P** induced by a displacement **r** of bound electrons of density N and charge $-e$ is

$$\mathbf{P} = -Ne\mathbf{r} \tag{56}$$

Assuming the electrons to be elastically bound (Hooke's law) with a force constant, ξ,

$$-e\mathbf{E}_{\text{loc}} = \xi\mathbf{r} \tag{57}$$

the differential equation of motion is

$$m\frac{d^2\mathbf{r}}{dt^2} + m\Gamma\frac{d\mathbf{r}}{dt} + \xi\mathbf{r} = -e\mathbf{E}_{\text{loc}} \tag{58}$$

where m is the electron mass and Γ is a damping constant. Here the lattice is assumed to have infinite mass and the magnetic interaction has been neglected. Solving the equation of motion for fields of frequency ω gives a relation for the complex refractive index and dielectric constant

$$\tilde{\eta}^2 = \frac{\tilde{\varepsilon}}{\varepsilon_o} = 1 + \frac{Ne^2}{m\varepsilon_o}\sum_j \frac{f_j}{(\omega_j^2 - \omega^2 - i\Gamma_j\omega)} \tag{59}$$

We have given the more general result for a number of resonant frequencies

$$\omega_j = \sqrt{\frac{\xi_j}{m}} \tag{60}$$

where the f_j represents the fraction of electrons which contributes to each oscillator with force constant ξ_j. f_j represents oscillator strengths.

A useful semi-empirical relation for refractive index in the transparency region of a crystal known as the Sellmeier formula follows directly from Eq. (59) under the assumption that, far from resonances, the damping constant terms $\Gamma_j\omega$ are negligible compared to $(\omega_j^2 - \omega^2)$

$$n^2 = 1 + \sum_j \frac{A_j\lambda^2}{\lambda^2 - \lambda_j^2} \tag{61}$$

Sum Rules

The definition of oscillator strength results in the sum rule for electronic interactions

$$\sum_j f_j = Z \tag{62}$$

where Z is the number of electrons per atom. The periodicity of the lattice in solids (see "Energy Band Structures" in Sec. 8.7) leads to the modification of this sum rule to

$$\sum_m f_{mn} = \frac{m}{\hbar^2}\frac{\partial^2 \mathscr{E}_n}{\partial k^2} - 1 = \frac{m}{m_n^*} - 1 \tag{63}$$

where m_n^* is an effective mass (see "Energy Band Structures" in Sec. 8.7).

Another sum rule for solids equivalent to Eq. (62) relates the imaginary part of the permittivity or dielectric constant and the plasma frequency, ω_p,

$$\int_0^\infty \omega \varepsilon_2(\omega)\, d\omega = \frac{1}{2}\pi\omega_p^2 \tag{64}$$

where $\omega_p^2 = Ne^2/\varepsilon_o m$ (see "Drude Model" in Sec. 8.6).

Dispersion relations are integral formulas which relate refractive properties to absorptive process. Kramers-Kronig relations are commonly used dispersion integrals based on the condition of causality which may be related to sum rules. These relations can be expressed in alternative forms. For instance, the reflectivity of a solid is often measured at normal incidence and dispersion relations used to determine the optical properties. Writing the complex reflectivity amplitude as

$$\tilde{r}(\omega) = r_r(\omega)\, e^{i\theta(\omega)} \tag{65}$$

the phase shift, θ, can be determined by integrating the experimental measurement of the real amplitude r_r

$$\theta(\omega) = -\frac{2\omega}{\pi}\mathscr{P}\int_0^\infty \frac{\ln r_r(\omega')}{\omega'^2 - \omega^2}\, d\omega' \tag{66}$$

and the optical constants determined from the complex Fresnel relation

$$r_r(\omega)e^{i\theta} = \frac{(n-1+i\kappa)}{(n+1+i\kappa)} \tag{67}$$

Sum rules following from the Kramers-Kronig relations relate the refractive index $n(\omega)$ at a given frequency, ω, to the absorption coefficient, $\alpha(\omega')$, integrated over all frequencies, ω', according to

$$n(\omega) - 1 = \frac{c}{\omega}\mathscr{P}\int_0^\infty \frac{\alpha(\omega')\, d\omega'}{\omega'^2 - \omega^2} \tag{68}$$

Similarly, the real and imaginary parts of the dielectric constant, ε_1 and ε_2, may be related via the integral relations

$$\varepsilon_1(\omega) - 1 = \frac{2}{\pi}\mathscr{P}\int_0^\infty \frac{\omega'\varepsilon_2(\omega')}{\omega'^2 - \omega^2}\, d\omega' \tag{69}$$

$$\varepsilon_2(\omega) = -\frac{2\omega}{\pi}\mathscr{P}\int_0^\infty \frac{\varepsilon_1(\omega') - 1}{\omega'^2 - \omega^2}\, d\omega' \tag{70}$$

8.5 LATTICE INTERACTIONS

The adiabatic approximation is the normal starting point for a consideration of the coupling of light with lattice vibrations, i.e., it is assumed that the response of the outer shell electrons of the atoms to an electric field is much faster than the response of the core together with its inner electron shells. Further, the harmonic approximation assumes that for small displacements, the restoring force on the ions will be proportional to the displacement. The solution of the equations of motion for the atoms within a solid under these conditions gives normal modes of vibration whose frequency eigenvalues and displacement eigenvectors depend on the crystal symmetry, atomic separation, and the detailed form of the interatomic forces. The frequency of lattice vibrations in solids is typically in the 100 to 1000 cm^{-1} range (wavelengths between 10 and 100 μm). Longitudinal and doubly degenerate transverse vibrational modes have different natural frequencies due to long range Coulomb interactions. Infrared or Raman activity can be determined for a given crystal symmetry by representing the modes of vibration as irreducible representations of the space group of the crystal lattice.

Infrared Dipole Active Modes

If the displacement of atoms in a normal mode of vibration produces an oscillating dipole moment, then the motion is dipole active. Thus, harmonic vibrations in ionic crystals contribute directly to the dielectric function, whereas higher order contributions are needed in nonpolar crystals. Since photons have small wavevectors compared to the size of the Brillouin zone in solids, only zone center lattice vibrations, (i.e. long wavelength phonons), can couple to the radiation. This conservation of wavevector (or momentum) also implies that only optical phonons interact. In a dipole active, long wavelength optical mode, oppositely charged ions within each primitive cell undergo oppositely directed displacements giving rise to a nonvanishing polarization. Group theory shows that, within the harmonic approximation, the infrared active modes have irreducible representations with the same transformation properties as x, y, or z. The strength of the light-dipole coupling will depend on the degree of charge redistribution between the ions, i.e., the relative ionicity of the solid.

Classical dispersion theory leads to a phenomenological model for the optical interaction with dipole active lattice modes. Because of the transverse nature of electromagnetic radiation, the electric field vector couples with the transverse optical (TO) phonons and the maximum absorption therefore occurs at this resonance. The resonance frequency, ω_{TO}, is inserted into the solution of the equation of motion, Eq. (59). Since electronic transitions typically occur at frequencies 10^2 to 10^3 higher than the frequency of vibration of the ions, the atomic polarizability can be represented by a single high frequency permittivity, $\varepsilon(\infty)$. The dispersion relation for a crystal with several zone center TO phonons may be written

$$\tilde{\varepsilon}(\omega)=\varepsilon(\infty)+\sum_j \frac{S_j}{(\omega_{TOj}^2-\omega^2-i\Gamma_j\omega)} \tag{71}$$

By defining a low frequency permittivity, $\varepsilon(0)$, the oscillator strength for a crystal possessing two atoms with opposite charge, Ze, per unit cell of volume, V, is

$$S=\frac{(\varepsilon(\infty)/\varepsilon_0+2)^2(Ze)^2}{9m_rV}=\omega_{TO}^2(\varepsilon(0)-\varepsilon(\infty)) \tag{72}$$

where Ze represents the "effective charge" of the ions, m_r is the reduced mass of the ions and the local field has been included based on Eq. (31). Figure 4 shows the form of the real and imaginary parts of the dielectric constant, the reflectivity and the polariton dispersion curve. Observing that the real part of the dielectric constant is zero at longitudinal phonon frequencies, ω_{LO}, the

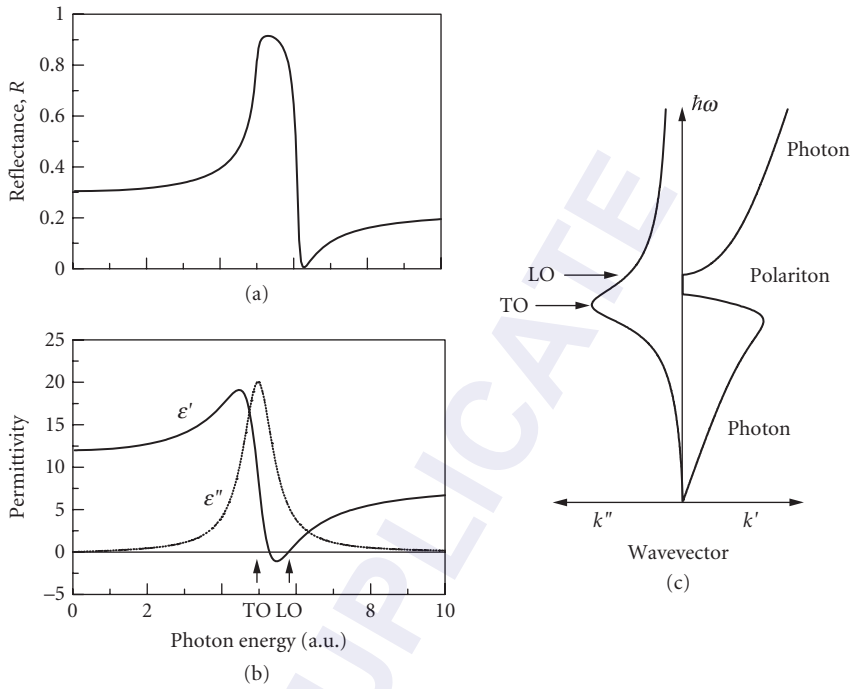

FIGURE 4 (*a*) Reflectance and (*b*) real and imaginary parts of the permittivity of a solid with a single infrared active mode. (*c*) Polariton dispersion curves (real and imaginary parts) showing the frequencies of the longitudinal and transverse optical modes.

Lyddane-Sachs-Teller relation may be derived, which in its general form for a number of dipole active phonons, is given by

$$\frac{\varepsilon(0)}{\varepsilon(\infty)} = \prod_j \left(\frac{\omega_{\mathrm{L}j}}{\omega_{\mathrm{T}j}} \right)^2 \tag{73}$$

These relations [see Eqs. (71) to (73)] give good fits to measured reflectivities in a wide range of ionically (or partially ionically) bonded solids. The LO-TO splitting and effective charge, Ze, depends on the ionicity of the solid; however, the magnitude of Ze determined from experiments does not necessarily quantify the ionicity since this "rigid ion" model does not account for the change of polarizability due to the distortion of the electron shells during the vibration.

In uniaxial and biaxial crystals, the restoring forces on the ions are anisotropic resulting in different natural frequencies depending on the direction of light propagation as well as the transverse or longitudinal nature of the vibration. Similar to the propagation of light, "ordinary" and "extraordinary" transverse phonons may be defined with respect to the principal axes. For instance, in a uniaxial crystal under the condition that the anisotropy in phonon frequency is smaller than the LO-TO frequency splitting, infrared radiation of frequency ω propagating at an angle θ to the optic axis will couple to TO phonons according to the relation

$$\omega_T^2 = \omega_{T\parallel}^2 \sin^2\theta + \omega_{T\perp}^2 \cos^2\theta \tag{74}$$

where $\omega_{T\parallel}$ is a TO phonon propagating with atomic displacements parallel to the optic axis, and $\omega_{T\perp}$ is a TO phonon propagating with atomic displacements perpendicular to the optic axis. The corresponding expression for LO modes is

$$\omega_L^2 = \omega_{L\parallel}^2 \cos^2\theta + \omega_{L\perp}^2 \sin^2\theta \tag{75}$$

In Table 2, the irreducible representations of the infrared active normal modes for the different crystal symmetries are labeled *x*, *y*, or *z*.

Brillouin and Raman Scattering

Inelastic scattering of radiation by acoustic phonons is known as Brillouin scattering, while the term Raman scattering is normally reserved for inelastic scattering from optic phonons in solids. In the case of Brillouin scattering, long wavelength acoustic modes produce strain and thereby modulate the dielectric constant of the medium thus producing a frequency shift in scattered light. In a Raman active mode, an incident electric field produces a dipole by polarizing the electron cloud of each atom. If this induced dipole is modulated by a lattice vibrational mode, coupling occurs between the light and the phonon and inelastic scattering results. Each Raman or Brillouin scattering event involves the destruction of an incident photon of frequency, ω_i, the creation of a scattered photon, ω_s, and the creation or destruction of a phonon of frequency, ω_p. The frequency shift, $\omega_i \pm \omega_s = \omega_p$, is typically 100 to 1000 cm^{-1} for Raman scattering but only a few wavenumbers for Brillouin scattering.

Atomic polarizability components have exactly the same transformation properties as the quadratic functions $x^2, xy, \ldots, z^2$. The Raman activity of the modes of vibration of a crystal with a given point group symmetry can thus be deduced from its group theoretical character table. Polarization selection rules may be deduced from the Raman tensors given in Table 2. The scattering efficiency, S_R, for a mode corresponding to one of the irreducible representations listed is given by

$$S_R = A\left[\sum_{\rho,\sigma} e_i^{\sigma} R_{\sigma,\rho} e_s^{\rho}\right]^2 \tag{76}$$

where A is a constant of proportionality, $R_{\sigma,\rho}$ is the Raman coefficient of the representation, and e_i^{σ} and e_s^{ρ} are components of the unit vectors of polarization of the incident, *i*, and scattered, *s*, radiation along the principal axes, where σ and $\rho = x, y$, and z.

Not all optic modes of zero wavevector are Raman active. Raman activity is often complementary to infrared activity. For instance, since the optic mode in the diamond lattice has even parity, it is Raman active but not infrared active, whereas the zone center mode in sodium chloride is infrared active but not Raman active because the inversion center is on the atom site and so the phonon has odd parity. In piezoelectric crystals, which lack a center of inversion, some modes can be both Raman and infrared active. In this case the Raman scattering can be anomalous due to the long-range electrostatic forces associated with the polar lattice vibrations.

The theory of Brillouin scattering is based on the elastic deformation produced in a crystal by a long wavelength acoustic phonon. The intensity of the scattering depends on the change in refractive index with the strain induced by the vibrational mode. A strain, s_{ij} in the lattice produces a change in the component of permittivity, $\varepsilon_{\mu\nu}$, given by

$$\delta\varepsilon_{\mu\nu} = -\sum_{\rho,\sigma} \varepsilon_{\mu\rho} p_{\rho\sigma,ij} \varepsilon_{\sigma\nu} s_{ij} \tag{77}$$

where $p_{\rho\sigma,ij}$ is an elasto-optical coefficient.[3] The velocity of the acoustic phonons and their anisotropy can be determined from Brillouin scattering measurements.

8.6 FREE ELECTRON PROPERTIES

Fundamental optical properties of metals and semiconductors with high densities of free carriers are well described using a classical model. Reflectivity is the primary property of interest because of the high absorption.

Drude Model

The Drude model for free electrons is a special condition of the classical Lorentz model (Sec. 8.4) with the Hooke's law force constant, $\xi = 0$, so that the resonant frequency is zero. In this case,

$$\frac{\varepsilon_1}{\varepsilon_o} = n^2 - \kappa^2 = 1 - \frac{\omega_p^2}{\omega^2 + \tau^{-2}} \tag{78}$$

and

$$\frac{\varepsilon_2}{\varepsilon_o} = 2n\kappa = \frac{\omega_p^2}{\omega^2 + \tau^{-2}}\left(\frac{1}{\omega\tau}\right) \tag{79}$$

where ω_p is the plasma frequency

$$\omega_p = \sqrt{\frac{Ne^2}{\varepsilon_o m}} = \sqrt{\frac{\mu_o \sigma c^2}{\tau}} \tag{80}$$

and τ (= $1/\Gamma$) is the scattering or relaxation time for the electrons. In ideal metals ($\sigma \to \infty$), $n = \kappa$. Figure 5*a* shows the form of the dispersion in the real and imaginary parts of the dielectric constant for free electrons, while the real and imaginary parts of the refractive index are illustrated in Fig. 5*b*. The plasma frequency is defined by the point at which the real part changes sign. The reflectivity is plotted in Fig. 5*c* and shows a magnitude close to 100 percent below the plasma frequency but falls rapidly to a small value above ω_p. The plasma frequency determined solely by the free electron term is typically on the order of 10 eV in metals accounting for their high reflectivity in the visible.

Interband Transitions in Metals

Not all metals are highly reflective below the plasma frequency. The nobel metals possess optical properties which combine free electron intraband (Drude) and interband contributions. A typical metal has d-levels at energies a few electron volts below the electron Fermi level. Transitions can be optically induced from these d-states to empty states above the Fermi level. These transitions normally occur in the ultraviolet spectral region but can have a significant influence on the optical properties of metals in the visible spectral region via the real part of the dielectric constant. Describing the interband effects $\delta\varepsilon_b$ within a classical (Lorentz) model the combined effects on the dielectric constant may be added.

$$\tilde{\varepsilon} = 1 + \delta\tilde{\varepsilon}_b + \delta\tilde{\varepsilon}_f \tag{81}$$

The interband contribution to the real part of the dielectric constant is positive and shows a resonance near the transition frequency. On the other hand, the free electron contribution is negative below the plasma frequency. The interband contribution can cause a shift to shorter wavelengths of the zero cross-over in ε_1, thus causing a reduction of the reflectivity in the blue. For instance d-states in copper lie only 2 eV below the Fermi level, which results in its characteristic color.

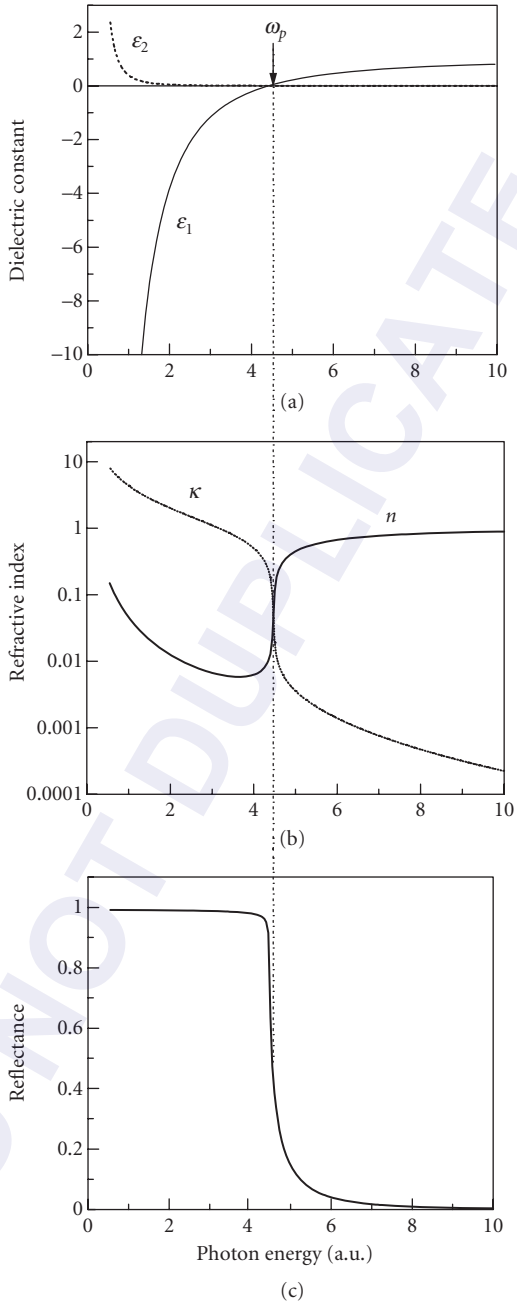

FIGURE 5 Dispersion of: (*a*) the real and imaginary parts of the dielectric constant; (*b*) real and imaginary parts of the refractive index; and (*c*) the reflectance according to the Drude model where ω_p is the plasma frequency.

Reflectivity

Absorption in metals is described by complex optical constants. The reflectivity is accompanied by a phase change and the penetration depth is

$$d_M = \frac{c}{2\omega\kappa} = \frac{\lambda}{4\pi\kappa} \tag{82}$$

At normal incidence at an air-metal interface, the reflectance is given by

$$R = \frac{(n-1)^2+\kappa^2}{(n+1)^2+\kappa^2} = 1 - \frac{2}{\kappa} = 1 - 2\sqrt{\frac{2\varepsilon_o}{\varepsilon_2}} \tag{83}$$

By analogy with the law of refraction (Snell's Law) a complex refractive index can be defined by the refraction equation

$$\sin\theta_t = \frac{1}{\tilde{\eta}}\sin\theta_i \tag{84}$$

Since $\tilde{\eta}$ is complex, θ_t is also complex and the phase change on reflection can take values other than 0 and π. For nonnormal incidence, it can be shown that the surfaces of constant amplitude inside the metal are parallel to the surface, while surfaces of constant phase are at an angle to the surface. The electromagnetic wave in a metal is thus inhomogeneous. The real and imaginary parts of the refractive index can be determined by measuring the amplitude and phase of the reflected light. Writing the s and p components of the complex reflected fields in the form

$$E_{\mathrm{rp}} = \rho_p e^{i\phi_p}; \quad E_{\mathrm{rs}} = \rho_s e^{i\phi_s} \tag{85}$$

and defining the real amplitude ratio and phase differences as

$$P_M = \tan\psi = \frac{\rho_s}{\rho_p}; \qquad \Delta_M = \phi_p - \phi_s \tag{86}$$

then the real and imaginary parts of the refractive index are given by

$$n \approx -\frac{\sin\theta_i \tan\theta_i \cos 2\psi}{1+\sin 2\psi \cos\Delta_M} = -\sin\bar{\theta}_i \tan\bar{\theta}_i \cos 2\bar{\psi} \tag{87}$$

$$\kappa \approx \tan 2\psi \sin\Delta_M = -\tan 2\bar{\psi} \tag{88}$$

$\bar{\theta}_i$ is the principal angle which occurs at the maximum in P_M at the condition $\Delta_M = \pi/2$, (see Fig. 3*c* and 3*d*), which is equivalent to Brewster's angle at an interface between two nonabsorbing dielectrics, (see Fig. 3*a* and 3*b*).

Plasmons

Plasmons are oscillations of fluctuations in charge density. The condition for these oscillations to occur is the same as the condition for the onset of electromagnetic propagation at the plasma frequency. Volume plasmons are not excited by light at normal incidence since they are purely longitudinal. Oscillations cannot be produced by transverse electromagnetic radiation with zero divergence. However at the surface of a solid, an oscillation in surface charge density is possible. At an interface

between a metal with permittivity, ε_m and a dielectric with permittivity, ε_d, the condition $\varepsilon_m = -\varepsilon_d$ such that (neglecting damping and assuming a free electron metal) a surface plasmon can be created with frequency

$$\omega_s = \frac{\omega_p}{(\varepsilon_d/\varepsilon_o + 1)^{1/2}} \tag{89}$$

By altering the angle of incidence, the component of the electromagnetic wavevector can be made to match the surface plasmon mode.

8.7 BAND STRUCTURES AND INTERBAND TRANSITIONS

Advances in semiconductors for electronic and optoelectronic applications have encouraged the development of highly sophisticated theories of interband absorption in semiconductors. In addition, the development of low dimensional structures (quantum wells, quantum wires, and quantum dots) have provided the means of "engineering" the optical properties of solids. The approach here has been to outline the basic quantum mechanical development for interband transitions in solids.

Quantum Mechanical Model

The quantum theory of absorption considers the probability of an electron being excited from a lower energy level to a higher level. For instance, an isolated atom has a characteristic set of electron levels with associated wavefunctions and energy eigenvalues. The absorption spectrum of the atom thus consists of a series of lines whose frequencies are given by

$$\hbar\omega_{\text{fi}} = \mathscr{E}_f - \mathscr{E}_i \qquad (\mathscr{E}_f > \mathscr{E}_i) \tag{90}$$

where $\mathscr{E}_f$ and $\mathscr{E}_i$ are a pair of energy eigenvalues. We also know that the spontaneous lifetime, τ, for transitions from any excited state to a lower state sets a natural linewidth of order $\hbar/\tau$ based on the uncertainty principle. The Schrödinger equation for the ground state with wavefunction, φ_i, in the unperturbed system

$$\mathscr{H}_o \varphi_i = \mathscr{E}_i \varphi_i \tag{91}$$

is represented by the time-independent hamiltonian, $\mathscr{H}_o$. The optical interaction can be treated by first order perturbation theory. By introducing a perturbation term based on the classical oscillator

$$\mathscr{H}' = e\mathbf{E}\cdot\mathbf{r} \tag{92}$$

this leads to a similar expression to the Lorentz model, Eq. (59)

$$\tilde{\eta}^2 = \frac{\varepsilon}{\varepsilon_o} = 1 + \frac{Ne^2}{m\varepsilon_o}\sum_m \frac{f_{\text{fi}}}{(\omega_{\text{fi}}^2 - \omega^2 - i\Gamma_{\text{fi}}\omega)} \tag{93}$$

where

$$f_{j'j} = \frac{2\left|\mathbf{p}_{j'j}\right|^2}{m\hbar\omega_{j'j}} \tag{94}$$

and $\mathbf{p}_{j'j}$ are momentum matrix elements defined by

$$\mathbf{p}_{j'j} = \left\langle \varphi_{j'} \middle| \mathbf{p} \middle| \varphi_j \right\rangle = \int \varphi_{j'}^{*} (i\hbar\nabla)\, \varphi_j d\mathbf{r} \tag{95}$$

Perturbation theory to first order gives the probability per unit time that a perturbation of the form $\mathcal{H}(t) = \mathcal{H}_p \exp(i\omega t)$ induces a transition from the initial to final state,

$$W_{\mathrm{fi}} = \frac{2\pi}{\hbar} \left| \left\langle \varphi_f \middle| \mathcal{H}_p \middle| \varphi_i \right\rangle \right|^2 \delta(\mathscr{E}_f - \mathscr{E}_i - \hbar\omega) \tag{96}$$

This is known as Fermi's golden rule.

Energy Band Structures

If we imagine N similar atoms brought together to form a crystal, each degenerate energy level of the atoms will spread into a band of N levels. If N is large, these levels can be treated as a continuum of energy states. The wavefunctions and electron energies of these energy bands can be calculated by various approximate methods ranging from nearly free electron to tight binding models. The choice of approach depends on the type of bonding between the atoms.

Within the one electron and adiabatic assumptions, each electron moves in the periodic potential, $V(\underline{\mathbf{r}})$, of the lattice leading to the Schrödinger equation for a single particle wavefunction

$$\left[\frac{p^2}{2m} + V(\mathbf{r}) \right] \psi(\mathbf{r}) = \mathscr{E} \psi(\mathbf{r}) \tag{97}$$

where the momentum operator is given by $\mathbf{p} = -ih\nabla$. The simple free electron solution of the Schrödinger equation (i.e., for $V(\underline{\mathbf{r}}) = 0$), is a parabolic relationship between energy and wavevector. The solution including a periodic potential, $V(\underline{\mathbf{r}})$ has the form

$$\psi_{\mathbf{k}}(\mathbf{r}) = \exp(i\mathbf{k}\cdot\mathbf{r}) \cdot u_{\mathbf{k}}(\mathbf{r}) \tag{98}$$

where $\mathbf{k}$ is the electron wavevector and $u_{\mathbf{k}}(\mathbf{r})$ has the periodicity of the crystal lattice. This is known as the Bloch solution. The allowed values of $\mathbf{k}$ are separated by $2\pi/L$, where L is the length of the crystal. The wavevector is not uniquely defined by the wavefunction, but the energy eigenvalues are a periodic function of $\mathbf{k}$. For an arbitrarily weak periodic potential

$$\mathscr{E} = \frac{\hbar^2}{2m} \left| \mathbf{k} + \mathbf{G} \right|^2 \tag{99}$$

where $\mathbf{G}$ is a reciprocal lattice vector (in one dimension $\mathbf{G} = 2\pi n/a$, where a is the lattice spacing and n is an integer. Thus we need only consider solutions which are restricted to a reduced zone, referred to as the first Brillouin zone, in reciprocal space (between $\mathbf{k} = -\pi/a$ and π/a in one dimension). Higher energy states are folded into the first zone consistent with Eq. (99) to form a series of energy bands. Figure 6 shows the first Brillouin zones for face centered cubic (fcc) crystal lattices and energy levels for a weak lattice potential.

A finite periodic potential, $V(\mathbf{r})$, alters the shape of the free electron bands. The curvature of the bands is described by m^*, an "effective mass," which is defined by the slope of the dispersion curve at a given $\mathbf{k}$:

$$\frac{1}{m_{\mathbf{k}}^*} = \frac{1}{\hbar^2 k} \frac{d\mathscr{E}}{dk} \tag{100}$$

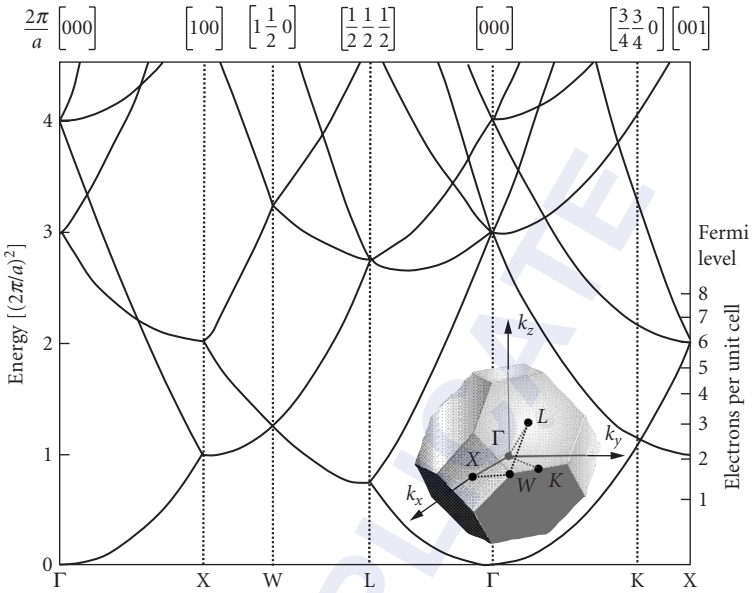

FIGURE 6 Free electron band structure in the reduced Brillouin zone for face-centered-cubic lattices. The insert shows the first Brillouin zone with principal symmetry points labeled. This applies to crystals such as Al, Cu, Ag, Si, Ge, and GaAs.[5]

At the zone center, $\mathbf{k} = 0$, this reduces to the parabolic relationship

$$\mathscr{E} = \frac{\hbar^2 k^2}{2m_o^*} \tag{101}$$

Effective masses can be related to interband momentum matrix elements and energy gaps using perturbation theory. Substituting the Bloch function, Eq. (98), into the Schrödinger equation, Eq. (97), and identifying each band by an index, j, gives

$$\left[\frac{p^2}{2m} + \frac{\hbar}{m}\mathbf{k}\cdot\mathbf{p} + \frac{\hbar^2 k^2}{2m} + V(\mathbf{r})\right] u_{j\mathbf{k}}(\mathbf{r}) = \mathscr{E}_{j\mathbf{k}}(\mathbf{r}) u_{j\mathbf{k}}(\mathbf{r}) \tag{102}$$

The $\mathbf{k}\cdot\mathbf{p}$ term can be treated as a perturbation about a specific point in k-space. For any $\mathbf{k}$, the set of all $u_{j\mathbf{k}}(\mathbf{r})$ (corresponding to the N energy levels) forms a complete set, i.e., the wavefunction at any value of $\mathbf{k}$ can be expressed as a linear combination of all wavefunctions at another $\mathbf{k}$. Second order perturbation theory then predicts an effective mass given by

$$\frac{1}{m^*} = \frac{1}{m} + \frac{2}{m}\sum_{j'} \frac{|\mathbf{p}_{j'j}|^2}{\mathscr{E}_j(\mathbf{k}) - \mathscr{E}_{j'}(\mathbf{k})} \tag{103}$$

In principle the summation in Eq. (103) is over all bands; however, this can usually be reduced to a few nearest bands because of the resonant denominator. For example, in diamond- and zinc-blended structured semiconductors, the Kane momentum matrix element, P, defined by

$$P = -\frac{i\hbar}{m}\left\langle S_{\text{co}} \middle| p_x \middle| X_{\text{vo}} \right\rangle \tag{104}$$

successfully characterizes the band structure and optical properties close to zone center. Here S_{CO} is a spherically symmetric s-like atomic wavefunction representing the lowest zone center conduction band state and X_{VO} is a p-like function with x symmetry from the upper valence bands. In this case, including only the three highest valence bands and the lowest conduction band in the summation of Eq. (91), the conduction band effective mass is given by

$$\frac{1}{m_{co}^*}=\frac{1}{m}+\frac{2}{3\hbar^2}\left[\frac{2P^2}{\mathscr{E}_g}+\frac{P^2}{\mathscr{E}_g+\Delta_{SO}}\right] \tag{105}$$

where $\mathscr{E}_g$ is the band gap energy and Δ_{SO} is the spin-orbit splitting. By inverting this expression, the momentum matrix element may be determined from measurements of effective mass and the bandgaps. P is found to have similar magnitudes for a large number of semiconductors. Equation (105) illustrates the general rule that the effective mass of the conduction band is approximately proportional to the band gap energy.

Direct Interband Absorption

In the case of a solid, the first order perturbation of the single electron hamiltonian by electromagnetic radiation is more appropriately described by

$$\mathscr{H}'(t)=\frac{e}{mc}\mathbf{A}\cdot\mathbf{p} \tag{106}$$

rather than Eq. (92). **A** is the vector potential,

$$\mathbf{A}(\mathbf{r},t)=A_o\hat{\boldsymbol{\xi}}\exp[i(\mathbf{q}\cdot\mathbf{r}-\omega t)]+c.c. \tag{107}$$

$\mathbf{q}$ is the wavevector and $\hat{\boldsymbol{\xi}}$ is the unit polarization vector of the electric field. (Note that this perturbation is of a similar form to the $\mathbf{k}\cdot\mathbf{p}$ perturbation described earlier.) Using Fermi's golden rule, the transition probability per unit time between a pair of bands is given by

$$W_{fi}=\frac{2\pi}{\hbar}\left(\frac{eA_o}{mc}\right)^2\left|\left\langle\psi_f\left|\hat{\boldsymbol{\xi}}\cdot\mathbf{p}\right|\psi_i\right\rangle\right|^2\delta(\mathscr{E}_f(\mathbf{k})-\mathscr{E}_i(\mathbf{k})-\hbar\omega) \tag{108}$$

Conservation of momentum requires a change of electron momentum after the transition; however, the photon momentum is very small, so that vertical transitions in k-space can be assumed in most cases (the electric dipole approximation). The total transition rate per unit volume, $W_T(\omega)$ is obtained by integrating over all possible vertical transitions in the first Brillouin zone taking account of all contributing bands:

$$W_T(\omega)=\frac{2\pi}{\hbar}\left(\frac{2\pi e^2 I}{ncm^2\omega^2}\right)\sum_f\int\frac{d\mathbf{k}}{(2\pi)^3}\left|\hat{\boldsymbol{\xi}}\cdot\mathbf{p}_{fi}(\mathbf{k})\right|^2\delta(\mathscr{E}_f(\mathbf{k})-\mathscr{E}_i(\mathbf{k})-\hbar\omega) \tag{109}$$

Here the vector potential has been replaced with the irradiance, I, of the radiation through the relation

$$A_o=\frac{2\pi c}{n\omega^2}I \tag{110}$$

Note that the momentum matrix element as defined in Eq. (95) determines the oscillator strength for the absorption. $\mathbf{p}_{fi}$ can often be assumed slowly varying in $\mathbf{k}$ so that the zone center matrix element can be employed for interband transitions and the frequency dependence of the absorption coefficient is dominated by the density of states.

Joint Density of States

The delta function in the integration of Eq. (109) represents energy conservation for the transitions between any two bands. If the momentum matrix element can be assumed slowly varying in $\mathbf{k}$, then the integral can be rewritten in the form

$$J_{fi}(\omega)=\frac{1}{(2\pi)^3}\int d\mathbf{k}\,\delta(\mathscr{E}_f(\mathbf{k})-\mathscr{E}_i(\mathbf{k})-\hbar\omega)=\frac{1}{(2\pi)^3}\int\frac{d\mathbf{S}}{|\nabla_k\mathscr{E}_{fi}(\mathbf{k})|} \tag{111}$$

where $d\underline{\mathbf{S}}$ is a surface element on the equal energy surface in $\mathbf{k}$-space defined by $\mathscr{E}_{fi}(\mathbf{k})=\mathscr{E}_f(\mathbf{k})-\mathscr{E}_i(\mathbf{k})=\hbar\omega$. Written in this way, $J(\omega)$ is the joint density of states between the two bands (note the factor of two for spin is excluded in this definition). Points in k-space for which the condition

$$\nabla_k\mathscr{E}_{fi}(\mathbf{k})=0 \tag{112}$$

hold form critical points called van Hove singularities which lead to prominent features in the optical constants. In the neighborhood of a critical point at $\mathbf{k}_c$, a constant energy surface may be described by the Taylor series

$$\mathscr{E}_{fi}(\mathbf{k})=\mathscr{E}_c(\mathbf{k}_c)+\sum_{\mu=1}^{3}\beta_\mu k_\mu^2 \tag{113}$$

where μ represents directional coordinates. Minimum, maximum, and saddle points arise depending on the relative signs of the coefficients, β_μ. Table 3 gives the frequency dependence of the joint density of states in three-dimensional (3D), two-dimensional (2D), one-dimensional (1D), and zero-dimensional (0D) solids. The absorption coefficient, α, defined by Beer's law may now be related to the transition rate by

$$\alpha(\omega)=I^{-1}\frac{dI}{dz}=\frac{\hbar\omega}{I}W_T \tag{114}$$

Thus, the minimum fundamental absorption edge of semiconductors and insulators (in the absence of excitonic effects) has the general form (Fig. 7*a*)

$$\alpha=A(\hbar\omega-\mathscr{E}_o)^{1/2} \tag{115}$$

Selection Rules and Forbidden Transitions

Direct interband absorption is allowed when the integral in Eq. (95) is nonzero. This occurs when the wavefunctions of the optically coupled states have opposite parity for single photon transitions. Transitions may be forbidden for other wavefunction symmetries. Although the precise form of the wavefunction may not be known, the selection rules can be determined by group theory from a knowledge of the space group of the crystal and symmetry of the energy band. Commonly, a single photon transition which is not allowed at the zone center because two bands have like parity, will

TABLE 3 Density of States in 3, 2, 1, and 0 Dimensions

	β_1 β_2 β_3	$E < E_c$	$E > E_c$	
3D				
M_0, min.	+ + +	0	$C_0(E-E_c)^{1/2}$	
M_1, saddle	+ + −	$C_1-C_1'(E_c-E)^{1/2}$	C_1	
M_2, saddle	+ − −	C_2	$C_2-C_2'(E-E_c)^{1/2}$	
M_3, max.	− − −	$C_3(E_c-E)^{1/2}$	0	
2D				
P_0, min.	+ +	0	B	
P_1, saddle	+ −	$-\frac{B}{\pi}\ln\left\|1-\frac{E}{E_c}\right\|$		
P_2, max	− −	B	0	
1D				
Q_0, min.	+	0	$A(E_c-E)^{-1/2}$	
Q_1, max	−	$A(E-E_c)^{-1/2}$	0	
0D		$\delta(E-E_c)$		

be allowed at finite **k** because wavefunction mixing will give mixed parity states. In this case, the momentum matrix element may have the form

$$p_{\mathrm{fi}}(\mathbf{k})=(\mathbf{k}-\mathbf{k}_0)\cdot\nabla_{\mathbf{k}}[p_{\mathrm{fi}}(\mathbf{k})]_{\mathbf{k}=\mathbf{k}_o} \tag{116}$$

that is, the matrix element is proportional to **k**. For interband transitions at an M_0 critical point, the frequency dependence of the absorption coefficient can be shown to be (Fig. 7*b*)

$$\alpha(\omega)=A'(\hbar\omega-\mathscr{E}_o)^{3/2} \tag{117}$$

Indirect Transitions

Interband transitions may also take place with the assistance of a phonon. The typical situation is a semiconductor or insulator which has a lowest conduction band near a Brillouin zone boundary. The phonon provides the required momentum to move the electron to this location but supplies little energy. The phonon may be treated as an additional perturbation and therefore second order

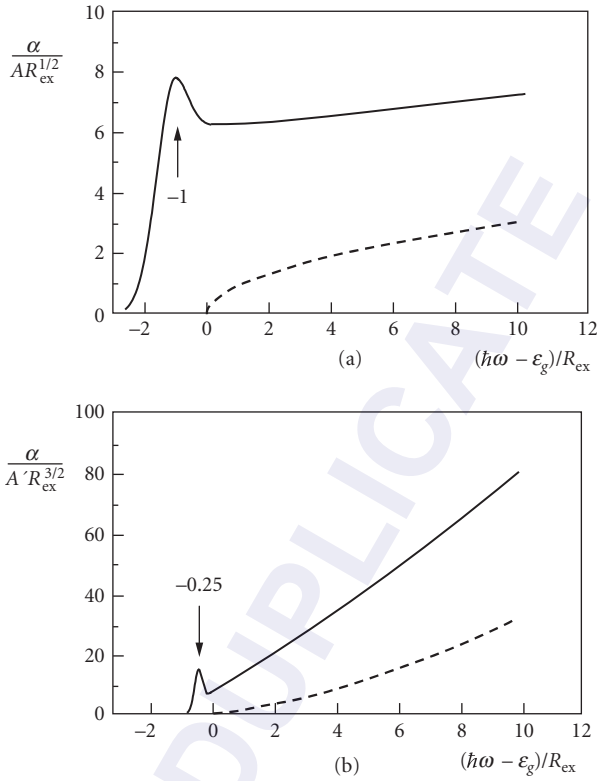

FIGURE 7 Illustration of absorption edge of crystals with: (*a*) direct allowed transitions and (*b*) direct forbidden transitions, based on density of state (dashed lines) and excitonic enhanced absorption models (solid lines).

perturbation theory is needed in the analysis of this two step processes. Theory predicts a frequency dependence for the absorption of the form

$$\alpha(\omega) \approx (\hbar\omega \pm \hbar\omega_{\text{ph}} - \mathscr{E}_o)^2 \tag{118}$$

where ω_{ph} is the phonon frequency, absorption or emission being possible. For forbidden indirect transitions, this relationship becomes

$$\alpha(\omega) \approx (\hbar\omega \pm \hbar\omega_{\text{ph}} - \mathscr{E}_o)^3 \tag{119}$$

Multiphoton Absorption

Multiphoton absorption can be treated by higher order perturbation theory. For instance, second order perturbation theory gives a transition rate between two bands

$$W_{\text{fi}}^{(2)} = \frac{2\pi}{\hbar}\left(\frac{eA_o}{mc}\right)^4 \left| \sum_t \frac{\langle \psi_f | \hat{\xi}\cdot\mathbf{p} | \psi_t \rangle \langle \psi_t | \hat{\xi}\cdot\mathbf{p} | \psi_i \rangle}{\mathscr{E}_t - \mathscr{E}_i - \hbar\omega} \right|^2 \delta(\mathscr{E}_f(\mathbf{k}) - \mathscr{E}_i(\mathbf{k}) - 2\hbar\omega) \tag{120}$$

where the summation spans all intermediate states, *t*. The interaction can be regarded as two successive steps. An electron first makes a transition from the initial state to an intermediate level of the system, *t*, by absorption of one photon. Energy is not conserved at this stage (momentum is) so that the absorption of a second photon must take the electron to its final state in a time determined by the energy mismatch and the uncertainty principle. In multiphoton absorption, one of the transitions may be an intraband self-transition. Since the probability depends on the arrival rate of the second photon, multiphoton absorption is intensity dependent. The total transition rate is given by

$$W_T^{(2)}(\omega)=\frac{2\pi}{\hbar}\left(\frac{4\pi^2e^4I^2}{n^2c^2m^4\omega^4}\right)\sum_f\int\frac{d\mathbf{k}}{(2\pi)^3}\left|\sum_t\frac{\hat{\xi}\cdot\mathbf{p}_{\mathrm{ft}}(\mathbf{k})\,\hat{\xi}\cdot\mathbf{p}_{\mathrm{ti}}(\mathbf{k})}{\mathscr{E}_t-\mathscr{E}_i-\hbar\omega}\right|^2\delta(\mathscr{E}_f(\mathbf{k})-\mathscr{E}_i(\mathbf{k})-2\hbar\omega) \tag{121}$$

The two photon absorption coefficient is defined by the relation

$$-\frac{dI}{dz}=\alpha I+\beta I^2 \tag{122}$$

so that,

$$\beta(\omega)=\frac{2\hbar\omega}{I^2}W_T^{(2)}(\omega) \tag{123}$$

Excitons

The interband absorption processes discussed earlier do not take into account Coulomb attraction between the excited electron and hole state left behind. This attraction can lead to the formation of a hydrogen-like bound electron-hole state or exciton. The binding energy of free (Wannier) excitons is typically a few meV. If not thermally washed out, excitons may be observed as a series of discreet absorption lines just below the bandgap energy. The energy of formation of an exciton is

$$\mathscr{E}_{\mathrm{ex}}=\mathscr{E}_g+\frac{\hbar^2|\mathbf{k}|^2}{2(m_e^*+m_h^*)}-\frac{R_{\mathrm{ex}}}{n^2} \tag{124}$$

where R_{ex} is the exciton Rydberg,

$$R_{\mathrm{ex}}=\frac{m_r^*e^4}{2\hbar^2\varepsilon_1^2} \tag{125}$$

m_r^* is the reduced effective mass and n is a quantum number. Optically created electron-hole pairs have equal and opposite momentum which can only be satisfied if $\mathbf{K} = 0$ for the bound pair and results in discreet absorption lines. Coulomb attraction also modifies the absorption above the bandgap energy. The theory of exciton absorption developed by Elliot predicts a modification to Eq. (113) for the direct allowed absorption coefficient above the band edge (Fig. 7*a*)

$$\alpha=\frac{\pi AR_{\mathrm{ex}}^{1/2}e^{\pi\gamma}}{\sinh\pi\gamma} \tag{126}$$

where

$$\gamma=\left(\frac{R_{\mathrm{ex}}}{\hbar\omega-\mathscr{E}_g}\right)^{1/2} \tag{127}$$

Excitons associated with direct forbidden interband transitions do not show absorption to the lowest ($n = 1$) state but transitions to excited levels are allowed. Above the band edge for direct forbidden transitions the absorption has the frequency dependence (Fig. 7*b*)

$$\alpha = \frac{\pi A' R_{\text{ex}}^{3/2}\left(1+\frac{1}{\gamma^2}\right)e^{\pi\gamma}}{\sinh \pi\gamma} \tag{128}$$

Figure 7 compares the form of the absorption edge based on the density of states function and a discreet exciton absorption line (dashed lines) with the absorption functions based on the Elliot theory and a typically broadened exciton (solid lines). Figure 7*a* is an illustration of a direct allowed gap, e.g., GaAs with the $n = 1$ exciton visible and Fig. 7*b* shows a forbidden direct absorption edge, e.g., Cu_2O. In the latter case, optical excitation of the $n = 1$ exciton is forbidden, but the $n = 2$ and higher exciton transitions are allowed.

9.2 INTRODUCTION

Electromagnetic waves are known to undergo partial reflection at dielectric interfaces. The magnitude of the reflection is a function of the wave polarization, angle of incidence, and refractive index of the materials at the interface. Inside quarter-wave stacks, electromagnetic waves undergo reflection at multiple interfaces. The multiple reflections can lead to the destructive interference of the waves and the formation of bands of forbidden electromagnetic states. If the frequency of an electromagnetic wave lies inside such a forbidden band, the wave is prevented from propagating inside the stack; instead it is reflected and its amplitude decays exponentially through successive layers.

The operational principle behind fiber Bragg gratings,[1] interference filters,[2] and distributed feedback (DFB) lasers,[3] is also based on multiple reflections that occur inside periodic dielectric materials. The range of frequencies over which waves are reflected (i.e., over which wave propagation is forbidden) defines a stop band, or bandgap, the width of which is proportional to the grating strength (i.e., to the effective index contrast between the different materials). The range is typically less than 1 percent of the midgap frequency, and in some cases much less than 1 percent.

In addition to being forbidden over a small range of frequencies, propagation in dielectric stacks is also forbidden over a small range of angles from normal incidence. This small range of angles defines a cone with its principal axis normal to the surface. Light incident at an angle outside the cone is not reflected, but rather is transmitted through the stack. To increase the angle of the reflection cone, one can increase the index contrast between the different dielectric layers. The cone can be made to extend as far as 90°, allowing light to be reflected off the stack from *any* angle of incidence.[4] Stacks that reflect light from every direction are referred to as *omnidirectional reflectors*.

The existence of omnidirectional reflectors does not necessarily imply the existence of omnidirectional bandgaps. In fact, omnidirectional reflectors do not have complete three-dimensional (3D) bandgaps. Electromagnetic states exist inside the reflectors at every frequency, but incident light cannot couple to them; the wave vector of the incident light cannot be matched to the wave vector of the electromagnetic states inside the reflector. However, if light were to be generated from *within* the reflector, light could propagate along the dielectric planes—hence the absence of a three-dimensional bandgap.

In order to create a complete three-dimensional bandgap and prevent light from propagating anywhere inside the material, periodic structures must possess a three-dimensional periodicity. The principal feature of three-dimensional (3D) bandgap materials is their ability to eliminate the density of electromagnetic states everywhere inside the materials over a given range of frequencies. Since the rate of spontaneous radiative decay of an atom or molecule scales with the density of allowed states at the transition frequency, photonic bandgap (PBG) materials can be used to greatly affect the radiative dynamics of materials and lead to significant changes in the properties of optical devices.

In addition to affecting the radiative properties of atoms, PBG materials can also be used to control the flow of light by allowing certain states to exist within the bandgap. This feature has triggered the imagination of many researchers as it promises to enable the very large-scale integration of photonic components.

Though three-dimensional PBG materials can completely suppress the density of states, some three-dimensional structures possess partial gaps (i.e., gaps that do not extend along every direction). These pseudogaps can lead to small (but nonzero) densities of states and to significant changes in the radiative properties of materials. Moreover, dielectric stacks, in effect one-dimensional periodic structures, can reduce the density of states by suppressing states with wave vectors normal to the layers but they cannot eliminate every state along every direction.

In this chapter, we discuss the radiative properties of emitters and the control of light flow in PBG materials with pseudogaps and complete gaps. An in-depth review of PBG materials can be found in Ref. 5. Early fabrication efforts of 3D PBG materials are described in Ref. 6; a review of PBG materials at near-infrared frequencies is presented in Ref. 7.

9.3 MAXWELL'S EQUATIONS

Although the word *photon* is used, the appearance of bandgaps arises from a strictly classical treatment of the problem. The properties of PBG materials can be determined from the classical vector wave

equation with a periodic index of refraction. If the fields are expanded in a set of harmonic modes, in the absence of external currents and sources, Maxwell's equations can be written in the following form:

$$\nabla \times \left[\frac{1}{\varepsilon(\mathbf{r})} \nabla \times \mathbf{H}(\mathbf{r}) \right] = \frac{\omega^2}{c^2} \mathbf{H}(\mathbf{r}) \tag{1}$$

where $\mathbf{H}(\mathbf{r})$ is the magnetic field, $\varepsilon(\mathbf{r})$ is the macroscopic dielectric function equal to the square of the index of refraction, $\mathbf{r}$ is the position vector, ω is the angular frequency, and c is the speed of light in vacuum. The macroscopic dielectric function has a periodic spatial dependence. Equation (1) is an eigenvalue problem; it can be rewritten as

$$\Theta \mathbf{H}_i = \frac{\omega_i^2}{c^2} \mathbf{H}_i \tag{2}$$

where

$$\Theta = \nabla \times \frac{1}{\varepsilon(\mathbf{r})} \nabla \times \tag{3}$$

is a periodic Hermitian differential operator and ω_i^2/c^2 is the ith eigenvalue. The solutions $\mathbf{H}_i$ and ω_i are determined entirely from the strength and symmetry properties of $\varepsilon(\mathbf{r})$. The solutions are characterized by a wave vector $\mathbf{k}$ and a band number i. The region of all allowed wave vectors is called a *Brillouin zone*, and the collection of all solutions is termed a *band structure*.

Equation (2) closely resembles Schrödinger's equation for the problem of an electronic wave function inside a periodic atomic potential. Since the solutions of Schrödinger's equation lead to band diagrams for allowed and forbidden electronic states in crystalline structures, and since PBG materials have similar effects on electromagnetic waves, PBG materials are often referred to as *photonic crystals*. In this chapter, the terms *PBG material* and *photonic crystal* are used interchangeably.

An interesting feature of Eq. (1) is that there is no fundamental constant with dimensions of length, hence no fundamental length scale other than the assumption that the system is macroscopic. The solution at one length scale determines the solutions at all other length scales, assuming a frequency-independent dielectric function. This simple fact is of considerable practical importance as it allows results to be scaled from one wavelength to another, from the ultraviolet to microwaves and beyond, simply by expanding all distances.

The solutions $\mathbf{H}_i$ and ω_i provide information about the frequency of the allowed electromagnetic modes in a PBG structure and their polarization, symmetry, and field distribution. Although Eq. (1) can be applied to any dielectric structure—the only assumptions made were the absence of external currents and sources—early work in this field focused on the search for a complete bandgap, that is, a range of frequencies with no allowed electromagnetic mode for any wave vector $\mathbf{k}$ inside the Brillouin zone.[6] A review of three-dimensional photonic crystals follows.

Several numerical methods have been used to solve Maxwell's equations in periodic structures, including the use of a variational approach[8] where each eigenvalue in Eq. (2) is computed separately by minimizing the functional $< \mathbf{H}_i \mid \Theta \mid \mathbf{H}_i >$. In this method, fast Fourier transforms are used repeatedly to switch back and forth between real and reciprocal space to avoid storing large matrices.

Other methods include the transfer matrix method[9] and the finite-difference time-domain (FDTD) method,[10] to name but two. In the former, Maxwell's equations are solved at a fixed frequency by stepping the fields forward in space, one plane at a time, satisfying the continuity conditions at every step. The transfer matrix method is well-suited for transmission and reflection computations in photonic crystals. By imposing Bloch conditions, the transfer matrix method can also be used to compute the band structure. In the case of the FDTD method, Maxwell's equations are discretized on a three-dimensional grid, and the derivatives are approximated at each grid point by a corresponding centered difference. Maxwell's equations are solved everywhere in the computational cell at every time step, allowing the temporal response of the fields to be determined inside photonic crystals.

9.4 THREE-DIMENSIONAL PHOTONIC CRYSTALS

Criteria for 3D Bandgaps

The existence of bandgaps in periodic structures is determined entirely from the symmetry and strength of the periodic dielectric function. Since photonic crystals do not occur naturally, somehow one must arrange dielectric material in a 3D periodic structure, and, as with multilayer dielectric stacks, the length of the repeating unit must be on the order of one-half the wavelength in the material. Most structures exhibiting 3D bandgaps satisfy the following three general criteria: the periodic structure has a spherelike Brillouin zone; the refractive index contrast between the different materials is typically larger than 2; and the high- and low-dielectric materials form connected networks.

Spherelike Brillouin Zone Waves propagating inside a periodic structure sense a periodicity that leads to the formation of stop bands at the edges of the irreducible Brillouin zone. Since the waves sense a different periodicity along the different directions, the wave vectors at the different points on the surface of the Brillouin zone have different magnitudes. Hence, the gaps are likely to be centered at different frequencies. Spherical Brillouin zones (if they were possible) would guarantee the overlap of all the gaps along every direction, since every point on the surface of a sphere is equidistant from the center—but crystal geometries do not allow for spherical Brillouin zones.

Several hundred years of mineralogy and crystallography have led to the classification of the various three-dimensionally periodic lattice geometries. The Brillouin zone of the face-centered-cubic (fcc) lattice is closer to a sphere than any other common crystal geometry. However, despite having the most spherelike Brillouin zone, the farthest point on the surface of the fcc Brillouin zone (i.e., the point with the largest wave vector, the so-called **W** point) lies 29 percent farther from the origin than the closest point, the **L** point. For a gap to open along every direction, the gaps at **W** and **L** must be large enough to overlap.

Large Index Contrast The size of the bandgap at each point on the surface of the Brillouin zone scales with the index contrast between the different materials. For the different gaps to overlap over the entire Brillouin zone the refractive index contrast must be large, typically 2 to 1 or greater. Semiconductor materials such as Si ($n = 3.5$ at $\lambda = 1.5$ μm) and GaAs ($n = 3.4$) in combination with air or low-index oxides are excellent candidates for the fabrication of photonic crystals at infrared wavelengths.

A large index contrast and a spherelike Brillouin zone, however, are not sufficient to guarantee the formation of a bandgap in 3D structures. It is not sufficient to specify the structure in reciprocal space—there are essentially an infinite number of structures with an fcc lattice, since anything can be put inside the fundamental repeating unit. One must also specify the dielectric structure in real space. An example of a successful 3D photonic crystal is shown in the forthcoming section labeled "Examples of 3D Crystals."

Connected Networks To appreciate the importance of having a connected network, it is useful to consider a one-dimensionally periodic structure such as a multilayer dielectric stack. The energy density of the mode below the stop band is more strongly localized in the high-index layers than the mode above the stop band. The more strongly the energy density of the lower mode is localized in the high-index material and the more strongly the energy density of the upper mode is localized in the low-index material, the larger the bandgap.

In 3D periodic structures, it is generally advantageous for the high-index material to be fully connected to allow the electric field of the mode in the lower band to run through the high-index material as much as possible without having to go through the low-index material. One should be able to connect any point in the high-index material to any other point without having to cross over into the low-index material. The same also holds for the low-index material. Moreover, the low-index material should occupy typically over 50 percent of the total volume. A detailed discussion of the nature of bandgaps in periodic structures is given in Refs. 5 and 11.

The three general criteria just presented should serve only as guidelines. They do not constitute necessary conditions for the creation of 3D bandgaps. For example, though the fcc lattice is the most spherelike, other lattice geometries have been shown to generate 3D bandgaps.

Examples of 3D Crystals

The earliest antecedent to photonic bandgaps is the observation by Sir Lawrence Bragg of narrow stop bands in crystals from x-ray diffraction. The refractive index contrast, however, was very small, typically less than 1.001 to 1, and produced only narrow rings on the surfaces of the Brillouin zone.

The first structure with a full 3D bandgap was discovered by K. M. Ho et al. in 1990 and consisted of a diamond lattice of air spheres (i.e., an fcc lattice with two air spheres per unit cell) inside a high-index material.[12] Since then, there has been considerable effort to develop a process for the manufacturing of diamond (or diamondlike) structures at micrometer wavelengths. One such approach consists of etching a large number of hole triplets at off-vertical angles in a slab;[13,14] another consists of building an orderly stacking of dielectric rods;[15] yet another consists of etching a series of horizontal grooves into sequentially grown layers and etching vertical holes.[16] These structures are variations of the same diamond lattice grown along either the (1, 1, 1), (0, 0, 1), or (1, 1, 0) directions, respectively.

An example of the structure grown along the (0, 0, 1) direction is shown in Fig. 1. It consists of multiple layers of polycrystalline silicon rods with a stacking sequence that repeats itself every four layers. Within each layer, the rods are parallel to each other; the rods are shifted by half a period every other layer. Only five layers are shown. The structure was fabricated by S. Y. Lin et al. at Sandia National Laboratories in 1998 using a process that involves the repetitive deposition and etching of multiple dielectric films.[17] The width of each rod is roughly 1.2 μm. The bandgap is centered at a wavelength of 10 μm. In addition to fabricating this structure, the researchers also fabricated a structure at shorter wavelengths centered at $\lambda = 1.5$ μm.[7]

An overview of the fabrication of 3D PBG materials at micrometer and submicrometer length scales can be found in Ref. 7.

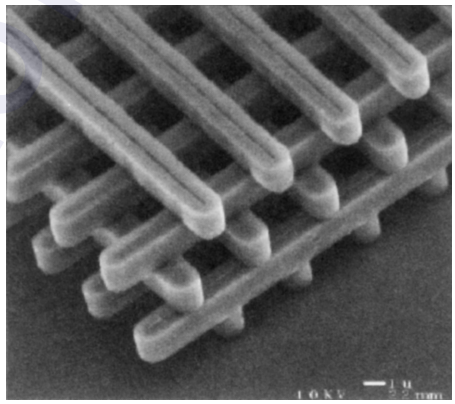

FIGURE 1 Scanning electron micrograph of a three-dimensional photonic crystal built at Sandia National Laboratories. The crystal consists of five layers of polycrystalline silicon rods. The width of the rods is 1.2 μm. The photonic bandgap is centered around a wavelength of 10 μm.

9.5 MICROCAVITIES IN THREE-DIMENSIONAL PHOTONIC CRYSTALS

From Fermi's golden rule, we know that the rate of spontaneous radiative decay of an atom scales with the density of allowed states at the atomic transition frequency. In free space, the density of states scales quadratically with frequency, and the probability of finding an atom in an excited state simply decays exponentially with time.

The introduction of boundaries in the vicinity of the atom has the effect of changing the density of allowed states. For example, in the case of a bounded system with reflecting walls—such as a laser cavity—the density of states is reduced to a spectrally discrete set of peaks, each corresponding to a resonant longitudinal mode of the cavity. When no mode falls within the emission linewidth of the atomic transition, atomic radiative decay is essentially suppressed. However, if the transition frequency overlaps one of the resonant frequencies, the density of available modes for radiative decay becomes very large, which in turn enhances the rate of spontaneous emission. In conventional solid-state lasers, several modes fall within the atomic emission linewidth. The free spectral range of the modes is given by $c/2nL$, where n is the refractive index of the host material and L is the distance between the reflectors. If L was made very small, it would be possible to increase the mode spacing such that only one (or even zero) mode would fall within the emission linewidth.

An example of a small laser cavity is the distributed feedback (DFB) laser consisting of a spatially corrugated waveguide with a quarter-wave phase shift. The phase shift defines a cavity, and the grating on either side acts like a mirror. The length L of the cavity is characterized by the decay length of the evanescent field along the axis of the grating and typically extends over hundreds of wavelengths in the material. The grating creates a stop band along the periodic axis. While the absence of longitudinal modes inside the stop gap reduces the total density of states, the presence of a quarter-wave phase shift generates a resonant mode inside the gap and increases the density of states. The increase is sufficiently large to allow single-mode action of the laser at the resonant frequency. Though DFB lasers have longitudinal stop bands, the total density of states is not zero, since the stop band extends only inside a small cone along one direction. Leaky radiation modes exist along every other direction.

3D PBG materials have the ability to open 3D stop bands that reflect light along every direction in space and that completely eliminate the density of states for a given range of frequencies. In the case where the radiative transition frequency of an atom falls within the frequency gap of the crystal, spontaneous radiative decay is essentially suppressed.

If a small defect (or phase shift) is introduced in the photonic crystal, a mode can be created within the structure at a frequency that lies inside the gap. If the size of the defect is such that it supports a mode, the defect behaves like a microcavity surrounded by reflecting walls. If the radiative transition frequency of the atom matches that of the defect mode, the rate of spontaneous emission can be enhanced.

Figure 2 shows the vector plot of a resonant mode in a 3D photonic crystal similar to the one shown in Fig. 1. The defect is located at the center of the crystal and consists of a broken high-index rib. (The defect could be introduced, for instance, in one of the layers during the growth of the crystal.) The electric field is shown in the vertical plane through the middle of the defect. The mode is strongly localized in all three dimensions, and its amplitude falls off sharply away from the defect. The electric field *jumps* from one edge of the broken rib to the other, while the magnetic field (not shown) has the shape of a torus and runs around the electric field. The frequency of the mode is $f = 0.59c/a$, where a is the lattice constant (i.e., the length of the repeating unit cell) of the crystal. In this particular example, the high-index material has a refractive index of 3.4; the low-dielectric material has an index of 1.0; and the gap extends from $f = 0.52c/a$ to $0.66c/a$.

In contrast to defects in one-dimensional periodic structures (such as DFB lasers), arbitrarily small defects in 3D crystals do not necessarily lead to the creation of localized modes. The volume of the defect must reach a certain threshold to sustain a resonant mode. Furthermore, quarter-wave shifts in DFB lasers lead to resonant modes at the center of the gap. There is no simple equivalent in 3D crystals.

The frequency of the resonant mode changes with the size and shape of the defect. The simple action of adjusting the defect size provides tunability of the resonant mode and affects the localization

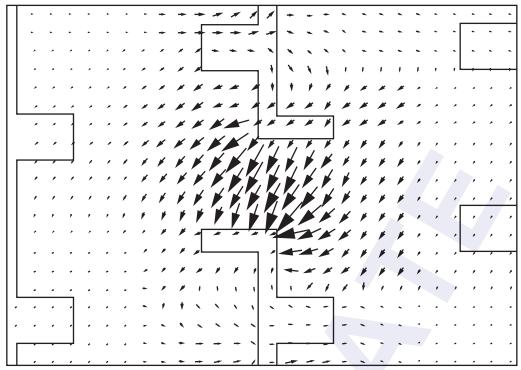

FIGURE 2 Vector plot of the electric field in a 3D PBG with a defect. The overlay indicates the edges of the high-dielectric material. The defect, located at the center of the figure, is fabricated by breaking one of the dielectric ribs. The defect supports a localized resonant mode inside the crystal.

strength. The field attenuation through successive unit cells is stronger for modes lying near the center of the gap than for those lying near the edges.

Although the microcavity in the just-noted example was created by removing part of a high-index rib, a cavity could equally have been created either by adding material between ribs or by changing the shape of one or more ribs. Also, multiple high-order localized modes may appear inside the crystal as the size of the defect is made bigger.

Quality Factor

One important aspect of microcavities in finite-sized crystals is the quality factor Q of the resonator defined as:[18]

$$Q = \frac{2\pi f_0 E}{P} = -\frac{2\pi f_0 E}{dE/dt} \tag{4}$$

where f_0 is the resonant frequency, E is the energy stored inside the resonator, and $P = -dE/dt$ is the dissipated power. Hence, a resonator can sustain Q oscillations before its energy decays by a factor of $e^{-2\pi}$ (i.e., a reduction of 99.8 percent) of its initial value. In the specific case where the line-shape of the resonance is a Lorentzian, Eq. (4) reduces to $f_0/\Delta f$, where Δf is the width of the resonance.

Since the quality factor is a measure of the optical energy stored in the microcavity over the cycle-average power radiated out of the cavity, Q is expected to be largest for modes lying near the center of the gap where the field attenuation is strongest. Q is also expected to increase with the size of the crystal, since the reflectivity increases with the number of periods (i.e., the leakage from the edges of the crystal becomes progressively smaller). The quality factor of the mode shown in Fig. 2 is plotted in Fig. 3 as a function of the size of the crystal. The quality factor is computed using the finite-difference time-domain method described in Sec. 9.3. First the resonant mode is excited and the total energy is monitored as a function of time. Then the time required for 99.8 percent of the energy to escape is recorded. Results are shown for crystal sizes of dimension $2N \times 2N \times 2N$. In each case, the defect is surrounded by N unit cells along every direction. Q increases exponentially with the size of the crystal and reaches a value close to 10^4 with as little as four unit cells on either side of the defect. The steepness

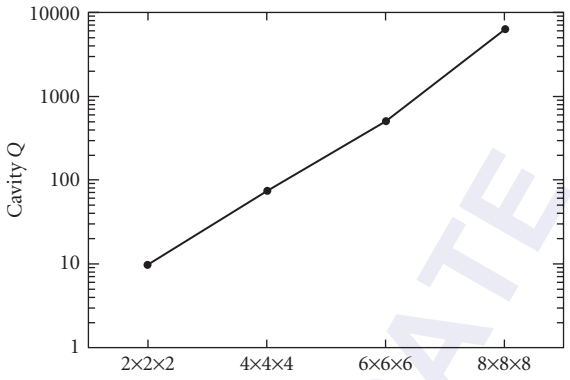

FIGURE 3 Quality factor of the resonant cavity shown in Fig. 2 as a function of the size of the 3D photonic crystal, given in units of cubic lattice constants.

of the slope in Fig. 3 follows directly from the field attenuation through each successive lattice of the crystal. Since the only energy loss in the structure occurs from tunneling through the walls of the finite-sized crystal (i.e., intrinsic losses due to material absorption is not considered), Q does not saturate even for a large number of unit cells. A more detailed description of the properties of resonant modes in photonic crystals can be found in Ref. 19.

Enhancement of Spontaneous Emission

By coupling an optical transition to the microcavity resonance, the spontaneous emission rate can be enhanced by a factor η over the rate without a cavity. The expression for η is given by:[20]

$$\eta = \frac{2Q}{\pi V_m}\left(\frac{\lambda}{2n}\right)^3 \tag{5}$$

where V_m is the modal volume, n is the refractive index of the medium, and λ is the free-space wavelength of the optical transition. Photonic crystals have the ability to enhance the rate of spontaneous emission by enabling microcavities with large quality factors and small modal volumes. In the case where the modal volume is on the order of a cubic half-wavelength in the material [i.e., $V_m \sim (\lambda/2n)^3$], the enhancement factor is on the order of Q. A detailed example is provided in the following section.

9.6 MICROCAVITIES IN PHOTONIC CRYSTALS WITH TWO-DIMENSIONAL PERIODICITY

Three-dimensional field confinement can be achieved in dielectric structures, in part by the effect of a photonic bandgap and in part by index confinement. An example was given in Sec. 9.5 for the case of a DFB laser (i.e., a structure with a one-dimensional periodicity). One important aspect of structures with dimensional periodicity lower than three is the coupling to radiation modes. By reducing the dimensionality of the periodicity and by resorting to standard index guiding to confine light along the nonperiodic direction(s), one no longer has the ability to contain light completely, and leaves open possible decay pathways through which light can escape.

In this section, we consider a dielectric slab waveguide with a two-dimensional periodic lattice. The periodic lattice is used to confine light in the plane of the waveguide (the *xy*-plane, say), and the slab keeps the light from escaping along the transverse direction (the *z*-direction). It is useful to begin with a uniform waveguide, and consider the effect of adding a periodic array of holes. The slab is chosen to have a large refractive index ($n = 3.4$) and, for simplicity, is assumed to lie in air. The thickness of the slab is set equal to $0.5a$, where a is a scaling parameter as defined in the text that follows. The use of a high-index waveguide is twofold: first, the high index provides strong field confinement along the *z*-direction (i.e., the extent of the guided modes outside the waveguide is small), allowing a large fraction of each mode to interact with the photonic crystal; and second, the high-index contrast between the dielectric material and the holes will increase the likelihood of having a bandgap in the *xy*-plane.

The waveguide is shown in Fig. 4*a*. Its corresponding dispersion relation is shown in Fig. 4*b*. The solid lines correspond to guided modes, and the shaded region corresponds to the continuum of radiation (i.e., nonguided) modes. The guided modes are labeled transverse electric (TE) and transverse magnetic (TM) with respect to the *xy*-plane of symmetry in the middle of the waveguide. TE (TM) modes are characterized by the absence of electric field components in the *z* (*x* and *y*) direction at the center of the waveguide.

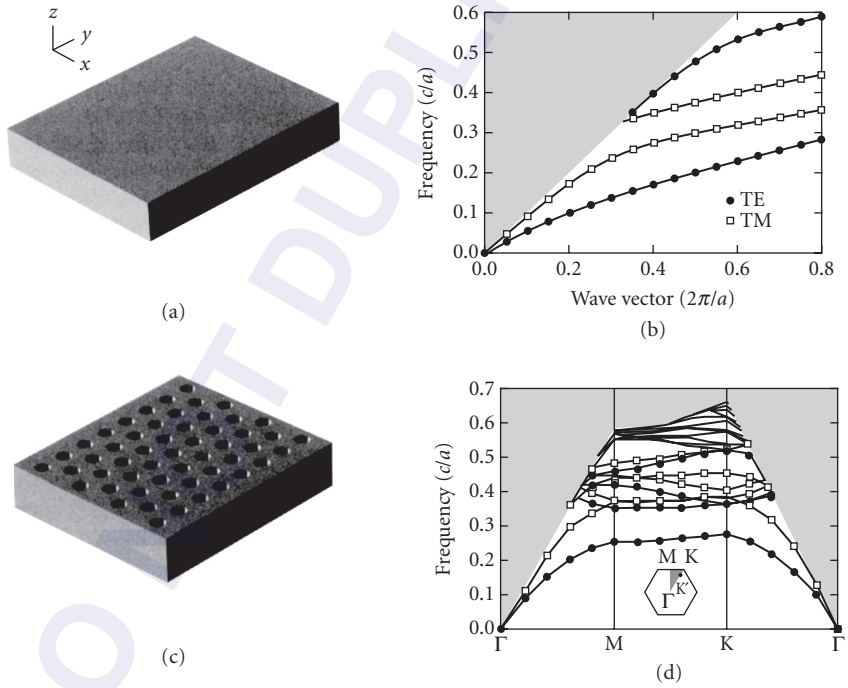

FIGURE 4 (*a*) Schematic diagram of a dielectric slab waveguide of thickness $0.5a$ and refractive index 3.4. (*b*) Band diagram of the slab waveguide shown in (*a*). The solid lines correspond to guided modes; the shaded region corresponds to the continuum of radiation modes. The guided modes are labeled TE or TM with respect to the *xy*-plane of symmetry in the middle of the slab, (*c*) Schematic diagram of a slab waveguide with a two-dimensional triangular array of holes with radius $0.3a$, where a is the lattice constant of the periodic array. The parameters of the slab are identical to those in (*a*). (*d*) Band diagram for the slab waveguide shown in (*c*). Only the lowest nine bands are labeled TE and TM. Guided modes do not exist above the cut-off frequency of $0.66c/a$. The inset shows the Brillouin zone and symmetry points for a triangular lattice, with the irreducible zone shaded.

The dispersion relation shown in Fig. 4*b* extends to the right of the figure; there is no upper bound on the wave vector. The introduction of a periodic array of holes in the waveguide has the effect of folding the dispersion relation into the first Brillouin zone and splitting the guided-mode bands. Figure 4*c* shows a waveguide with a triangular array of holes. The holes have a radius of 0.30*a*, where *a* is the lattice constant of the array. The associated dispersion relation is shown in Fig. 4*d*. Again, the shaded region above the light line corresponds to the continuum of radiation modes. The solid lines below the light line correspond to guided modes. These modes remain perfectly guided in spite of the holes and propagate in the waveguide with no loss. A bandgap can be seen between the first and second TE bands. An experimental observation of bandgaps in this type of structure is described in Ref. 21.

The introduction of holes in the waveguide also creates a frequency cutoff for guided modes. Every mode above the frequency $0.66c/a$ is folded into the radiation continuum, and is Bragg-scattered out of the slab. The cutoff frequency is independent of the refractive index of the slab or the size of the holes, and depends only on the lattice geometry of the array of holes.

If a defect is introduced in the PBG structure shown in Fig. 4*c*, localized modes can be formed in the vicinity of the defect. Since each localized mode has a specific polarization, it is possible to create a TE mode between the first and second TE bands, orthogonal to TM modes. If, for example, light were to originate from a quantum well located at the middle of the waveguide, atomic transitions could be made to couple only to TE modes.

Two competing decay mechanisms contribute to the overall decay rate of the localized mode; horizontal in-plane coupling to guided modes at the edges of the crystal in the unperturbed (i.e., holeless) waveguide, and vertical coupling to radiation modes. For some applications (such as photonic integrated circuits) it may be preferable for the localized mode to decay primarily into guided modes, while for other applications (such as off-chip emission) it may be preferable for the mode to decay primarily into the radiation continuum. These two cases are considered separately in the following text.

The total quality factor of the resonant mode, Q_{tot}, is given by:[22]

$$\frac{1}{Q_{\text{tot}}} = \frac{1}{Q_{\text{wg}}} + \frac{1}{Q_{\text{rad}}} \tag{6}$$

where $1/Q_{\text{wg}}$ is a measure of the coupling to waveguide modes and $1/Q_{\text{rad}}$ is a measure of the coupling to radiation modes. The strength of the two competing coupling mechanisms depends on the size of the crystal (i.e., the total number of holes around the defect), the modal volume, and the choice of substrate.

In-Plane Coupling

We present the case of an array of 45 holes with a missing hole at the center (i.e., one hole is filled). The structure supports a localized mode inside the TE bandgap. The total quality factor of the mode is computed using the finite-difference time-domain method described in Sec. 9.3 and is found to be 240. The modal volume, V_m, is defined as:[23]

$$V_m = \frac{\int \varepsilon(\mathbf{r})|\mathbf{E}(\mathbf{r})|^2 d^3\mathbf{r}}{(\varepsilon(\mathbf{r})|\mathbf{E}(\mathbf{r})|^2)_{\max}} \tag{7}$$

where $\mathbf{E}(\mathbf{r})$ is the electric field distribution of the mode. The computed modal volume is only three cubic half-wavelengths in the material. The spontaneous emission rate enhancement factor, computed from Eq. (5), is equal to 50.

Since the structure does not have a complete three-dimensional bandgap, Q_{tot} cannot be made arbitrarily large. While the addition of extra holes would reduce the coupling to the guided modes outside the crystal, light could not be prevented from coupling to radiation modes. Any significant

increase in the number of holes would cause the mode to primarily radiate outside of the waveguide. Moreover, coupling to radiation modes would be enhanced if the waveguide was positioned on a substrate. The substrate would provide a favorable pathway for radiation loss. It has been shown, however, that the adverse effects of a substrate could be minimized with the use of a low-index insulating layer between the waveguide and the substrate.[24,25]

The coupling to radiation modes is also enhanced by reducing the modal volume. The more tightly a mode is confined, the more likely it is to radiate out of the waveguide. Conversely, if the modal volume is made larger, the coupling to radiation modes can be reduced, and, provided the coupling to guided modes remains largely unchanged, Q_{tot} can be increased. To increase the modal volume, one could create a different type of defect in the structure. If, instead of removing a single hole from the two-dimensional array, the radius of seven nearest-neighbor holes was reduced from $0.3a$ to $0.2a$ while otherwise leaving the structure unchanged, the localized mode would become more extended—the modal volume would increase by 20 percent to $3.6(\lambda/2n)^3$—and Q_{tot} would increase by more than one order of magnitude to 2500. The frequency of the new localized mode would remain unchanged, and the enhancement factor would exceed 400.

Out-of-Plane Coupling

While it may be possible to fabricate high-Q cavities that couple predominantly to guided modes, some applications (such as light-emitting diodes) may require a large fraction of the emitted light to be extracted from the high-index guiding layer. As mentioned previously, the emitted radiation can be made to decay primarily into radiation modes by increasing the total number of holes surrounding the defect. In this case, Q_{wg} would essentially be infinite, and $Q_{tot} \sim Q_{rad}$. For simplicity, in this example, we write $Q_{tot} = Q_{rad} = Q$.

Light-emitting diodes (LEDs) are widely used as incoherent light sources in applications such as lighting, displays, and short-distance fiber communications. Two important performance characteristics of LEDs are the output efficiency (i.e., the amount of light extracted from the structure for a given injection current) and the modulation rate (i.e., the information emission capacity).

Photonic crystals with two-dimensional periodicity can lead to the enhancement of the rate of spontaneous emission and consequently to higher modulation rates. However, photon reabsorption and nonradiative recombination can affect the performance of LEDs by reducing the extraction efficiency and the modulation rate. High-Q cavities, though seemingly favorable for the enhancement of the rate of spontaneous emission, may cause severe reabsorption in certain material systems, since the likelihood of observing photon reabsorption increases with the photon lifetime inside the cavity.

Display Applications For display applications, it is usually desired to get as much light as possible out of the high-index material over the entire spontaneous emission bandwidth for a constant applied current. If all emitted frequencies fall inside the guided-mode bandgap, all available optical modes can contribute to the output signal. In the ideal case where there are no nonradiative recombination processes, the extraction efficiency is unity; every photon escapes from the high-index waveguide. Even photons reabsorbed by the atomic system, if given enough time, eventually get reemitted and contribute to the output signal. However, when nonradiative processes are present, reabsorbed photons can be lost. In order to achieve high output efficiency, the effective spontaneous emission rate—the spontaneous emission rate reduced by photon reabsorption—has to dominate over the nonradiative recombination rate. The relative rate of the radiative and nonradiative processes can be controlled by modifying the quality factor of the cavity.

Two limit cases are identified: the case where photon reabsorption is negligible, and the case where it is important. The former arises in certain organic emitters, where the energy levels of the molecules are such that absorption and spontaneous emission are spectrally separated. The latter arises in most semiconductor systems, where both absorption and emission processes occur between the conduction and valence bands.

In the case of low reabsorption, if the cavity linewidth is larger than the emission linewidth, an increase of the cavity Q can result in an increase of the effective spontaneous emission rate and of

the output efficiency. However, a reduction of the cavity linewidth beyond the material emission linewidth does not further enhance the spontaneous emission rate or output efficiency. In the case of large reabsorption, the rate of spontaneous emission and the output efficiency reach a maximum when the cavity linewidth is comparable to the material linewidth, but fall to zero when the cavity linewidth becomes much smaller than the material linewidth. A more detailed description of these conditions can be found in Ref. 26.

Communications Applications For communications applications, it is advantageous to reduce the emission linewidth below the material emission linewidth to improve the temporal coherence of the emitted light. It is also advantageous to increase the modulation speed to improve the information emission capacity. If a time-varying current is applied to the LED, the response time of the electron-photon system will be determined by the slowest of the different relaxation processes.

While electronic recombination lifetimes are typically on the order of a few nanoseconds in both semiconductors and organic dyes, the photon lifetime in a cavity depends on the cavity Q and, in the case where, say, $Q = 1000$, is on the order of several picoseconds. Since the modulation speed is limited by the slower of the two processes, the electronic recombination rate, which is a sum of the effective spontaneous emission rate and the nonradiative recombination rate, constitutes the limiting factor. To achieve high modulation speeds, it is therefore necessary to increase the spontaneous emission rate.

In the case where photon reabsorption is small, such as in organic dyes, the rate of spontaneous emission and the modulation speed increase with the cavity Q. Conversely, when photon reabsorption is large, such as in semiconductors, the maximum rate of spontaneous emission and the maximum modulation rate are achieved when the cavity linewidth is comparable to the material linewidth. These conclusions are similar to those found for display applications.

Examples of Low-Q and High-Q Cavities Low-Q cavities can be fabricated in high-index dielectric waveguides by introducing an array of holes with no defects. The absence of defects ensures that photons inside the waveguide—emitted from a quantum well, say—spend as little time as possible inside the waveguide and minimize the risk of being reabsorbed. The cavity is defined by the waveguide itself, which provides vertical field confinement. To avoid removing active material, the holes can be made to extend only partly into the guiding layer so as to not penetrate into the quantum well. Bandgaps for guided modes can be generated even when the holes do not extend through the entire thickness of the waveguide. The waveguide can also be positioned on a dielectric or metallic mirror to ensure that the output radiation escapes through the top surface.

High-Q cavities can be fabricated in structures similar to those used for low-Q cavities except that, in the case of high-Q cavities, defects are introduced in the periodic array. The introduction of defects creates highly confined modes in the area of the defects, hence only a small fraction of the quantum well overlaps with the resonant modes (i.e., only a fraction of the electron-hole pairs contributes to the emitted signal). To eliminate this problem, high-Q cavities could be generated by placing the dielectric layer between two vertical Bragg mirrors—in analogy to resonant-cavity LEDs—and by getting rid of the defects. The entire active region would then overlap with the resonant cavity mode.

Experimental results of quantum-well emitters and dyes in photonic crystals with two-dimensional periodicity can be found in Refs. 27 through 31. A detailed analysis of the output efficiency and modulation rate of LEDs can be found in Refs. 26 and 32.

9.7 WAVEGUIDES

While three-dimensional field confinement can be achieved by introducing local-point defects in photonic crystals, two-dimensional field confinement can be achieved by introducing extended line defects. Both point defects and line defects can generate localized modes with

frequencies that lie inside the bandgap. However, unlike point defects, line defects can generate modes that propagate along the lines with nonzero group velocity. Line defects can be made, for example, by *carving* channels in photonic crystals or by creating line dislocations. Electromagnetic waves propagating along the lines are guided not from total internal reflection but from the bandgap effect; they are prevented from leaking into the crystal since their frequencies lie inside the bandgap.

The absence of radiation modes in three-dimensional photonic crystals suggests that it may also be possible to create waveguides with very sharp bends. Since electromagnetic waves are prevented from propagating inside photonic crystals, the waves would only either propagate through the bend or be reflected back. It will be shown in the subsection labeled "Waveguide Bends" that, for certain frequencies, reflection may be eliminated altogether, leading to complete transmission. In three-dimensional crystals, waveguide bends could extend along any direction and could be used for the implementation of interconnected integrated optical circuits on multiple planes. In this chapter, however, we focus only on line defects in photonic crystals with two-dimensional periodicity.

Waveguides in Photonic Crystals with Two-Dimensional Periodicity

As we saw in Sec. 9.6, photonic crystals with two-dimensional periodicity rely on the existence of bandgaps to control propagation in the plane and on index guiding to confine electromagnetic fields along the third dimension. An example of a photonic crystal with two-dimensional periodicity was shown in Fig. 4*c*; its corresponding dispersion relation was shown in Fig. 4*d*. In the bandgap, no *guided* mode existed for TE polarization.

In this section, a line defect is introduced in the photonic crystal shown in Fig. 4*c* by increasing the radius of a line of nearest-neighbor holes along the Γ-K direction from 0.30*a* to 0.45*a*. The resulting dispersion relation is shown in Fig. 5. The dispersion relation is computed using the plane-wave expansion method described in Sec. 9.3. The wave vector along the line defect is plotted on the abscissa.

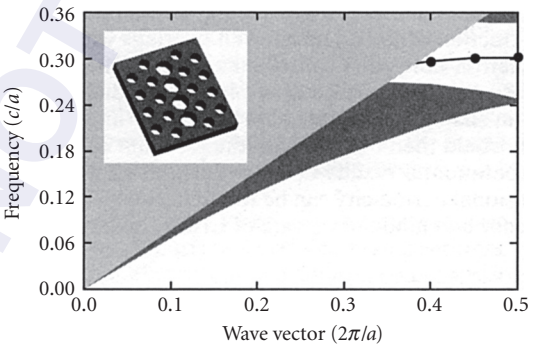

FIGURE 5 Projected dispersion relation of the TE modes in the waveguide structure shown in the inset. The dispersion relation is projected along the axis of the waveguide (i.e., along the line defined by the series of larger holes). The light gray region corresponds to the continuum of radiation modes, and the dark gray regions correspond to modes inside the bulk PBG dielectric slab. The thickness of the slab is 0.5*a*, the refractive index is 3.4, the radius of the small holes is 0.3a, and the radius of the large holes is 0.45*a*. The figure is to be compared with Fig. 4*d* along the Γ-K direction.

In this structure, it is necessary to distinguish between the modes which are guided inside the dielectric slab (the so-called bulk crystal modes that correspond to the different bands in Fig. 4*d*) and the modes which are guided along the line defect. The dispersion relation is obtained from Fig. 4*d* by projecting the wave vector of every mode along the Γ-K direction; the dark gray regions correspond to the continuum of bulk crystal modes and the light gray region corresponds to the continuum of radiation modes. The bulk crystal modes and radiation modes are depicted with a uniform shading despite the nonuniform density of states in these regions. Since the structure retains an inherent periodicity along the line defect, the wave vector has an upper limit. However, although the line defect extends along the Γ-K direction, K is not the point at the edge of the dispersion relation. The boundary is located at the projected M point along the Γ-K direction, labeled K′ as shown in the inset of Fig. 4*d*.

Only modes lying outside the shaded regions are truly guided along the line defect. A single guided mode appears inside the bandgap. Since the line defect consists of a series of larger holes, the effective index of the waveguide is lower than that of the surrounding photonic crystal. Hence, the mode is not index-guided in the plane; it is constrained horizontally by the bandgap. The effective index, however, is higher in the waveguide than in the regions above and below the slab, allowing the mode to be guided vertically by index confinement. The electric field of the guided mode is mostly concentrated in the dielectric material. The fraction of electric-field energy inside the high-dielectric material at K′, for example, is close to 75 percent.

Alternatively, a line defect could have been created by reducing the radius of a series of holes, or by creating lattice dislocations. Also, instead of using a high-index slab with holes, one could have used an array of high-index posts. High-index posts can generate dispersion relations similar to the one shown in Fig. 4*c* except that the open (solid) circles would now correspond to TE (TM) polarization. A more detailed analysis of these and other similar structures can be found in Refs. 33 and 34.

Waveguide Bends

If a sharp bend is introduced in a PBG waveguide—with a radius of curvature on the order of a few lattice constants—it may be possible to obtain high transmission through the bend for a wide range of frequencies. To obtain high transmission, the waveguide must support a single mode at the frequency of interest, and the radiation losses must be small, since coupling to high-order guided modes and to radiation modes reduces the transmission and increases the reflection.

While it may be possible to obtain 100 percent transmission in photonic crystals with two-dimensional periodicity, we choose to consider waveguide bends in purely two-dimensional crystals. Two-dimensional crystals can be viewed either as flat structures in a two-dimensional Cartesian space or as structures of infinite thickness with no field variation along the vertical direction. Since there is no index confinement along the vertical direction, there are no radiation modes and no light cone. The bandgap in a 2D structure is analogous to a three-dimensional bandgap in that there are truly no modes inside the bandgap.

For simplicity, we consider a 2D photonic crystal of dielectric columns on a square lattice, surrounded by air. The refractive index of the rods is chosen to be 3.4 and the radius 0.20*a*, where *a* is the lattice constant of the array. A large bandgap appears in this structure for TM polarization (electric field parallel to the axis of the columns). A line defect is created inside the crystal by removing a row of rods. The line defect introduces a single guided TM mode inside the gap, similar to the one shown in Fig. 5. The main difference between the dispersion relation for this 2D crystal and the one shown in Fig. 5 is the absence of radiation modes in the 2D crystal. The bandgap extends over the entire range of wave vectors. If a bend is introduced in the waveguide, light will either travel through the bend or be reflected back, since there are no radiation modes to which light can couple. Only back reflection can hinder perfect transmission.

The transmission and reflection can be studied using the finite-difference time-domain method described in Sec. 9.3. In this method, a dipole located at the entrance of the waveguide creates a pulse with a Gaussian envelope in time. The field amplitude is monitored inside the waveguide at two points, one before the bend and one after the bend. The pulses are then Fourier-transformed to

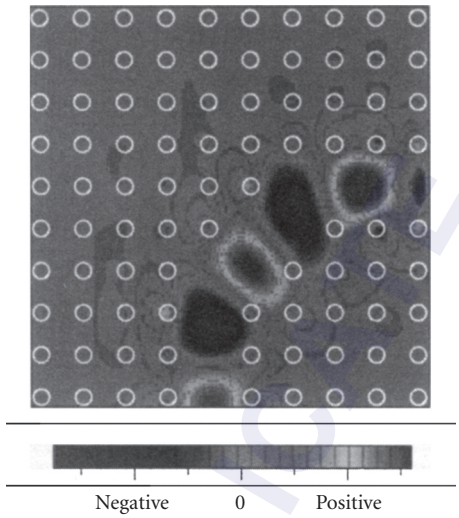

FIGURE 6 Electric field pattern of a guided mode in a photonic crystal in the vicinity of a bend. The white circles indicate the position of the high-dielectric columns. The electric field is polarized along the axis of the columns. The mode is strongly confined inside the guide and is completely transmitted through the bend. The radius of curvature of the bend is on the order of the wavelength of the guided mode.

obtain the reflection and transmission coefficients for each frequency. A detailed description of this method and computational results are presented in Ref. 35.

The electric field pattern of a mode propagating through the bend is shown in Fig. 6. The mode is strongly guided inside the photonic crystal. One hundred percent of the light travels through the bend despite a radius of curvature on the order of one wavelength.

The transmission through the bend can be modeled as a simple one-dimensional scattering process. The bend can be broken down into three separate waveguide sections: the input waveguide in the (01) direction; the output waveguide in the (10) direction; and a short waveguide section in the (11) direction, connecting the input and output waveguides. Each section supports a single guided mode with wave vector $\mathbf{k}_1(f)$ for propagation along the (01) or (10) direction, and $\mathbf{k}_2(f)$ for propagation along (11). These wave vectors are given by dispersion relations similar to the one shown in Fig. 5. The mode propagating along the (01) direction is scattered into the mode propagating along (11), then into the mode propagating along (10). At the interfaces, the fields and their derivatives must be continuous. By complete analogy with the one-dimensional Schrödinger equation for a square potential well, the transmission through the sharp bend can be mapped onto that of a wave propagating in a square *dielectric potential*. This potential consists of three constant pieces corresponding to the (01), (11), and (10) directions, respectively. The model differs from the standard one-dimensional scattering problem in that the depth of the well, determined by the difference $|\mathbf{k}_1(f)|^2 - |\mathbf{k}_2(f)|^2$, now depends on the frequency of the traveling wave. The scattering model correctly predicts the general quantitative features of the transmission spectrum obtained from the FDTD method, as well as the frequencies where the reflection coefficient vanishes.[35]

The results have been experimentally confirmed using a structure consisting of a square array of tall circular rods.[36] The rods were made of alumina with a refractive index of 3.0 and a radius of 0.25 mm. The lattice constant was chosen to be 1.27 mm and the rods were close to 10 cm in length. The large aspect ratio between the length and the lattice constant provided a good approximation

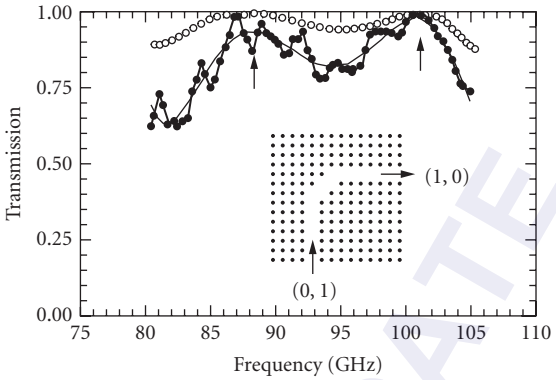

FIGURE 7 Normalized transmission spectrum for the PBG structure shown in the inset. The solid circles correspond to experimental data; the open circles are computed from the one-dimensional scattering model. Near-perfect transmission is observed through the bend near 87 and 101 GHz. The arrows indicate the positions of the reflection nodes from theory. The experimental data is fitted with a polynomial curve.

of a two-dimensional system. Because of the absence of vertical confinement, the waveguides were made to extend over less than 100 lattice constants to minimize loss in the vertical direction. The bandgap extended from 76 to 105 GHz. The experiment was carried out at millimeter-wave frequencies to facilitate the fabrication of structures with a large aspect ratio.

To test the PBG structure, millimeter-wave transmitters and receivers were placed next to the entrance and exit of the PBG waveguide. This coupling scheme closely resembled the setup used in the computational simulations. The transmitted signal is shown in Fig. 7. The signal is normalized to the transmitted signal of a straight waveguide. The PBG bend exhibits near-perfect transmission around 87 and 101 GHz. The two arrows indicate the expected positions of the reflection nodes computed from the one-dimensional scattering model. The positions of the nodes confirm a subtle and important point about PBG waveguides: The detection of light at the end of a straight waveguide would not be a sufficient condition, in itself, to confirm PBG guiding. It is the existence of transmission peaks around the sharp bend, along with the specific position of these peaks, that confirms PBG guiding.

Waveguide Intersections

In addition to sharp bends, photonic crystals can be used to fabricate waveguide intersections with low crosstalk. If two waveguides intersect each other on the same plane, light traveling along one waveguide typically leaks into the second waveguide, causing signal loss and crosstalk. The insertion of a microcavity at the center of the intersection of two PBG waveguides can reduce the crosstalk and increase the throughput. If the resonant mode inside the cavity is such that it can couple only to one waveguide, the crosstalk can be essentially eliminated. In this case, the problem reduces to the well-known phenomenon of resonant tunneling through a cavity.

Figure 8*a* shows two intersecting waveguides in a two-dimensional photonic crystal identical to the one shown in Fig. 7. At the center of the intersection, a microcavity is created by adding rods inside the waveguides and by increasing the radius of one rod by 60 percent. The cavity is outlined by a dashed box. The cavity supports two degenerate modes with opposite symmetry at a frequency lying inside the bandgap. From symmetry, each resonant mode can couple to only one waveguide, as shown schematically in Fig. 8*b*. Therefore, under the approximation that the waveguides couple

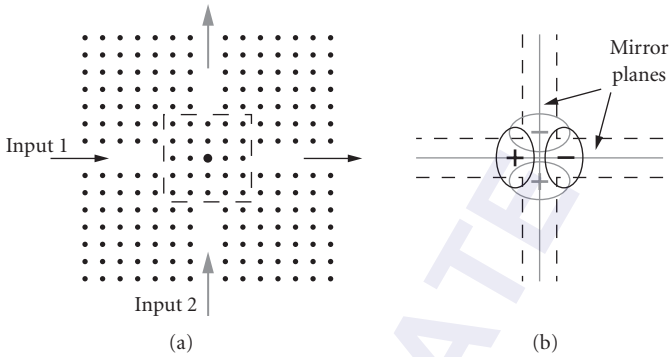

FIGURE 8 (*a*) Diagram of two intersecting waveguides inside a photonic crystal. The two waveguides are aligned along the (10) and (01) directions. A microcavity—outlined by the dashed line—is created at the center of the intersection by adding columns inside the waveguides and by increasing the size of the dielectric column at the center. The microcavity supports two degenerate modes with opposite symmetry. The mode contours are shown schematically in (*b*). By symmetry, the modes corresponding to the black contour lines cannot couple to even modes in the waveguide along the (01) direction, and the modes corresponding to the gray contour lines cannot couple to even modes in the waveguide along the (10) direction.

to one another only through the resonant cavity, crosstalk is prohibited. The throughput in each waveguide is described by resonant tunneling; the throughput spectrum is a Lorentzian function with 100 percent transmission at resonance. The width of the resonance is given by the inverse of the quality factor of the microcavity.

In general, large throughput and low crosstalk can be achieved if each waveguide has a single guided mode in the frequency range of interest, and if the microcavity supports two resonant modes, each mode having even symmetry with respect to the mirror plane along one waveguide and odd symmetry with respect to the other mirror plane. The presence of radiation loss would reduce the throughput and increase the crosstalk. A detailed description of PBG waveguide intersections can be found in Ref. 37.

9.8 CONCLUSION

The routing and interconnection of optical signals through narrow channels and around sharp bends are important for large-scale all-optical circuit applications. In addition to sharp bends and low-crosstalk intersections, photonic bandgap materials can also be used for narrowband filters, add/drop filters, light emitters, low-threshold lasers, modulators, attenuators, and dispersion compensators. PBG materials may enable the high-density integration of optical components on a single chip.

While this chapter focuses mostly on applications for high-density optical circuits, many other applications have been proposed for PBG materials. One such application is the PBG fiber.[38] While photonic crystals can guide light along a periodic plane (as shown in Sec. 9.7), they can also guide light along the direction perpendicular to the plane of periodicity. A PBG fiber is a two-dimensional periodic structure that essentially extends to infinity along the nonperiodic direction. Light is confined inside the fiber by a defect located at the center. PBG fibers may have interesting features such as single-mode operation over a large bandwidth and preferred dispersion compensation properties. Other applications can be found in Ref. 39.

10.1 GLOSSARY

c	velocity of light in free space
$\mathbf{D}$	displacement vector
d_{mn}	Kleinman's **d**-coefficient
$\mathbf{E}$	electric field in lightwave
$\tilde{\mathbf{E}}$	complex amplitude of electric field
e	electronic charge
f	oscillator strength
$\hbar$	Planck's constant
I	intensity of lightwave
$\mathbf{k}$	propagation vector
m	mass of electron
N	number of equivalent harmonic or anharmonic oscillators per volume
$n_{1,2}$	index of refraction at the fundamental and second-harmonic frequencies, respectively
$\mathbf{P}$	macroscopic polarization
$\mathbf{P}^{(n)}$	nth-order macroscopic polarization
$P_{0,2,+,-}$	power of lightwave at the fundamental, second-harmonic, sum-, and difference-frequencies, respectively
$\tilde{\mathbf{P}}$	complex amplitude of macroscopic polarization
$\mathbf{Q}$	amplitude of vibrational wave or optic phonons
$\mathbf{S}$	strain of acoustic wave or acoustic phonons
T_{mn}	relaxation time of the density matrix element ρ_{mn}
Γ_j	damping constant of jth optical transition mode
δ	Miller's coefficient
$\boldsymbol{\varepsilon}(\mathbf{E})$	field-dependent optical dielectric tensor
$\boldsymbol{\varepsilon}_n$	nth-order optic dielectric tensor
ε_0	optical dielectric constant of free space
$\boldsymbol{\eta}$	amplitude of plasma wave or plasmons
λ	wavelength
ρ_{mn}	density matrix element

$\boldsymbol{\chi}(\mathbf{E})$	field-dependent optic susceptibility tensor
$\boldsymbol{\chi}_1$ or $\boldsymbol{\chi}(1)$	linear optic susceptibility tensor
$\mathbf{X}_n$ or $\boldsymbol{\chi}(n)$	nth-order optic susceptibility tensor
ω_p	plasma frequency
$\langle a \mid \mathbf{p} \mid b \rangle$	dipole moment between states a and b

10.2 INTRODUCTION

For linear optical materials, the macroscopic polarization induced by light propagating in the medium is proportional to the electric field:

$$\mathbf{P} = \varepsilon_0 \boldsymbol{\chi}_1 \cdot \mathbf{E} \tag{1}$$

where the linear optical susceptibility $\boldsymbol{\chi}_1$ and the corresponding linear dielectric constant $\boldsymbol{\varepsilon}_1 = \varepsilon_0(1 + \boldsymbol{\chi}_1)$ are field-independent constants of the medium.

With the advent of the laser, light intensities orders of magnitude brighter than what could be produced by any conventional sources are now possible. When the corresponding field strength reaches a level on the order of, say, 100 KV/m or more, materials that are normally "linear" at lower light-intensity levels may become "nonlinear" in the sense that the optical "constants" are no longer "constants" independent of the light intensity. As a consequence, when the field is not weak, the optical susceptibility $\boldsymbol{\chi}$ and the corresponding dielectric constant $\boldsymbol{\varepsilon}$ of the medium can become functions of the electric field $\boldsymbol{\chi}(\mathbf{E})$ and $\boldsymbol{\varepsilon}(\mathbf{E})$, respectively. Such a field-dependence in the optical parameters of the material can lead to a wide range of nonlinear optical phenomena and can be made use of for a great variety of new applications.

Since the first experimental observation of optical second-harmonic generation by Franken[1] and the formulation of the basic principles of nonlinear optics by Bloembergen and coworkers[2] shortly afterward, the field of nonlinear optics has blossomed into a wide-ranging and rapidly developing branch of optics. There is now a vast literature on this subject including numerous review articles and books.[3–6] It is not possible to give a full review of such a rich subject in a short introductory chapter in this *Handbook*; only the basic principles underlying the lowest order, the second-order, nonlinear optical processes and some illustrative examples of related applications will be discussed here. The reader is referred to the original literature for a more complete account of the full scope of this field.

If the light intensity is not so weak that the field dependence can be neglected and yet not too strong, the optical susceptibility and the corresponding dielectric constant can be expanded in a Taylor series:

$$\boldsymbol{\chi}(\mathbf{E}) = \boldsymbol{\chi}_1 + \boldsymbol{\chi}_2 \cdot \mathbf{E} + \boldsymbol{\chi}_3 : \mathbf{E}\mathbf{E} + \cdots \tag{2}$$

or

$$\boldsymbol{\varepsilon}(\mathbf{E}) = \boldsymbol{\varepsilon}_1 + \boldsymbol{\varepsilon}_2 \cdot \mathbf{E} + \boldsymbol{\varepsilon}_3 : \mathbf{E}\mathbf{E} + \cdots \tag{3}$$

where

$$\boldsymbol{\varepsilon}_1 = \varepsilon_0(1 + \boldsymbol{\chi}_1) \tag{4}$$

$$\boldsymbol{\varepsilon}_n = \varepsilon_0 \boldsymbol{\chi}_n \quad \text{for} \quad n \geq 2 \tag{5}$$

and ε_0 is the dielectric constant of free space. When these field-dependent terms in the optical susceptibility are not negligible, the induced macroscopic polarization in the medium contains terms that are proportional nonlinearly to the field:

$$\begin{aligned}\mathbf{P} &= \varepsilon_0 \boldsymbol{\chi}_1 \cdot \mathbf{E} + \varepsilon_0 \boldsymbol{\chi}_2 : \mathbf{EE} + \varepsilon_0 \boldsymbol{\chi}_3 \vdots \mathbf{EEE} + \cdots \\ &= \mathbf{P}^{(1)} + \mathbf{P}^{(2)} + \mathbf{P}^{(3)} + \cdots \end{aligned} \tag{6}$$

As the field intensity increases, these nonlinear polarization terms $\mathbf{P}^{(n>1)}$ become more and more important, and will lead to a large variety of nonlinear optical effects.

The more widely studied of these nonlinear optical effects are, of course, those associated with the lower-order terms in Eq. (6). The second-order nonlinear effects will be discussed in some detail in this chapter. Many of the higher-order nonlinear terms have been observed and are the bases of a variety of useful nonlinear optical devices. Examples of the third-order effects are third-harmonic generation[7,8] associated with $|\chi^{(3)}(3\omega = \omega + \omega + \omega|^2$, two-photon absorption[9] associated with Im $\chi^{(3)}(\omega_1 = \omega_1 + \omega_2 - \omega_2)$, self-focusing[10,11] and light-induced index-of-refraction[12] change associated with Re $\chi^{(3)}(\omega = \omega + \omega - \omega)$, four-wave mixing[13] $|\chi^{(3)}(\omega_4 = \omega_1 + \omega_2 - \omega_3)|^2$, degenerate four-wave mixing or phase-conjugation[14,15] $|\chi^{(3)}(\omega = \omega + \omega - \omega)|^2$, optical Kerr effect[16] Re $\chi^{(3)}(\omega = 0 + 0 + \omega)$, and many others.

There is also a large variety of dynamic nonlinear optical effects such as photon echo,[17] optical nutation[18] (or optical Rabi effect[19]), self-induced transparency,[20] picosecond[21] and femtosecond[22] quantum beats, and others.

In addition to the nonlinear optical processes involving only photons that are related to the nonlinear dependence on the **E**-field as shown in Eq. (6), the medium can become nonlinear indirectly through other types of excitations as well. For example, the optical susceptibility can be a function of the molecular vibrational amplitude Q in the medium, or the stress associated with an acoustic wave S in the medium, or the amplitude η of any space-charge or plasma wave, or even a combination of these excitations as in a polariton, in the medium:

$$\begin{aligned}\mathbf{P} &= \varepsilon_0[\boldsymbol{\chi}_1 + \boldsymbol{\chi}_2 : \mathbf{E} + \boldsymbol{\chi}_3 \vdots \mathbf{EE} + \cdots]\mathbf{E} \\ &\quad + \varepsilon_0[\boldsymbol{\chi}_q : \mathbf{Q} + \boldsymbol{\chi}_a : \mathbf{S} + \boldsymbol{\chi}_\eta : \boldsymbol{\eta} + \cdots]\mathbf{E}\end{aligned} \tag{7}$$

giving rise to the interaction of optical and molecular vibrational waves, or optical and acoustic phonons, etc. Nonlinear optical processes involving interaction of laser light and molecular vibrations in gases or liquids or optical phonon in solids can lead to stimulated Raman[23–25] processes. Those involving laser light and acoustic waves or acoustic phonons lead to stimulated Brillouin[26–28] processes. Those involving laser light and mixed excitations of photons and phonons lead to stimulated polariton[29] processes. Again, there is a great variety of such general nonlinear optical processes in which excitations other than photons in the medium may play a role. It is not possible to include all such nonlinear optical processes in the discussions here. Extensive reviews of the subject can be found in the literature.[3–5]

10.3 BASIC CONCEPTS

Microscopic Origin of Optical Nonlinearity

Classical Harmonic Oscillator Model of Linear Optical Media The linear optical properties, including dispersion and single-photon absorption, of optical materials can be understood phenomenologically on the basis of the classical harmonic oscillator model (or Drude model). In this simple model, the optical medium is represented by a collection of independent identical harmonic oscillators

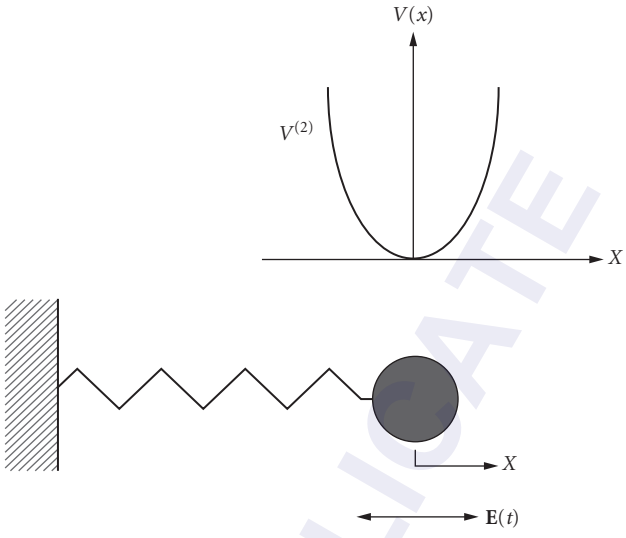

FIGURE 1 Harmonic oscillator model of linear optical media.

embedded in a host medium. The harmonic oscillator is characterized by four parameters: a spring constant k, a damping constant Γ, a mass m, and a charge $-e\sqrt{f}$ as shown schematically in Fig. 1. f is also known as the oscillator-strength and $-e$ is the charge of an electron. The resonance frequency ω_0 of the oscillator is then equal to $[k/m]^{1/2}$.

In the presence of, for example, a monochromatic wave:

$$\mathbf{E} = \tfrac{1}{2}[\tilde{\mathbf{E}}e^{-i\omega t} + \tilde{\mathbf{E}}^* e^{i\omega t}] \tag{8}$$

the response of the medium is determined by the equation of motion of the oscillator in the presence of the field:

$$\frac{\partial^2 X^{(1)}(t)}{\partial t^2} + \Gamma \frac{\partial X^{(1)}(t)}{\partial t} + \omega_0^2 X^{(1)}(t) = \frac{-e\sqrt{f}}{2m}[\tilde{\mathbf{E}}e^{-i\omega t} + \text{c.c.}] \cdot x \tag{9}$$

where $X^{(1)}(t)$ is the deviation of the harmonic oscillator from its equilibrium position in the absence of the field. The corresponding linear polarization in the steady state and linear complex susceptibility are from Eqs. (8) and (9):

$$\begin{aligned} \mathbf{P}^{(1)} &= -NeX^{(1)}(t)x = \tfrac{1}{2}[\tilde{\mathbf{P}}^{(1)}e^{-i\omega t} + \tilde{\mathbf{P}}^{(1)*}e^{i\omega t}] \\ &= \frac{Ne^2 f \tilde{\mathbf{E}}}{2mD(\omega)} e^{-i\omega t} + \text{c.c.} \end{aligned} \tag{10}$$

and

$$\varepsilon_0 \chi^{(1)} = \frac{|\tilde{\mathbf{P}}|}{|\tilde{\mathbf{E}}|} = \frac{Ne^2 f}{mD(\omega)} \tag{11}$$

where N is the volume density of the oscillators and $D(\omega) = \omega_0^2 - \omega^2 - i\omega\Gamma$. The corresponding real and imaginary parts of the corresponding linear complex dielectric constant of the medium Re ε_1

and Im ε_1, respectively, describe then the dispersion and absorption properties of the linear optical medium. To represent a real medium, the results must be summed over all the effective oscillators (j):

$$\mathrm{Re}\,\varepsilon_1 = \varepsilon_0 + \sum_j \frac{\omega_{pj}^2 f_j(\omega_{0j}^2 - \omega^2)}{(\omega_{0j}^2 - \omega^2)^2 + \omega^2\Gamma_j^2} \tag{12}$$

and

$$\mathrm{Im}\,\varepsilon_1 = \sum_j \frac{\omega_{pj}^2 f_j \omega\Gamma_j}{(\omega_{0j}^2 - \omega^2)^2 + \omega^2\Gamma_j^2} \to \frac{\omega_{pj}^2 f_j}{2\omega} \frac{\Gamma_j/2}{(\omega - \omega_{0j})^2 - (\Gamma_j/2)^2} \quad \text{for} \quad \omega \approx \omega_{0j} \tag{13}$$

where $\omega_{pj}^2 = 4\pi N_j e^2/m$ is the plasma frequency for the jth specie of oscillators. Each specie of oscillators is characterized by four parameters: the plasma frequency ω_{pj}, the oscillator-strength f_j, the resonance frequency ω_{0j}, and the damping constant Γ_j. These results show the well-known anomalous dispersion and lorentzian absorption lineshape near the transition or resonance frequencies.

The difference between the results derived using the classic harmonic oscillator or the Drude model and those derived quantum mechanically from first principles is that, in the latter case, the oscillator strengths and the resonance frequencies can be obtained directly from the transition frequencies and induced dipole moments of the transitions between the relevant quantum states in the medium. For an understanding of the macroscopic linear optical properties of the medium, extended versions of Eqs. (12) and (13), including the tensor nature of the complex linear susceptibility, are quite adequate.

Anharmonic Oscillator Model of the Second-Order Nonlinear Optical Susceptibility An extension of the Drude model with the inclusion of suitable anharmonicities in the oscillator serves as a useful starting point in understanding the microscopic origin of the optical nonlinearity classically. Suppose the spring constant of the oscillator representing the optical medium is not quite linear in the sense that the potential energy of the oscillator is not quite a quadratic function of the deviation from the equilibrium position, as shown schematically in Fig. 2. In this case, the response of the oscillator to a harmonic force is asymmetric. The deviation (solid line) from the equilibrium position is larger and smaller on alternate half-cycles than that in the case of the harmonic oscillator. This means that there must be a second-harmonic component (dark shaded curve) in the response of the oscillator as shown schematically in Fig. 3. It is clear, then, that the larger the anharmonicity and the corresponding asymmetry in the oscillator potential, the larger the second-harmonic in the response. Extending this kind of consideration to a three-dimensional model, it implies that to have second-harmonic generation, the material must not have inversion symmetry and, therefore, must be crystalline. It is also clear that for the third and higher odd harmonics, the anharmonicity in the oscillator potential should be symmetric. Even harmonics will always require the absence of inversion symmetry. Beyond that, obviously, the larger the anharmonicities, the larger the nonlinear effects.

Consider first the second-harnomic case. The corresponding anharmonic oscillator equation is:

$$\frac{\partial^2 X(t)}{\partial t^2} + \Gamma\frac{\partial X(t)}{\partial t} + \omega_0^2 X(t) + vX(t)^2 = \frac{-e\sqrt{f}}{2m}[\tilde{\mathbf{E}}e^{-i\omega t} + \text{c.c.}]\cdot x \tag{14}$$

Solving this equation by perturbation expansion in powers of the **E**-field:

$$X(t) = X^{(1)}(t) + X^{(2)}(t) + X^{(3)}(t) + \cdots \tag{15}$$

leads to the second-order nonlinear optical susceptibility

$$\varepsilon_0\chi^{(2)} = \frac{\left|\tilde{\mathbf{P}}^{(z)}\right|}{\left|\tilde{\mathbf{E}}^2\right|} = \frac{Ne^3 fv}{2m^2 D^2(\omega)D(2\omega)} \tag{16}$$

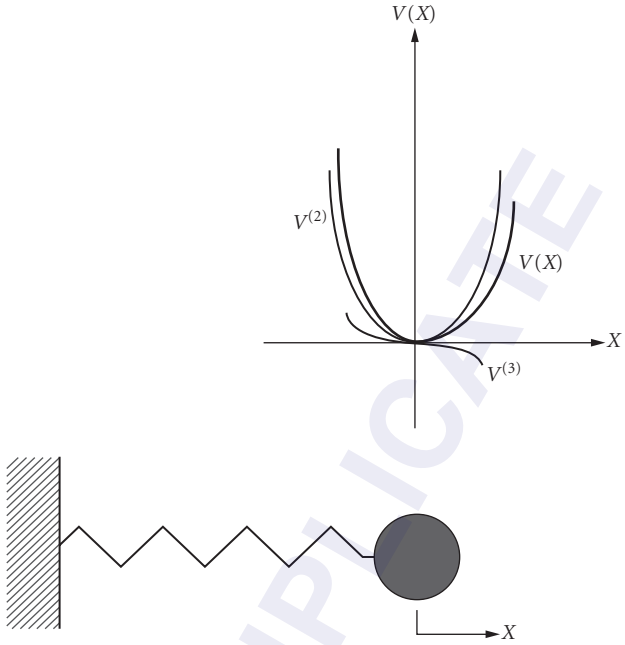

FIGURE 2 Anharmonic oscillator model of nonlinear optical media.

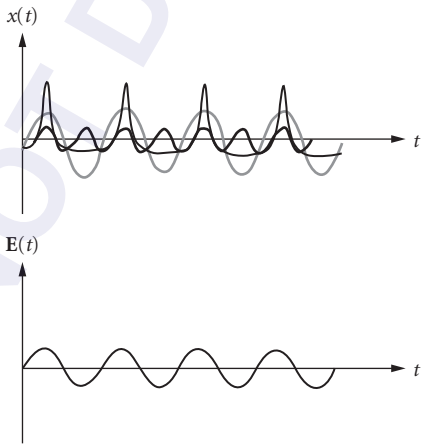

FIGURE 3 Response $[x(t)]$ of anharmonic oscillator to sinusoidal driving field $[\mathbf{E}(t)]$.

Unlike in the linear case, a more exact expression of the nonlinear susceptibility-derived quantum mechanically will, in general, have a more complicated form and will involve the excitation energies of, and dipole matrix elements between, all the states. Nevertheless, an expression like Eq. (16) obtained on the basis of the classical anharmonic oscillator model is very useful in discussing qualitatively the second-order nonlinear optical properties of materials. Equation (16) is particularly useful in understanding the dispersion properties of the second nonlinearity.

It is also the basis for understanding the so-called Miller's rule[30] which gives a very rough estimate of the order of magnitude of the nonlinear coefficient. We note that the strong frequency dependence in the denominator of the $\chi^{(2)}$ involves factors that are of the same form as those that appeared in $\chi^{(1)}$. Suppose we divide out these factors and define a parameter which is called Miller's coefficient:

$$\delta = \chi^{(2)}(2\omega) / [\chi^{(1)}(\omega)]^2 \chi^{(1)}(2\omega)\varepsilon_0^2 = mv / 2e^3 f^{1/2} N^2 \varepsilon_0^2 \tag{17}$$

from Eqs. (16) and (11). For many inorganic second-order nonlinear optical crystals, it was first suggested by R. C. Miller that δ was approximately a constant for all materials, and its value was found empirically to be on the order of $2–3 \times 10^{-6}$ esu. If this were true, to find materials with large nonlinear coefficients, one should simply look for materials with large values of $\chi^{(1)}(\omega)$ and $\chi^{(1)}(2\omega)$. This empirical rule was known as Miller's rule. It played an important historical role in the search for new nonlinear optical crystals and in explaining the order of magnitude of nonlinear coefficients for many classes of nonlinear optical materials including such well-known materials as the ADP-isomorphs—for example, KH_2PO_4(KDP), NH_4PO_4(ADP), etc.—and the ABO_3 type of ferroelectrics—for example, $LiIO_3$, $LiNbO_3$, etc.—or III-V and II-VI compound semiconductors in the early days of nonlinear optics.

On a very crude basis, a value of δ can be estimated from Eq. (17) by assuming that the anharmonic potential term in Eq. (14) becomes comparable to the harmonic term when the deviation X is on the order of one lattice spacing in a typical solid, or on the order of an Angstrom. Thus, using standard numbers, Eq. (17) predicts that, in a typical solid, δ is on the order of 4×10^{-6} esu in the visible. It is now known that there are many classes of materials that do not fit this rule at all. For example, there are organic crystals with Miller's coefficients thousands of times larger than this value.

A more rigorous theory for the nonlinear optical susceptibility will clearly have to come from appropriate calculations based upon the principles of quantum mechanics.

Quantum Theory of Nonlinear Optical Susceptibility Quantum mechanically, the nonlinearities in the optical susceptibility originate from the higher-order terms in the perturbation solutions of the appropriate Schrödinger's equation or the density-matrix equation.

According to the density-matrix formalism, the induced macroscopic polarization **P** of the medium is specified completely in terms of the density matrix:

$$\mathbf{P} = N \text{ Trace}[\mathbf{p}\rho] \tag{18}$$

where **p** is the dipole moment operator of the essentially noninteracting individual polarizable units, or "atoms" or molecules or unit cells in a solid, as the case may be, and N is the volume density of such units.

The density-matrix satisfies the quantum mechanical Boltzmann equation or the density-matrix equation:

$$\frac{\partial \rho_{mn}}{\partial t} + i\omega_{mn}\rho_{mn} + \frac{\rho_{mn} - \bar{\rho}_{mn}}{T_{mn}} = \frac{i}{\hbar}\sum_k [\rho_{mk}V_{kn} - V_{mk}\rho_{kn}] \tag{19}$$

where $\bar{\rho}_{mn}$ is the equilibrium density matrix in the absence of the perturbation V and T_{mn} is the relaxation time of the density-matrix element ρ_{mn}. The nth-order perturbation solution of Eq. (19) in the steady state is:

$$\rho_{mn}^{(n)}(t) = \frac{i}{\hbar}\sum_k \int_{-\infty}^{t} [\rho_{mk}^{(n-1)}(t')V_{kn}(t') - V_{mk}(t')\rho_{kn}^{(n-1)}(t')] \exp\left[\left(i\omega_{mn} + \frac{1}{T_{mn}}\right)(t'-t)\right] dt' \tag{20}$$

The zeroth-order solution is clearly that in the absence of any perturbation or:

$$\rho_{mn}^{(0)} = \bar{\rho}_{mn} \tag{21}$$

In principle, once the zeroth-order solution is known, one can generate the solution to any order corresponding to all the nonlinear optical processes. While such solutions are formally complete and correct, they are generally not very useful, because it is difficult to know all the excitation energies and transition moments of all the states needed to calculate $\chi^{(n\geq 2)}$. For numerical evaluations of $\chi^{(n)}$, various simplifying approximations must be made.

To gain some qualitative insight into the microscopic origin of the nonlinearity, it can be shown on the basis of a simple two-level system that the second-order solution of Eq. (20) leads to the approximate result:

$$\chi^{(2)} \infty [(\omega_{ge} - \omega)(\omega_{ge} - 2\omega)]^{-1} \left|\langle g|\mathbf{p}|e\rangle\right|^2 \left[\langle e|\mathbf{p}|e\rangle - \langle g|\mathbf{p}|g\rangle\right] \tag{22}$$

It shows that for such a two-level system at least, there are three important factors: the resonance denominator, the transition-moment squared, and the change in the dipole moment of the molecule going from the ground state to the excited state. Thus, to get a large second-order optical nonlinearity, it is preferable to be near a transition with a large oscillator strength and there should be a large change in the dipole moment in going from the ground state to that particular excited state. It is known, for example, that substituted benzenes with a donor and an acceptor group have strong charge-transfer bands where the transfer of charges from the donor to the acceptor leads to a large change in the dipole moment in going from the ground state to the excited state. The transfer of the charges is mediated by the delocalized π electrons along the benzene ring. Thus, there was a great deal of interest in organic crystals of benzene derivatives. This led to the discovery of many organic nonlinear materials. In fact, it was the analogy between the benzene ring structure and the boroxal ring structure that led to the discovery of some of the best known recently discovered inorganic nonlinear crystals such as β-BaB_2O_4 (BBO)[31] and LiB_3O_5 (LBO).[32]

In general, however, there are few rules that can guide the search for new nonlinear optical crystals. It must be emphasized, however, that the usefulness of a material is not determined by its nonlinearity alone. Many other equally important criteria must be satisfied for the nonlinear material to be useful, for example, the transparency, the phase-matching property, the optical damage threshold, the mechanical strength, chemical stability, etc. Most important is that it must be possible to grow single crystals of this material of good optical quality for second-order nonlinear optical applications in bulk crystals. In fact, optical nonlinearity is often the easiest property to come by. It is these other equally important properties that are often harder to predict and control.

Form of the Second-Order Nonlinear Optical Susceptibility Tensor

The simple anharmonic oscillator model shows that to have second-order optical nonlinearity, there must be asymmetry in the crystal potential in some direction. Thus, the crystal must not have inversion symmetry. This is just a special example of how the spatial symmetry of the crystal affects the form of the optical susceptibility. In this case, if the crystal contains inversion symmetry, all the elements of the susceptibility tensor must be zero. In a more general way, the form of the optical susceptibility tensor is dictated by the spatial symmetry of the crystal structure.[33]

For second-order nonlinear susceptibilities in the cartesian coordinate system:

$$P_i^{(2)} = \sum_{j,k} \varepsilon_0 \chi_{ijk}^{(2)} E_j E_k \tag{23}$$

$\chi_{ijk}^{(2)}$ in general has 27 independent coefficients before any symmetry conditions are taken into account. Taking into account the permutation symmetry condition, namely, the order E_j and E_k appearing in Eq. (23) is not important, or

$$\chi_{ijk}^{(2)} = \chi_{ikj}^{(2)} \tag{24}$$

the number of independent coefficients reduces down to 18. With 18 coefficients, it is sometimes more convenient to define a two-dimensional 3×6 tensor, commonly known as the Kleinman **d**-tensor:[34]

$$\begin{pmatrix} P_x \\ P_y \\ P_z \end{pmatrix} = \varepsilon_0 \begin{pmatrix} d_{11} & d_{12} & d_{13} & d_{14} & d_{15} & d_{16} \\ d_{21} & d_{22} & d_{23} & d_{24} & d_{25} & d_{26} \\ d_{31} & d_{32} & d_{33} & d_{34} & d_{35} & d_{36} \end{pmatrix} \begin{pmatrix} E_x^2 \\ E_y^2 \\ E_z^2 \\ 2E_yE_z \\ 2E_xE_z \\ 2E_xE_y \end{pmatrix} \tag{25}$$

rather than the three-dimensional tensor $\chi^{(2)}_{ijk} = \chi^{(2)}_{ikj}$. One obvious advantage of the $\mathbf{d}_{im}$ = tensor form is that the full tensor can be written in the two-dimensional matrix form, whereas it would be difficult to exhibit on paper any three-dimensional matrix.

An additional important point about the **d**-tensor is that it is defined in terms of the complex amplitudes of the **E**-field and the induced polarization with the 1/2 factor explicitly separated out in the front as shown in Eq. (8). In contrast, the definition of χ_{ijk} may be ambiguous in the literature because not all the authors define the complex amplitude with a 1/2 factor in the front. For linear processes, it makes no difference, because the 1/2 factors in the induced polarization and the **E**-field cancel out. In nonlinear processes, the 1/2 factors do not cancel and the numerical value of the complex susceptibility will depend on how the complex amplitudes of the **E**-field and polarization are defined.

For crystalline materials, the remaining 18 coefficients are, in general, not all independent of each other. Spatial symmetry requires, in addition, that they must satisfy the characteristic equation:

$$\chi^{(2)}_{ijk} = \sum_{\alpha\beta\gamma} \chi^{(2)}_{\alpha\beta\gamma} R_{\alpha i} R_{\beta j} R_{\gamma k} \tag{26}$$

where $R_{\alpha i}$, etc., represent the symmetry operations contained in the space group for the particular crystal structure and Eq. (26) must be satisfied for all the Rs in the group. For example, if a crystal has inversion symmetry, or $R_{\alpha i,\beta j,\gamma k} = (-1)\delta_{\alpha i,\beta j,\gamma k}$, Eq. (26) implies that $\chi^{(2)}_{ijk} = (-1)\chi^{(2)}_{ikj} = 0$ as expected. From the known symmetry elements of all 32 crystallographic point groups, the forms of the corresponding second-order nonlinear susceptibility tensors can be worked out and are tabulated. Equation (26) can in fact be generalized[33] to an arbitrarily high order n:

$$\chi^{(n)}_{ijk\cdots} = \sum_{\alpha\beta\gamma\cdots} \chi^{(n)}_{\alpha\beta\gamma} \cdots R_{\alpha i} R_{\beta j} R_{\gamma k} \cdots \tag{27}$$

for all the Rs in the group. Thus, the forms of any nonlinear optical susceptibility tensors can in principle be worked out once the symmetry group of the optical medium is known.

The **d**-tensors for the second-order nonlinear optical process for all 32-point groups derived from Eq. (26) are shown in, for example, Ref. 34. Similar tensors can in principle be derived from Eq. (27) for the nonlinear optical susceptibilities to any order for any point group.

Phase-Matching Condition (or Conservation of Linear Photon Momentum) in Second-Order Nonlinear Optical Processes

On a microscopic scale, the nonlinear optical effect is usually rather small even at relatively high light-intensity levels. In the case of the second-order effects, the ratio of the second-order term to

the first-order term in Eq. (2), for example, is very roughly the ratio of the applied **E**-field strength to the "atomic **E**-field" in the material or:

$$\frac{\chi_2 E}{\chi_1} \approx \frac{E}{E_{\text{atomic}}} \tag{28}$$

which is on the order of 10^{-4} even at an intensity level of 1 MW/cm^2. The same ratio holds very roughly in each successively higher order. To see such a small effect, it is important that the waves generated through the nonlinear optical process add coherently on a macroscopic scale. That is, the new waves generated over different parts of the optical medium add coherently on a macroscopic scale. This requires that the phase velocities of the generated wave and the incident fundamental wave be "matched."[35]

Because of the inevitable material dispersion, in general the phases are not matched because the freely propagating second-harmonic wave will propagate at the phase velocity corresponding to the second-harmonic while the source polarization at the second-harmonic will propagate at the phase velocity of the fundamental. Phase matching requires that the propagation constant of the source polarization $2\mathbf{k}_1$ be equal to the propagation constant $\mathbf{k}_2$ of the second-harmonic or:

$$2\mathbf{k}_1 = \mathbf{k}_2 \tag{29}$$

Multiplying Eq. (29) by $\hbar$ implies that the linear momentum of the photons must be conserved. As shown in the schematic diagram in Fig. 4, in a normally dispersive region of an optical medium, $\mathbf{k}_2$ is always too long and must be reduced to achieve proper phase matching.

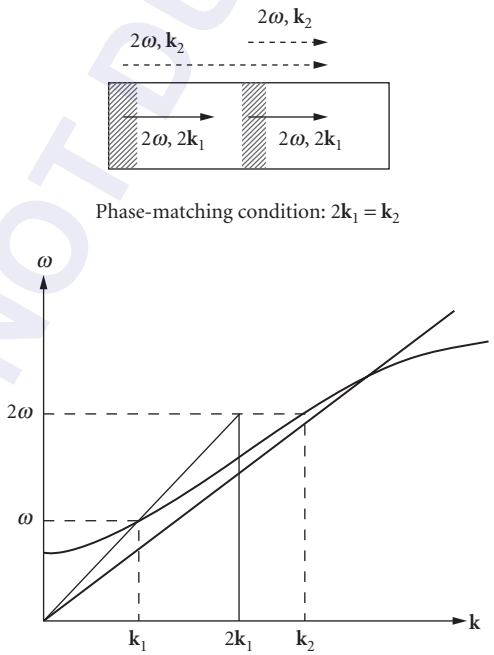

FIGURE 4 Phase-matching requirement and the effect of materials dispersion on momentum mismatch in second-harmonic process.

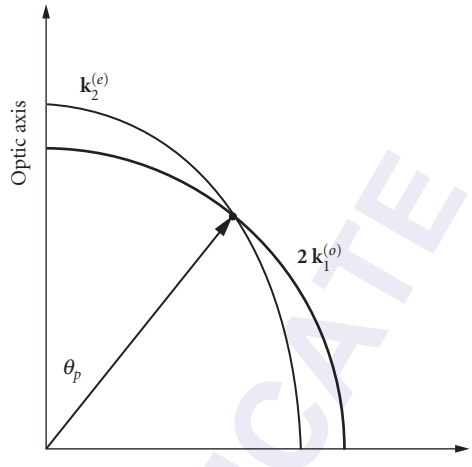

FIGURE 5 Phase matching using birefringence to compensate material dispersion in second-harmonic generation.

In bulk crystals, the most effective and commonly used method is to use birefringence to compensate for material dispersion, as shown schematically in Fig. 5. In this scheme, the **k**-vector of the extraordinary wave in the anisotropic crystal is used to shorten $\mathbf{k}_2$ or lengthen $2\mathbf{k}_1$ as needed. For example, in a negative uniaxial crystal, the fundamental wave is sent into the crystal as an ordinary wave and the second-harmonic wave is generated as an extraordinary wave in a so-called Type I phase-matching condition:

$$2\mathbf{k}_1^{(o)} = \mathbf{k}_2^{(e)} \tag{30}$$

or the fundamental wave is sent in both as an ordinary wave and an extraordinary wave while the second-harmonic is generated as an extraordinary wave in the so-called Type II phase-matching condition:

$$\mathbf{k}_1^{(o)} + \mathbf{k}_1^{(e)} = \mathbf{k}_2^{(e)} \tag{31}$$

In a positive uniaxial crystal, $\mathbf{k}_2^{(e)}$ in Eqs. (30) and (31) should be replaced by $\mathbf{k}_2^{(o)}$ and $\mathbf{k}_1^{(o)}$ in Eq. (30) should be replaced by $\mathbf{k}_1^{(e)}$. Crystals with isotropic linear optical properties clearly lack birefringence and cannot use this scheme for phase matching. Semiconductors of zinc-blende structure, such as the III-V and some of the II-VI compounds, have very large second-order optical nonlinearity but are nevertheless not very useful in the bulk crystal form for second-order nonlinear optical processes because they are cubic and lack birefringence and, hence, difficult to phase match. Phase matching can also be achieved by using waveguide dispersion to compensate for material dispersion. This scheme is often used in the case of III-V and II-VI compounds of zinc-blende structure. Other phase-matching schemes include the use of the dispersion of the spatial harmonics of artificial period structures to compensate for material dispersion.

These phase-matching conditions for the second-harmonic processes can clearly be generalized to other second-order nonlinear optical processes such as the sum- and difference-frequency processes in which two photons of different frequencies and momenta $\mathbf{k}_1$ and $\mathbf{k}_2$ either add or subtract to create a third photon of momentum $\mathbf{k}_3$. The corresponding phase-matching conditions are:

$$\mathbf{k}_1 \pm \mathbf{k}_2 = \mathbf{k}_3 \tag{32}$$

The practical phase-matching schemes for these processes are completely analogous to those for the second-harmonic process. For example, one can use the birefringence in a bulk optical crystal or the waveguide dispersion to compensate for the material dispersion in a sum- or difference-frequency process.

Conversion Efficiencies for the Second-Harmonic and Sum- and Difference-Frequency Processes

With phase matching, the waves generated through the nonlinear optical process can coherently accumulate spatially. The spatial variation of the complex amplitude of the generated wave follows from the wave equation:

$$\frac{\partial^2}{\partial z^2}E_i(z,t)-\frac{1}{c^2}\frac{\partial^2}{\partial t^2}E_i(z,t)=\frac{1}{c^2\varepsilon_0}\frac{\partial^2}{\partial t^2}P_i(z,t) \tag{33}$$

where

$$E_i(z,t)=\tfrac{1}{2}[\tilde{E}_{0,i}e^{ik_0z-i\omega_0t}+\text{c.c.}]+\tfrac{1}{2}[\tilde{E}_{2,i}(z)e^{-ik_2z-i\omega_2t}+\text{c.c.}] \tag{34}$$

and

$$P_i(z,t)=P_i^{(\omega_0)}(z,t)+[P_{\text{source},i}^{(2\omega_0)}(z,t)+P_i^{(2\omega_0)}(z,t)] \tag{35}$$

$$P_i^{(2\omega_0)}(z,t)=\tfrac{1}{2}\left[\sum_j\varepsilon_0\chi_{ij}^{(1)}(2\omega_0)\tilde{E}_{2,j}(z)e^{ik_2z-i\omega_2t}+\text{c.c.}\right] \tag{36}$$

$$P_{\text{source},i}^{(2\omega_0)}(z,t)=\tfrac{1}{2}[\tilde{P}_{s,i}(z)e^{-i2k_0z-i\omega_2t}+\text{c.c}] \tag{37}$$

$$\tilde{P}_{s,t}^{(2\omega_0)}(z,t)=\tfrac{1}{2}\sum_{jk}\varepsilon_0\chi_{ijk}^{(2)}(2\omega_0)\tilde{E}_{0,j}\tilde{E}_{0,k} \tag{38}$$

The spatial variation in the complex amplitude of the fundamental wave $\tilde{\mathbf{E}}_{0,i}$ in Eq. (34) is assumed negligible and, in fact, we assume it to be that of the incident wave in the absence of any nonlinear conversion in the medium. It is, therefore, implied that the nonlinear conversion efficiency is not so large that the fundamental intensity is appreciably depleted. In other words, the small-signal approximation is implied. Solving Eq. (33) with the boundary conditions that there is no second-harmonic at the input and no reflection at the output end of the crystal, one finds the second-harmonic at the output end of the crystal $z = L$ to be:

$$I^{2\omega_0}(z=L)=\frac{2d^2I_0^2}{c\varepsilon_0n_2(n_1-n_2)^2}\sin^2\left(\frac{L\omega_0}{c}\right)(n_1-n_2) \tag{39}$$

where d is the appropriate Kleinman **d**-coefficient and the intensities refer to those inside the medium. When the phases of the fundamental and second-harmonic waves are not matched, or $n_1 \neq n_2$, it is clear from Eq. (39) that the second-harmonic intensity is an oscillating function of the crystal length. The maximum intensity is reached at a crystal length of:

$$L_{\max}=\frac{\lambda}{4|n_2-n_1|} \tag{40}$$

which is also known as the coherence length for the second-harmonic process. The maximum intensity that can be reached is:

$$I_{\max}^{2\omega_0}(z = L_{\max}) = \frac{2d^2}{c\varepsilon_0 n_2 (n_1 - n_2)^2} I_0^2 \tag{41}$$

regardless of the crystal length as long as it is greater than the coherence length. The coherence length for many nonlinear optical materials could be on the order of a few microns. Therefore, without phase matching, the second-harmonic intensity in such crystals corresponds to what is generated within a few microns of the output surface of the nonlinear crystal. A much more interesting or important case is clearly when there is phase matching or $n_1 = n_2$.

The second-harmonic intensity under the phase-matched condition is, from Eq. (39):

$$I_2 = \left(\frac{8\pi^2}{c\varepsilon_0 n_1^2 n_2}\right)\left(\frac{L}{\lambda_1}\right)^2 d_{\text{eff}}^2 I_0^2 \tag{42}$$

where d_{eff} is the effective **d**-coefficient which takes into account the projections of the **E**-field and the second-harmonic polarization along the crystallographic axes and the form of the proper **d**-tensor for the particular crystal structure. The intensities in this equation refer to the intensities inside the nonlinear medium and the wavelength refers to the free-space wavelength. Equation (42) shows that the second-harmonic intensity under phase-matched conditions is proportional to the square of the length of the crystal measured in the wavelength, as expected for coherent processes. The second-harmonic intensity is also proportional to the effective **d**-coefficient squared and the fundamental intensity squared, as expected.

One might be tempted to think that, to increase the second-harmonic power conversion efficiency indefinitely, all one has to do is to focus the beam very tight since the left-hand side is inversely proportional to the beam cross section while the right-hand side is inversely proportional to the cross section squared. Because of diffraction, however, as the fundamental beam is focused tighter and tighter, the effective focal region becomes shorter and shorter. Optimum focusing is achieved when the Rayleigh range of the focal region becomes the limiting interaction length rather than the crystal length. A rough estimate assumes that a beam of square cross section doubles in width (w) due to diffraction in an "optimum focusing length," $L_{\text{opt}} \sim w^2/\lambda_2$, and that this optimum focusing length is equal to the crystal length L. Under such a nominally optimum focusing condition, the maximum second-harmonic power that can be generated in practice is, therefore, approximately:

$$P_2^{(\text{opt})} = \left(\frac{2\pi^2}{c\varepsilon_0 n_1^2 n_2}\right)\left(\frac{L}{\lambda_2^3}\right) d_{\text{eff}}^2 P_0^2 \tag{43}$$

Note that this maximum power is linearly proportional to the crystal length. It must be emphasized, however, that this linear dependence is not an indication of incoherent optical process. It is because the beam spot size (area) under the optimum focusing condition is linearly proportional to the crystal length. Numerically, for example, approximately 3 W of second-harmonic power could be generated under optimum focusing in a 1-cm-long $LiIO_3$ crystal with 30 W of incident fundamental power at 1 μm.

Equation (43) can, in fact, be generalized to other three-photon processes such as the sum-frequency and difference-frequency processes:

$$P_+^{(\text{opt})} = \left(\frac{2\pi^2}{c\varepsilon_0 n_1 n_2 n_+}\right)\left(\frac{L}{\lambda_+^3}\right) d_{\text{eff}}^2(\omega_+ = \omega_1 + \omega_2) P_1 P_2 \tag{44}$$

and

$$P_{-}^{(\mathrm{opt})} = \left(\frac{2\pi^2}{c\varepsilon_0 n_1 n_2 n_-}\right)\left(\frac{L}{\lambda_-^3}\right) d_{\mathrm{eff}}^2(\omega_- = \omega_1 - \omega_2) P_1 P_2 \tag{45}$$

In using Eqs. (44) and (45), one must be especially careful in relating the numerical values of the d_{eff} coefficients for the sum- and difference-frequency processes to that measured in the second-harmonic process because the two low-frequency photons degenerate in frequency in the latter process.

The Optical Parametric Process

A somewhat different, but rather important, second-order nonlinear optical process is the optical parametric process.[36,37] Optical parametric amplifiers and oscillators powerful solid-state sources of broadly tunable coherent radiation capable of covering the entire spectral range from the near-UV to the mid-IR and can operate down to the femtosecond time domain. The basic principles of optical parametric process were known even before the invention of the laser, dating back to the says of the masers. The practical development of the optical parametric oscillator had been impeded, however, due to the lack of suitable nonlinear optical materials. As a result of recent advances[38] in nonlinear optical materials research, these oscillators are now practical devices with broad potential applications in research and industry. The basic physics of the optical parametric process and recent developments in practical optical parametric oscillators are reviewed in this section as an example of wavelength-shifting nonlinear optical devices.

Studies of the optical parameters of materials clearly have always been a powerful tool to gain access to the atomic and molecular structures of optical materials and have played a key role in the formulation of the basic principles of quantum mechanics and, indeed, modern physics. Much of the information obtained through linear optics and linear optical spectroscopy came basically from just the first term in the expansion of the complex susceptibility, Eq. (2). The possibility of studying the higher-order terms in the complex susceptibility through nonlinear optical techniques greatly expands the power of such studies to gain access to the basic building blocks of materials on the atomic or molecular level. Of equal importance, however, are the numerous practical applications of nonlinear optics. Although there are now thousands of known laser transitions in all kinds of laser media, the practically useful ones are still relatively few compared to the needs. Thus, there is always a need to shift the laser wavelengths from where they are available to where they are needed. Nonlinear optical processes are the way to accomplish this. Until recently, the most commonly used wavelength-shifting processes were harmonic generation, sum-, and difference-frequency generation processes. In all these processes, the generated frequencies are always uniquely related to the frequencies of the incident waves. The parametric process is different. In this process, there is the possibility of generating a continuous range of frequencies from a single-frequency input.

For harmonic, sum-, and difference-frequency generation, the basic devices are nothing more than suitably chosen nonlinear optical crystals that are oriented and cut according to the basic principles already discussed in the previous sections and there is a vast literature on all aspects of such devices. The spontaneous optical parametric process can be viewed as the inverse of the sum-frequency process and the stimulated parametric process, or the parametric amplification process, can be viewed as a repeated difference-frequency process.

Spontaneous Parametric Process The spontaneous parametric process, also known as the parametric luminescence or parametric fluorescence process, is described by a simple Feynman diagram as shown in Fig. 6. It describes the process in which an incident photon, called a pump photon, propagating in a nonlinear optical medium breaks down spontaneously into two photons of lower frequencies, called signal and idler photons using a terminology borrowed from earlier microwave

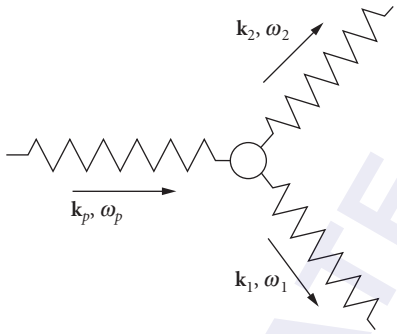

FIGURE 6 Spontaneous breakdown of a pump photon into a signal and an idler photon.

parametric amplifier work, with the energy and momentum conserved:

$$\omega_p = \omega_s + \omega_i \tag{46}$$

$$\mathbf{k}_p = \mathbf{k}_s + \mathbf{k}_i \tag{47}$$

The important point about this second-order nonlinear optical process is that the frequency condition Eq. (46) does not predict a unique pair of signal and idler frequencies for each fixed pump frequency ω_p. Neglecting the dispersion in the optical material, there is a continuous range of frequencies that can satisfy this condition. Taking into account the dispersion in real optical materials, the frequency and momentum matching conditions Eqs. (46) and (47), in general, cannot be satisfied simultaneously. In analogy with the second-harmonic or the sum- or difference-frequency processes, one can use the birefringence in the material to compensate for the material dispersion for a set of photons propagating in the nonlinear crystal. By rotating the crystals, the birefringence in the direction of propagation can be tuned, thereby leading to tuning of the signal and idler frequencies. This tunability gives rise to the possibility of generating photons over a continuous range of frequencies from incident pump photons at one particular frequency, which means the possibility of constructing a continuously tunable amplifier or oscillator by making use of the parametric process.

A complete theory for the spontaneous parametric emission is beyond the scope of this introductory chapter because, as all spontaneous processes, it requires the quantization of the electromagnetic waves. Detailed descriptions of the process can be found in the literature.[4]

Stimulated Parametric Process, or the Parametric Amplification Process With only the pump photons present in the initial state, spontaneous emission occurs at the signal and idler frequencies under phase-matched conditions. With signal and pump photons present in the initial state, stimulated parametric emission occurs in the same way as in a laser medium, except here the pump photons are converted directly into the signal and the corresponding idler photons through the second-order nonlinear optical process and no exchange of energy with the medium is involved. The stimulated parametric process can also be viewed as a repeated difference-frequency process in which the signal and idler photons repeatedly mix with the pump photons in the medium, generating more and more signal and idler photons under the phase-matched condition.

The spatial dependencies of the signal and idler waves can be found from the appropriate coupled-wave equations under the condition when the pump depletion can be neglected. The corresponding complex amplitude of the signal wave at the output $\mathbf{E}_s(L)$ is proportional to that at the input $\mathbf{E}_s(0)$, as in any amplification process:[39]

$$\mathbf{E}_s(L) = \mathbf{E}_s(0)\cosh gL \tag{48}$$

where

$$g = \frac{d_{\text{eff}} |E_p| \sqrt{k_s k_i}}{2 n_s n_i} \tag{49}$$

is the spatial gain coefficient of the parametric amplification process. d_{eff} is the effective Kleinman **d**-coefficient for the parametric process. k_s and k_i are the phase-matched propagation constants of the signal and idler waves, respectively; n_s and n_i are the corresponding indices of refraction.

Optical Parametric Oscillator Given the parametric amplification process, a parametric oscillator can be constructed by simply adding a pair of Fabry-Perot mirrors, as in a laser, to provide the needed optical feedback of the stimulated emission. The optical parametric oscillator has the unique characteristic of being continuously tunable over a very broad spectral range. This is perhaps one of the most important applications of second-order nonlinear optics.

The basic configuration of an optical parametric oscillator (OP) is extremely simple. It is shown schematically in Fig. 7. Typically, it consists of a suitable nonlinear optical crystal in a Fabry-Perot cavity with dichroic cavity mirrors which transmit at the pump frequency and reflect at the signal frequency or at the signal and idler frequencies. In the former case, the OPO is a singly resonant OPO (SRO) and, in the latter case, it is a doubly resonant OPO (DRO). The threshold for the SRO is much higher than that for the DRO. The trade-off is that the DRO tends to be highly unstable and, thus, not as useful.

Tuning of the oscillator can be achieved by simply rotating the crystal relative to the direction of propagation of the pump beam or the axis of the Fabry-Perot cavity. As an example of the spectral range that can be covered by the OPO, Fig. 8 shows the tuning curve of a β-barium borate OPO pumped by the third-harmonic output at 355 μm and the fourth-harmonic at 266 μm of a Nd:YAG laser. Also shown are the corresponding spontaneous parametric emissions. The symbols correspond to the experimental data and the solid curves are calculated.[38] With a single set of mirrors to resonate the signal wave in the visible, the entire spectral range from about 400 nm to the IR absorption edge of the β-barium borate crystal can be covered. With $KTiO_2PO_4$ (KTP) or the more recently developed $KTiO_2AsO_4$ (KTA) crystals, the tuning range can be extended well into the mid-IR range to the 3- to 5-μm range. With $AgGaSe_2$, the potential tuning range could be extended to the 18- to 20-μm range.

The efficiency of the SRO that can be achieved in practice is relatively high, typically over 30 percent on a pulsed basis. Since the OPO is scalable, the output energy is only limited by the pump energy available and can be in the multijoule range.

A serious limitation at the early stage of development is the oscillator linewidth that can be achieved. Without rather complicated and special arrangements, the oscillator linewidth is typically a few Angstroms or more, which is not useful for high-resolution spectroscopic applications. The linewidth problem is, however, not a basic limitation inherent in the parametric process. It is primarily due to the finite pulse length of the pump sources, which limits the cavity length that can be used so that the number of passes by the signal through the nonlinear crystal is not too small. As more suitable pump sources are developed, various line-narrowing schemes[40] typically used in tunable lasers can be adapted for use in OPOs as well.

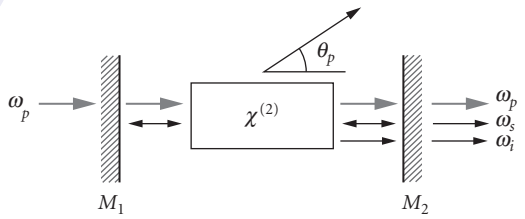

FIGURE 7 Schematic of singly resonant optical parametric oscillator.

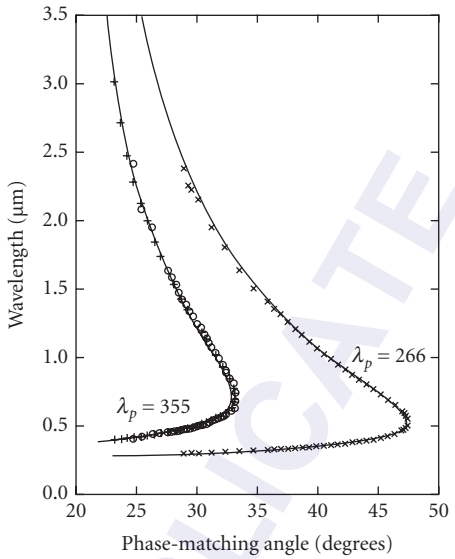

FIGURE 8 Tuning characteristics of BBO spontaneous parametric emission (× and +) and OPO (circles) pumped at the third (355 nm) and fourth (266 nm) harmonics of Nd-YAG laser output. Solid curves are calculated.

The OPO holds promise to become a truly continuously tunable powerful solid-state source of coherent radiation with broad applications as a research tool and in industry.

10.4 MATERIAL CONSIDERATIONS

The second-order nonlinearity is the lowest-order nonlinearity and the first to be observed as the intensity increases. As the discussion following Eq. (26) indicates, only materials without inversion symmetry can have second-order nonlinearity, which means that these must be crystalline materials. The lowest-order nonlinearity in a centrosymmetric system is the third-order nonlinearity.

To observe and to make use of the second-order nonlinear optical effects in a nonlinear crystal, an effective **d**-coefficient on the order of 10^{-13} m/V or larger is typically needed. In the case of the third-order nonlinearity, the effect becomes nonnegligible or useful in most applications when it is on the order of 10^{-21} MKS units or more.

Ever since the first observation of the nonlinear optical effect[1] shortly after the advent of the laser, there has been a constant search for new efficient nonlinear materials. To be useful, a large nonlinearity is, however, hardly enough. Minimum requirements in other properties must also be satisfied, such as transparency window, phase-matching condition, optical damage threshold, mechanical hardness, thermal and chemical stability, etc. Above all, it must be possible to grow large single crystals of good optical quality for second-order effects. The perfection of the growth technology for each crystal can, however, be a time-consuming process. All these difficulties tend to conspire to make good nonlinear optical materials difficult to come by.

The most commonly used second-order nonlinear optical crystals in the bulk form tend to be inorganic crystals such as the ADP-isomorphs $NH_4H_2PO_4$ (ADP), KH_2PO_4 (KDP), $NH_4H_2AsO_4$ (ADA), CsH_2AsO_4 (CDA), etc. and the corresponding deuterated version; the ABO_3 type of ferroelectrics such as $LiIO_3$, $LiNbO_3$, $KNbO_3$, etc.; and the borates such as β-BaB_2O_4, LiB_3O_5, etc.

Although the III-V and II-VI compounds such as GaAs, InSb, GaP, ZeTe, etc. generally have large **d**-coefficients, because their structures are cubic, there is no birefringence that can be used to compensate for material dispersion. Therefore, they cannot be phase-matched in the bulk and are useful only in waveguide forms. Organic crystals hold promise because of the large variety of such materials and the potential to synthesize molecules according to some design principles. As a result, there have been extensive efforts at developing such materials for applications in nonlinear optics, but very few useful second-order organic crystals have been identified so far. Nevertheless, organic materials, especially for third-order processes, continue to attract a great deal of interest and remain a promising class of nonlinear materials.

To illustrate the important points in considering materials for nonlinear optical applications, a few examples of second-order nonlinear crystals with their key properties are tabulated in Tables 1 through 3. It must be emphasized, however, that because some of the materials are relatively new, some of the numbers listed are subject to confirmation and possibly revision. Discussions of other inorganic and organic nonlinear optical crystals can be found in the literature.[41]

As nonlinear crystals and devices become more commercialized, the issues of standardization of nomenclature and conventions and quantitative accuracy are becoming increasingly important. Some of these issues are being addressed[42] but much work remains to be done.

TABLE 1 Properties of Some Nonlinear Optical Crystals*

Crystal	LiB_3O_5	β-BaB_2O_4[f]

10.5 APPENDIX

The results in this article are given in the rationalized MKS systems. Unfortunately, many of the pioneering papers on nonlinear optics were written in the cgs gaussian system. In addition, different conventions and definitions of the nonlinear optical coefficients are used in the literature by different authors. These choices have led to a great deal of confusion. In this Appendix, we give a few key results to facilitate comparison of the results using different definitions and units.

First, in the MKS system, the displacement vector **D** is related to the **E**-field and the induced polarization **P** in the medium as follows:

$$\begin{aligned}\mathbf{D} &= \varepsilon_0\mathbf{E} + \mathbf{P} \\ &= \varepsilon_0\mathbf{E} + \mathbf{P}^{(1)} + \mathbf{P}^{(2)} + \cdots\end{aligned} \tag{A-1}$$

TABLE 3 Properties of Several UV, Visible, and Near-IR Crystals*

Crystal	KDP	KTP (II)†

Predominant growth defects	Organic impurities	Flux inclusions
Chemical properties	Hygroscopic (m.p. ~253°C)	Nonhygroscopic (m.p. ~1172°C)

*Unless otherwise stated, all data for 1064 nm. (Data taken from *c*, *e*; *a*, *b*, *f*, *m*; and *d*, *g*–*i*, respectively.)

†KTP Type I interaction gives $d_{eff} \sim d_{36}$ (KDP) or less for most processes.[m] The d_{ij} values[d] are for crystals grown by the hydrothermal technique.[j–l] Significantly lower damage thresholds were reported for hydrothermally grown crystals.

‡The anomalously large spectral bandwidth is a manifestation of the λ-noncritical phase matching.[n] This is equivalent to a very good group-velocity matching ($\Delta v_g^{-1} \sim 8$ fs/mm) for this interaction in KDP.

The corresponding wave equation is given in Eq. (33). For the second-order polarization and the corresponding Kleinman **d**-coefficients, two definitions are in use. A more popular definition in the current literature is as follows:

$$\mathbf{P}^{(2)} = \varepsilon_0 \mathbf{d}_2 : \mathbf{EE} \tag{A-2}$$

In an earlier widely used reference,[34] Yariv defined his **d**-coefficient as follows:

$$\mathbf{P}^{(2)} = \mathbf{d}_2^{(\text{Yariv})} : \mathbf{EE} \tag{A-3}$$

The numerical values of $\mathbf{d}_2^{(\text{Yariv})}$ in this reference (e.g., Table 16.2)[34] are given in $(1/9) \times 10^{-22}$ MKS units. The numerical value of ε_0 in the MKS system is $10^7 \times (1/4\pi c^2)$ in MKS units. Thus, for example, a tabulated value of $\mathbf{d}_2^{(\text{Yariv})} = 0.5 \times (1/9) \times 10^{-22}$ MKS units in Ref. 34 converts to a numerical value of $d_2 = 0.628$ pm/V in MKS units.

In the cgs gaussian system, the displacement vector **D** is related to the **E**-field and the induced polarization **P** in the medium as follows:

$$\begin{aligned}\mathbf{D} &= \varepsilon_0 \mathbf{E} + 4\pi \mathbf{P} \\ &= \varepsilon_0 \mathbf{E} + 4\pi \mathbf{P}^{(1)} + 4\pi \mathbf{P}^{(2)} + \cdots\end{aligned} \tag{A-4}$$

The corresponding wave equation is:

$$\frac{\partial^2}{\partial z^2} E_i(z,t) - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} E_i(z,t) = \frac{4\pi \partial^2}{c^2 \partial t^2} P_i(z,t) \tag{A-5}$$

The conventional definition of $\mathbf{d}_2$ is as follows:

$$\mathbf{P}^{(2)} = \mathbf{d}_2 : \mathbf{EE} \tag{A-6}$$

The numerical value of $\mathbf{d}_2$ in cgs gaussian units is, therefore, equal to $(3 \times 10^4/4\pi)$ times the numerical value of $\mathbf{d}_2$ in rationalized MKS units. Thus, continuing with the numerical example given in the preceding paragraph, $\mathbf{d}_2 = 0.628$ pm/V is equal to 1.5×10^{-9} cm/Stat-Volt or 1.5×10^{-9} esu.

As a final check, the expression Eq. (42) for the second-harmonic intensity in the MKS system becomes, in the cgs gaussian system:

$$I_2 = \left(\frac{512\pi^5}{c n_1^2 n_2} \right) \left(\frac{L}{\lambda_1} \right)^2 d_{\text{eff}}^2 I_0^2 \tag{A-7}$$

All the intensities refer to those inside the medium, and the wavelength is the free-space wavelength.

11.1 GLOSSARY

$\mathbf{E}(\mathbf{R}, t)$	electric field vector
$E(t)$	electric field amplitude
ω	field frequency
$\phi(t)$	field phase
ω_0	atomic transition frequency
$\overline{\omega}_0$	average atomic transition frequency
δ	atom-field detuning
δ_0	average atom-field detuning
$\Omega_0(t)$	Rabi frequency
$\mathbf{\Omega}(t)$	pseudofield vector
$\Omega(t)$	generalized Rabi frequency
$\mathbf{U}(t)$	Bloch vector
$\rho_{ij}(Z, t)$	density matrix element in a field interaction representation
$\rho_{ij}^T(\mathbf{R}, t)$	density matrix element in Schrödinger representation
(u, v, w)	elements of Bloch vector
γ	transverse relaxation rate
γ_2	excited-state decay rate or longitudinal relaxation rate
$\mathbf{P}(\mathbf{R}, t)$	polarization vector
$\mathbf{k}$	field propagation vector
$E_S(Z, t)$	complex signal electric field amplitude
$P(Z, t)$	complex polarization field amplitude
$\mathcal{N}$	atomic density

This chapter is dedicated to Richard G. Brewer, a pioneer in coherent optical transients, a mentor and a friend.

L	sample length
μ	dipole moment matrix element
τ, τ_{ref}	pulse durations
θ	pulse area
Δ	difference between local and average transition frequency in a solid
$W_f(\Delta)$	distribution of frequencies in a solid
σ_w	width of $W_f(\Delta)$
$\mathbf{v}$	atomic velocity
u	most probable atomic speed
$W_0(\mathbf{v})$	atomic velocity distribution
$I(L, t)$	signal intensity exiting the sample
T_{21}, T	time interval between pulses
Γ_t	transit time decay rate
$\Gamma_{2,0}$, $\Gamma_{2,1}$	branching decay rates of the excited state
$\Omega_i^{(s)}t$	two-photon Rabi frequency
ω_k	recoil frequency
$\mathbf{P}$	center-of-mass momentum
$E_b(t_1, t_2)$	backscattered electric field amplitude
$J_N(x)$	Bessel function
ξ	one-half of the frequency chirp rate
ω_{RD}	frequency offset between reference and data pulses

11.2 INTRODUCTION

Optical spectroscopy is a traditional method for determining transition frequencies in atoms and molecules. One can classify optical spectroscopy into two broad categories: *continuous-wave* (CW) or stationary spectroscopy and *time-dependent* or transient spectroscopy. In CW spectroscopy, one measures absorption or emission line shapes as a function of the incident frequency of a probe field. The absorption or emission maximum determines the transition frequency, while the width of the line is a measure of relaxation processes affecting the atoms or molecules. It is necessary to model the atom-field interaction to obtain predictions for the line shapes, but, once this is done, it is possible to extract the relevant transition frequencies and relaxation rates from the line shapes. In transient spectroscopy, one can also determine relaxation rates and transition frequencies, but the methodology is quite different. Atomic state populations or coherences between atomic states are excited by pulsed optical fields. Following the excitation, the time-evolution of the atoms is monitored, from which transition frequencies and relaxation rates can be obtained. In certain cases the transient response is studied as a function of incident field frequency or intensity. Whether or not transient or CW spectroscopy offers distinct advantages depends on a number of factors, such as signal to noise and the reliability of lineshape formulas.[1]

In this chapter, we present basic concepts of coherent optical transient spectroscopy,[2–12] along with applications involving atomic vapors or condensed matter systems. Experimental techniques are discussed in Sec. 11.11. As in the case of CW spectroscopy, it will prove useful to consider both linear and nonlinear interactions of the atoms with the fields. The examples chosen to illustrate the concepts are relatively simple, but it is important to note that sophisticated coherent transient techniques can now be used to probe complex structures, such as liquids and semiconductors. Although we consider ensembles of atoms interacting with the applied fields, current technology allows one to study the transient response of single atoms or molecules.[13]

11.3 OPTICAL BLOCH EQUATIONS

Many of the important features of coherent optical transients can be illustrated by considering the interaction of a radiation field with a two-level atom, with lower state $|1\rangle$ having energy $-\hbar\omega_0/2$ and upper state $|2\rangle$ having energy $\hbar\omega_0/2$. For the moment, the atom is assumed to be fixed at $\mathbf{R} = 0$ and all relaxation processes are neglected. The incident electric field is

$$\mathbf{E}(\mathbf{R}=0,t)=\tfrac{1}{2}\boldsymbol{\varepsilon}\{E(t)\exp(-i[\omega t-\phi(t)])+E(t)\exp(i[\omega t-\phi(t))\} \tag{1}$$

where $E(t)$ is the field amplitude, $\boldsymbol{\varepsilon}$ is the field polarization, $\phi(t)$ is the field phase, and ω is the carrier frequency. The time dependence of $E(t)$ allows one to consider pulses having arbitrary shape while the time dependence of $\phi(t)$ allows one to consider arbitrary frequency *chirps*. It is convenient to expand the atomic state wave function in a field interaction representation as

$$\left|\psi(t)\right\rangle=c_1(t)\exp\left\{\frac{i[\omega t-\phi(t)}{2}\right\}|1\rangle+c_2(t)\exp\left\{\frac{-i[\omega t-\phi(t)]}{2}\right\}|2\rangle \tag{2}$$

The atom-field interaction potential is

$$V(\mathbf{R},t)=-\boldsymbol{\mu}\cdot\mathrm{E}(\mathbf{R},t) \tag{3}$$

where $\boldsymbol{\mu}$ is a dipole moment operator. Substituting the state vector Eq. (2) into Schrödinger's equation and neglecting rapidly varying terms (rotating-wave approximation), one finds that the state amplitudes evolve according to

$$i\hbar\frac{d\mathbf{c}}{dt}=\tilde{\mathbf{H}}\mathbf{c}\qquad \tilde{\mathbf{H}}=\left(\frac{\hbar}{2}\right)\begin{pmatrix}-\delta(t) & \Omega_0(t)\\ \Omega_0(t) & \delta(t)\end{pmatrix} \tag{4}$$

where $\mathbf{c}$ is a vector having components (c_1, c_2),

$$\delta=\omega_0-\omega \tag{5}$$

is an atom-field detuning,

$$\Omega_0(t)=-\frac{\mu E(t)}{\hbar}=-\frac{\mu}{\hbar}\sqrt{\frac{2S(t)}{\varepsilon_0 c}} \tag{6}$$

is a Rabi frequency, $\mu=\langle 1|\boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}|2\rangle=\langle 2|\boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}|1\rangle$ is a dipole moment matrix element, ε_0 is the permittivity of free space, $\mathbf{S}(t)$ is the time-averaged Poynting vector of the field, and

$$\delta(t)=\delta+\frac{d\phi(t)}{dt} \tag{7}$$

is a generalized atom-field detuning. Equation (4) can be solved numerically for arbitrary pulse envelope and phase factors.

Expectation values of physical observables are conveniently expressed in terms of density matrix elements defined by

$$\rho_{ij}=c_i c_j^* \tag{8}$$

which obey equations of motion

$$\begin{aligned}
\dot{\rho}_{11} &= -\frac{i\Omega_0(t)}{2}(\rho_{21}-\rho_{12}) \\
\dot{\rho}_{22} &= \frac{i\Omega_0(t)}{2}(\rho_{21}-\rho_{12}) \\
\dot{\rho}_{12} &= -\frac{i\Omega_0(t)}{2}(\rho_{22}-\rho_{11})+i\delta(t)\rho_{12} \\
\dot{\rho}_{21} &= \frac{i\Omega_0(t)}{2}(\rho_{22}-\rho_{11})-i\delta(t)\rho_{21}
\end{aligned} \tag{9}$$

An alternative set of equations in terms of real variables can be obtained if one defines new parameters

$$\begin{aligned}
u &= \rho_{12}+\rho_{21} & \rho_{12} &= \frac{u+iv}{2} \\
v &= i(\rho_{21}-\rho_{12}) & \rho_{21} &= \frac{u-iv}{2} \\
w &= \rho_{22}-\rho_{11} & \rho_{22} &= \frac{m+w}{2} \\
m &= \rho_{11}+\rho_{22} & \rho_{11} &= \frac{m-w}{2}
\end{aligned} \tag{10}$$

which obey the equations of motion

$$\begin{aligned}
\dot{u} &= -\delta(t)v \\
\dot{v} &= \delta(t)u-\Omega_0(t)w \\
\dot{w} &= \Omega_0(t)v \\
\dot{m} &= 0
\end{aligned} \tag{11}$$

The last of these equations reflects the fact that $\rho_{11} + \rho_{22} = 1$, while the first three can be rewritten as

$$\dot{\mathbf{U}} = \Omega(t)\times\mathbf{U} \tag{12}$$

where the *Bloch vector* **U** has components (u, v, w) and the *pseudofield vector* $\mathbf{\Omega}(t)$ has components $[\Omega_0(t), 0, \delta(t)]$. An important feature of a density matrix description is that relaxation can be incorporated easily into density matrix equations, but *not* into amplitude equations.

Equations (9) or (11) constitute the *optical Bloch equations* without decay.[8–10,14] The vector **U** has unit magnitude and precesses about the pseudofield vector with an instantaneous rate

$$\Omega(t) = \sqrt{[\Omega_0(t)]^2+[\delta(t)]^2} \tag{13}$$

that is referred to as the *generalized Rabi frequency*. The tip of the Bloch vector traces out a path on the *Bloch sphere*. The component w is the population difference of the two atomic states, while u and v are related to the quadrature components of the atomic polarization (see following discussion).

It is possible to generalize Eqs. (9) and (11) to include relaxation. In the most general situation, each density matrix element can be coupled to all density matrix elements via relaxation. For optical transitions,

however, it is often the case that the energy separation of levels 1 and 2 is sufficiently large to preclude any relaxational transfer of population from level 1 to level 2, although state $|2\rangle$ can decay to state $|1\rangle$ via spontaneous emission. For the present, we also assume that $\rho_{11} + \rho_{22} = 1$; there is no relaxation outside the two-level subspace. In this limit, relaxation can be included in Eq. (9) by modifying the equations as

$$\dot{\rho}_{11} = -\frac{i\Omega_0(t)}{2}(\rho_{21} - \rho_{12}) + \gamma_2\rho_{22} \tag{14a}$$

$$\dot{\rho}_{22} = \frac{i\Omega_0(t)}{2}(\rho_{21} - \rho_{12}) - \gamma_2\rho_{22} \tag{14b}$$

$$\dot{\rho}_{12} = -i\frac{\Omega_0(t)}{2}(\rho_{22} - \rho_{11}) - [\gamma - i\delta(t)]\rho_{12} \tag{14c}$$

$$\dot{\rho}_{21} = i\frac{\Omega_0(t)}{2}(\rho_{22} - \rho_{11}) - [\gamma + i\delta(t)]\rho_{21} \tag{14d}$$

where γ_2 is the spontaneous decay rate of level 2, γ is the real part of the decay rate of the coherence ρ_{12}, and the detuning

$$\delta(t) = \delta + \frac{d\phi(t)}{dt} - s \tag{15}$$

is modified to include the imaginary part s of the decay rate of the coherence ρ_{12}. The corresponding equations for the Bloch vector are

$$\begin{aligned} \dot{u} &= -\delta(t)v - \gamma u \\ \dot{v} &= \delta(t)u - \Omega_0(t)w - \gamma v \\ \dot{w} &= \Omega_0(t)v - \gamma_2(w+1) \\ \dot{m} &= 0 \end{aligned} \tag{16}$$

With the addition of decay, the length of the Bloch vector is no longer conserved.

One can write

$$\gamma = \frac{\gamma_2}{2} + \mathrm{Re}(\Gamma_{12}) \qquad s = \mathrm{Im}(\Gamma_{12}) \tag{17}$$

where $\gamma_2/2$ is a radiative component and Γ_{12} is a complex decay parameter that could arise, for example, as a result of phase-interrupting collisions with a background gas. The quantity γ_2 is referred to as the *longitudinal relaxation rate*. Moreover, one usually refers to $T_1 = \gamma_2^{-1}$ as the *longitudinal relaxation time* and $T_2 = \gamma^{-1}$ as the *transverse relaxation time*. In the case of purely radiative broadening, $\gamma_2 = 2\gamma$ and $T_1 = T_2/2$.

The optical Bloch equations are easily generalized to include additional levels and additional fields. In particular, for an ensemble of three-level atoms interacting with two radiation fields, new

classes of coherent optical transient effects can appear. Moreover, the sensitivity of the coherent transients to the polarization of the applied fields offers an additional degree of selectivity in the detection of the transient signals. Some examples of coherent transient phenomena in three-level and multilevel systems can be found in the references.[11,15–20] Chapter 14, "Electromagnetically Induced Transparency," contains some interesting phenomena associated with such multilevel systems.

11.4 MAXWELL-BLOCH EQUATIONS

The optical Bloch equations must be coupled to Maxwell's equations to determine in a self-consistent way the modification of the atoms by the fields and the fields by the atoms. To accomplish this task, we start with Maxwell's equations, setting $\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P}$. The wave equation derived from Maxwell's equations is

$$\nabla^2 \mathbf{E} - \nabla(\nabla \cdot \mathbf{E}) = \frac{1}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2} + \frac{1}{\varepsilon_0 c^2}\frac{\partial^2 \mathbf{P}}{\partial t^2} \tag{18}$$

As a result of atom-field interactions, it is assumed that a polarization is created in the medium of the form

$$\mathbf{P}(\mathbf{R}, t) = \tfrac{1}{2}\varepsilon[P(\mathbf{R}, t)\exp i(kZ - \omega t) + P^*(\mathbf{R}, t)\exp -i(kZ - \omega t)] \tag{19}$$

which gives rise to a signal electric field of the form

$$\mathbf{E}_S(\mathbf{R}, t) = \tfrac{1}{2}\varepsilon[E_S(\mathbf{R}, t)\exp i(kZ - \omega t) + E_S^*(\mathbf{R}, t)\exp -i(kZ - \omega t)] \tag{20}$$

The Z axis has been chosen in the direction of $\mathbf{k}$. It is assumed that the complex field amplitudes $P(\mathbf{R}, t)$ and $E_S(\mathbf{R}, t)$ vary slowly in space compared with exp (ikZ) and slowly in time compared with exp $(i\omega t)$. To simplify matters further, transverse effects such as self-trapping, self-focusing, diffraction, and ring formation[21–25] are neglected. In other words, we take $P(\mathbf{R}, t)$ and $E_S(\mathbf{R}, t)$ to be functions of Z and t only, choose $\varepsilon \cdot \mathbf{k} = 0$, and drop the $\nabla(\nabla \cdot \mathbf{E})$ term in the wave equation. When Eqs. (19) and (20) are substituted into the wave equation and terms of order $\partial^2 E_S(Z, t)/\partial t^2$, $\partial^2 E_S(Z, t)/\partial Z^2$, $\partial^2 P(Z, t)/\partial t^2$, and $\partial P(Z, t)/\partial t$ are neglected, one finds

$$2ik\left(\frac{\partial}{\partial Z} + \frac{\omega}{kc^2}\frac{\partial}{\partial t}\right)E_S(Z, t) - \left(k^2 - \frac{\omega^2}{c^2}\right)E_S(Z, t) = -\frac{\omega^2}{\varepsilon_0 c^2}P(Z, t) \tag{21}$$

It is important to note that the polarization field acts as the source of the signal field. Consequently, the signal field does *not* satisfy Maxwell's equations in vacuum, implying that there can be cases when $k \neq \omega/c$. For the moment, however, we assume that this *phase-matching* condition is met. Moreover, it is assumed that a quasi-steady state has been reached in which one can neglect the $\partial E_S(Z, t)/\partial t$ in Eq. (21). With these assumptions, Eq. (21) reduces to

$$\frac{\partial E_S(Z, t)}{\partial Z} = \frac{ik}{2\varepsilon_0}P(Z, t) \tag{22}$$

Additional equations would be needed if the applied fields giving rise to the polarization of the medium are themselves modified to any extent by the signal field.

The polarization $P(Z, t)$ is the link between Maxwell's equations and the optical Bloch equations. The polarization is defined as the average dipole moment per unit volume, or

$$\mathbf{P}(\mathbf{R},t)=\mathrm{Tr}(\rho^{T}\mu)=\frac{1}{V}\mathrm{Tr}\left[\sum_{j}\int d\mathbf{R}_{j}\rho^{T(j)}(\mathbf{R}_{j},t)\mu\delta(\mathbf{R}-\mathbf{R}_{j})\right]$$
$$=\mathcal{N}\mu[\langle\rho_{12}^{T}(\mathbf{R},t)\rangle+\langle\rho_{21}^{T}(\mathbf{R},t)\rangle] \tag{23}$$

where $\rho^{T(j)}(\mathbf{R}_j, t)$ and $\rho_{12}^{T}(\mathbf{R},t)$ are single-particle density matrix elements, V is the sample volume, and $\mathcal{N}$ is the atomic density. The superscript T indicates that these are "total" density matrix elements written in the Schrödinger representation rather than the field interaction representation. The relationship between the two is

$$\rho_{12}^{T}(\mathbf{R},t)=\rho_{12}(Z,t)\exp[-i(kZ-\omega t)] \tag{24}$$

The angle brackets in Eq. (23) indicate that there may be additional averages that must be carried out. For example, in a vapor, there is a distribution of atomic velocities that must be summed over, while in a solid, there may be an inhomogeneous distribution of atomic frequencies owing to local strains in the media. By combining Eqs. (19), (23), and (24), one arrives at

$$\frac{\partial E_{S}(Z,t)}{\partial Z}=\frac{ik\mathcal{N}\mu}{\varepsilon_{0}}\langle\rho_{21}(Z,t)\rangle=\frac{ik\mathcal{N}\mu}{2\varepsilon_{0}}\langle u(z,t)-iv(Z,t)\rangle \tag{25}$$

which, together with Eqs. (14) or (16), constitute the Maxwell-Bloch equations.

11.5 FREE POLARIZATION DECAY

As a first application of the Maxwell-Bloch equations, we consider free polarization decay (FPD),[26–30] which is the analog of free induction decay (FID) in nuclear magnetic resonance (NMR).[31,32] The basic idea behind FPD is very simple. An external field is applied to an ensemble of atoms and then removed. The field creates a phased array of atomic dipoles that radiate coherently in the direction of the incident applied field. The decay of the FPD signal provides information about the transverse relaxation times. We will discuss several possible scenarios for observing FPD. For the present, we assume that there is no inhomogeneous broadening of the sample (all atoms have the same frequency). Moreover, in this and all future examples, it is assumed that one can neglect any changes in the applied fields' amplitudes or phases as the fields propagate in the medium; the Rabi frequencies of the applied fields are functions of t only.

A short pulse is applied at $t = 0$, *short* meaning that

$$\left|\delta(t)\right|\tau,\gamma\tau,\gamma_{2}\tau<<1 \tag{26}$$

where τ is the pulse duration. The inequality Eq. (26) allows one to neglect any effects of detuning or relaxation during the pulse's action. Before the pulse arrives, the atom is in its ground state, implying that the components of the Bloch vector are $u = v = 0$, $w = -1$; that is, the Bloch vector points down (see Fig. 1*a*). *During* the pulse, the pseudofield vector can be approximated as $\mathbf{\Omega}(t) = [\Omega_0(t), 0, 0]$, owing to Eq. (26). The Bloch vector precesses in the wv plane and reaches a final value following the pulse given by

$$u(0^{+})=0\quad v(0^{+})=\sin\theta\quad w(0^{+})=-\cos\theta \tag{27}$$

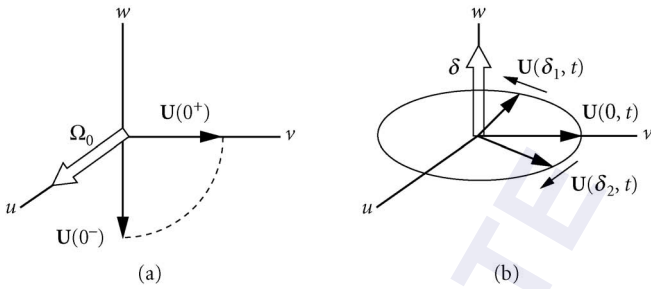

FIGURE 1 Evolution of the Bloch vector in free polarization decay. (*a*) A radiation pulse brings the Bloch vector from its initial position along the $-w$ axis to the uv plane. (*b*) With the field off, the Bloch vector precesses in the uv plane. In an inhomogeneously broadened sample, atoms having different detunings δ precess at different rates. The decay of the Bloch vector is not indicated in the figure.

where

$$\theta = \int_{-\infty}^{\infty} \Omega_0(t)\,dt \tag{28}$$

is a *pulse area* and 0^+ is a time just after the pulse. *Following* the pulse, the pseudofield vector is $\mathbf{\Omega} = (0, 0, \delta)$, and the Bloch vector precesses about the w axis as it decays (see Fig. 1*b*). Explicitly, one finds

$$\begin{aligned} u(t) &= -\sin\theta \sin(\delta t)\exp(-\gamma t) \\ v(t) &= \sin\theta \cos(\delta t)\exp(-\gamma t) \\ w(t) &= -1+(1-\cos\theta)\exp(-\gamma_2 t) \end{aligned} \tag{29}$$

From this result, we can draw two conclusions. First, since the applied field is off when the atoms radiate, radiation is emitted at the natural frequency ω_0. This conclusion follows formally from Eqs. (29), (10), (23), and (24), which can be used to show that $P(Z, t)$ varies as exp $(-i\delta t)$, and both $\mathbf{P}(\mathbf{R}, t)$ and $\mathbf{E}(\mathbf{R}, t)$ oscillate at frequency $\omega + \delta = \omega_0$. Second, one can use Eqs. (29) and (25) to obtain

$$\frac{\partial E_S(Z,t)}{\partial Z} = \frac{k\mathcal{N}\mu}{2\varepsilon_0}\sin\theta\exp[-(\gamma+i\delta)t] \tag{30}$$

If the sample under consideration is optically thin, the power exiting a sample of length L in the $\hat{\mathbf{Z}}$ direction is proportional to

$$I(L,t) = \left|E_S(L,t)\right|^2 = \left(\frac{k\mathcal{N}\mu L}{2\varepsilon_0}\sin\theta\right)^2 \exp(-2\gamma t) \tag{31}$$

The signal is maximal for a pulse area of $\pi/2$. A measure of the output power as a function of time following the excitation pulse enables one to obtain a value for the transverse relaxation rate. For a pencil-like sample, the neglect of cooperative effects such as superradiance is based on the assumption that $\mathcal{N}L/k^2 << 1$.[25,33–35]

An alternative means for observing an FPD signal is to use an atomic beam that traverses a field interaction zone. The atom "sees" a radiation pulse in the atomic rest frame. If the atoms all have

the same longitudinal velocity u_0, then the FPD signal measured at a distance L from the field interaction zone arises from atoms which were excited at time $t_e = t - L/u_0$. This implies that the phase factor $\exp[-(\gamma + i\delta)t]$ in Eq. (30) should be replaced by $\exp[-(\gamma+i\delta)(t-t_e)] = \exp[-(\gamma+i\delta)L/c]$. The emitted field is radiated at the incident field frequency ω rather than the atomic frequency ω_0. If the intensity is monitored as a function of L, one can obtain the transverse relaxation rate.

Often the atoms or molecules are characterized by an inhomogeneous distribution of frequencies. In a solid, this can occur as a result of different strains in the host medium. In a vapor, the velocity distribution of the atoms is equivalent to a distribution of atomic transition frequencies, when viewed in the laboratory frame. To discuss both solids and vapors in the same context, we define

$$\delta \equiv \delta(\omega_0, \mathbf{v}) = \omega_0 - \omega + \mathbf{k}\cdot\mathbf{v} = \delta_0 + \Delta + \mathbf{k}\cdot\mathbf{v} \tag{32}$$

where

$$\delta_0 = \bar{\omega}_0 - \omega \qquad \Delta = \omega_0 - \bar{\omega}_0 \tag{33}$$

and $\bar{\omega}_0$ is the average transition frequency. In a solid, $\mathbf{v} = 0$, but there is an inhomogeneous distribution of frequencies given by

$$W_f(\Delta) = \frac{1}{\sqrt{\pi}\sigma_w}\exp\left(-\frac{\Delta}{\sigma_w}\right)^2 \tag{34}$$

where σ_w characterizes the width of the inhomogeneous distribution. In a vapor, $\Delta = \sigma_w = 0$, but there is a Maxwellian velocity distribution

$$W_0(\mathbf{v}) = \frac{1}{(\pi u^2)^{3/2}}\exp[-(v/u)^2] \tag{35}$$

where u is the most probable atomic speed. The net effect is that Eq. (31) must be replaced by

$$\begin{aligned} I(L,t) &= \left(\frac{k\mathcal{N}\mu L}{\varepsilon_0}\right)^2 \left|\langle\rho_{21}(t)\rangle\right|^2 \\ &= \left(\frac{k\mathcal{N}\mu L}{2\varepsilon_0}\sin\theta\right)^2 \left|\int d\mathbf{v} W_0(\mathbf{v}) \int d\Delta W_f(\Delta)\exp\left(-[\gamma - i(\bar{\omega}_0 + \Delta + \mathbf{k}\cdot\mathbf{v})]t\right)\right|^2 \\ &= \left(\frac{k\mathcal{N}\mu L}{2\varepsilon_0}\sin\theta\right)^2 \exp(-2\gamma t)\exp\left[\frac{-(\sigma_\omega t)^2}{2}\right]\exp\left[\frac{-(kut)^2}{2}\right] \end{aligned} \tag{36}$$

If $\sigma_\omega >> \gamma$ (solids) or $ku >> \gamma$ (vapors), the signal decays mainly owing to inhomogeneous broadening. Bloch vectors corresponding to different frequencies process about the w axis at different rates, implying that the optical dipoles created by the pulse lose their relative phase in a time of order $T_2^* = (2\sigma_\omega)^{-1}$ or $(2ku)^{-1}$ (see Fig. 1*b*). The FPD signal can be used to measure T_2^*, which can be viewed as an inhomogeneous, transverse relaxation time. At room temperature, ku/γ is typically on the order of 100. In a solid, σ_ω/γ can be orders of magnitude larger. An experimental FPD signal is shown in Fig. 2.

It is also possible to produce an FPD signal by preparing the atoms with a CW laser field and suddenly turning off the field. This method was used by Brewer and coworkers in a series of experiments on coherent optical transients in which Stark fields were used to tune molecules in a vapor into and out of resonance.[26] The CW field modifies the velocity distribution for the molecules. In

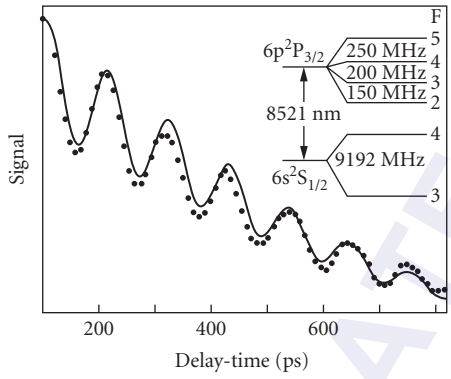

FIGURE 2 An FPD signal obtained on the D_2 transition in cesium. The excitation pulse has a duration of 20 ps. The decay time of the signal is determined by the inhomogeneous transverse relaxation rate $T_2^* = 1.4$ ns. Oscillations in the signal originate from the ground state hyperfine splitting. (*From Ref. 28. Reprinted with permission.*)

the linear field regime, this again leads to an FPD signal that decays on a time scale of order $(ku)^{-1}$. It is fairly easy to obtain this result. To first order in the field, the steady-state solution of Eq. (14*d*), generalized to include the Doppler shift $\mathbf{k}\cdot\mathbf{v}$ and initial velocity distribution $W_0(\mathbf{v})$, is

$$\rho_{21}(\mathbf{v}) = -i\left(\frac{\Omega_0}{2}\right)[\gamma - i(\delta_0 + \mathbf{k}\cdot\mathbf{v})]^{-1} W_0(\mathbf{v}) \tag{37}$$

With this initial condition, it follows from Eq. (14*d*) that, for $t > 0$,

$$\begin{aligned}\langle\rho_{21}(\mathbf{v},t)\rangle &= \int d\mathbf{v}\,\frac{-i(\Omega_0/2)\exp[-\gamma t - i(\delta_0 + \mathbf{k}\cdot\mathbf{v})t]}{\gamma + i(\delta + \mathbf{k}\cdot\mathbf{v})} W_0(\mathrm{v}) \\ &= -i\frac{\sqrt{\pi}\Omega_0}{2ku}\exp\left[\left(\frac{\gamma + i\delta_0}{ku}\right)^2\right]\left[1 - \Phi\left(\frac{\gamma + i\delta_0}{ku} + \frac{kut}{2}\right)\right]\end{aligned} \tag{38}$$

where Φ is the error function. For $kut > 1$ and $|\gamma + i\delta_0|/ku << 1$, $\langle\rho_{21}(\mathbf{v})\rangle \sim -i[\Omega_0/(k^2u^2t)]\exp(-k^2u^2t^2/4)$.

When one considers *nonlinear* interactions with the field, the situation changes. The CW field excites only those atoms having $\mathbf{k}\cdot\mathbf{v} = -\delta \pm \gamma'$, where γ' is a power-broadened homogeneous width. These velocity-selected atoms are no longer subject to inhomogeneous broadening and give rise to a contribution to the FPD signal that decays with rate $T_2^{-1} = (\gamma + \gamma')$.[26] Thus, by using *nonlinear* atom-field interactions, one can extract *homogeneous* decay rates in situations where there is large inhomogeneous broadening. The price one pays is that only a small percentage of the atoms (those that have velocities for which the applied field is resonant) contribute to the signal. An example of an FPD signal of this type is shown in Fig. 3.

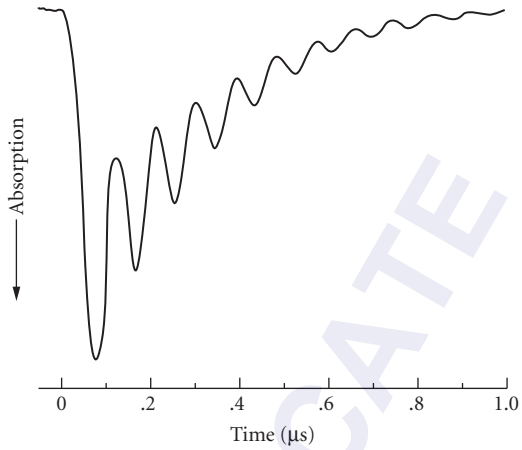

FIGURE 3 An FPD signal obtained in NH_2D at 10.6 μm using the method of Stark switching of a molecular transition frequency. Molecules that interact resonantly with a CW field are suddenly tuned out of resonance by the Stark switching. The oscillations result from the heterodyne detection method that is used, while the slowly varying increase in the signal is the result of optical nutation of molecules switched *into* resonance by the Stark pulse. The FPD signal manifests itself as a *reduction of the amplitude of the oscillation* with time. This amplitude decays with the (power-broadened) *homogeneous* decay rate T_2, owing to the fact that the nonlinear interaction with a CW field results in the excitation of only a small fraction of the Doppler profile of the molecules. (*From Ref. 26. Reprinted with permission.*)

11.6 PHOTON ECHO

We have seen that it is possible to measure the transverse relaxation rate T_2 in an inhomogeneously broadened sample using FPD, but only a relatively small percentage of the atoms participate. The question arises as to whether other techniques would allow for full participation of the atoms. The *photon echo* is one such method.[8–10,36–38] The photon echo has very little to do with either photons or echoes, but the name has a nice ring to it. The photon echo, the optical analog of the spin echo,[39] was first observed in ruby by Kurnit et al.[36] A pulse having propagation vector $\mathbf{k}_1$ is applied at $t = 0$, a second pulse having propagation vector $\mathbf{k}_2 = \mathbf{k}_1$ is applied at $t = T_{21}$, and an echo is radiated at time $t = 2T_{21}$ in a direction $\mathbf{k} = \mathbf{k}_1$. There are many ways to explain echo formation, and some of these are indicated in the following discussion.

In the Bloch vector picture, a $\pi/2$ pulse excites the optical dipoles at $t = 0$, bringing the Bloch vector along the v axis (Fig. 4*a*). The Bloch vector then begins to precess in the uv plane at a rate equal to the atom-field detuning. In an inhomogeneously broadened medium, different atoms have different resonant frequencies. As a consequence, the Bloch vectors associated with different atoms precess at different rates and dephase relative to each other in a time T_2^* (Fig. 4*b*). The dipole coherence is not lost, however. If at time T_{21} a π pulse is applied, the net effect of the pulse is to cause a reflection about the uw plane (Fig. 4*c*). As the atoms continue to precess at different rates (Fig. 4*d*), the rates are such that the Bloch vectors for *all* the atoms will become aligned with the $-v$ axis at time $t = 2T_{21}$ and an *echo signal* is emitted (Fig. 4*e*). From time $t = 0$ to $t = 2T_{21}$ the dipoles decay with the homogeneous decay rate γ.

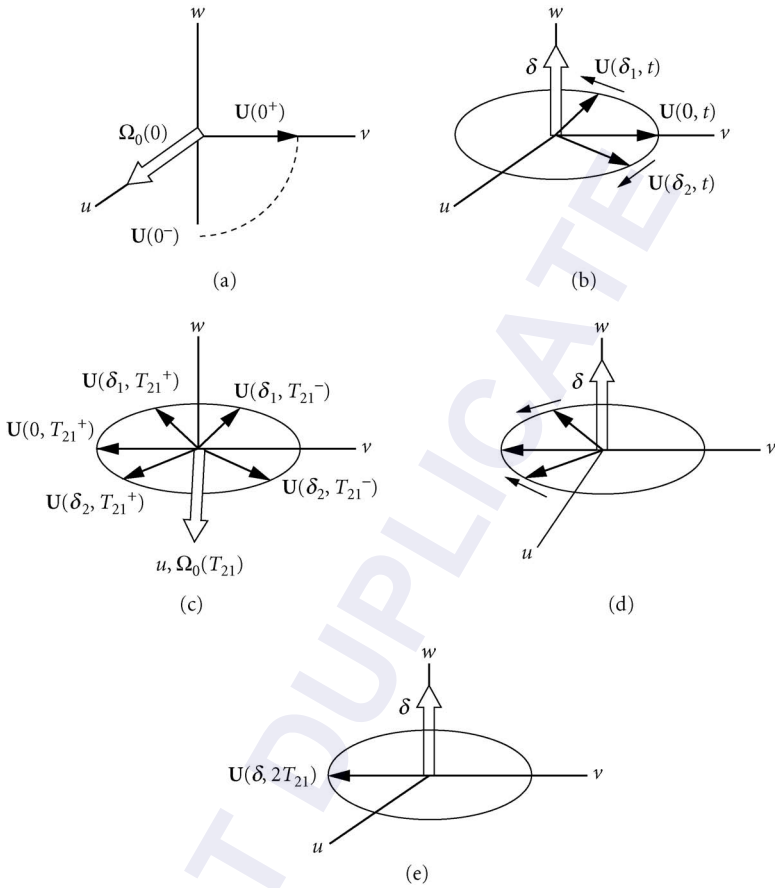

FIGURE 4 Bloch vector picture of echo formation. (*a*) An initial $\pi/2$ pulse brings the Bloch vector to the *uv* plane. (*b*) In a field-free region, the Bloch vector precesses in the *uv* plane; atoms with different detunings dephase relative to one another in a time equal to the inhomogeneous, transverse relaxation rate T_2^*. (*c*) At time T_{21}, a second pulse, this time a π pulse, reflects the Bloch vectors with respect to the *uw* plane. (*d*) In a field-free region, the Bloch vectors continue to precess. (*e*) At time $t = 2T_{21}$, all the vectors are aligned along the $-v$ axis (the optical dipoles have rephased), and an echo signal is emitted. The decay of the Bloch vector is not indicated in the figure.

By measuring the echo signal as a function of delay time T_{21} between the pulses, one can obtain the transverse relaxation time $T_2 = \gamma^{-1}$.

It is not necessary that the pulse areas be equal to $\pi/2$ and π, although these areas lead to a maximal signal. What *is* necessary is that the second pulse produce at least a partial reflection about the *uw* plane. This reflection takes the Bloch vector components $u + iv$ into $u - iv$, or, equivalently, takes density matrix element ρ_{12} into ρ_{21}. Since ρ_{12} and ρ_{21} are related to the real and imaginary parts of the average dipole moment operator, the second pulse must couple these real and imaginary parts. *Such coupling is impossible for a linear atom-field interaction*. Thus, by its very nature, the photon echo can occur only when nonlinear atom-field interactions are present.

An alternative way to picture echo formation is to use double-sided Feynman diagrams[40] that keep track of the relative phase of the different dipoles. Diagrams similar to those indicated in Fig. 5 were

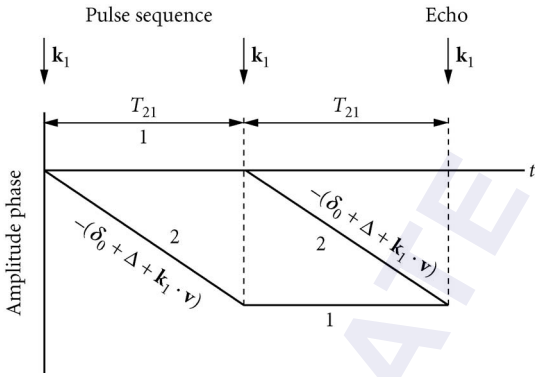

FIGURE 5 A phase diagram that can be used to analyze coherent transient phenomena. Each line corresponds to a state amplitude, and density matrix elements are obtained by multiplying a top line by the conjugate of a bottom line *at the same time*. The relative phase of a given density matrix element is given by the vertical separation of the two lines. The slopes of various line segments are shown on the graph. Lines corresponding to atoms having different atom-field detunings Δ (solid) or different velocities $\mathbf{v}$ (vapor) would have different slopes. The pulse sequence is shown at the top of the figure along with the temporal position and direction of the echo. This diagram corresponds to the two-pulse photon echo. Regardless of the atom-field detuning or atomic velocity, all lines cross at $t = 2T_{21}$, indicating that all the optical dipoles are in phase at this point.

introduced by Hartmann and Friedberg in the context of a billiard ball echo model[41] and have been used extensively in theories of atom interferometry.[42–44] Each line represents a field amplitude. The abscissa is time, and the ordinate is the *phase* associated with the amplitude. In the absence of any interactions, it follows from Eq. (4) that the phase associated with the state $|1\rangle$ amplitude is $\delta t/2$ and that associated with the state $|2\rangle$ amplitude is $-\delta t/2$. In these diagrams, the phase of each amplitude is displaced by $-\delta t/2$ so that the state $|1\rangle$ amplitude evolves without any phase change and the state $|2\rangle$ amplitude evolves with a phase equal to $-\delta t$.

We start with the atom in state $|1\rangle$ at $t = 0$. The atom-field interaction takes state $|1\rangle$ to $|2\rangle$ on absorption with a phase factor exp $(i\mathbf{k}_1 \cdot \mathbf{R})$ and $|2\rangle$ to $|1\rangle$ on emission with a phase factor exp $(-i\mathbf{k}_1 \cdot \mathbf{R})$. A vertical cut establishes the density matrix element of interest and the vertical distance between the two amplitudes is a measure of the *relative* phase of the amplitudes. For example, between $t = 0$ and $t = T_{21}$ in Fig. 5, the density matrix element ρ_{12} has been created with relative phase $(\delta_0 + \Delta + \mathbf{k}_1 \cdot \mathrm{v})t$ which grows with increasing t. One finds significant contributions to the dipole coherence at a given time *only* when the relative phase is the *same* for all the optical dipoles at that time. In a solid $\mathbf{v} = 0$, but $\Delta = \omega_0 - \bar{\omega}_0$ is different for different atoms owing to variations in ω_0; in a vapor $\Delta = 0$, but $\mathbf{k}_1 \cdot \mathbf{v}$ is different for different velocity subclasses of atoms. Thus, the slopes of the lines in Fig. 5 would differ for different atoms in both solids and vapors. On averaging over an inhomogeneous frequency distribution, the average dipole coherence would vanish, except at times near crossings of the state amplitudes, where the relative phase of all the dipoles is nearly equal to zero. Between $t = 0$ and $t = T_{21}$, this occurs only near $t = 0$, where an FPD signal is emitted. The application of a second pulse at $t = T_{21}$, however, converts ρ_{12} into ρ_{21} and begins a rephasing process for the dipoles. The state amplitudes in Fig. 5 intersect and the dipoles are rephased at $t = 2T_{21}$, *independent of the value of* $\mathbf{v}$ or Δ. The echo signal is radiated for times $t \approx 2T_{21}$.

Analytical calculations of the signal intensity can be carried out using Eqs. (14) and (16). One simply pieces together periods in which the pulses act with periods of free evolution. The results are rather complicated, in general. However, if $\sigma_w T_{21} >> 1$ (solid) or $k_1 u T_{21} >> 1$ (vapor), only terms in the density matrix sequence indicated schematically in Fig. 5 survive the average over the inhomogeneous frequency distribution in the vicinity of the echo at $t \approx 2T_{21}$. At these times, one finds a total averaged density matrix element

$$\langle \rho_{21}^T(\mathbf{R},t)\rangle = \langle \rho_{21}(t)\rangle \exp(i[kZ-\omega t])$$

where

$$\mathbf{k} = -\mathbf{k}_1 + 2\mathbf{k}_1 = \mathbf{k}_1$$

$$\langle \rho_{21}(t)\rangle = \frac{1}{2}\sin\theta_1 \sin^2\left(\frac{\theta_2}{2}\right)\exp(-2\gamma T_{21})\exp[-i\delta_0(t-2T_{21})]$$
$$\times \exp\left[\frac{-\sigma_\omega^2(t-2T_{21})^2}{4}\right]\exp\left[\frac{-k_1^2u^2(t-2T_{21})^2}{4}\right] \tag{39}$$

and θ_i is the pulse area of pulse i. The corresponding echo intensity is

$$I(L,t) = \left(\frac{kN\mu L}{\varepsilon_0}\right)^2 \left|\langle \rho_{21}(t)\rangle\right|^2 = \left[\frac{kN\mu L}{2\varepsilon_0}\sin\theta_1 \sin^2\left(\frac{\theta_2}{2}\right)\right]^2$$
$$\times \exp(-4\gamma T_{21})\exp\left[\frac{-\sigma_\omega^2(t-2T_{21})^2}{2}\right]\exp\left[\frac{-k_1^2u^2(t-2T_{21})^2}{2}\right] \tag{40}$$

It is interesting to note that the echo intensity near $t = 2T_{21}$ mirrors the FPD intensity immediately following the first pulse.

For experimental reasons it is often convenient to use a different propagation vector for the second pulse. Let $\mathbf{k}_1$ and $\mathbf{k}_2$ be the propagation vectors of the first and second pulses, which have identical carrier frequencies ω. In this case, one must modify the definition (24) of the field interaction representation to account for the different $\mathbf{k}$ vectors. The final result for the total averaged density matrix element in the vicinity of the echo is

$$\langle \rho_{21}^T(\mathbf{R},t)\rangle = \langle \rho_{21}(t)\rangle \exp(i[kZ-\omega t])$$

where

$$\mathbf{k} = 2\mathbf{k}_2 - \mathbf{k}_1$$

and

$$\langle \rho_{21}(t)\rangle = \frac{i}{2}\sin\theta_1 \sin^2\left(\frac{\theta_2}{2}\right)\exp(-2\gamma T_{21})\exp[-i\delta_0(t-2T_{21})]$$
$$\exp\left[\frac{-\sigma_\omega^2(t-2T_{21})^2}{4}\right]\int d\mathbf{v}\, W_0(\mathbf{v})\exp\{i\mathbf{k}_1\cdot\mathbf{v}T_{21} - \mathbf{k}_2\cdot\mathbf{v}(t-T_{21})\} \tag{41}$$

Recall that $\sigma_\omega = 0$ for a vapor and $W_0(\mathbf{v}) = \delta_D(\mathbf{v})$ for a solid, where δ_D is the Dirac delta function. In these equations there are three things to note. First, the signal is emitted in a direction different from that of the applied fields, a desirable feature from an experimental point of view. Second, the phase

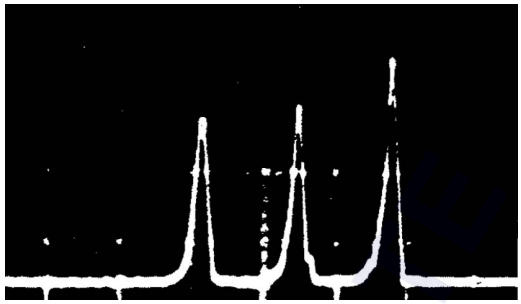

FIGURE 6 A photon echo signal from ruby. Time increases to the right with a scale of 100 ns/division. The pulse on the right is the echo signal, while the first two pulses are the (attenuated) input pulses. The echo appears at $t = 2T_{21}$ where T_{21} is the separation of the input pulses. (*From Ref. 36. Reprinted with permission.*)

matching condition $k = \omega/c$ is no longer satisfied since $k = |2\mathbf{k}_2 - \mathbf{k}_1|$ and $k_1 = k_2 = \omega/c$; however, if the fields are nearly collinear such that $(k^2 - \omega^2/c^2)L^2 << 1$, the effects of phase mismatch are negligible. Third, there is now a qualitative difference between the solid and vapor case. Owing to the fact that the detuning depends on the propagation vectors for the vapor, it is not possible to exactly rephase all the dipoles in the vapor when $\mathbf{k}_1 \neq \mathbf{k}_2$. If $|\mathbf{k}_2 - \mathbf{k}_1|/k_1 << 1$, however, nearly complete rephasing of the dipoles occurs for $t \approx 2T_{21}$. The photon echo signal observed by Kurnit et al.[36] is shown in Fig. 6.

As can be deduced from Fig. 5, the signal is sensitive only to off-diagonal density matrix elements in the entire time interval of interest. Thus, any disturbance of the off-diagonal density matrix elements or optical coherence will be reflected as a decrease in the echo intensity. As such, echo signals can serve as a probe of all contributions to transverse relaxation. Transverse relaxation generally falls into two broad categories which can lead to qualitatively different modifications of the coherent transient signals. First, there are *dephasing processes*, which produce an exponential damping of the coherences and contribute to γ. Second, there are *spectral diffusion* (solid)[45–48] or *velocity-changing collisions* (vapor),[47–49] which change the frequency associated with the optical coherences. Such terms enter the optical Bloch equations as *integral* terms, transforming the equations into differentio-integral equations. In a solid the change in frequency can be produced by fluctuating fields acting at each atomic site. Spectral diffusion of coherences in solids is difficult to detect, since phase-interrupting processes often dominate the signals. It has been measured in FPD using impurity ions in a crystalline host.[50] The situation in vapors is a bit more subtle. The phase-changing and velocity-changing aspects of collisions are entangled and cannot be separated, in general.[49] If the collisional interaction is *state independent*, however, as it is for some molecular transitions, then collisions are purely velocity changing in nature, leading to an echo that decays exponentially as T_{21}^3 for early times and T_{21} for later times.[51] For electronic transitions, collisions are mainly phase changing in nature, but there is a velocity-changing contribution that persists in the forward diffractive-scattering cone. This diffractive scattering has been observed for Na–,[52] Li–,[53] and Yb-rare gas collisions[54] using photon echo techniques.

11.7 STIMULATED PHOTON ECHO

Up to this point, we have considered pulse sequences that are useful for measuring transverse relaxation times. Now we examine *stimulated photon echoes*,[8–10] which can be used to *simultaneously* measure both transverse and longitudinal relaxation times. Stimulated photon echoes have become an important diagnostic probe of relaxation in condensed-matter systems. The pulse sequence consists of three pulses, having

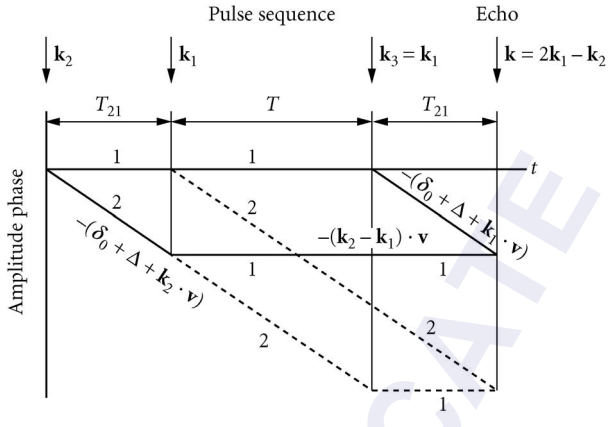

FIGURE 7 A phase diagram for the stimulated photon echo in which field 2 acts first and the echo is emitted in the $(-\mathbf{k}_2 + \mathbf{k}_1 + \mathbf{k}_3) = (2\mathbf{k}_1 - \mathbf{k}_2)$ direction. The solid lines involve the intermediate state population ρ_{11} while the dashed lines involve the intermediate state population ρ_{22}. All dipoles are in phase at $t = 2T_{21} + T$.

areas θ_1, θ_2, θ_3 and propagation vectors $\mathbf{k}_1$, $\mathbf{k}_2$, $\mathbf{k}_3$, with $k_i = \omega/c$. In this section we take $\mathbf{k}_3 = \mathbf{k}_1$, and in the next section we will set $\mathbf{k}_3 = -\mathbf{k}_1$. The time interval between the first two pulses is T_{21}, and pulse 1 can precede or follow pulse 2. Pulse 3 occurs at time $t = T_{21} + T$ (Fig. 7). Signals can be generated in many different directions. For the sake of definiteness, we consider only the signal radiated in the $-\mathbf{k}_2 + \mathbf{k}_1 + \mathbf{k}_3$ direction. The phase diagram giving rise to this signal is shown in Fig. 7. For radiation to be emitted in the $-\mathbf{k}_2 + \mathbf{k}_1 + \mathbf{k}_3$ direction when $\mathbf{k}_3 = \mathbf{k}_1$ pulse 2 must precede pulse 1. (Of course, there are diagrams with pulse 1 preceding pulse 2, but these give rise to radiation in the $-\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3$ direction.) It is assumed that T_{21} is greater than the inhomogeneous relaxation time T_2^*. The signal contains contributions from the optical coherence (off-diagonal density matrix elements) in the time intervals $(0, T_{21})$, $(T + T_{21}, t)$ and contributions from atomic state populations (diagonal density matrix elements) in the time interval T between the second and the third pulses. The echo appears when $t - (T_{21} + T) = T_{21}$.

The calculation of the echo signal is straightforward. Just before the second pulse, the density matrix $\rho_{12}(T_{21})$ varies as $\exp[-(\gamma - i\delta_2)T_{21}]$, where $\delta_i = \omega_0 - \omega + \mathbf{k}_i \cdot \mathbf{v}$. In the time interval T, the population difference $\omega = \rho_{22} - \rho_{11}$ decays at rate γ_2 and *oscillates* at frequency $\delta_2 - \delta_1 = (\mathbf{k}_2 - \mathbf{k}_1) \cdot \mathbf{v}$. In the final time interval, $\rho_{21}(t)$ varies as $\exp[-(\gamma + i\delta_3)(t - T - T_{21})]$, where $\delta_3 = \delta_1$ since $\mathbf{k}_3 = \mathbf{k}_1$. Combining the various field interaction and free propagation zones, one finds that the total averaged density matrix element in the vicinity of the echo $t \approx T + 2T_{21}$ is

$$\langle \rho_{21}^T(\mathbf{R}, t) \rangle = \langle \rho_{21}(t) \rangle \exp[i(kZ - \omega t)]$$

with

$$\mathbf{k} = -\mathbf{k}_2 + \mathbf{k}_1 + \mathbf{k}_3 = 2\mathbf{k}_1 - \mathbf{k}_2$$

and

$$\begin{aligned}\langle \rho_{21}(t) \rangle = &\left(\frac{i}{8}\right) \sin\theta_1 \sin\theta_2 \sin\theta_3 \sin(-\gamma_2 T) \exp(-2\gamma T_{21}) \exp\{-i\delta_0[t - T_{21} - T) - T_{21}]\} \\ &\times \exp\left\{\frac{-\sigma_\omega^2[(t - T_{21} - T) - T_{21}]^2}{4}\right\} \int d\mathbf{v} W_0(\mathbf{v}) \\ &\times \exp\left\{i[\mathbf{k}_2 \cdot \mathbf{v} T_{21} + (\mathbf{k}_2 - \mathbf{k}_1) \cdot \mathbf{v} T - (2\mathbf{k}_1 - \mathbf{k}_2) \cdot \mathbf{v}(t - T_{21} - T)]\right\}\end{aligned} \tag{42}$$

The optimal pulse sequence consists of three $\pi/2$ pulses. Phase matching can be achieved only for $|\mathbf{k}_1 - \mathbf{k}_2|L << 1$. In a solid, the integral in Eq. (42) is equal to unity, and the echo signal is maximal for $t = T + 2T_{21}$. In a vapor, the echo signal is degraded if $\mathbf{k}_1 \neq \mathbf{k}_2$; however, if $\mathbf{k}_1 \approx \mathbf{k}_2$, then, at $t = T + 2T_{21}$, the echo amplitude varies as

$$\exp(-\gamma_2 T)\exp(-2\gamma T_{21})\exp\left[-\frac{|\mathbf{k}_1 - \mathbf{k}_2|^2 u^2 (T + 2T_{21})^2}{4}\right]$$

By varying the angle between $\mathbf{k}_1$ and $\mathbf{k}_2$, one can determine the Doppler width ku. By monitoring the echo signal as a function of $T_{21}(T)$, one obtains information on the transverse (longitudinal) relaxation.

Relaxation other than spontaneous emission can occur for the populations in the time interval T. The inhomogeneous phase $\delta_1 T_{21}$, acquired in the time interval T_{21}, is canceled by the phase $\delta_3 T_{21}$, acquired in the interval T_{21} following the third pulse. If, between the second and third pulses, the frequency (solid) or velocity (vapor) has changed owing to spectral diffusion (solid)[45–48] or velocity-changing collisions (vapor),[47–49,55,56] the phase cancellation will not be complete. Thus, the echo signal as a function of T provides information on these relaxation processes. The rate of spectral diffusion or velocity-changing collisions must be of order or greater than γ_2 to be observable. One would have a longer time to observe such effects if it were the ground-state lifetime rather than the excited-state lifetime that was the relevant time scale, but, in a closed two-level system, such is not the case.

The situation changes if a three-level system, such as the one shown in Fig. 8, is used. The fields drive the 1–2 transition, but level 2 decays to both level 1 and level 0. The total population of the 1–2 state subsystem is no longer conserved, requiring an *additional* decay rate to account for relaxation. Let us suppose that all states decay with rate Γ_t as a result of their finite time in the laser beams. Moreover, let $\Gamma_{2,1}$ and $\Gamma_{2,0}$ be the decay rates of level 2 to levels 1 and 0, respectively, such that $\gamma_1 = \gamma_0 = \Gamma_t$ and $\gamma_2 = \Gamma_{2,1} + \Gamma_{2,0} + \Gamma_t$. For simplicity, let us also take $\mathbf{k}_1 \approx \mathbf{k}_2$. In the interval T, the decay dynamics resulting from spontaneous emission and transit time effects is

$$\dot{\rho}_{22} = -\gamma_2 \rho_{22} = -(\Gamma_{2,1} + \Gamma_{2,0} + \Gamma_t)\rho_{22}$$
$$\dot{\rho}_{11} = -\Gamma_t \rho_{11} + \Gamma_{2,1}\rho_{22}$$

Assuming that $\gamma_2 T >> 1$, one finds that at time $t = T_{21} + T$, $\rho_{22}(T_{21} + T) \sim 0$, and

$$\rho_{11}(T_{21} + T) \sim \frac{\Gamma_{2,0}}{\Gamma_{2,1} + \Gamma_{2,0}} \exp(-\Gamma_t T)$$

which then replaces the factor $\exp(-\gamma_2 T)$ in Eq. (42). If $\Gamma_{2,0} \neq 0$, there is a long-lived component in the ground-state population. One can exploit this feature of *open systems* to study spectral diffusion or velocity-changing collisions with very high sensitivity.[57,58] In Fig. 9, stimulated echo data is shown

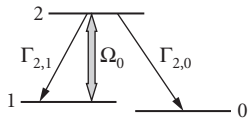

FIGURE 8 Open atomic-level scheme that can be used to observe transient signals limited only by some effective ground state lifetime. The field couples only states $|1\rangle$ and $|2\rangle$, but level 2 decays to both levels 1 and 0.

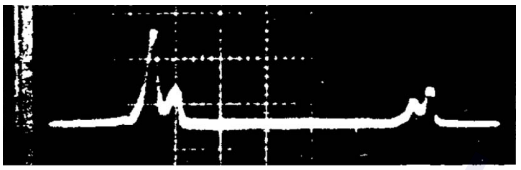

FIGURE 9 Stimulated photon echo observed on the D_1 transition in sodium. This is an "open" system for which a stimulated echo signal can be produced for separations T between the second and third pulses much larger than the excited-state lifetime. In this diagram T is 17 times the 16-ns lifetime of the excited state. The first three pulses are scattered light from the three input pulses and the fourth pulse is the echo. The echo appears at $t = T + 2T_{21}$, where T_{21} is the separation of the first two input pulses. (*From Ref. 58. Reprinted with permission.*)

that was used to measure a cross section for collisions between ground-state Na and He atoms.[58] The echo occurs for time separations T much greater than the excited-state lifetime.

Open systems also offer interesting possibilities as storage devices. Since the effective ground-state lifetime can be as long as days in certain solids, one can write interferometric information into the sample by replacing one of the first two pulses by a signal pulse and reading it out at a later time with the third pulse.[59–62] In the case of vapors, it is also possible to replace some of the incident pulses by standing-wave fields.[63–71] In this manner, modulated ground-state populations with associated Doppler phases of order kuT can be created and rephased, providing sensitivity to velocity-changing collisions as small as a few centimeters per second.[72]

Before leaving this section, it is perhaps useful to make a slight digression on *homogeneously* broadened systems. A diagram similar to that shown in Fig. 10, *in which field 1 acts first*, also leads to a signal in the $\mathbf{k} = \mathbf{k}_1 - \mathbf{k}_2 + \mathbf{k}_3 = 2\mathbf{k}_1 - \mathbf{k}_2$, provided $\mathbf{k}_3 = \mathbf{k}_1$ (in the figure, $\mathbf{k}_3 = -\mathbf{k}_1$). We have not considered this contribution for inhomogeneously broadened systems since such a diagram leads to an overall phase of $\phi_d = -2(\delta_0 + \Delta + 2\mathbf{k}_1 \cdot \mathbf{v})T_{21}$ at time $t = T + 2T_{21}$. On averaging over either Δ or $\mathbf{v}$ in an inhomogeneously broadened sample, this contribution would vanish. In a homogeneously broadened sample, however, $\Delta = 0$ and $\mathbf{v} = 0$, giving an *identical* relative phase ϕ_d to all the atoms. For $t > T + T_{21}$, the corresponding density matrix element associated with this diagram is

$$\langle \rho_{21}(t) \rangle = \left(\frac{i}{8}\right) \sin\theta_1 \sin\theta_2 \sin\theta_3 \exp(-\gamma_2 T) \exp[-\gamma(t-T)] \exp[-i\delta_0(t-T)] \tag{43}$$

Equation (43) does not constitute an echo in the usual sense, since there is no dephasing-rephasing cycle. The signal appears promptly (it is actually an FPD signal) following the third pulse. If one measures the *time-integrated* intensity in the signal following the third pulse, however (as is often the case with ultrafast pulses in which time resolution of the echo is not possible), it is impossible to tell directly whether an echo has occurred or not. For such measurements, a signal emitted in the $\mathbf{k} = 2\mathbf{k}_1 - \mathbf{k}_2$ direction when pulse 1 acts first is a clear signature of a homogeneously broadened system, since such a signal vanishes for inhomogeneously broadened samples.

The time-integrated signal is proportional to

$$\int_{T+T_{21}}^{\infty} \left| \langle \rho_{21}(t) \rangle \right|^2 dt$$

When field 2 acts first, the time integrated, inhomogeneously broadened signal varies as exp $(-4\gamma T_{21})$, while the homogeneously broadened signal varies as exp $(-2\gamma T_{21})$. When field 1 acts

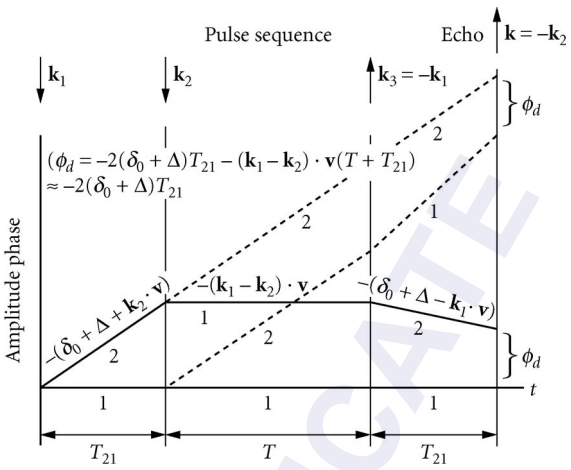

FIGURE 10 A phase diagram for the stimulated photon echo in which field 1 acts first. The direction of field 3 is opposite to that of field 1, and the echo is emitted in the $(\mathbf{k}_1 - \mathbf{k}_2 + \mathbf{k}_3) = -\mathbf{k}_2$ direction. We have taken $\mathbf{k}_2 \approx \mathbf{k}_1$. The solid lines involve the intermediate state population ρ_{11}, while the dashed lines involve the intermediate state population ρ_{22}. At time $t = 2T_{21} + T$, the relative phase is $\phi_d \approx -2(\delta_0 + \Delta)T_{21}$. For solids, the average over Δ washes out the signal. For vapors, $\Delta = 0$, the phase $\phi_d \approx -2\delta_0 T_{21}$ is the same for all the atoms, and an echo is emitted.

first, the signal is vanishingly small {varying as $\exp[-(\sigma_w^2 + k^2u^2)T_{21}^2/2]$} for inhomogeneously broadened samples, while the homogeneously broadened signal strength is essentially unchanged from that when pulse 2 acts first. This time-ordering asymmetry can be used to distinguish between homogeneously and inhomogeneously broadened samples.[73]

11.8 PHASE CONJUGATE GEOMETRY AND OPTICAL RAMSEY FRINGES

A qualitative difference between stimulated photon echo signals arises when $\mathbf{k}_3$ is in the $-\mathbf{k}_1$ direction rather than the $\mathbf{k}_1$ direction.[61,74,75] In this case, it is possible to generate a phase-matched signal in the

$$\mathbf{k} = \mathbf{k}_1 - \mathbf{k}_2 + \mathbf{k}_3 = -\mathbf{k}_2$$

direction for *both* time orderings of fields 1 and 2. Moreover, in weak fields, the amplitude of the signal field is proportional to the conjugate of input field 2. As a consequence, the signal is referred to as a *phase conjugate* signal for this geometry.[76,77] To simplify matters, we will set $\mathbf{k}_1 \approx \mathbf{k}_2 = -\mathbf{k}$ and neglect terms of order $|\mathbf{k}_1 - \mathbf{k}_2|u(T + 2T_{21})$.

The appropriate phase diagrams are shown in Fig. 10 when field 1 acts before field 2 and Fig. 11 when field 2 acts before field 1. There is a qualitative difference between the phase diagrams of Fig. 10 and Fig. 7. At time $t = 2T_{21} + T$, the lines representing the state amplitudes *do not cross* in Fig. 10. Rather, they are separated by a phase difference of $\phi_d = -2(\delta_0 + \Delta)T_{21}$. The phase shift resulting from *Doppler shifts* cancels at $t = 2T_{21} + T$, but *not* the phase shift resulting from the atom-field detuning.

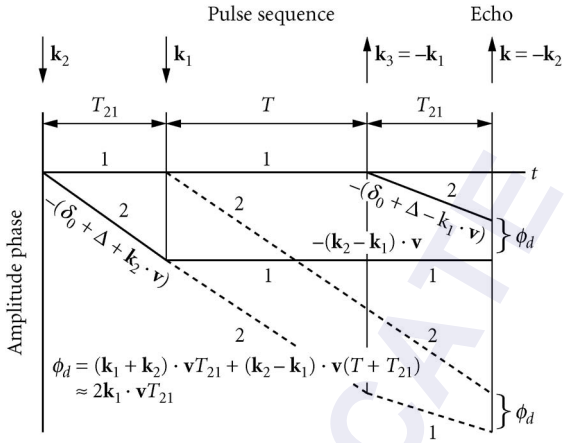

FIGURE 11 A phase diagram for the stimulated photon echo in which field 2 acts first and $\mathbf{k}_3 = -\mathbf{k}_1$.The echo is emitted in the $(-\mathbf{k}_2 + \mathbf{k}_1 + \mathbf{k}_3) = -\mathbf{k}_2$ direction, and we have taken $\mathbf{k}_2 \approx \mathbf{k}_1$. The solid lines involve the intermediate state population ρ_{11}, while the dashed lines involve the intermediate state population ρ_{22}. At time $t = 2T_{21} + T$, the relative phase is $\phi_d \approx 2\mathbf{k}_1 \cdot \mathbf{v}T_{21}$. For vapors, the average over the velocity distribution washes out the signal. For solids, $\mathbf{v} = 0$, the relative phase is zero for all the atoms, and an echo is emitted.

The significance of these results will become apparent immediately. The averaged density matrix element in the vicinity of the echo is

$$\langle \rho_{21}(t) \rangle = \left(\frac{i}{8}\right) \sin\theta_1 \sin\theta_2 \sin\theta_3 \exp(-\gamma_2 T) \exp(-2\gamma T_{21}) \exp\{-i\delta_0(t - T_{21} - T) + T_{21}]\}$$
$$\times \exp\left[\frac{-\sigma_\omega^2[(t - T_{21} - T) + T_{21}]^2}{4}\right] \exp\left[\frac{-k^2u^2[(t - T_{21} - T) - T_{21}]^2}{4}\right] \tag{44}$$

In a solid, the signal vanishes near $t = 2T_{21} + T$, since $\sigma_\omega T_{21} >> 1$.

In a vapor, an echo is formed at time $t = T + 2T_{21}$. At this time, the averaged density matrix element varies as $\exp(-2i\delta_0 T_{21})$, a factor which was absent for the nearly collinear geometry. This phase factor is the optical analog[78–80] of the phase factor that is responsible for the generation of Ramsey fringes.[81] One can measure the phase factor directly by heterodyning the signal field with a reference field, or by converting the off-diagonal density matrix element into a population by the addition of a *fourth pulse* in the $\mathbf{k}_3$ direction at time $t = T + 2T_{21}$.* In either case, the signal varies as $\cos(2\delta_0 T_{21})$. In itself, this dependence is useless for determining the optical frequency since one cannot identify the fringe corresponding to $\delta_0 = 0$. To accomplish this identification, there are two possibilities. If the experiment is carried out using an atomic beam rather than atoms in a cell, $T_{21} = L/u_0$ will be different for atoms having different u_0 (L = spatial separation of the first two pulses and u_0 is the

*In the case of atoms moving through spatially separated fields with different longitudinal velocities, one must first average Eq. (44) over *longitudinal* velocities before taking the absolute square to calculate the radiated field. As a result of this averaging, the radiated signal intensity is maximum for $\delta_0 = 0$. Consequently, for spatially separated fields, heterodyne detection or a fourth field is not necessary since the radiated field intensity as a function of δ_0 allows one to determine the line center.

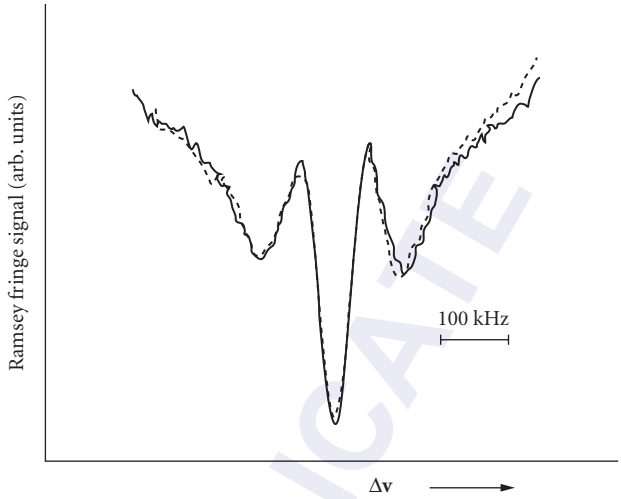

FIGURE 12 An optical Ramsey fringe signal on the 657-nm intercombination line in calcium. Four field zones were used. The most probable value of T_{21} was about 10^{-5} s for an effusive beam having a most probable longitudinal speed equal to 800 m/s, giving a central fringe width on the order of 60 kHz. The dashed and dotted lines represent runs with the directions of the laser field reversed, to investigate phase errors in the signals. (*From Ref. 82. Copyright © 1994; reprinted with permission from Elsevier Science.*)

longitudinal velocity of the atoms). When a distribution of u_0 is averaged over, the fringe having $\delta_0 = 0$ will have the maximum amplitude. Experiments of this type allow one to measure optical frequencies with accuracy of order T_{21}^{-1} (see Fig. 12). For experiments carried out using temporally separated pulses acting on atoms in a cell, it is necessary to take data as a function of δ_0 for several values of T_{21}, and then average the data over T_{21}; in this manner the central fringe can be identified. The optical Ramsey fringe geometry has been reinterpreted as an atom interferometer.[42,83] Atom interferometers are discussed in Sec. 11.9.

We now move to Fig. 11, in which field 2 acts before field 1. At time $t = 2T_{21} + T$, the lines representing the state amplitudes are separated by a phase difference of $\phi_d = -2\mathbf{k}\cdot\mathbf{v}T_{21}$. The phase shift resulting from the atom-field detuning cancels at $t = 2T_{21} + T$, but *not* the phase shift resulting from the Doppler effect. The corresponding density matrix element is

$$\langle \rho_{21}(t)\rangle = \frac{i}{8}\sin\theta_1 \sin\theta_2 \sin\theta_3 \exp(-\gamma_2 T)\exp(-2\gamma T_{21})\exp\{-i\delta_0[(t-T_{21}-T)-T_{21}]\}$$
$$\times \exp\left[\frac{-\sigma_\omega^2[(t-T_{21}-T)-T_{21}]^2}{4}\right]\exp\left[\frac{-k^2u^2[(t-T_{21}-T)+T_{21}]^2}{4}\right] \tag{45}$$

Near $t = T + 2T_{21}$, the signal vanishes for a vapor since $kuT_{21} >> 1$, but gives rise to a phase conjugate signal in solids ($u = 0$). There are no Ramsey fringes in this geometry; optical Ramsey fringes cannot be generated in an inhomogeneously broadened solid.

When the first two fields are *identical*, there is no way to distinguish which field acts first, and Eqs. (44) and (45) must be added before taking the absolute square to determine the radiated electric field. There is no interference between the two terms, however, since one of the terms is approximately equal to zero in the vicinity of the echo for either the solid or the vapor.

11.9 TWO-PHOTON TRANSITIONS AND ATOM INTERFEROMETRY

In the previous section, we have already alluded to the fact that optical Ramsey fringes can serve as the basis of an atom interferometer.[44] There is some disagreement in the literature as to exactly what constitutes an atom interferometer. Ramsey fringes and optical Ramsey fringes were developed without any reference to quantization of the atoms' center-of-mass motion. As such, optical Ramsey fringes can be observed in situations where quantization of the center-of-mass motion is irrelevant. The interference observed in these interferometers is based on an *internal state* coherence of the atoms. Matter-wave effects (that is, effects related to quantization of the center-of-mass motion) may play a role under certain circumstances, but they are not critical to the basic operating principle associated with optical Ramsey fringes.

In this section, we consider a time-domain, matter-wave atom interferometer[84] which relies on the wave nature of the center-of-mass motion for its operation. Moreover, the interferometer illustrates some interesting features of coherent optical transients not found in NMR. We return to an ensemble of two-level atoms, which have been cooled in a magneto-optical trap. See Chap. 20, "Laser Cooling and Trapping of Atoms," for a more detailed description of trapping of atoms. The atoms are subjected to two *standing-wave* optical pulses separated in time by T. The electric field amplitude of pulse $i (i = 1, 2)$ is given by $\mathbf{E}_i(\mathbf{Z}, t) = \varepsilon E_i(t) \cos(kZ) \cos(\omega t)$. Either off-resonant[84,85] or resonant[86] pulses can be used. For resonant pulses, grating echoes can be observed in situations where a classical description of the center-of-mass motion is valid.[66–68] We consider only off-resonant pulses in this discussion, for which echoes can occur only when quantized motion of the atoms is included. For an atom-field detuning $|\delta| >> \Omega_0, \gamma, \gamma_2, ku$, it is possible to adiabatically eliminate the excited state amplitude and arrive at an effective hamiltonian for the ground state atoms given by

$$H = \frac{P^2}{2M} - \sum_{i=1,2} \hbar \Omega_i^{(s)}(t) \cos(2kZ)$$

where $\mathbf{P}$ is the center-of-mass momentum operator, M is the atomic mass, and

$$\Omega_i^{(s)}(t) = \frac{\mu^2 E_i^2(t)}{8\hbar^2 \delta}$$

is a two-photon Rabi frequency. A spatially homogeneous term has been dropped from the hamiltonian.

The net effect of the field is to produce a spatially modulated, AC Stark or light shift of the ground state energy. Let us assume that the pulse duration τ is sufficiently short to ensure that $\tau^{-1} >> \omega_{2k}, \gamma, \gamma_2, ku, \sqrt{\omega_{2k}\Omega_i^{(s)}(t)}$, where

$$\omega_{2k} = \frac{\hbar(2k)^2}{2M}$$

is a two-photon recoil frequency whose importance will become apparent. In this limit, any motion of the atoms during the pulses can be neglected. The net effect of pulse i is to produce a ground state amplitude that varies as $\exp[i\theta_i^{(s)} \cos(2kZ)]$, where $\theta_i^{(s)} = \int \Omega_i^{(s)}(t) dt$ is a pulse area. In other words, the standing-wave field acts as a *phase grating* for the atoms. One can think of the two traveling-wave

components of the standing-wave field exchanging momentum via the atoms. All even integral multiples of $2\hbar k$ can be exchanged by the fields, imparting impulsive momenta of $2n\hbar k$ (n is a positive or negative integer) to the atoms. The frequency change associated with this momentum change for an atom having momentum **P** is

$$\frac{E_{\mathbf{P},\mathbf{P}\pm 2n\hbar k\hat{Z}}}{\hbar}=\frac{\left(\dfrac{P^2}{2M}-\dfrac{\left|\mathbf{P}\pm 2n\hbar k\hat{Z}\right|^2}{2M}\right)}{\hbar}=\mp\frac{2nP_z k}{M}-\omega_{2nk}$$

and consists of two parts. The first part is independent of $\hbar$ and represents a classical Doppler shift, while the second part is proportional to $\hbar$ and represents a quantum matter-wave effect. The quantum contribution will become important for times of order ω_{2nk}^{-1}. In other words, following the first pulse, the atomic density will remain approximately constant for times $t<\omega^{-1}{}_{2nk}$ (the maximum value of n is the larger of $\theta_i^{(s)}$ and unity). For times larger than this, the quantum evolution of the center-of-mass motion can transform the phase grating into an amplitude grating which can be deposited on a substrate or probed with optical fields. In contrast to closed two-level systems, the signals can persist here for arbitrarily long times. The recoil associated with absorption and emission "opens" the system and allows for long-lived transients.[87]

The evolution of the system can be followed using phase diagrams in a manner similar to that used in Secs. 11.6 to 11.8. The situation is more complex, however, since a standing-wave field generates an infinity of different phase shifts $\mp 2nkvt$, where $v = P_z/M$. Details of the calculation can be found in the article by Cahn et al.[84] Here we sketch the general idea. The first pulse creates all even spatial harmonics of the fields, with weighting functions that are Bessel functions of the pulse area. The atomic density remains constant until a time $t\sim\omega_{2nk}^{-1}$. At this time one would expect to find a spatially modulated atomic density; however, if $ku >> \omega_{2k}$ as is assumed, by the time the spatial modulation is established, the modulation is totally destroyed as a result of Doppler dephasing. As in the photon echo experiment, the Doppler dephasing can be reversed by the second pulse at time $t = T$. Since standing waves are used, there is an infinity of echo positions possible, corresponding to different dephasing-rephasing conditions for the various momentum components created by the fields.

Of the many echoes that can be produced, we consider only those echoes that are formed at times $t_N=(N+1)T$, $N=1,2,\ldots$. Moreover, in an expansion of the atomic density in harmonics of the field, we keep only the second harmonic, since it can be probed by sending in a traveling-wave field and observing a *backscattered* signal. Phase matching is automatically guaranteed for the backscattered signal. For times $t = t_N + t_d$, with $t_d \gtrsim \frac{1}{2}ku << T$, the backscattered electric field amplitude varies as[84]

$$E_b(t_d,NT)=\exp\left[\frac{-(2k)^2u^2(t_d)^2}{4}\right]J_N[2\theta_1\sin(\omega_{2k}t_d)]J_{N+1}[2\theta_2\sin(N\omega_{2k}T+\omega_{2k}t_d 0] \qquad (46)$$

where the Js are Bessel functions. The electric field can be measured using a heterodyne technique. The experimental data is shown as a function of t_d and T for $N = 1, 2$ in Figs. 13 and 14. One sees that the signal vanishes identically at the echo times, but not in the immediate vicinity of the echo points. The uniform atomic density at the echo point mirrors the uniform atomic density immediately after excitation by the first pulse. As a function of T, the signal is periodic with period $\pi/N\omega_{2k}$ for N odd and $2\pi/N\omega_{2k}$ for N even. By measuring the period, one can obtain values for $\hbar/M$. The interferometer can also be used to measure inertial effects such as the acceleration of the atoms owing to gravity. The advantage of this interferometer is that large interaction times are possible—one is limited only by the time it takes for the atoms to leave the atom-field interaction zone.

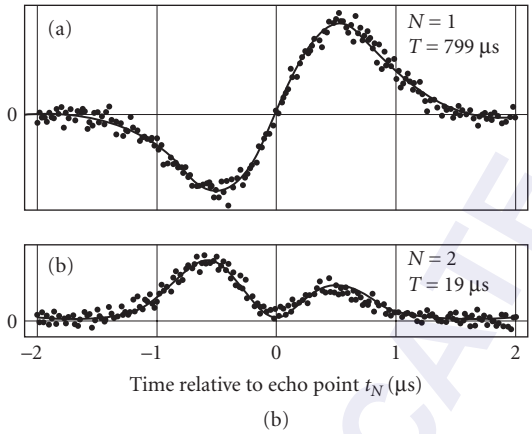

FIGURE 13 A time-domain atom interferometer. Two off-resonant, standing-wave optical pulses separated in time by T are applied to rubidium atoms in a magneto-optical trap and a probe field is applied near (*a*) $t = 2T$ or (*b*) $t = 3T$, giving rise to backscattered electric field signals. The electric field amplitude $E_b(t_d, NT)$ is recorded in the graphs as a function of t_d, the time from the echo position. The solid line is theory and the dots are experimental points. Note that the time delay between pulses is 799 μs in (*a*), indicating that these ground-state transients are limited only by some effective ground-state lifetime. (*From Ref. 84. Reprinted with permission.*)

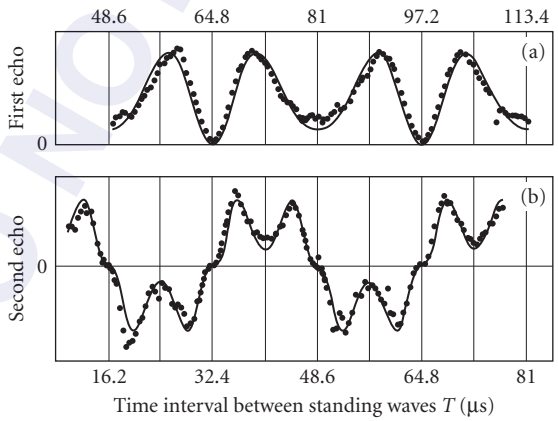

FIGURE 14 Same as in Fig. 13, but $E_b(t_d, NT)$ is now recorded as a function of T, the time separation of the pulses. The period of the signals is $\pi/\omega_{2k} = 32.39$ μs. (*From Ref. 84. Reprinted with permission.*)

11.10 CHIRPED PULSE EXCITATION

The discussion in this chapter has focused on transform-limited optical pulses, possessing smooth Fourier transforms centered about the carrier frequency. Alternative pulse shapes offer new and interesting possibilities. If one uses *stochastic* pulse envelope functions,[88–90] the correlation time τ_c associated with the pulse is much smaller than the pulse duration. In some sense, *each* pulse can be viewed as a sequence of pulses having duration of order τ_c. As a consequence, stimulated photon echoes using stochastic pulses can be used to measure relaxation times as short as τ_c rather than the pulse duration.

The idea of using a pulse whose effective coherence time is shorter than the pulse duration has been exploited by others[91–93] in schemes involving chirped pulses. It was shown both theoretically[91] and experimentally[92,93] that, by sweeping the pulse frequency, one can write and read data encoded in solids, using the equivalent of stimulated echoes, a process Mossberg[91] refers to as *swept-carrier time-domain optical memory*. Without going into the mathematical details of the calculations needed to arrive at expressions for the signals, we present the underlying physical concepts pertinent to this excitation scheme.

There are three pulses, as in a traditional stimulated photon echo, but the pulse characteristics differ markedly from those discussed in Sec. 11.7. The first pulse is a reference pulse having electric field

$$\mathbf{E}_1(\mathbf{R},t)=\boldsymbol{\varepsilon}E_1(t)\cos(\mathbf{k}_1\cdot\mathbf{R}-\bar{\omega}_0 t-\xi t^2)$$

where the amplitude $E_1(t)$ is a smooth function of t centered at $t = 0$ having temporal width τ_{ref} and $\phi(t)=-\xi t^2$ is the pulse phase. The central frequency of the pulse coincides with the optical frequency, but the frequency is chirped at rate 2ξ, giving an instantaneous frequency $\omega(t)=\omega-\phi=\omega+2\xi$ and an atom-field detuning $\delta(t)=\Delta-2\xi t$. The frequency shifts $\pm\xi\tau_{\text{ref}}$ are assumed to be less than the inhomogeneous width σ_w. As the frequency is scanned, different atoms in the inhomogeneous distribution in the sample come into resonance with the field at different times. If $\sqrt{\xi} >> \gamma, \tau_{\text{ref}}^{-1}$, for atoms having detuning $\Delta = \omega_0 - \omega$, the field comes into resonance at time $t_1 = \Delta/2\xi$ for a duration of order $\xi^{-1/2} << \tau_{\text{ref}}$. Thus, for each frequency group of atoms, the field acts as a *pulse having temporal width much less than the width of the pulse*. In calculating ρ_{12} resulting from this pulse one finds a phase factor of the form $\exp[i(-\mathbf{k}_1\cdot\mathbf{R}+\Delta t_1-\xi t_1^2)]=\exp[-i(\mathbf{k}_1\cdot\mathbf{R}-\Delta^2/4\xi)]$.

The second or data pulse

$$\mathbf{E}_2(\mathbf{R},t)=\boldsymbol{\varepsilon}E_2(t)\cos[\mathbf{k}_2\cdot\mathbf{R}-(\bar{\omega}_0-\omega_{\text{RD}})t-\xi t^2]$$

is similar to the first except that it is offset from the first by frequency ω_{RD}. Moreover, the field amplitude $E_2(t)$ is now assumed to consist of a sequence of input data, such as a number of individual pulses contained in the overall pulse envelope. If the Fourier spectrum of $E_2(t)$ contains frequency components ω_f, then the second pulse will come into resonance with atoms having detuning Δ at time $t_2 = (\Delta + \omega_{\text{RD}} - \omega_f)/2\xi$. To have pulse 2 act on the same atoms at a time greater than t_1, one must restrict the maximum value of ω_f to be less than ω_{RD}. We shall neglect ω_f in what follows. For each frequency group, the first two pulses act as a *sequence of short pulses*, separated in time by

$$T_{21}=\omega_{\text{RD}}/2\xi$$

As in the normal stimulated photon echo, the second pulse converts the density matrix element ρ_{12} created by the first pulse into population. One finds a population difference $(\rho_{22} - \rho_{11})$ that varies as $\exp[-i(\mathbf{k}_1\cdot\mathbf{R}-\Delta^2/4\xi)]\exp(-\gamma T_{21})\exp\{i[\mathbf{k}_2\cdot\mathbf{R}-(\Delta+\omega_{\text{RD}})^2/4\xi]\}+\text{c.c.}$ Although the pulse durations are of order τ_{ref}, homogeneous decay occurs only on a time scale $T_{21} = \omega_{\text{RD}}/2\xi << \tau_{\text{ref}}$, which is

the effective pulse separation for a given frequency group. The phase factor $\exp\{i[(\mathbf{k}_2 - \mathbf{k}_1)\cdot\mathbf{R} - \Delta T_{21}]\}$ associated with $(\rho_{22} - \rho_{11})$ is identical in form to that found in the normal stimulated photon echo. It is not surprising then that a third pulse, identical to the first but propagating in the $\mathbf{k}_3$ direction and displaced in time from the first by $T > \tau_{ref}$ leads to a reconstruction of the data pulse propagating in the $(-\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3)$ direction. In other words, on averaging over the inhomogeneous frequency distribution, one finds contributions to the signal only for those times that correspond to the time sequence of pulse 2, displaced by time T.

11.11 EXPERIMENTAL CONSIDERATIONS

Early coherent optical transient experiments were the optical analogs of NMR experiments. These experiments firmly established coherent transient spectroscopy as a viable technique in the optical domain. The relatively simple atomic and molecular vapors or rare earth-doped crystals that were used for these studies were chosen for practical reasons—their transition frequencies coincided with available laser frequencies and relaxation times (T_2 is typically on the order of 10 ns or longer) were longer than the lasers' pulse widths. The methodology is well described in numerous earlier reviews (see, for example, Levenson[9]). These relaxation time scales are relatively long by today's standards. Hence, the technology that was available based on photomultipliers, high-speed diodes, and fast oscilloscopes made it possible to observe the coherent transient phenomena that were created by fast laser-frequency or Stark switching. With high-speed detectors, photon echoes were readily observed with single-shot Q-switched lasers.

The continued advances in the development of ultrafast lasers have now reduced the pulse widths by nearly 6 orders of magnitude compared to the early Q-switched lasers. In addition, modern laser systems are characterized by high repetition rates (100 MHz if no amplification is used) compared to the relatively slow repetition rates of older laser systems (1 to 10 Hz). Ultrafast lasers have opened a host of possibilities for studying complex molecules, fluids, and solids, including semiconductors. This new capability was accompanied by new challenges, since standard detectors and electronics were not capable of time-resolving the emitted signals. In some cases, it was not even known whether the materials being investigated were homogeneously or inhomogeneously broadened. For these cases, it is important to check for the asymmetry predicted as a function of time delay in the stimulated photon echo, as described in Sec. 11.7. For the very shortest pulses (typically < 100 fs), even the simplest laboratory operations of reflection from a mirror or transmission through a cryostat window or beam splitter become an issue. The transform-limited pulse bandwidth is so large that the linear dispersion in these systems leads to a chirp in the pulse, which can give rise to artifacts in the data if the chirp is not compensated at the sample by incorporation of grating or prism pairs in the system. High-repetition-rate systems also can give rise to thermal heating of the sample, leading to gratings which give signals that easily dominate the electronic signals of interest. Discrimination against these signals is critical. Sometimes, it is possible to perform the measurements of interest using orthogonally polarized fields, giving rise to a signal that is sensitive to spatially modulated magnetic-state coherence, but not thermal gratings. An alternative approach is to amplitude modulate one of the optical fields at a high frequency and use phase-sensitive detection. If the modulation frequency chosen is sufficiently high, then the modulation of the thermal grating is weak, and the electronic term dominates.

In the case of photon echo spectroscopy, determining the time origin $t = 0$ is important for accurate analysis of the signals. Although this does not pose any serious technical problems when dealing with nanosecond time-scale resolution, for femtosecond laser pulses, where distance scales can be as small as a few microns, the problem is not trivial. One solution, discussed in a recent review of photon echo spectroscopy,[73] is to measure the time-integrated signal as a function of pulse separation for the ordinary signal (in the $2\mathbf{k}_2 - \mathbf{k}_1$ direction for self-diffracted four-wave mixing) and the complimentary echo (in the $2\mathbf{k}_1 - \mathbf{k}_2$ direction). The intersection of the two superimposed mirror images allows one to determine the time origin. In some cases, it may be necessary to time-resolve the emission either to confirm absolutely that the signal is indeed an echo or to determine the

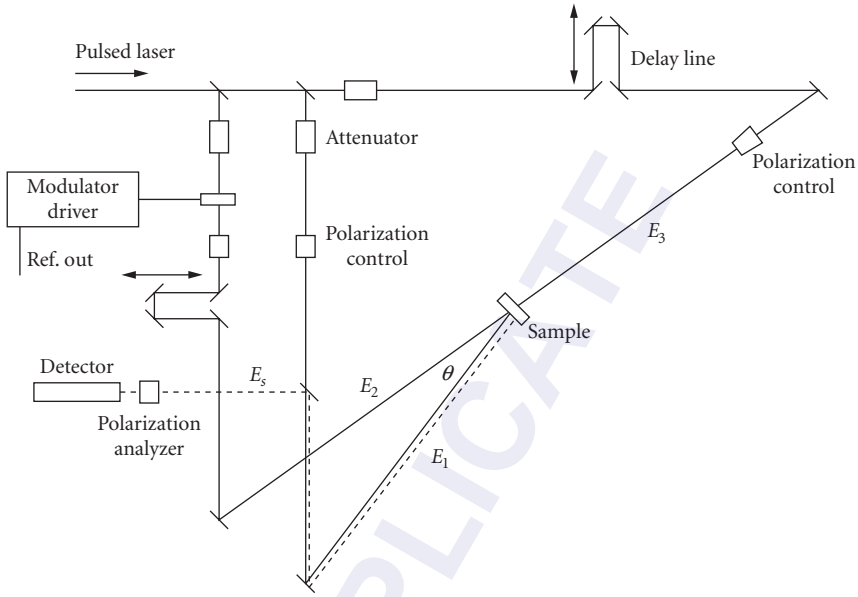

FIGURE 15 A typical experimental configuration, employing a high-repetition short-pulse laser system, that can be used for stimulated photon echo or transient four-wave mixing studies of an arbitrary sample.

inhomogeneous broadening. The usual approach to achieve this goal is to mix some of the original laser beam with the signal beam in a second harmonic crystal and detect the upconverted signal. The signal is time resolved by measuring the upconverted signal as a function of delay between the signal and reference fields.[94,95]

An experimental configuration incorporating many of these features is shown in Fig. 15. Measurements of the dephasing rate are made by monitoring the signal amplitude as a function of time delay between fields E_1 and E_2, while measurements of the energy relaxation rate are made as a function of the time delay between fields E_2 and E_3. In the latter case, measurement of the relaxation rate as a function of the angle between fields E_1 and E_2 allows one to measure the grating (e.g., spatially modulated population) relaxation rate, due, for example, to diffusion.[96] Control of the fields' polarizations is essential in these experiments since the allowed electronic excitation depends critically on the selection rules. The modulator is used to amplitude modulate one of the optical fields to allow phase-sensitive detection. Because of scattering, it may also be necessary in some cases to modulate field E_1 at a different frequency and detect the sum or difference frequency in the lock-in amplifier. The forward three-pulse geometry is most prevalent in the literature; however, the more recently developed phase conjugate geometry shown in the figure is more desirable, owing to reduced incoherent scattering into the detector. In addition, this system is much easier to align, since the signal is exactly counterpropagating with respect to field E_2. Usually, the feedback into the oscillator for spectroscopy applications is small because of the presence of the attenuators. However, for high-intensity studies it may be necessary to add an optical isolator to eliminate feedback, or, as is more typical, simply arrange for a slight misalignment of fields E_1 and E_3. This results in a slight deviation of the signal field from the $-\mathbf{k}_2$ direction, but this poses no problem. It should also be noted that for ultrafast laser systems, the narrow pulses may experience group velocity dispersion (GVD) in propagating through various optical components and in reflection, requiring GVD compensation to avoid artifacts due to frequency chirps. In some cases, additional information can be obtained by time-resolving the optical phase[97] and/or polarization[98] of the signal, both of which may change during the time interval in which the signal is emitted.

Atoms undergoing collisions in a vapor and rare earth-doped solids provided a convenient laboratory environment both to study coherent transients and to examine new physical phenomena associated with reservoir interactions. Moreover, such studies allowed one to gain theoretical and experimental insights upon which the new technology could build. It has now been possible to elevate the utility of these spectroscopic tools for application to more complex systems. In particular, coherent optical transients have yielded important data in both chemical physics[99,100] and condensed-matter physics.[101] In many cases, the theoretical framework described here, with appropriate refinements of the unperturbed hamiltonian and reservoir interactions, can adequately model these systems. For example, local field corrections and excitation-induced scattering can be accounted for by a relatively simple modification of the optical Bloch equations. As a result, additional phase diagrams, with time orderings different from those shown in Figs. 10 and 11, can contribute to echo signals.[102] However, in other cases, a major revision of the theoretical picture is needed to account for more complex many-body interactions.[103–105] An approach based on modified optical Bloch equation may not be appropriate in this limit.

11.12 CONCLUSION

Information on level structure and relaxation processes in vapors, solids, and liquids can be extracted from coherent optical transient signals. The most basic coherent optical transients have been reviewed in this chapter. Coherent optical transient spectroscopy is still an evolving field, as new techniques are being added to established ones. It is likely that one will see increased use of both temporal and spatial masks for coherent control of atomic state coherence. Although many of the coherent optical transients are direct analogs of similar effects in NMR, others are unique to the optical domain. The velocity selectivity associated with the Doppler effect offers unique possibilities. Velocity diffusion has been studied extensively using coherent optical transients, and coherent optical transients are being rediscovered as an important probe of cold atoms and Bose condensates.[106,107] Beyond the gas phase, developments in the area of coherent optical transient spectroscopy are moving very rapidly, as the power of this methodology is seen as a key that can help unlock the decay dynamics of complex molecules and semiconductor systems. One is also examining whether coherent optical transient methods similar to those employed in multidimensional NMR[108,109] can be used to probe electronic and molecular structure.

12.1 INTRODUCTION

The photorefractive effect is a real time holographic optical nonlinearity that is effective for low-power lasers over a wide range of wavelengths. It is relatively easy to use even in modestly equipped laboratories: all that is needed to get started is a sample of photorefractive material, almost any laser operating in the visible or near-infrared, and a few simple optics such as lenses and beam splitters. The diffraction efficiency of photorefractive holograms is roughly independent of the intensity of the writing beams and in many materials, the diffraction efficiency of these holograms can approach 100 percent, so that sophisticated detectors are not required. Its simplicity of use has been largely responsible for its widespread popularity. As is often the case, however, attractive features such as these come only with associated disadvantages. For the photorefractive effect, the main disadvantage is one of speed. The nonlinearities come to steady state at a rate which is approximately inversely proportional to intensity. The fastest high-diffraction efficiency materials have response times of the order of 1 ms at 1 W/cm^2. Even so, in certain applications, the characteristic slowness is not a disadvantage. In the first part of this chapter, we explain the basic mechanisms of the photorefractive effect. The second part deals with material selection considerations and the third part describes some typical applications. For the reader in need of an extensive overview of the photorefractive effect and its applications, we recommend a two-volume set edited by Gunter and Huignard and the three-volume updated version two.[1]

Grating Formation

The photorefractive effect is observed in materials which

1. Exhibit a linear electro-optic effect
2. Are photoconductive
3. Have a low dark conductivity

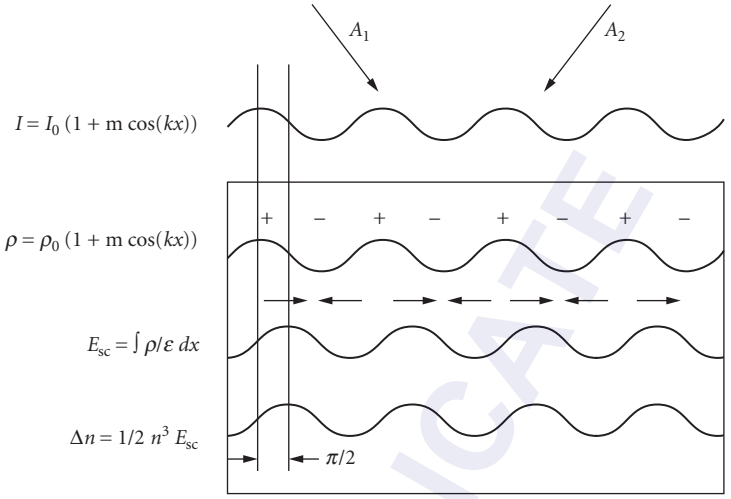

FIGURE 1 The photorefractive mechanism. Two laser beams intersect, forming an interference pattern $I(x)$. Charge is excited where the intensity is large and migrates to regions of low intensity. The electric field E_{sc} associated with the resultant space charge ρ_{sc} operates through the linear electro-optic coefficients to produce a refractive index grating Δn.

Two laser beams record a photorefractive hologram when their interference pattern is incident on a photorefractive crystal (Fig. 1). Charge carriers are preferentially excited in the bright fringes and are then free to drift and diffuse until they recombine with traps, most likely in the darker regions of the interference pattern. In this way, a space charge builds up inside the crystal in phase with the interference pattern. The electric field of this space charge acts through the linear electro-optic effect to form a volume holographic refractive index grating in real time. Real time means that the development occurs with a time constant of the order of the response time of the photorefractive crystal. The writing beams then diffract from the hologram into each other. Even though the process depends on the linear electro-optic effect, which is second-order, the whole process acts effectively as a third-order nonlinearity as far as the writing beams are concerned, and third-order coupled-wave equations can be written for their amplitudes. It is important to notice that the electric field is spatially shifted by 90° with respect to the interference pattern because of the Gauss's law integration that links the space charge to the electric field. The refractive index gradient is also shifted by ±90°. This shift is possible because the refractive index perturbation depends on the direction of the electric field, not just on its magnitude. The direction of the grating shift is determined by the sign of the electro-optic coefficient and crystal orientation. This dependence on crystal orientation is due to the lack of inversion symmetry associated with the linear electro-optic coefficient: if the crystal is inverted through its origin, the sign of the phase shift changes. In uniaxial crystals, inversion corresponds simply to reversing the direction of the optic axis. These symmetry effects are intimately related to the origin of photorefractive beam amplification.

The reason that use of the linear electro-optic effect is important is that a Bragg-matched volume hologram should have the same period as the optical interference pattern that wrote it. The refractive index change should be directly proportional to the space charge electric field. This is only possible if the material displays the linear electro-optic effect leading to a refractive index distribution $\Delta n \propto r_{\mathrm{eff}} E_{sc}$, where r_{eff} is an effective electro-optic coefficient and E_{sc} is the space charge field. The lack of inversion symmetry needed by the linear electro-optic effect may be found in ferroelectric

materials such as barium titanate, optically active materials such as bismuth silicon oxide and cubic compound semiconductors such as GaAs and InP.

When the charge transport is purely diffusive, the magnitude of the spatial phase shift is 90°. However, in certain circumstances the phase shift can depart from 90°. This occurs if electric fields are applied to the crystal or if the crystal exhibits the photovoltaic effect[2] so that drift mechanisms come into play, or, if the writing beams have different frequencies, so that the interference pattern moves in the crystal with the index grating lagging behind it.

The second requirement implies that the material should contain photoexcitable impurities. Direct band-to-band photoconductivity is usually not useful since it limits the optical interaction distances to rather small absorption depths.

The requirement for low dark conductivity ensures that the space charge can support itself against decay by leakage through background conduction.

The Standard Rate Equation Model

The simplest model, as formulated by Vinetskii and Kukhtarev,[3] involves optical excitation of charge carriers. For the purposes of this introduction, we will assume that the carriers are electrons which can be excited from a donor species such as Fe^{2+} and which can recombine into an acceptor such as Fe^{3+}. Let n be the local number density of mobile excited electrons and $N_D = N + N^+$ be the number density of the impurities or defects responsible for the photorefractive effect, where N^+ is the number density of acceptor dopants (e.g., Fe^{3+}) and N is the number density of donor dopants (e.g., Fe^{2+}). Let N_A be the number density of negative ions that compensate the excess positive charge of acceptor dopants when the charge is uniformly distributed in the dark. Neglecting the photovoltaic effect, we may write the following rate equations of generation and recombination, continuity, electric field (Poisson equation), and total drift and diffusion current:

$$\begin{aligned}
\frac{\partial N^+}{\partial t} &= (sI+\beta)N - \gamma n N^+ \\
\frac{\partial N^+}{\partial t} &= \frac{\partial n}{\partial t} - \frac{1}{e}\nabla \cdot \mathbf{j} \\
\nabla \cdot \mathbf{E} &= (N^+ - N_A - n)e/\varepsilon \\
\mathbf{j} &= \mu e n \mathbf{E} + k_B T \mu \nabla n
\end{aligned} \tag{1}$$

where s is proportional to the photoionization cross section $\sigma(s = \sigma/h\nu)$, β is the dark generation rate, γ is a recombination coefficient, $\mathbf{j}$ is the electric current density. At steady state, the space charge is determined by a balance between charge diffusion away from bright fringes and electrostatic repulsion from charge concentrations. Extensions of these equations to include the effects of electron-hole competition,[4] multiple dopants,[5,6] photovoltaic effects,[7,8] and short pulse excitation[9] have been developed over the past few years. Nevertheless, the most important features of the photorefractive effect may be well-modeled by the simple equations shown here. Assuming that the number density of charge carriers is much less than the optically induced donor density perturbation $(N^+ - N_A)$, a situation that almost always holds, the rate equations can be linearized to give the following solution for the fundamental spatial Fourier component of the space charge field E_{sc} induced by a sinusoidal optical fringe pattern of wave number k_g and fringe visibility m when a dc field E_0 is applied to the crystal:

$$E_{sc} = \frac{m/2}{1 + \beta/sI_0} \frac{E_q(iE_0 - E_d)}{E_0 + i(E_d + E_q)} \tag{2}$$

where I_0 is the total average intensity of the interacting beams, E_q and E_d are characteristic fields of maximum space charge and diffusion, respectively $E_d = k_B T k_g / e$, $E_q = eN_A / \varepsilon k_g$. The response time τ is given by

$$\tau = \frac{N_A}{SN_D(I_0 + \beta/s)} \frac{E_0 + i(E_d + E_\mu)}{E_0 + i(E_d + E_q)} \tag{3}$$

where E_μ is the characteristic mobility field $E_\mu = \gamma N_A / \mu k_g$. These results show that the steady-state space charge field is approximately independent of total intensity and that the response time is inversely proportional to total intensity if the intensity exceeds the saturation intensity β/s.

In the absence of a dc applied field, the fundamental Fourier component of the space charge field is purely imaginary, indicating a 90° spatial phase shift between the interference pattern and the index grating. The effect of an applied dc field is to increase the magnitude of the space charge field and to move the spatial phase shift from 90°. The 90° phase shift is optimal for two-beam coupling amplifiers, as will be indicated, and can be restored by inducing a compensating phase difference through detuning the writing beams from each other to cause the grating to lag behind the interference pattern.[10] Alternatively, an ac applied field may be used to enhance the magnitude of the photorefractive grating and maintain the 90° phase shift.[11,12] For externally pumped four-wave mixing, the 90° phase shift is not optimum, so the applied field-induced deviation of the phase shift is advantageous.[13]

Wave Interactions

Two-Beam Coupling Consider two laser beams writing a grating in a photorefractive medium as depicted in Fig. 2. The effect of the photorefractive nonlinearity on the writing beams can be described quite accurately by conventional coupled-wave theory. Coupled-wave equations for two-beam coupling can be found by taking the slowly varying envelope approximation and substituting the optical electric fields into the scalar wave equation.[14]

$$\nabla^2 E + k^2 E = 0 \tag{4}$$

where

$$k = \frac{\omega n}{c} = \frac{\omega(n_0 + \Delta n)}{c} \tag{5}$$

with Δn being the optically induced refractive index change.

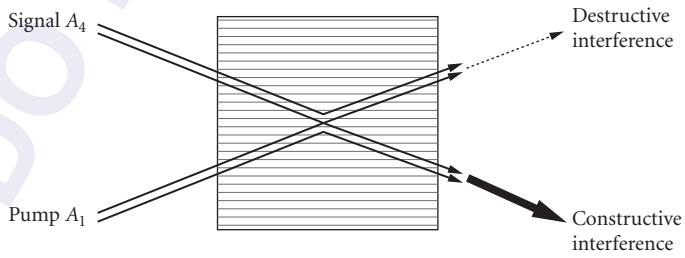

FIGURE 2 Two-beam coupling amplification. Beams 1 and 4 write a diffraction grating. Beam 1 diffracts from the grating to constructively interfere with and amplify beam 4. Beam 4 diffracts from the grating to destructively interfere with and attenuate beam 1.

The resultant coupled-wave equations read:

$$\frac{dA_1}{dz} = -\gamma \frac{A_1 A_4^*}{I_0} A_4$$
$$\frac{dA_4^*}{dz} = \gamma \frac{A_1 A_4^*}{I_0} A_1^* \tag{6}$$

where I_0 is sum of the intensities I_1 and I_4 of the interacting beams. The coupling constant γ is related to the space charge field by

$$\gamma = \frac{i\omega}{c\cos\theta} \frac{r_{\text{eff}} n^3 E_{\text{sc}}/m}{2} \tag{7}$$

It is proportional to the effective electro-optic coefficient r_{eff}[15] and is real when the index grating is 90° out of phase with the interference pattern (as in the case without an applied dc electric field, or with high-frequency ac applied fields). In that case, the coupled-wave equations show that beam 4 is amplified at the expense of beam 1 if γ is positive. The amplification effect can be explained in physical terms: the light diffracted by the grating from beam 1 interferes constructively with beam 4, so beam 4 is amplified. The light diffracted by the grating from beam 4 interferes destructively with beam 1, which consequently loses energy. At the same time, the phases of the interacting beams are preserved. If the spatial phase shift departs from 90° then the energy transfer effect becomes less, and phase coupling begins to appear.

The photorefractive beam coupling gain can be substantial in materials with large electro-optic coefficients. The intensity gain coefficient Γ which characterizes the transfer of energy between two beams [$\Gamma = \gamma + \gamma^*$; see Eq. (8)] can exceed 60 cm^{-1} in $BaTiO_3$[16] and in SBN.[17] Such high gain makes possible the construction of devices such as photorefractive parametric oscillators and recursive image processors. In the high gain case, signal-to-noise issues become important. Generally, defects in photorefractive crystals act as scattering centers. In a process similar to amplified spontaneous emission, this scattered light can be very strongly amplified into a broad fan of light. This fanning effect[18–20] is a significant source of noise for photorefractive image amplifiers, and considerable effort has been devoted to lessening the effect by growing more uniform crystals and making device design modifications.[21, 22] On the other hand, the fanning effect can be a useful source of seed beams for various oscillators[23, 24] or as the basis for optical limiters.[25]

In the undepleted pump approximation ($I_1 >> I_4$), theoretical analysis is extremely simple: the gain is exponential, with amplitude gain coefficient simply γ. But even in the pump depletion case, analysis is quite straightforward because, as in the case of second-harmonic generation, the nonlinear coupled-wave equations can be solved exactly.[14]

$$I_1(z) = \frac{I_0}{1 + (I_4(0)/I_1(0))\exp(\Gamma z)}$$
$$I_4(z) = \frac{I_0}{1 + (I_1(0)/I_4(0))\exp(-\Gamma z)}$$
$$\psi_1(z) = \psi_1(0) - \Gamma' z + \frac{\Gamma'}{\Gamma}\ln(I_4(z)/I_4(0)) \tag{8}$$
$$\psi_4(z) = \psi_4(0) - \Gamma' z - \frac{\Gamma'}{\Gamma}\ln(I_1(z)/I_1(0))$$

where $\Gamma = \gamma + \gamma^*$ and $\Gamma' = (\gamma - \gamma^*)/2i$. The physical implications of these equations are clear: for $I_4(0) \exp(\Gamma z) << I_1(0)$, beam 4 is exponentially amplified; for $I_4(0) \exp(\Gamma z) >> I_1(0)$, beam 4

receives all of the intensity of both input beams, and beam 1 is completely depleted. There is phase transfer only if γ has an imaginary component. Linear absorption is accounted for simply by multiplying each of the intensity equations by $\exp(-\alpha z)$, where α is the intensity absorption coefficient.

The plane-wave transfer function of a photorefractive two-beam coupling amplifier may be used to determine thresholds (given in terms of $\gamma\ell$, where ℓ is the interaction length), oscillation intensities, and frequency pulling effects in unidirectional ring oscillators based on two-beam coupling.[26–29]

Four-Wave Mixing Four-wave mixing and optical phase conjugation may also be modeled by plane-wave coupled-wave theories for four interacting beams[13] (Fig. 3). In general, when all four beams are mutually coherent, they couple through four sets of gratings: (1) the transmission grating driven by the interference term $(A_1A_4^* + A_2^*A_3)$, (2) the reflection grating driven by $(A_2A_4^* + A_1^*A_3)$, (3) the counterpropagating pump grating $(A_1A_2^*)$, and (4) the signal/phase conjugate grating $(A_3A_4^*)$. The theories can be considerably simplified by modeling cases in which the transmission grating only or the reflection grating only is important. The transmission grating case may be experimentally realized by making beams 1 and 4 mutually coherent but incoherent with beam 2 (and hence beam 3, which is derived directly from beam 2). The four-wave mixing coupled-wave equations can be solved analytically in several useful cases by taking advantage of conservation relations inherent in the four-wave mixing process,[30, 31] and by using group theoretic arguments.[32] Such

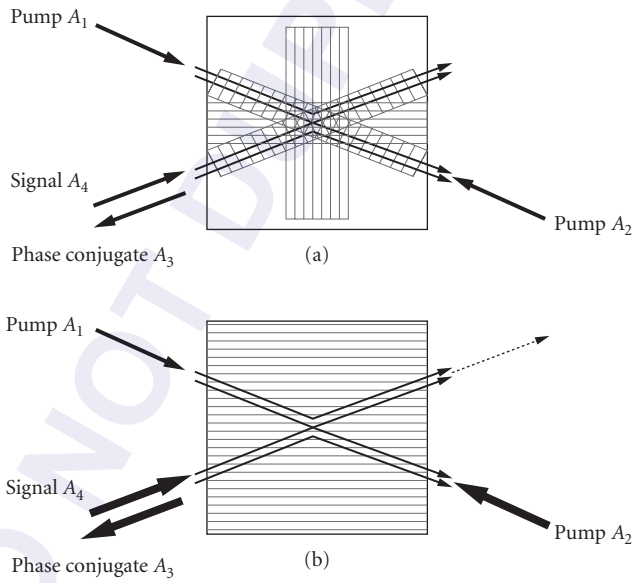

FIGURE 3 Four-wave mixing phase conjugation. (*a*) Beams 1 and 2 are pump beams, beam 4 is the signal, and beam 3 is the phase conjugate. All four interaction gratings are shown: reflection, transmission, counterpropagating pump, and signal/phase conjugate. Beam 1 interferes with beam 4 and beam 2 interferes with beam 3 to write the transmission grating. Beam 2 interferes with beam 4 and beam 1 interferes with beam 3 to write the reflection grating. Beam 1 interferes with beam 2 to write a counterpropagating beam grating, as do beams 3 and 4. (*b*) If beams 1 and 4 are mutually incoherent, but incoherent with beam 2, only the transmission grating will be written. This interaction is the basis for many self-pumped phase conjugate mirrors.

analytic solutions are of considerable assistance in the design and understanding of various four-wave mixing devices. But as in other types of four-wave mixing, the coupled-wave equations can be linearized by assuming the undepleted pump approximation. Considerable insight can be obtained from these linearized solutions.[13] For example, they predict phase conjugation with gain and self-oscillation. The minimum threshold for phase conjugation with gain in the transmission grating case is $\gamma\ell = 2\ln(1+\sqrt{2}) \approx 1.76$, whereas the minimum threshold for the usual $\chi^{(3)}$ nonlinearities is $\gamma\ell = i\pi/4 \approx 0.79i$.

Self-oscillation (when the phase conjugate reflectivity tends to infinity) can only be achieved if the coupling constant is complex. In the $\chi^{(3)}$ case this is the normal state of affairs, but in the photorefractive case, as mentioned, it requires some additional effect such as provided by applied electric fields, photovoltaic effect, or frequency detuning. Photorefractive four-wave mixing thresholds are usually higher than the corresponding $\chi^{(3)}$ thresholds because photorefractive symmetry implies that either the signal or the phase conjugate tend to be deamplified in the interaction. In the $\chi^{(3)}$ case, both signals and phase conjugate can be amplified. This effect results in the fact that while the optimum pump intensity ratio is unity in the $\chi^{(3)}$ case, the optimum beam intensities are asymmetric in the photorefractive case. A consequence of the interplay between self-oscillation and coupling constant phase is that high-gain photorefractive phase conjugate mirrors tend to be unstable. Even if the crystal used is purely diffusive, running gratings can be induced which cause the coupling constant to become complex, giving rise to self-oscillation instabilities.[33,34]

Anisotropic Scattering Because of the tensor nature of the electro-optic effect, it is possible to observe interactions with changing beam polarization. One of the most commonly seen examples is the anisotropic diffraction ring of ordinary polarization that appears on the opposite side of the amplified beam fan when a single incident beam of extraordinary polarization propagates approximately perpendicular to the crystal optic axis.[35–37] Since the refractive indices for ordinary and extraordinary waves differ from each other, phase matching for such an interaction can only be satisfied along specific directions, leading to the appearance of phase-matched rings. There are several other types of anisotropic scattering, such as broad fans of scattered light due to the circular photovoltaic effect,[38] and rings that appear when ordinary and extraordinary polarized beams intersect in a crystal.[39]

Oscillators with Photorefractive Gain and Self-Pumped Phase Conjugate Mirrors

Photorefractive beam amplification makes possible several four-wave mixing oscillators, including the unidirectional ring resonator and self-pumped phase conjugate mirrors (SPPCMs). The simplest of these is the linear self-pumped phase conjugate mirror.[40] Two-beam coupling photorefractive gains supports oscillation in a linear cavity (Fig. 4*a*). The counterpropagating oscillation beams pump the crystal as a self-pumped phase conjugate mirror for the incident beam. The phase conjugate reflectivity of such a device can theoretically approach 100 percent, with commonly available crystals. In practice, the reflectivity is limited by parasitic fanning loss. Other types of self-pumped phase conjugate mirrors include the following. The semilinear mirror, consisting of a linear mirror with one of its cavity mirrors removed[40] (Fig. 4*b*). The ring mirror (transmission grating[41] and reflection grating[42] types). The transmission grating type is shown in Fig. 4*c*. The double phase conjugate mirror[43] (Fig. 4*d*). This device is also sometimes known as a mutually pumped phase conjugator (MPPC). Referring to Fig. 4*b,* it can be seen that the double phase conjugate mirror is part of the semilinear mirror. Several variants involving combinations of the transmission grating ring mirror and double phase conjugate mirror: the cat mirror[23] (Fig. 4*e*) so named after its first subject, frogs legs[44] (Fig. 4*f*), bird-wing[45] (Fig. 4*g*), bridge[46] (Fig. 4*h*), and mutually incoherent beam coupler[47] (Fig. 4*i*). The properties of these devices are sometimes influenced by the additional simultaneous presence of reflection gratings and gratings written between the various pairs of counterpropagating beams. The double phase conjugate mirror can be physically understood as being supported by a special sort of photorefractive self-oscillation in which beams 2 and 4 of Fig. 3 are

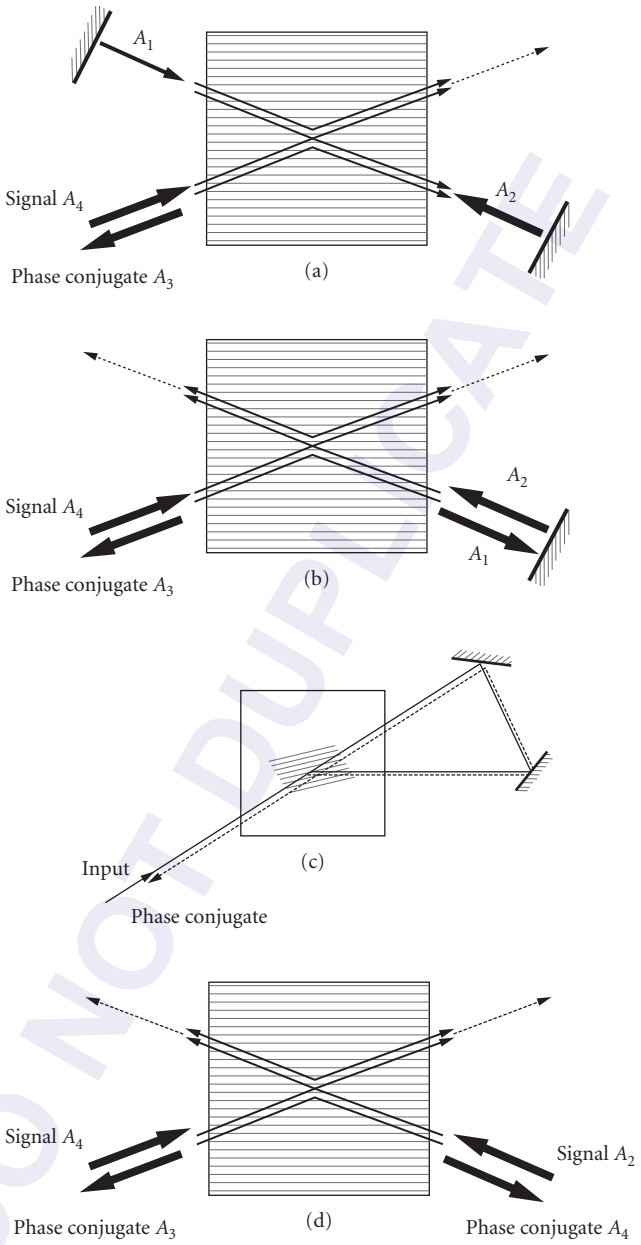

FIGURE 4 Self-pumped phase conjugate mirrors: those with external feedback: (*a*) linear; (*b*) semilinear; (*c*) ring; those self-contained in a single crystal with feedback (when needed) provided by total internal reflection; (*d*) double phase conjugate mirror; (*e*) cat; (*f*) frogs' legs; (*g*) bird-wing; (*h*) bridge; and (*i*) mutually incoherent beam coupler.

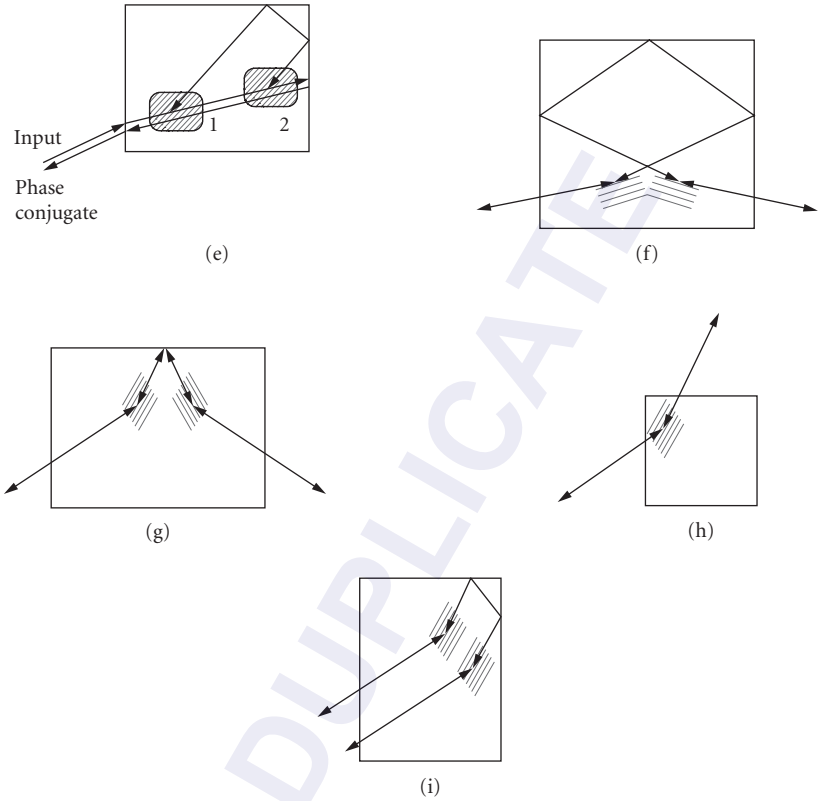

FIGURE 4 (*Continued*)

taken as strong and depleted. The self-oscillation threshold for the appearance of beams 1 and 3 is $\gamma\ell = 2.0$ with purely diffusive coupling.[48] It can be shown that a transmission grating ring mirror with coupling constant $\gamma\ell$ is equivalent in the plane-wave theory to a double phase conjugate mirror with coupling constant $2\gamma\ell$.[49]

The matter of whether the various devices represent the results of absolute instabilities or convective instabilities has been the subject of some debate.[50, 51]

Stimulated Photorefractive Scattering

It is natural to ask whether there is a photorefractive analogue to stimulated Brillouin scattering (SBS, a convective instability). In SBS, an intense laser beam stimulates a sound wave whose phase fronts are the same as those of the incident radiation. The Stokes wave reflected from the sound grating has the same phase fronts as the incident beam, and is traveling in the backward phase conjugate sense. The backward wave experiences gain because the sonic grating is 90° spatially out of phase with the incident beam. In the photorefractive case, the required 90° phase shift is provided automatically, so that stimulated photorefractive scattering (SPS) can be observed without any Stokes frequency shift.[52,53] However, the fidelity of SPS tends to be worse than that of SBS because the intensity gain discrimination mechanism is not as strong, as can be seen by examining the coupled-wave equations in each case.[54]

Time-Dependent Effects

Time-dependent coupled-wave theory is important for studying the temporal response and temporal stability of photorefractive devices. Such a theory can be developed by including a differential equation for the temporal evolution of the grating. The spatiotemporal two-beam coupled-wave equations can be written, for example, as

$$\frac{\partial A_1}{\partial z} = -GA_4$$

$$\frac{\partial A_4^*}{\partial z} = GA_1^* \tag{9}$$

$$\frac{\partial G}{\partial t} + G/\tau = \frac{\gamma}{\tau}\frac{A_1 A_4^*}{I_0}$$

where τ is an intensity-dependent possibly complex response time determined from photorefractive charge transport models. Models like this can be used to show that the response time for beam amplification and deamplification is increased by a factor of $\gamma\ell$ over the basic photorefractive response time τ.[55] The potential for photorefractive bistability can be studied by examining the stability of the multiple solutions of the steady-state four-wave mixing equations. In general, there is no reversible plane-wave bistability except when other nonlinearities are included in photorefractive oscillator cavities.[56,57] (See the section on "Thresholding.") Temporal instabilities generate interesting effects such as deterministic chaos, found both experimentally[58] and theoretically[59,60] in high-gain photorefractive devices.

Influence of the Nonlinearity on Beam Spatial Profiles

In modeling the changes in the transverse cross section of beams as they interact, it is necessary to go beyond simple one-dimensional plane-wave theory. Such extensions are useful for analyzing fidelity of phase conjugation and image amplification, and for treating transverse mode structure in photorefractive oscillators. Several different methods have been used to approach the transverse profile problem.[61] In the quasi-plane-wave method, one assumes that each beam can be described by a single plane wave whose amplitude varies perpendicular to its direction of propagation. The resulting two-dimensional coupled partial differential equations give good results when propagative diffraction effects can be neglected.[62] Generalization of the one-dimensional coupled-wave equations to multi-coupled wave theory also works quite well,[63] as does the further generalization to coupling of continuous distributions of plane waves summed by integration.[20] This latter method has been used quite successfully to model beam fanning.[20] The split-step beam propagation method has also been used to include diffractive beam propagation effects as well as nonlinear models of the optically induced grating formation.[64]

Spatiotemporal instabilities have been studied in phase conjugate resonators.[65,66] These instabilities often involve optical vortices.[67]

12.2 MATERIALS

Introduction

Photorefractive materials have been used in a wide variety of applications, as will be discussed later. These materials have several features which make them particularly attractive.

- The characteristic phase shift between the writing intensity pattern and the induced space charge field leads to energy exchange between the two writing beams, amplified scattered light (beam fanning), and self-pumped oscillators and conjugators.

- Photorefractive materials can be highly efficient at power levels obtained using CW lasers. Image amplification with a gain of 4000[68] and degenerate four-wave mixing with a reflectivity of 2000 percent[69] have been demonstrated.
- In optimized bulk photorefractive materials, the required energy to write a grating can approach that of photographic emulsion (50 μJ/cm^2), with even lower values of write energy measured in photorefractive multiple quantum wells.
- The response time of most bulk photorefractive materials varies inversely with intensity. Gratings can be written with submillisecond response times at CW power levels and with nanosecond response times using nanosecond pulsed lasers. Most materials have a useful response with picosecond lasers.
- The high dark resistivity of oxide photorefractive materials allows the storage of holograms for time periods up to a year in the dark.

In spite of the great appeal of photorefractive materials, they have specific limitations which have restricted their use in practical devices. For example, oxide ferroelectric materials are very efficient, but are rather insensitive. Conversely, the bulk compound semiconductors are extremely sensitive, but suffer from low efficiency in the absence of an applied field. In this section we will first review the figures of merit used to characterize photorefractive materials, and then discuss the properties of the different classes of materials.

Figures of Merit

The figures of merit for photorefractive materials can be conveniently divided into those which characterize the steady-state response, and those which characterize the early portion of the transient response[70–72] Most applications fall into one or the other of these regimes, although some may be useful in either regime. For example, aberration correction, optical limiting, and laser coupling are applications which generally require operation in the steady state. On the other hand, certain optical processing applications require a response only to a given level of index change or efficiency, and are thus better characterized by the initial recording slope of a photorefractive grating.

Steady-State Performance The steady-state change in the refractive index is related to the space charge electric field by

$$\Delta n_{ss} = \frac{1}{2} n_b^3 r_{eff} E_{sc} \tag{10}$$

where n_b is the background refractive index, r_{eff} is the effective electro-optic coefficient (which accounts for the specific propagation direction and optical polarization in the sample), and E_{sc} is the space charge electric field. For large grating periods where diffusion limits the space charge field, the magnitude of the field is independent of material parameters and thus $\Delta n_{ss} \propto n_b^3 r_{eff}$. In this case (which is typical for many applications), the ferroelectric oxides are favored, because of their large electro-optic coefficients. For short grating periods or for very large applied fields, the space charge field is trap-limited and $\Delta n_{ss} \propto n_b^3 r_{eff}/\varepsilon_r$, where ε_r is the relative dielectric constant.

The temporal behavior of the local space charge field in a given material depends on the details of the energy levels which contribute to the photorefractive effect. In many cases, the buildup or decay of the field is exponential. The fundamental parameter which characterizes this transient response is the write or erase energy W_{sat}. In many materials the response time τ at an average intensity I_0 is simply given by

$$\tau = W_{sat}/I_0 \tag{11}$$

This clearly points out the dependence of the response time on the intensity. As long as enough energy is provided, photorefractive gratings can be written with beams ranging in intensity from mW/cm^2 to MW/cm^2. The corresponding response time can be calculated simply from Eq. (11).

In the absence of an applied or photovoltaic field (assuming only a single charge carrier), the response time can be written as[70]

$$\tau = \tau_{\mathrm{di}}(1+4\pi^2 L_d^2/\Lambda_g^2) \tag{12}$$

where τ_{di} is the dielectric relaxation time, L_d is the diffusion length, and Λ_g is the grating period. The diffusion length is given by

$$L_d = (\mu \tau_r k_B T/e)^{1/2} \tag{13}$$

where μ is the mobility, τ_r is the recombination time, k_B is Boltzmann's constant, T is the temperature, and e is the charge of an electron. The dielectric relaxation time is given by

$$\tau_{\mathrm{di}} = \varepsilon_r \varepsilon_0/(\sigma_d + \sigma_p) \tag{14}$$

where σ_d is the dark conductivity and σ_p is the photoconductivity, given by

$$\sigma_p = \alpha e \mu \tau_r I_0/h\nu \tag{15}$$

where α is the absorption coefficient.

In as-grown oxide ferroelectric materials, the diffusion length is usually much less than the grating period. In this case, the response time is given by

$$\tau = \tau_{\mathrm{di}} \tag{16}$$

In addition, the contribution from dark conductivity in Eq. (14) can be neglected for intensities greater than ~mW/cm^2. In this regime, materials with large values of absorption coefficient and photoconductivity ($\mu\tau_r$) are favored.

In bulk semiconductors, the diffusion length is usually much larger than the grating period. In this case, the response time is given by

$$\tau \approx \tau_{\mathrm{di}}(4\pi^2 L_d^2/\Lambda_g^2) \tag{17}$$

If we again neglect the dark conductivity in Eq. (14), then

$$\tau \approx \pi \varepsilon k_B T/e^2 \alpha I_0 \Lambda_g^2 \tag{18}$$

In this regime, materials with small values of dielectric constant and large values of absorption coefficient are favored. For a typical bulk semiconductor with $\varepsilon_r \approx 12, \alpha = 1\,\mathrm{cm}^{-1}$, and Λ_g = 1 μm, we find $W_{\mathrm{sat}} \approx 100\,\mu\mathrm{J/cm}^2$. This saturation energy is comparable to that required to expose high resolution photographic emulsion. In photorefractive multiple quantum wells (with $\alpha \approx 10^{13}\,\mathrm{cm}^{-1}$), the saturation energy can be much smaller. Note finally that an applied field leads to an increase in the write energy in the bulk semiconductors.[72]

Transient Performance In the transient regime, we are typically concerned with the time or energy required to achieve a design value of index change or diffraction efficiency. This generally can be obtained from the initial *recording slope* of a photorefractive grating. One common figure of merit which characterizes the recording slope is the sensitivity,[70–72] defined as the index change per absorbed energy per unit volume:

$$S = \Delta n/\alpha I_0 \tau = \Delta n/\alpha W_{\mathrm{sat}} \tag{19}$$

TABLE 1 Materials Parameters for $BaTiO_3$, BSO, and GaAs

Material Class	Ferroelectric Oxide	Ferroelectirc Nonoxide	Sillenite	Compound Semiconductor
Material	$BaTiO_3$	$Sn_2P_2S_6$	BSO	GaAS
Wavelength range (μm)	0.4–1.1	0.65–1.3	0.45–0.65	0.9–1.3
Electro-optic coefficient r_{eff} (pm/V)	**100**(r_{33}) **1640**(r_{42})	174(r_{11}) 92(r_{21}) 140(r_{31}) –25(r_{51})	4(r_{41})	1.4(r_{41})
Dielectric constant	135(ε_{33}) 3700(ε_{11})	230–300 (ε_{11})	56	13.2
$n_b^3 r_{eff}/\varepsilon$(pm/V)	10(r_{33}) 6(r_{42})	18(r_{11})	1.4	3.3
Mobility μ(cm²/V-s)	0.01		0.1	**6000**
Recombination time τ_r (s)	10^{-8}		**10^{-6}**	3×10^{-8}
Diffusion length L_d (μm)	0.01	0.55	0.5	20
Photoconductivity $\mu\tau_r$ (cm²/V)	10^{-10}	1.6×10^{-7}	10^{-7}	1.8×10^{-4}

(The parameters in bold type are particularly distinctive for that material.)

In the absence of an applied field and for large diffusion lengths, we find the limiting value of the sensitivity:

$$S \approx 1/4\pi(n_b^3 r_{eff}/h\nu\varepsilon)(me/\varepsilon_0)\Lambda_g \tag{20}$$

where m is the modulation index.

We will see that the only material dependence in the limiting sensitivity is through the figure of merit $n_b^3 r_{eff}/\varepsilon$. This quantity varies little from material to material. Using typical values of the materials parameters and assuming $\Lambda_g = 1\,\mu m$, we find the limiting value $S = 400$ cm³/kJ. Values in this range are routinely observed in the bulk semiconductors. In the as-grown ferroelectric oxides, in which the diffusion length is generally less than the grating period, the sensitivity values are typically two to three orders of magnitude smaller.

Comparison of Materials In the following sections, we will briefly review the specific properties of photorefractive materials, organized by crystalline structure. To introduce this discussion, we have listed relevant materials parameters in Table 1. This table allows the direct comparison among $BaTiO_3$, $Sn_2P_2S_6$ (SPS), $Bi_{12}SiO_{20}$ (BSO), and GaAs, which are representative of the four most common classes of photorefractive materials.

The distinguishing feature of $BaTiO_3$ is the magnitude of its electro-optic coefficients, leading to large values of steady-state index change. The sillenites are distinguished by their large value of recombination time, leading to a larger photoconductivity and diffusion length. The compound semiconductors are distinguished by their large values of mobility, leading to very large values of photoconductivity and diffusion length. Note also the different spectral regions covered by these four materials.

Ferroelectric Materials

The photorefractive effect was first observed in ferroelectric oxides that were of interest for electro-optic modulators and second-harmonic generation.[73] Initially, the effect was regarded as "optical

damage" that degraded device performance.[74] Soon, however, it became apparent that refractive index gratings could be written and stored in these materials.[75] Since that time, extensive research on material properties and device applications has been undertaken.

The photorefractive ferroelectric oxides can be divided into three structural classes: ilmenites ($LiNbO_3$, $LiTaO_3$), perovskites [$BaTiO_3$, $KNbO_3$, KTa_{1-x}, Nb_xO_3(KTN)], and tungsten bronzes [$Sr_{1-x}Ba_xNb_2O_6$(SBN), $Ba_2NaNb_5O_{15}$(BNN) and related compounds]. In spite of their varying crystal structure, these materials have several features in common. They are transparent from the bandgap (~350 nm) to the intrinsic IR absorption edge near 4 μm. Their wavelength range of sensitivity is also much broader than that of other photorefractive materials. For example, useful photorefractive properties have been measured in $BaTiO_3$ from 442 nm[76] to 1.09 μm,[77] a range of a factor of $2\frac{1}{2}$. Ferroelectric oxides are hard, nonhygroscopic materials—properties which are advantageous for the preparation of high-quality surfaces. Their linear and nonlinear dielectric properties are inherently temperature-dependent, because of their ferroelectric nature. As these materials are cooled below their melting point, they undergo a structural phase transition to a ferroelectric phase. Additional transitions may occur in the ferroelectric phase on further lowering of the temperature. In general, samples in the ferroelectric phase contain regions of differing polarization orientation called domains, leading to a reduction in the net polar properties of the sample. To make use of the electro-optic and nonlinear optic properties of the ferroelectric oxides, these domains must be aligned to a single domain state. This process, called poling, can take place during the growth process, or more commonly, after polydomain samples have been cut from an as-grown boule.

Growth of large single crystals of ferroelectric oxides has been greatly stimulated by the intense interest in photorefractive and nonlinear optic applications. Currently, most materials of interest are commercially available. However, considerably more materials development is required before optimized samples for specific applications can be purchased.

Lithium Niobate and Lithium Tantalate $LiNbO_3$ was the first material in which photorefractive "damage" was observed.[73] This material has been developed extensively for frequency conversion and integrated optics applications. It is available in large samples with high optical quality. For photorefractive applications, iron-doped samples are generally used. The commonly observed valence states are Fe^{2+} and Fe^{3+}. The relative populations of these valence states can be controlled by annealing in an atmosphere with a controlled oxygen partial pressure. In a reducing atmosphere (low oxygen partial pressure), Fe^{2+} is favored, while Fe^{3+} is favored in an oxidizing atmosphere. The relative Fe^{2+}/Fe^{3+} population ratio will determine the relative contributions of electrons and holes to the photoconductivity.[78] When Fe^{2+} is favored, the dominant photocarriers are electrons; when Fe^{3+} is favored, the dominant photocarriers are holes. In most oxides, electrons have higher mobilities, so that electron-dominated samples yield faster photorefractive response times. Even in heavily reduced $LiNbO_3$, the write energy is rarely lower than 10 J/cm^2, so this material has not found use for real-time applications. The properties of $LiTaO_3$ are essentially the same as those of $LiNbO_3$.

Currently, the most promising application of $LiNbO_3$ is for holographic storage. $LiNbO_3$ is notable for its very large value of dark resistivity, leading to very long storage times in the dark. In addition, the relatively large write or erase energy of $LiNbO_3$ makes this material relatively insusceptibe to erasure during readout of stored holograms.

Improved retention of stored holograms can be obtained by fixing techniques. The most common fixing approach makes use of complementary gratings produced in an ionic species which is not photoactive.[79, 80] Typically, one or more holograms are written into the sample by conventional means. The sample is then heated to 150°C, where it is annealed for a few hours. At this temperature, a separate optically inactive ionic species is thermally activated and drifts in the presence of the photorefractive space charge field until it compensates this field. The sample is then cooled to room temperature to "freeze" the compensating ion grating. Finally, uniform illumination washes out the photorefractive grating and "reveals" the permanent ion grating.

Another important feature of $LiNbO_3$ for storage applications is the large values of diffraction efficiency (approaching 100 percent for a single grating) which can be obtained. These large efficiencies arise primarily from the large values of space charge field, which, in turn, result from the very large value of photovoltaic field.

Barium Titanate $BaTiO_3$ was one of the first ferroelectric materials to be discovered, and also one of the first to be recognized as photorefractive.[81] The particular advantage of $BaTiO_3$ for photorefractive applications is the very large value of the electro-optic coefficient r_{42} (see Table 1), which, in turn, leads to large values of grating efficiency, beam-coupling gain, and conjugate reflectivity. For example, four-wave mixing reflectivities as large as 20 have been observed,[69] as well as an image intensity gain of 4000.[68]

After the first observation of the photorefractive effect in $BaTiO_3$ in 1970, little further research was performed until 1980 when Feinberg et al.[82] and Krätzig et al.[83] pointed out the favorable features of this material for real-time applications. Since that time, $BaTiO_3$ has been widely used in a large number of experiments in the areas of optical processing, laser power combining, spatial light modulation, optical limiting, and neural networks.

The photorefractive properties of $BaTiO_3$ have been reviewed in Ref. 84. Crystals of this material are grown by top-seeded solution growth in a solution containing excess TiO_2.[85] Crystal growth occurs while cooling the melt from 1400 to 1330°C. At the growth temperature, $BaTiO_3$ has the cubic perovskite structure, but on cooling through $T_c = 132^{\circ}C$, the crystal undergoes a transition to the tetragonal ferroelectric phase. Several approaches to poling have been successfully demonstrated. In general, the simplest approach is to heat the sample to just below or just above the Curie temperature, apply an electric field, and cool the sample with the field present.

Considerable efforts have been expended to identify the photorefractive species in as-grown $BaTiO_3$. Early efforts suggested that transition metal impurities (most likely iron) were responsible.[86] In later experiments, samples grown from ultrapure starting materials were still observed to be photorefractive.[87] In this case, barium vacancies have been proposed as the dominant species.[88] Since that time, samples have been grown with a variety of transition metal dopants. All dopants produce useful photorefractive properties, but cobalt-doped samples[89] and rhodium-doped samples[90] appear particularly promising, because of their reproducible high gain in the visible and enhanced sensitivity in the infrared.[90]

One particular complication in developing a full understanding of the photorefractive properties of $BaTiO_3$ is the presence of shallow levels in the bandgap, in addition to the deeper levels typically associated with transition-metal impurities or dopants. The shallow levels are manifested in several ways. Perhaps the most prominent of these is the observation that the response time (and photoconductivity) of as-grown samples does not scale inversely with intensity [see Eq. (11)], but rather has a dependence of the type $\tau \sim (I_o)^{-x}$ is observed, where $x = 0.6–1.0$.[81–84,91] Several models relating to the sublinear behavior of the response time and photoconductivity to shallow levels have been reported.[92–95]

The characteristic sublinear variation of response time with intensity implies that the write or erase energy W_{sat} increases with intensity, which is a clear disadvantage for high-power, short-pulse operation. Nevertheless, useful gratings have been written in $BaTiO_3$ using nanosecond pulses[96,97] and picosecond pulses.[98] Another manifestation of the presence of shallow levels is intensity-dependent absorption.[99] The shallow levels have been attributed to oxygen vacancies or barium vacancies, but no unambiguous identification has been made to date.

The major limitation of $BaTiO_3$ for many applications is the relatively slow response time of this material at typical CW intensity levels. In as-grown crystals, typical values of response time are 0.1 to 1 s at 1 W/cm^2. These values are approximately three orders of magnitude longer than theoretical values determined from the band transport model (see "Steady-State Performance"), or from more fundamental arguments.[100,101]

Two different approaches have been studied to improve the response time of $BaTiO_3$. In the first, as-grown samples can be operated at an elevated temperature (but below the Curie temperature). In a typical experiment (see Fig. 5), an improvement in response time by two orders of magnitude was observed[102] when different samples were operated at 120°C. In some of these samples, the magnitude of the peak beam-coupling gain did not vary significantly with temperature. In these cases, the improvement in response time translates directly to an equivalent improvement in sensitivity.

While operation at an elevated temperature may not be practical for many experiments, the importance of the preceding experiment is that it demonstrates the *capability for improvement in response time,* based on continuing materials research.

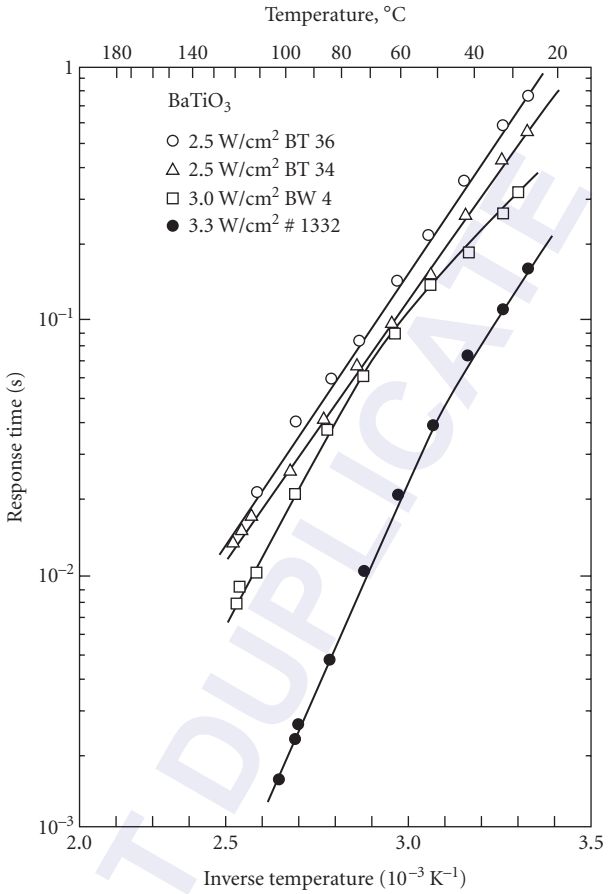

FIGURE 5 Measured response time as a function of temperature for four samples of $BaTiO_3$. The measurement wavelength was 515 nm and the grating period was 0.79 μm.

Other materials research efforts concentrated on studies of new dopants, as well as heat treatments in reducing atmospheres.[88,89,103,104] The purpose of the reducing treatments is to control the valence states of the dopants to produce beneficial changes of the trap density and the sign of the dominant photocarrier. While some success has been achieved,[89,104] a considerably better understanding of the energy levels in the $BaTiO_3$ bandgap is required before substantial further progress can be made.

Potassium Niobate $KNbO_3$ is another important photorefractive material with the perovskite structure. It undergoes the same sequence of phase transitions as $BaTiO_3$, but at higher transition temperatures. At room temperature it is orthorhombic, with large values of the electro-optic coefficients r_{42} and r_{51}.

$KNbO_3$ has been under active development for frequency conversion and photorefractive experiments since 1977 (Ref. 70). Unlike $BaTiO_3$, undoped samples of $KNbO_3$ have weak photorefractive properties. Iron doping has been widely used for photorefractive applications,[70] but other transition metals have also been studied.

Response times in as-grown $KNbO_3$ at 1 W/cm² are somewhat faster than those of $BaTiO_3$, but are still several orders of magnitude longer than the limiting value. The most common approach

to improving the response time of $KNbO_3$ is electrochemical reduction. In one experiment at 488 nm,[101] a photorefractive response time of 100 μs at 1 W/cm^2 was measured in a reduced sample. This response time is very close to the limiting value, which indicates again the promise for faster performance in all the ferroelectric oxides.

Strontium Barium Niobate and Related Compounds $Sr_{1-x}Ba_xNb_2O_6$ (SBN) is a member of the tungsten bronze family,[105] which includes materials such as $Ba_2NaNb_5O_{15}$ (BNN) and $Ba_{1-x}Sr_xK_{1-y}Na_yNb_5O_{15}$(BSKNN). SBN is a mixed composition material with a phase transition temperature which varies from 60 to 200°C as x varies from 0.75 to 0.25. Of particular interest is the composition SBN-60, which melts congruently,[106] and is thus easier to grow with high quality. SBN is notable for the very large values of the electro-optic tensor component r_{33}. In other materials such as BSKNN, the largest tensor component is r_{42}. In this sense it resembles $BaTiO_3$.

In general, the tungsten bronze system contains a large number of mixed composition materials, thus offering a rich variety of choices for photorefractive applications. In general, the crystalline structure is quite open, with only partial occupancy of all lattice sites. This offers greater possibilities for doping, but also leads to unusual properties at the phase transition, due to its diffuse nature.[105]

The photorefractive properties of SBN were first reported in 1969,[107] very soon after gratings were first recorded in $LiNbO_3$. Since that time, there has been considerable interest in determining the optimum dopant for this material. The most common dopant has been cerium.[108–110] Cerium-doped samples can be grown with high optical quality and large values of photorefractive gain.[111,112] Another promising dopant is rhodium, which also yields high values of gain coefficient.[113]

As with $BaTiO_3$ and $KNbO_3$, as-grown samples of SBN and other tungsten bronzes are relatively slow at an intensity of 1 W/cm^2.[114] Doping and codoping has produced some improvement. In addition, the use of an applied dc electric field has led to improvement in the response time.[115]

The photorefractive effect has also been observed in fibers of SBN.[116] The fiber geometry has promise in holographic storage architectures.

Tin Hypothiodiphosphate $Sn_2P_2S_6$ has been known as a ferroelectric since 1974,[117] but has been investigated as a photorefractive material only since 1991.[118] Its Curie point is 337 K, only a few tens of degrees above room temperature, so its electro-optic coefficients are expected to be high (Table 1). It is distinguished from the ferroelectric oxide photorefractives by its useful wavelength range and speed of response. Its bandgap is narrower than that of typical photorefractive oxides, so its wavelength range is pushed deeper into the infrared, and will operate with high gain from 0.65 to 1.3 μm[119,120] and at least as far as 1.55 μm for tellurium doped crystals.[121] There are several variants of nominally undoped material, known by their color (type I yellow, type II yellow, and modified brown), as well as doped crystals, each with their different characteristics. The properties of type I yellow crystals depend on their history of illumination, and are characterized by the existence of a photoinduced fast grating mediated by positive charge carriers and a thermally induced slow grating mediated by electrons. By virtue of the fact that these are due to oppositely charged carriers, they are 180° out of phase with each other, and tend to cancel each other out. In type II yellow crystals, the slow grating is suppressed, thus improving the steady-state gain.[122] The response time of the fast grating at 1.06 μm is 300 ms at 1W/cm^{-2} and is inversely proportional to intensity while the response time of the slow grating is of the order of 100 s, and is approximately independent of intensity. Brown crystals are produced by modifying the vapor transport crystal growth method in such a way as to increase the concentration of intrinsic defects. Typical photorefractive properties for type II, brown, and Te-doped crystals are shown in Table 2.

Cubic Oxides (Sillenites)

The cubic oxides are notable for their high photoconductivity, leading to early applications for spatial light modulation[123] and real-time holography using the photorefractive effect.[124] The commonly used sillenites are $Bi_{12}SiO_{20}$ (BSO), $Bi_{12}GeO_{20}$ (BGO), and $Bi_{12}TiO_{20}$(BTO). Some relevant properties of these materials are listed in Table 3.

The sillenites are cubic and noncentrosymmetric, with one nonzero electro-optic tensor component $\mathbf{r}_{41}$. The magnitude of $\mathbf{r}_{41}$ in the sillenites is small, ranging from approximately 4 to 6 pm/V in the

TABLE 2 Typical Photorefractive Parameters of Various $Sn_2P_2S_6$ Crystals at Two Light Wavelengths

$Sn_2P_2S_6$ Sample	λ (nm)	α_x (cm^{-1})	Γ_{max} (cm^{-1})	τ (ms)	N_{eff} 10^{16} cm^{-1}
Yellow type II	633	0.5	4–7	10–50	0.7
	780	0.2	2–5	100	0.2
Brown	633	5.7	38	4	2.5
	780	1.0	18	10	0.7
Te-doped (1%)	633	1.0	10	2.5	0.9
	780	0.4	6	7	1.0

λ, without pre-illumination; α_x, absorption coefficient for x-polarized light; Γ_{max}, maximal two-wave mixing gain: τ, faster response time at a grating spacing of 1 μm and scaled to a light intensity of 1 W/cm^{-2}; N_{eff}, effective trap density. (*After Grabar et al.*[117])

TABLE 3 Material Properties of BSO, BGO, and BTO

Material	BSO	BGO	BTO
Wavelength range (μm)	0.5–0.65	0.5–0.65	0.6–0.75
Electro-optic coefficient r_{41} (pm/V)	4.5	3.4	5.7
$n_b^3 r_{41}$ (pm/V)	81	56	89
Dielectric constant	56	47	48
$n_b^3 r_{41}/\varepsilon$ (pm/V)	1.4	1.2	1.9
Optical activity at 633 nm (degrees/mm)	21	21	6

visible. In addition, the sillenites are optically active, with a rotatory power (at 633 nm) of 21°/mm in BSO and BGO, and 6°/mm in BTO. These values increase sharply at shorter wavelengths. The optical activity of the sillenites tends to reduce the effective gain or diffraction efficiency of samples with normal thickness, but in certain experiments it also allows the use of an output analyzer to reduce noise.

The energy levels due to defects and impurities tend to be similar in each of the sillenites. In spite of many years of research, the identity of the photorefractive species is still not known. It is likely that intrinsic defects such as metal ion vacancies play an important role. With only one metal ion for each 12 bismuth ions and 20 oxygen ions, small deviations in metal ion stoichiometry can lead to large populations of intrinsic defects. In each of the sillenites, the effect of the energy levels in the bandgap is to shift the fundamental absorption edge approximately 100 nm to the red.

BSO and BGO melt congruently and can be grown from stoichiometric melts by the Czochralski technique. On the other hand, BTO melts incongruently and is commonly grown by the top-seeded solution growth technique, using excess Bi_2O_3. BTO is particularly interesting for photorefractive applications (compared with BSO and BGO), because of its lower optical activity at 633 nm and its slightly larger electro-optic coefficient (5.7 pm/V).[125] It has been studied extensively at the Ioffe Institute in Russia, where both material properties and device applications have been examined.[126–128]

In the sillenites it is very common to apply large dc or ac electric fields to enhance the photorefractive space charge field, and thus provide useful values of gain or diffraction efficiency. A dc field will increase the amplitude of the space charge field, but the spatial phase will decrease from the value of 90° which optimizes the gain. In order to restore the ideal 90° phase shift, moving grating techniques are typically used.[129,130] By contrast, an ac field can enhance the amplitude of the space charge field, while maintaining the spatial phase at the optimum value of 90°.[12] In this case, the best performance is obtained when a square waveform is used, and when the period is long compared with the recombination time, and short compared with the grating formation time. Both dc and ac field techniques have produced large gain enhancements in sillenites and semiconductors, but only when the signal beam is very weak, i.e., when the pump/signal intensity ratio is large. As the amplitude of the signal beam increases, the gain decreases sharply, by an amount which cannot be explained by pump depletion. This effect is significant for applications such as self-pumped phase conjugation, in which the buildup of the signal wave will reduce the effective gain and limit the device performance.

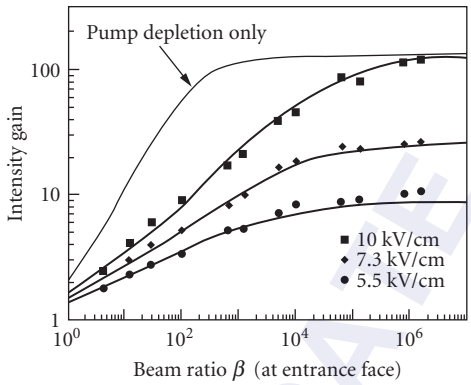

FIGURE 6 Measured two-wave mixing gain as a function of input pump-to-signal beam ratio in BTO. The measurement wavelength was 633 nm, the applied field was a 60-Hz ac square wave, and the grating period was 5.5 μm. The individual points are experimental data; the bold curves are fits using a large signal model. The thin curve is the standard pump depletion theory for the 10-kV/cm case.

A typical plot of intensity gain in BTO as a function of beam ratio for several values of ac square-wave voltage amplitude is given in Fig. 6.[127] Note that the highest gain is observed only for a beam ratio on the order of 10^5 (small signal limit). The simplest physical description of this nonlinearity is that the internal space charge field is clamped to the magnitude of the applied field; this condition only impacts performance for decreasing beam ratios (large signal limit). In a carefully established experiment using a very large beam ratio (10^5), gain coefficients approaching 35 cm^{-1} have been measured using an ac square wave field with an amplitude of 10 kV/cm (see Fig. 7).[131]

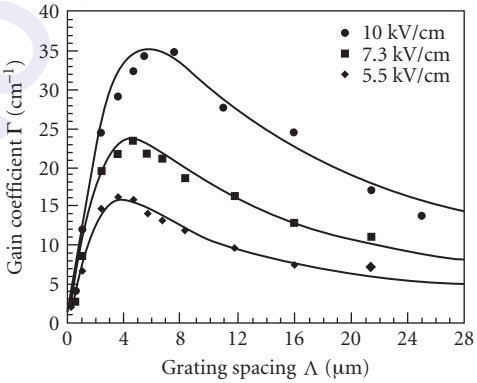

FIGURE 7 Measured gain coefficient as a function of grating spacing in BTO. The measurement wavelength was 633 nm, the applied field was a 60-Hz ac square wave, and the beam ratio was 10^5. The individual points are experimental data; the solid curves are fits using the basic band transport model.

Bulk Compound Semiconductors

The third class of commonly used photorefractive materials consists of the compound semiconductors (Si and Ge are cubic centrosymmetric materials, and thus have no linear electro-optic effect). Gratings have been written in CdS,[132] GaAs:Cr,[133] GaAs:EL2,[134] InP:Fe,[133] CdTe,[135] GaP,[136] and ZnTe.[137] These materials have several attractive features for photorefractive applications (see Table 4). First, many of these semiconductors are readily available in large sizes and high optical quality, for use as electronic device substrates. These substrates are generally required to be semi-insulating; the deep levels provided for this purpose are generally photoactive, with favorable photorefractive properties. Second, the semiconductors have peak sensitivity for wavelengths in the red and near-infrared. The range of wavelengths extends from 633 nm in GaP,[136] CdS,[139] and ZnTe[137] to 1.52 μm in CdTe:V.[135] Third, the mobilities of the semiconductors are several orders of magnitude larger than those in the oxides. There are several important consequences of these large mobilities. Most importantly, the resulting large diffusion lengths lead to fast response times [see Eqs. (12) and (18)]. The corresponding values of write/erase energies (10 to 100 $\mu J/cm^2$) are very near the limiting values. These low values of write/erase energy have been observed not only at the infrared wavelengths used for experiments in InP and GaAs, but also at 633 nm in ZnTe.[137]

The large mobilities of the compound semiconductors also yield large values of dark conductivity (compared with the oxides), so the storage times in the dark are normally less than 1 s. Thus, these materials are not suited for long-term storage, but may still be useful for short-term memory applications. Finally, the short diffusion times in the semiconductors yield useful photorefractive performance with picosecond pulses.[96]

The electro-optic coefficients for the compound semiconductors are quite small (see Table 4), leading to low values of beam-coupling gain and diffraction efficiency in the absence of an applied electric field. As in the sillenites, both dc and ac field techniques have been used to enhance the space charge field. Early experiments with applied fields produced enhancements in the gain or diffraction efficiency which were considerably below the calculated values.[140–142] The causes of these discrepancies are now fairly well understood. First, space charge screening can significantly reduce the magnitude of the applied field inside the sample. This effect is reduced by using an ac field, but even in this case the required frequencies to overcome all screening effects are quite high.[142] Second, the mobility-lifetime product is known to reduce at high values of electric field due to scattering of electrons into other conduction bands and cascade recombination. This effect is particularly prominent in GaAs.[143] Third, large signal effects act to reduce the gain when large fields are used.[144] As in the sillenites, the highest gains are only measured when weak signal beams (large pump/signal beam ratios) are used. Finally, when ac square-wave fields are used, the theoretical gain value is only obtained for sharp transitions in the waveform.[145,146]

Another form of electric field enhancement has been demonstrated in iron-doped InP.[147,148] This material is unique among the semiconductors in that the operating temperature and incident intensity can be chosen so that the photoconductivity (dominated by holes) exactly equals the dark conductivity (dominated by electrons). In this case, an applied field will enhance the amplitude of the space charge field, while maintaining the ideal spatial phase of 90°. Gain coefficients as high as 11 cm^{-1} have been reported in InP:Fe at 1.06 μm using this technique.[148]

TABLE 4 Relevant Materials Properties of Photorefractive Compound Semiconductors

Material	GaAs	InP	GaP	CdTe	ZnTe
Wavelength range (μm)	0.92–1.3	0.96–1.3	0.63	1.06–1.5	0.63–1.3
EO coeff. r_{41} (pm/V)	1.2	1.45	1.1	6.8	4.5
$n_b^3 r_{41}$ (pm/V)	43	52	44	152	133
$n_b^3 r_{41}/\varepsilon$	3.3	4.1	3.7	16	13
Dielectric constant	13.2	12.6	12	9.4	10.1

(Most of the values are taken from Ref. 138.)

In early research on the photorefractive semiconductors, the wavelengths of operation were determined by available laser sources. Thus, all early experiments were performed at 1.06 μm (Nd:YAG), ~1.3 μm (Nd:YAG or laser diode), and ~1.5 μm (laser diode). Later, the He-Ne laser (633 nm) was used to study wider bandgap materials. As the Ti:sapphire laser became available, interest turned to investigating the wavelength variation of photorefractive properties, especially near the band edge. Near the band edge, a new nonlinear mechanism contributes to the refractive index change: the Franz-Keldysh effect.[149] In this case, the internal space charge field develops as before. This field slightly shifts the band edge, leading to characteristic electroabsorption and electrorefraction. These effects can be quite large at wavelengths near the band edge, where the background absorption is also high. However, the peak of the electrorefraction spectrum is shifted slightly to longer wavelengths, where the background absorption is smaller. This is generally the wavelength region where these effects are studied.

The electrorefractive photorefractive (ERPR) effect has different symmetry properties than the conventional electro-optic photorefractive effect. It is thus possible to arrange an experiment so that only the ERPR effect contributes, or both effects contribute to the gain. In addition, the ERPR effect is quadratic in applied electric field. Thus, energy transfer between two writing beams only occurs when a dc field is present. The direction of energy transfer is determined by the sign of the electric field; this allows switching energy between two output beams via switching of the sign of the applied field.

In the first report of the band-edge photorefractive effect,[149] a gain coefficient of 7.6 cm^{-1} was measured in GaAs:EL2 at 922 nm, for a field of 10 kV/cm. In this case, both nonlinear mechanisms contributed to the gain. When a moving grating was used to optimize the spatial phase of the grating, the gain coefficient increased to 16.3 cm^{-1}.

In InP the temperature/intensity resonance can be used to optimize the spatial phase, thus eliminating the need for a moving grating. In the first experiment using band-edge resonance and temperature stabilization, gain coefficients approaching 20 cm^{-1} were measured in InP:Fe (see Fig. 8).[150] Later experiments on a thin sample using a beam ratio of 10^6 resulted in a measured gain coefficient of 31 cm^{-1}.[151]

The photorefractive effect can also be used to measure basic materials properties of electro-optic semiconductors, without the need for electrical contacts.[152–154] Quantities which can be measured include the populations of filled and empty traps and the mobility-recombination time product. One particular feature of the photorefractive technique is the ability to map properties across a wafer.[154]

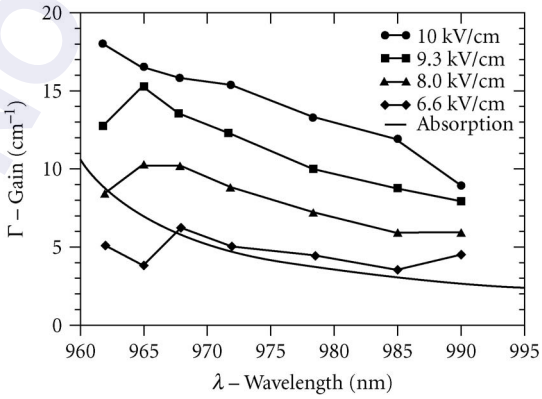

FIGURE 8 Measured gain coefficient as a function of wavelength in InP:Fe, for a grating period of 5 μm and four values of applied dc field. The beam ratio was 1000, and the intensity was adjusted at each point to produce the maximum gain. The background absorption coefficient is also plotted.

Multiple Quantum Wells

While the enhancement of the electro-optic effect near the band edge of bulk semiconductors is significant, much larger nonlinearities are obtained at wavelengths near prominent band-edge exciton features in multiple quantum wells (MQWs). In addition, the large absorption in these structures yields much faster response times than those in bulk semiconductors. Finally, the small device thickness of typical MQW structures (typically 1 to 2 μm) provides improved performance of Fourier plane processors such as optical correlators.[155,156] One disadvantage of the small device thickness is that diffraction from gratings in these devices is in the Raman-Nath regime, yielding multiple diffraction orders.

In their early stages of development, MQWs were not optimized for photorefractive applications because of the absence of deep traps and the large background conductivity within the plane of the structure. It was later recognized that defects resulting from ion implantation can provide the required traps and increase the resistivity of the structure.

The first photorefractive MQWs were GaAs/AlGaAs structures which were proton-implanted for high resistivity ($\rho = 10^9$/ohm-cm).[157,158] Two device geometries were considered (see Fig. 9), but only devices with applied fields parallel to the layers were studied. The principles of operation are initially the same for both device geometries. When two incident waves interfere in the sample, the spatially modulated intensity screens the applied field in direct proportion to the intensity, leading to a spatially modulated internal field. This spatially modulated field induces changes in both the refractive index and the absorption coefficient. The mechanism for these changes[158] is field ionization of excitons (Franz-Keldysh effect) in the parallel geometry and the quantum-confined Stark effect in the perpendicular geometry.

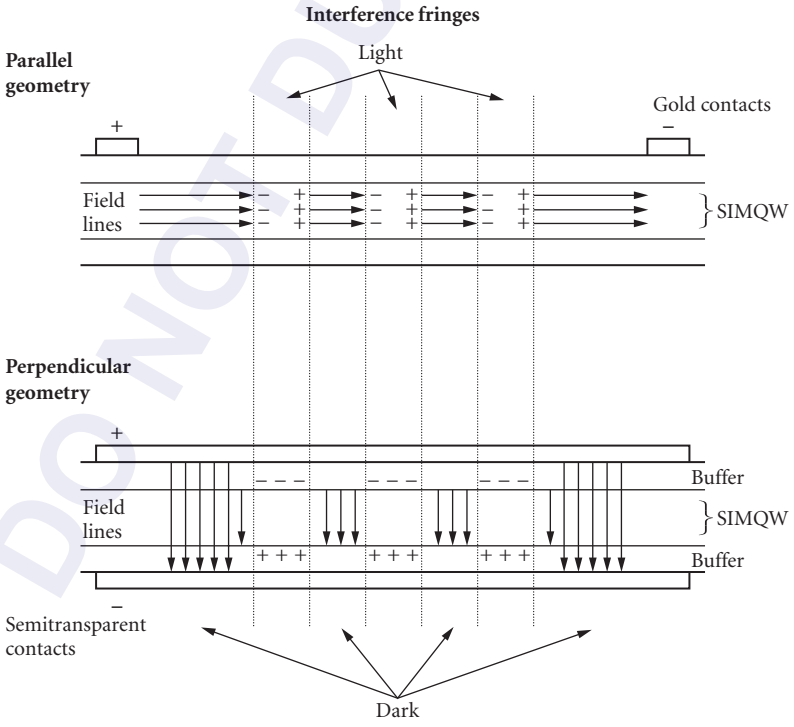

FIGURE 9 Device geometries for photorefractive MQWs.

The magnitudes of the change in refractive index and absorption coefficient are strongly dependent on wavelength near the characteristic exciton peak. Both the index and the absorption grating contribute to the diffraction efficiency through the relationship

$$\eta = (2\pi\ \Delta nL/\lambda)^2 + (\Delta\alpha L/2)^2 \tag{21}$$

where Δn and $\Delta\alpha$ are the amplitudes of the index and absorption gratings, respectively, and L is the device thickness. Although the device thickness of typical MQWs is much less than the thickness of a typical bulk sample (by 3 to 4 orders of magnitude), the values of Δn can be made larger, leading to practical values of diffraction efficiency (see following).

The first III-V MQWs using the parallel geometry[157,158] had rather small values of diffraction efficiency (10^{-5}). In later experiments, a diffraction efficiency of 3×10^{-4} and a gain coefficient of 1000 cm^{-1} were observed.[159] Still higher values of diffraction efficiency (on the order of 1.3 percent) were obtained using the perpendicular geometry in CdZnTe/ZnTe MQWs.[160] These II-VI MQWs have the added feature of allowing operation at wavelengths in the visible spectral region, in this case 596 nm.

In recent work on GaAs/AlGaAs MQWs in the perpendicular geometry, several device improvements were introduced.[161] First, Cr-doping was used to make the structure semi-insulating, thus eliminating the added implantation procedure and allowing separate control of each layer. Second, the barrier thickness and Al ratio were adjusted to give a reduced carrier escape time, leading to a larger diffraction efficiency. In these samples, a diffraction efficiency of 3 percent was observed at 850 nm for an applied voltage of 20 V across a 2-μm-thick device. The response time was 2 μs at an intensity of 0.28 W/cm^2, corresponding to a very low write energy of 0.56 $\mu J/cm^2$. The diffraction efficiency cited here was obtained at a grating period of 30 μm. For smaller values of grating period, the diffraction efficiency was smaller, due to charge smearing effects. The fast response time and small thickness of these structures make them ideal candidates for Fourier plane processors such as optical correlators. Competing bulk semiconductors or spatial light modulators have frame rates which are 2 to 3 orders of magnitude below the potential frame rate of $\sim10^6\ s^{-1}$ which is available from photorefractive MQWs.

Future work on photorefractive MQWs would include efforts to grow thicker devices (so as to reduce the diffraction into higher grating orders) and to improve the diffraction efficiency at high spatial frequencies.

Organic Crystals and Polymer Films

Organic materials are increasingly providing a viable alternative to their inorganic counterparts. Examples include organic crystals for frequency conversion applications and polymer films for electro-optic waveguide devices. These materials are, in general, simpler to produce than their inorganic counterparts. In addition, the second-order nonlinear coefficients in these materials can be quite large, with values comparable to those of the well-known inorganic material $LiNbO_3$. In most organic materials the electronic nonlinearity results from an extended system of π electrons produced by electron donor and acceptor groups. For a purely electronic nonlinearity, the dielectric constant ε is just the square of the refractive index, leading to much smaller values of ε than those in inorganic crystals. Thus, the electro-optic figure of merit n_b^3/ε is enhanced in organic materials. This enhancement makes organic materials very appealing for photorefractive applications.

The first experiments reported on the photorefractive effect in organic crystals were those of Sutter et al.[162,163] on 2-cyclooctylamino-5-nitropyridine (COANP) doped with the electron acceptor 7,7,8,8,-tetracyanoquinodimethane (TCNQ). Pure COANP crystals (used for frequency doubling) are yellow, whereas the TCNQ-doped samples are green, due to a prominent extrinsic absorption band between 600 and 700 nm. In experiments at 676 nm with a grating period of 1.2 μm, both absorption and refractive index gratings were observed. Typical diffraction efficiencies were 0.1 percent, with a corresponding refractive index grating amplitude of 10^{-6}. The recorded buildup times of the index gratings were on the order of 30 to 50 min at 3.2 W/cm^2. Following this initial demonstration of the photorefractive effect in organic crystals there has been very little progress since most attempts at doping these

crystals for photoexcitation and charge transport have simply resulted in expulsion of the dopants from the crystal structure. Only one additional crystal has been reported.[164]

The situation is much more promising for the photorefractive effect in composite polymer films. These materials were first reported in 1991[165,166] and from a materials science point of view, they are much easier to prepare than organic single crystals. In addition, there is greater flexibility in modifying the films to optimize photorefractive performance. In this respect, there are four requirements for an efficient photorefractive material:

1. A linear electro-optic effect, or a quadratic electrooptic effect with a linear component induced by a dc bias electric field
2. A source of photoionizable charges
3. A means of transporting these charges
4. A means of trapping the charges

In an organic polymer composite, each of these functions can be separately optimized. The space charge field due to the holographic interference pattern not only perturbs the refractive index via the electro-optic effect, but can also reorient molecules in the medium giving rise to a refractive index variation via polarizability anisotropy, an effect known as orientational enhancement.[167]

In spite of the large EO coefficients and the great flexibility in the materials engineering of organic polymers, there are also some practical problems which need to be addressed. First, polymers are most easily prepared as thin films. If propagation in the plane of the films is desired, then extremely high optical quality and low absorption are required. If propagation through the film is desired, then the grating diffraction efficiency is reduced. As the film thickness is made larger to enhance efficiency, the quality of the films is harder to maintain.

One important requirement of polymer films is that they must be poled to induce a linear electro-optic effect. If the poling voltage is applied normal to the film plane, then there is no electro-optic effect for light diffracted from gratings written with their wave-vectors in the plane of the film. In a practical sense, this means that the writing beams must enter the film at large angles to its normal. In addition, it becomes more difficult to provide large poling fields as the film thickness increases.

The first polymeric photorefractive material[165,166] was composed of the epoxy polymer bisphenol-A-diglycidylether 4-nitro-1,2-phenylenediamine (bisA-NPDA) made photoconductive by doping with the hole transport agent diethylamino-benzaldehyde diphenyl hydrazone (DEH). In this case, the polymer provided the nonlinearity leading to the electro-optic effect, as well as a mechanism for charge generation. The dopant provided a means for charge transport, while trapping was provided by intrinsic defects.

Films of this material with thicknesses between 200 and 500 μm were prepared. The material was not cross-linked, so a large field was required at room temperature to maintain the polarization of the sample. For an applied field of 120 kV/cm, the measured value of the electro-optic figure of merit $n_b^3\gamma/\varepsilon$ was 1.4 pm/V. Using interference fringes with a spacing of 1.6 μm oriented 25° from the film plane, the measured grating efficiency at 647 nm was 2×10^{-5}. The grating buildup time was on the order of 100 s at an intensity of 25 W/cm^2. Analysis of the data showed that the photorefractive trap density had the relatively small value of 2×10^{15} cm^3. In spite of the low value of trap density, relatively large values of space charge electric field were obtained, due to the low value of dielectric constant.

Subsequent research has led to general design principles for photorefractive polymer composites. Photoexcitation of charge is often accomplished by using donor-acceptor charge transfer complexes. In this way, the absorption spectrum can be tailored to the wavelengths of interest. Carbazole is often used as an electron donor entity, coupled with electron acceptors 2,4,7-trinitro-9-fluorenone (TNF),[168] (2,4,7-trinitro-9-fluorenylidene) malononitrile (TNFM),[168,169] or C_{60}.[170,171] As in the case of the formation of inorganic photorefractive gratings in response to illumination by the optical interference pattern of two intersecting laser beams, the photoexcited charges should be free to move away from the site of excitation and be preferentially retrapped in the darker regions of the interference pattern to form a spatially varying charge distribution following the interference pattern. However, in contrast to the case of inorganic crystals, diffusion is not effective in driving charge separation, so electric fields

have to be applied to force charge separation by drift. These fields are applied by sandwiching a several micrometer thick layer of the polymer system between transparent electrodes. The electrodes have to be tilted with respect to the grating wave vector so as to provide a component of the bias field parallel to the grating vector. Another way in which organics differ from inorganics is that both the photogeneration rate and mobility depend on the electric fields in the material. Hole mobility is usually much greater than electron mobility. This has the effect of allowing the hole grating to dominate the electron grating. If the hole and electron gratings were of similar magnitude, their electric fields would tend to cancel each other out and weaken the photorefractive grating.

The holes migrate via hopping along a network of oxidizable charge transport agents. This network can be provided by the donor entity carbazole itself, or by hydrazones such as DEH or arylamines such as tri-tolyamine (TTA) or *N*,*N*-bis(4-methylphenyl)-*N*,*N*-bis-(phenyl)-benzidine (TPD). These can be added as dopants, or attached to the polymer backbone of the host polymer, as is the case in PVK. As in the case of inorganic photorefractives, a population of empty shallow traps is required to enable the nonuniform space charge distribution of the photorefractive grating. This is often achieved by providing a population of deep traps for some of the shallow traps to empty into, and it has been shown that the nonlinear optical chromophores can serve this purpose in PVK-based materials. These chromophores serve double duty as the moieties providing the optical nonlinearity. They should have large hyperpolarizability β for electro-optic susceptibility and/or large polarizability anisotropy $\Delta\alpha = \alpha_{||} - \alpha_{\perp}$, where parallel and perpendicular refer to the molecular axis. They should also have a large ground state dipole moment μ_g to enable the molecular orientation effect. These parameters can be combined into a single figure of merit (FOM) defined as

$$\text{FOM} = \frac{1}{M}\left[9\mu_g\beta + \frac{2\mu_g^2\Delta\alpha}{k_B T}\right] \tag{22}$$

where M is the molar mass, k_B is Boltzmann's constant, and T is the temperature.

The final component in the composite is a plasticizer to lower the glass transition temperature T_g so as to better enable the orientational orientation effect.

An example of a complete composite comprising hole transporter-electron donor/nonlinear chromophore-deep trap/plasticizer/sensitizer-electron acceptor is PVK/AODCST/BBP/C_{60} in the ratio 49.5:35:15:0.5 percent, where AODCST 2-[[4-[bis(2-methoxyethyl)amino]phenyl]methylene]-malononitrile and BBP is butyl benzyl phthalate. It showed a gain coefficient of 235 cm^{-1} with a response time of 5 ms at 1 Wcm^{-2} for 647-nm light.[170,172] There are many variations on this theme for the design of photorefractive polymer systems, including the use of sol-gel processing,[171] and the use of alternative sensitizers such as gold nanoparticles,[173] transition metal complexes,[174–177] and quantum dots. Quantum dots have been investigated as sensitizers;[178] this is attractive since the spectral sensitivity of the system could be tuned through selection of the size of the quantum dots. It is tempting to try to increase the nonlinearity by increasing the proportion of nonlinear chromophore; however, this can lead to phase separation in a composite polymer. This drawback can be overcome by using an organic amorphous glass as photoconductor and NLO molecule simultaneously, or by using fully functionalized polymers in which the charge generator, charge transporter, and NLO components are incorporated as side chains. Liquid crystals have large orientational nonlinearity, and they have been successfully made photorefractive via the addition of small amounts of sensitizer.[179] They have also been combined with photoconductive polymers as polymer-dispersed or polymer-dissolved liquid crystals.[180,181] Another approach is to replace the transparent electrodes that bias the liquid crystal with thin plates of inorganic photorefractive material such as cerium-doped strontium barium niobate.[182] In this way, the large photorefractive space charge generated in the inorganic plates can extend into the liquid crystal layer and generate a large orientational nonlinearity. This removes the need to tilt the liquid crystal cell and resulted in gain coefficients as large as 1600 cm^{-1} and grating periods as small as 300 nm.

Table 5, reprinted from a review article by Ostroverkhova and Moerner,[183] shows the characteristics of several organic photorefractive systems. That review provides many further details on modeling, design, and characterization of organic photorefractive materials.

External (η_{ext}) or internal (η_{int}) diffraction efficiency is indicated, where applicable (electric field **E**, at which the indicated η was obtained); (9) PR speed τ_{FWM}^{-1} obtained from fits to either formation or erasure of the PR grating measured in the FWM experiment (total light intensity of either writing beams or erasing beam); (10) refractive index modulation Δn, calculated from the diffraction efficiency (electric field **E**, at which the indicated refractive index modulation was obtained); (11) reference to work from which the data was taken. All data reported were obtained in Bragg regime (volume grating) at room temperature, unless stated otherwise. [b]Prepoled material. [c]Temperature of the measurements T_m) 30°C. [d]Includes scattering losses. [e]All the measurements were done in the Raman-Nath regime. See discussion about the relevance of the gain coefficient in the text. [f]Maximal diffraction efficiency possible in the Raman-Nath regime is ~34 percent. The authors attributed their high diffraction efficiency by nonsinusoidal space-charge field. [g]Molar concentrations. [h]This value was obtained with p-polarized writing beams and p-polarized readout.

12.3 DEVICES

Real-Time Holography

The real-time phase holograms produced by the photorefractive effect can be used to perform any of the functions of regular holograms. In fact, many of the first applications of photorefractive nonlinear optics were replications of experiments and ideas first introduced in the 1960s in terms of the then new static holography. These include distortion correction by phase conjugation and one-way imaging through distortions, holographic interferometry for nondestructive testing, vibration mode visualization, and pattern recognition by matched filtering. A concise overview of these applications may be found in Goodman's classic text.[202] Their photorefractive realizations are well described in Huignard and Gunter.[1] Some of the advantages of photorefractive holography over conventional holography are

- Photorefractive holograms are volume phase holograms. This results in high diffraction efficiencies.
- Photorefractive holograms are self-developing.
- Photorefractive holograms diffract light from the writing beams into each other during the writing process. This gives rise to a dynamic feedback process in which the grating and writing beams influence each other.
- Photorefractive holograms adapt to changing optical fields.

It is the last two features that most strongly differentiate the photorefractive effect from regular holography.

Pattern Recognition As an example of the transfer of applications of conventional holography to photorefractive nonlinear optics we consider the case of pattern recognition by matched filtering.

A matched filter for pattern recognition is simply a Fourier transform hologram of the desired impulse response. It can be made in real time in a photorefractive crystal, a lens being used to produce the Fourier transform. The best-known system is a nonlinear optical triple processor based on four-wave mixing[203] (Fig. 10). For a phase conjugate mirror, the coupled-wave equation for beam 3 which is the phase conjugate of beam 4 pumped by beams 1 and 2 is

$$\frac{dA_3}{dz} = \gamma \frac{(A_1 A_4^* + A_2^* A_3)}{I_0} A_2$$

$$= \frac{\gamma}{I_0} I_2 A_3 + \frac{\gamma}{I_0} A_1 A_2 A_4^* \tag{23}$$

where the A_j and I_j are the amplitudes and intensities of beams j, respectively, and I_0 is the total intensity of the interacting beams. The first term on the right-hand side simply corresponds to amplification of beam 3. The second term is the source for beam 3. Thus, the amplitude of beam 3 is proportional to the product $A_1 A_2 A_4^* / I_0$. As depicted in Fig. 10, A_1, A_2, and A_4 are the Fourier transforms of the spatially varying input fields a_1, a_2, and a_4. The output a_3 is proportional to the inverse Fourier transform of the product of the three Fourier transforms $A_1 A_2 A_4^* / I_0$. If I_0 is spatially constant the output is beam 1 convolved with beam 2 correlated with beam 4 ($a_3 \propto a_1 \otimes a_2 * a_4$) where $*$ represents the spatial correlation operation and $\otimes$ represents the convolution operation, all produced in real time. Modified filters such as phase-only filters can be produced by taking advantage of energy transfer during the filter writing process,[204–206] or by saturation induced by the presence of the possibly spatially varying intensity denominator I_0.[207–209]

Sometimes, applications directly transferred from static holography inspire further developments made possible by exploitation of the physical mechanisms involved in the photorefractive effect. For example, acoustic signals can be temporally correlated with optical signals. An acoustic

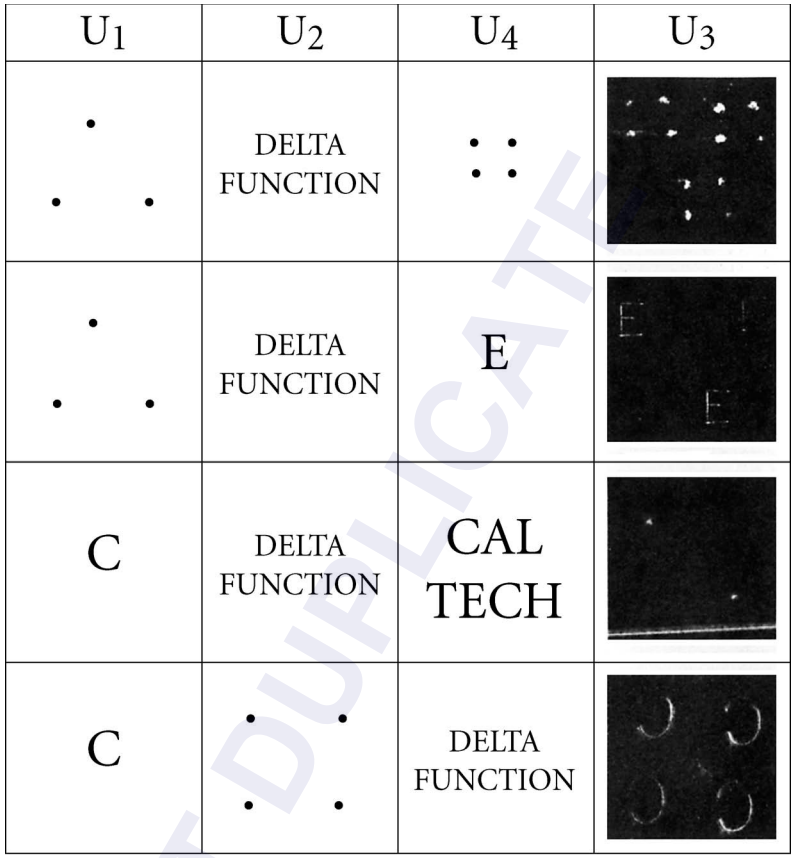

FIGURE 10 (*a*) Results demonstrating real-time spatial convolution and correlation of two-dimensional images. The input fields are labeled $\mathbf{E}_1$, $\mathbf{E}_2$, and $\mathbf{E}_p$; the output is labeled $\mathbf{E}_c$. (*After White and Yariv.*[203])

signal applied to a photorefractive crystal induces piezoelectric fields. If the crystal is illuminated by a temporally varying optical signal, then the photorefractive space charge generated by the photocurrent will be proportional to the product of the time-varying photoconductivity and the time-varying piezoelectric fields. Such correlators can be used to make photorefractive tapped delay lines with tap weights proportional to correlation values.[210–212] It is also possible to make acoustic filters which detect Bragg-matched retroreflection of acoustic waves from a photorefractive grating in a crystal such as lithium niobate that has low acoustic loss.[213]

Applications of Photorefractive Gain in Two-Beam Coupling

Coherent Image Amplification Coherent image amplification is especially important for coherent optical processors. Without it, the losses introduced by successive filtering operations would soon become intolerable. Practical considerations include maintenance of signal-to-noise ratio and

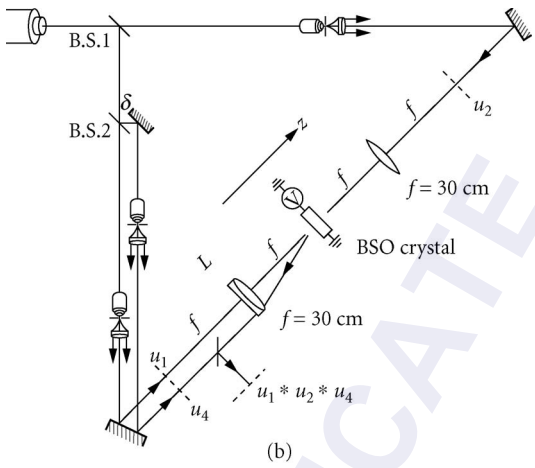

FIGURE 10 (*b*) Experimental apparatus for performing spatial convolution and correlation using four-wave mixing in photorefractive bismuth silicon oxide. Input and output planes are shown by dashed lines. (*After White and Yariv.*[203])

amplification fidelity. The main contribution to noise introduced by photorefractive amplifiers is from the fanning effect. Although it can be reduced in a given crystal in a variety of different ways, such as by crystal rotation[21] and multiwavelength recording,[22] by far the best approach to this problem would be to undertake research to grow cleaner crystals. Amplification fidelity is determined by gain uniformity. In the spatial frequency domain, it is limited because photorefractive gain depends on the grating period. Images with a high spatial bandwidth write holograms with a wide range of spatial frequencies and grating periods. Optimal uniformity is obtained for reflection gratings, in which the image beam counterpropagates with respect to the pump. In that case, the change in grating period depends only to second order on the image spatial frequency. Any remaining first-order nonuniformity is due to the angular dependence of the effective electro-optic coefficient. In the space domain, gain uniformity is limited by pump depletion so that the most accurate results will be obtained if the pump beam is strong enough that it is not significantly depleted in the interaction.

Two-beam coupling amplification can also be used for beam cleanup:[214] a badly distorted beam, say from a laser diode, can be converted to a gaussian beam. A small sample of the beam is split off, spatially filtered and amplified in two-beam coupling by the remaining bulk of the distorted beam. The efficiency of the method can be quite high: fidelity limitations due to spatial variations in gain are usually quite small and can be removed by a second round of spatial filtering. A unidirectional ring resonator with an intracavity spatial filter can also be used for beam cleanup.[215]

Laser Power Combining An application related to two-beam coupling image amplification is coherent power combining, which would be especially useful for semiconductor lasers. The output of a single laser gain stripe is limited to values of the order of a few hundred milliwatts. Some applications require diffraction-limited beams containing many watts produced at high efficiency. Such a source can in principle be made by using two-beam coupling amplification of a diffraction-limited seed by the mutually injection locked outputs of many diode stripes. The injection locking can be achieved by evanescent coupling between laser gain stripes[216,217] or by retroreflecting a portion of the amplified beam with a partially transmitting mirror.[218] Another possibility involves forming a double phase conjugate mirror[219,220] or ring self-pumped phase conjugate mirror with a master laser providing one input, and the light from the gain elements loosely focused into the crystal providing the other inputs. Such a system will be self-aligning and will correct intracavity distortions by phase conjugation.

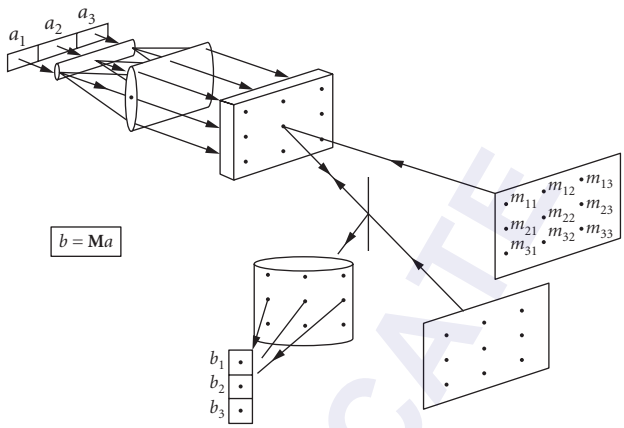

FIGURE 11 Schematic drawing of the basic principle of optical matrix vector multiplication through four-wave mixing in nonlinear media. Light from a linear source array a is fanned out by a cylindrical lens, where it diffracts from an image plane hologram of the matrix $\mathbf{M}$ to produce a set of beams bearing the required products $\mathbf{M}_{ij}a_j$. A second cylindrical lens sums the diffracted beams to form $b = \mathbf{M}a$. (*After Yeh and Chiou.*[229])

Phase conjugate master oscillator/power amplifiers have also been used with some success.[221] Practical problems include the need to control the spectral effects of the associated multiple coupled cavities. Reference[222] gives an excellent exposition of these problems. Also, while self-pumped phase conjugate reflectivities and two-beam coupling efficiencies can theoretically approach 100 percent, in practice these efficiencies rarely exceed 80 percent. Among oxide ferroelectrics, barium titanate exhibits high gain at GaAs laser wavelengths. However, while some bulk semiconductors such as InP:Fe and CdTe:V are sensitive in the 1.3- to 1.5-μm wavelength range of interest for optical fiber communications, high gain requires the application of high electric fields.

Optical Interconnects Use of the double phase conjugate mirror for laser locking suggests another application. The beam-coupling crystal can be viewed as a device that provides optical interconnection of the laser gain elements to each other.[223] The basic idea exists in the realm of static holography in terms of computer interconnection by holographic optical elements[224,225] (HOEs). The use of photorefractive crystals should enable the construction of reprogrammable interconnects that would be self-aligning if phase conjugation were used:[226] the laser gain elements in the power combining case can be imagined as the input/output ports of an electronic chip.[227] Another way to go about the interconnection problem is to design in terms of an optical crossbar switch, or matrix vector multiplier.[228,229] The vector is an array of laser diode sources and the matrix describes connection patterns of the sources to a vector array of detectors (Fig. 11). The interconnection matrix is realized as a photorefractive hologram.

Applications of Photorefractive Loss in Two-Beam Coupling

If the sign of the coupling constant is reversed (for example, by rotation of the uniaxial crystal by 180° so that the direction of the optic axis is reversed) the pump interferes destructively with the signal so that the output is reduced to a very low level. This resulting photorefractive loss can be used in a number of applications such as for optical limiters, optical bistability,[230] and novelty filters and achieved using a variety of different devices such as ring resonators and phenomena such as beam fanning.

Optical Limiters The process of beam depletion in photorefractive materials forms the basis of their use as optical limiters. For this application, another important property of photorefractive materials is their ability to respond selectively to coherent optical inputs. Any portion of the input which is temporally incoherent is transmitted through a photorefractive material in a linear manner. Thus, photorefractive limiters will also selectively attenuate (or *excise*) a coherent beam while transmitting an incoherent beam; these devices have thus also been referred to as excisors.

The first studies of photorefractive limiters were published in 1985.[25] A number of device architectures involving resonators and self-pumped phase conjugate mirrors were discussed, but the primary emphasis was on beam fanning. Several features of limiters or excisors using beam fanning were pointed out: (1) the device design is very simple, with a single input beam and no separate external paths required; (2) the limiting mechanism is due to scattering (and not absorption), so that added heating is not present; (3) the device will operate at one or more wavelengths within the bandwidth of its photorefractive response, which (for ferroelectric oxides) extends over the entire visible band; and (4) the device will respond to sources with a relatively small coherence length, including mode-locked lasers producing picosecond pulses.

Experiments at 488 nm using $BaTiO_3$ in the beam fanning geometry[25] produced a steady-state device transmission of 2.5 percent, and a response time of 1.1 s at 1 W/cm^2. Using the measured response time and intensity, we note that 1.1 J/cm^2 will pass through the device before it fully activates. In later measurements in the beam fanning geometry, attenuation values exceeding 30 dB and device activation energies as low as 1 to 10 mJ/cm^2 have been measured.

Two-beam coupling amplification of a second beam produced by beam splitters[231,232] or gratings in contact with the crystal[233,234] has also been studied as a mechanism for optical limiting. This mechanism is closely related to fanning, with the only difference that the second beam in a fanning device is produced internally by scattering.

Novelty Filters Novelty filters are devices whose output consists of only the changing part of the input. The photorefractive effect can be used to realize the novelty filter operation in several different ways. The simplest way is to use two-beam coupling for image deamplification as was used in the fanning and two-beam coupling optical limiters. In that case, the pump interferes destructively with the signal so that the output is reduced to a very low level. Now if the signal suddenly changes, the output will be the difference between the new input signal and the reconstruction of the old signal by diffraction of the pump from the old grating. Thus, the output will show the changed parts of the scene until the grating adapts during the photorefractive response time to the new scene.[235,236] Such interferometers have been used, for example, to map turbulent flow,[237,238] to make photothermal measurements,[239] and to build acoustic spectrum analyzers.[240]

Phase Conjugate Interferometry

Another way to produce a novelty filter is to use a phase conjugate interferometer.[241,242] This is an interferometer in which some or all of the conventional mirrors are replaced by phase conjugate mirrors, thus achieving the benefit of self-alignment. The effects of phase objects inserted in the interferometer are canceled out by phase conjugation. One of the most common realizations is a phase conjugate Michelson interferometer (Figs. 12 and 13). If the phase conjugate mirrors have common pumping beams (this can be achieved by illuminating the same self-pumped phase conjugator with the beams in both arms), the phase of reflection for both beams will be the same and there will be a null at the output from the second port of the device. If a phase object inserted in one of the arms suddenly changes, the null will be disturbed, and the nonzero output will represent the changing parts of the phase object. The nonzero output persists until the gratings in the phase conjugate mirror adapt to the new input fields.[243] If two amplitude objects are inserted in the interferometer, one in each arm, the intensity of the output at the nulling port is the square of the difference between the squared moduli of the objects. This architecture thus gives rise to image subtraction.[244,245] A slightly modified version can be used to measure thin-film properties (refractive index, absorption coefficient, and thickness): the film under test on its substrate is used as the interferometer beam splitter.[246]

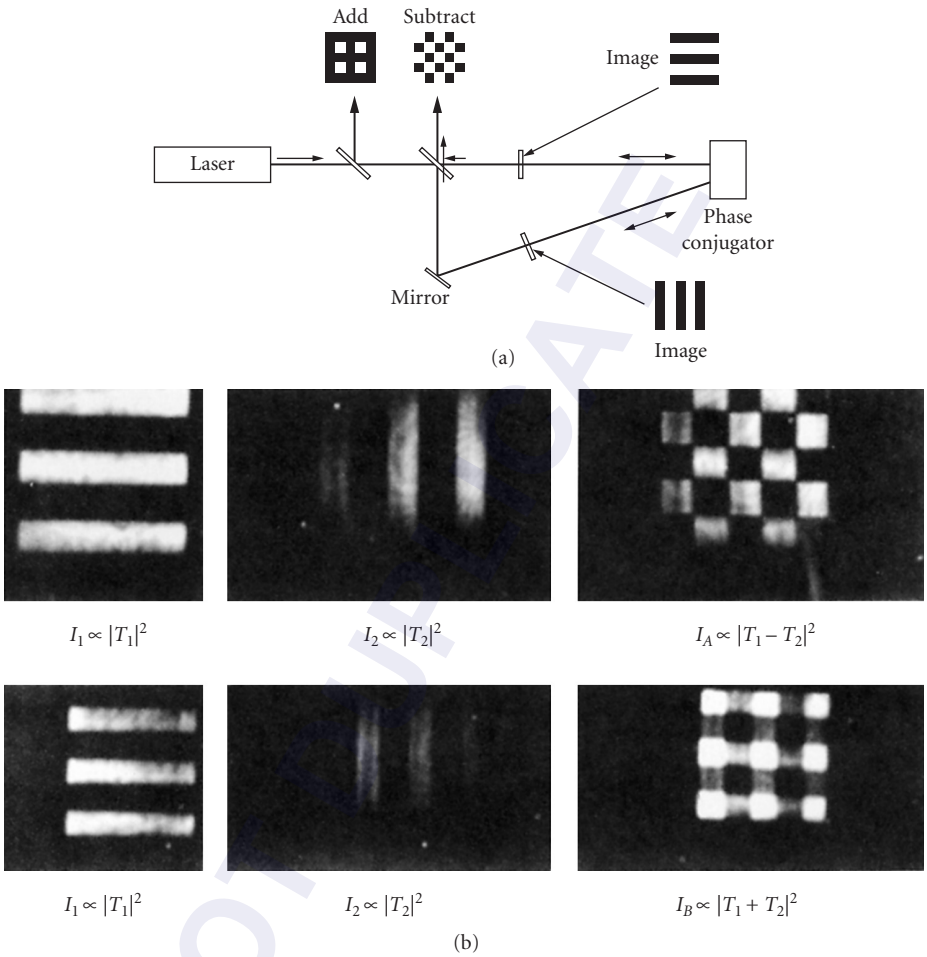

FIGURE 12 Phase conjugate interferometer for image subtraction: *(a)* amplitude images are placed in the interferometer arms. Their difference appears at the nulling output, the sum appears at the retroreflection output. (*b*) Real-time image subtraction and addition of images using above apparatus. (*After Chiou and Yeh.*[245])

Associative Memories and Neural Networks

There are a number of adaptive processors that can be designed using photorefractive beam coupling. In addition to novelty filters, these include associative memories, neural network models, and other recursive image processors.

Photorefractive phase conjugate mirrors provide an elegant way to realize linear associative memories in which a fragment of an image can be used to recall the entire image from a bank of multiplexed holograms stored in a long-term storage photorefractive crystal such as lithium niobate.[247,248] Neural networks, on the other hand, are nets of interconnected signals with nonlinear feedback. They have been extensively investigated in the artificial intelligence community.[249] Typical applications are modeling of neural and cognitive systems and the construction of classification machines. As we have seen, there are a number of different ways to realize optical interconnections

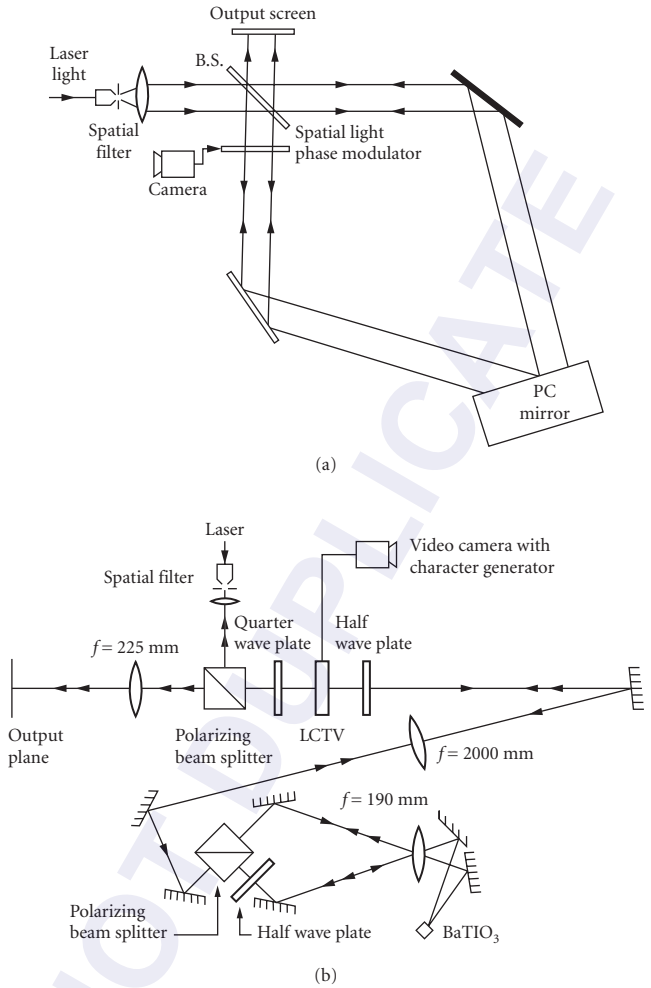

FIGURE 13 Phase conjugate interferometer as a novelty filter: any phase change in the object arm disturbs the null at the output until the phase conjugate mirror adjusts to the change. (*a*) Optical tracking novelty filter incorporating a spatial phase modulator. BS, beam splitter; PC, phase conjugate mirror. (*b*) Modification of preceding device to enable the use of a polarization modulating liquid crystal television (LCTV).

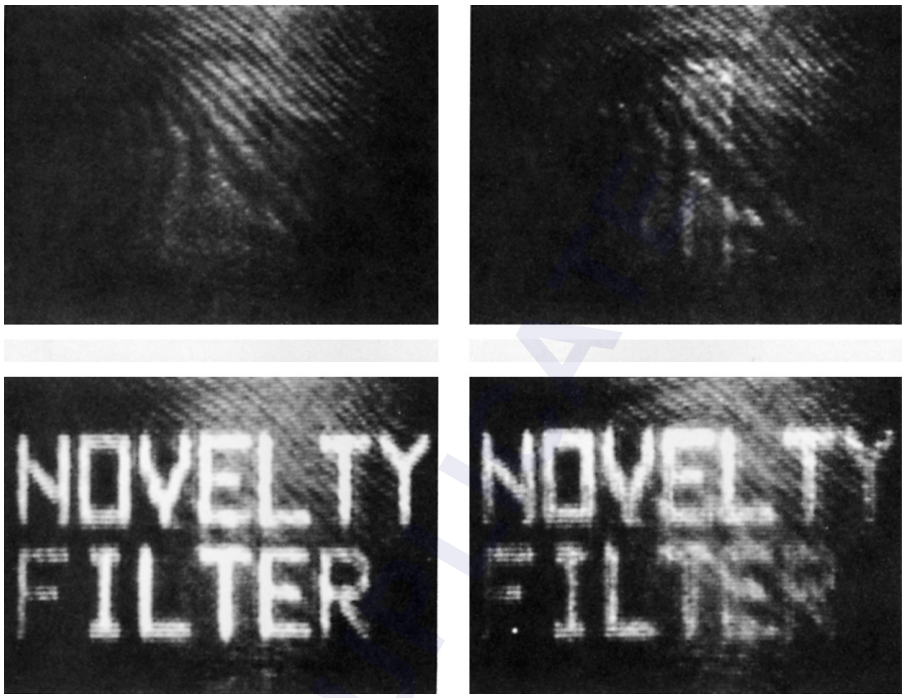
using the photorefractive effect, and nonlinear feedback can be introduced by using the nonlinear transfer properties of pumped photorefractive crystals. A pattern classifier can be built by recording a hologram for each image class (e.g., represented by a clear fingerprint) in a photorefractive crystal with a long time constant. Many holograms can be superposed if they are recorded with spatially orthogonal reference beams. As in the case of the linear associative memory, a smudged fingerprint introduced to the system will partially reconstruct each of the reference beams. The brightest reconstruction will be the reference associated with the fingerprint most like the smudged input. An oscillator with internal saturable absorption is built to provide competitive feedback of the reference reconstructions to themselves. The oscillator mode should be the mode associated with the proper fingerprint. That



(c)

FIGURE 13 (*c*) Photograph of the output of the tracking novelty filter shown in (*b*). Input to the LCTV is taken from a character generator driving a video camera: (1) the character generator is off; the interferometer is essentially dark; (2) the character-generator display, showing the phrase NOVELTY FILTER is activated; (3) the filter adapts to the new scene and becomes nearly blank, as in (1). Some letters are visible; (4) the character-generator display is deactivated. The previous phrase appears at the output of the interferometer. Shortly thereafter it fades to (1). (*After Anderson et al.*[243])

mode then reconstructs the clear fingerprint. The output of the device is the stored fingerprint which is most like the smudged input. We have described just one optical neural network model, but just as there are many theoretical neural network models, there are also many optical neural network models.[250–254] Each of them has its own practical difficulties, including those of reliability, suitability of available threshold functions, and stability.

In addition, the optical gain of photorefractive oscillators makes possible the design of other recursive image processors, for example, to realize Gerschberg-Saxton-type algorithms in phase conjugate resonators.[255]

Thresholding

In optical data processing it is often necessary to determine if one or more elements of an optical pattern has an intensity above (or below) a set threshold value. For example, in optical associative memory applications, it is necessary to select the stronger modes among many in an optical resonator. In optical correlator applications, the output information plane may be thresholded to determine whether a correlation has been obtained, and to determine the location of the correlation peak(s). A closely related operation which is also useful for these applications is the Max or winner-take-all operation.

The ideal thresholding device should have the following properties: (1) the capability to process complex images with high resolution, (2) high sensitivity, (3) low crosstalk between pixels, (4) a sharp threshold, with constant output for intensities above the threshold value, (5) large signal-to-noise, and (6) the ability to control the threshold level by external means.

A large number of thresholding schemes using the photorefractive effect have been proposed or demonstrated, although only a few experimental demonstrations of thresholding of spatial patterns or images have been reported. Techniques used in early investigations include (1) uniform incoherent erasure of self-pumped phase conjugate mirrors[256] and of photorefractive end mirrors in phase conjugate resonators[257,258] and (2) pump depletion in externally pumped phase conjugate mirrors and double phase conjugate mirrors.[55] A number of thresholding devices using ring resonators have also been demonstrated.[55,259] One way of increasing the sharpness of the threshold is to insert additional nonlinear media in the photorefractive resonator cavities.

Ingold et al.[260] demonstrated winner-take-all behavior in a nonresonant cavity containing a nematic liquid crystal and a photorefractive crystal. In later experiments,[261] a thresholding phase conjugate resonator containing a saturable absorber consisting of a thin film of fluorescein-doped boric acid glass demonstrated several performance improvements. In this architecture (shown schematically in Fig. 14) the input image was amplitude-encoded as a two-dimensional array of pixels on an incoherent control beam that was incident on the saturable absorber (a single pixel is shown in Fig. 14). If the intensity at a given pixel was above a threshold intensity, the saturable absorber bleached locally by an amount sufficient to switch on the phase conjugate resonator. The phase conjugate resonator continued to oscillate at these pixel locations even when the control beam was removed. The output was thus bistable and latching.

Photorefractive Holographic Storage

The neural networks described above rely on optical information storage in a material whose gratings are long-lived. One of the earliest potential applications for the photorefractive effect was for

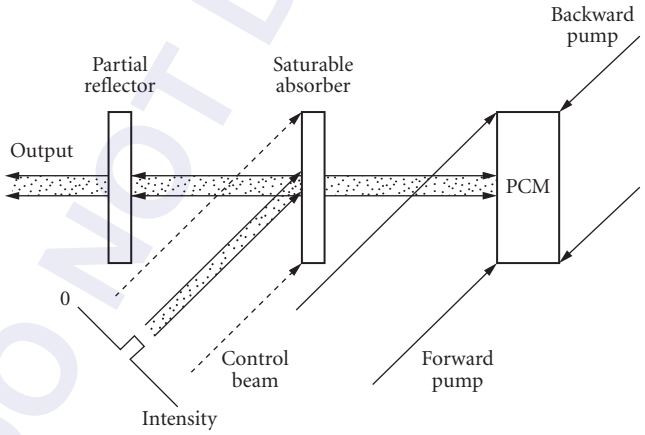


FIGURE 14 Schematic diagram of linear phase conjugate resonator containing an intracavity saturable absorber. Information is read into the resonator by means of a separate control beam incident on the saturable absorber. The control beam can be brought in through a beam splitter, or at an angle to the optic axis (as shown). The fluorescein-doped boric acid glass saturable absorber had a saturation intensity ($I_s = 20$ mW/cm^2) at its absorption peak (450 nm). The $BaTiO_3$ phase conjugate mirror was pumped at the neighboring Ar laser wavelength of 458 nm. The control beam was generated from the same laser, and cross-polarized to a void feedback into the resonator. (*After McCahon et al.*[261])

holographic information storage. One of the best materials for the purpose was and still is lithium niobate; it has storage times which can be as long as years. The principal concerns for holographic storage are information density, crosstalk minimization, fixing efficiency, signal-to-noise ratio, and development of practical readout/writing architectures. There has been a recent renewed interest in optical memory design, now that materials and computer technology have improved and schemes for rapid addressing have matured. The two main classes of addressing scheme use spatially orthogonal reference beams[262–264] and temporally orthogonal reference beams[265] (spatial multiplexing vs. frequency multiplexing). Spatial multiplexing has the advantage that relatively simple optical sources can be used. Frequency multiplexing has the advantage that spatial crosstalk is reduced compared to that associated with spatial multiplexing. However, it has the drawback of requiring frequency-tunable laser sources. An important consideration is the need to pack as much information as possible into each individual hologram. Here the frequency multiplexing approach is superior, because the information density can reach much higher values before crosstalk sets in. Crosstalk can also be reduced by storing information in photorefractive fiber bundles instead of bulk, so that the information is more localized.[266,267]

Holographic Data Storage

A photorefractive holographic digital storage system demonstrated in 1994 had a storage capacity of 163 kB using lithium niobate as the storage medium.[268] It used angular multiplexing to record data pages as separate holograms and distributed consecutive bits over multiple pages to reduce the probability of burst errors. The raw bit error rate was between 10^{-3} and 10^{-4} but was improved to 10^{-6} by use of a Hamming error correcting code. Shortly after that, the capacity was increased to 5 MB using Reed-Solomon error correcting codes,[269] and in 2000 a 1-GB lithium niobate system was demonstrated with 50 μs seek time.[270] Lithium niobate suffers from a low recording sensitivity, of the order of 0.1 cm/J and it has been largely replaced as a holographic recording medium by photopolymers, whose sensitivity can be several orders of magnitude larger (1000 cm/J).[269]

Photorefractive Waveguides

There are three essentially different ways to prepare electro-optic (possibly photorefractive) waveguides. One is to produce local alterations in the chemistry of an electro-optic substrate, for example, by titanium in-diffusion into $LiNbO_3$ or ion implantation in $BaTiO_3$.[271] Another way is to grow waveguides in layers by techniques such as RF sputtering, liquid phase epitaxy, laser ablation,[272] and metalorganic chemical vapor deposition (MOCVD).[273] A third way is to polish bulk material down to a thin wafer.[274]

The performance of electro-optic waveguide devices such as couplers and switches can be seriously compromised by the refractive index changes induced by the photorefractive effect in the host electro-optic materials such as lithium niobate. Therefore, one of the main motivations for understanding the photorefractive effect in waveguides is to develop ways to minimize its effects. MgO doping of lithium niobate is commonly used in attempts to reduce the photorefractive effect.[275]

Some researchers have taken advantage of waveguide photorefractivity. Optical confinement in waveguides enhances the effectiveness of optical nonlinearities. With conventional $\chi^{(3)}$ materials, waveguiding confinement increases the coupling constant-length product by maintaining high intensity over longer distances than would be possible in bulk interactions. In the photorefractive case, optical confinement reduces the response time.

An excellent review of earlier work on photorefractivity in waveguides may be found in Ref. 276 More recently Eason and coworkers have measured a response time improvement by a factor of 100 in an ion-implanted $BaTiO_3$ waveguide.[271] A bridge mutually pumped phase conjugator was also demonstrated.[277]

Photorefractive Solitons

In 1992, the possibility that photorefractive crystal might be able to support spatial solitons was proposed,[278] and subsequently demonstrated, first as a transient effect,[279] and then in the steady state.[280] Optical spatial solitons are beams of light in which the normal tendency toward diffractive spreading is counterbalanced by a nonlinear optical self-focusing effect. Solitons that are stable in 2 transverse directions and the 1 propagation direction (2 + 1 solitons) are made possible by the fact that the photorefractive nonlinearity is saturable, in contrast to the situation with Kerr nonlinearities where self-focusing leads to catastrophic collapse.[281] Solitons can form in photorefractive crystals, where drift is made to dominate diffusion through the application of a DC electric field (screening solitons) or by use of the photovoltaic effect (photovoltaic solitons) and where the degree of saturation of the nonlinearity is controlled through provision of background illumination.[282] These solitons can be described by the nonlinear Schrodinger equation with saturable nonlinearity:[283]

$$i\frac{\partial u}{\partial z} + \frac{1}{2}\frac{\partial^2 u}{\partial x^2} - \frac{u}{|u|^2 + 1} = 0 \tag{24}$$

where u is the amplitude of the soliton normalized by the square root of the sum of the background and dark intensities, x is the transverse coordinate, and z is the propagation direction. More exact versions of this equation have been used, for example, including the diffusion component of the photorefractive effect,[284] but Eq. (24) does describe the basic features.

Since the initial demonstration of basic screening solitons, many different types of solitons have been found, providing a very active research area both in fundamental physics and potential applications. These include bright and dark solitons,[285] vortex solitons,[286] vector solitons,[287] incoherent,[288] and white light solitons.[289] One of the main research interests has been in the study of soliton collisions and interactions.[290] Applications have included optically induced waveguides for optical routing,[291] and for beam confinement for nonlinear frequency conversion.[292]

OPTICAL LIMITING

University of Central Florida
Orlando, Florida

13.1 INTRODUCTION

As the name implies, an optical limiter is a device designed to keep the power, irradiance, energy, or fluence transmitted by an optical system below some specified maximum value, regardless of the magnitude of the input. It must do this while maintaining high transmittance at low input powers. The most important application of such a device is the protection of sensitive optical sensors and components from laser damage. There are many other potential applications for such devices, including laser power regulation or stabilization, or restoration of signal levels in optical data transmission or logic systems, but this chapter will primarily concentrate on devices for sensor protection.

Perhaps the most obvious way of achieving optical limiting is by active control, where input light levels are monitored by a sensor, which through some processor activates a modulator or shutter that in turn limits the transmitted light. The best-known examples of these are the iris and blink response of the eye. However, these are limited in speed to about 0.1 second, so that any intense pulse of light shorter than this can get past these defense mechanisms and damage the retina before they can respond. Speed is an issue with most active control systems for optical limiting. To protect sensors, the transmittance must be reduced in a time much shorter than the width of the potentially damaging pulse. Even very fast electro-optic shutters are limited to rise times on the order of 1 ns, which may be insufficient to adequately block Q-switched pulses shorter than 50 ns or so in duration. Even for protection against longer pulses, cost and complexity are disadvantages of active optical limiting systems. Another direct way to protect sensors against high-power lasers is to use narrow-line spectral filters. These can work well when the laser wavelength is known, such as in laboratory laser safety goggles, but would be largely ineffective against tunable lasers.

Passive systems, on the other hand, use a nonlinear optical material that functions as a combined sensor, processor, and modulator. This offers the potential for high speed, simplicity, compactness, and low cost. However, passive systems place severe requirements on the nonlinear medium.[1–3] While many materials exhibit the type of effects that produce optical limiting, usually these effects prove not to be large enough. Because of this, all prototype passive systems demonstrated to date place the nonlinear optical component in or near a focal plane. In a focal plane, the energy density of a beam from a distant laser source is $10^5 \sim 10^8$ times greater than in a pupil plane. Even in this focused geometry, material nonlinearities are barely large enough, and systems that adequately protect eyes and other common sensors over a broad wavelength band have yet to be demonstrated, at least in the

visible and near-infrared. The idea of using a nonlinear material in a pupil plane (e.g., a coating on the surface of goggles) is therefore far from reality. For mid-infrared (3 to 12 μm wavelength range), optical nonlinearities are typically much larger than in the visible and results have been more promising than in the visible.[4–6] Still, however, limiting elements must be placed near a focal plane. Hence, research to date on optical limiting has predominantly focused on the search for new or modified materials with stronger nonlinearities, and on how to optimally use the best available nonlinear materials. This chapter will concentrate on passive devices.

The response of an *ideal* optical limiter is shown in Fig. 1, along with some typical responses of passive limiters. Clearly, an optical sensor requires high linear transmittance, T_L, at low input light levels for the transmission of images. Meanwhile, for higher inputs the limiter must clamp the transmitted energy below some maximum value, E_{max}, up to the maximum energy the limiter can withstand, E_D. This is usually the energy damage threshold for the limiting material itself. Usually the minimum transmittance of the device, T_{min}, occurs at this energy. Often, the performance of a limiting system or device is characterized by some type of figure of merit (FOM).[7,8] One of the most commonly used is FOM = T_L/T_{min}, which states that a large linear transmittance combined with a low minimum transmittance is desirable.[8] A slightly different way of expressing this is in terms of the optical density (OD), defined as OD = $-\log_{10}(T)$, so that the FOM may be reexpressed as the change in OD, or $\Delta OD = \log_{10}(T_L/T_{min})$. For the ideal limiter shown in Fig. 1, the FOM is equivalent to the *dynamic range*, which is defined as D.R. = E_D/E_L.[7] However, although such merit figures are of some use, it is usually necessary to separately specify parameters such as linear transmittance, maximum transmitted energy, and damage energy. For example, in some applications, a linear transmittance of >50 percent could be an absolute requirement that cannot be offset by an improvement in

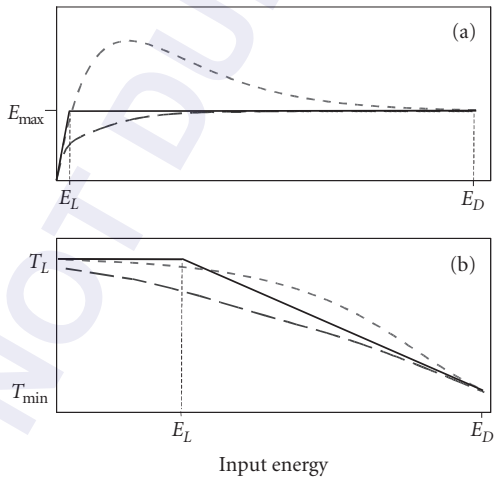

FIGURE 1 Typical limiting curves, drawn as (*a*) transmitted energy versus input energy, and (*b*) transmittance versus input energy, on a log-log scale. The solid line is the *ideal* optical limiter response, while the short- and long-dashed lines are typical of real systems. E_D is the energy at which the limiter undergoes irreversible laser damage. E_{max} is the maximum transmitted energy, here measured at the maximum input energy E_D. E_L is the limiting threshold for the ideal limiter, T_L is the linear transmittance, and T_{min} is the minimum transmittance, usually obtained for the maximum input energy, E_D.

protection. In addition, for nonideal limiting responses, the FOM may not give a clear indication of whether a device provides adequate protection at all input energies. For example, the dashed curves in Fig. 1*b* look very similar when plotted as transmittance versus input energy. Although they have the same FOM, when plotted as transmitted versus input energy, it is clear that the long-dashed curve provides considerably better protection than the short-dashed curve.

The maximum permissible transmitted energy is highly dependent on the threat laser wavelength and pulse width, on the sensor to be protected, and on the *f*-number (defined as the ratio of focal length to lens diameter) of the imaging system. Most practical imaging systems use an *f*-number of 5 or less. However, one very common sensor for which we can specify maximum safe exposure levels is the human eye.[9] Mostly, we are concerned with retinal damage. Visible or near-infrared radiation is not absorbed in the cornea or lens of the eye, and the focusing of light onto the retina produces an optical gain on the order of 10^4 [i.e., the fluence (incident energy/unit area) at the retina is $\sim 10^4$ times that incident on the cornea]. Hence for visible or near-infrared radiation, damage will always occur first at the retina. For wavelengths in the UV and further into the infrared, light does not reach the retina, as it is absorbed in the lens or cornea where the fluence is much lower. If necessary, damage may be avoided by use of optical elements that simply block those wavelengths by reflection or absorption, as the eye cannot detect those wavelengths anyway. As shown in Fig. 2, the ANSI standard for the maximum safe energy entering the eye for pulse lengths less than 17 μs is 0.2 μJ.[10] However, larger energies may be tolerated where there is a finite probability of a retinal lesion but little chance of retinal hemorrhaging. For example, the ED-50 exposure level, for which there is a 50 percent chance of a retinal lesion but little chance of permanent damage, corresponds to ~1 μJ in the visible. Therefore, ideally one would desire $E_{max} << 1$ μJ for an eye-protection limiter. However, since no practical prototype limiter so far has come close to this value, a more common target value for E_{max} in recent literature has been ~1 μJ.[11,12] As will be subsequently described, the total energy entering the eye is not a complete measure of performance, as many nonlinear optical mechanisms that give rise to limiting strongly distort a laser beam as well as controlling its total transmitted energy. Therefore, a better measure of limiting performance is the focusable component of the energy entering the eye, E_{foc}. E_{foc} is defined as the energy falling within a 1.5-mrad-diameter circle in the retinal plane.[13] The accepted value for the minimum resolution of the eye is 1.5 mrad. Should the limiter defocus the beam enough that the focused beam significantly exceeds 1.5 mrad, an E_{max} of > 1 μJ may be tolerable as long as $E_{foc} < 1$ μJ.

In the remainder of this chapter, we describe some of the fundamental principles of passive optical limiting, including nonlinear mechanisms and optimization of geometry. We also present a few examples of experimental demonstrations of some types of optical limiters, although this is by no means intended

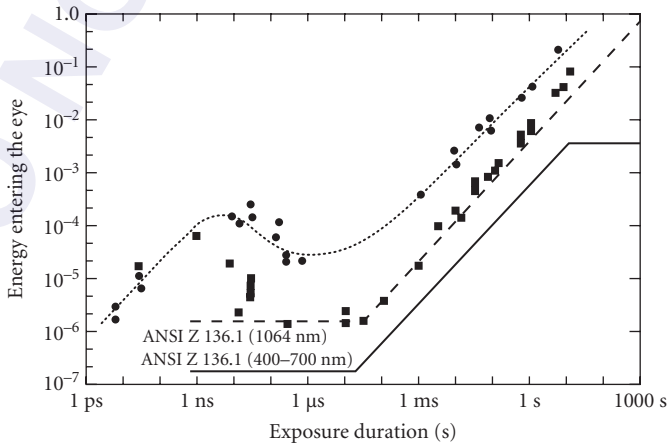

FIGURE 2 Damage thresholds for the eye. (*After Ref. 10.*)

to be a comprehensive review. Rather, this chapter is intended as a starting point for newcomers to the field of optical limiting. For more detailed surveys of published research in this field, the reader is referred to the review papers,[1,3,12] journal special issues,[14] and conference proceedings[15–22] on the subject.

13.2 BASIC PRINCIPLES OF PASSIVE OPTICAL LIMITING

By way of an introduction to passive optical limiting, we briefly describe five of the most common nonlinear mechanisms used. As summarized in Fig. 3, these are (*a*) nonlinear absorption, (*b*) nonlinear refraction, (*c*) nonlinear scattering, (*d*) photorefraction, and (*e*) optically induced phase transitions. There have been many other schemes proposed for passive optical limiting, but those mentioned here form the basis for the vast majority of practical limiting devices that have appeared in the literature. A common theme to all schemes is that they each require the nonlinear optical material to be placed in or near a focal plane. Here we concentrate on how each nonlinear optical property results in limiting and we avoid detailed descriptions of the nonlinear mechanisms. For a more complete description of nonlinear optical phenomena and mechanisms, the reader is referred to Chap. 16, "Third-Order Optical Nonlinearities," of this volume.

Limiting via Nonlinear Absorption

Perhaps the most obvious and direct way to produce passive optical limiting is via nonlinear absorption (NLA), where we require the absorption to increase with increasing incident pulse fluence or irradiance. This can occur in a number of ways, as illustrated in Fig. 4, which shows some of the possible optical transitions for a generic material system. These could represent electronic transitions in many different material types (for example, an organic molecule or a semiconductor crystal).

Two-photon absorption (2PA) is a third-order nonlinear optical process that involves the simultaneous absorption of two photons.[23] For 2PA, the absorption increases in proportion to the incident irradiance, *I*. Another possibility is a two-step absorption process, where linear absorption populates excited states, from which a second absorption to a higher-lying energy state is possible.[24,25] If the

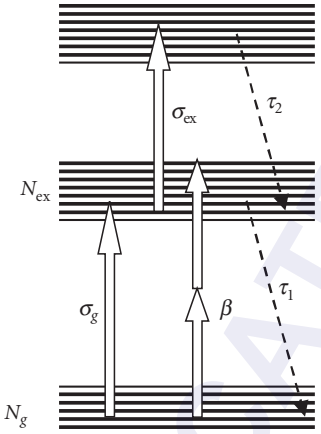

FIGURE 4 Nonlinear absorption processes.

excited state cross section, σ_{ex}, exceeds the ground state cross section, σ_g, then the absorption will increase with increasing excited state population density, N_{ex}, and hence with increasing incident fluence. This is usually referred to as *excited state absorption* (ESA) or *reverse-saturable absorption* (RSA). The latter nomenclature grew out of the more commonly observed *saturable absorption*, where $\sigma_{ex} < \sigma_g$ and the absorption decreases with increasing fluence. In materials with suitable energy levels, it is also possible to populate the excited state by two-photon absorption, and still produce excited state absorption at the excitation wavelength.[23,26] For any of these cases, we may write an approximate effective absorption coefficient, α_{eff},

$$\alpha_{\text{eff}} = \alpha + \beta I + \sigma_{\text{ex}} N_{\text{ex}} = \sigma_g N_g + \beta I + \sigma_{\text{ex}} N_{\text{ex}} \tag{1}$$

where β is the 2PA coefficient and N_g and N_{ex} are the ground state and excited state absorption cross sections, respectively. For a laser pulse shorter than the excited state lifetime, τ_1, and for low excitation levels, N_{ex} is directly proportional to the incident fluence. However, an optical limiter is required to work under high levels of excitation, so usually rate equations must be solved to determine the overall transmittance. Nevertheless, it is clear that a large ratio of σ_{ex}/σ_g is desirable, as we want large ESA, but small linear absorption. However, σ_g cannot be too small, as N_{ex} must become large enough to produce a strong limiting effect. The minimum achievable transmittance should occur when all molecules have been promoted to the first excited state, so that the transmittance is $T_{min} = \exp(-\sigma_{ex} NL)$, where N is the total molecular density and L is the material thickness. Hence the maximum achievable FOM is $T_{min}/T_L = \exp[-(\sigma_{ex} - \sigma_g)NL]$.[27] However, it is not practical to expect such a physical situation. Before such a high excitation is reached, other effects, including ionization, heating, and so forth will occur.[11]

In theory, 2PA is ideal for optical limiting, as the linear absorption is zero. Moreover, it can be shown that there is an absolute upper limit to the irradiance that can propagate through a two-photon absorber, given by $I_{max} = (\beta L)^{-1}$. 2PA also may populate excited states without the inconvenience of linear absorption, so that one can obtain limiting due to both 2PA and ESA. However, it is difficult to find materials with sufficiently large and broadband 2PA coefficients to work well with nanosecond or longer pulses.[26,28,29]

Regardless of the excitation mechanism, it is desirable to have an excited state lifetime, τ_1, longer than the laser pulse width, so that each electron or molecule need only be excited one time per pulse. A short upper excited state lifetime, τ_2, is required to reduce saturation of the excited state absorption, which detracts from limiting performance.

Optimization of NLA Limiters While NLA gives the best optical limiting by placing the nonlinear material in a focal plane, this is also where the damage energy threshold of the nonlinear material is lowest. Very often, this gives an unacceptably low FOM. The damage threshold may be greatly increased by placing another nonlinear absorber in front of the one at focus, hence protecting it from damage. In the case of 2PA, this can be achieved by using a *thick* 2PA material, as illustrated in Fig. 5*a*.[7,28,30] Here, the term *thick* means that the material thickness is much greater than the depth of focus of the beam. The front surface is far from focus, and the 2PA away from focus protects the material near focus. Theoretically, this can be done with no reduction in T_L, as there need be no linear absorption. In reality, parasitic linear transmittance and scatter may reduce T_L. For RSA materials, the intrinsic linear absorption does not permit us to use an arbitrarily thick medium. Instead, discrete elements can be used. This geometry is usually referred to a *cascaded* or *tandem* limiter.[31] In the simplest case, this can consist of two or more elements in tandem, as illustrated in Fig. 5*b*. The elements can be positioned so that the damage fluence, F_d, is reached simultaneously by all elements. This gives the maximum damage energy.[8,11,27] It has been shown that the total FOM of the limiter is given by the product of the FOMs of each individual element. However, because of beam distortion due to NLA or to any NLR that may be present in the material, the FOM of an individual element in a cascaded geometry does not usually approach the FOM of the same element when used alone. Miles[11] pointed out that this geometry helps keep the fluence high through the length of the limiter, by balancing the decrease in fluence due to absorption with the increase in fluence due to focusing. This is illustrated in Fig. 5*b*, which shows a sketch of on-axis fluence versus distance for a four-element tandem limiter. This can be understood by considering the example of a limiter with $T_{min} = 10^{-4}$. If such a limiter were to have only a single element, the fluence on the front surface of the cell would have to exceed that on the rear surface by 10^4. If damage to the front of the cell were to be avoided, the fluence on the rear surface would be so low that the molecules near the rear surface could not contribute significantly to the limiting. Therefore, these molecules only serve to reduce the linear transmittance. However, for a 4-cell tandem limiter, $T_{min} = 0.1$ for each element, and the net value of T_{min} for the tandem limiter is 10^{-4}. This is much easier to achieve. The greater the number of cells, the larger the average fluence in each cell, and the separation of the cells is proportional to the square of the distance from focus, Z.[8] This can be extended to the limiting case of a single element with a graded molecular density, $N(z) \approx 1/\sigma_{ex}|Z|$.[11,32] In this case, the on-axis fluence

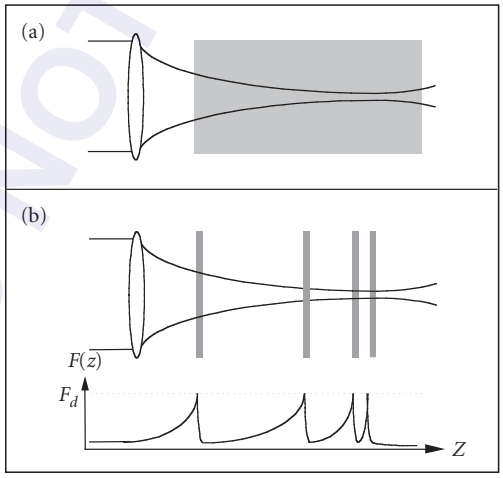

FIGURE 5 Optimization of limiter geometry: (*a*) for a 2PA limiter and (*b*) for an RSA limiter. The graph in (*b*) is a sketch of the on-axis fluence through the limiter near the maximum operating energy.

would remain constant through the RSA material at some designed value of the input energy, usually just below the damage threshold. To avoid problems of generating the exact molecular density distribution, approximating the distribution with a steplike series of adjacent cells of different thickness and density has also been proposed. Like the tandem devices, these designs must be modified to account for beam distortion.[27]

Limiting via Nonlinear Refraction

From Kramers-Krönig relations, we know that all materials exhibiting nonlinear absorption must also exhibit nonlinear refraction.[33] A consequence of this is that each process that gives rise to optically induced changes in absorption must also result in changes to the refractive index. This can usually be expressed as

$$n_{\text{eff}} = n_0 + n_2 I + \sigma_r N_{\text{ex}} \tag{2}$$

where n_2 describes instantaneous index changes proportional to incident irradiance and σ_r describes the change in index due to population of excited states. As described in Chap. 16, "Third-Order Optical Nonlinearities," of this volume and in Refs. 33 and 34, n_2 is related to the 2PA coefficient, β, by Kramers-Krönig relations. σ_r and σ_{ex} are related in a similar manner. Such index changes can occur even at wavelengths where there is no change in absorption.

As a focused beam has a spatially varying irradiance, then the induced index change varies across the beam profile, causing the beam to be strongly distorted upon propagation. Near focus, the beam is usually brightest in the center, so for a negative index change (where the index decreases with increasing irradiance or fluence), the nonlinear material will behave like a lens with negative focal length, and the beam is defocused. This process is referred to as *self defocusing*. If the sign of the index change is positive, *self-focusing* results. Both of these effects can cause the beam to spread in the far field and hence limit the energy density in the far field, although the geometrical alignment may be different for optimal limiting in each case.[35] This means that E_{foc} may be strongly limited without necessarily limiting E_{max}. The presence of pupil-plane apertures in the imaging system combined with the beam distortion may also result in limiting of E_{max}. An advantage of this method over nonlinear absorption devices is that there is no need to absorb large amounts of energy in the nonlinear material, which could cause thermal damage problems. A potential problem is that inadvertent refocusing of the eye could reduce the defocusing effect of the limiter. However, the nonlinear refraction usually aberrates the beam sufficiently that this is not a concern.

In terms of NLR, a *thick* limiter is defined as one where the propagation path in the nonlinear material is long enough that the index changes cause the beam to change its size inside the material. This process is sometimes refers to as *internal self-action*.[36] In this situation, the limiting behavior differs considerably between positive and negative index changes. Self-focusing causes the irradiance to be increased, causing more self-focusing, which becomes a catastrophic effect once a critical input power is reached.[37] This results in breakdown of the medium, which can strongly scatter the light and hence effectively limit the transmitted energy. It also causes damage to the material, but this is not a problem if the nonlinear medium is a liquid. Self-defocusing, on the other hand, reduces the irradiance, so that the limiting occurs more gradually as the input energy is increased.

Thermally induced index changes are also important in optical limiters. In liquids, where the thermal expansion is large, the index change results from the change in density upon heating due to laser absorption.[38] Hence the index decreases with temperature, giving a selfdefocusing effect. The turn-on time for defocusing is dictated by the time taken for the liquid to expand across the width of the laser beam, which is roughly given by the beam radius divided by the speed of sound.[39] The turn-off time is dictated by thermal diffusion. In solids, thermal expansion is much smaller, but other effects, such as temperature dependence of the absorption edge, can cause thermally induced index changes. These usually result in an increase in index with temperature. As this is a local effect, the turn-on time is usually very fast, but turn-off times depend again on thermal diffusion. Thermal

self-focusing in solid-state limiters can be a problem, leading to optical damage. Although thermal defocusing in liquids can be used to produce limiting, and some of the first passive optical limiters were based on this effect,[38] it usually degrades the performance of limiters based on NLA. This is one reason to use solid polymer host matrices for RSA dyes.[40]

Limiting via Nonlinear Scattering

Like absorption, scattering is also capable of strongly attenuating a transmitted beam. Nonlinear scattering is possible by laser-induced creation of new scatter centers or by laser-induced changes in the refractive index difference between existing scatter centers and their surroundings. In the latter case, glass scatterers (such as small particles, a rough surface, highly porous glass, or a regular array of holes in glass) are index-matched by immersion in a liquid.[41–43] In this state, the composite material is clear and highly transparent. A small amount of absorber dye is dissolved in the liquid, so that when illuminated by a strong laser pulse, the solvent is heated and the index matching is lost, resulting in strong scattering.

In the former case, new scatter centers can be created when small particles, such as carbon black, molecular clusters, or other absorbing particles, are exposed to intense laser radiation.[44,45] In their normal state, such particles are very small, and although they may have a very strong optical absorption coefficient, due to their small size they neither absorb nor scatter much radiation. Upon absorption of radiation, the particles rapidly heat and ionize. This can cause the formation of microplasmas, which grow rapidly and strongly scatter the laser radiation. If the particles are suspended in a liquid, the heating can cause subsequent formation of microbubbles, which also strongly scatter light.[46,47] In either event, the scattering produces strong optical limiting. As the size of the scattering particles approaches the wavelength, the scattering is predominantly in the forward direction, which could reduce performance for low *f*-number imaging systems. Another problem is that the limiting process destroys the particles, making this mechanism unsuited to protection against high repetition-rate lasers. This might be overcome by flowing the suspensions. It has been shown that nonlinear scattering may also be an important yet unintentional mechanism in the operation of RSA limiters based on organic molecules.[47] It is likely that that this is due to incomplete dissolution of the organic material, which leaves small clusters of undissolved material in suspension in the solvent.

Other Mechanisms

While the majority of the results reported on passive limiting employ one of the three previously noted mechanisms, many other schemes have been proposed and demonstrated. Most of these may involve some sort of change in refractive index or absorption, but they may use the change in a manner different from those just described. Although such schemes are too numerous to fully document here, the two following examples are worthy of mention.

Photorefraction Photorefractives change their index when exposed to light, and they do so in such a way that the index change is in proportion to the gradient of light intensity. This is achieved by a complex process involving photoexcitation of charge carriers and diffusion of those carriers that results in a space charge field.[48] This field in turn causes an index change via the electro-optic effect. Due to the dependence on the gradient of intensity, the photo-refractive effect is usually employed in situations where a periodic modulation of the irradiance induces a phase grating (a periodic modulation of the index). For optical-limiting applications, the interference is obtained by picking off a portion of the input laser beam with a beam splitter and overlapping it with the original beam in a photorefractive crystal.[49] Alternatively, a reflection from the rear surface of the crystal is used to interfere with the forward-going beam.[50] In both cases, a grating is produced that, via *two-beam coupling*, strongly scatters the incoming laser beam, limiting the transmitted energy.[51] An interesting side effect of this mechanism is that the limiting is coherence-dependent as well as

intensity-dependent. Due to the requirement for charge diffusion, the turn on time is relatively slow, so that this type of limiter is usually only suitable for pulses of millisecond or longer duration.

Optically Induced Phase Change A number of materials show a reversible, thermally induced semiconductor-metal phase transition upon illumination with strong laser radiation.[52] These materials are transparent to infrared radiation in their semiconducting state but highly reflective in their metallic state. Hence, in the infrared these materials may be transparent for low powers, while at high powers, weak optical absorption and subsequent heating may induce the strongly reflecting metallic phase, blocking the transmitted light. Some examples of materials of this type are Ag_2S, $TmSe_xTe_{1-x}$, and vanadium oxides, V_xO_{2x-1}. To be effective, such a material must be stable in its transparent state, have a small latent heat associated with the phase transition, and require a reasonably small temperature change (~ 100 K) to induce the phase transition. Vanadium oxides with compositions close to VO_2 or V_2O_3 comprise the most-studied class of these materials for optical limiting, having a phase transition temperature at around 70°C. In thin-film form and with appropriate antireflection coatings, these materials have high broadband transmission through the infrared (3 to 12 μm) which drops to around 1 percent in the metallic phase.[52]

13.3 EXAMPLES OF PASSIVE OPTICAL LIMITING IN SPECIFIC MATERIALS

Unavoidably, most of the materials used for passive optical limiting exhibit a combination of the nonlinear properties previously described. This usually complicates matters, but in some cases the different nonlinearities may be used to complement each other. In this section, we briefly present a few specific examples of limiting devices that illustrate how some of the principles just described may be applied in practice.

Semiconductors

Semiconductors exhibit a variety of strong nonlinear absorption and refraction effects.[53] Due to their broad absorption bands, they are capable of producing 2PA over a broad wavelength range where the linear absorption is low. Moreover, the carriers excited by 2PA produce very strong absorption and negative nonlinear refraction. The wavelength range of operation for 2PA, avoiding linear interband absorption, is $E_g/2 < h\nu < E_g$. E_g is the bandgap of the semiconductor and $h\nu$ is the photon energy. For example, in ZnSe, this corresponds to an operating wavelength range of about 480 to 900 nm, while in InSb the range is 7 to 14 μm at room temperature. Over this range, the combined effects of 2PA and free carrier absorption and refraction are more or less constant for a given semiconductor. However, the nonlinearities scale very strongly with bandgap. If we keep the ratio of photon energy to bandgap energy fixed, 2PA scales as E_g^{-3} and free carrier absorption and refraction scale approximately as E_g^{-2}.[6,23] Hence, semiconductors work significantly better for the infrared than for the visible. A problem with semiconductors is that they tend to have low damage thresholds. It was shown by Van Stryland et al.[28] that this can be overcome by the use of the thick-limiter geometry. In this case, a thick sample of the large-gap semiconductor ZnSe was used to demonstrate limiting of 30-ps pulses at a wavelength of 532 nm, as shown in Fig. 6. Due to a combination of 2PA and free-carrier absorption and refraction that occurs prior to focus, it was not possible to damage the ZnSe in the bulk. Hence, these devices were labeled *self-protecting* limiters. The FOM was measured as 2×10^4. The linear transmittance was 40 percent, probably due to a combination of scatter and parasitic absorption. Despite this good performance with ps pulses, the self-protection does not prevail for nanosecond pulses. This is thought to be due to the effects of carrier recombination and diffusion, which reduce the carrier defocusing effect, allowing positive thermal index changes to dominate.

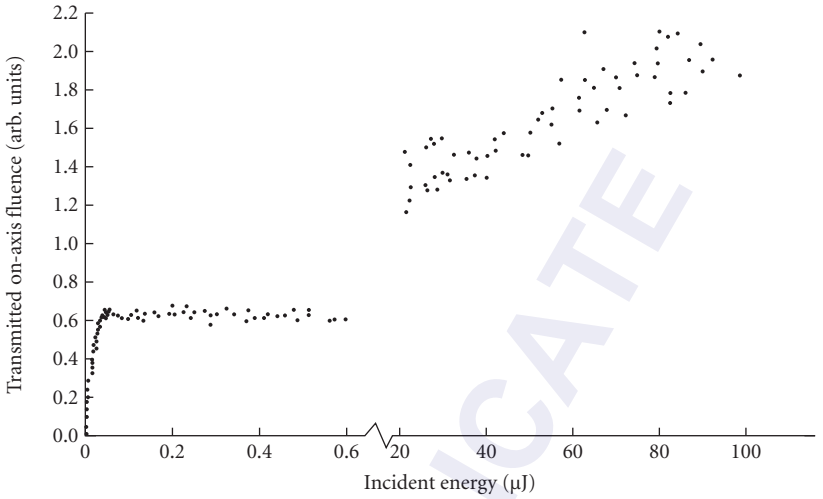

FIGURE 6 Limiting curve for ZnSe thick limiter for 30 ps, 532 nm. (*After Ref. 28.*)

Organics

Organic molecules have attracted interest for optical limiting for their attractive NLA properties in the visible and near-infrared. While some materials have shown promise for their combined 2PA and excited-state absorption properties,[26,29] so far these effects have not proven large enough over a sufficiently broad wavelength band to be practical. By far the most attention has been paid to organics for their RSA properties.[25,54] Generally, the mechanism is as shown in Fig. 4, but often the excited states may also relax into long-lived triplet states. This effectively increases the lifetime of the highly absorbing excited state. The transfer to triplet states may be enhanced by the addition of heavy atoms or paramagnetic groups to the molecule or solvent.[55] Several groups have demonstrated promising results with optimized limiting devices using phthalocyanines or other similar RSA molecules.[40,56] One example of an optimized limiter based on this type of material is that of Perry et al.[40] Here an indium phthalocyanine chloride (InClPc) was incorporated into a PMMA polymer host to make a solid-state limiting material. Slices of this material were used to make a three-element tandem limiter. The device, which had a linear transmittance of about 55 percent (70 percent internal transmittance), was designed to operate with a maximum fluence of 3 J/cm^2 in an *f*/5 focusing geometry. The combination of solid-state host and low design fluence helps minimize the detrimental effects of thermally induced refractive index changes. The device had a minimum transmittance of 0.185 percent at the maximum input energy of 6.5 mJ, corresponding to a maximum output energy of 12 μJ. This was a factor of four greater than predicted by simple design models, which assume a constant beam shape. This discrepancy is small compared with similar liquid-based limiters, which suffer from much greater thermal refraction. To properly design limiters of this type, propagation codes have been developed that account for all NLA and NLR mechanisms, including thermal refraction, and that are capable of modeling internal self-action.[57]

Carbon-Black Suspensions

It was shown by Mansour et al.[44] that dilute ink exhibits very strong, broadband optical limiting properties for nanosecond pulses. Ink is a liquid suspension of amorphous carbon particles. Figure 7 shows an example of limiting of 14-ns, 532-nm pulses using a carbon-black suspension (CBS) in a 50:50 water/ethanol mixture with $T_L = 70$ percent. Similar results are obtained with a

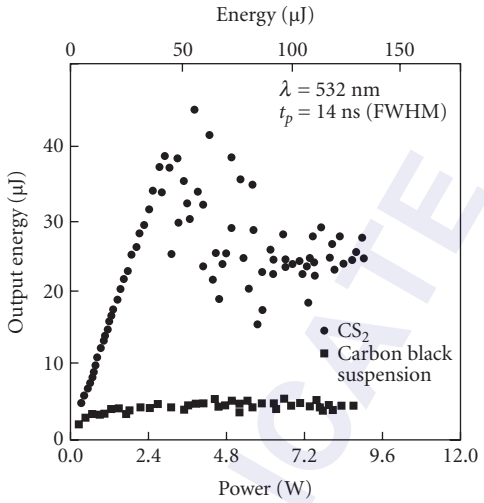

FIGURE 7 Optical limiting of 14-ns pulses at 532-nm wavelength in 1-cm thick, 70 percent linear transmittance CBS. Also shown are results of limiting in CS_2, for comparison. (*After Ref. 44.*)

1064-nm laser wavelength, indicating an extremely broadband limiting response. By observing scattered light intensity as a function of input irradiance, it was clearly shown that the incident light becomes very strongly scattered as the incident energy increases. Measurements of the angular distribution of scattered light show a Mie scattering pattern typical of scattering particles a factor of ≈ 3 larger than the original carbon-black particles. Similar results were found for a layer of small carbon particles deposited on a glass surface. It was concluded from this that the limiting is a result of scattering and absorption by microplasmas formed after thermionic emission from the laser-heated carbon particles. Later studies have indicated that the nonlinear scattering may result from microbubbles formed in the solvent by heating of the carbon. There is clear evidence that for longer pulses, the limiting is dependent on the volatility of the solvent,[46] and imaging techniques have shown that bubbles may persist in the focal volume 100 ns after the pulse.[47] It is quite feasible that microplasmas may be responsible for limiting on shorter (< 10 ns) time scales, while bubbles play a more important role for longer (~ 100 ns) pulses.

Photorefractives

Although it has been shown that the photorefractive effect can occur over a vast range of time scales, effects large enough for practical devices typically have millisecond and longer response times. Cook et al.[50] exploited the large photorefractive two-beam coupling gain in Fe:$LiNbO_3$ to demonstrate strong optical limiting for millisecond pulses or c.w. lasers. A weak reflection of the input beam from the rear surface of the lithium niobate crystal was sufficient to initiate the two-beam coupling. As shown in Fig. 8, this produced a change in OD of up to 4 with a response time of about 2 ms. The linear transmittance for these samples is typically in the range of 30 to 60 percent. The limiting effect is not strongly sensitive to wavelength, operating between 420 and 670 nm. It is found that the optimum *f*-number for limiting was about *f*/20, and limiting performance drops off rapidly as the *f*-number is decreased. This results from the trade-off between the high irradiance produced by small focused spot sizes and the long interaction length produced by large spot sizes.

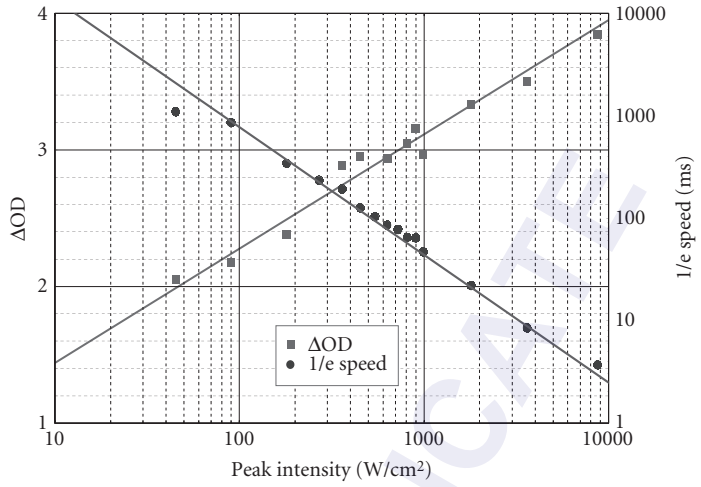

FIGURE 8 Far-field optical limiting and response time in a 3.4-mm path crystal of 0.03 percent Fe + 0.05 percent Tb:$LiNbO_3$ at 523.5 nm. (*After Ref. 50.*)

Liquid Crystals

Liquid crystals are composed of highly anisotropic molecules. By illuminating a nematic liquid crystal with a linearly polarized laser beam, the molecules can align with the electric field in the beam, inducing an irradiance-dependent birefringence in the bulk liquid. These effects are large, but typically take milliseconds to seconds for the realignment process. Recently, it has been shown that doping a liquid crystal with certain dyes can induce molecular reorientation at extremely low powers.[58] Khoo et al.[59] have shown that this effect may be used to achieve extremely low-power c.w. limiting. Using a twisted nematic 5CB film with 1 percent methyl red doping, between crossed polarizers, the maximum transmitted energy of a c.w. argon ion laser beam was kept below 13 μW for inputs up to 140 mW, with $T_L = 10$ percent, including Fresnel reflections and losses at the polarizers. Figure 9 shows a photograph of the transmitted beam for low and high powers, with an image that was simultaneously transmitted by the system. An advantage of liquid crystals is that they can be highly transparent across the entire visible spectrum.

14.1 GLOSSARY

Terms and Acronyms

EIT	electromagnetically induced transparency
CPT	coherent population trapping
STIRAP	stimulated Raman adiabatic passage
RAP	rapid adiabatic passage
SCRAP	Stark chirped rapid adiabatic passage
CPR	coherent population return
LWI	lasing without inversion
lambda (Λ) scheme	three coupled atomic levels with the initial and final states at lower energy than the intermediate state
ladder scheme	three coupled atomic levels with the energy of the initial state below the intermediate state, and the energy of the intermediate state below the final state
vee (V) scheme	three coupled atomic levels with the initial and final states at higher energy than the intermediate state
cw	continuous wave

Symbols

$\|a\rangle$	quantum state of atom
E_a	energy of quantum state $\|a\rangle$
ω_{ab}	angular transition frequency between states $\|a\rangle$ and $\|b\rangle$ (rad s^{-1})
Δ_{ab}	detuning of a light field from an atomic transition at ω_{ab} (rad s^{-1})
μ_{ab}	transition dipole moment between two states $\|a\rangle$ and $\|b\rangle$ (Cm)

Re $\chi^{(1)}$	real part of linear susceptibility (dispersion)
Im $\chi^{(1)}$	imaginary part of linear susceptibility (absorption)
$\chi^{(3)}$	nonlinear susceptibility of third order ($m^2 V^{-2}$)
N_A	number of atoms
n_A	atomic density (cm^{-3})
E	electric field strength (Vm^{-1})
ω	angular frequency of a radiation field (rad s^{-1})
λ	wavelength of a radiation field (nm)
P	macroscopic polarization (Cm^{-2})
Ω	Rabi frequency (rad s^{-1})
ρ_{ab}	density matrix element
Γ_a	decay rate of state $\|a\rangle$ (rad s^{-1})
γ_{ab}	dephasing rate of the coherence ρ_{ab} (rad s^{-1})
$\gamma_{Doppler}$	Doppler (inhomogeneous) linewidth (rad s^{-1})
γ_{laser}	laser bandwidth (rad s^{-1})

14.2 INTRODUCTION

Electromagnetically induced transparency (EIT) is a quantum interference phenomenon that arises when coherent optical fields couple to the states of a material quantum system. In EIT the interference occurs between alternative transition pathways, driven by radiation fields within the internal states of the quantum system. Interference effects arise, because in quantum mechanics the probability amplitudes (which may be positive or negative in sign), rather than probabilities, must be summed and squared to obtain the total transition probability between the relevant quantum states. Interference between the amplitudes may lead to either an enhancement (constructive interference) or a complete cancellation (destructive interference) in the total transition probability. As a consequence, interference effects can lead to profound modification of the optical and nonlinear optical properties of a medium. Thus, control of optical or nonlinear optical properties and processes becomes possible.

Interference effects of this kind are well known in physics. These occur naturally if there are two transition pathways available to the same final state. Fano interferences exhibit an example of interference between two transition pathways. In this case the two pathways are direct photoionization from a quantum state to the ionization continuum and photoionization from the quantum state via an intermediate autoionizing state.[1,2] The interference between these two pathways leads to asymmetric resonances in the photoionization spectrum. The photoionization cross section vanishes at certain excitation frequencies, that is, complete destructive interference occurs. This process is well known for radiative transitions to autoionizing states in atoms or to predissociating states in molecules. It was also predicted to occur in semiconductor quantum wells.[3]

Interfering transition pathways can also be deliberately induced by application of resonant laser fields to multilevel atomic systems. Perhaps the most striking example for this type of interference is the cancellation of absorption for a probe radiation field, tuned in resonance to an atomic transition. Usually the resonant excitation would lead to strong absorption of the probe field. However, if the atoms are prepared by EIT,[4–6] the absorption is essentially switched off. EIT exhibits a laser-induced interference effect between the quantum coherences in the atom, which renders an initially highly opaque medium into an almost transparent medium. Similarly the refractive properties of the medium may be greatly modified.[5,7,8] For instance the usual correlation of high refractive index with high absorption can be broken, leading to the creation of media with unique optical properties.

There has been a considerable research effort devoted to EIT and related topics over the last few years. This has been motivated by the recognition of a number of new potential applications, for example, lasers without inversion, highly efficient nonlinear optical processes, storage of light pulses

and quantum information, lossless propagation of laser beams through optically thick media, and highly efficient and selective population transfer via coherent adiabatic processes. EIT is one of an interrelated group of processes, for example, including coherent population trapping (CPT) and coherent adiabatic population transfer, that result from externally induced quantum mechanical coherence and interference. In contrast, the earlier ideas associated with CPT (first observed in 1976)[9] had found application mostly as a tool of high-resolution spectroscopy, rather than as a new direction in nonlinear optics. Therefore, the concept of EIT has contributed a distinctive new thrust to work on atomic coherence and its applications—a thrust, which is of direct interest to optical scientists and engineers.

To explain the basic idea and applications of EIT, an equivalent picture to interfering transition pathways is provided by the concept of laser-dressed states. In terms of quantum mechanics, the *dressed states* are the eigenstates of the quantum system, including strong interaction with driving radiation fields. The dressed states are coherent superpositions of the *bare states*, that is, the eigenstates of the quantum system without external interaction. The coherent superpositions have well-defined amplitudes and phases that describe the relationship between the atomic states in the superposition. The reader is referred to *The Theory of Coherent Atomic Excitation* by Shore[10] for a complete account of these ideas. An important feature of EIT is the preparation of large populations of these coherently driven, uniformly phased atoms. Such media are termed *phasesonium* by Scully,[7] to convey the basic idea. The (both linear and nonlinear) optical properties of the coherent medium are very different from those of a normal, incoherently driven medium. In the dressed medium the terms of linear and nonlinear susceptibilities can be retained only to the extent that it is recognized that all these resonant processes are highly nonpeturbative. As we will discuss later, even the so-called "linear" processes now involve the coupling of atoms with many photons. An important consequence of this is that the magnitudes of linear and nonlinear susceptibilities can reach equality in a phase-coherent medium. This is in marked contrast to the normal situation. Usually the nonlinear susceptibility would give rise to nonlinear optical processes, which are many orders of magnitude weaker than those arising from the linear susceptibility.

The exceptionally high efficiencies of nonlinear optical processes in gas phase media, prepared by EIT, therefore constitute an important feature of EIT. The large conversion efficiencies in gas phase media, driven to EIT, become comparable to nonlinear optical processes in optical crystals. Thus a renewed interest in gas phase nonlinear optical devices possessing unique capabilities [e.g., high conversion efficiencies into the spectral regions of vacuum-ultraviolet (VUV) and far-infrared (IR) radiation] has occurred. There have been a number of notable recent demonstrations of EIT, applied to frequency conversion. A near-unity frequency conversion into the far-ultraviolet spectral region was reported for a four-wave mixing scheme in lead vapor. The lead atoms were prepared in the state of *maximal coherence*, that is, maximal polarization, by EIT. The uniquely high conversion efficiency arises since the nonlinear terms become equal in magnitude to the linear terms. Besides applications in dense gas phase media with thermal velocity distribution, large optical nonlinearities, induced by EIT were also studied in laser-cooled atoms. In such media, a successful implementation of EIT requires only quite weak laser couplings. Thus, at maximum transparency there is an extremely steep dispersion as a function of the driving laser frequency, that is, the detuning from the atomic resonance. The consequence of this steep slope is a very slow group velocity for optical pulses propagating through the medium.[11] Massive optical nonlinearities accompany the steep dispersion. These are manifested as very large nonlinear refractive indices that are many orders of magnitude larger than any previously observed. These huge nonlinearities are the subject of current research activity. They offer the likelihood of efficient nonlinear optical processes at the few photon level.

In addition to the applications, described above, the coherence and interference effects related to EIT may also permit new possibilities to build short wavelength lasers, that is, lasers in the x-ray spectral range. As the Einstein coefficient for spontaneous emission scales with the cube of the transition frequency ω,[3] it is usually hard to achieve population inversion by optical pumping in an x-ray laser. In contrast, the laser concept based on EIT does not rely on population inversion in the atomic laser medium anymore.[12,13] Lasing without inversion (LWI) has been demonstrated in sodium atoms and rubidium atoms in the visible range.[14,15] The prospects that this might lead to the construction of lasers which are able to circumvent the usual constraints of achieving inversion in short wavelength

lasers has been much discussed.[16,17] Related effects on LWI and EIT in semiconductor quantum wells have also been theoretically explored using laser-induced processes[18] or bandgap engineering[19] to create the necessary coherences. Moreover, atomic and molecular coherences, driven by EIT, were also exploited for efficient frequency conversion and the generation of ultrashort laser pulses.[20–27,28–39]

It is the aim of this chapter to provide an accessible summary of EIT and to present some of the main results obtained in recent research. It is not possible in the space available to cover all work in this field, and we apologize to authors whose important contributions are not directly mentioned. An extensive review of all theoretical and experimental work on related atomic coherence phenomena is also beyond the scope of the present article. The reader is advised to look at a number of reviews on LWI,[16,17] coherent population trapping,[10,40–43] coherent adiabatic population transfer,[44] efficient frequency conversion in coherently prepared media[45] and laser-induced continuum structure[46–50] to find these topics presented in detail. The theory pertinent to EIT is sketched in the text, but again the reader is referred to the more detailed treatments published in the literature.[5] References to relevant literature will be given as they arise. The purpose of the chapter is (1) to communicate the underlying physical principles of EIT and related effects, (2) to describe the manifestations of EIT and to summarize the conditions required to create EIT, and (3) to introduce some potential applications in optical technology.

14.3 COHERENCE IN TWO- AND THREE-LEVEL ATOMIC SYSTEMS

The first experimental work on laser-induced atomic coherence was carried out in the 1970s. Earlier relevant work includes the investigation of dressing two-level systems by strong microwave fields. This led to the observation of splittings between dressed states, that is, Autler-Townes splittings,[51] and photon echoes in two-level systems.[52] Mollow[53,54] reported novel features, subsequently termed the Mollow triplet, of resonance fluorescence in a two-level system driven by a strong resonant laser. Much work on two-level systems has been carried out since.[10,44,55,56] Although two-level systems remain a subject of considerable interest, our concern here is primarily with three-level systems (and in some cases four-level systems).

Atomic coherence and interference in three-level systems was first observed experimentally by Alzetta, Arimondo et al.,[9,57] and by Gray et al.[58] The first group of authors performed experiments that established coherence between the Zeeman split lower levels of a sodium atom using a multimode laser. By employing a spatially varying magnetic field Alzetta, Arimondo et al. observed a series of spatially separated dark lines. These resonances correspond to the locations in the magnetic field where the Zeeman splitting matched the frequency difference between modes of the coupling laser. This situation corresponds to a two-photon resonant lambda-type level scheme. Thus, this was the first experimental observation of CPT. The experiments of Gray et al.[58] involved the preparation of coherence between the hyperfine lower levels of sodium atoms. In these experiments two coincident laser fields are coupled to a three-level lambda scheme of states to create superpositions of the two lower states $|1\rangle$ and $|2\rangle$ (see Fig. 1). One of the superpositions, that is, the coupled state or *bright state* $|C\rangle$ interacts with the fields [see Eq. (1)]. For the other superposition, that is, the noncoupled or *dark state* $|NC\rangle$, interference causes cancellation of the two driven dipoles. Once the coherent states are formed, the population in the system will all be "optically pumped" into the dark state through spontaneous emission from the intermediate state. The optical pumping process occurs on the timescale of a few times the radiative decay time. Once in the dark state there is no process to remove the population. Thus the population is trapped in the dark state.

The basic idea of CPT has been extended to systems, driven by time-varying optical fields to yield very efficient excitation of atomic and molecular states.[44,59–61] In stimulated Raman adiabatic passage (STIRAP), the noncoupled state $|NC\rangle$ exhibits a specific evolution in time. Initially $|NC\rangle$ is prepared such that it is composed purely of the lowest state $|1\rangle$. For intermediate times $|NC\rangle$ evolves as a superposition of the two lower states $|1\rangle$ and $|2\rangle$, with no contribution from the intermediate state $|3\rangle$. Finally $|NC\rangle$ is composed purely of state $|2\rangle$. Thus, population is transferred completely

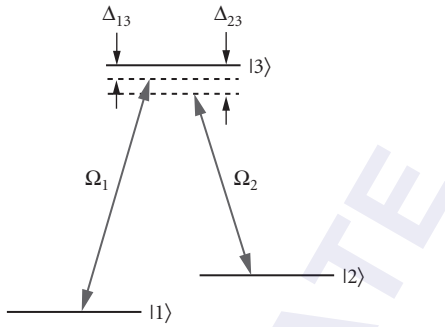

FIGURE 1 CPT in a three-level lambda configuration. Two radiation fields, that is, couplings Ω_1 and Ω_2, are applied with frequencies close to the single-photon resonances at ω_{13} and ω_{23}.

between the lower states $|1\rangle$ and $|2\rangle$, with no intermediate storage in state $|3\rangle$. The bright state is not populated during the process. This specific preparation of a dark state in STIRAP is achieved by employing counterintuitive pulse sequences, that is, the couplings (or the laser pulses) Ω_1 and Ω_2 still partly overlap in time, but Ω_2 reaches its peak value *prior* to the peak of Ω_1. The timescale for STIRAP is determined by the evolution of the laser pulses. This contrasts to conventional CPT, that is, driven with coincident radiation fields, when the time evolution is determined by spontaneous emission. We also note that recently extended work has been performed to utilize CPT also in laser cooling and manipulation of trapped atoms. The technique, used in these experiments was termed *velocity-selective coherent population trapping* (VSCPT).[62–64]

In experiments, dedicated to CPT the primary concern is focused on the manipulation of state populations, essentially of individual atoms. In contrast, for EIT the main interest is the optical response, rather than simply the populations, of the entire medium. The optical response is determined by the coherences rather than the populations. In terms of density matrix elements, in CPT the pertinent quantities are the on-diagonal density matrix elements, that is, the populations; while in EIT they are the off-diagonal density matrix elements, that is, the coherences. Most important, in the limit of a strong coupling field Ω_2 and population initially in the ground state, the coherences, driven by EIT are almost instantaneously established. The timescale of the evolution in EIT is determined by $1/\Omega_2$. For strong excitation, even driven by quite long nanosecond (ns) pulses, the timescale of $1/\Omega_2$ easily reaches the regime of picoseconds, that is, well below the pulse duration. For a successful implementation of population trapping a timescale of several radiative lifetimes is required, that is, typically in the regime of many nanoseconds. From these considerations we see, that though EIT and CPT are closely related, some of their important features as well as their aim are very different.

14.4 THE BASIC PHYSICAL CONCEPT OF ELECTROMAGNETICALLY INDUCED TRANSPARENCY

As discussed in the preceding section, there is a close link between EIT and other phenomena, relying on atomic coherence, that is, adiabatic population transfer processes.[9,43,44,57–61,65–67] In all these processes, three-level atomic systems are involved—that is, systems that can be adequately reduced to three levels when interaction with the pertinent electromagnetic fields are considered. The atomic dipole selection rules require that two pairs of levels are dipole-coupled, while the transition between the third pair is dipole-forbidden. In Fig. 2, we show the basic three-level schemes. All of the level schemes, discussed in this paper can be reduced to one or other of these schemes. Following

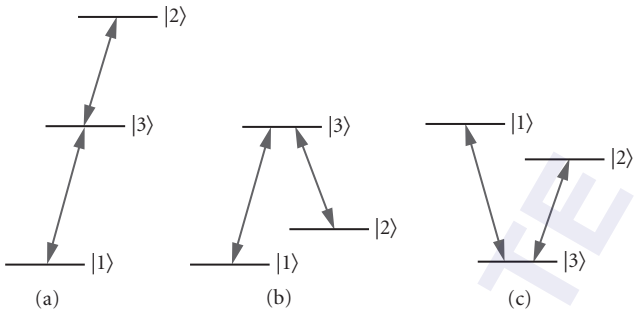

FIGURE 2 Basic three-level schemes: (*a*) ladder (or cascade) scheme with $E_1 < E_3 < E_2$; (*b*) lambda (Λ) scheme with $E_1 < E_2 < E_3$; and (*c*) vee scheme with $E_3 < E_1$ and $E_3 < E_2$.

the nomenclature of Harris et al,[6] we label the levels $|1\rangle$, $|2\rangle$, and $|3\rangle$. The dipole-allowed transitions are between states $|1\rangle$ and $|3\rangle$ and between states $|2\rangle$ and $|3\rangle$. Classification of the schemes then depends upon the relative energies of the three states: (1) ladder (or cascade) scheme with $E_1 < E_3 < E_2$ (2) lambda (Λ) scheme with $E_1 < E_2 < E_3$, and (3) vee (V) scheme with $E_3 < E_1$ and $E_3 < E_2$. EIT has been extensively studied in all three of these configurations. In a lambda or ladder scheme state $|1\rangle$ is normally the ground state of the atom. This is, where initially the majority of the population resides. In EIT there is no need for significant population transfer. Thus states $|2\rangle$ and $|3\rangle$ remain essentially unpopulated throughout the process. It should be noted that the lambda scheme has a special importance due to the metastability of state $|2\rangle$. As a consequence, very long-lived coherences can be established between states $|1\rangle$ and $|2\rangle$. This leads to near-perfect conditions for EIT.

To understand in more detail, how laser fields interact with a three-level atom to create coherent superpositions of the atomic bare states, we will consider now CPT in a lambda scheme. A three-level lambda system (see Fig. 1) is coupled by two near-resonant laser fields. The interaction strength is defined by the Rabi frequencies $\Omega_1 = \mu_{13}\, E_1/\nabla$ at frequency ω_1 and $\Omega_2 = \mu_{23}\, E_2/\nabla$ at frequency ω_2 with the dipole transition moments μ_{13} and μ_{23}, and the electric fields E_1 and E_2. The transition frequencies are defined as ω_{12} and ω_{23}. The one-photon detunings of the radiation fields from the atomic resonances are $\Delta_{13} = \omega_{13} - \omega_1$, $\Delta_{23} = \omega_{23} - \omega_2$ .The two-photon (Raman) detuning is $\Delta = [(\omega_{13} - \omega_{23}) - (\omega_1 - \omega_2)]$. The Hamiltonian of the bare atom H_0 must be modified to include the interactions due to the two couplings. Thus $H = H_0 + V_1 + V_2$, with the interactions $V_j = \hbar\, \Omega_j$. The eigenstates of this new Hamiltonian will be linear superpositions of the bare atomic states $|1\rangle$, $|2\rangle$, and $|3\rangle$ (see Refs. 10, 42, 68). For exact two-photon resonance and, that is, $\Delta = 0$, two of the three eigenstates of the total Hamiltonian H turn out to be symmetric and antisymmetric coherent superpositions of the two lower bare states. These superpositions read

$$|\mathrm{C}\rangle = \frac{1}{\Omega'}(\Omega_1 |1\rangle + \Omega_2 |2\rangle) \tag{1a}$$

$$|\mathrm{NC}\rangle = \frac{1}{\Omega'}(\Omega_2 |1\rangle + \Omega_1 |2\rangle) \tag{1b}$$

where $\Omega' = [\Omega_1^2 + \Omega_2^2]^{1/2}$. It is important to note that no component of the bare state $|3\rangle$ appears in these superpositions. The superposition state $|\mathrm{C}\rangle$ is coupled to the intermediate state $|3\rangle$ via electric dipole interaction, that is, $|\mathrm{C}\rangle$ is a bright state. In contrast, the other state $|\mathrm{NC}\rangle$ is not coupled to state $|3\rangle$, that is, $|\mathrm{NC}\rangle$ is a *dark state* or *trapped state*. This is obvious from the total dipole moment for a transition from state $|\mathrm{NC}\rangle$ to the bare state $|3\rangle$. If the magnitudes of the coupling fields Ω_1 and Ω_2 are appropriately balanced, the negative sign in the superposition of $|1\rangle$ and $|2\rangle$, which forms the state $|\mathrm{NC}\rangle$, causes the transition moment $\langle \mathrm{NC}|\mu|3\rangle$ to vanish. In effect, the two terms

that are summed to give the transition amplitude between $|NC\rangle$ and $|3\rangle$ are of equal and opposite magnitude, and hence the total amplitude will vanish. In a classical picture, this corresponds to the electron driven by two fields, both of which may be strong, but which exert forces of exactly equal magnitude and opposite directions. This interaction leads to a zero net force and hence the electron stays at rest. In conventional CPT and assuming steady-state conditions, the superposition state $|NC\rangle$ will acquire all of the population of the system through optical pumping. Thus spontaneous emission from state $|3\rangle$ populates state $|NC\rangle$, but absorption losses from state $|NC\rangle$ back to state $|3\rangle$ are not possible.

The noncoupled state $|NC\rangle$ also serves as the key component for coherent population transfer by STIRAP,[44] which was already briefly discussed above. We assume, that initially all population is in state $|1\rangle$. State $|2\rangle$ is assumed to be metastable, for example, if the level scheme is of lambda-type configuration. If at early times the Rabi frequencies (i.e., the corresponding radiation fields) are applied such that $\Omega_2 >> \Omega_1$, state $|NC\rangle$ is equal to state $|1\rangle$ [see (Eq. 1)]. All population of the system is prepared in the dark state $|NC\rangle$. No population is in the bright state $|C\rangle$. If at the end of the interaction $\Omega_1 >> \Omega_2$, state $|NC\rangle$ aligns now parallel to the target state $|2\rangle$. As $\Omega_1 >> \Omega_2$, the contribution of state $|1\rangle$ is negligible, that is, all population is transferred to the target state $|2\rangle$. The sequence of an initially strong coupling between the states $|2\rangle$ and $|3\rangle$ and a finally strong coupling between the states $|1\rangle$ and $|2\rangle$ exhibits a counterintuitive laser pulse order, which is the typical feature of STIRAP.

We note that in the previous description we ignored a fast time oscillation of the bare states $|1\rangle$ and $|2\rangle$ in the superpositions in Eq. (1). The oscillation occurs at frequencies $\varepsilon_1/\hbar$ and $\varepsilon_3/\hbar$, with the energy of the bare states ε_i. In fact these terms disappear when the dipole moments are formed. In typical implementations of CPT, for example, STIRAP, the couplings are of comparable strength, that is, $\Omega_1 \approx \Omega_2$, and the two-photon transition is strongly driven. The transition is "saturated" if the terminology of incoherent excitation is used. We note an interesting feature of CPT with respect to the coherences for the case of the laser frequencies tuned to exact two-photon resonance, but with large single-photon detunings. In this case, state $|3\rangle$ can be adiabatically eliminated from the level scheme.[10] Thus state $|3\rangle$ does not enter into the consideration of the coupling between atoms and fields any more. However, also in this case, that is, even far detuned from the single-photon resonances, the two-photon resonance condition alone is sufficient to drive large coherences between states $|1\rangle$ and $|2\rangle$. We also stress the point that in general in CPT the initial population may be distributed between the lower states $|1\rangle$ and $|2\rangle$. This is usually the case if the lower states are provided by sublevels of an atomic ground state, for example, for Zeeman or hyperfine split states. As the energy difference of the lower states $|1\rangle$ and $|2\rangle$ is very small in this case, the initial thermal populations will be almost the same. In this case, a careful analysis of states $|NC\rangle$ and dark state $|C\rangle$ is required to determine the population dynamics for the specific CPT process under consideration, for example, STIRAP. However, also in the case of an initial population in both lower states, the state $|NC\rangle$ is still a dark state. In contrast, in implementations of EIT, the population is initially and for all times completely stored in state $|1\rangle$.

In CPT, interference effects arise from both coupling fields, since they are of comparable strength. If only one of the fields is strong, that is, $\Omega_1 << \Omega_2$, only interference effects due to processes driven by Ω_2 will be important. This is the situation in many implementations of EIT and is discussed by a number of authors (see, e.g., Ref. 5 and references therein). In such EIT experiments, Ω_2 is usually called the coupling field and labeled Ω_C, and Ω_1 is a weaker probe field, labeled Ω_P. In the following we will use the notations Ω_C and Ω_P, whenever appropriate. Based on the considerations, presented above, we will now discuss some simple and straightforward approaches alternative approaches to understand the basic concept of EIT.

First, let us consider the basis, formed by the coupled state $|C\rangle$ and the noncoupled state $|NC\rangle$ [see Eq. (1)]. We can write the bare state $|1\rangle$ in this basis:

$$|1\rangle = \frac{1}{\Omega'}(\Omega_C|NC\rangle + \Omega_P|C\rangle) \tag{2}$$

Very obviously, for the case $\Omega_P << \Omega_C$ state $|1\rangle$ is almost equivalent to $|NC\rangle$, that is, the dark state. Thus absorption to state $|3\rangle$ vanishes. The population remains in the ground state $|1\rangle$ throughout

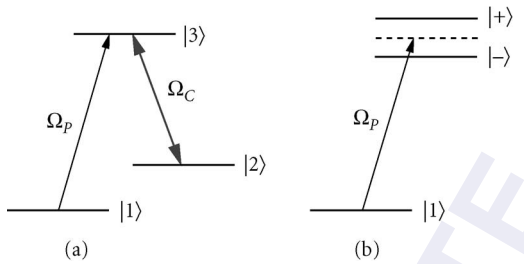

FIGURE 3 EIT in a lambda scheme (compare Fig. 4) viewed in terms of (*a*) bare atomic states, driven by a weak probe field Ω_p and a strong coupling field Ω_C and (*b*) dressed states, generated by the strong coupling Ω_C. The probe field is still at the bare state resonance frequency ω_{13}.

the interaction with the two radiation fields. The probe laser propagates through the medium without any absorption losses, that is, the medium is driven to EIT.

Alternatively, as $\Omega_p << \Omega_C$, we can treat the three-level system of states $|1\rangle$, $|2\rangle$, and $|3\rangle$ as a composition of a strongly coupled two-level subsystem of states $|2\rangle$ and $|3\rangle$, with the weakly coupled state $|1\rangle$ attached to the subsystem. Thus it is straightforward to describe the subsystem in terms of the dressed states, which arise due to the strong interaction[5] (see Fig. 3). For a strong resonant coupling at the single-photon resonance $\Delta_{23} = 0$ the dressed states of the subsystem are

$$|+\rangle = \frac{1}{\sqrt{2}}(|2\rangle + |3\rangle) \tag{3a}$$

$$|-\rangle = \frac{1}{\sqrt{2}}(|2\rangle - |3\rangle) \tag{3b}$$

The transition amplitude at the (undressed) resonant frequency ω_{13} from the ground state $|1\rangle$ to the dressed states will be the sum of the contributions to the dressed states $|+\rangle$ and $|-\rangle$, that is, $[\langle 1|\,\mu\,|+\rangle + \langle 1|\,\mu\,|-\rangle\,] \sim [\,\langle 1|\,\mu\,|2\rangle + \langle 1|\,\mu\,|3\rangle + \langle 1|\,\mu\,|2\rangle - \langle 1|\,\mu\,|3\rangle\,] = \mu_{12} + \mu_{13} + \mu_{12} - \mu_{13}$, with the transition moments μ_{ij}. As we assumed in the definition of our three-level system, the transition between states $|1\rangle$ and $|2\rangle$ is forbidden, that is, $\mu_{12} = 0$. The transition moments μ_{13} enter the sum with opposite signs. Thus the transition amplitude, that is, the absorption, reduces exactly to zero. The system is driven now to EIT.

Finally, another approach to an understanding of EIT is based on the concept of quantum interferences.[13,69–71] Interference, associated with EIT, arises because the transition amplitude between states $|1\rangle$ and $|3\rangle$ includes different pathways from the ground state $|1\rangle$ to the excited state $|3\rangle$: One term, which is due to excitation by the resonant field Ω_P only, that is, a direct path from state $|1\rangle$ to state $|3\rangle$; an additional term, which is due to the presence of the second field Ω_C (see Fig. 4), that is, a indirect path from state $|1\rangle$ to $|3\rangle$ further on to state $|2\rangle$ and back to $|3\rangle$. The additional term and similar higher-order terms have a negative sign with respect to the direct path. Hence the higher-order terms cancel completely the direct path. This situation is closely related to interferences, mediated at Fano-type resonances,[1] for example, via autoionizing states, or to laser-induced continuum structure.[46–50]

Equivalently within the picture of EIT in terms of the interfering pathways between the bare atomic states, the coherences are the quantities pertinent to the interference. Coherences can be thought of, in a semiclassical picture, as associated with the oscillating electric dipoles driven by the coupling fields applied between pairs of quantum states of the system, for example, between states $|i\rangle$ and $|j\rangle$. Strong excitation of these dipoles occurs whenever electromagnetic fields are applied close to resonance with an electric dipole transition between two states. If there are several pathways

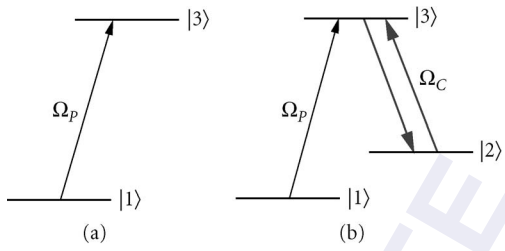

FIGURE 4 EIT in a lambda scheme, viewed in terms of Fano-type interference (compare Fig. 3), (*a*) shows the direct channel for the excitation $|1\rangle \rightarrow |3\rangle$ by the probe field Ω_p, (*b*) shows the lowest-order multiphoton channel induced by the coupling field Ω_c, that is, the sequence $|1\rangle \rightarrow |3\rangle \rightarrow |2\rangle \rightarrow |3\rangle$. Interference between pathway (*a*) and (*b*) (also including higher-order terms) occurs.

to excite the oscillating dipole at frequency ω_{ij}, then interference arises between the various contributions to this dipole. These contributions must be summed to give the total amplitude to the electric dipole oscillation (see Fig. 4).

Mathematically, coherences are identified with the off-diagonal density matrix elements ρ_{ij}. These are formed by taking bilinear combinations of probability amplitudes of two quantum states, that is, by the weighting factors associated with the outer products such as $|i\rangle\langle j|$.[72] Off-diagonal elements in the density matrix play a critical role in the evolution of an atom coupled to electro-magnetic fields.[73] Many calculations of atomic coherence effects and of EIT, as well as general nonlinear optics and laser action, in three-level systems are therefore developed in terms of the density matrix. The magnitudes of the relevant density matrix elements are computed from the basic coupled evolution equations, that is, the Liouville equation,[10,72] and are found to depend upon experimental parameters (e.g., detunings and laser intensities). This approach also naturally lends itself to the inclusion of dampings that cause the decay of populations and coherences (e.g., radiative decay and collisions).[67]

EIT serves to control the absorption of a probe laser on the transition between the states $|1\rangle$ and $|3\rangle$ in the three-level systems, defined and discussed above. Thus EIT will manifest itself in the density matrix element ρ_{13}. The real and imaginary parts of ρ_{13} both vanish at zero detuning, that is, the coherence is cancelled by interference of the excitation pathways. A set of coupled equations connecting the density matrix elements (e.g., ρ_{12}, ρ_{23}, and ρ_{13}) and their temporal derivatives is deduced from the Liouville equation. These coupled equations are then solved for various sets of conditions by either analytical or numerical means. Interference that leads to EIT arises from the coherences ρ_{23} and ρ_{12}, which are coupled to ρ_{13}. The coherence ρ_{12} between the ground state $|1\rangle$ and state $|2\rangle$ is present only due to the additional laser coupling. The contribution to the coherence ρ_{13} from the coherences ρ_{23} and ρ_{12} (driven by both laser fields) cancels with the direct contribution (driven by the probe laser field alone).

Although this use of density matrix elements is convenient, it is by no means essential, and many theoretical treatments that give clear physical insight have been performed in terms of probability amplitudes. Additional physical insights have been obtained by adopting alternative approaches, for instance by a careful consideration of the Feynman diagrams representing the various processes involved that lead to interference,[69–71] or by applying a quantum jump approach.[74] In all cases the predictions are essentially identical.

Analytical solutions are generally only possible for steady-state conditions [corresponding to continuous wave (cw) laser fields]. A time-dependent calculation of the density matrix is appropriate, if laser pulses rather than cw radiation drives the atom. A time-dependent calculation is also vital to account for transient effects or pulse propagation. Some analytical solutions also for time-dependent calculations of the density matrix have been obtained, but unless restrictive simplifying assumptions are applied,[75] time-dependent calculations must be performed numerically. In many

cases the results of a full time-dependent treatment will be comparable to the results, obtained in a steady-state approach. This holds true at least in so far, as qualitative trends are concerned. To calculate the propagation of laser pulses through an extended medium the time-dependent equations for the density matrix elements must be coupled to Maxwell's equations.[10] This is necessary, for example, to compute the propagation of matched pulses,[76–78] the efficiency of frequency conversion processes in coherently prepared media,[20–27,28–39] to account for losses in the driving laser fields or to model pulse shape modifications.[79]

14.5 MANIPULATION OF OPTICAL PROPERTIES BY ELECTROMAGNETICALLY INDUCED TRANSPARENCY

Any optical process in a medium, driven by radiation pulses, is determined by the polarization, that is induced be the light fields. The macroscopic polarization P at the transition frequency ω_{13} can be related to the microscopic coherence ρ_{13} via the expression

$$P_{13} = n_A \mu_{13} \rho_{13} \tag{4}$$

where n_A is the number of atoms per unit volume in the ground state within the medium, and μ_{13} is the dipole matrix element associated with the (undressed) transition.[73] In this way imaginary and real parts of the linear susceptibility at frequency ω can be directly related to ρ_{13} via the macroscopic polarization.[55] The latter is defined as

$$P_{13}(\omega) = \varepsilon_0 \chi(\omega) E \tag{5}$$

introducing the susceptibility $\chi(\omega)$. In this paper, the microscopic coherences are treated quantum mechanically, while the electromagnetic fields are treated classically (i.e., using Maxwell's equations and the susceptibilities). This semiclassical approach is not essential, and fully quantum mechanical treatments for CPT (see, Ref. 41) and EIT[78–80] have been developed. These fully quantum approaches are appropriate for cases such as the coupling of atoms to modes in cavities,[80,81] or when the statistical properties of the light fields are of interest. The latter is the case, for example, in proposals to generate squeezed light using EIT.[79] For relatively strong light fields, present in most laser experiments, a semiclassical treatment, with spontaneous decay added as a phenomenological damping process, proves adequate.

The real and imaginary parts of the (dressed) linear susceptibility, associated with the dispersion and absorption of the medium respectively, are given by[5,6]

$$\mathrm{Re}\,\chi_D^{(1)}(-\omega_P, \omega_P) = \frac{|\mu_{13}|^2 n_A}{\varepsilon_0 \hbar}\left[\frac{-4\Delta_{21}(|\Omega_C|^2 - 4\Delta_{21}\Delta_{32}) + 4\Delta_{31}\Gamma_2^2}{(4\Delta_{31}\Delta_{21} - \Gamma_3\Gamma_2 - |\Omega_C|^2)^2 + 4(\Gamma_3\Delta_{21} + \Gamma_2\Delta_{31})^2}\right] \tag{6a}$$

$$\mathrm{Im}\,\chi_D^{(1)}(-\omega_P, \omega_P) = \frac{|\mu_{13}|^2 n_A}{\varepsilon_0 \hbar}\left[\frac{8\Delta_{21}^2\Gamma_3 + 2\Gamma_2(|\Omega_C|^2 + \Gamma_3\Gamma_2)}{(4\Delta_{31}\Delta_{21} - \Gamma_3\Gamma_2 - |\Omega_C|^2)^2 + 4(\Gamma_3\Delta_{21} + \Gamma_2\Delta_{31})^2}\right] \tag{6b}$$

To deduce the linear susceptibility, monochromatic fields and negligible collisional or Doppler broadening were assumed. The real and imaginary parts of the linear susceptibility, along with the nonlinear susceptibility, are plotted in Fig. 5 (see figure caption for explanation of the labeling) as a function of the detuning Δ_{13}, at $\Delta_{23} = 0$, that is, for resonant excitation by the coupling field Ω_C. A striking result, the absorption for the probe field vanishes at exact resonance, if the coupling field Ω_C is switched on and state $|2\rangle$ is perfectly metastable (i.e., $\Gamma_2 = 0$). Simultaneously the dispersion is significantly modified. The dispersion is still zero at line center, that is, the same value as in the case of the coupling field Ω_C switched off. However, the group velocity (dependent upon the slope of [Re $\chi^{(1)}$]) becomes anomalously low[5,82] when absorption has vanished. This offers the possibility of

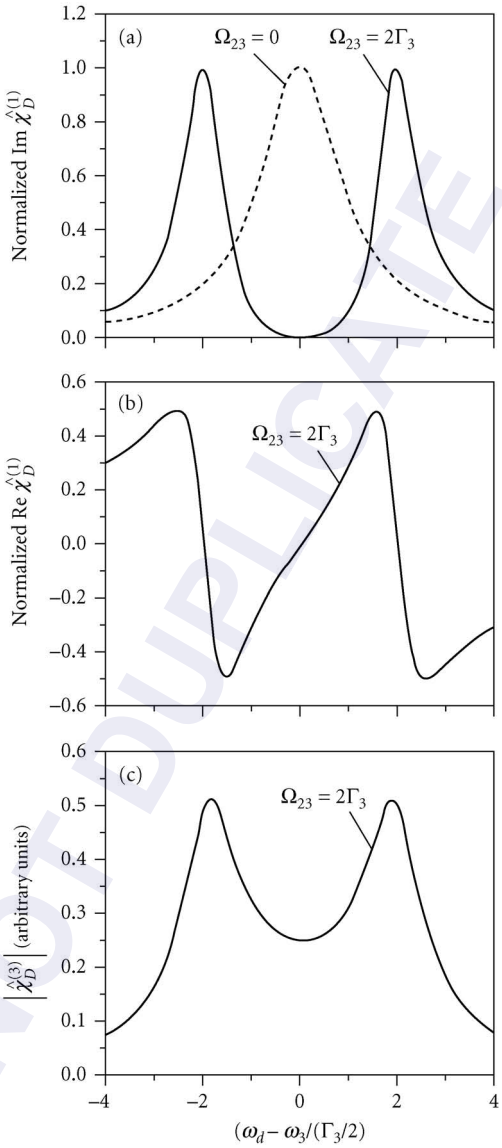

FIGURE 5 The dressed susceptibilities in terms of the normalized detuning $(\omega_d - \omega_3)/(\Gamma_3/2)$ [in our notation this corresponds to the detuning of the probe laser, scaled to the decay rate, i.e., $\Delta_{13}/(\Gamma_3/2)$] for a value of the coupling Rabi field $\Omega_{23} = 2\,\Gamma_3$ [in our notation $\Omega_C = 2\,\Gamma_3$]. (*a*) [Im $\chi^{(1)}$], i.e. absorption; (*b*) [Re $\chi^{(1)}$], i.e., dispersion; and (*c*) $|\chi^{(3)}|$, i.e., nonlinear response. [*Reprinted figure with permission from Ref 6. Copyright (1990) by the American Physical Society.*]

slowing down the speed of light by EIT, that is, a most prominent example for the striking features of EIT, which is discussed elsewhere in this book. Inclusion of finite laser linewidths, collisional and Doppler broadening in these deductions is straightforward.[6] Including these effect, the dressed susceptibilities still retain the key features, provided some limits for the experimental parameters are kept in view.

The medium that would in the absence of the coupling field be optically thick is now rendered transparent. The reduction in absorption is not merely that caused by the effective detuning induced by the Autler-Townes splitting of the dressed state absorption peaks (see Fig. 3), that is, the absorption that would be measured if the probe field were interrogating the absorption coefficient of the medium in the wing of the absorption lines of the dressed states. Additionally, there is destructive interference at the transition frequency ω_{13} that leads to *complete* cancellation of all absorption, provided there are no additional dephasing processes in the system. Even if the transition dipole moment μ_{12} is not zero (i.e., if the spontaneous decay rate is $\Gamma_2 \neq 0$), the absorption due to EIT will be reduced compared to the weak field absorption by a factor of Γ_2/Γ_3.[6]

In the preceding considerations it was implicitly assumed that the probability amplitudes of state $|3\rangle$ remain close to zero (i.e., the probe field is very weak). If there is an incoherent population pump process into the upper states $|2\rangle$ or $|3\rangle$, such that these populations no longer remain negligible, then gain on the transition between the states $|3\rangle$ and $|1\rangle$ can result (see Sec. 14.8). The remarkable feature of this gain is that under the circumstances in which EIT occurs, that is, when absorption is cancelled, the gain can be present without the requirement of population inversion in the bare atomic states. This is an example of amplification without inversion. The process has successfully been implemented in a vee-type scheme in Rubidium atoms[15] and a lambda scheme in sodium atoms.[83] Much theoretical work[12–14, 84–86] has been reported on LWI. In early work, LWI was predicted by Arkhipkin and Heller,[85] and then further elucidated by Harris,[86] Kocharovskaya and Khanin,[12] and Scully et al.[84] A long-term objective in this work is the prospect of overcoming the familiar difficulties of constructing short wavelength lasers, that is, the requirement of very high energy pump fields in order to compensate for the small transition moment at far-infrared wavelengths.

In addition to gain without population inversion, any incoherent pumping of population into the upper states also modifies the dispersion in the medium. In particular, it is then possible to obtain a very large refractive index for specific wavelength regimes. The refractive index can reach values comparable to those normally encountered very close to an absorption line, while here the absorption now vanishes.[8] The prospects for engineering the refractive properties of media to give novel combinations of absorption, gain, and dispersion have been explored in a number of theoretical[87–93] and experimental studies (see Sec. 14.9).

The successful implementation of EIT depends upon a number of critical parameters, both inherent to the quantum system and the experimental setup, for example, the driving laser pulses. A correct choice of the atomic energy level configuration is essential. The configuration must satisfy the conditions, already discussed above, that is, dipole allowed transitions $|1\rangle \rightarrow |3\rangle$ and $|2\rangle \rightarrow |3\rangle$, while the transition $|1\rangle \rightarrow |2\rangle$ is dipole forbidden. Radiative couplings to other energy levels outside of these states, that lead to an open three-level system, and additional level substructure must also be considered. Collisions with other species in the medium or photoionization must be minimized in order to prohibit perturbing decay or dephasing of the coherence ρ_{12}, which is essential to EIT. The couplings may be either driven by cw or pulsed lasers. In both cases the couplings must be sufficiently strong to overcome the inhomogeneous broadening. Morover, sufficiently monochromatic or radiation with transform-limited bandwidth in the pulsed case is required, in order not to dephase the coherence ρ_{12}. These critical parameters are summarized in Table 1. In the following section we discuss in more detail the most crucial parameters for a successful implementation of EIT.

Intrinsic Dephasing of Atomic Coherence in Gas Phase Media

For processes of laser-induced atomic coherence in a realistic medium the maintenance of the phase of the coherence during the interaction is essential for effective quantum interference. Any dephasing of the coherence will wash out and eventually nullify the interference effects. Dephasing can

TABLE 1 Summary of Critical Experimental Parameters for a Successful Implementation of EIT

Physical Parameter	Constraint	Typical Values
Radiative decay rate Γ_3 of state $\|3\rangle$	–	1–100 MHz
Radiative decay rate Γ_2 of state $\|2\rangle$	$\Gamma_2 \ll \Gamma_3$	<1 MHz
Photoionization rate Γ_{ion}	$\Gamma_{\text{ion}} \gg \Gamma_3$	Depends upon the laser intensity
Coherence dephasing γ_{ij}	$\gamma_{12} < \gamma_{13}, \gamma_{23}$	0–1 MHz (gases), 0–100 GHz (solids)
Laser linewidth γ_{laser}	Transform-limited	<1 MHz (cw) or $1/\tau_{\text{pulse}}$ (pulsed)
Doppler linewidth γ_{Doppler}	$\gamma_{\text{Doppler}} < \Omega_C$	1 GHz
Rabi frequency Ω_C	$\Omega_C > \gamma_{12}$	$\Omega_C = \mu_{23} E_C/\nabla$
Laser pulse energy E_C [see Eq. (8)]	$E_C > f_{13}/f_{23}\ \hbar\omega N_A$	

arise from a variety of different sources, for example, the excitation of a multitude of closely spaced hyperfine or Zeeman components (see, e.g., Refs. 10,15,94), radiative decay of state $|2\rangle$, photoionization channels,[95] and collisions.[6,96] Following these arguments, it is obvious, that in a ladder scheme perfect EIT is usually not possible, because state $|2\rangle$ is not metastable, but undergoes spontaneous emission to state $|3\rangle$—as well as to other states outside the three-state system. Collisional broadening with atoms of the same and other species is also critical and places strict limits on sample purity, otherwise leading to foreign gas broadening. Possibly also limits are imposed on the sample density. Moreover, at large atomic density the local field effects due to dipole-dipole couplings between the atoms may be important.[96,97] In this case the simple relationship between macroscopic polarization and the coherences in Eq. (5) may break down.

Dephasing due to Phase Fluctuations in the Laser Fields

If cw lasers with narrow bandwidth $\Delta\nu < 1$ MHz (i.e., negligible phase fluctuations) are used, the quality of an implementation of EIT usually approaches the expectations, based on steady-state conditions and strictly monochromatic excitation. Due to phase-diffusion processes[92–102] laser line broadening gives rise to linewidths above the limit of the allowed radiative decay rate. This will destroy EIT. EIT may also be implemented with pulsed laser, provided the laser pulses exhibits transform limited bandwidth. Though these transform-limited bandwidth is inevitably larger than those of cw lasers, EIT is not reduced at all. A single-mode transform-limited laser pulse (i.e., without excess phase fluctuation) will introduce insufficient dephasing during the interaction time (i.e., the pulse duration τ_{pulse}) to disturb the phases of the atomic coherences. It should also be appreciated that hyperfine sublevels will in general cause dephasing of coherences on a timescale, which is given by the inverse of their frequency separation $\Delta\omega_{\text{HFS}}$.[10] In a pulsed excitation the dephasing due to hyperfine splitting within the laser bandwidth will therefore be negligible, provided $\tau_{\text{pulse}} < 1/\Delta\omega_{\text{HFS}}$ (i.e., if the hyperfine splittings are sufficiently small).

Dephasing Processes in Solids

A few experiments on EIT have also been performed in solid-state media.[103–115] In contrast to implementations of EIT in gaseous media, coherent interactions in solids suffer from additional dephasings. These dephasings are induced by quantum processes in the crystal lattice (e.g., by photon-phonon interactions). The dephasings lead to significant additional homogeneous broadening in spectral lines of optical transitions. At room temperature the broadening may reach the regime of many gigahertz. In the gas phase, homogeneous broadening (e.g., as observed in the natural linewidth of a transitions) is usually much smaller than inhomogeneous broadening [e.g., induced by Doppler shifts (see below)]. In contrast, in solids it is usually the homogeneous broadening which dominates. This homogeneous broadening (i.e., the dephasing) will wash out any quantum interferences. In principle, there are two ways to deal with the fast dephasing processes in solids: (1) to "freeze" phonon processes, that is, to cool

the medium to cryogenic temperatures such that phonon interactions may be neglected; (2) to drive the medium with ultrafast laser pulses, that is, pulse durations below the timescale of the dephasing processes. However, ultrashort laser pulses usually do not provide sufficient pulse energy to saturate the transitions in EIT. Thus, in most experiments on EIT in solids, cryogenic cooling of the medium is a necessary requirement.

Inhomogeneous Broadening

In many experiments (inhomogeneous) Doppler broadening presents a serious limit since it introduces a randomization in the effective laser detunings over the ensemble of atoms in the sample.[6,116,117] Various methods have been employed to eliminate this effect, for example, Doppler-free excitation[118,119] or using cooled atoms in a magneto-optical trap.[120,121] Alternatively, at coupling Rabi frequencies larger than the Doppler width the influence of inhomogeneous broadening can be overcome.[6] In spectroscopic terms, the laser-induced power broadening beats the Doppler broadening in this case. This concept requires Rabi frequencies exceeding the Doppler width, that is, typically in the regime of 1 GHz. Such Rabi frequencies can be provided by a cw laser, with a typical power of 1 W or less, only under conditions of tight focusing. This may lead to undesirable effects such as defocusing due to the interplay between the dressed refractive index and the transverse intensity variation across the beam waist in the region of the focus.[119] For pulsed lasers, with intrinsically high peak power, it is usually not necessary to focus the laser to reach the required intensity. Thus defocusing effects are negligible and the interaction volume (i.e., the atom number) will be much larger than under conditions of focusing. Moreover, for short- or ultrashort laser pulses the laser bandwidth already exceeds the Doppler width. However, short- or ultrashort laser pulses are usually no good choice to drive EIT (see below).

Inhomogeneous broadening also plays a major role for applications of EIT in solid-state systems. Such inhomogeneous broadenings are induced, for example, when doped atoms in a crystal experience different electric fields in the background of the host crystal. This leads to an inhomogeneous distribution of transition frequencies. In general, the implementation of EIT in inhomogeneously broadened solids requires large laser intensities. This increases the risk of optical damage to the sample. An exception to this is the work on solids under conditions of cryogenic cooling. In such media, exceptionally small inhomogeneous widths are encountered.[122] Moreover, inhomogeneous broadening in doped solids can be overcome by appropriate optical preparation (e.g., spectral hole burning). In this case, a specific ensemble of atoms in the inhomogeneously broadened medium is prepared to exhibit spectrally narrow transitions.

Coupling Laser Power

In addition to the conditions, described above, there are some more constraints for the coupling laser Rabi frequency: (1) The coupling laser Rabi frequency must be sufficiently large to induce a transparency with a spectral width exceeding the linewidth of the Raman (two-photon) transition. For Raman transitions involving large detunings from the single-photon resonances, this may require large laser powers. (2) Harris and Luo[79] derived a condition for the laser pulse energy, which demands a sufficient number of photons in the laser pulse to match the number of atoms, weighted by the transition oscillator strength, in the laser path [see Eq. (8)]. Essentially, the number of photons in the coupling laser pulse must exceed the number of atoms in the medium. (3) In the adiabatic limit, the pulse durations must exceed the time evolution of the transparency, which is in the order of $1/\Omega_C$. Thus, the product $\Omega \cdot \tau_{pulse}$ must be large, that is, $\Omega \cdot \tau_{pulse} >> 1$. In terms of incoherent excitation, the laser must "saturate" the transition. This adiabaticity criterion can be derived in a very similar form also for other adiabatic processes.[44] As $\Omega \cdot \tau_{pulse}$ is a combination of the electric field and the pulse duration, laser pulses with large intensity and/or large interaction time are a good choice to fulfill the adiabaticity criterion. An analysis of typical laser systems with specific pulse duration reveals that laser pulses with medium pulse duration [i.e., in the regime of short nanosecond (ns)

or long picosecond (ps) pulses] yield the largest product $\Omega \cdot \tau_{pulse}$, if one-photon transitions are driven. Shorter laser pulses usually cannot compensate for the reduced pulse duration by a sufficient increase in the electric field. On the other hand, long pulses or cw radiation permits for long interaction time, but the electric field is weak. Thus, laser pulses with intermediate pulse duration and pulse energies in the regime of mJ are the best choice. However, if multiphoton excitations or specific atomic systems with large transition moments are considered, also ultrashort laser pulses may drive adiabatic interactions.

14.6 ELECTROMAGNETICALLY INDUCED TRANSPARENCY, DRIVEN BY PULSED LASERS

In the earliest work on EIT, driven by pulsed lasers, the *linear* optical response of an extended ensemble of atoms in the gas phase was investigated. In these experiments the transmission of a weak probe laser pulse, propagating through an otherwise optically dense medium, was measured. The medium was rendered transparent in the presence of a strong coupling laser pulse. In pulsed laser experiments there is usually no difficulty to induce Rabi frequencies, which exceed the inhomogeneous bandwidth of the medium (i.e., to drive the complete medium in EIT). It is essential, however, that the laser pulse exhibits transform-limited bandwidth. Thus, for example, single-mode transform-limited nanosecond lasers are an appropriate choice (see Sec. 14.5). Such laser pulses are, for example, provided by injection seeding an amplifier or optical parametric oscillator (OPO) with narrow-bandwidth cw radiation of appropriate frequency.

The first demonstration of EIT, driven with pulsed lasers, was performed by Harris et al. in strontium vapor[123] and lead vapor.[124] In both experiments laser pulses with transform-limited radiation were used. In the experiment on strontium (see Fig. 6) the atoms are initially optically pumped into the excited state 5s 5p $^1P_1$. The transition between state $|1\rangle$ = 5s 5p $^1P_1$ and the autoionizing state $|3\rangle$ = 4d 5d $^1D_2$ at a wavelength of λ_p = 337.1 nm is rendered transparent. A coupling laser, derived from a single-mode Littman dye laser, at wavelength λ_C = 570.3 nm drove the transition between the metastable state $|2\rangle$ = 4d 5p $^1D_2$ and $|3\rangle$ = 4d 5d $^1D_2$. As in the prototypical scheme, the probe field excited the system to a state $|3\rangle$ with a large decay rate. In the absence of the coupling laser the probe laser experienced strong absorption. Thus the strontium vapor was completely opaque at resonance, with an inferred transmission of exp(–20 ± 1). When the coupling laser was applied, the transmission at line center increased dramatically to exp(–1 ± 0.1). It was pointed out by the authors that for this large transparency the interference effect is essential. The detuning from the (dressed) absorption lines, separated by the Autler-Townes splitting alone would only account for an increase in transmission to a value of exp(–7.0).

The experiment in lead vapor[124] demonstrated EIT within the bound states of a medium, experiencing significant collisional broadening. Here EIT was implemented in a ladder configuration with the probe laser, driving the transition between the ground state $|1\rangle = 6s^2\,6p^2\,{}^3P_0$ and the excited state $|3\rangle = 6s^2\,6p\,7s\,{}^3P_1^0$. The coupling laser drove the transition between states $|2\rangle = 6s^2\,6p\,7p\,{}^3D_1$ and $|3\rangle = 6s^2\,6p\,7s\,{}^3P_1^0$. The reduction in opacity, driven by the transform-limited coupling laser, reached a factor of exp(–l0). The particular coupling scheme in lead was chosen because of approximate coincidence between the frequency of an injection seeded Nd:YAG laser at λ_C = 1064 nm and the transition frequency ω_{23}. The detuning was Δ_{23} = 6 cm^{-1}. An important feature of this experiment was the role of resonance broadening, which was the dominant broadening channel for state $|3\rangle$, that is, about 40 times larger than the natural linewidth. Due to the destructive interference between the contributions to state $|3\rangle$ in the two dressed states (see Sec. 14.4), these collisions have no effect on transparency. In contrast, the collisions, which dephase state $|2\rangle$, also affect the degree of EIT. As these are no resonance collisions, their strength is small.

Both experiments served to demonstrate the principle of EIT in a three-level system. They show, that EIT also works in systems including autoionization or collisional broadening. In both cases the coupling laser exhibited near transform-limited bandwidth. No special requirements were imposed on the probe laser, although the probe laser bandwidth must be less than the spectral width of the EIT.

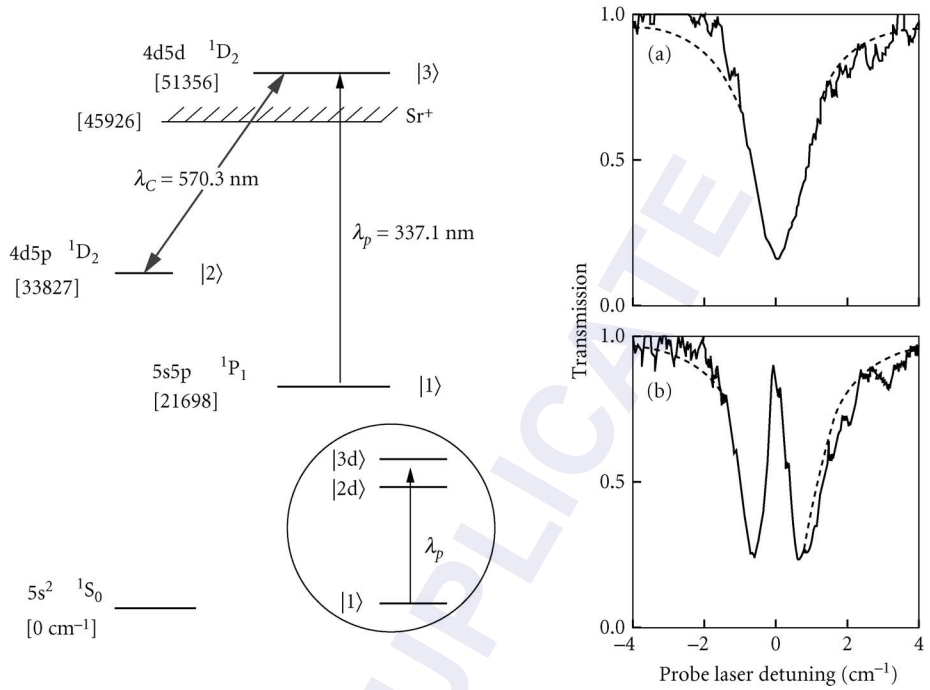

FIGURE 6 Coupling scheme for EIT in strontium atoms and transmission of a probe laser pulse versus the probe laser detuning. Inset in the coupling scheme: dressed states [in our notation state $|-\rangle$ corresponds to $|2d\rangle$ and state $|+\rangle$ corresponds to $|3d\rangle$; compare Fig. 3]. (*a*) When the coupling laser is switched off, the probe laser experiences absorption in the line center. (*b*) When the coupling laser is switched on, the probe laser absorption is dramatically reduced in the line center. [*Reprinted figure with permission from Ref. 123. Copyright (1991) by the American Physical Society.*]

Experiments using pulsed lasers continue to be important, most especially in the context of nonlinear optics and matched pulse propagation. A related resonant EIT scheme in lead has been explored by Kasapi as a technique for enhanced isotope discrimination.[125] This method utilized the resonant opacity of a low abundance lead isotope ^{207}Pb at EIT for the most common lead isotope ^{208}Pb in their sample. Additional work has also recently illustrated how EIT can be established in the lead isotope ^{207}Pb despite the presence of hyperfine structure. This was done by adjusting the laser frequencies to coincide with the center of gravity of the hyperfine split transitions.[126,127] Under this condition, interference of the manifold of hyperfine states yields EIT.

14.7 STEADY STATE ELECTROMAGNETICALLY INDUCED TRANSPARENCY, DRIVEN BY CW LASERS

Continuous wave (cw) lasers permit the implementation of EIT under steady-state conditions. Such experiments provide an excellent case to test the theoretical concept of EIT against experimental data from excitations under near-ideal conditions. Investigations of new effects in the cw regime permit straightforward comparison with theoretical predictions. A monochromatic laser is required, with a linewidth significantly less than the radiative decay rate Γ_3 (i.e., in the range of 10 kHz to 10 MHz). Such radiation is typically provided by either dye or titanium sapphire ring lasers or more cheaply,

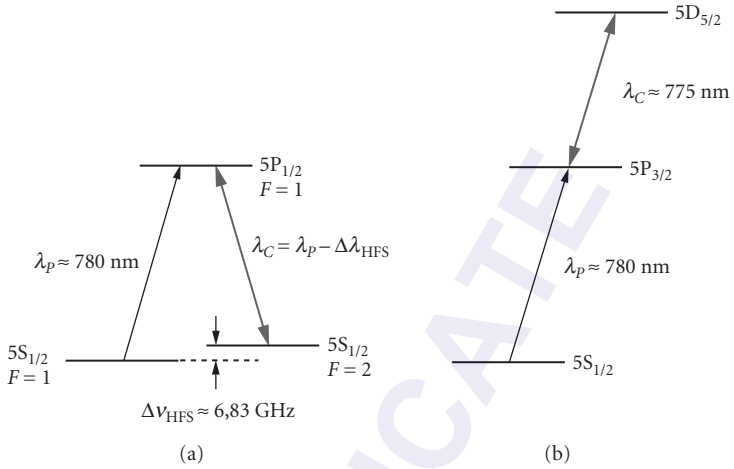

FIGURE 7 Coupling schemes for EIT in rubidium atoms. (*a*) A lambda scheme involving the hyperfine sublevels of the ground state [which correspond to states $|1\rangle$ and $|2\rangle$ in our notation] of ^{87}Rb (or ^{85}Rb) and the excited states $5P_{1/2}$ or $5P_{3/2}$ [which correspond to state $|3\rangle$ in our notation] and (*b*) a ladder-type scheme involving the ground state $5S_{1/2}$ [i.e., state $|1\rangle$ in our notation], and the excited states $5P_{3/2}$ [i.e., state $|3\rangle$ in our notation] and $5\,D_{5/2}$ [i.e., state $|2\rangle$ in our notation].

but also with limited tunability and power, by external cavity stabilized laser diodes. However, in contrast to pulsed laser experiments, in cw EIT experiments it is more difficult to reach sufficient coupling strengths Ω_C in order to exceed the inhomogeneous broadening. This has required the employment of both Doppler-free techniques and the reduction of the Doppler width by atom cooling methods.

Much work has been carried out in rubidium vapor. This is due to suitability of the rubidium atom's energy level configuration for EIT (see Fig. 7), the possibility of near-complete elimination of Doppler shifts in certain configurations, and the ease of handling the vapor. Xiao et al. as well as Moseley et al. performed important demonstrations of steady state EIT in rubidium atoms. A near-ideal lambda scheme is formed in rubidium (see Fig. 7*a*) between the ground states $5S_{1/2}$ (F = 1) and (F = 2) and the excited state $5P_{1/2}$ (F = 1) state. The transitions in this case are around 780 nm, separated by the ground state hyperfine splitting of $\Delta\nu_{HFS} \approx 6.83$ GHz. In a detailed theoretical treatment of this system it is necessary to include all hyperfine sublevels of the three states. However, in essence the behavior is that of a simple three-level system. Likewise, also a ladder scheme is formed in this atom between the states $5S_{1/2}$, $5P_{3/2}$, and $5D_{5/2}$ (see Fig. 7*b*), with the transition wavelengths at $\lambda_p = 780$ nm and $\lambda_C = 775$ nm. Excitation of the transition at these wavelengths is easily possible using either cw titanium sapphire ring lasers or grating stabilized laser diodes. These schemes in rubidium also exhibit the additional advantage of Doppler-free excitation with the two closely spaced wavelengths. In such experimental configuration, Xiao et al. and Moseley et al. studied transparency,[116,128,129] refractive index modification,[118] and propagation effects.[119,130]

Observation of EIT in the rubidium ladder scheme showed good agreement with a steady-state calculation, involving residual effects of inhomogeneous (Doppler) broadening.[116] Due to the near-frequency coincidence between the transitions at 780 and 775 nm in this scheme, the effect of inhomogeneous broadening on the experiment was almost eliminated by using counterpropagating beams. This elimination of inhomogeneous broadening permitted the application of grating-stabilized laser diodes, operating with relatively low power ($P < 10$ mW), to provide both probe and coupling fields in these experiments.

Results of experiments on the rubidium lambda scheme also proved to be consistent with theory. EIT was observed at the probe transition line center with a linewidth and depth in reasonable

agreement with the steady-state calculation.[128] In the case of the lambda scheme, copropagating beams lead to a Doppler-free excitation. Again this was possible due to the closely spaced probe and coupling laser wavelengths. As mentioned before, also here only low laser powers were required for EIT. This elimination of Doppler broadening was exploited by the same authors to perform an experiment that stresses the quantum interference nature of the EIT effect. By employing a coupling laser strength $\Omega_C < \Gamma_3$ (i.e., the Rabi splitting is too small to give rise, on its own, to any significant absorption reduction) a well-developed transparency, with a depth limited only by the laser linewidths, was reported.[129] This experiment illustrates clearly how the additional coherence due to the coupling laser causes interference that cancels the effect of probe absorption.

The limits for a successful implementation of steady-state EIT with respect to the probe laser power has also been examined in the rubidium ladder scheme, as discussed above.[131] When the coupling laser was strong, but the probe relatively weak, EIT was induced as usual. In the case of a strong probe with a power comparable to the coupling laser ($\Omega_p \sim \Omega_C$), the EIT was destroyed and replaced by enhanced absorption (i.e., electromagnetically induced absorption). This is explained by the opening of additional pathways in the absorption process (due to higher-order interactions with the probe field) leading to constructive interference in absorption. This result has implications in certain nonlinear frequency mixing schemes where a strong field should be generated at the probe frequency. The results suggest that there may be a limitation to the strength of the generated fields (see Sec. 14.12).

Besides operation in Doppler-free excitation schemes, also laser cooling of the atoms can be used to fully eliminate Doppler broadening. This also enables steady-state EIT in systems where the laser frequencies ω_C and ω_p differ significantly. Recently work has been reported on EIT (and CPT) in lambda systems in cold rubidium and cesium atoms, confined in a magneto-optical trap (MOT).[120,121] In rubidium a coupling scheme involving Zeeman splittings has also been studied.[129] These systems are close to ideal as the trapped atoms are very cool, that is, Doppler broadening is almost absent. Moreover the system exhibits very low density and hence may be considered as collisionless. If required, larger densities of trapped atoms can be provided by using dark-spot trap techniques.[132] Work has been carried out that exploits the characteristics of cold, confined rubidium atoms to study nonlinear absorption and dispersion.[133] Also temporal evolution of EIT in the transient regime has been investigated in a MOT with rubidium atoms.[134] In cold cesium atoms in a MOT the nonlinear sum rule[135] for EIT-type situations has been experimentally verified.[136]

14.8 GAIN WITHOUT INVERSION AND LASING WITHOUT INVERSION

We consider now the case of population, transferred via an incoherent pump process into the excited states of a three-level system, driven in EIT. Thus a small population in the upper state of the probe transition results in inversionless gain of the probe field. The reader is referred to the extensive literature on this subject for further discussion (see, Ref. 16). In studying gain without inversion, precautions should be taken to confirm that the system is indeed noninverted. This is in practice rather difficult to confirm. Experimenters must verify that there is clear evidence for gain on the probe transition and truly no population inversion on this transition.

Gao et al.[137] performed an early experiment that stimulated discussion and subsequent work. A four-level system of the hyperfine ground states $3S_{1/2}$ (F = 0, 1) and the excited states $3P_{3/2}$ and $3P_{1/2}$ in sodium atoms, driven in a Raman process, was investigated. A laser pulse excited the transition between the ground states $3S_{1/2}$ (F = 0, 1) and state $3P_{1/2}$. This created a coherence between the two hyperfine ground states. A cw probe laser was tuned close to the transition between the ground states $3S_{1/2}$ (F = 0, 1) and state $3P_{3/2}$. The probe laser experienced amplification, when the probe laser frequency was appropriately tuned—and provided a small amount of population was pumped into the $3P_{3/2}$ state. The incoherent pumping process was driven by a DC gas discharge in the sodium vapor. The authors claimed, that the amplification process was inversionless. Initial criticism arose, as there was no independent monitoring of the excited state populations in this experiment.

Subsequent work on this issue, involving measurements of absorption, provided firmer evidence for inversionless conditions.[138] A similar excitation and amplification scheme in potassium vapor was reported by Kleinfeld et al.[139] The authors performed a careful numerical analysis that supports their claims for amplification without inversion. Further evidence for amplification without inversion has been found in several systems. In a lambda scheme in sodium atoms, with additional incoherent pumping into the upper state, Fry et al.[140] observed effects, based on atomic coherence, leading to amplification without inversion. The role of atomic coherence was confirmed by switching the coupling field on or off. Amplification was only observed when the field was present, and when it was absent the large population always present in the lowest state led to absorption of the probe. In another demonstration, picosecond pulses were used to excite atomic coherence among the Zeeman sublevels of the ground state in sodium atoms. Amplification without inversion was monitored and unambiguously confirmed by Nottelman et al.[141] Amplification without inversion was also demonstrated in a transient scheme in cadmium vapor through the formation of a linear superposition of coherently populated Zeeman sublevels by van de Veer et al.[142] In this experiment nanosecond laser pulses were used. The coherent nature of the process was proven (1) by the dependence of the gain on the time delay between the coherence preparation and probe pulse; and (2) by the dependence of the gain on the magnitude of the Zeeman splitting, which controlled the period for coherent transfer of population in the atom. Recently a double lambda scheme in helium atoms, driven by infrared radiation at 877.9 nm radiation in a helium-neon gas discharge, was used to observe amplification at both wavelengths 1079.8 and 611 nm (i.e., the latter in an up-conversion process). Here the evidence for amplification without inversion rests on comparison to calculation.[143]

To demonstrate LWI, the gain medium must be placed within an optical cavity. In two experiments[15,83]on this subject, amplification of a probe laser in the inversionless medium was demonstrated. Then the cavity was set up and lasing was observed even under conditions where no inversion was possible at all. The first of these experiments by Zibrov et al.[15] was implemented in a vee-type scheme, formed on the Dl and D2 lines of rubidium, with incoherent pumping from the $F = 2$ hyperfine level into the upper state of the Dl transition. The latter provided the lasing transition. Laser diodes were used to derive all driving fields. The incoherent pump was generated by injecting white noise into an acousto-optic modulator (AOM). The AOM modulated one of the diodes. This work was also the first experiment to demonstrate amplification without inversion using laser diodes. An important conceptual advantage of the vee scheme is that there is no possibility for "hidden" inversion in a dressed basis at all. Thus the vee scheme serves as a very appropriate basis to demonstrate inversionless gain. The coupling scheme in the experiment could be considered in a simplified form as a four-level system, that is, three levels coherently coupled and a fourth coupled via the incoherent field. There are, however, 32 hyperfine sublevels in the particular experiment in rubidium, which must be considered in a detailed analysis. This complete analysis was carried out by the authors to yield predictions in good agreement with their experiment. Subsequently work was reported by Padmabandu et al.[83] demonstrating LWI in the same lambda scheme in sodium atoms, as also considered by the authors of Ref. 140.

14.9 MANIPULATION OF THE INDEX OF REFRACTION IN DRESSED ATOMS

Besides the manipulation of absorption or transmission, EIT also permits control of the refractive index of a laser-driven medium. Figure 5 shows the dependence of the real part of the linear susceptibility [Re $\chi^{(1)}$], which determines the refractive index, on the probe laser detuning. The dispersion is most significantly modified between the absorption peaks, that is, for probe laser detunings in the range $\Delta_{13} = \pm\Omega_C/2$. In the absence of a coupling field the usual form of [Re $\chi^{(1)}$], for an atom leads to anomalous dispersion, that is, a negative slope in [Re $\chi^{(1)}$], in the vicinity of the resonance (i.e., for detunings $\Delta_{13} = \pm\Gamma_3$). The dispersion [Re $\chi^{(1)}$] vanishes at exact resonance. This usual behavior of [Re $\chi^{(1)}$] is not significant, since the medium is highly opaque in the frequency range close to the resonance. However, in EIT the absorption is nearly zero close to resonance. Thus the modified dispersion can have a large effect on the refractive properties of the medium.

In a medium, driven to EIT, the dispersion [Re $\chi^{(1)}$] = 0 at resonance. Thus the refractive index will attain the vacuum value (n = 1), while the medium is fully transparent. As the assumption of a (closed) three-level atomic system is only an approximation, there will always be a contributions to the total refractive index due to all other states of the atom. These other levels, however, are typically far from resonant with the driving laser fields. Thus they lead to relatively small contributions to the dispersion. In nonlinear frequency mixing the vanishing dispersion results in near-perfect phase-matching, which is essential for efficient frequency up-conversion (see Sec. 14.12). A second important modification to the dispersion in the frequency range $\Delta_{13} = \pm\Omega_C/2$ is that the medium shows *normal* dispersion, that is, a positive slope in [Re $\chi^{(1)}$]. The value of the dispersion in this frequency range will depend on the shape of the curve and hence on the coupling laser intensity, which determines Ω_C. In Sec. 14.11, we will examine the situation, when Ω_C is small. In this case the dispersion profile can be very steep, and consequently very low group velocities result. The intensity dependence of [Re $\chi^{(1)}$] leads also to the strong spatial dependence of the refractive index across the intensity profile of a focused laser beam.

Investigations of the modification of dispersion (i.e, the refractive index) as induced by EIT have been carried out for steady-state excitation with cw lasers.[118,119,130] Direct measurements of the modified refractive index confirm the theoretical predictions. The dispersive properties of rubidium atoms, driven by EIT, was investigated using a Mach-Zehnder interferometer.[118] The dispersion measured at the center frequency was inferred to be equivalent to a small group velocity of $v_g = c/13.2$. In the last years, many experiments have been implemented in order to slow down the speed of light in media, driven to EIT. In this article we will only briefly mention some of the experiments, while a detailed discussion of slow light and storage of photons is subject to another article in this book.

A number of observations on electromagnetically induced focusing and defocusing, based on spatial variations in the index of refraction, have also been performed. A wavelength-dependent-induced focusing or defocusing was reported by Moseley et al.[119,130] employing a coupling scheme in rubidium. Constraints are introduced to the tightness of focusing in strongly driven media. However, these experiments also indicate possibilities to control the spatial properties of a beam at frequency ω_P by a beam at another (i.e., perhaps very different, frequency ω_C).

In a scheme where a small amount of population is incoherently pumped into the excited state, gain was predicted[8] at exact resonance (i.e., $\Delta_{13} = 0$). Thus, the imaginary part of the linear susceptibility [Im $\chi^{(1)}$] becomes negative at resonance. When absorption vanishes at nearby frequencies, that is, [Im $\chi^{(1)}$] = 0, the value of [Re $\chi^{(1)}$] can be very large. This situation is termed *enhanced refraction*. Enhanced refraction has been observed in a lambda scheme in rubidium, provided there is an additional pumping field to result in a small (noninverted) population in the upper state of the system.[144] In this experiment an enhanced index of refraction was found at frequencies where the absorption was zero. A proposed application for refractive index modifications of this kind is high-sensitivity magnetometry.[145] The large dispersion at the point of vanishing absorption could be used to detect magnetic level shifts via optical phase measurements in a Mach-Zehnder interferometer with high accuracy.

14.10 PULSE PROPAGATION EFFECTS

Propagation of pulses is significantly modified in the presence of EIT. Figure 5*b* shows the changes to [Re $\chi^{(1)}$] in media, driven in EIT. An analysis of the refractive changes has been provided by Harris et al.[82] who expanded the susceptibilities (both real and imaginary parts) of the dressed atom in a series around the resonance frequency to determine various terms in [Re $\chi^{(1)}$]. The first term of the series (zero order) [Re $\chi^{(1)}(\omega_{13})$] = 0 corresponds to the vanishing dispersion at resonance. The next term $\partial/\partial\omega$ [Re $\chi^{(1)}$] gives the slope of the dispersion curve. At the transition frequency ω_{13} this slope yields

$$\frac{\partial}{\partial\omega}[\mathrm{Re}\,\chi^{(1)}] = \mu_{13}^2 \frac{4n_A}{\hbar\varepsilon_0} \frac{(\Omega_C^2 - \Gamma_2^2)}{(\Omega_C^2 + \Gamma_2\Gamma_3)^2} \tag{7}$$

This expression shows the dependence of the slope of [Re $\chi^{(1)}$] on Ω_C. The latter parameter permits controls of the group velocity of a laser pulse at frequency ω_{13} propagating through the medium. Higher-order terms in the expansion lead to pulse distortions (group velocity dispersion), but at resonance the lowest nonvanishing term is of third order.

The first experimental studies of pulse propagation in media, driven to EIT system, were conducted by Kasapi et al.[146] In a lambda scheme in lead vapor, Kasapi et al. measured the delay of a probe pulse for various coupling laser strengths. Whilst the transmission through the medium was still large (i.e., 55%), pulses were found to propagate with velocities as low as $v_g = c/165$. The authors showed that the delay time τ_{delay} for the pulse in the medium compared to a propagation through the vacuum was correlated to the attenuation of the transmitted pulse and the residual decay rate γ_{12} of the (dipole forbidden) transition $|1\rangle \rightarrow |2\rangle$—transition via the relation $\ln\{E_{\text{out}}/E_{\text{in}}\} = -\gamma_{12} \cdot \tau_{\text{delay}}$, with E_{out} and E_{in} as the energies of the probe pulse leaving and entering the medium. This idea was subsequently demonstrated as a method for measuring Lorentzian linewidths.[147] It was also demonstrated[146] that the presence of the coupling pulse leads to a near-diffraction-limited transmitted beam quality for a strong probe field under conditions where severe spatial distortion was present in the absence of the coupling laser. The situation where probe and coupling pulses were both strong was studied in a subsequent experiment that investigated further the elimination of optical self-focusing and filamentation, which afflict a strong probe field.[148]

The prospects of controlling the refractive index using strong off-resonant pulses was examined theoretically for a lambda scheme.[93] In this treatment it was shown that the off-resonant bound and continuum states lead to Stark shifts of states $|1\rangle$ and $|2\rangle$, which can be compensated by detuning the lasers from the exact Raman resonance between the bare states. If this is done correctly, the additional coherence ρ_{12} will lead to EIT-like modification of the refractive index experienced by both pulses. This extends to the situation for which the probe pulse is also strong. With both strong laser pulses, off-resonant CPT is possible. Formation of an off-resonance trapped state is an important aspect of an experiment investigating the elimination of optical-self focusing,[148] in which a nonlinear refractive index would otherwise lead to self-focusing, filamentation, and beam breakup of the strong probe field. Off-resonant CPT is also important in nonlinear frequency mixing, as demonstrated in experiments in lead vapor[149] and solid hydrogen.[126] In this case the condition $\Omega' > [\Delta \cdot \gamma_{12}]$ must be met, where Δ is the detuning of the fields from the intermediate resonances. This leads to the requirement of high peak powers, if the detunings Δ are large.

Propagation of two coupled strong pulses in a lambda-type system was discussed by Harris[76,77] and Eberly et al.[42,78] The discussed excitations scheme was equivalent to EIT. However, if both fields Ω_P and Ω_C are strong, the dressed atomic system reacts back on the field modes. This results in lossless propagation through the medium for both fields. For laser pulses with matched intensity envelopes (i.e., an identical form of temporal variation) any losses are minimal. If two initially matched pulses are simultaneously launched into a medium comprising atoms in the ground state, the system will self-organize so as to preserve the matched pulses and generate states, showing CPT. As the atoms are initially in the ground state $|1\rangle$, the probe pulse will initially experience loss and will have a lower group velocity than the coupling pulse. It will then start to lag the coupling pulse and so the pulse pair will automatically satisfy the condition for adiabatic preparation of trapped states (i.e., a counterintuitive pulse sequence). So, following the initial loss of probe pulse energy, the medium is set up for lossless transmission.

A proper insight into this process is best obtained in terms of CPT. The laser fields cause the formation of the superposition states $|C\rangle$ and $|NC\rangle$ [see Eq. (1)]. However, the atoms in the phase-coherent medium that is formed are also responsible for driving the two fields, and this means that even intensity envelopes which are initially different will evolve into matched pulses. This process results in the self-consistent formation of stable normal modes of the driving fields, one of which is uncoupled from the "uncoupled" atomic state and the other of which is "uncoupled" from the coupled atomic state. These new field modes result in the lossless propagation of pulses through a normally lossy medium, once a certain preparation energy has been extracted from the laser fields.

In the adiabatic limit the pulses are sufficiently intense, such that the timescale to establish EIT (i.e., $1/\Omega_C$) in the whole medium is fast with respect to the envelope evolution. Indeed, EIT can be much faster than the timescale required to establish population-trapped states in an individual

atom. This is due to the fact, that the latter process requires transfer of population, that is, irreversible exchange of energy between the field and the medium. In fact, the preparation time for EIT corresponds to a certain necessary pulse energy. The minimum energy $E_C^{(\min)}$ required to prepare the medium in EIT is essentially given by the photon energy of the coupling laser multiplied by the oscillator strength-weighted number of atoms:[79]

$$E_C^{(\min)} = \frac{f_{13}}{f_{23}} \hbar\omega N_A \tag{8}$$

with the number of atoms N_A in the interaction volume and the oscillator strengths of the transitions at ω_{13} and ω_{23}. If the oscillator strength (or dipole moments) of the two transitions are comparable, Eq. (8) simply demands photon numbers, which exceed the number of atoms. Once the coupling laser pulse fulfills this condition (e.g., is long enough to provide a sufficient number of photons), the medium will be rendered transparent for all subsequent times. Application of this effect to the propagation of strong picosecond (ps) and femtosecond (fs) pulses a straightforward consideration. The preparation energy is not transferred irreversibly to the medium but is stored reversibly in the coherent excitation of state $|2\rangle$.

14.11 ULTRASLOW LIGHT PULSES

As already briefly discussed above (see Sec. 14.9), the steep, positive slope of the dispersion [Re $\chi^{(1)}(\omega)$] leads to a reduced group velocity v_g. The group velocity depends upon the slope, that is, the derivative of $\chi^{(1)}(\omega)$, as follows:

$$\frac{1}{v_g} = \frac{1}{c} + \frac{\pi}{\lambda}\left(\frac{\partial}{\partial\omega}[\mathrm{Re}\,\chi^{(1)}]\right) \tag{9}$$

From the expression for the derivative $\partial\chi^{(1)}/\partial\omega$ [Eq. (7)], we see that this slope is steepest (i.e., v_g reaches a minimum) for $\Omega_C >> \Gamma_2$ and $\Omega_C^2 >> \Gamma_2\Gamma_3$, but when Ω_C is still small compared to Γ_3. Hence $\partial\chi^{(1)}/\partial\omega \sim 1/\Omega_C^2$. In the limit of small coupling Rabi frequency Ω_C the group velocity v_g therefore yields

$$v_g = \frac{\hbar c \varepsilon_0 \Omega_C^2}{2 n_A \omega_P \mu_{13}^2} \tag{10}$$

In an inhomogeneously broadened system the requirement for EIT is $\Omega_C > \gamma_{\mathrm{Doppler}}$ (see Sec. 14.5). For typical atomic systems this usually also means $\Omega_C > \Gamma_3$. This condition constrains the group velocity reduction to relatively modest values. Thus in experiments in lead vapor[146] (see also Sec. 14.13), a group velocity reduction was clearly demonstrated, but the absolute reduction was only $v_g = c/165$. Further reductions in v_g are possible in media with small Doppler broadening $\gamma_{\mathrm{Doppler}}$. In these media lower values for Ω_C (i.e., $\Omega_C << \Gamma_3$) still permit implementation of EIT. An elimination of Doppler broadening of spectral transitions is, for example, possible in a coupling scheme with transition frequencies $\omega_{13} \approx \omega_{23}$ and employing a Doppler-free geometry for the laser beams, that is, copropagating beams in a vee or lambda scheme and counterpropagating beam in a ladder scheme. Alternatively, laser-cooled and -trapped atomic samples can be used to reduce the Doppler width such that $\gamma_{\mathrm{Doppler}} << \Gamma_3$. Cooled atoms also permit an excitation at frequencies $\omega_{13} \neq \omega_{23}$ and no restrictions are set on the beam geometry.

The spectral bandwidth of a light pulse determines a limitation for the possible reduction in the group velocity in a medium, or vice versa. The limit is set by the spectral linewidth of the EIT and by increased group velocity dispersion at frequencies detuned from exact resonance $\omega_P = \omega_{13}$. These effects

limit the permitted bandwidth of a light pulse with reduced group velocity to values significantly less than Ω_C. Thus only light pulses with sufficiently long duration (i.e., small spectral bandwidth without significant contribution from frequency components outside the bandwidth of EIT) are subject to an efficient reduction of the group velocity.

A number of experimental observations of ultraslow group velocity have been reported. In a Doppler-free excitation scheme, closely related to CPT, in cesium vapor the dispersion profile near resonance was determined using a Mach-Zehnder interferometer.[150] From the measured steep dispersion, a group velocity of $v_g = c/3000$ was inferred. A Doppler-free experiment in rubidium vapor was carried out, which directly measured a very large group velocity reduction. A probe beam with fast modulated amplitude was passed through the sample. The phase lag of the modulation with reference to the input signal was used to measure the group velocity. Very low values of $v_g = 90$ ms^{-1} were determined, even though the temperature of the sample was as high as 360 K.[151] A lambda-type coupling scheme with Zeeman sublevels in rubidium was recently investigated and a magnetic field dependent group velocity as low as $v_g = 8$ ms^{-1} was measured.[152]

A very dramatic demonstration of ultraslow light propagation was provided by Hau et al.[11] They employed a laser-cooled sodium sample trapped in a novel magnetic trap. Evaporative cooling of this sample was used to prepare a Bose-Einstein condensed (BEC) state. Experiments were performed (see Fig. 8) to investigate the delay in propagation of a probe pulse with pulse duration $\tau_p = 2.5$ μs, when a coupling laser was applied to the sample in the perpendicular direction. The reduced group velocity was studied both above and below the BEC transition temperature T_C. The lower group velocities found below T_C were due to the increased density of the sample when in this state. The lowest value of v_g that was measured was $v_g = 17$ ms^{-1}. Other experiments on EIT also permitted the reduction of the speed of light in solids. We will discuss these experiments below (see Sec. 14.15).

In this section we gave only a very short introduction to the field of ultraslow light in coherently prepared media. The subject of ultraslow light as well as the related topic of storing light in media, prepared by EIT, attracted a huge attention in the last years. For a detailed review on ultraslow light and storage of light pulses, we like to draw the attention of the reader to a related article on this subject elsewhere in this book.

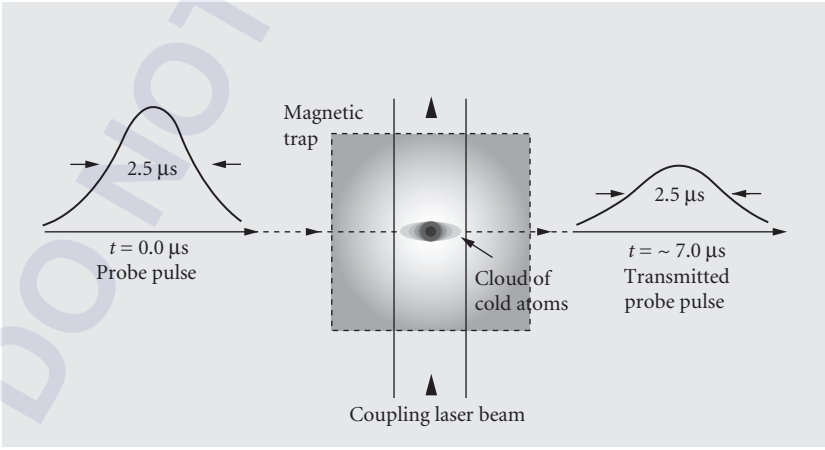

FIGURE 8 Schematic experimental setup for the observation of ultraslow light in a cloud of cold atoms, as reported by Hau et al.[11] A circularly polarized probe pulse passes through a cloud of cold atoms (length $L = 0.2$ mm) with a transit time of $T = 7$ μs. This corresponds to a group velocity of 1/10 millionth of the speed of light in vacuum. [*Reprinted by permission from Ref. 153. Copyright (1999).*]

14.12 NONLINEAR OPTICAL FREQUENCY CONVERSION

In the previous sections, we discussed the manipulation of linear optical propertie (i.e., absorption and dispersion) by EIT. In addition to these effects, also the nonlinear optical response of a medium is significantly modified by EIT. This has been shown to lead to frequency mixing with greatly enhanced efficiencies and to large Kerr-type nonlinearities. In addition to the dressed linear susceptibility [see Eq. (6)], there is also a dressed nonlinear susceptibility. This nonlinear susceptibility describes the coupling of the atom to fields at frequencies other than the frequencies of the probe laser and the coupling laser, that is, to frequencies which are generated by nonlinear interaction between the driving radiation fields. Consider, for example, a four-wave mixing process. Three fields at frequencies ω_A, ω_B, and ω_C couple via the nonlinear response of the medium to generate a new field at frequency ω_P with $\omega_P = \omega_A \pm \omega_B \pm \omega_C$. In general, the nonlinear susceptibility reaches maxima close to atomic resonances. Thus laser fields with frequencies tuned close to atomic resonances will yield enhanced frequency conversion. Figure 9 shows some basic coupling schemes for resonantly enhanced frequency conversion. Figure 9*a* depicts a situation, which we are already familiar with: Two radiation fields at frequencies ω_A and ω_B are tuned close to single-photon resonances at transitions $|1\rangle \rightarrow |4\rangle$ and $|2\rangle \rightarrow |4\rangle$ in a lambda-type level scheme. A third radiation field at frequency ω_C (i.e., tuned to resonance at the transition $|2\rangle \rightarrow |3\rangle$) mixes with the radiation fields at ω_A and ω_B to produce a wave at $\omega_P = \omega_A - \omega_B + \omega_C$. It is obvious from the coupling scheme, that the radiation fields ω_A and ω_B as well as the fields ω_C and ω_P will be automatically tuned close to two-photon resonance between the two lower states $|1\rangle$ and $|2\rangle$. The same holds true for the slightly modified coupling scheme in Fig. 9*b*. Here the lasers at ω_A and ω_B are far detuned from any single-photon resonance. Still, the two-photon resonance between the lower states $|1\rangle$ and $|2\rangle$ is maintained. If the laser frequencies ω_A and ω_B are degenerate (i.e., $\omega_A = \omega_B$) and the lambda system is modified to a ladder-type system, as depicted in Fig. 9*c*, the probe field is generated at frequency $\omega_P = 2\omega_A + \omega_C$. The latter is a typical scheme for frequency conversion to the regime of short-wavelength radiation [e.g., to the regime of vacuum-ultraviolet (VUV) or extreme-ultraviolet (XUV) radiation].

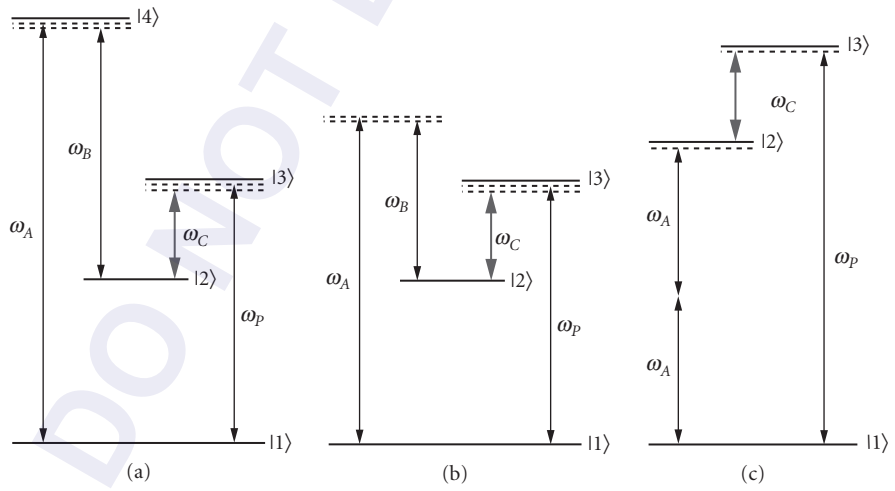

FIGURE 9 Three basic coupling schemes for four-wave mixing in coherently driven media. (*a*) Double-lambda system, driven on single-photon transitions by four radiation fields ω_A, ω_B, and ω_C generating a probe radiation field at frequency $\omega_P = \omega_A - \omega_B + \omega_C$. (*b*) Modified lambda system with the fields at ω_A and ω_B still tuned close to two-photon, but far detuned from any single-photon resonance. (*c*) Ladder system with degenerated fields at $\omega_A = \omega_B$, driving a four-wave mixing process to generate the probe field at $\omega_P = 2\omega_A + \omega_C$.

In conventional "incoherent" frequency mixing, the laser-driven resonances will enhance the efficiency of the frequency conversion process. There is also a significant drawback of this resonant excitation scheme: As also the generated wave at ω_p is resonant with the transition $|1\rangle \rightarrow |3\rangle$, it will be reabsorbed in the medium. However, if coherent interaction by EIT is considered, reabsorption is suppressed. To understand this feature of four-wave mixing, supported by EIT, let us consider the excitation processes in Fig. 9*a* in a slightly different way. The excitation scheme is equivalent to two coupled lambda systems. One lambda system is defined by the states $|1\rangle$, $|2\rangle$, and $|4\rangle$. The other lambda system is defined by the states $|1\rangle$, $|2\rangle$, and $|3\rangle$. If the laser at frequency ω_C is strong, it will drive EIT in the second lambda system of states $|1\rangle$, $|2\rangle$, and $|3\rangle$. In our previous notation, the generated wave at ω_p corresponds to the probe laser, and the laser at ω_C corresponds to the coupling laser. As the medium is prepared in EIT now for the probe laser, the generated field at frequency ω_p will experience no reabsorption any more, that is, the dressed linear susceptibility at the transition $|1\rangle \rightarrow |3\rangle$ is zero. In contrast, the dressed nonlinear susceptibility is not reduced to zero (see below and Fig. 5*c*). Thus the susceptibility provides a nonlinear coupling between the radiation fields, while absorption is suppressed.

The nonlinear susceptibility is calculated from Eqs. (4) and (5) in the same way as the linear susceptibilities in Eq. (6), however, now terms in ρ_{13} involving the fields at frequencies ω_A and ω_B are also included. The nonlinear susceptibility for the four-wave mixing process reads[5]

$$\chi_D^{(3)}(-\omega_P, \omega_A, \omega_B, \omega_C) = \frac{2\mu_{23}\mu_{31}n_A}{3\varepsilon_0\hbar^3} \frac{1}{\Omega_C^2 + (\Gamma_3 + 2i\Delta_{13})(\Gamma_2 + 2i[\Delta_{13} - \Delta_{23}])} \times \sum_j \mu_{1j}\mu_{j2}\left(\frac{1}{\omega_{j1} - \omega_A} + \frac{1}{\omega_{j1} - \omega_B}\right) \tag{11}$$

where the sum on the right-hand side of Eq. (11) represents the contributions to the nonlinear susceptibility by all the states $|j\rangle$ of the atom, the fields at frequencies ω_A and ω_B are close to the two-photon resonance between the states $|1\rangle$ and $|2\rangle$. The modulus of this nonlinear susceptibility is plotted in Fig. 5*c*, although superficially similar to [Im $\chi_D^{(1)}$] (see Fig. 5*a*) in the sense that both display the familiar Autler-Townes splitting. However, there is a fundamental difference. Paying attention to the center of the profile at detuning $\Delta_{13} = 0$, we see that, instead of destructive interference, there is constructive interference at this point. The value of the nonlinear susceptibility is indeed larger than the incoherent sum of the contributions from the dressed states.

Constructive interference in the nonlinear optical response of the atom is one of the most significant consequences of EIT. It accompanies the destructive interference which causes transparency at the same frequency. Already in 1990 Harris et al. recognized how this could be used to greatly improve four-wave mixing efficiencies.[6] Enhancement of frequency mixing by atomic coherence and interference has been examined theoretically by a number of authors (see, e.g., Refs. 5, 6, 154, 155). The interference effects lead to improved frequency mixing in resonant systems because of three connected effects: (1) The resonant reabsorption in the medium is reduced due to the creation of transparency. (2) Phase matching is optimized due to vanishing dispersion near resonance. (3) Although the coupling field causes some reduction in the absolute value of the nonlinear susceptibility at resonance, the susceptibility is subject to constructive rather than destructive interference. For a medium with a large product of density and length ($n_A L$) (i.e., the uncoupled system is optically thick) there will be a large enhancement in the four-wave mixing conversion efficiency. This persists in a Doppler-broadened medium, providing the Rabi frequency Ω_C exceeds the Doppler width.

In a finite medium a calculation including absorption and phase-matching must be performed to predict the enhancement and the frequency dependence of the nonlinear response.[5,6,101,102] In the limit of an optically deep medium and considering plane wave fields, the figure of merit for the conversion efficiency is given by the ratio $|\chi_D^{(3)}/\chi_D^{(1)}|$. This is physically reasonable, since $\chi_D^{(1)}$ characterizes the reabsorption and wave-vector mismatch in the medium, while $\chi_D^{(3)}$ determines the strength of the nonlinear coupling, which generates the new field. Thus we can see the importance of the destructive interference in the value of $\chi_D^{(1)}$ in the same frequency range, where $\chi_D^{(3)}$ experiences constructive interference. This enhances the generation efficiency in a Doppler-broadened

medium by many orders of magnitude, provided the Rabi frequency Ω_C exceeds the Doppler width. Modifications of $\chi_D^{(1)}$ result in reduced absorption and the essentially perfect phase matching for all resonant fields. Residual phase mismatch then appears only because of the dispersion caused by the remaining off-resonant states.

Electromagnetically induced phase matching was observed in an off-resonance four-wave mixing scheme in lead vapor.[156] In this experiment, the small detuning from resonance $\Delta = 6$ cm^{-1} indicated that transparency played little role in the enhancement (since the sample was optically thin). However, once the coupling laser strength exceeded a critical value, that is, $\Omega_C > [\gamma^2_{\text{doppler}} + \Delta^2]^{1/2}$, the dispersion became effectively zero. This led to perfect phase matching and enhanced conversion efficiency.

In the first experiment to demonstrate enhancement by EIT, Hakuta, Stoicheff et al. investigated three-wave mixing (normally forbidden) in hydrogen when a DC electric field was applied to the sample.[157,158] This experiment can also be viewed in the context of EIT. The DC field may be considered as an electromagnetic field at zero frequency. This field dresses the atom, creating two Stark states between which absorption cancellation occurs through interference. Second harmonic generation of a field at wavelength 243 nm is then resonantly enhanced at the two-photon transition between the states 1s and 2s. Due to EIT, the generated radiation at the Lyman-α wavelength 121.6 nm is no more reabsorbed. Further experiments by the same group then demonstrated EIT enhancement of a resonant four-wave mixing scheme in hydrogen atoms.[159] This was achieved in a scheme involving the states 1s, 2s, and 3p (corresponding to states $|1\rangle$, $|2\rangle$ and $|3\rangle$ in our notation). The coupling laser at $\lambda_C = 656$ nm drove the transition between states 2s and 3p. The coupling laser mixed with a field at $\lambda_A = 243$ nm, driving the two-photon transition between states 1s and 2s. This nonlinear interaction generated a field at $\lambda_P = 103$ nm (see Fig. 10, compare also Fig. 9*c*). Both lasers at λ_C and λ_A were derived from single-mode pulsed dye lasers. In this scheme photoionization of state 2s was an order of magnitude smaller than the ionization loss from state 3p. This is an important feature, since the coherence between the states 1s and 2s is essential for EIT effect to survive. Thus decay due to photoionization is a critical effect. However, so long as the decay rate of state 2s is significantly smaller than the rate of state 3p, the destructive interference in the absorption will persist and still lead to enhancement of the frequency mixing efficiency.

High conversion efficiencies require that the product of density and path length ($n_A L$) is large enough to ensure that the medium is initially strongly opaque. An atomic hydrogen beam was specially designed in the experiments, discussed above, in order to increase the beam density and path length. Thus EIT could be studied for the regime of an optically thin up to an optically thick medium.[95,160] Working with products ($n_A L$) up to 10^{16}cm^{-2}, conversion efficiencies of $>10^{-3}$ were found. This is an extraordinarily large value for frequency conversion in a gaseous medium. There was, however, a limit to the obtainable conversion efficiency in this scheme, due to the large Doppler width in hydrogen. This a consequence of the low mass of hydrogen and the elevated temperatures in the discharge used to produce the atoms. The coupling Rabi frequency Ω_C had to exceed the large Doppler width, leading to large Autler-Townes splittings and reduction in the magnitude of $\chi^{(3)}$ available for mixing. To overcome this, four-wave mixing schemes in atoms with smaller Doppler widths (e.g., krypton) have been studied. Experiments with a four-wave mixing scheme at a large product $(n_A L) \approx 5 \times 10^{16}$cm^{-2} in krypton at room temperature have recently demonstrated a conversion efficiency of 10^{-2} for generation of a field at 123.6 nm.[161] Quantum interference effects arising from the generated field itself have been reported to a limit in the optimum density for resonantly enhanced four-wave mixing. In a conversion scheme in rubidium[162] at higher density the generated field itself became strong enough to cause a significant perturbation to the coherences in the system. This latter work, however, did not employ a single-mode coupling laser. Thus, the low limit in the rubidium density ($n_A < 10^{15}$cm^{-3}), measured in these experiments, may not be reflected in situations where EIT is present.

Finally, we mention some alternative frequency conversion processes in lambda-type coupling schemes. In such schemes, the metastable state $|2\rangle$ often exhibits very long lifetimes. This leads to intrinsically low decay rates for the coherence ρ_{12} and near-perfect transparency is possible. Also in some selected systems (e.g., rubidium or sodium atoms) where the two lower states are hyperfine sublevels, Doppler-free configurations can be employed. These features make lambda systems a

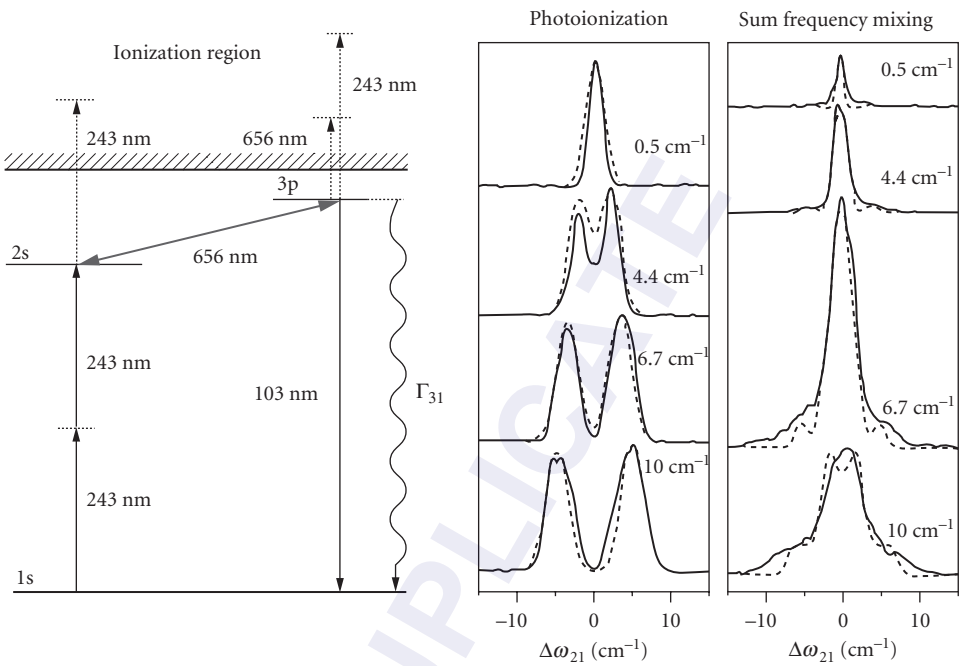

FIGURE 10 Four-wave mixing scheme in hydrogen atoms (compare also Fig. 9*c*). EIT is driven by the coupling laser at wavelength $\lambda_C = 656$ nm, tuned to the single-photon transition between states 2s and 3p [corresponding to states $|2\rangle$ and $|3\rangle$ in our notation]. A laser at $\lambda_A = 243$ nm drove the two-photon transition between states 1s and 2s [corresponding to states $|1\rangle$ and $|2\rangle$ in our notation]. A probe field was generated at wavelength $\lambda_P = 103$ nm, i.e., on the transition between the states 1s and 3p [corresponding to states $|1\rangle$ and $|3\rangle$ in our notation]. The photoionization yield and the sum-frequency mixing efficiency were measured versus the detuning $\Delta\omega_{21}$ [in our notation Δ_{21}] for different values of the coupling Rabi frequency Ω_C (given in wavenumbers). The photoionization spectra show, that the Autler-Townes splitting increases with the Rabi frequency Ω_C. The conversion efficiency increases faster than the Autler-Townes splitting. A maximum is reached for a Rabi frequency of $\Omega_C = 6.7$ cm^{-1}. The medium is driven in EIT. For larger Rabi frequency there is no further enhancement in the conversion efficiency, as the re-absorption is already completely cancelled. However, the Autler-Townes splitting still increases with $\Omega_C = 6.7$ cm^{-1}. Thus the nonlinear coupling (i.e., the value of the nonlinear susceptibility) is reduced for further increasing Rabi frequency (compare the separation of the dressed states in Fig. 5*c*). [*Reprinted figure with permission Ref 159. Copyright (1993) by the American Physical Society.*]

very favorable choice for frequency conversion processes. Let us consider again the lambda scheme in Fig. 9*a*. In contrast to the above discussion, we will permit now for alternative combinations of the applied laser frequencies. For example, consider the coupling field at ω_C applied so as to create EIT. With two additional fields, a large number of different frequency mixing processes may arise. Radiation at frequencies ω_P and ω_A (or ω_B) in combination with the coupling field at ω_C drive the generation of new fields via four-wave mixing. The sign of the detuning from resonance for the applied or generated fields ω_A or ω_B may be positive or negative. The additional state $|4\rangle$ may be present at small detuning (i.e., a double-lambda scheme is prepared) or the detuning may be very large (i.e., the lasers drive essentially a three-level system) (compare Fig. 9*b*). Also if only two fields (e.g., ω_C and ω_P) are applied, they will drive a coherence ρ_{12} that can give rise to four-wave mixing processes. The coherence ρ_{12} can mix again with either of the fields ω_C and ω_P to generate, via a stimulated Raman process, Stokes and anti-Stokes fields. Moreover, if strong fields at ω_C and ω_A and a weak field at ω_B are applied, four-wave mixing yields a field at frequency ω_P, which is phase-conjugated to ω_B.

Nondegenerate four-wave mixing (NDFWM) based on EIT in a lambda scheme has been experimentally studied. In rubidium[163] a coupling field ω_C was applied resonantly, while a second field ω_A and a weak probe at ω_B were both applied with a detuning of 450 MHz from the resonance to state $|3\rangle$. A phase-conjugate field was generated at frequency ω_B. Due to EIT, absorption of this generated field vanished, but the nonlinearity remained resonantly enhanced. The susceptibilities [Im $\chi^{(1)}$] and $\chi^{(3)}$ were measured independently under conditions of an optically thin medium. The data confirmed that $\chi^{(3)}$ was indeed enhanced by constructive interference. If an optically dense medium was used, a significant enhancement in NDFWM was observed. High phase-conjugate gain was also recently observed, applying very low laser powers. The effect arose from the presence of population trapping in a double-lambda scheme in sodium atoms.[105,164] Resonant four-wave mixing,[165] driven by cw lasers, and frequency up-conversion[166] have also been observed in an experiment investigating a double-lambda scheme in sodium dimers.

14.13 NONLINEAR OPTICS AT MAXIMAL ATOMIC COHERENCE

When two laser pulses (i.e., a probe and a coupling laser pulse) propagate as matched pulses through a medium (see Sec. 14.10), large amounts of populations are prepared in trapped states. This is possible under conditions of strong excitation, that is, when the laser electric field strengths are large enough to drive adiabatic evolution for all atoms in the beam path. In this case the coherence ρ_{12} will reach a maximum magnitude (i.e. $|\rho_{12}| = |c_1^* c_2| = 1/2$. Thus, all the atoms are prepared in the trapped state $|NC\rangle$, that is, in a coherent superposition of the ground and the excited state with equal amplitudes $|c_1| = |c_2| = \sqrt{1/2}$. As the polarization of an atom is directly proportional to the coherence [compare Eq. (4)], also the polarization reaches a maximum at maximal atomic coherence. Under these circumstances, mixing of additional fields with the atom will become extremely efficient. We must not fail to mention, that the preparation of maximal coherences is also possible by adiabatic passage processes, other than EIT. Thus, STIRAP (see Sec. 14.3), coherent population return (CPR), rapid adiabatic passage (RAP), or Stark chirped rapid adiabatic passage (SCRAP) serve as alternative tools.[45]

We consider now again a frequency conversion process under conditions of EIT in the coupling scheme, depicted in Fig. 9*a* and *b*. If the lasers at frequencies ω_P and ω_C induce a maximal coherence, any frequency conversion process, driven by the fields ω_A or ω_B occurs with high efficiency. This is due to the fact that the linear susceptibility, which governs the amount of absorption and dispersion, and the nonlinear susceptibility, which govern the frequency conversion efficiency, both have only a single nonresonant denominator with respect to the detuning. Thus the strengths for the nonlinear and the linear susceptibility for the fields at frequencies ω_A or ω_B are of the same order of magnitude. As a consequence, efficient energy exchange between the electric fields can occur in a distance of the order of the optical coherence length. The latter is determined by the real part of the susceptibility. This is equivalent to near-vacuum conditions for the dispersion and absorption of the medium while the nonlinearity is large.

The preparation of trapped states leading to the formation of a large atomic coherence has been applied by the Harris et al. to drive very efficient nonlinear frequency conversion.[149] The adiabatic frequency conversion process was implemented in a lambda-type scheme in lead vapor, driven by two strong lasers, that is, the coupling laser at $\lambda_C = 406$ nm and the probe laser at $\lambda_P = 283$ nm. A large, near-maximal coherence was created between the states $|1\rangle$ and $|2\rangle$ (see Fig. 11). The phase-coherent atoms acted as a local oscillator that mixed with a third laser field at 425 nm, detuned by 1112 cm^{-1} from the resonance frequency ω_{13}. By a four-wave mixing process, involving the three fields, a new field at 293 nm was generated. The conversion efficiency was exceptionally large, reaching ~40 percent. The high conversion efficiency occurs since in this system the preparation of the optimal coherence ρ_{12} yielded a large nonlinear susceptibility, which was of the same size as the linear susceptibility. The same scheme was used, this time mixing a field at 233 nm to generate a field in the far-ultraviolet spectral region at 186 nm. In this case, the nonresonant detuning from the

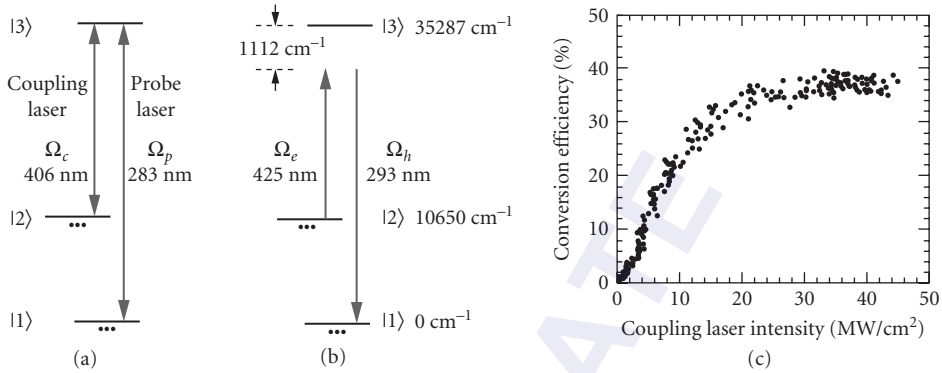

FIGURE 11 Efficient frequency conversion at maximal atomic coherence in lead vapor. (*a*) A large atomic coherence ρ_{12} was prepared by the probe and the coupling laser at wavelength λ_P = 283 nm and λ_C = 406 nm. (*b*) A laser at λ_e = 425 nm [in our notation λ_A] mixes with this coherence to generate a strong sum frequency mixing signal at λ_h = 293 nm [in our notation λ_B]. (*c*) Conversion efficiency versus coupling laser intensity. The efficiency increases linearly, till it reaches a plateau of 40 percent. This exhibits an extraordinary large value for a conversion process in a gaseous medium. [*Reprinted figure with permission from Ref. 149. Copyright (1996) by the American Physical Society.*]

third state in lead vapor was only ~40 cm^{-1}. A near-unity conversion efficiency was demonstrated in this case.[20]

The coupling scheme in lead vapor, as discussed above, was recently the subject of a proposal for a broadband, high-efficiency, optical parametric oscillator (OPO).[21,22] In this case, a maximal coherence ρ_{12} between the states $|1\rangle$ and $|2\rangle$ was created in the same fashion as discussed above. The coherence ρ_{12} then acts as a local oscillator in an optical parametric down-conversion process generating signal and idler waves in the infrared and far-infrared spectral region. In this system the nonlinear and linear responses of the medium were calculated to be of the same order and high conversion efficiencies up to 10 percent were predicted for the center of the OPO tuning range. Furthermore the device was predicted to cover the entire spectrum from the infrared to very long wavelength (i.e., essentially almost to the regime of DC fields).

The concept of maximal atomic coherence has been proposed to eliminate phase-mismatch in Raman scattering (i.e., the generation of Stokes and anti-Stokes radiation).[122] In this scheme, the vibrational states $v = 0$ and $v = 1$ in the electronic ground state of a molecule form the lower states $|1\rangle$ and $|2\rangle$ of a Raman-type excitation scheme. The Raman scheme is equivalent to a lambda-type excitation scheme with large single-photon detunings Δ_{12} and Δ_{13}, while still the laser frequencies are tuned close to two-photon resonance ($\Delta_{12} - \Delta_{13}$). In such an excitation scheme, the dephasing rate γ_{12} is very small. Thus interference can occur and cause the dispersion to become negligible. Because of the removal of the usual phase mismatch, efficient operation of Raman scattering over a broad range of frequencies, that is, from the infrared to the vacuum-ultraviolet is possible. Another important prediction concerned efficient generation of broadband coherent spectra, associated with strong-field refractive index control under conditions of maximal coherence.[23] In this case a pair of laser pulses are slightly detuned from exact two-photon (Raman) resonance. Also in this case, which is closely related to EIT, a maximal coherence is generated.

To understand this feature of adiabatic excitation, we consider a two-level system of states $|1\rangle$ and $|2\rangle$, driven by a single laser pulse (see Fig. 12*a*). The dressed (adiabatic) eigenstates of the system read

$$|+\rangle = \sin\vartheta(t)|1\rangle + \cos\vartheta(t)|2\rangle \tag{12a}$$

$$|-\rangle = \cos\vartheta(t)|1\rangle - \sin\vartheta(t)|2\rangle \tag{12b}$$

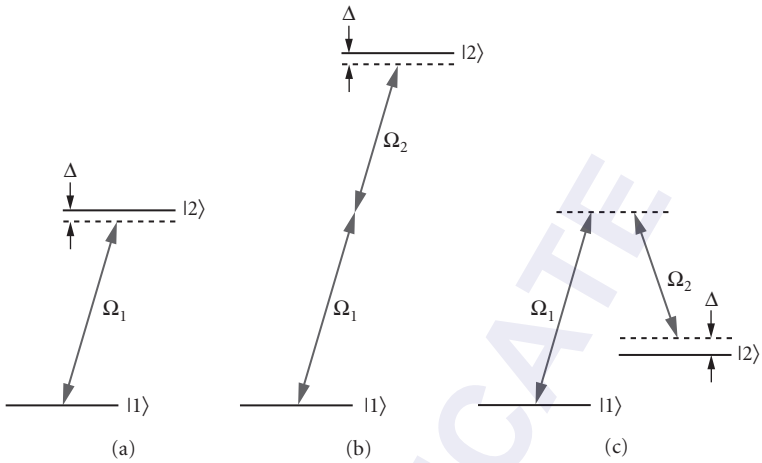

FIGURE 12 Coupling schemes for preparation of a maximal coherence by CPR. (*a*) Two-level system, driven by a single laser pulse on a single-photon transition. (*b*) Effective two-level system, driven by two laser pulses on a two-photon transition. (*c*) Effective two-level system, driven by two laser pulses on a Raman-type transition.

with the mixing angle $\vartheta(t)$, defined by $\vartheta(t) = 1/2 \arctan [\Omega_1(t)/\Delta]$. As we will consider now two strong laser pulses, we return to our previous designation of Ω_1 and Ω_2 (rather than Ω_P and Ω_C). We note that for resonant excitation at $\Delta = 0$ Eq. (12) yields the resonant form of the dressed states, as already introduced in Eq. (3). Let us assume now the Rabi frequency $\Omega_1(t)$ to be negligibly small outside a finite time interval $t_0 < t < t_1$, that is, outside the pulse duration $\tau_{pulse} = t_1 - t_0$. Consider now the case of the laser frequency detuned from exact resonance (i.e., $|\Delta| > 1/\tau_{pulse}$). If at the beginning of the interaction all the population is in the ground state, the state vector $\Psi(t)$ of the system at time $t = -\infty$ is aligned parallel to the adiabatic state $|-\rangle$. If the evolution of the system is adiabatic, the state vector $\Psi(t)$ remains always aligned with the adiabatic state $|-\rangle$ [see Eq. (12*b*) and the definition of the mixing angle ϑ]. Thus, during the excitation process (i.e., at intermediate times $t_0 < t < t_1$) the state vector $\Psi(t)$ is a coherent superposition of the bare states $|1\rangle$ and $|2\rangle$. Therefore, population is transiently excited to the upper state. However, at the end of the interaction at $t = +\infty$, the state vector $\Psi(t)$ becomes once again aligned with the initial state $|1\rangle$ [see Eq. (12*b*) and the definition of the mixing angle ϑ]. The population transferred during the process from the ground state $|1\rangle$ to the excited state $|2\rangle$ returns completely to the ground state after the excitation process. No population resides permanently in the excited state, no matter how large the transient intensity of the laser pulse may be. This phenomenon is called coherent population return (CPR), and is also known from coherent spectroscopy.[167–169] Figure 13 shows the bare state population dynamics in CPR. As expected from the analytical considerations, population flows from the ground state to the excited state during the excitation and returns back to the ground state after the excitation process. If the peak Rabi frequency $\Omega_1^{(max)}$ is sufficiently large (i.e., $\Omega_1^{(max)} >> \Delta$), the mixing angle during the process becomes $\vartheta = \pi/4$. Thus the coherence is $|\rho_{12}| = |c_1^* c_2| = \sin \vartheta \cos \vartheta = 1/2$ (i.e., a maximal coherence is prepared during the process).

The dynamics, discussed above, are not restricted to excitations of single-photon transitions, as depicted in Fig. 12*a*. Also multiphoton transitions [e.g., a two-photon transition (see Fig. 12*b*)], are driven in CPR, provided the laser frequencies are slightly detuned from the multiphoton transition frequency. This holds true also for Raman-type excitation schemes (see Fig. 12*c*), when the laser frequencies are tuned such that large detunings from any single-photon resonance as well as a small detuning from exact two-photon resonance occur. Thus, also in the case of Raman transitions between molecular vibrational states, a maximal coherence can be established and used for efficient frequency conversion processes. Moreover, a detailed theoretical analysis shows, that the adiabatic

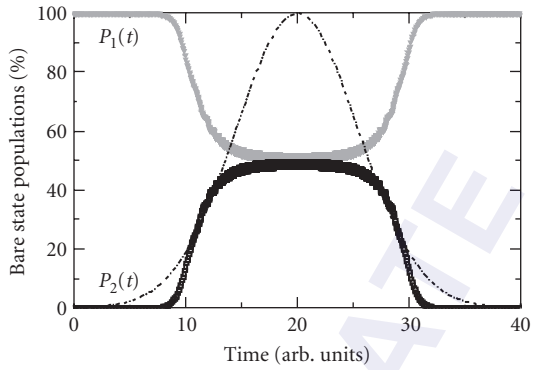

FIGURE 13 Numerical simulation of CPR.[167] When a transition in a two-level system is coherently driven, slightly detuned from the exact transition frequency (compare Fig. 12), population flows from the ground state $|1\rangle$ to the excited state $|2\rangle$ and back again [the probabilities $P_i(t)$ are indicated by the solid data points]. A transient maximal coherence is established during the process. The dashed line shows the temporal profile of the driving laser pulse.

excitation also permits control of the refractive index, that is, phase matching or phase mismatch plays only a minor role in the conversion process.

Harris et al. proposed, demonstrated, and applied the efficient generation of Raman sidebands in gaseous media under the conditions of maximal coherence.[22–24,26–28,33,35] The experiment was performed in deuterium molecules in the gas phase. The deuterium molecules were cooled to 77 K in order to increase the population in the lowest rotational state and to reduce dephasing by collisions. Two nanosecond radiation pulses at frequencies ω_1 (pump) and ω_2 (Stokes) excited a Raman transition between the vibrational ground state $v = 0$ and the first excited state $v = 1$ (compare Fig. 12*c*). If the laser frequencies are slightly detuned from the Raman resonance, a maximum coherence is established. The medium acts now like a molecular modulator, oscillating at the frequency $\Delta\omega$ (i.e., the difference frequency between the vibrational states $v = 0$ and $v = 1$). The generation of Raman sidebands can be viewed as subsequent mixing process of the molecular modulator and the laser fields: Interaction of the field at ω_2 with the coherence at $\Delta\omega$ produces the first anti-Stokes sideband at $\omega_2 + \Delta\omega$ with large efficiency. Interaction of the first sideband with the coherence generates the second anti-Stokes sideband at $\omega_2 + 2\Delta\omega$. The process proceeds to higher-order sidebands. In their experiment, Harris et al. demonstrated conversion of the two driving radiation fields into Raman sidebands, covering a spectral region from 2.94 μm to 195 nm (i.e., from the far-infrared to the far-ultraviolet).[24] The largest conversion efficiency occurs, when the two radiation fields are slightly detuned from exact two-photon resonance. This, on the first glance surprising feature, confirms the theoretical expectations, as discussed above: Adiabaticity is maintained and a maximal coherence is prepared for detunings $|\Delta| > 1/\tau_{\text{pulse}}$.

Harris, Sokolov et al. applied the scheme for efficient generation of Raman sideband, as discussed above, to generate intense ultrashort radiation pulses.[27,28,33] In an impressive experiment, Raman sidebands, with pulse durations in the nanosecond regime, were overlapped and combined. When their relative phases were appropriately adjusted, the combination of the phase-locked frequency components yielded a train of ultrashort radiation pulses with pulse duration in the regime of down to 1.6 fs (see Fig. 14).[33]

We must not fail to mention that Hakuta et al. performed some of the early investigations on Raman sideband generation in coherently prepared media.[25,31,32,34] These experiments were conducted in solid hydrogen. Other experiments on Raman sideband generation in media, coherently driven by nanosecond radiation pulses, were also performed by Marangos et al.[29,30] In these experiments

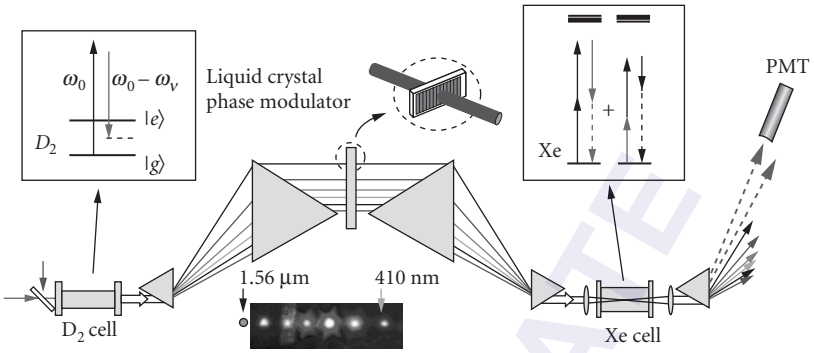

FIGURE 14 Experimental setup for temporal synthesis and characterization of single cycle optical pulses, generated by combination of Raman sidebands. The sidebands are generated in a cell with deuterium molecules, dispersed and their phases are independently varied by a liquid crystal modulator. The sidebands are recombined and focused into a target cell with xenon gas. The figure also shows the spectrum of the seven sidebands in the wavelength regime from 1.56 μm to 410 nm, used for generation of the ultrashort pulse. The duration of the ultrashort single-cycle pulses was 1.6 fs with a peak power of 1 MW. [*Reprinted figure with permission from Ref. 33. Copyright (2005) by the American Physical Society.*]

the coherence was probed by long (nanosecond) as well as ultrashort (femtosecond) radiation pulses.

Other work extended the concept of maximal coherence to the regime of excitations by ultrashort radiation pulses.[170,171] As discussed above (see Sec. 14.5), ultrashort pulses are usually not favourable choice to drive adiabatic excitations on single-photon transitions. Thus, usually a maximal coherence cannot be prepared by ultrashort radiation pulses. However, in selected molecular media and with sufficient pulse energies, already a significantly enhanced molecular coherence (though not maximal) may enable efficient frequency conversion. Thus the efficient generation of Raman sidebands with pulse durations in the femtosecond time domain was demonstrated in hydrogen and methane molecules. [170,171] The total conversion efficiency approached 10 percent.

Other extensions of the concepts, discussed above, utilize the excitation of Raman transitions by lasers of ultrabroad bandwidth.[36–39] If the bandwidth γ_{laser} of a single ultrashort laser pulse covers the spacing $\Delta\omega$ between the vibrational ground state and the first excited state, the Raman transition is driven with frequency components, deduced from the single radiation pulse. Using SF_6 molecules as the Raman-active medium, an ultrashort pump pulse with wavelength $\lambda_P = 800$ nm and an additional ultrashort probe pulse with wavelength $\lambda_{\text{Pr}} = 400$ nm, the molecular modulation technique has led to the generation of pulse trains and isolated pulses with a duration of a few femtoseconds.[37–39]

14.14 NONLINEAR OPTICS AT THE FEW PHOTON LEVEL

As we have noted, one of the most remarkable features of EIT is that the nonlinear susceptibility undergoes constructive interference, while the linear susceptibility undergoes destructive interference. In a system without inhomogeneous broadening, perfect transparency can be induced for a coupling Rabi frequency $\Omega_C << \Gamma_3$. In this case the medium becomes transparent. Due to the small size of Ω_C with respect to the decay rate Γ_3 the nonlinear susceptibility will reach a value essentially identical to the value in the bare atomic system. Since atomic resonances are generally much narrower than those of a solid-state system, the magnitudes of the nonlinearity in this case can be many orders of magnitude larger than that of any solid. For instance, a very large nonlinear refractive

index was reported by Hau et al.[11] for EIT in a ultracold sodium vapor. They measured a value for the nonlinear refractive index that was 0.18 $cm^2\,W^{-1}$. This was 10^6 times larger than the nonlinear refractive index measured for cold cesium atoms in a system, which was not driven to EIT.[172] In fact, the refractive index in cesium was itself much larger than the refractive index in a solid. For comparison, the largest nonlinear refractive indices of solid-state materials are on the order of less than $10^{-12}\ cm^2\,W^{-1}$.[173]

An important feature in the regime, discussed above, is the Kerr-type nonlinearity. This can be understood from examination of Fig. 9*a*. If fields at frequencies ω_P, ω_C, and ω_B are considered, the Kerr-type nonlinearity describes the coupling between the fields at ω_P and ω_B. The detuning between of field ω_A from state $|4\rangle$ is usually smaller than the detuning from state $|3\rangle$. Via the susceptibility [Re $\chi^{(3)}$], the field at ω_A causes a cross-modulation with the field at ω_P. This effect was recently predicted to lead to a giant Kerr nonlinearity if the field at ω_C is of moderate strength. This is viable even when extremely low-power laser fields at ω_P and ω_B are applied. In a theoretical analysis,[174] values of [Re $\chi^{(3)}$] $\approx 3 \times 10^{-6}\ m^2\,V^{-2}$ are found. These are large enough to permit measurable cross-phase modulations between fields containing only a few photons.

In the experiments of Hau et al.[11] under the same conditions where ultraslow light pulse propagation was measured, a large nonlinearity was deduced. This was extrapolated from the measurement of the AC Stark shift of the transparency minimum due to the interaction between the field at ω_C and state $|4\rangle$. This interaction is equivalent to the Kerr nonlinearity discussed in Ref. 174, when the field at ω_C also plays the role of the additional field (previously ω_B). The connection between the large nonlinearity and the ultraslow light propagation has been studied by several authors.[151,175] In the case of the experiments discussed here, the connection is seen clearly to arise through the AC Stark shift of the steep dispersion curve responsible for ultralow group velocities. For even very modest fields at ω_C, large changes in the absolute value of the dispersion are obtained, which result in significant phaseshifts. The latter are imparted on the probe field by itself. Similarly, in an experiment on ultraslow light, driven in a Doppler-free excitation scheme in rubidium,[151] very large nonlinearities are evidenced by the highly efficient four-wave mixing process that was observed. Therefore, the authors highlight the strong connection between ultraslow group velocities and ultralarge nonlinearity.

A number of investigations showed, that the huge nonlinearities available in the excitation schemes, discussed above, are large enough to mediate significant interaction between pairs of photons. There are important implications if a single photon can cause a measurable modification to another single photon (e.g., by a strong cross-phase modulation). For instance, applications are proposed for quantum nondemolition measurements and for quantum information processing. In the latter case strong mutual interactions can be utilized to generate entangled pairs of photons that form the basis of quantum logic gates. Discussions of this topic include an analysis of frequency mixing and nonlinear phase shifts at the few photon level,[175] techniques for generating squeezed light at very low input powers,[176] photon switching,[177] and photon blockade within an atom-cavity system.[178]

14.15 ELECTROMAGNETICALLY INDUCED TRANSPARENCY IN SOLIDS

While adiabatic processes (e.g., EIT) have been very extensively studied in the gas phase, only a few experiments were performed in solids.[105–107,108–115] In contrast to gaseous media, solids offer large density, scalability, compactness, and convenience in their preparation and usage. Moreover, atomic diffusion is absent in solids. All of these features are of significant interest for applications in optical data storage and quantum information processing. However, large homogeneous and inhomogeneous broadenings exhibit an obstacle for the implementation of EIT in solids (see Sec. 14.5). Thus, only very specific systems in the solid phase permit appropriate conditions for EIT.

Some larger classes of solids, which are appropriate candidates for the implementation of adiabatic processes, combine the advantages of gaseous media and solids. Such media are (e.g., quantum

wells) electron-hole pairs (excitons), doped solids, and specific color centers. Quantum wells show a quite defined level structure, which is very similar to atoms in the gas phase. However, quantum wells are also subject to tremendous inhomogeneous broadening, because it is very hard to control the size, shape, and depths of a larger ensemble during the manufacturing process. Thus, usually only coherent excitation of a very small ensemble (or even single) quantum wells is possible—which is a significant drawback for applications, as one major advantage of a solid state medium (i.e., a large density) is lost. Electron-hole pairs have also been discussed in the scientific community as appropriate quantum systems for the implementation of adiabatic interactions. Like quantum dots, the electron-hole pairs also exhibit relatively well-defined level structure. As the dephasing times in quantum wells and electron-hole pairs are in the order of picoseconds or below, experimental implementations require ultrashort laser pulses. On the other hand, ultrashort laser pulses are usually not a good choice for driving adiabatic excitation of single-photon transitions (see Sec. 14.5). However, if the transition moments and the laser pulse energies are large enough, quantum wells and electron-hole pairs may serve as appropriate media for the implementation of EIT. Thus, coherent excitations in quantum wells or related nanostructures attracted significant attention in the recent years and already lead to first successful implementations of EIT in quantum wells.[108–111]

A class of solid media, which combines the properties of the gas phase and the solid phase in a very advantageous way, are doped solids. In such media, atoms or ions are doped in a host crystal. The dopants in the host crystal still exhibit the level structure of the free atom. At room temperature, interaction with the host lattice leads to large homogeneous broadening. Moreover, as the dopants experience spatially varying electric fields from the host lattice, the atomic transitions are subject to substantial inhomogeneous broadening. At cryogenic temperatures, the homogeneous linewidth can be reduced well below the width of the inhomogeneous broadening, that is, selective optical excitation at zero-phonon transitions becomes possible. The still remaining inhomogeneous broadening might be considered as an advantage, as it permits the selective excitation of different ensembles of dopants. This was already utilized two decades ago, when spectral hole burning[179] was discovered as an appropriate way to address specific ensembles in an inhomogeneously broadened medium (e.g., for applications in frequency-selective, multichannel storage of information). Thus, when the dopants in a cryogenically cooled host crystal are appropriately prepared by spectral hole burning or related techniques, a specific subset of the atoms exhibits a quantum system with very narrow spectral linewidth.

Some basic adiabatic interactions have been demonstrated in the recent years in rare-earth doped solids. Thus, EIT,[105–107,112,113] RAP,[180,183] and recently STIRAP[182,183] were successfully implemented in praseodymium ions Pr^{3+}, doped in a cryogenically cooled Y_2SiO_5 host crystal. Pr^{3+}:Y_2SiO_5 is a well-established and commercially available material for optical data storage (e.g., by spectral hole burning). The spin coherence, that is, the dephasing time in the medium is pretty large (i.e., exceeding the timescale of 100 μs).[114,179] This enables the implementation and observation of EIT with long interaction times, driven, for example, by modulated radiation, derived from cw lasers.

In the first successful implementation of EIT in a doped solid, Hemmer et al.[105] used a cw laser, operating at 606 nm, split in three beams, which are frequency modulated in acousto-optical modulators. Two of the three beams form the probe and the coupling laser. A third beam (i.e., the repump laser) is necessary to refill the spectral holes, burned by the probe and coupling laser. The Pr^{3+}:Y_2SiO_5 crystal was cooled to a temperature of approximately 2 K to reduce the otherwise huge homogeneous broadening. Figure 15 shows the coupling scheme and the transmission of a probe laser in the medium. The praseodymium ions show a quite complicated level structure, as the ground state $^3H_4$ and the excited state $^1D_2$ interact with the electric field in the background of the host crystal and split in Stark components. The local variations in the electric field cause substantial inhomogeneous broadening in the crystal. However, by appropriate tuning and matching of the laser frequencies, a specific ensemble of ions is selected and driven in EIT. When the intensity of the coupling laser is large enough, the transmission of the probe laser is significantly enhanced in the center of the bare state resonance (see Fig. 15). Similar experiments on EIT in Pr^{3+}:Y_2SiO_5 were also conducted by Ichimura et al.[183]

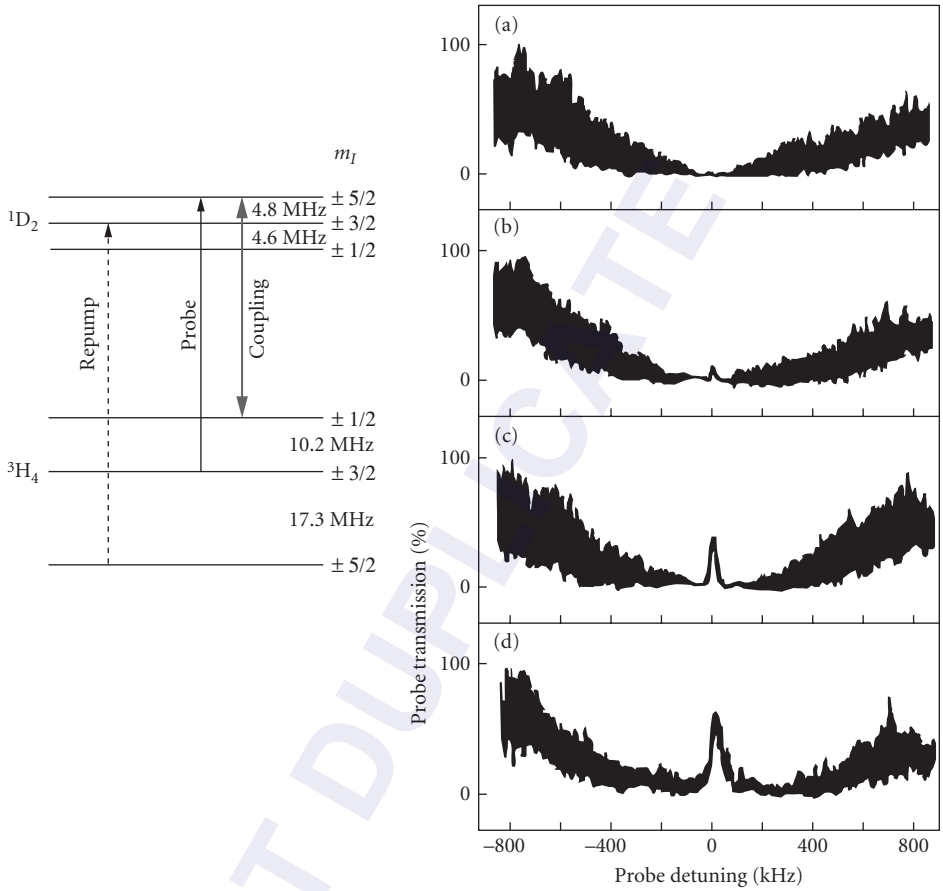

FIGURE 15 EIT in $Pr^{3+}:Y_2SiO_5$. Coupling scheme and transmission of the probe laser versus detuning. The intensity of the coupling laser increases from graph (*a*) to (*d*). When the coupling laser is strong, the medium is driven to EIT and the probe laser, tuned to the bare state resonance, passes the medium with largely reduced losses. [*The figure was published from Ref. 105. Copyright Elsevier (1997).*]

In projects, dealing with the manipulation of optical processes by EIT, Hemmer et al. also reported efficient phase conjugation as well as ultraslow propagation of light pulses in $Pr^{3+}:Y_2SiO_5$.[113] The speed of light was reduced down to values of $v_g = 45$ m/s. Moreover, in these experiments also stopping of a light pulse in the crystal was observed. Recently, Longdell et al. reported stopping of light with storage times larger than 1 second in $Pr^{3+}:Y_2SiO_5$, prepared by EIT (see Fig. 16).[115]

In addition to rare-earth doped solids, also special color centers are appropriate media for adiabatic interactions. Thus, Hemmer et al. also demonstrated EIT in nitrogen vacancy (N-V) color centers in diamond.[184] The transition moments in these color centers are much larger than in $Pr^{3+}:Y_2SiO_5$. Therefore lower laser intensities are required to drive the medium. N-V color centers are interesting candidates for applications in quantum computation.[185] Thus the experimental investigations in $Pr^{3+}:Y_2SiO_5$ and N-V diamonds, as well as theoretical proposals for EIT and other adiabatic interactions in nanostructures (see, e.g. Refs. 186 to 188 and references therein), may pave the way toward the implementation of solid state quantum information processors.

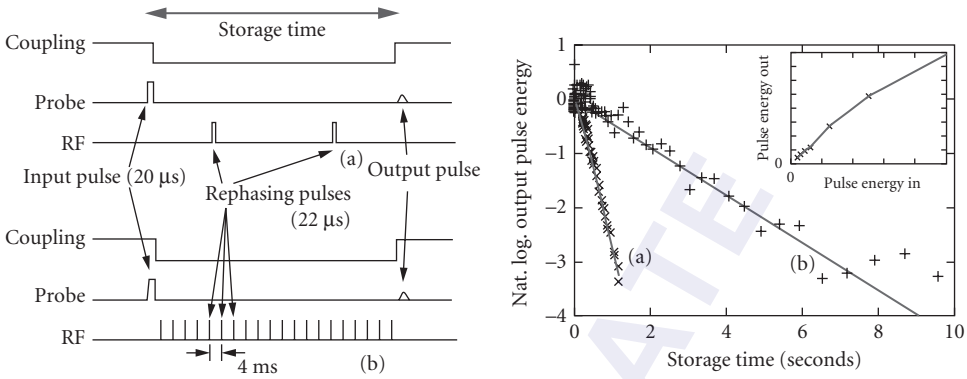

FIGURE 16 Demonstration of storage of light in $Pr^{3+}:Y_2SiO_5$, prepared by EIT. Pulse sequences and output pulse energy storage time, for two different techniques (*a*, *b*) to control decoherence by an additional radio frequency (RF) field. The coupling laser pulse prepares the medium in EIT for the probe laser pulse. When the coupling pulse is switched off, the probe pulse is stored in the medium and recovered, when the coupling pulse is switched on again. The storage time exceeds several seconds. 14.16 CONCLUSION

In this chapter, we reviewed the basic concepts, implementations, and applications of EIT. We discussed the principles of EIT in terms of quantum interferences, atomic coherences, and dressed atomic states in a system of three quantum states, coherently driven by two radiation fields, that is, the probe laser field and the coupling laser field. The concept of EIT is closely related to other coherent, adiabatic interactions, for example, RAP, SCRAP, STIRAP, CPT, and CPR. However, while the latter techniques are focused to a large extend on the manipulation of population distributions, the ideas of EIT are mainly connected with atomic coherences and the manipulation of optical properties.

From some very basic considerations, we derived the main features of EIT, that is, vanishing absorption and dispersion at atomic resonances (due to destructive quantum interference), a steep slope of the dispersion at the atomic resonance, and enhanced nonlinear optical response of the medium (by constructive quantum interference). Thus the optical properties of quantum systems, manipulated by EIT, are very different from the properties of common optical media. These features lead to a rich variety of applications in the field of optical physics, for example, transmission through otherwise optically dense media, gain in quantum systems without population inversion, propagation of light with ultraslow velocity, storage of light pulses, and the significant enhancement of nonlinear optical processes. In the latter field, EIT permits frequency conversion in gaseous media with extraordinary large efficiencies.

We reviewed convincing experiments and striking applications of EIT. The majority of these experiments were implemented in atoms or molecules in the gas phase, but some also in selected solids. The investigations, as conducted so far, already lead to tremendous impact in the fields of optical information processing and quantum computation, applied optics, laser physics and physics on ultrashort timescales. However, we believe, there is a huge potential of EIT and related concepts, which is still to be explored in the future.

Naval Research Laboratory
Washington, D.C.

15.1 INTRODUCTION

Raman and Brillouin scattering are inelastic scattering processes in which the wavelength of the scattered radiation is different from that of the incident light and a change in the internal energy of the scattering medium occurs. The main distinction between Raman and Brillouin scattering is the type of internal mode involved. Raman scattering involves nonpropagating collective modes in the material. Examples include electronic excitations and molecular vibrations and rotations in liquids and gases, electronic excitations and optical phonons in solids, and electron-plasma oscillations in plasmas. Brillouin scattering involves low-frequency propagating waves, for example acoustic waves in solids, liquids, and gases and ion-acoustic waves in plasmas. The two processes exhibit a range of similarities and differences in the properties of the scattering process as well as in the materials that are involved. General descriptions of Raman and Brillouin scattering are given in Refs. 1–8. Collections of papers on specific aspects of Raman and Brillouin scattering are contained in Refs. 9–11. Review articles are given in Refs. 12 and 13.

15.2 RAMAN SCATTERING

Raman scattering occurs in a wide variety of solids, liquids, gases, and plasmas. The most common form of Raman scattering is one in which the incident light, termed the *pump*, is scattered into light at a longer wavelength, termed the *Stokes wave*, with the energy difference between the incident and scattered photons being taken up in excitation of the appropriate mode of the material. The difference between the incident and scattered photon energy is termed the *Stokes shift*. The identification of the scattered wave as the Stokes wave is made in analogy with the Stokes shift to longer wavelengths in fluorescence, but the dynamics of the two processes are different except for interactions that are resonant with an allowed single-photon resonant transition. Raman scattering in which the incident light is scattered to a light wave at a shorter wavelength, accompanied by a deexcitation of an internal mode of the medium, is termed *anti-Stokes scattering*, and the scattered wave is termed the *anti-Stokes wave*. The difference between the anti-Stokes and pump photon energies is termed the

anti-Stokes shift. Again, the analogy is with the corresponding process in fluorescence. Raman shifts can range from tens to tens of thousands of wavenumbers, and are determined entirely by the material and the mode involved.

Raman Interactions

Raman scattering can be viewed in the semiclassical model as a two-photon interaction in which the material makes a real transition from an initial to a final state and a pump photon is destroyed while a Stokes or anti-Stokes photon is created. Several types of Raman interactions are possible. These are illustrated in the level diagrams of Fig. 1, which show Stokes scattering, anti-Stokes scattering, anti-Stokes scattering with four-wave mixing, multiple Stokes scattering, and hyper-Raman scattering. Of these, the most common is Stokes scattering (Fig. 1*a*), in which the pump photon at frequency ω_L is scattered into a longer-wavelength Stokes photon ω_S, accompanied by the excitation of an internal mode of the medium at frequency ω_o.

Anti-Stokes scattering (Fig. 1*b*), in which the pump photon is scattered into a shorter-wavelength anti-Stokes photon ω_{AS} accompanied by the deexcitation of an internal mode of the medium, requires initial excitation into upper levels of the medium. The anti-Stokes interaction illustrated in Fig. 1*b* is less common than the Stokes interaction, occurring most often in spontaneous Raman scattering when the levels are excited thermally. In stimulated processes, this interaction incurs exponential loss unless a population inversion is created between the initial and final states.

Anti-Stokes Raman scattering involving a four-wave mixing interaction, as illustrated in Fig. 1*c*, is much more common in Raman scattering. In this interaction, two pump photons are scattered into a Stokes and anti-Stokes interaction with no net excitation or deexcitation of the medium. This interaction requires perfect or approximate phase matching, depending on the conditions of the scattering interaction. Multiple Raman scattering (Fig. 1*d*) occurs when the Stokes wave becomes

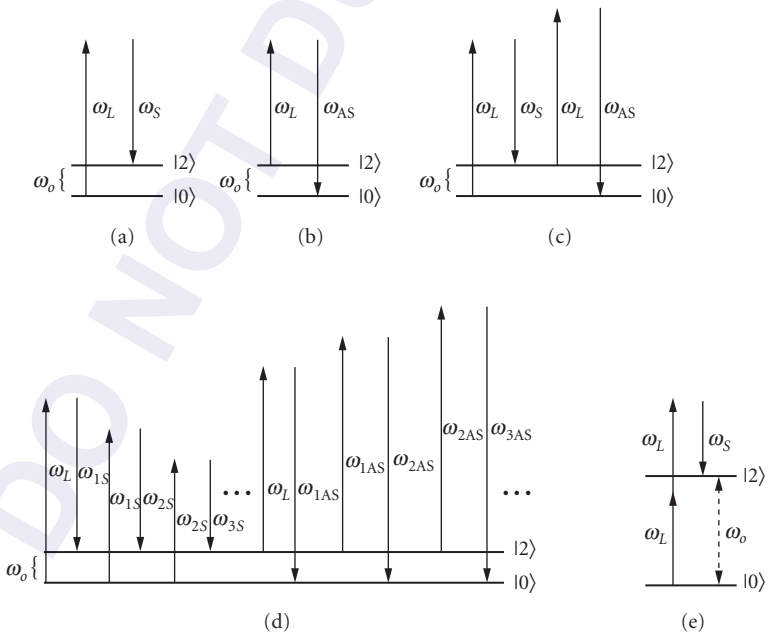

FIGURE 1 Level diagrams showing (*a*) stimulated Raman Stokes scattering; (*b*) stimulated Raman anti-Stokes scattering; (*c*) coherent anti-Stokes four-wave mixing; (*d*) multiple Stokes and anti-Stokes scattering; and (*e*) hyper-Raman scattering.

TABLE 1 Frequency and *k*-Vector Relationships in Various Raman Interactions

Stokes scattering	$\omega_s = \omega_L - \omega_o$ $k_o = k_L - k_s$
Anti-Stokes scattering	$\omega_{AS} = \omega_L + \omega_o$ $k_o = k_{AS} - k_L$
Coherent anti-Stokes scattering	$\omega_S + \omega_{AS} = 2\omega_L$ $k_{AS} = 2k_L - k_s$
Multiple Stokes scattering	$\omega_{ns} = \omega_{(n-1)S} - \omega_o = \omega_L - n\omega_o$ $k_o = k_{(n-1)S} - k_{nS}$
Hyper-Raman scattering	$\omega_s = 2\omega_L - \omega_o$ $k_o = 2k_L - k_s$

powerful enough to drive its own Raman interaction. This generally occurs when the pump wave is significantly above the stimulated Raman threshold. Under these conditions, multiple Stokes waves are generated, each one shifted from its effective pump wave by the frequency of the internal mode of the medium. Multiple Stokes and anti-Stokes waves can also be created through four-wave mixing processes involving one or more of the pump- or frequency-shifted waves. Hyper-Raman scattering (Fig. 1*e*) involves multiphoton interactions in which two or more pump photons are scattered into a single Stokes photon with excitation of an appropriate mode of the material.

In all of these interactions, energy is conserved among the incident and scattered photons and internal energy of the medium. The appropriate relations are summarized in Table 1.

Not all levels in a material can be involved in Raman scattering. In general, Raman scattering follows the rules for two-photon dipole transitions. In materials with inversion symmetry, the initial and final states must have the same parity, and therefore are mutually exclusive with absorptive transitions. In materials without inversion symmetry, internal levels can be both Raman and optically active.

Regimes of Raman Scattering

Raman scattering can occur in the spontaneous and stimulated regimes. In the spontaneous regime, the power of the Stokes and anti-Stokes waves is proportional to the power of the pump wave. The entire manifold of Raman-active internal modes is present in the scattered spectrum, with relative intensities of the Stokes components being determined by the relative Raman scattering cross sections for the various modes. Anti-Stokes scattering arises in spontaneous Raman scattering through thermal excitation of the internal modes. Therefore, the intensity of anti-Stokes modes is reduced from that of the Stokes modes for the same internal level by the thermal excitation factor $e^{-\hbar\omega_o/kT}$. Anti-Stokes scattering in the spontaneous regime is generally less common than Stokes scattering, except when low-lying rotational levels of molecules or low-frequency phonons in solids are involved, because thermal excitation of the internal mode is required. Anti-Stokes scattering can be more prominent in stimulated or coherent scattering processes, as will be described in later sections. Spontaneous Raman scattering is used primarily for spectroscopic studies, especially for modes that are forbidden in single-photon absorption or emission measurements.

Stimulated Raman Scattering (SRS) occurs when the intensity of the incident pump wave is strong enough to initiate a positive feedback effect in the medium, resulting in exponential growth of the scattered wave. Stimulated Raman scattering is used for wavelength shifting of coherent light, amplification, improved optical beam properties, pulse compression, phase conjugation, and beam combining. Coherent Raman interactions are used for spectroscopy.

Stimulated Raman Scattering

In stimulated Raman scattering, the internal mode of the medium is driven by the interference of the pump and Stokes waves while the Stokes wave is driven by the modulation of the pump wave

by the material oscillation. Thus, the growth rate of the Stokes wave, which is determined by the strength of the internal excitation, increases as the Stokes intensity increases. This is exactly the condition needed for exponential growth of the Stokes wave. Stimulated Raman scattering was observed soon after the development of Q-switched lasers.[14]

Stimulated Raman Geometries Stimulated Raman scattering can occur in several geometries, each with its own applications. Stimulated Raman generators are illustrated in Fig. 2*a* and *b*. In this arrangement, only a pump wave is incident on the medium, and the Stokes wave grows from quantum noise. Forward scattering is the most common form of Raman generator (Fig. 2*a*), but backward wave generation can occur under some conditions (Fig. 2*b*). Single-pass Raman generators involve amplified spontaneous emission (ASE), and the coherence and divergence properties are characteristic of ASE devices. If the interaction is strong enough to involve pump depletion, the coherence of the Stokes wave can approach that of the pump wave. Raman generators are typically used for frequency conversion from the pump to the Stokes wavelength or for creation of a Stokes wave for other applications. Conversion to multiple Stokes or anti-Stokes waves can also be done with Raman generators. Mirrors can be used with the Raman generator to create a Raman oscillator as in Fig. 2*c*. This arrangement is used with low-intensity continuous-wave (cw) or pulsed pump lasers to reduce the Raman threshold.[13]

Raman amplification can be achieved with the arrangements shown in Fig. 2*d* and *e*, in which a Stokes wave is supplied along with the pump wave. The Stokes wave is amplified at the expense of the pump wave. The Stokes wave is usually created in a separate low-power Raman generator and may be spatially filtered for control of the spatial divergence. Raman amplification is used when a high-quality Stokes beam is desired or when highly efficient conversion of the pump energy is desired without creation of multiple Stokes components. Backward amplification (Fig. 2*e*) is used for Stokes amplification or for pulse compression. In Raman generators, usually only a single Stokes frequency is generated corresponding to the material mode with the highest gain. Amplification of any of the Raman modes is possible if a suitable input Stokes signal is provided.

Coherent anti-Stokes Raman scattering (CARS) is illustrated in Fig. 2*f*. Here the pump and Stokes waves are supplied, often having comparable intensities and propagating at the appropriate phase-matching angle. The anti-Stokes wave is created at the appropriate angle for phase matching. CARS is used for spectroscopy and other diagnostic applications.

Raman Susceptibilities Classically, the Raman effect occurs because of modulation of the polarization in the medium induced by the pump at the difference frequency between the pump and material mode. This arises from the hyperpolarizability of the medium. The polarization of the medium is given by[6,7]

$$P=\varepsilon_o\left(\mu_o+\mu E+\frac{\partial\alpha}{\partial Q}QE+\cdots\right) \tag{1}$$

where μ_o is the permanent dipole moment of the material, μ is the first-order dipole moment, $(\partial\alpha/\partial Q)$ is the hyperpolarizability, and Q is the normal mode coordinate of the material oscillation. Spontaneous Raman scattering is given classically by the relation

$$P_S=NA\frac{\partial\sigma}{\partial\Omega}d\Omega P_L L \tag{2a}$$

where $d\sigma/d\Omega$ is the differential cross section of the Raman transition, L is the length of the scattering medium, A is the cross-sectional area, and $d\Omega$ is its solid angle. The Raman cross section is related to the hyperpolarizability by

$$\frac{\partial\sigma}{\partial\Omega}=\frac{\pi h n_S v_S^4}{4n_L m\omega_o c^2}\left(\frac{\partial\alpha}{\partial Q}\right)^2 \tag{2b}$$

The Raman effect can also be analyzed quantum-mechanically through the use of the density matrix[15] using the third-order elements ρ_{0i} and ρ_{i2} and the second-order element ρ_{02}, where the subscripts 0 and 2 designate the initial and final Raman levels and the subscript i designates intermediate levels. The classical parameter Q is related to the off-diagonal density matrix element ρ_{02}, while the population density is related to the element ρ_{22}. Thus the normal mode coordinate of the material oscillation is associated with quantum mechanical transition probabilities and not directly with the population of the excited state of the material.

The Raman cross section can be related to the susceptibilities of nonlinear optics[15] through density matrix calculations involving the third-order elements ρ_{0i} and ρ_{i2} and the second-order element ρ_{02}. The nonlinear Raman polarization amplitude is

$$P(\omega_S)=\frac{3}{2}\varepsilon_0\chi^{(3)}(-\omega_S,\omega_L,-\omega_L,\omega_S)|A_L|^2 A_S \tag{3a}$$

and the Raman susceptibility per atom or molecule is

$$\chi^{(3)}_{\text{Raman}}=\frac{1}{6\hbar^3\varepsilon_o}\frac{1}{\omega_{20}-(\omega_L-\omega_S)+i/T_2}\left|\sum_i\mu_{0i}\mu_{i2}\left(\frac{1}{\omega_{i0}-\omega_L}+\frac{1}{\omega_{i0}+\omega_S}\right)\right|^2 \tag{3b}$$

where T_2 is the homogeneous Raman dephasing time and M_{ij} is the transition dipole moment between states i and j.

The Raman susceptibility has real and imaginary parts. The imaginary part, which is negative and proportional to T_2, is responsible for spontaneous and stimulated Raman scattering. The real part contributes to the nonlinear refractive index through Raman-type interactions. The Raman susceptibility is related to the hyperpolarizability as

$$\chi''=-\frac{1}{12\Gamma m\omega_o}\left(\frac{\partial\alpha}{\partial Q}\right)^2 \tag{4}$$

where χ'' is the imaginary part of the Raman susceptibility, Γ is the inverse of the dephasing time, m is the effective mass of the material oscillator, and ω_0 is the frequency of the material transition. The Raman susceptibility is defined only for steady-state interactions. In transient interactions, the Raman polarization must be solved for as a dynamic variable along with the optical fields.

SRS Equations Stimulated Raman scattering is described in the most general form by the equations:[2]

$$\nabla_{\perp}^2 A_S + 2ik_S\left(\frac{\partial A_S}{\partial z} \pm \frac{1}{v_{gS}}\frac{\partial A_S}{\partial t}\right) = -\frac{\Delta N}{2}\frac{\omega_S^2}{c^2}\left(\frac{\partial \alpha}{\partial Q}\right)_S Q^* A_L \tag{5a}$$

$$\nabla_{\perp}^2 A_L + 2ik_L\left(\frac{\partial A_L}{\partial z} + \frac{1}{v_{gL}}\frac{\partial A_L}{\partial t}\right) = -\frac{\Delta N}{2}\frac{\omega_L^2}{c^2}\left[\left(\frac{\partial \alpha}{\partial Q}\right)_S Q A_S + \left(\frac{\partial \alpha}{\partial Q}\right)_{\mathrm{AS}} Q^* A_{\mathrm{AS}} e^{i\Delta kz}\right] \tag{5b}$$

$$\nabla_{\perp}^2 A_{\mathrm{AS}} + 2ik_{\mathrm{AS}}\left(\frac{\partial A_{\mathrm{AS}}}{\partial z} \pm \frac{1}{v_{g\mathrm{AS}}}\frac{\partial A_{\mathrm{AS}}}{\partial t}\right) = -\frac{\Delta N}{2}\frac{\omega_{\mathrm{AS}}^2}{c^2}\left(\frac{\partial \alpha}{\partial Q}\right)_{\mathrm{AS}} Q A_L e^{-i\Delta kz} \tag{5c}$$

$$\frac{\partial Q^*}{\partial t} + \left[i\left(\frac{\omega_o^2 - \Omega^2}{2\Omega}\right) + \Gamma\right]Q^* = -\frac{i}{4\omega_o m}\left[\left(\frac{\partial \alpha}{\partial Q}\right)_S A_L^* A_S + \left(\frac{\partial \alpha}{\partial Q}\right)_{\mathrm{AS}} A_{\mathrm{AS}}^* A_L e^{-i\Delta kz}\right] \tag{5d}$$

$$\frac{\partial \Delta N}{\partial \tau} + \frac{1}{T_1}(\Delta N - N) = -i\frac{\Delta N \varepsilon_o}{4\hbar}\left[\left(\frac{\partial \alpha}{\partial Q}\right)_S (Q^* A_L A_S^* - Q A_L^* A_S) + \left(\frac{\partial \alpha}{\partial Q}\right)_{\mathrm{AS}} (Q^* A_L^* A_{\mathrm{AS}} e^{i\Delta kz} - Q A_L A_{\mathrm{AS}}^* e^{-i\Delta kz})\right] \tag{5e}$$

where A_S, A_L, and A_{AS} are the slowly varying optical field amplitudes of the Stokes, laser (pump), and anti-Stokes waves given by

$$E_{S,L,\mathrm{AS}}(x, y, z, t) = \frac{1}{2}\left[A_{S,L,\mathrm{AS}}(x, y, z, t) e^{-i(\omega_{S,L,\mathrm{AS}} t - k_{S,L,\mathrm{AS}} z)} + c.c.\right] \tag{6}$$

where $\omega_{S,L,\mathrm{AS}}$ are the optical frequencies, $k_{S,L,\mathrm{AS}}$ are the k vectors, $v_{S,L,\mathrm{AS}}$ are the group velocities, ΔN is the difference in the population between the lower and the upper Raman transition levels, $\Delta N = N_0 - N_2$, N is the total population density, and Q is the amplitude of the normal mode coordinate of the material excitation defined by

$$\mathbf{Q}(x, y, z, t) = \frac{1}{2}\left[Q(x, y, z, t) e^{-i(\Omega t - k_o z)} + c.c.\right] \tag{7}$$

$(\partial\alpha/\partial Q)_S$ and $(\partial\alpha/\partial Q)_{\mathrm{AS}}$ are the hyperpolarizabilities for the Stokes and anti-Stokes waves, respectively, ω_o is the Raman transition frequency, and k_o is the nonpropagating k vector of the material excitation. Γ is the half-width at half-maximum of the Raman linewidth given by $\Gamma = 1/T_2$, Δk is the phase mismatch of the anti-Stokes scattering, m is the effective reduced mass of the material oscillation, and ε_0 is the permitivity of the free space.

The relation between various frequencies and k vectors is

$$\omega_S = \omega_L - \Omega \tag{8a}$$

$$\omega_{AS} = \omega_L + \Omega \tag{8b}$$

$$k_o = k_L - k_S \tag{8c}$$

$$\Delta k = k_S + k_{AS} - 2k_L \tag{8d}$$

The intensity of the various light waves is given by

$$I_{S,L,AS} = \frac{1}{2}(cn\varepsilon_o)|A_{S,L,AS}|^2 \tag{9}$$

Phase matching, which is of central importance in many nonlinear interactions, is automatically satisfied in stimulated Raman scattering because k_o automatically adjusts to satisfy Eq. (8*c*). Phase matching in anti-Stokes scattering through four-wave mixing is not automatic, and phase-matching conditions determine many of the properties of the four-wave mixing anti-Stokes scattering interaction.

These equations describe most of the effects that are commonly encountered in Raman scattering, including amplification, diffraction, growth from noise, multiple Stokes generation, forward and backward interactions, coherent anti-Stokes interactions, and transient and steady-state interactions. Each of these will be discussed individually in subsequent parts of this chapter. In most of these effects the population of the ground state is undisturbed and the approximation $\Delta N = N$ is valid. In some situations involving high-power lasers or resonant interactions, ΔN will vary and Eq. (5*e*) must be used.

Steady-State Stokes Scattering Many of the effects associated with stimulated Raman scattering can be illustrated by considering plane-wave steady-state forward Raman amplification. In this interaction, an incident Stokes wave at frequency ω_S is amplified by a pump wave at frequency ω_L in the geometry of Fig. 2*d*. The plane-wave steady-state Raman amplification equations are obtained from Eq. (5*a* and *b*) by assuming that the time variation of the wave envelopes is slow compared to the dephasing time T_2, allowing the time derivatives to be neglected; by neglecting the transverse spatial derivative; and by assuming that the ground state population is unchanged, allowing Eq. (5*e*) to be neglected and the ground state population $N_o = N$ to be treated as a constant. The resulting equations are

$$\frac{dA_S}{dz} = i\kappa_2 Q^* A_L \tag{10a}$$

$$\frac{dA_L}{dz} = i\frac{\omega_L n_S}{\omega_S n_L}\kappa_2 A_S Q \tag{10b}$$

$$Q^* = -i\frac{1}{4\omega_o m}\left(\frac{\partial\alpha}{\partial Q}\right)\frac{1}{\Gamma + i(\omega_0 - \Omega)}A_L^* A_S \tag{10c}$$

where

$$\kappa_2 = \frac{N\omega_S}{4n_S c}\left(\frac{\partial\alpha}{\partial Q}\right) \tag{11}$$

Equation (10*c*) results from solution of Eq. (5*d*) neglecting the time derivative and the anti-Stokes term.

Steady-state gain If the pump wave intensity is taken as a constant, then Eq. (10*a*) can be solved for the Stokes intensity:

$$I_S(L) = I_S(0)e^{g_{SS}I_L L} \tag{12}$$

where L is the length of the interaction region and g_{SS} is the steady-state Raman gain coefficient, given by

$$g_{SS} = \frac{N\omega_S}{4\Gamma n_S n_L m\omega_o c^2 \varepsilon_o}\left(\frac{\partial\alpha}{\partial Q}\right)^2 \tag{13}$$

This result is also written in the literature in the forms

$$I_S(L) = I_S(0)e^{G_{SS}} \tag{14a}$$

$$I_S(L) = I_S(0)e^{N\sigma_R I_L L} \tag{14b}$$

where

$$G_{SS} = g_{SS}I_L L \tag{15a}$$

is the total steady-state Raman gain and

$$\sigma_R = \frac{\omega_S}{4\Gamma n_S n_L m\omega_o c^2 \varepsilon_o}\left(\frac{\partial\alpha}{\partial Q}\right)^2 \tag{15b}$$

is the stimulated Raman cross section. The gain coefficient is given in terms of the Raman susceptibility as

$$g_{SS} = -\frac{3N\omega_S}{c^2 n_S n_L \varepsilon_o}\chi'' \tag{16}$$

The classical Raman scattering cross section is related to the Raman gain, given in Eq. (13), by

$$g_{SS} = \frac{2Nc^2}{\pi n_S^2 h\nu_S^3 \Delta\nu_R}\frac{\partial\sigma}{\partial\Omega} \tag{17}$$

where $\Delta\nu_R$ is the Raman linewidth [full width at half-maximum (FWHM)] related to the dephasing time as

$$\Delta\nu_R = \frac{1}{\pi T_2} \tag{18}$$

In transparent regions of the spectrum, the Raman cross section scales as ν_S^4 and the Raman gain coefficient scales as ν_S. In dispersive regions of the spectrum, as for example when the pump wavelength is in the ultraviolet, additional frequency variation in the Raman gain arises from the resonant term $1/(\omega_{i0} - \omega_L)$ in the susceptibility.

Initially, stimulated Raman gain coefficients were calculated from measurements of the spontaneous Raman scattering cross section or estimated from measurements of the Raman threshold. The most accurate determinations of Raman gain coefficients are now made with steady-state amplification measurements in the low-gain regime.

The conditions for steady-state Raman amplification are encountered when both the pump and incident Stokes radiation are either cw or narrowband pulses with pulse duration longer than a steady-state time given by[16–19]

$$t_{SS} = G_{SS} T_2 \tag{19}$$

and contain no rapid internal temporal variation, requiring that the linewidths $\Delta\nu_L$ and $\Delta\nu_S$ satisfy the condition

$$\Delta\nu_{L(S)} << \Delta\nu_R \tag{20}$$

Raman linewidths The steady-state Raman gain scales as the medium density and inversely with the Stokes wavelength and the material linewidth. In materials such as some molecular gases, the linewidth is pressure dependent due to pressure broadening with a variation of the form:[20]

$$\Delta\nu_R = \Delta\nu_o + \beta\rho \tag{21}$$

where ρ is the density of the material and $\Delta\nu_0$ is the Raman linewidth at low pressures. In materials that exhibit this behavior, the gain increases at low pressures but levels off at higher pressures, becoming independent of pressure in the limit of high pressures. In hydrogen, for example, the steady-state gain for the Q(1) vibrational mode is effectively independent of pressure for pressures above about 10 atmospheres. The rotational lines in some gases such as hydrogen reach their pressure-broadened limit at lower pressures than do the vibrational lines. As a result, rotational Raman scattering in these materials is more prominent at low pressures, while the vibrational scattering is dominant at higher pressures.

The linewidth for forward scattering in some gases such as hydrogen exhibits Dicke narrowing,[21] in which inelastic collisions cause a narrowing of the linewidth at small but nonzero pressures before the material enters a pressure-broadened regime. The linewidth exhibits a variation in a region above some cutoff pressure of the form:[22]

$$\Delta\nu_R = \frac{A}{\rho} + B\delta\rho \tag{22}$$

This behavior is shown for hydrogen in Fig. 3. Raman frequency shifts for a number of materials are shown in Table 2. Linewidths and gain coefficients for selected materials are given in Table 3. The temperature dependence of the frequency shift parameters for hydrogen is given in Table 4. Temperature dependence of line-broadening parameters for hydrogen and nitrogen is given in Table 5. Formulas for quantities appropriate for Raman scattering in molecular gases are given in Table 6.

Pump depletion If the Stokes intensity becomes large enough, the depletion of the pump wave must be taken into account and Eq. (10*a* and *b*) must be solved together.

The solutions are

$$I_S(z) = \frac{\left[I_S(0) + \dfrac{\omega_S}{\omega_L} I_L(0)\right] \dfrac{\omega_L}{\omega_S} \dfrac{I_S(0)}{I_L(0)} e^{\left[I_L(0) + \frac{\omega_L}{\omega_S} I_S(0)\right] gz}}{1 + \dfrac{\omega_L}{\omega_S} \dfrac{I_S(0)}{I_L(0)} e^{\left[I_L(0) + \frac{\omega_L}{\omega_S} I_S(0)\right] gz}} \tag{23a}$$

$$I_L(z) = \frac{\left[1 + \dfrac{\omega_S}{\omega_L} \dfrac{I_L(0)}{I_S(0)}\right] I_L(0) e^{-\left[I_L(0) + \frac{\omega_L}{\omega_S} I_S(0)\right] gz}}{1 + \dfrac{\omega_S}{\omega_L} \dfrac{I_L(0)}{I_S(0)} e^{-\left[I_L(0) + \frac{\omega_L}{\omega_S} I_S(0)\right] gz}} \tag{23b}$$

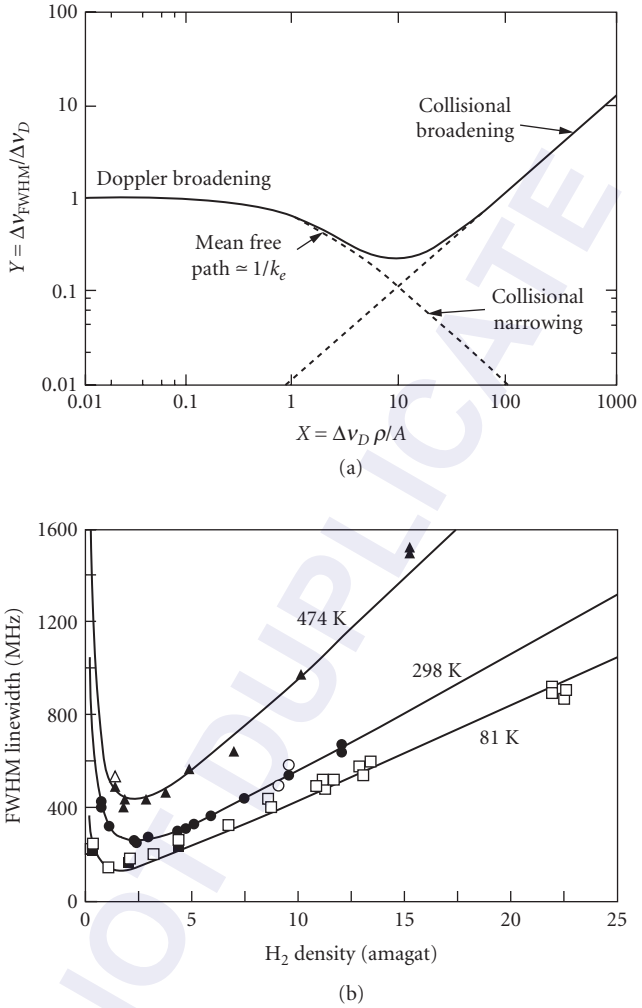

FIGURE 3 Calculated (*a*) and experimental (*b*) variation with pressure of the linewidth of the Q(1) transition in hydrogen gas showing Dicke narrowing and pressure broadening. (*From Ref. 22; copyright 1986 by the American Physical Society.*)

When $I_S(0) << I_L(0)$, the pump depletion solutions simplify to

$$I_S(z) = \frac{I_S(0)e^{I_L(0)gz}}{1+\dfrac{\omega_L}{\omega_S}\dfrac{I_S(0)}{I_L(0)}e^{I_L(0)gz}} \tag{24a}$$

$$I_L(z) = \frac{\left[1+\dfrac{\omega_S}{\omega_L}\dfrac{I_L(0)}{I_S(0)}\right]I_L(0)e^{-I_L(0)gz}}{1+\dfrac{\omega_S}{\omega_L}\dfrac{I_L(0)}{I_S(0)}e^{-I_L(0)gz}} \tag{24b}$$

[b]Product of 3M Co., St. Paul, Minnesota.
[c]1:1 mixture with tetrachloroethylene.
[d]Very weak and diffuse.
[e]Deuterated.
[f]Product of Cargille Laboratories, Cedar Falls, N.J.
[g]Stimulated electronic Raman scattering (SERS).
[h]Generally tunable transitions in the infrared (IR) and far infrared (FIR).

The conditions for exponential Raman amplification can now be identified. In order for the approximate solution of Eq. (12) to be valid, it is necessary for the condition

$$I_S(0)e^{g_{SS}I_L z} << I_L(0) \tag{25}$$

to be satisfied. When the condition in Eq. (25) is not satisfied, the full solution of Eq. (23) [or Eq. (24), if $I_S(0) << I_L(0)$] must be used. The calculated behavior of the pump and Stokes waves in the depletion regime is shown in Fig. 4.

In the limit of large pump depletion, the Stokes intensity becomes

$$I_S(z) = I_S(0) + \frac{\omega_S}{\omega_L} I_L(0) \tag{26}$$

Equation (26) indicates that the maximum energy that can be added to the Stokes wave is reduced from the energy of the pump wave by the fraction (ω_S/ω_L). This ratio is termed the *Manly Rowe fraction*. The difference between the energy given up by the pump wave and that gained by the Stokes wave is taken up by energy deposited in the material excitation. Although complete energy

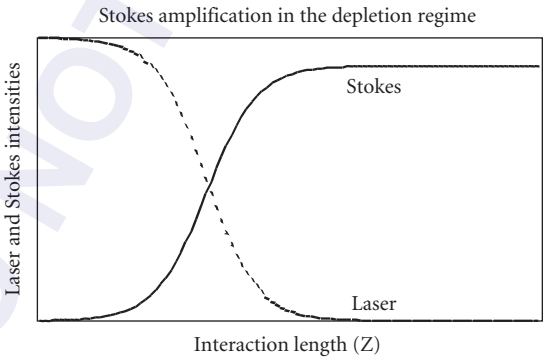

FIGURE 4 Calculated pump and Stokes dependence on interaction length in pump depletion regime.

conversion is not possible with Raman scattering, in principle 100 percent of the pump photons can be converted to the Stokes wave. In practice, high photon conversion efficiency to a single Stokes wave is limited in Raman generators by multiple Stokes or anti-Stokes scattering. High conversion efficiencies are generally obtained in practice in Raman amplifiers or in Raman generators where multiple Stokes generation is unfavorable because of energy level structure. Photon conversion efficiencies in excess of 90 percent have been reported with pulsed lasers.

Gain narrowing Gain narrowing can occur when the Raman gain varies in one of the parameters of the interaction—for example, time, because of pulsed radiation; space, because of a special mode profile; or spectrum, because of use of broadband light; or when a Raman generator is used.

Spectral gain narrowing Spectral gain narrowing is commonly encountered in Raman generators. The spontaneous Stokes emission has the spectral variation of the appropriate Raman transition. For a lorentzian line shape, this variation is given by

$$P_S(\Delta\omega) = P_S(0)\frac{1}{\Delta\omega^2 T^2 + 1} \tag{27}$$

where $\Delta\omega = \omega_o - (\omega_L - \omega_S)$.

This variation with detuning also appears in the Raman gain of Eq. (13) or (15). The Stokes light generated from such a signal can be represented approximately as

$$I(\Delta\omega, L) = I(0)\frac{1}{\Delta\omega^2 T^2 + 1}\exp\left[\frac{G(0)}{\Delta\omega^2 T^2 + 1}\right] \tag{28}$$

The reduced gain at nonzero detunings from the Raman resonance leads to narrowing of the amplified Stokes spectrum relative to the spontaneous spectrum.[22] If we use the quantity $\Delta\omega(G)$ to describe the spectral width (FWHM) of the generated or amplified Stokes light, then the spectral width of the amplified Stokes light is

$$\Delta\omega(G) = \Delta\omega(0)\sqrt{\frac{\ln 2/G(0)}{1 - \ln 2/G(0)}} \tag{29}$$

where $G(0)$ is the gain at the center of the line. If we consider the range of values of G that can be achieved without driving the interaction into saturation to be $23 < G_{\max} < 40$, then the maximum gain narrowing that can be experienced without driving the interaction into saturation is on the order of 5.5 to 7.5.

Photon description The steady-state Raman gain can be recast in the formulation of photon interactions. In this situation, the pump and Stokes intensities are given by

$$I_S = h\nu_S n_S \tag{30a}$$

$$I_L = h\nu_L n_L \tag{30b}$$

where n_S and n_L are the photon flux densities (photons per square centimeter per second), which are related to the corresponding photon densities (photons per cubic centimeter) without dispersion as

$$n_S = N_S c \tag{31a}$$

$$n_L = N_L c \tag{31b}$$

Equations for the growth of pump and Stokes photon densities can be derived from quantum mechanical rate equations as[7]

$$\frac{dN_S}{dt} = K(N_S + 1)N_L \tag{32a}$$

$$\frac{dN_L}{dt} = -K(N_L + 1)N_S \tag{32b}$$

where K is the appropriate transition rate for the Raman interaction.

These can be converted to the spatial gain equations for the photon flux density through the relations

$$\frac{dN_S}{dt}=\frac{dn_S}{dz} \tag{33a}$$

$$\frac{dN_L}{dt}=\frac{dn_L}{dz} \tag{33b}$$

giving

$$\frac{dn_S}{dz}=K(n_S+1)n_L \tag{34a}$$

$$\frac{dn_L}{dt}=-K(n_L+1)n_S \tag{34b}$$

The 1 in Eq. (34*a* and *b*) arises from quantum mechanical commutators and represents spontaneous Raman scattering. When the number of Stokes photons per mode is small compared to unity, the spontaneous Raman emission result is obtained:

$$n_S=Kn_L L \tag{35}$$

where L is the length of the scattering medium. When $n_S >> 1$, the exponential gain of stimulated Raman scattering is obtained:

$$n_S(L)=n_S(0)e^{Kn_L z} \tag{36}$$

where $K = h\nu g_{SS}$. The relation of spontaneous and stimulated Raman scattering will be discussed again later in the chapter.

Transient Effects When the temporal structure of the pump or Stokes wave varies on a time scale comparable to or shorter than the steady-state time given in Eq. (19), transient effects must be taken into account. In this situation, the integrating effects of the material excitation affect the properties of the Raman interaction. Depending on the situation, this can result in reduced Raman gain for pulses of a given intensity or alteration of the coherence properties of the Stokes radiation. Transient effects can occur for short pump pulses or broadband pump and/or Stokes waves.

Pulsed transient effects Transient Raman scattering with pulsed Raman radiation is described by the equations

$$\frac{\partial A_S(z,t)}{\partial z}+\frac{n_S}{c}\frac{\partial A_S(z,t)}{\partial t}=i\kappa_2 Q^*(z,t)A_L(z,t) \tag{37a}$$

$$\frac{\partial A_L(z,t)}{\partial z}+\frac{n_L}{c}\frac{\partial A_L(z,t)}{\partial t}=i\frac{\omega_L n_S}{\omega_S n_L}\kappa_2 Q(z,t)A_S(z,t) \tag{37b}$$

$$\frac{\partial Q^*(z,t)}{\partial t}+\Gamma Q^*=-i\kappa_1 A_S(z,t)A_L^*(z,t) \tag{37c}$$

where

$$\kappa_1=\frac{1}{4\omega_0 m}\left(\frac{\partial\alpha}{\partial Q}\right) \tag{38}$$

and κ_2 is given in Eq. (11).

In the most general form, when pump depletion is involved, these equations must be solved numerically. When pump depletion and dispersion can be neglected, the pump field can be taken as a prescribed function of z and t, and the equations take on the form

$$\frac{\partial A_S(z',\tau)}{\partial z'} = i\kappa_2 Q^*(z',\tau)A_L(\tau) \tag{39a}$$

$$\frac{\partial Q^*(z',\tau)}{\partial \tau} + \Gamma Q^*(z',\tau) = -i\kappa_1 A_S(z',\tau)A_L^*(\tau) \tag{39b}$$

where z' and τ are coordinates moving with the common velocity of the pump and Stokes pulses:

$$z' = z \tag{40a}$$

$$\tau = t - z/c \tag{40b}$$

An integral solution for these equations can be written as[16–19]

$$A_S(z,\tau) = A_S(0,\tau) + \sqrt{\kappa_1\kappa_2 z}\,A_L(\tau)\int_{-\infty}^{\tau} \frac{e^{-\Gamma(\tau-\tau')}A_L^*(\tau')A_S(0,\tau')I_1\left(\sqrt{4\kappa_1\kappa_2 z[p(\tau)-p(\tau')]}\right)}{\sqrt{p(\tau)-p(\tau')}}\,d\tau' \tag{41a}$$

where I_0 and I_1 are modified Bessel functions and

$$p(\tau) = \int_{-\infty}^{\tau} |A_L(\tau')|^2\, d\tau' \tag{42}$$

is proportional to the total pump energy integrated to time τ.

In the extreme transient regime, when $t_p << T_2$, and when the incident Stokes pulse has the same functional form as the pump, an analytic solution for the Stokes intensity can be found:

$$I_S(z,\tau) = I_S(0,\tau)I_0^2(u(z,\tau)) \tag{43}$$

where

$$u(z,\tau) = \sqrt{4\kappa_1\kappa_2 z p(\tau)} = \sqrt{2g_{ss}\Gamma z\int_{-\infty}^{\tau} I_L(\tau')\,d\tau'} \tag{44}$$

and g_{ss} is the steady-state gain coefficient as given in Eq. (13).

When the conditions for Eq. (43) are valid, the solution can be approximated for values of u greater than about 3, corresponding to intensity amplifications of about 24, with the first term in the asymptotic expansion:

$$I_S(z,\tau) = I_S(0,\tau)\frac{e^{2u}}{2\pi u} \tag{45}$$

Quantities other than the instantaneous intensity, such as power density, energy density, or total pulse energy, are useful for characterizing transient Raman measurements done with short pulses. Expressions corresponding to Eq. (45) and for the first and second terms of the expansion of Eq. (43) in u are given in Table 7. The variation of these quantities with the transient gain parameter

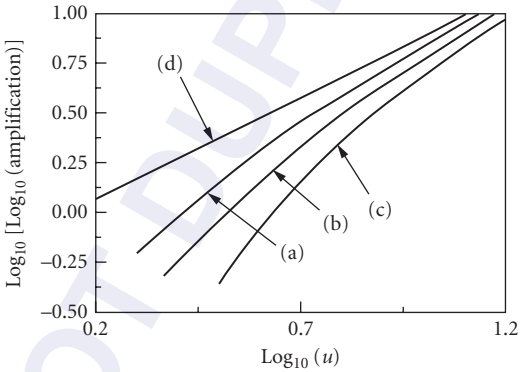

FIGURE 5 Theoretical dependence of the small-signal amplification on the transient gain parameter u for (*a*) the intensity, (*b*) the energy density or power, and (*c*) the energy as predicted by the exact Bessel function solution. The exponential form $\exp(2u)$ is shown for comparison in (*d*). (*From Ref. 19.*)

u is shown in Fig. 5. These solutions are useful for modeling the approximate properties of transient interactions. However, in most practical situations the incident pump and Stokes pulses do not have the same functional form, and the more general integral solution of Eq. (41*a*) must be used for accurate results, taking into account the specific variation of the Stokes amplitude and phase and the relative timing between the incident Stokes and pump pulses. An approximate analytic expression has been given in the limit of high conversion in which the Stokes pulse evolves to an approximate constant form and the pump pulse is described by regular Bessel functions.[79]

In the extreme transient regime $t_p \ll T_2$, growth of the Stokes pulse in the leading part of the pulse is dominated by the Bessel function and the Stokes pulse rises more slowly than the pump. In the trailing part of the pulse, the integral contribution remains fairly constant and the Stokes amplitude

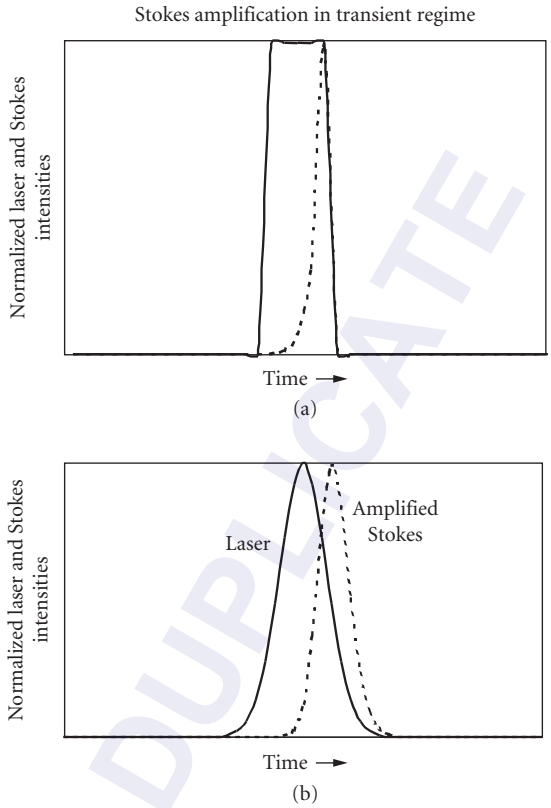

FIGURE 6 Calculated Stokes intensity (dotted line) and pump (solid line) for square pump pulses (*a*) and gaussian pump pulses (*b*). The input Stokes signal was assumed to be constant in both cases.

follows the pump amplitude.[17] The result is that the Stokes pulse is delayed relative to the pump and is shorter than the pump. Ideal square pulses can be shortened by an arbitrarily large factor, while more realistic gaussian pulses can be shortened by about a factor of 2.[17,80] The transient response for square and gaussian pulses is illustrated in Fig. 6. Optimal amplification of the Stokes pulse has been shown to require that the incident Stokes pulse arrive earlier than the pump by about half the pulse duration.[19] An example of experimentally measured transient Raman amplification is given in Fig. 7 along with a theoretical comparison. The theoretical curve was obtained by integrating the square magnitude of Eq. (41*a*) over space and time using the experimentally measured amplitude and phase variations of the incident Stokes pulse. Agreement between experiment and theory was obtained over approximately eight orders of magnitude using one adjustable parameter in the region below pump depletion.

The peak intensity amplification in the extreme transient limit is reduced from the steady-state amplification for pump pulses with the same peak intensity. The intensity amplification grows as the pulse length increases, approaching the steady-state value when $t_p >> G_{ss}T_2$. For pulses of a given energy, the total integrated energy amplification increases steadily as the pulse duration decreases, reaching a maximum in the extreme transient regime.

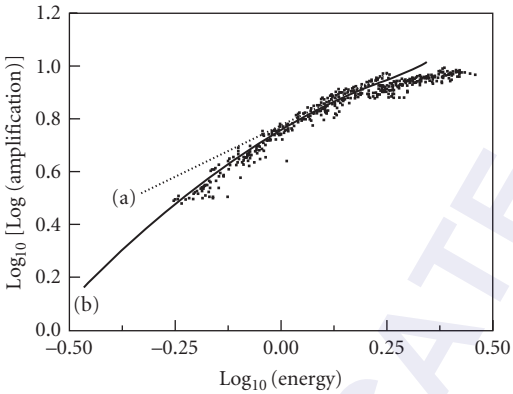

FIGURE 7 Experimental measurement of transient Stokes amplification in hydrogen gas. Solid line includes measured phase and amplitude structure of incident Stokes pulse. Dotted line was calculated for the same conditions, neglecting the phase structure of the incident Stokes pulse. The deviation of the solid curve from the measurements at the high end is due to pump depletion. (*From Ref. 19.*)

Phase pulling There is a tendency for the Stokes phase to become locked to the pump phase in the transient regime. This can be seen from the equations for the phases of the pump and Stokes pulses:[19]

$$\frac{\partial \phi_S}{\partial z} = -\kappa_2 \frac{A_L}{A_S} Q \sin\Phi \tag{46a}$$

$$\frac{\partial \phi_L}{\partial z} = -\kappa_2 \frac{n_S \omega_L}{n_L \omega_S} \frac{A_S}{A_L} Q \sin\Phi \tag{46b}$$

$$\frac{\partial \phi_Q}{\partial z} = -\kappa_1 \frac{A_L A_S}{Q} \sin\Phi \tag{46c}$$

where $\Phi = \phi_S + \phi_Q - \phi_L$.

The phase driving terms vanish for the condition $\Phi = 0$ or π, which are the conditions for optimum power transfer from the pump beam and to the pump beam, respectively. Phase pulling occurs only when $\Phi \neq 0$ or π and when the time derivatives are important. When the time derivatives are not important, ϕ_Q automatically adjusts itself so that the condition $\Phi = 0$ is satisfied. When the transient response is important, phase pulling occurs whenever ϕ_S and ϕ_L have different time dependencies. If the amplitude of the initial Stokes wave is small compared to that of the pump, the phase of the material excitation will be established at some constant value early in the pulse after the material excitation has been amplified above the noise level. At later times the phase of the Stokes wave will be driven according to Eq. (46*a*) so as to establish the condition $\Phi = 0$. In the early stages of the amplification, the corresponding driving term for the pump phase is much smaller, so that the Stokes phase becomes effectively locked to that of the incident pump, with a possible constant offset due to the phase of the material excitation. If the amplitude of the incident Stokes wave is comparable to that of the pump, the phases of all of the waves can evolve during the interaction, and the

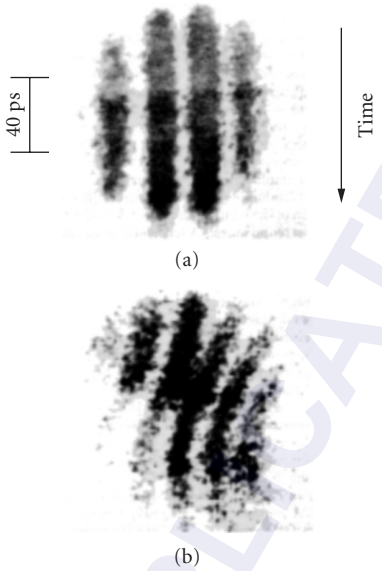

FIGURE 8 Experimental demonstration of phase pulling in transient Raman amplification. The pump beam and incident Stokes beam both carry phase modulation due to the nonlinear index in the laser. The measurement shows time-dependent interference between the incident and amplified Stokes waves. When the incident Stokes phase structure is aligned with the pump phase structure, no phase pulling is observed (*a*). When the incident Stokes pulse is advanced to misalign the pump and Stokes phase structure, phase pulling is observed (*b*). (*From Ref. 19.*)

transfer of power from the pump to the Stokes wave can be affected or greatly reduced. An example of phase pulling in short-pulse Raman interactions is shown in Fig. 8.

Solitons Soliton and other self-similar solutions to the transient Raman equations can also be derived. Using Eq. (37) in the form

$$\frac{\partial A_S}{\partial \xi} = i\kappa_2 A_L Q^* \tag{47a}$$

$$\frac{\partial A_L}{\partial \xi} = i\frac{\omega_L}{\omega_S}\kappa_2 A_S Q \tag{47b}$$

$$\frac{\partial Q}{\partial \tau} + \Gamma Q = i\kappa_1 A_L A_S^* \tag{47c}$$

where κ_1 and κ_2 are given in Eqs. (38) and (11), respectively, and ξ and τ are moving coordinates related to the laboratory coordinates by

$$\xi = z \tag{48a}$$

$$\tau = t - zn/c \tag{48b}$$

In the extreme transient limit, the term with Γ in Eq. (47*c*) can be neglected and the equations can be expressed in normalized quantities as

$$\frac{\partial A_1}{\partial \chi} = -A_2 X \tag{49a}$$

$$\frac{\partial A_2}{\partial \chi} = A_1 X^* \tag{49b}$$

$$\frac{\partial X}{\partial \tau'} = A_1 A_2^* \tag{49c}$$

where $A_1 = \sqrt{\omega_S n_L \kappa_1 / \omega_L n_S \kappa_2}\, A_L$, $A_2 = \sqrt{\kappa_1 / \kappa_2}\, A_S$, and $X = -i\sqrt{\omega_L n_S / \omega_S n_L}\, Q$, $\chi = \kappa_2 \xi$, $\tau' = (\omega_L n_S / \omega_S n_L)\kappa_2 \tau$.

The soliton solutions are:[81]

$$A_1(\chi, \tau) = K(\tau)\left(1 - \frac{a^2}{4\alpha^2}\right)^{1/2} \exp(i\alpha\chi/2)\operatorname{sech}\left\{\left(\alpha^2 - \frac{a^2}{4}\right)^{1/2}\left[\chi - \frac{I(\tau)}{\alpha^2}\right]\right\} \tag{50a}$$

$$A_2(\chi, \tau) = K(\tau)\left(1 - \frac{a^2}{4\alpha^2}\right)^{1/2} \tanh\left\{\left(\alpha^2 - \frac{a^2}{4}\right)^{1/2}\left[\chi - \frac{I(\tau)}{\alpha^2}\right]\right\} \tag{50b}$$

$$X(\chi, \tau) = \left(\alpha^2 - \frac{a^2}{4}\right)^{1/2} \exp(i\alpha\chi/2)\operatorname{sech}\left\{\left(\alpha^2 - \frac{a^2}{4}\right)^{1/2}\left[\chi - \frac{I(\tau)}{\alpha^2}\right]\right\} \tag{50c}$$

where $K^2(\tau) = |A_1(\chi, \tau)|^2 + |A_2(\chi, \tau)|^2$, $I(\tau) = \int_{-\infty}^{\tau} K^2(\tau')d\tau'$ and a and α are arbitrary parameters such that $a > \alpha/2$.

These are transient solutions in which the Stokes pulse is large everywhere except for a dip centered on the position $\chi = I(\tau)/\alpha^2$. The Stokes pulse also has a phase shift at its center. When $a = 0$, the phase shift is π, and when $a \neq 0$, it is smaller. The pump intensity is small except for a narrow region centered about $\chi = I(\tau)/\alpha^2$, and the behavior of the material excitation is similar to that of the pump.

The form of these solutions is opposite to those normally encountered in Raman interactions. Once they are established, they propagate in self-similar form at a speed that is slower than that of the optical pulses, gradually "walking" backward in the optical pulse and eventually disappearing. However, the pulse shapes necessary for soliton formation do not occur in all experimental situations. In normal transient experiments, with the incident Stokes wave weak and the pump strong, the Stokes phase will lock to the pump phase, and solitons cannot develop. They have been produced with a phase shift introduced onto the Stokes pulse externally.[82] In this situation, the soliton pulse of Eq. (50*a*), which is significantly shorter than T_2, evolves from longer pulses and damping plays a central role in its formation. An experimental demonstration of this behavior has been done by Druhl et al.[82] and their results are reproduced in Fig. 9. Conditions for soliton formation can also be encountered in growth from noise using narrowband pump pulses due to phase fluctuations in the zero point starting signal of the Stokes field. Other self-similar solutions are possible as well. Forms with damped oscillations, termed *accordion solutions*, have been described by Menyuk.[83]

Broadband effects Transient effects also appear in the conversion of broadband radiation, which is produced, for example, in many types of pulsed lasers, when the overall pulse duration is longer than T_2 but the pump linewidth is wider than the Raman linewidth:[84–99]

$$t_p >> T_2 \tag{51a}$$

$$\Delta\nu_L > \frac{1}{\pi T_2} \tag{51b}$$

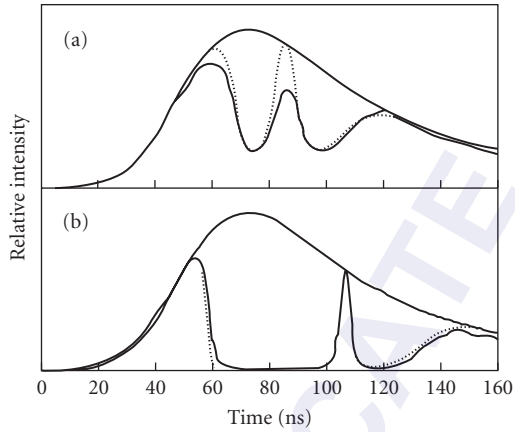

FIGURE 9 Experimental (solid curves) and theoretical (dashed curves) behavior of Raman soliton formation in hydrogen gas showing the input (upper curves) and output (lower curves) pump pulses. The soliton was initiated by introducing a phase shift on the incident Stokes pulse. The overall pulse duration was about 70 ns. The curves in (*b*) were obtained with higher pump power than the curves in (*a*). (*From Ref. 82; copyright 1983 by American Physical Society.*)

The equations for the Stokes and material excitation are as given in Eq. (37). The interaction can be modeled in the time domain, or in the frequency domain using a mode model for the laser radiation.

In the mode picture, the pump and Stokes radiation is modeled as being made up of a combination of randomly phased modes separated by an amount Δ, shown in Fig. 10:

$$E_S = \frac{1}{2}\sum_m A_{S,m} e^{-i(m\Delta t+\phi_{S,m})} e^{-i(\omega_S t - k_S z)} \tag{52a}$$

$$E_L = \frac{1}{2}\sum_m A_{L,m} e^{-i(m\Delta t+\phi_{L,m})} e^{-i(\omega_L t - k_L z)} \tag{52b}$$

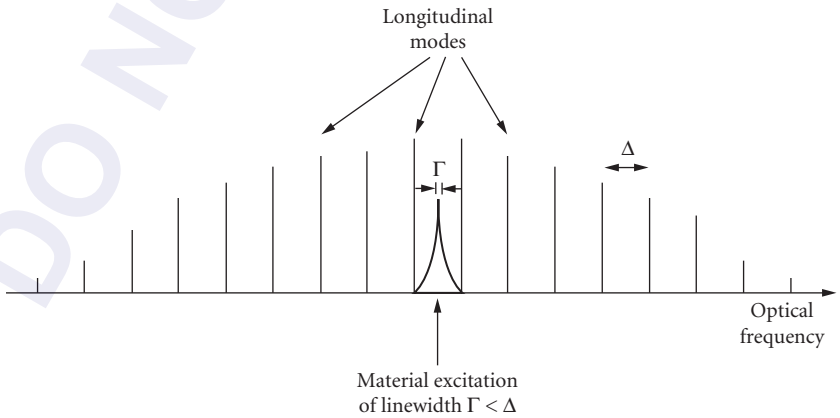

FIGURE 10 Mode structure used to model the broadband Raman scattering. The laser and Stokes modes are spaced by frequency Δ, and, for approximations of Eq. (56), the Raman linewidth is narrower than the mode spacing.

In the absence of dispersion, Eq. (37*c*) can be solved in the frequency domain:

$$Q_k^* = i\kappa_2 \sum_m \frac{A_{L,m+k}^* A_{S,m}}{\Gamma - im\Delta} \tag{53}$$

The average Stokes intensity is given by[93]

$$\bar{I}_S(z) = \bar{I}_S(0) + \bar{I}_S(0) \sum_k \left[\frac{\left| \sum_m A_{L,m+k} A_{S,m}^*(0) \right|^2}{\sum_m A_{L,m} A_{L,m}^* \sum_m A_{S,m}(0) A_{S,m}^*(0)} \right] \left\{ \exp\left[\frac{\bar{I}_L g z}{1 + (k\Delta/\Gamma)^2} \right] - 1 \right\} \tag{54}$$

where the bar symbol denotes the average intensity given by

$$\bar{I}_S = \frac{1}{2} c n_S \varepsilon_o \sum_m A_{S,m}^* A_{S,m} \tag{55}$$

If the longitudinal mode spacing is much wider than the Raman linewidth and the pump linewidth is broad enough, the material excitation Q will not be able to follow the temporal variations of the light due to the mode structure. This is equivalent to the steady-state approximation. Only the $k = 0$ term survives in Eq. (54), and the average intensity is given by

$$\bar{I}_S(z) = \bar{I}_S(0)[1 + R(e^{\bar{g}\bar{I}Lz} - 1)] \tag{56}$$

where R is the field cross-correlation function given by

$$R = \frac{\left| \sum_n A_{S,n}(0) A_{P,n}^*(0) \right|^2}{\sum_n |A_{S,n}|^2 \sum_n |A_{L,n}|^2} \tag{57}$$

In this approximation the double summation in the product of the Stokes and pump waves has collapsed to a single sum. Each Stokes mode m interacts only with the corresponding pump mode m.

When the Stokes field is correlated with the pump, the correlation function is unity and the broadband Stokes light has the same exponential gain as in a narrowband interaction with the same average pump intensity. When the incident Stokes wave is not fully correlated with the pump, the component of the Stokes wave that is correlated with the pump has the largest gain, while Stokes components that are not correlated with the pump ($R = 0$) do not receive amplification.[86–88] The Stokes wave thus becomes more correlated with the pump wave as it is amplified. This behavior is equivalent to the phase-pulling effects discussed earlier. The effective Stokes input signal to the amplifier is reduced by the factor $1/M$, where M is the number of spectral modes of the Stokes wave. However, when growth from noise is considered, the total input Stokes signal increases in proportion to the Stokes bandwidth and the effective Stokes input is one photon per mode independent of the Stokes bandwidth. The threshold for growth from noise is therefore the same for broadband and narrowband interactions.

When dispersion is taken into account,[84,88,96] the exponential gain becomes:

$$G = G_0 - \frac{4\tau_w^2}{G_0 \tau_c^2} \tag{58}$$

where G_0 is the gain without dispersion, τ_c is the correlation time of the laser radiation, defined by $\tau_c = [1/\delta\omega_L^2]^{1/2}$ where $\delta\omega_L^2$ is the variance of the laser spectrum, and τ_w is the beam walkoff time, given by

$$\tau_w = z\Delta(1/v) \tag{59}$$

where $\Delta(1/v) = 1/v_{gL} - 1/v_{gS}$.

Solutions also exist for pump depletion when the mode spacing is large and the dispersion can be neglected:[98]

$$I_S(z)=I_S(0)\frac{1+\alpha}{2}\frac{(1+\beta)\gamma+(1-\beta)e^{-\beta\left[I_L(0)+\frac{\omega_L}{\omega_S}I_{S(0)}\right]gz}}{\gamma+e^{-\beta\left[I_L(0)+\frac{\omega_L}{\omega_S}I_S(0)\right]gz}} \tag{60}$$

where

$$\alpha=\frac{\omega_S}{\omega_L}\frac{I_L(0)}{I_S(0)} \tag{61}$$

$$\beta=\left[\left(I_S(0)-\frac{\omega_S}{\omega_L}I_L(0)\right)^2+4\frac{\omega_S}{\omega_L}I_L(0)I_S(0)R\right]^{1/2}\Bigg/\left[I_S(0)-\frac{\omega_S}{\omega_L}I_L(0)\right] \tag{62}$$

$$\gamma=\frac{(1+\beta)-\alpha(1-\beta)}{\alpha(1+\beta)-(1-\beta)} \tag{63}$$

Broadband Raman scattering has also been analyzed within the time domain.[99] Here the starting point is Eq. (39*a* and *b*). The average of quantities is calculated as

$$\langle f(t)\rangle=\frac{1}{T}\int_t^{t+T}f(t')dt' \tag{64}$$

where the interval T is chosen to be large enough to provide a stationary average of the temporal structure in the signal. Generally speaking,

$$T>>\frac{1}{\Delta\nu_L} \tag{65}$$

If $\Delta\nu_L >> \Delta\nu_R$, again the material excitation cannot follow the time variations of the optical signals and Eq. (39b) can be solved as

$$\langle Q^*(t)\rangle=-\frac{i\kappa_1}{\Gamma}\langle A_S(t)A_L^*(t)\rangle \tag{66}$$

$\langle Q^*(t)\rangle$ is a slowly varying quantity even though $A_S(t)$ and $A_L(t)$ individually have rapid time variations. The equation for the average Stokes intensity is

$$\frac{\partial}{\partial z}\langle A_S(t)A_S^*(t)\rangle=i\kappa_2\langle A_S^*(t)A_L(t)Q^*(t)-A_S(t)A_L^*(t)Q(t)\rangle \tag{67}$$

Making use of the fact that Q is not correlated with A_L or A_S and using Eq. (66) gives

$$\frac{\partial}{\partial z}\langle A_S(t)A_S^*(t)\rangle=i\kappa_2[\langle A_S^*(t)A_L(t)\rangle\langle Q^*(t)\rangle-\langle A_S(t)A_L^*(t)\rangle\langle Q(t)\rangle] \tag{68}$$

$$\frac{\partial}{\partial z}\langle A_S(t)A_S^*(t)\rangle=\frac{\kappa_1\kappa_2}{\Gamma}[\langle A_S^*(t)A_L(t)\rangle\langle A_S(t)A_L^*(t)\rangle] \tag{69}$$

The Stokes intensity is given by

$$\langle I_S(z,t)\rangle=\langle I_S(0,t)\rangle[1+R(e^{g\langle I_L\rangle L}-1)] \tag{70a}$$

where R is the normalized Stokes pump cross-correlation function at the input:

$$R=\frac{\langle A_S(0,t)A_L^*(0,t)\rangle\langle A_S^*(0,t)A_L(0,t)\rangle}{\langle|A_S(0,t)|^2\rangle\langle|A_L(0,t)|^2\rangle} \tag{70b}$$

The result of Eq. (70*a*) has the same form as that of Eq. (56). Akhmanov et al.[99] have discussed the statistical properties of stimulated Raman scattering with broadband radiation under a number of other conditions.

Spectral properties As described, the Stokes radiation produced in a Raman generator in the steady-state regime is expected to be a gain-narrowed version of the spontaneous Stokes emission. Druhl et al.[82] have shown that when narrowband pump radiation is used, the linewidth of the generated Stokes radiation with single pulses varies randomly from the same width as the pump radiation to a value several times greater than the spontaneous Raman linewidth. Only in the ensemble average does the linewidth of the generated Stokes radiation coincide with the gain-narrowed spontaneous line. Individual pulses exhibit considerable spectral structure. This behavior is traceable to the stochastic nature of the damping process, by which the Raman coherence has decreased to $1/e$ of its initial value on a statistical basis.

When broadband radiation is used, the Stokes wave has a tendency to be pulled into correlation with the pump and the Stokes spectral variation matches that of the pump. Duncan et al.[100] have shown that the spectrum of transient spontaneous Raman scattering matches that of the pump.

Anti-Stokes Raman Scattering Anti-Stokes scattering produces a scattered wave at a shorter wavelength than the pump with frequency

$$\omega_{\mathrm{AS}}=\omega_L+\omega_o \tag{71}$$

Anti-Stokes scattering can occur either as a two-photon transition between an upper and lower state, as illustrated in Fig. 1*b*, or as a resonant four-wave mixing process, as illustrated in Fig. 1*c*. The first interaction is directly analogous with the transitions involved in stimulated Stokes Raman scattering that have been discussed in previous sections. For a normal thermal distribution of population, the stimulated version of the anti-Stokes interaction incurs exponential loss. Anti-Stokes components are produced in the spontaneous Raman spectrum. When a population inversion is created between the upper and lower states, the anti-Stokes process has exponential gain, with properties similar to those of normal stimulated Stokes Raman scattering. This interaction, termed as *anti-Stokes Raman laser*, has been described by several authors.[101–104]

Anti-Stokes radiation can also be produced through a four-wave mixing process, illustrated in Fig. 1*c* (Refs. 1, 71, 105–107,107a, 107b). In this interaction, two pump wave photons are converted to one Stokes and one anti-Stokes photon with the relation

$$2\omega_L=\omega_S+\omega_{\mathrm{AS}} \tag{72a}$$

The process is sensitive to the phase mismatch given by

$$\Delta k=k_{\mathrm{AS}}-2k_L+k_S \tag{72b}$$

Usually, four-wave mixing processes are optimized when the phase mismatch is zero. For materials with normal dispersion, this occurs when the Stokes and anti-Stokes waves propagate at angles to the pump light, as shown in Fig. 11. The angles θ_S and θ_{AS} are given in the small angle and small Δk approximation by

$$\theta_S=\sqrt{\frac{2(k_S+k_{\mathrm{AS}}-2k_L)}{k_S(1+k_S/k_{\mathrm{AS}})}} \tag{73a}$$

$$\theta_{\mathrm{AS}}=\sqrt{\frac{2(k_S+k_{\mathrm{AS}}-2k_L)}{k_{\mathrm{AS}}(1+k_{\mathrm{AS}}/k_S)}} \tag{73b}$$

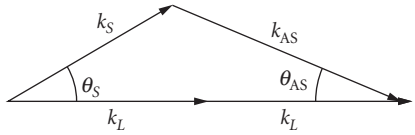

FIGURE 11 *k* vector diagram for coherent anti-Stokes Raman scattering showing laser and Stokes and anti-Stokes propagation directions for a medium with positive dispersion.

When the dispersion of the material is small, so that the refractive indexes at the various wavelengths can be approximated as $n_S = n_L - \delta$ and $n_{AS} = n_L + \delta$, the phase-matching angles are given by

$$\theta_S = \sqrt{\frac{2(\lambda_S - \lambda_{AS})\delta}{n_L \lambda_{AS}(1+\lambda_{AS}/\lambda_S)}} \tag{74a}$$

$$\theta_{AS} = \sqrt{\frac{2(\lambda_S - \lambda_{AS})\delta}{n_L \lambda_S(1+\lambda_S/\lambda_{AS})}} \tag{74b}$$

The plane-wave steady-state equations describing anti-Stokes generation with four-wave mixing are

$$\frac{dA^*s}{dz} = K_3 |A_L|^2 A_S^* + K_2 \left(\frac{\omega_S n_{AS}}{\omega_{AS} n_S}\right) A_L^{*2} A_{AS} e^{i\Delta kz} \tag{75a}$$

$$\frac{dA_{AS}}{dz} = -K_1 |A_L|^2 A_{AS} - K_2 A_L^2 A_S^* e^{-i\Delta kz} \tag{75b}$$

where $K_1 = -iK_{AS}\chi_{AS}$; $K_2 = -iK_{AS}\sqrt{\chi_{AS}\chi_S^*}$; $K_3 = -iK_S\chi_S^*$; χ_S, and χ_{AS} are nonlinear susceptibilities for stimulated growth of the Stokes and anti-Stokes waves, respectively; $K_{S(AS)} = N\omega_{S(AS)}/n_{S(AS)}c$; N is the number density, and $\Delta k = k_S + k_{AS} - 2k_L$ is the phase mismatch.

General solutions have been discussed by Bloembergen and Shen.[105] These have shown that the Stokes and anti-Stokes waves grow as part of a mixed mode with amplitudes

$$A_{Raman} = \begin{pmatrix} A_S \\ A_{AS} \end{pmatrix} \tag{76}$$

One mode is primarily anti-Stokes in character and has exponential loss. The other mode is primarily Stokes in character and has exponential gain given by

$$A_{Raman} = \begin{pmatrix} A_S \\ A_{AS} \end{pmatrix} e^{gz} \tag{77}$$

where g is given by

$$g = \mathrm{Re}\{(1/2)(K_3 - K_1)|A_L|^2 - (i/2)[\Delta k^2 + 2i\Delta k(K_3 + K_1)|A_L|^2 - (K_1 - K_3)^2 |A_L|^4]^{1/2}\} \tag{78}$$

The exponential gain for the coupled mode is zero for exact phase matching, $\Delta k = 0$, and increases for nonzero Δk until it reaches its full decoupled value for $\Delta k > 2g_{SS}$, where g_{SS} is the steady-state gain

coefficient. For nonzero Δk, the maximum gain occurs at small detunings from exact resonance. The ratio of anti-Stokes to Stokes intensities is given by

$$\frac{|A_{AS}|^2}{|A_S|^2}=\left(\frac{\omega_S^2}{c^2 k_{Sz}}\right)^2 |\chi_S|^2 |A_L|^4\,\Delta k^{-2} \tag{79}$$

Solutions for phase-matched conditions have been discussed by Duncan et al.[106] They have the form

$$A_S(z)=A_S(0)\left\{\frac{K_1}{K_1-K_3}-\left(\frac{K_3}{K_1-K_3}\right)\exp[-(K_1-K_3)|A_L|^2 z\right\}$$
$$+\left(\frac{\omega_S n_{AS}}{\omega_{AS} n_S}\right)\left(\frac{K_2}{K_1-K_3}\right)A_{AS}(0)\left\{1-\exp[-(K_1-K_3)|A_L|^2 z]\right\} \tag{80}$$

$$A_{AS}(z)=A_{AS}(0)\left\{\left(\frac{K_1}{K_1-K_3}\right)\exp[-(K_1-K_3)|A_L|^2 z]-\left(\frac{K_3}{K_1-K_3}\right)\right\}$$
$$-\left(\frac{K_2}{K_1-K_3}\right)A_S(0)\left\{1-\exp[-(K_1-K_3)|A_L|^2 z]\right\} \tag{81}$$

Initially the Stokes and anti-Stokes amplitudes grow linearly in z with opposite phases. The growth slows down as z increases and the condition

$$\frac{A_{AS}(z)}{A_S(z)}=-\frac{K_2}{K_1}=\sqrt{\frac{\chi_S^*}{\chi_{AS}}} \tag{82}$$

is approached asymptotically in the limit of large z. This ratio is approximately equal to unity except when there is strong resonant enhancement of the anti-Stokes susceptibility. The maximum value of the anti-Stokes amplitude is

$$A_{AS,\max}(z)=-A_{AS}(0)\frac{K_3}{K_1-K_3}-A_S(0)\frac{K_2}{K_1-K_3} \tag{83a}$$

$$\approx -A_{AS}(0)\frac{\omega_S}{\omega_{AS}-\omega_S}-A_S(0)\frac{\omega_{AS}}{\omega_{AS}-\omega_S} \tag{83b}$$

where the second of these relations is approximately valid when $\chi_S^* \approx \chi_{AS}$ and $n_{AS} \approx n_S$.

If the initial Stokes amplitude is small, as for example in a Raman generator, the limiting value of the anti-Stokes amplitude will be small and the predominant anti-Stokes generation will occur at small but finite phase mismatches. For Raman generators, the anti-Stokes radiation is produced in a cone about the phase-matching angle with a dark ring at exact phase matching. Experimental limitations can make the phase-matching minimum difficult to observe, but measurements of the dark ring in the phase-matching cone have been reported, as shown in Fig. 12. If the incident Stokes intensity is comparable to the pump intensity, considerable conversion can be made to the anti-Stokes wave at exact phase matching.[107]

In spectroscopic applications of CARS,[108] the usual input condition is for approximately equal pump and Stokes amplitudes with no anti-Stokes input. These experiments are usually performed under conditions of low exponential gain well below the limiting conditions of Eq. (82). Under these conditions, the anti-Stokes generation is maximized at the phase-matching conditions.

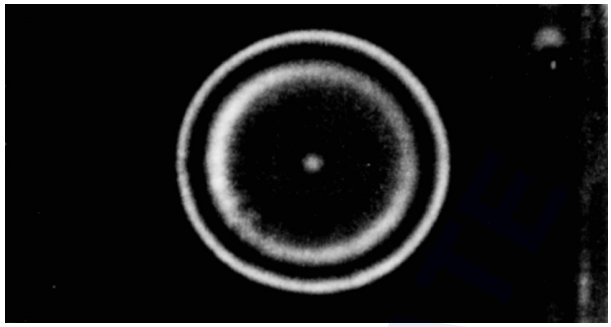

FIGURE 12 Photograph of the far field of the anti-Stokes emission pattern in hydrogen gas at a pressure of 14 atm. The anti-Stokes radiation is emitted in a cone about the phase-matching angle. The dark ring in the center of the cone is due to parametric gain suppression. (*From Ref. 106.*)

Growth from Noise The most common configuration for Stokes Raman interactions is a Raman generator in which only a pump signal is provided at the input, as shown in Fig. 1*a*. The Stokes wave is generated in the interaction. The Stokes generation process can be viewed as one in which the effective Stokes noise at the beginning of the cell is amplified in the stimulated Raman interaction as described in the previous sections.

Classically, the Stokes noise is considered as arising from the spontaneous Raman scattering that is produced at the beginning of the cell. If we consider the effective spontaneous Stokes radiation that serves as a source for amplification to be that generated in the first *e*-folding length of the Raman generator, the Stokes intensity at the output is

$$I_S = \frac{\partial \sigma}{\partial \Omega} d\Omega N A (e^{N\sigma I_L L} - 1) \tag{84}$$

where N is the number density of the medium, A is the cross-sectional area, and $d\Omega$, is the solid angle of the gain column.

The growth from noise has been modeled more rigorously in terms of quantum fluctuations of the Stokes field amplitude and material excitation.[97,100,109–112] In this treatment, the Stokes and material oscillators are described by quantum mechanical creation and annihilation operators while the pump field is treated classically. The equations for the Stokes and material oscillators are:[97]

$$\frac{\partial}{\partial z} \hat{A}_S^{(-)}(z,\tau) = i\kappa_2 A_L(t) \hat{Q}^{(+)}(z,\tau) \tag{85a}$$

$$\frac{\partial}{\partial \tau} \hat{Q}^{(+)}(\tau) + \Gamma \hat{Q}^{(+)}(\tau) = -i\kappa_1 A_L^*(\tau) \hat{A}_S^{(-)}(z,\tau) + \hat{F}^{(+)}(z,\tau) \tag{85b}$$

where the symbol ^ indicates a quantum mechanical operator, the symbols (−) and (+) indicate creation and annihilation operators, respectively, and $\hat{F}$ is a Langevin operator that ensures the correct longtime behavior of Q.

The initial fluctuations of the Stokes and material oscillators satisfy the conditions:

$$\langle \hat{A}_S^{(+)}(0,t) \hat{A}_S^{(-)}(0,t') \rangle = \frac{2\hbar\omega_S}{cn_S\varepsilon_o a} \delta(t-t') \tag{86a}$$

$$\langle \hat{A}_S^{(-)}(0,t) \hat{A}_S^{(+)}(0,t') \rangle = 0 \tag{86b}$$

$$\langle \hat{Q}^{(+)}(z,0)\hat{Q}^{(-)}(z',0)\rangle = \frac{1}{\rho}\delta(z-z') \tag{86c}$$

$$\langle \hat{Q}^{(-)}(z,0)\hat{Q}^{(+)}(z',0)\rangle = 0 \tag{86d}$$

$$\langle \hat{F}^{(+)}(z,t)\hat{F}^{(-)}(z',t')\rangle = \frac{2\Gamma}{\rho}\delta(z-z')\delta(t-t') \tag{86e}$$

$$\langle \hat{F}^{(-)}(z,t)\hat{F}^{(+)}(z',t')\rangle = 0 \tag{86f}$$

where a is the cross-sectional area of the beam. The average Stokes intensity is given by the expectation of the normally ordered number operator:

$$I_S(z,\tau) = \frac{1}{2}cn_S\varepsilon_o\langle A_S^{(-)}(z,\tau)A_S^{(+)}(z,\tau)\rangle \tag{87}$$

The formal solution is[97]

$$\begin{aligned}\hat{A}_s^{(-)}(z,\tau) &= \hat{A}_s^{(-)}(0,\tau)\\ &+(\kappa_1\kappa_2 z)^{1/2}A_L(\tau)\int_{-\infty}^{\tau}d\tau'\hat{A}_s^{(-)}(0,\tau')A_L^*(\tau')e^{-\Gamma(\tau-\tau')}\frac{I_1(\{4\kappa_1\kappa_2 z[p(\tau)-p(\tau')]\}^{1/2})}{[p(\tau)-p(\tau')]^{1/2}}\\ &-i\kappa_2 A_L(\tau)e^{-\Gamma\tau}\int_0^z dz'\hat{Q}^{+}(z',0)I_0(\{4\kappa_1\kappa_2(z-z')p(\tau)\}^{1/2})\\ &-i\kappa_2 A_L(\tau)\int_{-\infty}^{\tau}d\tau'\int_0^z dz'\hat{F}(z',\tau')e^{-\Gamma(\tau-\tau')}I_0(\{4\kappa_1\kappa_2(z-z')[p(\tau)-p(\tau')]\}^{1/2})\end{aligned} \tag{88}$$

The Stokes intensity obtained from use of Eq. (87) is

$$\begin{aligned}I_S(z,\tau) = \frac{1}{2}cn_S\varepsilon_o|\kappa_2 A_L(\tau)|^2 z\{e^{-2\Gamma\tau}(I_o^2[4\kappa_1\kappa_2 zp(\tau)]^{1/2})-I_1^2([4\kappa_1\kappa_2 zp(\tau)]^{1/2})\\ +2\Gamma\int_{-\infty}^{\tau}e^{-2\Gamma(\tau-\tau')}(I_o^2(4\kappa_1\kappa_2 z[p(\tau)-p(\tau')])^{1/2})-I_1^2(\{4\kappa_1\kappa_2 z[p(\tau)-p(\tau')]\}^{1/2})]d\tau'\}\end{aligned} \tag{89}$$

In this formulation, only the third and fourth terms of Eq. (88) survive because the expectation values on the right side are taken over the initial state, which contains no quanta in either the Stokes or molecular fields. The first and second terms involve a Stokes annihilation operator acting on the Stokes ground state and return zero. The third term returns a nonzero result because it involves a creation operator acting on the molecular ground state, as discussed by Raymer.[97] In this treatment the Stokes light is generated entirely from fluctuations in the material oscillators, while the material excitation is generated from zero-point fluctuations in the material oscillators.

In the extreme transient regime, this result reduces to

$$I_S(z,\tau) = \frac{1}{2}\Gamma g_{SS}I_L(\tau)z\left\{I_o^2((2g_{SS}zI_L\Gamma\tau)^{1/2})-I_1^2((2g_{SS}zI_L\Gamma\tau)^{1/2})\right\} \tag{90}$$

Comparison of this result with that of Eq. (43) shows a different functional dependence on the modified Bessel functions, which reflects the effects of buildup of the signal from the distributed noise source.

In the steady state, Eq. (89) reduces to

$$I_S(z,\tau=\infty) = \frac{1}{2}\Gamma g_{ss}I_L z[I_o(g_{ss}I_L z/2)-I_1(g_{ss}I_L z/2)]e^{g_{ss}I_L z/2} \tag{91}$$

An alternative analysis for transient scattering has been presented using antinormal ordering of the creation and annihilation operators for the intensity.[109] In this formalism, the zero-point term must be subtracted explicitly. The intensity is given by

$$I_S(z,\tau)=\frac{1}{2}cn_s\varepsilon_o\left\{\langle\hat{A}_S^{(+)}(z,\tau)\hat{A}_S^{(-)}(z,\tau)\rangle-\langle\hat{A}_S^{(-)}(0,\tau)\hat{A}_S^{(+)}(0,\tau)\rangle\right. \tag{92}$$

The Stokes intensity is given by

$$\begin{aligned}I_S(z,\tau)=\frac{1}{2}cn_s\varepsilon_o\Big\{&\kappa_2^2|A_L(\tau)|^2\iint dz'dz''I_o(\sqrt{4\kappa_1\kappa_2(z-z')p(\tau)})I_o(\sqrt{4\kappa_1\kappa_2(z-z'')p(\tau)})\\&\times\langle\hat{Q}^{(-)}(z',0)\hat{Q}^{(+)}(z'',0)\rangle+\kappa_1\kappa_2 z|A_L(\tau)|^2\iint I_1(\sqrt{4\kappa_1\kappa_2 z[p(\tau)-p(\tau')]})\\&\times I_1(\sqrt{4\kappa_1\kappa_2 z[p(\tau)-p(\tau'')]})/\sqrt{[p(\tau)-p(\tau')][p(\tau)-p(\tau'')]}\\&\times A_L(\tau')A_L^*(\tau'')\langle\hat{A}_S^{(+)}(0,\tau')\hat{A}_S^{(-)}(0,\tau'')\rangle d\tau'd\tau''+\sqrt{\kappa_1\kappa_2 z}\Big\{(A_L^*(\tau)-\int_{-\infty}^{t}A_L(\tau')\langle\hat{A}_S^{(+)}(0,\tau')\hat{A}_S^{(-)}(0,\tau)\rangle\\&\times I_1(\sqrt{4\kappa_1\kappa_2 z[p(\tau)-p(\tau')]})/\sqrt{p(\tau)-p(\tau')}d\tau'+A_L(\tau)\int_{-\infty}^{t}A_L^*(\tau')\\&\times\langle\hat{A}_S^{(+)}(0,\tau)\hat{A}_S^{(-)}(0,\tau')\rangle I_1(\sqrt{4\kappa_1\kappa_2 z[p(\tau)-p(\tau')]}/\sqrt{p(\tau)-p(\tau')}\,d\tau')\}\end{aligned} \tag{93}$$

Here the first term in Q is 0 because it represents an annihilation operator operating on the ground state. Further analysis shows that this result is identical to the one in Eq. (90). The second term gives the transient stimulated Raman signal, and the last two terms in brackets describe spontaneous Raman scattering. In this formalism, the Stokes wave is started by its own zero-point motion and does not involve the zero-point motion of the molecular oscillators. The zero-point motion of the molecular oscillators is responsible for the initiation of the molecular excitation. Further analysis has shown that the Stokes signal can be viewed as arising from quantum fluctuations of the Stokes radiation,[97] the material oscillator,[109] or a combination of both.[100]

The effective Stokes noise amplitude corresponds to one Stokes photon at the input of the generator. This result is expected for this model, which assumes plane wave propagation, effectively assuming a single mode in the amplifier. In a more general case, the effective Stokes noise level will be one Stokes photon for each temporal and spatial mode of the amplifier. The number of spatial modes is given by the square of the effective Fresnel number of the amplifier:[113]

$$N_{\text{spatial modes}}=F^2 \tag{94}$$

where

$$F=\frac{A}{\lambda L} \tag{95}$$

where A is the effective area of the gain region and L is the interaction length. Because of spatial gain narrowing, the effective area of the generator can be significantly less than the nominal diameter of the pump beam and can depend on the gain level. The number of temporal modes depends on the relation of the pump pulse duration to the dephasing time T_2. A single temporal mode will be present when $t_p \ll T_2$. For longer pulses, the number of temporal modes has been modeled as[110]

$$N_{\text{temporal modes}}=1, \quad t_p<t_{\text{ss}} \tag{96a}$$

$$N_{\text{temporal modes}}=\frac{t_p}{G_{\text{ss}}T_2}, \quad t_p>t_{\text{ss}} \tag{96b}$$

or alternatively as[114]

$$N_{\text{temporal modes}} = \sqrt{\frac{ln2/G_{ss}}{1-ln2/G_{ss}}}\,\frac{t_p}{\pi T_2} \tag{97}$$

The first of these derives the number of temporal modes from the steady-state time of Eq. (19) and the second from the gain-narrowing formula of Eq. (29).

Raman threshold Generation of first Stokes radiation from noise in a single-pass generator passes smoothly from exponential amplification of noise to depletion of the pump radiation without a true threshold. Thresholdlike behavior has been reported in some situations but has been due to multimode structure of the radiation or secondary reflections. A Raman threshold is, however, commonly associated with a single-pass gain. This is done by assigning the threshold to a pump value (intensity or energy) at which the Stokes signal from a Raman generator is an arbitrary fraction of the incident pump (typically of the order of 1 percent). At this level, pump saturation is generally not important, but for higher pump powers the process rapidly transitions to saturation. Thus, the concept of Raman threshold in Raman generators is reasonably practical, if not technically precise. The gain that is required to reach threshold depends on the number of noise modes present in the generator. For typical geometries of long, narrow interaction lengths, the Raman gain at threshold is of the order of e^{23} to e.[40] Raman amplifiers are typically operated at gain levels below threshold. Stable amplifier gains of the order of e^{19} are achievable.

Quantum fluctuations Macroscopic manifestations of the stochastic nature of the Raman initiating fluctuations have been reported in spatial fluctuations of the output Stokes intensity profile, in the pointing of the Stokes beam, and in the spectral and temporal structure of the Stokes signal generated by narrowband radiation.[110,111,115–120] The stochastic nature of the starting signal is manifest in the pulse energy statistics of Raman generators operated below threshold. In this regime, the statistical distribution of the Stokes pulse energy is of the form $p(W_S)=\exp\{-W_S/\langle W_S\rangle\}$, where W_S is the energy of a Stokes pulse and $\langle W_S\rangle$ is the average energy over an ensemble. When the Raman generator is operated below threshold, energy of the output pulses fluctuates in accordance with this distribution. As the generator approaches pump depletion, the Stokes pulse energy distribution approaches one that is peaked about the average value. Statistical distributions of pulse radiation in short pulse experiments show exponential behavior characteristic of stochastic input for gains below threshold, and a gradual evolution to coherent behavior as saturation is approached.

Competition of the quantum noise with real Stokes signals in Raman amplifiers at the quantum level has been reported by Duncan et al.[113] Their results show experimentally that the effective initiating signal is consistent with a noise level of one photon per mode of the amplifier. When the incident Stokes signal exceeds the noise level of one photon per mode by a sufficient amount, the fluctuations are effectively suppressed in both the spatial profile and the pulse energy statistics. An example of the evolution of the amplified Stokes signal from one dominated by quantum noise to one dominated by the coherent Stokes input signal in the image of bars in a resolution chart is shown in Fig. 13.

Multiple Stokes Generation Once a significant signal is produced in the first Stokes wave, it can serve as a pump wave for a second Raman process, generating a second Stokes wave at

$$\omega_{2S} = \omega_S - \omega_o = \omega_L - 2\omega_o \tag{98}$$

This usually occurs at a pump power such that significant Stokes conversion occurs within the first half of the Raman cell, allowing generation of the second Stokes wave in the last part of the cell. Once the first Stokes wave is generated, the second Stokes radiation can also arise from a four-wave mixing interaction of the form

$$\omega_{2S} = 2\omega_S - \omega_L \tag{99a}$$

which has properties similar to the anti-Stokes four-wave mixing interaction.

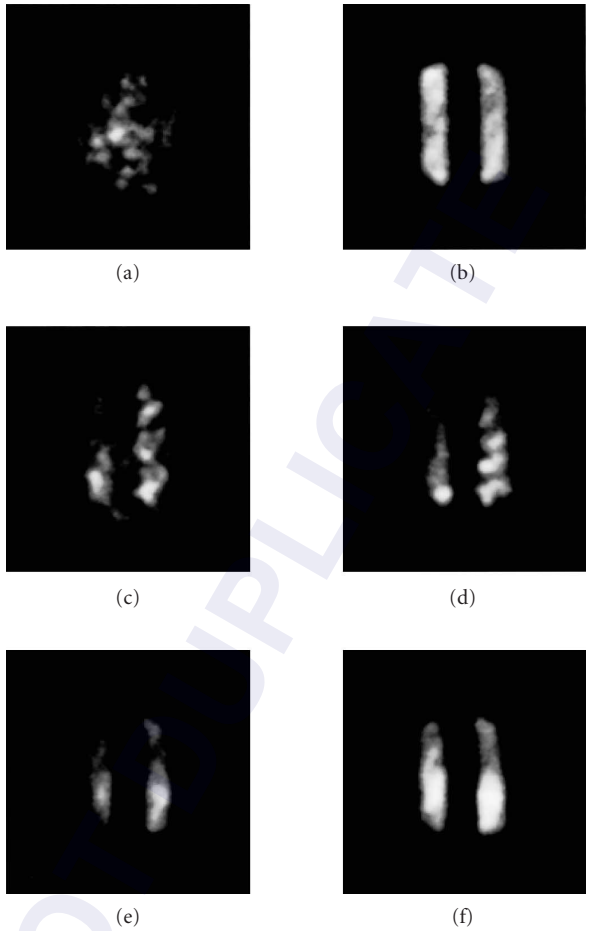

FIGURE 13 Images of bars in a resolution chart from a Stokes amplifier with amplification of 1.4×10^4 for different levels of incident Stokes energy, showing effects of competition between incident Stokes energy and quantum noise, (*a*) Incident Stokes wave blocked. (*b*) Incident Stokes wave. (*c*) 210 seed Stokes photons, camera sensitivity 1. (*d*) 800 seed Stokes photons, camera sensitivity 0.3. (*e*) 3.2×10^4 seed Stokes photons, camera sensitivity 7.4×10^{-3}. (*f*) 1.5×10^{10} seed Stokes photons, camera sensitivity 3.2×10^{-8}. (*From Ref. 121.*)

The four-wave mixing interaction is a coherent one and will produce second Stokes radiation with coherent statistics when the first Stokes radiation has saturated the pump. The second Stokes radiation generated from stimulated scattering will exhibit the stochastic behavior characteristic of growth from quantum noise. The relative importance of the two sources of second Stokes radiation is affected by the phase mismatch for the four-wave mixing interaction and depends on the density of the material.

Still higher pump powers can result in conversion to third or higher Stokes orders. Each of the orders involves a frequency shift due to the same material transition, rather than higher excitation of the material system. In most materials, conditions for multiple Stokes generation are sufficient

to produce significant amounts of anti-Stokes energy through the four-wave mixing interaction. Multiple-order anti-Stokes energy can also be generated using various combinations of Stokes and anti-Stokes orders of the form

$$\omega_{n\mathrm{AS}} = \omega_{mS} - \omega_{(m+1)S} + \omega_{(n-1)\mathrm{AS}} \tag{99b}$$

where n and m are orders of Stokes and anti-Stokes radiation and $\omega_{0S} = \omega_{0\mathrm{AS}} = \omega_L$. Multiple-order Stokes radiation can also be produced through four-wave mixing involving similar terms.

An ideal progression of Raman scattering through multiple Stokes modes is shown in Fig. 14*a*. Such a progression is seldom seen in practice because of the onset of anti-Stokes and four-wave mixing interactions. Higher-order Stokes energy can be suppressed through choice of resonant structure in the material or through use of high pressures that suppress four-wave mixing through disruption of phase matching. An example of second Stokes generation in hydrogen is shown in Fig. 14*b*, in which initiation through four-wave mixing occurs at low powers and initiation through a stimulated process, evidenced by the wide scatter of points, occurs at higher powers.[122]

FIGURE 14 (*a*) Theoretical calculation of multiple Stokes generation for gaussian pulses. (*From Ref. 2.*) (*b*) Second Stokes generation (lower curve) in hydrogen at 1600 psi showing growth from four-wave mixing at low pump energies and the transition to stimulated emission from quantum fluctuations at higher pump energies. The first Stokes wave is shown in the upper curve. (*From Ref. 122.*)

Focused Beams The effects of focusing are described by the spatial derivative in Eq. (5*a* and *b*). When the pump intensity varies with *z*, the gain must be integrated over the interaction length. For steady-state interactions, the Stokes intensity takes the form

$$I_S(r,z)=I_S(r,0)\exp\left[g\int_0^L I_L\,dz\right] \tag{100}$$

The profile of a gaussian beam is described by a $1/e$ field radius w, given by

$$w(z)=w_o\sqrt{1+\xi^2} \tag{101}$$

where w_o is the radius of the beam waist, $\xi = 2z/b$, and $b=2\pi w_o^2/\lambda$ is the confocal parameter. When $b >> L$, the pump beam is collimated over the interaction length and the primary effect of the gaussian profile is to produce gain narrowing, effectively confining the Stokes intensity near the beam axis. When the beam is tightly focused, so that $b << L$, the integrated gain is independent of the interaction length and depends only on the total pump power:

$$G=g\int I_L\,dz=g4P/b\lambda \tag{102}$$

where P is the total pump power. Amplification or generation with focused beams can result in changes of the Stokes beam divergence and displacements of the apparent source point for divergence of the Stokes beam.

Backward Raman Scattering Stimulated Raman scattering also occurs in the backward direction, for which the Stokes and pump waves travel in opposite directions.[2,69] This type of interaction is much more dependent on the geometry and the laser linewidth than the forward interaction. Backward interaction can involve growth from noise (Fig. 2*b*) or amplification (Fig. 2*d*). Generally, it occurs for sufficiently narrow line widths that the coherence length of the radiation is longer than the interaction length. One of the characteristic differences of the backward interaction is that the growing Stokes wave continually interacts with undepleted pump as it propagates. Thus, for conditions in which the Stokes wave can grow to saturate the Raman interaction, the Stokes wave continually experiences the full pump intensity rather than a continually decreasing intensity as in the forward direction. One consequence of this property is that the intensity of the backward Stokes pulse can grow to be much higher than the initial pump intensity, while the pulse duration decreases, producing pulse compression, one of the common applications for backward Raman scattering.[69] For this application, the optimal duration for the pump pulse is twice the length of the Raman cell. The Stokes wave grows to depletion level in the first half of the pump pulse and depletes the pump in the second half. Factors affecting pulse compression have been discussed in Ref. 69, where designs of systems to give a factor-of-10 shortening were described.

Backward scattering also results in Stokes pulses of higher spatial quality than are obtained in the forward direction. If the backward Stokes wave depletes the pump pulse too much before it travels an entire cell length, the initiating signal for Stokes radiation in subsequent parts of the pulse can be suppressed and oscillations can result.[123]

Polarization Dependence The Raman gain for various polarizations depends on the symmetry of the Raman transition and is governed by the depolarization ratio. For many materials and transitions, the maximum gain occurs for pump and Stokes polarizations that are linear and parallel. For other types of transitions—for example, rotational transitions in diatomic molecules—circular polarization is preferred with the pump and Stokes waves polarized in the opposite sense. The relative gains for various polarization combinations are shown in Table 8.[124]

The earliest and most common application of stimulated Raman scattering is the production of coherent sources at wavelengths different from those of the pump laser. Prior to the introduction of tunable lasers, this was one of the few methods available for obtaining coherent radiation at any but a small number of wavelengths at which fixed-frequency lasers existed. This application remains an important one today for extending the versatility of tunable lasers, and for generation of radiation

TABLE 8 Polarization Dependence of Relative Gain for SRS

	Laser Polarization	Stokes Polarization	Relative Gain
Rotational	Linear	Linear, parallel	1
scattering,	Linear	Linear, perpendicular	0.75
linear	Circular	Circular, same sense	0.25
molecules	Circular	Circular, opposite sense	1.5

at wavelengths required for specific applications such as the eye-safe region around 1.5 *M*m. Other applications of Raman scattering include Raman beam cleanup, pulse compression, time-gated imaging, and coherent spectroscopy. Two of these are described in the following text.

Coherent Spectroscopy Several Raman interactions are used for coherent spectroscopy.[108,125] These interactions have the advantage of producing a stronger signal than incoherent spectroscopy under some conditions. These advantages occur primarily when prominent Raman modes are studied in pure materials or the dominant constituent of a mixture. A summary of interactions used in coherent spectroscopy along with names given to them is given in Table 9. The most common of these is coherent anti-Stokes Raman scattering (CARS). A typical CARS spectroscopic interaction is shown in Fig. 11. Incident light at both the pump and Stokes wavelengths is supplied. The anti-Stokes signal is measured as the wavelength of the Stokes light is varied. The spectral structure is recorded as the frequency difference $\omega_L - \omega_S$ is tuned through Raman resonances of the material.

The anti-Stokes intensity is given in a steady-state plane-wave approximation as

$$I_{AS} = |\chi_R + \chi_{NR}|^2 I_L^2 I_S \tag{103}$$

where χ_R is the Raman susceptibility that carries the resonance and χ_{NR} is the nonresonant nonlinear susceptibility due to electronic or other transitions in the medium. The Raman susceptibility exhibits resonant behavior as $\omega_L - \omega_S$ is tuned through the Raman resonance ω_o, while the nonresonant susceptibility is generally constant through the resonance region. The wavelength variation of the anti-Stokes intensity reflects the influence of the interference between the resonant and nonresonant susceptibilities. In particular, the anti-Stokes intensity goes through zero when $\chi_R = -\chi_{NR}$, which always occurs on the high-frequency side of the resonance. Depending on the situation, the anti-Stokes intensity can exhibit a resonant-like peak if χ_{NR} is small compared to χ_R at the resonance or a dispersive-like behavior if χ_{NR} is larger than χ_R. Intermediate behavior between these two extremes is also possible depending on the relative magnitudes of χ_R and χ_{NR}. Dispersive-like behavior can occur for relatively weak Raman transitions, or for Raman transitions in materials that are minor constituents in mixtures. An example of CARS spectral behavior for various conditions is shown in Fig. 15.

Time-Gated Imaging Raman amplification has also been applied to time-gated imaging to suppress background light in highly scattering materials, for example biological tissue or materials such as ceramics.[127–129] Time gating with Raman scattering can be done with either short pulses, in which case the gate time is comparable to the pulse duration, or with broadband radiation, in which case the time gate is determined by the coherence time of the pulse. In pulsed gating, only that part of the signal that overlaps with the pump pulse in time is amplified, and light that is delayed through multiple scattering is suppressed. In coherence gating, only the Stokes components that are coherent with the pump are amplified, and components that

TABLE 9 Raman Interactions Used for Coherent Spectroscopy

Interaction	Frequency Relations	Measured Quantity
Coherent anti-Stokes Raman scattering (CARS)	$\omega_{AS} = 2\omega_L - \omega_S$	Anti-Stokes power
Coherent Stokes Raman spectroscopy (CSRS)	$\omega_S = \omega_L - \omega_o$	Amplified Stokes power
Raman-induced Kerr effect spectroscopy (RIKES)	$\omega_S = \omega_L - \omega_o$	Stokes power in orthogonal polarization component

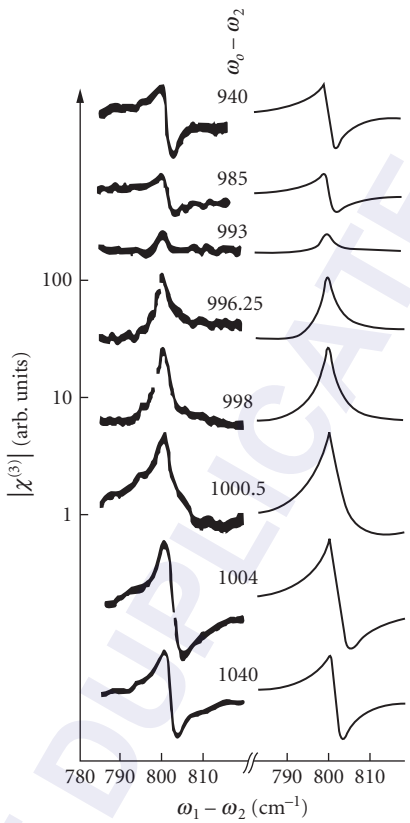

FIGURE 15 Signal from coherent anti-Stokes Raman scattering showing variation of line shape due to interference of Raman and nonresonant susceptibilities. (*From Ref. 126; copyright 1976 by American Physical Society.*)

are decorrelated because of multiple-path scattering are suppressed. Gate contrasts of the order of 10^9 are possible with pulse gating, while contrasts of the order of 10^6 can be obtained with correlation gating. An example of the use of pulsed gating for imaging in a scattering solution is shown in Fig. 16.

15.3 STIMULATED BRILLOUIN SCATTERING

Brillouin scattering involves low-frequency propagating waves—for example, acoustic waves in solids, liquids, and gases and ion-acoustic waves in plasmas. Again, scattering can be to a longer or shorter wavelength than the incident radiation, with the long-wavelength scattered wave being termed the *Stokes wave* and the short-wavelength scattered wave termed the *anti-Stokes* wave. The difference between the incident and scattered frequencies is again termed the *Stokes shift* or *anti-Stokes shift* as appropriate. For Brillouin scattering, the energies of the modes are much lower than for Raman scattering, and anti-Stokes radiation is much more common. Common Brillouin shifts are typically on the order of 0.1 to 100 GHz, and depend on the excitation wavelength and interaction geometry as well as on material properties. Brillouin scattering is used most commonly for phase conjugation and pulse compression. It is also prominent as a limiting process for intensity in fiber-optic systems.

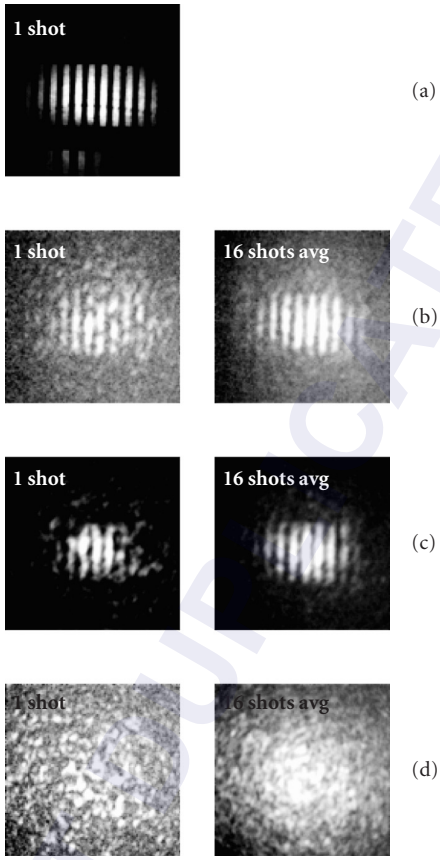

FIGURE 16 Use of Raman amplification with short pulses for time gating to photograph objects through scattering materials. (*a*) Image of bar chart, no scatterer. The relative timing of the pump and Stokes pulses were (*b*) −16 ps, (*c*) 0 ps, and (*d*) + 24 ps. (*From Ref. 128.*)

The equations for Stokes Brillouin scattering for forward ($+v_g$) and backward ($-v_g$) waves are[2,6,7]

$$\frac{\partial A_S}{\partial z} \pm \frac{1}{v_g}\frac{\partial A_S}{\partial t} = i\frac{\omega_S}{4n_S c}\gamma\frac{\Delta\rho^*}{\rho_o}A_L \tag{104a}$$

$$-2i\Omega\frac{\partial\Delta\rho^*}{\partial t} + (v^2q^2 - \Omega^2 + iq^2\Gamma'\Omega)\Delta\rho^* + 2iqv^2\frac{\partial\Delta\rho^*}{\partial z} - \frac{v^2sq^2\beta_p\rho_o}{\gamma}\Delta T^* + 2iq\frac{v_S^2\beta_p\rho_o}{\gamma}\frac{\partial\Delta T^*}{\partial z} = q^2\gamma A_L^* A_S \tag{104b}$$

$$\rho_o C_v\frac{\partial\Delta T^*}{\partial t} - i\Omega\rho_o C_v\Delta T^* - \frac{C_v(\gamma-1)}{\beta_p}\frac{\partial\Delta\rho}{\partial t} + i\Omega\frac{C_v(\gamma-1)}{\beta_p}\Delta\rho + \kappa q^2(\Delta T) = cn\varepsilon_o\alpha A_L^* A_S \tag{104c}$$

where v_s is the sound velocity and

$$\Gamma' = \frac{1}{\rho}\left[\frac{4}{3}\eta_s + \eta_b + \frac{\kappa}{C_p}\left(\frac{C_p}{C_v} - 1\right)\right] \tag{105}$$

and η_s is the coefficient of shear viscosity, η_b is the coefficient of bulk viscosity, κ is the thermal conductivity, C_p is the specific heat at constant pressure, and C_v is the specific heat at constant volume.

The fields are described by the equations

$$E_L(z,t) = \frac{1}{2}[A_L(z,t)e^{-i(\omega_L t - k_L z)} + \text{c.c.}] \tag{106a}$$

$$E_S(\xi,t) = \frac{1}{2}[A_S(z,t)e^{-i(\omega_S t - k_S \xi)} + \text{c.c.}] \tag{106b}$$

$$\rho(\zeta,t) = \rho_o + \frac{1}{2}[\Delta\rho e^{-i(\Omega t - q\zeta)} + \text{c.c.}] \tag{106c}$$

where A_L, A_S, and ρ are the amplitudes of the laser, scattered optical wave, and sound wave density, respectively, and ω_L, ω_S, Ω_L, and k_L, k_S, and q are the frequencies and k vectors of the various waves. The scattered optical wave propagates along the direction ξ and the sound wave propagates along direction ζ, neither of which is required to coincide with z. The frequencies and k vectors obey the following relations:

$$\omega_L - \omega_S = \Omega \tag{107a}$$

$$\vec{k}_L - \vec{k}_S = \vec{q} \tag{107b}$$

$$q = \frac{2\pi}{\Lambda_s} \tag{107c}$$

where Λ_s is the sound wavelength. The k vectors of the various waves are arranged according to the diagram in Fig. 17.

Because the sound frequency is much less than the optical frequency, $|k_L| \approx |k_S|$ and

$$q \approx 2k_L \sin(\theta/2) \tag{108}$$

The Brillouin frequency shift can then be written as

$$\Omega_B = 2n_L\omega_L \frac{v_s}{c}\sin(\theta/2) \tag{109}$$

Unlike the Raman frequency shift, the Brillouin frequency shift depends on the laser frequency and the interaction geometry. It has its maximum value for backward scattering ($\theta = 180°$).

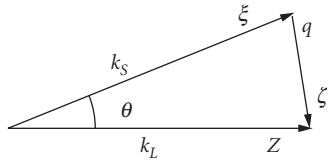

FIGURE 17 k vector diagram for stimulated Brillouin scattering showing k vectors for laser k_L Stokes k_S and sound wave q.

The Brillouin interaction involves both electrostrictive and thermal effects. Equation (104*c*) was obtained from the equation for the low-frequency acoustic and thermal response of liquids and gases to optical radiation:[2,6,7]

$$-\frac{\partial^2\Delta\rho}{\partial t^2}+\frac{v_S^2}{\gamma}\nabla^2(\Delta\rho)+\frac{2\eta_s+\eta_b}{\rho_o}\nabla^2\frac{\partial\Delta\rho}{\partial t}+\frac{v_S^2\beta_p\rho_o}{\gamma}\nabla^2(\Delta T)=\frac{1}{2}cn\varepsilon_o\gamma_e\nabla^2\langle E_{\text{tot}}\rangle^2 \tag{110a}$$

$$\rho_o C_v\frac{\partial\Delta T}{\partial t}-\frac{C_v(\gamma-1)}{\beta_p}\frac{\partial\Delta\rho}{\partial t}-\kappa\nabla^2(\Delta T)=cn\varepsilon_o\alpha\langle E_{\text{tot}}\rangle^2 \tag{110b}$$

where $\gamma = C_p/C_v$ is the ratio of specific heats at constant pressure and volume, η_s is the coefficient of shear viscosity, η_b is the coefficient of bulk viscosity, β_p is the thermal expansion coefficient at constant pressure, $\gamma_e = \rho(\partial\varepsilon/\partial\rho)$ is the electrostrictive constant, α is the absorption coefficient, κ is the thermal conductivity, $E_{\text{tot}} = E_L + E_S$ is the total optical field, and ΔT is the change in temperature. The following form for the temperature

$$T=T_o+\frac{1}{2}[\Delta T e^{-i(\Omega t-qz)}+\text{c.c.}] \tag{111}$$

can be used to reduce Eq. (110*a* and *b*) to first order, giving Eq. (104*b* and *c*).

The Brillouin equations can be solved under various approximations. The propagating terms in $\partial\Delta\rho/\partial z$ and $\partial\Delta T/\partial z$ are usually neglected because the sound waves are strongly damped. The steady-state solution for the Stokes intensity is

$$I_S(L)=I_S(0)e^{gIL} \tag{112}$$

where the gain coefficient g is given by $g = g^e + g^a$, where g^e is the electrostrictive gain coefficient given by

$$g^e=\frac{\omega_S\gamma_e^2\Omega_B}{n_S n_L c^2\varepsilon_o\rho_o\Gamma_B v_s^2}\frac{1}{1+\left(\dfrac{2\delta\Omega}{\Gamma_B}\right)^2} \tag{113a}$$

and g^a is the absorptive Brillouin gain coefficient given by

$$g^a=\frac{\omega_S\gamma_e\gamma_a\Omega_B}{2n_S n_L c^2\varepsilon_o\rho_o\Gamma_B v_s^2}\frac{4\delta\Omega/\Gamma_B}{1+\left(\dfrac{2\delta\Omega}{\Gamma_B}\right)^2} \tag{113b}$$

where $\gamma_a = 2\alpha n v^2\beta_p/C_p\Omega_B$,

$$\Omega_B = v_s q \tag{114}$$

is the Brillouin frequency shift, $\delta\Omega = \Omega - \Omega_B$, and

$$\Gamma_B=q^2\left[\frac{1}{\rho}(2\eta_s+\eta_b)+\frac{\kappa}{C_p}\left(\frac{C_p}{C_v}-1\right)\right] \tag{115a}$$

$$=q^2\Gamma'' \tag{115b}$$

is the Brillouin damping constant.

The gain due to the electrostrictive interaction is peaked about the Brillouin frequency shift $\Omega = \Omega_B$ with a linewidth (FWHM) of $\Delta\nu_B = \Gamma_B/2\pi$. The acoustic energy damping time is given by

$$\tau_B = 1/2\pi\Delta\nu_B \tag{116}$$

The electrostrictive gain coefficient g can also be written as

$$g^e = \frac{2\omega_S\gamma_e^2\omega_L}{n_S c^3\varepsilon_o\rho_o\Gamma_B v_s}\sin(\theta/2)\frac{1}{1+\left(\dfrac{\delta\Omega}{\Gamma_B/2}\right)^2} \tag{117a}$$

$$= \frac{\omega_S\gamma_e^2}{2\omega_L n_S n_L^2 c\varepsilon_o\rho_o\Gamma'' v_s}\frac{1}{\sin(\theta/2)}\frac{1}{1+\left(\dfrac{\delta\Omega}{\Gamma_B/2}\right)^2} \tag{117b}$$

The maximum steady-state gain is

$$g^e_{B,\max} = \frac{\omega_S\omega_L\gamma_e^2}{\pi n_S c^3\varepsilon_o\rho_o v_s\Delta\nu_B} \tag{118}$$

and occurs for backward scattering ($\theta = 180°$). The frequency shift for backward scattering is

$$\Omega_B(180°) = 2n\omega_L\frac{v_s}{c} \tag{119}$$

Since the Brillouin frequency shift is small, $\omega_S \approx \omega_L$ and the maximum Brillouin gain apparently scales as ω_L^2. However, the linewidth also scales as ω_L^2 [see Eq. (115*b*)], leaving the maximum Brillouin gain independent of wavelength as indicated in Eq. (117*b*).

The dependence of the linewidth on q^2 causes the steady-state gain in the forward direction to go to infinity [Eq. (117*b*)] rather than to zero [Eq. (117*a*)]. However, the forward interaction is always transient because the steady-state time for forward scattering also goes to infinity. As a result, the forward gain is zero. Brillouin scattering at 90° is important in propagation of high-power laser radiation through large-diameter optics.

Transient Brillouin scattering has been described by Kroll[16] and Faris et al.[130] The transient solutions to the stimulated Brillouin scattering are formally similar to those for Raman scattering and can be written as

$$A_S(z,\tau) = A_S(0,\tau) + \sqrt{\Gamma_B g_B z/cn_L\varepsilon_o}\,A_L(\tau)\int_{-\infty}^{\tau}\frac{e^{-(\tau-\tau')/T_2}A_L^*(\tau')A_S(0,\tau')I_1\left(\sqrt{\Gamma_B g_B z[p(\tau)-p(\tau')]/cv_L\varepsilon_o}\right)}{\sqrt{p(\tau)-p(\tau')}}d\tau \tag{120}$$

Again, the transient gain depends on the time integral of the laser intensity, and the scattered intensity grows as a Bessel function. The steady-state solution of Eq. (112) applies when the pulse duration is greater than the steady-state time given by

$$t_{SS} = \frac{G_{SS}}{\Gamma_B} \tag{121}$$

where $G_{SS} = GI_L L$.

Brillouin scattering in solids has been discussed in Refs. 131 to 134. The formal equations for electrostrictive Brillouin scattering are similar to those for liquids and gases. However, the gain coefficient depends on the polarization of the laser and scattered light, and Brillouin resonances exist for both longitudinal and shear acoustic waves. The Brillouin gain is given by

$$g^e = \frac{\omega_S \Omega_B n_S^3 n_L^4 p'^2}{n_S n_L c^2 \varepsilon_o \rho_o \Gamma_B v_s^2} \frac{1}{1+\left(\dfrac{2\delta\Omega}{\Gamma_B}\right)} \tag{122}$$

where p' is the photoelastic constant appropriate for the specific combination of polarizations for the optical and acoustic waves. For longitudinal acoustic waves in isotropic materials[134]

$$p' = p_{12}(\hat{\varepsilon}_L \cdot \hat{\varepsilon}_S) + p_{44}[(\hat{\varepsilon}_L \cdot \hat{\kappa}_a)(\hat{\varepsilon}_L \cdot \hat{\varepsilon}_S) + (\hat{\varepsilon}_L \cdot \hat{\varepsilon}_a)(\hat{\varepsilon}_S \cdot \hat{\kappa}_a)] \tag{123a}$$

while for shear acoustic waves

$$p' = p_{44}[(\hat{\varepsilon}_L \cdot \hat{\kappa}_a)(\hat{\varepsilon}_S \cdot \hat{\varepsilon}_a) + (\hat{\varepsilon}_L \cdot \hat{\varepsilon}_a)(\hat{\varepsilon}_S \cdot \hat{\kappa}_a)] \tag{123b}$$

where $\hat{\varepsilon}_{L(S)(a)}$ is the unit polarization vector of the pump (Stokes) (acoustic) wave and κ_a is the unit propagation vector of the acoustic wave.

Buildup of noise in a generator with Brillouin scattering is similar in principle to buildup with Raman scattering. However, the primary noise source for Brillouin scattering is the thermally excited acoustic phonons. As a result, the equivalent noise level for Brillouin scattering can be several orders of magnitude larger than the Raman noise level.[135–137] The noise power into a given solid angle $d\Omega = \pi\theta^2/4$ is given by[135]

$$P_{\text{noise}} = \frac{\omega_S}{\Omega} k_B T \Delta\nu_B \left(\frac{\theta}{2\theta_D}\right)^2 \tag{124}$$

where $\theta_D = \lambda/2\pi D$ is the diffraction angle that can be resolved by a gain column of diameter D. Brillouin scattering with broadband radiation is discussed in Refs. 138 and 139. Multiline Brillouin scattering is treated in Ref. 140. As with backward Raman scattering, the gain decreases when the coherence length becomes comparable to or shorter than the interaction length.

Thermal Brillouin scattering is driven by nonuniform heating due to absorption and is described by g^a in Eq. (113*b*). The gain shows a dispersive behavior with frequency, with zero gain at the Brillouin frequency, gain for frequencies less than Ω_B, and loss for frequencies greater than Ω_B. Brillouin scattering parameters for various materials are listed in Table 10.

Brillouin Phase Conjugation

One of the major uses of stimulated Brillouin scattering (SBS) is phase conjugation.[140a] Phase conjugation is also possible with stimulated Raman scattering, but SRS is not used for this purpose as much as SBS. Phase conjugation is used to correct distortions on optical beams that arise from propagation through nonideal optical media, such as the atmosphere or low-quality optical components. It can also be used for correcting or stabilizing aiming errors that arise from motion of components in an optical train, for improving the beam quality of laser oscillators and oscillator amplifier systems, and for beam combining.

A typical arrangement for phase conjugation is shown in Fig. 18. The distorting medium impresses a transverse phase variation on the optical beam propagating from left to right that can result in increased divergence, intensity structure, or reduced focal plane intensity if focused by a subsequent lens or mirror. If the beam entering the distorting material carried an initial distortion that would be undone by the material, then the beam would emerge from the medium undistorted.

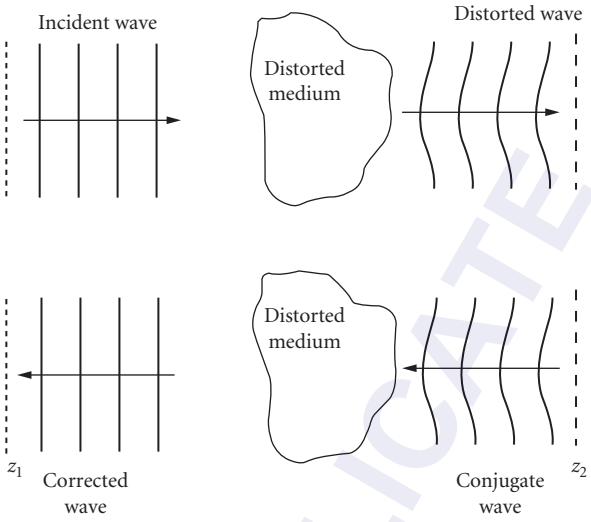

FIGURE 18 Schematic diagram for correction of phase distortions caused by distorting medium with double-pass propagation.

The general concept is that the initial distortion required for this compensation is the inverse of the distortion imposed by the medium. However, determining precisely what that distortion is and imposing it on the initial beam is the heart of the matter in phase compensation.

The arrangement shown in Fig. 19 illustrates how this is done with nonlinear optical phase conjugation. The beam propagating from left to right is initially undistorted. It emerges from the medium at point B with a complete record of the distortion imposed by the medium. In the nonlinear medium, the beam undergoes a backward nonlinear optical interaction in which a second beam is generated that travels in the opposite direction and has phase variations that are reversed from the original distorted beam. When this beam propagates through the distorting medium again from right to left, the medium again impresses a phase variation on it, but this time the process simply undoes the initial phase distortion instead of creating one. The beam emerging from the distorting medium at point A is undistorted.

Several types of nonlinear interactions have been used for phase conjugation, including degenerate and nondegenerate four-wave mixing, stimulated Brillouin scattering, Brillouin-enhanced four-wave mixing, and stimulated Raman scattering. Of these, degenerate four-wave mixing is used most often for low-power interactions and stimulated Brillouin scattering is used for high-power applications. Brillouin-enhanced four-wave mixing provides a high-gain Brillouin system.

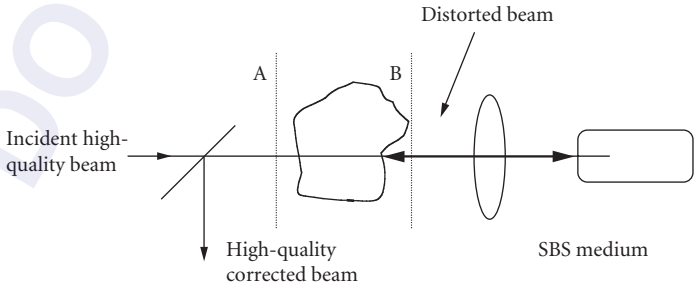

FIGURE 19 Schematic diagram of use of stimulated Brillouin scattering for phase distortion correction with phase conjugation.

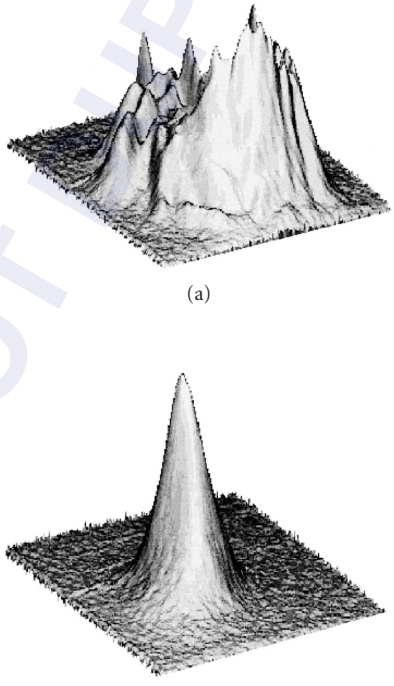
Phase conjugation with SBS is the result of mode competition in which the mode that corresponds to the conjugate of the pump has higher gain than other possible modes. The gain for the backward-generated beam involves a sum over all possible spatial modes of the backward Stokes wave. The mode that matches the pump wave has the highest gain because the high- and low-intensity points coincide, providing reinforcement of that mode over the entire interaction length. The exponential gain for this mode is twice that for the noncorrelated modes when the pump beam carries a large number of spatial modes.

In order for the conjugate mode to dominate over the other modes, it is necessary that it experiences preferential gain over an extended region. Essentially, it is required that the Stokes beam diffract across the entire pump beam in the interaction region before it grows to a saturation level. This has been accomplished by using a light guide to confine the beams. In free-focused interactions, it requires that the divergence of the pump beam be sufficient to provide a wide focal area relative to its depth. An example of phase conjugate correction in a two-pass Q-switched Nd:YAG amplifier system is shown in Fig. 20 using liquid Freon-113 as the conjugating medium.[148] Properties of phase-conjugated beams, quality of correction, and efficiency of conversion are given in Ref. 10.

Brillouin-Enhanced Four-Wave Mixing Brillouin-enhanced four-wave mixing (BEFWM) is a nearly degenerate four-wave mixing process where the four waves are coupled by the Brillouin nonlinearity as shown schematically in the Fig. 21. BEFWM was first observed and explained by Basov et al.[149] In addition to the beam to be conjugated, two oppositely propagating pump beams are



(a) (b)

FIGURE 20 Spatial beam profiles of a Q-switched Nd:YAG oscillator-amplifier system using a two-pass amplifier configuration with a conventional mirror in the two-pass amplifier (*a*) and an SBS mirror (*b*). The Brillouin mirror was a cell of liquid Freon-113. (*From Ref. 148.*)

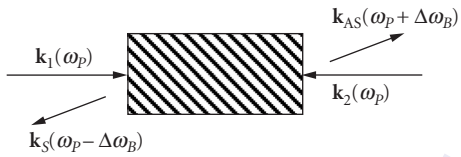


FIGURE 21 k vector diagram for Brillouin-enhanced four-wave mixing.

provided at frequency ω_L. In general, the two pump beams do not need to be at the same frequency, but in practice they usually are. The signal beam k_s at a frequency $\omega_S = \omega_P - \Delta\omega_B$ interacts with the laser beam k_1 at a frequency ω_P to produce an acoustic wave that moves in the direction of the laser beam. The second laser beam k_2 scatters from the moving grating to generate the conjugated anti-Stokes beam k_{AS} at a frequency $\omega_{AS} = \omega_P + \Delta\omega_B$. The phase-conjugated beam, traveling in the opposite direction of the signal beam, can be amplified when the pump beams do not interact with each other. Therefore, BEFWM represents a mirror with reflectivity greater than 1. The pump beams are usually decoupled by frequency or polarization control. A reflectivity as high as $\sim 7 \times 10^5$ has been observed.[150] The process can also be done with the anti-Stokes wave as the signal beam. The signal Stokes beam is usually generated externally via a separate SBS process. The angles between the beams can be adjusted to make the phase matching possible. Various aspects of BEFWM are described in detail in Ref. 151.

THIRD-ORDER OPTICAL NONLINEARITIES

Mansoor Sheik-Bahae and Michael P. Hasselbeck

Department of Physics and Astronomy
University of New Mexico
Albuquerque, New Mexico

16.1 INTRODUCTION

The subject of this chapter could well fill a textbook, and indeed the topic comprises a significant portion of the many books on nonlinear optics. A large (but by no means exhaustive or complete) list of texts that provide extensive discussion of high-order nonlinearities appears in Refs. 1 through 30. We have not attempted to write a review chapter nor mentioned or even listed every known third-order nonlinear optical phenomenon. Our aim is to illustrate important and representative third-order effects, emphasizing qualitative descriptions. Details can be found in the references. An exception is our discussion of the Kramers-Kronig relations in nonlinear optics. A fundamental premise of this transformation is the causal link between nonlinear refraction and nonlinear absorption, which is a key aspect of the third-order susceptibility. It has not been treated in most texts; some of the important mathematical steps are given here. Our treatment of third-order nonlinear optics assumes that the reader is familiar with electromagnetic theory, physical optics, and quantum mechanical energy level diagrams.

Any real, physical oscillating system will exhibit a nonlinear response when it is overdriven. In an optical system, a nonlinear response can occur when there is sufficiently intense illumination. The nonlinearity is exhibited in the polarization ($\vec{\mathcal{P}}$) of the material, which is often represented by a power series expansion of the total applied optical field ($\vec{\mathcal{E}}$):

$$(\vec{\mathcal{P}}) = \varepsilon_0 \chi^{(1)} \vec{\mathcal{E}} + \varepsilon_0 \chi^{(2)} \vec{\mathcal{E}}^2 + \varepsilon_0 \chi^{(3)} \vec{\mathcal{E}}^3 + \cdots \tag{1}$$

Here $\chi^{(1)}$ is the linear susceptibility representing the linear response (i.e., linear absorption and the refractive index) of the material. The two lowest-order nonlinear responses are accounted for by the second- and third-order nonlinear susceptibilities $\chi^{(2)}$ and $\chi^{(3)}$. The subject of this chapter is third-order effects. Processes arising from the second-order response (including second-harmonic generation and optical parametric processes) are discussed elsewhere (see Chap. 10, "Nonlinear Optics" and Chap. 17, "Continuous-Wave Optical Parametric Oscillators"). We will, however, briefly consider the cascading of second-order nonlinearities that appear as an *effective* third-order process in Sec. 16.10.

Third-order optical nonlinearities cover a vast and diverse area in nonlinear optics. A simple illustration of this point is the reported range of magnitudes and response times for $\chi^{(3)}$ in various materials, which span 15 orders of magnitude! This has led to unavoidable inconsistency and confusion in the definition and interpretation of the nonlinear susceptibility. We will not be immune from such inconsistencies and errors. In that spirit, we note that the simple power series representation of the nonlinear optical response described by Eq. (1) is not rigorously correct because it assumes the response is instantaneous. In the case of the bound electronic nonlinearity, for example, this assumption is excellent because the response is exceedingly fast. The response is not *infinitely* fast, however. Response times can vary by orders of magnitude depending on the physical mechanism and resonance conditions involved. Furthermore, Eq. (1) assumes locality, which implies that the nonlinear polarization at a given point in space depends on the magnitude of the electric field only at that point. This condition is not always satisfied. The electrostrictive nonlinearity, for example, is the result of physical displacement of charged particles in a material subject to the ponder-motive force due to the gradient of light irradiance. It is therefore nonlocal. It is nevertheless instructive to apply Eq. (1) to describe various third-order effects that are local and (single photon) nonresonant.

The nonlinear polarization represented in Eq. (1) excludes *effective* third-order nonlinear processes involving linear absorption ($\chi^{(1)}$ process) of one of the excitation beams. An example is the thermal nonlinearity resulting from linear absorption and heating that causes a change of refractive index. Although this is effectively a third-order nonlinear response, we group this and similar phenomena in Sec. 16.9 on cascaded $\chi^{(1)}$:$\chi^{(1)}$ effects.

The term involving $\tilde{\mathscr{E}}^3$ in Eq. (1) implies that three optical fields interact to produce a fourth field. The $\chi^{(3)}$ interaction is thus a four-photon process. This is a consequence of the quantum mechanical picture of the nonlinear susceptibility. Conservation of photon energy is always required to complete the interaction process. Assuming the applied optical fields are monochromatic plane waves, we write the total input electric field $\tilde{\mathscr{E}}$ as

$$\tilde{\mathscr{E}}(r,t)=\tilde{\mathscr{E}}_1(r,t)+\tilde{\mathscr{E}}_2(r,t)+\tilde{\mathscr{E}}_3(r,t) \tag{2}$$

In general, each beam has a different frequency (ω) and wave vector ($\vec{k}$), represented in complex notation:

$$\tilde{\mathscr{E}}_j(r,t)=\frac{\vec{E}_j}{2}\exp(i\omega_j t-i\vec{k}_j.r)+\text{c.c.} \qquad \text{for } j=1,2,3 \tag{3}$$

where c.c. stands for complex conjugate and $\vec{E}_j$ is a complex vector describing the amplitude, phase, and polarization of each beam. It is important to realize that there can be up to three different input laser frequencies, but there can also be as few as one. Ignoring the $\chi^{(1)}$ and $\chi^{(2)}$ components in Eq. (1), the nonlinear polarization resulting from the $\tilde{\mathscr{E}}^3$ interaction leads to a total of 108 terms involving all possible permutations of the fields at three frequencies. The nonlinear polarization occurs at frequencies given by

$$\omega_4=\pm\omega_i\pm\omega_j\pm\omega_k \qquad \text{for } i,j,k=1,2,3 \tag{4}$$

The existence of 108 terms does not mean there are as many distinct mechanisms involved. For instance, three terms give $\omega_4 = 3\omega_j$, for $j = 1, 2, 3$, describing exactly the same process of third-harmonic generation (THG). Furthermore, THG is a special case of sum frequency generation (SFG) involving one, two, or three different frequencies giving $\omega_4 = \omega_i + \omega_j + \omega_k$, $i, j, k = 1, 2, 3$ accounting for 27 terms.

One realizes 108 permutations with different time ordering of three different laser beams distinguished by frequency, and/or wave vector, and/or polarization. If only two distinguishable laser beams are available, the number of permutations decreases to 48. When the system is driven by a single beam, the third-order response involves only four terms in three fields. In general, the $\chi^{(3)}$ coefficients associated with each term will be different due to the ever-present dispersion (i.e., frequency dependence) of the susceptibilities. The frequency dependence is a direct consequence of the finite response time of the interaction. We will expand on this subject in the discussion of the Kramers-Kronig dispersion relations in Sec. 16.4.

Another important property of nonlinear susceptibilities is their tensor nature. Because of the molecular or lattice structure of materials, the nonlinear response will depend on the state of

polarization of the optical fields. For the sake of brevity, we neglect the tensor properties of $\chi^{(3)}$ and treat all the susceptibilities and electric fields as scalar quantities. The reader may consult textbooks on nonlinear optics for detailed discussions of this subject.

Propagation of interacting beams is also an important consideration, and one must account for wave vector summation (i.e., conservation of momentum) that results from the $\bar{\mathscr{E}}^3$ operation. It is useful to invoke the four photon picture, recalling that the momentum of each photon is given by $\hbar\vec{k}_j$. Taking the resultant nonlinear polarization to be a plane wave with a wave vector $\vec{k}_4$, momentum conservation requires that:

$$\vec{k}_4 = \pm\vec{k}_i \pm \vec{k}_j \pm \vec{k}_k \tag{5}$$

where $|\vec{k}_j| = n(\omega_j)\omega_j/c$. This phase-matching requirement is not necessarily satisfied in every interaction due to dispersion of the linear refractive index in the material. Phase matching can be a serious obstacle in interactions leading to new-frequency generation, that is, when $\omega_4 \neq \omega_1$, ω_2 and ω_3 (e.g., Sec. 16.6 on THG). When the nonlinear polarization is at one of the driving frequencies, $\omega_4 = \omega_i$ for example, conservation of energy [Eq. (4)] implies that $\omega_j = -\omega_k$. In this case, Eq. (5) reduces to a vector-matching condition that depends only on the geometry (i.e., direction) of the beams (Secs. 16.11 and 16.12).

The frequency terms arising from the third-order nonlinear polarization described by Eq. (1) are collected in Table 1. In the following section, we discuss the physical mechanisms and important features of these processes.

TABLE 1 Frequency Terms Arising from Third-Order Nonlinear Polarization

Nonlinear Process	$8P(\omega_4)/\varepsilon_0\chi^{(3)}$	ω_4
• Third-harmonic generation (THG)	$E_j^3\, j=1,\ldots 3$	$3\omega_1, 3\omega_2, 3\omega_3$
• Sum frequency generation (SFG)	$3E_iE_j^2\; i,j=1,2,3\, i\neq j$	$2\omega_1+\omega_2, 2\omega_1+\omega_3,$ $2\omega_2+\omega_3, 2\omega_2+\omega_1,$ $2\omega_3+\omega_1, 2\omega_3+\omega_2,$
	$6E_1E_2E_3$	$\omega_1+\omega_2+\omega_3$
• Frequency mixing	$3E_i^*E_j^2\; i,j=1,2,3\, i\neq j$	$2\omega_1-\omega_2, 2\omega_1-\omega_3,$
• Parametric amplification		$2\omega_2-\omega_3, 2\omega_2-\omega_1,$ $2\omega_3-\omega_1, 2\omega_3-\omega_2,$
• Coherent Stokes and anti-Stokes Raman scattering (CSRS and CARS)	$6E_i^*E_jE_k\; i,j,k=1,2,3\, i\neq j\neq k$	$\omega_1+\omega_2-\omega_3,$ $\omega_1-\omega_2+\omega_3,$ $-\omega_1+\omega_2+\omega_3$
	$6E_i^*E_j^*E_k\; i,j,k=1,2,3\, i\neq j\neq k$	$\omega_1-\omega_2-\omega_3,$ $-\omega_1-\omega_2+\omega_3,$ $-\omega_1+\omega_2-\omega_3$
• Bound electronic optical Kerr effect	$3E_i^2E_i^*\; i=1,2,3$	$\omega_1, \omega_2, \omega_3$
• Raman-induced Kerr effect (RIKE)		
• Molecular orientational Kerr effect	$6E_iE_jE_j^*\; i,j=1,2,3, i\neq j$	
• Two-photon absorption (2PA)		
• ac Stark effect		
• Stimulated Raman scattering (SRS)		
• Stimulated Rayleigh-Wing Scattering		

16.2 QUANTUM MECHANICAL PICTURE

The conservation of energy shown in the frequency summation of Eq. (4) contains both positive and negative signs from each of the input beams. A positive sign represents the annihilation (absorption) of a photon, while the negative sign is interpreted as the generation (gain) of a photon. Both annihilation and generation of photons involve atomic and/or molecular transitions from one state to another. It is instructive to use diagrams to keep track of transitions participating in the nonlinear interactions. Let us take the most general case, where four distinguishable beams (i.e., three input photons at ω_1, ω_2, ω_3, and the final photon at ω_4) are involved. The third-order nonlinear interaction follows a path corresponding to one of 14 sign-ordering possibilities, assuming emission at the photon frequency ω_4. All possible time-ordering sequences are illustrated in Fig. 1. In addition, the interacting photons are in general distinguishable; to preserve the clarity of presentation we have not shown this in Fig. 1. Because the photons are (in general) distinct, we must allow for permutation of frequencies in the diagrams. Assuming emission at ω_4 (i.e., we can only assign ω_4 to a downward-pointing arrow), we count up the various time-ordering permutations for each interaction path shown in Fig. 1. This gives a total of 168 terms! Little would be gained by a tedious analysis of all these terms, and such a task is far beyond the scope of this chapter. Instead, we illustrate some important third-order mechanisms and the role of resonances in Fig. 2, where we have labeled the three most important diagrams in Fig. 1. The energy level $|g\rangle$ is the ground state, while $|a\rangle$, $|u\rangle$, and $|b\rangle$ are intermediate states of the system in a sequence of transitions involving photons with frequencies ω_i, ω_j, ω_k, and ω_l ($i, j, k, l = 1, 2, 3, 4$) such that $\pm\omega_i \pm \omega_j \pm \omega_k \pm \omega_l = 0$. The three time-ordering processes shown in the figure are:

Figure 2*a*. Consecutive absorption of three photons followed by the generation of the final photon, partly describing sum frequency generation and third-harmonic generation. The reverse process is third-order parametric amplification, which is the absorption of a photon together with emission of three photons.

Figure 2*b*. An absorption-emission-absorption-emission sequence. Difference frequency generation and frequency mixing are examples of this type of interaction. Coherent anti-Stokes Raman spectroscopy (CARS) is also represented by this transition sequence.

Figure 2*c*. Absorption of two photons followed by emission of the two photons. As can be seen in the third section of Table 1, a variety of physical mechanisms fall under this general description. Note that the essential difference between (*b*) and (*c*) is the time ordering of the transitions. This is extremely important in resonant cases: a Raman-type resonance occurs in (*b*), and a two-photon resonance exists in (*c*).

Energy conservation is strictly obeyed upon the completion of the interaction [as dictated by Eq. (4)] but may be violated in the time frame of intermediate state transitions. This is allowed by Heisenberg's Uncertainty Principle. In many cases, an intermediate state is a virtual state, which is a convenient way of stating that a real, intermediate state of the system does not exist to support the transition of a photon at the selected wavelength. The virtual, intermediate state allows for energy bookkeeping in transition diagrams, but a physical description of the optical interaction using quantum mechanics involves only real eigenstates of the system. In particular, there must be a dipole-allowed transition between the initial state $|g\rangle$ and a real state *associated* with the virtual state. The time scale and strength of the interaction is partly determined by the energy mismatch between the virtual, intermediate state and an associated real, electronic state. This means a system can absorb a photon of energy $\hbar\omega_i$ and make a transition from the ground state $|g\rangle$ to a real intermediate state $|a\rangle$ even though there is insufficient photon energy to bridge the gap (i.e., there is an energy mismatch $\Delta E = |\hbar\omega_i - E_a + E_g| > 0$). This is possible, provided the interaction occurs in a time faster than the observation time $\Delta t \sim \hbar/\Delta E$ permitted by the Uncertainty Principle. Transitions of this type are called *virtual* transitions, as opposed to *real* transitions, where energy is conserved. In the former case, Δt is known as the virtual lifetime of the transition.

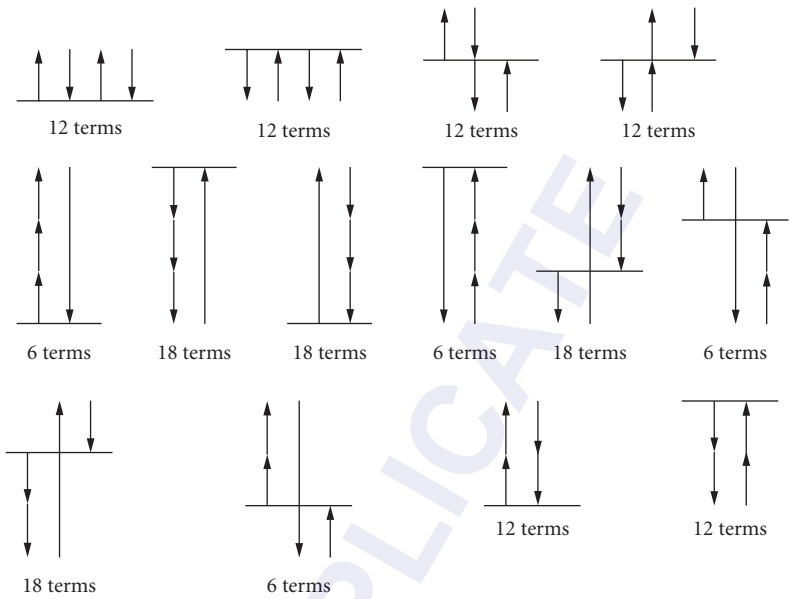

FIGURE 1 Time-ordering sequence illustrating all possible third-order paths. Arrows depict photons. Note that in general, the size of the arrows can be different provided their vector sum is zero. The number of terms is obtained assuming emission of a photon at ω_4. For clarity, arrows are not marked.

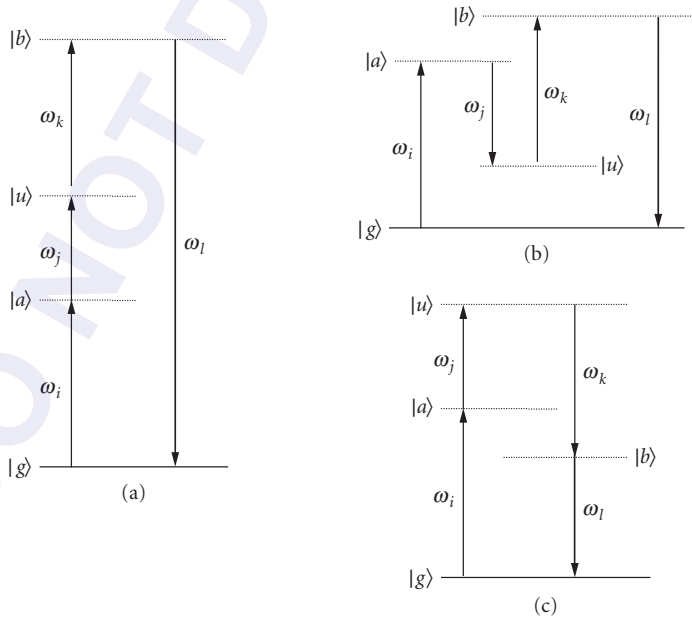

FIGURE 2 Energy level diagrams for some important third-order nonlinear optical processes: (*a*) third-harmonic generation (THG); (*b*) coherent anti-Stokes Raman scattering (CARS); and (*c*) two-photon absorption (2PA).

If the entire sequence of transitions comprising the third-order interaction is not completed within the virtual lifetime, the intermediate state collapses back to the ground state, and no nonlinear interaction occurs. In other words, all the required particles must be present in the system during the virtual lifetime. The longer the virtual lifetime, the greater the probability that the required photons will appear, allowing the multiparticle interaction to run to completion. A longer virtual lifetime translates to a larger third-order nonlinear susceptibility $\chi^{(3)}$. The closer an input photon moves to a dipole-allowed system resonance, the longer the virtual lifetime and the stronger the resulting $\chi^{(3)}$ will be.

These quantum mechanical issues are manifest in the mathematical formulation of $\chi^{(3)}$ derived from perturbation theory:[1,3,17]

$$\chi^{(3)}(\pm\omega_1,\pm\omega_2,\pm\omega_3)=\frac{N}{\hbar^3}\sum_{i,j,k,l}\sum_{a,u,b}\mu_{ga}\frac{\mu_{au}}{(\omega_{ag}\mp\omega_i)}\frac{\mu_{ub}}{(\omega_{ug}\mp\omega_i\mp\omega_i)}\frac{\mu_{bg}}{(\underbrace{\omega_{bg}\mp\omega_i\mp\omega_j\mp\omega_k}_{\mp\omega_l})} \tag{6}$$

In Eq. (6), N is the total population in the ground state $|g>$, and μ's are dipole-moment matrix elements associated with each of the transitions. The first sum describes the frequency permutations: i, j, k, and l can take any integer value 1, 2, 3, 4, provided energy conservation ($\pm\omega_i \pm \omega_j \pm \omega_k \pm \omega_l = 0$) is obeyed. The second sum is over all possible real, intermediate quantum eigenstates of the system. This complicated-looking equation is nothing more than the sequence of optical transitions weighted by the appropriate virtual lifetime. The first coefficient represents the virtual transition initiated by a photon of energy $\hbar\omega_i$ from the ground state to the intermediate state $|a>$ with strength given by the matrix element μ_{ga}. The next three matrix elements are weighted by the virtual lifetimes of their initial state. The virtual lifetimes are represented by energy (i.e., frequency) denominators; as the photon frequency approaches a system resonance, the virtual lifetime and magnitude of $\chi^{(3)}$ grow accordingly.

The ± signs in front of the frequency arguments in Eq. (6) indicate there is a physical significance to the time ordering of the participating photons. This representation distinguishes the various components of the third-order susceptibility. In many textbooks, a permutation of all the frequencies (including the signs) is already incorporated in the final calculation of $\chi^{(3)}$.[3,4] In that case, for a given ω_4, one obtains the total contribution to $\chi^{(3)}$ with the order of frequency arguments having no particular physical relevance.

We also point out that the nonlinear susceptibility described by Eq. (6) and shown in our example is *real*. A resonance condition occurs when any one of the energy/frequency denominators approaches zero. This not only enhances $\chi^{(3)}$ but also makes it a complex quantity (i.e., a resonance condition introduces an imaginary component to $\chi^{(3)}$). This is better understood by making the following substitution:

$$\frac{1}{\Delta\omega}\rightarrow\frac{1}{\Delta\omega+i\Gamma} \tag{7}$$

where Γ represents a phenomenological broadening of the particular transition. This complex damping term accounts for the physical impossibility of the nonlinear susceptibility becoming infinite in a resonance condition. Even in the case of vanishing damping, a basic theorem of complex variables can be applied to Eq. (7):

$$\lim_{\Gamma\to 0}\frac{1}{\Delta\omega+i\Gamma}=\mathcal{P}\left(\frac{1}{\Delta\omega}\right)+i\pi\delta(\Delta\omega) \tag{8}$$

where $\mathcal{P}$ stands for the principle value and δ is the Dirac delta function. The important message is that in general, the nonlinear susceptibility $\chi^{(3)}$ is a complex quantity that will be dominated by its imaginary component when photon frequencies move into resonance with real eigenstates of the system.

The resonance conditions leading to a strong imaginary $\chi^{(3)}$ are associated with one or more of the following processes: three-photon ($\omega_i + \omega_j + \omega_k = -\omega_l \approx \omega_{bg}$), two-photon ($\omega_i + \omega_j = -\omega_k - \omega_l \approx \omega_{ug}$), Raman-type ($\omega_i - \omega_j = \omega_l - \omega_k \approx \omega_{ug}$), and/or single-photon ($\omega_i \approx \omega_{ag}$) resonances. The latter cases (i.e., those having linear resonance) will be discussed in Sec. 16.9, which deals with cascaded $\chi^{(1)}$:$\chi^{(1)}$ nonlinearities. A special case of linear resonance can occur in Raman-type transitions, where $\omega_{ug} = 0$ (i.e., when the second intermediate state is degenerate with the ground state). This corresponds to the optical Stark effect (ac Stark effect). The three-photon resonance that gives rise to an imaginary $\chi^{(3)}$ in third-harmonic generation does not have a significant physical implication. It only influences the phase of the interacting fields, similar to the case of second-order effects (e.g., second-harmonic generation).[1] The remaining two processes involving two-photon and Raman resonances are of significant interest and will be discussed in detail.

16.3 NONLINEAR ABSORPTION AND NONLINEAR REFRACTION

Just as the real and imaginary components of the linear susceptibility $\chi^{(1)}$ are associated with refraction and absorption, the real and imaginary parts of $\chi^{(3)}$ describe nonlinear refraction (NLR) and nonlinear absorption (NLA) or gain. This can be understood by considering situations in which the nonlinear polarization is at one of the driving frequencies. These are particular cases of Fig. 2*b* and *c*, with corresponding polarization terms given in the third section of Table 1. Taking the interacting photons to have frequencies ω_a and ω_b, the total polarization (linear and third order) at ω_a can be written as

$$P(\omega_a) = \varepsilon_0 \left\{ \frac{1}{2}\chi^{(1)}(\omega_a)E_a + \frac{3}{8}\chi^{(3)}(\omega_a, \omega_a, -\omega_a)E_a^2 E_a^* + \frac{6}{8}\chi^{(3)}(\omega_a, \omega_b, -\omega_b)E_a E_b E_b^* \right\} \tag{9}$$

For the sake of brevity, we ignore time ordering in the frequency arguments of $\chi^{(3)}$. This means that the $\chi^{(3)}$ component in Eq. (9) is assumed to contain the various permutations of frequencies including, for example, two-photon as well as Raman transitions shown in Fig. 2*b* and *c*. From Eq. (9), we introduce an effective susceptibility χ_{eff}:

$$\chi_{\text{eff}}(\omega_a) = \chi^{(1)}(\omega_a) + \frac{3}{4}\chi^{(3)}(\omega_a, \omega_a, -\omega_a)|E_a|^2 + \frac{6}{4}\chi^{(3)}(\omega_a, \omega_b, -\omega_b)|E_b|^2 \tag{10}$$

Deriving the coefficients of nonlinear absorption and refraction from Eq. (10) is now straightforward. The complex refractive index is defined as

$$n + i\kappa = (1 + \chi_{\text{eff}})^{1/2} \tag{11}$$

Making the very realistic assumption that the nonlinear terms in Eq. (10) are small compared to the linear terms, we use the binomial expansion to simplify Eq. (11):

$$n + i\kappa \cong n_0 + i\frac{c}{2\omega_a}\alpha_0 + \Delta n + i\frac{c}{2\omega_a}\Delta\alpha \tag{12}$$

where $n_0 = (1 + \Re e\{\chi^{(1)}\})^{1/2}$. We also assume the background linear absorption coefficient is small, that is, $\alpha_0 \propto \Im m\{\chi^{(1)}\} << \Re e\{\chi^{(1)}\}$. We define the irradiance as $I_i = (1/2)c\varepsilon_0 n_0(\omega_i)|E_i|^2$ $(i = a, b)$ and the nonlinear refraction coefficient n_2 and the nonlinear absorption coefficient α_2 as follows:

$$n_2(\omega_a;\omega_b) = \frac{3}{4\varepsilon_0 n_0(\omega_a) n_0(\omega_b) c} \Re e\{\chi^{(3)}(\omega_a, -\omega_b, \omega_b)\} \tag{13}$$

$$\alpha_2(\omega_a;\omega_b) = \frac{3\omega_a}{4\varepsilon_0 n_0(\omega_a) n_0(\omega_b) c^2} \Im m\{\chi^{(3)}(\omega_a, -\omega_b, \omega_b)\} \tag{14}$$

The change of refractive index due to the presence of fields E_a and E_b is

$$\Delta n(\omega_a) = n_2(\omega_a;\omega_a) I_a + 2n_2(\omega_a;\omega_b) I_b \tag{15}$$

and the change of absorption is

$$\Delta\alpha(\omega_a) = \alpha_2(\omega_a;\omega_a) I_a + 2\alpha_2(\omega_a;\omega_b) I_b \tag{16}$$

where I_a and I_b are the irradiances of the two beams. Note that without loss of generality we assume the measurement is performed on the laser beam corresponding to field E_a, while the field E_b acts as an excitation source only. The first terms on the right-hand side of the just-noted equations correspond to self-action (i.e., commonly performed single-beam experiments). The second terms correspond to the case of an excite-probe experiment where the two beams are distinguishable either by frequency and/or wave vector. The factor of 2 in front of the second terms in Eqs. (15) and (16) arises from the larger number of permutations in this component of the nonlinear susceptibility.[3,4,31] The stronger nondegenerate response (i.e., distinguishable beams) is sometimes referred to as *weak-wave retardation*.[32] While most reported measurements and applications involve degenerate self-action processes (i.e., a single laser beam), the theoretical treatment presented in this chapter considers the more general nondegenerate case. One must keep in mind that degenerate third-order coefficients are only the limit of the nondegenerate case, where $\omega_a = \omega_b$. The need for generality in the theoretical approach is very important for correct implementation of the Kramers-Kronig dispersion relations in nonlinear optics. This allows us to establish a rigorous mathematical relation between NLR and NLA, discussed in the next section.

Another commonly used coefficient for describing the nonlinear index is $\tilde{n}_2$ defined as

$$n = n_0 + \tilde{n}_2(\omega_a;\omega_a)\frac{|E_a|^2}{2} + 2\tilde{n}_2(\omega_a;\omega_b)\frac{|E_b|^2}{2} \tag{17}$$

where $\tilde{n}_2$ is usually given in Gaussian units (esu). $\tilde{n}_2$ is related to n_2 by

$$\tilde{n}_2(\text{esu}) = \frac{cn}{40\pi} n_2(\text{SI}) \tag{18}$$

where the right-hand side is in SI/MKS units. The reader is cautioned that in the literature various symbols and definitions different from those given here are often used to describe the nonlinear refractive index. The symbol β is commonly used in place of α_2 to denote two-photon absorption (2PA).

The propagation of electromagnetic waves E_a and E_b through a nonlinear medium, ignoring the effect of diffraction and dispersion (i.e., pulse distortion), is governed by the following equations for the irradiance and phase of the probe beam (E_a):

$$\frac{dI_a}{dz} = -\alpha_0(\omega_a)I_a - \alpha_2(\omega_a;\omega_a)I_a^2 - 2\alpha_2(\omega_a;\omega_b)I_aI_b \tag{19}$$

and

$$\frac{d\phi_a}{dz} = \frac{\omega_a}{c}[n_0(\omega_a) + n_2(\omega_a;\omega_a)I_a + 2n_2(\omega_a;\omega_b)I_b] \tag{20}$$

The coefficient n_2 is often used to describe the nonlinear index change due to mechanisms such as thermally induced material changes, molecular orientation effects, saturation of absorption, and ultrafast $\chi^{(3)}$ processes. Here, consistent with our definition of $\chi^{(3)}$, we designate the n_2 notation for local and linearly nonresonant nonlinearities only. Processes that appear as an *effective* n_2 are treated separately as cascaded $\chi^{(1)}{:}\chi^{(1)}$ or $\chi^{(2)}{:}\chi^{(2)}$ phenomena.

As a consequence of the principle of causality, the real and imaginary parts of the linear susceptibility are connected through the Kramers-Kronig relations of linear optics. Equations (19) and (20) suggest a similar relation in nonlinear optics. We discuss the Kramers-Kronig relations of nonlinear optics and their underlying physics next.

16.4 KRAMERS-KRONIG DISPERSION RELATIONS

The complex response function of any linear, causal system obeys a dispersion relation linking its real and imaginary parts as Hilbert transform pairs. In linear optics, causality is manifest in the Kramers-Kronig (K-K) dispersion relations (see Chap. 5, "Optical Properties of Semiconductors") that tie the frequency-dependent refractive index, $n(\omega)$, to the absorption coefficient $\alpha(\omega)$ and vice versa:

$$n(\omega) - 1 = \frac{c}{\pi}\mathcal{P}\int_0^\infty \frac{\alpha(\omega')}{\omega'^2 - \omega^2}d\omega' \tag{21}$$

where $\mathcal{P}$ denotes the Cauchy principal value. The principal value is really just a warning to be careful when integrating near the singularity in the denominator of the integrand. We drop the $\mathcal{P}$ notation for simplicity, although it is always implied. There is an equivalent relation for the real and imaginary parts of the linear susceptibility:

$$\Re e\{\chi^{(1)}(\omega)\} = \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{\Im m\{\chi^{(1)}(\omega')\}}{\omega' - \omega}d\omega' \tag{22}$$

The K-K relation is the mathematical expression of causality, and a simple, intuitive derivation of these relations can be made.[33,34]

Causality clearly holds for any real, linear system. Real, nonlinear systems must also be causal—does that imply there are dispersion relations as well? If so, what form do they take? The Kramers-Kronig relations of linear optics are derived from linear dispersion theory, suggesting this procedure is completely inappropriate for a nonlinear system. Fortunately, this is not the case, and since the early days of nonlinear optics, many authors have addressed the K-K relations in the nonlinear regime.[35–39]

The usefulness of these relations was not fully appreciated until recently, however.[31,39,40] The key insight is that one can linearize the system; we view it as the material *plus* a strong perturbing light beam. This new linear system, which is different from the system in the presence of weak light, has a modified absorption spectrum. The linear Kramers-Kronig relation is applied in the presence of and in the absence of a high field perturbation, and we study the difference between these two regimes. It is important to appreciate the fact that our new system is causal even in the presence of an external perturbation. This allows us to write down a modified form of the Kramers-Kronig relation linking the index of refraction to the absorption[31,39]:

$$[n(\omega)+\Delta n(\omega;\zeta)]-1=\frac{c}{\pi}\int_{-\infty}^{\infty}\frac{\alpha(\omega')+\Delta\alpha(\omega';\zeta)}{\omega'^2-\omega^2}d\omega' \tag{23}$$

After subtracting the linear terms n and α, we are left with a relationship between the changes in refractive index and change of absorption:

$$\Delta n(\omega;\zeta)=\frac{c}{\pi}\int_{0}^{\infty}\frac{\Delta\alpha(\omega';\zeta)}{\omega'^2-\omega^2}d\omega' \tag{24}$$

where ζ denotes the perturbation. An equivalent relation also exists that allows calculation of the change in absorption coefficient, given the change in the refractive index. This relation is rarely used in practice for reasons described momentarily. In evaluating Eq. (24), it is essential that the perturbation be independent of the frequency of observation (ω'). In other words, the excitation ζ must remain constant as ω' is varied.

It is an interesting fact that calculation of the refractive index change from data obtained in nonlinear optics experiments is often easier than extracting the absolute refractive index from the K-K transform in linear optics! The reason is that absorption changes in nonlinear optics are usually strong only in a very limited frequency range; the integration range in Eq. (24) need only consider this spectrum. In contrast, evaluation of the linear index based on the linear absorption spectrum normally involves a much larger amount of data. One must take full account of the entire linear absorption data to obtain quantitative agreement with experiments that measure the refractive index. In the same way, the reverse transformation in nonlinear optics (obtaining $\Delta\alpha$ from Δn) is not as accommodating as the transformation of Eq. (24). Experiments show that irradiance-dependent changes of the refractive index occur over a relatively broad frequency spectrum. A large and impractical amount of nonlinear dispersion data must be collected and incorporated into a K-K calculation of nonlinear absorption. The reverse transformation is thus difficult to accomplish in practice.

Equation (24) has been used to determine refractive changes due to *real* excitations (i.e., $\chi^{(1)}{:}\chi^{(1)}$ cascaded processes) such as thermal and free-carrier nonlinearities in semiconductors.[41,42] In these examples, ζ denotes either change of temperature or change of free-carrier density, respectively. This K-K methodology has also been applied with great success to the situation where the perturbation is *virtual* or nonresonant. This work unified the bound electronic Kerr effect in bulk semiconductors (i.e., the dispersive nonlinearity resulting from anharmonic motion of bound, valence electrons) to its absorptive counterparts: two-photon absorption, the electronic Raman effect, and the ac Stark effect.[31,39,43–45] The dispersion relation between α_2 and n_2 is given by

$$n_2(\omega_a;\omega_b)=\frac{c}{\pi}\int_{0}^{\infty}\frac{\alpha_2(\omega';\omega_b)}{\omega'^2-\omega_a^2}d\omega' \tag{25}$$

Note that in the general case we are dealing with two frequencies: ω_a and ω_b. Even in the degenerate situation (i.e., $n_2 = n_2(\omega_a;\ \omega_a)$) where we desire the nonlinear index coefficient at a single frequency ω_a, we are still required to provide the nondegenerate absorption spectrum $\alpha_2(\omega';\omega_b)$ at

all frequencies ω' as input to the calculation. We also point out that Eq. (25) can be used to derive relations linking the real and imaginary parts of the nonlinear susceptibility via Eq. (13) [the inverse transformation is obtained with Eq. (14)]:

$$\Re e\{\chi^{(3)}(\omega_a,\omega_b,-\omega_b)\}=\frac{2}{\pi}\int_0^{\infty}\frac{\omega'\Im m\{\chi^{(3)}(\omega',\omega_b,\omega_b)\}}{\omega'^2-\omega_a^2}d\omega' \tag{26}$$

Using the symmetry properties of $\chi^{(3)}$, an equivalent representation is

$$\Re e\{\chi^{(3)}(\omega_a,\omega_b,-\omega_b)\}=\frac{1}{\pi}\int_{-\infty}^{\infty}\frac{\Im m\{\chi^{(3)}(\omega',\omega_b,\omega_b)\}}{\omega'-\omega_b}d\omega' \tag{27}$$

Equation (27) can also be derived in a very general way from a first-principles approach that applies the causality condition directly in the temporal nonlinear response. In this way, one can obtain the dispersion relations for the *n*th order optical susceptibility:[39]

$$\chi^{(n)}(\omega_1,\omega_2,\ldots,\omega_j,\ldots,\omega_n)=\frac{-i}{\pi}\int_{-\infty}^{\infty}\frac{\chi^{(n)}(\omega_1,\omega_2,\ldots,\omega',\ldots,\omega_n)}{\omega_j-\omega'}d\omega' \tag{28}$$

where $\chi^{(n)}$ is a complex quantity. By separating the real and imaginary parts of this equation, we get the generalized Kramers-Kronig relation for a nondegenerate, *n*th order nonlinear susceptibility:

$$\Re e\chi^{(n)}(\omega_1,\omega_2,\ldots,\omega_j,\ldots,\omega_n)=\frac{1}{\pi}\int_{-\infty}^{\infty}\frac{\Im m\chi^{(n)}(\omega_1,\omega_2,\ldots,\omega',\ldots,\omega_n)}{\omega'-\omega_j}d\omega' \tag{29}$$

Note that for $n = 3$ with the substitutions $\omega_1 = \omega_a$, $\omega_2 = \omega_b$, and $\omega_3 = -\omega_b$, Eq. (29) becomes identical to Eq. (27). When the susceptibilities for generating frequency harmonics are included, Eq. (29) can be further generalized.[39] If we consider the $\chi^{(3)}$ associated with third-harmonic generation, it can be shown that:

$$\Re e\{\chi^{(3)}(+\omega,+\omega,+\omega)\}=\frac{1}{\pi}\int_{-\infty}^{\infty}\frac{\Im m\{\chi^{(3)}(+\omega',+\omega',+\omega')\}}{\omega'-\omega}d\omega' \tag{30}$$

Such relationships have been utilized in calculations of the total $\chi^{(3)}$ (THG) in semiconductors. It is computationally more convenient to first calculate the imaginary part because of the presence of δ functions in its frequency domain. The real part is then calculated using the K-K dispersion relations.[46]

16.5 OPTICAL KERR EFFECT

The $\chi^{(3)}$ process leading to an intensity-dependent refractive index is known as the *optical Kerr effect* (OKE). Experimental observation is relatively straightforward, usually requiring just a single laser beam. The OKE is described by Eq. (15) where, for the sake of brevity, we ignore cross-modulation terms and drop the frequency terms to write

$$n=n_0+n_2I \tag{31}$$

There are a variety of physical mechanisms that submit to this mathematical representation, many different ways to observe the effect experimentally, and an assortment of practical devices that can be built.

Optical transitions giving rise to a nonlinear susceptibility $\chi^{(3)}$ (see Figs. 1 and 2, for example) are intimately related to the energy eigenstates of the system. These eigenstates can be associated with bound electronic motion, molecular vibrations, or molecular rotations of the system. Electronic transitions involve the largest energy separation and rotational transitions the smallest. In a given material (gas, liquid, or solid), one or more of these excitations may contribute to the optical Kerr effect. In general, the various contributions differ in their response time, magnitude, and frequency dependence. Referring to our earlier discussion of Eq. (6), the time response of an optical nonlinearity is governed by the virtual lifetime of the relevant transitions. This implies that the nonlinearities associated with the electronic transitions give the fastest response time because they possess large energy denominators. Experiments have shown that electronic nonlinearities are usually faster than the time resolution provided by the shortest optical pulses available at the time of this writing (<10 fs). For practical purposes, then, the nonlinearity associated with the motion of bound electrons can be regarded as instantaneous. At the other extreme, the nonlinearity associated with rotational motion of molecules is relatively sluggish—response times in the picosecond regime have been measured. In the middle range are nonlinearities arising from molecular vibrations. For a Raman-type transition as shown in Fig. 2*b* this effect is manifest as the Raman-induced Kerr effect (RIKE). We discuss two important cases of NLR: the bound electronic Kerr effect in solids (n_2), and the rotational (or orientational) Kerr effect in liquids.

Bound Electronic Optical Kerr Effect in Solids

The optical Kerr effect in solids has been extensively studied in materials ranging from large-gap dielectrics and glasses to narrow-gap semiconductors.[31,44,47–50] The fundamental energy gap E_g turns out to be a parameter of critical importance. Because of direct, linear absorption of the incident laser light, we are interested in the transparency regime where the photon frequency is less than the bandgap energy (i.e., $\omega < \omega_g = E_g/\hbar$). We estimate the response time (τ_r) of the nonlinearity using the virtual lifetime of the transition: $\tau_r \approx 1/|\omega - \omega_g|$. Far below the bandgap, where $\omega << \omega_g$, the response time can be very fast (<<10 fs) and for most applications can be assumed as instantaneous. This ultrafast response has been exploited in soliton propagation in glass fibers[5,51] (Sec. 16.11) and in the generation of femtosecond pulses in solid-state lasers.[52] The optical Kerr effect also causes self-focusing, sometimes resulting in beam distortion and damage in transparent media (Sec. 16.11). Another significant application is the development of ultrafast all-optical-switching devices.[53,54] Although much progress has been made in this area of research, development of a practical switch has been hindered by the relatively small magnitude of bound electronic nonlinearities.

The bound electronic optical Kerr effect in optical solids has been analyzed using semiempirical methods[55] and, more recently, by simple two-band models appropriate for semiconductors.[31,44] The latter treatment provides information about the dispersion, bandgap scaling, and the relationship between the NLA (e.g., two-photon absorption) and NLR through Kramers-Kronig transformation. The resulting simple formula allows one to predict the nonlinear refraction coefficient n_2 knowing only the photon frequency (ω), energy bandgap (E_g), and linear index (n_0):

$$n_2(m^2/W) = \frac{A}{n_0^2 E_g^4} \bar{G}_2\left(\frac{\hbar\omega}{E_g}\right) \tag{32}$$

where $A \approx 3 \times 10^{-35}$ (MKS); E_g is in joules. The function $\bar{G}_2$ describes the normalized dispersion of the coefficient n_2 and is depicted in Fig. 3, along with the normalized two-photon absorption spectrum for bulk semiconductors (Sec. 16.8).

Recall that NLA and NLR correspond to the imaginary and real parts of the third-order susceptibility, respectively. The derivation of Eq. (32) by a Kramers-Kronig transformation required knowledge of the NLA spectrum. Three different mechanisms of NLA were employed in the analysis, corresponding to the three relevant time-ordering sequences depicted in Fig. 2: two-photon absorption, electronic

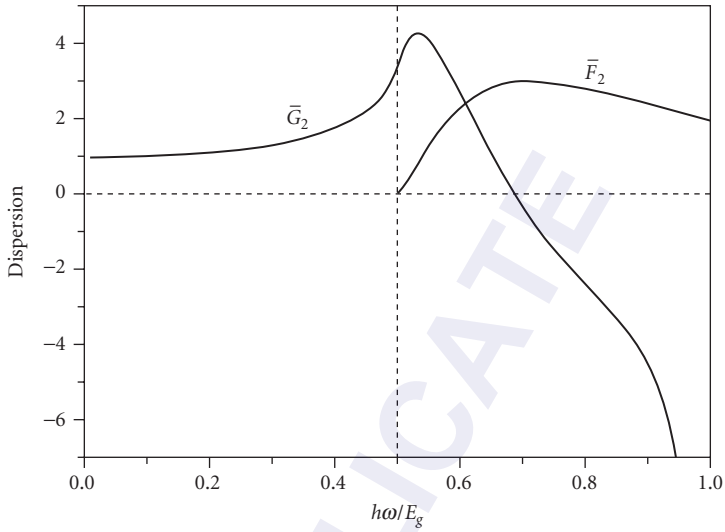

FIGURE 3 Calculated dispersion of nonlinear absorption. Also shown is the two-photon absorption spectrum.

Raman scattering, and the optical (ac) Stark shift of electronic states. The optical Stark effect is a change of the fundamental energy gap that occurs when the oscillating laser field becomes comparable to the electric field binding valence electrons to the positively charge nuclei. In experiments where only a single beam is used (i.e., all the input frequencies are the same), the only observable NLA effect is two-photon absorption, which is discussed in Sec. 16.8.

The plot of the dispersion function $\bar{G}_2$ (Fig. 3) is consistent with our intuitive arguments about resonance enhancement presented in Sec. 16.2. At long wavelengths (i.e., for $\hbar\omega << E_g$), we are far from resonance so $\bar{G}_2 \approx 1$ and is nearly frequency independent (i.e., there is very weak dispersion). Approaching the two-photon resonance (i.e., as $2\hbar\omega$ gets close to E_g), there is an approximately fivefold enhancement of n_2. With increasing photon energy, the sign of n_2 reverses; this is a direct consequence of the sign change in the energy denominator associated with two-photon absorption. With further photon energy increase, there is enhancement due to resonances ascribed to two-photon absorption and the optical Stark effect. The inverse fourth-power bandgap scaling (i.e., E_g^{-4}) and the dispersion predicted by this simple expression display remarkable agreement with data obtained with many different semiconductors and dielectrics.[44]

Reorientational Kerr Effect in Liquids

The reorientational Kerr effect involves transitions between rotational energy levels of a molecule. It is nonresonant and therefore associated with the real part of $\chi^{(3)}$. The absorptive nonlinearity associated with these rotational levels gives an imaginary component to $\chi^{(3)}$; this is a Raman-type transition known as *Rayleigh-wing scattering*.[3,17] For simplicity, we make a classical description of this phenomenon. Consider a carbon disulfide (CS_2) molecule as shown in Fig. 4. This is a cigar-shaped molecule with different polarizabilities along its principal axes (here we show $\alpha_3 > \alpha_1$). As discussed in Sec. 16.7, the polarizability describes the propensity for an external field to produce a dipole in a molecule. In the first step of the interaction, the optical field polarizes this molecule (i.e., induces a dipole moment). The induced dipole interacts with the applied field and aligns itself along the direction of polarization. This molecular reorientation (rotation) causes a birefringence in an isotropic

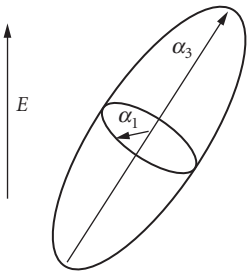

FIGURE 4 Simple picture of CS_2 molecule.

solution; initially, the molecules were randomly oriented and there was no birefringence. The response time of the molecule depends on its mass: the heavier molecule, the slower the response. As an example, CS_2 has a reorientational $n_2 \approx 3.4 \times 10^{-18}$ m^2/W with a relaxation time $\tau \approx 1$ to 2 ps.[56]

16.6 THIRD-HARMONIC GENERATION

In crystals where there is no inversion symmetry, $\chi^{(2)}$ vanishes, making sum and difference frequency mixing impossible. The possibility of third-harmonic generation always exists in principle, although it usually suffers from practical drawbacks. Typical values of $\chi^{(3)}$ are orders of magnitude smaller than $\chi^{(2)}$ coefficients found in popular frequency conversion crystals. This means the laser irradiance must be increased to compensate, often leading to material damage. Moreover, third-harmonic generation in crystals is usually difficult to phase match. Because of these obstacles, cascading of two second-order effects (second-harmonic generation, followed by sum-frequency generation) in two separate crystals is usually the preferred method of obtaining high multiples of the pump laser frequency (see Sec. 16.10).

Gases do not have the damage limitations of crystals. Third-harmonic generation was extensively studied in many different gases around the time that high-power, Q-switched lasers became widely available, and conversion efficiencies as high as several percent were obtained. Studies of sodium vapor have been helpful in elucidating the resonant enhancement that occurs near ω, 2ω, and 3ω.

16.7 STIMULATED SCATTERING

Useful spectroscopic information can be obtained when light is scattered from material, often at frequencies far removed from absorption and emission resonances. Spontaneous scattering is a linear process, in which the material is unmodified by the probing light beam. The various forms of spontaneous scattering (Raman, Brillouin, and Rayleigh) have been known for the better part of a century. In the presence of a sufficiently intense laser beam, however, these scattering processes can be strongly amplified by a nonlinear interaction of the excitation beam with the material, resulting in stimulated scattering.

Raman scattering is most commonly described as the interaction of light with vibrational waves in a material. (Electronic and magnetic excitations can also be measured in Raman experiments.) These vibrational frequencies are typically in the infrared, meaning that Raman-scattered light can have a substantial spectral shift with respect to near-infrared or visible excitation light. Brillouin scattering involves the interaction of light with acoustic waves—waves associated with the propagation of pressure in the medium, leading to periodic density fluctuations. Acoustic waves occur at frequencies that are orders of magnitude smaller than material vibrations; Brillouin scattered light is therefore frequency-shifted from the incident light by a much smaller amount. Rayleigh scattering

results from the interaction of light with stationary density variations—variations much smaller than the wavelength of the incident light. Scattering takes place without any frequency shift relative to the incident light. Rayleigh scattering is of interest because of its strong wavelength dependence and polarization properties. Spontaneous scattering processes scale linearly with input irradiance.

Stimulated Raman Scattering

In Raman scattering (Fig. 5), a photon is absorbed by a material that makes a quantum-mechanical transition from a low energy state $|1>$ to a high energy state $|2>$. At some short time later (i.e., not instantaneously), the material relaxes to a lower energy state $|3>$ different from the original state, giving up its energy in the form of a photon of different energy than the excitation photon. If the lower state $|3>$ is at a higher energy than state $|1>$, the emitted photon will be at a longer wavelength than the excitation light. This is called *Stokes shifted Raman scattering*. If the terminal state $|3>$ is at a lower energy than state $|1>$, the emitted photon will be shorter in wavelength than the incident light, leading to *anti-Stokes shifted Raman scattering*. The difference between the incident and emitted light thus provides information about the relative positions of the different energy levels. Maintaining the same nomenclature, there is also Stokes and anti-Stokes shifted Brillouin scattering. Note that when state $|1>$ and $|3>$ are the same, there is no frequency shift and we have Rayleigh scattering.

The intermediate state can be a real state corresponding to a quantum mechanical energy level of the system; this is known as *resonant Raman scattering*. In the theme of this chapter, resonant Raman scattering is an example of a cascaded linear process leading to an effective $\chi^{(3)}$. More often, the intermediate level is not resonant with the photon, and the transition from $|1>$ to $|2>$ is virtual (illustrated by a horizontal dotted line in Fig. 5). The distinction between the resonant and nonresonant processes can be confusing because both are referred to as Raman scattering. To maintain consistency with standard nomenclature, we briefly depart from the logical organization of this chapter and discuss both resonant and nonresonant Raman scattering in this section.

The essential physics of Raman scattering can be understood from the classical picture of a diatomic molecule of identical atoms vibrating back and forth at frequency ω_L. The diatomic molecule is an illustrative example; in principle all Raman-active and some normal modes of vibration of a solid, liquid, or gas can be probed with Raman techniques.[57] We assume that the electronic charge distribution on the molecule is perfectly symmetric, hence there is no permanent dipole or a dipole moment modulated by the vibration. This normal mode is therefore not dipole active, that is, it cannot absorb electromagnetic radiation (see Chap. 8, "Fundamental Optical Properties of Solids").

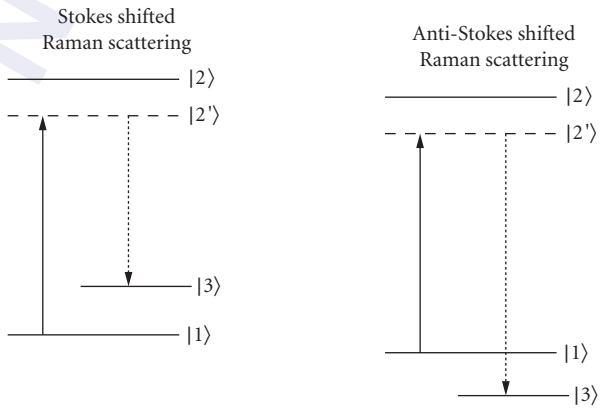

FIGURE 5 Raman scattering.

When an external electric field is applied, the situation changes. The field in an electromagnetic wave polarizes the charge distribution on the molecule and it acquires a dipole. If the induced dipole is also modulated by a normal mode of vibration, the mode is said to be Raman active. The extent to which an external field can polarize the molecule is quantified by the following equation:

$$\mathbf{p}(r,t)=\alpha\mathbf{E}(r,t) \tag{33}$$

where $\mathbf{p}(r, t)$ is the induced dipole moment, α is the polarizability, $\mathbf{E}(r, t)$ is the time- and spatially-varying electric field, and bold type denotes vector quantities. The polarizability is not constant, however, but rather is a function of the molecular separation distance q. Writing the first two terms of a Taylor series expansion of $\alpha(q)$ we have:

$$\alpha(q)=\alpha_o+\left(\frac{\partial\alpha}{\partial q}\right)_{q_o} q \tag{34}$$

where α_0 is a constant representing the polarizability at the equilibrium position of the molecule (q_o). The molecule vibrates at a frequency $\pm\,\omega_L$, which is the energy difference between the states $|1>$ and $|3>$ in Fig. 5, hence:

$$q=q_o\exp(\pm i\omega_L t) \tag{35}$$

Inserting Eqs. (34) and (35) into Eq. (33), and realizing that the electromagnetic field varies sinusoidally at the optical frequency ω, we find that the second term in the polarizability expansion is responsible for the appearance of induced dipoles oscillating at a frequency offset from the incident electromagnetic wave by $\pm\,\omega_L$:

$$p(r,t)_{\text{Raman}}=E_o(r)\left(\frac{\partial\alpha}{\partial q}\right)_{q_o} q_o\exp(i\omega t\pm i\omega_L t) \tag{36}$$

These dipoles can radiate and are the origin of spontaneous Raman scattering. There is also an oscillating dipole unaffected by the vibration corresponding to the term α_0. This dipole oscillation is exactly at the frequency of the incident light and corresponds to spontaneous Rayleigh scattering:

$$p(r,t)_{\text{Rayleigh}}=E_o(r)\alpha_o\exp(i\omega t) \tag{37}$$

In stimulated scattering, we have to consider the force exerted on the vibrating molecule by the external field as a consequence of its polarizability. This force involves only the second term in Eq. (34):

$$F=\frac{1}{2}\left(\frac{\partial\alpha}{\partial q}\right)_{q_o}\langle E^2(r,t)\rangle \tag{38}$$

where the angular brackets represent a time average over an optical period. In a dipole-active interaction, the lowest order forcing term is proportional to E, resulting in linear absorption of light. In the case of a Raman-active mode, Eq. (38) shows the force scales as E^2; therefore, the force is nonlinear in the field. The forcing term is negligible at low light intensities, but becomes important when large electromagnetic field levels generated by lasers are encountered.

Because the Raman active mode of the molecule is subject to a force proportional to E^2, there must be two input photons driving the interaction. If the two photons are at different frequencies,

the molecule will experience a force at the beat frequency of the two photons. If the wavelengths of the two photons are chosen so that their beat frequency equals that of the molecular vibration ω_L, strong amplification of all three waves (two input electromagnetic waves and the molecular vibration) can occur, resulting in stimulated scattering. The molecular polarizability thus acts as a nonlinear mixing term to reinforce and amplify the interacting waves. It is important to realize this is of practical consequence only when the input electromagnetic fields are sufficiently high.

The nonlinear polarizability impresses sidebands on the pump light, resulting in three distinct electromagnetic waves (laser beam, Stokes shifted Raman, and anti-Stokes shifted Raman) propagating in the medium. The same nonlinear mixing process that led to the generation of the Raman sidebands in the first place can cause coherent excitation of additional molecules due to their polarizability. In this way, a coherent vibrational wave builds up, which in turn feeds more energy into the Raman-shifted components, thus amplifying them. In stimulated scattering, the fluctuations of the optical medium (vibrations, density variations, etc.) are *induced* and *amplified* by the external electromagnetic radiation. In contrast, spontaneous scattering originates from the naturally occurring (thermally driven, for example) fluctuations of the material. Because the linear optical properties of the medium are modified by the presence of an exciting laser beam (specifically its irradiance), the various stimulated scattering mechanisms are classified as third-order nonlinear optical processes.

In stimulated Raman scattering (SRS), one is most often looking for a new frequency generation at the wavelength corresponding to the energy difference of levels $|2'>$ (or $|2>$) and $|3>$ shown in Fig. 5. Stimulated Raman gain and loss applied to an input beam at this frequency can be obtained as well. Polarization effects occurring in the nonlinear wave mixing process can also be studied in what is known as *Raman-induced Kerr effect spectroscopy* (RIKES, see Chap. 5, "Optical Properties of Semiconductors"). We also mention two other classes of third-order nonlinear spectroscopy: coherent anti-Stokes Raman spectroscopy (CARS) and coherent Stokes Raman spectroscopy (CSRS). In these interactions, illustrated in Fig. 6, two external laser fields at frequencies ω_1 and ω_2 are supplied. There must be a third-order nonlinear polarization present as in SRS, leading to frequency mixing and new wavelengths.

The somewhat subtle differences distinguishing SRS, CARS, and CSRS are the number and location of intermediate levels (designated by dashed lines in Fig. 6). Consider two excitation frequencies

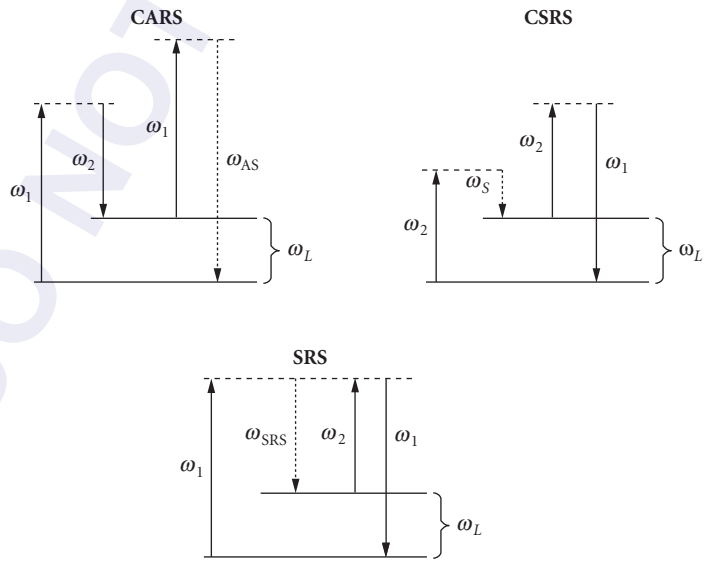

FIGURE 6 Stimulated Raman processes.

with $\omega_1 > \omega_2$ probing a given material system with real energy levels separated by frequency ω_L in Fig. 6. In CARS, short-wavelength photons are detected at $\omega_{as} = 2\omega_1 - \omega_2$. For the CSRS arrangement, the excited intermediate states are at lower energy and a longer-wavelength photon at frequency $\omega_s = 2\omega_2 - \omega_1$ is detected. Note that SRS is obtained when the intermediate levels are degenerate; SRS is thus a special case of the nonlinear interaction. In linear, spontaneous Raman scattering, a single exciting electromagnetic wave is required. In SRS, two input fields are involved; they just happen to be at the same frequency and invariably are supplied by a single laser source. Unlike spontaneous Raman scattering, however, SRS is a function of the third-order nonlinear susceptibility and hence depends nonlinearly on the irradiance of the excitation laser.

It is important to emphasize that all three of these stimulated Raman processes (SRS, CARS, and CSRS) are essentially a mixing of three waves to produce a fourth wave via the third-order nonlinear polarization. Analysis of the problem is made using second-order perturbation theory in quantum mechanics. The tensor nature of the third-order susceptibility and the multitude of ways the interacting waves of various polarization states can mix lead to complicated expressions. One finds resonance denominators quantifying the efficiency of the wave mixing process. The scattering efficiency is governed by the proximity of photon energies to real energy eigen states in the system. In principle, SRS, CSRS, and CARS can all take place in an experiment; the various generated beams can be distinguished by substantially different angles of propagation when leaving the irradiated sample. These angles are readily determined by phase-matching conditions for the nonlinear interaction. The wave vectors of the interacting photons can be arranged for maximum output signal of the desired Raman process. The phase-matching condition is obtained automatically in SRS, but careful orientation of the interacting beams can lead to very narrow linewidths and extremely accurate spectroscopic measurements. Some applications of stimulated Raman scattering include high-resolution spectroscopy of gases,[11,17,58,59] spin-flip Raman scattering, stimulated polariton (the quanta of photon-phonon coupling) scattering, and ultrafast time-resolved measurements.[60,61] The reader should also be aware that Raman spectroscopy beyond the third-order nonlinear susceptibility has been demonstrated. Further information can be obtained in texts on nonlinear laser spectroscopy.[3,6,10,16,62–65]

Stimulated Brillouin Scattering

Stimulated Brillouin scattering (SBS) is an important third-order nonlinear optical effect that has been widely used for efficient phase conjugate reflection of high-power lasers.[26] An incident laser beam can scatter with the periodic refractive index variations associated with a propagating acoustic wave. The scattered light, depending on the propagation direction of the acoustic wave, will be Stokes or anti-Stokes shifted by the frequency of the acoustic wave. The process is stimulated because the interference of the incident and scattered wave can lead to an amplification of the acoustic wave, which then tends to pump more energy into the scattered wave. This positive feedback process can cause an exponential growth of the SBS beam and very high efficiencies in the right circumstances. Optical feedback to the medium is accomplished in one of two ways: (1) *electrostriction* is local compression of the material in response to the strength of the electromagnetic field with a commensurate refractive index change; and (2) *linear optical absorption* by the laser field leads to local heating, expansion, density fluctuations, and thus periodic modulation of the refractive index. The latter effect is an example of a cascaded $\chi^{(1)}{:}\chi^{(1)}$ process, which is the subject of Sec. 16.9. Electrostriction is usually associated with SBS, and we discuss it here.

Consider again the diatomic molecule that was used to illustrate the Raman effect. In the presence of an external electric field, it acquires a polarizability described by Eq. (34). As we have seen, the induced dipole can interact with the field. Electrostriction accounts for the ability of the electric field to do work on the polarized molecule—pulling and pushing it by electrostatic forces. The molecules will move and tend to pile up in regions of high field, increasing the local density. Associated with these density changes will be a change of refractive index. Density fluctuations can also be generated by the change in pressure that accompanies a propagating acoustic wave: Pressure nodes will exist in the peaks and valleys of the acoustic wave. Electrostriction therefore provides a coupling mechanism between acoustic waves and electromagnetic waves.

It is important to emphasize that the periodic modulations in an electrostrictive medium are propagating spatial fluctuations modulated at the frequency of traveling acoustic waves. When the density fluctuations are stationary, we can have stimulated Rayleigh scattering. A thorough, detailed discussion of the many (often intricate) issues in stimulated Brillouin and Rayleigh scattering can be found in textbooks on nonlinear optics.[3,11,16,17,28]

16.8 TWO-PHOTON ABSORPTION

Two-photon absorption (2PA) is the process by which the energy gap between two real states is bridged by the simultaneous (in the context of the Uncertainty Principle discussed in Sec. 16.2) absorption of two photons, not necessarily at the same frequency. Both photons have insufficient energy to complete the transition alone; 2PA is thus observed in the spectral range where the material is normally transparent. When the two photons are present together for a fleeting instant of time determined by the Uncertainty Principle, an optical transition can take place.

Quantum mechanically, we can think of the first photon making a virtual transition to a nonexistent state between the upper and lower levels (Fig. 2*c*). If the second photon appears within the virtual lifetime of that state, the absorption sequence to the upper state can be completed. If not, the virtual transition collapses back to the ground state, and no absorption takes place. To have an appreciable rate of 2PA, photons must be supplied at a rate high enough that there is a reasonable probability two photons will both be present during the virtual lifetime. Because the virtual lifetime is so short, photon fluxes must be high, and therefore power levels from laser beams are required.

The efficiency of 2PA is affected by the proximity of the input photons to a real state of the system. It is important to note that there must be an allowed optical transition linking the initial state and this real state. The closer one of the input photons coincides with a real state, the stronger the 2PA. When the intermediate state of 2PA is also a system resonance, the situation is commonly referred to as *excited state absorption* (ESA)—a sequence of two linear absorption processes that leads to an effective third-order nonlinearity. Excited state absorption is thus a cascaded $\chi^{(1)}{:}\chi^{(1)}$ effect, giving rise to an effective third-order nonlinearity (Sec. 16.9). It has implications for optical power limiting and is discussed in Chap. 13, "Optical Limiting."

In stimulated scattering, the *difference* frequency of two input electromagnetic fields $\hbar\omega_i - \hbar\omega_j$ equals a characteristic energy resonance of the material system. In 2PA, an energy resonance exists at the *sum* of the two input fields: $\hbar\omega_i + \hbar\omega_j$. In Secs. 16.2 and 16.3, 2PA was shown to be associated with the imaginary part of $\chi^{(3)}$. This is because it is an absorption process (i.e., it is exactly resonant with two eigenstates of the system). It is the only NLA process (i.e., a process associated with the imaginary part of $\chi^{(3)}$) that can be simply studied with a single photon frequency.

Two-photon absorption in semiconductors is one of the most thoroughly studied subjects in the entire field of nonlinear optics.[66] The 2PA coefficient (often written β or α_2^{2PA}) of bulk semiconductors has been calculated using models involving only two parabolic bands and also with more complex band structure.[67] It is defined by the rate of electron-hole pair excitation: $dN/dt = \beta I^2/(2\hbar\omega)$. The two-parabolic band model gives a comparatively simple yet general and accurate description of 2PA for a large class of semiconductors. The theoretical result for single frequency excitation can be expressed as

$$\beta(m/W) \simeq \frac{B}{n_0^2 E_g^3} \bar{F}_2\left(\frac{\hbar\omega}{E_g}\right) \tag{39}$$

where $\bar{F}_2(x) = 2(2x-1)^{3/2}/x^5$ and $B = 5.67 \times 10^{-66}$ ($x = \hbar\omega/E_g$ and the energy bandgap E_g is in joules). The best empirical fit to experimental data is obtained with B adjusted to a slightly higher value of 9.06×10^{-66}. The function $\bar{F}^2$ describes the dispersion of 2PA and is plotted in Fig. 3. The intimate relation between NLA and NLR and the role of 2PA in semiconductors is explored in Sec. 16.4 and in Refs. 31 and 67 to 69. There are important practical implications for 2PA in

semiconductors and dielectrics. It can enhance or degrade optical switching performance in semiconductor devices and lead to optical damage in laser window materials. 2PA is also the basis of Doppler-free spectroscopy of gases.[57,59]

16.9 EFFECTIVE THIRD-ORDER NONLINEARITIES; CASCADED $\chi^{(1)}$:$\chi^{(1)}$ PROCESSES

Effective third-order nonlinearities occur when one of the transitions in our four-photon interaction picture is resonant, providing a path of linear absorption. Linear absorption is a mechanism to directly couple laser light into the system—with sufficiently intense laser light, the linear optical properties of a material can be modified. An effective third-order nonlinearity occurs when linear absorption affects the refractive index. We give some examples here.

Optically Generated Plasmas

Optical generation of stable plasmas is readily obtained in semiconductors and most studies of this subject have been made with these materials (see Chap. 8, "Fundamental Optical Properties of Solids" and Chap. 5, "Optical Properties of Semiconductors"). For cascaded linear processes that we discuss here, the formation of a free electron-hole pair occurs by direct bandgap excitation by an incident photon. The optically produced carriers augment the background electron-hole density, and the plasma remains electrostatically neutral. If the generation of an excess amount of plasma exceeds the rate of loss (by recombination or diffusion) on the time scale of interest, the plasma will modify the linear optical properties of the semiconducting material. The simplest way to see this is via the classical Drude model, where the refractive index of a metal or semiconductor is[70,71]

$$n = n_0 \sqrt{1 - \frac{\omega_p^2}{\omega^2}} \tag{40}$$

In this equation, ω is the angular frequency of the light, n_0 is the linear index in the absence of significant free carrier density, and ω_p is the density-dependent plasma frequency:

$$\omega_p = \sqrt{\frac{Ne^2}{m\varepsilon}} \tag{41}$$

where N is the electron-hole pair density, e is the electronic charge, m is the reduced mass of the positive and negative charge carriers (electrons, holes, or ions), and ε is an appropriate background dielectric constant. Note that as the carrier density increases, the refractive index decreases. The material is usually excited by a laser beam with a nonuniform spatial profile such as a Gaussian, giving rise to negative-lensing and self-defocusing, assuming $\omega < \omega_p$.

The situation becomes complicated at densities where many-body effects become important or when the Drude model ceases to be valid. We also note that optical generation of plasmas can also occur as the result of nonlinear mechanisms in the presence of high laser fields, and we aren't, of course, restricted only to solid-state plasmas. Examples of nonlinear plasma production are multiphoton absorption, laser-induced impact ionization, and tunneling. Because plasma generation and the concomitant refractive index modification are caused by a nonlinear optical process, the order of the nonlinearity is higher than three. Although high-order nonlinearities are a rich subset of the field, they are not dealt with in this chapter. A number of review articles and textbooks on laser-induced change to the refractive index due to plasma generation via linear absorption are available.[31,42,72–74]

Absorption Saturation

Absorption saturation is a well-known example of a cascaded linear process. Consider a homogeneously broadened system of two-level atoms (i.e., a system of identical two-level atoms) with the energy diagram shown in Fig. 7. The lower and upper states are resonant with a photon depicted by the vertical arrow, and there is linear absorption of incident light. Associated with the absorption is a spectral linewidth (with a Lorentzian shape for a homogeneous system), illustrated on the right side of the diagram in Fig. 7. An induced dipole or polarization is set up between the two states upon excitation by a photon. The states are coherently coupled, and this coherence is in phase with the exciting electromagnetic field. In a real system, this coherence will be quickly destroyed by collisions with other atoms. The rate at which the coherence is washed out determines the spectral width of the absorption profile and hence the frequency response of the imaginary component of the linear susceptibility. The real part of the linear susceptibility is obtained by the Kramers-Kronig transformation, giving rise to what is traditionally known as anomalous dispersion of the refractive index shown on the left side of Fig. 7. Note that the refractive index is positive for frequencies below resonance and negative at frequencies above it.

We have assumed that the rate at which photons are supplied to the system produces a negligible change of population in the upper and lower states. This means that the rate of population relaxation (recombination and diffusion, for example) is much faster than excitation. When the incident irradiance is sufficiently high, however, this may no longer be the case. The upper level can become appreciably occupied, reducing the availability of terminal states for optical transitions. The absorption thus decreases or bleaches, indicated by the dashed lines in Fig. 7. Associated with the change of absorption is a change of refractive index. The relationship between absorption and refraction can again be handled with the Kramers-Kronig transformation *provided* we consider the system as being composed of both the atoms *and* the input light beam, specifically the nonequilibrium change of population created by the input light. This is exactly the same mathematical formulation used in the description of nonresonant third-order nonlinearities introduced in Sec. 16.4. The difference here is that the absorption of photons is a resonant, linear process. The linear absorption of light then affects the linear optical properties of absorption and dispersion. Because the reduction of absorption depends directly on laser irradiance, it behaves like a third-order nonlinearity. We point out that the resonant nature of absorption saturation (and the associated nonlinear refraction) can lead to an unacceptable deviation from a third-order susceptibility description when the input irradiance goes even higher. In the high-power regime, a nonperturbative approach (i.e., not represented by a power series expansion) must be used.[75]

Absorption saturation spectroscopy (with emphasis on gases) is discussed at length in Ref. 59. It is also a principle nonlinear effect in bulk and quantum-confined semiconductors (where the simple two-level picture previously outlined must be substantially modified), having implications for optical switching and bistability.[42,53,72,76]

We briefly mention the density matrix (see Chap. 10,[76] "Nonlinear Optics"). This is a powerful method of analysis for the resonant interaction of light with a two-level system. In addition to absorption saturation, the nonlinear optical effects described by the density matrix include Rabi oscillations, photon echoes, optical nutation, superradiance, self-induced transparency, and optical-free induction

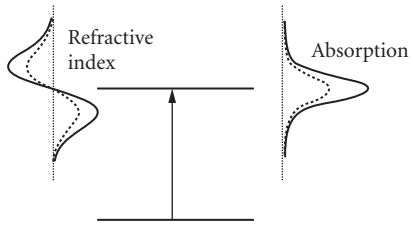

FIGURE 7 Absorption saturation and refraction of a two-level atomic system.

decay, which are not immediately associated with a third-order nonlinearity derived from a perturbation expansion of the polarization. Experimental manifestations of these phenomena, however, can often be represented by an effective third-order nonlinearity. The nonlinear optics of the two-level system and the associated optical Bloch equations derived from the density matrix formulation of the problem are discussed in Chap. 11, "Coherent Optical Transients." The reader is also referred to many excellent textbooks and monographs.[3,11,24,77,78]

Thermal Effects

Linear absorption of light must result in energy deposition in the irradiated material. If the rate of energy deposition significantly exceeds its rate of removal, heating can take place. As the energy of a collection of atoms and molecules increases, it's easy to understand that their macroscopic optical properties will be altered. When there is a linear relationship between laser irradiance and the refractive index, an effective third-order nonlinearity will result. The thermo-optic effect has a relatively straightforward physical interpretation and is arguably one of the most important optical nonlinearities. It is often the power-limiting mechanism of a high-power solid-state laser—where excessive circulating optical flux can cause *thermal blooming* in the laser crystal. This heat-induced lensing effect can destroy the beam quality. Thermal-index coefficients have been extensively tabulated, and the reader is referred to Refs. 18 and 42.

Photorefraction

Photorefraction results from the spatial redistribution of electrons and/or holes in a solid (see Chap. 12, "Photorefractive Materials and Devices"). Electron-hole pairs are generated by linear absorption of laser light. If the excitation geometry produces a spatial modulation of irradiance such as a two-beam interference pattern, the electrons and holes will arrange themselves in accordance with the spatial irradiance profile. Often the linear absorption involves impurity levels. Mobile carriers tend to diffuse from the bright regions, leaving fixed charges behind. If a sinusoidally modulated, two-beam interference fringe pattern is written in a doped photorefractive crystal, for example, fixed charges of ionized states will be prevalent in the high irradiance regions while mobile charge carriers will tend to accumulate in regions with low light levels. A modulated space charge must exist, and therefore a modulated electric field pattern must be present as well. This field alters the refractive index via the linear electro-optic effect (i.e., Pockel's effect). The photorefractive nonlinearity is clearly nonlocal, as it requires a spatial modulation of charge density. Manipulation of the carriers can also be obtained with static electric fields, and the response time tends to be of the order of seconds.[3,18,79,80]

16.10 EFFECTIVE THIRD-ORDER NONLINEARITIES; CASCADED $\chi^{(2)}$:$\chi^{(2)}$ PROCESSES

Materials lacking a center of inversion symmetry have nonzero $\chi^{(2)}$ and exhibit a second-order nonlinear polarization. This is the second term in the polarization power series expansion of Eq. (1) that is responsible for the most well-known effects in nonlinear optics, including second-harmonic generation (sum and difference frequency generation, optical rectification), and optical parametric processes (see Chap. 17, "Continuous-Wave Optical Parametric Oscillators"). It is also possible to cascade two $\chi^{(2)}$ processes to produce an effect that mimics a $\chi^{(3)}$ process. The most common and efficient way of producing THG, for example, is by a $\chi^{(2)}$ cascade process. In this interaction, an input source at ω generates SHG via the second-order susceptibility $\chi^{(2)}$ $(2\omega = \omega + \omega)$; the second harmonic and fundamental then mix in a second (or the same) nonlinear crystal to produce the third harmonic by sum frequency generation $\chi^{(2)}(3\omega = 2\omega + \omega)$. This type of nonlinearity is nonlocal because the two processes (SHG and SFG) take place in spatially separate regions.

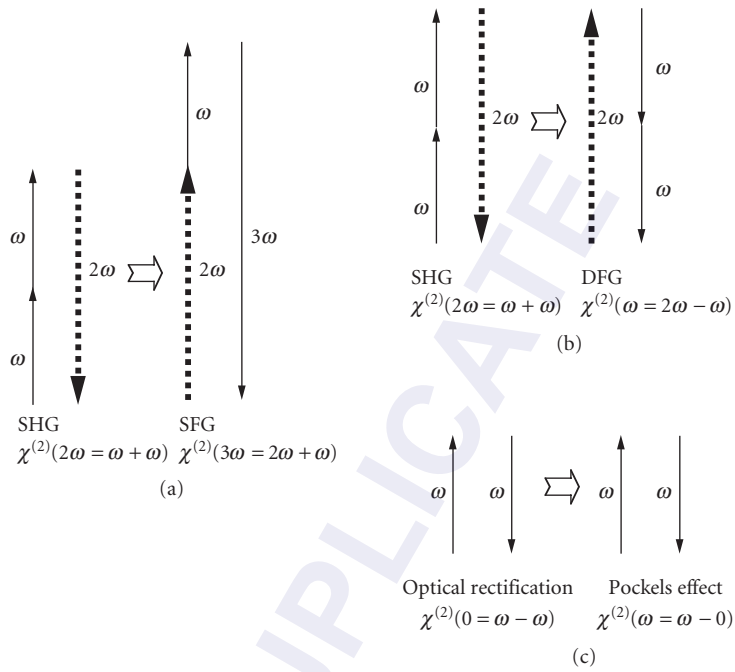

FIGURE 8 Cascaded $\chi^{(2)}$:$\chi^{(2)}$ effective third-order nonlinearities.

In addition to THG, all other $\chi^{(3)}$ effects have an analogous process in $\chi^{(2)}$:$\chi^{(2)}$ cascading. Consider the case where we have one frequency ω. The corresponding cascaded $\chi^{(2)}$ effects are depicted in Fig. 8. Recall that the intrinsic $\chi^{(3)}$ is manifest as: (1) THG, (2) 2PA, and (3) the ac Stark effect. The horizontal block arrows indicate the point of cascade (i.e., the propagation of the beams between the two $\chi^{(2)}$ interactions). There are always two distinguishable $\chi^{(2)}$ interaction regions; hence $\chi^{(2)}$:$\chi^{(2)}$ is clearly nonlocal. We also point out that in general the photon frequencies can be different.

Although the analogy is limited, cascaded $\chi^{(2)}$ effects exhibit NLA and NLR mimicking $\chi^{(3)}$. In the case of SHG, for example, the manifestation of $\chi^{(3)}$ NLA is depletion of the pump beam. The utility of cascaded $\chi^{(2)}$:$\chi^{(2)}$ for producing large nonlinear phase shifts has been realized only recently.[81–83] The analysis of $\chi^{(2)}$ is relatively straightforward, involving the coupled amplitude equations governing the propagation of the interacting beams. For example, the nonlinear phase shift imposed on a fundamental beam (ω) as it propagates through an SHG crystal of length L with a phase mismatch $\Delta k = k(2\omega) - 2k(\omega)$ and assuming small depletion is[82]

$$\Delta\phi \approx \tan^{-1}\left(\frac{\Delta kL}{2}\frac{\tan(\beta L)}{\beta L}\right) - \frac{\Delta kL}{2} \tag{42}$$

where $\beta = \sqrt{(\Delta kL/2)^2 + \Gamma^2}$, $\Gamma = \omega\chi^{(2)}|E_0|/2c\sqrt{n(2\omega)n(\omega)}$, and E_0 denotes the electric field of the fundamental beam. An effective $\chi^{(3)}$ can be obtained if we expand $\Delta\phi$ to lowest order in Γ and use $\Delta\phi = \omega L n_2^{\text{eff}} I/c$ to give[84]

$$n_2^{\text{eff}} = \frac{9}{c^2 4\pi\varepsilon_0}\frac{\omega d_{\text{eff}}^2 L}{n^2(\omega)n(2\omega)}\left[\frac{\pi}{\Delta kL}\left(1 - \frac{\sin(\Delta kL)}{\Delta kL}\right)\right] \tag{43}$$

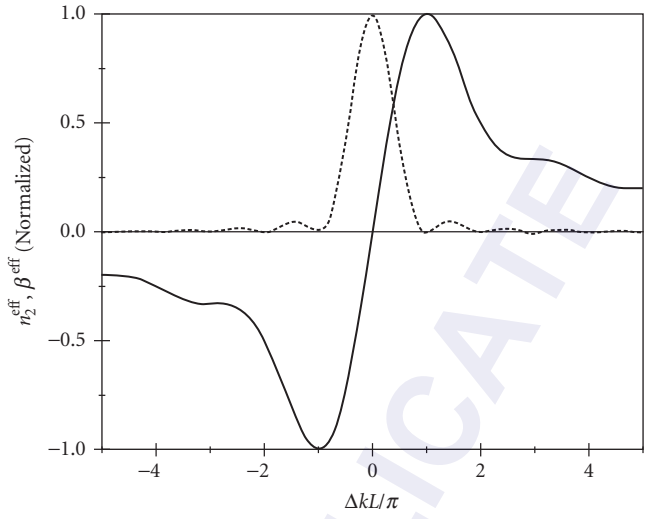

FIGURE 9 Calculated phase shifts in cascaded $\chi^{(2)}$:$\chi^{(2)}$.

Here $d_{\text{eff}} = \chi^{(2)}(2\omega = \omega + \omega)/2$ is the effective tensor component of the second-order nonlinear susceptibility for a given experimental geometry.

Phase mismatch is represented by the bracketed term in Eq. (43), plotted in Fig. 9. Also shown in Fig. 9 is the depletion of the fundamental beam which, on the same level of approximation, can be regarded as an effective two-photon absorption coefficient that scales as $\beta^{\text{eff}} \sim \text{sinc}^2(\Delta kL)$. Cascaded $\chi^{(2)}$ leads to an effective refractive index modulation (n_2^{eff}) and two-photon absorption (β^{eff}), but one should not conclude that the material's index of refraction is altered or energy is deposited in the material. These coefficients describe only nonlinear phase shifts and the conversion of the fundamental beam to second-harmonic beams. The nonlinear phase shift from the $\chi^{(2)}$:$\chi^{(2)}$ process has been used to demonstrate nonlinear effects analogous to those observed previously with the intrinsic optical Kerr effect. These include self-focusing and self-defocusing,[81] all-optical switching,[85,86] soliton propagation,[87,88] and laser mode-locking.[89]

16.11 PROPAGATION EFFECTS

When the nonlinear optical polarization $P^{\text{NL}}(t)$ is known, the propagation of optical fields in a nonlinear medium can be analyzed with the aid of Maxwell's equations:

$$\nabla \times \nabla \times E + \frac{1}{c^2}\frac{\partial^2 E}{\partial t^2} = -\mu \frac{\partial^2 P}{\partial t^2} \tag{44}$$

where $P(t)$ is the total polarization including the linear and nonlinear terms. The slowly varying envelope approximation is then usually made to reduce the above equation to a system of four coupled nonlinear differential equations for the four interacting fields. For *thin* nonlinear media, where there is no significant distortion of the spatial beam and temporal shape upon propagation, the problem simplifies greatly. Equations (19) and (20) were obtained with this approximation. For *thick* nonlinear media, however, linear and nonlinear diffraction as well as dispersion cannot be ignored. In this section, we discuss two important propagation phenomena: *self-focusing* and *soliton formation*.

Self-Focusing

Self-focusing occurs in materials with a positive intensity-dependent refractive index coefficient ($n_2 > 0$). Self-focusing (or *Kerr-lensing*) causes spatial collapse of the laser beam when it propagates through transparent optical materials, often leading to optical damage. It is a consequence of the nonuniform spatial profile of the laser beam.[2,3,17,18] For a *thin* nonlinear material, one makes the so-called parabolic approximation for the nonlinear phase shift to obtain an approximate Kerr-lens focal length, assuming a Gaussian beam of radius w ($1/e$ of the electric field profile):[90]

$$f_{\mathrm{NL}} \simeq \frac{aw^2}{4Ln_2I} \tag{45}$$

where L is the thickness of the medium, I is the irradiance, and $6 > a > 4$ is a correction term. Note that when n_2 is negative, Eq. (45) shows there will be a negative focal length and thus self-defocusing of the incident beam.

Equation (45) is valid for $f_{\mathrm{NL}} >> L$ and $Z_0 >> L$, where Z_0 is the diffraction length (Rayleigh range) of the incident beam. This is the so-called *external self-action* regime.[91] This approximation fails for thick nonlinear media and/or at high irradiance (i.e., *internal self-action*). Equation (44) must then be solved numerically. Analysis shows that self-lensing of a Gaussian beam overcomes diffraction at a distinct threshold power (i.e., the self-focusing threshold), given by the approximate formula:[90,92]

$$P_{\mathrm{cr}} \simeq \frac{a\lambda^2}{8\pi n_2 n_0} \tag{46}$$

Note that for sufficiently thick media, the self-focusing threshold occurs at a critical power, not at a threshold irradiance (i.e., the power at which the self-focusing overcomes diffraction). Self-focusing and diffraction both scale with beam area, thus canceling out the spot size dependence in Eq. (46). Self-focusing and self-defocusing (collectively called *self-action effects*) are often employed in optical limiting applications. Self-action is also the essential mechanism for mode-locking cw solid-state lasers, commonly known as *Kerr-lens mode-locking*.[93]

Solitons

Soliton waves are realized in many different physical circumstances, ranging from mechanical motion to light propagation. In general, they are robust disturbances that can propagate distortion-free for relatively long distances. The robustness of optical solitons can be manifest in the time domain (temporal solitons), transverse space (spatial solitons), or both (light bullets). Temporal solitons have been extensively studied in optical fibers because of their tremendous utility in long-distance optical communication. They exist as a consequence of a balance between the competing effects of linear refractive index dispersion and nonlinear phase modulation.

Assume a single beam propagating in a long nonlinear waveguide characterized by an instantaneous nonlinear index coefficient n_2 and a linear refractive index $n(\omega)$. Ignoring spatial effects (i.e., diffraction), we write the electric field as $\mathscr{E}(z,t) = A_0 u(z, t - z/v_g)\exp(i\omega_0 t - ik_0 z) + \mathrm{c.c.}$ From Eq. (44), one derives a differential equation describing the evolution of the soliton field envelope $u(z, t)$:[3,51,94]

$$-i\frac{\partial u}{\partial z} + \frac{k_2}{2}\frac{\partial^2 u}{\partial \tau^2} = \Delta k_{\mathrm{NL}} |u|^2 u \tag{47}$$

Here $v_g = d\omega/dk|_{\omega=\omega_0}$ is the soliton pulse group velocity, τ is a retarded time $\tau = t - z/v_g$, $k_2 = d^2k/d\omega^2|_{\omega=\omega_0}$ gives the group velocity dispersion (GVD), and $\Delta k_{\mathrm{NL}} = n_2 I_0 \omega_0/c$ is the irradiance-dependent change of the propagation wave vector. In MKS units, the peak intensity of the soliton pulse is $I_0 = n_0 \varepsilon_0 c|A_0|^2/2$. Equation (47) is called the *nonlinear Schrödinger equation* (NLSE) and can be solved exactly. One solution gives the fundamental soliton pulse:

$$u(z, \tau) = \sec h(\tau/\tau_0) e^{i\kappa z} \tag{48}$$

where $\tau_0^2 = -k_2/\Delta k_{NL}$ is the soliton pulsewidth and $\kappa = -k_2/2\tau_0^2$. Note that the modulus of the soliton pulse envelope $|u|$ remains unperturbed upon propagation. For this solution to exist, the GVD (k_2) and the nonlinear refraction (Δk_{NL}) must have opposite signs. For transparent optical solids, including silica glass optical fibers, the nonlinear index coefficient n_2 is almost always positive, which means that a negative GVD is required. In fused silica fibers, the point of balance is attained at a wavelength of $\lambda \approx 1.55$ μm. This is also a spectral region with very low absorption loss. This wavelength has become the standard for the telecommunications industry. Optical solitons in fibers were first reported by Mollenauer et al.[51]

Spatial solitons refer to the propagation of an optical beam without any change or distortion to its spatial irradiance distribution. In this type of soliton, a point of stability is achieved between linear diffraction (causing the beam to diverge) and nonlinear self-focusing. In the presence of a $\chi^{(3)}$ nonlinearity, a stable solution to the NLSE can be found in one spatial dimension only.[95,96] Using a cascaded $\chi^{(2)}$:$\chi^{(2)}$ nonlinearity, however, two-dimensional spatial solitons (or solitary waves) have been demonstrated.[87,88] Two-dimensional spatial solitons can be realized for a cascaded $\chi^{(2)}$:$\chi^{(2)}$ process because of its different behavior compared to $\chi^{(3)}$ at large nonlinear phase shifts. Specifically, cascaded $\chi^{(2)}$:$\chi^{(2)}$ exhibits a saturation of the nonlinear phase-shift that is a direct consequence of depletion of the fundamental beam.

16.12 COMMON EXPERIMENTAL TECHNIQUES AND APPLICATIONS

There are a variety of experimental methods for determining the characteristics (magnitude, response time, spectrum, etc.) of $\chi^{(3)}$ (or $\chi^{(3)}_{eff}$). The merit of a technique depends on the nature of the nonlinearity and/or the specific property that we wish to measure. An example is obtaining short-time resolution at the expense of sensitivity. Nonlinear optical coefficients can be determined absolutely or relative to a reference material. In the former case, accuracy is determined by the ability to precisely characterize the incident beams. There are many potential sources of error and misinterpretation in nonlinear optical measurements. In *thick* samples, for example, the phase shift that occurs during beam propagation can lead to varying irradiance at different points within the sample. This can be quite difficult to account for and properly model. It is usually best to work in the *external self-action* regime (i.e., thin-sample limit so that beam propagation effects can be ignored)[91] (see also Sec. 16.3). This greatly simplifies data analysis, since the equation describing nonlinear absorption can be separated from nonlinear refraction. Even if the thin-sample approximation is satisfied, nonlinear refraction can deflect light so strongly *after* the sample that the detector does not collect all the transmitted energy. This will lead to an overestimation of the nonlinear loss. Particular care must be exercised when using ultrashort pulses. Pulse broadening effects due to group velocity dispersion, for example, may cast ambiguity on the magnitude as well as response time associated with a nonlinearity.

We briefly discuss a few of the commonly used experimental methods: four-wave mixing, excite-probe techniques, interferometry, and Z-scan. It is practically impossible for any single technique to unambiguously separate the different nonlinear responses. Experiments are generally sensitive to several different nonlinearities at once. Different measurements are usually required to unravel the underlying physics, by varying parameters such as irradiance and pulse width. Near-instantaneous nonlinearities such as two-photon absorption and the optical Kerr effect should be independent of pulse width. Slower nonlinear responses will change as the pulse width approaches the response time. Ultrafast and cumulative nonlinearities are often present simultaneously in experiments (e.g., semiconductors), thus hindering their experimental isolation.

Time-Resolved Excite-Probe Techniques

Pump-probe (excite-probe) measurements allow the study of temporal dynamics in nonlinear absorption.[27,60] In the usual implementation, a relatively strong pump pulse excites the sample and

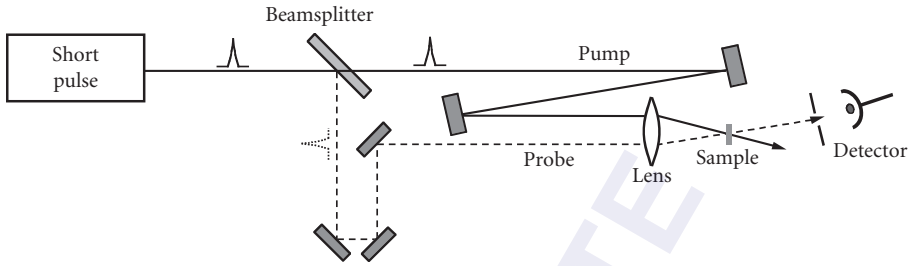

FIGURE 10 Pump-probe experiment.

changes its optical properties (see Fig. 10). A weaker probe pulse interrogates the excitation region and detects changes. By varying the relative time separation of the two pulses (i.e., by appropriately advancing and delaying the probe pulse), the temporal response can be mapped out. Specifically, relatively slow and fast nonlinear responses can be identified. Often, but not always, the probe is derived from the excitation beam. In degenerate pump-probe (identical frequencies), the probe beam is isolated from the pump beam in a noncollinear geometry (i.e., spatial separation as in Fig. 10) or by orienting the probe with a different polarization.

Nondegenerate nonlinear absorption spectra can also be measured; one approach is to use a fixed-frequency laser pump and continuum (white light) probe such as the output of a flash-lamp.[97] The temporal width of a flashlamp source is usually much longer than the laser pulse, which causes a convolution of the fast two-photon response with much longer-lived cumulative nonlinearities in the probe spectrum. The availability of femtosecond white-light continuum sources has allowed nondegenerate spectra to be obtained on short time scales where the ultrafast response dominates.[27,98]

Interpretation of the nonlinear response is complicated by the fact that pump-probe experimental methods are sensitive to any and all induced changes in transmission (or reflection); pump-induced phase shifts on the probe are not readily detected. A time-resolved technique that is very sensitive to index changes is the optical Kerr-gate. This is a form of the pump-probe experiment where induced anisotropy in a time-gated crystal leads to polarization changes.[99] Beyond the two-beam pump probe, three-beam interactions can produce a fourth beam through NLA and/or NLR. This is known as *four-wave mixing* and is discussed in the next section. The development of high-irradiance, femtosecond-pulsed laser systems has led to the evolution of pump-probe measurements that automatically yield the nondegenerate nonlinear absorption spectrum. The femtosecond pulse is split into two beams: one beam is used for sample excitation while the other beam is focused into an appropriate material to produce a white-light continuum for probing. This white-light continuum is used to measure the response over a range of frequencies ω'; this data is suitable for numerical evaluation via the K-K integral in Eq. (24). For a sufficiently broad spectrum of data, the K-K integration yields the nondegenerate n_2 coefficient.[100]

Four-Wave Mixing

The most general case of third-order interaction has all four interacting waves (three input and one scattered) at different frequencies. Generating and phase-matching three different laser wavelengths in an experiment is a formidable task; the benefit is often an improved signal-to-noise ratio.

The other extreme is when all four waves have identical frequency, a situation known as *degenerate four-wave mixing* (DFWM), although it is commonly (and less precisely) referred to as *four-wave mixing* (see Chap. 12, "Photorefractive Materials and Devices" and Chap. 5, "Optical Properties of Semiconductors"). DFWM is readily implemented in the laboratory, since only a single laser source is needed. There are two general cases: *nonresonant* and *resonant* DFWM. In transparent media (i.e., nonresonant) the index of refraction is usually a linear function of laser irradiance, and nonresonant DFWM (wavelength far from an absorption resonance) leads to optical phase conjugation. Phase

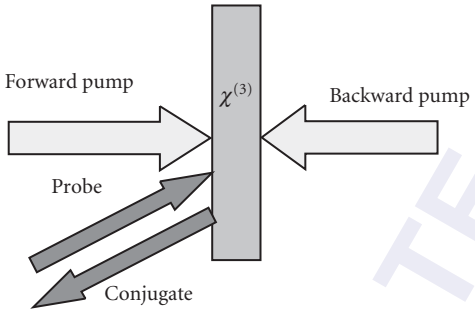

FIGURE 11 Schematic diagram of a four-wave mixing experiment.

conjugation by the optical Kerr effect (Sec. 16.5) is one of the most important applications involving third-order nonlinearities.[26] Nonresonant DFWM leads to the formation of a phase grating due the spatial modulation of the refractive index. Two of the beams write the phase grating while a third reads or probes the grating by diffracting from it, thereby generating a fourth beam (see Fig. 11). The diffracted beam can either be transmitted or reflected (i.e., a phase-conjugate beam) from the material in a direction determined by the wave vectors of the interacting photons. In some experiments, the writing beams also serve to read the grating. One of the difficulties in interpreting DFWM data for third-order nonlinearities is that the signal is proportional to $|\chi^{(3)}|^2 = |\Re e\{\chi^{(3)}\} + \Im m\{\chi^{(3)}\}|^2$ (i.e., NLA and NLR both contribute). Separating the effects is difficult without performing additional experiments. Techniques that study different polarizations can provide information on the symmetry properties of $\chi^{(3)}$.

In resonant DFWM, there is the added complication of optical absorption at the frequency of the interacting light beams.[101] This is an example of a cascaded $\chi^{(1)}:\chi^{(1)}$ effective third-order nonlinearity discussed in Sec. 16.9, where absorption causes population in excited states, resulting in a spatial grating due the spatial modulation of population. In principle, both phase and absorption gratings are present in resonant DFWM. In practice, it is usually the intensity-dependent changes of population (i.e., effective $\chi^{(3)}$) that dominate the nonlinear polarization, although this is not always the case.[76] For example, photocarrier generation in a semiconductor can alter the bulk plasma frequency and thus modulate the refractive index, leading to a strong phase grating (see Sec. 16.9).

The diffracted beam contains a wealth of information about the system under study. In nonresonant DFWM, the absolute magnitude and spectral width of the Kerr-effect nonlinearity (n_2) can be obtained. Even more can be deduced from time-resolved DFWM, where the interacting beams are short laser pulses. If the pulses (two and sometimes three separate pulses) are delayed with respect to each other, the dynamic response of the nonlinear polarization can be measured. In resonant DFWM, the diffracted beam measures the coherent response of the optically coupled eigenstates of the system. The linewidth of the diffracted beam indicates the rate at which various physical processes broaden the transition. The nonlinear polarization can be washed out by mechanisms such as population relaxation and diffusion and scattering events associated with optically coupled states. Because of selection rules linking resonant states, various polarization geometries can be employed to study specific transitions. This can be very useful in studies of a complex system such as a semiconductor. Time-resolved experiments with short pulses provide information that complements and elucidates spectral linewidth data obtained from measurements with long duration or continuous laser beams.[26,60,102]

Interferometry

Interferometric methods can be used to measure nonlinearly induced phase distortion.[103,104] One implementation of this approach places a sample in one path (e.g., arm) of an interferometer,

and the interference fringes are monitored as a function of irradiance. If the interferometer is set up to give a series of straight-line interference fringes for low-input irradiance (linear regime), the fringes become curved near the region of high irradiance, such as the center of a Gaussian beam. The addition of a streak camera can add time resolution.[27] Alternatively, a third beam can be added to the experiment. The sample is in the path of one weak beam and the strong third beam. The fringe pattern of the two weak beams is monitored as a function of sample irradiance provided by the strong beam. The relative fringe shift observed when the strong beam is present and blocked gives the optical path length change. The nonlinear phase shift can thus be determined. Interferometric experiments require excellent stability and precise alignment. When these conditions are met, sensitivities of better than $\lambda/10^4$ induced optical path length change can be measured.

Z-Scan

The Z-scan was developed to measure the magnitude and sign of nonlinear refraction (NLR). It is also useful for characterizing nonlinear absorption (NLA) and for separating the effects of NLR from NLA.[105,106] The essential geometry is shown in Fig. 12. Using a single, focused laser beam, one measures the transmittance of a sample through a partially obscuring circular aperture (Z-scan) or around a partially obscuring disk (EZ-scan[107]) placed in the far field. The transmittance is determined as a function of the sample position (Z) measured with respect to the focal plane. Employing a Gaussian spatial profile beam simplifies the analysis.

We illustrate how Z-scan (or EZ-scan) data is related to the NLR of a sample. Assume, for example, a material with a positive nonlinear refractive index. We start the Z-scan far from the focus at a large value of negative Z (i.e., close to the lens). The beam irradiance is low and negligible NLR occurs; the transmittance remains relatively constant near this sample position. The transmittance is normalized to unity in this linear regime as depicted in Fig. 13. As the sample is brought closer to focus, the beam irradiance increases, leading to self-focusing. This positive NLR moves the focal point closer to the lens, causing greater beam divergence in the far field. Transmittance through the aperture is reduced. As the sample is moved past the focus, self-focusing increasingly collimates the beam, resulting in enhanced transmittance through the aperture. Translating the sample farther toward the detector reduces the irradiance to the linear regime and returns the normalized transmittance to unity. Reading the data right to left, a valley followed by peak is indicative of positive NLR. In negative NLR, one finds exactly the opposite: a peak followed by a valley. This is due to laser-induced self-defocusing. Characteristic curves for both types of NLR are shown in Fig. 12. The EZ-scan reverses the peak and valley in both cases. In the far field, the largest fractional changes in irradiance occur in the wings of a Gaussian beam. For this reason, the EZ-scan can be more than an order of magnitude more sensitive than the Z-scan.

We define an easily measurable quantity ΔT_{pv} as the difference between the normalized peak and valley transmittance: $T_p - T_v$. Analysis shows that variation of ΔT_{pv} is linearly dependent on the

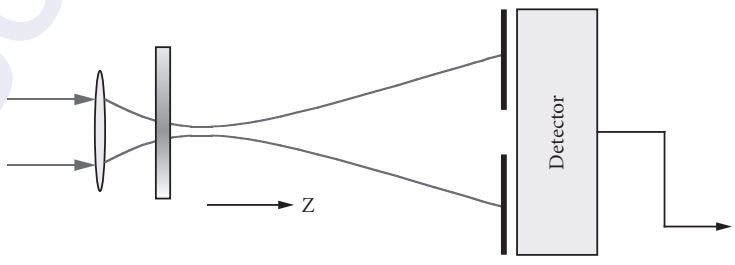

FIGURE 12 Z-scan experimental arrangement.

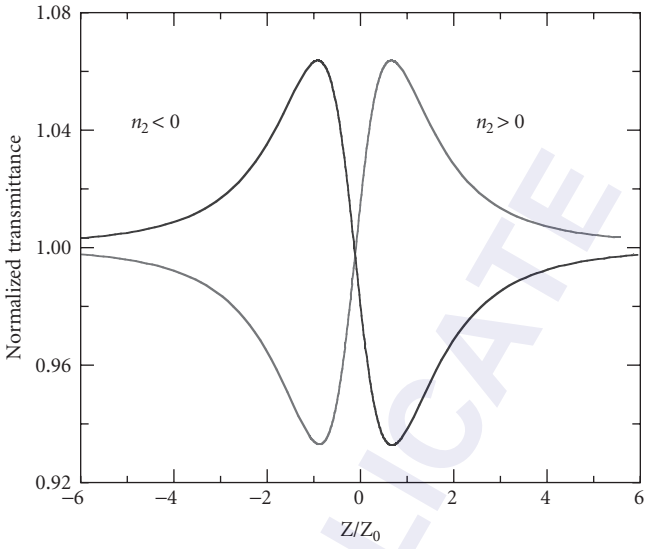

FIGURE 13 Representative curves depicting nonlinear refraction (both positive and negative) as measured by the Z-scan.

temporally averaged induced phase distortion, defined here as $\Delta\Phi_0$. If the Z-scan aperture is closed to allow linear transmission of less than 10 percent, and $\Delta T_{pv} < 1$:[105,108]

$$\Delta T_{pv} \cong 0.41|\Delta\Phi_0| \tag{49}$$

assuming cw illumination. If the experiment is capable of resolving transmission changes $\Delta T_{pv} \cong 1\%$, the Z-scan will be sensitive to wavefront distortion of less than $\lambda/250$ (i.e., $\Delta\Phi_0 = 2\pi/250$). The Z-scan has demonstrated sensitivity to a nonlinearly induced optical path length change of nearly $\lambda/10^3$, while the EZ-scan has shown a sensitivity of $\lambda/10^4$, including temporal averaging over the pulsewidth.

To this point in the discussion, we have assumed a purely refractive nonlinearity with no NLA. It has been shown that two-photon absorption will suppress the peak and enhance the valley. If NLA and NLR are present simultaneously, a numerical fitting procedure can extract both the nonlinear refractive and absorptive coefficients. Alternatively, a second Z-scan with the aperture removed (all the transmitted light collected) can independently determine the NLA. Considering 2PA only and a Gaussian input beam, the Z-scan traces out a symmetric Lorentzian shape. The so-called *open aperture* Z-scan is sensitive *only* to NLA. One can then divide the partially obscuring Z-scan data by the open aperture data to give a curve that shows only nonlinear refraction. By performing these two types of Z-scans, we can isolate NLR and NLA without the need for a complicated numerical analysis of a single data set obtained with an aperture.

All-Optical Switching and Optical Bistability

Since the early 1980s, there has been substantial interest in third-order nonlinear optical behavior in materials because of the potential for performing high-speed switching operations—gate speeds many orders of magnitude faster than conventional electronics have been demonstrated. The possibility of increasing data rates on information networks provides the obvious motivation for this

research. A bistable optical switch has two stable output states for a given input (i.e., a specific optical power level). This has implications for applications such as optical data storage and power limiting. Both nonresonant $\chi^{(3)}$ and resonant effective $\chi^{(3)}$ processes have been extensively studied, primarily in semiconductors. The early work looked at bulk semiconductor behavior, but as the technology matured the emphasis shifted to specially designed optical waveguides made from suitable material. At the time of this writing, both resonant and nonresonant approaches have encountered problems that have limited practical use. The bound electronic nonlinearity responds on a femtosecond time-scale but is inherently weak. The laser irradiance must be increased to compensate, but this leads to the unwelcome presence of 2PA and associated losses. Resonant nonlinearities must involve the generation of carriers (electrons and holes). While such nonlinearities can be exceptionally strong, the speed of an optical switch depends crucially on the ability to manipulate the carriers. Generation of electron-hole pairs, for example, may dramatically affect the refractive index of a semiconductor and its ability to modulate light, but if the carriers have a long recombination lifetime the switch recovery time will be relatively slow. Other significant issues that must be weighed when comparing optical switching schemes to the all-electronic approach (i.e., transistors and integrated circuits) include device packaging density and heat removal.[18,42,53,72,109,110]

17.1 INTRODUCTION

Since the publication of an earlier review on optical parametric oscillators (OPOs) in 2000,[1] there has been remarkable progress in the technological development and applications of OPO devices. Once considered an impractical approach for the generation of coherent radiation, OPOs have now been finally transformed into truly viable, state-of-the-art light sources capable of accessing difficult spectral regions and addressing real applications beyond the reach of conventional lasers. While the first experimental demonstration of an OPO was reported in 1965,[2] for nearly two decades thereafter there was little or no progress in the practical development of OPO devices, owing to the absence of suitable nonlinear materials and laser pump sources. With the advent of a new generation of birefringent nonlinear crystals, most notably β-BaB_2O_4 (BBO), LiB_3O_5 (LBO), and $KTiOPO_4$ (KTP), but also $KTiOAsO_4$ (KTA) and $RbTiOAsO_4$ (RTA) in the mid-1980s, and advances in solid-state laser technology, there began a resurgence of interest in OPOs as potential alternatives to conventional lasers for the generation of coherent radiation in new spectral regions. The high optical damage threshold, moderate optical nonlinearity, and favorable phase-matching properties of the newfound materials led to important breakthroughs in OPO technology. In the years to follow, tremendous progress was achieved in the development of OPO devices, particularly in the pulsed regime, and a variety of OPO systems from the nanosecond to the ultrafast picosecond and femtosecond timescales, and operating from the near-ultraviolet (near-UV) to the infrared (IR) were rapidly developed. These developments led to the availability of a wide range of practical OPO devices and their deployment in new applications, with some systems finding their way to the commercial market. A decade later, in the mid-1990s, the emergence of quasi-phase-matched (QPM) ferroelectric nonlinear crystals, particularly periodically poled $LiNbO_3$ (PPLN) stimulated new impetus for the advancement of continuous-wave (cw) OPO devices, traditionally the most challenging regime for OPO operation due to almost negligible nonlinear gains available under cw pumping. The flexibility offered by grating-engineered QPM materials, allowing access to the highest nonlinear tensor coefficients, combined with noncritical phase matching (NCPM) and long interaction lengths (>50 mm in PPLN), enabled the low available nonlinear gains to be overcome, hence permitting the development of practical cw OPOs in a variety of resonance configurations. As such, the advent of QPM

materials, most notably PPLN, but also periodically poled KTP (PPKTP), $RbTiOAsO_4$ (PPRTA), and $LiTaO_3$ (PPLT), has had an unparalleled impact on cw OPO technology. Combined with advances in novel high-power solid-state crystalline, semiconductor, and fiber pump sources over the past decade, these developments have led to the practical realization of a new class of cw OPOs with previously unattainable performance capabilities with regard to wavelength coverage, output power and efficiency, frequency and power stability, spectral and spatial coherence, and fine frequency tuning.

With their exceptional spectral coverage and tuning versatility, temporal flexibility from the cw to femtosecond timescales, practical performance parameters, and compact solid-state design, OPO devices have now been firmly established as truly competitive alternatives to conventional lasers and other technologies for the generation of widely tunable coherent radiation in difficult spectral and temporal domains. In the current state of technology, OPO devices can provide spectral access from ~400 nm in the ultraviolet (UV) to ~12 μm in the mid-infrared (mid-IR), as well as the terahertz (THz) spectral region. They can also provide temporal output from the cw and long-pulse microsecond regime to nanosecond, picosecond, and ultrafast sub-20 fs timescales. Many of the developed OPO systems are now routinely deployed in a variety of applications including spectroscopy, optical microscopy, environmental trace gas detection and monitoring, life sciences, biomedicine, optical frequency metrology and synthesis, and imaging.

The aim of this chapter is to provide an overview of the advances in OPO device technology and applications since the publication of the earlier review in 2000.[1] The chapter is concerned only with the developments after 2000, since many of the important advances in this area prior to that date can already be found in the previous treatment[1] as well as other reviews on the subject.[3–10] Because of limited scope, and given that most of the important advances over the last decade have been in the CW operating regime, the chapter is focused only on a discussion of cw OPOs. Reviews on pulsed and ultrafast OPOs can be found elsewhere.[3,4,6–10] This chapter also does not include a description of the fundamental concepts in nonlinear and crystal optics, parametric generation, amplification and gain, or a comprehensive description of the design criteria and operating principles of OPO devices, which have been the subject of several earlier treatments.[11–16]

17.2 CONTINUOUS-WAVE OPTICAL PARAMETRIC OSCILLATORS

Of the different types of OPO devices developed to date, advancement of practical OPOs in the cw operating regime has been traditionally most difficult, since the substantially lower nonlinear gains available under cw pumping necessitate the use of high-power cw pump laser or the deployment of multiple-resonant cavities to reach operation threshold. As in a conventional laser oscillator, the OPO is characterised by a threshold condition, defined by the pumping intensity at which the growth of the parametric waves in one round-trip of the optical cavity just balances the total loss in that round-trip. Once threshold has been surpassed, coherent light at macroscopic levels can be extracted from the oscillator. In order to provide feedback in an OPO, a variety of resonance schemes may be deployed by suitable choice of mirrors forming the optical cavity, as illustrated in Fig. 1*a* to *e*. The mirrors may be highly reflecting at only one of the parametric waves (*signal* or *idler*, but not both), as in Fig. 1*a*, in which case the device is known as a *singly resonant oscillator* (SRO). This configuration is characterised by the highest cw operation threshold. In order to reduce threshold, alternative resonator schemes may be employed where additional optical waves are resonated in the optical cavity. These include the *doubly resonant oscillator* (DRO), Fig. 1*b*, in which both the signal and idler waves are resonant in the optical cavity, and the *pump-resonant* or *pump-enhanced* SRO, Fig. 1*c*, where the *pump* as well as one of the generated waves (signal or idler) is resonated. In an alternative scheme, Fig. 1*d*, the pump may be resonated together with both parametric waves, in which case the device is known as a *triply resonant oscillator* (TRO). Such schemes can bring about substantial reductions in threshold from the cw SRO configuration, with the TRO offering the lowest operation threshold. In an alternative scheme, the external pump power threshold for a cw SRO may also be substantially reduced by deploying internal pumping, where the OPO is placed inside

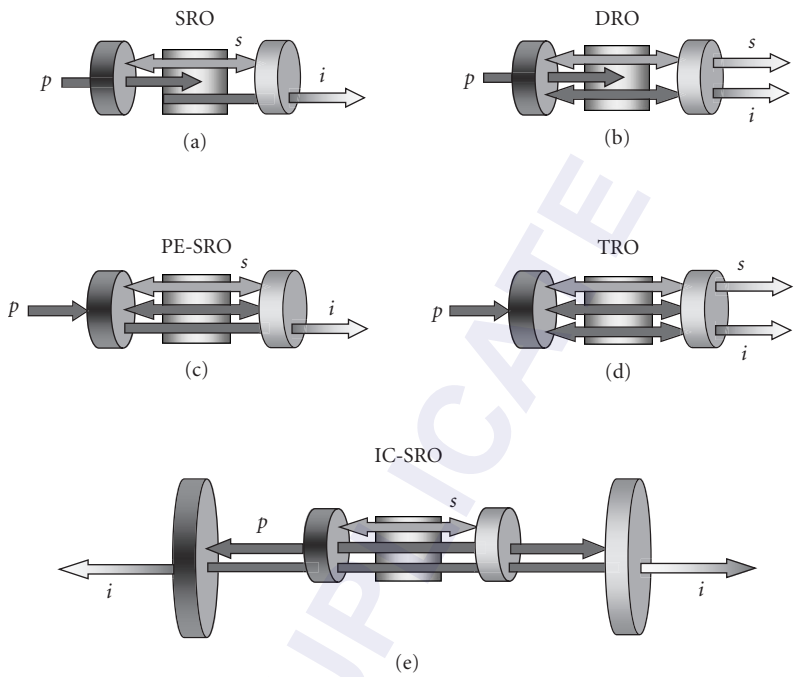

FIGURE 1 Cavity resonance configurations for cw OPOs. The symbols *p*, *s*, and *i* denote *pump, signal*, and *idler*, repectively.

a minimally output-coupled pump laser. A schematic of such an *intracavity SRO* (*IC-SRO*) is illustrated in Fig. 1*e*.

The comparison of steady-state threshold for conventional externally pumped cw OPOs under different resonance schemes is shown in Fig. 2, where the calculated external pump power threshold is plotted as a function of the effective nonlinear coefficient of several materials including LBO, KTA, KTP, $KNbO_3$, PPLN, and PPRTA. From the plot, it is clear that for the majority of birefringent materials the attainment of cw SRO threshold requires pump powers on the order of tens of watts, well outside the range of the most widely available cw laser sources. However, in the case of PPLN, the cw SRO threshold is substantially reduced to acceptable levels below ~1 W, bringing operation of cw SROs within the convenient range of widespread cw solid-state pump lasers. With the cw PE-SRO, considerably lower thresholds can be achieved, from a few hundred milliwatts to ~1 W for birefringent materials and below ~100 mW for PPLN. In the case of cw DRO, still lower thresholds of the order of 100 mW are attainable with birefringent materials, with only a few milliwatts for PPLN, whereas with the cw TRO, thresholds from below 1 mW to a few milliwatts can be obtained in birefringent materials.

It is thus clear that practical operation of cw OPOs in SRO configurations is generally beyond the reach of birefringent materials, but requires DRO, TRO, and PE-SRO cavities. On the other hand, implementation of cw SROs necessitates the use of PPLN or similar QPM materials, offering enhanced optical nonlinearities, and long interaction lengths under NCPM. However, the threshold reduction from SRO to PE-SRO, DRO, and TRO cavity configurations is often achieved at the expense of increased spectral and power instability in the OPO output arising from the difficulty in maintaining resonance for more than one optical wave in a single optical cavity. For this reason, the cw SRO offers the most direct route to the attainment of high output stability and spectral control without stringent demands on the frequency stability of the laser pump source. On the other hand,

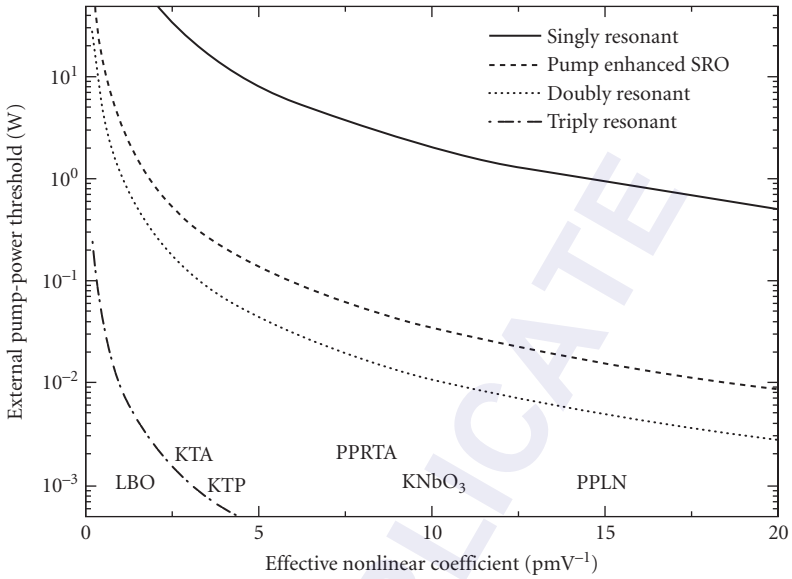

FIGURE 2 Calculated minimum thresholds for different OPO resonance configurations versus the effective nonlinear coefficients in various nonlinear materials. The calculation assumes confocal focusing and loss values that are typically encountered in experimental cw OPOs, the finesses representing round-trip power losses of approximately 2.0 percent. The plots correspond to a pump wavelength of 800 nm, degenerate operation, a pump refractive index of ~1.7, a crystal length of 20 mm, signal and idler cavity finesses of ~300, and a pump enhancement factor of ~30. In the case of PE-SRO and TRO, the enhancement factor of 30 represents the maximum enhancement attainable with parasitic losses of ~3 percent at the pump.[17]

practical implementation of cw PE-SRO, DRO, and TRO requires active stabilization techniques to control output power and frequency stability, with the PE-SRO offering the most robust configuration for active stabilization and TRO representing the most difficult in practice. In addition, practical operation of OPOs in multiple resonant cavities can only be achieved using stable, single-frequency pump lasers and such devices also require more complex protocols for frequency tuning and control than the cw SRO. More detailed description of the different resonance and pumping schemes for OPOs and analytical treatment of tuning mechanisms, spectral behavior, frequency control, and stabilisation can be found in an earlier review.[1]

Singly Resonant Oscillators

By deploying the intracavity pumping scheme using a Ti:sapphire laser in combination with a 20-mm PPKTP crystal, Edwards et al.[18] reported a cw IC-SRO capable of providing up to 455 mW of non-resonant infrared idler power at a down-conversion efficiency of 87 percent. Using a combination of pump tuning at room temperature and crystal temperature tuning, idler (signal) coverage in the 2.23 to 2.73 μm (1.14 to 1.27 μm) spectral ranges was demonstrated. By configuring the Ti:sapphire pump laser and the SRO in ring cavity geometries and using intracavity etalons, 115 mW of unidirectional, single-frequency idler power was generated at 2.35 μm with mode-hop-free operating time intervals of about 10 s under free-running conditions. The resonant signal was measured to have a linewidth <15 MHz for a pump linewidth <25 MHz.

The advent of PPLN with large effective nonlinearity (d_{eff} ~15 pm/V) and long interaction lengths (currently up to 80 mm) under NCPM has enabled the development of cw SROs in conventional

external pumping configurations using more commonly available, moderate- to high-power solid-date pump sources. By deploying a fixed-frequency, cw, single-mode Nd:YVO_4 pump laser at 1.064 μm, Bisson et al.[19] developed a portable source for mid-IR photoacoustic spectroscopy based on a PPLN cw SRO by using discrete mode-hop tuning of the idler. The SRO, based on a 50-mm PPLN crystal with fanned grating (Λ = 29.3 to 30.1 μm), was configured in a ring cavity, and frequency selection and fine tuning was implemented using solid or air-spaced intracavity etalons. With an uncoated, 400-μm-thick, solid Nd:YAG etalon, a total mode-hop-tuning range of ~4 cm^{-1} for the idler in discrete steps of 0.02 to 0.1 cm^{-1} was achieved by rotation of the etalon. The SRO could deliver a maximum idler power of ~120 mW at a pump depletion of 40 to 50 percent for 6 W of pump power. Using the mode-hop-tuned idler output near 3.3 μm, photoacoustic spectroscopy of the methane Q branch was performed at atmospheric pressure by simultaneous tuning of the PPLN crystal combined with etalon rotation. A total of four etalon scans covering ~10 cm^{-1} was necessary to trace the Q branch spectrum. In an effort to achieve a constant tuning rate as well as minimize insertion loss due to etalon rotation, which in turn leads to mode hops arising from variable heating of the PPLN crystal due to the changes in intracavity power, an alternative air-spaced fused silica etalon with ~0.5 to 1.5 mm spacing and ~5 percent reflectivity at the signal (~1.57 μm) was also employed in the present device. While resulting in a higher oscillation threshold (~4 W) and lower idler output (~80 mW), the combination of PPLN tuning and piezoelectric scan of the etalon over a distance of 3 μm (at 1.5 mm separation) yielded a total mode-hop tuning range of ~14 cm^{-1} for the idler at a constant tuning rate and in discrete steps of 0.1 cm^{-1}, providing sufficient resolution for atmospheric sensing and pressure-broadened spectroscopy. The measured linewidth of the idler was <10 MHz with a passive stability of ~50 MHz over 30 s.

By using a 10-W cw single-frequency diode-pumped Nd:YAG laser at 1.064 μm, Van Herpen et al.[20] demonstrated a cw SRO based on PPLN with a mid-IR idler tuning range of 3.0 to 3.8 μm. The SRO, configured in a ring cavity and using a crystal with fanned grating (L = 50 mm, Λ = 29.3 to 30.1 μm) exhibited a pump power threshold of ~3 W and could provide a maximum idler output power of 1.5 W at 3.3 μm for 9 W of pump power. The combination of the single-mode pump laser, a ring cavity for the SRO, and the inclusion of an intracavity air-spaced etalon enabled mode-hop-free tuning of the idler over 12 GHz by tuning the pump frequency over 24 GHz, with the idler mode-hop tuning range limited by mode hopping in the pump laser. Under this condition, 700 mW of single-frequency, smoothly tunable idler power could be provided by the SRO. In a later experiment,[21] using the same PPLN crystal and identical cavity design for the SRO, the authors were able to improve the idler output power in the 3.0 to 3.8 μm range by increasing the available Nd:YAG pump power to 15 W and by optimizing pump focusing and the SRO cavity length. The SRO similarly exhibited a cw power threshold of ~3 W, but could provide 2.2 W of idler power for 10.5 W of input pump power. The coarse and fine tuning properties of this SRO were similar to the earlier device. For fine tuning, an intracavity air-spaced etalon with variable spacing of 0.2 to 3 mm (FSR = 50 to 750 GHz) was used. Continuous scanning of etalon spacing resulted in discrete mode-hop tuning of the idler over 100 GHz. With a 400-μm uncoated solid YAG etalon (FSR = 207 GHz), an idler mode-hop tuning range of 10 cm^{-1} in steps of 0.02 to 0.1 cm^{-1} (0.6 to 3 GHz) could be obtained by rotation of the etalon. Subsequently, using the same pump laser, the authors reported a cw SRO based on a multigrating PPLN crystal (Λ = 25.9 to 28.7 μm) and providing extended idler coverage into the 3.7 to 4.7 μm spectral range in the mid-IR.[22] The ring-cavity SRO exhibited an oscillation threshold of between 5 and 7.5 W over this spectral range and for an input pump power of 11 W could provide a maximum idler output of 1.2 W at 3.9 μm, decreasing to 120 mW at 4.7 μm. The increase in SRO threshold and corresponding decrease in output power were attributed to the increasing idler absorption in PPLN at longer wavelengths toward 5 μm. With the inclusion of the same 400-μm uncoated YAG etalon to stabilize the resonant signal frequency, continuous mode-hop free tuning of the idler was achieved by tuning the pump frequency over 24 GHz, but with a reduction in idler power by as much as 50 percent. Discontinuous mode-hop tuning of the idler output could also be obtained through rotation of the intracavity etalon. In a later report, the use of a tunable high-power (>20 W) diode-pumped Yb:YAG laser in combination with two PPLN crystals with fanned gratings (Λ = 28.5 to 29.9 μm) and two sets of OPO mirrors enabled the generation of widely tunable idler radiation with a total tuning range of 2.6 to 4.66 μm, and at increased

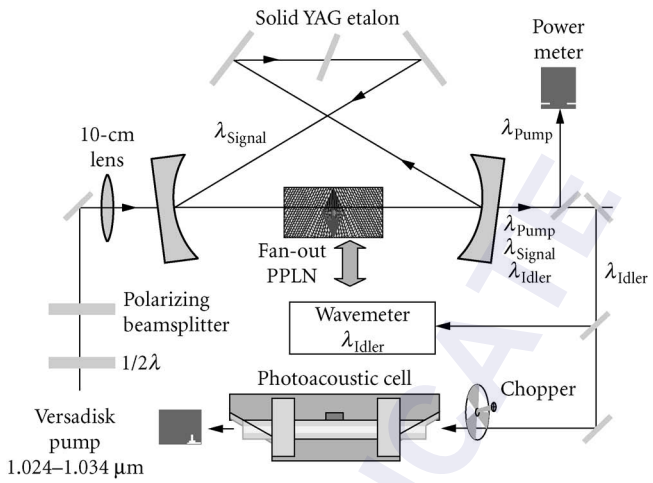

FIGURE 3 Experimental setup of the cw SRO. The pump wavelength varies from 1024 to 1034 nm and the idler wavelength from 2.6 to 4.7 μm. A pump rejecter mirror separates the pump light from the idler and signal beams, after which the idler beam is reflected toward the wavemeter and photoacoustic cell. The signal wavelength can be measured with the same wavemeter by replacing the idler reflector with a signal reflector.[23]

cw power levels up to 3 W.[23] For frequency stability, a 400-μm uncoated YAG etalon (FSR = 207 GHz) was similarly used internal to the SRO cavity (Fig. 3). The SRO had a threshold of 8 W and, with nonoptimized mirror and crystal coatings, could provide 3.0 W of mid-IR idler output at 2.954 μm for 18 W of pump power. The SRO could provide an idler mode-hop tuning range of 25 GHz in steps of 100 MHz (FSR of the pump laser cavity) by tuning the intracavity pump etalon. Combined with the tuning of the Lyot filter within the pump laser, a total mode-hop tuning range of 190 GHz could be scanned, limited by a mode hop in signal frequency of 207 GHz corresponding to the FSR of the YAG etalon within the SRO cavity. By recording the photoacoustic signal in ethane, the authors characterized the frequency stability of the SRO. Due to unoptimized coatings, the idler exhibited frequency instabilities of 90 MHz/s, while temperature fluctuations in the PPLN crystal resulted in an idler frequency drift of 250 MHz over 200 s. In the same report, the authors demonstrated extension of the idler wavelength to 3.3 to 4.66 μm using the broad tuning of the pump laser (1.024 to 1.034 μm) in combination with grating tuning of the PPLN crystal, providing 200 mW of idler power at 4.235 μm, corresponding to the strongest CO_2 absorption line.

Subsequently, Ngai et al.[24] reported a cw SRO with automatic tuning control based on a multigrating MgO:PPLN (L = 50 mm, Λ = 29.0 to 31.5 μm). A schematic of the experimental setup is shown in Fig. 4. The SRO was pumped by a master oscillator-power amplifier (MOPA) laser at 1064 nm, providing 11.5 W of single-frequency output with a linewidth of 5 kHz (over 1 ms), frequency stability of 50 MHz/h, and continuous tuning over 48 GHz. The combination of temperature and grating tuning in the MgO:PPLN crystal provided coarse coverage over 2.75 to 3.83 μm in the idler and 1.47 to 1.73 μm in the signal, with a maximum idler power of 2.75 W. By using a ring SRO cavity containing a 400-μm-thick uncoated solid YAG etalon (FSR = 207 GHz), a short-term frequency stability of 4.5 MHz over 1 s was attainable in the absence of active stabilization. Fine wavelength scanning of the idler output was achieved through a combination of pump tuning, etalon rotation, and temperature tuning using an automated process with computer control. First, by continuous tuning of the pump frequency over 48 GHz at a fixed etalon angle, the idler could be tuned over 12 GHz before the occurrence of a mode hop in the pump laser (Fig. 5). The total idler tuning range attainable in this way was 207 GHz, limited by an etalon mode hop. Then, by rotation of the

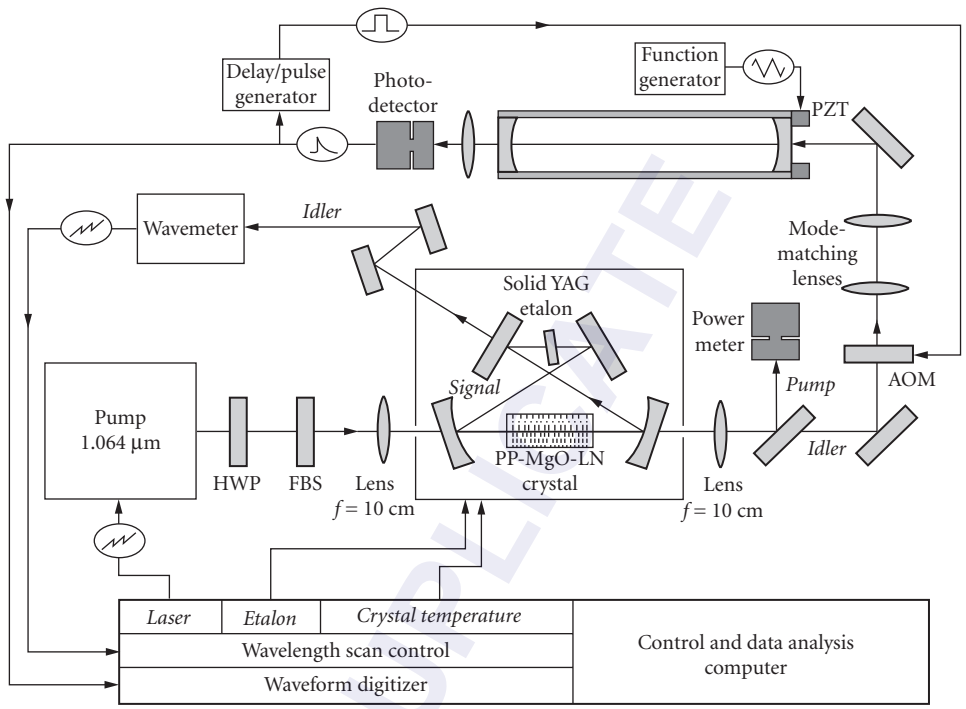

FIGURE 4 Experimental setup of automatically tunable cw SRO combined with continuous-wave cavity leak-out spectroscopy. The OPO cavity is resonant for the signal wavelength. The idler beam is sent to a cw leak-out cavity and to a wavemeter.[24]

etalon to a new angle, the pump was again scanned until a new total tuning range of 207 GHz was covered, and process was repeated. Finally, changing the crystal temperature by 2 to 5°C, and repeating the entire process, wavelength scans of up to 450 cm^{-1} with a resolution of $<5 \times 10^{-4}$ cm^{-1} could be obtained with a single grating period. Using this automated tuning process, the utility of the cw SRO for sensitive detection of CO_2, methane, and ethane was demonstrated with photoacoustic and cavity leak-out spectroscopy, and analysis of human breath was performed by recording the absorption spectra of methane, ethane, and water in two test persons using photoacoustic spectroscopy.

With the continued advances in pump laser technology, the development of cw SROs based on high-power diode-pumped fiber lasers and amplifiers has also become a reality. Fiber lasers are attractive alternatives as pump sources for cw SROs, because they combine the high-power properties of crystalline solid-state laser materials with significant wavelength tuning and excellent spatial beam quality in compact and portable design. The pump tuning capability allows rapid and wide tuning of the SRO output without recourse to temperature or grating period variation, while the high available powers and excellent beam quality allow access to SRO threshold and enable the generation of practical output powers. The use of fiber pump lasers can thus provide a versatile class of cw SROs for the mid-IR that offer the advantages of simplicity, compact all-solid-state design, portability, reduced cost, improved functionality, and high output power and efficiency. Operation of a cw SRO pumped by a fiber laser was first reported by Gross et al.[25] using a tunable Yb-doped fiber laser. The laser delivered more than 8 W of cw output power in excellent spatial beam quality and was tunable over the wavelength range of 1031 to 1100 nm. With the use of a 40-mm-long multigrating PPLN crystal and a ring cavity for the SRO, a cw idler output power of 1.9 W was generated at a wavelength of 3.2 μm in the mid-IR for 8.3 W of fiber pump power, with a corresponding SRO power threshold of 3.5 W. Idler wavelength tuning over 3.057 to 3.574 μm could be accomplished

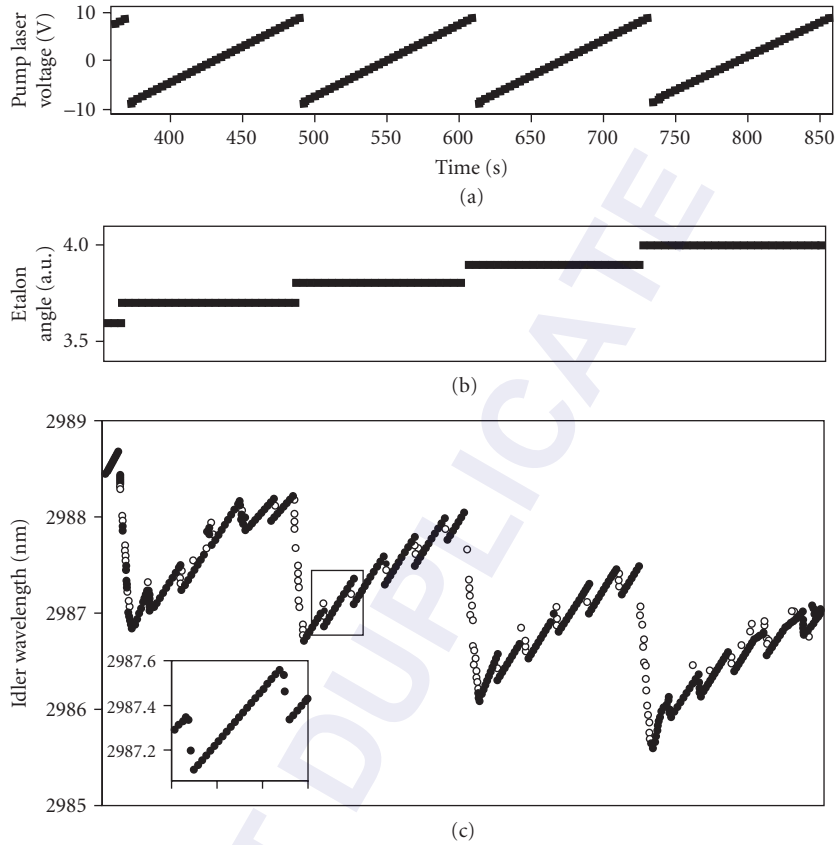

FIGURE 5 Combined pump-etalon scan. By scanning the pump laser (*a*) and stepping the etalon angle after each pump laser scan (*b*), a continuous wavelength coverage over 207 GHz can be realized (*c*). The resolution of the idler frequency is limited by the resolution of the wavemeter [*inset* in (*c*)].[24]

by varying the crystal temperature or changing the grating period. However, wider and more convenient wavelength tuning was also available by exploiting the tuning capability of the fiber pump laser, where an idler tuning range of more than 700 nm over 2.980 to 3.700 μm was obtained by varying the pump wavelength between 1.032 and 1.095 μm. In a subsequent experiment, Klein et al.[26] demonstrated rapid wavelength tuning of a similar cw SRO by using electronic wavelength control of the Yb-doped fiber pump laser with an acousto-optic tunable filter. The SRO, based on a 40-mm-long single-grating PPLN crystal, was arranged in a similar ring cavity and, at a fixed crystal temperature and grating period, could be rapidly tuned over 3.160 to 3.500 μm in the idler wavelength by electronically tuning the fiber pump laser from 1060 to 1094 nm. The 340-nm idler tuning could be achieved within a time interval of 330 μs, representing a frequency tuning rate of 28 THz/ms. The overall electronic tuning range of the fiber pump laser over 1.057 to 1.100 μm resulted in an SRO idler tuning range of 437 nm in the mid-IR, from 3.132 to 3.569 μm. For the maximum fiber pump power of 6.6 W at 1.074 μm, the SRO generated an idler output power of 1.13 W at 3.200 μm.

More recently, operation of a low-threshold mid-IR cw SRO was reported by Henderson and Stafford[27] using MgO:PPLN and an all-fiber laser pump source. A schematic of the experimental setup is shown in Fig. 6. The cw single-frequency pump at 1083 nm was configured in a MOPA

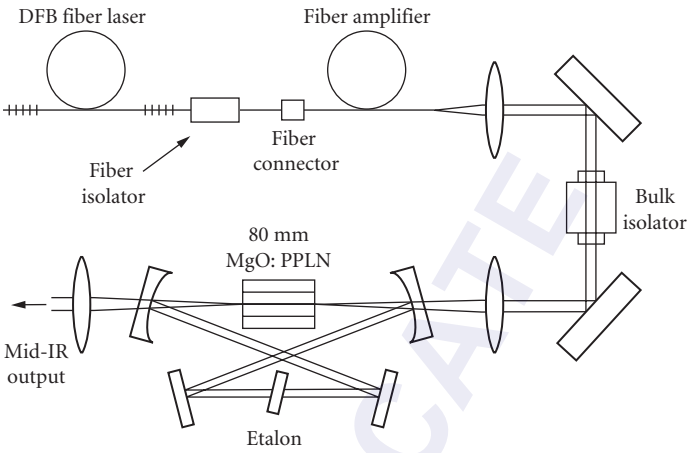

FIGURE 6 Schematic of experimental configuration for the fiber-pumped cw SRO.[27]

arrangement using a 20-mW distributed feedback (DFB) fiber laser with 50-kHz linewidth as the seed and a polarization-maintaining fiber as the amplifier. The use of fiber connection between the two stages ensured an all-fiber configuration with no free-space components, alignment-free injection, and minimum long-term cavity misalignment. The MOPA could provide up to 3.5 W of amplified single-mode pump power for 20 mW of input seed power. Using multigrating and fanned crystals (Λ = 31.3 to 32.5 μm) of 80-mm interaction length and operating the SRO just above room temperature (30°C), oscillation thresholds as low as 780 mW were obtained, with up to 750 mW of idler power generated for 2.8 W of fiber pump power. The idler output was tunable over 2650 to 3200 nm with a near-diffraction-limited spatial mode up to 500 mW and beam quality factor M^2 = 1.04. By exploiting the tunability of the pump laser through application of a voltage to the piezoelectric transducer attached to the fiber (rapid) and temperature variation of the seed source (slow), continuous mode-hop-free tuning of the idler over more than 120 GHz was demonstrated (Fig. 7). Using a Fabry-Perot interferometer, the idler linewidth was measured to be 1.1 MHz at 3.17 μm. The narrow linewidth, broad coarse wavelength coverage, and rapid mode-hop-free tuning of the idler through piezoelectric tuning of the pump enabled high-resolution spectroscopy in a variety of mid-IR gases including water vapor, CO_2, and methane.

The development of PPLN has also led to substantial reductions in cw SRO power threshold, compatible with the direct use of semiconductor diode lasers as pumps for cw SROs. In addition to a compact design, an important advantage of this approach is the tunability of diode laser, which allows rapid and continuous tuning of SRO output at a fixed temperature and grating period through pump tuning. However, to provide the sufficiently high cw pump powers (typically >1 W) and the highest beam quality to attain SRO threshold, it has been necessary to boost the available power from single-mode diode lasers using amplification schemes. By employing a grating stabilized, extended-cavity single-stripe InGaAs semiconductor diode laser at 924 nm as a master oscillator and a single-pass tapered amplifier, Klein et al.[28] demonstrated operation of a cw SRO based on a 38-mm-long PPLN crystal with a pump power threshold of 1.9 W. For 2.25 W of diode pump power, 200 mW of single-frequency idler radiation was generated at 2.11 μm. Wavelength tuning was achieved by electronic control of the master oscillator cavity, providing continuous mode-hop-free tuning of the diode pump radiation over 60 GHz from the power amplifier with a corresponding linewidth of <4 MHz. By using an intracavity etalon to fix the resonant signal frequency, a continuous mode-hop-free idler tuning of 56 GHz was obtained at 2.11 μm by tuning the pump wavelength. In an alternative scheme, using a distributed Bragg reflector (DBR) diode laser at 1082 nm, which was amplified in an Yb-doped fiber, Lindsay et al.[29] achieved rapid mode-hop-free tuning of a mid-IR cw SRO. A schematic of the experimental configuration is shown in Fig. 8, and the SRO idler

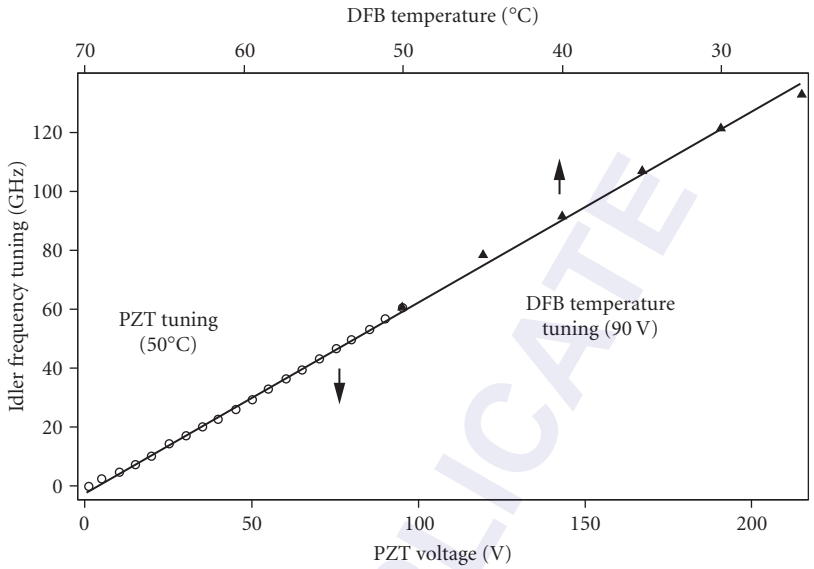

FIGURE 7 Fine tuning of the OPO idler frequency measured as a function of pump tuning parameter, performed by PZT voltage and fiber temperature variation.[27]

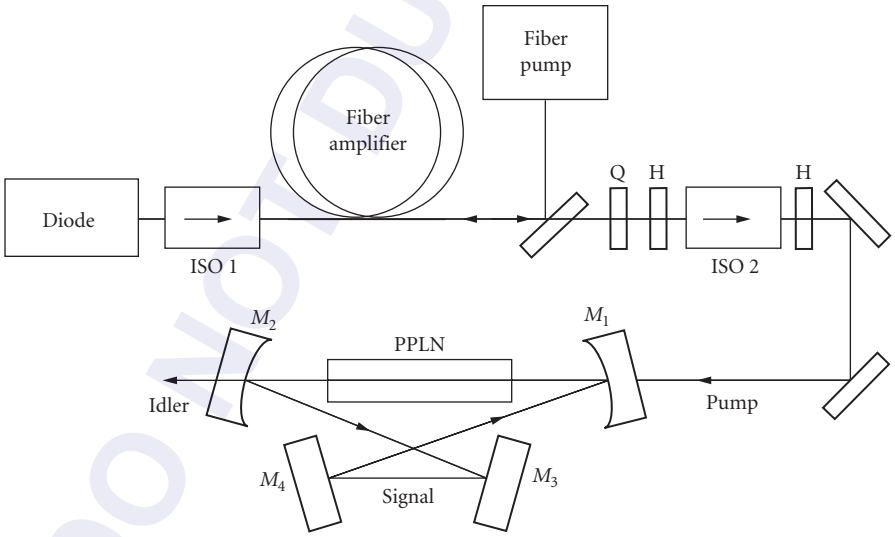

FIGURE 8 Schematic of experimental arrangement for the cw SRO pumped by a fiber-amplified DBR diode laser.[29]

output power and tuning range are shown in Fig. 9. The SRO was based on a 40-mm PPLN crystal and could provide rapid continuous tuning over 110 GHz in 29 ms. Coarse and discontinuous wavelength tuning of the idler wave was also obtained over 20 nm by tuning the DBR diode laser, and more than 1 W of idler output power was generated across the 3.405 to 3425 μm range for 6.9 W of input pump power. An overall idler tuning range of 300 nm in the 3 to 3.5 μm band in the mid-IR was also available by varying the temperature of the PPLN crystal.

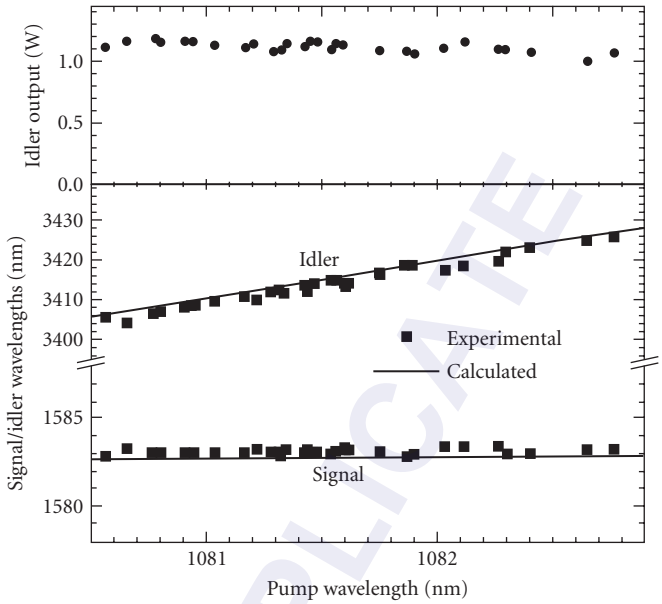

FIGURE 9 Variation of OPO output wavelengths (lower plot), and corresponding idler output power (upper plot), during pump tuning by seed laser DBR section alone. PPLN grating period was 29.75 μm and temperature was 180.5°C. Solid lines are calculated tuning range.[29]

The availability of increasingly powerful pump sources such as cw fiber lasers, together with the high nonlinear coefficient (d_{eff} ~17 pm/V) and long interaction lengths (50 to 80 mm) in PPLN, can now readily permit practical operation of cw SROs many times above operation threshold, providing multiwatt idler output powers. At the same time, the presence of high optical powers can lead to additional linear and nonlinear optical effects which can modify SRO output characteristics. These include thermal loading of the crystal due to linear absorption, which can result in thermal lensing, thermal phase mismatching and output beam quality degradation, or spectral generation and broadening due to higher-order nonlinear optical effects. As such, optimum performance of cw SROs at high pump powers requires strategies to combat such effects in order to achieve maximum conversion efficiency and output extraction at full pump power, while maintaining the highest spectral and spatial beam quality, power, and frequency stability. The performance characteristics of cw SROs at high pump powers many times threshold have been studied by Henderson and Stafford.[30] By deploying a 15-W cw single-frequency Yb fiber laser at 1064 nm as the pump and 50-mm MgO:PPLN crystals with multiple (Λ = 31.5 to 32.1 μm) and fanned (Λ = 30.8 to 31.65 μm) gratings, they investigated the effects of pump power on crystal heating, wavelength tuning, beam quality, and optimum output power and extraction efficiency. With the high beam quality of the fiber laser (M^2 ~ 1.06), and using a ring cavity with mirrors of highest reflectivity at the signal (R ~ 99.9 percent) and optimum mode-matching, they achieved a threshold as low as 1.0 W, enabling SRO operation at up to 15 times threshold. With the multigrating crystal, the SRO reached a pump depletion of 91 percent at 2.5 times threshold, remaining constant to within ~10 percent up to the maximum pump power at 15 times above threshold. The idler output, measured at 2610 nm, exhibited a linear increase with input pump power, reaching 4.5 W at 15 W of pump, with a corresponding external photon conversion efficiency of ~74 percent. However, operation of SRO at increasing levels of pump power was found to result in a passive increase in crystal temperature and thus a shift in the output wavelength. At the highest pump power the rise in crystal temperature was as much as 23°C, leading to a significant shift in

signal (26 nm) and idler (57 nm) wavelengths compared to operation at low pump power. Given the minimal absorption of the MgO:PPLN crystal at idler wavelengths of 2 to 3 μm in this SRO, the self-heating effect was attributed to the finite absorption of the intracavity signal power. To confirm this, the authors deployed output coupling of the signal by replacing one of the high reflectors with a 4.2 percent output coupler. By operating the SRO at an ambient temperature of 26°C, they observed a 22°C rise in crystal temperature to 47°C under minimum output coupling at the maximum pump power. However, when using the 4.2 percent output coupler, the corresponding temperature rise was only 2.5°C, from 26°C to 28.5°C. Using measurements of signal output power, they estimated the circulating signal power to be as high as ~1.4 kW at the maximum pump power under minimum output coupling, decreasing to ~100 W with the 4.2 percent output coupler. By estimating the total absorption in the 50-mm crystal as 0.4 percent (0.08 percent/cm), they were able to conclude that an absorbed signal power of 5 W was responsible for the 22°C rise in crystal temperature. These measurements clearly confirmed the role of the intracavity signal power in heating of the MgO:PPLN crystal and its influence on spectral shifting of SRO output. The rise in crystal temperature was also observed to have a significant influence on the degradation of spatial quality of the idler beam by inducing thermal lensing effects within the crystal. From measurement of idler beam quality at the same output power level of 3.2 W, they were able to deduce a quality factor of $M^2 \sim 1.35$ under minimum output coupling compared to $M^2 \sim 1.0$ when using the 4.2 percent output coupler, hence confirming the deleterious effects of high circulating signal power on SRO beam quality and thus the need for optimization of output coupling at a given pump power to achieve the highest beam quality while maintaining maximum extraction efficiency. To this end, the authors also investigated the optimization of SRO output power and extraction efficiency at the maximum pump power by using variable output coupling (0 to 5 percent) for the signal across a limited tuning range. Using the fanned crystal, they found the optimum output coupling value to be 3.0 percent, resulting in the simultaneous extraction of 3.0 W of idler and 4.2 W of signal at an overall extraction efficiency of 48 percent. Under this condition, the pump depletion was 78 percent and SRO threshold was 5.8 W, corresponding to the optimum pumping ratio of ~2.5 for maximum power extraction. The effect of use of signal output coupling as a means of optimizing the performance of cw SROs was also later investigated in a separate experiment by Samanta and Ebrahim-Zadeh.[31] Using a cw SRO based on MgO:sPPLT pumped at 532 nm, the authors demonstrated improvements of 1.08 W in total output power, 10 percent in total extraction efficiency, and a 130-nm extension in the useful tuning range, while maintaining pump depletions of 70 percent, idler output powers of 2.59 W, and a minimal increase in oscillation threshold of 24 percent. The output-coupled cw SRO could deliver a total power of up to 3.6 W at 40 percent extraction efficiency across 848 to 1427 nm. The single-frequency resonant signal also exhibited a higher spectral purity than the nonresonant idler output.

The high nonlinear gain coefficient of PPLN combined with the large optical powers present in cw SROs has also been observed to give rise to higher-order nonlinear effects in addition to the second-order parametric process. In a recent example of such an effect,[32] operation of a cw SRO based on MgO:PPLN was reported together with simultaneous Raman action driven by the high intracavity signal intensity. The SRO, based on a multigrating MgO:PPLN crystal (L = 50 mm, Λ = 28.5 to 31.5 μm), was configured in a linear standing-wave cavity and pumped by a 10-W Yb fiber laser at 1070 nm. Two sets of cavity mirrors were used for the SRO, providing different reflectivities for the signal over 1500 to 1700 nm. With the low-Q cavity (R = 98.2 to 99 percent; Q ~ 10^8), normal cw SRO operation with the expected signal and idler spectra was achieved with a 3.3-W threshold, and 1.6 W of idler power was generated at 3620 nm for 8 W of pump at an optical efficiency of 20 percent and slope efficiency of 35 percent. With the high-Q SRO cavity (R = 99.4 to 99.8 percent; Q ~ 10^9), stimulated Raman action with characteristic spectra was simultaneously observed in the vicinity of signal spectrum, driven by the tenfold increase in intracavity signal power to ~100 W. The cw SRO threshold in this case was reduced to 0.5 W, with a corresponding reduction in optical efficiency to 16 percent and slope efficiency to 15 percent. The pump power threshold for Raman conversion was 1.9 W. While stimulated by intracavity signal power, Raman action was present only for grating periods and mirror reflectivities with lowest loss at the corresponding wavelengths, confirming the resonant nature of the observed effect. It was also observed that the presence of Raman oscillation with the high-Q SRO cavity resulted in improved idler RMS power stability of 1.46 percent compared to a 4.1 percent variation with the low-Q cavity, suggesting power limiting of intracavity signal by the Raman conversion.

In a subsequent experiment, Henderson and Stafford[33] also observed stimulated Raman oscillation in a high-power cw SRO based on MgO:PPLN. Using a 14.5-W cw single-frequency Yb fiber laser at 1064 nm and the same SRO arrangement as in Ref. 30, they observed Raman conversion of the intracavity signal under minimum output coupling and at pump powers more than 2 times above threshold, corresponding to circulating signal powers in excess of 230 W. Because of the increasing loss of SRO cavity across an extended tuning range, only two components of the Raman spectrum could be observed. However, under conditions of output coupling no Raman generation was observed up to the maximum available pump corresponding to 170 W of intracavity signal power. In the same cw SRO, the authors also observed spectral broadening of the resonant signal wave at high pump powers. Using highly reflecting mirrors to minimize threshold to 1.5 W, they were able to investigate the evolution of signal spectrum with pump power above threshold. It was observed that while at pump powers up to 3 times above threshold, the signal spectrum remained single-frequency, at pumping ratios between 3 to 4.7 the spectrum exhibited broadening with a symmetric pattern of side modes. The side modes were separated by between 0.2 and 0.5 nm, with their number and intensity increasing with pump power. Above a pumping ratio of 4.7, the signal spectrum was observed to become continuous with a FWHM bandwidth of ~2 nm. These observations, which were found to be in qualitative agreement with predicted theory, confirm that the operation of cw SROs at high pump powers and under the conditions of minimum signal coupling must be limited below a critical pumping ratio of ~4.5, if single-frequency oscillation is to be maintained. Since the maximum conversion in the same experiments was found to be attainable at a pumping ratio of 2.5, by choosing an optimum output coupling of 3.0 percent, the authors increased the SRO threshold to 5.1 W and so were able to maintain single-frequency operation up to the full available pump power of 14.5 W by remaining above the optimum pumping ratio (~2.5) for optimum conversion, but below the critical ratio (~4.5) for spectral broadening and multimode operation. Under this condition, 5.1 W of single-mode signal and 3.5 W of single-mode idler were simultaneously generated for 14.5 W of pump at an overall extraction efficiency of nearly 60 percent, with a measured idler bandwidth of 30 kHz over 500 μs.

The advent of QPM nonlinear materials has had a profound impact on cw SROs, with the vast majority of devices developed to date based on PPLN as the nonlinear material. When pumped near ~1 μm by solid-state, amplified semiconductor, or fiber lasers, they can provide potential coverage from above ~1.3 μm up to the absorption edge of the material near ~5 μm. For wavelength generation below ~1.3 μm, the use of PPLN is generally precluded by photorefractive damage induced by visible pump or signal radiation. As such, the development of practical cw OPOs for visible and near-IR at wavelength below ~1.3 μm has remained difficult, particularly in high-power SRO configuration where strong visible pump and signal radiation are present. This has thus necessitated the use of additional frequency conversion schemes or deployment of alternative QPM materials such as PPKTP and, more recently, MgO-doped periodically poled stoichiometric $LiTaO_3$ (MgO:sPPLT). To extend the tunable range of cw SROs to the visible range, Strossner et al.[34] used an approach based on second harmonic generation (SHG) of the idler output from a cw SRO in an external enhancement cavity. By deploying a 10-W, single-frequency, cw pump laser at 532 nm in combination with multigrating PPKTP (L = 24 mm, Λ = 8.96 to 12.194 μm) and PPLN (L = 25 mm, Λ = 6.51 to 9.59 μm) crystals as the OPO gain medium, and PPLN (L = 43 mm, Λ = 6.51 to 20.93 μm) for SHG, a visible green-to-red tuning range of 550 to 770 nm in the frequency-doubled idler was demonstrated. Together with direct signal (656 to 1035 nm) and idler (1096 to 2830 nm) tuning, this resulted in a total system tuning range of 550 to 2830 nm, with a tuning gap of ~60 nm over 1035 to 1096 nm. The output power, limited by photorefractive damage to the PPLN crystal, and optical damage to the PPKTP crystal and coatings induced by input pump, was 60 mW (signal), 800 mW (idler), and 70 mW (visible frequency-doubled idler) for up to 3.3 W of pump. The output signal from the free-running SRO exhibited a short-term linewidth of 20 kHz over 50 μs, with a jitter of 300 kHz over 5 ms, and 5 MHz over 1 s. By frequency locking the SRO to a monolithic Nd:YAG laser, a jitter-free linewidth of 20 kHz was measured at a signal wavelength of 946 nm. In the absence of pump tuning, mode-hop-free tuning of SRO output was obtained by adjustment of the cavity length using piezo control and synchronous rotation of the etalon using a feedback loop, resulting in 38 GHz of fine tuning in the signal for PPKTP and 5 to 16 GHz for PPLN, limited by photorefractive effects. The

free-running SRO exhibited a mode hop over a free-spectral range (680 MHz) every 10 min, but locking the SRO cavity to the 532-nm pump ensured a long-term frequency drift of <50 MHz/h in the signal and idler, accompanied by a reduction in output power by ~10 percent.

More recently, the development of MgO:sPPLT has brought about new opportunities for the advancement of practical cw SROs for the visible and near-IR at wavelength below ~1.3 μm with the direct use of high-power solid-state laser sources in the green. By deploying a 10-W, single-frequency, cw, frequency-doubled Nd:YVO_4 pump laser at 532 nm, MgO:sPPLT (L = 30.14 mm, Λ = 7.97 μm) as the nonlinear crystal and temperature tuning, Samanta et al.[35] demonstrated a cw SRO with a tunable range of 848 to 1430 nm. Using a linear standing-wave cavity and double-pass pumping, the cw SRO had an oscillation threshold of 2.88 W, and could provide >1.51 W of single-pass idler power for 6 W of pump at an extraction efficiency of >25 percent and photon conversion efficiency of >56 percent. The maximum idler power and conversion efficiency in this SRO was limited by thermal lensing effects, attributed to the finite liner absorption of the green pump light in the MgO:sPPLT crystal. Despite this, the SRO could deliver >500 mW of single-pass power across the entire idler tuning range of 1104 to 1430 nm, and in a Gaussian profile, confirming the absence of photorefractive damage as is present in PPLN. With a standing-wave SRO cavity and in the absence of intracavity frequency selection, the output frequency in both signal and idler was characterized by mode hops. Soon after, by deploying a compact ring cavity with a 500-μm intracavity etalon, the authors demonstrated single-frequency operation of the cw SRO.[36] Using the same pump laser and MgO:sPPLT crystal in a single-pass pumping arrangement, the SRO had a pump power threshold of 2.84 W and could deliver 1.59 W of single-mode idler power over 1140 to 1417 nm for 7.8 W of pump at >20 percent extraction efficiency. The total SRO tuning range was 852 to 1417 nm, obtained for a variation in crystal temperature from 61 to 236°C. Under free-running conditions, the idler had an instantaneous linewidth of ~7 MHz and exhibited a peak-to-peak power stability of 16 percent over 5 hours. Measurements of idler power at different crystal temperatures revealed stronger thermal lensing at higher temperatures. In a separate experiment, operation of a similar cw SRO based on MgO:sPPLT and pumped by a Nd:YVO_4 laser at 532 nm was reported by Melkonian et al.,[37] providing tunable signal over 619 to 640 nm in the red. Using a ring cavity for the SRO containing a 30-mm multigrating crystal (Λ = 11.55 to 12.95 μm) and a 2-mm-thick intracavity silica etalon, the SRO could provide ~100 mW of nonresonant idler power. The resonant signal was extracted using a 1.7 percent output coupler, providing 100 mW of single-frequency red radiation for 10 W of input pump power. The cw SRO threshold varied from 3.6 W in the absence of the intracavity etalon up to 6.6 W with signal output coupling, and rising to 6.8 W depending on the exact signal wavelength. The maximum pump depletion was 15 percent, limited by thermal effects attributed to pump and signal absorption. The output signal frequency could be mode-hop-tuned over a total range of 27 GHz by rotation of the intracavity etalon, in steps of 255 MHz corresponding to free-spectral-range of the SRO cavity. With active stabilization of SRO cavity length, a frequency stability of 20 MHz over 3 min was obtained for the signal.

The development of practical, high-power, single-frequency cw SROs based on MgO:sPPLT pumped in the green and operating below 1 μm[35–37] has also provided new motivation for spectral extension to shorter wavelengths. By using internal SHG of the resonant near-IR signal in a cw SRO based on MgO:sPPLT, Samanta and Ebrahim-Zadeh[38] demonstrated the first cw SRO tunable in the blue. A schematic of the SRO configuration is shown in Fig. 10. The device was based on similar experimental design as in Ref. 36, except for the exclusion of the intracavity etalon and inclusion of a 5-mm BiB_3O_6 (BIBO) crystal at the secondary waist of the bow-tie SRO ring resonator to frequency double the circulating signal radiation in a single direction. By varying the temperature of the MgO:sPPLT crystal to tune the signal over 850 to 978 nm, and simultaneous rotation of the BIBO phase-matching angle, a wavelength range of 425 to 489 nm in the blue was accessed. The generated blue power varied from 45 to 448 mW across the tuning range, with the variation arising from the non-optimum reflectivity of the blue coupling mirror over the signal wavelength range. The output power behavior and pump depletion of the SRO with pump power is shown in Fig. 11. The frequency-doubled SRO had a threshold of 4 W (2.4 W without the BIBO crystal), and exhibited a pump depletion of up to ~73 percent under blue generation. In addition to the blue, the device could provide in excess of 100 mW of signal and as much as 2.6 W of idler output power. Without an intracavity etalon, the

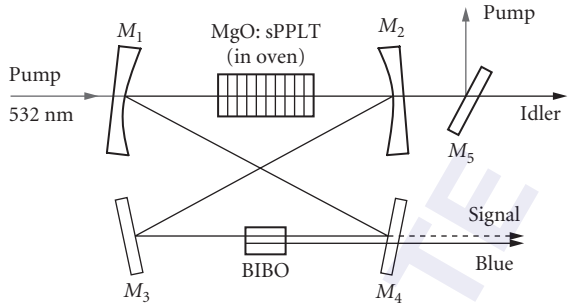

FIGURE 10 Schematic of the intracavity frequency-doubled MgO:sPPLT cw SRO for blue generation.[38]

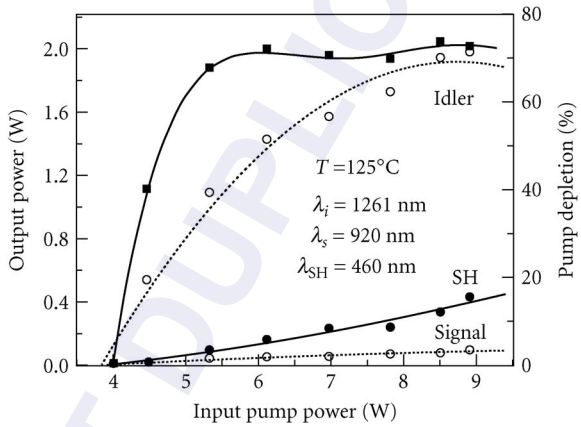

FIGURE 11 Single-frequency blue power, signal power, idler power, and pump depletion as functions of input pump power to the frequency-doubled cw SRO. Solid and dotted lines are guide for the eye.[38]

single-mode nature of the pump and resonant signal resulted in single-frequency blue generation and a measured instantaneous linewidth of ~8.5 MHz in the absence of active stabilization. The blue output beam also exhibited a gaussian spatial profile. In the meantime, operation of a intracavity frequency-doubled cw SRO based on MgO:sPPLT was also reported by My et al.,[39] providing tunable output in the orange-red. By resonating the idler wave in the 1170 to 1355 nm range in a ring resonator and employing a 10-mm intracavity β-BaB_2O_4 (BBO) crystal for doubling, tuning output over 585 to 678 nm was generated. With a 30-mm MgO:sPPLT crystal (Λ = 7.97 μm), up to 485 mW of visible radiation was internally generated for 7.6 W of pump, with 170 mW extracted as useful output. The device could also provide up to 3 W of nonresonant infrared signal power. The power threshold for the cw SRO was 4.5 W (4 W without the BBO crystal) and pump depletions of ~80 percent were measured for input powers >6 W. Without active stabilization, the visible SHG output was single mode with a frequency stability of 12 MHz over 12 min, and mode-hop-free operation could be maintained over several minutes.

In a departure from conventional cw OPOs based on bulk materials, the use of guided-wave nonlinear structures can also in principle offer an attractive approach to the realization of OPO sources in miniature integrated formats. The tight confinement of optical waves in a waveguide can

provide substantial enhancement in nonlinear gain per input pump power compared with the bulk materials, but a major drawback of the approach is the unacceptably high input and output coupling losses in the waveguide, hindering OPO operation. The problem is further exacerbated in the cw regime, and in the SRO configuration, which is characterized by the highest oscillation threshold. In an effort to overcome this difficulty, Langrock et al.[40] deployed the technique of fiber-feedback to achieve operation of a cw SRO based on a reverse-proton-exchanged (RPE) PPLN waveguide. In this approach, the SRO cavity was formed in a ring using a single-mode optical fiber pigtailed to both ends of the waveguide, providing feedback at the resonant signal wave. The pump was similarly coupled into the PPLN waveguide using a separate fiber and, together with the nonresonant idler, exited the waveguide in a single pass. The configuration resulted in minimum coupling losses of 0.7 dB (signal input) and 0.6 dB (signal output), and alignment-free operation. Using a 67-mm RPE PPLN waveguide containing a 49-mm grating (Λ = 16.1 μm), and a tunable external cavity diode laser at 779 nm as the pump, cw SRO threshold was reached at ~200 mW of coupled pump power. The waveguide cw SRO exhibited gain bandwidths in excess of 60 nm. Ultimately, however, practical realization of such waveguide cw SROs offering significant output will require further optimization of waveguide fabrication process to minimize propagation losses (α = 0.2 dB/cm) and loop losses (1.5 dB) in the present device, as well as further reductions in the waveguide-to-fiber coupling losses.

Multiple-Resonant Oscillators

Because the high pump power requirement for cw SROs can be prohibitive for many practical applications, extensive efforts have been directed to the development of cw OPOs in alternative resonance configurations, from the traditional DRO to the more recently devised PE-SRO and TRO, with the goal minimizing the pump power thresholds. These efforts have brought the operation of cw OPOs within the reach of more commonly available low- to moderate-power cw laser sources, albeit at the expense of added system complexity arising from the need for more elaborate cavity designs, more complex tuning protocols and the imperative requirement for active stabilization and control. In particular, the use of DRO and PE-SRO resonance schemes in combination with novel cavity designs have led to the practical generation of cw mid-IR radiation with the highest degree of frequency stability, and continuous mode-hop-free tuning capability over extended frequency spans at practical powers. These efforts have led to the realization of novel cw OPO systems in PE-SRO, DRO, and TRO configurations pumped by a variety of laser sources. These sources offer practical cw output powers in the mW to 100s mW range, high frequency stability, significant mode-hop-free tuning capability and extended wavelength coverage in the 1 to 5 μm spectral range.

Doubly Resonant Oscillators The use of DRO configurations in combination with PPLN has permitted substantial reductions in cw pump power threshold in cw OPOs, to levels compatible with the direct use single-mode semiconductor diode lasers, without the need for power amplification. The smooth wavelength tuning capability of the diode laser pump can then be similarly exploited to achieve continuous mode-hop-free tuning of the DRO output. In an example of such an approach, Henderson et al.[41] demonstrated a PPLN cw DRO pumped directly with a 150-mW, single-mode, single-stripe, DBR diode laser at 852 nm. Configured in a single, linear, standing-wave resonator and using a 19-mm-long multigrating crystal (Λ = 23.0 to 23.45 μm), the DRO exhibited a pump power threshold of ~17 mW, with thresholds as low as 5 mW under optimum alignment and minimum output coupling. Using three DRO mirror sets, a signal (idler) wavelength range of 1.1 to 1.4 μm (2.2 to 3.7 μm) was accessed by temperature tuning the PPLN crystal. The DRO generated a total signal and idler power of 18 mW at 1.3 and 2.3 μm, respectively, for 89 mW of input diode pump power, with 4 mW of output in the idler beam. Continuous mode-hop-free tuning of the signal (idler) at 1.3 μm (2.3 μm) could be obtained over 12 GHz (7 GHz) by smooth tuning the frequency diode laser using temperature variation and over 17 GHz (10 GHz) using current control in combination with active servo control of the DRO cavity length to follow the pump frequency scan. The continuous mode-hop-free tuning ranges were limited by the restrictions on DRO cavity length variation imposed by the piezoelectric transducer. With a pump linewidth of <3 MHz, the signal wave was measured to have

a linewidth of <7 MHz and a free-running frequency stability of ~20 MHz over 10 s without active stabilization. To demonstrate the utility of the diode-pumped cw DRO, continuous tuning of the idler was used in single-pass absorption spectroscopy of R6 line in CO gas at 2.3 μm.

In an effort to extend the wavelength coverage of cw OPOs to the visible spectrum, Petelski et al.[42] demonstrated a DRO tunable in the yellow, using a cascaded frequency scheme comprising three resonators including two external enhancement cavities, and a cw single-frequency monolithic ring Nd:YAG laser as the primary pump source. The pump light at 1.064 μm was frequency doubled in an external enhancement cavity using MgO:$LiNbO_3$ as the nonlinear crystal, to provide the input radiation for the cw DRO based on an identical crystal. With a threshold of 15 mW, the DRO delivered 95 mW of idler power for 450 mW of input at 532 nm, with the idler tunable over 1.130 to 1.190 μm by changing the temperature of the MgO:$LiNbO_3$ crystal. The generated idler output was then frequency doubled in an external enhancement cavity based on a 16-mm PPLN crystal (Λ = 8.0 to 8.6 μm) to provide tunable radiation across the 565 to 590 nm range. For 1.05 W of primary pump power at 1.064 μm, an output power of 3.8 mW was obtained at 580 nm, with active stabilization of the DRO and enhancement cavities providing single-mode output with a 3 percent intensity noise and stable operation over 10 hours. Fine tuning of the yellow output was obtained by smooth tuning of the Nd:YAG pump source, as well as mode-hop tuning of the DRO by scanning the cavity length. By tuning the pump frequency over 10 GHz, the yellow output at 580 nm was tuned continuously over 18 GHz, while mode-hop tuning could provide 160 GHz of step tuning across 20 mode pairs.

Pump-Enhanced Singly Resonant Oscillators In separate experiments, using a single-mode, single-stripe, grating-stabilized AlGaAs diode lasers at ~810 nm in both solitary and external-cavity configurations, Lindsay et al.[43] demonstrated a PPLN cw OPO in pump-enhanced configuration. Using a single, linear, standing-wave cavity for the OPO and a 50-mm, multigrating (Λ = 21.0 to 22.4 μm) crystal, a typical pump power threshold of 25 to 30 mW over a signal (idler) tuning range of 1.06 to 1.19 μm (2.58 to 3.44 μm) was demonstrated, with ~4 mW of single-mode idler power available for 62 mW of pump. Wavelength tuning could be achieved by the variation of pump wavelength, PPLN crystal temperature, or grating period. In the external cavity configuration, locking of the OPO cavity length to the pump laser frequency using the Pound-Drever technique enabled stabilized single-mode operation with a signal (idler) intensity fluctuation of ±3.5 percent (2.6 percent) at 0.5 mW (4 mW) power level over 1 hour. Over this period, pump frequency fluctuations of ±125 MHz resulted in ±100 MHz variation in signal frequency. However, mode-hop-free operation was maintained throughout the entire period. By continuous tuning of the external cavity diode laser over 510 MHz, a mode-hop-free tuning range of 377 MHz for the signal and 133 MHz for the idler was obtained, limited by the relative tuning rate of parametric gain curve and resonant signal modes with frequency tuning of the pump in the common-cavity PE-SRO, and so could be extended using a dual-cavity arrangement for the OPO.

By deploying a single-frequency cw Ti:sapphire pump laser, Turnbull et al.[44] demonstrated a cw PE-SRO based on a multigrating PPLN crystal (L = 19 mm, Λ = 21.0 to 22.4 μm) with an extended mid-IR idler coverage to 5.26 μm, well into the strong absorption region of the material beyond ~4.5 μm. The PE-SRO could provide idler tuning in two regions from 2.71 to 3.26 μm and from 4.07 to 5.26 μm, using a combination of temperature tuning and grating period variation. The oscillator exhibited a typical cw pump power threshold of 100 mW, increasing to more than 500 mW near 5 μm. For 750 mW of input pump power, the PE-SRO could typically provide a maximum one-way cw idler power of 16 mW. By employing a dual-cavity arrangement for the PE-SRO and a solid etalon in one arm of the resonant signal cavity, the authors were able to demonstrate mode-hop-free tuning of the idler over 10.8 GHz by smoothly tuning the pump laser over 12.3 GHz. In a further experiment, Stothard et al.[45] extended operation of the same PE-SRO to a single-cavity, traveling-wave ring geometry with the aim of extending the total fine-tuning performance of the oscillator and improving the idler output power. By using a low-finesse intracavity etalon to control the resonant signal frequency, the authors were able to achieve discontinuous mode-hop tuning of the idler frequency across the entire free spectral range of the etalon, corresponding to 83 GHz. The PE-SRO exhibited an oscillation threshold of 250 mW and could generate 35 mW of cw single-frequency mid-IR

idler radiation in the 2.8 to 3-μm spectral range for 600 mW of input Ti:sapphire pump power. In a separate experiment, Lindsay et al.[46] reported the operation of a cw PE-SRO based on PPRTA (L = 20 mm, Λ = 39.6 μm) as the nonlinear crystal. The PE-SRO was pumped by a diode-pumped cw single-frequency Nd:YVO_4 laser at 1.064 μm and was configured in a linear standing-wave resonator with the nonresonant idler double-passed through the cavity. With the 20-mm crystal length, the oscillator had an external pump power threshold of 250 mW and could deliver 87 mW of cw mid-IR idler output for 900 mW of input pump power. Coarse tuning of the idler over the wavelength range of 3.245 to 3.520 μm was achieved by temperature tuning the single-grating PPRTA crystal. Continuous mode-hop-free tuning of the PE-SRO over 0.7 GHz was also demonstrated by fine tuning the Nd:YVO_4 pump laser frequency.

In subsequent experiments, Muller et al.[47] investigated long-term frequency stability and linewidth properties of cw PE-SROs in common-cavity and dual-cavity configurations. Using multigrating PPLN crystals (L = 50 mm, Λ = 28.64 to 30.16 μm), a 2.5 W cw Nd:YAG pump laser (linewidth ~1 kHz/100 ms, frequency drift ~1 MHz/min) at 1064 nm, and linear standing-wave cavity arrangements for both configurations, they studied frequency stability and linewidth of the idler output tunable in the 3.1 to 3.9 μm spectral range. Schematics of the experimental setups for both cavity configurations are shown in Figs. 12 and 13. In the common-cavity PE-SRO (Fig. 12) with the pump and signal resonant in the same cavity, the OPO was locked to the pump laser using the Pound-Drever-Hall (PDH) technique, and the oscillator exhibited a threshold of 280 mW. In dual-cavity arrangement (Fig. 13), the pump and signal were resonated in separate linear cavities, with an intracavity 500-μm-thick Nd:YAG etalon inserted into the signal cavity for improved frequency control. The pump cavity was locked to the pump laser using the PDH method, while the signal cavity was locked to the point of maximum idler power using an intensity lock without an external reference. The use of dual-cavity configuration increased the threshold to 380 mW, but resulted in stable, mode-hop-free operation over 30 min. While an intrinsic advantage of the common-cavity PE-SRO is direct stabilization of the signal frequency to pump, it is more sensitive to mechanical perturbations, leading to mode hops. Moreover, reliable mode-hop-free operation and continuous frequency tuning by tuning the pump laser are more difficult due to the simultaneous resonance of two different wavelengths within a single cavity. On the other hand, the dual-cavity approach can overcome spontaneous mode hops and continuous tuning limitations of common-cavity PE-SROs, and can also offer several tuning methods combining etalon, signal cavity and pump frequency tuning. The

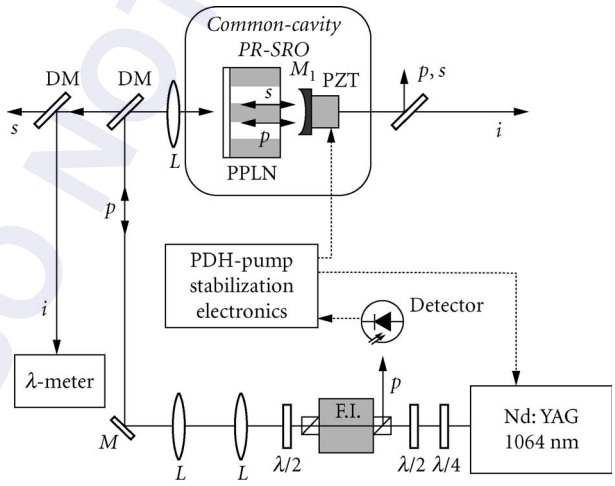

FIGURE 12 Common-cavity cw PE-SRO setup; M = mirror, DM = dichroic mirror, FI = Faraday isolator, L = lens, p = pump, s = signal, i = idler.[47]

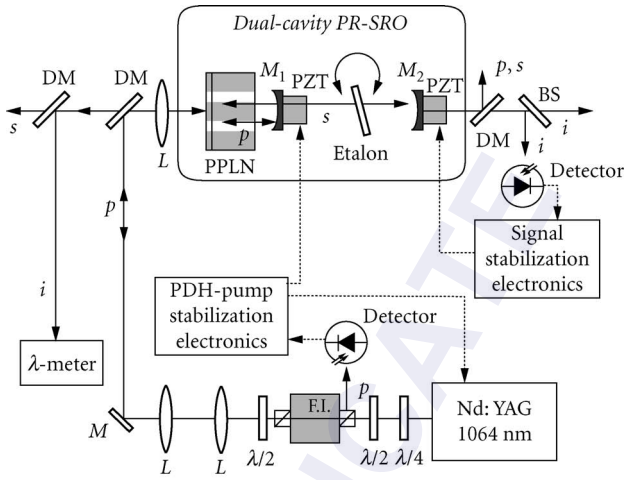

FIGURE 13 Dual-cavity cw PE-SRO setup; M = mirror, DM = dichroic mirror, FI = Faraday isolator, L = lens, p = pump, s = signal, i = idler.[47]

results of the investigations revealed long-term frequency stability better than ± 30 MHz over more than 30 min for both configurations (Figs. 14 and 15), limited by the resolution of the wavemeter. The short-term frequency jitter was 56 kHz over 1.8 s for the common-cavity PE-SRO and 13.5 MHz over 1.5 s for the dual-cavity PE-SRO. The short-term linewidths, measured using the cavity leak-out technique in external high-finesse cavities, were (9 ± 2) kHz for the common-cavity and (6 ± 1) kHz for the dual-cavity over 20 μs. The difference in frequency stability and linewidth of the two configurations is a result of the stabilization methods used. In the common-cavity PE-SRO, direct locking of the cavity to the pump laser provides a strong stabilization of the signal to pump frequency. In the

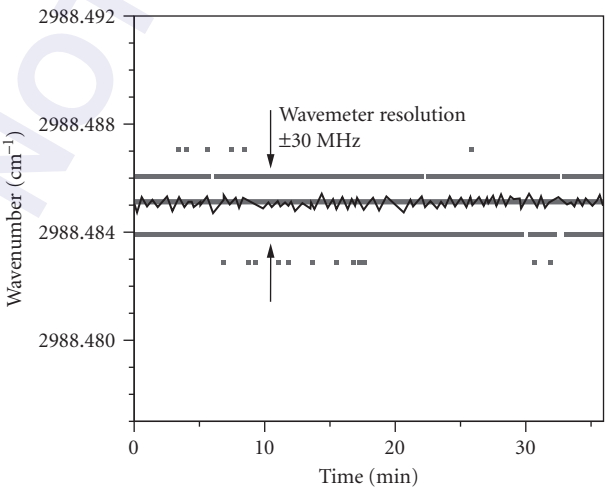

FIGURE 14 Long-term frequency stability (digital wavemeter read-out in 30 MHz steps and running average over 20 points) of the common-cavity cw PE-SRO.[47]

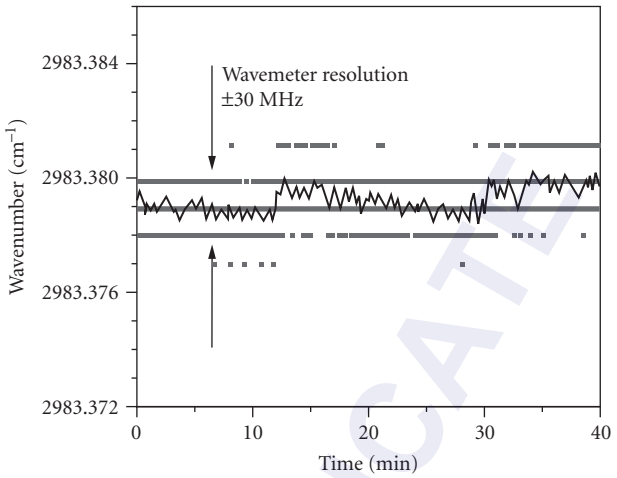

FIGURE 15 Long-term frequency stability (digital wavemeter read-out in 30 MHz steps and running average over 20 points) of the dual-cavity cw PE-SRO.[47]

dual-cavity PE-SRO, the signal cavity is locked to the maximum idler output power and so the idler frequency is coupled to the maximum of the phase-matching gain curve. Any shifts in the gain curve in time will also result in corresponding variations in the signal and idler frequencies. However, the reported results confirm that despite this limitation, the dual-cavity PE-SRO provides the required frequency stability and linewidths as well as continuous mode-hop-free tuning necessary for high-resolution spectroscopy.

Triply Resonant Oscillators Characterized by the lowest oscillation threshold, the TRO represents the least demanding configuration for cw OPOs with regard to pump power. However, practical operation of such oscillators requires active cavity length control to maintain simultaneous resonance of the pump, signal and idler within the OPO resonator. In an example of such a device, Gross et al.[48] reported a TRO based on a 58-mm PPLN crystal using only 14 mW of pump power from a grating-stabilized, single-frequency, extended-cavity diode laser at 805 nm. By deploying a linear two-mirror cavity, highly reflecting mirrors, optimum mode-matching and active stabilization, they achieved a threshold pump power as low as 600 μW at resonance, with a maximum total (signal and idler) output power of 47 μm generated for 13.5 mW of pump. With mirrors of higher transmission (4 percent) at the signal and idler, a total output power of 2.1 mW was generated for 13.8 mW of pump, but at the expense of an increase in pump power threshold to 4.5 mW. Using a segmented design for the PPLN crystal consisting of two 19-mm outer sections poled with multiple grating of identical periods (Λ = 20.2 to 20.8 μm) at 50 percent duty cycle and a single-domain section of length 20 mm at the centre, they demonstrated electro-optic tuning of the TRO output wavelengths at a fixed temperature, grating period, and pump wavelength. By applying an electric voltage of up to +1230 V across the single-domain section, wavelength tuning of the signal and idler over 1560 to 1660 nm could be obtained through modification of the phase-matching gain spectrum induced by the electro-optic effect. By applying a voltage modulation of amplitude 513 V at 0.11 Hz, signal (idler) tuning over 9.7 nm (10.8 nm) was demonstrated over 4.6 s, limited by the bandwidth of servo electronics.

Because of their phase coherent properties and the ability to generate exactly correlated frequencies, cw OPOs are also uniquely versatile sources for applications in optical frequency synthesis and metrology. Combined with compact solid-state semiconductor, or fiber pump lasers, they can offer practical tools for precision frequency generation, measurement, and control across extended regions spanning

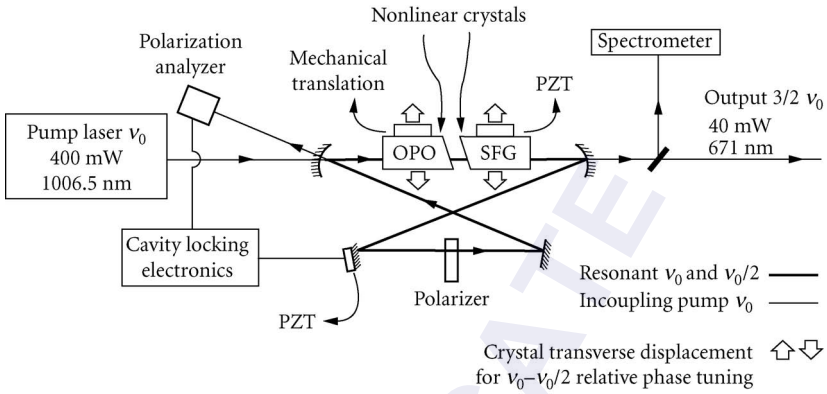

FIGURE 16 Schematic of the cw TRO for 3/2 frequency multiplier, converting a cw single-frequency radiation at 1006.5 nm into 671 nm. The wedged surfaces of the crystals are cut at an angle of 100 mrad with respect to the crystal axis. The input (output) facet of the OPO (SFG) crystal is at normal incidence. The two inclined surfaces facing each other are parallel. The transverse displacement of the nonlinear crystals provides an independent control over the cavity dispersion, ensuring simultaneous resonance of the two infrared fields.[49]

the optical spectrum. In a report, Ferrari[49] demonstrated a particular architecture for optical frequency synthesis based on a cw OPO in TRO configuration. By taking advantage of the lowest oscillation threshold offered by the TRO, the author developed a 3/2 pump frequency multiplier from the near-IR to visible using a 400-mW, single-mode semiconductor MOPA device at 1006.5 nm as the pump source (Fig. 16). The TRO, based on PPKTP as the nonlinear crystal (L = 20 mm, Λ = 38 μm), was operated at degeneracy to provide identical signal and idler frequencies at half the pump frequency. A second intracavity PPKTP crystal (L = 20 mm, Λ = 19.8 μm) was then used to sum the pump with the degenerate frequency, resulting in 3/2 frequency multiplication of the pump, corresponding to a wavelength of 671 nm in the red. To provide stable operation, the TRO cavity length was locked using the pump resonance, and independent control of the degenerate signal and idler oscillating modes was obtained by using wedged crystals. Fine tuning of the TRO cavity modes could be obtained while maintaining pump resonance by lateral translation of the wedged crystals to alter in the optical path lengths within the crystals, thus enabling single-frequency operation to be achieved at degeneracy. The TRO had a threshold of <50 mW and could provide 40 mW of single-mode output at degeneracy in a near-gaussian spatial mode with an RMS amplitude noise of 1.4 percent (50 kHz bandwidth) over 3 min at full power.

17.3 APPLICATIONS

The important advances in cw OPOs over the last decade have led to the realization of a new generation of practical coherent light sources in new spectral regions from the visible to the near- and mid-IR offering unprecedented optical powers, high frequency stability and narrow linewidth, excellent beam quality, and extended fine and coarse tuning. These capabilities have paved the way for the deployment of cw OPOs in new application areas, in particular spectroscopy. Most notably, cw OPOs based on PPLN have found important applications in sensitive detection and analysis of trace gases in mid-IR, where a variety of important molecular finger prints exist. A wide range of experiments, from simple single-pass absorption to high-resolution Doppler-free and cavity leak-out spectroscopy have been successfully performed by deploying cw OPOs based mainly on PPLN and operating in different resonance configurations of SRO, PE-SRO, or DRO. The higher cw output powers available to SROs and PE-SROs have also enabled detection of trace gases in the mid-IR with unprecedented sensitivity using photoacoustic spectroscopy.

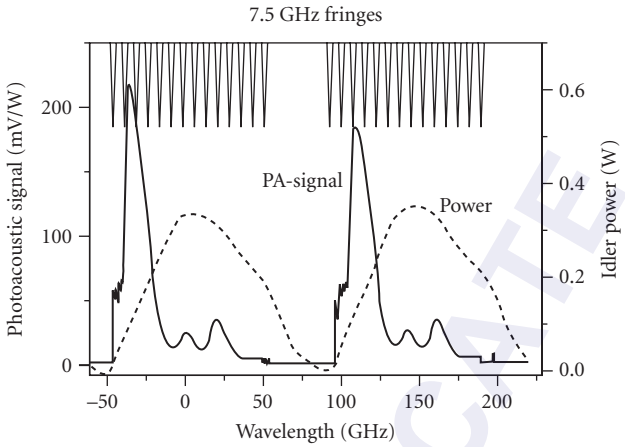

FIGURE 17 100-GHz-wide mode-hop scan of 10 ppm ethane in nitrogen was made around 2996.9 cm^{-1}. The solid line at the bottom shows the photoacoustic signal, the dashed line the idler power and the solid line at the top the fringes from a 7.5-GHz external Fabry-Perot etalon.[21]

By exploiting fine frequency tuning in a diode-pumped PPLN cw SRO, Klein et al.[28] performed single-pass absorption spectroscopy of rovibrational transitions in N_2O gas near 2.1 μm. The wide and continuous mode-hop-free tuning of the idler over 56 GHz enabled monitoring of three molecular lines separated by ~20 GHz within a single frequency scan.

Using a cw SRO based on PPLN, providing 700 mW of idler power and a total single-frequency fine tuning range of 24 GHz, Van Herpen et al.[20] recorded absorption line of ethane in nitrogen using the photoacoustic spectroscopy technique. In a later experiment,[21] by deploying a more powerful pump laser and a similar SRO configuration, photoacoustic spectroscopy of ethane in nitrogen was demonstrated with a detection sensitivity of 10 parts per trillion (ppt) (Figs. 17 and 18). The

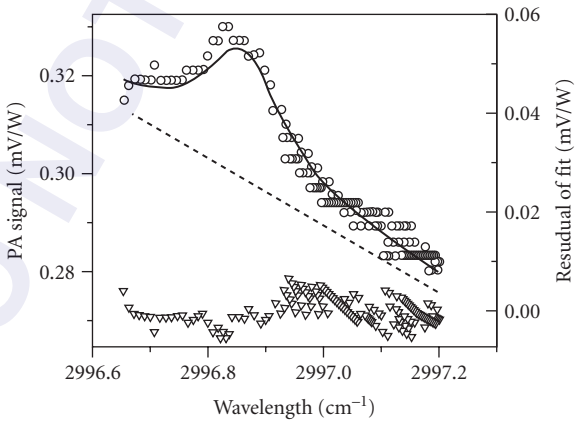

FIGURE 18 Pump-scan around 2996.9 cm^{-1} of 0.4-ppb ethane in nitrogen at atmospheric pressure. A lorentzian fit with linearly decreasing background has been plotted through the data (dashed line). The linearly decreasing background is also shown separately with a dotted line. The bottom of the picture shows the residual if the fit is subtracted from the data.[21]

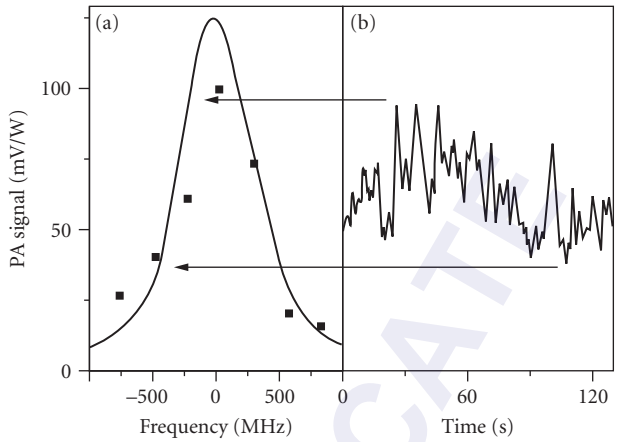

FIGURE 19 The high resolution performance and the wavelength stability of the SRO are demonstrated by recording the photo acoustic signal from the half maximum of a 77 mbar pressure broadened absorption line of 20 ppm of ethane in nitrogen at 2996.9 cm^{-1}. When not tuning the pump frequency, the photoacoustic signal shows random oscillations at a rather high frequency (90 MHz/s), combined with an oscillation at a lower frequency (250 MHz in 200 s).[23]

extension of operation of the SRO to the 3.7 to 4.7-μm spectral range enabled photoacoustic detection of the CO_2 absorption line in nitrogen near 4.235 μm using 24-GHz continuous scan of the idler frequency.[22] By using a high-power cw SRO based on PPLN operating in the 2.6 to 4.7 μm in the mid-IR, photoacoustic spectroscopy of a mixture of 20-ppm ethane in nitrogen was performed near 3.33 μm.[23] The SRO was pumped by a 20-W, cw single-frequency Yb:YAG laser (tunable over 1.024 to 1.034 μm) and could deliver 3 W of idler power at 2.954 μm (Fig. 3). By step-tuning the pump frequency using a combination of intracavity etalon and a Lyot filter, mode-hop-tuning of the idler over 190 GHz could be achieved, enabling coverage of several absorption lines of ethane. With 2.15 W of idler power available at 3.33 μm, a photoacoustic detection sensitivity of 0.005 ppb was deduced. By monitoring the photoacoustic signal corresponding to the strongest absorption peak in the same 20-ppm mixture of ethane in nitrogen at low pressure (77 mbar) as a function of time (Fig. 19), a slow idler frequency drift of 250 MHz over 200 s was measured, which was attributed to the fluctuations in the PPLN crystal temperature and lack of thermal isolation of the SRO from the environment. The idler frequency also exhibited fast frequency fluctuations of 90 MHz/s, attributed to the nonoptimized coatings of the PPLN crystal and cavity mirrors, which resulted in unwanted etalon and resonance effects in the SRO cavity. In a later report, Ngai et al.[24] performed photoacoustic and cavity leak-out spectroscopy of several trace gases including CO_2 and multicomponent gas mixtures of methane, ethane, and water in human breath using an automatically tunable cw SRO based on a multigrating MgO:PPLN crystal (Figs. 4 and 5). By deploying a ring SRO cavity with an uncoated intracavity YAG etalon and using a combination of pump tuning and etalon rotation, step-tuning of the idler over 207 GHz could be achieved. Adjustment of the crystal temperature could further be used to repeat this process, to provide wavelength scans of up to 450 cm^{-1} with a single grating period at high resolution ($<5 \times 10^{-4}$ cm^{-1}). By translating the crystal to other grating periods, an extended idler wavelength range of 2.75 to 3.83 μm could be accessed. Using the wide wavelength scanning capability, extended wavelength coverage, and automatic tuning capability of this source, photoacoustic spectroscopy of strong CO_2 combination bands in laboratory air (460 ppmv) extending over 14 nm (from 2788 to 2802 nm) was recorded by a combination of pump tuning, etalon rotation and crystal temperature tuning with a spectral resolution of 0.01 nm and a recording time of 1 hour. The recorded spectra were corrected for the water-vapor contribution to reveal the true

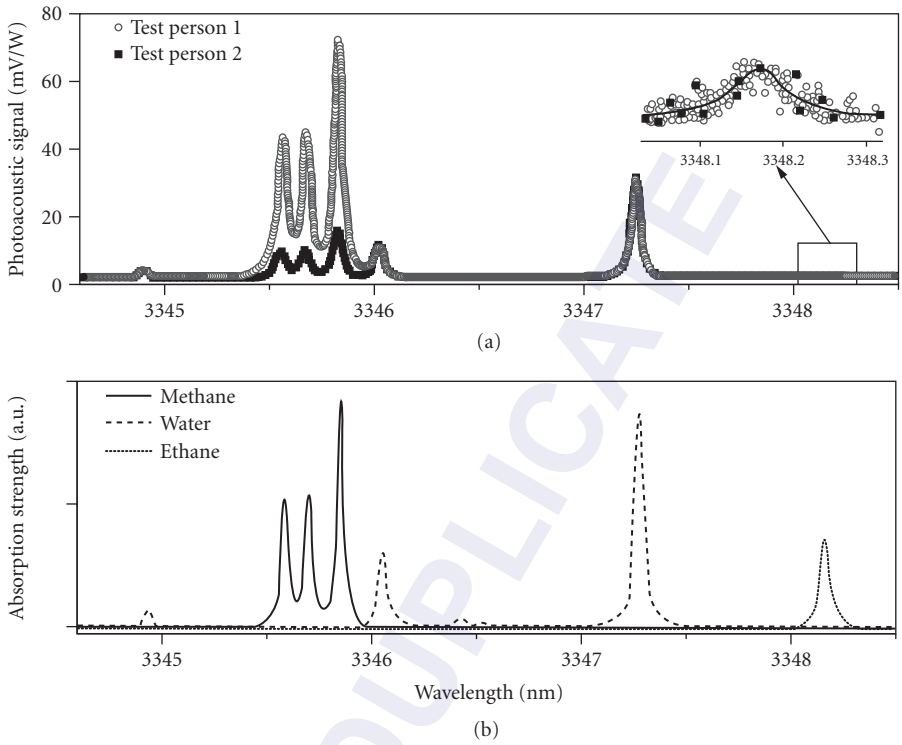

FIGURE 20 (*a*) Photoacoustic spectra measured from the breath of two different test persons. The recorded spectra reveal a higher methane concentration in the breath of person 1, indicating the presence of methanogenic flora. (*b*) Calculated absorption spectra based on the HITRAN database for methane, ethane, and water.[24]

CO_2 spectra, with the results in excellent agreement with calculations. Similarly, using the same automatic tuning protocol, photoacoustic spectroscopy of methane, ethane, and water vapor in human breath were simultaneously recorded by scanning the idler wavelength in the 3344 to 3349 spectral range (Fig. 20). Concentrations of 21 ppmv and 13 ppbv were calculated for methane and ethane, respectively, in the first sample, and 4.5 ppmv and 13 ppbv in the second sample. Using the same cw SRO, cavity leak-out spectroscopy was performed for gas mixtures containing methane (at 3.221 μm) and ethane (at 3.337 μm) in N_2 at 100 mbar pressure. In the case of methane, the absorption peak was scanned over 200 s with a spectral resolution of 0.001 cm^{-1}, resulting in a background methane concentration of 31 ppbv in N_2, a noise-equivalent detection limit of 0.16 ppbv, and a minimum detectable absorption coefficient of 2.0×10^{-9} cm^{-1}. For ethane, the idler was scanned over 60 s with a lower resolution of 0.01 cm^{-1}, resulting in concentrations from 5 to 100 ppbv, a noise-equivalent detection limit of 0.07 ppbv, and a minimum detectable absorption coefficient of 1.4×10^{-9} cm^{-1}. The cw SRO was also used to record the spectrum of $^{12}CH_4$ and $^{13}CH_4$ isotopes of methane in laboratory air with cavity leak-out spectroscopy. Scanning the idler wavelength from 3210 to 3211.5 nm revealed the absorption features corresponding to the two isotopes as well as water vapor, with the measured data in good agreement with calculated spectra.

The rapid and continuous mode-hop-free idler tuning over 110 GHz in a PPLN cw SRO pumped by a fiber-amplified DBR diode laser[29] has been used to perform real-time single-pass absorption spectroscopy of methane near 3.39 μm with a refresh period of 29 ms and a corresponding refresh rate of 34 Hz, demonstrating the suitability of the system for rapid spectroscopic measurements (Fig. 21). In a subsequent experiment,[50] by taking advantage of frequency modulation capabilities

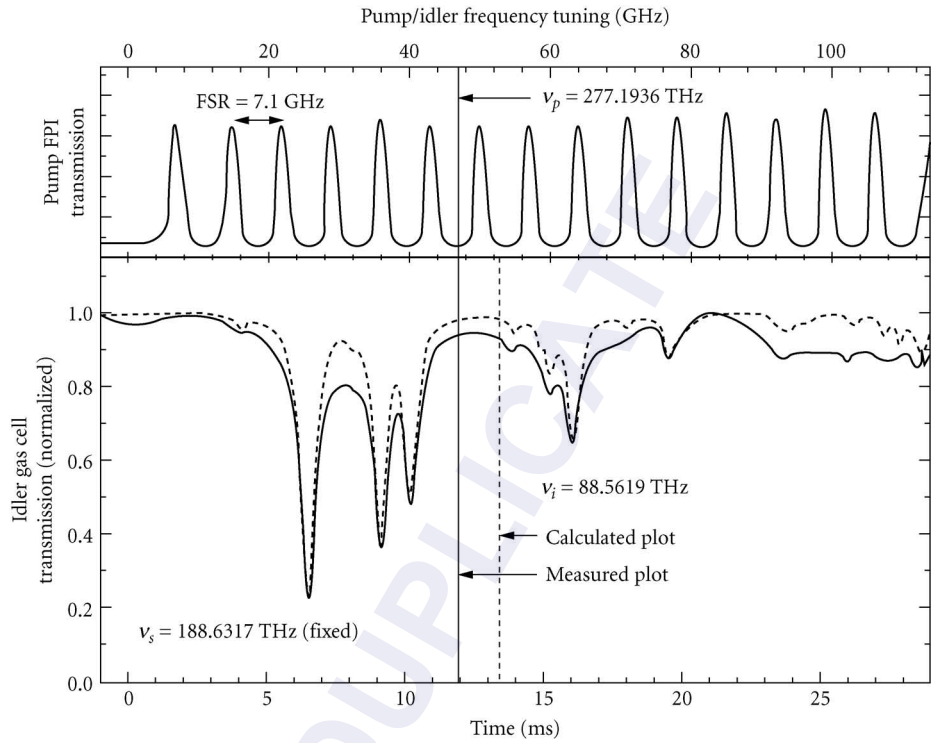

FIGURE 21 Rapid mode-hop-free tuning of a cw SRO pumped by a fiber-amplified DBR diode laser, and application absorption spectroscopy of CH_4.[29]

of the idler output from a similar fiber-amplified DBR diode-pumped cw SRO, sensitive detection of multicomponent trace gas mixtures was performed using quartz-enhanced photoacoustic spectroscopy (QEPAS). The SRO, based on a multigrating MgO:PPLN crystal (L = 50 mm, Λ = 28.5 to 31.5 μm), was similarly configured in a ring cavity with a 400-μm-thick uncoated intracavity YAG etalon to provide enhanced frequency selection and stability (Fig. 22). The pump laser delivered 7.9 W of single-frequency power at 1082 nm with a linewidth of ~100 MHz. The idler wavelength was tuned coarsely over 3 to 4 μm by a combination of grating and temperature tuning, in discrete steps of 1 to 4 cm^{-1} due to the combination of SRO cavity modes, etalon mode selection and phase-matching bandwidth of the crystal. Pump tuning was then used to provide fine wavelength control and mode-hop-free tuning of the idler over 5.2 cm^{-1}, which could be shifted within a total range of 16.5 cm^{-1} by current control of the DBR diode laser. By monitoring the idler wavelength with a wavemeter, and using a computer-controlled feedback loop to adjust the phase and current to the DBR, locking of idler frequency at 2990.076 cm^{-1} could be achieved with a stability of 1.7×10^{-3} cm^{-1} over 30 min. With the programmed tuning, idler wavenumbers from 2987 to 2994 cm^{-1} could be accessed in 1-cm^{-1} steps within the pump tuning range, with any desired wavelength reached within ~20 s of tuning the pump. Using this source, QEPAS spectral data of 2-ppmv ethane in nitrogen were successfully recorded at 2990.1 cm^{-1}, as well as isolated 1.2 percent water vapor at 2994.4 cm^{-1} (Fig. 23). By locking the pump laser frequency to the maximum ethane absorption peak at 2990.08 cm^{-1} and measuring concentrations from 20 ppmv down to 100 ppbv, a QEPAS detection limit of 25 ppbv was deduced. By keeping the idler wavelength fixed at the same absorption peak with a 2 ppmv methane concentration, a linear dependence of QEPAS signal on input power was verified, confirming the advantage of higher powers for improved detection sensitivity. To further demonstrate the

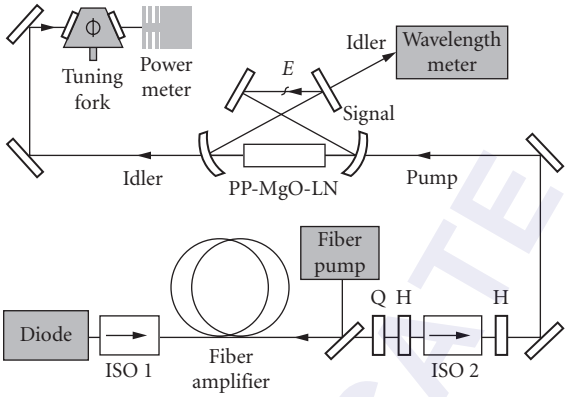

FIGURE 22 Schematic of the cw SRO experimental setup for quartz-enhanced photoacoustic spectroscopy.[50]

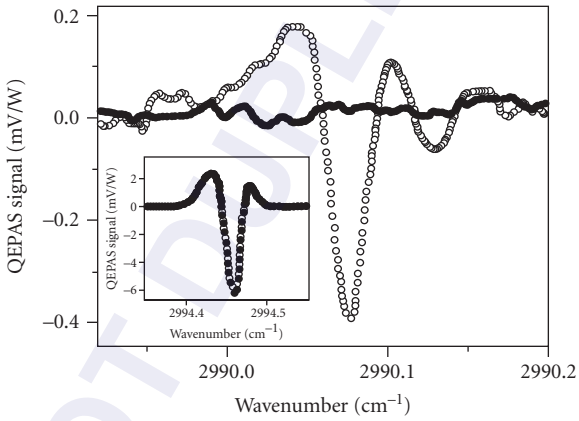

FIGURE 23 Example of a QEPAS scan over a 2 ppmv ethane peak at 2990.08 cm^{-1} (*open circles*) in 200 mbar nitrogen gas. QEPAS signal detected from pure nitrogen in the same spectral range is also shown, revealing a flat background signal (*filled circles*). Another example of a QEPAS scan is given in the *inset* for 1.2 percent water at 2994.4 cm^{-1}.[50]

unique advantages offered by the wide tuning coverage of the cw SRO, QEPAS data corresponding to a multiple gas mixture containing 2.2 ppmv ethane, 1.1 percent water, and 1.5 ppmv methane were successfully recorded by pump-tuning the idler from 2979.4 to 2994.6 cm^{-1}, with the obtained spectra in good agreement with calculations. From the obtained data, it was also possible to deduce an improved QEPAS detection limit of 13 ppbv for the stronger methane absorption line at 2983.3 cm^{-1} and 6.8 ppmv for water at 2994.4 cm^{-1}.

By deploying an all-fiber-pumped PPLN cw SRO,[27] single-pass absorption spectroscopy of several gases over the wavelength range of 2700 to 3200 nm was performed by continuous scanning of the idler frequency with a linewidth of ~1 MHz. Using piezoelectric tuning of the fiber pump laser allowed mode-hop-free tuning of the idler frequency up to 60 GHz, enabling high-resolution spectroscopy of various absorption features in water vapor (2709 nm), carbon dioxide (2810 nm), nitrous oxide (2879 nm), ammonia (2897 nm), and methane (3167 nm).

In a separate experiment, using a PPLN cw DRO pumped directly by a 150-mW DBR diode laser and delivering 4 mW of idler output with a mode-hop-free tuning range of 10 GHz, simple single-pass absorption spectroscopy of CO molecule at 2.3 μm was demonstrated.[41] Spectroscopic applications of cw OPOs in the visible spectral range has also been performed by external frequency doubling of the idler output from a cw DRO in an external enhancement cavity to generate yellow radiation in the 565 to 590 nm region.[42] The DRO was pumped by a cw, monolithic ring Nd:YAG laser at 1064 nm and by tuning the pump frequency over 10 GHz, the yellow output at 580 nm could be tuned smoothly over 18 GHz, while mode-hop tuning could provide 160 GHz of step-tuning across 20 mode pairs. This tuning capability enabled spectroscopy of the $^5D_0 \rightarrow {}^7F_0$ transition in $Eu3^+:Y_2SiO_5$ at 4 K, which is of interest because it exhibits the lowest known homogeneous linewidth for an optical transition in a solid. The step-tuning capability enabled the full spectrum of the transition containing two absorption peaks at 580.070 and 580.224 nm to be scanned, while the fine mode-hop-free tuning enabled continuous scan of each inhomogeneously broadened absorption peak, resulting in linewidths of $\Delta\nu = 3$ GHz and $\Delta\nu = 2.5$ GHz, respectively. Persistent spectral hole-burning was also observed by continuous tuning of the pump, and linewidths <1 MHz were recorded after 40 min of burning. By monitoring the hole spectrum every few hours, it was possible to follow the hole decay as long as 15 hours, demonstrating the repeatability of frequency tuning and stability of the cw DRO over many hours.

By deploying a cw PE-SRO based on a 19-mm-long PPLN crystal, Kovalchuk et al.[51] performed high-resolution Doppler-free spectroscopy of rovibrational transition of methane molecule at 3.39 μm. The PE-SRO, configured in semi-monolithic cavity design and containing an intracavity etalon, was pumped by a cw single-mode Nd:YAG ring laser with a linewidth of ~5 kHz. It could provide single-frequency idler output with a linewidth of ~100 kHz and a mode-hop-free tuning range of 1 GHz, obtained by smooth tuning of the pump laser. The PE-SRO had a minimum oscillation threshold of 305 mW and generated a total two-way idler power of 58 mW at 3.39 μm for 808 mW of input pump power. With this set-up, Doppler-free resonances with a resolution of ~500 kHz were recorded in methane, limited by the frequency jitter of the PE-SRO idler output and pressure broadening. Subsequently, Muller et al.[52] reported a transportable, all-solid-state photoacoustic spectrometer based on a cw PE-SRO using an alternative dual-cavity semi-monolithic cavity design. The PE-SRO used a 19-mm-long multigrating PPLN crystal and was pumped by a 2.5-W cw single-frequency Nd:YAG laser at 1.064 μm. The oscillator was characterized by a pump power threshold of 380 mW and could generate a total two-way idler power of 200 mW. Using active signal cavity length stabilization, an idler frequency stability better than ±30 MHz was obtained. Coarse tuning of the idler wavelength over 3.1 to 3.9 μm was performed by a combination of temperature and grating period variation, while the use of an etalon inside the signal cavity enabled continuous mode-hop-free tuning of the idler over 1.5 GHz by tuning the pump laser. Mode-hop tuning of the idler frequency in steps of 450 MHz could also be achieved over 52 GHz by rotation of the intracavity etalon. Using this mode-hop tuning method and with 70 mW of available idler power, photoacoustic spectroscopy of ethane was performed with a detection sensitivity of 110 ppt. By deploying the same dual-cavity cw PE-SRO in combination with cavity leak-out spectroscopy, substantial improvement in detection sensitivity of ethane down to 0.5 ppt was demonstrated near 3 μm,[53] and by exploiting the frequency tuning capability of the PE-SRO, simultaneous monitoring of ethane, methane, and water vapor in human breath could be performed, without significant interference from other gases.

In a further application, Stothard et al.[54] demonstrated the use of a cw PE-SRO for hyperspectral imaging of gases in the mid-IR. Based on a 20-mm-long, single-grating crystal of PPRTA and pumped by a 1-W diode-pumped $Nd:YVO_4$ laser, the PE-SRO could provide ~50 mW of idler output power and coverage in the 3.18 to 3.50-μm spectral range by temperature tuning the crystal. The use of a three-mirror standing-wave PE-SRO cavity and an intracavity etalon at the signal wavelength-enabled mode-hop tuning of the idler frequency over ~30 GHz, in steps of 1.4 to 2 GHz, by rotation of the etalon. This frequency resolution was sufficient compared to the typical linewidth of ~5 GHz for pressure-broadened transitions in gases under atmospheric pressure, thus enabling the deployment of the cw PE-SRO for imaging of methane gas in the atmosphere. By tuning the cw PE-SRO idler frequency to the strong methane absorption lines near 3.27 and 3.35 μm, gas concentrations of

the order of 30 ppm-m could be detected and significant target areas (~4 m^2 at 3 m) could be effectively imaged with the subsecond acquisition times.

As well as versatile spectroscopic tools, cw OPOs offer unique sources of correlated twin beams and nonclassical states of light for applications in quantum optics and quantum information processing. When pumped by cw all-solid-state lasers, they can provide compact twin-beam optical sources for quantum cryptography and sub-shot-noise measurement. In one configuration of such a device, a cw TRO based on a 10-mm KTP crystal and using a linear semi-monolithic resonator to separate the pump and parametric wave cavities, was reported by Hayasaka et al.[55] The TRO was pumped at 540 nm by the second harmonic of an extended-cavity single-stripe cw diode laser and was operated close to degeneracy. The use of this pump wavelength permitted type II NCPM in KTP, resulting in a TRO pump power threshold as low as 2.5 mW near degeneracy and providing 5.1 mW of cw output power for 16 mW of pump power. By recording the noise spectrum of the twin-beam intensities, 4.3 dB of intensity-difference squeezing was observed at ~3 MHz. In a subsequent experiment, Su et al.[56] demonstrated quantum entanglement between the signal and idler twin beams in a nondegenerate cw DRO above threshold. The DRO, based on a 10-mm PPKTP crystal cut for type II nondegenerate phase matching, was configured in a linear semi-monolithic cavity and was pumped by the stabilized cw single-mode output of a frequency-doubled Nd:YAP laser at 540 nm. Using a pair of unbalanced Mach-Zender interferometers with unequal arm lengths, the amplitude and phase noise of the signal and idler beams above threshold were recorded at 20 MHz, enabling quantum correlations to be deduced from the noise levels of the intensity difference and phase sum of the photocurrents measured by the unbalanced interferometers. Using this method, the authors were able to deduce correlations of amplitude and phase quadratures of signal and idler below the shot-noise-limit, amounting to ~2.58 and ~1.05 dB, respectively, and from the sum of the amplitude and phase correlation variances, demonstrate quantum entanglement of the twin beams below the shot-noise-limit. For 230 mW of input pump power, nearly twice the 120-mW DRO threshold, the output power in the correlated twin beams was 22 mW. The nondegenerate signal and idler twin beams were at wavelengths of 1079.130 and 1080.215 nm, respectively, separated by 1.085 nm. In another experiment, Tanimura et al.[57] deployed a cw DRO below threshold to generate squeezed vacuum on resonance with the rubidium *D* line at 795 nm. The DRO, based on a 10-mm crystal of PPKTP, was configured in a ring cavity and pumped at 397.5 nm by the second harmonic of a cw single-frequency Ti:sapphire laser to provide near-degenerate signal and idler frequencies at 795 nm (Fig. 24). Operating the cw DRO below threshold and using homodyne detection, the authors were able to measure strongly squeezed vacuum at the OPO output. With the DRO operated at 61 mW of input pump power, below a calculated threshold of 150 mW, a squeezing level of –2.75 dB below the shot-noise-limit and anti-squeezing level of +7.00 dB above the shot-noise-limit was observed (Fig. 25). Such a system could find useful applications for ultraprecise measurements of atomic spins as well as quantum information processing by mapping squeezed vacuum onto an atomic ensemble.

Because of their phase coherent properties and the ability to lock correlated frequencies to stable optical references, cw OPOs also represent highly promising light sources for applications in optical frequency synthesis and metrology. In an example of such application, a novel approach based on the combination of a cw OPO with a femtosecond Ti:sapphire frequency comb was used to provide a phase-coherent bridge from the visible to mid-IR spectral regions.[58] The cw PE-SRO, based on a 19-mm PPLN crystal and deploying a similar configuration to that in Ref. 51 was pumped by a cw single-frequency Nd:YAG laser. The oscillator provided idler emission in the 2.4 to 3.7-μm spectral range, with 50 mW of idler power and an instantaneous linewidth of ~10 kHz at 3.39 μm. The technique takes advantage of the fact that in a PPLN cw PE-SRO, in addition to the phase-matched signal and idler, there are also non-phase-matched frequencies generated by mixing of the resonant pump and signal waves. This process provides a range of visible frequencies within the emission bandwidth of a femtosecond Ti:sapphire laser, which can be used for frequency comparison with the nearest comb lines. By forming suitable differences of the heterodyne beat frequencies between the visible frequency components from the cw OPO and adjacent comb lines in the femtosecond laser, mutual phase locking of OPO optical frequencies, Ti:sapphire repetition frequency and carrier-envelope offset frequency could be obtained. Using this method, the authors performed direct frequency comparison between an iodine-stabilized Nd:YAG laser at 1.064 μm and a mid-IR methane

optical frequency standard at 3.39 μm. Subsequent demonstrations, taking advantage of the unique coherence properties of cw OPOs for frequency synthesis, include the development of a precise 3/2 frequency multiplier from a near-IR pump to the visible using a cw TRO.[49]

17.4 SUMMARY

This chapter has provided an overview of the latest advances in cw OPOs and their applications over the past decade. The advent of QPM nonlinear materials has had an unprecedented impact on cw OPO technology which, combined with major advances in solid-state laser technology and innovative design architectures, has led to the realization of a new generation of truly practical cw OPOs with performance capabilities surpassing conventional lasers. The mature technology and ready availability of PPLN has enabled the development of near- and mid-IR cw OPOs for the 1 to 5 μm spectral range in various resonance configurations, from TROs offering minimal oscillation threshold and lowest output power to cw SROs with highest threshold and watt-level output power, previously unattainable with birefringent nonlinear materials, and using a variety of pump sources from miniature semiconductor diode lasers to high-power solid-state and fiber lasers. The application of novel cavity designs and resonance schemes including pump enhancement, dual cavities and

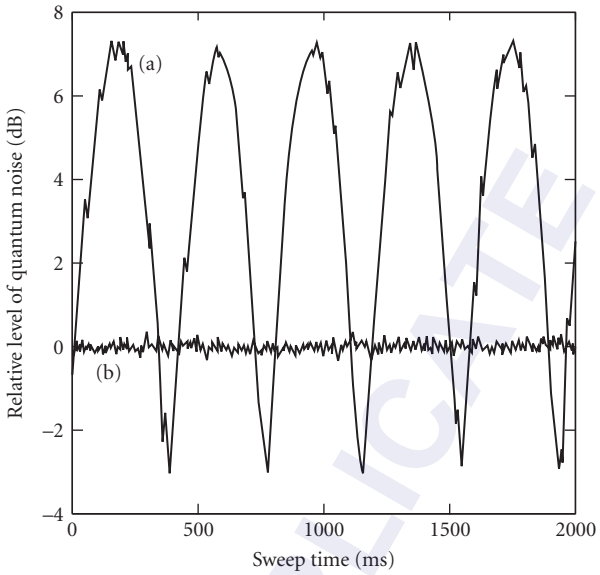

FIGURE 25 Measured quantum noise levels in cw DRO base on PPKTP. (*a*) Local oscillator beam phase was scanned. (*b*) Shot-noise level. Noise levels are displayed as the relative power compared to the shotnoise level (0 dB). The settings of the spectrum analyzer were zero-span mode at 1 MHz, resolution bandwidth = 100 kHz, and video bandwidth = 30 Hz.[57]

intracavity pumping, together with innovative tuning and stabilization techniques have enabled the generation of coherent output with excellent power and frequency stability and short-term linewidths down to a few kHz, long-term stability of a few MHz, and smooth mode-hop-free tuning of more than 100 GHz from cw OPOs. With the continuing advances in QPM material technology, reliable fabrication of MgO-doped PPLN has led to significant reductions in photorefractive damage, enabling its use at lower temperatures and higher powers with reduced output beam degradation. By deploying high-power fiber pump lasers in combination with MgO:PPLN, output powers in excess of 10 W have now been realized in cw SROs and power scaling to several tens of watts appears a clear possibility.

While photorefractive damage has placed limitations on the use of (MgO:)PPLN under visible pumping and confined operation of cw OPOs to near- and mid-IR above ~1 μm, advances in QPM material technology have enabled reliable fabrication of alternative QPM crystals with short grating periods, long interaction lengths, and immunity to photorefraction. This has paved the way for spectral extension of cw OPOs to the wavelengths below 1 μm by exploiting QPM materials including MgO:sPPLT and PPKTP and using direct pumping in the visible followed by additional frequency upconversion steps internal or external to the OPO cavity. By exploiting such techniques, spectral regions in orange and red have been successfully accessed and wavelengths down to 425 nm in the blue have been generated at several hundred milliwatts of output power in single-frequency spectrum and high beam quality. These developments have opened up new opportunities for the realization of practical solid-state sources with wide tunability across the visible and into the UV, where there is a severe shortage of conventional laser sources or other solid-state technologies.

The rapid advances in cw OPOs over the past decade have paved the way for the routine deployment of practical devices in a wide range of applications, from spectroscopy and imaging to frequency metrology and quantum optics. The unique capabilities of cw OPOs with regard to spectral versatility, output power, frequency and power stability, and compact solid-state design

open up new avenues for the ultimate development of these devices in real applications including portable gas detectors, mobile breath analyzers, handheld imaging systems or transportable optical frequency meters. At the same time, significant challenges and opportunities remain for further advancement of cw OPOs. In particular, wavelength extension of these devices into the mid-IR wavelength regions beyond 5 μm remains difficult because of the absorption of oxide-based QPM nonlinear materials, the key building blocks for the successful development of cw OPOs. The 5 to 12-μm spectral range is a particularly important and interesting region because of the presence of several atmospheric windows as well as many molecular absorption finger prints, including volatile substances in exhaled breath. The development of cw OPOs for this wavelength range will thus be of significant interest for spectroscopy, gas sensing, biomedicine, and atmospheric transmission. Progress toward the development of cw OPOs in this spectral range will require the deployment of alternative mid-IR birefringent nonlinear materials such as $ZnGeP_2$, or the more recently developed nonlinear crystals such as $CdSiP_2$ and orientation-patterned GaAs, together with suitable near- to mid-IR laser pump sources and cascaded two-step pumping schemes. On the other hand, advancement of cw OPOs toward shorter UV wavelengths below the current 425-nm limit will be feasible with the use of recently demonstrated frequency upconversion techniques internal to cw SROs by exploiting existing birefringent crystals such as BBO, BIBO, and LBO. With the rapid advances in cw fiber laser technology and the potential for wavelength extension toward the extremes of the optical spectrum, the realization of compact, high-power and practical coherent solid-state light sources across the entire 300 to 12000 nm range based on cw OPOs appears a clear possibility in not too distant a future.

18.1 GLOSSARY

A_A laser beam cross section on the absorber

A_L laser beam cross section in the laser gain material. If the cavity mode is not constant inside the gain medium, this area corresponds to an effective averaged value.

c light velocity in vacuum

D_2 total group delay dispersion inside the laser cavity per cavity round-trip (i.e., second-order dispersion)

d sample thickness

DR differential reflectivity

DT differential transmission

E_p intracavity pulse energy

$E_{\text{sat},A}$ saturation energy of the saturable absorber

$E_{\text{sat},L}$ saturation energy of laser material

$F_{p,A}$ pulse fluence on the absorber

$$F_{p,A} = \frac{E_p}{A_A} = \int I_A(t)dt$$

$F_{\text{sat},A}$ saturation fluence of the absorber

$$F_{\text{sat},A} = \frac{E_{\text{sat},A}}{A_A}$$

$F_{\text{sat},L}$ saturation fluence of laser material

$$F_{\text{sat},L} = \frac{h\nu}{2\sigma_L} = \frac{E_{\text{sat},L}}{A_L}$$

The factor of 2 is used in case of a linear resonator with a standing wave.

g saturated amplitude gain cross section

g_0 small signal amplitude gain coefficient

$I(t)$ time-dependent intensity

$I_A(t)$ time-dependent intensity on absorber

$I_L(t)$ time-dependent intensity inside the laser gain material

$I_{\text{sat},A}$ saturation intensity of the absorber

$$I_{\text{sat},A} = \frac{F_{\text{sat},A}}{\tau_A}$$

$I_{\text{sat},L}$ saturation intensity of laser material

$$I_{\text{sat},L} = \frac{F_{\text{sat},L}}{\tau_L}$$

k wave number in vacuum $k = \omega/c = 2\pi/\lambda$

k_n wave number in a dielectric with refractive index n: $k_n = kn$

$\mathbf{k}_1$ wave vector of the pump pulse in a pump-probe experiment or of the first pulse applied in an FWM experiment for positive time delay Δt

$\mathbf{k}_2$ wave vector of the probe pulse in a pump-probe experiment or of the second pulse applied in an FWM experiment for positive time delay Δt

L_L length of the laser gain medium

n_2 nonlinear refractive index

$P(t)$ time-dependent power: $E_p = \int P(t)dt$

$q(t)$ saturable amplitude loss coefficient (does not include any nonsaturable losses)

q_0 unsaturated amplitude loss coefficient, also corresponds to the maximal loss coefficient

α intensity absorption constant

$\Delta\alpha$ nonlinear change of the intensity absorption constant

ΔR maximum modulation depth of a saturable absorber integrated within a mirror structure (i.e., the maximum nonlinear intensity reflectivity change)

ΔR_{ns} nonsaturable loss of a saturable absorber integrated within a mirror structure

Δt time delay between the excitation pulses in a pump-probe or FWM experiment

ν frequency

ν_0 center frequency

$\Delta\nu_g$ FWHM (full width half maximum) gain bandwidth

λ wavelength in vacuum

λ_n wavelength in a dielectric medium with a refractive index n

λ_0 center wavelength

σ_L gain cross section: $F_{\text{sat},L} = h\nu/\sigma_L$, where h is the Planck's constant

σ_A absorber cross section: $F_{\text{sat},A} = h\nu/\sigma_A$

τ_p FWHM (full width half maximum) of pulse intensity

τ_A recovery time of the saturable absorber

τ_L upper state lifetime of laser medium

18.2 ABBREVIATIONS

A-FPSA	antiresonant Fabry-Perot saturable absorber
APM	additive pulse modelocking
As_{Ga}	arsenic antisite
As_{Ga}^{0}	neutral arsenic antisite
As_{Ga}^{+}	ionized arsenic antisite

FWM	four-wave mixing
KLM	Kerr lens modelocking
LT	low temperature
MBE	molecular beam epitaxy
MOCVD	metal-organic chemical vapor deposition
SAM	self-amplitude modulation
SBR	saturable Bragg reflector
SESAM	semiconductor saturable absorber mirror
SPM	self-phase modulation
V_{Ga}	Ga vacancy
VB	valence band

18.3 INTRODUCTION

Since 1990 we have observed tremendous progress in ultrafast laser sources—a development that was triggered by the invention of the Ti:sapphire laser.[1] The strong interest in all-solid-state ultrafast laser technology was the driving force and formed the basis for many new inventions and discoveries. Solid-state lasers provide some of the best laser qualities in terms of high-quality spatial modes, high output power, energy storage and large pulse energy when Q-switched, and large optical bandwidth necessary for ultrashort pulse generation. Today, the most important nonlinear optical processes that support short and ultrashort passive pulse generation are based on Kerr and/or semiconductor nonlinearities. Saturable absorbers based on either the Kerr effect or on semiconductors play a major role in ultrashort pulse generation. However, independent of the specific saturable absorber material or mechanism, we can define a few macroscopic saturable absorber parameters that will determine the pulse formation process. These parameters are defined in Sec. 18.4 and discussed in more detail for the specific cases of a slow and a fast saturable absorber. The material properties then can be modified over an even larger range if the absorber is integrated within a device structure. This will be discussed at the end of Sec. 18.4. Stable pulse generation can then be obtained when these macroscopic saturable absorber parameters are designed correctly. The crucial role of the optical Kerr effect in ultrashort pulse generation will be discussed in Sec. 18.5. Optimization of semiconductor saturable absorber parameters normally requires a better understanding of the underlying physics, that is, the microscopic properties (Sec. 18.6). Ultrafast nonlinear optical processes can be analyzed in various ways to extract the information about the material system involved in the process. Numerous studies with ultrafast laser pulses have been performed in atomic, molecular, and condensed matter systems. Thus, some of the most common experimental techniques in ultrafast spectroscopy will also be reviewed in Sec. 18.6. The results of such ultrafast spectroscopy measurements are then summarized for semiconductor materials because of their importance in ultrashort pulse generation.

Today ultrafast lasers demonstrate unsurpassed performances: pulse duration in the two-cycle regime,[2,3] compact and reliable picosecond and femtosecond all-solid-state lasers,[4,5] pulse repetition rates in the 100-GHz regime,[6,7] average powers well above 10 W,[8] and novel Q-switching performances that bridge the gap between modelocking and Q-switching both in terms of pulse durations and pulse repetition rates.[9] A more recent review is given in Ref. 10 with detailed tables summarizing the different modelocking results for many solid-state lasers. Further average power scaling towards the 1-kW regime looks very promising with SESAM modelocked Yb-doped thin disk lasers[11] and this concept could be transferred to optically pumped semiconductor lasers.[12,13]

Optical pulses in the two-cycle regime have been produced by a variety of methods: direct generation in a modelocked laser oscillator,[2,3] continuum generation together with parametric optical amplification,[14] and external pulse compression.[15,16] In Fig. 1, interferometric autocorrelation measurements of the two-cycle pulses are shown. Although this is a relatively crude characterization technique, it is the only common measurement that has been performed on these sources; thus it allows for a direct comparison. These pulse generation techniques rely essentially on three identical ingredients:[17] (1) an ultrabroadband amplifying process, (2) precise control of dispersion, and (3) the nonlinear optical Kerr effect.

Ultrafast all-solid-state lasers are based on diode-pumped solid-state lasers. Semiconductor saturable absorbers were the first intracavity saturable absorbers that reliably started and sustained passive modelocked diode-pumped solid-state lasers.[18,19] Any previous attempts to passively modelock such lasers with intracavity saturable absorbers resulted in Q-switching instabilities or Q-switched modelocking (see Fig. 2). The precise control of optical nonlinearities was necessary to resolve

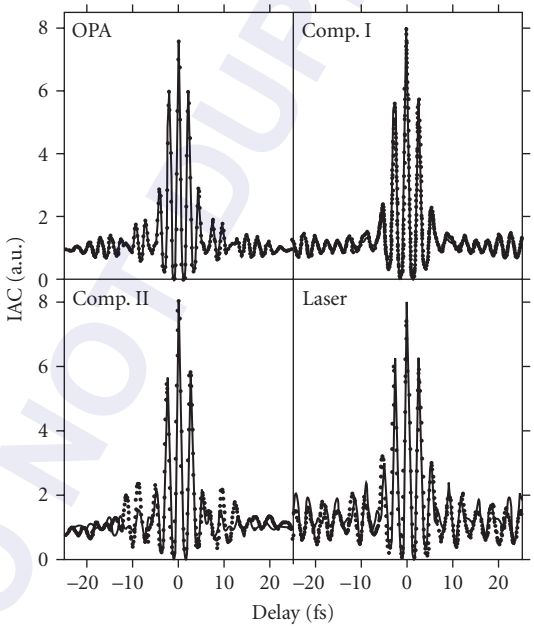

FIGURE 1 Interferometric autocorrelation measurements of different sources in the 5-fs range: OPA: optical parametric amplification.[14] Comp. FIGURE 2 Different modes of operation of a laser with a saturable absorber. Continuous wave (cw) Q-switching typically occurs with much longer pulses and lower pulse repetition rates than cw mode-locking.

the Q-switching problem. Such a control can be achieved with epitaxially grown semiconductor saturable absorbers, which makes them very attractive for use as saturable absorbers in solid-state lasers. Semiconductor saturable absorbers provide a variety of bandgaps, ranging from the visible to the infrared, and can be easily integrated into different device structures (such as a mirror, for example), which allows for the control of the absorber parameters over an even larger range. This is actually required to obtain stable pulse generation with many solid-state lasers. The specific saturable absorber nonlinearities required for stable cw modelocking or Q-switching have recently been discussed in much more detail in Ref. 4 and will be briefly summarized in Sec. 18.4.

In this section we will put the emphasis on the nonlinearities used for ultrashort pulse generation. It is not our goal to provide a tutorial for pulse generation techniques such as passive modelocking or Q-switching. A more tutorial-type overview of the physics of ultrashort pulse generation was given in Refs. 5, 10, 20, and 21. We would like to refer the interested readers to those chapters and the extensive references therein.

18.4 SATURABLE ABSORBERS: MACROSCOPIC DESCRIPTION

Saturable Absorber: Self-Amplitude Modulation

Saturable absorbers have been used to passively Q-switch and modelock many different lasers. Different saturable absorbers, such as organic dyes, colored filter glasses, dye-doped crystals, and semiconductors have been used. Independent of the specific saturable absorber material, we can define a few macroscopic absorber parameters that will determine the pulse generation process. The macroscopic properties of a saturable absorber are the modulation depth, the nonsaturable loss, the saturation fluence, the saturation intensity, and the impulse response or recovery times. These parameters determine the operation of a passively mode locked or Q-switched laser. In our notation we assume that the saturable absorber is integrated within a mirror structure. Thus we are interested in the nonlinear reflectivity change or the *differential reflectivity* DR(t) as a function of time or in the reflectivity $R(F_{p,A})$ as a function of the incident pulse energy fluence on the saturable absorber. If the saturable absorber is used in transmission, we simply characterize the absorber by nonlinear transmission measurements. Both the saturation fluence $F_{\text{sat},A}$ and the absorber recovery time τ_A are determined

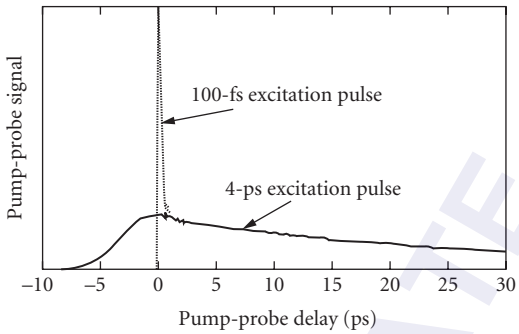

FIGURE 3 Standard pump-probe techniques determine the impulse response DR(t). (Here we assume that the saturable absorber is integrated within a mirror structure.) DR(t) for the same saturable absorber is different for different excitation pulse durations. For excitation with a picosecond pulse, the pump-probe trace clearly shows no significant modulation depth with a fast time constant.

experimentally without any need to determine the microscopic properties of the nonlinearities. Thus, the saturation fluence of the absorber is not only dependent on material properties but also on the specific device structure the absorber is integrated in.

Standard pump-probe techniques determine the impulse response DR(t) and therefore τ_A (see Fig. 3). In the picosecond regime we normally only have to consider one recovery time, because much faster femtosecond nonlinearities in the saturable absorber result in a negligible modulation depth. This is shown in Fig. 3, where the impulse response DR(t) was measured for two different excitation pulse durations. For excitation with a picosecond pulse, the pump-probe trace clearly shows no significant modulation depth with a fast time constant. In the femtosecond pulse regime we normally have to consider more than one absorber recovery time. In this case the slow component normally helps to start the initial pulse formation process. The modulation depth of the fast component then determines the pulse duration at steady state. Further improvements of the saturable absorber normally require some better understanding of the underlying physics, which will be discussed in more detail in Sec. 18.6.

The saturation fluence $F_{\text{sat},A}$ is determined and defined by the measurement of the nonlinear change in reflectivity $R(F_{p,A})$ as a function of increased incident pulse fluence (see Fig. 4). The common traveling wave rate equations[22] in the slow absorber approximation normally give a very good fit and determine the saturation fluence $F_{\text{sat},A}$, modulation depth ΔR, and nonsaturable losses ΔR_{ns} of the absorber. The modulation depth is typically small to prevent Q-switching instabilities in passively modelocked solid-state lasers.[23] Thus it is reasonable to make the following approximation:

$$\Delta R = 1 - e^{-2q_0} \approx 2q_0, q_0 << 1 \tag{1}$$

where q_0 is the unsaturated amplitude loss coefficient. Here, it is assumed that the nonsaturable losses are negligible.

The saturation of an absorber can be described with the following differential equation:[22]

$$\frac{dq(t)}{dt} = -\frac{q(t) - q_0}{\tau_A} - \frac{q(t)P(t)}{E_{\text{sat},A}} \tag{2}$$

where $q(t)$ is the saturable amplitude loss coefficient that does not include any nonsaturable losses. At any time t the reflected (or transmitted) intensity $I_{\text{out}}(t)$ from the saturable absorber is given by

$$I_{\text{out}}(t) = R(t)I_{\text{in}}(t) = e^{-2q(t)}I_{\text{in}}(t) \tag{3}$$

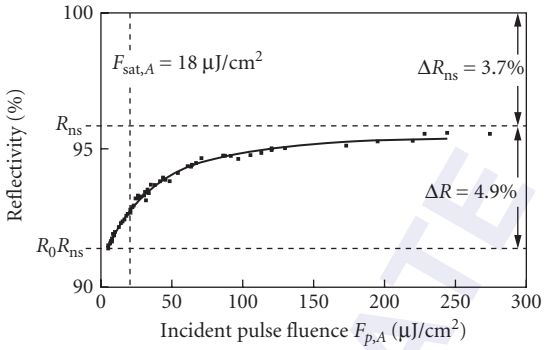

FIGURE 4 Nonlinear Reflectivity as function of the incident pulse fluence $R(F_{p,A})$. The measurement was made with a SESAM supporting 34-fs pulses in a Ti:sapphire laser. The measurements are fitted with common traveling wave rate equations[22] in the slow absorber approximation which normally give a very good fit and determine the saturation fluence $F_{sat,A}$, modulation depth ΔR, and nonsaturable losses ΔR_{ns} of the absorber. Detailed guidelines how to measure the macroscopic SESAM parameters are given in Refs. 24 and 25.

Then the total net reflectivity is given by

$$R_{tot} = \frac{\int I_{out}(t)dt}{\int I_{in}(t)dt} = \frac{F_{out}}{F_{in}} = 1 - \frac{2}{F_{in}} \int q(t) I_{in}(t) dt \tag{4}$$

This determines the total absorber loss coefficient q_p, which results from the fact that part of the excitation pulse needs to be absorbed to saturate the absorber:

$$R_{tot} = e^{-2q_p} \approx 1 - 2q_p \tag{5}$$

From Eqs. (4) and (5) it then follows that for $q_p << 1$

$$q_p = \frac{1}{F_{in}} \int q(t) I_{in}(t) dt = \int q(t) f(t) dt \tag{6}$$

where

$$f(t) \equiv \frac{I_{in}(t)}{F_{in}} = \frac{P_{in}(t)}{E_{p,in}}, \quad \text{with} \quad \int f(t)dt = \frac{1}{F_{in}} \int I_{in}(t)dt = 1 \tag{7}$$

We then distinguish between two typical cases: a slow and a fast saturable absorber.

Slow Saturable Absorber

In the case of a slow saturable absorber, we assume that the excitation pulse duration is much shorter than the recovery time of the absorber (i.e., $\tau_p << \tau_A$). Thus, we can neglect the recovery of the absorber during pulse excitation, and Eq. (2) reduces to:

$$\frac{dq(t)}{dt} \approx -\frac{q(t)P(t)}{E_{sat,A}} \tag{8}$$

This differential equation can be solved, and we obtain for the self-amplitude modulation (SAM):

$$q(t)=q_0\exp\left[-\frac{E_p}{E_{\text{sat},A}}\int_0^t f(t')dt'\right] \tag{9}$$

Equation (6) then determines the total absorber loss coefficient for a given incident pulse fluence $F_{p,A}$:

$$q_p(F_{p,A})=\int q(t)f(t)dt=q_0\frac{F_{\text{sat},A}}{F_{p,A}}(1-e^{-F_{p,A}/F_{\text{sat},A}}) \tag{10}$$

It is not surprising that q_p does not depend on any specific pulse form, because $\tau_p \ll \tau_A$.

A slow saturable absorber has been successfully used to passively modelock dye and semiconductor lasers. In this case, dynamic gain saturation was supporting the pulse formation process (Fig. 5*a*), and much shorter pulses than the recovery time of the saturable absorber were obtained.[26,27] Dynamic gain saturation means that the gain experiences a fast pulse-induced saturation that then recovers again between consecutive pulses. Therefore, an ultrashort net-gain window can be formed by the combined saturation of absorber and gain for which the absorber has to saturate and recover faster than the gain, while the recovery time of the saturable absorber can be much longer than the pulse duration. Haus's master equation formalism can describe this passive modelocking technique very well.[28] This formalism is based on linearized differential operators that describe the temporal evolution of a pulse envelope inside the laser cavity. Generally, the linearized master equations of Haus describe modelocking very well, as long as they only have to deal with small nonlinearities and loss modulation. This is true for most lasers; otherwise a strong tendency for instabilities is observed. A review of Haus's modelocking formalism is presented in more recent articles and book chapters.[5,10,21,29] Assuming passive modelocking according to Fig. 5*a*, Haus predicts a mode locked pulse duration for a fully saturated absorber

$$\begin{aligned}\tau &\approx \frac{4}{\pi}\frac{1}{\Delta\nu_g}\\ \tau_p &\approx 1.76\times\frac{4}{\pi}\frac{1}{\Delta\nu_g}\end{aligned} \tag{11}$$

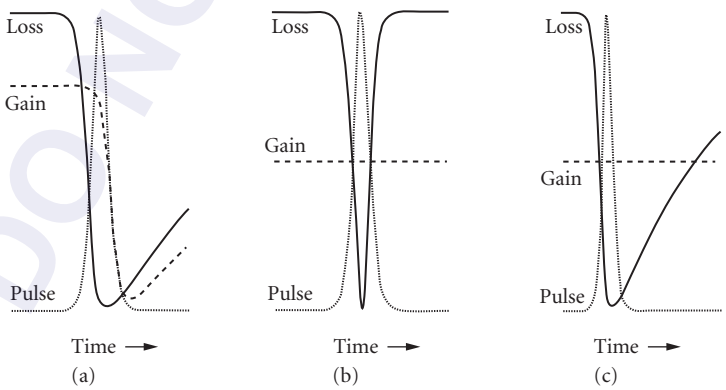

FIGURE 5 Passive modelocking mechanisms explained by three fundamental models: (*a*) slow saturable absorber modelocking with dynamic gain saturation, (*b*) fast saturable absorber modelocking, and (*c*) soliton modelocking.

with a predicted pulse form of

$$I(t)=I_0\,\mathrm{sech}^2(t/\tau),\qquad \tau_p=1.76\cdot\tau \tag{12}$$

where τ_p is the FWHM pulse width of the pulse intensity. For dye lasers using Rhodamin 6G with a gain bandwidth $\Delta\nu_g \approx 4\cdot10^{13}$ Hz and DODCI as the saturable absorber with an absorber cross section $\sigma_A = 0.52\cdot10^{-16}$ cm^2, we would then predict a pulse duration τ_p of 56 fs at a center wavelength of 620 nm [Eqs. (11) and (12)]. Slightly shorter pulses of 27 fs duration were demonstrated.[30,31] The interplay of self-phase modulation and negative group velocity dispersion can result in pulses that are shorter than would be predicted by the SAM alone [Eq. (10)]. Martinez estimated the additional pulse shortening to be about a factor of 2.[32,33] This will be discussed in Sec. 18.5.

For solid-state lasers we cannot apply slow saturable absorber modelocking as shown in Fig. *5a*, because no significant dynamic gain saturation is taking place, due to the small gain cross section and the long upper state lifetime of the laser. The gain cross section of ion-doped solid-state lasers is typically 10^{-19} cm^2 and smaller. This is at least 1000 times smaller than dye, semiconductor, or color center lasers. In addition, the upper-state lifetime of ion-doped solid-state lasers is typically in the μs to ms regime—much longer than the pulse repetition period that is typically in the ns regime. We therefore do not observe any significant dynamic gain saturation, and the gain is only saturated to a constant level by the average intracavity intensity (Fig. 5*b* and *c*).

Fast Saturable Absorber

In the case of a fast saturable absorber, the absorber recovery time is much faster than the pulse duration (i.e., $\tau_p >> \tau_A$). Thus, we can assume that the absorption instantaneously follows the absorption of a certain power $P(t)$, and Eq. (2) reduces to

$$0=-\frac{q(t)-q_0}{\tau_A}-\frac{q(t)P(t)}{E_{\mathrm{sat},A}} \tag{13}$$

The saturation of the fast absorber then follows directly from Eq. (13):

$$q(t)=\frac{q_0}{1+\dfrac{I_A(t)}{I_{\mathrm{sat},A}}} \tag{14}$$

where we used the fact that $P_{\mathrm{sat},A}=E_{\mathrm{sat},A}/\tau_A$ and $P(t)/P_{\mathrm{sat},A}=I_A(t)/I_{\mathrm{sat},A}$. In the linear regime we can make the following approximation in Eq. (14):

$$q(t)\approx q_0-\gamma I_A(t),\qquad \text{with}\qquad \gamma\equiv\frac{q_0}{I_{\mathrm{sat},A}} \tag{15}$$

The total absorber loss coefficient q_p [Eqs. (10) to (12)] now depends on the pulse form, and for a sech^2-pulse shape we obtain for an incident pulse fluence $F_{p,A}$ and the linear approximation of $q(t)$ [Eq. (15)]:

$$q_p(F_{p,A})=\frac{1}{F_{p,A}}\int q(t)I_A(t)dt=q_0\left(1-\frac{1}{3}\frac{F_{p,A}}{\tau I_{\mathrm{sat},A}}\right) \tag{16}$$

We only obtain an analytic solution for fast saturable absorber modelocking if we assume an ideal fast absorber that saturates linearly with pulse intensity over the full modulation depth [Eq. (15)].

For a maximum modulation depth, we then can assume that $q_0 = \gamma I_{0,A}$, where $I_{0,A}$ is the peak intensity on the saturable absorber. We then obtain with Eq. (16) a residual saturable absorber loss of $q_0/3$, which the pulse experiences to fully saturate the ideal fast saturable absorber.

A fast saturable absorber has been successfully used to passively modelock solid-state lasers (Fig. 5*b*). An analytical solution with Haus's master formalism[34] is only obtained if we assume an ideal fast saturable absorber that produces a decreased loss directly proportional to intensity of the incident laser pulse [Eq. (15)]. Then again a sech^2-pulse shape [Eq. (12)] with the following pulse duration is predicted:

$$\tau_p = 1.76 \frac{4D_g}{\gamma F_{p,A}}, \quad \text{with} \quad D_g = \frac{g}{\pi^2 (\Delta \nu_g)^2} \tag{17}$$

where D_g is the gain dispersion. Unfortunately, fast saturable absorbers with femtosecond recovery times are often not sufficient for reliable self-starting of the modelocking process. In passive modelocking, pulse formation should start from normal noise fluctuations in a laser. One noise spike is strong enough to start saturating the absorber and thereby lowers the loss. This noise spike begins to grow in amplitude and becomes shorter until a stable pulse duration is obtained. Initially, these noise spike durations are on the order of the cavity round-trip time, introducing only very small loss modulations in a fast saturable absorber (see Fig. 3). A combination of a fast and a slow saturable absorber can help to solve this problem. Thus, semiconductor saturable absorbers are very interesting because they typically have a bitemporal impulse response which even can be modified.

For picosecond solid-state lasers, the self-amplitude modulation of a fast saturable absorber with a picosecond recovery time is sufficient for stable pulse generation. A picosecond recovery time can be achieved with low-temperature-grown semiconductor saturable absorbers where midgap defect states form very efficient traps for the photoexcited electrons in the conduction band. A more detailed description of the microscopic nonlinearities is given in Sec. 18.6. In the picosecond regime, we developed a very simple stability criteria for stable passive modelocking without Q-switching instabilities:[23]

$$E_p^2 > E_{p,c}^2 = E_{\text{sat},L} E_{\text{sat},A} \Delta R \tag{18}$$

The critical intracavity pulse energy $E_{p,c}$ is the minimum intracavity pulse energy that is required to obtain stable cw modelocking; that is, for $E_p > E_{p,c}$ we obtain stable cw modelocking and for $E_p < E_{p,c}$ we obtain Q-switched modelocking (see Fig. 2). For good stability of a mode locked laser against unwanted fluctuations of pulse energy, operation close to the stability limit is not recommended. Thus, a large modulation depth supports shorter pulses [Eqs. (1), (15), and (17)], but an upper limit is given by the onset of self-Q-switching instabilities [Eq. (18)].

Semiconductor Saturable Absorber Mirrors

Semiconductor saturable absorbers were used as early as 1974 in CO_2 lasers and as early as 1980 for semiconductor diode lasers. A color center laser was the first solid-state laser that was cw modelocked with an intracavity semiconductor saturable absorber.[35] However, for both the diode and color center laser, dynamic gain saturation supported pulse formation, and a slow saturable absorber was sufficient for pulse generation (Fig. 5*a*). In addition, because of the much larger gain cross section and therefore smaller saturation energy $E_{\text{sat},L}$ [Eq. (18)] (i.e., typically 1000 to 10,000 times smaller than ion-doped solid-state lasers), Q-switching instabilities were not a problem. Thus, semiconductor saturable absorber parameters (see Figs. 3 and 4) have to be chosen much more carefully for stable cw modelocking.

We typically integrate the semiconductor saturable absorber into a mirror structure that results in a device whose reflectivity increases as the incident optical intensity increases. This general class of device is called a *semiconductor saturable absorber mirror* (SESAM).[18,36] A detailed description and guidelines on how to design a SESAM for either passive modelocking or Q-switching for different laser parameters is

given in Ref. 4. Such a SESAM device structure can be a simple Bragg mirror, where at least one quarter-wave-layer contains an absorber layer (saturable Bragg reflector -SBR).[37–39] A larger parameter range for the saturation fluence and modulation depth can be achieved if the saturable absorber is integrated inside a Fabry-Perot structure that is operated at antiresonance (A-FPSA).[18,40] The antiresonant Fabry-Perot structure is broadband and can be designed to have no significant bandwidth limitations even in the sub-10-fs pulse-width regime.[41] The top reflector of the A-FPSA provides an adjustable parameter that determines the intensity entering the semiconductor saturable absorber and therefore the saturation fluence of the saturable absorber device. A SiO_2/TiO_2 dielectric top reflector has an additional advantage in that the damage threshold for this SESAM design is significantly higher compared to a SESAM design with the same saturation fluence but based on semiconductor materials alone. We also distinguish between resonant and antiresonant SESAM designs. There are different trade-offs between these design regimes, but a compromise can be found to obtain both low saturation fluence and sufficiently small group delay dispersion.[42]

More recently, semiconductor-doped dielectric films have been demonstrated for saturable absorber applications.[43] Semiconductor-doped glasses have been used to modelock lasers as early as 1990.[44] However, the recently developed InAs-doped thin-film rf-sputtering technology offers similar advantages as SESAMs, which allows for the integration of the absorber into a device structure. At this point, however, the saturation fluence of ≈ 10 mJ/cm^2 is still rather high for stable solid-state laser modelocking [Eq. (18)]. In comparison, MBE or MOCVD-grown SESAMs have typically a saturation fluence of ≈ 10 μJ/cm^2, even though they can be modified from the μJ/cm^2 to the mJ/cm^2-range depending on the specific device structure.[4,36]

A more detailed discussion of microscopic semiconductor nonlinearities will be presented in Sec. 18.6. In principle, knowledge of the macroscopic absorber parameters is sufficient to understand pulse generation. However, further improvements of saturable absorbers will require a more detailed understanding of microscopic optical nonlinearities.

18.5 KERR EFFECT

Longitudinal and Transverse Kerr Effect

The extremely rapid response and broad bandwidth of the Kerr nonlinearity are very attractive for a modelocking process. For high intensities, polarization inside a dielectric medium does not proportionally follow the electric field anymore. This gives rise to an index change that is proportional to intensity. Off-resonance, this nonlinear optical effect is extremely fast, with estimated response times in the few-femtosecond range. The transverse and longitudinal effects resulting from the intensity dependence are shown schematically in Fig. 6. The transverse Kerr effect retards the central and most intense part of a plane wavefront, thus acting as a focusing lens, referred to as the Kerr lens. Later we will indicate concepts that make use of the Kerr lens to produce short pulses. Along the axis of propagation, the longitudinal Kerr effect retards the center of an optical pulse, producing a red shift of the leading part of the pulse and a blue shift in the trailing part. Consequently, the longitudinal Kerr effect has been named *self-phase modulation* (SPM).

Longitudinal Kerr Effect for External Pulse Compression

SPM generates extra bandwidth; in other words, it spectrally broadens the pulse. SPM alone does not modify the pulse width—but a much shorter pulse can be generated with the extra bandwidth and proper dispersion compensation.[45] To create a short pulse, the blue spectral components have to be advanced relative to the red ones, exactly counteracting the phase delays induced by the SPM (assuming $n_2 > 0$). To do so an effect opposite to the normal material dispersion is needed. This type of dispersion is called *anomalous* or *negative* dispersion. A careful balance between a nonlinear spectral broadening process and negative dispersion is needed for efficient compression of a pulse.

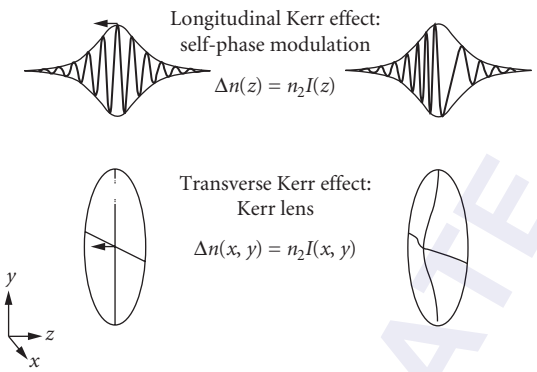

FIGURE 6 The Kerr effect produces a nonlinear intensity-dependent refractive index change. The longitudinal Kerr effect (top) causes self-phase modulation (SPM). The transverse Kerr effect (bottom) causes a nonlinear focusing lens (Kerr lens).

Typically, self-phase modulation in a single-mode fiber is used to chirp the pulse, which is then compressed with a grating pair compressor.[46]

Ultimately, compression schemes are limited by uncompensated higher-order dispersion and higher-order nonlinearities. For pulses shorter than 100 fs, compression is typically limited to factors of less than 10. Compression of amplified CPM dye laser pulses with 50 fs duration produced the long-standing world record of 6 fs for short pulses.[47] Similar concepts have been recently used for external pulse compression of 13-fs pulses from a cavity dumped Ti:sapphire laser[15] and of 20-fs pulses from a Ti:sapphire laser amplifier[16] resulting, in both cases, in approximately 4.5-fs pulses (see Fig. 1). In the latter case, the use of a noble-gas-filled hollow fiber resulted in unsurpassed pulse energies of about 0.5 mJ, with 5.2-fs pulses and a peak power of 0.1 TW.[48]

Longitudinal Kerr Effect for Broadband Parametric Amplification

The extra bandwidth obtained with SPM can be extremely large, producing a white-light continuum[49] that can be used as a seed for broadband parametric amplification. Parametric processes can provide amplification with even broader bandwidth than can typically be achieved in laser amplifiers. Noncollinear phase-matching at a crossing angle of 3.8° in Barium beta borate (BBO) provides more than 150 THz amplification bandwidth.[50] With this type of setup, parametric amplification has been successfully demonstrated with pulse durations of less than 5 fs.[14]

Longitudinal Kerr Effect for Passive Modelocking: Soliton Modelocking

It was recognized early on that the longitudinal Kerr effect or SPM together with negative dispersion results in soliton formation and further reduces pulse duration by about a factor of 2 in dye lasers.[32,33] However, at that time an analytic solution for the pulse-shortening effect was not presented. Using soliton perturbation theory, an analytic solution has been derived that describes how to make use of much more significant soliton pulse shortening in solid-state lasers.[51,52] This modelocking model, referred to as *soliton* modelocking, is fundamentally different from any previous models, because it treats soliton pulse shaping as the dominant pulse formation process and the saturable absorber as a perturbation to the soliton. This strongly relaxes the requirements of the saturable absorber as compared to pure saturable absorber modelocking. However, the saturable

absorber is still required to start the modelocking process and to stabilize the soliton pulses against continuous wave breakthrough.

The soliton modelocking model was experimentally confirmed by the production of 300-fs-long soliton pulses with a saturable absorber response time of only 10 ps.[53] Pulses of 13 fs were achieved with a saturable absorber response time of about 60 fs.[52] Further improvements of extremely broadband saturable absorbers[41] with a higher modulation depth would be necessary to obtain even shorter pulses based on this modelocking mechanism.

In soliton modelocking the pulse duration is given by the soliton condition:

$$\tau_p = 1.76 \frac{|D_2|}{k n_2 L_L F_{p,L}} \tag{19}$$

where D_2 is the total group delay dispersion inside the laser cavity per cavity round-trip. Here we assume that the dominant SPM is produced in the laser material (i.e., n_2 is the nonlinear refractive index of the laser material, L_L is the length of the laser material, and $F_{p,L}$ the pulse fluence inside the laser material). In other cases we have to add all other contributions as well. The pulse duration scales linearly with the negative intracavity dispersion. Reducing the intracavity dispersion results in shorter transform-limited pulses.[53] However, there is a limit. The soliton loses energy due to gain dispersion and losses in the cavity. This lost energy, called *continuum* in soliton perturbation theory,[54] is initially contained in a low-intensity background pulse, which experiences negligible SPM, but spreads in time due to group velocity dispersion. This continuum experiences a higher gain compared to the soliton pulse, because it only sees the gain at line center (while the soliton sees an effectively lower average gain due to its larger bandwidth). After a sufficient build-up time, the continuum would actually grow until it reaches lasing threshold, destabilizing the soliton. However, we can stabilize the soliton by introducing a "slow" saturable absorber into the cavity. This "slow" absorber has to be fast enough to add sufficient additional loss for the growing continuum that spreads in time so that it no longer reaches lasing threshold. For a given recovery time of the saturable absorber, the continuum pulse will not broaden fast enough when the negative dispersion becomes too small. Therefore there is a minimum pulse duration that can be achieved for a given set of absorber and laser parameters:

$$\tau_{p,\min} = 1.7627 \left(\frac{1}{\sqrt{6}\pi \Delta \nu_g} \right)^{3/4} \phi_s^{-1/8} \left(\frac{\tau_A g^{3/2}}{q_0} \right)^{1/4} \tag{20}$$

where ϕ_s is the phase shift of the soliton per cavity round trip (assuming that the dominant SPM occurs in the laser gain medium) and is given by

$$\phi_s = \phi_s(z = 2L_L) = k n_2 L_L I_{0,L} \tag{21}$$

Here we assume a fully saturated slow absorber with a linear approximation for the exponential decay of the slow saturable absorber, and a slow saturable absorber.

In the femtosecond regime, we observe a significant reduction of the tendency of Q-switching instabilities compared to pure saturable absorber modelocked picosecond lasers [Eq. (18)]. This can be explained as follows: If the energy of an ultrashort pulse rises slightly due to relaxation oscillations, SPM and/or SAM broadens the pulse spectrum. A broader spectrum, however, reduces the effective gain due to the finite gain bandwidth, which provides some negative feedback, thus decreasing the critical pulse energy which is necessary for stable cw modelocking. The simple stability requirement of Eq. (18) then has to be modified as follows:[23]

$$E_{\text{sat},L} g K^2 E_p^2 + E_p^2 > E_{\text{sat},L} E_{\text{sat},A} \Delta R \tag{22}$$

where K is given by

$$K \equiv \frac{0.315}{1.76} \frac{4\pi n_2 L_L}{D_2 A_L \lambda_0 \Delta \nu_g} \tag{23}$$

Here we assume that the dominant SPM is produced in the laser medium. In other cases we have to add all other contributions as well.

Longitudinal Kerr Effect for Passive Modelocking with a Coupled Cavity: Soliton Laser, Additive Pulse Modelocking

The longitudinal Kerr effect can also be used to produce the same effect as a fast saturable absorber. To do this, the phase nonlinearity provided by the longitudinal Kerr effect has to be converted into an effective amplitude nonlinearity. The earliest modelocking schemes (based only on SPM) used a coupled cavity to convert SPM into SAM. In the soliton laser,[55] pulses compressed by SPM and anomalous dispersion in the coupled cavity are directly coupled back into the main laser cavity. This provides more gain for the center of the pulse. Pulses as short as 19 fs have been demonstrated with color center lasers.[56] Later, the SPM-to-SAM conversion with a coupled cavity was demonstrated for a case when the pulses inside the coupled cavity were broadened due to positive group velocity dispersion.[57] In this case, no compressed pulse was fed back into the main cavity. An effective SAM was obtained because SPM inside the coupled cavity generates a phase modulation on the pulse that adds constructively at the peak of the pulse in the main cavity and destructively in the wings, thus shortening the pulse duration inside the main cavity. This was also referred to as additive pulse modelocking (APM).[58] Although very powerful in principle, these coupled-cavity schemes have the severe disadvantage that the auxiliary cavity has to be stabilized interferometrically. An alternative method for converting the reactive Kerr nonlinearity into an effective saturable absorber has been developed: Kerr-lens modelocking (KLM).[59]

Transverse Kerr Effect for Passive Modelocking: Kerr Lens Modelocking

The discovery of Kerr lens modelocking has been a breakthrough in ultrashort pulse generation.[59] Initially the modelocking mechanism was not understood and was somewhat of a mystery. But within a short time after the initial discovery it became clear that the transverse Kerr effect provides a fast saturable absorber. In KLM, the transverse Kerr effect produces a Kerr lens (see Fig. 6) that focuses the high intensity part of the beam more strongly than the low intensity part. Thus, combined with an intracavity aperture the Kerr lens produces less loss for high intensity and forms an effective fast saturable absorber.[60–62] A similar modelocking effect can be obtained without a hard aperture when the Kerr lens produces an increased overlap of the laser mode with the pump profile in the gain medium.[63] The Kerr lens provides the strongest advantage for the pulsed operation when the cavity is operated close to the stability limit. Optimization guidelines for SAM produced by the Kerr lens in different cavities can be found in Ref. 64. Unfortunately, the transverse Kerr effect couples the modelocking process with the laser cavity mode. In contrast, the use of only the longitudinal Kerr effect in modelocking decouples the modelocking process from the laser mode. This allows optimum cavity design for scaling the laser to higher powers and to higher pulse repetition rates without being constrained by the Kerr lens.

KLM is well described by the fast absorber modelocking model discussed above[65] even though it is not so easy to determine the exact saturable absorber parameters such as the effective saturation fluence. However, the linearized model does not describe the pulse generation with Ti:sapphire lasers in the sub-10-fs regime very well. Pulse-shaping processes in these lasers are more complex.[66,67] Under the influence of the different linear and nonlinear pulse shaping mechanism, the pulse is significantly broadened and recompressed, giving rise to a "breathing" of the pulse width. The order of

the pulse shaping elements in the laser cavity becomes relevant and the spectrum of the modelocked pulses becomes more complex. In this case, an analytical solution can no longer be obtained. As a rough approximation, the pulses still behave like solitons and consequently these lasers are also called solitary lasers.[66]

Longitudinal Kerr Effect for Passive Modelocking with Nonlinear Polarization Rotation

A Kerr effect-induced nonlinear polarization rotation in a weakly birefringent fiber has been used as a "pulse cleaner" to reduce the low-intensity pulse pedestals.[68,69] The same effect can also be used to form an effective fast saturable absorber.[70] Pulses as short as 38 fs have been generated with Nd-doped fiber lasers.

18.6 SEMICONDUCTOR ULTRAFAST NONLINEARITIES: MICROSCOPIC PROCESSES

The discussion of saturable absorbers in Sec. 18.4 has shown that semiconductors are well-suited absorber materials for ultrashort pulse generation. In contrast to saturable absorber mechanisms based on the Kerr effect (Sec. 18.5), ultrafast semiconductor nonlinearities can be studied outside the laser. Such studies give insight into the microscopic processes that determine the nonlinear optical properties of semiconductors on ultrashort time scales. This insight has substantially contributed to our understanding of the physics of semiconductors. Moreover, the information obtained from ultrafast semiconductor spectroscopy provides the basis for further improvement of ultrashort pulse generation with semiconductor saturable absorbers.

In this section, we will first give an overview of ultrafast semiconductor dynamics, which will be followed by a description of the most important experimental techniques for the study of ultrafast processes and nonlinearities. Then we summarize some of the results that have been obtained with these experimental techniques. This summary emphasizes aspects that are particularly relevant for saturable absorber applications, but goes beyond the saturable absorber issue if this is helpful to illustrate general concepts.

In ultrafast semiconductor spectroscopy, it is often convenient to distinguish between excitonic excitations (i.e., Coulomb-bound electron-hole pairs at the band edge[71]) and unbound electron-hole pairs in the continuum of the spectrum. Laser pulses with a temporal width well below 100 fs have a spectral bandwidth that is much larger than the spectral width of the exciton resonance and the exciton binding energy in most semiconductors. This is illustrated in Fig. 7 for the example of

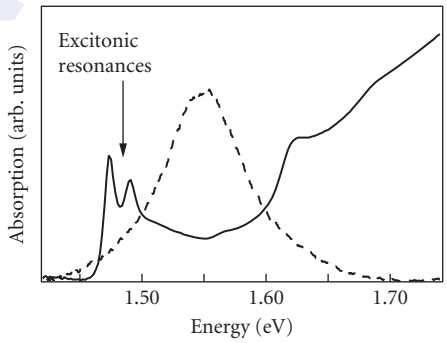

FIGURE 7 Room temperature linear absorption spectrum (solid) of a GaAs/AlGaAs semiconductor quantum well and power spectrum of a 16-fs laser pulse (dashed).

a 16-fs pulse and the absorption spectrum of a GaAs/AlGaAs quantum well[72] at room temperature. Therefore, saturable absorber applications with sub-100-fs pulses very often involve broadband continuum excitations. For this reason, we will focus on ultrafast continuum nonlinearities and dynamics. Exciton dynamics will be discussed only to outline some general concepts of ultrafast semiconductor spectroscopy. For a comprehensive, in-depth review of ultrafast semiconductor spectroscopy the interested reader is referred to Ref. 73.

Overview

Semiconductors are characterized by closely spaced electronic eigenstates in energy space. This electronic structure gives rise to strong interaction among optical excitations on ultrafast time scales and very complex dynamics. Despite the complexity of the dynamics, different time regimes can be distinguished in the evolution of optical excitations in semiconductors.[73,74] These different time regimes are schematically illustrated in Fig. 8, which shows the energy dispersion diagram of a 2-band bulk semiconductor. Optical excitation with an ultrafast laser pulse prepares the semiconductor in the coherent regime (time regime I in Fig. 8). In this regime, a well-defined phase relation exists between the optical excitations and the electric field of the laser pulse and among the optical excitations themselves. The coherence among the excitations in the semiconductor gives rise to a macroscopic polarization (dipole moment density). Since the macroscopic polarization enters as a source term in Maxwell's equations, it leads to an electric field which is experimentally accessible. The magnitude and decay of the polarization provide information on the properties of the semiconductor in the coherent regime. The irreversible decay of the polarization is due to scattering processes and is usually described by the so-called dephasing or transversal relaxation time. For a mathematical definition of this time constant the reader is referred to Refs. 73, 75, 76, and 77. Some more details about dephasing and coherent dynamics in semiconductors will be given later.

After the loss of coherence, ultrafast spectroscopy of semiconductors is solely concerned with the dynamics of the population (i.e., electron and hole distributions). In this incoherent regime, the time regimes II–IV can be distinguished, as described in the text that follows. The initial electron and hole distributions are nonthermal in most cases (i.e., they cannot be described by Fermi-Dirac statistics with a well-defined temperature). Scattering among charge carriers is mainly responsible for the redistribution of energy within the carrier distributions and for the formation of thermal

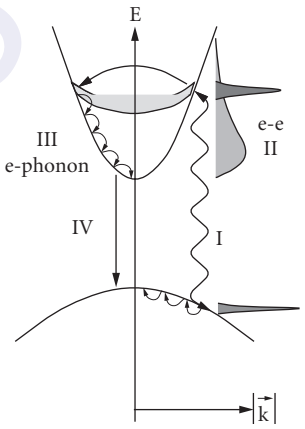

FIGURE 8 Schematic dispersion diagram of a two-band bulk semiconductor showing the time regimes I–IV after optical excitation; see text for more details. e–e: electron-electron scattering, e-phonon: electron-phonon scattering.

distributions. This thermalization is shown as time regime II in Fig. 8, for the example of a thermalizing electron distribution where thermalization occurs through scattering among the electrons. For excitation of the continuum, thermalization usually occurs on a time scale of 100 fs under most experimental conditions. More details about the dynamics in the thermalization regime will be presented later.
