Out-of -band radiation error The second type of spectral error is called the out-of-band or spectrally stray radiation error. This error is due to the radiation transmitted at both longer and shorter wavelengths that are beyond the edges of the principle transmission band of the filter or monochromator. This radiation is not taken into account if the limits in the integral in Eq. (11) are restricted to the edges of the principle transmission band. Although the relative amount of radiation transmitted at any wavelength beyond the edges of the principle transmission band may appear to be negligible with respect to the amount of radiation within the band, it is the spectrally total radiation that "leaks through" that is the error signal. It is therefore necessary to determine the transmission of the filter or monochromator over the entire spectrum of either the detector's response and/or the light source's output, whichever is greater. If the out-of-band radiation effect is small, it is possible to determine the correction factor from nominal values or limited accuracy measurements of the out-of-band spectra of the source, detector, and filter (monochromator).

Temperature Dependence The effect of temperature on the various elements in a radiometric instrument must not be overlooked. Unless the temperature of the instrument at the time of its calibration is maintained during subsequent applications, there may be substantial changes introduced in the instrument calibration factor that could well be above the uncertainty of its traceability to absolute SI units. The simple solution is to control the temperature of the system from the calibration

to the subsequent measurements. A more practical solution is often to measure the relative change in the instrument calibration factor as a function of temperature and then apply this as a correction factor to account for the temperature difference in the subsequent measurements.

34.6 PHOTOMETRY

Definition and Scope

Photometry is the measurement of radiation in a way that characterizes its effectiveness in stimulating the normal human visual system.[4–5,80–82] Since visual sensation is a subjective experience, it is not directly quantifiable in absolute physical units. Attempts to quantify human visual sensation, therefore, were by comparison to various specified sources of light. The first sources used as standards were candles and later flames of prescribed construction. About the turn of the century, groups of incandescent lamps were selected as photometric standards and eventually a planckian radiator at a specific temperature was adopted by international agreement as the standard source. At present, the SI base unit for photometry, the candela, is no longer defined in terms of a given light source but is related to the radiant intensity by a multiplicative constant. Therefore, either an absolute source or detector can be used to establish an internationally recognized photometric calibration. Furthermore, there is no need for a human observer to effect a quantitative photometric measurement.

Photometry, as discussed here, is more precisely referred to as physical photometry to distinguish it from psychophysical photometry. Early photometric calibrations relied on human observers to compare an unknown light source to a standard. Presently, photometric calibrations are based on measurements using physical instruments. The instrument simulates human visual response either by having a detector with a spectral response that approximates that of the CIE standard observer or by using the CIE standard observer spectral response function in the data analysis.

Psychophysical photometry is the measurement of the effectiveness of light in individual observers and is more generally referred to as visual science. An individual's visual system may differ from that of the CIE standard observer defined for physical photometry, and these differences are sometimes important in experiments in visual science.

Photometry is restricted to the measurement of the magnitude of the visual sensation without regard to color, although it is well known that the perception of brightness is highly dependent on color in many circumstances. Measurement of the human response to color in terms of color matching is known as colorimetry. See Vol. III, Chap. 10, "Colorimetry."

Under reasonable light levels, the human eye can detect a difference of as little as 0.5 percent between two adjacent fields of illumination. For fields of illumination which are not adjacent, or are viewed at substantially different times, the eye can only detect differences of 10 to 20 percent. A discussion of the performance of the human visual system can be found in Vol. III, Chap. 2, "Visual Performance." Extensive treatments of photometry can be found in Walsh,[80] and Wyszecki and Stiles.[81]

Photopic, Scotopic, and Mesopic Vision

Electromagnetic radiation of sufficient power and in the wavelength range from about 360 to 830 nm, will stimulate the human visual system and elicit a response from an observer. The spectral range given here is the range over which measurements in physical photometry are defined. The range of reasonably perceptible radiation is usually given as about 400 to 700 nm. After light enters through the optical system of the eye—the cornea, iris or pupil, lens, and vitreous humor—the next stage of the visual response occurs in the retina. The retina contains two types of receptor cells: cones, which are the dominant sensors when the eye is adapated to higher radiance levels of irradiation (*photopic* vision), and rods, the dominant sensors at lower radiance levels (*scotopic* vision). Between the higher and lower levels of light adaptation is the region of *mesopic* vision, the range of radiance levels where both cones and rods contribute in varying degrees to the visual process.

Three types of cones having different spectral sensitivity functions exist in the normal human eye. The brain is able to distinguish colors by comparison of the signals from the three cone types. Of the three cone types, only the middle- and long-wavelength-sensitive cones contribute to the photopic sensation of the radiation entering the eye. The relative spectral sensitivity functions of the photopically and scotopically adapted human eye have been measured for a number of observers. From averages of these measurements, a set of values has been adopted by international agreement as the spectral efficiency for the CIE standard observer for photopic vision and another set for the CIE standard observer for scotopic vision (CIE, Commission Internationale de l'Eclairage). Because of the complexity of the spectral sensitivity of the eye at intermediate irradiation levels, there is no standard of spectral efficiency for mesopic vision. Values of the photopic and scotopic spectral efficiency functions are listed in Table 2.

TABLE 2 Photopic and Scotopic Spectral Luminous Efficiency Functions

Photometric quantities can be calculated or measured as either photopic or scotopic quantities. Adaptation to luminance levels of ≥3 cd m^{-2} (see further discussion) in the visual field usually leads to photopic vision, whereas adaptation to luminance levels of $\leq 3 \times 10^{-5}$ cd m^{-2} usually leads to scotopic vision. Photopic vision is normally assumed in photometric measurements and photometric calculations unless explicitly stated to be otherwise.

Basic Concepts and Terminology

As noted in the earlier section on "Photometry," the principles of photometry are the same as those for radiometry with the exception that the spectral responsivity of the detector is defined by general agreement to be specific approximations of the relative spectral response functions of the human eye. Photometric quantities are related to radiometric quantities via the spectral efficiency functions defined for the photopic and scotopic CIE standard observers.

Luminous Flux If physical photometry were to have been invented after the beginning of the twentieth century, then the physical basis of measurement might well have been the relationship between visual sensations and the energy of the photons and their flux density. It would follow naturally because vision is a photobiological process that is more closely related to the quantum nature of the radiation rather than its thermal heating effects. However, because of the weight of historical precedent, the basis of physical photometry is defined as the relationship between visual sensation and radiant power and its wavelength. The photometric equivalent of radiant power is luminous flux, and the unit that is equivalent to the watt is the lumen.

Luminous flux, Φ_v, is the quantity derived from spectral radiant power by evaluating the radiation according to its action upon the CIE standard observer.

$$\Phi_v = K_m \int \Phi_\lambda V(\lambda) d\lambda \tag{78}$$

where $V(\lambda)$ is the spectral efficiency function for photopic vision listed in Table 2, and K_m is the luminous efficacy for photopic vision. The spectral luminous efficacy is defined near the maximum, $\lambda_m = 555$ nm, of the photopic efficiency function to be

$$K_m = 683 \frac{V(\lambda_m)}{V(555.016\,\text{nm})} \cong 683\ \text{lm W}^{-1} \tag{79}$$

The definitions are similar for scotopic vision

$$\Phi'_v = K'_m \int \Phi_\lambda V'(\lambda) d\lambda \tag{80}$$

where $V'(\lambda)$ is the spectral luminous efficiency function for scotopic vision listed in Table 2, and K'_m is the luminous efficacy for scotopic vision. The scotopic luminous efficiency function maximum occurs at $\lambda_m = 507$ nm. The defining equation for K'_m is

$$K'_m = 683 \frac{V'(\lambda_m)}{V'(555.016\,\text{nm})} \cong 1700\ \text{lm W}^{-1} \tag{81}$$

The spectral shifts indicated in Eqs. (79) and (81) are required in order to obtain the precise values for the photopic and scotopic luminous efficacies. The magnitudes of the shifts follow from the specification of an integral value of frequency instead of wavelength in the definition of the SI base unit for photometry, the candela.

Luminous Intensity, Illuminance, and Luminance The candela, abbreviated cd, is defined by international agreement to be the luminous intensity in a given direction of a source that emits monochromatic radiation of frequency 540×10^{12} Hz (equal to 555.016 nm) and that has a radiant

intensity of 1/683 W sr^{-1} in that direction. The spectral luminous efficacy of radiation at 540×10^{12} Hz equals 683 lm W^{-1} for all states of visual adaptation.

Because of the long history of using a unit of intensity as the basis for photometry, the candela was chosen as the SI base unit instead of the lumen, notwithstanding the fact that intensity is, strictly speaking, measurable only for point sources.

The functional form of the definitions of illuminance, luminous intensity, and luminance were presented in Eqs. (13), (14), and (15). The concepts are briefly reviewed here for the sake of convenience.

Luminous intensity is the photometric equivalent of radiant intensity, that is, luminous intensity is the luminous flux per solid angle. The symbol for luminous intensity is I_v The unit for luminous intensity is the candela.

Illuminance is the photometric equivalent of irradiance, that is, illuminance is the luminous flux per unit area. The symbol for illuminance is E_v. The typical units for illuminance are lumens/meter^2.

Luminance is the photometric equivalent of radiance. Luminance is the luminous flux per unit area per unit solid angle. The symbol for luminance is L_v. The units for luminance are typically candelas/meter^2. In many older treatises on photometry, the term brightness is often taken to be equivalent to luminance, however, this is no longer the accepted usage.

In present usage, luminance and brightness have different meanings. In visual science (psychophysical photometry), two spectral distributions that have the same luminance typically do not have the same brightness. Operationally, spectral distributions of equal luminance are established with a psychophysical technique called heterochromatic flicker photometry. The observer views two spectral distributions that are rapidly alternated in time at the same spatial location, and the radiance of one is adjusted relative to the other to minimize the appearance of flicker. Spectral distributions of equal brightness are established with heterochromatic brightness matching, in which the two spectral distributions are viewed side-by-side and the radiance of one is adjusted relative to the other so that the fields appear equally bright. Though repeatable matches can easily be set with each technique, flicker photometric matches and brightness matches differ for many pairs of spectral distributions.

Photometric radiation transfer calculations and measurements are performed using the same methods and approximations that apply to the radiometric calculations discussed earlier. The exception, of course, is that the spectral sensitivity of the detector is specified.

Retinal Illuminance

In vision research it is frequently required to determine the effectiveness of a uniform, extended field of light (i.e., a large lambertian source that overfills the field of view of the eye) by estimating the illuminance on the retina. If it is assumed that the cornea, lens, and vitreous humor are lossless, then the luminous flux Φ_v in the image on the retina can be approximated from the conservation of the source luminance L_v as follows [see Eq. (22)],

$$L_v = \frac{L_e}{n_e^2} = \frac{\Phi_r S_{pr}^2}{n_e^2 A_r A_p} = E_r \frac{S_{pr}^2}{n_e^2 A_p} \tag{82}$$

where L_e is the radiance within the eye, n_e is the index of refraction of the ocular medium (the index of refraction of air is 1), Φ_r is the luminous flux at the retina, A_r is the area of the image of the retina, A_p is the area of the pupil, s_{pr} is the distance from the pupil to the retina, and E_r is the average illuminance in the image. Therefore, the average illuminance on the retina is

$$E_r = L_v \frac{n_e^2 A_p}{S_{pr}^2} \tag{83}$$

The luminance can, of course, be in units of either photopic or scotopic cd m^{-2}. The area of the pupil is measurable, but the distance between the pupil and retina is typically not available.

Therefore, a unit of retinal illuminance that avoids the necessity of determining this distance has been defined in terms of just the source luminance and pupil area. This unit is the troland, abbreviated td, and is defined as the retinal illumination for a pupil area of 1 mm^2 produced by a radiating surface having a luminance of 1 cd m^{-2}.

$$E_T = L_v A_p \tag{84}$$

Although it may be construed as an equivalent unit, one troland is *not equal* to one microcandela. The source is not a point but is infinite in extent. The troland is useful for relating several vision experiments where sources of differing luminance levels and pupil areas have been used.

The troland is, furthermore, not a measure of the actual illuminance level on the retina since the distance, index of refraction, and transmittance of the ocular medium are not included. For a schematic eye, which is designed to include many of the optical properties of the typical human eye, the effective distance between the pupil and the retina including the effect of the index of refraction is 16.7 mm[83] (see also Vol. III, Chap. 10, "Colorimetry"). For the schematic eye with a 1-mm^2 pupil area, the effective solid angle at the retina is approximately 0.0036 sr. The retinal illuminance equivalent to one troland is therefore 0.0036 lm m^{-2} times the ocular transmittance.

Recall from the section on "Radiometric Effects of Stops and Vignetting" the effect of the aperture stop on the light entering an optical system; that is, all of the light entering the optical system appears to pass through the exit pupil, and the image of the aperture stop on the retina is the exit pupil. If the source is uniform and very large so that it overfills the field of view of the eye, the illuminance on the retina is independent of the distance between the source and the eye. If there is no intervening optic between the eye and the source, then the pupil is the aperture stop. However, if one uses an optical system to image the source into the eye, then the aperture stop need not be the pupil. An external optical system enables both the use of a more uniform, smaller source and the precise control of the retinal illumination by adjustment of an external aperture. The first configuration is called the newtonian view and the second is the maxwellian view of a source[80] (see also Vol. III, Chap. 5, "Optical Generation of the Visual Stimulus").

Though the troland is a very useful and a commonly used photometric unit among vision researchers, it should be interpreted with some caution in situations where one wishes to draw quantitative inferences about the effect of light falling on the retina. The troland is not a precise predictor because, besides not including transmission losses, no angular information is conveyed. The photoreceptors exhibit directional sensitivity where light entering through the center of the pupil is more effective than light entering through the pupil margin (the Stiles-Crawford effect, see Vol. III, Chap. 1, "Optics of the Eye"). Finally, specifying retinal illuminance in photometric units of trolands does not completely define the experimental conditions because the spectral distribution of the light on the retina is unspecified. Rather, the relative spectral responsivity of the eye (including the spectral dependence of the transmittance) is assumed by the inclusion of the $V(\lambda)$ or $V'(\lambda)$ functions. Experiments performed under mesopic conditions will be particularly prone to error.

If one measures the absolute spectral radiance of the light source, then Eq. (83) may be used in the radiometric form; that is, one substitutes $E_{r\lambda}$ and L_λ for E_r and L_v. The retinal spectral irradiance will then be in absolute units: W $nm^{-1}m^{-2}$.

Because the process of vision is a photobiological effect determined by the number and energy of the incident photons, the photon flux irradiance may be a more meaningful measure of the effect of the light on the retina. Using the radiometric form of Eq. (83) and the conversion to photon flux in Eq. (17), the photon flux irradiance $N_{E\lambda}$ on the retina is as follows.

$$N_{E\lambda} = 5.03\times10^{15}\,\lambda\tau_e(\lambda)L_\lambda\frac{n_e^2 A_p}{s_{pr}^2} = 1.80\times10^{13}\,\lambda\tau_e(\lambda)L_\lambda A_p \tag{85}$$

The ocular transmittance is included in this expression as $\tau_e(\lambda)$. The wavelength is in nm and, for radiance in units of W m^{-2} sr^{-1} nm^{-1}, the photon flux irradiance is in units of photons s^{-1} m^{-2} nm^{-1}.

If one uses a monochromatic light source, then a relationship between a monochromatic troland $E_T(\lambda)$ and the photon flux irradiance may be derived.

$$N_{E\lambda} = 1.80 \times 10^{13} \lambda A_p \tau_e(555) \frac{L_v(\lambda)}{K_m V(\lambda)} = 1.53 \times 10^{10} \lambda \frac{E_T(\lambda)}{V(\lambda)} \tag{86}$$

Only the transmittance at the peak of the $V(\lambda)$ curve, $\tau_e(555) = 0.58$[83] needs to be included since the spectral dependence of the ocular transmittance is already included in the $V(\lambda)$ function. The term $L_v(\lambda)$ is the luminance of a monochromatic light source.

An equivalent expression can be derived for the scotopic form of the monochromatic troland $E'_T(\lambda)$. Here, an ocular transmittance at 505 nm of 0.55[83] has been used.

$$N_{E\lambda} = 5.82 \times 10^9 \lambda \frac{E'_T(\lambda)}{V'(\lambda)} \tag{87}$$

The reader is reminded that Eqs. (86) and (87) are valid only for a monochromatic source.

Absolute Photometric Calibrations

Photometric calibrations are in principle derived from the SI base unit for photometry, the candela. However, as one can see from the definitions of the candela and the other photometric quantities, photometric calibrations are in fact derived from absolute radiometric measurements using either a planckian radiator or an absolute detector. Typically, the relationship between illuminance and irradiance, Eq. (13), is used as the defining equation in deriving a photometric calibration.

The photometric calibration transfer devices available from national standards laboratories are usually incandescent lamps of various designs.[84] The photometric quantities commonly offered as calibrations are luminous intensity and total luminous flux.

The luminous intensity of a lamp, at a specified minimum distance and in a specified direction, is derived from a calibration of the spectral irradiance of the lamp, in the specified direction and at measured distance(s). The radiometric-to-photometric conversion [see Eq. (13)] is used to convert from spectral irradiance to illuminance. The inverse-square-law approximation, Eq. (24), is then used to derive luminous intensity.

Total luminous flux is a measure of all the flux emitted in every direction from a lamp. Total luminous flux is derived from illuminance (or luminous intensity) by measuring the flux emitted in all directions around the lamp. This procedure is known as goniophotometry. For an illuminance-based derivation, the total flux is the average of all the illuminance measurements times the surface area of the sphere described by the locus of the points at which the average illuminance was sampled. In the case of an intensity-based derivation, the total flux is the average of all the intensity measurements times 4π steradians. These are, in principle, the calculation methods for goniophotometry. In practice, the average illuminance (or intensity) is measured in a number of zones of fixed area (or solid angle) around the lamp. The product of the illuminance times the area of the zone (or the intensity times the solid angle of the zone) is the flux. The flux from each of the zones is then summed to obtain the total flux from the lamp.

A number of national standards laboratories provide luminance calibration transfer devices. These are typically in the form of a translucent glass plate that is placed at a specified distance and direction from a luminous intensity standard. One method of deriving the luminance calibration of the lamp/glass unit is to restrict the area of the glass plate with an aperture of known area. The intensity of the lamp/glass combination is then calibrated by comparison to an intensity standard lamp and the average luminance calculated by dividing the measured intensity by the area of the aperture.

Some national standards laboratories also offer calibrations of photometers,[85] also known as illuminance meters. A photometer is a photodetector that has been fitted with a filter to tailor its relative (peak normalized) spectral responsivity to match that of the CIE standard photopic observer.

Calibration of a photometer is usually obtained by reference to a luminous intensity standard positioned at a measured distance from the detector aperture. The inverse-square-law approximation is invoked to obtain the value of the illuminance at the measurement distance.

Other Photometric Terminology

Foot-candles, Foot-lamberts, Nits, etc The following units of illuminance are often used in photometry, particularly in older texts:

lux (abbreviation: lx) = lumen per square meter

phot (abbreviation: ph) = lumen per square centimeter

meter candle = lumen per square meter

footcandle (abbreviation: fc) = lumen per square foot

One foot-candle = 0.0929 lux.

The following units of luminance are often used:

nit (abbreviation: nt) = candela per square meter

stilb (abbreviation: sb) = candela per square centimeter

It is sometimes the practice, particularly in illuminating engineering, to express the luminance of an actual surface in any given direction in relation to the luminance of a uniform, diffuse, i.e., lambertian, source that emits one lumen per unit area into a solid angle of π steradians [see Eq. (30)]. This concept is one of relative luminance and its units (given following) are not equatable to the units of luminance. Furthermore, in spite of what may appear to be a similarity, this concept is not, strictly speaking, the photometric equivalent of the exitance of a source because, in its definition, the integral of the flux over the entire hemisphere is referenced. In other words, the equivalence to emittance is true only for a perfectly uniform radiance source. For all other sources it is the luminance in a particular direction divided by π. The units for luminance normalized to a lambertian source are:

1 apostilb (abbreviation: asb) = $(1/\pi)$ candela per square meter

1 lambert (abbreviation: L) = $(1/\pi)$ candela per square centimeter

1 foot-lambert (abbreviation: fL) = $(1/\pi)$ candela per square foot

Sometimes the total flux of a source is referred to as its *candlepower* or *spherical candlepower*. This term refers to a point source that uniformly emits in all directions, that is, into a solid angle of 4π steradians. Such a source does not exist, of course, so that the terminology is more precisely stated as the *mean spherical candle power*, which is the mean value of the intensity of the source averaged over the total solid angle subtended by a sphere surrounding the source.

Distribution Temperature, Color Temperature Distribution temperature is an approximate characterization of the spectral distribution of the visible radiation of a light source. Its use is restricted to sources having relative spectral outputs similar to that of a blackbody such as an incandescent lamp. The mathematical expression for evaluating distribution temperature is

$$\int_{\lambda_1}^{\lambda_2} \left[1 - \frac{\phi_x(\lambda)}{a\phi_b(\lambda, T)}\right]^2 d\lambda \Rightarrow \text{minimum} \tag{88}$$

where $\phi_x(\lambda)$ is the relative spectral radiant power distribution function of the test source, $\phi_b(\lambda, T)$ is the relative spectral radiant power distribution function of a blackbody at the temperature T, and a is an arbitrary constant. The limits of integration are the limits of visible radiation. Since distribution temperature is only an approximation, the exact values of the integration limits are arbitrary: typical limits are 400 and 750 nm. Values of a and T are adjusted simultaneously until the value of

the integral is minimized. The temperature of the best-fit blackbody function is the distribution temperature.

Color temperature and correlated color temperature are defined in terms of the perceived color of a source and are obtained by determining the chromaticity of the radiation rather than its relative spectral distribution. Because they are not related to physical photometry they are not defined in this section of the *Handbook*. These quantities do not provide information about the spectral distribution of the source except when the source has an output that closely approximates a blackbody. Although widely, and mistakenly, used in general applications to characterize the relative spectral radiant power distribution of light sources, color temperature and correlated color temperature relate only to the three types of cone cell receptors for photopic human vision and the approximate manner in which the human brain processes these three signals. As examples of incompatibility, there are the obvious differences between the spectral sensitivity of the human eye and physical receptors of visible optical radiation, e.g., photographic film, TV cameras. In addition, ambiguities occur in the ability of humans to distinguish the perceived color from different spectral distributions (metameric pairs). These ambiguities and the spectral sensitivity functions of the eye are not replicated by physical measurement systems. Caution must be exercised when using color temperature or correlated color temperature to predict the performance of a physical measurement system.

MEASUREMENT OF TRANSMISSION, ABSORPTION, EMISSION, AND REFLECTION

James M. Palmer*

College of Optical Sciences
University of Arizona
Tucson, Arizona

35.1 GLOSSARY

A	Area
a	absorption
bb	blackbody
c_2	second radiation constant
E	irradiance
f	bidirectional scattering distribution function
i	internal
L	radiance
P	electrical power
R	reflectance factor
r	reflection
T	temperature
t	transmission
α	absorptance
α'	absorption coefficient
ε	emittance (emissivity)
θ, ϕ	angles
ρ	reflectance
σ	Stefan Boltzmann constant
τ	transmittance
Φ	power (flux)
Ω	projected solid angle

*Deceased.

35.2 INTRODUCTION AND TERMINOLOGY

When radiant flux is incident upon a surface or medium, three processes occur: transmission, absorption, and reflection. Figure 1 shows the ideal case, where the transmitted and reflected components are either specular or perfectly diffuse. Figure 2 shows the transmission and reflection for actual surfaces.

The symbols, units, and nomenclature employed in this chapter follow the established usage as defined in *ISO Standards Handbook 2*,[1] Cohen and Giacomo,[2] and Taylor.[3] Additional general terminology applicable to this chapter is from ASTM,[4] IES,[5] IES,[6] Drazil,[7] and CIE.[8] The prefix *spectral* is used

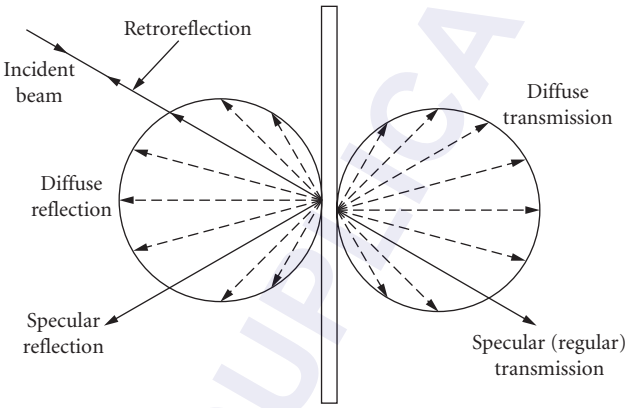

FIGURE 1 Idealized reflection and transmission.

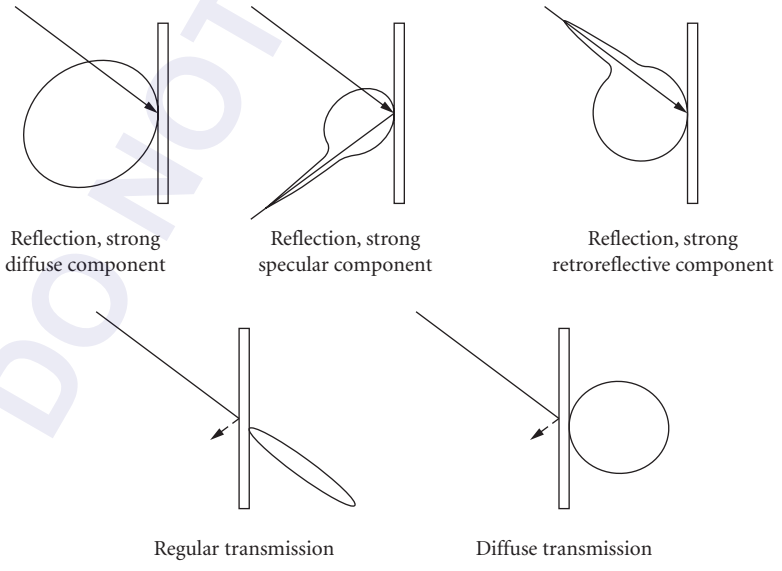

FIGURE 2 Actual reflection and transmission.

to denote a characteristic at a particular wavelength and is indicated by the symbol λ. The absence of the *spectral* prefix implies integration over all wavelengths with a source function included (omission of the source function is meaningless except where the characteristic is constant with wavelength).

There has been a continuing dialog over terminology, particularly between the suffixes *-ance* and *-ivity*.[9–13] The suggested usage reserves terms ending with *-ivity* (such as transmissivity, absorptivity, and reflectivity) for properties of a pure material and employs the suffix *-ance* for the characteristics of a specimen or sample. For example, one can distinguish between the *reflectivity* of pure aluminum and the *reflectance* of a particular sample of 6061-T6 aluminum with a natural oxide layer. This distinction can be extended to differentiate between emissivity (of a pure substance) and emittance (of a sample). This usage of *emittance* should not be confused with the older term *radiant emittance,* now properly called *radiant exitance.* In this chapter, the suffix *-ance* will be used exclusively inasmuch as the measurement of radiometric properties of materials is under discussion.

35.3 TRANSMITTANCE

Transmission is the term used to describe the process by which incident radiant flux leaves a surface or medium from a side other than the incident side, usually the opposite side. The spectral transmittance $\tau(\lambda)$ of a medium is the ratio of the transmitted spectral flux $\Phi_{\lambda t}$ to the incident spectral flux $\Phi_{\lambda i}$, or

$$\tau(\lambda) = \frac{\Phi_{\lambda t}}{\Phi_{\lambda i}} \tag{1}$$

The transmittance τ is the ratio of the transmitted flux Φ_t, to the incident flux Φ_i, or

$$\tau = \frac{\int_0^\infty \tau(\lambda)\Phi_{\lambda i} d\lambda}{\int_0^\infty \Phi_{\lambda i} d\lambda} \neq \int_\lambda \tau(\lambda) d\lambda \tag{2}$$

Note that the integrated transmittance is *not* the integral over wavelength of the spectral transmittance, but must be weighted by a source function Φ_λ as shown.

The transmittance may also be described in terms of radiance as follows:

$$\tau = \frac{\int_0^\infty \int_\Omega L_{\lambda i} d\Omega_t d\lambda}{\int_0^\infty \int_\Omega L_{\lambda i} d\Omega_i d\lambda} \tag{3}$$

where $L_{\lambda i}$ represents the spectral radiance $L_{\lambda i}(\lambda; \theta_i, \phi_i)$ incident from direction (θ_i, ϕ_i), $L_{\lambda t}$ represents the spectral radiance $L_{\lambda t}(\lambda; \theta_t, \phi_t)$ transmitted in direction (θ_t, ϕ_t), and $d\Omega$ is the elemental projected solid angle $\sin\theta \cos\theta \, d\theta \, d\phi$.

The bidirectional transmittance distribution function (BTDF, symbol f_t) relates the transmitted radiance to the radiant incidence as

$$f_t(\lambda; \theta_i, \phi_i) \equiv \frac{dL_{\lambda t}}{dL_{\lambda i} d\Omega_i} = \frac{dL_{\lambda t}}{dE_{\lambda i}} (\text{sr}^{-1}) \tag{4}$$

Geometrically, transmittance can be classified as specular, diffuse, or total, depending upon whether the specular (regular) direction, all directions other than the specular, or all directions are considered.

35.4 ABSORPTANCE

Absorption is the process by which incident radiant flux is converted to another form of energy, usually heat. Absorptance is the fraction of incident flux that is absorbed. The absorptance α of an element is defined by $\alpha = \Phi_a/\Phi_i$. Similarly, the spectral absorptance $\alpha(\lambda)$ is the ratio of spectral power absorbed $\Phi_{\lambda a}$ to the incident spectral power $\Phi_{\lambda i}$,

$$\alpha = \frac{\int_0^\infty \alpha(\lambda)\Phi_{\lambda i}\,d\lambda}{\int_0^\infty \Phi_{\lambda i}\,d\lambda} \neq \int_\lambda \alpha(\lambda)\,d\lambda \tag{5}$$

An absorption coefficient α' (cm^{-1} or km^{-1}) is often used in the expression $\tau_i = e^{-\alpha' t}$, where τ_i is internal transmittance and t is pathlength (cm or km).

35.5 REFLECTANCE

Reflection is the process where a fraction of the radiant flux incident on a surface is returned into the same hemisphere whose base is the surface and which contains the incident radiation. The reflection can be specular (in the mirror direction), diffuse (scattered into the entire hemisphere), or a combination of both. Table 1[14] shows a wide range of materials that have different goniometric (directional) reflectance characteristics.

TABLE 1 Goniometric Classification of Materials[14]

Material Classification	Scatter*	$\sigma^\dagger$	$\gamma^\ddagger$	Structure§	Example
Exclusively reflecting	None	0	≅0	None	Mirror
materials	Weak	≤0.4	≤27°	Micro	Matte aluminum
				Macro	Retroreflectors
$\tau = 0$	Strong	>0.4	>27°	None	Laquer & enamel coatings
				Micro	Paint films, $BaSO_4$, Halon
				Macro	Rough tapestries, road surfaces
Weakly transmitting, strongly	None	0	≅0	None	Sunglasses, color filters cold mirrors
reflecting Materials	Weak	≤0.4	≤27°	Micro	Matte-surface color filters
$\tau \leq 0.35$				Macro	Glossy textiles
	Strong	>0.4	>27°	None	Highly turbid glass
				Micro	Paper
				Macro	Textiles
Strongly transmitting	None	0	≅0	None	Window glass
materials	Weak	≤0.4	≤27°	None	Plastic film
				Micro	Ground glass
$\tau > 0.35$				Macro	Ornamental glass prismatic glass
	Strong	>0.4	>27°	None	Opal glass
				Micro	Ground opal glass
				Macro	Translucent acrylic plastic with patterned surface

*It is suggested that the diffusion factor is appropriate for strongly diffusing materials and that the half-angle is better for weakly diffusing materials.

†γ is a half-value angle, the angle from the normal where the radiance has dropped to one-half the value at normal.

‡σ is a diffusion factor, the ratio of the mean of radiance measured at 20° and 70° to the radiance measured at 5° from the normal, when the incoming radiation is normal. $\sigma = [L(20) + L(70)]/[2L(5)]$. It gives an indication of the spatial distribution of the radiance, and is unity for a perfect (lambertian) diffuser.

§Structure refers to the nature of the surface. In a microscattering structure, the scatterers cannot be resolved with the unaided eye. The macrostructure scatterers can be readily seen.

The most general definition for reflectance ρ is the ratio of the radiant flux reflected Φ_r to the incident radiant flux Φ_i, or

$$\rho = \frac{\Phi_r}{\Phi_i} \tag{6}$$

Spectral reflectance is similarly defined at a specified wavelength λ as

$$\rho(\lambda) = \frac{\Phi_{\lambda r}}{\Phi_{\lambda i}} \tag{7}$$

(Spectral) reflectance factor (symbol R) is the ratio of (spectral) flux reflected from a sample to the (spectral) flux which would be reflected by a perfect diffuse (lambertian) reflector.

No single descriptor of reflectance will suffice for the wide range of possible geometries. The fundamental geometric descriptor of reflectance is the bidirectional reflectance distribution function (BRDF, symbol f_r). It is defined as the differential element of reflected radiance dL_r in a specified direction per unit differential element of radiant incidence dE_i, also in a specified direction,[15] and carries unit of sr^{-1}:

$$f_r(\theta_i, \phi_i, \theta_r, \phi_r) = \frac{dL_r(\theta_i, \phi_i; \theta_r, \phi_r; E_i)}{dE_i(\theta_i, \phi_i)} \quad [sr^{-1}] \tag{8}$$

The polar angle θ is measured from the surface normal and the azimuth angle ϕ is measured from an arbitrary reference in the surface plane, most often the plane containing the incident beam. The subscripts i and r refer to the incident and reflected beams, respectively.

By integrating over varying solid angles, Nicodemus et al.,[15] based upon earlier work by Judd,[16] defined nine goniometric reflectances, and by extension, nine goniometric reflectance factors. These are shown in Tables 2 and 3 and Fig. 3. In these tables, the term *directional* refers to a differential solid angle $d\omega$ in the direction specified by (θ, ϕ). *Conical* refers to a cone of finite extent centered in direction (θ, ϕ); the solid angle ω of the cone must also be specified.

Details on these definitions and further discussion can be found in ASTM STP475,[4] ASTM E808,[17] Judd,[16] Nicodemus,[18] Nicodemus,[19] and Nicodemus et al.[15]

TABLE 2 Nomenclature for Nine Types of Reflectance[15]

1. Bidirectional reflectance	$d\rho(\theta_i, \phi_i; \theta_r, \phi_r) = f_r(\theta_i, \phi_i; \theta_r, \phi_r) d\Omega_r$
2. Directional-conical reflectance	$\rho(\theta_i, \phi_i; \omega_r) = \int_{\omega_r} f_r(\theta_i, \phi_i; \theta_r, \phi_r) d\Omega_r$
3. Directional-hemispherical reflectance	$\rho(\theta_i, \phi_i; 2\pi) = \int_{2\pi} f_r(\theta_i, \phi_i; \theta_r, \phi_r) d\Omega_r$
4. Conical-directional reflectance	$d\rho(\omega_i; \theta_r, \phi_r) = (d\Omega_r/\Omega_i) \int_{\omega_i} f_r(\theta_i, \phi_i; \theta_r, \phi_r) d\Omega_r$
5. Biconical reflectance	$\rho(\omega_i; \omega_r) = (1/\Omega_i) \int_{\omega_i} \int_{\omega_r} f_r(\theta_i, \phi_i; \theta_r, \phi_r) d\Omega_r d\Omega_i$
6. Conical-hemispherical reflectance	$\rho(\omega_i; 2\pi) = (1/\Omega_i) \int_{\omega_i} \int_{2\pi} \int_{2\pi} f_r(\theta_i, \phi_i; \theta_r, \phi_r) d\Omega_r d\Omega_i$
7. Hemispherical-directional reflectance	$d\rho(2\pi; \theta_r, \phi_r) = (d\Omega_r/\pi) \int_{2\pi} f_r(\theta_i, \phi_i; \phi_r, \phi_r) d\Omega_i$
8. Hemispherical-conical reflectance	$\rho(2\pi; \omega_r) = (1/\pi) \int_{2\pi} \int_{\omega_r} f_r(\theta_i, \phi_i; \theta_r, \phi_r) d\Omega_r d\Omega_i$
9. Bihemispherical reflectance	$\rho(2\pi; 2\pi) = (1/\pi) \int_{2\pi} \int_{2\pi} f_r(\theta_i, \phi_i; \theta_r, \phi_r) d\Omega_r d\Omega_i$

TABLE 3 Nomenclature for Nine Types of Reflectance Factor[15]

1.	Bidirectional reflectance factor	$R(\theta_i, \phi_i; \theta_r, \phi_r) = \pi f_r(\theta_i, \phi_i; \theta_r, \phi_r)$
2.	Directional-conical reflectance factor	$R(\theta_i, \phi_i; \omega_r) = (\pi/\Omega_r)\int_{\omega_r} f_r(\theta_i, \theta_j; \theta_r, \phi_r)d\Omega_r$
3.	Directional- hemispherical reflectance factor	$R(\theta_i, \phi_i; 2\pi) = \int_{2\pi} f_r(\theta_i, \phi_i; \theta_r, \phi_r)d\Omega_r$
4.	Conical-directional reflectance factor	$R(\omega_i; \theta_r, \phi_r) = (\pi/\Omega_i)\int_{\omega_i} f_r(\theta_i, \phi_i; \theta_r, \phi_r)d\Omega_i$
5.	Biconical reflectance factor	$R(\omega_i; \omega_r) = [\pi/(\Omega_i\Omega_r)]\int_{\omega_i}\int_{\omega_r} f_r(\theta_i, \phi_i; \theta_r, \phi_r)d\Omega_r d\Omega_i$
6.	Conical-hemispherical reflectance factor	$R(\omega_i; 2\pi) = (1/\Omega_i)\int_{\omega_i}\int_{2\pi} f_r(\theta_i, \phi_i; \theta_r, \phi_r)d\Omega_r d\Omega_i$
7.	Hemispherical-directional reflectance factor	$R(2\pi; \theta_i, \phi_r) = \int_{2\pi} f_r(\theta_i, \phi_i; \theta_r, \phi_r)d\Omega_i$
8.	Hemispherical-conical reflectance factor	$R(2\pi; \omega_r) = (1/\Omega_r)\int_{2\pi}\int_{\omega_r} f_r(\theta_i, \phi_i; \theta_r, \phi_r)d\Omega_r d\Omega_i$
9.	Bihemispherical reflectance factor	$R(2\pi; 2\pi) = (1/\pi)\int_{2\pi}\int_{2\pi} f_r(\theta_i, \phi_i; \theta_r, \phi_r)d\Omega_r d\Omega_i$

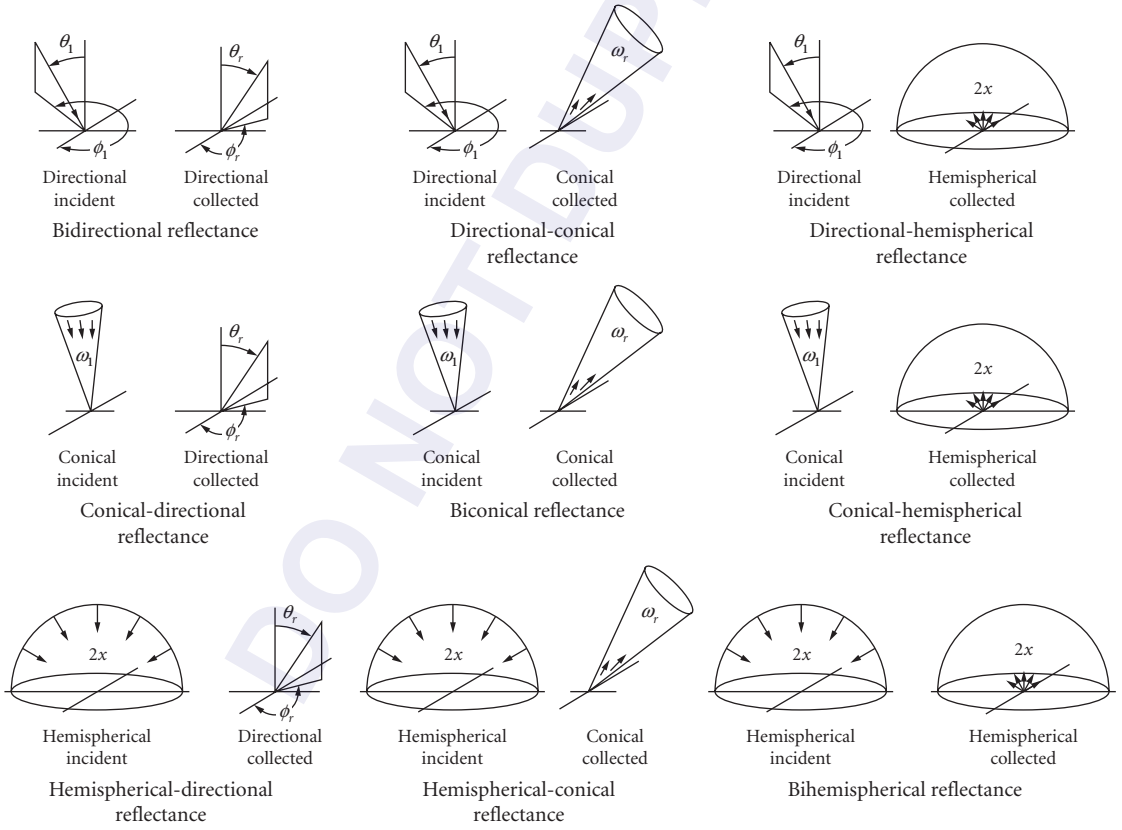

FIGURE 3 Nine geometrical definitions of reflectance.

35.6 EMITTANCE

Emittance (ε) is the ratio of the radiance of an object or surface to the radiance of a blackbody (planckian radiator) at the same temperature. It is therefore dimensionless and can assume values between 0 and 1 for thermal radiators at equilibrium. Spectral emittance $\varepsilon(\lambda)$ is the emittance at a given wavelength. If a radiator is neutral with respect to wavelength, with a constant spectral emittance less than unity, it is called a graybody.

$$\varepsilon = \frac{L}{L^{bb}}, \quad \varepsilon(\lambda) = \frac{L_\lambda}{L_\lambda^{bb}} \tag{9}$$

Directional emittance $\varepsilon(\theta, \phi)$ is defined by

$$\varepsilon(\theta, \phi) = \frac{L(\theta, \phi)}{L^{bb}} \tag{10}$$

Note that if the body is nongray, its emittance is dependent upon temperature inasmuch as the integral must be weighted by the source (Planck) function.

$$\varepsilon = \frac{\int_0^\infty \varepsilon(\lambda) L_\lambda^{bb} d\lambda}{\int_0^\infty L_\lambda^{bb} d\lambda} = \frac{1}{\pi} \frac{\int_0^\infty \varepsilon(\lambda) L_\lambda^{bb} d\lambda}{\sigma T^4} \tag{11}$$

35.7 KIRCHHOFF'S LAW

In a closed system at thermal equilibrium, conservation of energy necessitates that emitted and absorbed fluxes be equal. Since the radiation field in such a system is isotropic (the same in all directions), the directional spectral emittance and the directional spectral absorptance must be equal, i.e.,

$$\varepsilon(\lambda; \theta, \phi) = \alpha(\lambda; \theta, \phi) \tag{12}$$

This statement was first made by Kirchhoff.[20] Strictly, this equation holds for each orthogonal polarization component, and for it to be valid as written, the total radiation must have equal orthogonal polarization components. Kirchhoff's law is often simplified to the declaration $\alpha = \varepsilon$; however, this is not a universal truth; it may only be applied under a limited set of conditions. The geometrical and spectral averaging (integration) is governed by a specific set of rules as demonstrated by Siegel and Howell.[21] Table 4, adapted from Siegel and Howell[21] and Grum and Becherer,[22] shows the various geometrical and spectral conditions under which the absorptance may be related to the emittance.

35.8 RELATIONSHIP BETWEEN TRANSMITTANCE, REFLECTANCE, AND ABSORPTANCE

Radiant flux incident upon a surface or medium undergoes transmission, reflection, and absorption. Application of conservation of energy leads to the statement that the sum of the transmission, reflection, and absorption of the incident flux is equal to unity, or

$$\alpha + \tau + \rho = 1 \tag{13}$$

TABLE 4 Summary of Absorptance-Emittance Relations[21]

Quantity	Equality	Required Conditions
Directional spectral	$\alpha(\lambda;\theta,\phi,T_a)=\varepsilon(\lambda;\theta,\phi,T_a)$	None other than thermal equilibrium
Directional total	$\alpha(\theta,\phi,T_a)=\varepsilon(\theta,\phi,T_a)$	(1) Spectral distribution of incident energy proportional to blackbody at T_a, or (2) $\alpha(\lambda;\theta,\phi,T_a)=\varepsilon(\lambda;\theta,\phi,T_a)$ independent of wavelength
Hemispherical spectral	$\alpha(\lambda,T_a)=\varepsilon(\lambda,T_a)$	(1) Incident radiation independent of angle, or (2) $\alpha(\lambda;\theta,\phi,T_a)=\varepsilon(\lambda;\theta,\phi,T_a)$ independent of angle
Hemispherical total	$\alpha(T_a)=\varepsilon(T_a)$	(1) Incident energy independent of angle *and* spectral distribution proportional to blackbody at T_a, or (2) Incident energy independent of angle *and* $\alpha(\lambda;\theta,\phi,T_a)=\varepsilon(\lambda;\theta,\phi,T_a)$ independent of wavelength, or (3) Incident energy at each angle has spectral distribution proportional to blackbody at T_a *and* $\alpha(\lambda;\theta,\phi,T_a)=\varepsilon(\lambda;\theta,\phi,T_a)$ independent of angle, or (4) $\alpha(\lambda;\theta,\phi,T_a)=\varepsilon(\lambda;\theta,\phi,T_a)$ independent of angle and wavelength

In the absence of nonlinear effects (i.e., the Raman effect, etc.),

$$\alpha(\lambda)+\tau(\lambda)+\rho(\lambda)=1 \tag{14}$$

If the situation is such that one of the above Kirchhoff-type relations is applicable, then emittance ε may be substituted for absorptance α in the previous equations, or

$$\varepsilon=1-\tau-\rho \qquad \varepsilon(\lambda)=1-\tau(\lambda)-\rho(\lambda) \tag{15}$$

35.9 MEASUREMENT OF TRANSMITTANCE

A knowledge of the transmission of optical materials and elements, gaseous atmospheres, and various liquids is necessary throughout the realm of optics. Most of these measurements are made with commercial spectrophotometers. It is beyond the scope of this chapter to discuss the design and operation of spectrophotometric equipment except sample-handling practices. For further discussion, see Gram and Becherer,[22] ASTM E275,[23] and ASTM E409.[24]

Conventional spectrophotometers are of the double-beam configuration, where the output is the ratio of the signal in the sample beam to the signal in the reference beam plotted as a function of wavelength. It is incumbent upon the experimenter to ensure that the only difference between the two beams is the unknown. Therefore, if liquid or gas cells are employed, one should be placed in each beam. For gas cells, an equal amount of carrier gas should be injected into each cell, with the unknown to be sample placed in only one cell, destined for the sample beam. For liquids, an equal amount of solute should be placed in each cell. A critical issue with liquid and solid samples is the beam geometry. Most spectrophotometers feature converging beams in the sample space. If the

optical path length (the product of index of refraction and actual distance) for each beam is not identical, a systematic difference is presented to either the entrance slit or the detector. In addition, some specimens (e.g., interference filters) are susceptible to errors when measured in a converging beam. Most instruments also have a single monochromator which is susceptible to stray radiation, the limiting factor when trying to make measurements of samples that are highly absorbing in one spectral region and transmitting in another. Some recent instruments feature linear detector arrays along with single monochromators to allow the acquisition of the entire spectrum in several milliseconds; these are particularly applicable to reaction rate studies.

Conventional double-beam instruments are limited by these factors to uncertainties on the order of 0.1 percent. For lower uncertainties, the performance deficiencies found in double-beam instruments can largely be overcome by the use of a single-beam architecture. The mode of operation is sample-in–sample-out. If the source is sufficiently stable with time, the desired spectral range can be scanned without the sample, then rescanned with the sample in place. Otherwise, the spectrometer can be set at a fixed wavelength and alternate readings with and without the sample in place must be made. Care should be taken to ensure that the beam geometry is not altered between sequential readings.

To achieve the ultimate in performance from conventional spectrophotometry, several design characteristics should be included. A double monochromator is essential to minimize stray light. The beam geometry in the sample compartment should be highly collimated to avoid focus shifts with optically thick samples. Some form of beam integration, such as an integrating sphere or other diffuser, should be employed to negate the effects of nonuniform detectors and beam shifts. An exemplary instrument is the high-accuracy spectrophotometer developed by the National Institute for Standards and Technology (NIST), described in Mielenz and Eckerle,[25] Mielenz et al.,[26] Venable et al.,[27] Eckerle,[28] and Eckerle et al.[29] A particularly useful review is Eckerle et al.[30] Similar laboratory instruments have also been built elsewhere by Clarke,[31] Freeman,[32] and Zwinkles and Gignac.[33]

Numerous other instruments have been described in the literature; some have been designed for singular or limited purposes while others have a more universal appeal. Use of integrating spheres is common, both for the averaging effects and for the isolation of the specular and diffuse components, as shown in Fig. 4.[14,34] Several useful instruments are described by Karras,[35] Taylor,[36] Zerlaut and Anderson,[37] Clarke and Larkin,[38] and Kessell.[39]

Conventional instruments lack a wide dynamic range because there are simply not enough photons available in a narrow bandpass in a reasonable time. Solutions include Fourier transform spectrometers with a large multiplex advantage, the use of tunable lasers, and heterodyne spectrometry.[40]

Simple instruments can be purchased or constructed for specific purposes. For example, solar transmittance can be determined using either the natural sun (if available) or simulated solar radiation as the source. A limited degree of spectral isolation can be achieved with an abridged spectrophotometer using narrow bandpass interference or glass absorption filters.

Several publications have suggested methods for making accurate and repeatable measurements including Hughes,[41] Mielenz,[42] Venable and Hsia,[43] Burke and Mavrodineanu,[44] ASTM F768,[45] ASTM E971,[46] ASTM E903,[47] and ASTM E179.[48] Calibration and performance assessment of spectrophotometers includes photometric accuracy, linearity, stray light analysis, and wavelength calibration.

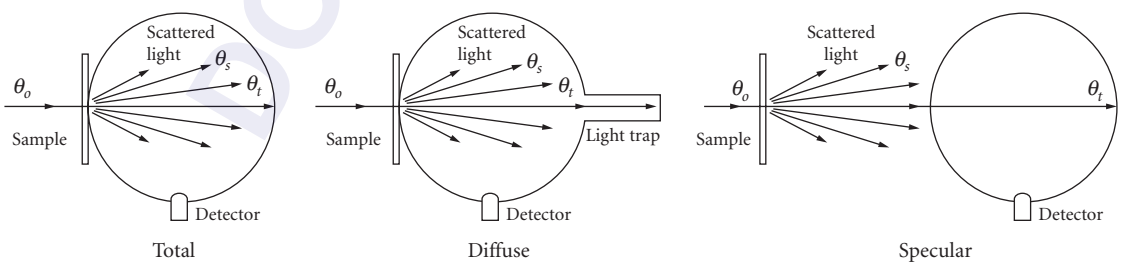

FIGURE 4 Measurement of total, diffuse, and specular transmittance using an integrating sphere.

Particular attention should be paid to luminescent samples that absorb radiant energy in one spectral region and re-emit it at longer wavelengths. Pertinent references include Hawes,[49] Bennett and Ashley,[50] ASTM E387,[51] ASTM E275,[23] and ASTM, E409.[24]

Standards of spectral transmittance are available as Standard Reference Materials from NIST. These take the form of metal-on-glass, metal-on-quartz, and solid glass filters. Most are used for verifying the photometric scale or for checking the wavelength calibration of a recording spectrophotometer. Descriptions of their development and use are given in Mavrodineanu and Baldwin,[52] Mavrodineanu and Baldwin,[53] Eckerle et al.,[30] and Hsia.[54] The standardization laboratories of several countries occasionally conduct international intercomparisons of traveling standards. Recent intercomparisons have been reported in Eckerle et al.[55] and Fillinger and Andor.[56]

35.10 MEASUREMENT OF ABSORPTANCE

In most cases, absorptance is not directly measured, but is inferred from transmission measurements, with appropriate corrections for reflection losses. These corrections can be calculated from the Fresnel equations if the surfaces are polished and the index of refraction is known. For materials where the absorption is extremely small, this method is unsatisfactory, as the uncertainties are dominated by the reflection contribution. In this case, direct measurements (such as laser calorimetry) must be made as discussed by Lipson et al.[57] and Hordvik.[58]

35.11 MEASUREMENT OF REFLECTANCE

Instrumentation for the measurement of reflectance takes many forms. Only a few of the definitions for reflectance (Table 2) and reflectance factor (Table 3) have been adopted as standard configurations. The biconical configuration with small solid angles is most suited to a measurement of specular (regular, in the mirror direction) reflection. A simple reflectometer for the absolute measurement of specular reflectance was devised by Strong[59,60] and is shown schematically in Fig. 5. Numerous detail improvements have been made on this fundamental design, including the use of averaging spheres. Designs range from simple[61–65] to complex.[66] Some reflectometers have been built specifically to measure at normal incidence.[67–69] Measurement methods and data interpretation are also given in ASTM F768,[45] ASTM D523,[70] ASTM F1252,[71] Hernicz and DeWitt,[72] and Snail et al.[73]

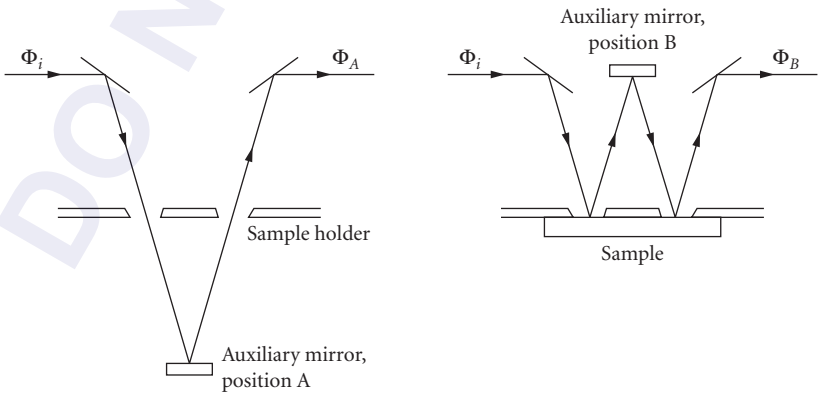

FIGURE 5 The Strong "VW" reflectometer.

The characterization of appearance of materials involves measurements of reflectance, both diffuse and specular. Numerous procedures and instruments have been devised for goniophotometry, the measurement of specular gloss with biconical geometry. Measurements are made at several angles from normal (20°, 30°, 45°, 60°, 75°, and 85°) depending upon the material under scrutiny. Further details can be found in ASTM C347,[74] ASTM E167,[75] ASTM D523,[70] ASTM E1349,[76] ASTM E179,[77] ASTM E430,[78] Erb,[79] and Hunter.[80]

The measurement of diffuse reflectance can be accomplished using any one of the nine definitions from Table 2 and integrating where necessary. One could, for example, choose to measure the bidirectional reflectance distribution function (BRDF) as a function of incident beam parameters and to integrate over the hemisphere, but this would be a tedious process, and the large amount of data generated would be useful only to those involved with detailed materials properties research. Most practical measurements of diffuse reflectance involve the use of an integrating sphere. Several papers have discussed the general theory of the integrating sphere.[81,82]

In the visible and near-IR spectral regions, the integrating sphere is the instrument of choice for both specular and diffuse specimens. Many papers have been written detailing instruments, methods, and procedures, some of which are shown in Fig. 6. The specular component of the reflected flux can be included to determine the total reflectance (Fig. 6*a*) or excluded to measure just the diffuse component (Fig. 6*b*). The angle of incidence can be varied by placing the sample at the center of the sphere (Fig. 6*c*), Edwards et al.[83] Others making contributions include Clarke and Compton,[84] Clarke and Larkin,[85] Dunkle,[86] Egan and Hilgeman,[87] Goebel et al.,[88] Hisdal,[89,90] Karras,[35] McNicholas,[91] Richter and Erb,[92] Sheffer et al.,[93,94] Taylor,[95] and Venable et al.[27] Some of these methods have been incorporated into standard methods and practices, such as ASTM C523,[96]

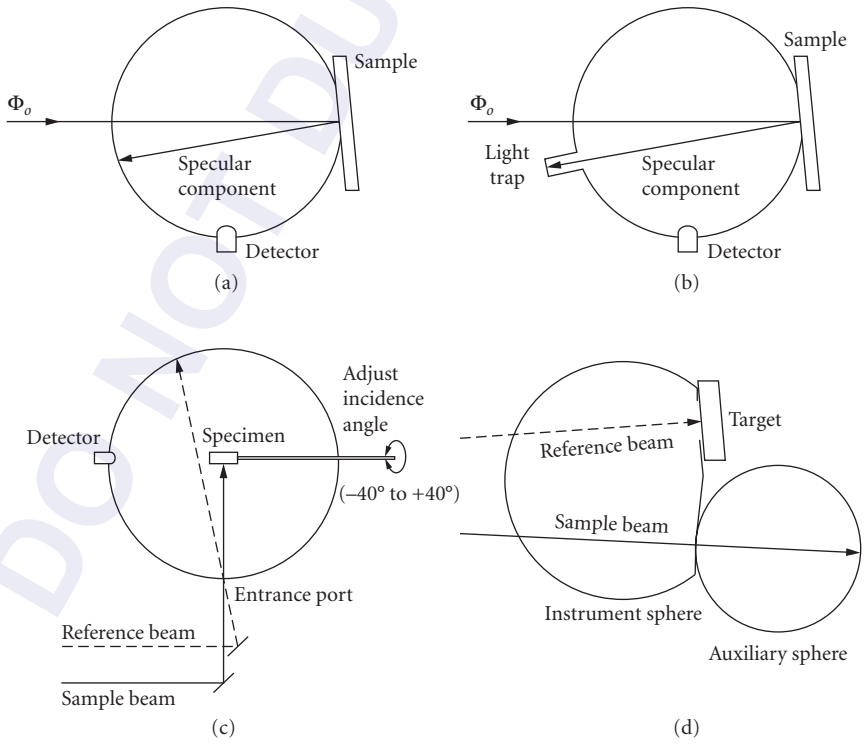

FIGURE 6 Measurement of diffuse reflectance using an integrating sphere.

ASTM E429,[97] ASTM E903,[47] CIE,[98] and IES.[99] Most integrating sphere measurements require reference to some form of an artifact standard, but the double-sphere method (Fig. 6*d*) produces absolute diffuse reflectance.[37,38,100,101] Lindberg[102] has demonstrated a method to scale relative measurements to absolute.

Alternative forms of hemispherical irradiation and/or collection have been described, several of which are shown in Fig. 7. Specular hemispherical (Fig. 7*a*), paraboloidal (Fig. 7*b*), and ellipsoidal (Fig. 7*c*) collectors have been used, particularly in those spectral regions where integrating sphere coatings are difficult to obtain.[86,103–109] The Helmholtz reciprocity principle has been invoked to demonstrate the reversibility of the source and the collector.[110] Hemispherical irradiation has also been employed by placing a cooled sample coplanar with the wall of a furnace and comparing the radiance of the sample with that of the wall of the furnace as shown in Fig. 7*d*.[86,111–113]

The procedures and instrumentation for the measurement of reflectance factor are identical with those for diffuse reflectance using the 0°/45° or 45°/0° geometry with annular, circumferential, or uniplanar illumination or viewing. Reference is made to a white reflectance standard characterized for reflectance factor, which must be compared with a perfect diffuse reflector. Pertinent references are ASTM E1349,[76] ASTM E97,[114] ASTM E1348,[115] Hsia and Weidner,[116] and Taylor. [36,117]

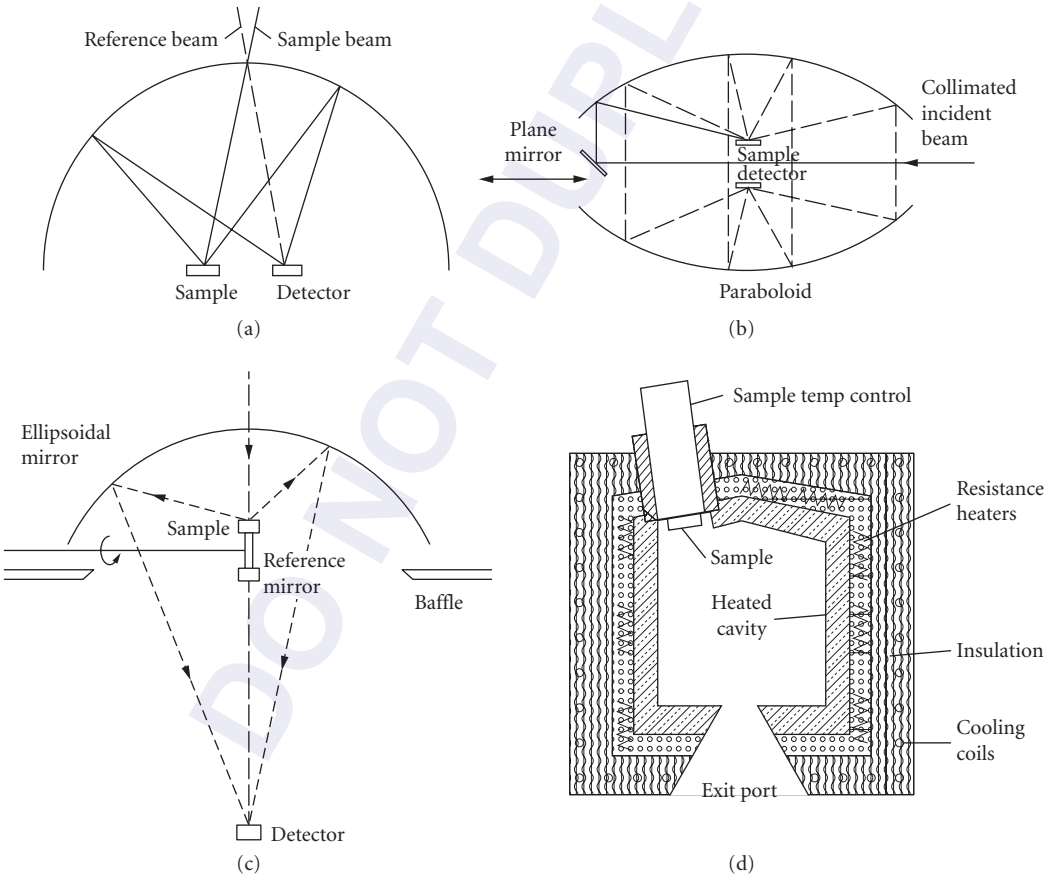

FIGURE 7 Measurement of diffuse reflectance using alternate methods.

Orbiting sensors measure the radiance of the earth-atmosphere system with some known geometry (generally nadir) and in well-defined wavelength bands. The quantity of interest is reflectance, as it is related to factors such as crop assessment, mineralization, etc. Corrections must be made for the atmospheric absorption, emission, and scattering and for the BRDF of the target. BRDF has been characterized in the field using the sun as the source, as described by Duggin.[118,119]

Laboratory measurements of BRDF are made using goniometers where the sample-source angle and sample-receiver angle are independently adjustable. Coherent sources (lasers) are employed for the characterization of smooth specimens where a large source power is necessary for adequate SNR for off-specular angles and where speckle is not a concern. Incoherent sources (xenon arcs, blackbody simulators, or tungsten-halogen) sources are often employed with spectral filters for more diffuse specimens. Similar measurements and techniques are employed to characterize bidirectional transmittance distribution function (BTDF) and bidirectional scattering distribution function (BSDF). For further information, see Asmail,[120] ASTM E1392,[121] and Bartell et al.[122]

The measurement of retroreflection poses the situation that the return beam coincides with the incident beam. The usual solution is to employ a beam splitter in the system, allowing the incident beam to pass and the return beam to be reflected. This immediately imposes both a significant loss in flux and the situation where the beam reaching the sample is partially polarized, unless a nonpolarizing beamsplitter is employed. In addition, it is imperative that the reflected component of the incident beam be well-trapped, as the radiometer is looking in the same direction. The special vocabulary for retroflection is given in CIE[123] and ASTM E808.[17] Test methods are given in ASTM E810,[124] ASTM E809,[125] and Venable and Johnson.[126] An instrument specifically designed to measure retroflection is detailed in Eckerle et al.[127]

Most measurements of reflectance are relative and require artifact standards. Specular reflectance measurements are occasionally made using the absolute technique shown in Fig. 5, but are more commonly done using a simple reflectance attachment for a commercial spectrophotometer, requiring a calibrated reference. Freshly deposited metallic films have been used, with the assumption that an individual coating is the same as accepted data as shown in Table 5 for Al and Au.[128–133] Standards for specular reflectance are also available.[135–137]

Diffuse reflectance standards exist in several forms. Ideally, a perfect ($\rho = 1$, lambertian) diffuser would be used, particularly for measuring reflectance factor.[138–140] Certain materials approach the ideal over a limited angular and wavelength range. Historically, MgO was used in the visible spectrum.[141,111] It was replaced first by $BaSO_4$[142] and more recently by PTFE[143,144] and ASTM E259.[145] Table 5 also shows a typical 6°/hemispherical reflectance factor for PTFE.[146] This fine, white powder, when pressed to a density of 1 g/cm^3, is close to ideal over a wide spectral range. It is not quite lambertian, showing a falloff of BRDF at angles far removed from the specular direction[147] and exhibiting a slight amount of retroreflection. It may also be slightly luminescent when excited by far-ultraviolet.[148]

In the infrared, two materials have proven useful. Flowers of sulfur[149–151] is suitable over the spectral range 1 to 15 μm. Gold is highly reflective and very stable. To be useful as a diffuse reflectance standard, it must be placed on top of a lambertian surface. Several substrates for gold have been suggested, including sandpaper[152] and flame-sprayed aluminum.

PTFE is a satisfactory laboratory standard but is not well-suited for field use as it is not particularly rugged and is highly adsorbant and therefore subject to contamination. Several solutions have been proposed for working standards, including Eastman integrating sphere paint ($BaSO_4$), Vitriolite tile, and the Russian MS20 and MS14 opal glasses. These materials are, in general, more rugged, stable, and washable than PTFE. Further details can be found in CIE[153] and Clarke et al.[154]

Discussion on the fabrication, calibration, and properties of various diffuse reflectance standards can be found in ASTM E259,[155] Budde,[156,157] Egan and Hilgeman,[158] Fairchild and Daoust,[147] Morren et al.,[159] TAPPI,[160] and Weidner.[161,162] International intercomparisons of laboratory standards of diffuse reflectance have been reported in Budde et al.,[163] and Weidner and Hsia,[146] and IES.[99]

There are no standards available for retroflection. However, NIST offers a Measurements Assurance Program (MAP) to enable laboratories to make measurements consistent with other national standards.

TABLE 5 Reflectance Standards

Wavelength (nm)	Aluminum	Gold	PTFE (6°/hemi)
250		0.295	0.973

35.12 MEASUREMENT OF EMITTANCE

Measurements of emittance can be done in several ways. The most direct method involves forming a material into the shape of a cavity in such a way that near-blackbody radiation is emitted. A measurement then compares the radiation from a location within the formed cavity to radiation from a flat, outside surface of the material, presumably at the same temperature.[164] The cavity can take the form of a cylinder, cone, or sphere. Similarly, a small-diameter, deep hole can be drilled into a specimen and radiation from the surface compared to radiation from the hole. Care must be taken that the specimen is isothermal and that the reflected radiation is considered. The definitive measurements of several materials, such as tungsten,[165] were determined in this fashion. The significant advantage in this direct method is that it is relative, depending on neither absolute radiometry or thermometry, but only requiring that the radiometer or spectroradiometer be linear over the dynamic range of the measurement. This linearity is also determinable by relative measurements.

If a variable-temperature blackbody simulator and a suitable thermometer are available, the specimen can be heated to the desired temperature T_s and the blackbody simulator temperature T_{bb} can be adjusted such that its (spectral) radiance matches that of the specimen. Then the (spectral)

emittance is calculable using the following equations for spectral emittance $\varepsilon(\lambda)$ and emittance ε (for a graybody only).

$$\varepsilon(\lambda)=\frac{e^{c_2/\lambda T_s}-1}{e^{c_2/\lambda T_{bb}}-1}, \qquad \varepsilon=\frac{T_{bb}^4}{T_s^4} \tag{16}$$

If an absolutely calibrated radiometer and a satisfactory thermometer are available, a direct measurement can be made, as L_b is calculable if the temperature is known. Again, the reflected radiation must be considered.

Simple "inspection meter" techniques have been developed, and instrumentation is commercially available to determine the hemispherical emittance over a limited range of temperatures surrounding ambient. These instruments provide a single number, as they integrate both spatially and spectrally. A description of the technique can be found in ASTM E408.[166]

Measurements of spectral emittance are most often made using spectral reflectance techniques, invoking Kirchhoff's law along with the assumption that the transmittance is zero. A review of early work is found in Dunn et al.,[167] and Millard and Streed.[168] The usual geometry of interest is the directional-hemispherical. This can be achieved by either hemispherical irradiation-directional collection, or, using Helmholtz reciprocity,[110] directional irradiation-hemispherical collection. Any standard reflectometry technique is satisfactory.

A direct method for the measurement of total (integrated over all wavelengths) hemispherical emittance is to use a calorimeter as shown in Fig. 8. A heated specimen is suspended in the center of a large, cold, evacuated chamber. The vacuum minimizes gaseous conduction and convection. If the sample suspension is properly designed, the predominant means of heat transfer is radiation. The chamber must be large to minimize the configuration factor between the chamber and the specimen. The chamber is cooled to T_c to reduce radiation from the chamber to the specimen. The equation used to determine emittance ε is

$$\varepsilon=\frac{P}{\sigma A(T_s^4-T_c^4)} \tag{17}$$

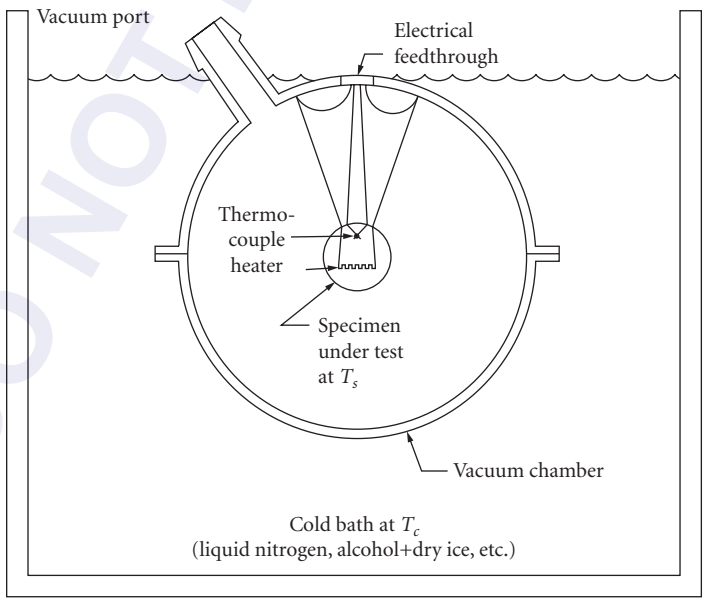

FIGURE 8 Calorimetric measurement of total hemispherical emittance.

where P is the power input to the specimen heater necessary to maintain an equilibrium specimen temperature T_s and A is the specimen area. The equation has been simplified with the aid of the following assumptions: (1) no thermal conduction from the specimen to the chamber, (2) no convective losses, (3) equilibrium has been achieved, and (4) the specimen area is much less than the chamber area. The power can be supplied electrically by means of a known heater or optically via a window in the chamber. In the latter case, a direct measurement of the ratio of solar absorptance α_s to thermal emittance ε_T can be directly obtained if the optical source simulates solar radiation. By varying the input power, the emittance can be determined as a function of temperature. There are numerous small corrections to account for geometry, lead conduction, etc. Details can be found in ASTM C835,[169] ASTM E434,[170] Edwards,[171] and Richmond and Harrison.[172]

Several attempts have been made to define and characterize artifact standards of spectral emittance for direct measurements.[10,11] These were specimens of a thermally stable metal (i.e., Inconel) which were calibrated for emittance as a function of wavelength at several temperatures. No such standards are currently available. Interlaboratory comparisons have been made and reported.[173]

Special problems include measurements at cryogenic temperatures[174] and effects of partially transparent materials.[175] Some additional references relating to emittance and its measurement are ASTM E307,[176] ASTM E423,[177] Clarke and Larkin,[85] DeWitt,[178] DeWitt and Richmond,[179] Hornbeck,[180] Millard and Streed,[168] Redgrove,[181] Sparrow et al.,[164] Stierwalt,[182] and Wittenberg.[183]

RADIOMETRY AND PHOTOMETRY: UNITS AND CONVERSIONS

James M. Palmer*

College of Optical Sciences
University of Arizona
Tucson, Arizona

36.1 GLOSSARY†

A	area, m^2
A_{proj}	projected area, m^2
E, E_e	radiant incidance (irradiance), W m^{-2}
E_p, E_q	photon incidance, s^{-1} m^{-2}
E_v	illuminance, lm m^{-2} [lux (lx)]
I, I_e	radiant intensity, W sr^{-1}
I_p, I_q	photon intensity, s^{-1} sr^{-1}
I_v	luminous intensity, candela (cd)
K_m	absolute luminous efficiency at λ_p for photopic vision, 683 lm/W
K'_m	absolute luminous efficiency at λ_p for scotopic vision, 1700 lm/W
$K(\lambda)$	absolute spectral luminous efficiency, photopic vision, lm/W
$K'(\lambda)$	absolute spectral luminous efficiency, scotopic vision, lm/W
L, L_e	radiance, W m^{-2} sr^{-1}
L_p, L_q	photon radiance (photonance), s^{-1} m^{-2} sr^{-1}
L_v	luminance, cd sr^{-1}
M, M_e	radiant exitance, W m^{-2}
M_p, M_q	photon exitance, s^{-1} m^{-2}
Q, Q_e	radiant energy, joule (J)
Q_p, Q_q	photon energy, J or eV
Q_v	luminous energy, lm s^{-1}

*Deceased.

†*Note.* The subscripts are used as follows: *e* (energy) for radiometric, *v* (visual) for photometric, and *q* (or *p*) for photonic. The subscript *e* is usually omitted; the other subscripts may also be omitted if the context is unambiguous.

$\Re(\lambda)$	spectral responsivity, A/W or V/W
$V(\lambda)$	relative spectral luminous efficiency, photopic vision
$V'(\lambda)$	relative spectral luminous efficiency, scotopic vision
$V_q(\lambda)$	relative spectral luminous efficiency for photons
λ	wavelength, nm or μm
λ_p	wavelength at peak of function, nm or μm
Φ, Φ_e	radiant power (radiant flux), watt (W)
Φ_p, Φ_q	photon flux, s^{-1}
Φ_v	luminous power (luminous flux), lumen (lm)
ω	solid angle, steradian (sr)
Ω	projected solid angle, sr

36.2 INTRODUCTION AND BACKGROUND

After more than a century of turmoil, the symbols, units, and nomenclature (SUN) for radiometry and photometry seem somewhat stable at present. There are still small, isolated pockets of debate and even resistance; by and large, though, the community has settled on the International System of Units (SI) and the recommendations of the International Organization for Standardization (ISO)[1] and the International Union of Pure and Applied Physics (IUPAP).[2]

The seed of the SI was planted in 1799 with the deposition of two prototype standards, the meter and the kilogram, into the Archives de la République in Paris. Noted physicists Gauss, Weber, Maxwell, and Thompson made significant contributions to measurement science over the next 75 years. Their efforts culminated in the Convention of the Meter, a diplomatic treaty originally signed by representatives of 17 nations in 1875 (currently there are 48 member nations). The Convention grants authority to the General Conference on Weights and Measures (CGPM), the International Committee for Weights and Measures (CIPM), and the International Bureau of Weights and Measures (BIPM). The CIPM, along with a number of subcommittees, suggests modifications to the CGPM. In our arena, the subcommittee is the Consultative Committee on Photometry and Radiometry (CCPR). The BIPM, the international metrology institute, is the physical facility that is responsible for realization, maintenance, and dissemination of standards.

The SI was adopted by the CGPM in 1960 and is the official system in the 48 member states. It currently consists of seven base units and a much larger number of derived units. The base units are a choice of seven well-defined units that, by convention, are regarded as independent. The seven base units are as follows:

1. Meter
2. Kilogram
3. Second
4. Ampere
5. Kelvin
6. Mole
7. Candela

The derived units are those that are formed by various combinations of the base units.

International organizations involved in the promulgation of SUN include the International Commission on Illumination (CIE), the IUPAP, and the ISO. In the United States, the American National Standards Institute (ANSI) is the primary documentary (protocol) standards organization. Many other scientific and technical organizations publish recommendations concerning the use of SUN for their scholarly journals. Several examples are the Illuminating Engineering Society

TABLE 1 Projected Areas of Common Shapes

Shape	Area	Projected area
Flat rectangle	$A = L \times W$	$A_{proj} = L \times W \cos \beta$
Circular disc	$A = \pi r^2 = \pi d^2/4$	$A_{proj} = \pi r^2 \cos \beta = (\pi d^2 \cos \beta)/4$
Sphere	$A = 4\pi r^2 = \pi d^2$	$A_{proj} = A/4 = \pi r^2$

(IESNA), the International Astronomical Union (IAU), the Institute for Electrical and Electronic Engineering (IEEE), and the American Institute of Physics (AIP).

The terminology employed in radiometry and photometry consists principally of two parts: (1) an adjective distinguishing between a radiometric, photonic, or photometric entity, and (2) a noun describing the underlying geometric or spatial concept. In some instances, the two parts are replaced by a single term (e.g., radiance).

There are some background concepts and terminology that are needed before proceeding further.

Projected area is defined as the rectilinear projection of a surface of any shape onto a plane normal to the unit vector. The differential form is $dA_{proj} = \cos(\beta)dA$, where β is the angle between the local surface normal and the line of sight. Integrate over the (observable) surface area to get

$$A_{proj} = \int_A \cos\beta \, dA \tag{1}$$

Some common examples are shown in Table 1.

Plane angle and solid angle are both derived units in the SI system. The following definitions are from National Institute of Standards and Technology (NIST) SP811.[3]

> The radian is the plane angle between two radii of a circle that cuts off on the circumference an arc equal in length to the radius.

The abbreviation for the radian is *rad*. Since there are 2π rad in a circle, the conversion between degrees and radians is 1 rad = $(180/\pi)$ degrees. (See Fig. 1.)

A solid angle is the same concept that is extended to three dimensions.

> One steradian (sr) is the solid angle that, having its vertex in the center of a sphere, cuts off an area on the surface of the sphere equal to that of a square with sides of length equal to the radius of the sphere.

The solid angle is the ratio of the spherical area (A_{proj}) to the square of the radius, *r*. The spherical area is a projection of the object of interest onto a unit sphere, and the solid angle is the surface area of that projection, as shown in Fig. 2. Divide the surface area of a sphere by the square of its radius to find that there are 4π sr of solid angle in a sphere. One hemisphere has 2π sr. The accepted symbols

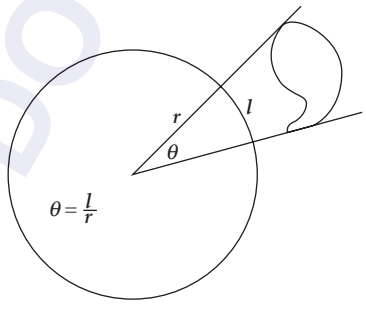

FIGURE 1 Plane angle.

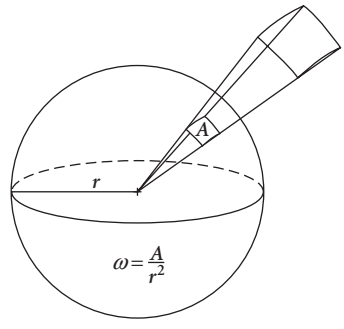

FIGURE 2 Solid angle.

for solid angle are either lowercase Greek omega (ω) or uppercase Greek omega (Ω). I recommend using ω exclusively for solid angle, and reserving Ω for the advanced concept of projected solid angle ($\omega \cos \theta$). The equation for solid angle is $d\omega = dA_{proj}/r^2$. For a right circular cone, $\omega = 2\pi(1 - \cos \theta)$, where θ is the half-angle of the cone.

Both plane angles and solid angles are dimensionless quantities, and they can lead to confusion when attempting dimensional analysis. For example, the simple inverse square law, $E = I/d^2$ appears dimensionally inconsistent. The left side has units W m^{-2} while the right side has W sr^{-1} m^{-2}. It has been suggested that this equation be written $E = I\Omega_0/d^2$, where Ω_0 is the unit solid angle, 1 sr. Inclusion of the term Ω_0 will render the equation dimensionally correct, but will far too often be considered a free variable rather than a constant equal to 1, leading to erroneous results.

Isotropic and lambertian both carry the meaning "the same in all directions" and, regrettably, are used interchangeably.

Isotropic implies a spherical source that radiates the same amount in all directions [i.e., the intensity (W/sr or cd) is independent of direction]. The term *isotropic point source* is often heard. No such entity can exist, for the energy density would necessarily be infinite. A small, uniform sphere comes very close. Small in this context means that the size of the sphere is much less than the distance from the sphere to the plane of observation, such that the inverse square law is applicable. An example is a globular tungsten lamp with a milky white diffuse envelope some 10 cm in diameter, as viewed from a distance greater than 1 m. From our vantage point, a distant star is considered an isotropic point source.

Lambertian implies a flat radiating surface. It can be an active emitter or a passive, reflective surface. The intensity decreases with the cosine of the observation angle with respect to the surface normal (Lambert's law). The radiance (W m^2 sr^{-1}) or luminance (cd m^{-2}) is independent of direction. A good approximation is a surface painted with a quality matte, or flat, white paint. The intensity is the product of the radiance, L, or luminance, L_v, and the projected area A_{proj}. If the surface is uniformly illuminated, it appears equally bright from whatever direction it is viewed. Note that the flat radiating surface can be used as an elemental area of a curved surface.

The ratio of the radiant exitance (power per unit area, W m^{-2}) to the radiance (power per unit projected area per unit solid angle, W m^2 sr^{-1}) of a lambertian surface is a factor of π and not 2π. This result is not intuitive, as, by definition, there are 2π sr in a hemisphere. The factor of π comes from the influence of the $\cos\theta$ term while integrating over a hemisphere.

A sphere with a lambertian surface illuminated by a distant point source will display a radiance that is maximum at the point where the local normal coincides with the incoming beam. The radiance will fall off with a cosine dependence to zero at the terminator. If the intensity (integrated radiance over area) is unity when viewing from the direction of the source, then the intensity when viewing from the side is $1/\pi$. Think about this and ponder whether our Moon has a lambertian surface.

36.3 SYMBOLS, UNITS, AND NOMENCLATURE IN RADIOMETRY

Radiometry is the measurement of optical radiation, defined as electromagnetic radiation within the frequency range from 3×10^{11} to 3×10^{16} hertz (Hz). This range corresponds to wavelengths between 0.01 and 1000 micrometers (μm) and includes the regions commonly called *ultraviolet, visible,* and *infrared.*

Radiometric units can be divided into two conceptual areas: (1) those having to do with power or energy, and (2) those that are geometric in nature. In the first category are:

Energy is an SI-derived unit, measured in joules (J). The recommended symbol for energy is Q. An acceptable alternate is W.

Power (also called *radiant flux*) is another SI-derived unit. It is the derivative of energy with respect to time, dQ/dt, and the unit is the watt (W). The recommended symbol for power is uppercase Greek phi (Φ). An accepted alternate is P.

Energy is the integral of power over time, and it is commonly used with integrating detectors and pulsed sources. Power is used for continuous sources and nonintegrating detectors. The radiometric quantity power can now be combined with the geometric spatial quantities area and solid angle.

Irradiance (also referred to *as flux density* or *radiant incidance*) is an SI-derived unit and is measured in W m^{-2}. Irradiance is power per unit area *incident* from all directions within a hemisphere onto a surface that coincides with the base of that hemisphere. A related quantity is *radiant exitance,* which is power per unit area *leaving* a surface into a hemisphere whose base is that surface. The symbol for irradiance is *E,* and the symbol for radiant exitance is *M.* Irradiance (or radiant exitance) is the derivative of power with respect to area, $d\Phi/dA$. The integral of irradiance or radiant exitance over area is power. There is no compelling reason to have two quantities carrying the same units, but it is convenient.

Radiant intensity is an SI-derived unit and is measured in W sr^{-1}. Intensity is power per unit of solid angle. The symbol is *I*. *Intensity* is the derivative of power with respect to solid angle, $d\Phi/dA$ The integral of radiant intensity over solid angle is power.

A great deal of confusion surrounds the use and misuse of the term *intensity.* Some use it for W sr^{-1}; some use it for W m^{-2}; others use it for W m^{-2} sr^{-1}. It is quite clearly defined in the SI system, in the definition of the base unit of luminous intensity—the candela. Attempts are often made to justify these different uses of intensity by adding adjectives like *optical* or *field* (used for W m^{-2}) or *specific* (used for W m^{-2} sr^{-1}). In the SI system, the underlying geometric concept for intensity is quantity per unit solid angle. For more discussion, see Palmer.[4]

Radiance is an SI-derived unit and is measured in W m^{-2} sr^{-1}. Radiance is a directional quantity, power per unit projected area per unit solid angle. The symbol is *L.* Radiance is the derivative of power with respect to solid angle and projected area, $d\Phi/d\omega\, dA \cos\theta$, where θ is the angle between the surface normal and the specified direction. The integral of radiance over area and solid angle is power.

Photon quantities are also common. They are related to the radiometric quantities by the relationship $Q_p = hc/\lambda$, where Q_p is the energy of a photon at wavelength λ, h is Planck's constant, and c is the velocity of light. At a wavelength of 1 μm, there are approximately 5×10^{18} photons per second in a watt. Conversely, one photon has an energy of about 2×10^{-19} J (W/s) at 1 μm.

36.4 SYMBOLS, UNITS, AND NOMENCLATURE IN PHOTOMETRY

Photometry is the measurement of light, electromagnetic radiation detectable by the human eye. It is thus restricted to the wavelength range from about 360 to 830 nanometers (nm; 1000 nm = 1 μm). Photometry is identical to radiometry *except* that everything is weighted by the spectral response of the nominal human eye. *Visual photometry* uses the eye as a comparison detector, while *physical photometry* uses either optical radiation detectors constructed to mimic the spectral response of the nominal eye, or spectroradiometry coupled with appropriate calculations to do the eye response weighting.

Photometric units are basically the same as the radiometric units, except that they are weighted for the spectral response of the human eye and have strange names. A few additional units have been introduced to deal with the amount of light that is reflected from diffuse (matte) surfaces. The symbols used are identical to the geometrically equivalent radiometric symbols, except that a subscript v is added to denote *visual.* Table 2 compares radiometric and photometric units.

The SI unit for light is the *candela* (unit of luminous intensity). It is one of the seven base units of the SI system. The candela is defined as follows:[5]

> The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of 1/683 watt per steradian.

The candela is abbreviated as *cd,* and its symbol is I_v. This definition was adopted by the 16th CGPM in 1979. The candela was formerly defined as the luminous intensity, in the perpendicular direction,

TABLE 2 Comparison of Radiometric and Photometric Units

Quantity	Radiometric	Photometric
Power	Φ: watt (W)	Φ_v: lumen (lm)
Power per area	E, M: W m^{-2}	E_v: lm m^{-2} = lux (1x)
Power per solid angle	I: W sr^{-1}	I_v: lm sr^{-1} = candela (cd)
Power per area per solid angle	L: W m^{-2} sr^{-1}	L_v: lm m^{-2}sr^{-1} = cd m^{-2} = nit

of a surface of 1/600,000 m^2 of a blackbody at the temperature of freezing platinum under a pressure of 101,325 newtons per square meter (N m^{-2}). This earlier definition was initially adopted in 1948 and later modified by the 13th CGPM in 1968. It was abrogated in 1979 and replaced by the current definition.

The 1979 definition was adopted for several reasons.[6–10] First, the realization of the candela using a platinum blackbody was extraordinarily difficult—only several were ever built, and there were large variations between the units realized by different national laboratories based upon the state of platinum at its freezing point. The difficulty in fabricating and operating the platinum point blackbody created an unacceptable uncertainty in the value of the candela. For example, if the platinum blackbody temperature is slightly off, possibly because of temperature gradients in the ceramic crucible or contamination of the platinum, the freezing point may change or the temperature of the cavity may differ. The sensitivity of the candela to a slight change in temperature is significant. At a wavelength of 555 nm, a change in temperature of only 1 K results in a luminance change approaching 1 percent. Second, the unit of the candela was realized on the specific broadband radiation, whose spectral power distribution was not known with satisfactory accuracy (because the platinum fix point temperature was not precisely known), thus there were large uncertainties in determining photometric quantities of various other practical light sources from their spectral power distributions. Third, recent advances in radiometry based on absolute radiometers offered new possibilities for realization of the candela using a much simpler device with much lower uncertainties if the candela is defined in relation to watt. In 1977, through an international comparison among several national laboratories, the Comité International des Poids et Mesures (CIPM) determined the numerical relationship (683 lm/W at 555 nm) to be recommended for the new standard for candela so that the magnitude of the unit was kept consistent with the previous unit of the candela.

The value of 683 lm/W was selected based upon the best measurements with existing platinum freezing point blackbodies at several national standards laboratories. It has varied over time from 620 to nearly 700 lm/W, depending largely upon the assigned value of the freezing point of platinum. The value of 1/600,000 m^2 was chosen to maintain consistency with prior standards. Note that neither the old nor the new definition of the candela say anything about the spectral responsivity of the human eye. There are additional definitions that include the characteristics of the eye, but the base unit (candela) and those SI units derived from it are "eyeless."

Note also that in the definition of the candela, there is no specification for the spatial distribution of intensity. Luminous intensity, while often associated with an isotropic point (i.e., small) source, is a valid specification for characterizing any highly directional light source, such as a spotlight or an LED.

One other issue: since the candela is no longer independent but is now defined in terms of other SI-derived quantities, there is really no need to retain it as an SI base quantity. It remains so for reasons of history and continuity and perhaps some politics.

The *lumen* is an SI-derived unit for luminous flux (power). The abbreviation is *lm*, and the symbol is Φ_v. The lumen is derived from the candela and is the luminous flux that is emitted into unit solid angle (1 sr) by an isotropic point source having a luminous intensity of 1 cd. The lumen is the product of luminous intensity and solid angle (cd sr). It is analogous to the unit of radiant flux (watt), differing only in the eye response weighting. If a light source is isotropic, the relationship between lumens and candelas is 1 cd = 4π lm. In other words, an isotropic source that has a luminous intensity of 1 cd emits 4π lm into space, which is 4π sr. Also, 1 cd = 1 lm sr^{-1}, which is analogous to the equivalent radiometric definition.

If a source is not isotropic, the relationship between candelas and lumens is empirical. A fundamental method used to determine the total flux (lumens) is to measure the luminous intensity (candelas) in many directions using a goniophotometer, and then numerically integrate over the

entire sphere. Later on, this "calibrated" lamp can be used as a reference in an integrating sphere for routine measurements of luminous flux.

The SI-derived unit of luminous flux density, or illuminance, has a special name: *lux.* It is lumens per square meter (lm m^{-2}), and the symbol is E_v. Most light meters measure this quantity, as it is of great importance in illuminating engineering. The IESNA's *Lighting Handbook*[11] has some 16 pages of recommended illuminances for various activities and locales, ranging from morgues to museums. Typical values range from 100,000 lx for direct sunlight to between 20 and 50 lx for hospital corridors at night.

Luminance should probably be included on the list of SI-derived units, but it is not. Luminance is analogous to radiance, giving the spatial and directional dependences. It also has a special name, *nit,* and is candelas per square meter (cd m^{-2}) or lumens per square meter per steradian (lm m^{-2} sr^{-1}). The symbol is L_v. Luminance is most often used to characterize the "brightness" of flat-emitting or -reflecting surfaces. A common use is the luminance of a laptop computer screen. They typically have between 100 and 250 nits, and the sunlight-readable ones have more than 1000 nits. Typical CRT monitors have luminances between 50 and 125 nits.

Other Photometric Units

There are other photometric units, largely historical. The literature is filled with now obsolete terminology, and it is important to be able to properly interpret these terms. Here are several terms for illuminance that have been used in the past.

1 meter-candle = 1 lx

1 phot (ph) = 1 lm cm^{-2} = 10^4 lx

1 footcandle (fc) = 1 lm ft^{-2} = 10.76 lx

1 milliphot = 10 lx

Table 3 is useful to convert from one unit to another. Start with the unit in the leftmost column and multiply it by the factor in the table to arrive at the unit in the top row.

There are two classes of units that are used for luminance. The first is conventional, directly related to the SI unit, the cd m^{-2} (nit).

1 stilb = 1 cd cm^{-2} = 10^4 cd m^{-2} = 10^4 nit

1 cd ft^{-2} = 10.76 cd m^{-2} = 10.76 nit

The second class was designed to "simplify" characterization of light that is reflected from diffuse surfaces by incorporating within the definition the concept of a perfect diffuse reflector (lambertian, reflectance $\rho = 1$). If 1 unit of illuminance falls upon this ideal reflector, then 1 unit of luminance is reflected. The perfect diffuse reflector emits $1/\pi$ units of luminance per unit of illuminance. If the reflectance is ρ, then the luminance is ρ/π times the illuminance. Consequently, these units all incorporate a factor of $1/\pi$.

1 lambert (L) = $(1/\pi)$ cd cm^{-2} = $(10^4/\pi)$ cd m^2 = $(10^4/\pi)$ nit

1 apostilb = $(1/\pi)$ cd m^{-2} = $(1/\pi)$ nit

1 foot-lambert (ft-lambert) = $(1/\pi)$ cd ft^{-2} = 3.426 cd m^{-2} = 3.426 nit

1 millilambert = $(10/\pi)$ cd m^{-2} = $(10/\pi)$ nit

1 skot = 1 milliblondel = $(10^{-3}/\pi)$ cd m^{-2} = $10^{-3}/\pi$ nit

TABLE 3 Illuminance Unit Conversions

	fc	lx	phot	milliphot
1 fc (lm/ft^2) =	1	10.764	0.0010764	1.0764
1 lx (lm/m^2) =	0.0929	1	0.0001	0.1
1 phot(lm/cm^2) =	929	10,000	1	0.001
1 milliphot =	0.929	10	0.1	1

TABLE 4 Illuminance Unit Conversions*

	nit	stilb	cd/ft^2	apostilb	lambert	ft-lambert
1 nit(cd/m^2) =	1	10^{-4}	0.0929	π	$\pi/10000$	0.0929π
1 stilb (cd/cm^2) =	10,000	1	929	$10^4\pi$	π	929π
1 cd/ft^2 =	10.764	1.0764×10^{-3}	1	10.764π	$\pi/929$	π
1 apostilb =	$1/\pi$	$10^4/\pi$	$0.0929/\pi$	1	10^{-4}	0.0929
1 lambert =	$10^4/\pi$	$1/\pi$	$929/\pi$	10^4	1	929
1 ft · lambert =	$10.76/\pi$	$1/(929\pi)$	$1/\pi$	10.764	1.076×10^4	1

*Note: Photometric quantities are the result of an integration over wavelength. It therefore makes no sense to speak of spectral luminance or the like.

Table 4 is useful to convert from one unit to another. Start with the unit in the leftmost column and multiply it by the factor in the table to arrive at the unit in the top row.

Human Eye The SI base unit and units derived therefrom have a strictly physical basis; they have been defined monochromatically at a wavelength of 555 nm. But the eye does not see all wavelengths equally. For other wavelengths or for band or continuous-source spectral distributions, the spectral properties of the human eye must be considered. The eye has two general classes of photosensors: *cones* and *rods.*

Cones The cones are responsible for light-adapted vision; they respond to color and have high resolution in the central foveal region. The light-adapted relative spectral response of the eye is called the *spectral luminous efficiency function for photopic vision*, $V(\lambda)$, and is published in tabular form.[12] This empirical curve, shown in Fig. 3, was first adopted by the CIE in 1924. It has a peak that is normalized to unity at 555 nm, and it decreases to levels below 10^{-5} at about 370 and 785 nm. The 50 percent points are near 510 and 610 nm, indicating that the curve is slightly skewed. A logarithmic representation is shown in Fig. 4.

More recent measurements have shown that the 1924 curve may not best represent typical human vision. It appears to underestimate the response at wavelengths shorter than 460 nm. Judd,[13] Vos,[14] and Stockman and Sharpe[15] have made incremental advances in our knowledge of the photopic response.

Rods The rods are responsible for dark-adapted vision, with no color information and poor resolution when compared with the foveal cones. The dark-adapted relative spectral response of the

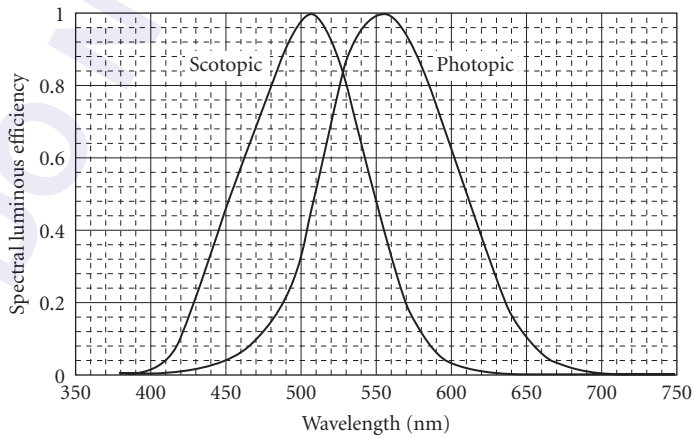

FIGURE 3 Spectral luminous efficiency for photopic and scotopic vision.

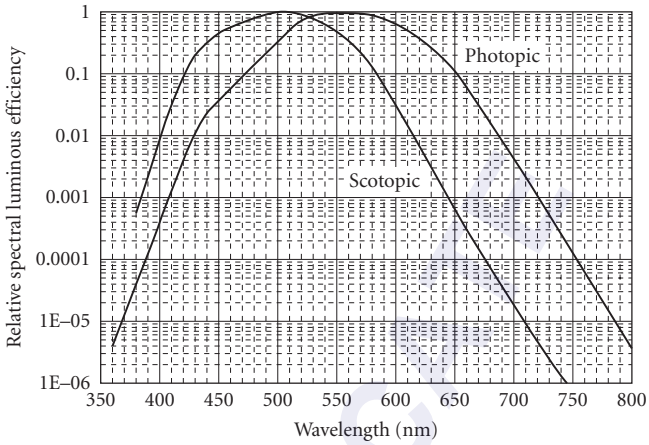

FIGURE 4 Spectral luminous efficiency for photopic and scotopic vision (log scale).

eye is called the *spectral luminous efficiency function for scotopic vision*, $V(\lambda)$, also published in tabular form.[12] Figures 3 and 4 also show this empirical curve, which was adopted by the CIE in 1951. It is defined between 380 and 780 nm. The $V(\lambda)$ curve has a peak of unity at 507 nm, and it decreases to levels below 10^{-3} at about 380 and 645 nm. The 50 percent points are near 455 and 550 nm.

Photopic (light-adapted cone) vision is active for luminances that are greater than 3 cd m^{-2}. Scotopic (dark-adapted rod) vision is active for luminances that are lower than 0.01 cd m^{-2}. In between, both rods and cones contribute in varying amounts, and in this range the vision is called *mesopic*. There have been efforts to characterize the composite spectral response in the mesopic range for vision research at intermediate luminance levels. Definitive values at 1-nm intervals for both photopic and scotopic spectral luminous efficiency functions may be found in CIE.[12] Values at 5-nm intervals are given by Zalewski.[16]

The relative spectral luminous efficiency functions can be converted for use with photon flux (s^{-1}) by multiplying by the spectrally dependent conversion from watts to photons per second. The results are shown in Fig. 5. The curves are similar to the spectral luminous efficiency curves, with the peaks shifted to slightly shorter wavelengths, and the skewness of the curves is different. This function

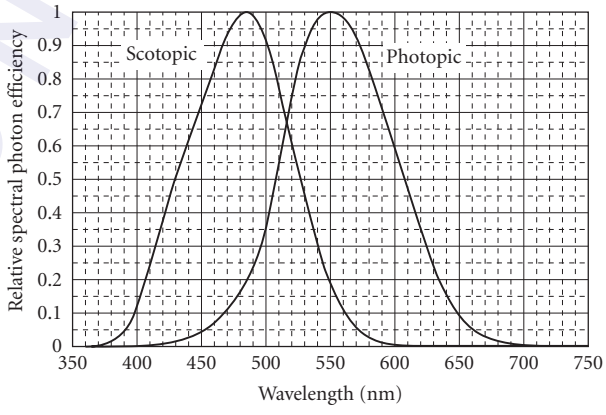

FIGURE 5 Spectral photon efficiency for scotopic and photopic vision.

can be called $V_q(\lambda)$ for photopic response or $V'_q(\lambda)$ for scotopic response. The conversion to an absolute curve is made by multiplying by the response at the peak wavelength. For photopic vision ($\lambda = 550$ nm), $K_{mp} = 2.45 \times 10^{-16}$ lm/photon s^{-1}. There are, therefore, 4.082×10^{15} photon s^{-1} lm^{-1} at 550 nm, and more at all other wavelengths. For scotopic vision ($\lambda_p = 504$ nm), $K'_{mp} = 6.68 \times 10^{-16}$ lm/photon s^{-1}. There are 1.497×10^{15} photon s^{-1} lm^{-1} at 504 nm, and more at all other wavelengths.

Approximations The $V(\lambda)$ curve appears similar to a Gaussian (normal) function. A nonlinear regression technique was used to fit the Gaussian shown in Eq. (2) to the $V(\lambda)$ data

$$V(\lambda) \cong 1.019e^{-285.4(\lambda - 0.559)^2} \tag{2}$$

The scotopic curve can also be fit with a Gaussian, although the fit is not quite as good as the photopic curve. My best fit is

$$V'(\lambda) \cong 0.992e^{-321.0(\lambda - 0.503)^2} \tag{3}$$

The results of the curve fitting are shown in Figs. 6 and 7. These approximations are satisfactory for application with continuous spectral distributions, such as sunlight, daylight, and incandescent sources. Calculations have demonstrated errors of less than 1 percent with blackbody sources from 1500 K to more than 20,000 K. The equations must be used with caution for narrowband or line sources, particularly in those spectral regions where the response is low and the fit is poor.

Usage The SI definition of the candela was chosen in strictly physical terms at a single wavelength. The intent of photometry, however, is to correlate a photometric observation to the visual perception of a human observer. The CIE introduced the two standard spectral luminous efficiency functions $V(\lambda)$ (photopic) and $V'(\lambda)$ (scotopic) as spectral weighting functions, and they have been approved by the CIPM for use with light sources at other wavelengths. Another useful function is the CIE $V_M(\lambda)$ Judd-Vos modified $V(\lambda)$ function,[14] which has increased response at wavelengths that are shorter than 460 nm. It is identical to the $V(\lambda)$ function for wavelengths that are longer than 460 nm. This function, while not approved by CIPM, represents more realistically the spectral responsivity of the eye. More recently, studies on cone responses have led to the proposal of a new, improved luminous spectral efficiency curve, with the suggested designation $V_2^*(\lambda)$.[15]

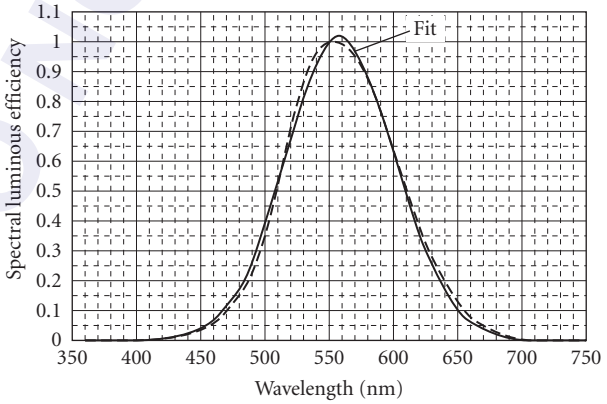

FIGURE 6 Gaussian fit to photopic relative spectral efficiency curve.

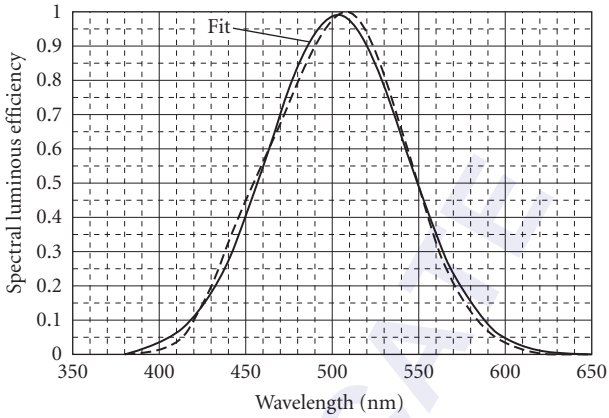

FIGURE 7 Gaussian fit to scotopic relative spectral efficiency curve.

36.5 CONVERSION OF RADIOMETRIC QUANTITIES TO PHOTOMETRIC QUANTITIES

The definition of the candela states that there are 683 lm W^{-1} at a frequency of 540 terahertz (THz), which is very nearly 555 nm (vacuum or air), the wavelength that corresponds to the maximum spectral responsivity of the photopic (light-adapted) human eye. The value 683 lm W^{-1} is K_m, the absolute luminous efficiency at λ_p for photopic vision. The conversion from watts to lumens at any other wavelength involves the product of the power (watts), K_m, and the $V(\lambda)$ value at the wavelength of interest. For example, a 5-mW laser pointer has 0.005 W × 0.032 × 683 lm W^{-1} = 0.11 lm. $V(\lambda)$ is 0.032 at 670 nm. At 635 nm, $V(\lambda)$ is 0.217, and a 5-mW laser pointer has 0.005 W × 0.217 × 683 lm W^{-1} = 0.74 lm. The shorter-wavelength laser pointer will create a spot that has nearly seven times the luminous power as the longer-wavelength laser.

Similar calculations can be done in terms of photon flux at a single wavelength. As was shown previously, there are 2.45×10^{-16} lm in 1 photon s^{-1} at 550 nm, the wavelength that corresponds to the maximum spectral responsivity of the light-adapted human eye to photon flux. The conversion from lumens to photons per second at any other wavelength involves the product of the photon flux (s^{-1}) and the $V_p(\lambda)$ value at the wavelength of interest. For example, again compare laser pointers at 670 and 635 nm. As shown before, a 5-mW laser at 670 nm [$V_p(\lambda) = 0.0264$] has a luminous power of 0.11 lm. The conversion is $0.11 \times 4.082 \times 10^{15}/0.0264 = 1.68 \times 10^{16}$ photon s^{-1}. At 635 nm [$V_p(\lambda) = 0.189$], the 5-mW laser has a luminous power of 0.74 lm. The conversion is $0.74 \times 4.082 \times 10^{15}/0.189 = 1.6 \times 10^{16}$ photon s^{-1}. The 635-nm laser delivers just 5 percent more photons per second.

In order to convert a source with nonmonochromatic spectral distribution to a luminous quantity, the situation is decidedly more complex. The spectral nature of the source must be known, as it is used in an equation of the form

$$X_v = K_m \int_0^\infty X_\lambda V(\lambda) d\lambda \tag{4}$$

where X_v is a luminous term, X_λ is the corresponding spectral radiant term, and $V(\lambda)$ is the photopic spectral luminous efficiency function. For *X,* luminous flux (lm) may be paired with spectral power (W nm^{-1}), luminous intensity (cd) with spectral radiant intensity (W sr^{-1} nm^{-1}), illuminance (lx) with spectral irradiance (W m^{-2} nm^{-1}), or luminance (cd m^{-2}) with spectral radiance (W m^{-2} sr^{-1} nm^{-1}). This equation represents a weighting, wavelength by wavelength, of the radiant spectral term

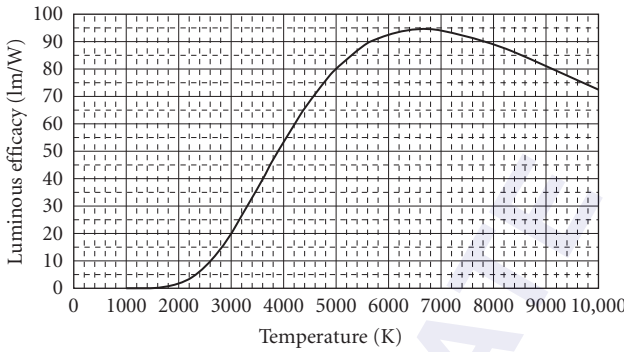

FIGURE 8 Luminous efficacy of blackbody radiation versus temperature (K).

by the visual response at that wavelength. The constant K_m is the maximum spectral luminous efficiency for photopic vision, 683 lm W^{-1}. The wavelength limits can be set to restrict the integration to only those wavelengths where the product of the spectral term X_λ and $V(\lambda)$ is nonzero. Practically, the limits of integration need only extend from 360 to 830 nm, limits specified by the CIE $V(\lambda)$ function. Since this $V(\lambda)$ function is defined by a table of empirical values,[12] it is best to do the integration numerically. Use of the Gaussian equation [Eq. (2)] is only an approximation.

For source spectral distributions that are blackbody-like (thermal source, spectral emissivity constant between 360 and 830 nm) and of known source temperature, it is straightforward to convert from power to luminous flux and vice versa. Equation (4) is used to determine a scale factor for the source term X_λ. Figure 8 shows the relationship between total power and luminous flux for blackbody (and graybody) radiation as a function of blackbody temperature. The most efficient temperature for the production of luminous flux is near 6630 K.

There is nothing in the SI definitions of the base or derived units concerning the eye response, so there is some flexibility in the choice of the weighting function. The choice can be made to use a different spectral luminous efficiency curve, perhaps one of the newer ones. The equivalent curve for scotopic (dark-adapted) vision can also be used for work at lower light levels. The $V'(\lambda)$ curve has its own constant, K'_m, the maximum spectral luminous efficiency for scotopic vision. K'_m is defined as 1700 lm/W at the peak wavelength for scotopic vision (507 nm). This value was deliberately chosen such that the absolute value of the scotopic curve at 555 nm coincides with the photopic curve, 683 lm/W at 555 nm. Some researchers are referring to "scotopic lumens," a term that should be discouraged because of the potential for misunderstanding. In the future, expect to see spectral weighting to represent the mesopic region as well.

The CGPM has approved the use of the CIE $V(\lambda)$ and $V'(\lambda)$ curves for determination of the value of photometric quantities of luminous sources.

36.6 CONVERSION OF PHOTOMETRIC QUANTITIES TO RADIOMETRIC QUANTITIES

The conversion from watts to lumens in the previous section required only that the spectral function, X_λ, of the radiation be known over the spectral range from 360 to 830 nm, where $V(\lambda)$ is nonzero. Attempts to go in the other direction, from lumens to watts, are far more difficult. Since the desired quantity was inside of an integral, weighted by a sensor spectral responsivity function, the spectral function, X_λ, of the radiation must be known over the entire spectral range where the source emits, not just the visible.

For a monochromatic source in the visible spectrum (between the wavelengths of 380 and 860 nm), if the photometric quantity (e.g., lux) is known, apply the conversion $K_m \times V(\lambda)$ and determine the

radiometric quantity (e.g., W m^{-2}). In practice, the results that one obtains are governed by the quality of the $V(\lambda)$ correction of the photometer and the knowledge of the wavelength of the source. Both of these factors are of extreme importance at wavelengths where the $V(\lambda)$ curve is steep (i.e., other than very close to the peak of the $V(\lambda)$ curve).

Narrowband sources, such as LEDs, cause major problems. Typical LEDs have spectral bandwidths ranging from 10- to 40-nm full width at half-maximum (FWHM). It is intuitive that in those spectral regions where the $V(\lambda)$ curve is steep, the luminous output will be greater than that predicted using the $V(\lambda)$ curve at the peak LED wavelength. This expected result increases with wider-bandwidth LEDs. Similarly, it is also intuitive that the luminous output is less than that predicted by using the $V(\lambda)$ curve when the peak LED wavelength is in the vicinity of the peak of the $V(\lambda)$ curve. Therefore, there must be two wavelengths where the conversion ratio (lm/W) is largely independent of LED bandwidth. An analysis of this conversion ratio was done using a Gaussian equation to represent the spectral power distribution of an LED and applying Eq. (4). Indeed, two null wavelengths were identified (513 and 604 nm) where the conversion between radiometric and photometric quantities is constant (independent of LED bandwidth) to within 0.2 percent up to an LED bandwidth of 40 nm. These wavelengths correspond (approximately) to the wavelengths where the two maxima of the first derivative of the $V(\lambda)$ curve are located.

At wavelengths between these two null wavelengths (513 and 604 nm), the conversion ratio (lm/W) decreases slightly with increasing bandwidth. The worst case occurs when the peak wavelength of the LED corresponds with the peak of $V(\lambda)$. It is about 5 percent lower for bandwidths up to 30 nm, increasing to nearly 10 percent for 40-nm bandwidth. At wavelengths outside of the null wavelengths, the conversion (lm/W) increases with increasing bandwidth, and the increase is greater when the wavelength approaches the limits of the $V(\lambda)$ curve. Figure 9 shows that factor by which a conversion ratio (lm/W) should be multiplied as a function of LED bandwidth, with the peak LED wavelength as the parameter. Note that the peak wavelength of the LED is specified as the radiometric peak and not as the dominant wavelength (a color specification). The dominant wavelength shifts with respect to the radiometric peak, the difference increasing with bandwidth.

Most often, LEDs are specified in luminous intensity [cd or millicandela (mcd)]. The corresponding radiometric unit is watts per steradian (W/sr). In order to determine the radiometric power (watts), the details of the spatial distribution of the radiant intensity must be known prior to integration.

For broadband sources, a photometric quantity cannot in general be converted to a radiometric quantity unless the radiometric source function, Φ_λ, is known over all wavelengths. However, if the source spectral distribution is blackbody-like (thermal source, spectral emissivity constant between 360 and 830 nm), and the source temperature is also known, then an illuminance can be converted to a spectral irradiance curve over that wavelength range. Again, use Eq. (4) to determine a scale factor

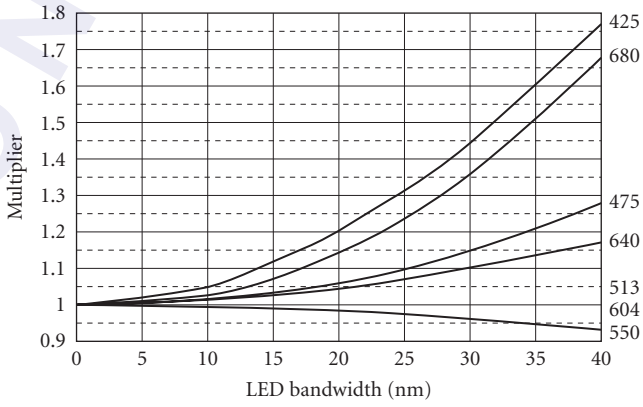

FIGURE 9 Multiplier for converting LED luminous intensity to radiant intensity.

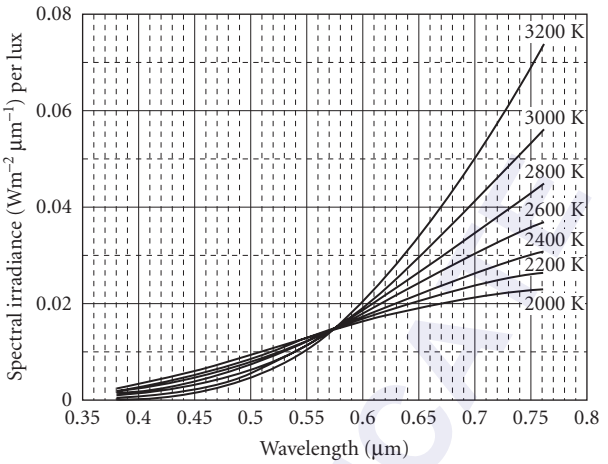

FIGURE 10 Spectral irradiance versus wavelength of blackbody radiation versus temperature.

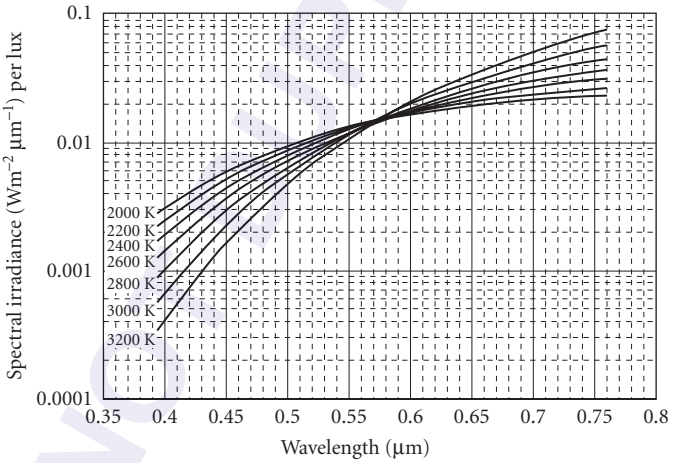

FIGURE 11 Spectral irradiance versus wavelength of blackbody radiation versus temperature.

for the source term, X_λ. Figures 10 and 11 show the calculated spectral irradiance versus wavelength for blackbody radiation with source temperature as the parameter.

36.7 RADIOMETRIC/PHOTOMETRIC NORMALIZATION

In radiometry and photometry, there are two mathematical activities that fall into the category called *normalization.* The first is bandwidth normalization. The second doesn't have an official title but involves a conversion between photometric and radiometric quantities, used to convert detector responsivities from amperes per lumen to amperes per watt.

The measurement equation relates the output signal from a sensor to its spectral responsivity and the spectral power that is incident upon it:

$$S = \int_0^\infty \Phi_\lambda \Re(\lambda) \mathrm{d}\lambda \tag{5}$$

An extended discourse on bandwidth normalization[17] showed that the spectral responsivity of a sensor (or detector) can be manipulated to yield more source information than is immediately apparent from the measurement equation. The sensor weights the input spectral power according to its spectral responsivity, $\Re(\lambda)$, such that only a limited amount of information about the source can be deduced. If either the source or the sensor has a sufficiently small bandwidth such that the spectral function of the other term does not change significantly over the passband, the equation simplifies to

$$S = \Phi_\lambda \cdot \Re(\lambda) \cdot \Delta\lambda \tag{6}$$

where $\Delta\lambda$ is the passband. Spectroradiometry and multifilter radiometry, using narrow-bandpass filters, take advantage of this simplified equation. For those cases where the passband is larger, the techniques of bandwidth normalization can be used. The idea is to substitute for $\Re(\lambda)$ an equivalent response that has a uniform spectral responsivity, $\Re_n$, between wavelength limits λ_1 and λ_2 and zero response elsewhere. Then, the signal is given by

$$S = \Re_n \int_{\lambda_1}^{\lambda_2} \Phi_\lambda \mathrm{d}\lambda \tag{7}$$

and now the integrated power between wavelengths λ_1 and λ_2 is determined. There are many ways of assigning values for λ_1 λ_2, and $\Re_n$ for a sensor. Some of the more popular methods were described by Nicodemus[17] and Palmer.[18] An effective choice is known as the *moments method*,[19] an analysis of the zeroth, first, and second moments of the sensor spectral responsivity curve. The derivation of this normalization scheme involves the assumption that the source function is exactly represented by a second-degree polynomial. If this condition is met, the moments method of determining sensor parameters yields exact results for the source integral. In addition, the results are completely independent of the source function. The errors encountered are related to deviation of the source function from the said second-degree polynomial.

Moments normalization has been applied to the photopic spectral luminous efficiency function, $V(\lambda)$, and the results are given in Table 5 and shown in Fig. 12. These values indicate the skewed nature of the photopic and scotopic curves as the deviation from the centroid and the peak wavelengths. The results can be applied to most continuous sources, like blackbody and tungsten radiation, which are both continuous across the visible spectrum. To demonstrate the effectiveness of moments normalization, the blackbody curve was multiplied by the $V(\lambda)$ curve for temperatures ranging from 1000 to 20,000 K to determine a photometric function [e.g., lumens per square meter (or lux)]. Then, the blackbody curve was integrated over the wavelength interval between λ_1 and λ_2 to determine the equivalent (integrated between λ_1 and λ_2) radiometric

TABLE 5 Bandwidth Normalization on Spectral Luminous Efficiency

	Photopic	Scotopic
Peak wavelength (λ_p)	555 nm	507 nm
Centroid wavelength (λ_C)	560.19 nm	502.40 nm
Short wavelength (λ_1)	487.57 nm	436.88 nm
Long wavelength (λ_2)	632.81 nm	567.93 nm
Moments bandwidth	145.24 nm	131.05 nm
Normalized $\Re_n$	0.7357	0.7407
Absolute $\Re_n$	502.4 lm/W	1260 lm/W

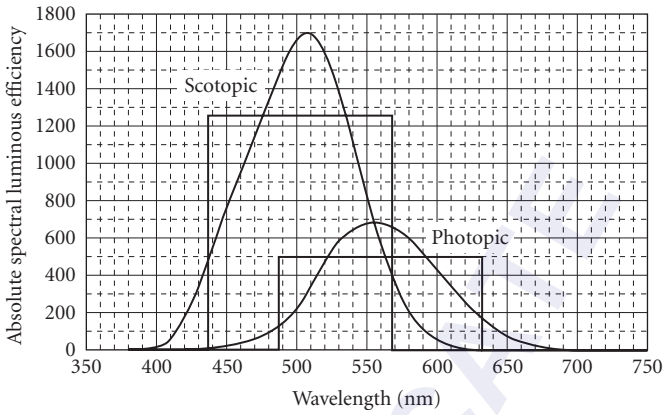

FIGURE 12 Absolute spectral luminous efficiency functions and equivalent normalized bandwidths

function (e.g., in-band watts per square meter). The ratio of lux to watt per square meter is 502.4 ± 1.0 (3σ) over the temperature range from 1600 to more than 20,000 K. This means that the in-band (487.6 to 632.8 nm) irradiance for a continuous blackbody-like source can be determined using a photometer that is properly calibrated in lux and that is well corrected for $V(\lambda)$. Simply divide the reading in lux by 502.4 to get the in-band irradiance in watts per square meter between 487.6 and 632.8 nm.

If a photometer is available with a $V'(\lambda)$ correction, calibrated for lux (scotopic) with K'_{m} of 1700 lm/W, a similar procedure is effective. The integration takes place over the wavelength range from 436.9 to 567.9 nm. The ratio of lux (scotopic) to watts per square meter is 1260 ± 2 (3σ) over the temperature range from 1800 K to more than 20,000 K. This means that the in-band (436.9 to 567.9 nm) irradiance for a continuous blackbody-like source can be determined using a $V'(\lambda)$-corrected photometer that is properly calibrated in lux (scotopic). Simply divide the reading in lux (scotopic) by 1260; the result is the in-band irradiance in watts per square meter between 436.9 and 567.9 nm.

A common problem is the interpretation of specifications for photodetectors, which are given in photometric units. An example is a photomultiplier with an S-20 photocathode, which has a typical responsivity of 200 μA/lm. Given this specification and a curve of the relative spectral responsivity, the problem is to determine the output when exposed to a known power from an arbitrary source.

Photosensitive devices, in particular vacuum photodiodes and photomultiplier tubes, are characterized using CIE Illuminant A, a tungsten source at 2854 K color temperature. The illuminance is measured using a photoptically corrected photometer, and this illuminance is applied to the device under scrutiny. This technique is satisfactory only if the source being used is spectrally comparable to Illuminant A. If a source with a different spectral distribution is used, a photometric normalization must be done. Eberhart[20] generated a series of conversion factors for various sources and standardized detector spectral responsivities (S-1, S-11, S-20, etc.).

The luminous flux from any source is given by

$$\Phi_{\mathrm{v}} = K_{\mathrm{m}} \int_{360}^{830} \Phi_{\lambda} V(\lambda) \mathrm{d}\lambda \tag{8}$$

and the output of a detector when exposed to the said luminous flux is

$$S = \int_{0}^{\infty} \Phi_{\lambda} \Re(\lambda) \mathrm{d}\lambda \tag{9}$$

where Φ_λ is spectral radiant flux, $V(\lambda)$ is the spectral luminous efficiency of the photopic eye, $\Re(\lambda)$ is the absolute spectral responsivity of the photodetector, and S is the photodetector signal. The luminous responsivity of the detector when exposed to this source is

$$\Re = \frac{\int_0^\infty \Phi_\lambda \Re(\lambda) \mathrm{d}\lambda}{K_\mathrm{m} \int_{360}^{830} \Phi_\lambda V(\lambda) \mathrm{d}\lambda} \mathrm{A/lm} \tag{10}$$

This luminous responsivity is specific to the source that is used to make the measurement, and it cannot be applied to other sources with differing spectral distributions.

36.8 OTHER WEIGHTING FUNCTIONS AND CONVERSIONS

The general principles that are outlined here can be applied to action spectra other than those already defined for the human eye (photopic and scotopic). Some action spectra take the form of defined spectral regions, such as UVA (315–400 nm), UVB (280–315 nm), UVC (100–280 nm), IR-A (770–1400 nm), IR-B (1400–3000 nm), and IR-C (3000–10^6 nm). Others are more specific. $A(\lambda)$ is for aphakic hazard, $B(\lambda)$ is for photochemical blue-light hazard, $R(\lambda)$ is for retinal thermal hazard, and $S(\lambda)$ is an actinic ultraviolet action spectrum.[21] PPF (a.k.a. PhAR) is a general action spectrum for plant growth. Many others have been defined, including those for erythema (sunburn), skin cancer, psoriasis treatment, mammalian and insect vision, and other generalized chemical and biological photoeffects. Various conversion factors from one action spectrum to another are scattered throughout the popular and archival literature. Ideally, they have been derived via integration over the appropriate spectral regions.

RADIOMETRY AND PHOTOMETRY FOR VISION OPTICS*

Yoshi Ohno

Optical Technology Division
National Institute of Standards and Technology
Gaithersburg, Maryland

37.1 INTRODUCTION

Radiometry is the measurement of optical radiation, which is electromagnetic radiation in the frequency range between 3×10^{11} Hz and 3×10^{16} Hz. This range corresponds to wavelengths between 10 nm and 1000 μm, and includes the regions commonly called the ultraviolet, the visible, and the infrared. Typical radiometric units include watt (radiant flux), watt per steradian (radiant intensity), watt per square meter (irradiance), and watt per square meter per steradian (radiance).

Photometry is the measurement of light, which is defined as electromagnetic radiation detectable by the human eye. It is thus restricted to the visible region of the spectrum (wavelength range from 360 nm to 830 nm), and all the quantities are weighted by the spectral response of the eye. Photometry uses either optical radiation detectors constructed to mimic the spectral response of the eye, or spectroradiometry coupled with appropriate calculations for weighting by the spectral response of the eye. Typical photometric units include lumen (luminous flux), candela (luminous intensity), lux (illuminance), and candela per square meter (luminance).

The difference between radiometry and photometry is that radiometry includes the entire optical radiation spectrum (and often involves spectrally resolved measurements), while photometry deals with the visible spectrum weighted by the response of the eye. This chapter provides some guidance in photometry and radiometry (Refs. 1 through 6 are available for further details). The terminology used in this chapter follows international standards and recommendations.[7–9]

37.2 BASIS OF PHYSICAL PHOTOMETRY

The primary aim of photometry is to measure visible optical radiation, light, in such a way that the results correlate with the visual sensation of a normal human observer exposed to that radiation. Until about 1940, visual comparison measurement techniques were predominant in photometry.

*Chapter 1 in Vol. III gives further treatment of issues in radiometry, and Chap. 35 in this volume describes measurement of optical properties of materials.

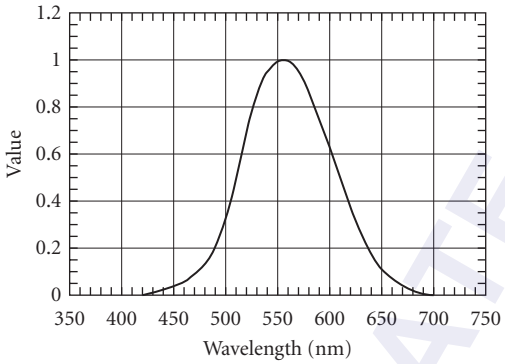

FIGURE 1 CIE $V(\lambda)$ function.

In modern photometric practice, measurements are made with photodetectors. This is referred to as *physical photometry.* In order to achieve the aim of photometry, one must take into account the characteristics of human vision. The relative spectral responsivity of the human eye was first defined by the CIE (Commission Internationale de l'Éclairage) in 1924,[10] and redefined as part of colorimetric standard observers in 1931.[11] Called the *spectral luminous efficiency for photopic vision,* or $V(\lambda)$, it is defined in the domain from 360 nm to 830 nm, and is normalized at its peak, 555 nm (Fig. 1). This model has gained wide acceptance. The values were republished by CIE in 1983,[12] and published by CIPM (Comité International des Poids et Mesures) in 1982[13] to supplement the 1979 definition of the candela. (The tabulated values of the function at 1-nm increments are available in Refs. 12 through 15.) In most cases, the region from 380 nm to 780 nm suffices for calculation with negligible errors because the value of the $V(\lambda)$ function falls below 10^{-4} outside this region. Thus, a photodetector having a spectral responsivity matched to the $V(\lambda)$ function replaced the role of human eyes in photometry.

Radiometry concerns physical measurement of optical radiation in terms of optical power, and in many cases, as a function of its wavelength. As specified in the definition of the candela by CGPM (Conférence Générale des Poids et Mesures) in 1979[16] and by CIPM in 1982,[13] a photometric quantity X_v is defined in relation to the corresponding radiometric quantity $X_{e,\lambda}$ by the equation:

$$X_{\mathrm{v}} = K_{\mathrm{m}} \int_{360\mathrm{nm}}^{830\mathrm{nm}} X_{\mathrm{e},\lambda} V(\lambda) \mathrm{d}\lambda \tag{1}$$

The constant, K_m, relating the photometric quantities and radiometric quantities, is called the *maximum spectral luminous efficacy* (*of radiation*) *for photopic vision.* The value of K_m is given by the 1979 definition of candela that defines the spectral luminous efficacy of light at the frequency 540×10^{12} Hz (at the wavelength 555.016 nm in standard air) to be 683 lm/W. The value of K_m is calculated as $683 \times V(555.000\ \mathrm{nm})/V(555.016\ \mathrm{nm}) = 683.002$ lm/W.[12] K_m is normally rounded to 683 lm/W with negligible errors.

It should be noted that $V(\lambda)$ is defined for the *CIE standard photometric observer for photopic vision,* which assumes additivity of sensation and a 2° field of view at relatively high luminance levels (higher than approximately 1 cd/m^2). The human vision in this level is called photopic vision. The spectral responsivity of human vision deviates significantly at very low levels of luminance (less than approximately 10^{-3} cd/m^2). This type of vision is called scotopic vision. Its spectral responsivity, peaking at 507 nm, is designated by $V'(\lambda)$, which was defined by CIE in 1951,[17] recognized by CIPM in 1976,[18] and republished by CIPM in 1982.[13] Human vision in the region between photopic vision and scotopic vision is called mesopic vision. While there have been active researches in this area,[19] there is no internationally accepted spectral luminous efficiency function for the mesopic region yet. In current practice, almost all photometric quantities are given in terms of photopic vision, even at low light levels. Quantities in scotopic vision are seldom used except for special calculations for research purposes. (Further details of the contents in this section are given in Ref. 12.)

37.3 PHOTOMETRIC BASE UNIT—THE CANDELA

The history of photometric standards dates back to the early nineteenth century, when the intensity of light sources was measured in comparison with a standard candle using visual bar photometers. At that time, the flame of a candle was used as a unit of luminous intensity that was called the *candle.* The old name for luminous intensity *candle power* came from this origin. Standard candles were gradually superseded by flame standards of oil lamps, and in the early twentieth century investigations on platinum point blackbodies began at some national laboratories. An agreement was first established in 1909 among several national laboratories to use such a blackbody to define the unit of luminous intensity, and the unit was recognized as the *international candle.* This standard was adopted by the CIE in 1921. In 1948, it was adopted by the CGPM[16] with a new Latin name *candela* with the following definition:

> The candela is the luminous intensity, in the perpendicular direction, of a surface of 1/600000 square meter of a blackbody (full radiator) at the temperature of freezing platinum under a pressure of 101325 newton per square meter.

Although the 1948 definition served to establish the uniformity of photometric measurements in the world, difficulties in fabricating the blackbodies and in improving accuracy were addressed. Beginning in the mid-1950s, suggestions were made to define the candela in relation to the unit of optical power, watt, so that complicated source standards would not be necessary. Finally, in 1979, a new definition of the candela was adopted by the CGPM[16] as follows:

> The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of (1/683) watt per steradian.

The value of K_m (683 lm/W) was determined in such a way that the consistency from the prior unit was maintained, and was determined based on the measurements by several national laboratories. (Technical details on this redefinition of the candela are reported in Refs. 20 and 21.) This 1979 redefinition of the candela has enabled photometric units to be derived from radiometric units using a variety of techniques. (The early history of photometric standards is described in greater detail in Ref. 22.)

37.4 QUANTITIES AND UNITS IN PHOTOMETRY AND RADIOMETRY

In 1960, the SI (Système International) was established, and the candela became one of the seven SI base units.[23] (For further details on the SI, Refs. 23 through 26 may be consulted.) Several quantities and units, defined in different geometries, are used in photometry and radiometry. Table 1 lists the photometric quantities and units, along with corresponding quantities and units for radiometry.

While the candela is the SI base unit, the luminous flux (lumen) is perhaps the most fundamental photometric quantity, as the other photometric quantities are defined in terms of lumen with an appropriate geometric factor. The definitions of these photometric quantities are given in the following sections. (The descriptions given here are somewhat simplified from the rigorous definitions for ease of understanding. Refer to Refs. 7 through 9 for official rigorous definitions.)

Radiant Flux and Luminous Flux

Radiant flux (also called *optical power* or *radiant power)* is the energy Q (in joules) radiated by a source per unit of time, expressed as

$$\Phi = \frac{dQ}{dt} \tag{2}$$

The unit of radiant flux is the *watt* (W = J/s).

TABLE 1 Quantities and Units Used in Photometry and Radiometry

Photometric Quantity	Unit	Relationship with Lumen	Radiometric Quantity	Unit
Luminous flux	lm (lumen)		Radiant flux	W (watt)
Luminous intensity	cd (candela)	lm sr^{-1}	Radiant intensity	W sr^{-1}
Illuminance	lx (lux)	lm m^{-2}	Irradiance	W m^{-2}
Luminance	cd m^{-2}	lm sr^{-1} m^{-2}	Radiance	W sr^{-1} m^{-2}
Luminous exitance	lm m^{-2}		Radiant exitance	W m^{-2}
Luminous exposure	lx · s		Radiant exposure	W m^{-2} · s
Luminous energy	lm · s		Radiant energy	J (joule)
Total luminous flux	lm (lumen)		Total radiant flux	W (watt)
Color temperature	K (kelvin)		Radiance temperature	K (kelvin)

Luminous flux (Φ_v) is the time rate of flow of light as weighted by $V(\lambda)$. The unit of luminous flux is the *lumen* (lm). It is defined as

$$\Phi_v = K_m \int_\lambda \Phi_{e,\lambda} V(\lambda) d\lambda \tag{3}$$

where ($\Phi_{e,\lambda}$) is the spectral concentration of radiant flux as a function of wavelength λ. The term luminous flux is often used in the meaning of total luminous flux in photometry (see the following subsection entitled "Total Radiant Flux and Total Luminous Flux").

Radiant Intensity and Luminous Intensity

Radiant intensity (I_e) or *luminous intensity* (I_v) is the radiant flux (luminous flux) from a point source emitted per unit solid angle in a given direction, as defined by

$$I = \frac{d\Phi}{d\Omega} \tag{4}$$

where $d\Phi$ is the radiant flux (luminous flux) leaving the source and propagating in an element of solid angle $d\Omega$ containing the given direction. The unit of radiant intensity is W/sr, and that of luminous intensity is the *candela* (cd = lm/sr). (See Fig. 2.)

Solid Angle The solid angle (Ω) of a cone is defined as the ratio of the area (A) cut out on a spherical surface (with its center at the apex of that cone) to the square of the radius (r) of the sphere, as given by

$$\Omega = \frac{A}{r^2} \tag{5}$$

The unit of solid angle is *steradian* (sr), which is a dimensionless unit. (See Fig. 3.)

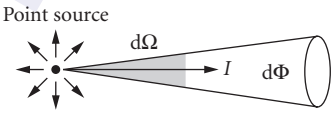

FIGURE 2 Radiant intensity and luminous intensity.

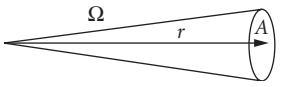

FIGURE 3 Solid angle.

Irradiance and Illuminance

Irradiance (E_e) or *illuminance* (E_v) is the density of incident radiant flux or luminous flux at a point on a surface, and is defined as radiant flux (luminous flux) per unit area, as given by

$$E = \frac{d\Phi}{dA} \tag{6}$$

where $d\Phi$ is the radiant flux (luminous flux) incident on an element dA of the surface containing the point. The unit of irradiance is W/m^2, and that of illuminance is *lux* ($lx = lm/m^2$). (See Fig. 4.)

Radiance and Luminance

Radiance (L_e) or *luminance* (L_v) is the radiant flux (luminous flux) per unit solid angle emitted from a surface element in a given direction, per unit projected area of the surface element perpendicular to the direction. The unit of radiance is $W\ sr^{-1}\ m^{-2}$, and that of luminance is cd/m^2. These quantities are defined by

$$L = \frac{d^2\Phi}{d\Omega \cdot A \cdot \cos\theta} \tag{7}$$

where $d\Phi$ is the radiant flux (luminous flux) emitted (reflected or transmitted) from the surface element and propagating in the solid angle $d\Omega$ containing the given direction. dA is the area of the surface element, and θ is the angle between the normal to the surface element and the direction of the beam. The term $dA \cos\theta$ gives the projected area of the surface element perpendicular to the direction of measurement. (See Fig. 5.)

Radiant Exitance and Luminous Exitance

Radiant exitance (M_e) or *luminous exitance* (M_v) is defined to be the density of radiant flux (luminous flux) leaving a surface at a point. The unit of radiant exitance is W/m^2 and that of luminous exitance is lm/m^2 (but it is not lux). These quantities are defined by

$$E = \frac{d\Phi}{dA} \tag{8}$$

where $d\Phi$ is the radiant flux (luminous flux) leaving the surface element. Luminous exitance is rarely used in the general practice of photometry. (See Fig. 6.)

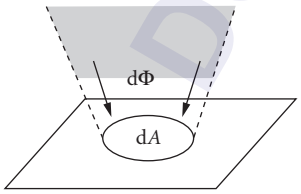

FIGURE 4 Irradiance and illuminance.

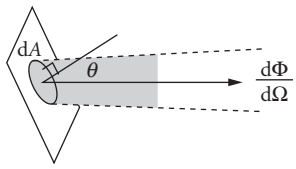

FIGURE 5 Radiance and luminance.

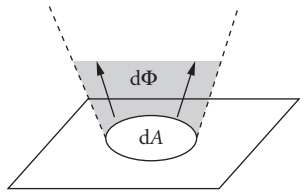

FIGURE 6 Radiant exitance and luminous exitance.

Radiant Exposure and Luminous Exposure

Radiant exposure (H_e) or *luminous exposure* (H_v) is the time integral of irradiance $E_e(t)$ or illuminance $E_v(t)$ over a given duration Δt, as defined by

$$H = \int_{\Delta t} E(t)\,\mathrm{d}t \tag{9}$$

The unit of radiant exposure is J m^{-2}, and that of luminous exposure is *lux·second* (lx·s).

Radiant Energy and Luminous Energy

Radiant energy (Q_e) or *luminous energy* (Q_v) is the time integral of the radiant flux or luminous flux (Φ) over a given duration Δt, as defined by

$$Q = \int_{\Delta t} \Phi(t)\,\mathrm{d}t \tag{10}$$

The unit of radiant energy is *joule* (J), and that of luminous energy is *lumen·second* (lm·s).

Total Radiant Flux and Total Luminous Flux

Total radiant flux or *total luminous flux* (Φ_v) is the geometrically total radiant (luminous) flux of a light source. It is defined as

$$\Phi = \int_{\Omega} I\,\mathrm{d}\Omega \tag{11}$$

or

$$\Phi = \int_{A} E\,\mathrm{d}A \tag{12}$$

where I is the radiant (luminous) intensity distribution of the light source and E is the irradiance (illuminance) distribution over a given closed surface surrounding the light source. If the radiant (luminous) intensity distribution or the irradiance (illuminance) distribution is given in polar coordinates (θ, ϕ), the total radiant (luminous) flux of the source Φ is given by

$$\Phi = \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} I(\theta, \phi) \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \tag{13}$$

or

$$\Phi = r^2 \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} E(\theta, \phi) \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \tag{14}$$

For example, the total luminous flux of an isotropic point source having luminous intensity of 1 cd would be 4π lm.

Radiance Temperature and Color Temperature

Radiance temperature (unit: kelvin) is the temperature of the Planckian radiator for which the radiance at the specified wavelength has the same spectral concentration as for the thermal radiator considered.

Color temperature (unit: kelvin) is the temperature of a Planckian radiator with radiation of the same chromaticity as that of the light source in question. This term is commonly used to specify the

colors of incandescent lamps whose chromaticity coordinates are practically on the blackbody locus. The next two terms are also important in photometry.

Distribution temperature (unit: kelvin) is the temperature of a blackbody with a spectral power distribution closest to that of the light source in question, and is used for quasi-Planckian sources such as incandescent lamps (refer to Ref. 27 for details).

Correlated color temperature (unit: kelvin) is the temperature of the Planckian radiator whose perceived color most closely resembles that of the light source in question. Correlated color temperature is used for sources with a spectral power distribution significantly different from that of Planckian radiation (e.g., discharge lamps; refer to Ref. 28 for details).

Relationship Between SI Units and English Units

The SI units as described previously should be used in all radiometric and photometric measurements according to international standards and recommendations on SI units. However, some English units are still rather widely used in some countries, including the United States. The use of these non-SI units is discouraged. The definitions of these English units are given in Table 2 for conversion purposes only.

The definition of footlambert is such that the luminance of a perfect diffuser is 1 fL when illuminated at 1 fc. In the SI unit, the luminance of a perfect diffuser would be $1/\pi$ (cd/m^2) when illuminated at 1 lx. For convenience of changing from English units to SI units, the conversion factors are listed in Table 3. For example, 1000 lx is the same illuminance as 92.9 fc, and 1000 cd/m^2 is the same luminance as 291.9 fL. (Conversion factors to and from some more units are given in Ref. 5.)

Troland

This unit is not an SI unit, not used in metrology, and is totally different from all other photometric units mentioned previously. It is introduced here because this unit is commonly used by vision scientists. Troland is defined as the retinal illuminance when a surface of luminance one candela per square meter is viewed through a pupil at the eye (natural or artificial) of area one square millimeter. Thus, the troland value, T, for the luminance, L (cd/m^2), of an external field and the pupil size, p (mm^2), is given by

$$T = L \cdot P \tag{15}$$

TABLE 2 English Units and Definition

Unit	Quantity	Definition
Footcandle (fc)	Illuminance	Lumen per square foot (lm ft^{-2})
Footlambert (fL)	Luminance	$1/\pi$ candela per square foot (π^{-1}cd ft^{-2})

TABLE 3 Conversion between English Units and SI Units

To Obtain the Value in	Multiply the Value in	By
lx from fc	fc	10.764
fc from lx	lx	0.09290
cd/m^2 from fL	fL	3.4263
fL from cd/m^2	cd/m^2	0.29186
m (meter) from feet	feet	0.30480
mm (millimeter) from inch	inch	25.400

or, for pupil size p(m^2),

$$T = L \cdot 10^6 \times p \tag{16}$$

The troland value is not the real illuminance in lux on the retina, but is a quantity proportional to it. Since the natural pupil size changes with luminance level, luminance changes do not have a proportional visual effect. Thus, troland value rather than luminance is often useful in visual experiments. There is no simple or defined conversion between troland value (for natural pupil) and luminance (cd/m^2), without knowing the actual pupil size. (Further details of this unit can be found in Ref. 29.)

37.5 PRINCIPLES IN PHOTOMETRY AND RADIOMETRY

Several important theories in practical photometry and radiometry are introduced in this section.

Inverse Square Law

Illuminance E (lx) at a distance d (m) from a point source having luminous intensity I (cd) is given by

$$E = \frac{I}{d^2} \tag{17}$$

For example, if the luminous intensity of a lamp in a given direction is 1000 cd, the illuminance at 2 m from the lamp in this direction is 250 lx. Note that the inverse square law is valid only when the light source is regarded as a point source. Sufficient distances relative to the size of the source are needed to assume this relationship.

Lambert's Cosine Law

The luminous intensity of a Lambertian surface element is given by

$$I(\theta) = I_n \cos\theta \tag{18}$$

(See Fig. 7.)

Lambertian Surface A surface whose luminance is the same in all directions of the hemisphere above the surface.

Perfect (Reflecting/Transmitting) Diffuser A Lambertian diffuser with a reflectance (transmittance) equal to 1.

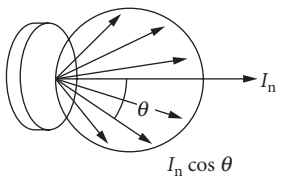

FIGURE 7 Lambert's cosine law.

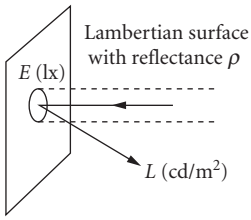

FIGURE 8 Relationship between illuminance and luminance.

Relationship between Illuminance and Luminance

The luminance L (cd/m^2) of a Lambertian surface of reflectance ρ, illuminated by E (lx) is given by

$$L = \frac{\rho \cdot E}{\pi} \tag{19}$$

(See Fig. 8.)

Reflectance (ρ) The ratio of the reflected flux to the incident flux in a given condition. The value of ρ can be between 0 and 1.

In the real world, there is no existing perfect diffuser nor perfectly Lambertian surfaces, and Eq. 19 does not apply. For real object surfaces, the following terms apply.

Luminance Factor (β) Ratio of the luminance of a surface element in a given direction to that of a perfect reflecting or transmitting diffuser, under specified conditions of illumination. The value of β can be larger than 1. For a Lambertian surface, reflectance is equal to the luminance factor. Equation (19) for real object is restated using β as

$$L = \frac{\beta \cdot E}{\pi} \tag{20}$$

Luminance Coefficient (q) Quotient of the luminance of a surface element in a given direction by the illuminance on the surface element, under specified conditions of illumination,

$$q = \frac{L}{E} \tag{21}$$

Using q, the relationship between luminance and illuminance is thus given by

$$L = q \cdot E \tag{22}$$

Luminance factor corresponds to radiance factor, and luminance coefficient corresponds to radiance coefficient in radiometry. BRDF (bidirectional reflectance distribution function) is also used for the same concept as radiance coefficient.

Integrating Sphere

An integrating sphere is a device to make a spatial integration of luminous flux (or radiant flux) generated (or introduced) in the sphere and to detect it with a single photodetector. In the case of measurement of light sources, the spatial integration is made over the entire solid angle (4π).

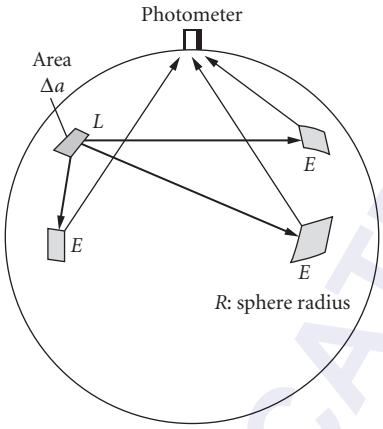

FIGURE 9 Flux transfer in a sphere.

In Fig. 1, assuming that the integrating sphere wall surfaces are perfectly Lambertian, the illuminance E on any part of the sphere wall created by luminance L of an element Δa is given by

$$E = \frac{L\Delta a}{4R^2} \tag{23}$$

where R is the radius of the sphere. This equation holds no matter where the two surface elements are. In other words, the same amount of flux incident anywhere on the sphere wall will create an equal illuminance on the detector port. In the case of actual integrating spheres, the surface is not perfectly Lambertian, but due to interreflections of light in the sphere, the distribution of reflected light will be uniform enough to assume the relationship of Eq. (23). (See Fig. 9.)

The direct light from an actual light source is normally not uniform; thus, it must be shielded from the detector. When a light source with luminous flux Φ is operated in a sphere having reflectance ρ, the flux created by interreflections is given by

$$\Phi(\rho + \rho^2 + \rho^3 + \cdots) = \Phi \cdot \frac{\rho}{1-\rho} \tag{24}$$

Then, the illuminance E_d created by all the interreflections is given by

$$E_d = \frac{\Phi \cdot \rho}{1-\rho} \cdot \frac{1}{4\pi \cdot R^2} \tag{25}$$

The sphere efficiency (E_d/Φ) is strongly dependent on reflectance ρ due to the term $1 - \rho$ in the denominator. For example, the detector signal at $\rho = 0.98$ is 10 times larger than at $\rho = 0.8$.

Planck's Law

The spectral radiance of a blackbody at a temperature T (K) is given by

$$I_e(\lambda, T) = c_1 n^{-2} \pi^{-1} \lambda^{-5} \left[\exp\left(\frac{c_2}{n\lambda T} \right) - 1 \right]^{-1} \tag{26}$$

where $c_1 = 2\pi hc^2 = 3.7417749 \times 10^{-16}$ W·m^2, $c_2 = hc/k = 1.438769 \times 10^{-2}$ m·K^2 (1986 CODATA from Ref. 9), h is Planck's constant, c is the speed of light in vacuum, k is the Boltzmann constant, n (= 1.00028) is the refractive index of standard air (12),[30] and λ is the wavelength.

Wien's Displacement Law

Taking the partial derivative of the Planck's equation with respect to temperature T, and setting the result equal to zero, the solution yields the relationship between the peak wavelength λ_m for Planck's radiation and temperature T(K), as given by

$$\lambda_m T = 2897.8\,\mu\text{m}\cdot\text{K} \tag{27}$$

This shows that the peak wavelength of blackbody radiation shifts to shorter wavelengths as the temperature of the blackbody increases.

Stefan-Boltzmann's Law

The (spectrally total) radiant exitance M_e from a blackbody in a vacuum is expressed in relation to the temperature T (K) of the blackbody, in the form

$$M_e(T) = \int_0^\infty M_e(\lambda, T)\,d\lambda = \sigma T^4 \tag{28}$$

where $M_e(\lambda, T)$ is the spectral radiant exitance of the blackbody, and σ is the Stefan-Boltzmann constant, equal to 5.67051×10^{-8} W·m^{-2}·K^{-4} (1986 CODATA from Ref. 9). Using this value, the unit for M_e is W·m^{-2}.

37.6 PRACTICE IN PHOTOMETRY AND RADIOMETRY

Photometry and radiometry are practiced in many different areas and applications, dealing with various light sources and detectors, and cannot be covered in this chapter. Various references are available on practical measurements in photometry and radiometry.

Further references in practical radiometry include books on absolute radiometry,[31] optical detectors,[32] spectroradiometry,[33] photoluminescence,[34] radiometric calibration,[35] etc. There are a number of publications from CIE that are regarded as international recommendations or standards. CIE publications in radiometry include reports on absolute radiometry,[36] reflectance,[37] spectroradiometry,[38] detector spectral response,[39] photobiology and photochemistry,[40] etc. There are also a number of publications from the National Institute of Standards and Technology (NIST) in radiometry, on spectral radiance,[41] spectral irradiance,[42] spectral reflectance,[43] spectral responsivity,[44] and so on (Ref. 45 provides greater depths of knowledge in radiometry).

For practical photometry, Ref. 4 provides the latest information on standards and practical measurements of photometry in many aspects. A recent publication from NIST[46] is also available. CIE publications are also available on many subjects in photometry, including characterization of illuminance meters and luminance meters,[47] luminous flux measurement,[48] measurements of LEDs,[49] characteristics of displays,[50] and many others. A series of measurement guide documents are published from the Illuminating Engineering Society of North America (IESNA) for operation and measurement of particular types of lamps[51–53] and luminaires. The American Society for Testing and Materials (ASTM) provides many useful standards and recommendations on optical properties of materials and color measurements.[54] Colorimetry is a branch of radiometry and is becoming increasingly important among color imaging industry and multimedia applications. The basis of colorimetry is provided by CIE publications[28,55,56] and many other authoritative references are available.[29,57]

38 SPECTRORADIOMETRY

Carolyn J. Sher DeCusatis

Pace University
White Plains, New York

38.1 INTRODUCTION

Spectroradiometry is the measurement of the spectral content of optical radiation. This has many important applications. The measure of terrestrial, direct, solar spectral irradiance between 295 and 305 nm can be used to calculate atmospheric ozone thickness.[1] More close to home, irradiance measurements are used to characterize light fixtures, and solar UV spectroradiometry methods also apply to the measurement of artificial sources that mimic the sun for applications like phototherapy to treat seasonal affective disorder (SAD) and tanning booths.[2] Transmission spectra are used to analyze the chemical composition of samples, such as the concentration of chlorophyll in a solution. Spectral reflectance quantifies the color of surfaces, with many practical applications to building, lighting, and design. Spectral responsivity is a necessary part of calibrating photodetectors.

38.2 DEFINITIONS, CALCULATIONS, AND FIGURES OF MERIT

Defining Quantities

There is a relationship between radiometric, photometric, and spectroradiometric quantities. Radiometric and photometric quantities, such as irradiance and luminous flux have been defined in other chapters of this book. Photometric quantities that are similar to radiometric quantities, such as radiant energy versus luminous energy, have the same symbol with a subscript of γ. In general, the spectroradiometric quantity that is defined by the similar radiometric quantity is preceded by the term "spectral," and designated by the symbol λ, either in parenthesis or with a subscript.

Spectral Irradiance is the quantity most frequently measured in spectroradiometry.[1] Irradiance E is the total radiant flux incident on an element of surface divided by the surface area of that element

$d\Phi/dA$, in watts per meter squared. The average spectral irradiance $\overline{E}_\lambda$ is the irradiance for a wavelength interval, or

$$\overline{E_\lambda} = \frac{\Delta\Phi}{\Delta\lambda \cdot \Delta A} \tag{1}$$

where $\Delta\Phi$ is the radiant flux within a wavelength interval $\Delta\lambda$ incident on a surface area ΔA. As the area and wavelength are made smaller, $\overline{E}_\lambda$ becomes the spectral irradiance for that wavelength,

$$E_\lambda(\lambda, P) = \frac{d^2\Phi}{d\lambda \cdot d\mathrm{A}} \tag{2}$$

where P is the position and λ is the wavelength. The SI unit for spectral irradiance is the watt per meter cube. However, more intuitive units, such as microwatt per square centimeter of area and per nanometer of wavelength ($\mu W \cdot cm^{-2} \cdot nm^{-1}$) are also used.

The spectral irradiance is dependant on the position, the size of the solid angle subtended, and the orientation of the surface. This leads to the cosine dependence, where the spectral irradiance of a point source is proportional to cosine θ, where θ is the angle between the normal to the surface and the direction of the source, and the inverse square law, relating to the distance between the point source and the detector.

When the radiation from a point source is emitted into a solid angle $d\Omega_s$ the *spectral radiance* L_λ is the flux per unit solid angle and per unit projected area perpendicular to the specified direction, per wavelength.

$$L_\lambda = \frac{d^3\Phi}{dA \cdot \cos\theta \cdot d\Omega \cdot d\lambda} \tag{3}$$

The unit for spectral radiance is $watt \cdot centimeter^{-2} \cdot steradian^{-1} \cdot nanometer^{-1}$.

Spectral radiance represents the flux density at a point for a particular direction through that point. While it is not usually the desired quantity an experiment is designed to measure, it is required for quantitatively analyzing data, and is also very useful for flux transfer calculations.

If you know the wavelength dependence of the radiant flux, you can also calculate *radiant flux* Φ, and *luminous flux* Φ_γ.

$$\phi = \int_\lambda \Phi(\lambda) d\lambda \quad \text{in watts} \tag{4}$$

$$\phi_\gamma = 683 \int_\lambda \Phi(\lambda) V(\lambda) d\lambda \quad \text{in lumens} \tag{5}$$

where $V(\lambda)$ is the relative photopic luminous efficiency curve (normalized at 555 nm). The absolute luminous efficacy at 555 nm is 683 lumens per watt.

Spectral transmittance $\tau(\lambda)$, which is widely measured during spectrometry, is

$$\tau(\lambda) = \phi^t(\lambda)/\phi^i(\lambda) \tag{6}$$

where t and i refer to transmitted and incident flux. The transmittance has two parts: the regular and diffuse transmittance. The regular transmittance follows Snell's law, while the diffuse transmittance is scattered by the roughness of the surface.

Similarly, *spectral reflectance* $\rho(\lambda)$ is also a flux ratio, but in this case, it is the ratio of the reflected radiant flux to the incident flux.

$$\rho(\lambda) = \phi^r(\lambda)/\phi^i(\lambda) \tag{7}$$

where r refers to reflected flux. The total reflectance is also composed of specular and diffuse components.

The *spectral responsivity* $R(\lambda)$ is the current from a detector divided by the incident flux for a specific wavelength.

$$R(\lambda) = r(\lambda)/\phi(\lambda) \tag{8}$$

where $r(\lambda)$ is the electric signal generated by the photodetector. The units of responsivity are amps per watt. Spectral responsivity is an important part of calibrating photodetectors. The spectroradiometer itself will be calibrated using a standard lamp.

Calculations

Since spectroradiometers provide the spectral content of light, it is natural to use their data to calculate color values. The *tristimulus values* for sources can be calculated,[3]

$$X = \sum_{\lambda=380}^{780} \bar{E}(\lambda)\bar{x}(\lambda)\Delta\lambda \tag{9}$$

$$Y = \sum_{\lambda=380}^{780} \bar{E}(\lambda)\bar{y}(\lambda)\Delta\lambda \tag{10}$$

$$Z = \sum_{\lambda=380}^{780} \bar{E}(\lambda)\bar{z}(\lambda)\Delta\lambda \tag{11}$$

where $E(\lambda)$ is the irradiance in watt $\cdot$ meters^{-1}, and $\bar{x}$, $\bar{y}$, and $\bar{z}$ are the CIE 1931 spectral tristimulus values.

When analyzing the reflection off an object, the values assume the color as seen under a standard light source.

$$X = k\sum_{\lambda=380}^{780} \bar{E}(\lambda)\Gamma(\lambda)\bar{x}(\lambda)\Delta\lambda \tag{12}$$

$$Y = k\sum_{\lambda=380}^{780} \bar{E}(\lambda)\Gamma(\lambda)\bar{y}(\lambda)\Delta\lambda \tag{13}$$

$$Z = k\sum_{\lambda=380}^{780} \bar{E}(\lambda)\Gamma(\lambda)\bar{z}(\lambda)\Delta\lambda \tag{14}$$

where $\Gamma(\lambda)$ is the *spectral reflectance* or *transmittance data*, and

$$k = \frac{100}{\sum_{\lambda=380}^{780} \bar{E}(\lambda)\bar{y}(\lambda)\Delta\lambda} \tag{15}$$

Since $\bar{y}(\lambda)$ is the photopic curve, k is a constant that can be used to couple the colorimetric (photometric) quantities with the radiometric ones. This can be expressed in equation form as

$$E_v[\text{lm cm}^{-2}] = 683Y[\text{W cm}^{-2}] \tag{16}$$

because absolute luminous efficacy of the photopic curve at 555 nm is 683 lumens per watt.

The CIE 1931 chromaticity x, y, z coordinates are

$$x = \frac{X}{X+Y+Z} \tag{17}$$

$$y = \frac{Y}{X+Y+Z} \tag{18}$$

$$z = \frac{Z}{X+Y+Z} \tag{19}$$

Similarly, the *R*, *G*, *B* tristimulus values are[4]

$$R = k\sum_{\lambda=380}^{780} P(\lambda)\bar{r}(\lambda)\Delta\lambda \tag{20}$$

$$G = k\sum_{\lambda=380}^{780} P(\lambda)\bar{g}(\lambda)\Delta\lambda \tag{21}$$

$$B = k\sum_{\lambda=380}^{780} P(\lambda)\bar{b}(\lambda)\Delta\lambda \tag{22}$$

where $P(\lambda)$ is the spectral power distribution in watts, and $\bar{r}$, $\bar{g}$, *and* $\bar{b}$ are the color-matching functions of the CIE 1931 Colorimetric Observer.

The UCS 1960 u and v coordinates, and the UCS 1976 u' and v' coordinates are[3]

$$v = \frac{6y}{12y - 12x + 3} = \frac{2}{3}v' \tag{23}$$

$$u = \frac{4x}{12y - 2x + 3} = u' \tag{24}$$

The *CIE LAB/LUV color space calculations* (1976) are calculated using the tristimulus values normalized equally to $Y = 100$. X_n, Y_n, and Z_n are the tristimulus values of the reference white. The coordinates can be defined in either the $L^*a^*b^*$ color space, or the $L^*u^*v^*$ color space. When X/X_n, Y/Y_n, and Z/Z_n are all greater than 0.01,

$$L^* = 116\left(\frac{Y}{Y_n}\right)^{1/3} - 16 \tag{25}$$

$$a^* = 500\left[\left(\frac{X}{X_n}\right)^{1/3} - \left(\frac{Y}{Y_n}\right)^{1/3}\right] \tag{26}$$

$$b^* = 200\left[\left(\frac{Y}{Y_n}\right)^{1/3} - \left(\frac{Z}{Z_n}\right)^{1/3}\right] \tag{27}$$

Otherwise

$$L^* = 116\left[f\left(\frac{Y}{Y_n}\right) - \left(\frac{16}{116}\right)\right] \tag{28}$$

$$a^* = 500\left[f\left(\frac{X}{X_n}\right)^{1/3} - f\left(\frac{Y}{Y_n}\right)^{1/3}\right] \tag{29}$$

$$b^* = 200\left[f\left(\frac{Y}{Y_n}\right)^{1/3} - f\left(\frac{Z}{Z_n}\right)^{1/3}\right] \tag{30}$$

where

$$f(Y/Y_n) = \left(\frac{Y}{Y_n}\right)^{1/3} \quad \text{for } Y/Y_n > 0.008\,856$$
$$f(Y/Y_n) = 7.787\left(\frac{Y}{Y_n}\right) + 16/116 \text{ for } Y/Y_n \le 0.008\,856 \tag{31}$$

and $f(X/X_n)$ and $f(Z/Z_n)$ are defined in the same way, and

$$u^* = 13L^*(u' - u_n') \tag{32}$$

$$v^* = 13L^*(v' - v_n') \tag{33}$$

These values represent a comparison to a standard illuminant for sources and an ideal white object illuminated by a standard illuminant for objects.[3]

The *correlated color temperature* is calculated using interpolation from a table of 30 isotemperature lines. Roberton's method, which uses successive approximation, should be accurate to within 0.1 μrad, with a maximum error from 1600 to 3000 K of less than 0.2 K plus the measurement uncertainty. This technique should only be used for sources with chromaticities farther than 0.01 from the Planckian locus.[3]

When using a spectroradiometer or spectrophotometer to measure transmission through a sample, the *Beer-Lambert law,* also known as *Beer's law* is used to calculate the *concentration* of a sample solution. The absorbance A is defines as

$$A = -\log_{10}(\tau) \tag{34}$$

where τ is the transmittance. The Beer-Lambert Law states:

$$A = cl\alpha \tag{35}$$

where c is the concentration, l is the path length, and α is the absorption coefficient.

The absorption coefficient is related to the wavelength by

$$\alpha = \frac{4\pi k}{\lambda} \tag{36}$$

where k is the extinction coefficient.

Figures of Merit

Spectroradiometry measurements have large errors compared to other physical measurements. During an intercomparison of solar ultraviolet monitoring between 14 instruments the measured solar irradiances agreed to within 3 percent when the instruments remained outdoors, but the spectral irradiance responsivities changed upon moving the instruments.[5] In a 2002 intercomparison study by the project Quality Assurance of Ultraviolet Measurements in Europe (QASUME), the spread of absolute irradiance between spectroradiometers was 12 percent(±6 percent).[6] There are two major reasons for the large uncertainties:

- The measurement has many dimensions—it is dependent on the magnitude of the flux, its position on the entrance aperture, its direction, its wavelength distribution, and its polarization.
- The instability of measuring instruments and standards, which are very dependent on room conditions such as temperature, and are frequently off by 1 percent or more.

Potential errors in spectroradiometer measurements include measurement noise, detector instability, wavelength instability, nonlinearity, directional and positional effects, spectral scattering, spectral distortion, polarization effects, and size of source effect.[1]

These errors can be characterized as[3]

- Random noise from the detector, electronics, and light source
- Systematic errors from
  The measurement of the geometry
  The calibration, including uncertainty from the calibration standard

Noncosine collection of light
Stray light
Nonlinearity of the detector and its electronics
Dark noise subtraction errors

- Periodic errors from drifts due to temperature, humidity, air movement, electronics, beating of AC sources, and changes in stray light

The way of calculating uncertainty was standardized in 1992 by the International Committee for Weights and Measures (CIPM), and the *Guide to the Expression of Uncertainty in Measurement* was published in 1993.[7] There are two ways to determine the uncertainty of a component: A. statistically or B. "usually based on scientific judgment using all the relevant information available."[8]

In spectroradiometry, Type B evaluation finds the upper and lower limits of the value (or correction), and then assumes a probability distribution between these values to obtain the standard uncertainty. If you have nothing to base the probability distribution on, you are instructed to assume that it is rectangular (uniform).

For example, for value a where $a=(a_+ - a_-)/2$, where a_+ is the upper limit and a_- is the lower limit, the standard uncertainty is $a/\sqrt{3}$, but assuming a triangular distribution makes it $a/\sqrt{6}$, and a Gaussian distribution makes it $a/3$.

The collected uncertainties for each identified potential error combines as the square root of the sum of the squares, called the *suggested* or *overall uncertainty*. Often this value is multiplied by a constant, under current international practice of value 2, to form the expanded uncertainty.

CIPM requires that all the standard uncertainties and their derivation are included in the uncertainty report.[7,8]

If your value for spectral irradiance can be expressed of the form

$$E_\lambda^{\text{report}} = E_\lambda^{\text{observed}} + c_1 + c_2 + c_3 + \cdots + c_n \tag{37}$$

where $E_\lambda^{\text{report}}$ is the reported spectral irradiance, $E_\lambda^{\text{observed}}$ is the measured value of the spectral irradiance, and the $c_i's$ are the corrections mentioned earlier in this section, then by the CIPM method, the uncertainty U is calculated from the uncertainties u of the parts as follows

$$U = 2\sqrt{u^2(E_\lambda^{\text{observed}}) + u^2(c_1) + u^2(c_2) + u^2(c_3) + \cdots + u^2(c_n)} \tag{38}$$

Spectroradiometers are calibrated by use of a standard, which has a known value with a reported error. Assuming your system is linear,

$$E_\lambda^{\text{obs}} = \frac{S}{S^s} E_\lambda^s \tag{39}$$

where S is the measurement and the superscript s refers to the standard.

Then, the uncertainty of the observed spectral irradiance can be calculated using

$$u(E_\lambda^{\text{obs}}) = E_\lambda^{\text{obs}} \sqrt{\left(\frac{u(S)}{S}\right)^2 + \left(\frac{u(S^s)}{S^s}\right)^2 + \left(\frac{u(E_\lambda^s)}{E_\lambda^s}\right)^2} \tag{40}$$

The values for $u(S)$ and $u(S^s)$ are typically calculated by a Type B evaluation, while the standard lamp's uncertainty $u(E_\lambda^s)$ is calculated from the uncertainty U reported by the standard lamp's supplier.[1]

38.3 GENERAL FEATURES OF SPECTRORADIOMETRY SYSTEMS

There are four parts in every spectroradiometer system

- Input or fore-optics
- A monochromator
- A detector
- Electronics and software to analyze data

There is a fifth aspect to every spectroradiometer system, although it is not usually included on these types of lists, because it is not a "part" of the spectroradiometer. However, I believe it is important to consider it while considering other fundamental parts of the system, because it is essential for the accurate measurement of optical radiation:

- Calibration, usually using standard lamps, reflectance standards, or a standard detector

The Input or Fore-Optics

The input optics gathers light from a specified field of view. The layout determines the quantity which is being measured. For example, when measuring spectral irradiance, the light must be diffused, so an integrating sphere or diffusing plate is used, but when measuring spectral radiance, imaging optics control the solid angle and source area, so a focusing mirror is typically used. Transmittance can be measured by placing a light source at the entrance of the system, and measuring the signal twice: with and without the object to be measured. However, an instrument dedicated to measuring transmittance may have a double beam optical design where the light source is split and recombines at the photodetector.

For measurements in the ultraviolet, or light below 190 nm, the radiation is absorbed by the oxygen in the air, so the whole system will be designed to be enclosed and under vacuum.

Telescoping input optics are used when the sources are large distances from the measurement system, turning a spectroradiometer into a telespectroradiometer. Mounting a microscope to the entrance port of the monochromator can make it possible to measure small radiating sources. Fiber-optic probes can be coupled directly to the monochromator, or in combination with any of the previously mentioned input optical devices.[3]

The Monochromator

The monochromator is the heart of the spectroradiometric system, because separating the radiation into its component wavelengths is the fundamental aspect of the system. While monochromators used to be made with prisms, they are now always made with diffraction gratings. Monochromators come in different sizes; a large monochromator will be more accurate, but a smaller monochromator can be easier to evacuate to measure the ultraviolet, or place in a dry carbondioxide-free enclosure to measure the infrared.

The monochromator is designed to collumnate and focus light. After the entrance slit, light hits a collumnating element. Since light is often diverging when it reaches the slit, a concave mirror can form it into a collimated beam directed at the grating.

Generally, the grating will rotate so this beam hits it at different angles. There are also monochromators with curved gratings, but they are limited in wavelength range.

The grating equation, which defines the wavelength of the diffracted flux to the angle of diffraction, is

$$m\lambda = d(\sin\theta \pm \sin\beta) \tag{41}$$

where m is an integer known as the *order of diffraction*, λ is the wavelength, d is the distance between grooves, θ is the angle of incidence, and β is the angle of diffraction. To remove higher orders ($m>1$), *blocking filters* that absorb short wavelengths while transmitting long wavelengths are used.

The maximum theoretical groove density is $2/\lambda$, although a practical limit is usually 0.85 of the maximum.

The efficiency of a monochromator is directly proportional to large grating area, short focal length, high groove density, long slit length, and high transmittance.[1] However, there is a trade-off between this efficiency and accuracy, which requires large focal lengths. The *f*-number is the focal distance divided by the entrance slit. Large *f*-numbers (>3 or 4) are required because the mirrors are spherical, not parabolic, and introduce errors.[3]

The *dispersion* is the width of the band of wavelengths per unit of slit width, in nm/mm. The *band pass* is the spectral interval that may be isolated. If the dispersion at a groove density k is known, then the band pass can be calculated

$$B=(n_k D(n_k)S)/n \tag{42}$$

where B is the bandpass (in nm), n_k (in grooves/mm) is the known groove density where $D(n_k)$ is its dispersion (in nm/mm), S is the slit width (in mm), and n (in grooves/mm) is the groove density of the grating used.

Bandpass should be small for the best precision. However, there is a trade-off between bandpass and *geometrical entendue* G the light gathering power of an optical system.

$$G=\frac{hnmG_A B}{F10^6} \tag{43}$$

where h is the slit height (mm), n groove density (groove/mm), m is order of the grating, G_A area of the grating(mm^2), B is the bandpass (nm), and F is the focal length (mm). The ratio h/F implies that the etendue may be increased by making the height of the entrance slit larger. However, this does not work as well in practice; increasing the height of the slit will increase stray light and may also increase the system aberrations, reducing the bandpass.

Geometrical entendue is a limiting function of system *throughput.*[9]

High signal, for which high throughput is necessary, is limited by bandpass. Sometimes the slit size is determined by other factors, like the field of view. But the slit size might be chosen to optimize other factors. In this case, monochromatic sources behave differently from broadband sources, and mixed sources are a combination of the two. For a fluorescent lamp, which is a mixed source, as you decrease the bandpass, the peaks due to the monochromatic lines become much higher in proportion to the broad emission spectra of the phosphors.[3]

In night vision systems, stray light becomes an important factor which affects system design. To limit stray light, a double monochromator system is used, where the output of the first monochromator is the input of the second one. This can reduce typical stray light levels from 10^{-4} to 10^{-8}.[3]

Some spectroradiometers are designed with multichannel detectors within the monochromator, or so multichannel detectors can be easily installed. Multichannel detectors can also eliminate the need to scan, reducing moving parts and allowing for longer integration times or quick measurements of unstable or short-lived sources. However, they are not suitable for all types of spectral irradiance and radiance measurements, and spectral transmission, reflection and responsivity require the monochromatic light to exit the monochromator and interact with samples.

The Detector

The desired wavelength range will strongly influence the type of detector used. In Table 1 the approximate wavelength ranges of different spectroradiometry detectors are shown. Other important factors in choosing a detector include the dynamic range, sensitivity, and response time required for the data, as well as environmental factors determining how rugged a detector is needed.

TABLE 1 Approximate Wavelength Ranges of Different Spectroradiometry Detector Types

Detector	Wavelength Range
PMT	200–850 nm
Si photodiode	200–1100 nm
Ge photodiode	1100–1800 nm
InGaAs photodiode	850–1700 nm
PbS photoconductor	1–4.5 μm
PbSe photodiode	1–4.5 μm
InSb photodiode	1.5–5 μm
Pyroelectric	500 nm–50 μm
CCD	200–1100 nm
InGas PDA	800–1700 nm

The two types of detectors most commonly used in spectroradiometry are photomultiplier tubes and semiconductor devices, although thermal detectors have some very limited applications. Detector sensitivity is measured in noise equivalent power (NEP) or equivalent noise input (ENI), which basically mean the same thing, the minimum detectable signal, whose units can betaken in watts.[1] The detectivity is the inverse of the NEP.

Photomultiplier tubes are the most sensitive detectors when used in their wavelength region, with ENIs ranging from 10^{-15} W at 1100 nm to 10^{-17} W from 850 nm to 200 nm and 5×10^{-16} W at 110 nm. They are usually used from 200–850 nm, their range of greatest sensitivity. Silicon photodiodes have NEPs reported of 2×10^{-14} W at 1100 nm, 10^{-15} W at 850 nm, 5×10^{-15} W at 350 nm, and 10^{-14} W between 300 and 200 nm. Silicon photodiodes are used in these wavelength ranges when the signal is sufficiently large, because they are more temperature stable and more rugged.[1]

From 1100 to 1800 nm, germanium photodiodes are the most sensitive, with NEPs in the 10^{-13} W range, and lead sulfide photoconductors the most sensitive from 1800–3800 nm, with NEPs ranging from 4×10^{-13} W to 4×10^{-12} W, although InAs may also be used in this range.[1]

Photomultipliers, germanium photodiodes, and PbS photoconductors would be cooled, but silicon photodiodes can operate at room temperature (25°C).

Thermal detectors are less sensitive, having NEPs of about 6×10^{-10} W, and have a flat response.[1]

When comparing detectors, it is also common to compare the normalized detectivity. There is some confusion in the nomenclature, in that sometimes this is D^*, and sometimes D^* refers to the specific detectivity, which has a different definition. Therefore, I will refer to the normalized detectivity as D_N.

$$D_N = D\sqrt{AB_w} \tag{44}$$

where D is the detectivity, A is the detector area, and B_w is the detector bandwidth.

For example, the D_N of an InAs photodiode is roughly the same as that of a PbS photoconductor at 3000 nm, and the rise time for InAs is one thousandth of PbS. At that specific wavelength, the two detector types have equivalent sensitivity, but InAs has a faster response. However, the D_N drops off more rapidly for InAs at longer and shorter wavelengths than for PbS.[1]

Multichannel detectors are sometimes used for spectroradiometry. They have the advantage in spectral irradiance and radiance measurements that they can eliminate the need to scan, reducing moving parts and allowing for longer integration times, as well as making measurements of nonstable sources or short-lived, such as flashbulbs, explosions, and solar measurements during changing weather conditions, possible. Silicon photodiode linear arrays (PDAs) and charge-coupled detectors (CCDs) both singly and with microchannel plates (intensified arrays) are used, as well as a combination of microchannel plates with resisitive film called resisitive anode (MCP-RA's).[1] These detectors are temperature dependent and therefore require cooling. Noise is also a factor.

The NEP of array detectors is measured with respect to integration time. This is because array detectors operate in the capacitive-discharge mode, which collects charge for a period of time before

TABLE 2 A Comparison of the NEP in Watts of Five Different Multichannel Detector Types with 5-Second Integration Times.

Detector Type	250 nm	550 nm	850 nm	1100 nm
Si PDA at −40°C	$1.4\ 10^{-15}$	$2.7\ 10^{-16}$	$2.2\ 10^{-16}$	$1.3\ 10^{-15}$
CCD at −110°C	$6.0\ 10^{-18}$	$1.6\ 10^{-18}$	$1.0\ 10^{-18}$	$2.5\ 10^{-17}$
Intensified Si PDA at −40°C	$1.3\ 10^{-18}$	$8.2\ 10^{-19}$	$1.1\ 10^{-17}$	
Intensified CCD at −110°C	$1.3\ 10^{-18}$	$8.3\ 10^{-19}$	$1.1\ 10^{-17}$	
MCP-RA at −30°C	$2.0\ 10^{-18}$	$1.3\ 10^{-18}$	$7.3\ 10^{-18}$	

This data is compiled from Tables 15.4, 15.6, 15.7, 15.9, and 15.11 of Ref. 1.

discharging, which will be discussed in more detail in the next section on electronics and software. However, in Table 2 you can see a comparison of the NEP of the five different types of detectors at integration times of 5 seconds. It can be noted that CCD detectors have NEPs comparable with photomultiplier tubes, even without the advantage of multichannel detection.

While the detectors compared above were all cooled, there exist many commercial spectroradiometers with multichannel detectors which are not cooled for applications where sensitivity is less important, such as projector calibration and film and video post production.

Signal to noise ratio is also a major concern when comparing detector types, but that is also dependent on the integration time. As a general rule, the signal to noise ratio is much lower for PDAs than other multichannel detectors, but at 0.5 second integration times, CCDs are superior.[1]

Spectral scattering is a more important concern with multichannel detectors than with single detectors. Interference filters are used to block the short wavelength scattered flux.

The Electronics and Software

In "The Detectors" section we have discussed photomultiplier tubes, semiconductor detectors (photodiodes and photoconductors), PDA-based detectors, and CCD-based detectors.

Photomultiplier tubes use a 250- to 2500-V power supply, and the gain of the detector is adjusted by changing the voltage of the power supply. The signal is the anode current, and the simplest way of measuring it is measuring the voltage drop over a load resistor. However, many problems can be eliminated by using an operational amplifier with a feedback resistor instead, creating a transimpedance current to voltage converter. For even lower signal to noise ratios, integrated current is used as the signal, and the amplifier is chosen to have a short enough time constant that the entire anode current is integrated during the entire sampling time. It is important to make sure that the integrating time is properly matched with the scanning time.

Photodiodes are usually used in the photovoltaic or unbiased mode to minimize noise. In this mode a voltage amplifier with a high-input impedance measures the voltage generated across the photodiode.

Photoconductors decrease in resistance when absorbing radiant flux. The detector is placed in series with a load resistor and a bias voltage. As the resistance of the detector decreases there is an increase in the voltage over the load resistor.

Lock-in amplifiers are often used with semiconductor detectors to decrease 1/f noise.

PDA-based detectors operate in the capacitive-discharge mode where the photodiodes store charge as well as sense light. The diodes are reverse biased for 5 V and then electrically isolated while being exposed to light. After an integration time, the charge required to bring the diode back to 5 V is measured.

CCD-based detectors have arrays of pixels that convert radiation to charge. Parallel gates between the pixels can release the charge at will. The charge is then moved along the channels of the arrays by changing the voltage at the gates, until it reaches an output shift register at the end of the channel. The charge is then amplified and measured. Sometimes neighboring pixel's values are intentionally combined, which is known as *binning* or *pixel summation*.

While the readout of a single detector's signal can be as simple as a digital voltmeter, in most cases spectroradiometric data will be recorded by a computer. Often it will be part of an automated system that also controls the drive mechanism. After the information is recorded by the computer, it is analyzed by the computer software. Examples of typical calculations performed on spectroradiometric data are in Sec. 38.2 "Definitions, Calculations, and Figures of Merit" under Calculations.

Calibration

To calibrate a spectroradiometer for irradiance and radiance, standard lamps are usually used, although standard detectors are available. While spectroradiometric standards available for use over the visible are based on the spectral radiance of a blackbody as defined by Planck's radiation law, most commercially available blackbodies are used primarily in the infrared at wavelengths above 1000 nm. Blackbodies suitable for the visible are very expensive because they must operate at temperatures of 2500 K or higher, and are not practical for normal laboratory calibrations.[3]

Standard lamps introduce a certain degree of error; in the ultraviolet intercomparison in 2002 where the error was 12 percent(±6 percent), 6 percent of that error was attributed to the calibration lamps.[6] In earlier intercomparisons, it was more like 1.4 percent from 250 to 2400 nm, but 3 to 4 percent in the infrared.[1]

Different lamps are used to calibrate over different wavelength regions. From wavelengths of 250 to 2400 nm, tungsten lamps are used; below 250 nm, a deuterium lamp, argon miniarc, or synchrotron radiation are used.[1]

In Table 3 the wavelength range of frequently used spectral irradiance and spectral radiance source standards is listed.

For a discussion of the history of calibration standards, and some additional standards see reference.[3]

The FEL 1000-W tungsten lamp is the most widely used source standard for spectral irradiance. It is a commercially available 1000-W clear quartz envelope tungsten-halogen, coiled coil filament lamp that is modified to a medium bipost base with 1/4-inch diameter stainless steel posts. It is 5 inches high with a filament about 1 inch long and 1/4 inch in diameter. It is operated at 8-A DC and about 120 V. It is mounted base down with the steel post vertical and the optic axis of the spectroradiometer is horizontal. For more details of the calibration procedure, see reference.[1]

It is important to recognize that any individual standard lamp may develop problems. It is recommended to have three standard lamps, so if one changes significantly, you still will have two that agree. It is also standard procedure to transfer the calibration of your newly acquired standards to working standards, lamps that you calibrate using your detector and the NIST traceable standards that have been shipped to you. These lamps can be commercially acquired, but then you must age them for 40 hours at 120-V DV and check them for stability; they must have a drift of less than 0.5 percent at 650 nm in 24 hours. The working standard should be compared to your three purchased standards after 50 to 100 hours of use.

The responsivity of the spectroradiometer can be modeled from a measurement equation, although it is necessary to actually calibrate any system.

TABLE 3 The Wavelength Range of Frequently Used Spectral Irradiance and Spectral Radiance Source Standards

Irradiance	
Tungsten FEL lamp	250–2400 nm
Deuterium lamp	165–350 nm
Argon mini-arc	90–350 nm
Radiance	
Tungsten strip lamp	225–2400 nm
Blackbody below 1000 K	1000–4000 nm
Argon miniarc	90–350 nm

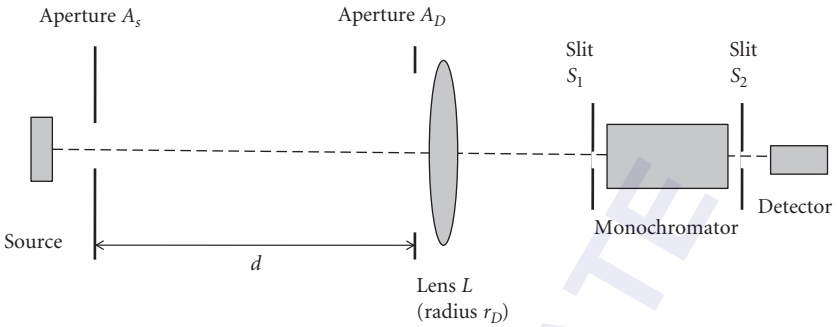

FIGURE 1 A schematic of the experimental setup to measure the spectroradiometer's responsivity.

If the monochromator is set to a wavelength λ_0, the spectral responsivity $R(\lambda_0, \lambda)$ can be separated into two parts: the slit scattering function $\rho(\lambda_0, \lambda)$ which is an envelope around wavelength λ_0 and the overall responsivity as a function of wavelength $R^f(\lambda)$

$$R(\lambda_0, \lambda) = \rho(\lambda_0, \lambda) R^f(\lambda) \tag{45}$$

When put in an experimental setup shown in Fig. 1, the signal response for a monochromator, ignoring small corrections, is

$$r(\lambda_0) = \frac{A_S A_D}{(r_S^2 + r_D^2 + d^2)} \int_\lambda L_\lambda(\lambda) \rho(\lambda_0, \lambda) R^f(\lambda) d\lambda \tag{46)}$$

where A_s is a circular aperture in front of a standard radiometric source of radius r_s, A_D is an aperture a distance d away from the source in front of a focusing lens L of radius r_D, and $L_\lambda(\lambda)$ is of the Lambertian calibration source.[10]

If the constants are collected in a term C, and a suitably averaged luminance is used, the signal response can be calculated by

$$r(\lambda_0) = C L_\lambda(\lambda_0) \int_\lambda \rho(\lambda_0, \lambda) R^f(\lambda) d\lambda \tag{47}$$

Detector standards are also available. In this case, the assumption is that any drift is not very wavelength specific. It is possible to interpolate between calibration laser wavelengths using a blackbody,[10] but that is not usually done, because it is very time consuming and probably an insignificant difference within the larger sources of error.[1] Detectors that presently are suitable for use in transfer standards include silicon, germanium, and InGas photodiodes, and certain types of thermal detectors. The basic approach is to have the two detectors measure the same sources. A typical source is a continuous wave (CW) laser directed at the entrance aperture of an integrating sphere. Types of lasers which can be used are helium-neon, argon, krypton, helium-cadmium, Nd:Yag, and Ti:sapphire.[11] When using a detector standard to calibrate a spectroradiometer's spectral irradiance, the area of the entrance aperture and spectral slit width become important and must be taken into account, so it is not a simple measurement.[1]

Spectroradiometers are used for reflectance measurements as well as irradiance and radiance measurements. For these purposes, reflectance standards are used for calibration. A number of reflectance standards are available which have been developed for spectroscopy applications, as well as to calibrate colorimeters and spectrophotometers. Specular reflectance standards are calibrated mirrors, and diffuse reflectance standards are made of material similar to the inside of integrating spheres.

Labsphere makes Spectralon into a diffuse white standard and a selection of diffuse gray and color standards, which are calibrated and NIST traceable. Halon, a trade name for polytetrafluoroethylene

(PTFE) powder (which is also used to coat integrating spheres) is also used to make NIST traceable reflectance standards. In a round-robin intercomparison of bidirection diffuse reflectance (BRDR) four types of diffuse reflectors (spectralon, halon, sintered halon, and vacuum deposited aluminum on a ground aluminum surface) were measured at five laboratories. These four types of standards were chosen because of their different scattering mechanisms; Spectralon and pressed PTFE scatter from the bulk, aluminum scatters from the surface, and sintered PTFE scatters from both the bulk and the surface. The purpose of this experiment was to test the laboratories, not the standards, but there was general agreement with the NIST specifications to 2 percent.[12]

38.4 TYPICAL SPECTRORADIOMETRY SYSTEM DESIGNS

Spectral Irradiance and Radiance

The input optics for spectral irradiance measurements require a diffuser in order to eliminate or reduce directional, positional, and polarization effects. This diffuser can be an integrating sphere coated with Halon, which is the best choice for sunlight and large or irregularly shaped sources, a plane reflector diffuser coated with $BaSO_4$, or a transmitting diffuser made of teflon.

In Fig. 2 we see a block diagram of a spectroradiometer designed to measure spectral irradiance. The basic steps that have to be taken are the signal must be diffused (cosine corrected), then wavelength selected by the monochromator, after which it is detected by the detector, amplified and analyzed.

In certain special cases, such as when measuring the spectral irradiance of point sources or collumnated sources, and if the spectroradiometer responds uniformly over the angular field viewed, no input optics are necessary. However, most of the time input optics are necessary. In Fig. 3 we see a typical setup of the input optics for measuring the irradiance of a large source using a small integrating sphere and a spherical mirror. A typical small sphere may have a 2.5-cm outer diameter with a 3-mm-thick PTFE coating (or $BaSO_4$ in the 310 to 350 nm wavelength region, where PTFE fluoresces weakly), and a circular entrance port of 1 cm^2 and a rectangular exit port with dimensions

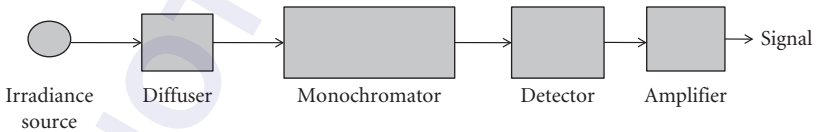

FIGURE 2 Block Diagram to measure spectral irradiance.

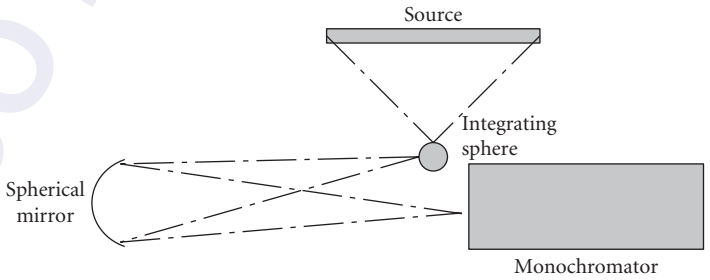

FIGURE 3 Typical setup of the input optics for measuring the irradiance of a large source using a small integrating sphere and a spherical mirror.

3 mm × 12 mm. The radiation which has one reflection does not get into the monochromator because it is reflected away from the spherical mirror. The radiation that does reach the monochromator is independent of the direction and position of the incident flux. However, it is worth noting that the attenuation of a system of this type is large.

In Fig. 4 we see more compact input optics to measure irradiance. The disadvantages are that the sphere is harder to reach, position, and orient, and more stray flux reaches the monochromator.

In Fig. 5 we see typical input optics using a plane diffuser instead of an integrating sphere. In Fig. 6 we see typical input optics using a transmitting diffuser.

In Fig. 7 we see the schematic of a single monochromator and Fig. 8 we see the schematic of a double monochromator. Both of these designs assume an external detector outside the exit slit. In Fig. 9 we see the layout of a single grating monochromator with a built-in multichannel detector.

The input optics for measuring spectral radiance form an image of the source on the entrance port of the monochromator. Possible geometries include a plane and spherical mirror which focus

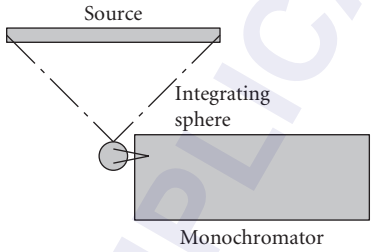

FIGURE 4 Measuring irradiance directly using an integrating sphere.

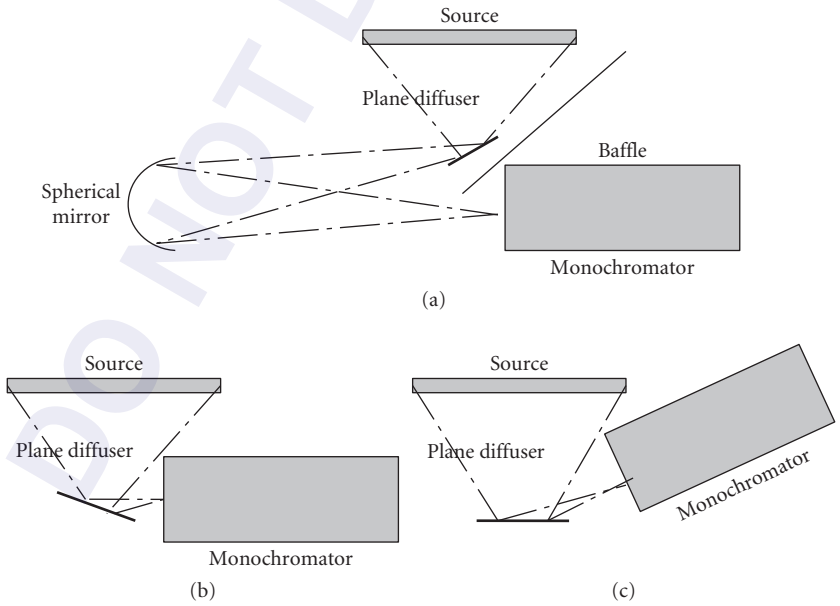

FIGURE 5 Typical setups using a plane diffuser to measure irradiance: (*a*) with a spherical mirror, (*b*) and (*c*) directly reflected off the diffuser into the sphere.

the radiation on the entrance slit, and a field of view baffle attachment to limit the acceptance angle of the monochromator.

In Fig. 10 we see the simplest input optics for measuring spectral radiance. However, it is much more likely you are using a system that measures both irradiance and radiance. In that case, your input optics are more likely to look like Fig. 11, where a mirror will reflect the light away from the integrating sphere, and toward the spherical mirror.

The same monochromator and detection electronics would be used for irradiance and radiance measurements.

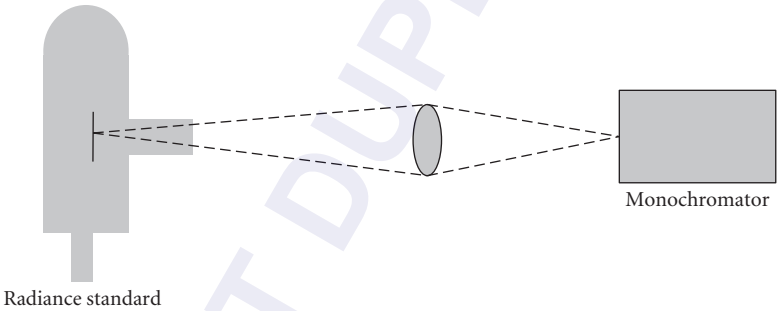

FIGURE 10 Measuring spectral radiance.

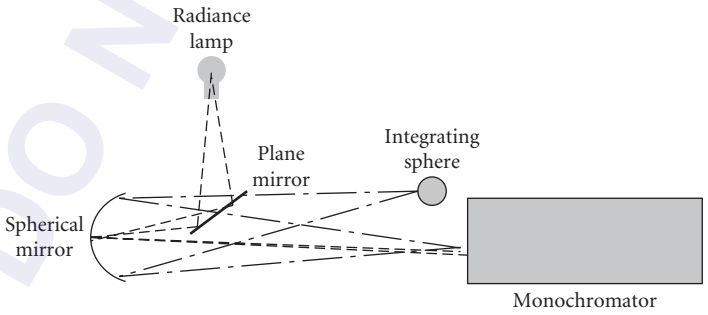

FIGURE 11 System for measuring both irradiance and radiance. The radiance setup adds a plane mirror and measures the radiance lamp. The irradiance setup removes the plane mirror and measures light after it passes the integrating sphere.

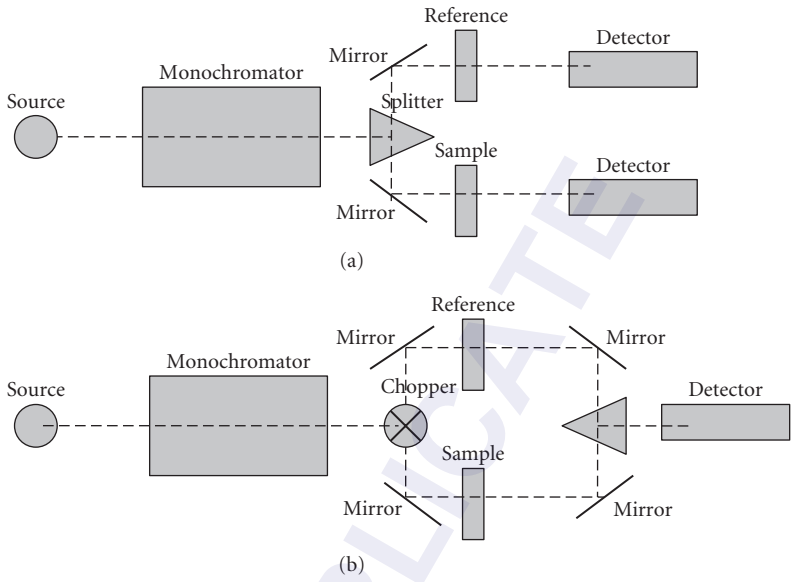

FIGURE 12 Spectrophotometer measuring spectral transmission: (*a*) dual-beam design and (*b*) double beam design.

Spectral Transmittance

Spectral transmittance measurements use the source and monochromator to create monochromatic radiation, rather than to measure it. The goal is to pass the radiation through a sample, to measure the sample's properties. This application is of vast importance to biology and chemistry, and there are many commercially available spectroradiometers dedicated to measuring transmittance and reflectance, known as *spectrophotometers*.

Chemists use absorbance spectroscopy to obtain qualitative and quantitative information about samples, using the Beer-Lambert law, also known as Beer's law, as was discussed in Sec. 38.2. Most spectrophotometers use a dual or double beam configuration, as is shown in Fig. 12. This experimental design measures regular transmittance, the signal that passes directly through the sample without being scattered and follows Snell's law. The output is the ratio of the signal in the sample beam to the signal in the reference beam with respect to wavelength. It is necessary to ensure that the only difference between the sample beam and the reference beam is the quantity to be measured, which implies that liquid cells with equal amounts of solute, or gas cells with equal amount of carrier gas, should be placed in the reference beam.[13]

Because of fluorescence, broadband illumination may have different results than monochromatic illumination. This should be considered when measuring transmittance and the setup should approximate the same manner in which the material will be used. Total spectral transmission, which is a combination of regular and diffuse transmission requires the addition of an integrating sphere after the beam transmits through the sample.[3]

Spectral Reflectance

Manufacturers use spectral reflectance information to provide color information about inks and textiles. There exist several spectral libraries (USGS,[14] Johns Hopkins,[15] JPL[16]) which contain almost 2000 spectra of powdered materials for use in spectroscopy, measured by using spectrophotometers and spectrometers in the diffuse reflectance mode.

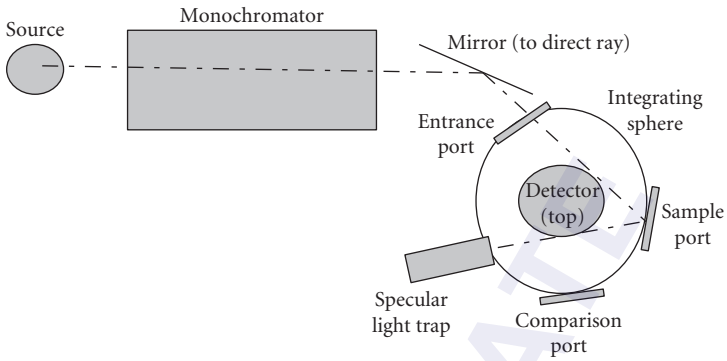

FIGURE 13 Schematic of a spectroradiometer measuring diffuse spectral reflectance.

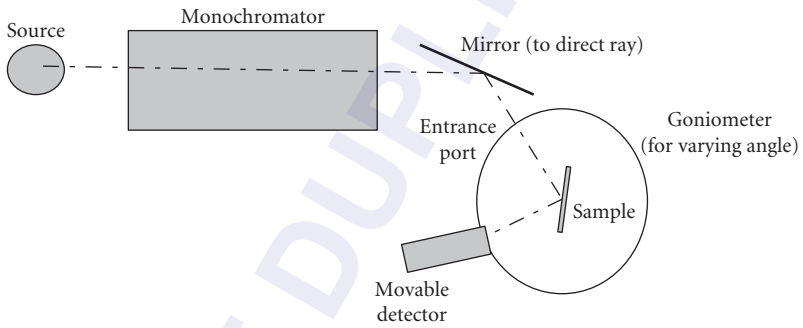

FIGURE 14 A schematic of a spectroradiometer measuring specular spectral reflectance.

Figure 13 is a spectroradiometer configured for measuring diffuse spectral reflectance. There is a double beam design, allowing for the comparison method of using a diffuse reflectance standard. An integrating sphere collects the diffuse radiation, with a removable light trap allows the user to block spectral reflectance. If the light trap is not in place, total reflectance, rather than diffuse reflectance, is measured. The sample to be measured is placed in the sample port, and the standard is placed in the comparison port. The detector is perpendicular to the samples and the incident radiation.

Figure 14 is a spectroradiometer configured for measuring specular spectral reflectance. Specular reflectance can be measured at various angles of incidence, including 0° for a 100 percent reading. A calibrated mirror (specular reflectance standard) is not necessary in this design.

Spectral Responsivity

In 38.3 General Features of Spectroradiometer Systems under "Calibration" we discussed how to calculate the spectral responsivity (see Fig. 1) of the spectroradiometer. Once that is known, spectroradiometers can be used to find the spectral responsivity of other detectors.

A spectroradiometer can be configured to measure detector spectral responsivity. The first step uses the spectroradiometer's standard detector to measure the monochromatic flux or irradiance of the source, generating a function $r^s(\lambda)$ for the standard detector, which has a known responsivity of $R^S(\lambda)$.

These values should not be confused with the responsivity of the total spectroradiometer system. This responsivity of the spectroradiometer system includes both the scatter from the slits and the detector responsivity. In this case we a singling out the detector responsivity. A NIST traceable standard silicon detector is usually used for measurements over the visible spectrum.[3]

Then the detector is replaced with the detector to be tested, and a signal response of $r^t(\lambda)$ is generated. The responsivity of the test detector $R^t(\lambda)$ will be

$$R^t(\lambda) = r^t(\lambda)/\Phi(\lambda) = r^t(\lambda)R^s(\lambda)/r^s(\lambda) \tag{48}$$

NONIMAGING OPTICS: CONCENTRATION AND ILLUMINATION

William Cassarly

Optical Research Associates
Pasadena, California

39.1 INTRODUCTION

Nonimaging optics is primarily concerned with efficient and controlled transfer of radiation. *Nonimaging* refers to the fact that image formation is not a fundamental requirement for efficient radiation transfer; however, image formation is not excluded and is useful in many cases. The two main aspects of radiation transfer that nonimaging optics attempts to solve are maximizing radiation transfer and creating a controlled illuminance distribution. These two problem areas are often described as *concentration* and *illumination.* Many systems require a blending of the concentration and illumination aspects of nonimaging optics, with an important example being the creation of a uniform illuminance distribution with maximum collection efficiency.

Solar collection is an area in which one of the dominant requirements is to maximize the concentration of flux collected by a receiver of a given size (e.g., the irradiance). Any small patch of area on the receiver surface can collect radiation from a hemispherical solid angle. A related problem exists in the detection of low levels of radiation (e.g., Cherenkov counters,[1] infrared detection,[2] and scintillators[3]). Nonimaging optics provides techniques to simultaneously maximize the concentration and collection efficiency. The compound parabolic concentrator[4] is the most well known nonimaging device and has been extensively investigated over the past 40 years.

In addition, there are situations in which collected solid angle must be less than a hemisphere, but the flux density must still be maximized. For a given solid angle and receiver size, the problem is then to maximize the average radiance rather than the irradiance. For example, many fibers only propagate flux that enters the lightpipe within the fiber's numerical aperture (NA), and minimizing the size of the fiber is a key aspect to making practical fiber optic lighting systems.[5] Projector systems often require maximum flux density at the "film gate," but only the flux reimaged by the projection lens is of importance.[6,7]

The collected flux must often satisfy certain uniformity criteria. This can be especially important when the luminance of the source of radiation varies or if the flux is collected in a way that introduces nonuniformities. Nonimaging optics provides techniques to control the uniformity. Uniformity control can sometimes be built into the optics used to collect the radiation. In other cases, a separate component is added to the optical system to improve the uniformity.

Uniformity control tends to be created using two main approaches: tailoring and superposition. Tailoring transfers the flux in a controlled manner and uses knowledge of the source's radiance distribution.[8] Superposition takes subregions of a starting distribution and superimposes them to provide an averaging effect that is often less dependent on the details of the source than tailoring. In many systems, a combination of tailoring and superposition is used. Examples of nonimaging approaches to uniformity control include mixing rods, lens arrays, integrating spheres, faceted reflectors, and tailored surfaces.

The emphasis of this chapter is on the transfer of incoherent radiation. Many of the techniques can be applied to coherent radiation, but interference and diffraction are only mentioned in passing.

39.2 BASIC CALCULATIONS

Some of the terms used in nonimaging optics have yet to be standardized. This section is an effort to collate some of the most common terms.

Photometric and Radiometric Terminology

Understanding nonimaging optics can sometimes be confusing if one is not familiar with photometric and radiometric terminology. This is especially true when reading papers that cross disciplines because terminology usage has not been consistent over time. Reference 9 discusses some of these terminology issues.

This chapter is written using photometric terminology. Photometry is similar to radiometry except that photometry weights the power by the response of the human eye. For readers more familiar with radiometric terminology, a chart showing the relationship between some of the most common photometric terms and radiometric terms is shown in Table 1. Reference 10 describes radiometry and photometry terminology in more detail.

Exitance and *emittance* are similar terms to *irradiance;* however, they denote the case of flux at the surface of a source, whereas irradiance applies to any surface. There are numerous textbooks and handbooks on radiometry and photometry.[11–16]

Etendue

Etendue describes the integral of the area and the angular extents over which a radiation transfer problem is defined. Etendue is used to determine the trade-off between the required area and angular extents in nonimaging optic designs. Reference 17 provides a brief review of various etendue descriptions with copious references to other work.

TABLE 1 Photometric and Radiometric Terminology

Quantity	Radiometric	Photometric
Power or flux	Watt (W)	Lumen (lm)
Power per unit area	Irradiance, W/m^2	Illuminance, lm/m^2 = lux (lx)
Power per unit solid angle	Radiant intensity, W/sr	Luminous intensity, lm/sr = candela (cd)
Power per unit solid angle per unit projected area or Power per unit projected solid angle per unit area	Radiance, W/m^2-sr	Luminance, cd/m^2

One definition of etendue is

$$\text{etendue} = n^2 \iint \cos(\theta) dA d\Omega \tag{1}$$

where n is the index of refraction and θ is the angle between the normal to the differential area dA and the centroid of the differential solid angle $d\Omega$.

In phase space nomenclature (e.g., Ref. 4, Appendix A), etendue is described by

$$\text{etendue} = \iint dx\,dy\,n\,dL\,n\,dM = \iint dx\,dy\,dp\,dq \tag{2}$$

where dL and dM *are* differential changes in the direction cosines (L, M, N), dx dy is the differential area, and dp dq is the differential projected solid angle within the material of index n. The term *phase space* is often used to describe the area and solid angle over which the etendue integral is performed.

Luminance

Luminance divided by the index of refraction squared is the ratio of the differential flux $d\Phi$ to the differential etendue:

$$L/n^2 = d\Phi/d\ \text{etendue} = d\Phi/[n^2 \cos(\theta) dA d\Omega] \tag{3}$$

The L/n^2 over a small area and a small angular extent is constant for a blackbody source (e.g., Ref. 18, p. 189). A consequence of constant L/n^2 is that if optical elements are added to modify the apparent area of the small region, then the angular extent of this small area must also change.

If the source of radiation is not a blackbody source, then flux that passes back to the source can either pass through the source or be reflected by the source. In this case, L/n^2 can increase. One example occurs with discharge sources where a spherical mirror is used to reflect flux back through the emitting region. Another example is observed by evaluating the luminance of tungsten in a coiled filament. The luminance is higher at the filament interior surface than the exterior surface because the interior filament surface emits radiation and also reflects radiation that is emitted from other coils.

Lambertian

In many situations the luminance of a radiation source does not vary as a function of angle or position. Such a source is often called a *Lambertian radiator.* In some nonimaging literature, the term *isotropic* is used. The context in which *isotropic* is used should be evaluated because *isotropic* is sometimes used to describe isotropic intensity instead of isotropic luminance.

If constant L/n^2 can be assumed for a given system, then etendue is an important tool for understanding the trade-offs between angular and spatial distributions. Etendue has been used to understand the limits to concentration,[4] projection display illumination,[19] and backlit display illumination.[20] Reference 21 investigates the situation where there is a spectral frequency shift.

In the imaging community, etendue conservation arises in many situations and is often described using the Lagrange invariant. Because imaging systems can often make paraxial assumptions, the approximation tan (θ) = sin (θ) is often used; however, sin (θ) should be used when the collection angles become large.

Clipped Lambertian

An aperture with a clipped Lambertian distribution is one where the source of flux appears to be Lambertian, but only over a finite range of angles. Outside of that range of angles, there is no flux and the range of angles is assumed to be constant across the aperture. The most common example is

when the source is at infinity and the flux at a planar aperture is considered. A clipped Lambertian distribution is also often found at an intermediate surface within an optical system. The terms *limited Lambertian* and *restricted Lambertian* are also used.

Generally, a clipped Lambertian distribution is defined across an aperture and the illuminance across the aperture is constant (e.g., a spatially uniform clipped Lambertian distribution). Another common distribution is a spatially uniform apodized Lambertian. In this case, the angular distribution is spatially uniform but the luminance is not Lambertian. A clipped Lambertian is a special case of an apodized Lambertian. The output of a fiber-optic cable is often assumed to have a spatially uniform apodized Lambertian distribution.

The etendue for clipped Lambertian situations is straightforward to compute. Consider the case of an infinite strip of width *2R* with a clipped Lambertian distribution defined between $\pm\theta_{max}$, relative to the surface normal. The etendue per unit length for this 2D clipped Lambertian case is

$$\text{etendue}_{2D} = n(2R)(2\sin\theta_{max}) \tag{4}$$

2D refers to a trough or extruded geometry and typically assumes that the distribution is infinite in the third dimension. Mirrors can often be placed at the ends of a finite length source so that the source appears to be infinitely long.

For a Lambertian disk with a half cone angle of θ_{max}, the etendue is

$$\text{etendue}_{3D} = n^2\text{Area}\,\pi\sin^2\theta_{max} = n^2\pi R^2\pi\sin^2\theta_{max} \tag{5}$$

In a system where the etendue is preserved, these etendue relationships highlight that increasing either θ_{max} or R requires a reduction in the other, as depicted in Fig. 1.

Hottel Strings

The etendue relationships described by Eqs. (4) and (5) are primarily defined for the case of a clipped Lambertian source. Such situations arise when the source is located at infinity (e.g., solar collection) or when considering the output of a fiber-optic cable. When the angular distributions vary spatially, Ref. 22 provides a method to compute the etendue that is very simple to use with 2D systems. The method is straightforward for the case of a symmetric system or an off-axis system, and even if there is an absorber positioned between the two apertures. The method is depicted in Fig. 2, where the etendue of the radiation that can be transferred between AB and CD is computed.

For a rotationally symmetric system, the etendue between two apertures (e.g., left side of Fig. 2) has been shown by Ref. 23 to be $(\pi^2/4)$ (AD–AC)^2. Reference 24 has provided a generalized treatment of the 3D case.

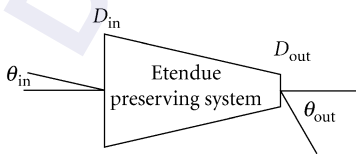

FIGURE 1 Graphical representation of etendue preservation.

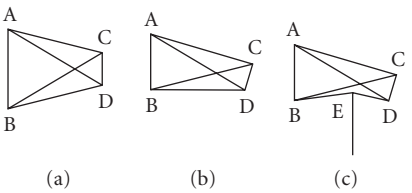

FIGURE 2 Hottel's crossed string relationship for computing etendue. This figure shows a symmetric case (*a*) and an asymmetric case (*b*) where the 2D etendue between aperture AB and CD is (AD-AC + BC-BD). In (*c*), radiation is blocked below point E and the etendue is (AD-AC + BC-BED).

Solid Angle and Projected Solid Angle

Solid angle is the ratio of a portion of the area of a sphere to the square of the sphere radius (see Chap. 3, and Refs. 24 and 25) and is especially important when working with sources that radiate into more than a hemisphere. Solid angle is directly applicable to point sources; however, when the size of the sphere is large enough, the solid angle is still used to characterize extended sources. For solid angle to be applied, the general rule of thumb is that the sphere radius should be greater than 10 times the largest dimension of the source, although factors of 30 or more are required in precision photometry (e.g., Ref. 26, pp. 4.29–4.31).

The etendue is sometimes called the *area-solid angle product;* however, this term can often cause confusion because etendue is actually the projected-area-solid-angle product [$\cos\theta\, dA\, d\Omega$] or area-projected-solid-angle product [$dA\cos\theta\, d\Omega$]. Reference 27 discusses some distinctions between projected solid angle (PSA) and solid angle. An important implication of the cosine factor is that the solid angle for a cone with half angle θ is

$$\text{Solid angle}_{\text{cone}} = 2\pi[1-\cos\theta] = 4\pi\sin^2(\theta/2) \tag{6}$$

but the projected solid angle for the cone is

$$\text{Projected solid angle}_{\text{cone}} = \pi\sin^2\theta \tag{7}$$

For a hemisphere, the solid angle is 2π and the PSA is π. This factor of 2 difference is often a source of confusion. PSA and solid angle are pictured in Fig. 3.

If the luminance at the receiver is constant, then PSA times luminance provides illuminance. Nonuniform luminance can be handled using weighted averages.[28]

In the 2D case, the projected solid angle analog is simply projected angle, and is 2 sin θ for angles between $\pm\theta$ or $|\sin\theta_1 - \sin\theta_2|$ for angles between θ_1 and θ_2.

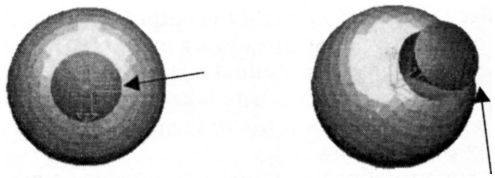
Concentration

Concentrators can be characterized by the ratio of the output area to the input area.[29] For an *ideal* system, the etendue at the input aperture and the output aperture are the same, which leads to the ideal concentration relationships

$$\text{Concentration}_{\text{2D}} = n_{\text{out}}\sin\theta_{\text{out}}/(n_{\text{in}}\sin\theta_{\text{in}}) \tag{8}$$

$$\text{Concentration}_{\text{3D}} = n_{\text{out}}^2\sin^2\theta_{\text{out}}/(n_{\text{in}}^2\sin^2\theta_{\text{in}}) \tag{9}$$

where the input and output distributions are clipped Lambertians, θ_{in} is the maximum input angle, and θ_{out} is the maximum output angle. Maximum concentration occurs when $\sin\theta_{\text{out}} = 1$, so that the



Projected area of intersected surface area of sphere
Max area = πR^2
Max projected solid angle = π

Max area = $4\pi R^2$
Max solid angle = 4π

FIGURE 3 PSA (*left*) versus solid angle (*right*).

maximum concentration ratios for 2D and 3D symmetric systems in air are $1/\sin\theta_{in}$ and $1/\sin^2\theta_{in}$, respectively. Concentrating the flux within a dielectric medium further increases the concentration ratio by a factor of n^2_{out} in the 3D case and n_{out} in the 2D case.

In general, maximum concentration occurs when the phase space of the receiver is completely filled (i.e., all portions of the receiver are illuminated from all angles). Maximum concentration can be obtained if the etendue of the input is greater than the etendue of the output. In this case, however, the efficiency of the system is less than 1. One example of this is provided by a two-stage system where the second stage is an ideal maximum concentrator and the etendue of the first stage is greater than the etendue of the second stage.[30,31] Such a system is not conventionally considered ideal because not all of the flux from the first stage is coupled into the entrance aperture of the second stage.

Dilution

Dilution is a term that is used to describe the situation in which the phase space of the receiver is unfilled. Consider the situation where a Lambertian disk of radius 1 is coupled directly to a receiver of radius 2. In this case, the area of the receiver is underfilled and represents *spatial dilution.* An example of *angular dilution* occurs when flux is transferred to a receiver using multiple discrete reflector elements. If there are gaps between the reflector elements, then the angular distribution of the flux incident on the receiver possesses gaps. The phrase *etendue loss* is also used to describe situations in which dilution is present.

39.3 SOFTWARE MODELING OF NONIMAGING SYSTEMS

The computer simulation of nonimaging systems is quite different from the computer simulation of imaging systems. Modeling of nonimaging systems typically requires three major items that imaging designers either do not need or tend to use infrequently. These are nonsequential ray tracing, spline surfaces, and modeling extended sources. Extended sources are often modeled using Monte Carlo techniques. Other differences include the need to model more complex surface properties including scattering surfaces; new methods to present simulation results including luminance, illuminance, and intensity distributions; and improved visualization because of the more complex geometries typically involved in nonimaging systems.

Nonsequential Ray Tracing

Nonsequential ray tracing means that the order of the surfaces with which the rays interact is not predetermined. In fact, rays can hit a single surface multiple times, which is especially common when skew rays are investigated. Nonsequential surfaces are especially important in the software modeling of lightpipes[32,33] and prisms.

Spline Surfaces

Spline surfaces have been successfully applied to the design of nonimaging optical systems. Design work in this area includes genetic algorithm-based approaches,[34,35] neural networks,[36] and variational principles.[37] Automotive headlamp designs also use spline surfaces routinely. Spline surfaces are also extremely important in computer-aided drafting (CAD) data exchange formats (e.g., IGES, STEP, and SAT) where Non-Uniform Rational B Splines (NURBS) have found tremendous utility.

Monte Carlo Techniques

Monte Carlo simulations are used to determine the intensity and/or illuminance distribution for optical systems. Typically, Monte Carlo techniques are used to model the source and/or surface properties of nonspecular surfaces. Reference 38 discusses some of the issues regarding Monte Carlo simulations. Some nonimaging systems that have been evaluated using Monte Carlo ray traces include an end-to-end simulation of a liquid crystal display (LCD) projector system,[39] light-emitting diodes,[40] integrating spheres,[41,42] scintillating fibers,[43,44] stray light,[45,46] and automotive headlamps.[47]

Source Modeling

Monte Carlo modeling of sources typically falls into three categories: point sources, geometric building blocks, and multiple camera images. Point sources are the simplest approach and are often used in the early stages of a design because of simplicity. Measured data, sometimes called *apodization data,* can be applied to a point source so that the intensity distribution of the source matches reality. The projected area of the source as seen from a given view angle can often be used to estimate the apodization data[8,48] when measurements are unavailable. Since the luminance of a point source is infinite, point source models are of limited utility when etendue limitations must be considered. Geometric models create the source through the superposition of simple emitters (e.g., disks, spheres, cylinders, cubes, ellipsoids, toroids). The simple emitters are typically either Lambertian surface emitters or isotropic volume emitters, and the emitters can have surface properties to model effects that occur when flux propagates back through the emitter. The simple emitters are then combined with models of the nonemissive geometry (e.g., bulb walls, electrodes, scattering surfaces) to create an accurate source model. Apodization of the spatial and/or angular distributions of sources can help to improve the accuracy of the source model. In the extreme, independent apodization files can be used for a large number of view angles. This often results in the use of multiple source images,[49,50] which has seen renewed interest now that charge-coupled device (CCD) cameras have matured.[51–55]

The most typical Monte Carlo ray trace is one in which the rays traced from the source are independent of the optical system under investigation. When information about the portions of the source's spatial and angular luminance distribution that are contributing to a region of the intensity/illuminance distribution is available, importance sampling can be used to improve the efficiency of the ray trace. An example of such an approach occurs when an f/1 condenser is used to collect the flux from a source. Use of importance sampling means that rays outside of the f/1 range of useful angles are not traced.

Backward Trace

When a simulation traces from the source to the receiver, rays will often be traced that land outside of the region of the receiver that is under investigation. A backward ray trace can eliminate those rays by only tracing from the observation point of interest. The efficiency of the backward ray trace becomes dependent upon knowing which ray directions will hit the receiver. Depending upon the details of the system and prior knowledge of the system, backward tracing can often provide far more efficient use of traced rays when only a few observation points are to be investigated. Use of the backward ray trace and examples for a number of cases have been presented.[28] Backward ray tracing has also been called the *aperture flash mode.*[56]

Field Patch Trace

Another trace approach is the field patch, where rays are traced backward from a point within the optical system and those rays are used to determine which rays to trace forward. Reference 56 describes the prediction of a distribution by summing results from multiple field patches. This

type of approach is especially useful if the effect of small changes in the system must be quantified because shifting the distributions and resuming can approximate small changes.

Software Products

There are many optical software vendors that have features that are primarily aimed toward the illumination market. A detailed comparison of the available products is difficult because of the speed at which software technology progresses. A survey of optical software products has been performed by Illuminating Engineering Society of North America (IESNA) and published in *Lighting Design and Application.*[57,58]

39.4 BASIC BUILDING BLOCKS

This section highlights a number of the building blocks for designing systems to collect flux when the angles involved are large. Many of these building blocks are also important for imaging optics, which reflects the fact that image formation is not a fundamental requirement for nonimaging optics but that image formation is often useful.

Spherical Lenses

Spherical lenses are used in nonimaging systems although the aberrations can limit their use for systems with high collection angles. The aplanatic points of a spherical surface[59] are sometimes used to convert wide angles to lower angles and remain free of all orders of spherical aberration and low orders of coma and astigmatism. There are three cases[60] in which a spherical surface can be aplanatic:

1. The image is formed at the surface (e.g., a field lens).
2. Both object and image are located at the center of curvature.
3. The object and image are located on radii that are rn/n' and rn'/n away from the center of curvature of the spherical surface.

Case 3 is used to construct hyperhemispheric lenses that are often used in immersed high-power microscope objectives. Such lenses can suffer from curvature of field and chromatism (see Ref. 60, pp. 258–262, and Ref. 61). Some example aplanats are shown in Fig. 4.

Hyperhemispheric lenses can also be used in LED packages[62] and have been used in photographic-type objectives and immersed IR detectors. Aplanatic surfaces for use as concentrators have been investigated[63] and can be nearly ideal if the exit surface is nonplanar (Ref. 4, pp. 37–38).

Aspheric Lenses

Spherical lenses have been the workhorse of the imaging industry because of the simplicity and accuracy with which they can be manufactured. Design requirements, especially the speed of the system, often necessitate the use of aspheric surfaces in nonimaging optics. Fortunately, the accuracy with which the surface figure must be maintained is often less severe than that of an imaging system. Aspheric lenses are often used as condensers in projection systems including LCD projectors, automotive headlamps, and overhead projectors.

The classic piano aspheric examples are the conic lenses where the eccentricity is equal to $1/n$ with the convex surface facing the collimated space and eccentricity = n with the piano surface facing the collimated space (see, for example, Ref. 64, pp. 112–113, and Ref. 65, pp. 100–103).

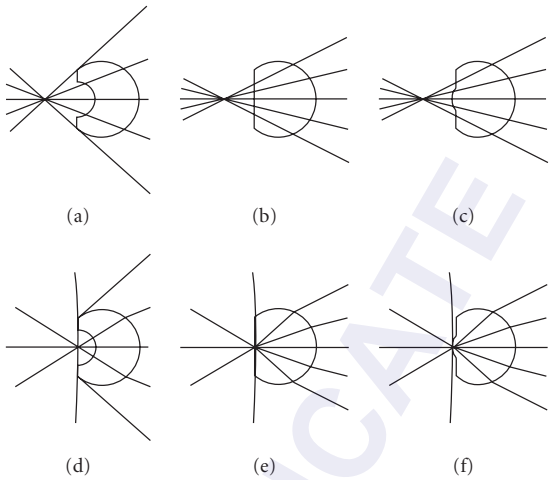

FIGURE 4 Several aplanats used to concentrate a virtual source. (*a–c*) The rays superimposed on top of the aplanats. (*d–f*) the ray trace. (*d*) A meniscus lens with hyperhemisphic outer surface and a spherical surface centered about the high concentration point. (*e*) A hyperhemisphere. (*f*) A hyperhemisphere with curved output surface.

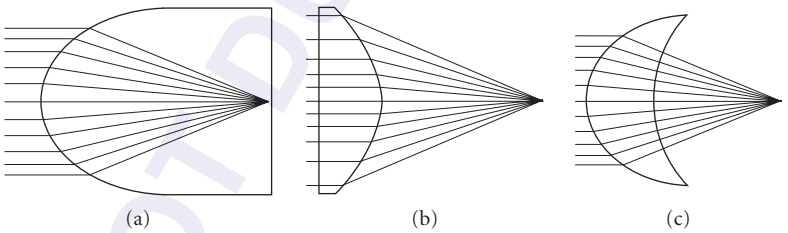

FIGURE 5 Conic collimators. (*a*) $e = 1/n$ and $f = Rn/(n-1)$. (*b*) $e = n$ and $f = R/(n-1)$. (*c*) $e = 1/n$ with other surface being spherical. e = eccentricity, n = index of refraction, $k = -e^2$.

Examples are shown in Fig. 5. The paraxial focal lengths are $Rn/(n-1)$ and $R/(n-1)$, respectively, where R is the radius of curvature. These examples provide correction for spherical aberration but still suffer from coma.

Refractive aspheric surfaces are often used in the classic Schmidt system.[60,66] Reference 67 has described a procedure for determining the aspheric profile for systems with two aspheric surfaces that has been adapted to concentrators by Minano.[68]

Fresnel Lenses

The creation of a lens using a symmetric arrangement of curved prisms is typically attributed to A. J. Fresnel and commonly called a *Fresnel lens*. General descriptions of Fresnel lenses are available.[69,70]

Fresnel lenses provide a means to collect wide angular distributions with a device that can be easily molded. Standard aspheric lenses can be molded, but the center thickness compared to the edge thickness adds bulk and fabrication difficulties.

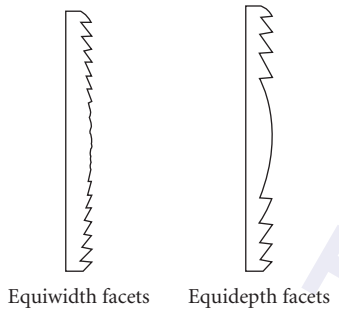

FIGURE 6 Two main types of Fresnel lenses: equiwidth and equidepth.

In imaging applications, Fresnel lenses are used, but the system designer must be careful to consider the impact of the facets on the image quality. The facet structure is also important in nonimaging applications where the use of facets introduces losses either by blocking flux or by underfilling the aperture, which typically results in an etendue loss.

Fresnel lenses have two main variations: constant-depth facet structures and constant-width facet structures (see Fig. 6). As the width of the facets becomes smaller, the effects of diffraction should be considered.[71] Although Fresnel lenses are typically created on planar substrates, they can be created on curved surfaces.[72,73]

The design of a Fresnel lens requires consideration of the riser angle (sometimes called the *draft angle*) between facets.[74,75] A typical facet is depicted in Fig. 7. The riser angle should be designed to minimize its impact on the rays that are controlled by the facets that the riser connects.

Total Internal Reflection Fresnel Lenses As the Fresnel lens collection angle increases, losses at the outer facets increase.[76] One solution is the use of total internal reflection (TIR) facets. In this case, the flux enters the substrate material, hits the TIR facet, and then hits the output surface. The entering, exiting, and TIR facets can also have power in more sophisticated designs. The basic TIR Fresnel lens idea has been used in beacon lights since at least the 1960s.[77] TIR Fresnel lenses have received more recent design attention for applications including fiber illumination, LEDs, condensers, and concentrators.[76,78–82] Vanderwerf[83] investigates achromatic issues with catadioptric Fresnel lenses.

In some applications, the TIR Fresnel lens degenerates into one refractive facet and two or more TIR facets. Combined TIR and refractive designs have been proposed for small sources with significant attention to LEDs.[84–86]

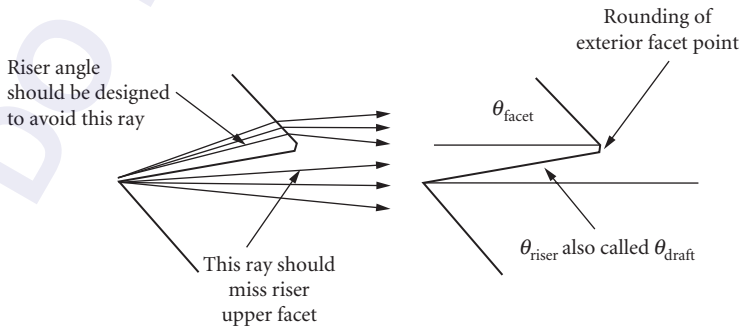

FIGURE 7 Facet terminology and design issues.

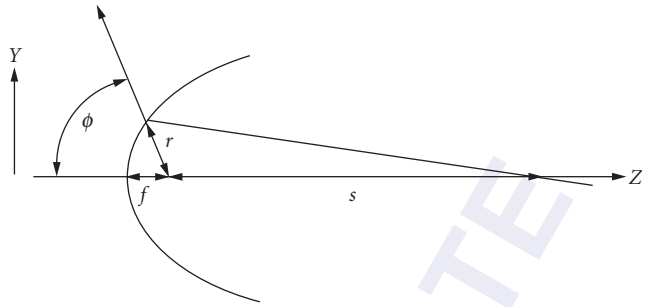

FIGURE 8 Conic reflector showing *r, f, s,* and ϕ.

Conic Reflectors

Reflectors made from conic sections (parabolas, ellipses, and hyperbolas) are commonly used to transfer radiation from a source to a receiver. They provide spherical-aberration-free transfer of radiation from one focal point to the other. The problem is that the distance from a focal point to a point on the surface of the reflector is not constant except for the case of a sphere. This introduces a nonuniform magnification (coma) that can result in a loss of concentration.

Many textbooks describe conic surfaces using equations that have an origin at the vertex of the surface or at center of symmetry. Reference 17 (page 1.34) shows a number of different forms for a conic surface. In nonimaging systems, it is often convenient to define conic reflectors using an origin shifted away from the vertex. Reference 87 describes these surfaces in Cartesian coordinates as *apovertex surfaces.* They can also be described in polar coordinates where the focal point is typically the origin. The polar definition of a conic surface[8] is

$$r = \frac{f(1+e)}{1+e\cos\phi}$$

where r is the distance from the foci to the surface, f is the distance from one focus to its nearest vertex, ϕ is the angle from the foci to the vertex, e is $s/(s+2f)$, and s is the distance between the two foci. In Cartesian coordinates, $z = r\sin\phi$ and $y = r\cos\phi$. An example is shown in Fig. 8.

Macrofocal Reflectors

One can consider the standard conic reflector to map the center of a sphere to a single point. What can sometimes be more valuable for nonimaging optics is to map the edge of the sphere to a single point. Reflectors to provide this mapping have been called macrofocal reflectors.[88] They have also been called extinction reflectors[8] because of the sharp edge in the illuminance distribution that they can produce. Reference 89 describes an illumination system that provides a sharp cutoff using tilted and offset parabolic curves.

Involute

A reflector that is used in many nonimaging systems is an *involute.* An involute reflector sends tangential rays from the source back onto themselves. One way to produce an involute for a circle is to unwind a string that has been wrapped about the circle. The locus of points formed by the string equals the involute. In Cartesian coordinates, the equation for the involute of a circle is[90]

$$x = r(\sin\theta - \theta\cos\theta) \tag{10}$$

$$y = -r(\cos\theta + \theta\sin\theta) \tag{11}$$

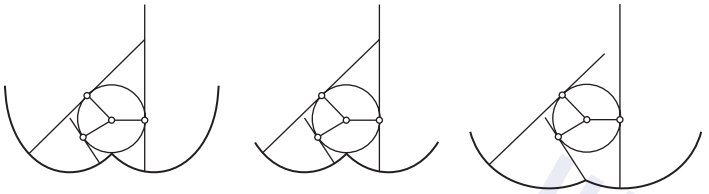

FIGURE 9 Full involute, partial involute, and involute with gap. Rays tangent to the source reflect back toward the same location on the source.

where r is the radius of the circle, $\theta = 0$ at the cusp point, and the origin is at the center of the circle. An example is shown in Fig. 9, where rays are drawn to highlight the fact that rays tangent to the circle reflect off of the involute and retrace their path.

The term *full involute* has been used to describe an involute that is continued until the output aperture is tangent to the surface of the source. *A partial involute* is an involute that is less than a full involute. An involute with gap is also shown in Fig. 9, and is sometimes called a *modified involute.*[91] Involute segments can also be applied to noncircular convex shapes and to disjoint shapes.[92]

39.5 CONCENTRATION

The transfer of radiation in an efficient manner is limited by the fact that the luminance of the radiation from a source in a lossless system cannot increase as the radiation propagates through the system. A consequence is that the etendue cannot be reduced and maximizing the luminance means avoiding dilution. A less understood constraint that can impact the transfer of radiation is that rotationally symmetric optical systems conserve the skewness of the radiation about the optical axis (see for example Ref. 4, Chap. 2.8, and more recently Ref. 93). This section describes some of the basic elements of systems used to transfer radiation with an emphasis on those that preserve etendue.

Many papers on nonimaging optics can be found in the Society of Photooptical Instrumentation Engineers (SPIE) proceedings. SPIE conferences specifically focused on nonimaging optics include Refs. 94–99. Reference 100 also provides a large number of selected papers. Textbooks on nonimaging optics include Refs. 4 and 101. Topical articles include Refs. 102 and 103.

Discussions of biological nonimaging optic systems have also been written.[104–108]

Tapered Lightpipes

Lightpipes can be used to transport flux from one location to another. This can be an efficient method to transport flux, especially if total internal reflection (TIR) at the lightpipe surface is utilized to provide lossless reflections. Lightpipes can provide annular averaging of the flux. In addition, if the lightpipe changes in size from input to output over a given length (e.g., the lightpipe is tapered), then the change in area produces a corresponding change in angles. If the taper occurs over a long enough distance, then in most cases the etendue will be preserved (see, for example, Ref. 109). If the taper occurs over too short a length, the etendue will not be preserved, which can result in an increase in angles or possibly rays lost, such as when they are reflected back toward the input.

An interesting geometric approach to determining if meridional rays in a conical lightpipe can propagate from input to output end was shown by Williamson,[110] and is informally called the Williamson construction or a tunnel diagram. An example is shown in Fig. 10, where the duplicate copies of the primary lightpipe are all centered about a single point. Where the rays cross the copies

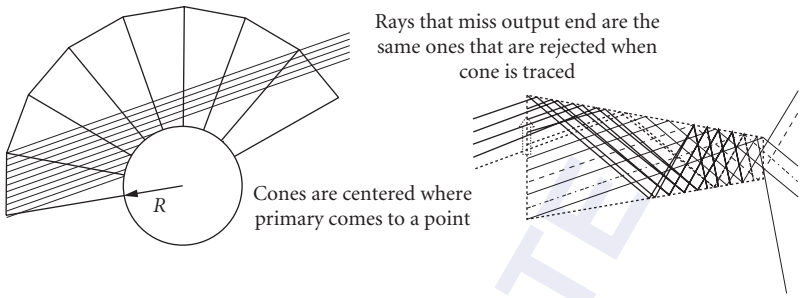

FIGURE 10 Williamson construction. Multiple copies of the primary cone are drawn. Where rays cross, there copies are the same as where they hit the actual cone. Rays that do not cross the output end are reflected back to the input end.

shows the position and at what angle the rays will hit the primary lightpipe. As seen in Fig. 10, the rays that do not cross the output end of any of the copies of the cone are also the rays that are reflected back out the input end of the cone. Other analyses of tapered geometries have been performed by Welford[4] (pp. 74–76), and Meyer[111] provides numerous references.

Witte[112] has performed skew ray analysis using a variation of the Williamson construction. Witte also shows how a reference sphere centered at the point where the cone tapers to a point can be used to define a pupil when cones are used in conjunction with imaging systems analysis. Burton[113] simplified the expressions provided by Witte.

Vector flux investigations have shown that a cone is an ideal concentrator for a sphere (Ref. 114, p. 539). An important implication of this result, which is similar to the information presented by Witte,[112] is that a cone concentrator can be analyzed by tracing from the cone input aperture to the surface of a sphere. If the rays hit the sphere surface, then they will also hit the sphere after propagating through the lightpipe. This is true for both meridional and skew rays.

CPC

A compound parabolic collector (CPC) can be used to concentrate the radiation from a clipped Lambertian source in a nearly etendue-preserving manner. Welford[4] provides a thorough description of CPCs. An example CPC is shown in Fig. 11, where the upper and lower reflective surfaces are tilted parabolic surfaces. The optical axis of the parabolic curves is not the same for the upper and lower curves, hence the use of the term *compound.*

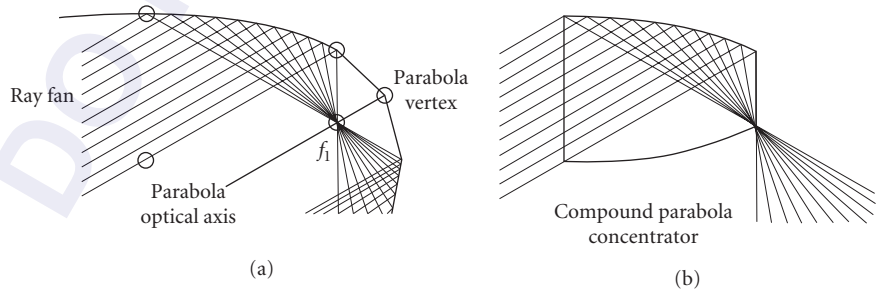

FIGURE 11 Compound parabolic concentrator (CPC). (*a*) Upper parabolic curve of CPC. Circles are drawn to identify the parabola vertex and the edges of the CPC input and output apertures. (*b*) Compound parabola concentrator.

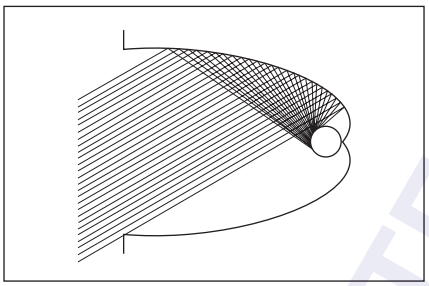

FIGURE 12 A CPC-type reflector for a tubular source.

In 2D, the CPC has been shown to be an ideal concentrator.[4] In 3D, a small fraction of skew rays are rejected and bound the performance. For a CPC, this skew ray loss increases as the concentration ratio increases. Optimization procedures have produced designs that provide slightly better performance than the CPC in 3D.[37] Molledo[115] has investigated a crossed cylindrical CPC configuration.

The length of a CPC concentrator is

$$\text{Length} = (R_{\text{in}} + R_{\text{out}})/\tan(\theta_{\text{in}}) \tag{12}$$

A particularly important aspect of the CPC is that the length is minimized for the case where the input port can see the exit port. If the distance between the input and output ports is made smaller than the CPC length, then rays higher than the maximum design angle could propagate directly from input to output aperture. The reduction in concentration is often small, so many practical systems use truncated CPC-like designs.[90,116–118] A cone that is the same length as an untruncated CPC will provide lower concentration, but as the cone is lengthened, the performance can exceed the performance of the CPC.

In the literature, CPC is sometimes used to denote any ideal concentrator. For nonplanar receivers, the reflector shape required to create an ideal concentrator is not parabolic. The convention is to use CPC-type.

An example of a CPC-type concentrator for a tubular receiver is shown in Fig. 12. Part of the reflector is an involute and the remainder reflects rays from the extreme input angle to the tangent of the receiver. The design of CPC-type concentrators for nonplanar sources has been described.[4,116,119,120] Designs with gaps between reflector and receiver[121–123] and with prisms attached to the receiver[124,125] have also been described.

CPC-type geometries are also used in laser pump cavities.[126]

Arrays of CPCs or CPC-like structures have also been applied to the liquid crystal displays,[127,128] illumination,[89] and solar collection.[129]

CEC

When the source of radiation is located at a finite distance away from the input port of the concentrator, a construction similar to the CPC can be used; however, the reflector surface is now elliptical.[130] In a similar manner, if the source of radiation is virtual, then the reflector curvature becomes hyperbolic. These two constructions are called compound elliptical concentrators (CEC) and compound hyperbolic concentrators (CHC). A CEC is shown in Fig. 13, where the edge of the finite size source is reimaged onto the edge of the CEC output aperture. Hottel strings can be used to compute the etendue of the collected radiation (see Sec. 39.2). The CPC is similar to the CEC, except the edge of the source is located at infinity for the CPC.

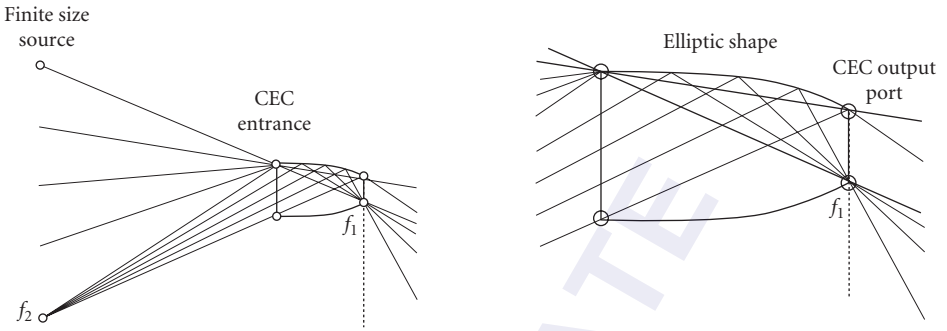

FIGURE 13 Compound elliptical concentrator (CEC). Rays originating at finite size source and collected at the CEC entrance are concentrated at the CEC output port. Edge of source is imaged onto edge of output aperture.

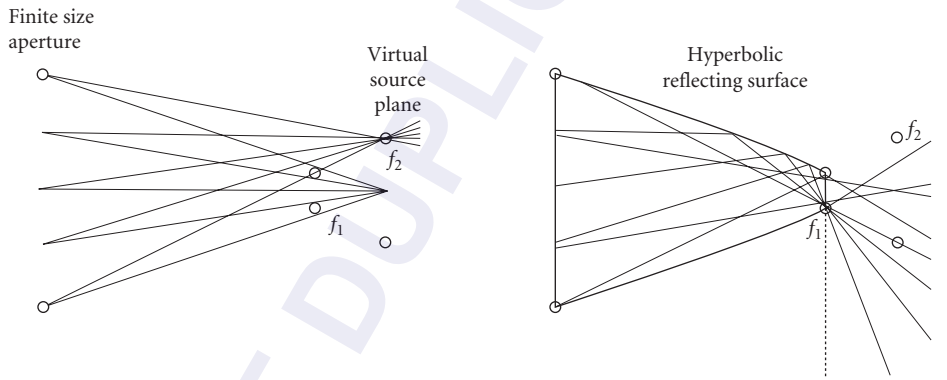

FIGURE 14 Compound hyperbolic concentrator for use with virtual source. Edge of virtual source is imaged onto the edge of the output port.

CHC

A CHC is shown in Fig. 14 where the rays that pass through the finite-size aperture create a virtual source. The CHC concentrates the flux. Arrangements where the CHC is just a cone are possible.[131] Gush[132] also describes a hyperbolic cone-channel device.

If the virtual source is located at the output aperture of the concentrator, then an ideal concentrator in both 2D and 3D can be created (see Fig. 15). Generically, this is a hyperboloid of revolution and is commonly called a *trumpet.*[133] The trumpet maps the edge of the virtual source to ±90°. The trumpet can require an infinite number of bounces for rays that exit the trumpet at nearly 90°, which can limit the performance when finite-reflectivity mirrors are used.

DCPC

The CPC construction can also be applied when the exit port is immersed in a material with a high index of refraction. Such a device is called a *dielectric compound parabolic concentrator* (DCPC).[134] This allows concentrations higher than those found when the exit port is immersed in air. In this immersed exit port case, the standard CPC construction can still be used, but the exit port area is now n times smaller in 2D and n^2 smaller in 3D. Another motivation for a DCPC is that the reflectivity

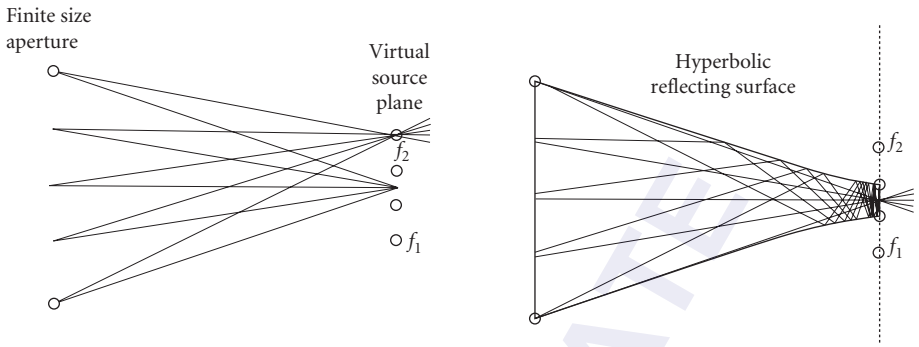

FIGURE 15 Trumpet with exit aperture located at virtual source plane. Rays "focused" at edge of virtual source exit the trumpet at ±90°.

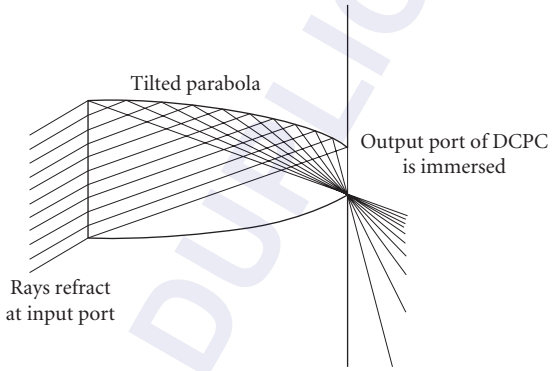

FIGURE 16 Dielectric CPC: same as CPC, except output port is immersed.

losses for a hollow CPC can be minimized because TIR can provide lossless reflections. A DCPC is shown in Fig. 16. A DCPC that uses frustrated TIR at the DCPC to receiver interface has been investigated.[135]

A hollow CPC can also be attached to a DCPC to minimize the size of the DCPC.[136] Extraction of flux from a high-index medium into a lower-index medium has been investigated[137,138] using faceted structures.

Multiple Surface Concentrators

CPC-type concentrators can produce a long system when θ_{in} is small. To avoid excessively long systems, other optical surfaces are typically added. Often, a CPC-type concentrator is combined with a primary element such as a condensing lens or a parabolic reflector. There are also designs where the optical surface of the primary and the optical surface of the concentrator are designed together, which often blurs the distinction between primary and concentrator.

Lens + Concentrator There are numerous examples of lenses combined with a nonimaging device in the literature. One approach is to place a lens with the finite-size aperture shown in Figs. 13, 14, or 15 and illuminate the lens with a relatively small angular distribution. The lens produces higher angles that are then concentrated further using the conventional CPC, CEC, CHC, or trumpet. Such a combination typically produces a shorter package length than a CPC-type concentrator.

A lens/CHC can be attractive because the CHC is placed between the lens and lens focal plane, whereas the CEC is placed after the lens focal plane. Thus, the lens/CHC provides a shorter package than a lens/CEC. Both the lens curvature and the CHC reflector can be optimized to minimize the effects of aberrations, or the combination can be adjusted so that the CHC turns into a cone. Investigations of lens/cone combinations include Williamson,[10] Collares-Pereira,[75] Hildebrand,[139] Welford,[4] and Keene.[140] Use of a cone simplifies fabrication complexity.

After the theoretical implications of the trumpet were recognized, Winston[141] and O'Gallagher[133] investigated the case of a lens/trumpet.

When TIR is used to implement the mirrors, the mirror reflection losses can be eliminated, with the drawback that the package size grows slightly. A design procedure for a lens mirror combination with maximum concentration was presented by Ning,[142] who coined the term *dielectric total internal reflecting concentrator* (DTIRC) and showed significant package improvements over the DCPC.

Eichhorn[143] describes the use of CPC, CEC, and CHC devices in conventional optical systems, and uses explicit forms for the six coefficients of a generalized quadric surface.[144] A related "imaging" lens and reflector configuration is the Schmidt corrector system.[145]

Arrays of lenses with concentrators have also been investigated for use in illumination.[146]

Mirror + Concentrator There have been numerous investigations of systems that have a parabolic primary and a nonimaging secondary.[137,147–150] Other two-stage systems have been investigated.[29–31,151–153] Kritchman[154] has analyzed losses due to aberrations in a two-stage system.

Asymmetric concentrators have also been investigated. Winston[152] showed that an off-axis parabolic system can improve collection by tilting the input port of a secondary concentrator relative to the parabolic axis. Other asymmetric designs have been investigated.[155,156]

Related two-mirror "imaging" systems (e.g., Ref. 60, Chap. 16) such as the Ritchey-Chretien can be used as the primary. Ries[157] also investigated a complementary Cassegrain used for concentration.

Simultaneous Multiple Surfaces Minano and coworkers have investigated a number of concentrator geometries where the edge of the source does not touch the edge of a reflector. The procedure has been called simultaneous multiple surfaces (SMS) and builds on the multisurface aspheric lens procedure described by Schultz.[67] Minano uses the nomenclature *R* for refractive, *X* for reflective (e.g., refleXive), and *I* when the main mode of reflection is TIR. The *I* surface is typically used for refraction the first time the ray intersects the surface and TIR for the second ray intersection. The *I* surface is sometimes mirrored over portions of the surface if reflection is desired but the angles do not satisfy the TIR condition. Illustrative citations include RR,[158] RX,[159,160] and RXI.[161,162] Example RX and RXI devices are shown in Fig. 17. SMS can be used to design all reflecting configurations.

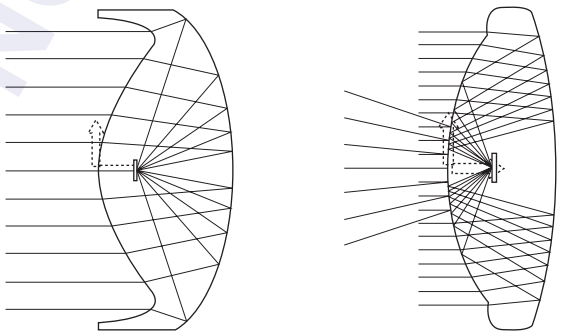

FIGURE 17 RX (*a*) and RXI (*b*) concentrators. The receiver is immersed in both cases. In the RXI case, the central portion of the refractive surface is mirrored.

Restricted Exit Angle Concentrators with Lenses

If the angular distribution of the flux is constant across an aperture and the centroid of the distribution is normal to the aperture, then the distribution is called *telecentric.* Many optical systems require the transfer of flux from one location to another. If the desired distribution of flux at the second location is also telecentric, then the system is called doubly telecentric. An afocal imaging system can be modified to provide a doubly telecentric imaging system when used with finite conjugates. An example is shown in Fig. 18.

In nonimaging systems, flux must often be transferred from one aperture to another and the angular distribution at the second aperture must be constant across the aperture. However, the point-by-point mapping is not required in nonimaging systems. A single lens can provide this transfer of radiation, as shown in Fig. 19. This type of lens is a collimator and is similar to a Fourier transform lens; it has been called a *beam transformer.*[163]

The aberrations introduced by a lens can limit the etendue preservation of the aggregate flux collected by the lens. The increase in etendue tends to become more severe as range of angles collected by the lens increases. Somewhere around f/1, the change can become quite significant.

θ_1/θ_2

θ_1/θ_2 concentrator[29,163,164] maps a limited-angle Lambertian distribution with maximum angle θ_1 into another limited-angle Lambertian with maximum angle θ_2. One version of the θ_1/θ_2 is a compound parabolic construction with a cone replacing part of the small end of the CPC (Ref. 4, pp. 72–74, sec. 5.3). A picture is shown in Fig. 20. The length of a θ_1/θ_2 is given by the same equation as the CPC [e.g., Eq. (12)]. If the θ_1/θ_2 is hollow and $\theta_2 = 90°$, then the cone disappears and the θ_1/θ_2 becomes a CPC.

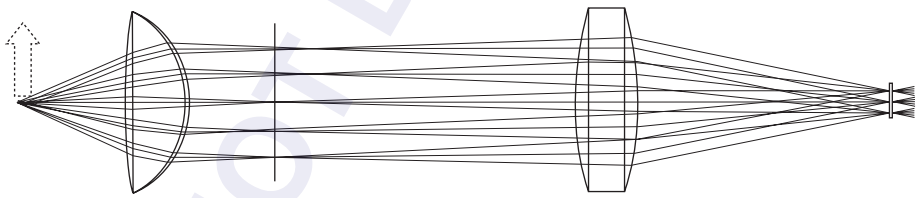

FIGURE 18 Doubly telecentric system showing a twofold increase in size and a twofold decrease in angles.

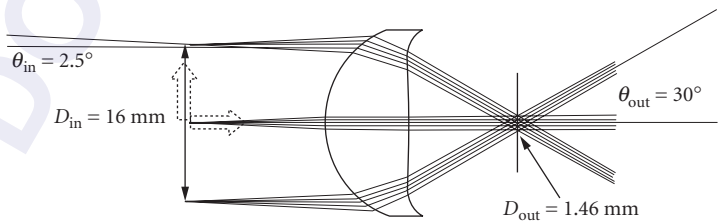

FIGURE 19 Condenser to provide an angle to area transformation and produce a distribution that is symmetric about the optical axis at both input and output planes. $D_{in} \sin \theta_{in} = D_{out} \sin \theta_{out}$.

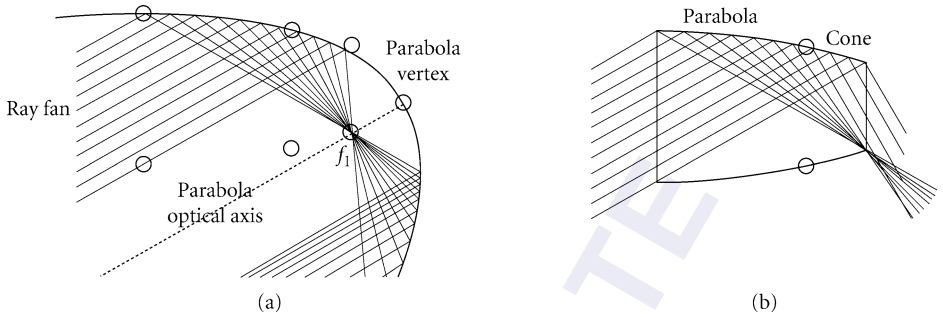

FIGURE 20 θ_1/θ_2 implemented using cone with compound parabolic. (*a*) Construction information. (*b*) θ_1/θ_2, (*b*) compound parabola + cone.

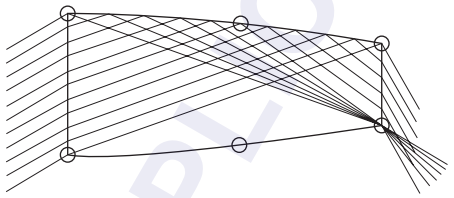

FIGURE 21 Dielectric θ_1/θ_2 implemented using cone with compound parabolic. The rays refract at the input port, total internally reflect (TIR) at the sidewalk, and then refract at the output port.

To reduce losses introduced by nonunity mirror reflectivities, a θ_1/θ_2 converter can also be created using a solid piece of transparent material. The design is similar to the hollow θ_1/θ_2 and must take into account the refraction of rays at the input and output port. A dielectric θ_1/θ_2 converter is shown in Fig. 21.

If the θ_1/θ_2 is an all-dielectric device, nearly maximum concentration for an air exit port can be obtained without the mirror losses of a hollow CPC; however, Fresnel surface reflections at the input and output ports should be considered.

Similar to the lens-mirror combination for maximal concentration, the θ_1/θ_2 can be implemented with a lens at the input port. Going one step further, the output port of the θ_1/θ_2 can also incorporate a lens. Similar to a Galilean telescope, the θ_1/θ_2 with lenses at both the input and output ports can provide a short package length compared to embodiments with a flat surface at either port.[164]

In many cases, a simple tapered cone can be used to implement a θ_1/θ_2 converter. One reason is that when the difference between θ_1 and θ_2 is small, the compound parabolic combined with a cone is nearly identical to a simple cone. By using an approximation to the ideal shape, some of the flux within θ_1 maps to angles outside of θ_2. In many practical systems, the input distribution does not have a sharp transition at θ_1, so a small mapping outside of θ_2 has minor impact. In general, the transition can be made sharper by increasing the cone length; however, there may be multiple local minima for a specific situation.[165]

Uniformity at the output port of a θ_1/θ_2 compared to a CPC has been investigated.[166] Tabor[118] describes hot spots that can occur with CPCs used in solar energy systems. Edmonds[125] uses a prism where hot spots that may occur are defocused after propagating through the prism. Emmons[167] discusses polarization uniformity with a dielectric 90/30 converter.

Two CPCs can be placed "throat-to-throat" to provide a θ_1/θ_2 converter that also removes angles higher than the desired input angle.[168] The removal of higher angles is a result of the CPCs ability to transfer rays with angles less than θ_1 and reject rays with angles greater than θ_1. Two nonimaging concentrators have also been investigated for use in fiber-optic coupling.[169]

Tight lightpipe bends are also made possible by inserting a bent lightpipe between the throats of the two concentrators.[33] In the special case of $\theta_1 = \theta_2 = 90°$, a bent lightpipe has also been used as an ideal means to transport the flux for improved packaging.[170]

2D versus 3D Geometries

Skew Ray Limits One of the standard design methods for concentrators has been to design a system using a meridional slice and then simply rotate the design about the optical axis. In some cases, such as the CPC used with a disk receiver, this may only introduce a small loss; however, there are cases where the losses are large.

The standard CPC-type concentrator for use with a circular receiver[90,171] is an example where this loss is large. To assess the loss, compare the 2D and 3D cases. In 2D a concentrator can be designed where the input port is $2R_{in}$ with $a \pm \theta_{in}$ angular distribution; the size of the tube-shaped receiver is $2\pi R_{tube} = 2R_{in}\sin\theta_{in}$. The 2D case provides maximum concentration. In the 3D case where the 2D design is simply spun about the optical axis, the ratio of the input etendue to the output etendue is $\pi R_{in}^2 \pi \sin^2\theta_{in}/(4\pi R_{tube}^2) = \pi^2/4 \sim 2.5$. The dilution is quite large. Feuermann[172] provides a more detailed investigation of this type of 2D-to-3D etendue mismatch.

Ries[93] shows how skew preservation in a rotationally symmetric system can limit system performance even though the etendue of the source and receiver may be the same. The skewness distributions (*d*etendue/*d*skewness as a function of skewness) for an example disk, sphere, and cylinder aligned parallel to the optical axis are shown in Fig. 22. The etendues of the disk, sphere, and cylinder are all the same. A second example where a cylinder is coupled to a disk is shown in Fig. 22*b*. This figure highlights losses and dilution. For skew values where the skewness distribution for the receiver is greater than the source, dilution occurs. Where the source is greater than the receiver, losses occur. If the size of the disk is reduced, then the dilution will also decrease, but the losses increase. If the disk is made bigger, then the losses decrease, but the dilution increases. Skew ray analysis of inhomogeneous sources and targets has also been considered.[173]

Star Concentrator One way of avoiding the skew ray limit in a system with a rotationally symmetric source and a rotationally symmetric receiver is to avoid the use of rotationally symmetric optics to couple the flux from source to target. A device called a *star concentrator* has been devised[174] and shown to improve the concentration. The star concentrator derives its name from the fact that the cross section of the concentrator looks like a star with numerous lobes. The star concentrator is designed using a global optimization procedure. Performance of the star concentrator, assuming a reflectivity of 1, provides performance that exceeds the performance possible using a rotationally

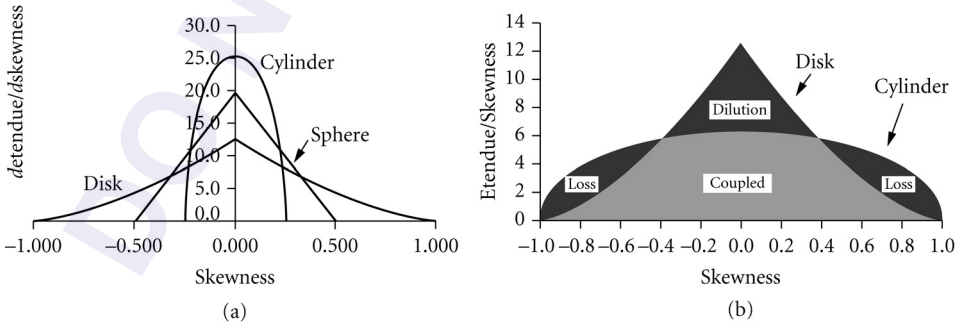

FIGURE 22 Skewness distributions (Ries[93]). (*a*) Skewness distribution for a disk with unit radius, a cylinder with length = 2 and radius = 0.25, and a sphere of radius 0.5. The etendue for all three cases is constant, (*b*) Comparison of the coupling of a disk to a cylinder where the coupled flux is distinguished from the losses and the dilution.

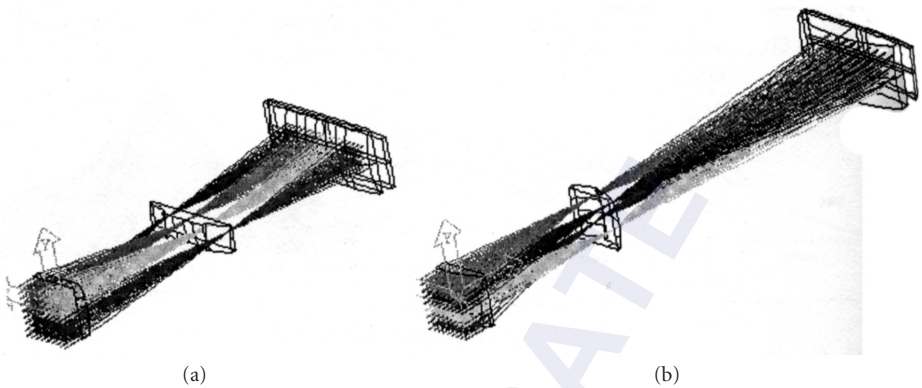

(a) (b)

FIGURE 23 Square-to-rectangular mapping with an image dissector (*a*) and a lens array (*b*) where the output angular distribution is symmetric. The image dissector uses an array of discrete field lenses. The lens array uses a single field lens.

symmetric system. The star concentrator approach has also been investigated for the case of coupling from a cylindrical source to a rectangular aperture.[7,175]

Image Dissectors The problem of coupling flux from a rotationally symmetric source to a spectrometer slit motivated some earlier efforts to overcome the skewness limit. Benesch[176] shows a system with two sets of facets that "dissect" an X by Y aperture into N regions of size X/N by Y and relay those images to create an X/N by NY region. The dissection can be done while preserving the NA of the input (e.g., the etendue is preserved but the skew is changed). Benesch calls this system an *optical image transformer* and it is similar in function to Bowen's image slicer.[177] Refractive versions are also possible (see for example Ref. 178). One issue that must be addressed for some systems, which use these dissectors, is that the adjoining regions of the X/N by Y areas can produce a nonuniform illuminance distribution. Laser arrays can also use dissectors to improve performance.[179,180]

Tandem-lens-array approaches can be used that provide the image dissection and superimpose all the images rather than placing them side by side.[181,182]

An example of a refractive image dissector compared to a lens array is shown in Fig. 23. The image dissector breaks an input square beam into four smaller square regions that are placed side by side at the output. The lens array breaks the input beam into four rectangles that are superimposed at the output. Both systems use field lenses at the output. The lens array does not have a gap between mapped regions at the output plane compared to the dissector.

Fiber bundles can also be used as image dissectors. For example, the fibers can be grouped in a round bundle at one end and a long skinny aperture at the other end. Feuermann[183] has provided a recent investigation of this idea. If the fibers in the bundle have a round cross section, tapering the ends of each of the fibers can help improve the uniformity at the output.[184] Special systems that use slowly twisted rectangular light guides have also been investigated for scintillators,[185–187] document scanning,[188,189] and microlithography.[190]

Bassett[191] also shows that arrays of ideal fibers can be used to create ideal concentrators, and Forbes[192] uses the same approach to create a θ_1/θ_2 transformer.

Geometrical Vector Flux

The edge ray design method does not show how the jumble of rays from multiple reflections yields a Lambertian output. The geometric vector formalism was investigated in an attempt to understand the process. Summaries can be found in Bassett[101] and Welford.[4] The proof that a trumpet provides ideal performance has been performed using the flow line concept.[114]

The vector flux formalism provides the lines of flow and loci of constant geometric vector flux *J*. The vector *J* is the PSA for three orthogonal patches where the PSA on the front side of a patch can subtract from the PSA on the back side. The magnitude of *J* describes what the PSA would be for a surface aligned perpendicular to *J*. The flow line concept uses the idea that an ideal mirror can be placed along lines of flow without modifying the flow.

In the context of vector flux, the CPC, θ_1/θ_2, and light cone are discussed in Winston.[141] The light cone is demonstrated using an orange in Winston.[95] The 2D CEC and θ_1/θ_2 are discussed by Barnett.[193,194] Gutierrez[195] uses Lorentz geometry to show that other rotationally symmetric ideal concentrators can be obtained using surfaces that are paraboloid, hyperboloid, and ellipsoid. Greenman[196] also describes vector flux for a number of ideal concentrators.

Edge Rays

The design of nonimaging optics has been facilitated by the use of the edge ray method[4,68,101,197] and is sometimes called the string method.[4,8] In the design of an ideal concentrator, the main principle is that extreme rays at the input aperture must also be extreme rays at the output aperture. Minano[198] describes the edge rays as those that bound the others in phase space. In many cases, the result is that the edge of the source is imaged to the edge of the receiver, and the reflector surface to perform the mapping is a compound conic. When the location of the source edge or the receiver edge is not constant (e.g., a circular source), the required reflectors are not simple conies (e.g., see the preceding section). Gordon[199] describes a complementary construction that highlights the fact that what is conventionally the "outside" of a concentrator can also be used in nonimaging optics.

Davies[200] further explores the continuity conditions required by the edge-ray principle. Ries[201] refines the definition of the edge ray principle using topology arguments. Rabl[202] shows examples where the analysis of specular reflectors and Lambertian sources can be performed using only the edge rays.

Tailoring a reflector using edge rays is also described in the next section.

Inhomogeneous Media

A medium with a spatially varying index of refraction can provide additional degrees of freedom to the design of nonimaging optics. In imaging optics, examples of inhomogeneous media include Maxwell's fisheye and the Luneburg lens.[4,18] In concentrator design, 2D and 3D geometries have been investigated.[198,203]

39.6 UNIFORMITY AND ILLUMINATION

In many optical systems, an object is illuminated and a lens is used to project or relay an image of the illuminated object to another location. Common examples include microscopes, slide projectors, overhead projectors, lithography, and machine vision systems. In a projection system the uniformity of the projected image depends upon the object being illuminated, the distribution of flux that illuminates the object, and how the projection optics transport the object modulated flux from object to image. The portion of the system that illuminates the object is often called the *illumination subsystem.*

Beam forming is another broad class of illumination systems. In beam forming, there is often no imaging system to relay an image of the illuminated object. Since the human eye is often used to view the illuminated object, the eye can be considered an imaging subsystem. Application examples include commercial display cases, museum lighting, room lighting, and automotive headlamps.

Approaches to provide uniform object illumination are discussed in this section. The discussed approaches include Kohler/Abbe illumination, integrating cavities, mixing rods, lens array, tailored

optics, and faceted structures. Many of the approaches discussed in this section can be designed to preserve etendue, but the design emphasis is on uniformity so they have been placed in this section rather than the preceding one.

Classic Projection System Uniformity

In classical projection systems, there is typically a source, a transparency (or some other item to be illuminated), and a projection lens. There are two classic approaches to obtaining uniformity in those systems: Abbe and Kohler illumination (see Fig. 24). In both cases, a source illuminates a transparency that is then often imaged onto a screen. *Transparency* is a general term that includes items such as spatial light modulators, film, slides, gobos, and microscope slides.

Some general references regarding Abbe/Kohler illumination include Jones,[204] Kingslake,[205] O'Shea,[206] Wallin,[207] Weiss,[208] Ray (pp. 455–461),[66] Bradbury,[209] Inoue,[210] and Born.[18] A description of Kohler with partial coherence is included in Lacombat.[211]

Abbe Abbe (also called Nelsonian and Critical illumination) images the source onto the transparency. When the source is spatially uniform, the Abbe approach works fine. A frosted incandescent bulb is a good example. Sometimes a diffuser is inserted in the system and the diffuser is imaged onto the transparency. Fluorescent tubes are another case where a light source provides excellent spatial uniformity. The luminance of sources that are spatially uniform is typically lower than that of sources that are not uniform.

Kohler Even though the source's illuminance distribution may be nonuniform, there are often uniform regions of the source's intensity distribution. This phenomenon is used in the design of Kohler-type systems where the source is imaged into the projection lens aperture stop and a mapping of the source intensity distribution illuminates the transparency. One reason this approach works well is that far from the source, the illuminance distribution over a small area is independent of where the flux originated. This tends to provide uniformity over portions of the source's intensity distribution.

A nearly spherical reflector is sometimes added behind the source to improve the collection efficiency of a Kohler illumination system. Typically, the spherical reflector produces an image of the source that is aligned beside the primary source. The direct radiation from the source and the flux

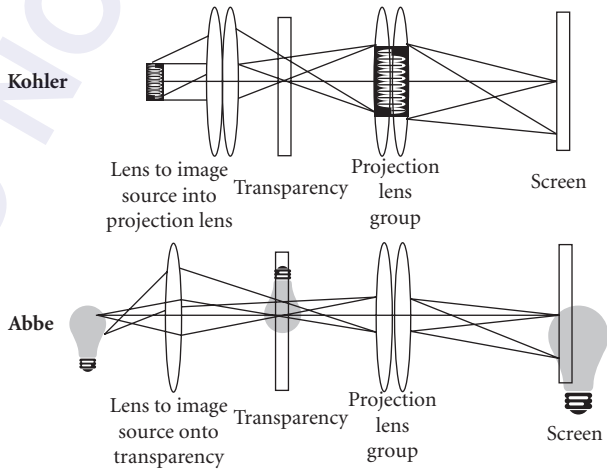

FIGURE 24 Abbe versus Kohler layout comparison.

from the image of the source then become the effective source for the Kohler illuminator. If the source is relatively transparent to its own radiation, then the image of the source can be aligned with the source itself. Blockage by electrodes and leads within the bulb geometry often limit the flux that can be added using the spherical reflector. Scattering and Fresnel surface reflections also limit the possible improvement. Gordon[212] provides a recent description of a back reflector used with filament sources.

In Kohler illuminators, tailoring the illuminance distribution at the transparency to provide a desired center-to-edge relative illumination can be performed using the edge ray approach described by Zochling.[213] Medvedev[82] also applied the edge ray principle to the design of a projection system. The other tailoring approaches described later in this section may also be relevant.

Integrating Cavities

Integrating cavities are an important example of nonimaging optics that are used in precision photometry,[16] backlighting systems, collection systems (Basset,[101] Sec. 7, and Steinfeld[214]), scanners,[41] and reflectometers.[215] They provide a robust means for creating a distribution at the output port that is independent of the angular and spatial luminance distributions at the input port, thereby removing "hot spots" that can be obtained using other methods. Integrating cavities are limited by a trade-off between maximizing the transmission efficiency and maximizing the luminance at the output port. The angular distribution exiting the sphere is nominally an unclipped Lambertian, but there are a number of techniques to modify the Lambertian distribution.[216]

Nonuniformities with Integrating Spheres Integrating cavities, especially spherically shaped cavities, are often used in precision photometry where the flux entering the sphere is measured using the flux exiting the output port of the sphere. For precision photometry, the angular distribution of the exiting flux must be independent of the entering distribution. In general, the flux is scattered multiple times before exiting the sphere, which provides the required independence between input and output distributions. The two main situations where this independence is not obtained are when the output port views the input port and when the output port views the portion of the sphere wall in which the direct illumination from the input port illuminates the sphere wall.

Figure 25 shows an integrating sphere with five ports. A source is inserted into the upper port and the other four ports are labeled. Figure 26 shows the intensity distribution that exits output port 1 of the sphere shown in Fig. 25. The structure in the exiting intensity distribution is roughly Lambertian, but there are nonuniformities in the distribution that occur at angles that can "see" the source or the other output ports. To highlight this effect, rotated views of the sphere are included in Fig. 26. The bright peak in the intensity distribution occurs at the view angle where the output port

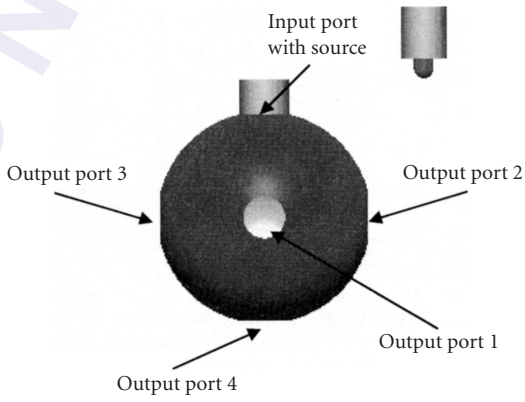

FIGURE 25 Spherical integrating cavity with one input port and four output ports.

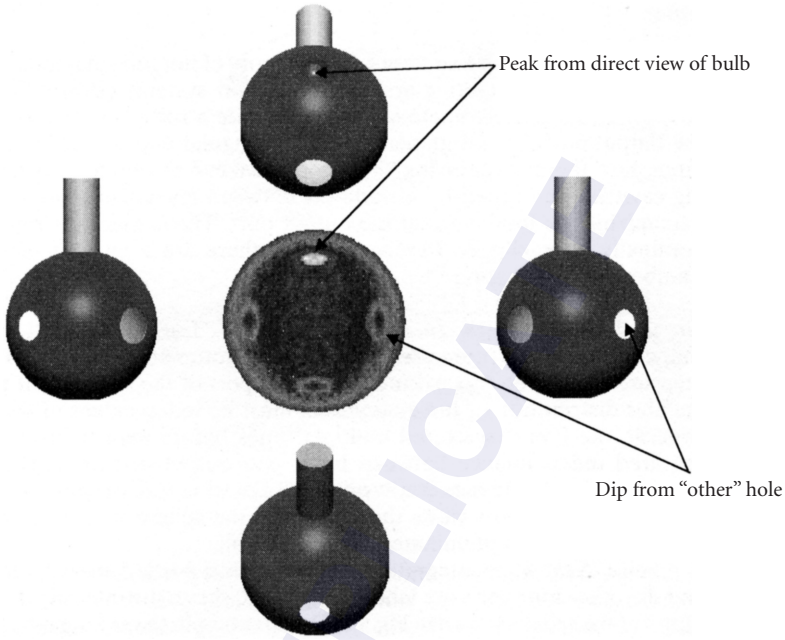

FIGURE 26 Relationship between the intensity distribution from the flux that exits an integrating sphere to what you see when looking back into the sphere.

can "see" direct radiation from the source. The dips in the intensity distribution occur at view angles where the output port can "see" the unused ports in the sphere.

If the source is replaced by a relatively collimated source that illuminates only a small region of the cavity interior (e.g., a collimated laser), then the output port intensity also shows a peak as shown in Fig. 27.

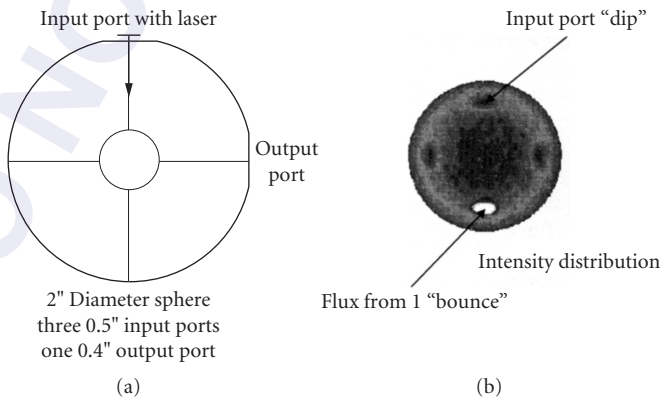

FIGURE 27 Intensity distribution (*a*) for an integrating sphere (*b*) that is illuminated with a highly collimated source. The flux that exits the sphere with only one bounce produces a higher intensity than the flux that rattles around and exits in a more uniform manner. The intensity distribution is shown normal to the orientation of the output port.

Three methods that are often used in precision photometry to create an output intensity distribution that is independent of the input involve the use of baffles, satellite spheres, and diffusers. Baffles block radiation from exiting the sphere directly, thereby forcing the exiting flux to scatter multiple times before exiting the sphere. A *satellite sphere* is a secondary sphere that is added to the primary sphere. Diffusers superimpose flux from multiple angles to provide an averaging effect that removes observable structure.

Finite-thickness walls at the exit port will also alter the view angle of external ports and can improve the on-axis intensity because light that reflects off of the walls can go back into sphere and have a chance to add to the output.

Efficiency versus Luminance An important aspect of an integrating cavity is that structure in the angular and spatial distribution of the source's light flux are removed by multiple reflections from the diffuse reflector. Under the assumption that the flux inside of an integrating sphere is scattered in a Lambertian manner, Goebel[217] has provided a description of the relationship between the fraction of flux that enters the sphere and the fraction of flux that exits the sphere (see also the Technical Information chapter in the LabSphere catalog). Goebel's results can be used to show that the ratio of the flux that exits the sphere via one port to the flux that exits out another port is

$$\text{Efficiency} = \eta = \frac{f_{\text{output}} R_{\text{sphere}}}{1 - f_{\text{input}} R_{\text{input}} - f_{\text{output}} R_{\text{output}} - f_{\text{sphere}} R_{\text{sphere}}} \tag{13}$$

where f_{sphere} = (total sphere surface area – port areas)/total sphere surface area
f_{output} = output port area/total sphere surface area
f_{input} = input port area/total sphere surface area
R_x = reflectivity of x

When the input and output have zero reflectivity, the result is

$$\text{Efficiency} = \eta = \frac{f_{\text{output}} R_{\text{sphere}}}{1 - f_{\text{sphere}} R_{\text{sphere}}} \tag{14}$$

Averaging the input flux over a hemisphere gives a ratio of the luminance at the output port to the luminance at the input port of

$$\frac{\text{Output luminance}}{\text{Input luminance}} = \frac{\eta / \text{area}_{\text{output}}}{1/\text{area}_{\text{input}}} = \frac{\eta f_{\text{input}}}{f_{\text{output}}} = \frac{R_{\text{sphere}} f_{\text{input}}}{1 - f_{\text{input}} R_{\text{input}} - f_{\text{output}} R_{\text{output}} - f_{\text{sphere}} R_{\text{sphere}}} \tag{15}$$

When the input and output ports have zero reflectivity, then the result is

$$\frac{\text{Output luminance}}{\text{Input luminance}} = \frac{R_{\text{sphere}} f_{\text{input}}}{1 - f_{\text{sphere}} R_{\text{sphere}}} \tag{16}$$

The efficiency and the ratio of input to output luminances are shown in Fig. 28 for the case of R_{sphere} = 98.5 percent.

When the fractional input port size equals the fractional output port size, the sphere transmission is less than 50 percent and the output luminance is less than 50 percent of the input luminance. Increasing the output port size provides higher transmission, but the luminance of the output port is now less than 50 percent of that of the input port. Reducing the output port size can increase the output luminance to values greater than the input luminance; however, the transmission is now less than 50 percent. Thus, an integrating cavity offers the possibility of improving uniformity at the expense of either luminance or efficiency.

Integrating Cavity with Nonimaging Concentrator/Collectors The flux exiting an integrating cavity tends to cover a hemisphere. Adding a nonimaging collector, such as a CPC, to the output port can

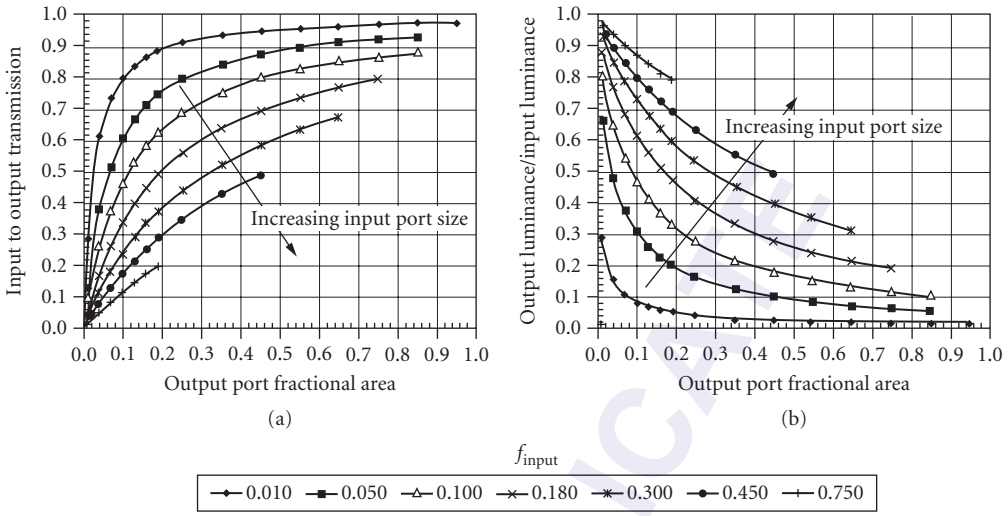

FIGURE 28 Input to output transmission (*a*) and relative output luminance *(b)* for the case of sphere reflectivity = 0.985. The different curves are for various input port fractional areas.

reduce the angular spread. The integrating cavity can also include a concentrator at the input port so as to minimize the size of the input port if the angular extent of the radiation at the input port does not fill a hemisphere.

A CEC can be added to the output port of an integrating cavity so that the portion of the sphere surface that contributes to the output distribution is restricted to a region that is known to have uniform luminance.[215] Flux outside of the CEC field of view (FOV) is rejected by the CEC. CPCs and lenses with CHCs have also been investigated.[215,218,219]

Modifying the Cavity Output Distribution Prismatic films can also be placed over the exit port of an integrating cavity, which is an approach that has been used by the liquid crystal display community (e.g., the BEFII films commercialized by 3M). The prismatic films increase the intensity at the angles that exit the sphere by reflecting the undesired angles back into the sphere so that they can be rescattered and have another chance to exit the sphere. For systems that require polarized light, nonabsorbing polarizing films can also be used to return the undesired polarization state back into the sphere.

Another approach to selectively controlling the exit angles is the addition of a hemispherical or hemiellipsoid reflector with a hole in the reflector. Webb[220] described this approach for use with lasers.

In a similar manner, reflecting flux back through the source has been used with discharge sources, and is especially effective if the source is transparent to its own radiation.

Mixing Rods (Lightpipes)

When flux enters one end of a long lightpipe, the illuminance at the other end can be quite uniform. The uniformity depends upon the spatial distribution at the lightpipe input, the intensity distribution of the input flux, and the shape of the lightpipe.[306] Quite interestingly, straight round lightpipes often do not provide good illuminance uniformity, whereas some shapes like squares and hexagons do provide good illuminance uniformity. This is shown in Fig. 29.

Shapes (Round versus Polygon) Square lightpipes have been used very successfully to provide extremely uniform illuminance distributions. To understand how a lightpipe works, consider the

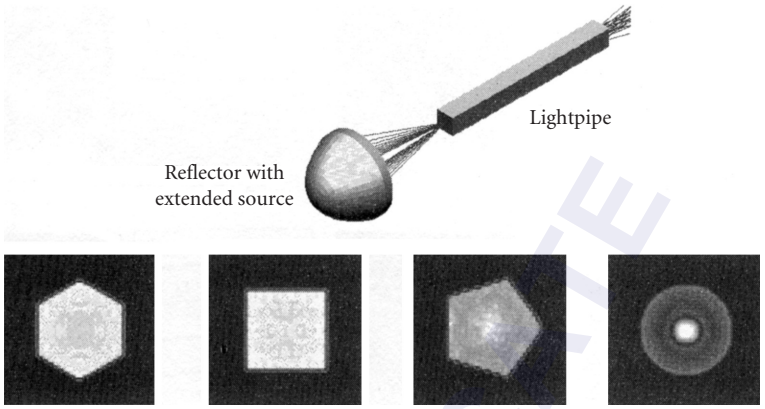

FIGURE 29 When flux from a source is coupled into a mixing rod, the illuminance at the output end of the mixing rod is significantly affected by the shape of the lightpipe. Square and hexagonal lightpipes work much better than round or many other regular polygons.

illuminance distribution that would result at the output face of the lightpipe if the lightpipe's sidewalls were removed. Including the sidewalls means that various regions of the illuminance distribution with no lightpipe are superimposed. In the case of a square, the multiple regions add in a controlled manner such that there is improved uniformity by virtue of the superposition of multiple distributions. If the source distribution is symmetric about the optical axis, then distributions with a positive slope are superimposed onto distributions with a negative slope. This means that the uniformity from N distributions can be better than the addition of N uncorrelated distributions that would provide uniformity with a $1/\sqrt{N}$ standard deviation.

One way to view the operation of a rectangular mixing rod is to consider the illuminance distribution that would occur at the output face of the mixing rod if no sidewall reflections were present. The sidewalls force subregions of this unreflected illuminance distribution to superimpose in a well-controlled manner.[221] This is shown in Fig. 30, where a Williamson-type construction is shown on the left. The illuminance distribution at the lightpipe output with no sidewalls is also shown, as is the superposition of the subregions when sidewall reflection is included. Every other subregion is inverted because of the reflection at the sidewall. This inversion provides a difference between a lightpipe used for homogenization and a lens array.

Figure 31 shows the results of a Monte Carlo simulation where a source with a Gaussian illuminance distribution and a Gaussian intensity distribution are propagated through a square lightpipe. The illuminance at the lightpipe input and output faces is shown in the top of the figure. The illuminance distribution in the lower right shows the illuminance distribution if no sidewall reflections occurred. Lines are drawn through the no-sidewall reflection illuminance distribution to highlight the subregions that are superimposed to create the illuminance distribution when the lightpipe is present. The lower left illuminance distribution results from propagating the flux from the output end of the lightpipe back to the input end. Multiple images of the source are present, similar to the multiple images observed in a kaleidoscope. This kaleidoscope effect is one reason why lightpipe mixing is sometimes considered to be the superposition of multiple virtual sources.

In general, if the cross-sectional area is constant along the lightpipe length, and the area is covered completely by multiple reflections with respect to straight sidewalls of the lightpipe, then excellent uniformity can be obtained. The shapes that provide this *mirrored tiling* include squares, rectangles, hexagons, and equilateral triangles.[222] A square sliced along its diagonal and an equilateral triangle sliced from the center of its base to the apex will also work. Pictures of these shapes

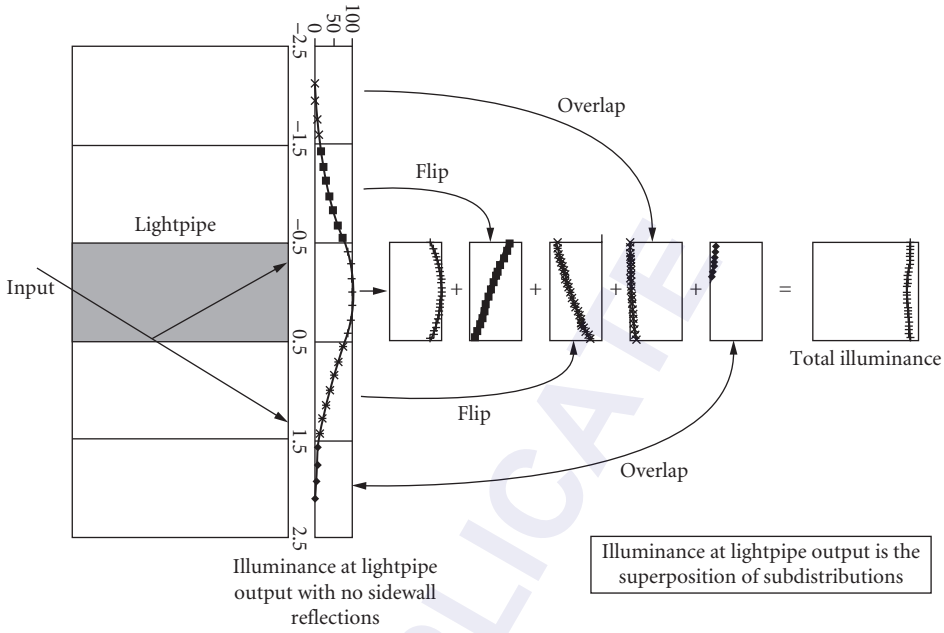

FIGURE 30 Flip-and-fold approach[221] for use with rectangular mixing rods. Subregions of the illuminance at the lightpipe output with no sidewall reflections are superimposed to create a uniform distribution. The lightpipe is shown shaded and a Williamson construction is included. The path of one ray is shown with and without sidewall reflection.

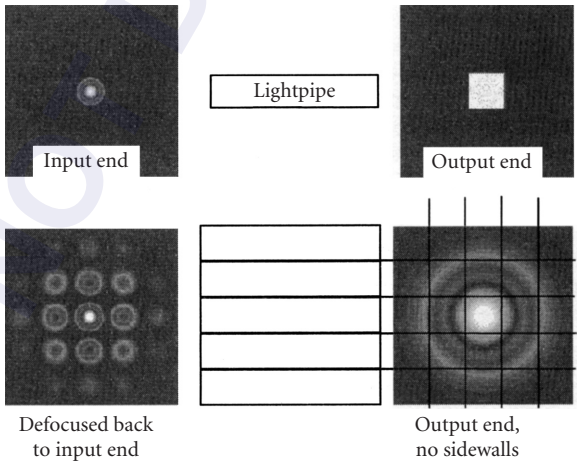

FIGURE 31 Example with a source that has a Gaussian intensity distribution. If the source is propagated to the end of the lightpipe without sidewall reflections, the illuminance distribution at the output can be sliced into distinct regions. These regions are superimposed to create the illuminance distribution that actually occurs with the sidewall reflections. If the flux at the lightpipe output is propagated virtually back to the input end, the multiple images can be observed.

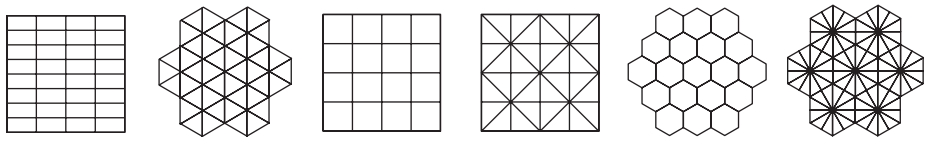

FIGURE 32 Mirror-tiled shapes that can ensure uniformity with adequate length.

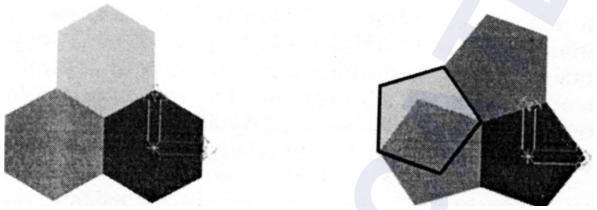

FIGURE 33 Diagram showing why pentagon does not tile like the hexagon. Simulation results are shown in Fig. 29.

arranged in a mirror-tiled format are shown in Fig. 32. The lightpipe length must be selected so as to provide an adequate number of mirrored regions. In particular, the regions near the edge that do not fill a complete mirror-tiled subregion must be controlled so that they do not add a bias to the output distribution.

Shapes that do not mirror-tile may not provide ideal uniformity as the lightpipe length is increased, at least for a small clipped Lambertian source placed at the input to the lightpipe. One explanation is shown in Fig. 33.

Round lightpipes can provide annular averaging of the angular distribution of the flux that enters the input end. Because of this, the illuminance distribution along the length of the lightpipe tends to be rotationally symmetric; however, the illuminance distribution tends to provide a peak in the illuminance distribution at the center of the lightpipe. The magnitude of this peak relative to the average varies along the length of the lightpipe. If the distribution entering the lightpipe is uniform across the whole input face, and the angular distribution is a clipped Lambertian, then the round lightpipe maintains the uniformity that was present at the input end. However, if either the input spatial distribution or the input angular distributions are not uniform, then nonuniform illuminance distributions can occur along the lightpipe length. This presents the interesting effect that a source can be coupled into a square lightpipe of adequate length to provide a uniform illuminance distribution at the lightpipe output face; however, if the angular distribution is nonuniform and coupled into a round lightpipe, then the illuminance at the output face of the round lightpipe may not be uniform.

Periodic Distributions If the unmirrored illuminance distribution has a sinusoidal distribution with certain periods that match the width of the lightpipe, then the peaks of the sinusoid can overlap. A Fourier analysis of the lightpipe illuminance distribution can help to uncover potential issues.[221]

Length The length of the lightpipe that is required to obtain good uniformity will depend upon the details of the source intensity distribution. In general, overlapping a 9×9 array of mirrored regions provides adequate uniformity for most rotationally symmetric distributions. For an f/1 distribution with a hollow lightpipe, this means that the lightpipe aspect ratio (length/width) should be greater than 6:1. For a lightpipe made from acrylic, the aspect ratio needs to be more like 10:1.

Solid versus Hollow In addition to a solid lightpipe requiring a longer length to obtain a given uniformity, the design of the solid case should consider the following: Fresnel surface losses at the input

and output ends, material absorption, cleanliness of the sidewalls (heat shrink Teflon can help here), and chipping of the corners. For the hollow case, some considerations include dust on the inside, coatings with reflectivities of less than 100 and angular/color dependence, and chips in mirrors where the sidewalls join together.[221]

With high-power lasers and high-power xenon lamps, a solid coupler may be able to handle the average power density, but the peak that occurs at the input end may introduce damage or simply cause the solid lightpipe to shatter.

Hollow lightpipes can also be created using TIR structures.[223,224]

Angular Uniformity Although the illuminance at the output end of a lightpipe can be extremely uniform, the angular distribution may not be, especially the "fine" structure in the distribution. One method to smooth this fine structure issue is to add a low-angle diffuser at the lightpipe output end.[225] A diffuser angle that is about the angular difference between two virtual images is often sufficient. Since multiple images of the source are usually required to obtain illuminance uniformity at the lightpipe output, the diffuser does not increase the etendue much. Making the lightpipe longer reduces the angular difference between neighboring virtual images and the required diffuser angle is reduced accordingly. Combinations of lightpipes and lens arrays have also been used.[226]

Tapered Lightpipes If the lightpipe is *tapered,* meaning that the input and output ends have different sizes, excellent uniformity can still be obtained. Since the lightpipe tends to need a reasonable length to ensure uniformity, the tapered lightpipe can provide reasonable preservation of etendue. This etendue preservation agrees with Garwin's[3] adiabatic theorem. In general, for a given light pipe length, better mixing is obtained by starting with high angles at the light pipe input and tapering to lower angles than if the input distribution starts with the lower angles.[227] A Williamson construction can be used to explain why the tapered pipe has more virtual images than a straight tapered case. Tapered lightpipes have been used with multimode lasers[228] and solar furnaces.[222]

An example with a small Lambertian patch placed at the entrance to a tapered lightpipe and a straight lightpipe is shown in Fig. 34. The input NA for the untapered case is 0.5/3 for the 100-mm-long

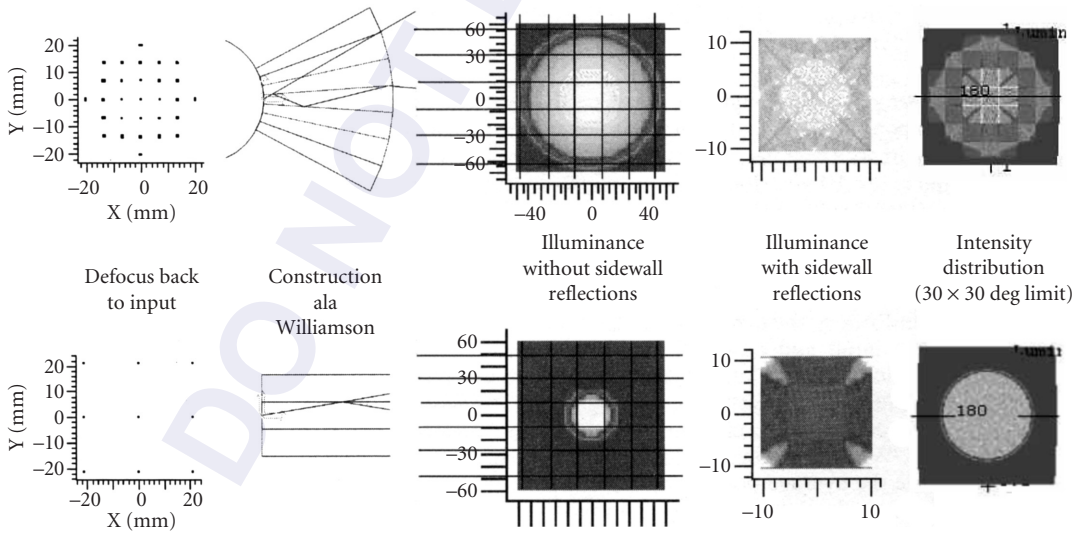

FIGURE 34 Tapered lightpipe example. The upper and lower rows are for the tapered and untapered cases, respectively. Moving left to right, the drawings show the source when defocused from the lightpipe output back to the lightpipe input, a Williamson construction, the no-sidewall illuminance at the lightpipe output, the illuminance at the lightpipe output, and the angular distribution of the flux exiting the lightpipe.

straight lightpipe and 0.5 for the 100-mm-long tapered lightpipe. The input size of the straight lightpipe is a square with a 30-mm diagonal. The input size of the tapered lightpipe is a 10-mm diagonal and the output size is a 30-mm diagonal. The Williamson construction shows that the extreme rays for the 0.5-NA meridian have almost three bounces for the tapered case, but only slightly more than one bounce for the extreme ray in the 0.5/3-NA straight lightpipe case. The illuminance distribution that would occur at the lightpipe output if the lightpipe sidewalls were removed is shown in Fig. 34. Gridlines are superimposed on the picture to highlight that the tapered case has numerous regions that will be superimposed, but the superposition will be small for the straight lightpipe case. The tapered case provides superior uniformity, although the output NA in the tapered case is higher than 0.5/3 because the angular distribution has "tails." These results are obtained using a source that is a small Lambertian patch. The comparison is typically far less drastic when the input face of the lightpipe is better filled.

Applications of Mixing Rods Mixing rods have found use in a number of applications. Examples include projection systems,[229] providing uniformity with a bundle of fibers using discharge lamps,[227] fiber-to-fiber couplers,[230] and solar simulators.[222]

Mixing rods have also been used with coherent sources. Some applications include semiconductor processing;[231] hyperpigmented skin lesions;[232,233] lithography, laser etching, and laser scanning;[228] and high-power lasers.[234] If the coherence length of the laser is not small compared to the path length for overlapping distributions, then speckle effects must be considered.[231,234] Speckle effects can be mitigated if the lightpipe width is made large compared to the size of the focused laser beam used to illuminate the input end of the lightpipe (e.g., Refs. 231 and 236). A negative lens for a laser illuminated lightpipe is described by Grojean;[235] however, this means that etendue of the source is less than the etendue of the lightpipe output.

Speckle can be controlled in lightpipes by adding a time-varying component to the input distribution. Some methods include placing a rotating diffuser at the lightpipe input end and moving the centroid of the distribution at the input end. In principle, the diffuser angle can be small so that the change in etendue produced by the diffuser can also be small.

Coherent interference can also be used advantageously, such as in the use of mixing rods of specific lengths that provide sub-Talbot plane reimaging. This was successfully applied to an external cavity laser.[237]

In addition to uniformity and the classic kaleidoscope, mixing rods can also be used in optical computing systems by reimaging back to the lightpipe input.[238,239]

Lens Arrays

Lens arrays are used in applications including Hartmann sensors,[240] diode laser array collimators,[241] beam deflection,[242] motion detectors,[243] fiber-optic couplers,[244] commercial lighting, and automotive lighting. In commercial and automotive lighting, lens arrays are often used to improve uniformity by breaking the flux into numerous subregions and then superimposing those subregions together. This superposition effect is illustrated in Fig. 35, where fans of rays illuminate three lenslets and are superimposed at the focal plane of a condensing lens. The condensing lens is not used if the area to be illuminated is located far from the lens array.

If the incident flux is collimated, then the superposition of wavefronts provides improved uniformity by averaging the subregions. However, when the wavefront is not collimated, the off-axis beams do not completely overlap the on-axis beams (see Fig. 35*b*). Tandem lens arrays add additional degrees of design freedom and can be used to eliminate the nonoverlap problem (see Fig. 35*c*).

Literature Summary Some journal citations that describe the use of lens arrays with incoherent sources include Zhidkova's[245] description of some issues regarding the use of lens arrays in microscope illumination. Ohuchi[246] describes a liquid crystal projector system with an incoherent source and describes the use of two tandem lens arrays with nonuniform sizes and shapes for the second lens array. This adjustment to the second lens array provides some adjustment to the coma introduced by the conic reflector.

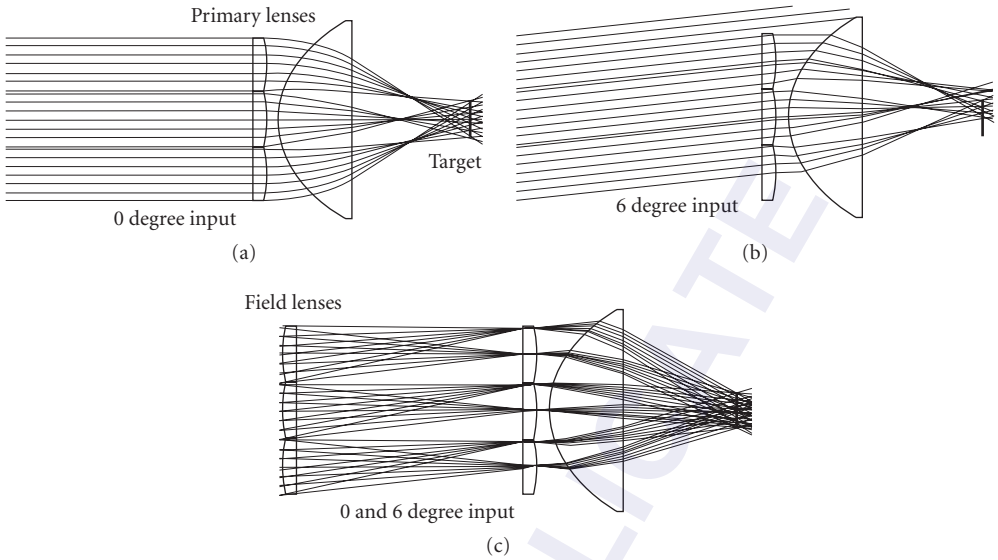

FIGURE 35 Lens arrays used for illumination. (*a*) Superposition of three subregions of the input wavefront. (*b*) Off-axis angles are displaced relative to the on-axis angles. (*c*) Tandem lens array case, where the addition of an array of field lenses allows the superposition to work with a wide range of angles.

Rantsch[247] shows one of the earliest uses of tandem lens arrays. Miles[248] also uses a tandem lens array system and is concerned about the distribution in the pupil. Ohtu[249] uses two sets of tandem lens arrays in a lithography system where one array controls the spatial distribution of the image and the other controls the angular (pupil) distribution of the image. Kudo[226] combines a lens array and lightpipe to provide the same type of control over the illuminance and intensity distributions. Matsumoto[250] adds a second set of tandem lens arrays with a sparse fill to correct the fact that an odd spatial frequency term in the illuminance distribution can result in a final nonuniformity, independent of the number of lenslets. Van den Brandt[251] shows numerous configurations using tandem lens arrays, including the use of nonuniform sizes and shapes in the second lens array. Watanabe[252] provides design equations for tandem lens arrays in a converging wavefront.

Journal publications that include lens arrays often involve the use of lens arrays with coherent sources rather than incoherent sources. Deng[253] shows a single lens array with a coherent source and shows that the distribution at the target is a result of diffraction from the finite size of each lenslet and interference between light that propagates through the different lenslets. Nishi[254] modifies the Deng system to include structure near the lenslet edges so as to reduce the diffraction effects. Ozaki[255] describes the use of a linear array of lenses with an excimer laser, including the use of lenslets where the power of the lenslets varies linearly with distance from the center of the lens array. Glockner[256] investigates the performance of lens arrays under coherent illumination as a function of statistical variation in the lenslets. To reduce interference effects with coherent sources, Bett[257] describes the use of a hexagonal array of Fresnel zone plates where each zone incorporates a random phase plate. Kato[258] describes random phase plates.

Single-Lens Arrays Single-lens-array designs for uniformity tend to have two extremes. One occurs when adding the lens array significantly changes the beam width. This is the beam-forming category where the shape of the beam distribution is essentially determined by the curvature and shape of the lenslets. The other extreme occurs when adding the lens array does not significantly change the beam width. This is the beam-smearing category and is useful for removing substructure in the beam, such as structure from filament coils or minor imperfections in the optical elements. There are many designs that lie between these two extremes.

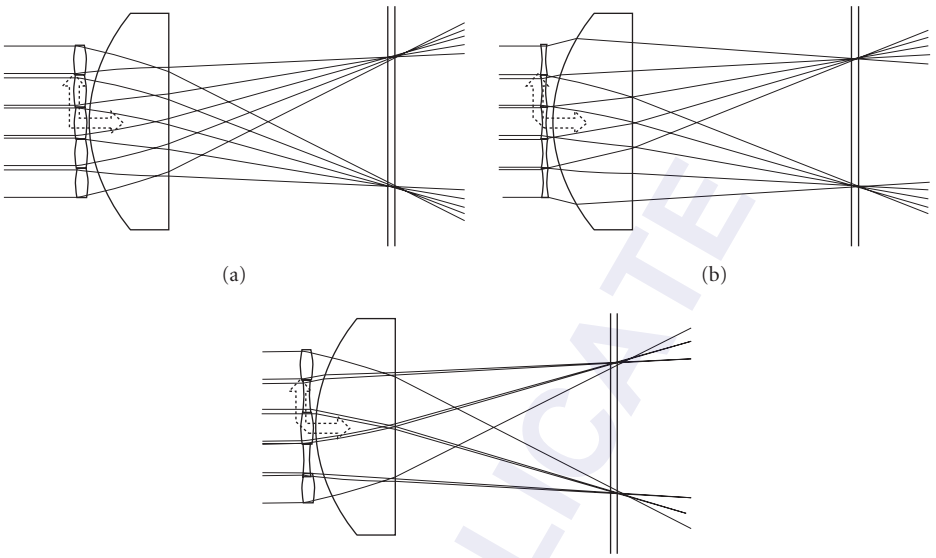

FIGURE 36 Superposition using an array of positive lenses (*a*), negative lenses (*b*), and also a hybrid system (*c*) that uses negative and positive lenses. A collimated wavefront passing through each lenslet is mapped over the target. The hybrid system offers the possibility of a continuous surface with no slope discontinuities.

Figure 36 depicts the beam-forming case where the source divergence is assumed to be small. Positive and/or negative lenses can be used to create the distribution. Hybrid systems where mixtures of positive and negative lenses are used provide the added benefit that the slope discontinuity between neighboring lenses can be eliminated. Slope discontinuities can degrade performance in many systems.

Tandem-Lens Arrays The use of a single-lens array has two issues that sometimes limit its use: First, the lens array increases the etendue because the angles increase but the area stays the same. Second, the finite size of the source introduces a smearing near the edges of the "uniform" distribution. Adding a second lens array in tandem with the first can minimize these limitations.

Figure 37*a* shows a 1:1 imager in an Abbe (critical) illumination system. Figure 37*b* shows the same imager with two-lens arrays added. Adding the lens arrays has changed the system from Abbe to Kohler (see the preceding text). In addition, as shown in Fig. 38, the lenslets provide channels that can be designed to be independent of one another. There are three main reasons why two tandem-lens arrays provide uniformity:

1. Each channel is a Kohler illuminator, which is known to provide good uniformity assuming a slowly varying source-intensity distribution.
2. Adding all the channels provides improved uniformity as long as the nonuniformities of one channel are independent of the nonuniformities of the other channels (e.g., a factor of $1/\sqrt{N}$ improvement by adding independent random variables).
3. For symmetric systems, the illuminance from channels on one side of the optical axis tends to have a slope that is equal but opposite to the slope on the other side of the optical axis. The positive and negative slopes add to provide a uniform distribution.

Reflector/Lens-Array Combinations Using a reflector to collect the flux from the source can provide a significant increase in collection efficiency compared to the collection efficiency of a single lens. The

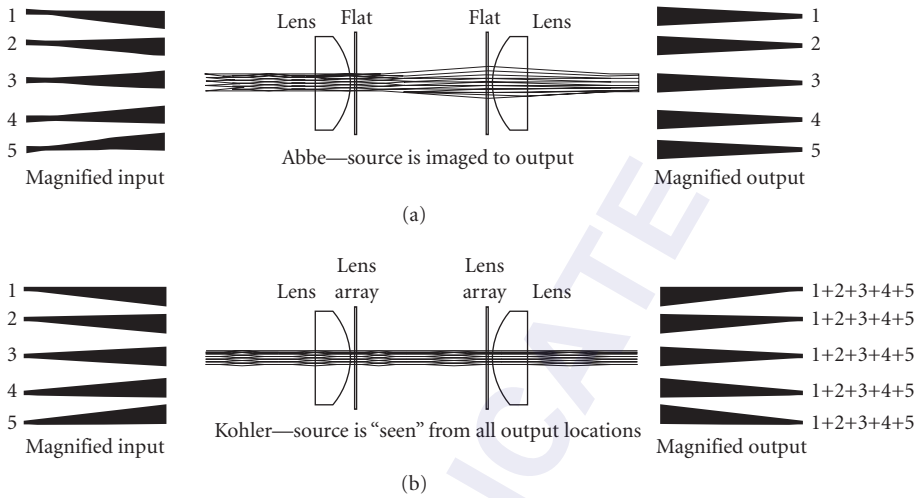

FIGURE 37 Critical illumination (Abbe, *a*) compared to Kohler (*b*). In Abbe, the source is imaged to the output. In Kohler, most of the source is "seen" from all output points.

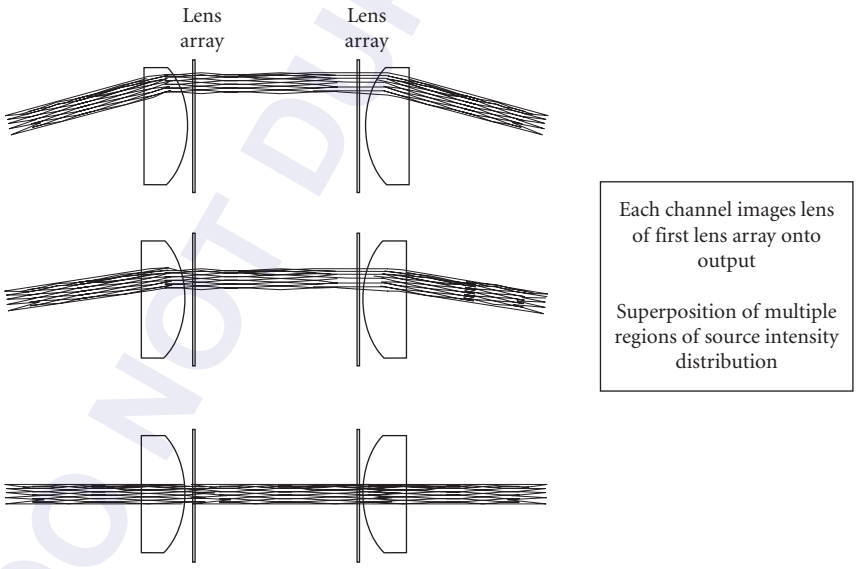

FIGURE 38 Multiple channels in a tandem-lens array. Each channel images a subregion of the flux at the first lens array. The flux from the different channels is superimposed.

drawback is that a single conic reflector does not generally provide uniform illuminance. The use of a lens array in this situation allows the illuminance distribution to be broken into multiple regions, which are then superimposed on top of each other at the output plane.

Examples showing the illuminance distribution at the first lens array, the second lens array, and the output plane are shown in Fig. 39 for the case of a lens collector, Fig. 40 for the case of a parabola

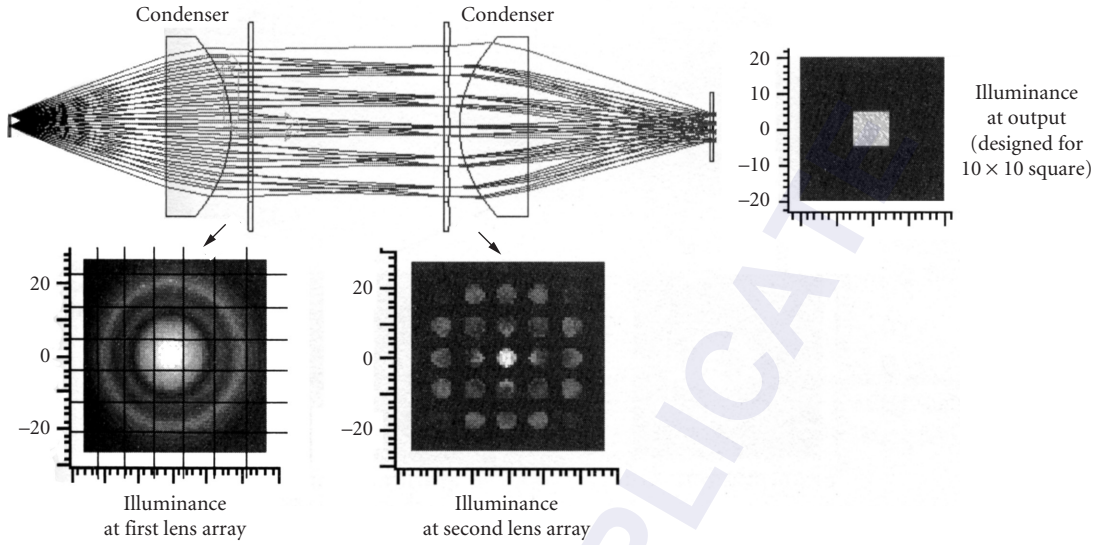

FIGURE 39 Source/condenser/tandem lens arrays/condenser configuration. Illuminance at first lens array is broken into subregions that are superimposed at the target by the second lens array/second condenser. All units are millimeters.

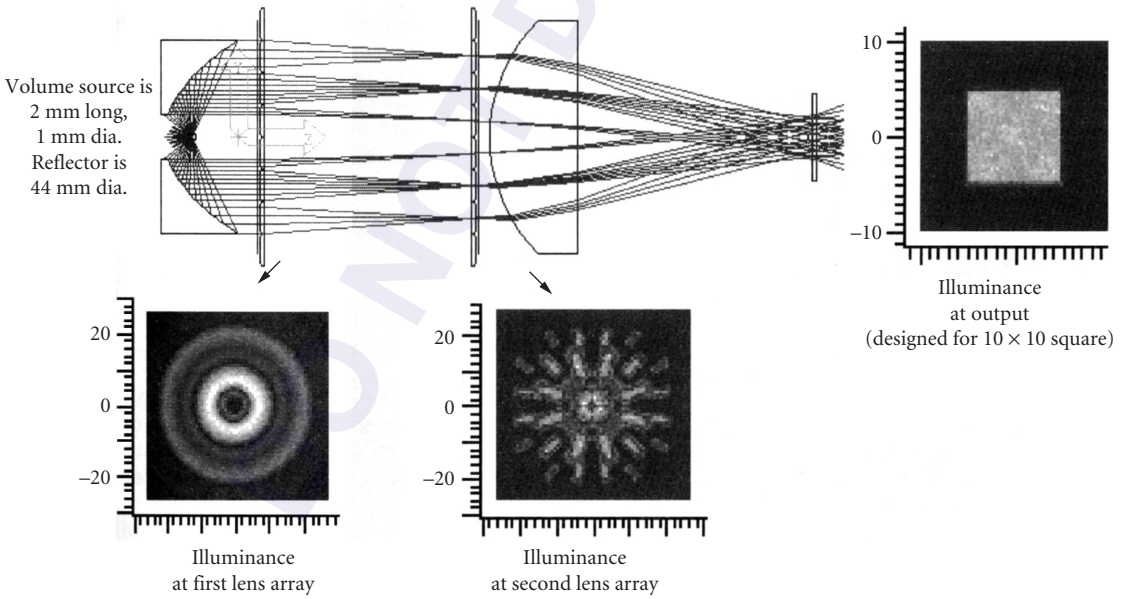

FIGURE 40 Parabola/tandem lens arrays/condenser configuration. Nonuniform magnification from the reflector (coma) is seen in the array of images at the second lens array. The illuminance at the target is the superposition of subregions at the first lens array. All units are millimeters.

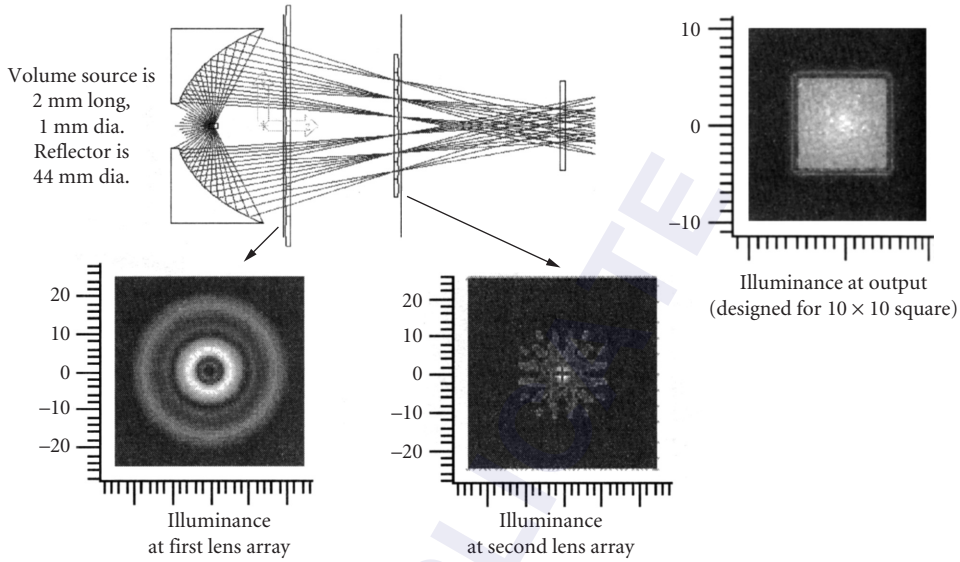

FIGURE 41 Ellipse/tandem lens arrays/condenser configuration. Nonuniform magnification from the reflector (coma) is seen in the array of images at the second lens array. The illuminance at the target is the superposition of subregions at the first lens array. The spacing between lenses is different for the two lens arrays. All units are millimeters.

collector, and Fig. 41 for the case of an elliptical collector. These examples show that nonuniform illuminance distribution at the first lens array is broken into regions. Each region is focused onto the second set of lenses, which creates an array of images of the source. The lenslets in the second array image the illuminance distribution at the first lens array onto the output plane. Enhanced uniformity is obtained because the distributions from each of the channels are superimposed at the target. The discrete images of the source that are seen at the second lens array indicate that the pupil of the output distribution is discontinuous.

Improvements to this basic idea include the use of lens arrays where the lenslets in the second lens array do not all have the same size/shape.[251] The curvature of each lenslet in the first array is decentered to "aim" the flux toward the proper lenslet in the second array. When nonuniform lenslet size/shapes are used, the etendue loss that results from the use of a conic reflector can be minimized. Such a system can be used to create asymmetric output distributions without a correspondingly misshaped pupil distribution (see earlier section on image dissectors).

Tailored Optics

The tailoring of a reflector to provide a desired distribution with a point or line source has been explored.[8,259–265] Some simple cases are available in closed form.[88,266,267] Refractive equivalents have also been investigated.[268,269]

In a manner similar to the lens configurations shown in Fig. 36, tailored reflectors can produce converging or diverging wavefronts. Examples are shown in Fig. 42. The converging reflector creates a smeared image of the source between the reflector and the target. The diverging reflector creates a smeared image of the source outside of the region between the reflector and target. This terminology was developed assuming that the target is far from the reflector. The terms *compound hyperbolic* and *compound elliptic* are also used to describe these two types of reflector configurations.[270]

If the flux from the two sides of the reflector illuminates distinct sides of the target, then there are four main reflector classifications (e.g., Ref. 26, pp. 6.20–6.21; Refs. 91 and 260). Examples of the

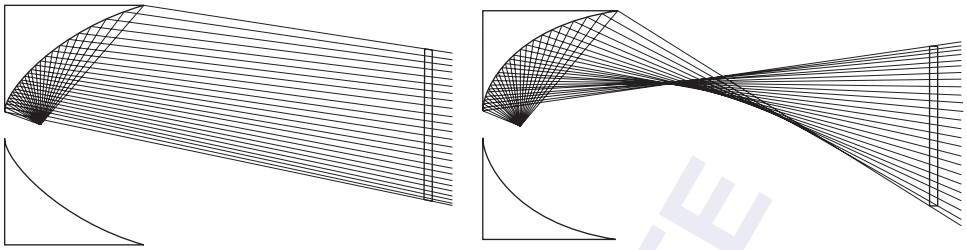

FIGURE 42 Two main classes of reflector types—diverging (*left*) and converging (*right*). The target is shown on the right of each of the two figures.

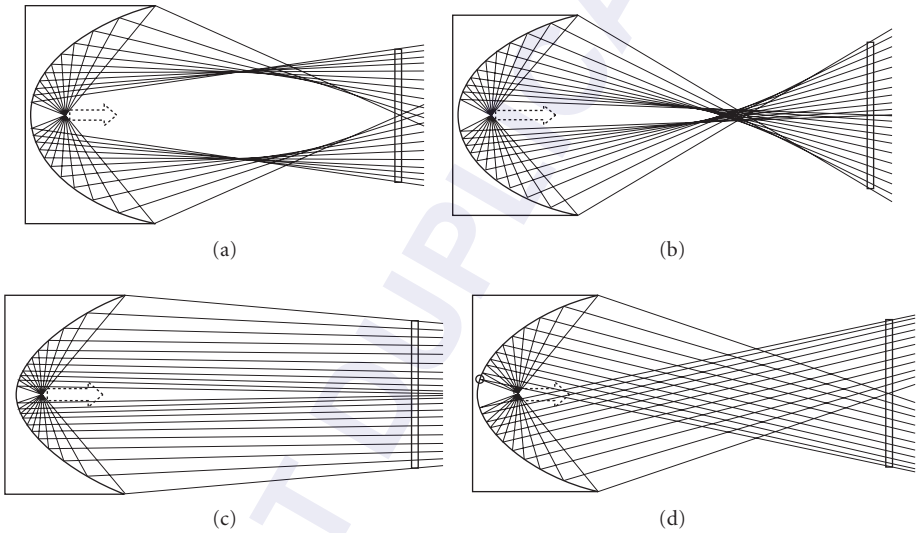

FIGURE 43 Four types of one-to-one mapping reflectors where the flux from each side of the reflector does not overlap at the target. (*a*) Uncrossed converging. (*b*) Crossed converging. (*c*) Uncrossed diverging. (*d*) Crossed diverging.

four cases are pictured in Fig. 43. They are the crossed and uncrossed versions of the converging and diverging reflectors, where *crossed* is relative to the center of the optical axis. Elmer[271] uses the terms *single* and *divided* for uncrossed and crossed, respectively. The uncrossed converging case tends to minimize issues with rays passing back through the source. The four cases shown provide one-to-one mappings because each point in the target receives flux from only one portion of the reflector.

Tailored Reflectors with Extended Sources Elmer[8] describes some aspects of the analysis/design of illumination systems with extended sources using what are now called *edge rays* (see also Ref. 271). Winston[266] sparked renewed interest in the subject. The following is a brief summary of some of the edge-ray papers that have been published in recent years. Some concentration related citations are included. Edge rays were also discussed earlier.

Gordon[272] adds a gap between the source and reflector to offset the cosine cubed effect and obtain a sharp cutoff. Gordon[273] explores the case where the extreme direction is a linear function of polar angle. Friedman[147] uses a variable angle to design a secondary for a parabolic primary. Gordon[274] describes a tailored edge ray secondary for a Fresnel primary, in particular for a heliostat field. Winston[270] describes the tailoring of edge rays for a desired functional rather than maximal

concentration. Ries[275] describes the tailoring based on a family of edge rays. Rabl[276] tailors the reflector by establishing a one-to-one correspondence between target points and edge rays for planar sources. Ong[277,278] explores tailored designs using full and partial involutes. Jenkins[279] also describes a partial involute solution and generalizes the procedure as an integral design method.[280] Ong[91] explores the case of partial involutes with gaps. Gordon[281] relates the string construction to tailored edge ray designs for concentrators.

Faceted Structures

Nonuniform distributions can be made uniform through the use of reflectors where the reflector aims multiple portions of the flux from the source toward common locations at the target. In many cases, the resulting reflector has a faceted appearance. If the source etendue is significantly smaller than the etendue of the illumination distribution, then smearing near the edges of the uniform region can be small. However, if the source etendue is not negligible compared to the target, then faceted reflectors tend to experience smearing similar to the case of one lens array.

The term *faceted reflector* identifies reflectors composed of numerous distinct reflector regions. Elmer[270] uses the term *multiphase* and Ong[91] uses the term *hybrid* to describe these types of reflectors. If there are more than two regions, then the regions are often called *facets.* As with lens arrays, there are two extremes for faceted reflector designs. One is the beam-smearing category, where the facets remove substructure in the beam. The other extreme is the beam-forming category, where each facet creates the same distribution. If all facets create the same distribution, Elmer[271] calls the reflector *homogeneous.* If the distributions are different, then the term *inhomogeneous* is used.

For a given meridional slice, each facet can create an image of the source either in front of or behind the reflector. Using the convergent/divergent terminology to distinguish where the blurred image of the source occurs (see Fig. 42), a meridional slice of a faceted reflector can be composed of an array of convergent or divergent facets. These two cases are shown in Fig. 44 *a* and *b.* Flat facets are

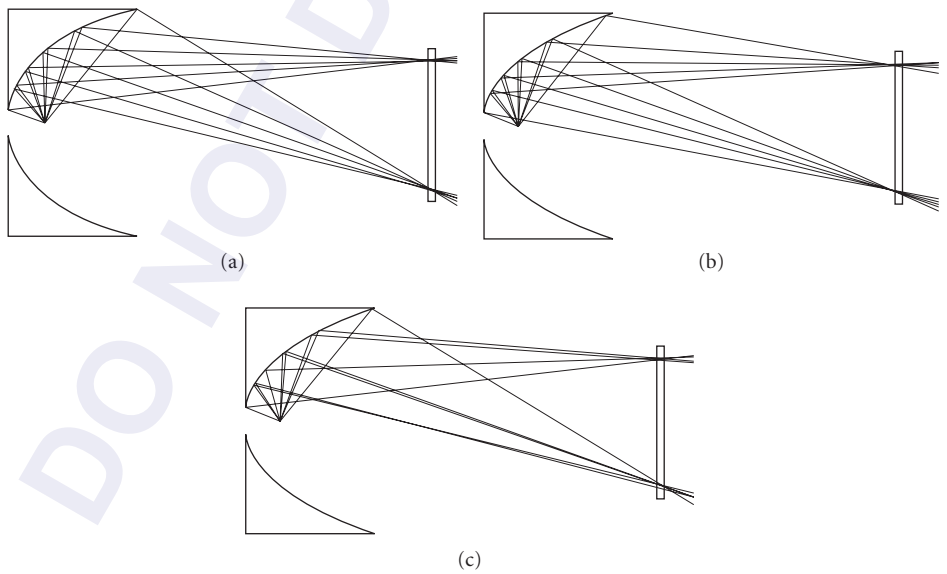

FIGURE 44 Some faceted reflector profiles. Convergent (*a*), divergent (*b*), and mixed convergent/diver gent (*c*) profiles are all shown with five facets for the upper half of the reflector. Rays from the source that hit near the edges of the facets are shown. The rays for the upper facets are highlighted for all three cases. The rays for the second facet are highlighted in the mixed case.

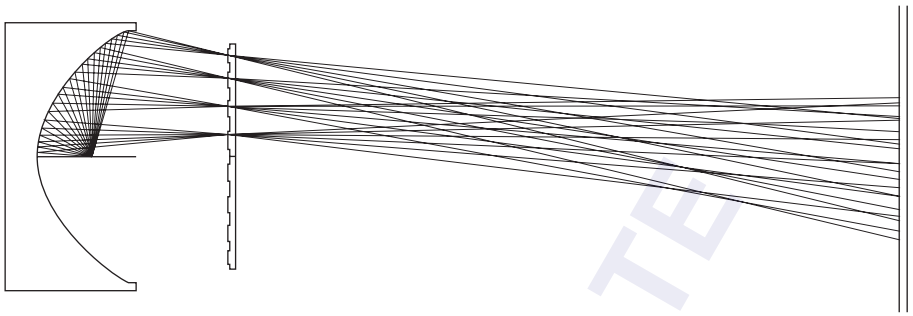

FIGURE 45 Reflector with array of concave facets and an array of lenslets. The lenslets image the facets.

often desired because of the simplicity of fabrication and fall under the divergent category because the image of the source is behind the reflector.

The intersection between facets of the same type introduces a discontinuity in the slope of the reflector. Mixed convergent/divergent versions are possible, as shown in Fig. 44*c*. Mixed versions offer the possibility of minimizing discontinuities in the slope of the reflector curve.

If all the distributions are superimposed, then improved uniformity can arise through superposition if sufficient averaging exits. Consider a manufacturing defect where a subregion of the reflector that is about the size of a facet is distorted. If a superposition approach is used, then the effect of the defect is small because each facet provides only a small contribution to target distribution. However, if a one-to-one mapping approach is used, then the same defect distorts an entire subregion of the target distribution because there is no built-in redundancy.

The effects of dilution should be considered when faceted optics are used. A single-lens array provides insufficient degrees of freedom to provide homogeneous superposition without introducing dilution, which is why a second lens array is often added (e.g., the tandem-lens-array configuration). Schering[282] shows lenslets placed on a reflector combined with a second array of lenslets. A straightforward extension of lenslets on a reflector is the use of concave facets, as pictured in Fig. 45.

Some Literature on Faceted Structures If the source is highly collimated (e.g., a laser) and has a Gaussian distribution, then only a couple of regions of the wavefront need to be superimposed to provide excellent uniformity. Descriptions of optical implementations that emphasize nearly Gaussian wavefronts include a four-surface prism by Kawamura,[283] a wedge prism by Lacombat,[211] and a multipass wedge prism by Sameshima.[284] Austin[285] has described a prism system for an excimer laser. Brunsting[286] has described a system with nonplanar wedges. Bruno[287] and Latta[228] have discussed examples of mirrored systems with very few superimposed wavefronts.

For the more general case, uniformity can be obtained by superimposing a number of different regions of the beam. Dourte[288] describes a 2D array of facets for laser homogenization. Ream[289] discusses a system with a convex array of flat facets for a laser. Doherty[290] describes a segmented conical mirror that can be used to irradiate circular, annular, and radial surfaces with a laser source. Dagenais[291] describes the details of a system with nonplanar facets for use with a laser in paint stripping. Dickey[292] shows a laser-based system composed of two orthogonal linear arrays of facets and includes curvature in the facet structures to minimize the effects of diffraction. Experimental data for two orthogonal linear arrays of facets [called a *strip mirror integrator* (SMI)] are provided by Geary.[293] Lu[294] has described a refractive structure using a multiwedge prism structure. Henning[295] and Unnebrink[296] show curved facets for use with UV laser systems.

Laser-based systems provide the degree of freedom that the wavefront divergence can be small, although the effects of diffraction and coherence must be considered in those designs. The divergence of nonlaser sources is often an important issue.

Jolley[259] describes a faceted mirror design with disc and spherical sources. David[297] describes faceted reflectors like the ones used in commercial lighting products and highlights the fact that facets on a

conic reflector base can improve uniformity with very little increase in "spot size" for long linear sources. Coaton[298] provides a brief description of a faceted reflector design with a point source. Donohue[299] describes faceted structures in headlamps.

There are many patents that describe the use of faceted structures for incoherent sources. Examples include Wiley,[300] who uses the facets to remove filament image structure; Laudenschlarger,[301] who describes design equations for a faceted reflector; Heimer,[302] who uses a faceted reflector in a lithography system; and Hamada,[303] who uses a faceted structure with a linear lamp.

Ronnelid[304] uses a corrugated reflector to improve the angular acceptance of a 2D CPC in solar applications. Receiver uniformity can also be improved in CPCs using irregular surfaces (Ref. 4, pp. 153–161).

Faceted structures have often been used in complex lightpipes such as those used in the illumination of backlit liquid-crystal displays and instrument panels. For instrument-panel application, more recent efforts have been directed toward using aspheric surfaces.[305]

39.7 ACKNOWLEDGMENTS

Special acknowledgement is given to Doug Goodman, whose list of uniformity references and OSA course notes provided an important starting point for portions of this chapter. The support of Optical Research Associates (ORA) during the manuscript preparation is also appreciated, as are the editorial and terminology discussions with many of the technical staff at ORA. Simulation and ray trace results were all generated using either LightTools® or CodeV®.

40.1 GLOSSARY

Illuminance. Luminous flux incident on a surface per unit projected area in the direction of emission relative to the surface normal. 1 lux = 1 lumen/m^2.

Intensity. Luminous flux emitted by a source per unit solid angle in a given direction. 1 candela = 1 lumen/steradian.

Luminance. Luminous flux emitted in a given direction per unit solid angle per unit projected area in the direction of emission relative to the surface normal. 1 nit = 1 lumen/($m^2 \times$ steradian).

Luminaire. Lamp or lighting fixture that includes optical components, baffles, housing, and electronics.

Display. It refers to many things: a computer monitor, a projected image, and a piece of art or a decorative item.

Backlighting. It refers to illumination of an object from behind. The object can be opaque, translucent, or transparent. The light source is usually large in size and diffuse.

40.2 INTRODUCTION

Lighting is an area of science that includes the interaction between light and people in their daily lives. The primary goals of lighting are to provide the illumination to perform tasks, direct people to desired locations and provide a sense of security. Additionally, lighting has a profound effect on mood and sleep-wake cycles of all living beings. As mankind has advanced technologically, the needs fulfilled by lighting have also increased to additionally provide relaxation, alter moods, attract people, provide entertainment, create virtual environments and improve human productivity.

Unlike most of other fields in optics, lighting is a more subjective field than objective—it is based on the emission aspects and how it is perceived within its surroundings. The subjective nature is based upon our interactions with lighting shaped by vision biology and brain perception. The capabilities of the human eye largely determine the detectable range and variations (in both time and space) in colors and brightness. Perception depends upon the brain's interpretation of the input from the eye and is influenced by past experiences. For example, although brightness and the color

of lit objects are mathematically represented by luminance metrics as a function of distance, direction and wavelength, the perception of these quantities is context dependent based upon the observer's experiences and environment. Thus, the same illumination levels in two different environments can be perceived as two drastically different lighting outcomes.

The importance of understanding lighting goes beyond the basic need to illuminate objects or surroundings. The importance of representing lighting accurately has been exemplified in art over the centuries.[1] Understanding lighting in the context of human perception and the ability to represent and simulate lighting on computers has attracted attention in fields such as virtual reality for training especially in the fields of medicine, aviation and computer-aided design, and entertainment such as video games and movies. As our understanding and computational capabilities have increased over time, so has the sophistication and quality of virtual environments and the entertainment media.

An effective lighting design is contextual, cultural and is well integrated into its surroundings. Light interacts intimately with everything it impinges upon. Every object, including humans, plants and architectural elements, has distinct scatter, reflective, transmissive, and absorptive properties that are dependent upon wavelength and direction of light. As a result, the lit objects contribute to the appearance of the scene. Lighting therefore must complement in concert with the architecture and its surroundings in form, composition, and style to meet our expectations for the lit environment. For example, our expectations for the lighting environment of a casino are quite different to that of a sports stadium, a retail store, an office or a hospital. In each case, there is a distinct purpose that directs the layout of the light sources with respect to the objects. Therefore, the lighting must change in each case as dramatically as the differences between the contexts of lighting. If it does not, then responses to the lit environment are often not positive, typically making, for example, a poor work environment for an office, a lackluster sales venue for retail, or an uncomfortable room in someone's home. This subjectivity is the most difficult aspect of lighting design. After all, the success of any lighting scheme depends upon being able to meet the expectations of its users. Simply said, we know a good lighting design as soon as we see it, but it has limited quantifiable metrics.

The history of modern lighting traces its origin back to the advent of artificial light sources: the incandescent light bulb, more than a century ago. Currently there is a wide variety of sources to choose from: incandescent (includes halogen), discharge (fluorescent, high-intensity discharge, sodium vapor), lasers, electroluminescent (includes LEDs and OLEDs), and daylight. The choice of light source depends on operating characteristics, cost, efficiency, and safety. The luminaire optics play a critical role in shaping the light distribution from the source. Thus the choice of the source and luminaire optics is an integral part of the lighting design process.

Any lighting design must comply with the relevant government regulations for the specific purpose of lighting. For example, safety is critical in transportation lighting, so there are stringent regulations on the relative intensity distribution from street lights and automobile headlamps to minimize glare and achieve the desired visibility. There are increasing numbers of government mandates on using efficient sources in many countries, such as the banning of inefficient incandescent sources in favor of fluorescent and LED light sources. In addition to regulations, there are guidelines for best lighting practices in various situations. These guidelines are published by national and international committees such as CIE (Commission Internationale de l'Eclairage or The International Commission on Illumination), IESNA (Illumination Engineering Society of North America), SAE International (Society of Automotive Engineers), CIBSE (Chartered Institution of Building Services Engineers), and many others. These groups publish guidelines on many aspects of lighting in the interiors and exteriors of homes, offices, educational institutions, hospitals, entertainment facilities, malls, industrial complexes, sports stadiums, theatres, museum, streets, parks, transportation, and even underwater. The goals of these guidelines are to help, at a minimum, to create designs that are functional, efficient and provide safe and comfortable lighting. It is in the hands of the lighting designer to add to this mandated objective illumination to achieve the desired subjective lighting—in other words, the aesthetics.

In this chapter, we provide an introduction to many facets of lighting by touching upon the perceptual and biological factors that guide lighting design (Sec. 40.3), design elements and methods

to create functional and aesthetically pleasing designs (Sec. 40.4), technology of sources and design of relevant optics (Sec. 40.5), and measurement of lighting conditions (Sec. 40.6). We end the chapter with application examples on interior and exterior lighting in Sec. 40.7. These sections provide comprehensive data on source selection and guidelines for best practices in general and in specific application areas such as lighting for offices, homes, healthcare, retail, and transportation. Although very important aspects of lighting engineering, we do not discuss electronic control mechanisms, maintenance, and commissioning of a lighting design due to limited space.

We make extensive use of terms used in Radiometry and Photometry. The reader is encouraged to refer to the chapters on various aspects of radiometry and photometry in Chaps. 34 to 39 in this volume.

40.3 VISION BIOLOGY AND PERCEPTION

The lighting design is guided by our understanding of perception and vision biology. In this section, we touch upon various aspects of biology of vision and perception.

Vision Biology

Biological aspects of human visual system response[2] that are parameterized and used in lighting design are visual acuity (resolution, vernier, recognition, and stereoscopic), color sensitivity, accommodation, field of view, and adaptability to color and brightness changes.

Once adapted, the human visual system response does not change appreciably with time. The human visual system responds to over eleven orders of magnitude of luminance. However, at any given instance, only 2 to 3 orders of magnitude are adapted to by the eye. It takes up to 60 minutes to fully adapt to lighting conditions. Light adaptation takes place via change in the eye pupil size that controls the amount of light entering the eye (2 mm to 8 mm), photochemical processes in the retinal cells and neural processes that respond to change in the luminance below 600 nits when cone cells have not fully bleached. Neural adaptation occurs quickly, within the first 200 ms, and allows us to adapt to 2 to 3 orders of magnitude of luminance fluctuation, such as in lit spaces of building interiors. Pupil adaptation via change in the pupil size takes up to few minutes and allows us to adapt up to 1 to 2 orders of magnitude of luminance fluctuation. For tasks that require good color discrimination, several minutes to an hour are needed for this color adaptation. The higher the luminance, the shorter is the adaptation time. Based upon luminance, three vision conditions exist:

1. Photopic vision occurs when bright illumination conditions in the visible (luminance >3 nits) exist. Both the rod and the cone cells in the retina are excited, but the rods are saturated and thus effectively ignored except for peripheral vision. Full color vision with highest resolution is possible. Most indoor lighting conditions ensure photopic enabling lighting conditions.
2. Scotopic vision occurs when low illumination level in the visible (luminance <0.001 nits) exists. Only the rod cells in the retina are excited. No color vision occurs and only low-resolution peripheral vision is possible. Lighting design is usually not done for the scotopic domain but it must take into account our peripheral vision capability wherever possible to help guide the individual toward relevant objects.
3. Mesopic vision is described by the transition between photopic and scotopic. The rod cells are excited and the cone cells are partially excited. The eye has limited color discrimination and resolution capabilities. Most outdoor artificial lighting conditions operate in this region.

The luminance and color distributions should be such that it includes individuals with impaired vision that cannot be corrected such as reduced illumination at the retina (50 percent for a 50-year old as compared to a 20-year old) due to smaller pupil size and reduced transmission efficiency of the eye, reduced contrast, increased glare sensitivity, loss of accommodation and reduced field of view caused by ageing, macular degeneration, cataract, or glaucoma. For most such cases

increased illuminance, slow transients from the light to dark regions and an environment with reduced glare help considerably.[3]

Perception

It is the perception of lit environment that eventually determines the acceptability and adequateness of lighting conditions. Lighting perception is ultimately determined by the human visual system response and brain processes that are individual dependent. It is the latter that brings considerable subjectivity to lighting perception. Lighting design criteria for specific environments are often guided by studies that determine average perceptual responses. These guidelines are continually evolving, in response to geopolitical factors, research on vision biology and technology.

Depending upon an object's optical and physical characteristics and how it is viewed in relation to its surroundings, lighting can alter its perceived visual attributes. Visual attributes of physical objects are defined in terms of brightness, lightness, hue, saturation, transparency, and glossiness. We explain each of these attributes below and also show that not every object has each of these attributes.

Brightness is the perceptual correlate of luminance. Although, in the absence of a background, the perception of brightness of an object is proportional to its luminance in a logarithmic manner (log of brightness is proportional to log of luminance), the perception of brightness is dependent upon adaptation to the surroundings and the relative hue and saturation of the object. Figure 1 shows an example of how the brightness perception is altered by surroundings.[50] Different portions of a uniform luminance bar appear to have different brightness depending upon the local background. Similarly, car headlights appear much brighter in the dark than in daylight. Both vision biology and perception play a role here. Due to low ambient lighting, the pupil dilates and admits much more light (up to 16 times in night than in the day). Therefore, any bright source leads to sudden pupil contraction and ensuing discomfort. The sources appear even brighter due to a dark background, an effect similar to Fig. 1. Color perception is similarly affected. Color-saturated objects tend to appear brighter and vice versa.

Lightness is the perceptual correlate of diffuse reflectance. Our perception of an object being dark or light depends upon our estimate of its reflectance. For example, a piece of white paper appears white irrespective of the illumination falling upon it as we know from prior experience that it has a high reflectance. We tend to perceive it whiter than other objects of lesser reflectance even when the flux reflected by white paper in relatively low illumination is lower than a grey object that is placed under higher illumination. This confusion would not occur if we view a small region of the object through an aperture without knowing anything about the object. The aperture masks the contextual information and forces us to make objective judgments.

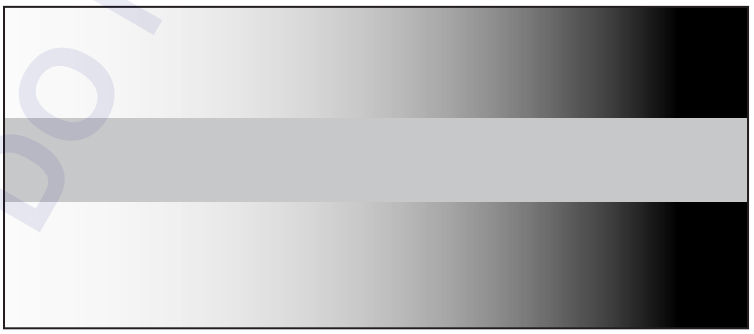

FIGURE 1 Perception of brightness. The rectangular bar in the center has constant luminance yet it seems brighter against a darker background at the right hand side.

Hue is the perception of dominant wavelength of the color spectrum transmitted or reflected by the object. It helps us judge if an object appears close to a known color such as red, blue, yellow, purple, green, colorless, or a combination of multiple colors such as bluish-green. Saturation is the perception of the extent of color purity. Highly saturated colors have a narrow band of wavelengths, centered on the hue. Transparency is the perception of the degree of light penetration into the object. Glossiness is the perception of smoothness of a surface relative to a matte finish.

Depending upon the properties of an object, the lighting conditions and how it is viewed, one or more visual attributes can be determined. For example, if an object is viewed through an aperture that hides the information of its surroundings or is illuminated such as nothing other than the object is visible then only attributes like brightness, hue, and saturation can be observed. A self-illuminated object or an object that gives the appearance of being so (such as a lit computer monitor) does not display lightness or glossiness, but if it stops emitting light, these attributes can be observed under external illumination.

Our brain attempts to maintain a perceptual constancy of shape, color, size, and lightness of lit objects based on past experiences and the context in which an object exists. Perceptual constancy allows us to maintain a certain perception of an object or a scene under changing viewing conditions. For example, we can recognize an apple as such when viewed at different angles, surroundings, or lit conditions. We can perceive a skyscraper as a tall building even if seen from far away and having a small image on the retina. Similarly, a tilted book appears rectangular although the image in the retina is trapezoidal. We can perceive the colors of common objects around us fairly correctly while wearing mildly colored glasses. Lighting can help maintain or alter perceptual constancies. To maintain perceptual constancies the lighting conditions must be such as there is adequate ambient lighting with high-color-rendering sources and without any disability glare. We discuss the terms such as color rendering, glare, and the impact of ambient lighting in the next section. The position of the light sources must be obvious to the observer even if not directly visible to establish the directionality of illumination. Direction of illumination is important as we tend to expect light to come from above and our perception of lit objects takes that into account at a subconscious level.

The relative distribution of light can impact the perception of the space itself and as such can impact human behavior.[4] For example, there is a general tendency among humans to be attracted to brighter regions of space. It can be demonstrated by viewing people that there is a clear trend toward walking on brighter areas of pathways or facing brightly illuminated areas of a restaurant. That is why brightly lit shopping malls are quite effective in attracting traffic as compared to a poorly lit shopping complex. The knowledge of human behavior toward lit space is also used in making more effective lit object displays and navigational aids. There are four distinct categories of light distribution[5] that affect the perception of space: privacy, relaxation, visual clarity, and spaciousness. An effect of privacy can be created by utilizing nonuniform high-brightness illumination across the vertical surfaces in the room with dark spaces in the occupant domains and low ambient luminance. An effect of relaxation can be created by using nonuniform warm (correlated color temperature (CCT) <3500 K) ambient light across the room. Visual clarity in the environment is emphasized with cool light (CCT >4000 K), high and uniform brightness near the center of the room and at all task planes. In addition, higher emphasis is given to ceiling and horizontal surfaces. A sense of spaciousness can be implemented with uniform room illumination and relatively higher levels of brightness on the walls and ceilings.

Summary

Understanding perception and biology of vision helps us develop models to describe desired lighting conditions. An example is the development of the relative visual performance (RVP) model. This model has been extensively developed by Mark Rea and his colleagues over the last few decades[6] to obtain the relative visual performance of a given task under different lighting conditions and establish lighting guidelines. RVP is provided as a probability of performing a visual task successfully under given lighting conditions. Task performance depends upon both visual and nonvisual aspects

of the task. To obtain the true impact of lighting conditions on task performance, it is necessary to isolate those tasks for evaluation that are dominated by the visual component. The impact of the nonvisual components is minimized by quantifying their effect to the fullest possible extent and subtracting it from the overall task performance. A key finding of the RVP model is that the visual performance improves rapidly as the luminance contrast between the task and the background increases up to 40 percent. Beyond this value, the improvement in visual performance is negligible with increase in contrast. Luminance contrast in this context is defined as

$$\text{Luminance contrast} = 100(L_{\text{Task}} - L_{\text{background}})/L_{\text{background}} \tag{1}$$

Visual performance curves (performance metric versus luminance contrast) can be evaluated for various task sizes and background luminance. A major limitation of the existing RVP model is its limited validity to only those tasks that are quantifiable by task size, luminance contrast, and background luminance and only under the conditions of foveal vision. We need more sophisticated task performance models to cover a larger range of tasks.

In the sections to follow, design guidelines make use of the understanding of lighting perception and vision biology to justify their development.

40.4 THE SCIENCE OF LIGHTING DESIGN

The lighting design process begins with identifying the needs to be addressed. An understanding of the functions of lighting and knowledge of basic building blocks helps us in making a preliminary design. The quality of lighting is determined by its ability to fulfill human needs in an economical and environmental friendly manner while at the same time complementing the architecture in form, composition, style, codes, and standards. We discuss the lighting design process in the following subsections:

Design considerations. We discuss the factors involved in creating a lighting environment for an application. The categories discussed are: goals, context, illuminance, color, visual discomfort, trespass and light induced damage of objects.

Functions of lighting. Here we discuss the four primary functions of lighting: ambient, task, decorative and accent.

Lighting geometries to achieve specific functions of lighting. Here we discuss the building blocks for lighting design.

Properties of objects and their impact on lit scene are discussed.

Modeling. Here we discuss the techniques used to simulate a lit environment in order to achieve the best design.

Design Considerations

Goals Lighting for any application must take into account the needs (both human and nonhuman such as plants or animals), lighting economics, environment impact, and architectural aspects of the application. Human needs include the desired degree of visibility, comfort, ability to perform the needed tasks, social communication, ambience, and aesthetics.

Context Lighting helps create a perceptual environment or ambience to suit a specific application such as office, home, lobby, restaurant, casino, or a sports stadium. Appropriate selection of lighting schemes and luminaires that complement the architecture and interior design helps in achieving the desired ambience.

TABLE 1 IESNA Guidelines on Illumination Categories and Average Illuminance Levels

Category	Average Illuminance (lx)
Public spaces	30
Simple orientation or short visits in a new environment	50
Working spaces where simple visual tasks are performed	100
Performance of visual tasks of high contrast and large size	300
Performance of visual tasks of high contrast and small size, or visual tasks of low contrast and large size	500
Performance of visual tasks of low contrast and small size	1,000
Performance of visual tasks near vision threshold	3,000–10,000

Large size: Object's projected solid angle subtense at the eye $>4.0 \times 10^{-6}$ sr.
Small size: Object's projected solid angle subtense at the eye $\leq 4.0 \times 10^{-6}$ sr but not near the visual acuity limit.
Low contrast: ≤0.3 but greater than visual threshold.
High contrast: >0.3.

Illuminance—Horizontal and Vertical Horizontal and vertical illuminances refer to illuminance distribution on horizontal and vertical planes respectively. Table 1 describes IESNA guidelines on illumination categories and average illuminance levels needed for each.[7] These guidelines do not apply to special situations that involve setting up a particular ambience or focusing on an object for emphasis.

The uniformity of luminance/illuminance is generally defined by the ratio of maximum to minimum luminance/illuminance. The need for uniformity across the field of view and across the entire space depends upon the application. The human eye is a brightness detector and is thus responsive to changes in luminance. To calculate luminance, illuminance, and the reflectivity of surfaces must be taken into account. For Lambertian surfaces (surfaces of constant luminance, independent of the viewing direction),

$$\text{Luminance} = (\text{illuminance} \times \text{surface reflectivity})/\pi \tag{2}$$

Generally, a luminance uniformity of 0.7 within the field of view across the task is considered adequate as the eye is unable to detect these variations. Not all tasks require high luminance uniformity. For example, in tasks involving inspection of 3D objects, nonuniform illumination is able to highlight the geometrical features, especially surface textures much better due to being able to provide better depth perception. In lit environments, a nonuniform light distribution is used to provide perceptions of privacy or exclusivity, for example in retail lighting or in restaurants. A luminance ratio (maximum luminance: minimum luminance) of greater than 15:1 is generally considered undesirable. In the applications section, we discuss the recommended luminance ratios for several scenarios in a variety of applications.

Color Lighting influences the color appearance of lit objects. For most lighting applications, white light is the standard form of illumination: exteriors (landscape, roadways, buildings, city, and stadiums) and interiors (homes, offices, restaurants, museums, industrial complexes, and shopping malls). Saturated colors in lighting are used only in special applications like indicators or signals, displays, color-specific industrial applications such as those involving color discrimination, special effects in casinos, hotels, malls, or discotheques, and so forth. The chapter on colorimetry in this *Handbook* (Vol. III, Chap. 10) provides an excellent introduction to the subject of color.

Depending upon needs such as aesthetics, task performance, and color-dependent reflective properties of objects, an appropriate light spectrum must be selected. The desired light spectrum can be achieved by using light sources that emit in that spectrum, by using static filters on the sources to tailor the spectrum or by spatial and time-averaged color mixing. Spatial color mixing involves using multiple light sources that emit in different portions of the desired spectrum but are laid out in such a manner that the lit environment or object appear to be illuminated by light

having the combined spectrum of individual light sources. Time-averaged color mixing involves high-frequency (>60 Hz) mixing of different portions of the light spectrum in different proportions. If the frequency of color mixing is high enough, the brain perceives a specific color based on the time average of the varying spectra used in their respective strengths. For example, in modern digital projectors, a color wheel is used that has various segments of different spectral transmission. When it rotates through those segments, one can create the appearance of any color within the color gamut of the light source. In the section on LEDs, we discuss color mixing to create white light or any desired color. Spatial and temporal color mixing can be used together to create a variety of effects. Although color mixing can achieve the visual perception of any desired color in emission, its ability to color render the object it illuminates depends upon the product of incident light spectrum and wavelength-dependent reflectance of the object. In this section we discuss how white light is specified and how its ability to render objects is estimated.

It is tedious to choose light sources if we have to analyze the spectrum and its impact on common objects. For white light, the color rendering index (CRI) and the correlated color temperature (CCT) help provide a quick estimate of the appearance of light and its color rendering of lit objects. For example, at a CCT of 2700 to 6500 K, a CRI ≥70 is adequate for common situations such as in offices and homes, a CRI ≥50 is sufficient for most industrial tasks and a CRI ≥90 is needed for stringent color discrimination tasks such as hospital surgery, paint mixing, or color matching. In the future, it is likely that different metrics based on color-appearance models would be in use. This is especially true with the increasing use and availability of a variety of light sources, especially LEDs, which have significantly different emission spectra from incandescent sources.

The CCT is the temperature of the planckian (perfect blackbody) radiator in Kelvin whose perceived color most closely resembles that of a given stimulus at the same brightness and under specified viewing conditions.[8] To find the CCT, the nearest point on the planckian locus is considered but only in a perceptually uniform color space. The isotherms across the planckian locus in a uniform color space are represented as normal to locus curve but in a nonuniform color space such as XYZ, these are no longer perpendicular to the locus.

Color rendering is defined as the effect of an illuminant on the color appearance of objects by conscious or subconscious comparison with their color appearance under a reference illuminant.[8] Two functional reference illuminants are currently used for calculating CRI: (1) for a source CCT up to 5000 K, a blackbody at the same color temperature is used and (2) for a source CCT above 5000 K, one of the phases of daylight is used. The phase of daylight selected is such that its chromaticity is within 1/(15E6 K) to that of the test source. It is defined by a mathematical formula based on the CCT of the test source.[9] For all cases, a CRI value of 100 is considered to be a perfect match between the test source and the illuminant. The precise steps and calculations needed to calculate the CRI are recommended by the CIE.[10] Here we summarize the results:

$$\mathrm{CRI}(R_a) = 100 - 4.6\overline{E}_{\mathrm{UVW}} \tag{3}$$

where R_a refers to the general CRI and $\overline{E}_{\mathrm{UVW}}$ is the average of the Euclidean distances between the color coordinates of the reflected reference and test light sources from the first 8 out of the 14 CIE-prescribed test samples (see Ref. 10). The color coordinates of the test source are chromatically adapted to the reference source and are expressed in the CIE 1964 color space. The CRI calculation is valid only when the color difference between the test source and the reference source is not large.

Although CRI is a useful metric and is widely used, it has several shortcomings. The existing method of calculating CRI is not perceptually well correlated. The high CRI predicted for sources with extreme CCT do not have good color-rendering properties. CRI is not valid for sources such as discrete spectral LEDs where CCT cannot be defined. CRI cannot be used to evaluate white-light LEDs with nonuniform spectra; the CRI predicted is quite low although the quality of white light appears to be better. The practice of using only eight test samples, none of which are saturated creates situations where high CRI sources do not color render color-saturated objects correctly. The CRI formulation can be modified to include the impact of different reference illuminants for different source types, color spaces, test sample set, different chromatic adaptation formulas or even a

reduced focus on absolute color fidelity. CIE reviews various propositions in this regard and updates its recommendations.

Visual Discomfort Visual discomfort can be caused by a variety of reasons.[11] Many of these reasons are context dependent where the expectation of the nature of lit environment determines the suitability of lighting. It also depends on cultural differences between various groups of people. For example, lighting flicker in a dance club may be desirable as opposed to almost all other situations. Similarly, the preference of color among different cultural groups varies considerably. Visual discomfort occurs when lighting creates perceptual confusion. For example, if the pattern of illumination is such that surfaces of higher reflectance reflect less light than the surfaces of lower reflectance, perceptual confusion may result. The causes of visual discomfort that are more specific to lighting are summarized as follows:

Insufficient lighting Insufficient lighting, especially for task performance, results in eye strain besides reduced task performance. For different tasks, there are different levels of horizontal and vertical illuminance necessary to be considered adequate. Table 1 describes suggested horizontal illuminance levels needed for certain situations. Lighting communities across the world have established guidelines for illuminance levels for a wide variety of specific tasks and environments.

Uniformity Visual discomfort occurs when the uniformity across the field of view is not as expected. A high uniformity can be as undesirable as a high degree of nonuniformity especially when considered across the entire visual field of view. Both can cause severe eye strain. In the section on applications, we provide examples of preferred luminance ratios between task and its vicinity.

Glare Glare results when there are regions of unexpected very high levels of luminance in the field of view. Glare can be direct or indirect. Direct glare occurs when a light source or a portion of it visible such as in overhead lamps, automobile headlights, or direct sunlight. Indirect glare occurs when the light is reflected or scattered directly into the eye, such as the sky reflecting off a lake surface and obscuring the view beneath the water surface. Glare comes in many forms:[12]

1. Flash blindness: This is caused by a sudden onset of bright light leading to temporary bleaching of retinal pigment.
2. Paralyzing glare: This is caused by sudden illumination with bright light that can temporarily "freeze" the movements of the observer.
3. Distracting glare: This is caused by flashing bright sources of light in the peripheral vision field.
4. Retinal damage: When the light is bright enough to cause retinal damage.
5. Saturation or dazzle: When a large portion of the vision field is dominated by bright source(s), which can be alleviated by wearing low transmittance eye glasses.
6. Adaptation: When one enters from a low ambient illumination region to a bright ambient illumination region without a transition region to help in vision adaptation.
7. Disability: This is caused by intraocular light scattering which reduces the luminance contrast [See Eq. (1)] of the task image at the retina. The impact is loss in task performance due to reduced visibility.
8. Discomfort: When the glare causes discomfort or distraction but does not affect the task visibility to the extent of limiting its performance

Note that several forms of glare can exist concurrently, especially discomfort with the other types. Discomfort and disability glare are the most commonly experienced glare forms. There are several mechanisms available to estimate the impact of these forms of glare. We discuss briefly the CIE-recommended models for disability and discomfort glare.

Disability glare Disability glare occurs when the luminance contrast [Eq. (1)] of the task image at the retina falls due to the superposition of intraocular scattered light on the retinal image.

This background noise from scattered light can be thought of as viewing through a veil. Therefore, it makes sense to define an equivalent glare (or veiling) luminance (EVL) that mimics the impact of disability glare. The luminance contrast C is described as

$$C = \left| \frac{(L_b + L_{\text{EVL}}) - (L_{\text{object}} + L_{\text{EVL}})}{(L_b + L_{\text{EVL}})} \right| = \left| \frac{L_b - L_{\text{object}}}{L_b + L_{\text{EVL}}} \right| \tag{4}$$

where L is object luminance and b is background.

As the equivalent veiling luminance L_{EVL} increases, contrast at the retina C reduces. The contrast reduction is especially severe during difficult viewing conditions such as fog or nighttime when the object luminance is low. That is why car headlights are a much stronger glare source in the night than in the day.

Equivalent veiling luminance L_{EVL} is defined as:[13]

$$L_{\text{EVL}} = \sum_i \left[\frac{10}{\theta_i^3} + \left\{ \frac{5}{\theta_i^2} + \frac{0.1p}{\theta_i} \right\} \cdot \left\{ 1 + \left(\frac{A}{62.5} \right)^4 \right\} + 0.0025p \right] \cdot E_i \tag{5}$$

where E_i = illuminance at the eye due to ith glare source
θ_i = angle of the glare source (in degrees) from the line of sight, $0.1° < \theta_i < 100°$
p = eye pigmentation factor (0 for black eyes, 0.5 for brown eyes, 1.0 for light eyes, and 1.2 for very light-blue eyes)
A = age of the viewer in years

For young adults (<35 years of age) and for glare source angle, $1° < \theta_i < 30°$, Eq. (5) approximates to

$$L_{\text{EVL}} = \sum_i 10(E_i / \theta_i^2) \tag{6}$$

The EVL as described above is strictly due to intraocular scatter. In practice, it is necessary to add to this the luminance from external scatterers, such as fog or dust in the atmosphere, to yield the correct retinal contrast.

Equation (5) is currently the most sophisticated recommended treatment for disability glare. It can be applied toward a wide variety of circumstances, including indoor lighting, street lighting, and bright sky at a tunnel's exit.

For road lighting, the CIE recommendation on disability glare[14] is given by a percentage threshold increment (TI) described by Eq. (7). TI is limited between 10 and 15 percent.

$$TI = 65(L_{\text{EVL}} / L^{0.8}) \tag{7}$$

where L_{EVL} = equivalent veiling luminance as described by Eq. (5)
L = average road surface luminance

Discomfort glare There are many formulations that describe discomfort glare. Each model is prescribed for well defined geometries and sources. Discomfort glare has been described by the visual comfort probability (VCP) model[15] in North America, British Glare Index system[16] (CIBSE) and the European glare limiting system.[17–19] Each of these systems has validity under specific constraints. Many luminaire manufacturers in North America and Europe provide VCP or glare index tables for worst case scenarios. CIE has proposed a Unified Glare Rating (UGR) model[20] to replace these systems. We describe here the formulation recommended by CIE.

The UGR formula is described by Eq. (8). UGR values range from 5 to 30, the higher values signifying a greater level of discomfort. For home and offices, UGR is specified at <20 and for industrial application it is >20. This formula is valid for source areas between 0.005 and 1.5 m^2. For smaller

TABLE 2 Glare Specification for Large Sources Such as an Illuminated Ceiling

Maximum Average Illuminance (lx)	UGR
300	13
600	16
1000	19
1600	22

sources, UGR overestimates the glare and for larger sources, UGR underestimates the glare. Therefore, for ranges outside the validity of UGR, CIE has provided detailed prescriptions to tackle small, large, and complex luminaires.[21] For source areas smaller than 0.005 m^2, Eq. (9*a*) is recommended. In practice, any bare incandescent lamp, frosted or clear qualifies as small. For source areas larger than 1.5 m^2, but not as large as an illuminated ceiling or uniform indirect lighting (see Section, "Lighting Geometries," for a definition of indirect lighting), UGR is modified into a large room glare rating (GGR) and is described by Eq. (9*b*). The same UGR and GGR values represent an identical level of discomfort. For very large sources, only the maximum average illuminance values correspond to a specific UGR rating, as shown in Table 2. For nonuniform indirect source, CIE has provided guidelines.[21] Each of the glare formulations discussed in this section are independent of the light spectrum.

Equations (9*a*) and (9*b*) are expressed for a single small and a single large source, respectively. Equation (9) is valid for viewing angles greater than 5° from the line of sight. For a combination of sources of different sizes, Eq. (8) must be modified to include glare from sources specified by equations (9*a*) and (9*b*).

$$\mathrm{UGR} = 8\log_{10}\left(\frac{0.25}{L_b}\right)\sum_i \frac{L_i^2\omega_i}{P_i^2} \tag{8}$$

$$\mathrm{UGR}_{\mathrm{SingleSmallSource}} = 8\log_{10}\left(\frac{0.25}{L_b}\right)\frac{200(I^2/R^2)}{P_i^2} \tag{9a}$$

$$\mathrm{GGR}_{\mathrm{SingleLargeSource}} = \mathrm{UGR} + \{1.18 - (0.18/\mathrm{CC})\}8\log[2.55\{1+(E_d/220)\}/\{1+(E_d/E_i)\}] \tag{9b}$$

where L_b = average luminance of the field of view without the luminaire or glare source
L_i = luminance of the ith luminaire in the observer's direction
ω_i = solid angle of the ith luminaire subtended at the observer's eye
P_i = Guth Position index[22] of the ith luminaire. [It is a function of angular deviations (vertical and horizontal) from the line of sight and valid up to 53° of deviation from the line of sight. See Eq. (10).]
I = luminous intensity of the small source expressed in lumens per steradians. The source must be >5° away from the line of sight
E_d = direct illuminance at the eye due to the source
E_i = indirect illuminance at the eye = πL_b
CC = ceiling coverage = (area projected by the source at nadir)/(area lit by the source)

$$P_i = \exp\{(35.2 - 0.31889\alpha - 1.22e^{-2\alpha/9})10^{-3}\beta + (21 + \mathbf{0}.26667\alpha - 0.002963\alpha^2)10^{-5}\beta^2\} \tag{10}$$

where α = angle of the plane containing the observer's line of sight and a line from the observer to the source from the vertical direction. [Vertical direction is the height above (orthogonal to) the floor on which the observer is positioned.]
β = angle between the observer's line of sight and the line from the observer to the source

For roadway lighting, the glare rating is affected by driver fatigue, vehicular speed, and whether the person in the car is driving or not. All these effects must be dealt with comprehensively to formulate a single glare rating model that is largely driver independent. There is ongoing research in this field to develop better models for evaluating glare for road and vehicular lighting.[23,24] Current CIE recommendation for limiting the discomfort glare for road lighting is identical to disability glare as described by Eq. (7).

Veiling reflections Veiling reflections are reflections from the task surface that result in the luminance contrast [Eq. (1)] reduction of the task itself. Veiling reflections can be evaluated from the source-task-eye geometry. It has been found that 90 percent of test subjects find a luminance contrast reduction of 25 percent as acceptable.[25] Veiling reflections are sometimes used as highlights to reveal the specular nature of a display (a lit object).

Miscellaneous Design Issues Other issues include designing against unacceptable light pollution or trespass, light-induced degradation or damage of objects and flicker from light sources. UV and IR filters are used with luminaires when there is a potential of damage to artwork or object displays. Flicker is more noticeable with high levels of the percentage modulation, area of visual field that is impacted by it, or the adaptation luminance. The impact of flicker can be reduced by using high frequency electronic ballasts or multiphase power supplies for different sources.

Functions of Lighting

There are four functions of lighting: ambient, task, decorative, and accent.[26] For each function, there are several implementation geometries. For most applications, more than one of these functions is necessary. We first discuss each of these lighting functions and then the lighting geometries used to accomplish these functions.

Ambient lighting fills up the space and is integral to almost any lighting scheme and yet is commonly ignored. It reduces the difference between the magnitudes of vertical and horizontal illuminance. As a result, it reduces glare, softens shadows, and provides a well-lit appearance. A common mistake is to consider any light that is illuminating the space as ambient light. For example, ceilings with recessed down lights with a narrow angular spread cause harsh shadows of objects on the ground. Even facial features show unflattering shadows. This is a result of insufficient level of vertical illuminance. So although there seems to be enough light to illuminate the space, it does not achieve a proper balance between vertical and horizontal illuminances resulting in cast shadows. To achieve proper ambient illumination, it is necessary to use those lighting geometries that spread light into large angles and from many directions. Ambient lighting is provided by large overhead luminaires with diffusers, torchieres, wall sconces, cove lighting, cornice lighting, valence and wall slot lighting, illuminated ceilings and wall washings. Figure 2 illustrates some of these schemes. Figure 4 illustrates ambient lighting with wall sconces.

Task lighting is used to provide sufficient illumination at the task plane such as a desk or work plane. Task lighting should be free of glare and shadows caused by the illuminated objects such as shadows from the hand and body or shadows from machine parts. Several lamp types and lighting geometries are available to reduce the impact of shadows. Lamps such as Banker or Bouillotte (Fig. 24) or large overhead luminaires with diffusers are good choices. The light emanating from these lamps is spread over a wide range of angles from an effectively large source. In a Banker lamp, a significant portion of light from the source undergoes multiple reflections from the inside of the luminaire before exiting. Large fluorescent light sources in a vertical configuration in the Bouillotte lamp provide excellent vertical and horizontal illuminance. Lamps with batwing lenses achieve cross illumination or lighting from two different directions overlapping in the task region. A batwing lens has a linear prism array (Fig. 23*c*) at the front of the source that leads to spreading of the light in predominantly two directions from each source point. Side lights installed in the vicinity of the task region increase vertical illuminance, and when used with overhead lighting provide excellent task lighting. Sometimes backlighting is necessary for certain tasks that involve transparent objects. Task lights must have

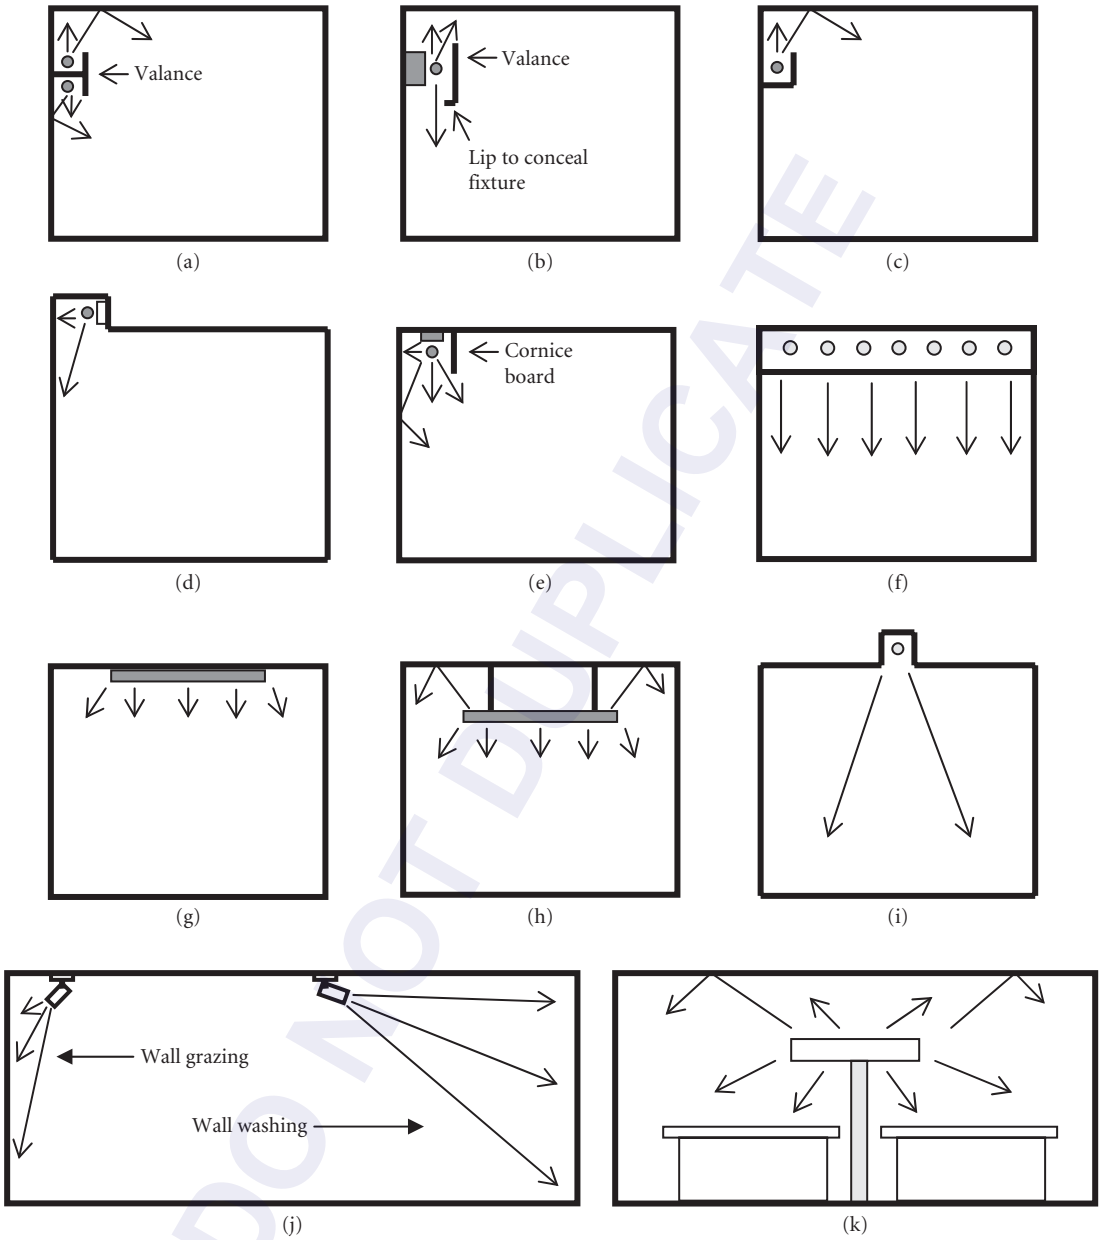

FIGURE 2 Various lighting geometry components. (*a*) and (*b*) Valence lighting. (*c*) Cove lighting. (*d*) and (*e*) Wall slot and Cornice lighting for wall illumination. It can be used to create an effect of a floating ceiling. (*f*) Illuminated ceiling. There is a diffuser below the row of line sources. This scheme can also be used to create illuminated wall panels. Backlighting is another technique. (*g*) Overhead luminaire. (*h*) Suspended luminaire. (*i*) Recessed downlight. (*j*) Wall-grazing and wall-washing illumination emphasizes and flattens the wall textures respectively. (*k*) Furniture-integrated lighting system. In cases (*a*) to (*i*), the sources are lines sources such as fluorescent tubes along the length of the wall. In each case, the neighboring surfaces whether wall or shielding surfaces are coated with high reflectance diffuse paints. The distance of light source from the ceiling/wall determines the uniformity of illumination across the respective regions.

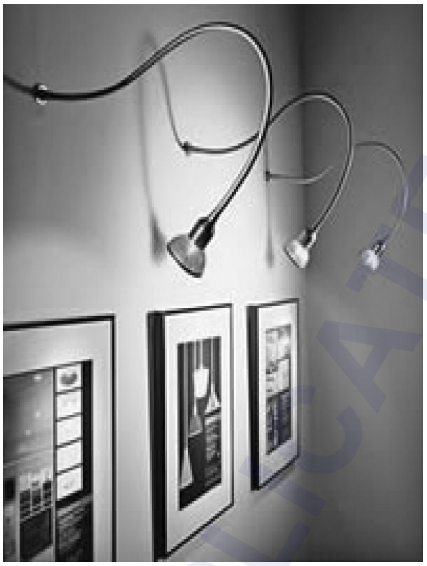

FIGURE 3 Accent lighting. (See also color insert.) (*Courtesy of Pegasus Associates Lighting, www.pegasusassociates.com.*)

the light sources well shielded by the luminaire and baffles to avoid direct glare. For large overhead sources, louvers (Fig. 24*e*) are used to limit the direct source view. Veiling reflections are avoided by ensuring that the source-task-eye geometry does not direct the reflections off the task into the eye.

Decorative lighting, as the term implies, is used to add sparkle to the lit environment. Decorative lighting is most effective when it appears to provide most of the lighting in a scene. Using decorative lighting to provide other functions of lighting by increasing the lamp brightness is not a suitable solution, although it increases the illumination in the region. It draws too much attention toward the lamp itself and creates undesirable levels of source brightness against the background leading to glare and unsightly shadows; therefore, decorative lighting must be immersed in an environment with good ambient light. Decorative lighting is provided by low-wattage table or floor lamps, gas lights, chandeliers, sconces, bare light sources, backlighting, light art, and torchieres. See the use of chandelier in Fig. 5.

Accent lighting primarily provides highlighting of objects such as artwork (Fig. 3), plants and decorative objects within a lit environment. Track lights, adjustable recessed lights, uplights, and backlights are commonly used to provide accent lighting.

Lighting Geometries

Lighting geometries can essentially be broken down into four broad classifications. These classifications are not mutually exclusive.

1. Direct Lighting: Most of the light (>90 percent) from a luminaire is targeted toward a certain region such as in downlighting in an office by overhead light fixtures. Applications of direct lighting include all the lighting functions such as ambient, task, decorative, and accent.
2. Indirect Lighting: An object or a region is illuminated by light that is not directly coming from the source. For example, the light from a lamp is directed toward the ceiling, wall, or even a

FIGURE 4 Wall sconces for providing ambient lighting and the much needed vertical illumination in various situations. (See also color insert.) (*Courtesy of Lightcrafters Inc., www.lightcrafters.com.*)

diffuse reflecting region of the luminaire. The reflections illuminate the space around the luminaire. Indirect lighting tends to give a more spacious appearance and eliminates shadows. Its primary application is to provide ambient lighting. See Figs. 4, 5, and 24*c*.

3. Diffuse Lighting: When lighting does not appear to come from any specific direction. Examples of diffuse lighting include indirect lighting and certain direct lighting geometries such as overcast skies, large area lighting fixtures with diffusing or prismatic optics or large spatial extent fluorescent lamps. It is mostly used for ambient illumination but can also be used to create local areas of high and uniform brightness for task lighting or accent lighting.
4. Direct-Indirect/Semi-Direct/Semi-Indirect Lighting: These terms typically apply to lamps that distribute some portion of their light toward the target and the remaining portion toward a surface that reflects (specular and/or diffuse) light toward the target. Semi-direct typically refers to the case where 60 to 90 percent of the light is directed toward the target while semi-indirect refers to the case where 60 to 90 percent of the light is directed away from the target. Applications include all the lighting functions: ambient, task, accent, and decorative. See Fig. 24*d* for an example of direct-indirect lighting fixture.

Figure 2 illustrates several implementations of these lighting geometries[5] within the confines of indoor lighting. A practical lighting layout is likely to include one or more of these concepts.

FIGURE 5 Indirect lighting with cove lighting in a restaurant using light strips. The chandelier provides the decorative lighting without significantly contributing to any other lighting function. (See also color insert.) (*Courtesy of Pegasus Associates Lighting, www.pegasusassociates.com.*)

Properties of Objects and Their Impact on Lit-Scene

Objects in a lit-scene have geometrical (shape, location, and orientation) and optical properties (wavelength dependent absorption, reflection, transmission, and diffraction). Reflection and transmission include both diffuse and specular components. Lit-scene characteristics are then in-part determined by geometrical and optical properties of the objects and also in part determined by the interaction of these characteristics with the light sources in the environment. The object-light source interaction gives rise to such phenomena as glare, nonuniform illumination and color change. Major indoor features that impact a lighting environment are walls, floors (including large area carpeting) room partitions and ceilings. Minor features consist of temporary objects such as wall coverings, furniture, partitions, art, displays and plants. Major outdoor features that impact lighting environment are ground, buildings, vegetation, distant and close landscape features. Minor outdoor features are temporary objects.

System Layout and Simulation

Based upon the lighting design criteria, appropriate lamps with desired lighting schemes are selected. However, to obtain the desired illuminance distribution over time, appropriate calculations and simulations are needed. In this section, we discuss the tools for system simulation.

For any given system layout, a certain light level is needed. Equation (11) provides an approximation of the number and type of luminaires needed to obtain a certain horizontal illuminance over a work plane. This equation is useful when expressed as a summation of individual luminaires with their specific constants.

$$E_{\text{maintained}} = Fn\text{LLF CU}/A \tag{11}$$

where $E_{\text{maintained}}$ = average illuminance maintained
F = total rated luminaire lumen
n = number of luminaires

CU = coefficient of utilization (It defines the percentage of light from the lamp reaching the work plane. CU depends upon the relative placement of lamp and work plane and illuminance distribution at the work plane corresponding to the geometry.)
A = work plane area
LLF = total light loss factor

LLF[27] accounts for the lamp output reduction over time. LLF has both recoverable and nonrecoverable components. Nonrecoverable factors are due to permanent degradation of the luminaire surface, reduction of output due to deviation from ideal operating temperature and environment (convection and ambient temperature), inefficiency of the electronic drive components and deviation in the operating position (tilt) from the ideal position. Recoverable factors are those whose effects can be mitigated by regular cleaning of the luminaire, operation in a clean environment, and regular replacement of bulbs or sources upon their natural degradation with time. LLF is a product of all these factors. Many of these factors also affect the intensity profile of the lamp output and can therefore affect the CU. The *Lighting Handbook* by IESNA[28] lists a detailed procedure for calculating the room surface dirt depreciation factor and luminaire dirt depreciation factor. Other factors can be obtained either by lamp manufacturer specification data or by measurement in an as-used configuration of each lamp before use.

System simulation can be done in two ways: manually or using specialized software. To do it manually, the lumen method [see Eq. (11)] and the zonal cavity method are used. The zonal cavity method[29] involves modifying the CU by calculating the effects of room geometry, wall reflectance, luminaire intensity, luminaire suspension distance and workplane height. The impact of various parameters is available in the form of look-up tables that can be consulted to provide estimates. These methods are quite powerful but outside the allowable space in this chapter, please consult the mentioned references.

System simulation with specialized software allows unparalleled accuracy and flexibility. Modern software tools allow easy modeling of 3D geometries, material and source properties. Sophisticated analysis tools allow for calculation of luminance, intensity, illuminance and chromaticity at any location, and they also provide photorealistic rendering of lit models that account for specular as well as diffuse reflections. Accurate system modeling involves the following steps:

1. Model the 3D geometry of the lit region. Windows, skylights, and light shelves must be modeled with their coverings: blinds or glazings with their optical properties.
2. Model the surfaces and paints. The reflectance is a combination of specular and diffuse components. For those surfaces and paints that cannot be simply described by specular or Lambertian properties, the bidirectional reflectance distribution function (BRDF) is used.[30] The dependency of BRDF is composed of the incident direction and the direction of observation. This concept has been explained in much more detail in Chap. 7, "Control of Stray Light," in this volume. BRDF measurements are mostly obtained experimentally. These measurements are available sometimes by paint vendors or makers of specific surfaces. It is also possible to simulate BRDF approximately by assigning texture and reflective properties to the surface and performing a ray trace. Once the reflectance properties of each surface are available, they are assigned to the surfaces in the optical model and allow accurate photorealistic rendering of the model for all cases of source and viewer locations.
3. Model the lamps: luminaire geometry and source model. Source models are increasingly being made available by the lamp vendors. If the model is not available, source measurements may be needed. Source models consist of a collection of rays that represent the output from the source. Each ray is described by its position and direction cosines in 3D space. Daylight can be simulated by creating two sources outside the model: sun and sky and assigning diffuse reflective properties (10 to 20 percent) to the ground outside the model. There are a variety of ways to model the sun. One way is to represent it as a Lambertian disk of its angular extent (0.52°) and a luminance value that provides the insolation on the earth's surface at the geographic location (~1000 W/m^2). The final step is to locate the Sun's position relative to the model. The sky is modeled as a large Lambertian disk of a prescribed luminance. For example, a clear sky is represented by 8000 nits and an overcast sky is represented by 2000 nits.
4. Decide upon the location of the measurement surfaces. These could be real or virtual. A photorealistic scene rendering helps in realizing the most promising layouts.

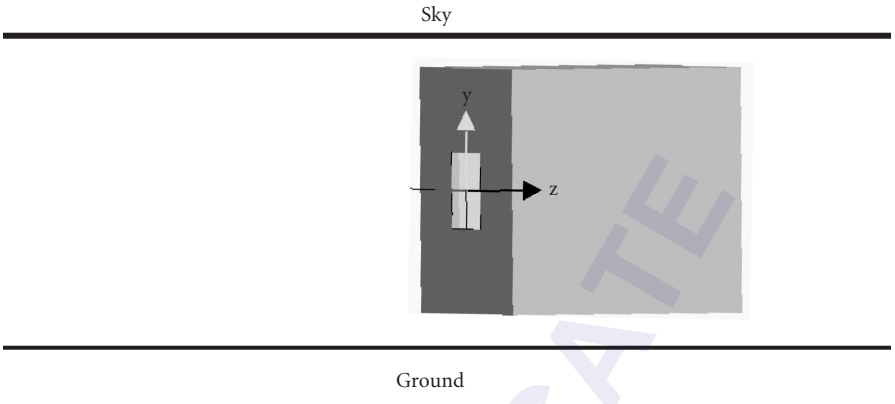

FIGURE 6 System layout. (Source: Clear sky 8000 cd/m^2. Room Size: 3 m × *3* m. Window size: 1 m × 1 m. Window location: center of the wall. Wall reflectance: 35 percent. Roof Reflectance: 60 percent. Floor reflectance: 40 percent. Ground reflectance exterior to room: 20 percent.)

Figures 6 and 7 show an example that illustrates the above steps.[31] We simulate a room with one window. All the light received in the room is daylight from a clear sky. In this example, we calculate the light distribution across the floor for two cases: with and without assuming that the room surfaces are diffuse reflective. Figure 7 shows the impact of including reflectances from various objects which results in a wider spread of illumination across the floor.

It is easy to make the model more complex by adding internal light sources, objects with a variety of surface properties, skylights, influence of sun and so forth. Next, we discuss the software tools available to perform such simulations.

Software Tools There are extensive software tools to assist the lighting designer in simulating illumination systems. The software includes computer-aided design (CAD), source modeling, optical analysis and design, and computer graphics. Each of these plays a crucial role in the design process, so they are described in the following subsections. Some of the software areas have applicability in a number of aspects of the design process. Finally, we do not mention the explicit names of the software packages since they are continuously evolving, and we make use of certain ones in our daily lives, so we do not want to bias the discussion presented here.

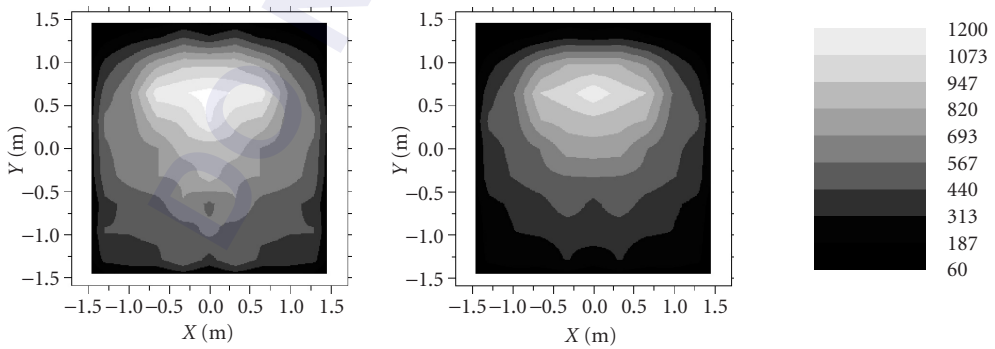

FIGURE 7 Horizontal illuminance (lux) on the floor (*a*) with and (*b*) without taking into account the room reflectance.

CAD software Computer-aided design software is used to build the geometry of any system and is then interfaced with machine tools to fabricate the components. Lighting design makes great use of CAD software to ease the process of integration of complex optical components and the mechanics that hold them and the electronics. Not only are there self-standing, mechanical CAD software packages, but native CAD geometry generation capabilities in the optical analysis software packages discussed later. The latter provide a wealth of tools for the generation of complex illumination systems, but they do not have the range of tools that mechanical CAD software provides. The software can be broken down into two subsets: surface based and solid based. The former implies that each surface is defined separately (e.g., a cube is made up of six separate surfaces), while the latter implies that each object is defined (e.g., a cube is made from one function call). Of course tools are provided in each code such that the design process is simplified (e.g., in a surface-based code a macro could generate all of the six surfaces of the cube with one function call). Solid-based codes tend to provide a more efficient process to enter the geometry of the system, but surface-based codes have a longer market history. None of the mechanical CAD packages provide optical analysis and design tools, but they do provide hooks to integrate into them. In fact, some of the optical analysis and design software companies have developed plug-ins that allow the user to specify optical characteristics such as materials and surfaces. These tools assist with the design process by requiring only one iteration of assigning such properties and simplify the transfer of the geometry to the optical analysis software. The transfer of the geometry is typically accomplished by two formats: International Graphics Exchange Specification (IGES) and Standard for the Exchange of Product model data (STEP). Other protocols including proprietary ones, DXF, DWG, STL, and SAT are understood by certain optical design and analysis tools.

IGES IGES is a standard first published in 1980 by the National Bureau of Standards (now the National Institute of Standards and Technology, NIST) as NBSIR 80–1978, and then approved by an ANSI committee as Version 1.0.[32] It was first known as Digital Representation for Communication of Product Definition Data. It is essentially a surface/curve-based method to represent the geometry that comprises a component or system. The IGES standard was updated through the years, with Version 5.3 in 1996 being the last published version.[33] STEP (see the next section) was to replace IGES, but IGES remains the prevalent neutral-based method to transfer geometry data. Most optical analysis codes can read and interpret various versions of IGES, but the surface-based optics codes tend to have better performance (i.e., fewer import errors).

STEP STEP is a standard first published in 1994 by the International Standards Organization (ISO) as ISO 10303 with the goal of replacing IGES. It is essentially a solid-based method to represent a system, but it also has 2D and database aspects.[34] It has been updated through the years and is now comprised of many part and application protocols. STEP is developed and maintained by the ISO technical committee TC 184, Technical Industrial automation systems and integration, subcommittee SC4 Industrial data.[35] Most optical analysis codes can read and interpret various versions of STEP, but the solid-based optics codes tend to have better performance (i.e., fewer import errors).

Source modeling software In order to perform accurate simulation of a lighting system it is imperative that an accurate source model is used. There are essentially three methods to accomplish this:

- Generation of ray data based on manufacturer data sheets
- Experimental measurements of the emitted radiation to create ray sets
- Modeling of the geometry of the source and the physics of emission to create ray sets

The first method creates either ray sets or Illuminating Engineering Society (IES) intensity distributions that can be used to model the performance of a lighting system that incorporates the prescribed source. The second, experimental measurement uses a goniometer or similar device to measure the output of the source both as a function of position and angle; therefore, it measures the luminance distribution of the source. The last is based on modeling of the source components, such as filament, base, and glass envelope in an incandescent bulb; electrodes, glass envelope, and

base for an HID lamp; and die, epoxy dome, and reflector cup for a LED. Based on the physics of the source, rays are assigned to the emission areas. A number of optical analysis software companies are providing geometrical and ray source model libraries to their customers. All three methods are based on the data, measurements, or model of a single source, called the nominal source. Thus, there is the opportunity for error between the nominal source and what is used in your fabricated system.

Source manufacturers and architectural lighting software tend to use the IES source files to specify their sources. These files are not as precise as the other two methods, but they provide a good enough and fast method to implement the source emission characteristics into the design process. Companies that make these accurate experimental measurements keep libraries of the data, so that their customers can include them in their lighting system models. The CAD software allows a designer to make a complex model of the source, and then the optical analysis software allows the rays to be generated. This method also provides accurate source models, but with the only time expenditure to develop such models. It has been found that methods that employ both the geometry and experimental emission measurements provide the highest level of accuracy while also giving an avenue to model the tolerances of the emission.[36,37]

Optical modeling software As previously stated, optical analysis and design software not only allows for the modeling of optical systems, but it also provides tools for inclusion of geometry, source modeling, and rendering (discussed later). There are both solid-based and surface-based codes. Most optical phenomena occur at the surface interfaces, such as reflection, refraction, scattering, and diffraction, but there are volume effects, such as scattering, absorption, and emission. Therefore, though a single software packages is based around solids or surfaces, it must be able to effectively model the other type of phenomena. A number of the codes are generic in nature, such that they can handle virtually any type of system or application, from backlights to luminaires to biomedical applications. There are application specific codes in a number of areas, especially external automotive lighting and architectural illumination. The software is increasingly adding tools such as source modeling macros, optimization, tolerancing, and rendering.

There are essentially three types of software packages that can be used to model a lighting system: optically based ray tracing, lighting-based radiosity, and computer graphics rendering. Ray tracing is simply the tracing of a multitude of rays from sources through the optical system. It is quite accurate, only limited both by the characterization of the geometry and the assigned optical properties within the model and the number of rays that are traced. Radiosity algorithms are essentially scatter-based methods that propagate approximate wavefronts from one object to another. Initially, Lambertian scatter properties of all objects were assumed, but more recently radiosity implementations propagation based on the bidirectional surface distribution function (BSDF), generally, or the respective reflective (BRDF) or transmissive (BTDF) forms, specifically, have been developed.[38] Ray tracing can handle both specular and diffuse reflections, but radiosity is limited to diffuse reflections. Ray tracing has a number of benefits including accuracy and utility from the near field to far field. Radiosity is for the most part limited to far field calculations, where the approximations of the propagation model are minimized. As the distance between the source and target is reduced, the limitations of the scatter-based propagation inhibit accuracy. The primary limitation of ray tracing is the calculation time, which is several orders of magnitude more than radiosity. Thus, hybrid methods that employ both ray tracing and radiosity are in use. The goal of hybrid methods is to obtain the benefits of both ray tracing and radiosity in a single algorithm.

In the next three subsections the three types of software packages are discussed in more detail. Notably, the lines between these three types of software packages is disappearing, especially between the lighting design and computer graphics sectors. In each of these sections the applicability to lighting design and modeling is provided. These software packages are seeing rapid growth, so consultation of the literature on active research on future development is suggested.

Optical design and analysis software There are two types of optical design and analysis software: imaging system software and general analysis software. The first is typically called lens design software, and has limited utility to the design of lighting systems. The second uses nonsequential ray tracing from the source to the target. This process allows the illumination distribution at the

target to be accurately determined. This type of software often includes, at the discretion of the user, such features as spectrum, coherence, polarization, and so forth. Thus, the accuracy is only limited by the user input. The design of the actual luminaire is best done with this type of software. It allows the designer to design efficient systems that effectively couple and broadcast the emission from the light source. These codes also provide tools for optimization and tolerancing of the luminaire. However, due to lengthy computation time, optical design and analysis codes have limited (but increasing, due to the advances in computer speeds) utility in determination of a lit scene (i.e., rendering).

Lighting design software Unlike optical design and analysis software, lighting design software typically makes use of radiosity algorithms.[39] Radiosity codes are quite fast and have acceptable accuracy in the far field. The use of Lambertian or BSDF scatter properties allows the diffuse reflection from objects to be quickly ascertained and propagated further into the system. The diffuse emission is both collected at the observation location and is cascaded to other objects in the scene. In order to obtain a higher convergence speed objects are typically parameterized with polygons, while optical phenomena such as refraction or specular reflection are approximated or even ignored. This type of software thus provides at worst a first-order approximation of the lit appearance such that architects and lighting designers can view the results of their design work. Lit-scene rendering or illumination in the far field of a luminaire is the best use of lighting design software. More advanced software packages can then be employed, such as those that employ some semblance of ray tracing—see the previous and next sections.

Computer graphics software In the past two decades the computer graphics community has grown rapidly. The tools they develop and employ are useful in the illumination community of optics. Foremost they have tools to model the simulated look of an unlit or lit lighting system, called unlit-and lit-appearance modeling respectively. These tools are important in illumination since acceptance of a system is often based on subjective criteria such as appearance. Thus, these tools provide such before potential costly and time-consuming manufacture. Additionally, the computer graphics community uses both ray-based and scatter-based radiosity methods, while also employing hybrid methods. These methods are especially geared to the rendering of scenes in video games, movies, and other types of visual media. Thus, they tend to have the least amount of accuracy since the completion of numerous images in a timely manner is demanded.

Computer graphics software makes direct use of forward ray tracing (from the source to observer) and reverse ray tracing (from the observer to the source). The latter is especially useful for the rendering of scenes where there is a discrete viewpoint, like that of a virtual observer. These codes and algorithms are increasingly being used to model the lit appearance of illumination systems such as luminaires and lightpipes. This process involves some form of ray tracing and/or radiosity calculations and then employs vision biology (Sec. 40.3). As an example, consider a star-shaped taillight as shown in Fig. 8.[40,41] The taillight is oriented at several angles such that the effects of changing ones aspect to the lit taillight is taken into account. The combination of these different angular views of the taillight provides the luminance distribution, or essentially what an observer would see by walking around the lamp. A ray tracing method employing a pupil collection of 15° is used for each of the plots within Fig. 8. Note that saturation of the retinal cones is included, which is evidenced by the whitish appearance of the filament at the center of the lit patterns.

Furthermore, the resulting intensity pattern for the lit-appearance model can be projected into a scene to provide a rendering of what the illumination from the lamp will look like. For example consider Fig. 9, which shows three view aspects of an automobile headlight designed to meet standards (see section on vehicular lighting): (a) the driver's perspective, (b) 20 m above and behind the drive, and (c) the bird's eye view.[42] These renderings are quite accurate since the goal is to completely mimic the lit-scene appearance prior to fabrication. These types of renderings can be extended to any scene that involves sources and objects with accurate optical characteristics applied to them. Figure 10*a* shows the rendering of a south-facing office room[43] in Tucson, Arizona. The illumination was modeled from average direct and diffuse insolation data for November 15 at noon for this location. The CAD model was generated from architectural blueprints of the facility. Surface reflectances were determined from first principles. The scene outside the window was created from a

digital photograph taken in the mountains outside of Tucson. 100,000,000 rays were traced from the source throughout the model. Similarly, Fig. 10*b* shows the rendering of a desk surface lit by interior, incandescent lighting.[44] All surfaces, except the three objects on the desk (shown in wireframe to ease view through the objects), are diffuse Lambertian reflectors. The three objects: wine glass, ice cube, and crystal ball, display the effects of specular refraction and total internal reflection.

40.5 LUMINAIRES

A luminaire is a packaged light source consisting of emitter, optics to baffle or redirect light, fixture and electrical components. Luminaires form an integral part of the lighting design by the virtue of the illumination they provide and also by their appearances. In this section, we discuss the optical components of luminaires: types of light sources, both artificial and natural (daylight), and the design of luminaires with optical components such as reflectors, lenses, lightguides, fibers, windows, skylights and baffles to achieve the desired light distribution.

Types of Light Sources

Light sources are optically characterized by their luminous spectrum (lumens as a function of wavelength), intensity (in candela), and efficiency (lumens per watt, lpw). For white light, CCT and CRI are derived from the spectrum of the source and are typically reported on the data sheets to give an estimate of its appearance and its ability to color render lit objects. Other source characteristics are cost, safety, government regulations, package size/type, lamp sockets, electrical driver requirements and constraints related to environment or operating conditions. Cost is defined in terms of luminous flux per dollar per hour of use, replacement, and initial installation costs.

We discuss daylighting and the following artificial light sources: incandescent, fluorescent, high-intensity discharge (HID), light-emitting diode (LED), electrodeless HID, electroluminescent, nuclear, laser, bare discharge, low-pressure sodium (LPS), and short arc sources. In the next few subsections we discuss various light sources in terms of operating principles, construction, and packaging. Refer to Table 3, which provides the performance comparison of various lamps; and Table 4, which

TABLE 3 General Lamp Characteristics for Most Lighting Applications

	Watts	Efficacy lpw	CCT K	CRI	Lifetime K hours	Notes
Standard Incandescent	40–100[a]	10–17[T]	2700	>95	0.75	Undesired IR radiation, fire hazard. Naturally low flicker, instant-on and dimming to 0.
Tungsten-Halogen	300[a]	20	2850–3200	>95	<6	Same as standard incandescent.
Fluorescent/ CFL	5–55	15–100 60–70[T]	3000–6500 4100[T]	50–98 70–85[T]	5–20[b]	Complex ballasts for good dimming range, short start-up, low hum, low flicker. Hg disposal issue, EMI.
HID-Hg	50–1000	30–65	3900–5700[c]	15–20 higher with phosphor coatings	16–24	Complex ballasts for start-up and flicker control, poor dimming, high flicker, explosion, fire and UV hazard, lamp disposal issue, high start-up and re-strike intervals, poor color stability with time, operating position affects performance.
HID-MH	30–18 K 50–1000[T]	75–125	2500–6000	60–70	7.5–20	Same as HID-Hg. Lifetime <1 K hours for >10 kW lamps.
HID-HPS	175–1000	45–150	1900–2700	22–85	7.5–24	Same as HID-Hg, CRI is inversely proportional to efficacy. 110 lpw corresponds to CRI 20, CCT 1900–2100 K.
HID-CMH	20–400	70–90	3000–4200	80–96	7.5–20	Same as HID-Hg except for good color stability with time and performance independent of operating position.
Electrodeless	4	60+	2700–6500	50–98	15–30[d], <100[e]	Complex ballast, EMI.
LPS	20–100	80–150	1800	0	14–18	
LED[f]	LEDs (large chip or arrays) are likely to replace most of the existing lamp sources. Efficacy can reach up to and beyond 200[g] lpw with the theoretical limit being the CIE standard observer luminous efficacy curve, lifetimes up to 100 K hours. Key advantages are: fast turn-on times, color tunability, high dimming range, low voltage operation, no Hg or Lead, no UV or IR, no catastrophic failures and scalable packages. Phosphor coated LEDs can provide white light at desired CRI and CCT.					

HID—high-intensity discharge, Hg—mercury, MH—metal halide, HPS—high-pressure sodium, CMH—ceramic mercury halide, Xe—xenon, LED—light-emitting diode, CFL—compact fluorescent lamps, [T]—typical.

[a]Also available in kW. Lifetimes shrinks to a few hundred hours, [b]Regular Fluorescent have typical lifetimes >10 K hours, Compact Fluorescent lamps have lifetimes >5 K hours, [c]CCT 5700 K at CRI 15, CCT 3900 K at CRI 50, [d]developing technology, [e]with integrated ballasts, [f]separate ballast, [g]only light generation efficiency inside the LED die.

lists various lamp types, currently available packages and their applications. Figure 11 shows various lamp packages. The alphabetic designation is explained in Fig. 11. The numeric designation with the letters is the diameter specified in 1/8th of an inch. For example, MR16 refers to a multifaceted reflector, 2 in. in diameter.

Incandescent Sources These are thermal sources that emit electromagnetic radiation from a heated filament, which is a phenomenon known as *incandescence*. Incandescent light sources are being steadily replaced with fluorescent lamps, LEDs, and potentially with electrodeless lamps. Other sources are able to provide similar or improved performance at higher efficiency and lifetime leading to reduced operational costs.

Modern day incandescent sources use a tungsten filament.[45] Tungsten has a high melting point (3382°C), high ductility, high conductivity, and low thermal expansion that make it a preferred material for use as a lamp filament. Tungsten is alloyed with tiny amounts of potassium (60 ppm), aluminum oxide (10 ppm), and silicon (1 ppm) to give it high strength near its melting point. This allows lamp operation close to the melting point, thus improving its efficacy. Sometimes tungsten

TABLE 4 Common Lamp Packages and Applications

	Available Packaging	Current Applications
Tungsten	A-line, elliptical, decorative (B, C, CA, F, G, M), PAR, reflector (R, BR, ER), appliance and indicators (S), tubular (T)	General purpose, 3-way, reader, decorative (chandelier, Globe, ceiling fan), Track and Recessed (Indoor floodlight and spot light), outdoor (post & lantern, pathway, garden & deck, motion-sensing & security, bug light, yard stake), appliances, colored lamp, display, exit sign, freshwater and saltwater aquarium, heat lamp, marine, nightlight, party, recreation vehicle, plant, rough service, sewing machine, shatter resistant, terrarium, vacuum cleaner, airport, emergency, city lighting, projection, photoflood, filmstrip, retail display, restaurants.
Tungsten-Halogen	A-line, decorative (B, G, F, T10), PAR, AR, MR, single ended, double ended	General purpose, 3-way, reader, decorative (chandelier, Globe, ceiling fan), Track and Recessed (Indoor floodlight), outdoor (post & lantern, pathway, garden & deck, motion-sensing & security, yard stake), camera light, microfilm, curio cabinet, display, enlarger & printer, equipment, fiber optics, landscape lighting, projection, stage & studio, torchiere, airport, emergency, city lighting, special service, monuments, museums, heat lamp.
Fluorescent (Linear)	Straight linear (T5, T6, T8, T10, T12), circular (T9), U-shaped (T8, T12), grooved (PG17)	Kitchen, bath, shop, work light, Appliances, blacklight, blacklight blue, cold temperature, colored lamp, freshwater and saltwater aquarium, plant, shatter resistant, terrarium, stage & studio, projection, diazo reprographic, germicidal, gold UV blocking, superstores, warehouses.
Compact Fluorescent	Plug-in (2-pin, 4-pin, proprietary), self-ballasted (decorative, reflectors, proprietary)	General purpose, reader, decorative (chandelier, Globe, ceiling fan), Track and Recessed (Indoor floodlight and spot light), outdoor (post & lantern, pathway, garden & deck, bug light), appliances, blacklight blue, facilities, hospitality, office, plant, restaurant, retail display, saltwater aquarium, terrarium, torchiere, warehouse.
HID - Hg	A-line, elliptical, reflector	Street lighting.
HID - MH	Elliptical, PAR, single ended, double ended, tubular	Street lighting, sports lighting, decorative lighting of architectural wonders.
HID - HPS	Elliptical, double ended, tubular	Street lighting, horticulture.
HID -CMH	Elliptical, par, single ended, double ended, tubular	Track and Recessed (Indoor floodlight and spot light), retail display.
Miniature	B, G, R, RP, S, T, TL, discharge	Outdoor (post & lantern, pathway, garden & deck, motion-sensing & security, yard stake), automotive (headlamp, fog, daytime running, parking, directional front & rear, tail, stop, high mount stop, side-marker front & rear, backup/cornering, instrument, license plate, glove compartment, map, dome, step/convenience, truck/cargo and under hood), flashlight, landscape lighting, low voltage, marine, telephone, traffic signal, emergency.
Sealed Beam	PAR, rectangular	Outdoor (motion-sensing & security, yard stake), automotive headlamp, railway, shatter resistant, stage & studio, directional lighting, aircrafts, tractors, airport, emergency, city lighting.
LPS	Tubular	Street lighting, parking lots.
Electrodeless	T, P	Any application where long lifetimes and high efficacy are needed due to high replacement costs and/or difficult access. Road signs, warehouses.
LED	MR16, miniature (2, 3, 5 mm)	LEDs can potentially replace most of other light sources being used for various applications. Currently being used in building interiors (homes, offices, commercial places such as health clubs, hospitals rooms) stairways and pathways, flashlights, traffic lights, signs, digital projection, instrument indicator panels, backlighting applications, decorative, display.

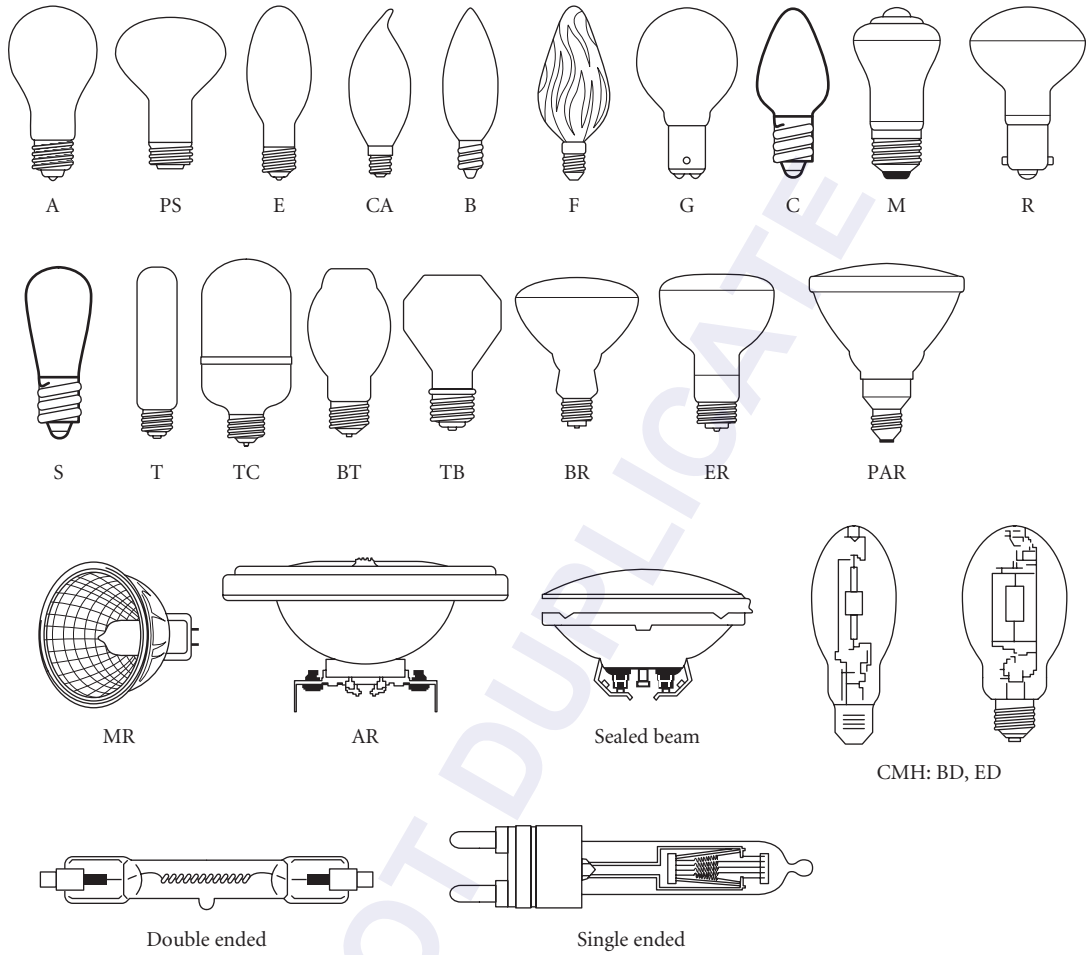

FIGURE 11*a* Various lamp package representations. Shape and sizes are not to scale. Various sizes are available for each package type. For each bulb shape, a variety of bases are available. A—arbitrary spherical shape tapered to narrow neck, B—bulged or bullet shape, BT—bulged tubular, C—conical, CA—conical with blunt tip, E—elliptical, blunt tip, ED—elliptical with dimple in the crown, F—flame shaped, decorative, G—globe, M—mushroom-shaped with rounded transitions, MR—multifaceted reflector, PS—pear shaped with straight neck, PAR—parabolic aluminized reflector, BD—bulged with dimple in crown, S—straight, T—tubular, TB—Teflon bulb, TL—tubular with lens in crown. is alloyed with rhenium (3 to 25 percent) to make it more ductile at low temperatures and achieve higher recrystallization temperatures thereby giving the lamp a longer life. Alloying tungsten with thoria provides increased strength, better machinability and high recrystallization temperatures. Such filaments are used for very high voltage applications.

Figure 12 shows the radiating characteristic of tungsten at 3000 K and its comparison with a blackbody emitter. It differs from the blackbody due to wavelength-dependent low emissivity. A perfect blackbody has an emissivity of one for all wavelengths. The hotter the filament, the higher are the luminous flux radiated per watt, the percentage of luminous flux of the total radiation, and the CCT. However, the lifetime is inversely proportional to the filament temperature as filament evaporation is

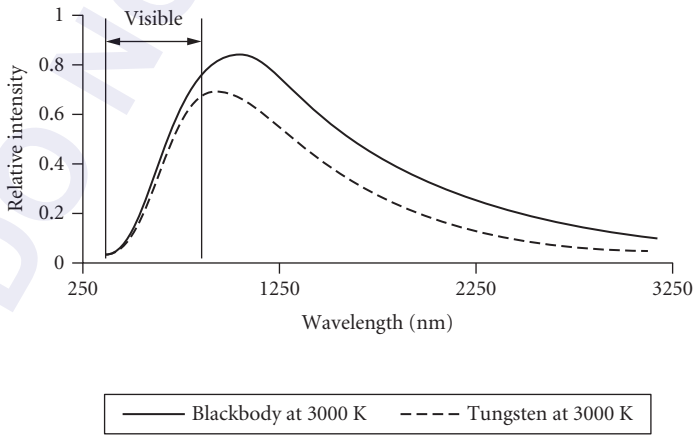

FIGURE 12 Blackbody at 3000 K versus tungsten filament at 3000 K.

the primary mode of lamp failure. The best engineered solution consists of the hottest possible lamp filament at an acceptable lifetime, voltage rating, and packaging. Near its melting point, an uncoiled tungsten wire has a luminous efficacy of 53 lm/W. To achieve an acceptable lifetime, the tungsten filament is operated at much lower temperatures. The luminous efficacy of typical incandescent lamps with tungsten filaments ranges from about 5 to 20 lm/W for lamp wattages 5 to 300, respectively.

A typical incandescent lamp consists of an evacuated glass envelope; filament, with or without fill gases; filament leads; and base. Figure 13 shows the key characteristics.

The bulb material is application dependent. For most applications soda lime glass is used. For applications requiring heat resistant glass, borosilicate, quartz, or aluminosilicate is used. When the bulb envelope is frosted from the inside or coated with powdered silica, it provides diffuse illumination from the bulb surface and masks the bright filaments from direct view. The bulb envelope material can be used to filter the radiation to alter the CCT. Daylight application bulbs filter out the longer wavelengths to provide a higher CCT.

Lead-in wires are made of borax coated dumet (alloys of nickel, copper, and iron). Dumet is able to form a glass-metal seal. It is important to match the thermal expansion of the lead-in wires with the envelope material. When high bulb-envelope temperatures are involved, molybdenum strips bonded to lead-in wires are used for glass-metal seals. The bulb base is cemented to the bulb envelope and is designed to withstand the operating temperatures. The filament itself comes in various configurations depending upon the application. Various filament configurations are a straight wire (designated as S),

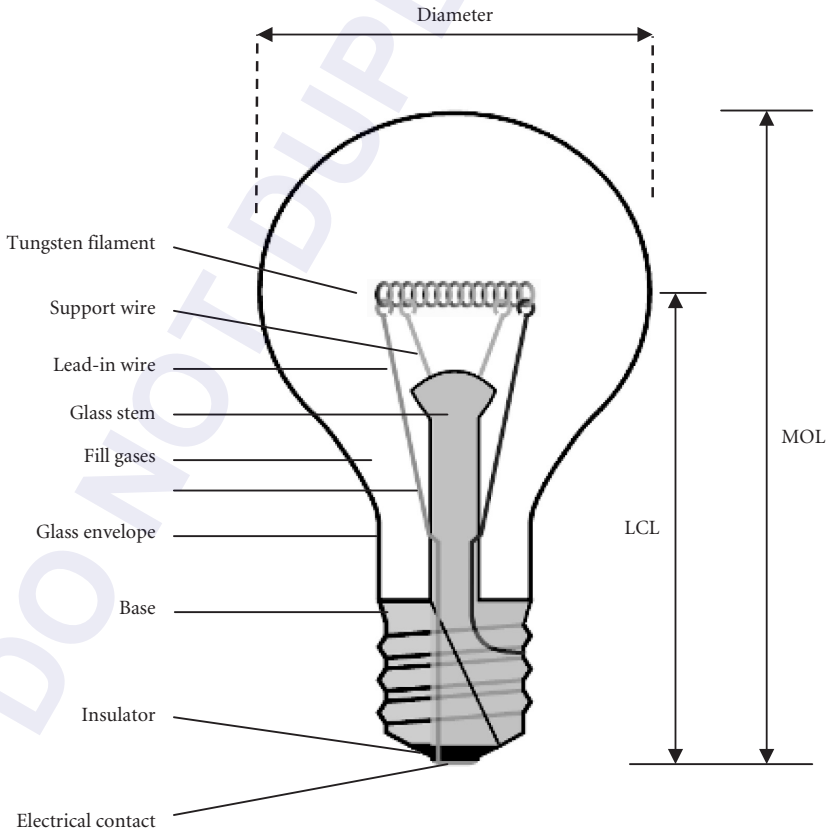

FIGURE 13 An incandescent bulb. (MOL—maximum overall length, LCL—light center length.) (*Adapted from Wikimedia Commons.*)

a coiled wire (designated as C) or a coiled coil (the coiled wire is further coiled onto itself, designated as CC). See Fig. 16 in Chap. 15, "Artificial Sources," in this volume. Coiling increases the surface area per unit length of the filament as well as volume packing density. This allows higher operation temperature at higher efficiency due to relative reduction in heat lost to convection. Multiple supports are used to reduce filament vibration. The number and type of supports depend upon the bulb operating characteristics. A higher number of supports is needed for rough/vibration service lamps. These lamps have low wattages and efficiency and operate in environments that involve shock and vibration for the lamp. Heavier filaments withstand vibrations much better and need fewer filament supports.

Fill gases at low pressure are used to prolong the lamp life at high operating temperatures (high efficacy and power) by reducing the evaporation rate of tungsten. For most applications, mixtures of argon and nitrogen are used as fill gases. More expensive gases such as krypton and xenon are added to the mixture when the higher efficacy justifies the cost increase. Bromine is added to create a new class of lamps called tungsten-halogen lamps which we discuss next.

Tungsten-halogen lamps operate at substantially higher temperatures leading to higher CCT and efficacy. In addition, they have longer lifetimes. At high temperatures, evaporated tungsten combines with the halogen gas and forms a gaseous compound. This gaseous compound circulates throughout the bulb via convection. When this gaseous compound comes in contact with the hottest parts of the lamp such as electrodes the halogen compound breaks down. Tungsten is re-deposited on the electrodes and the halogen is freed up to take part in the halogen regenerative cycle. For the halogen regenerative cycle to work, the bulb envelope must reach a high temperature (>250°C). At lower temperatures, the tungsten will deposit on the bulb envelope instead and lead to lamp blackening and filament thinning, a common failure mode of incandescent lamps. Operating a tungsten-halogen lamp at less than the rated voltage inhibits the halogen regenerative cycle and takes away the longevity advantage. Tungsten halogen lamps have relatively compact bulb envelopes to allow for high bulb-envelope temperatures. The bulb envelope may also have an IR reflective coating to enhance the heat density inside the bulb. Compact bulb sizes make them good candidates for use with reflectors (such as a PAR) to provide directional properties for the lamp emission. The bulb envelopes for such lamps are made of heat resistant material to withstand high temperatures. The high filament temperature in halogen lamps generates UV. The UV rays must be blocked by a UV absorbing lamp cover or UV absorbing but heat resistant bulb envelope such as high-silica or aluminosilicate.

Flicker in incandescent lamps is naturally very low due to slow response of filament temperature to voltage fluctuations caused by power supply frequency or noise.

Incandescent lamps fail when bulb blackening or filament notching (thinning of the filament by evaporation) reduces the output substantially or the filament breaks either by vibration or by complete evaporation of some filament portion. With the exception of halogen lamps, operating the incandescent lamps at less than rated voltage dramatically extends the lifetime (by reducing the filament evaporation rate) at the cost of reduced efficacy, CCT, and luminous flux. In situations, where long lifetimes are needed such as when the lamps are located in a hard to replace areas and/or under tough environmental conditions, heavy filament lamps that are operated at less than the rated voltage are used. But using lower operating voltage to extend the lifetime is not always economical once the increased cost of electricity due to reduced efficacy and compensation of the reduced flux by using more bulbs is taken into account.

Fluorescent Lamps These are luminous sources based on light emission by excited states of phosphors, a phenomenon known as *fluorescence*. These phosphors are typically excited by UV emission due to spectral line transitions across gases such as mercury vapor and/or rare gases such as Xe and Ar. Most commonly available fluorescent lamps are mercury-vapor-based although mercury-free fluorescent sources are available. Phosphors are now available that are excitable by visible light. Such phosphors are also being used for LED-based light sources to produce white light. Fluorescent lamps are actively replacing incandescent light sources and in many cases are themselves being replaced by LEDs.

As shown in Fig. 14, a fluorescent lamp consists of a closed tubular fluorescent material coated glass envelope filled with low-pressure mercury vapor, electrodes at each end of the tube and a ballast to provide high-strike voltage across the electrodes and limit the current during operation. A high-strike voltage across the electrodes initiates a gas discharge in the mercury vapor with light

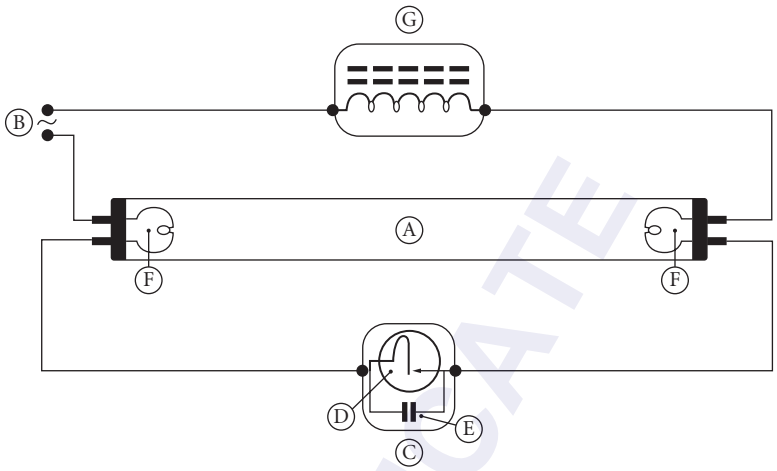

FIGURE 14 A preheat fluorescent lamp circuit using an automatic starting switch. A—fluorescent tube with fill gases, B—power, C—starter, D—switch (bimetallic thermostat), E—capacitor, F—filaments, and G—ballast. (*Courtesy of Wikipedia Commons.*)

emissions across various wavelengths. The UV emission lines of mercury, mostly at 254 nm, excite the phosphors coated on the inside of the tube, cause them to fluoresce and lead to emission in the visible. The fill gases consist of mercury vapor at low pressure (10^{-5} atm) for UV emission and mixtures of inert gasses such as argon, krypton, neon, or xenon at a relatively higher pressure (10^{-3} atm). Inert gases help in lowering the strike voltage across the electrodes as discussed later.

Mercury-free fluorescent lamps mostly use excimers (excited dimers of rare gases and/or their halides with Xe being popular) to produce UV to excite the phosphors. High-wattage operation and high lifetime is achievable but the efficacy is low as compared to the mercury-based lamps. Xenon-filled fluorescent lamps are also available but far less efficient than excimer based. Both excimer and Xe-based fluorescent lamps have additional advantages: instant-on, instant restrike, and color stability.

Fluorescent lamp envelope material is made of soft soda lime glass. This glass material blocks all UV. The length and diameter of the fluorescent tubes affect the efficacy and operating characteristics (voltage, current, and temperature). Longer tubes need higher voltage and power but provide higher efficacy. The efficacy is optimized for a certain tube diameter. To reduce the angular extent of emission, fluorescent tubes are coated across a prescribed region for high reflection in the visible. In such cases, only the uncoated regions of the tube emit light.

The fluorescent coating consists of different mixtures of phosphor salts.[46,47] Phosphor salts consist of oxides, sulfides, selenides, halides, or silicates of zinc, cadmium, manganese, aluminum, silicon, or rare earth materials. Inclusions to the base phosphor material help tailor the emission characteristics. There is a large variety of phosphors available. Each phosphor emits light in one or more narrow wavelength bands. A fluorescent coating consists of one or more phosphor materials to produce a desired CRI and CCT for white light emission or specific spectral characteristics. Halophosphates (wide band) and triphosphors (blends of three narrow band red, green, and blue rare-earth phosphors) are commonly used for general lighting applications. Figure 15 shows an example of the spectrum from a halophosphate phosphor. Figure 17 shows the spectrum of a standard fluorescent lamp.

Due to the variety of fluorescent lamp spectra available, it is possible to achieve the desired CCT, CRI, and color requirements of an application. For example, an application may require a specific blend of white light such as "warm white" (CCT 3000 K, CRI 53), "cool white" (CCT 4100 K, CRI 62), "daylight" (CCT 6500 K, CRI 79), or special requirements such as aquarium lighting for providing optimal plant and coral growth and color enhancing of the display. CFLs use triphosphor coating to produce a high CRI (>90) in order to effectively replace the incandescent lamps. Special application

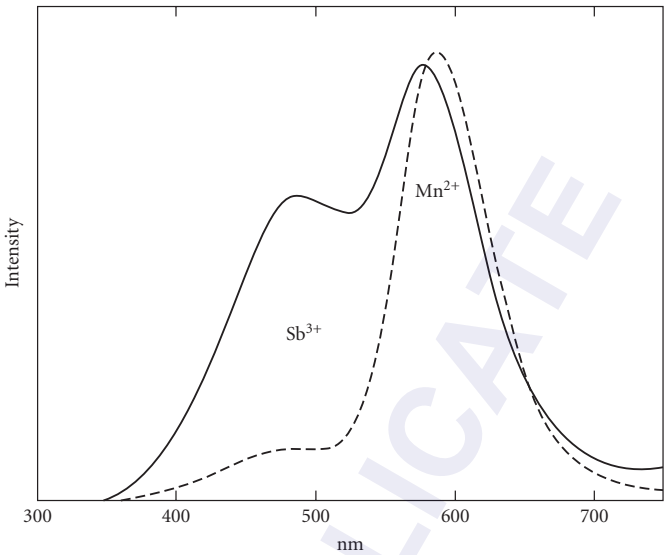

FIGURE 15 Emission spectrum of halophophate phosphor:[47] Sb^{3+}, Mn^{2+} activated $Ca^5(PO_4)^3(Cl, F)$. The ratio of Sb^{3+} and Mn^{2+} species can be adjusted to adjust the spectral distribution.

fluorescent lamps include backlight and tanning lamps. These lamps have phosphors that convert short-wave UV into long-wave UV for applications in tanning (UVA and UVB), detecting materials that fluoresce at long UV (urine, paints, or dyes), or attracting insects.

The lamp electrodes are coated with materials such as oxides of barium, calcium, and strontium to provide low-temperature thermionic emission (electron emission from a heated electrode). Under a potential, these electrons accelerate and ionize the inert gas atoms by impact ionization. Each ionization event generates more electrons that are available to accelerate and further ionize leading to an avalanche that rapidly lowers the gas conductivity. Eventually mercury atoms are ionized. The operating voltage drops and a steady current is established. UV is emitted by transitions across the excited states of mercury atoms. The electrodes can be operated in either of the two modes: cold cathode (arc mode) or hot cathode (glow mode). In the hot cathode mode, the electrodes are preheated to improve the thermionic emission and lower the strike voltage. To enable preheating, electrodes at each end are in an incandescent bulb-like configuration with a tungsten filament (straight wire or coiled). The ballast circuitry allows for preheating (up to 1100°C) before the voltage strike. Hot cathode operation allows operation at relatively higher power and over larger tube sizes. In contrast, cold cathode can be a single cylindrical pin electrode at each end. The strike voltage across the electrodes is relatively higher (~10×). The high voltage strips the electrons from the cathode at ambient temperature and initiates the breakdown process of the gas. The coatings on the electrode surface amplify production of secondary electrons, which are produced when high-energy ions and electrons collide against the cathode. These electrons further increase the gas conductivity. Cold cathode fluorescent lamps (CCFL) are compact (~3-mm diameter) and are used in applications such as thin monitors (i.e., LCDs), backlights, timers, photocells, dimmers, closets, and bathrooms. CCFLs are less efficient (<50 lm/W) but provide instant-on and have long lifetimes (50,000 hours). CCFLs operate at high surface temperatures and require complex power supplies which are fairly compact.

The primary functions of the lamp ballast are to provide a high-strike voltage to start the lamp, give regulated current supply during lamp operation and sometimes provide for cathode preheating for rapid restart applications. Often starter circuitry is deployed to preheat the electrodes. It is critical to use the correct lamp-ballast combination for proper operation. Lamp ballast can be a current limiting resistor, magnetic ballast or electronic high-frequency ballast (most modern ballasts). Due to high-frequency operation of electronic ballasts, flicker in fluorescent lamps is reduced to

almost unnoticeable. Flicker is caused by fast response of the fluorescent lamps to the voltage fluctuations in the lamp power supply caused by noise or operating power supply frequency.

Lamp failure mode consists of thermionic emission electrode coating degradation (a function of strike voltage and the number of strikes), phosphor degradation, mercury loss (diffusion or absorption by lamp materials) and ballast malfunction. Fluorescent lamps fail to operate far outside the ambient temperature range for which they are designed. Most fluorescent lamps are designed to operate in an ambient temperature of ~20°C. For operation at low temperatures, special cold start circuitry and mercury amalgams are needed.

High-Intensity Discharge (HID) and Low-Pressure Sodium (LPS) Lamps These sources emit light across the spectral line transition of enclosed gases by electrical discharge. The source spectrum also includes background thermal radiation due to the heated electrodes and plasma. These sources are similar to fluorescent sources in basic physics involving discharge and emission of light in the UV and visible due to transitions between the excited states of gas atoms. Unlike fluorescent lamps, the electrodes are separated by less than 1 mm up to a few inches. The enclosed gases are at a pressure that is three orders of magnitude higher than in fluorescent sources. As a result, HID sources are far brighter than fluorescent sources with much higher lumen output. The following types of HID lamps are commonly available: mercury vapor (Hg), metal halides (MH), high-pressure sodium (HPS or nicknamed as White SON), and ceramic metal halides (CMH). CMH combines the advantages of MH and HPS technologies. Each HID lamp technology has very different performance and operating characteristics. An LPS lamp is similar to HID lamps in construction and operation with some differences that are identified as we describe the HID lamps below. Figure 16 describes the construction of various HID and LPS lamps. Figure 17 shows the relative spectrum of various HID lamps and comparison with the fluorescent lamp spectrum.

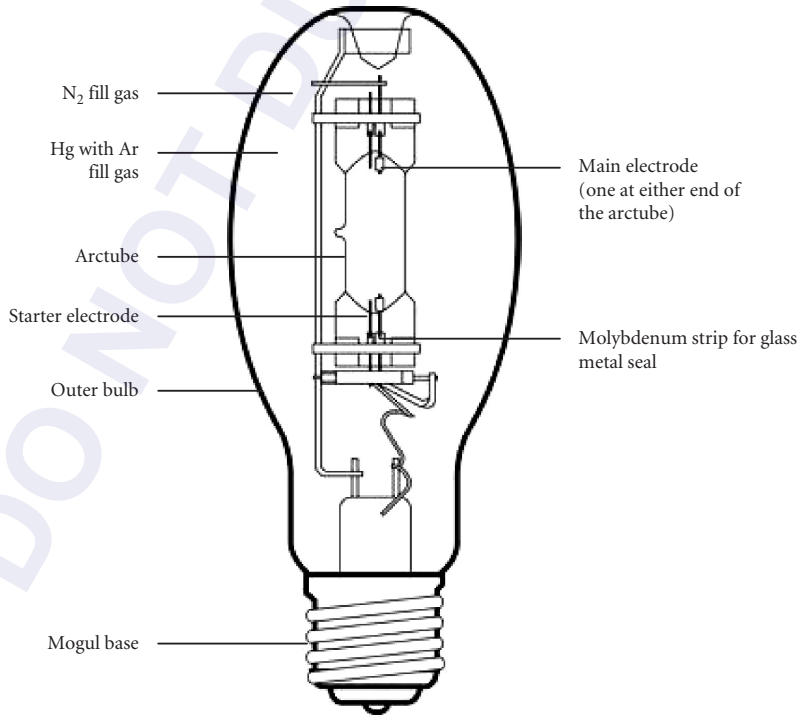

FIGURE 16*a* Mercury lamp construction. (*Illustration courtesy of General Electric Company.*)

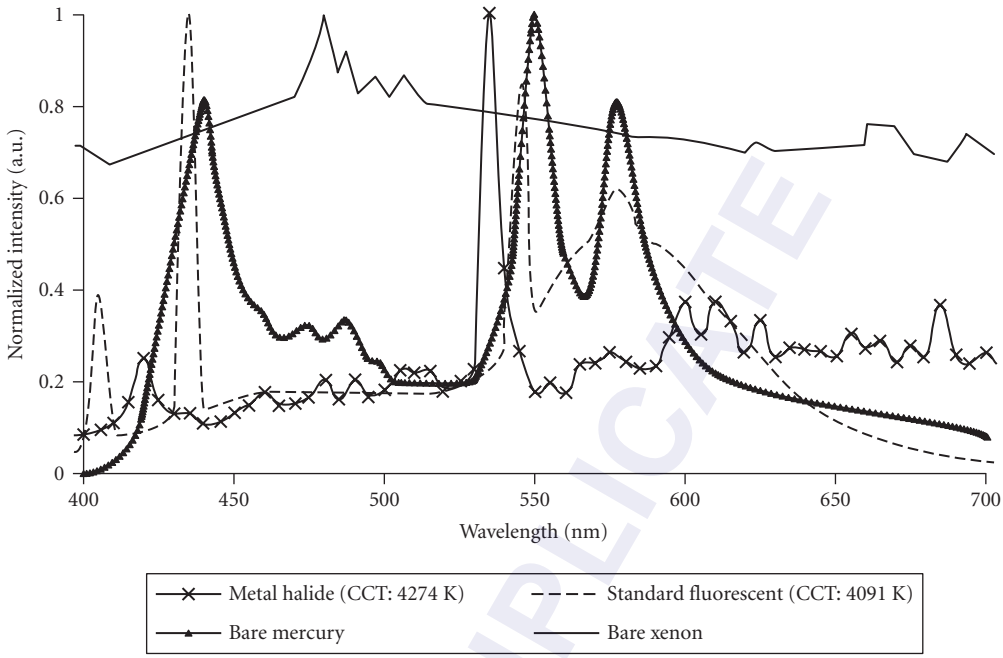

FIGURE 17 Representative lamp spectra of standard fluorescent, bare mercury, bare xenon, and metal halide lamps.

An HID lamp consists of two glass envelopes: inner and outer. The inner glass envelope or the arc tube is made of quartz for MH and Hg and alumina ceramic for HPS, LPS, and CMH lamps. The arc tube houses the discharge gases at high pressure (several atmospheres) and the tungsten electrodes. The outer glass envelope is made of borosilicate and sometimes with soft glass in Hg lamps. It absorbs UV and insulates the arc tube from outer convection currents and from large ambient temperature ranges. It houses the lead-in wires, circuitry to help initiate the high-voltage discharge, getters in case of MH to absorb impurities and has a vacuum (HPS) or low-pressure nitrogen (MH and Hg) to prevent shorting of the lead-in wires. The outer-envelope Hg lamp is sometimes coated with phosphors to provide white light at high CRI and CCT like in regular fluorescent lamps.

Tungsten electrodes are coated with various oxides in a tungsten matrix (except in MH lamps where gases can react with such electrodes) to slow down evaporation and assist in thermionic emission when heated. Starter electrodes, when used in MH and Hg lamps, assist in arc initiation via an electric field between the starter electrode and the adjacent main electrode. During operation the starter electrode is removed from the active circuitry with a bimetallic strip, otherwise premature lamp failure results.

An LPS lamp is similar in construction and operation to HID lamps. Key differences are lower arc tube pressure (0.7 atm), long arc length with a U-shaped arc tube. The arc tube gases include sodium vapor and small amounts of Ne, Ar, or Xe as startup gases.

Different HID lamp types have different gas mixtures. An easily ionizable gas such as Argon (Ar), Neon (Ne), or Xenon (Xe) is used in the arc tube to help in arc initiation. Similarly, mercury is used in most HID lamps to achieve high pressure and improved color rendering. An HPS lamp used sodium (Na)-Hg amalgam. Mercury-free HPS lamps are also available. An LPS lamp uses sodium vapor. The MH lamps use halides of metals in addition to mercury, argon, and xenon.

A low-pressure sodium lamp (LPS) has a CRI of zero due to spectral emission only at 589.0 nm and 589.6 nm (sodium-D line). An HPS lamp has broader spectrum and thus better CRI due to

pressure broadening of the sodium-D line. At very high pressures (27 atm), the sodium-D line is self absorbed by the cooler outer layers of the arc leading to a narrow spectral hole around 589 nm. Mercury atoms help in further broadening of the red end of the pressure broadened sodium-D line due to Van Der Walls forces. A CRI from 22 to 85 is achievable depending upon the pressure which can be greater than 90 atm. MH lamps achieve a rich spectrum due to the line spectra of metals like sodium, tin, dysprosium, holmium, thulium, scandium, iron, or cesium. An MH lamp may have mixtures of halides of one or more metals to achieve the desired efficacy, CRI, and CCT.

An MH lamp using a single metal halide compound can also be used to generate discrete spectral output: orange (sodium), green (thallium), blue (indium), and UV (iron). The metal-halide compound is stable at low temperatures and does not react with the arc tube material unlike some metals. At high temperatures, near the arc, the metal-halide compound breaks down and provides the spectral line emission from the metals. The operating temperature is lower than would be the case where the metals are evaporated to see the spectral emission lines. CRI is usually traded for lifetime and efficacy. CMH lamps combine the advantages of MH and HPS by using a poly crystalline alumina as the bulb envelope material. This material does not allow diffusion of metals, especially sodium or reaction of metals with the bulb material. The bulb is operated at a much higher temperature and pressure than the MH lamps. These advantages lead to high color stability with high CRI, uniformity, and efficacy over the lifetime in spite of the bulb material allowing only ~90 percent transmission.

HID lamps require several minutes of start-up time (time to reach stable output) and restrike. A long start-up is due to the time taken to reach a stable operating temperature and pressure within the arc tube. The restrike time interval results from the need to have low pressure inside the arc tube for arc initiation. Complex ballasts are needed to provide startup, restrike, and stable operation with constant current. To improve startup, restrike, and operations at low voltage, a high voltage-low current pulsed start is used. Sometimes, multiple arc tubes within the outer bulb envelope are used to provide faster restrike. Only one arc tube operates at a time in such lamps. Xe-based HID lamps are capable of instant-on and restrike. Automotive HID lamps use Xe with metal halides to improve the start and restrike times dramatically.

The physical orientation of HID lamps such as Hg and MH during operation is far more important than with the other lamps. Due to convection, within and outside the lamp, different portions of any lamp, not just HID, are heated to different temperatures. The lamp engineering must take this into account and ensure that the hottest regions do not constitute a failure mode either by design or by providing instructions to the user for best operating configuration. In MH and Hg HID, the high convection roll within the long arctube has an overwhelming effect on the arc shape and position under gravity. It can make the arc shape curved and lead to nonuniform degradation of the electrode tips and impact the light output, lifetime, and light distribution patterns. HPS lamps, however, can be operated in any position primarily due to a compact arc tube at high gas pressure (5 to 27 atmospheres).

Lamp degradation and failure occur due to electrode degradation by evaporation, arc tube blackening due to electrode material deposition, loss of gas pressure, and selective diffusion of gases leading to change in the lamp color. Arctube blackening also leads to the rise in the arctube temperature leading to an analogous rise in pressure and operating voltage. The effect is especially pronounced in HPS where lamp cycling can occur: as the lamp cools down, it is able to restrike but after some time temperature rises to the point that it shuts down.

Electrodeless Lamps As the name suggests, electrodeless lamps do not have any electrodes internal to the bulb envelope. As a result lifetime is not limited by electrode degradation. The concept behind these sources is over a century old.[48] These sources are being sought to replace conventional light sources where high flux is needed at low operational costs (long lifetimes and high efficiency). There are two kinds of electrodeless lamps: induction lamps (IL) also known as *electrodeless fluorescent lamps* and microwave powered lamps also known as *electrodeless sulfur lamps* (ESL). Extraordinary high bulb life times (>25,000 hours) are possible due to lack of electrodes that degrade under operation. The causes of lamp failure are due to electrical components rather than the bulb itself, which implies a greater lifetime.

In each case, the goal is to excite a discharge with an EM field without the need of electrodes inside the bulb. Alternating magnetic fields in IL or microwaves in ESL initiate the discharge by

accelerating the free electrons of a gas with low ionization potential, such as argon or krypton. Free electrons are created in the gas by a spark from a high-voltage pulse across two electrodes in the vicinity of the bulb. These free electrons ionize the gas atoms by impact ionization. Ionization yields more free electrons and ions and the process resumes, eventually resulting in plasma formation. Excited states of gas atoms produce light via spectral transitions across various wavelengths. In case of IL, mercury is present in addition to argon/krypton to produce UV from excited mercury atoms. The UV excites the phosphor coating on the inner surface of the bulb envelope and emits white light just like a regular fluorescent lamp.

In ESL, microwaves are used to produce an intense plasma inside a rotating quartz ball containing argon/krypton and sulfur. The rotation of the quartz ball helps in stabilizing the fill for uniform emission as well as convective cooling with a fan to prevent its meltdown. Initially, the microwaves create a high-pressure (several atmospheres) noble gas plasma. This heats sulfur to a high temperature resulting in brightly emitting plasma. Light emission by sulfur plasma is due to the molecular emission spectra of the sulfur dimer molecules (S_2). The spectrum is continuous across the visible and has >70 percent of its emission in the visible. It peaks at 510 nm, giving a greenish hue. The resultant CRI is 79 at a CCT 6000 K. The lamp spectrum can be modified with additives such as calcium bromide, lithium iodine, or sodium iodide or by using an external color filter.

Electroluminescent Sources Electroluminescent sources are materials that emit light in response to an electric field. Examples of such materials include powdered ZnS doped with copper or silver, thin film ZnS doped with manganese, natural blue diamond (pure diamond with boron as a dopant), III-V semiconductors or inorganic LED materials such as AlGaAs, phosphors coated on a capacitor plane and powered by pulsating current, organic LED (OLED) also known as light-emitting polymer or organic electroluminescent. The sources can operate at low electrical power with simple circuitry.

Electroluminescent sources are commonly used for providing illumination across small regions such as indicator panels. LEDs are already a major lighting source that is rapidly replacing incandescent and fluorescent light sources. The remainder of this section discusses LEDs and OLEDs.

LEDs emit light by electron-hole pair recombination across the P-N junction of a diode. The wavelength of the emitted light corresponds to the band gap (energy gap between valence and conduction bands) across which the electron hole pair is created. The degeneracy in the valence and conduction bands leads to a closely spaced band of wavelengths that constitute light from the LED. Narrow spectral bandwidth enables applications that require saturated colors. Although LEDs are not available for every desired color, it is possible to combine LEDs of different colors to create any color within the color gamut defined by these LEDs. As such, color mixing has become an important field. LEDs emitting in specific bandwidths can be combined with sources with continuous spectra to either enhance a certain spectral region or to provide an easy dynamic color control. One easy method of combining multiple LEDs is using lightguides. Lightguides with rippled surface texture along the cross section are particularly efficient in combining multiple colors with excellent uniformity in a short path length.[49,50]

LED lamps may have an array of small LED chips or a single large chip to achieve the desired power levels. The directionality is controlled by appropriately mounted optics. DC operation of LEDs makes them flicker free sources. Figure 18 shows the structure of a simple packaged LED. Chapter 17 in this volume is dedicated to the subject of LEDs.

LED packages come in various sizes and shapes. Surface mount LEDs (SMD) have minimum packaging and are almost a bare die. LED packages are also offered in multicolored die formats.

Over the years, a variety of materials for LEDs have been used with the goal of obtaining higher efficiencies and different colors across the visible spectrum. LED technology is fast evolving with ever increasing brightness, lifetime, colors, and materials and decreasing costs. The available materials, at the time this chapter was written, are listed in Table 5.

Most lighting applications require white light. Some of the processes for making white-light LEDs are listed below:

- Arrays of small red, green, and blue dies placed in close proximity in a single LED package. Good color mixing takes place in angular space.
- Color-mixing of red, green, and blue colors using lightguide or other optical means.[50,52]

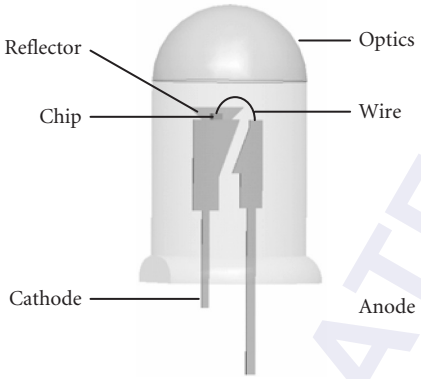

FIGURE 18 Structure of a simple packaged LED.

TABLE 5 LED Materials and Emitted Colors

Material	Color
AlGaAs	red, infra
AlGaP	green
AlGaInP	higher brightness orange, orange-red, yellow, and green
GaAsP	orange, orange-red, orange, and yellow
GaN	green and blue
InGaN	blue (450–470 nm), near UV, bluish-green, and blue
SiC (as substrate)	blue
Si (as substrate)	blue
Sapphire (as substrate)	blue
ZnSe	blue
Diamond	UV
AlN, AlGaN, AlGaInN	UV(<210 nm)[51]
Organic light-emitting diodes (OLED)	Red, green, and blue

- Phosphor excitation by blue or UVEDs.
- Novel techniques like quantum dot blue LEDs or homoepitaxially grown ZnSe blue LEDs on a ZnSe substrate. The active region emits blue light while the substrate emits yellow light.[53,54]

There is a continuous push to improve the LED efficiency and brightness while keeping the lifetimes high. High brightness LEDs became possible due to large area chips, efficient heat extraction and better light extraction from the chip. Internal quantum efficiency of LEDs can be increased by placing emitters inside a cavity[55] to increase the radiative recombination rate. Due to the high internal Fresnel reflections and lateral waveguiding, a lot of light fails to exit the chip. Techniques such as texturing the surface with photonic crystals assist in increasing the light extraction from large dies.[56–58] Figure 19 shows the internal structure of a photonic crystal LED.

Organic LEDs (OLEDs)[59,60] in contrast to inorganic LEDs are size-scalable light sources with richer color spectra. OLEDs can be used to create flexible transparent lighting solutions as they can be printed on a malleable substrate with transparent electrodes. Currently OLEDs are being used for displays and are competing with LCD flat panels. Conceptually, OLEDs are no different from inorganic

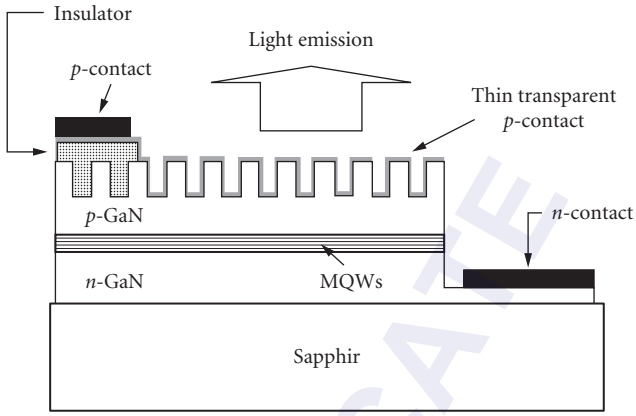

FIGURE 19 Internal Structure of a Photonic Crystal LED. MQW refers to "multiple quantum wells." (*Courtesy: Seoul National University, Korea, http://optics.org/cws/article/research/23635/1/sem_image.*)

semiconductor based LEDs. An OLED deploys layers of organic materials on polymer substrates to form conductive and emissive layers connected to a cathode and anode respectively. Much of the OLED research is aimed at making them brighter and longer lasting.

LED failure causes include damage due to degradation of the active layers with time (spontaneously or in operation); plastic package degradation due to ambient UV; electrostatic discharge; current crowding or inhomogeneous current distribution across the junction leading to hot spots; and thermal stresses causing rupture of the LED package, diffusing of the metal contact material into the die material at high currents, high output leading to facet melting and phosphor degradation in white LEDs, and degradation of organic layers in OLEDs.

Miscellaneous Artificial Light Sources *Neon signs* are essentially cold cathode-like operation of a fluorescent tube without phosphors. A low-pressure mixture of noble gases such as neon, argon, helium, xenon and a small amount of mercury is used in the discharge tube. Neon emits a reddish-orange color; argon emits blue; and krypton, helium, and xenon emit over a wider spectrum. Colored filter glass can be use for making different colors.

Short arc sources function almost identical to HID lamps with the only difference being that the electrodes are much closer (less than 1 mm to 12 mm). The gases are mercury (with argon), mercury-xenon, pure xenon, or metal halides (with mercury and argon). These lamps are primarily used in illuminating high loss systems where the source étendue needs to be as small as possible. Projectors, medical optical instruments, metrology instruments, and daylight or solar simulators use such lamps. These lamps have lifetimes from a few hundred hours up to 10,000 hours. The light sources are typically used with a reflector (parabolic or ellipsoidal). Sometimes the reflector is an integral part of the source/lamp package.

Pure *Xe arc lamps* have an instant-on capability and provide high CRI (>80) at high CCT (>6000 K). Digital cinema projectors and flash tubes (for warning signs, entertainment applications, camera flash lights, and warning or emergency signs and indicators) often deploy pure Xe-arc sources.

Lasers are used for visual displays for entertainment. The subject of Lasers is discussed in Chap. 16 in this volume.

Nuclear sources are self luminous light sources that function by phosphor excitation caused by beta radiation from radioactive materials such as tritium. These light sources are used to illuminate tiny spaces such as watches or displays of instrument panels in very low ambient light.

Glow lamps are low wattage arc sources with gases such as argon emitting in the UV to excite UV-excitable materials or neon to emit orange light to be used as indicator lights.

Carbon arc sources are now obsolete but still find applications in illuminating small areas with bright light under demanding environmental conditions (such as outer space). An arc is struck across a pair of carbon rods and the incandescence from the heated carbon rods provides the light.

Gas lights that operate by the burning of gases like methane, ethylene or hydrogen are used with appropriate lanterns primarily for decorative applications.

Natural Sources: Daylight Daylight can be utilized in the lighting design of buildings to provide a pleasing environment that enhances physiological well-being and productivity and also energy savings during the day by reducing the need for artificial lighting and solar influx contribution to building heating. Daylight is primarily used for ambient lighting. It can be used for task lighting when integrated with electrical lighting. Daylight constitutes direct sunlight, scattered sunlight from the atmosphere, reflected sunlight from the clouds, and reflected light from the surroundings such as ground (especially snow) and objects such as buildings. The solar spectrum changes with atmospheric conditions and so does scattered light from the sky or reflected light from the ground. The CCT of Sun is 1000 to 5500 K, clear blue sky is 10000 to 100000 K, overcast sky is 4500 to 7000 K and clear sky with sunlight is 5000 to 7000 K. Figure 20 shows an example of the solar spectrum at the ground, at noon, at Golden, Colorado. Note the IR content in the spectrum and the shift in spectrum from noon to evening.

Designing for daylight requires close attention to many factors:

- Goals of providing daylight: physiological well being of occupants and/or energy savings.
- Intended distribution of light inside the building during the day and in the night. Penetration of daylight into the interiors and the impact of reflectivity from various surfaces.
- Impact of daylight on materials such as wall paints, artwork, plastic materials, furniture, and plants. The UV component of daylight is generally harmful to most materials via solarization of plastics or fading of paints and stains. If the impact of UV is not known and acceptable, then the UV should be rejected by the optical system components through coatings or materials.
- Integration of daylighting-based building design with other controls such as for electrical lighting, cooling and any automated systems.

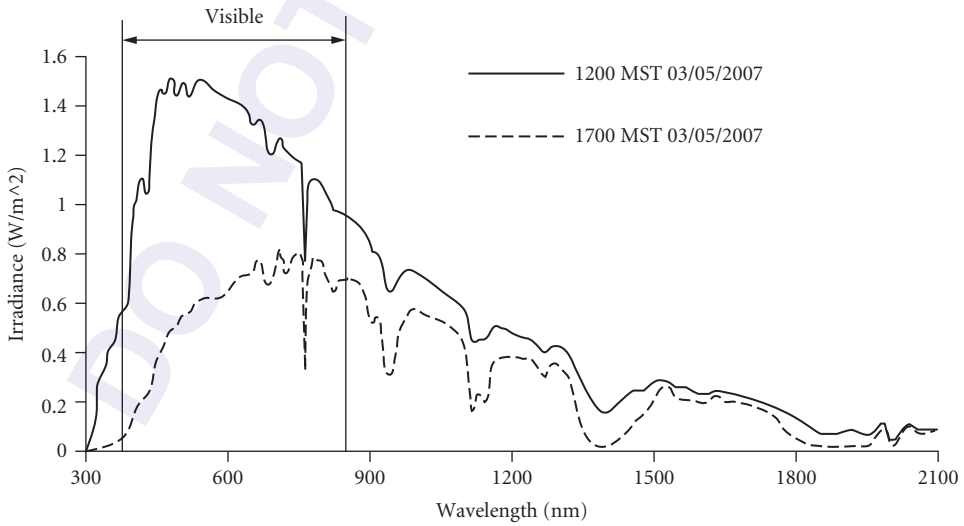

FIGURE 20 Solar spectrum recorded at ground at Golden, Colorado at two different times during the day. (*Courtesy of National Renewable Energy Laboratory, USA.*)

- Location (latitude and longitude) and orientation of the building relative to the surroundings. Simulating the daylight entering the building during various times of the day and the year.
- Design for reduction or elimination of glare from daylight sources. Internal layout of the building during intended use will play a key role.
- Outside view requirements via windows. A minimum window size[61–63] is needed for a given geographic location, and a certain window location is dictated by aesthetic reasons including the desired view from the window. The minimum window size can also depend upon the prevalent building regulations based on wall size or floor size. Under such circumstances, the daylight entering must be controlled or balanced with interior lighting and cooling for uniformity, glare, and heat management. Daylight can be controlled by providing appropriate window shades, glazings, or even additional windows or skylights at appropriate places.

It is not always possible to obtain energy savings with daylight due to increased heat load, especially during summers and the need to supplement daylight with electrical lighting during the night. Infrared rejection is achieved by using special glazings. To limit glare, glazing such as high reflectance, low transmittance, electrically controlled transmission, tilted glazings with angularly dependent transmittance or IR reflecting films are used. Adequate consideration must be given to the window view impact due to any of the daylight control mechanisms. A very low-transmittance glazing can make the outside view appear gloomy on a bright day.

Luminaire Design

The source is the starting point of the luminaire design. The optics performs at a minimum two functions: first to capture the light from source and second to transfer light efficiently to the desired distribution at the target (i.e., illuminance, intensity, and/or luminance). The choice of the optics is also a challenging process. First, the designer must select if refractive, reflective, or both types of optics (i.e., hybrid) are to be used in the design. Reflective optics have been a standard for most sources, with flat refractive optics used at the output aperture in order to protect the other optics. Until recently reflectors were standard conics such as ellipses, hyperbolas, parabolas, or spheres. Standard refractors in use include cover plates (still called a lens), pillow lens arrays, Fresnel lenses, and other faceted designs. However, with advances in LEDs, refractive optics are increasingly being used for advanced function. Solid-state lighting optics are either plastic or glass that surround individual or a limited number of LEDs. They are hybrid optics that use at least total internal reflection (TIR) and refraction at the input and output facets, but they can also use reflection, scattering, and even diffraction. With the advent of better technology, especially manufacturing capabilities and software for modeling, faceted and continuously smooth surfaces parameterized with nonuniform rational B-splines (NURBS) are being developed. For high-performance, injection molding of plastic or glass is being increasingly used. For refractive optics, the surfaces are left bare, but for reflective optics there is vacuum metallization of the surfaces. Reflectors are also made with stamping methods, but these optics tend to have lower performance.

Baffles (louvers) are often considered by many to be optics of the system; however, many, rather than shaping a distribution through redirection of the light, block or even absorb incident radiation. Thus, while some baffles are reflective and provide some shaping of the illumination distribution, they most often achieve shaping through subtraction rather than addition. They are primarily added to alleviate glare, trespass, and pollution, but they are also included for aesthetic reasons, correcting errors in the design process, and to hide structure within the luminaire.

The source coupling aspect is the focus of the next section, following that is a discussion of the design of the optics and subsections on baffling in the form of luminaire cutoff classification and types of luminaires. Following this process from the source to the optics to the baffle to the target, while always considering the perception aspects of the illumination (see Sec. 40.3), means that aesthetically pleasing while technically sound lighting can be developed.

Étendue and Source Coupling For reflective optics, the source-coupling components also act as the transfer optics, often in conjunction with a front, protective lens. With the advances in source

technology that use hybrid, dielectric components, coupling of the sources, is increasingly important in order to improve upon system efficiency. Typically, individual LEDs are placed in recesses in the dielectric optic, and by obeying the conditions for TIR, all of the emitted light can be captured by the coupler and then transferred to following optics that shape the emitted distribution.

In all cases, the term étendue describes the flux transfer characteristics of the optics, starting with the coupling optics, of an optical system, such as a luminaire. Étendue is a geometrical quantity that is the integrated product of an area and solid angle. In paraxial form it is the Lagrange Invariant, but in nonparaxial form it is given by

$$\mathscr{E} = n^2 \iint_{\text{pupil}} \cos\theta dA d\Omega \tag{12}$$

where $\mathscr{E}$ is the étendue, dA is the differential area, $d\Omega$ is the differential solid angle, θ is the angle with respect to the surface of interest (i.e., normal), and n is the index of refraction of the space. The limits of integration in area are over some aperture (e.g., a lens clear aperture or a reflector exit aperture), while the solid angle integration is over the limits that are passed by the aperture. For example, consider a source of area A_s that emits into a half angle of θ_0 from every point on the surface. The étendue for this source is

$$\mathscr{E} = n^2 A_s \int_0^{2\pi} \int_0^{\theta_0} \cos\theta \sin\theta d\theta d\phi = \pi n^2 A_s \sin^2\theta_0 \tag{13}$$

In lossless optical systems, étendue is conserved. Thus, in order to design the most efficient luminaire, one must continue to match the étendue as one progresses through the optical components of the system. For example, if the source of Eq. (13) is used for a luminaire, one must keep this étendue quantity consistent. If one desires to reduce the angular spread of the output from an optic ($\theta_0 > \theta_{\text{optic}}$), then the area of the optic must be increased ($A_s < A_{\text{optic}}$). The counter also holds true: to reduce the real extent ($A_s > A_{\text{optic}}$), one must increase the angle ($\theta_0 < \theta_{\text{optic}}$). An expression for conservation of étendue in a generalized form is

$$dx\,dy\,dp\,dq = dx'\,dy'\,dp'\,dq' \tag{14}$$

where the dx and dy terms are the differential position terms and the dp and dq terms are the differential optical direction cosine terms, which are equivalent to ndL and ndM respectively. More information about étendue can be found in Chap. 39, "Nonimaging Optics: Concentration and Illumination," in this volume. Another factor related to étendue through a differential is skewness, which denotes the twist on individual rays of light in an optical system. Skewness is also invariant and implies that transfer from one source geometry (e.g., a square) cannot be transformed to another source geometry (e.g., a circle) without loss except if some rotational asymmetry is added to the optical system. Further information about étendue and associated terms like skewness can be found in the literature.[64]

Luminaire Design Methods There are a multitude of design principles for the design of the optics of a luminaire. Fundamentally, most design methods are based on the basic conic shapes as listed in Table 6. Each of these shapes provides a basic intensity distribution at its output aperture. However, increasing demands of tailored light distributions and also increased efficiency require perturbations to these basic design forms. Furthermore, the topics of light trespass, light pollution, and glare are receiving a wealth of attention from ordinance and regulatory agencies. To reduce glare issues it is best to use diffuse optics with a well-defined cutoff. In the field of nonimaging optics (see Chap. 39), the edge-ray theorem provides a means to have a well delineated cutoff. The edge ray is defined by the maximum extent of the source, thus providing a maximum cone of light from the reflector designed around the source shape. However, the edge-ray principle is passive with respect to the luminance distribution of the source—it contends for the maximum extents but not the physical distribution of light in the radiation pattern.

Thus, tailoring methods have been developed. The tailoring methods specify the shape of the optics based upon the luminance distribution of the source and the desired illumination pattern

TABLE 6 Basic Conic Shapes, Their Conic Provide at Their Output Aperture Constant, and the Basic Intensity Distribution That They Provide at Their Output Aperture

Shape	Conic Constant (k)	Base Intensity Distribution
Hyperbolic	k <−1	Diverging; far-field applications
Parabolic	k = −1	Collimating; pseudocollimation applications
Elliptic	−1 <k<0	Converging; near-field applications
Spheric	k = 0	Converging; self-imaging applications

(i.e., luminance, illuminance, and/or intensity) at the target. These methods are extensive and beyond the confines of this chapter. The reader is encouraged to consult the *Handbook* chapter on nonimaging optics (Chap. 39) for a brief introduction, the theoretical book on nonimaging optics by Winston, Miñano, and Benítez,[64] and the applied book on nonimaging optics by Chaves.[65]

Luminaire Cutoff Classification A cutoff ensures that light from the luminaire is restricted above the horizon with respect to the lamp geometry. Cutoff is designed into the luminaire through the optics (i.e., edge-ray designs) and/or the integration of baffles. While most applications do not require cutoff classification, except for those used on the exterior, such as automotive, roadway, and landscape lighting, most designers include such to make effective lighting systems by alleviating potential glare, trespass, and pollution concerns. Often strict cutoff guidelines are mandated by governmental standards, such as for automotive, traffic signal, and roadway lighting. The goals are to provide the required lighting level to its users, while also alleviating light pollution and light trespass. Light pollution is light that is directed up into the atmosphere, causing sky glow, which is especially present in urban settings. The reduction of light pollution is a growing trend being addressed by the astronomy community. When light is incident on surfaces outside the intended illumination region, it is called *light trespass*. The impact of light trespass from roadway lighting is a major concern in residential areas.

For both trespass and pollution the luminaire cutoffs provide a protocol to reduce both. Automotive lighting does not use the criteria presented here, but rather use a set of governmental standards. Roadway and external lighting make the most use cutoff criteria as shown in Table 7. See Fig. 22 for a depiction of the angles listed in Table 7.[66]

Luminaire Classification System In 2007 the IESNA published research results for refinement of the cutoff classification system of the previous section.[67] This study focused on light distribution in front of the luminaire (forward light), behind the luminaire (back light), and above the luminaire (uplight) as shown in Fig. 21. They found the photometric luminaire efficiency ($\eta_{\text{luminaire}}$) to be

$$\eta_{\text{luminaire}} = 100\frac{\Phi_{\text{forward}} + \Phi_{\text{back}} + \Phi_{\text{uplight}}}{\Phi_{\text{source}}} \tag{15}$$

where Φ_{forward}, Φ_{back}, Φ_{uplight}, and Φ_{source} are the integrated fluxes in lumens over the solid angles shown in Fig. 21 for forward light, back light, uplight, and the bare source, respectively.

TABLE 7 Amount of Emitted Light Criteria for the Luminaire Cutoff Classification[66]

Type	Horizon and above (90° and greater)	10° below Horizon (80° to 90°)	Remainder (0° to 80°)
Full Cutoff	0%	≤10%	≥90%
Cutoff	<2.5%	≤10%	≥87.5%
Semicutoff	<5%	≤20%	≥75%
Noncutoff	No restrictions over entire angular space		

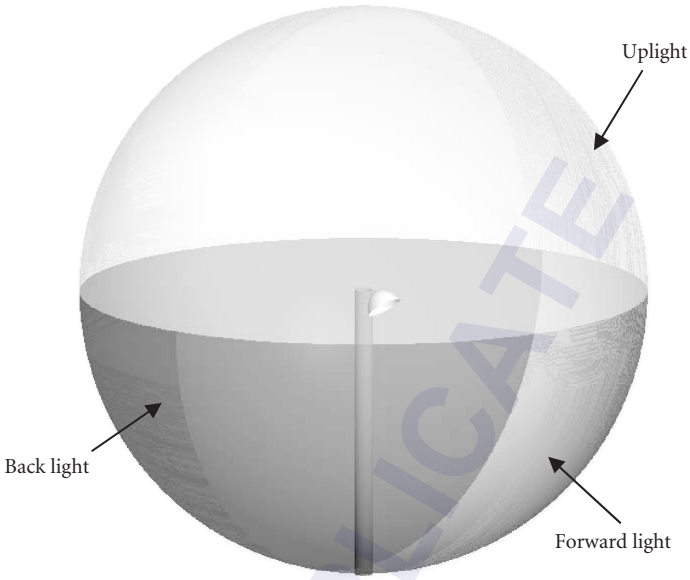

FIGURE 21 Lighting classification system zones for forward light, back light, and uplight based upon the exit aperture of the luminaire.

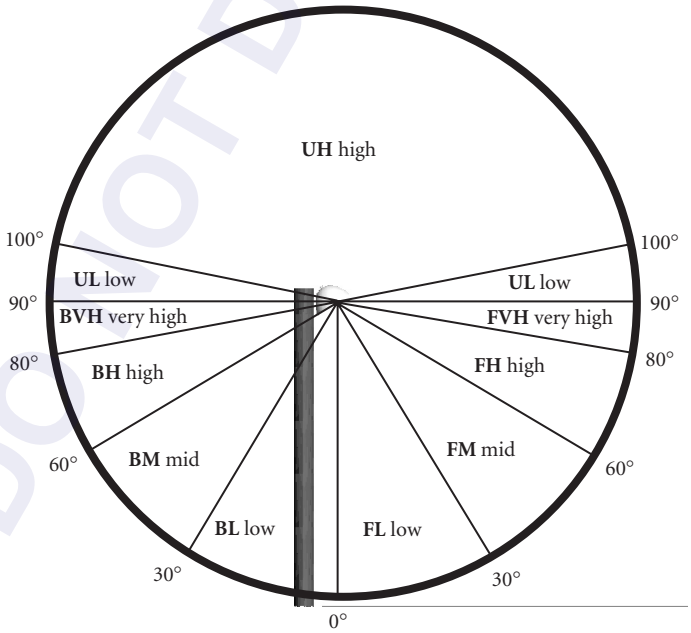

FIGURE 22 Layout of the light classification system subzones. (See also color insert.)

These three zones are then broken down into a total of 10 subzones as shown in Fig. 22. The lumens in each subzone is measured with respect to the bare source flux, as in Eq. (15), in each of these subzones and then reported as an evaluation of the luminaire. These subzones indicate the distribution of light over several regions rather than restricted to the 80° and greater as per the previous section. Standard goals include reduction of light above the horizon (i.e., all uplight subzones and the BVH and FVH subzones) and the desired uniformity over the other zones. This new classification system provides for better control of the illumination such that both vertical and horizontal surface illuminances can be addressed in the design process. Horizontal surface illuminance criteria are met by increasing the flux in the BM to FM subzones. Vertical surface illuminance criteria are met by increasing the flux in the BM, BH, FM, and FH subzones.

Luminaire Optics There are innumerable schemes to the design and availability of luminaire optics, both for artificial and natural sources. Methods employing reflectors, refractors, TIR optics, and combinations thereof have been developed. Additionally, the optics are both specular and diffuse or a combination of these two are used. In the next few subsections, we provide examples of commonly available luminaire optics. Finally, as per Table 6, the shapes of the optics are typically based on conic shapes.

Luminaire optics for artificial sources While the design of the optics of the luminaire is to provide a desired illumination distribution, we learned from the previous sections that light cutoff is important in the design of the luminaire. In fact, the ability to hide or shield the source from direct view in order to reduce glare concerns is as equally important as obtaining the desired illumination distribution. A reflector as shown in Fig. 23*a* has a fairly wide direct view of the source, denoted as the shielding angle or similarly the cutoff angle. Room lamps are perfect examples of this dual requirement since it is typical to use a diffuse shade around the source. The source and shade (which also acts as a diffuse reflector) provide the desired general illumination, while the shade provides the requisite cutoff. Besides using the body of the reflector to hide the direct view of the source, louvers or baffles (see Fig. 23*b*), a prismatic or Fresnel lens (see Fig. 23*c*), or a bulb shield (see Fig. 23*d*) are

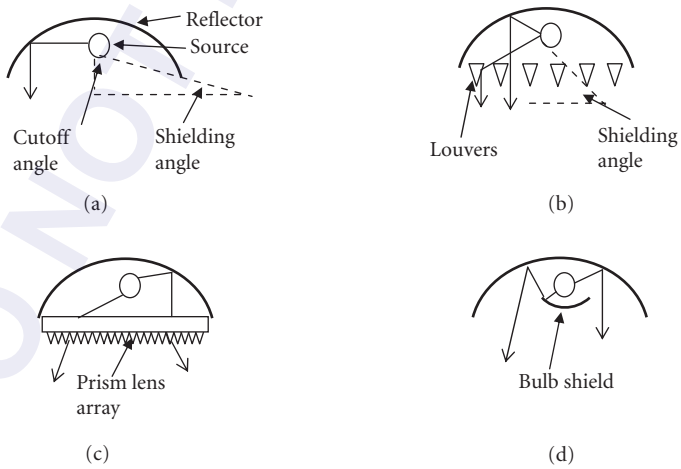

FIGURE 23 Glare issues of four luminaire geometries: (*a*) the reflector providing the cutoff; (*b*) louvers, flat or parabolic, increasing the shielding angle; (*c*) a lens array, prismatic or Fresnel, which directs more of the light emission downward thus reducing the direct intensity level of the source; and (*d*) the inclusion of a bulb shield to ensure that all emission strikes the primary reflector at least once. (*Adapted from Ref. 5, p. 71.*)

added to the luminaire. For the baffle case two standard options are typically used: vertical, strongly absorbing louvers, or specular reflecting parabolic louvers. The former inhibits direct view of the source in the luminaire while also absorbing the glare-inducing light. The latter also reduces the direct view angle of the source, but it uses the parabolic, specular louvers to direct the glare-producing light into directed radiation typically outside the direct view of an observer. The lens, prismatic or Fresnel, coupled to a reflector causes most of the emission to be directed downward, thus frustrating the direct imaging of the source. This obscuration of the source means glare effects are reduced. The bulb shield, which is typically spherical, ensures that all light from the source is incident on the primary reflector of the luminaire, thus completely hiding the source from direct view and in turn greatly reducing the glare potential.

The specifics of the lamp design depend on the application. Figure 24 shows some representative luminaire designs. Figure 24*a* shows a banker's desk lamp, which has multiple bounces within the glass envelope optic. It creates a wide illumination distribution, but the colored glass and the multiple bounces softens the appearance of the bulb located within. The envelope optic can be positioned by the user to alleviate source glare while also providing the desired illumination over a desk surface. Figure 24*b* shows a Bouillotte table lamp, which uses two vertically oriented fluorescent lamps. The shade hides part of the bulbs from direct view, and the coating on the fluorescent tubes causes near-Lambertian emission; therefore, the illumination for this lamp is wide and glare issues are minimal. Figure 24*c* shows an indirect RLM lamp fixture that is suspended from a ceiling. The indirect nature

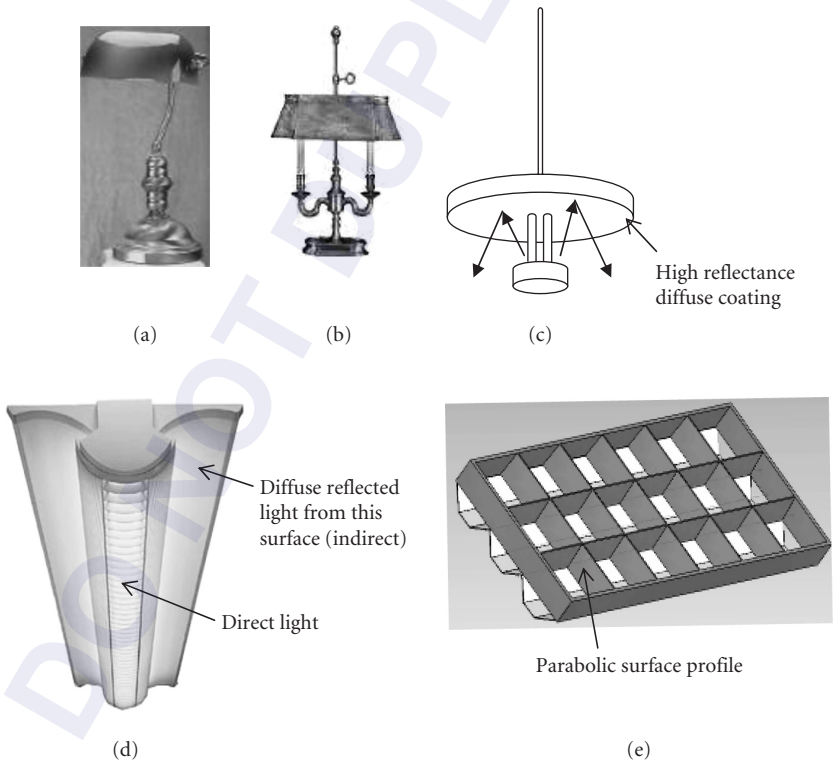

FIGURE 24 Depictions of luminaires: (*a*) Bankers lamp: multiple bounces inside the reflector create a wide angled uniform illumination; (*b*) Bouillotte lamp: vertical fluorescent tubes provide diffuse illumination; (*c*) indirect lighting with RLM fixture where the top surface reflects light into a wide angular range; (*d*) overhead direct-indirect lighting fixture using fluorescent tubular bulbs; and (*e*) parabolic louvered trough reflector for fluorescent tubes. (See also color insert.)

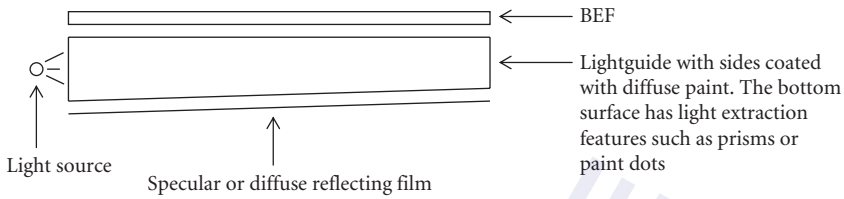

FIGURE 25 An edge lit backlight. (BEF: Brightness enhancing films.)

is due to the inclusion of a bulb shield and a highly reflective diffuse primary reflector thus alleviating glare. Figure 24*d* depicts a direct-indirect overhead, fluorescent lamp fixture. The white, diffuse wing structures provide indirect lighting, while the central section is louvered direct lighting. The direct lighting provides task illumination needs, while the indirect lighting provides a general light level for the room. Finally, Fig. 24*e* shows a standard overhead office luminaire: a series of parabolic troughs (called a troffer) in which long, tubular fluorescent lamps are located. The parabolic louvers reduce glare concerns by increasing the shielding angle, while also increasing the task illumination due to the specular reflectivity of the vanes. Instead of using the louvers, a pillow lens array or prismatic lens can be used; however, computer monitor glare issues can arise with these lenses. Other luminaire geometries not presented here include track lighting, recessed lights, chandeliers, and spot lamps. Please see Refs. 71 and 5 for more information.

Backlighting Backlighting is used extensively in photography to separate the background from the subject and create 3D effects. It can be used for the same purpose in interior lighting to illuminate displays from behind. Backlighting is used extensively in signage, to illuminate instrument panels and device display panels such as laptop and cellphone screens. A typical edge lit backlight operation is illustrated in Fig. 25. Light enters the planar lightguide[68] (for example, 50 mm × 50 mm × 5 mm) from the thin edges and bounces around. Carefully designed and positioned light extraction features such as prism or spheres deflect the light out of the lightguide. As a result the entire planar surface is lit and appears as a planar light source. Modern backlights use sources such as CCFLs and LEDs. With LEDs, dynamic multicolored backlit displays are possible as lightguides allow for efficient color mixing. Edge lit backlighting can be used in direct lighting of large spaces such as living rooms by creating illuminated ceilings, walls, or artificial windows. Figure 26 shows one such application where backlit ceiling tiles are used to create an illuminated ceiling or an artificial skylight. A picture of sky and vegetation is superimposed on the tiles to create an effect of natural sky with vegetation on the roof. Backlights could be replaced by OLEDs which provide not only illumination but also information content.

Luminaire optics for daylight sources Daylighting schemes[69,70] involve careful layout of windows, skylights, skytubes, and controls such as shades, window overhangs, window depths, light shelves, and hybrids with electrical lighting. For effective daylight illumination, it is necessary to determine the access to sunlight by taking into account the sun path across the sky during the day and across different months and the impact of neighboring buildings and ground features. Daylight can be used for city lighting too with careful planning. Heliostats or large plane mirrors have been used atop buildings or even mountains to direct sunlight into the city interior.

Layout of windows and skylights can utilize schemes such as side lighting, top-level lighting, and clerestory lighting. Placement of nonview providing windows for providing daylight must be designed carefully for maximum daylight penetration and controlled glare. Side lighting allows daylight in from the walls usually at eye level, top lighting allows daylight in from skylights, and clerestory lighting allows daylight in from the side windows near the roof above the eye level. Clerestory windows provide more uniform ambient illumination over a larger region. However, proper attention must be given to glare from the sky or direct sun by using baffles. The depth of windows near the ceilings or window overhangs also helps in limiting such glare. Figure 27 shows several different

FIGURE 26 A conference room with artificial skylight made up of backlit ceiling image tiles. (See also color insert.) (*Courtesy of The Sky Factory, LLC.*)

layouts of windows and skylights that bring daylight into the interiors. [71,72] The location and number of openings for daylight determine the penetration and uniformity of the illumination achieved. The height and the slope of the ceilings determine the penetration and the illumination gradient achieved inside the room. For example, for daylight from windows located near the ground, having a tall ceiling allows light to penetrate to the farthest ends of the room. Similarly a sloping ceiling with windows located near the ground allows a gentler illumination gradient from the window to interior.

The reflective properties of the walls and the ceiling must be taken into consideration when simulating the impact of daylight. High reflectance paints on the ceiling can be used to spread the daylight entering from the window portion near the ceiling into the building interiors. Window blinds, shades, and mechanical louvers are commonly used to control daylight. Sometimes partition walls around certain window sections are used to control glare or even limit the extent of illuminated region such as artwork in museums.

Light shelves are used interior or exterior to the windows to allow daylight from the sky in without glare. Light shelves consist of large horizontal sections hanging below the top edge of the window. A layout of mirrors or even just a plane aluminum sheet directs the daylight from the sky toward the ceiling or deep into the room without hitting the ground. A reflective ceiling will scatter daylight into the room. Combinations and variations of these schemes can be used to suit a particular situation. Figure 28 illustrates the concept of light shelves. Suncatchers are similar in concept as shown in Fig. 29.

Skytubes are lightguides that carry daylight into the building interiors. The inside walls are specular with high reflectance. These tubes may be straight or curved, as needed, to transport daylight to different regions. Curved lightguides have a symmetric cross section to maximize light transfer efficacy across the bends.

Hybrid daylighting systems consist of daylight integrated with electrical light as shown in Fig. 30.

Solar lighting systems include the use of tracked or untracked mirrors, lenses or apertures for collecting sunlight and channeling it into the building interior via skytubes, lightguides or fiber-optical cables. Heliostats or large plane mirrors are used at locations with access to the Sun and they direct that light into building interiors or even city interiors. Optimally, these mirrors track the Sun.

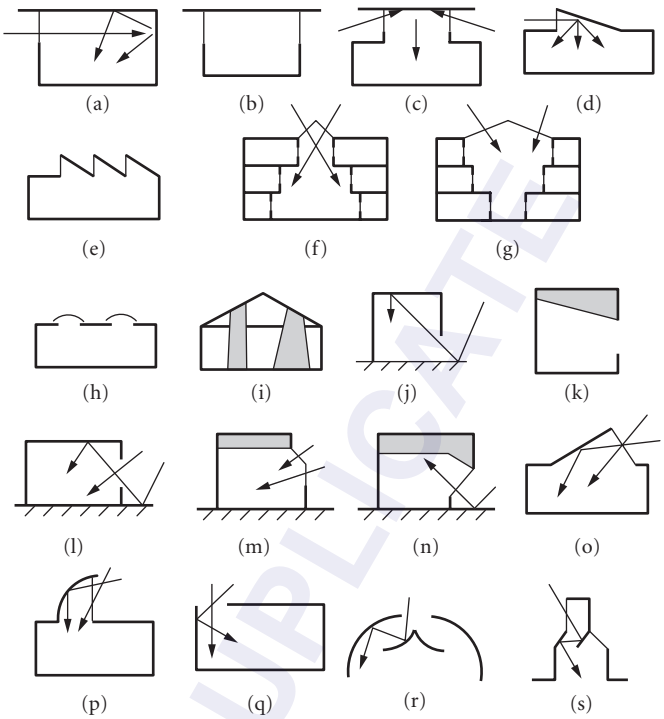

FIGURE 27 Windows for gathering daylight: (*a*) Unilateral, side lighting. (*b*) Bilateral, side lighting (*c*) Roof monitoring. (*d*) Clerestory. (*e*) Sawtooth skylighting. (*f*) Atrium. (*g*) Litrium. As opposed to atrium it provides best light distribution to adjacent spaces. (*h*) Top skylighting. (*i*) Skywells: straight and splayed sections. Shaded region shows the lit region. Splayed section distributes light farther, more evenly and with reduced peak brightness. (*j*) Window near the ground. Deep ceiling allow deeper light penetration. (*k*) Tilted ceiling reduced the illumination gradient from the window to interior. (*l*) Window in the mid-section allows direct skylight and ground reflected skylight. (*m*) "Greenhouse" opening for overcast sky. (*n*) "Overbite" opening for ground reflected skylight. (*o*) Tilted glazing with clerestory opening to allow sunlight from a wider range of elevations. (*p*) Capturing daylight via top lighting. (*q*) Using high reflectance wall adjacent to top lighting to provide glare free light. (*r*) and (*s*) Top lighting via lightguiding.

Figure 31 shows use of a solar light pipe (SLP) to bring sunlight deep into the building interior. The atrium is 140 ft deep, 60 ft long, and 9 ft across. Without the SLP, the view in the building interior was a dark concrete wall. A rooftop heliostat captures sunlight and directs in down into a prismatic glass cone. The glass refracts the incoming sunlight horizontally onto an outboard cylinder of open weave fabric; creating a glowing, translucent, 120-ft-long tube of diffuse sunlight. This display is visible from the 14 floors of atrium offices and also from the ground floor lobby, elevator lobbies, and the library. The SLP projects a 10-in diameter sunburst onto the lobby floor (Fig. 31*b*). Besides injecting daylight into dark spaces, the SLP's unique design provides a compelling and a very dynamic visual focus for the atrium occupants. It constantly updates their understanding of the Sun, the sky, and the weather patterns and reconnects them to the otherwise solar rhythms of the day and seasons. At night, powerful searchlights use the "at rest" heliostat and SLP to inject a shifting palette of colored light into atrium.

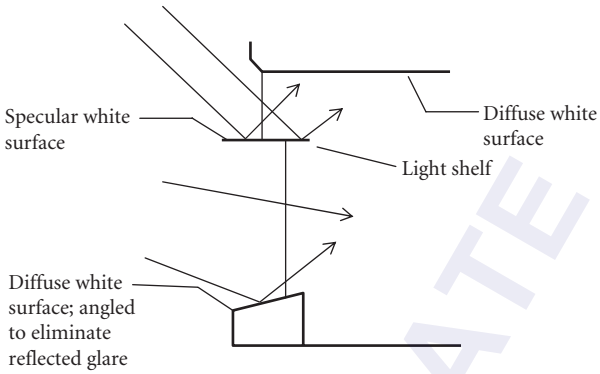

FIGURE 28 Light shelf to limit glare from direct skylight and redirect light to the ceiling.[72] The light shelf can be curved in shape and moveable angularly. The position of the light shelf relative to the window can be interior, exterior, or both. Exterior light shelf provides shading while interior light shelf limits glare. Blinds or moveable shades can further help in glare control.

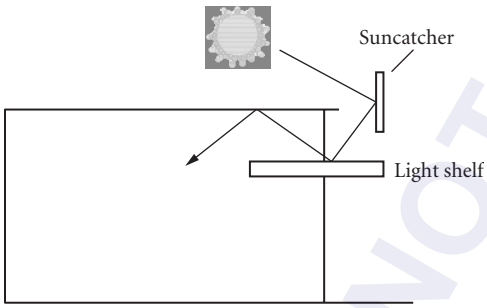

FIGURE 29 The concept of suncatcher. The surfaces of suncatcher and light shelf are of high reflectance specular or diffuse finish. Light shelf is optional. Suncatcher reduces the view, eliminates direct glare and increased illumination when the sun is at a particular location.

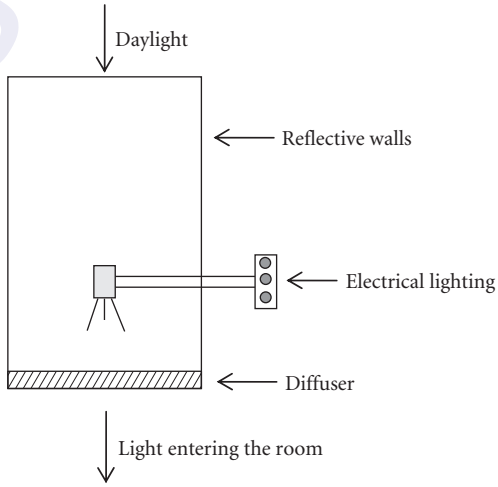

FIGURE 30 A skytube or skywell with integrated Daylight and electrical light.

The use of modern CAD software, especially radiosity based, makes it easy simulate the daylight (that includes sun-tracking, scattered and reflected light from the sky, ground, and neighboring buildings throughout the day and the year), its interaction with optical components such as optical fibers, lightguides, lenses, and diffusers; its penetration through the windows into the interior; impact of reflection from walls, ceilings or furniture, and interaction with interior lighting.

40.6 LIGHTING MEASUREMENTS

In this section, we discuss briefly the tools and techniques used for measuring light, 3D object profiles and optical properties of objects, in the context of lighting applications. The quantities most relevant for light measurement are horizontal/vertical illuminance and luminance of lamps and lit objects as a function of wavelength. To measure the optical properties of objects, luminance measurements in transmission and reflection as a function of wavelength, magnitude, angle of viewing, and direction and angle of incident light are needed. To model the objects in CAD software, measurement of 3D object profiles is needed. These measurements help in picking the lamps and their placement geometry to achieve desired lighting goals.

For measuring light from the source, we discuss the following instruments: illuminance meters and goniometers. For measuring the optical properties of objects, including luminaire optics, in reflection or in transmission, we discuss instruments such as reflectometers and luminance meters. For the measurement of luminaires conformance to the design, we present two methods: CMM and laser scanning.

Illuminance Meters

Illuminance meters or luxmeters measure illuminance in lumens/area. These are typically handheld devices, as shown in Fig. 32 that consist of a photodiode with a photopic correction filter and a cosine corrector on top of it. The photopic correction filter multiplies the incident light spectrum by the eye's photopic response to convert the incident energy in watts into lumens. The cosine corrector consists of a diffuser such as a plastic disk or flashed opal disk or a small integrating sphere with a knife edge entrance port. The goal of the diffuser is to provide a constant relative distribution of angles to the detector regardless of the incident angle of light on the diffuser. High Fresnel losses at high angles of incidence at the surface of the diffusers such as plastic disk or opal glass can still introduce errors. These errors can be minimized by allowing some light to leak through the edges of the diffuser and then using a screening ring to prevent additional error due to leaked light.[73]

(a) (b) (c)

FIGURE 32 Handheld lighting measurement instruments. (*a*) Simple Luxmeter; (*b*) Luxmeter (*from Labsphere*) with an integrating sphere as a diffuser; and (*c*) luminance meter (*from Konica Minolta*).

Luminance Meters

Luminance meters measure luminance in lumen/area/solid angle. These are handheld instruments (Fig. 32) and are equivalent to using a lens and placing a luminance meter at the image location of the image formed by the lens of the target object. Thus it consists of a detector, a photopic correction filter or a color filter, a cosine corrector and an imaging lens. The lens is used to image the region of the object to be measured on the entrance to the detector (or the cosine corrector surface). Since the NA of the lens is known, the solid angle is known. This allows us to obtain the luminance by dividing the detected illuminance by the solid angle. Care must be taken to focus the lens only on the region whose average luminance has to be evaluated. Apertures with different field of view are provided to limit the region over which luminance is evaluated.

These instruments can be made more sophisticated by using a high-quality CCD detector array to image an entire scene and provide luminance distribution across it. The imaging lens has a flat field and is telecentric in image (detector) space.

The use of neutral density filter helps in expanding the dynamic range of the instrument. The measurement on color coordinates in various colors spaces is provided by using multiple detectors, each with a characteristic color filter. The incoming spectrum is multiplied by the transmission spectrum of the color filter for each detector. The relative signals on the detectors help in determining the color coordinates. Similarly the CCT can be evaluated.

Reflectometers

Reflectometers measure the reflectance from samples for cases such as reflectance as a function of wavelength, angle of incidence, angle of viewing and polarization. Depending upon the requirements, not all of these parameters are needed. The sample surfaces may be diffuse, specular, or a mix of two. When samples must be characterized by BRDF, scatterometers are used. Reflectometers are discussed in Chap. 35 in this volume and Scatterometers are discussed in Chap. 1 in Vol. V of this *Handbook*.

Goniometers

Goniometers are instruments that measure the irradiance or illuminance distribution of a source or luminaire. They accomplish this by measuring the illumination distribution at a number of points. By locating the detector in the far field with respect to the source or luminaire, one is actually measuring the intensity distribution. The far field is when the irradiance/illuminance distribution closely matches that of the respective intensity distribution, which means the inverse

TABLE 8 Three Types of Standard Goniophotometer with Their Respective Standard Coordinate Systems[74]

	Type A	Type B	Type C
Polar axis	Vertical	Horizontal	Vertical
Vertical angle designation	Y	V	V
Horizontal angle designation	X	H	L
Range of vertical angles*	$Y \in [-90°, 90°]$	$V \in [-180°, 180°]$	$V \in [0°, 180°]$
Range of horizontal angles	$X \in [-180°, 180°]$†	$H \in [-90°, 90°]$*	$L \in [0°, 360°]$‡
Straight ahead/down	Ahead: $Y = 0°, X = 0°$	Ahead: $V = 0°, H = 0°$	Down: $V = 0°, L = 0°$
Primary applications	Optical systems Automotive lighting	Floodlights	Indoor lighting Roadway lighting

*The lower angle is in the nadir direction while the upper angle is in the zenith direction.
†The lower angle is measured to the left from the perspective of the luminaire.
‡Measured from the primary axis of the luminaire.

square law applies. A good rule of thumb is ten times or greater the greatest extent of the emitter. For example, a luminaire with a 100-mm-diameter aperture indicates that measurement should be made at no closer than 1 m. Of course, better results are obtained as the distance between the source and detector is increased. By rotating either the source or detector with respect to the other, the full intensity distribution can be measured. The inclusion of a rotation device on either the luminaire or detector while the other remains fixed defines a goniometer. For the purposes of the lighting community, the luminous intensity is measured, so goniometers are better known as goniophotometers in the community.

There are three standard types of goniophotometers (Type A, Type B, and Type C), which are listed with their design criteria in Table 8. There are also three coordinate systems used for the purposes of the measurement reporting. These spherical coordinate systems are also labeled Types A, B, and C, and they typically conform to the type of goniophotometers.[74] However, individual goniophotometers may be of one type and report measurements in another coordinates system. Table 8 assumes that the goniophotometers types and coordinates systems agree.

For Types A and B goniophotometers the detector is held fixed while the luminaire is located in the rotating device. Typically guidelines or standards define the distance that the detector is located away from the luminaire. For example, for U.S. and European automotive headlamps this distance is 75 ft and 25 m, respectively. Type C goniophotometers have the detector rotate around the horizontal axis of the luminaire while the luminaire is rotated around its vertical axis. This setup is important for sources that have limitations to orientation (e.g., metal halide arc lamps). Figure 33 shows a Type C goniometer that is used to measure the luminance distribution from sources.

There are many other types of goniophotometers, especially those labeled as snapshot systems. Snapshot systems capture an "image" of the intensity distribution through one measurement. Examples include systems with several detectors; rapid scanning systems for smaller sources such as LEDs; camera-capture systems that incorporate an intermediate diffuse, reflective screen; and tapered-fiber bundles integrated to detector arrays.[74]

Surface Measurement Systems

Not only are the illumination distributions, spectra, scatter distributions, and optical characteristics measured, but also the geometry of the optics. These measurareements are done to characterize the geometry of the fabricated optic in regard to the design. This step is done, in conjunction with tests from the previous testing sections, when there is a disagreement between the laboratory and modeling results. There are essentially two methods in use: coordinate measurement method (CMM) and laser scanning. [75,76] CMM uses a probe that is drawn across the surface of the optic, which provides the (x, *y, z)* data at a series of points on the surface. This method is analogous to using a sphereometer

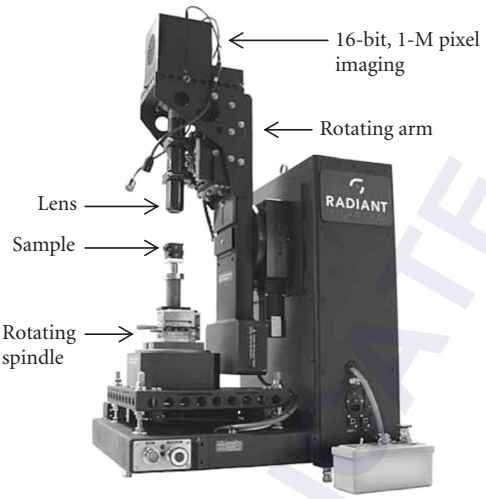

FIGURE 33 Photograph of a source measurement goniometer that is used to ascertain the luminance distribution of the source. The system wobble (electro-mechancial-software runout) is 15 μm to allow for measuring small light sources like LED die. (See also color insert.) (*Courtesy of Radiant Imaging, Inc., model SIG 400.*)

to measure the sag and thus curvature of a lens surface. CMM is a contact method so the optic under test can be detrimentally affected (e.g., scratched) during measurement. Noncontact methods such as laser scanning essentially replace the mechanical probe with a laser beam. The position is measured through location of the reflected spot, triangulation, and/or time of flight as the laser is scanned across the part. Software can then determine the slopes of the test points, and thus rebuild the shape through a point cloud. If the component under test reflects well, then the surface must be coated or a fine, white powder can be placed across the surfaces. Laser scanning is a rapid method to ascertain the part shape. It provides a multitude of points in a short time; however, laser scanning accuracy is currently limited in comparison to CMM.

40.7 LIGHTING APPLICATION AREAS

In this section, we discuss several lighting application areas. We broadly divide the applications into two areas: interior lighting (office, residential, retail and healthcare) and exterior lighting (industrial and transportation). This set of applications is limited; we provide design concepts, metrics and data reference on major application areas. These ideas could be readily applied to other areas of lighting such as entertainment, sports, theatre, and so forth. Each field has its own region-specific and time-dependent guidelines and standards to implement.

The data provided here is primarily from IESNA suggested guidelines, thus exceptions are expected. For example, an office lobby is likely to have far dimmer ambient lighting than dictated by general office lighting guidelines. In essence high-end retail guidelines provide the design goals in order to provide a desired ambience. Although we have provided the guideline data to indicate the relevant specification parameters, by no means is this complete and the guidelines and standards are evolving with time, place, and technology advances. The reader must check the prevalent guidelines for the exact numbers to use. Previous sections of this chapter describe in detail the general aspects

of the lighting design process, principles, and techniques for the applications described here. Each of the following subsections provides insights into the specifics of the lighting design process for the given application.

Interior Lighting

Interior lighting includes the office, retail, residential, and health-care facility subfields. In each of these areas there are established guidelines to provide a pleasing environment to the users of the space. Of special importance are required illuminance levels, luminance ratios, and the reduction of glare. The following four subsections describe each of these application areas in more detail.

Office Lighting Modern office lighting has assumed greater importance than in the past as more people work in them. The goals of office lighting include efficient task performance, energy-efficient lighting, nonmonotonic ambient lighting that provides a balance between horizontal and vertical illuminance and minimum glare.

The task surface in offices has historically been the horizontal desk surface. However, computer monitors are ubiquitous these days and present a self luminous vertical task surface. In addition it is specular and reflects light which can cause glare. Lighting goals are to provide adequate task illumination and adequate light in the task vicinity to eliminate eye strain due to varying brightness and disability glare. This is ensured by limiting the maximum luminance ratio of task to nontask regions. Veiling reflections (see section on glare) from computer monitor screens and paper surfaces must be avoided by taking into account source task and eye geometry. The glare from the computer monitor arises typical from ceiling source, and it is avoided by putting a limit upon the maximum ceiling luminance. Glare across the horizontal surface can be eliminated by using low luminance, wide-area lighting from overhead luminaires or special desk lamps (Fig. 24). Daylight from windows at desk level or near the ceiling can be a source of glare and steps such as daylight control via blinds or changing the task-eye geometry with respect to the glare source must be taken into account.

Balancing of daylight with electrical lighting, preferably with automatic controls, is not only energy efficient but also preferred by the workers. Therefore electrical lighting with high CRI (>70) is desirable as it mimics daylight illumination quality better.

Table 9 summarizes the common specifications and major guidelines on office lighting. The reflectivity of room parameters such as walls and ceiling is provided to aid in room modeling to aid in determining the layout of luminaires.

Retail Lighting The goal of lighting for the retail environment is to attract the customer, facilitate evaluation of the merchandise by the ucstomer, and provide light for completing the transaction.[77] There are varying lighting methods dependent on the type of retail store, what goods are being illuminated, and the background. Table 10 provides various guidelines on lighting levels dependent on the type of store and what is being illuminated. Note that this table is not complete by any standard, so the reader is encouraged to consult the literature (see, for example, Ref. 77) for more specific information for a given retail lighting environment. Note that there are particular design issues that have varying importance levels for each type of retail outlet, such as, glare reduction in jewelry and china stores.[78]

The circulation areas are those not typically used for the display of merchandise such as walkways, aisles, and foyers. The general areas are those for the generic display of merchandise. Perimeter areas are the walls where merchandise is placed for sale. Feature areas are where important displays are positioned. Horizontal illuminance values are listed for all of the columns in Table 10 except the perimeter areas, which provide vertical illuminance values. The feature areas have peak illuminance values of 5:1 to 10:1 compare to the respective general area peak illuminance. Of particular note in Table 10, the trends indicate

- Bulk stores, or those described as "big box," tend to have much higher illuminance levels with higher uniformity across areas. This type of illumination provides the user with an abundance of light to fully inspect the merchandise, associated labeling, and compare to similar products.

TABLE 9 Summary of Specifications and Guidelines for Office Lighting

Specifications	Goals
Maximum luminance ratios:	
Task to neighboring areas	3:1 to 1:3
Task to distant regions	10:1 to 1:10
Max ambient illuminance (lx)	500
Max ceiling luminance (nits)	<1000 (in the presence of computer monitors) <425 nits does not cause glare
Reflectivity of room objects* (%)	
Ceiling	≥80
Walls	50–70
Partition	40–70
Furniture	25–45
Floors	20–40
Corridor Floors	>20 (of the illuminance of the adjacent areas)
CRI	>70
Lighting schemes	Direct, indirect and direct-indirect
Key considerations	Eliminate shadows on faces or tasks, glare control, provide a spacious ambience
Ceiling uniformity (max: min)	<8:1 (for indirect lighting only)
Common light sources	Daylighting, LED, CMH, fluorescent, and CFL
Glare sources to be eliminated or reduced	Veiling reflections from direct sources or ceilings on computer monitor screen, reflections from any specular surface including walls and desks

*Valid for matte or diffuse finish.

TABLE 10 Suggested Illuminance Levels for Circulation, General, Perimeter, and Feature Areas for Various Types of Retail Stores[77]

Type of Retail Store	Circulation Area Illuminance (lx)	General Area Illuminance (lx)	Perimeter Area Illuminance (lx)	Feature Area Illuminance (lx)
Warehouse	250–300	750–850	750–850	3750–8500
Supermarket	250–300	750–1000	750–1000	3750–5000
Discount	250–300	750–850	750–850	3750–8500
Mass merchant	200–250	500–600	750–850	2000–5000
Department	200–250	400–500	500–750	2000–3500
Upscale	150–200	300–400	400–800	1500–4000
Specialty	200–250	400–500	500–750	2000–3500
Upscale	150–200	300–400	400–800	1500–4000
Boutique	80–120	200–300	200–600	1000–3000
Jewelry	80–120	200–600	200–600	1000–6000
Upscale China	80–120	200–600	200–600	1000–6000
Drugstore	250–300	750–850	750–850	3750–8500
Home	200–250	400–500	500–750	2000–3500
Furniture	80–120	200–300	200–600	1000–3000

- More specialized or exclusive, the lighting levels tend to be reduced. This type of lighting provides a more intimate environment between the customer and the salesperson with illumination to highlight the item under evaluation.

Essentially, Table 10 can be broken down into three categories: mass merchandising, department, and exclusive stores. At the lower end, mass merchandising, one typically specifies ambient illuminance

TABLE 11 Suggested Illuminance Values for Areas within a Department Store[77]

Department Store Area	Horizontal Illuminance (lx)	Vertical Illuminance (lx)	Very Important Design Issues
Alteration room	500	300	Color appearance and source geometry
Dressing area	300	50	Color appearance and object modeling
Fitting area	500	300	Color appearance and object modeling
Stock room	300	50	
Sales area	300		Direct glare
General merchandise area	500		Color appearance
Feature display	2,500		Appearance of area, color appearance, direct glare, and object modeling
Display window	2,000 (day) 500 (night)		Appearance of area, color appearance, daylighting, object modeling, and reflected glare
Feature	10,000 (day) 5,000 (night)		

between 750 and 1000 lx and a CCT of 3500 to 4100 K. Department stores are in the range of 400 to 600 lx with a color temperature around 3500 K. High-end stores have ambient light levels of 150 to 300 lx and color temperatures of 2700 to 3000 K.

The values provided in Table 10 are guidelines, and values are expected to vary dependent on the background, the items being illuminated, and any external lighting. The reasoning behind this is that observers see luminance rather than illuminance. Thus, the lighting designer must take into account the reflectance, both diffuse and specular, from the merchandise and background. Thus, Table 10 assumes that there is constant reflectance between the features and the background, such that illuminance ratios of 5:1 to 10:1 are specified, when in actuality luminance ratios in this range are prescribed.

Within any type of store there are different lighting levels dependent on the application. Consider, for example, a department store, which is made up of several different environments, from the entrance areas to fitting areas, to general displays areas. Table 11 provides illuminance level guidelines for typical areas in a department store. It also includes the very important design issues for each of the retail areas.

The methods of lighting a given area are dependent on the application of the space. Ambient lighting provides the baseline lighting level, while the addition of secondary lighting units provides the increased illuminance values as listed in Tables 10 and 11. Table 12 provides a synopsis of these other application space lighting demands, including the typical luminaire used and design issues.

As previously noted the lighting designer must remain cognizant of external lighting conditions when specifying the artificial retail lighting environment. A large facet of external lighting is better known as daylighting, and of particular concern are the varying light level that is provided through the day, direct glare through windows and doors, and the strong background to incorrectly situated merchandise. Other aspects of the retail lighting environment include

- The CRI should be 70 or greater for most environments.
- Transitions between spaces in stores should have luminance ratios of no greater than 3:1 for similar neighboring spaces, greater than 3:1 when there is a distinct transition between the neighboring spaces, and 5:1 to 10:1 for abrupt transitions.
- The perimeter area illuminance should be greater than the overhead area in order to draw the attention of the shopper to the merchandise.
- Calculating baseline lighting levels for retail spaces one should use diffuse reflection values of office spaces.

Residential Lighting The goals of residential lighting are to provide ambient illumination to create a pleasing ambience due to a well-lit environment; sufficient task lighting in workspaces such

TABLE 12 Specific Application Space Lighting for Illumination of Merchandise Locations

Application Space Lighting	Typical Luminaires Used	Design Issues
Ambient Light		
Mass merchandising department	Fluorescent and halogen fluorescent, recessed fluorescent and halogen	Uniformity
High end	Recessed fluorescent and halogen, track lighting	Flexibility for change
Perimeter	Fluorescent, incandescent, or HID wall wash, track or recessed spot lighting	Uniform vertical illuminance, hidden luminaires
Rack	Recessed or track dpot lighting	Direct glare reduction
Shelf	Ambient lighting with recessed surface lighting	Direct glare reduction, hidden luminaires
Counter	Focused downlighting	Direct glare reduction, 3 to 5 times ambient lighting
Mirror	Downlighting	Glare reduction, color appearance, object modeling, and consistent lighting with use of product
Showcase	Fluorescent and fiber-optic lighting	Hidden luminaires
Accent	Small (point-like) sources	Provide luminance ratios of 5:1 to 15:1
Decorative	Sconces, chandelier, table, and torchiere lamps	For high-end stores to provide a desired look and feel

as office, garage, kitchen, and workshop; and decorative lighting and accent lighting for lit object displays. A variety of lighting techniques are used to create layers of lighting that perform different lighting functions (see book by Whitehead on "Residential Lighting" in Ref. 26). Like retail lighting, residential lighting can be quite complex and creative. Although we summarize many common guidelines for residential lighting requirements in Table 13, other specialized guidelines are more relevant in some areas of the house, such as retail lighting guidelines for the kitchen, office lighting guidelines for the home office, industrial lighting guidelines for task lighting in garage or workshop and exterior lighting guidelines for landscaping and the house facade. Thus depending upon the purpose of a specific region of the house the lighting scheme must be tailored. However, the different lighting schemes used across the house must be gently blended into one another. For example, exterior lighting for residences includes the lighting of entry, walkways, and landscape. Although the primary goals are to provide direction, safety, identification and aesthetic appearance, achieving a balance between interior and exterior lighting makes the interior and exterior spaces extensions of one another. Residential lighting should be customized to maximize the comfort of the inhabitants especially when the inhabitants are disabled or elderly. For example, elderly people require much higher levels of illumination especially for task performance.

Other than those areas that require excellent task lighting such as offices or workshops, the limits on luminance ratios are relatively relaxed when compared to other lighting applications, such as the maximum residential luminance ratio of 5:1 between Task and neighboring areas is higher than that of office lighting of 3:1. The idea of limiting the maximum luminance ratio is to minimize visual discomfort caused by disability glare and adapting to variations in brightness. The integration of daylight with artificial lighting is highly desirable.

Health-Care Facility Lighting The lighting in health-care facilities, which includes hospitals, outpatient clinics, chronic and extended care centers, and other facilities, requires careful understanding of the lighting requirements for not only the patients but also the individuals working therein. The lighting must be pleasing and comforting to the patients in order to put them at ease and assist in their healing. The patients and visitors have a wide range of ages, with the majority being elderly;

TABLE 13 Summary of Specifications and Guidelines for Residential Lighting

Specifications	Goals
Maximum luminance ratios	
Task to neighboring areas	5:1 to 1:5 (in general) 3:1 for demanding tasks such as sewing
Task to distant regions	10:1 to 1:10
Lumnaire to ceiling	20:1
Hallway or stair to adjacent area	1:5
Reflectivity of room objects* (%)	
Ceiling	60–90
Walls, curtains, draperies†	35–60
Floors†	40–70
Average luminance for luminaire (nits)	1700
Maximum luminance for luminaire (nits)	2700 (in utility areas)
CRI	>80 (kitchen and clothing closets)
Lighting schemes	Direct, indirect, and direct-indirect
Key considerations	Eliminate shadows on faces or tasks, glare control, providing a spacious and cozy ambience as well cozy as desired
Common light sources	Daylighting, LED, fluorescent, and CFL.
Glare sources to be eliminated or reduced	Direct glare from light sources, veiling reflections, indirect glare from shiny objects

*Valid for matte or diffuse finish.
†Reflectance of walls and floor can be increased by 40% and 25%, respectively, to improve visual task lighting where needed.

therefore, there is a large variance in the response to lighting, especially increased glare sensitivity, loss of contrast sensitivity, the need for higher lighting levels, and slow adaptation to changes in brightness as one ages.[79] The lighting levels also need to provide for the medical staff such that they can effectively carry out their job—from meticulous and demanding surgery to patient interviews and diagnoses to manning the check-in desk. Finally, since in a number of these facilities patients may be there for extended periods, circadian system illumination levels that conform to the human biological clock are the norm. As can be seen, there is an extensive range of tasks, observers, and daily requirements for illumination in health-care facilities, thus, making the lighting design a challenging assignment.

Foremost is the need to specify the light requirements for a given location based on the tasks to be performed there. Table 14 provides a synopsis of the illuminance level guidelines and important design issues for a number of locations in health-care facilities; however, since these are only guidelines, controls for the area illumination are often available to the medical staff and/or patients. This flexibility in the control of lighting levels based on the specific function of the environment and even mood of the occupants is important in health-care facilities. Note that there are many other areas and functions than can be included in Table 14, so the reader is encouraged to see Ref. 79 for this additional information.

The operating room environment is especially challenging since the lighting is preferentially directed to the task area; however, this has the potential of creating large luminance ratio variation within the room. Practices suggest three regions within the operating room with the following luminance ratios: task area to the surgical table of 3:1 or less and task area to the background (i.e., walls) of 10:1 or less. Additionally, there are specific guidelines for the finishes for the surfaces within the surgery theatre as provided in Table 15. In most cases all surfaces are white or pastels with a matte finish to reduce reflected glare. The lighting in an operating room is provided by a multitude of sources including ambient and even daylighting, directed spotlights, surgeon headlamps, and increasingly fiber-optic lighting.

Concurrent to the design guidelines of Table 14, the lighting designer must remain cognizant of the specifications for reflectances of the walls, floor, ceiling, and other objects that occupy the design area.

TABLE 14 Suggested Illuminance Values and Other Criteria in Health-Care Facilities[79]

Health Care Facility Area and Current Function	Horizontal Illuminance (lx)	Vertical Illuminance (lx)	Important Design Issues
Patient room			
Normal	200+, as home	30+, as home	Patient control, CRI >80, daylighting
Examination	1000	300	Glare reduction, CRI >80, CCT>3000 K, doctor control
Observation (night)	30	30	Red/amber CCT, no higher than 18" off floor
Nursing station	300	50	Glare reduction, CRI>80
Critical care unit			
Normal	300	50	Patient control, CRI>85, daylighting
Examination	1000	300	Glare reduction, CRI>85, CCT>3000 K, doctor control
Nursery	100	30	Glare reduction, CRI>80, lighting control, daylighting
Mental health center	As per other functions	As per other functions	Daylighting, CRI >80, CCT of 4100–5000 K with fluorescent, 3500 K otherwise, glare reduction
Operating room			
Normal	1000	500	CRI >85, matched light
Table	25000+ in 20-cm spot (adjustable)	1000	Sources for illumination, shadow, and glare reduction, doctor control, CCT of 3500–6700 K, high uniformity
Dental unit			
Normal	300	50	
Examination	24000+ in central spot	500	As operating room
Radiography unit	50, but depends on test	30, but depends on test	CRI >80, glare reduction, doctor control
Pharmacy	300	100	Glare reduction, high uniformity, CRI >80

TABLE 15 Suggested Reflectances for the Various Objects in a Health-Care Facility Room for a General Application and the Operating Room Environ[79]

Surface	General Reflectance	Operating Room Reflectance
Ceiling	70–80%	90–100%
Walls	40–60%	60%
Furniture/fabrics	25–45%	0–30%
Equipment	25–45%	25–45%
Floors	20–40%	20–30%

Table 15 provides this data for two locations, general and operating room. Using these values in conjunction with the optical design process one can find suitable illumination configurations to provide the Table 14 guidelines.

Industrial Lighting The goals of trial lighting are to provide energy efficient lighting with adequate task and ambient lighting, direction, safety, and visual comfort. Many common requirements for industrial lighting requirements are summarized in Table 16.

TABLE 16 Summary of Commonly Suggested Specifications and Guidelines for Industrial Lighting

Specifications	Goals
Maximum luminance ratios	
Task to neighboring areas	3:1 to 1:3 (in general)
Task to distant regions	10:1 to 1:10
Luminaire (including daylight sources) to adjacent surfaces	20:1
Anywhere within the FOV	40:1
Reflectivity of objects* (%)	
Ceiling	80–90
Walls	40–60
Floors	≥20
Desk/bench tops, machines, equipment	25–45
CRI	>65
Lighting schemes	Direct, indirect, and direct-indirect
Key considerations	Eliminate shadows on faces or tasks, provide high illuminance uniformity, sufficient illuminance, and glare control
Common light sources	Daylighting, LED, fluorescent, HID, and CFL
Glare sources to be eliminated or reduced	Direct glare from light sources, veiling glare, indirect glare from shiny objects
Direct view of the luminaire (deg)	>25 (preferably >45)

*Valid for matte or diffuse finish.

The ambient lighting is provided by daylighting and/or large area, overhead, wide angle luminaires (direct and semidirect). Task lighting is provided by fixed and portable direct or diffuse light sources. Backlights are used for translucent task surfaces. Direction of illumination with respect to the view angle(s) is important in tasks where surface features of the object cause shadows to enhance depth perception. Illumination at grazing incidence is used to highlight specific feature that can scatter light and render themselves visible. To emphasize specular but uneven surfaces, specific patterns of light (like bright and dark lines) can be projected onto the task surface to be reflected into the viewer's eyes. For lighting in regions where there is a high density of workstations or areas where there are several similar process, a high level of uniformity in horizontal illuminance is recommended. In such areas, variation of horizontal illuminance should be less than 1/6th the average horizontal illuminance. Otherwise, the variations in luminance across the work space must be within the luminance ratios prescribed in Table 16. The level of horizontal illuminance needed varies with task. In industrial lighting, the quality of horizontal illuminance is of special importance as efficient and safe task performance is needed. The reader is referred to IESNA published guidelines for horizontal illuminance values for a wide variety of tasks in different industries.[80]

In addition to providing the task lighting and ambient lighting, it is often necessary to provide additional lighting dedicated for emergency, safety, and security within the industrial complex and its exteriors.

Visual discomfort must be avoided especially during task performance and in situation where safety could be compromised. Special attention should be given to situations causing veiling reflections and glare. The various limits placed on the luminance ratios in Table 16 between task and nontask regions help eliminate the impact of glare.

Exterior Lighting

Of course the primary aspect of exterior lighting is to provide illumination during hours of darkness. The lighting not only provides illumination for general use, it also provides safety and security; indication of direction of travel for paths, roadways, and so forth; and architectural enhancement.

External lighting is attempting to replicate the illumination of the sun; however, it can in no fashion accomplish this feat. The illumination provided by any lighting source cannot match that of the sun, which means that the sky will appear dark rather than blue; numerous sources are required to provide the necessary illumination level so glare from the many sources is a major factor; distance from the light sources, mesopic vision and even scotopic levels may be demanded; and the many sources can confuse the viewer such that objects can be difficult to discern from one another.[81] Additionally, this section is rather broad in scope, including design aspects such as roadway lighting, path lighting, outdoor event lighting, and façade illumination. Thus, the reader may need to consult specific literature for a certain type of lighting. Please consult the transportation lighting section for further information on vehicular and roadway. In the next two subsections details are presented about the issues present for external lighting design and design examples, excluding the transportation applications discussed later.

External Lighting Design Issues There are several topics that a lighting designer for external spaces must consider. First and foremost is the specific application guidelines (for example, see the section on illuminating roadways), glare issues, light pollution and trespass, and perception issues. All of these factors are interrelated, and the subsections herein provide insight into them.

Glare A primary issue of external lighting is glare. Since users of a space in the hours of darkness are relying on nonphotopic vision, glare can blind the viewer as one approaches a bright source thus not only causing the scotopic vision receptors (e.g., rods) to naturally saturate but also the photopic vision receptors (e.g., cones). This "blinding" is due to disability glare, which will hide objects or reduce their contrast. Other levels of glare can also inhibit observation: discomfort glare, which is attributed to a large variance on and around the object under view; and annoyance glare, which is light that in the opinion of the observer should not be present, such as light trespass.

The major source of glare is directly from the source in comparison to the object under observation. Comparison between the luminaire luminance to the object's illuminance is the factor that often defines the level of glare, from disabling to discomfort. Depending on the orientation of the object one either compares the horizontal or vertical surface luminance to the luminaire luminance. The horizontal luminance is used for horizontal surfaces such as walkways and roads, while the vertical luminance is used for vertical surfaces such as building façades, people, and structures.

Light Pollution and Light Trespass Associated to glare is light pollution and light trespass. Light pollution, also called sky glow, is light that is directed upward to the atmosphere.[82] This sky glow hides stars from observation, and on cloudy days provides a glow, typically red in hue, which can distract from one's appreciation of the view of their surroundings. Astronomers have been particularly vocal in the reduction of light pollution, and there is increasingly consideration of energy efficiency demands. In 2008 it was hypothesized that over $10B U.S. was wasted through light pollution,[83] which means that this amount has only increased since then. Like light pollution, light trespass is unwanted light, but in this case it is light that illuminates objects outside of the intended illumination region.[84] Such stray light enters through windows, illuminates someone's property, or can impair the vision of drivers. Light pollution and trespass arise from improperly designed luminaires. There are increasing regulations for the design of outdoor lighting to alleviate such concerns. A primary correcting factor is the use of luminaire cutoffs as presented in the section on luminaire design.

External Lighting Example Pole lighting is the most common form of outdoor illumination providing a significant amount of light, safety and security, and indication of the path of travel for walkways, roadways, and so forth. In the United States, there are five primary forms of classifications of pole-mounted luminaires, but there are numerous variations based upon the lighting requirements, the shape of the illumination region, and illumination level demands.[85] Table 17 provides descriptions of the five types, the typical application(s) of the type, and an iso-illuminance plot for each of the types. Per the iso-illuminance plots of Table 17, the larger the illumination distribution the more ground is illuminated, which means not only the roadway is illuminated but also sidewalks, shoulders, and other neighboring areas. Thus, Type IV and V luminaires tend to have more light trespass.

TABLE 17 Description, Applications, and Iso-Illuminance Plots for the Five Primary Luminaire Types Used for Pole-Mounted Outdoor Lighting[85]

Type	Description	Applications	Iso-Illuminance Plot
I	Little setback to the road or mounted over the roadway; narrow oval illumination distribution	Roadways	II	Moderate setback to pedestrian area; moderate oval illumination distribution	Pedestrian areas	
III	Large setback to the road; Moderate elliptical illumination distribution	Pedestrian areas roadways, parking lots	IV	Great setback to the roadway; large elliptical illumination distribution	Roadways	V	Mounted over pedestrian area rotationally symmetric illumination	Pedestrian areas parking lots	
Transportation Lighting

Transportation lighting includes the subfields of vehicular and roadway lighting. In both cases rather than just guidelines, there are many stringent governmental standards that must be met by the illumination systems. For example, there are governmental standards for traffic lights and vehicular taillights and headlights. If these standards are not met, then the lighting systems are not legal for use on our roadways.

Vehicular Lighting Vehicular lighting is the external illumination aspects of vehicles, including automobiles, motorcycles, snowmobiles, emergency vehicles, airplanes, ships, and heavy machinery including construction, industrial and agricultural. Ground vehicles are especially important due to their pervasiveness in society. For the remainder of this section, we highlight ground vehicle standards, but there are similar standards for other types of vehicles. In the United States, the U.S. Federal Government standardizes the lighting requirements through the Federal Motor Vehicle Safety Standards (FMVSS) from the offices of the National Highway Traffic Safety Administration (NHTSA) within the Department of Transportation (DOT). In Europe and a number of other countries spanning the globe, the United Nations Economic Commission for Europe (UNECE or better known as ECE) sets the standards. The FMVSS calls upon the standards delineated by the Society of Automotive Engineers (SAE) to provide the explicit lighting requirements for distinct lighting systems. While FMVSS 108 provides the framework for lighting systems on ground vehicles within the United States,[86] the SAE provides the accepted standards to design into the lighting systems.

For example, SAE standard J581 provides the upper-beam requirements to be an accepted high beam on U.S. roads,[87] while R113 is the accepted ECE standard.[88] The associated low-beam standards are SAE J582 in the U.S.[89] and ECE R112 in Europe,[90] but there is currently an active dialogue to harmonize the standards between the U.S., European, and Japanese markets. The SAE J1735 standard is currently addressing the low-beam harmonization, and in time it will also address the high-beam requirements. The end results will be, excepting the inherent difference of left-hand (e.g., United Kingdom) and right-hand (e.g., United States) traffic, harmonization has the goal of making the lighting standards the same at as many places possible across the globe. This increased standardization means that the design and fabrication costs will be reduced for manufacturers.

There are essentially two types of lighting on a ground vehicle: forward lighting for illuminating the road surface and nearby surrounds and indicator and warning lighting including turn signals, brake lights, side markers, and tail lights. Each vehicular light system is defined by its own set of regulations including the distribution of light, the color and characteristics of the protective lens, mounting requirements, and a number of enviromechanical tests including vibration, dust, moisture, corrosion, and warpage. In the United States, the test procedures and protocols are typically governed by SAE J575, while each individual standard provides the photometric requirements. In the United States, the photometric requirements are the luminous intensity distribution at a distance of 18.3 m from the lamp, while the ECE requirements are for the illuminance distribution at a distance of 25 m. The typical instrument to make this measurement is a goniometer that holds the lamp and allows it to be rotated so that a different angle is incident on a fixed photodetector at the end of an absorbing light tunnel. By rotating the lamp within the goniometer and making a series of measurements the full distribution of light can be determined; however, rather than measuring across the whole lit region, the standards dictate a series of test points and test areas that must be measured. In the remainder of this section, we highlight two applications: low-beam headlamp and stop lamp. In each subsection, the requirements for both U.S. and ECE standards are provided, a depiction of a typical distribution of light, discussion of design strategies, and additional optical requirements of the standards. Note that while we highlight these two applications and their respective standards, there are numerous other optical standards governing the external lighting systems on vehicles (see Refs. 86 to 92) for further information about these additional standards).

Design and Standards for a Low-Beam Headlamp A headlamp, as shown in Fig. 34*a*, must illuminate the road surface for the driver, illuminate to the sides for both the driver and any other observer, provide a low level of illumination to oncoming drivers, and in all cases remove the formation of hot spots above the horizon such that glare is not a concern to oncoming traffic. Of note in Fig. 34*a* is

- High-beam luminaire:
  - Rightmost recess of the lamp.
  - Faceted reflector, but other options include smooth, tailored reflector (e.g., NURBS surface as designed in CAD); faceted lens in conjunction with smooth reflector (e.g., parabolic); and projection lens in conjunction with reflector.

(a) (b)

FIGURE 34 (*a*) A faceted headlamp including high-beam (right), low-beam (middle), and turn signal (left) luminaire. Note the yellowish tinge of the turn signal, which is due to the coating placed on the bulb used therein. (*b*) A faceted taillight including the following functions: tail (upper left), stop (upper right), turn signal (lower right), reflex reflector (lower middle), and backup (lower left). (See also color insert.)

  - Filament source, but other options include high-intensity discharge lamp or array of white-light LEDs.
- Low-beam luminaire:
  - Middle recess of the lamp.
  - Faceted reflector, but other options are as the high-beam luminaire above.
  - Filament source, but other options are as the high-beam luminaire above.
  - Bulb shield: reflective structure in the middle of the lamp and covers direct view of the filament source. The bulb shield greatly alleviates direct light above the horizon.
- Turn signal luminaire:
  - Leftmost recess of the lamp.
  - Faceted reflector, but other options are as the high-beam luminaire above.
  - Filament source, but other options are as the high-beam luminaire above. Note that the bulb has a yellow coating placed on its glass envelope, which then provides the yellowish appearance of such lamps. This coating provides the color as specified by its respective standard.

Headlamp reflectors have a parabolic base shape in order to provide a high degree of collimation in the forward direction. The reflector, both faceted and smooth, is then deformed to provide the distribution that meets standards. Designing such deformations can be difficult, but there are software codes to assist in the process. Design guidelines include a goal of having the emitted radiation only incident once on the reflector; avoid secondary interactions with the bulb shield, bulb, or reflector shelves (i.e., the reflector sides, as shown in Fig. 34*a*); and angling intersegment fillers (i.e., spaces between the facets) such that they cannot be directly seen from the source emission region. In order to avoid secondary interactions with the bulb and its respective shield, one typically angles the reflected light across the luminaire, except that striking near the reflector near the source. The latter is directed away from the source. In systems with projection and faceted lenses, the reflector is there to capture bulb emission, while the lens provides the required distribution that meets standards. Due to demanding illumination requirements, it is best if most of the bulb emission is incident on the reflector; therefore, in almost all cases the filament or arc is oriented along the axis of the reflector (i.e., orthogonal to the filament as shown in Fig. 13). This axial filament orientation also ensures less light goes above the horizon in the low-beam luminaire.

Table 18 provides the SAE J582 luminous intensity requirements, while Table 19 provides the ECE R1 12 requirements. Figure 35 shows a typical SAE luminous intensity distribution that meets the requirements of Table 18. Figure 36 shows a typical ECE illuminance distribution that meets the requirements of Table 19. The SAE standards of Table 18 and Fig. 35 are in the units of candelas

(cd, lumens/steradian). The test points are given in degrees and a letter designation, which mean U = up direction, D = down direction, L = left direction, and R = right direction as measured from the point (H, V), which is the center point where H = horizontal and defines the horizon, and V = vertical and defines the lane of traffic. The ECE standards of Table 19 and Fig. 36 are in the units of lux (lx, lumens/m^2), and, while the letter designations still hold, the test point locations and zones are given as position coordinates in millimeters (mm).

Design and Standards for a Stop Lamp A taillight, as shown in Fig. 34*b*, is typically comprised of a number of different functions, such as a stop light, turn signal, backup lamp, and so forth. The taillight of Fig. 34*b* has the following optics in its functions.

- Tail lamp (upper left, red): for night-driving conditions or when headlamps are on. Indicates to follwing traffic the presence of the vehicle during reduced lighting conditions. The governmental standards are SAE J585 and ECE. R7
- Stop lamp (upper right, red): indicates when the driver has applied the brakes. This luminaire is also lit for night driving conditions but a lower output level. The governmental standards are SAE J586 and ECE R7.
- Turn Signal Lamp(lower right, red): indicates the driver is to make a turn a turn in the designated direction. The governmental standards are SAE J588 and ECE R6.
- Reflex reflectors (middle right, red): this area, directly neighboring the turn signal is comprised of prism structures that provide retroreflection to the driver of following vehicles. It is important for dark-driving conditions to highlight the presence of this vehicle to following drivers or indicate its presence when the vehicle is not in operation. Note that this function of the taillight is passive in the sense that no internal light source is used. The governmental standards are SAE J594 and ECER3.
- Backup lamp (lower left, white): this luminaire indicates when the vehicle is in reverse. The governmental standards are SAE J593 and ECE R6.

In Fig. 34*b*, faceted reflectors are used for all the active luminaires. Typically, a transverse filament is used, as per Fig. 13, since the illumination standards for taillight functions are quite broad angularly. Thus, direct radiation from the filament is useful to filling in the required light distribution, while the reflected component of the illumination fills in the required hot spots. LEDs are replacing filament lamps to become the norm for most taillight functions. For LED sources, refractive optics that also employ total internal reflection provide a better means to meet the illumination requirements.

In the remainder of this section, we focus our attention on the design and standards of the stop lamp function, but the other taillight functions have similar requirements. The stop lamp is to inform following vehicles and pedestrians that the vehicle is slowing. In Fig. 34*b*, the stop lamp is located on the upper right of the taillight. Table 20 provides the SAE J586 luminous intensity requirements,[91] while Table 21 provides the ECE R7.[92]

Figure 37 shows a typical SAE luminous intensity distribution that meets the requirements of Table 20. Figure 38 shows a typical ECE illuminance distribution that meets the requirements of Table 21. The SAE standards of Table 20 and Fig. 37 are in the units of candelas (cd, lumens/steradian). The ECE standards of Table 21 and Fig. 38 are in the units of candelas (cd, lumens/steradian). In all cases, the letter designations as per the previous section (headlamps), but in this case the angles are with respect to rear direction of the vehicle.

Roadway Lighting There are multiple subfields that make up roadway lighting: street lighting, roadway signage, tunnel lighting, and integration of collocated pedestrian, bike, and analogous areas. The goal of all forms of roadway lighting is to reduce the potential of accidents, aid in the flow of traffic, provide a higher level of safety and security, and assist in commerce during hours of darkness. There are a multitude of light sources that affect roadway lighting, including the external lighting from vehicles (see section on vehicular lighting); direct roadway lighting, which is the subject of this section; traffic lights, as governed in the United States by the International Transportation Engineers

society; and lighting from other sources such as residential, industrial, and retail. An added difficulty of roadway lighting is the harsh conditions in which they reside. There are stringent maintenance demands that include replacement of sources, cleaning of the optics, and trimming of foliage around the luminaire.[93]

Street Lighting There are essentially three metrics for defining the lighting of a roadway: illuminance (lux, lumens/m^2), luminance (nit, lumens/sr/m^2), and small target visibility (STV).[94] Illuminance modeling provides the level of illumination across a surface. Luminance modeling predicts the level of light (i.e., glare), both direct and reflected, that is directed to a driver. STV is the visibility of a target array (18×18 cm^2 and 50 percent reflective) on the road. Table 22 provides the illuminance, luminance, and STV guidelines for a number of road types, four road surfaces in dry conditions, and the interaction level with pedestrians. The illuminance and luminance ratios of Table 22 provide limits such that disabling glare does not blind drivers or pedestrians. Table 23 qualifies the road types, the four road surfaces, and the pedestrian interaction levels of Table 22.

TABLE 23 Road Types and Surfaces, and Pedestrian Interaction Levels as per Table 22[94]

Road Type	
Class A Freeway	Divided high traffic highways with full access control
Class B Freeway	All other divided highways with full access control
Expressway	Divided highways with limited access control
Major	Primary roadways within and leaving metropolitan areas
Collector	Service roads connecting major and local roadways
Local	Provide direct access to residential, retail, and industrial areas
Road Surface Class	
R1	Portland cement concrete and asphalt with at least 12% artificial brightener aggregates; treat as diffuse
R2	Asphalt road surface with a minimum 60% gravel aggregate; treat as both diffuse and specular
R3	Asphalt with dark aggregates; slightly specular
R4	Smooth asphalt surface; specular
Pedestrian Interaction	
High	Large amount of pedestrian traffic during hours of darkness (100 or more pedestrians in one block during an hour): retail and entertainment areas
Medium	Moderate amount of pedestrian traffic during hours of darkness (11 to 100 pedestrians in one block during an hour): office area, apartment area, older city neighborhoods
Low	Little pedestrian traffic during hours of darkness (10 or less pedestrians in one block during an hour): rural and suburban areas

The luminaire cutoff classification, as described earlier, is used extensively in the design of roadway lighting. The luminaire cutoffs suppress glare to drivers and pedestrians while also alleviating light pollution and light trespass.

There are a number of other road types (e.g., sidewalks, bike paths, and intersections), environmental conditions (e.g., fog, rain, and wet roads), and special considerations with interaction with pedestrians. The reader is encouraged to consult Ref. 94 for these additional circumstances.

Sign Lighting A number of governmental standards have been developed for the lighting of road signs, but a set of guidelines have been developed by the IESNA.[95] Light for signs can be from external sources (e.g., car headlamps) or an internal source for a transmissive sign. Externally lit signs either make use of associated lights that illuminate it or retroreflectors that reflect back to the observer. In the United States the Federal Government provides the standards that must be met for lit roadway signage.[96]

Tunnel Lighting Tunnel lighting is an important factor to increase drive safety while also allowing drivers to maintain their speed. In the United States a structure is considered a tunnel when it is greater than 25 m in length.[97] Distances greater than this require additional lighting to supplement any available daylight. Tunnel lighting is broken up into a number of regions including the approach, adaptation, threshold, transition, interior, and exit zones. Each of these zones has different guidelines to ensure driver comfort; however, these guidelines are dependent on the time of the year, the average speed of traffic, and the presence of oncoming traffic in undivided tunnels. For more information please consult Ref. 97.

40.8 ACKNOWLEDGMENTS

We are grateful to Jim McGuire and Kevin Thompson for providing valuable feedback on this chapter. We would like to acknowledge the financial support on literature purchase for this chapter by Optical Research Associates and our past and present employers for allowing us the use of their software: Optical Research Associates for LightTools, Photon Engineering for FRED, Lambda Research for TracePro and Breault Research Organization for ASAP.

INDEX

Index note: The *f* after a page number refers to a figure, the *n* to a note, and the *t* to a table.

The combined index for all five volumes can be downloaded from www.HandbookofOpticsOnline.com.

COLOR PLATES

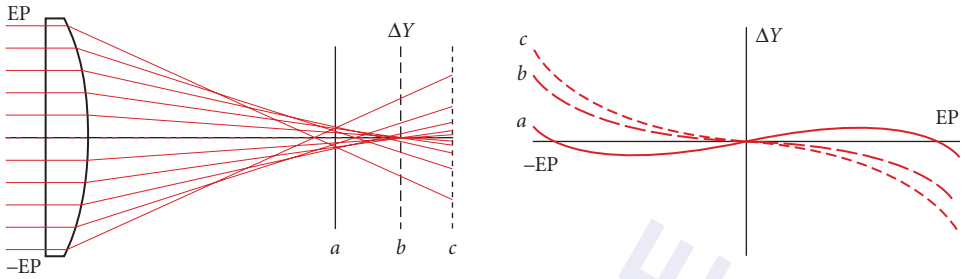

FIGURE 2.1 (*Left*) Rays exiting a lens are intercepted at three evaluation planes. (*Right*) Ray intercept curves plotted for the evaluation planes: (*a*) at the point of minimum ray error (circle of least confusion); (*b*) at the paraxial image plane; and (*c*) outside the paraxial image plane.

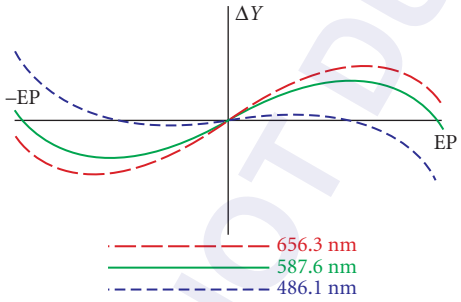

FIGURE 2.2 Meridional ray intercept curves of a lens with spherical aberration plotted for three colors.

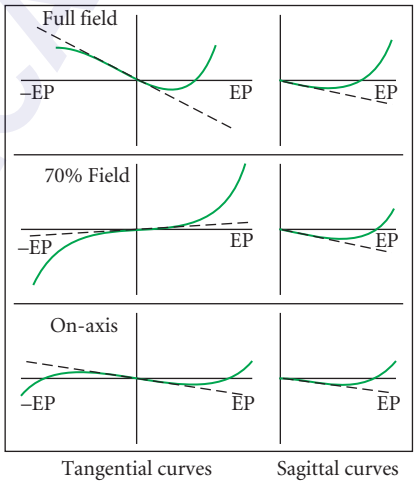

FIGURE 2.3 Evaluation of a lens on-axis and at two off-axis points. The reduction of the length of the curve with higher field indicates that the lens is vignetting these angles. The differences in slopes (dashed lines) at the origin between the meridional and skew curves indicate that the lens has astigmatism at these field angles. The variation in the slopes with field indicates the presence of field curvature.

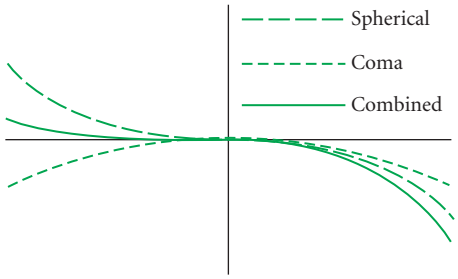

FIGURE 2.4 Ray intercept curve showing coma combined with spherical aberration.

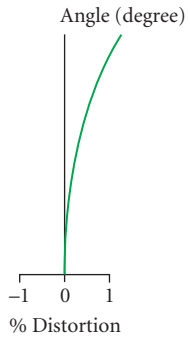

FIGURE 2.5 Field curve: distortion plot. The percentage distortion is plotted as a function of field angle. Note that the axis of the dependent variable is the horizontal axis.

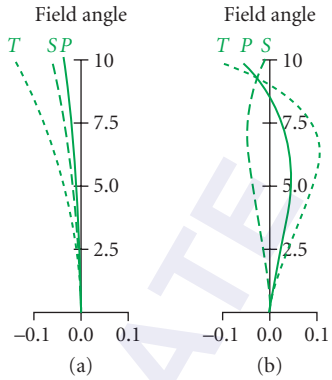

FIGURE 2.6 Field curve: field curvature plot. The locations of the tangential *T* and sagittal *S* foci are plotted for a full range of field angles. The Petzval surface *P* is also plotted. The tangential surface is always three times farther from the Petzval surface than from the sagittal surface: (*a*) an uncorrected system and (*b*) a corrected system.

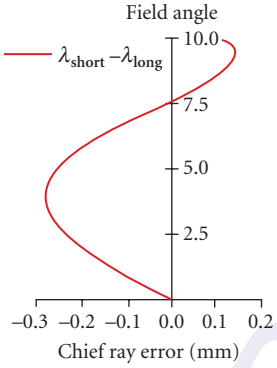

FIGURE 2.7 Field curve: lateral color plot. A plot of the transverse ray error between red and blue chief ray heights in the image plane for a full range of field angles. Here the distance along the horizontal axis is the color error in the image plane.

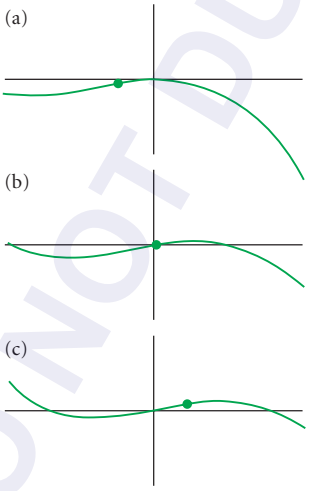

FIGURE 2.8 The effect of stop shifting on the meridional ray intercept curves of a double Gauss lens. (*a*) Stop located in front of the normal centrally located stop. (*b*) Stop at the normal stop position. (*c*) Stop behind the normal stop position. The dot locates the point on the curve where the origin is located for case (*b*).

ABOUT THE EDITORS

Editor-in-Chief: Dr. Michael Bass is professor emeritus at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

Associate Editors:
Dr. Casimer M. DeCusatis is a distinguished engineer and technical executive with IBM Corporation.

Dr. Jay M. Enoch is dean emeritus and professor at the School of Optometry at the University of California, Berkeley.

Dr. Vasudevan Lakshminarayanan is professor of Optometry, Physics, and Electrical Engineering at the University of Waterloo, Ontario, Canada.

Dr. Guifang Li is a professor at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

Dr. Carolyn MacDonald is a professor at the University at Albany, and director of the Center for X-Ray Optics.

Dr. Virendra N. Mahajan is a distinguished scientist at The Aerospace Corporation.

Dr. Eric Van Stryland is a professor at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

COVER ILLUSTRATIONS

A Photograph Taken of a Lady Viewing Her Face Using One of the World's Oldest Ground and Polished Mirrors. The oldest known manufactured mirrors (ground and polished), made of obsidian (volcanic glass) have been found in ancient Anatolia in the ruins of the City of Çatal Hüyük = "mound at a road-fork." The locations where the mirrors were discovered were dated 6000 to 5900 B.C.E. by Mellaart and his coworkers. That city is located in the South Konya Plane of Modern Turkey. Thus, these mirrors are about 8000 years old (B.P.). The obsidian was transported over a distance of more than one hundred miles to the city for processing. These mirrors can be found at the Museum of Anatolian Civilizations in Ankara. One cannot fail to be impressed by the quality of this image seen by reflectance from this ancient mirror! These mirrors had been buried twice. There is an extended history of processing of obsidian at that site for scrapers, spear, and arrow points and other tools. This very early city contained an estimated 10,000 individuals at that time(!); it was a center for development of modern agriculture, Indo-European languages, various crafts, etc., and had established road connections and trade relations [Enoch, J., *Optom. Vision Sci.* **83**(10):775–781, 2006]. (*This figure is published with permission of Prof. Mellaart, the Director of the Museum of Anatolian Civilizations, the author, and the editor of the Journal.*)

Waveguide Modal Patterns in Vertebrate Eyes (Including Human). This illustration demonstrates the variety of waveguide modal patterns observed in freshly removed retinas obtained from normal human, monkey, and rat retinas [Enoch, J., *J. Opt. Soc. Am.* **53**(1):71–85, 1963]. These modal patterns have been recorded in paracentral retinal receptors. Reverse path illumination was employed. These modes were photographed in near monochromatic light. This figure provides representative modal patterns observed and recorded near terminations of these photoreceptor waveguides. With variation of wavelength, at cutoff (please refer to the "V" parameter), it is possible to witness sharp modal pattern alterations. In this figure, the intent was to show the classes of modal patterns observed in these retinal receptors. (*This figure is reproduced with permission of JOSA and the author.*)

Photoreceptors in the Human Eye. This figure shows the first map ever made of the spatial arrangement of the three cone classes in the human retina. The three colors (red, green, and blue) indicate cones that are sensitive to the long, middle, and short wavelength ranges of the visible spectrum and are classified as L, M, and S cones. The image was recorded from a living human eye using the adaptive optics ophthalmoscope, which was developed by David Williams' lab at the University of Rochester [Liang, J., Williams, D. R., and Miller, D. (1997). Supernormal vision and high-resolution retinal imaging through adaptive optics, *J. Opt. Soc. Am.* A **14:**2884–2892]. This image was first published in the journal Nature [Roorda, A., and Williams, D. R. (1999). The arrangement of the three cone classes in the living human eye, *Nature* **397:**520–522]. (*Courtesy of Austin Roorda and David Williams.*)

BRIEF CONTENTS OF ALL VOLUMES

VOLUME I. GEOMETRICAL AND PHYSICAL OPTICS, POLARIZED LIGHT, COMPONENTS AND INSTRUMENTS

VOLUME II. DESIGN, FABRICATION, AND TESTING; SOURCES AND DETECTORS; RADIOMETRY AND PHOTOMETRY

PART 1. DESIGN

PART 2. FABRICATION

PART 3. TESTING

PART 4. SOURCES

PART 5. DETECTORS

PART 6. IMAGING DETECTORS

PART 7. RADIOMETRY AND PHOTOMETRY

VOLUME III. VISION AND VISION OPTICS

VOLUME IV. OPTICAL PROPERTIES OF MATERIALS, NONLINEAR OPTICS, QUANTUM OPTICS

PART 1. PROPERTIES

PART 5. X-RAY AND NEUTRON OPTICS

Subpart 5.1. Introduction and Applications

Subpart 5.2. Refractive and Interference Optics

Subpart 5.3. Reflective Optics

EDITORS' PREFACE

The third edition of the *Handbook of Optics* is designed to pull together the dramatic developments in both the basic and applied aspects of the field while retaining the archival, reference book value of a handbook. This means that it is much more extensive than either the first edition, published in 1978, or the second edition, with Volumes I and II appearing in 1995 and Volumes III and IV in 2001. To cover the greatly expanded field of optics, the *Handbook* now appears in five volumes. Over 100 authors or author teams have contributed to this work.

Volume I is devoted to the fundamentals, components, and instruments that make optics possible. Volume II contains chapters on design, fabrication, testing, sources of light, detection, and a new section devoted to radiometry and photometry. Volume III concerns vision optics only and is printed entirely in color. In Volume IV there are chapters on the optical properties of materials, nonlinear, quantum and molecular optics. Volume V has extensive sections on fiber optics and x ray and neutron optics, along with shorter sections on measurements, modulators, and atmospheric optical properties and turbulence. Several pages of color inserts are provided where appropriate to aid the reader. A purchaser of the print version of any volume of the *Handbook* will be able to download a digital version containing all of the material in that volume in PDF format to one computer (see download instructions on bound-in card). The combined index for all five volumes can be downloaded from www.HandbookofOpticsOnline.com.

It is possible by careful selection of what and how to present that the third edition of the *Handbook* could serve as a text for a comprehensive course in optics. In addition, students who take such a course would have the *Handbook* as a career-long reference.

Topics were selected by the editors so that the *Handbook* could be a desktop (bookshelf) general reference for the parts of optics that had matured enough to warrant archival presentation. New chapters were included on topics that had reached this stage since the second edition, and existing chapters from the second edition were updated where necessary to provide this compendium. In selecting subjects to include, we also had to select which subjects to leave out. The criteria we applied were: (1) was it a specific application of optics rather than a core science or technology and (2) was it a subject in which the role of optics was peripheral to the central issue addressed. Thus, such topics as medical optics, laser surgery, and laser materials processing were not included. While applications of optics are mentioned in the chapters there is no space in the *Handbook* to include separate chapters devoted to all of the myriad uses of optics in today's world. If we had, the third edition would be much longer than it is and much of it would soon be outdated. We designed the third edition of the *Handbook of Optics* so that it concentrates on the principles of optics that make applications possible.

Authors were asked to try to achieve the dual purpose of preparing a chapter that was a worthwhile reference for someone working in the field and that could be used as a starting point to become acquainted with that aspect of optics. They did that and we thank them for the outstanding results seen throughout the *Handbook*. We also thank Mr. Taisuke Soda of McGraw-Hill for his help in putting this complex project together and Mr. Alan Tourtlotte and Ms. Susannah Lehman of the Optical Society of America for logistical help that made this effort possible.

We dedicate the third edition of the *Handbook of Optics* to all of the OSA volunteers who, since OSA's founding in 1916, give their time and energy to promoting the generation, application, archiving, and worldwide dissemination of knowledge in optics and photonics.

PREFACE TO VOLUME III

Volume III of the *Handbook of Optics*, Third Edition, addresses topics relating to vision and the eye which are applicable to, or relate to the study of optics. For reasons we do not understand fully, in recent years, there seems to have been a tendency for the optics and the vision science communities (the latter group was known in earlier times as "physiological optics") to drift somewhat apart. Physiological optics had become a meaningful component within optics during the latter part of the nineteenth century. As but one example, we urge interested readers to read H. von Helmholtz's masterful three-volume *Handbook of Physiological Optics* (third edition) which was translated by J. P. C. Southall, of Columbia University, into English by the Optical Society of America in the 1920s.[1] It should also be noted that Allvar Gullstrand received the Nobel Prize in Physiology/Medicine in 1911 for his work on model eyes, which was a direct application of thick lens theory. Gullstrand was not only a professor of ophthalmology at the University of Uppsala, but was also a professor of physiological and physical optics at that institution. He also added five new chapters to the first volume of Helmholtz's treatise published in 1909. Not only is this a remarkable scientific work, but much of it remains applicable today! The simple fact is that the two groups, optical science and vision science need each other, or, alternatively, are effectively "joined at the hip." Thus, here, we seek to provide a broad view of vision, vision processes, and discussions of areas where vision science interacts with the ever broadening field of optics.

Obviously, no treatment such as this one can be complete, but we have tried here to present applicable topics in an orderly manner. In the current edition, we have taken a wide-ranging view of vision and its relationship with optics. In particular, in recent years, we have seen a rapid increase of interest in new technologies and applications in the areas of adaptive optics (AO), scanning laser ophthalmoscopy (SLO), and optical coherence tomography (OCT), amongst others. Separately, there has been rapid growth of refractive surgery (LASIK, etc.), use of intraocular lenses (IOLs), and other forms of visual corrections. And, we do not overlook the incredible expansion of information technology, the broad utilization of computer, video, and other forms of displays which have been employed in myriad applications (with associated implications in vision).

We want to call the reader's attention to the three cover illustrations. Here, of course, our choices were many! We have chosen one for its historical value, it is a photograph taken of a modern young lady viewing herself in an obsidian mirror in bright sunlight. That obsidian mirror, buried twice for extended time periods in its history, is ca. 8000 years old (!), and it is one of a number of the oldest known mirrors. These items are displayed in the Museum of Anatolian Civilizations, located in Ankara, Turkey[2] and/or at the Konya Museum in Konya which is in the south-central valley of Turkey and is located near to the dig site. This photograph falls into the evolving field of archaeological optics (not treated in this edition).[3,4] Please consider the quality of the image in that "stone-age" mirror which was manufactured during the mesolithic or epipaleolithic period! A second figure displays a wave-guide modal pattern obtained radiating from a single human or primate photoreceptor in the early 1960s. There is further discussion of this topic in Chap. 8 on biological waveguides. The third figure is of human parafoveal cone photoreceptors taken from the living human eye by Austin Roorda (see Chap. 15). It was obtained using adaptive optics technology. The long (seen in red), middle (seen in green), and short (seen in blue) wavelength absorbing pigments contained in these individual cone photoreceptors are readily defined.

Please note, with the formation of the section on radiometry and photometry in this edition, the chapter addressing such measurements (as they pertain to visual optics), written by Dr. Yoshi Ohno, was relocated to Volume II, Chap. 37. A new, relatively brief, chapter on radiometry and photometry associated with the Stiles-Crawford effect (of the first kind) (Chap. 9) has been added. It was added after the chapter on biological waveguides (Chap. 8). This chapter fitted more logically there (where

the Stiles-Crawford effects are discussed) than in the new section on radiometry and photometry. The new chapter raises issues suggesting that revision is needed for specification of the visual stimulus (retinal illuminance) in certain test situations, particularly if the entrance pupil of the eye is larger than about 3 mm in diameter.

The outline of the "Vision" section of the this edition offers the reader a logical progression of topics addressed. Volume III leads off with an extensive chapter on optics of the eye written by Neil Charman (Chap. 1). This material has been considerably expanded from the earlier version in the second edition. William S. Geisler and Martin S. Banks reproduced their earlier chapter on visual performance (Chap. 2); and Denis G. Pelli and Bart Farrell similarly repeated their chapter on psychophysical methods used to test vision (Chap. 3). We are pleased that Prof. Gerald Westheimer wrote a new chapter on visual acuity and hyperacuity for this edition (Chap. 4). Professors Stephen A. Burns and Robert H. Webb repeated their chapter on optical generation of the visual stimulus (Chap. 5). Gerald Westheimer also kindly allowed the editors to reproduce a "classic" article he wrote some years ago in *Vision Research* on the topic of the Maxwellian view for inclusion in this edition. He also added a valuable addendum updating material in that discussion (Chap. 6). These chapters as a group provide a valuable introduction to this volume. As in other sections of the *Handbook of Optics*, all material written is intended to be at the first-year graduate student level. So saying, it is intended to be readable and readily appreciated by all parties.

The next set of topics is intended to broaden the discussion in several specific areas of interest. Chap. 7 by David H. Sliney addresses radiation hazards associated with vision and vision testing. Vasudevan Lakshminarayanan and Jay M. Enoch address biological waveguides in Chap. 8. This rapidly broadening subject grew out of work on the Stiles-Crawford effects, that is, "the directional sensitivity of the retina," first reported in 1933. The 75th anniversary of this discovery was celebrated recently at the meeting of the Optical Society of America held in Rochester, New York, in 2008. In Chap. 9, Enoch and Lakshminarayanan speak of issues associated with the specification of the visual stimulus and the integration of the Stiles-Crawford effect of the first kind (SCE-1). These are meaningful matters associated with photometric and radiometric characterization of visual stimuli.

In Chaps. 10 and 11 David H. Brainard and Andrew Stockman address issues associated with color vision and colorimetry. The associate editors felt strongly that it was necessary to expand coverage of these topics in the third edition of the handbook. The chapter on refraction and refractive techniques (Chap. 12) was prepared by a different author, B. Ralph Chou, in this edition. He also broadened the topics covered from those treated in the second edition. Clifton Schor updated his chapter on binocular vision (Chap. 13), and John S. Werner, Brooke E. Schefrin, and Arthur Bradley updated the discussion on the optics of vision and the aging eye (Chap. 14), a very important topic due to the rapid increase in aging of populations occurring worldwide!

The next portion of this volume addresses new/emerging technology. Donald T. Miller and Austin Roorda teamed-up to write about the rapidly evolving field of adaptive optics (AO) (Chap. 15). The reader will find that AO techniques are being combined with other emerging techniques in order to enhance utility of instruments, those both in development and also now appearing on the market. Included are scanning laser ophthalmoscopy (SLO), optical coherence tomography (OCT), and flood illumination. That is, these emerging technologies offer additional unique advantages. Interestingly, SLO technology originated some years ago in the laboratory of Prof. Robert H. Webb (Chap. 5). Optical coherence tomography (OCT), a powerful new tool useful in ophthalmic examinations (both for study of the anterior and posterior segments of the eye), is discussed by the researcher, Prof. Dr. Johannes F. deBoer (Chap. 18). New techniques for refractive surgery have been addressed by Harilaos Ginis and L. Diaz-Santana in Chap. 16. Dr. Barry R. Masters has considered confocal imaging of the cornea in Chap. 17; and Prof. Barbara K. Pierscionek has addressed the current state of graded index of refraction in the eye lens (GRIN profiles) in Chap. 19. Perhaps the Pierscionek chapter might have been better placed earlier in the order of things. Edward S. Bennett addresses the always very lively field of contact lens optics in Chap. 20 and Dr. Jim Schweigerling considers the optics of intraocular lenses in Chap. 21.

Clearly, we cannot overlook imaging and display problems associated with modern optical science. Thus, from an information processing point of view as applied to optical problems, William Cowan considers displays for vision research in Chap. 22. And Jeffery Anshel has added to, modified

and updated, the chapter which James E. Sheedy had written in the second edition of the *Handbook of Optics* (Chap. 23). That chapter addressed visual problems and needs of the observer when using computers—often for long periods of time. Bernice Rogowitz, Thrasyvoulos N. Pappas, and Jan P. Allerbach discussed human vision and electronic imaging, which is a major issue in the modern environment (Chap. 24). Finally, Brian H. Tsou and Martin Shenker address visual problems associated with heads-up displays (Chap. 25). The latter problems have been a particular challenge in the aviation industry.

Thus, we have tried to cover reasonably "the waterfront" of interactions between man/eye and instruments (human engineering/ergonomics, if one prefers). And we have sought to address directly issues related to optics per se. These changes have resulted in a longer volume than in the past. So saying, we wish to emphasize that the material is not encyclopedic; that is, we wish we had more material on eye movements, as well as subjects such as aniseikonia or problems encountered by individuals with unequal image sizes in their two eyes. Relating man to the optical instruments or images presented is no small thing from a number of points of view. So saying, we sought to achieve a reasonable balance in topics presented, and in the lengths of these discussions. Obviously, we were constrained by time and availability of authors. We thank all of our diligent group of authors spread out around the world and their helpers, as well as the editorial team at McGraw-Hill and those representing the Optical Society of America, particularly Editor-in-Chief, Michael Bass!

GLOSSARY AND FUNDAMENTAL CONSTANTS

Introduction

This glossary of the terms used in the Handbook represents to a large extent the language of optics. The symbols are representations of numbers, variables, and concepts. Although the basic list was compiled by the author of this section, all the editors have contributed and agreed to this set of symbols and definitions. Every attempt has been made to use the same symbols for the same concepts throughout the entire Handbook, although there are exceptions. Some symbols seem to be used for many concepts. The symbol α is a prime example, as it is used for absorptivity, absorption coefficient, coefficient of linear thermal expansion, and more. Although we have tried to limit this kind of redundancy, we have also bowed deeply to custom.

Units

The abbreviations for the most common units are given first. They are consistent with most of the established lists of symbols, such as given by the International Standards Organization ISO[1] and the International Union of Pure and Applied Physics, IUPAP.[2]

Prefixes

Similarly, a list of the numerical prefixes[1] that are most frequently used is given, along with both the common names (where they exist) and the multiples of ten that they represent.

Fundamental Constants

The values of the fundamental constants[3] are listed following the sections on SI units.

Symbols

The most commonly used symbols are then given. Most chapters of the Handbook also have a glossary of the terms and symbols specific to them for the convenience of the reader. In the following list, the symbol is given, its meaning is next, and the most customary unit of measure for the quantity is presented in brackets. A bracket with a dash in it indicates that the quantity is unitless. Note that there is a difference between units and dimensions. An angle has units of degrees or radians and a solid angle square degrees or steradians, but both are pure ratios and are dimensionless. The unit symbols as recommended in the SI system are used, but decimal multiples of some of the dimensions are sometimes given. The symbols chosen, with some cited exceptions, are also those of the first two references.

RATIONALE FOR SOME DISPUTED SYMBOLS

The choice of symbols is a personal decision, but commonality improves communication. This section explains why the editors have chosen the preferred symbols for the *Handbook*. We hope that this will encourage more agreement.

Fundamental Constants

It is encouraging that there is almost universal agreement for the symbols for the fundamental constants. We have taken one small exception by adding a subscript B to the k for Boltzmann's constant.

Mathematics

We have chosen i as the imaginary almost arbitrarily. IUPAP lists both i and j, while ISO does not report on these.

Spectral Variables

These include expressions for the wavelength λ, frequency ν, wave number σ, ω for circular or radian frequency, k for circular or radian wave number and dimensionless frequency x. Although some use f for frequency, it can be easily confused with electronic or spatial frequency. Some use $\tilde{\nu}$ for wave number, but, because of typography problems and agreement with ISO and IUPAP, we have chosen σ; it should not be confused with the Stefan-Boltzmann constant. For spatial frequencies we have chosen ξ and η, although f_x and f_y are sometimes used. ISO and IUPAP do not report on these.

Radiometry

Radiometric terms are contentious. The most recent set of recommendations by ISO and IUPAP are L for radiance [$Wcm^{-2}sr^{-1}$], M for radiant emittance or exitance [Wcm^{-2}], E for irradiance or incidance [Wcm^{-2}], and I for intensity [Wsr^{-2}]. The previous terms, W, H, N, and J, respectively, are still in many texts, notably Smith[4] and Lloyd[5] but we have used the revised set, although there are still shortcomings. We have tried to deal with the vexatious term *intensity* by using *specific intensity* when the units are $Wcm^{-2}sr^{-1}$, *field intensity* when they are Wcm^{-2}, and *radiometric intensity* when they are Wsr^{-1}.

There are two sets to terms for these radiometric quantities, which arise in part from the terms for different types of reflection, transmission, absorption, and emission. It has been proposed that the *ion* ending indicate a process, that the *ance* ending indicate a value associated with a particular sample, and that the *ivity* ending indicate a generic value for a "pure" substance. Then one also has reflectance, transmittance, absorptance, and emittance as well as reflectivity, transmissivity, absorptivity, and emissivity. There are now two different uses of the word emissivity. Thus the words *exitance, incidence,* and *sterance* were coined to be used in place of emittance, irradiance, and radiance. It is interesting that ISO uses radiance, exitance, and irradiance whereas IUPAP uses radiance excitance [*sic*], and irradiance. We have chosen to use them both, i.e., emittance, irradiance, and radiance will be followed in square brackets by exitance, incidence, and sterance (or vice versa). Individual authors will use the different endings for transmission, reflection, absorption, and emission as they see fit.

We are still troubled by the use of the symbol E for irradiance, as it is so close in meaning to electric field, but we have maintained that accepted use. The spectral concentrations of these quantities, indicated by a wavelength, wave number, or frequency subscript (e.g., L_λ) represent partial differentiations; a subscript q represents a photon quantity; and a subscript ν indicates a quantity normalized to the response of the eye. Thereby, L_ν is luminance, E_ν illuminance, and M_ν and I_ν luminous emittance and luminous intensity. The symbols we have chosen are consistent with ISO and IUPAP.

The refractive index may be considered a radiometric quantity. It is generally complex and is indicated by $\tilde{n} = n - ik$. The real part is the relative refractive index and k is the extinction coefficient. These are consistent with ISO and IUPAP, but they do not address the complex index or extinction coefficient.

Optical Design

For the most part ISO and IUPAP do not address the symbols that are important in this area.

There were at least 20 different ways to indicate focal ratio; we have chosen FN as symmetrical with NA; we chose f and efl to indicate the effective focal length. Object and image distance, although given many different symbols, were finally called s_o and s_i since s is an almost universal symbol for distance. Field angles are θ and ϕ; angles that measure the slope of a ray to the optical axis are u; u can also be sin u. Wave aberrations are indicated by W_{ijk}, while third-order ray aberrations are indicated by σ_i and more mnemonic symbols.

Electromagnetic Fields

There is no argument about **E** and **H** for the electric and magnetic field strengths, Q for quantity of charge, ρ for volume charge density, σ for surface charge density, etc. There is no guidance from Refs. 1 and 2 on polarization indication. We chose $\perp$ and $\|$ rather than p and s, partly because s is sometimes also used to indicate scattered light.

There are several sets of symbols used for reflection transmission, and (sometimes) absorption, each with good logic. The versions of these quantities dealing with field amplitudes are usually specified with lower case symbols: r, t, and a. The versions dealing with power are alternately given by the uppercase symbols or the corresponding Greek symbols: R and T versus ρ and τ. We have chosen to use the Greek, mainly because these quantities are also closely associated with Kirchhoff's law that is usually stated symbolically as $\alpha = \epsilon$. The law of conservation of energy for light on a surface is also usually written as $\alpha + \rho + \tau = 1$.

Base SI Quantities

length	m	meter
time	s	second
mass	kg	kilogram
electric current	A	ampere
temperature	K	kelvin
amount of substance	mol	mole
luminous intensity	cd	candela

Derived SI Quantities

energy	J	joule
electric charge	C	coulomb
electric potential	V	volt
electric capacitance	F	farad
electric resistance	Ω	ohm
electric conductance	S	siemens
magnetic flux	Wb	weber
inductance	H	henry
pressure	Pa	pascal
magnetic flux density	T	tesla
frequency	Hz	hertz
power	W	watt
force	N	newton
angle	rad	radian
angle	sr	steradian

Prefixes

Symbol	*Name*	*Common name*	*Exponent of ten*
F	exa		18
P	peta		15
T	tera	trillion	12
G	giga	billion	9
M	mega	million	6
k	kilo	thousand	3
h	hecto	hundred	2
da	deca	ten	1
d	deci	tenth	–1
c	centi	hundredth	–2
m	milli	thousandth	–3
μ	micro	millionth	–6
n	nano	billionth	–9
p	pico	trillionth	–12
f	femto		–15
a	atto		–18

Constants

c	speed of light vacuo [299792458 ms^{-1}]
c_1	first radiation constant = $2\pi c^2h = 3.7417749 \times 10^{-16}$ [Wm^2]
c_2	second radiation constant = hc/k = 0.014838769 [mK]
e	elementary charge [$1.60217733 \times 10^{-19}$ C]
g_n	free fall constant [9.80665 ms^{-2}]
h	Planck's constant [$6.6260755 \times 10^{-34}$ Ws]
k_B	Boltzmann constant [1.380658×10^{-23} JK^{-1}]
m_e	mass of the electron [$9.1093897 \times 10^{-31}$ kg]
N_A	Avogadro constant [6.0221367×10^{23} mol^{-1}]
R_∞	Rydberg constant [10973731.534 m^{-1}]
ϵ_o	vacuum permittivity [$\mu_o^{-1}c^{-2}$]
σ	Stefan-Boltzmann constant [5.67051×10^{-8} Wm^{-1} K^{-4}]
μ_o	vacuum permeability [$4\pi \times 10^{-7}$ NA^{-2}]
μ_B	Bohr magneton [$9.2740154 \times 10^{-24}$ JT^{-1}]

General

B	magnetic induction [Wbm^{-2}, kgs^{-1} C^{-1}]
C	capacitance [f, C^2 s^2 m^{-2} kg^{-1}]
C	curvature [m^{-1}]
c	speed of light in vacuo [ms^{-1}]
c_1	first radiation constant [Wm^2]
c_2	second radiation constant [mK]
D	electric displacement [Cm^{-2}]
E	incidance [irradiance] [Wm^{-2}]
e	electronic charge [coulomb]
E_v	illuminance [lux, lmm^{-2}]
E	electrical field strength [Vm^{-1}]
E	transition energy [J]
E_g	band-gap energy [eV]
f	focal length [m]
f_c	Fermi occupation function, conduction band
f_v	Fermi occupation function, valence band

FN	focal ratio (f/number) [—]
g	gain per unit length [m^{-1}]
g_{th}	gain threshold per unit length [m^1]
H	magnetic field strength [Am^{-1}, Cs^{-1} m^{-1}]
h	height [m]
I	irradiance (see also E) [Wm^{-2}]
I	radiant intensity [Wsr^{-1}]
I	nuclear spin quantum number [—]
I	current [A]
i	$\sqrt{-1}$
Im()	imaginary part of
J	current density [Am^{-2}]
j	total angular momentum [kg m^2 sec^{-1}]
$J_1()$	Bessel function of the first kind [—]
k	radian wave number $=2\pi/\lambda$ [rad cm^{-1}]
k	wave vector [rad cm^{-1}]
k	extinction coefficient [—]
L	sterance [radiance] [Wm^{-2} sr^{-1}]
L_v	luminance [cdm^{-2}]
L	inductance [h, m^2 kg C^2]
L	laser cavity length
L, M, N	direction cosines [—]
M	angular magnification [—]
M	radiant exitance [radiant emittance] [Wm^{-2}]
m	linear magnification [—]
m	effective mass [kg]
MTF	modulation transfer function [—]
N	photon flux [s^{-1}]
N	carrier (number)density [m^{-3}]
n	real part of the relative refractive index [—]
$\tilde{n}$	complex index of refraction [—]
NA	numerical aperture [—]
OPD	optical path difference [m]
P	macroscopic polarization [C m^{-2}]
Re()	real part of [—]
R	resistance [Ω]
r	position vector [m]
S	Seebeck coefficient [VK^{-1}]
s	spin quantum number [—]
s	path length [m]
S_o	object distance [m]
S_i	image distance [m]
T	temperature [K, C]
t	time [s]
t	thickness [m]
u	slope of ray with the optical axis [rad]
V	Abbe reciprocal dispersion [—]
V	voltage [V, m^2 kgs^{-2} C^{-1}]
x, y, z	rectangular coordinates [m]
Z	atomic number [—]

Greek Symbols

α	absorption coefficient [cm^{-1}]
α	(power) absorptance (absorptivity)

ϵ	diclectric coefficient (constant) [—]
ϵ	emittance (emissivity) [—]
ϵ	eccentricity [—]
ϵ_1	Re (ϵ)
ϵ_2	lm (ϵ)
τ	(power) transmittance (transmissivity) [—]
ν	radiation frequency [Hz]
ω	circular frequency = $2\pi\nu$ [rads^{-1}]
ω	plasma frequency [H_2]
λ	wavelength [μm, nm]
σ	wave number = $1/\lambda$ [cm^{-1}]
σ	Stefan Boltzmann constant [Wm^{-2}K^{-1}]
ρ	reflectance (reflectivity) [—]
θ, ϕ	angular coordinates [rad, °]
ξ, η	rectangular spatial frequencies [m^{-1}, r^{-1}]
ϕ	phase [rad, °]
ϕ	lens power [m^{-2}]
Φ	flux [W]
χ	electric susceptibility tensor [—]
Ω	solid angle [sr]

Other

$\Re$	responsivity
exp (x)	e^x
$\log_a (x)$	log to the base a of x
ln (x)	natural log of x
log (x)	standard log of x: $\log_{10} (x)$
Σ	summation
Π	product
Δ	finite difference
δx	variation in x
dx	total differential
∂x	partial derivative of x
$\delta(x)$	Dirac delta function of x
δ_{ij}	Kronecker delta

OPTICS OF THE EYE

Neil Charman

Department of Optometry and Vision Sciences
University of Manchester
Manchester, United Kingdom

1.1 GLOSSARY

F, F' focal points
N, N' nodal points
P, P' principal points

Equation (1)

r distance from axis
R_0 radius of curvature at corneal pole
p corneal asphericity parameter

Equation (2)

s distance from Stiles-Crawford peak
η/η_{max} relative luminous efficiency
ρ coefficient in S-C equation

Equation (3)

d pupil diameter
P_A ratio of effective to true pupil area

Transmittance and reflectance

$T_E(\lambda)$ total transmittance of the eye media
$R_R(\lambda)$ reflectance of the retina
λ wavelength

Equation (4)

(θ,ϕ) angular direction coordinates in visual field
$\delta(\lambda)$ wavelength interval
$L_{e\lambda}(\theta,\phi)$ spectral radiance per unit wavelength interval per unit solid angle in direction (θ,ϕ)
$p(\theta,\phi)$ area of pupil as seen from direction (θ,ϕ)

$t(\theta,\phi,\lambda)$ fraction of incident radiation flux which is transmitted by the eye
$m(\theta,\phi,\lambda)$ areal magnification factor

Equation (5)
I normalized illuminance
z dimensionless diffraction unit

Equation (6)
γ angular distance from center of Airy diffraction pattern
d pupil diameter

Equation (7)
$\theta_{\min}$ angular resolution by Rayleigh criterion

Equation (8)
R spatial frequency
R_R reduced spatial frequency

Equation (9)
ΔF dioptric error of focus
g number of Rayleigh units of defocus

Equation (10)
β angular diameter of retinal blur circle

Equation (11)
$T(R)$ modulation transfer function

Equation (13)
$R_x(\lambda)$ chromatic difference in refraction with respect to 590 nm

Equation (14)
L_{eq} equivalent veiling luminance
E illuminance produced by glare source at eye
ω angle between direction of glare source and visual axis

Equations (15) and (16)
$M_{IT}(R)$ threshold modulation on the retina
$M_{OT}(R)$ external threshold modulation

Equation (17)
DOF_{go} total depth-of-focus for an aberration-free eye according to geometrical optics
ΔF_{tol} tolerable error of focus
β_{tol} tolerable angular diameter of retinal blur circle

Equation (18)
DOF_{po} total depth-of-focus for an aberration-free eye according to physical optics

Equation (19)
OA objective amplitude of accommodation

Equation (20)
l object distance
p interpupillary distance
δl minimum detectable difference in distance
$\delta\theta$ stereo acuity

1.2 INTRODUCTION

The human eye (Fig. 1) contains only a few optical components. However, in good lighting conditions when the pupil is small (2 to 3 mm), it is capable of near diffraction-limited performance close to its axis. Each individual eye also has a very wide field of view (about 65, 75, 60, and 95 deg in the superior, inferior, nasal, and temporal semimeridians, respectively, for a fixed frontal direction of gaze, the exact values being dependent upon the individual's facial geometry). The binocular field, where the two monocular fields overlap, has a lateral extent of about 120 deg. Optical image quality, while somewhat degraded in the peripheral field is, in general, adequate to meet the needs of the neural network which it serves, since the spatial resolution of the neural retina falls rapidly away from the visual axis (the latter joins the point of regard, the nodal points and the fovea). The orientation of the visual axis typically differs by a few degrees from that of the optical axis, as the fovea, where neural resolution is optimal, is usually slightly displaced from the intersection of the optical axis with the retina.[1,2] Control of ocular aberrations is helped by aspheric optical surfaces and by the gradients of refractive index in the lens, the lens index progressively reducing from the lens center toward its outer layers. Off-axis aberrations are further reduced by the eye's approximation to a homocentric system, in which the optical and detector surfaces are concentric with a common center of curvature at the aperture stop.[3] Although aberration levels increase and optical image quality falls as the pupil dilates at lower light levels (to reach a maximum diameter of about 8 mm, corresponding to a numerical aperture of about 0.25 mm), neural performance also declines, so that optical and neural performances remain reasonably well matched. When the eye is in its basic "relaxed" state it is nominally in focus for distant objects. In the younger eye (<50 years) the power of the crystalline lens can be increased to allow near objects to be clearly focused, a process known as *accommodation*. These general characteristics will now be discussed in more detail.

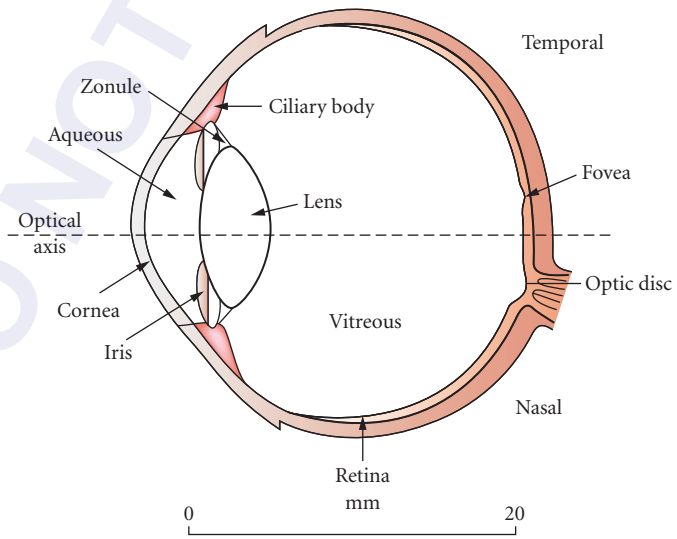

FIGURE 1 Schematic horizontal section of the eye. The bar gives the approximate scale.

1.3 OCULAR PARAMETERS AND AMETROPIA

Variation in Ocular Parameters across the Population

In the first few years of life there is substantial overall ocular growth, with axial length increasing from about 17 mm at birth to about 23 mm by the age of 3 years.[4–6] Some growth continues thereafter, the axial length in adults being about 24 mm.[7–12] Although most dimensions remain almost stable during adulthood, the lens continues to grow in thickness and volume, but not diameter, throughout life. The thickness increases approximately linearly by about 50 percent between birth and the age of 70,[10,13–15] there being accompanying changes in its index distribution.[16–19] Surface curvatures, component separations, and axial lengths show considerable variation (~10 percent) between individuals of the same age, although the refractive indices of the cornea, vitreous, and aqueous humours are essentially constant.[7–9,20,21] Figure 2 shows some typical measured adult distributions of the values of several parameters: most of the distributions shown are approximately normal (dashed curves), but this is not true for the axial length.

As noted earlier, the optical surfaces may be aspheric. The form of the anterior cornea is particularly significant. Owing to the large refractive index change at its anterior surface it contributes about three-quarters of the total refractive power of the eye. Its topography also has obvious relevance to contact lens design and to the monochromatic aberrations of the eye. It is often modeled as a conicoid, of the form

$$r^2 + pz^2 - 2R_0 z = 0 \tag{1}$$

where the axis of symmetry lies in the z direction, r is the distance perpendicular to the axis, and R_0 is the radius of curvature at the pole of the surface. Figure 3 shows experimental measurements of the distribution of the parameter p.[22,23] The distribution is fairly wide and peaks at a value of

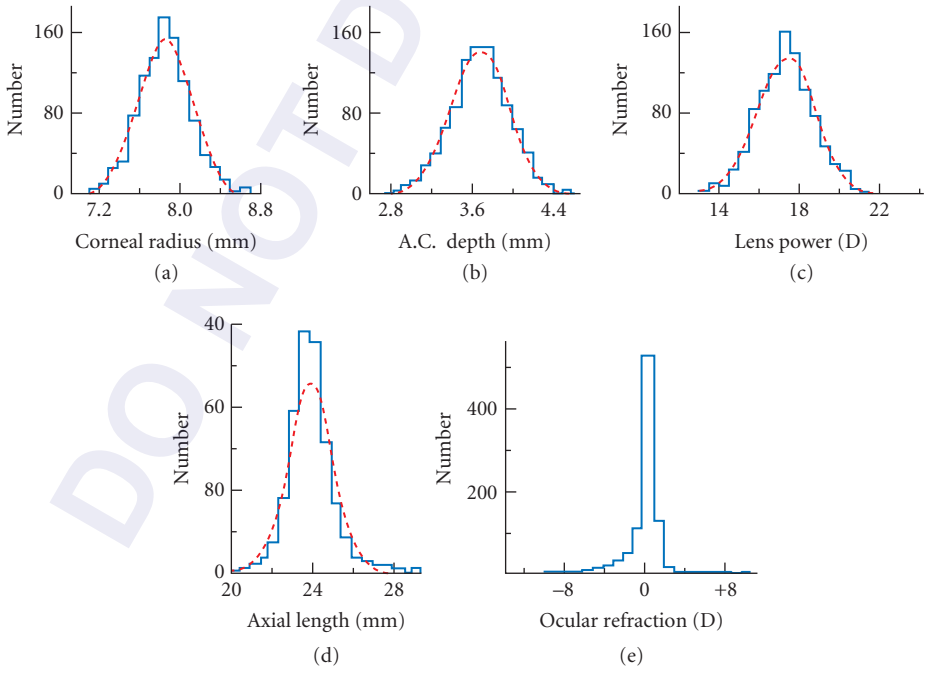

FIGURE 2 Distributions of some dimensional parameters for the adult human eye. (*After Stenström.*[21])

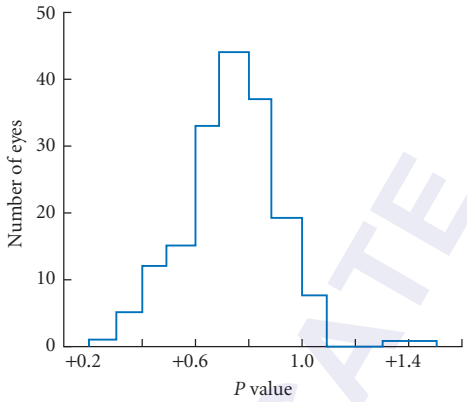

FIGURE 3 Histogram showing the distribution of the corneal asphericity parameter p. A value of $p = 1$ corresponds to a spherical surface, values between 0 and 1.0 represent prolate (flattening) ellipsoids and $p > 1.0$ oblate (steepening) ellipsoids. (*Based on Refs. 22 and 23.*)

about +0.8, corresponding to a flattening ellipsoid in which the radius of curvature is smallest at the center of the cornea and increases toward the corneal periphery. At the corneal vertex the radius of curvature is about 7.8 ± 0.25 mm.[22,23]

The least understood optical feature of the eye is the distribution of refractive index within the lens. As noted earlier, the lens grows throughout life,[10,13,14] with new material being added to the surface layers (the cortex). The oldest part of the lens is its central region (the nucleus). While there is general agreement that the refractive index is highest at the lens center and falls toward its outer layers, the exact form of the gradients involved has proved difficult to measure.[16–19] Description is complicated by the fact that the shape of the lens and its gradients change when the eye accommodates to view near objects and with age. To illustrate the general trend of the changes with age, Fig. 4 shows some

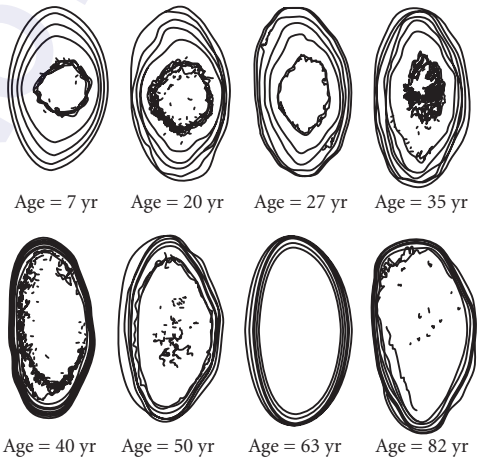

FIGURE 4 Contours of refractive index in lenses of different ages (7 to 82 years). The contour interval is 0.01. (*After Ref. 18.*)

recent *in vitro* iso index contours for isolated lenses, obtained using magnetic resonance imaging: when measured *in vitro* the lenses take up their fully accommodated form. It can be seen that, with age, the region of relatively constant index at the lens center increases in volume and that the gradient becomes almost entirely confined to the surface layers of the lens. The central index remains constant at 1.420 ± 0.075 and the surface index at 1.371 ± 0.004.[18] These index distributions have been modeled as a function of age and accommodation by several authors. (see, e.g., Refs. 24–30)

In addition to these general variations, each eye may have its own idiosyncratic peculiarities, such as small tilts or lateral displacements of surfaces, lack of rotational symmetry about the axis, or irregularities in the shape or centration of the pupil.[1,2,31] These affect both the refractive error (*ametropia*) and the higher-order aberrations.

Ocular Ametropia

If the combination of ocular parameters is such that, with accommodation relaxed, a distant object of regard is focused on the retinal fovea, the region where the density of the cone receptors is highest and photopic neural performance is optimal (Fig. 1), the eye is *emmetropic*. This condition is often not achieved, in which case the eye is *ametropic*. If the power of the optical elements is too great for the axial length, so that the image of the distant object lies anterior to the retina, the eye is *myopic*. If, however, the power is insufficient, the eye is *hypermetropic* (or *hyperopic*). These defects can be corrected by the use of appropriately powered diverging (myopia) or converging (hypermetropia) spectacle or contact lenses to respectively reduce or increase the power of the lens-eye combination. (see Chap. 20 by Edward S. Bennett and William J. Benjamin for reviews.) Spherical ametropia tends to be associated with axial length differences, that is, myopic eyes tend to be longer than emmetropic eyes while hyperopic eyes are shorter.[32]

In some individuals the ocular dioptrics lack rotational symmetry, one or more optical surfaces being toroidal, tilted, or displaced from the axis. This leads to the condition of ocular astigmatism, in which on the visual axis two longitudinally separated, mutually perpendicular, line images of a point object are formed. In the vast majority of cases (*regular astigmatism*) the meridians of maximal and minimal power are perpendicular: there is a strong tendency for the principal meridians to be approximately horizontal and vertical but this is not always the case. Eyes in which the more powerful meridian is vertical are often described as having *with-the-rule astigmatism* and those in which it is horizontal as having *against-the-rule astigmatism*. The former is more common. Correction of astigmatism can be achieved by including an appropriately oriented cylindrical component in any correcting lens. It is sometimes convenient to talk of the *best-*, *mean-*, or *equivalent-sphere* correction. This is the power of spherical lens which brings the circle of least confusion onto the retina: its value is $S + C/2$, where S and C are respectively, the spherical and cylindrical dioptric components of the correction.

In addition to spectacle and contact lens corrections, surgical methods of correction for both spherical and astigmatic errors are now widely used. Most common are those using excimer lasers which essentially reshape the anterior surface of the cornea by selectively ablating its tissue across the chosen area to appropriately modify its sphero-cylindrical power. A popular current method is laser-assisted keratomileusis (LASIK) which involves cutting a thin, uniform "flap" of material from the anterior cornea and then ablating the underlying corneal stroma to change its curvature. The flap is then replaced. (see Chap. 16 by L. Diaz-Santana and Harilaos Ginis for details.) Intraocular lenses can be used to replace the crystalline lens when the latter has lost transparency due to cataract: single-vision, bifocal and multifocal designs are available and efforts are being made to develop lenses of dynamically varying power to simulate the accommodative abilities of the younger eye. (see Chap. 21 by Jim Schwiegerling.)

Figure 5 shows representative data for the frequency of occurrence of different spherical[21] and astigmatic[34] errors in western adults. Myopia is more common in many eastern populations. Note particularly that the spherical errors are not normally distributed and that a state of near-emmetropia is most common. It is believed that the correlation of component values required to achieve near-emmetropia is achieved partly as a result of genetic factors and partly as a result of

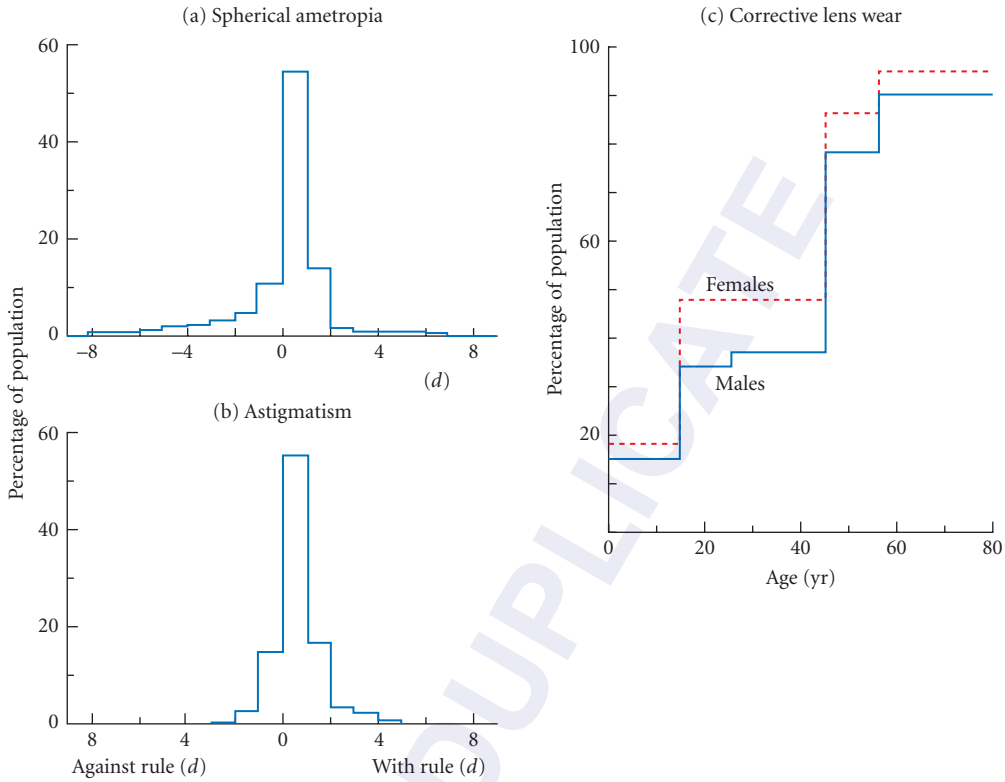

FIGURE 5 Typical adult data for the frequency of occurrence of spherical and cylindrical (astigmatic) refractive errors, together with the fraction of the population wearing corrective spectacle or contact lenses. (*a*) Spherical errors (diopters) in young adult males. (*After Stenstrom.*[21]) (*b*) Cylindrical errors. (*Based on Lyle.*[34]) Cases in which the meridian of greatest power is within 30 deg of the horizontal (against-the-rule) and within 30 deg of the vertical (with-the-rule) are shown: the remaining 4 percent of the population have axes in oblique meridians. (*c*) Percentage of the population wearing lenses, as a function of age. (*After Farrell and Booth.*[35])

environmentally influenced growth processes which drive the development of the young eye toward emmetropia (*emmetropization*).[33]

Not all individuals with ametropia actually wear a correction; the fraction of the population that typically does so is shown in Fig. 5. The increase in lens wear beyond the age of 40 is due to the need for a near correction for close work, a condition known as *presbyopia*. This arises as a result of the natural, progressive failure with age of the eye's own accommodation system (see "Age-dependent Changes in Accommodation").

The widespread existence of ametropia among users of visual instruments such as telescopes and microscopes, means that it is desirable to make provision for focusing the eyepiece to compensate for any spherical refractive error of the observer. This is particularly the case where the eyepiece contains a graticule. Since the refractive errors of the two eyes of an individual may not be identical (*anisometropia*), differential focusing should be provided for the eyepieces of binocular instruments. As correction for cylindrical errors is inconvenient to incorporate into eyepieces, astigmatic users of instruments must usually wear their normal refractive correction. For spectacle wearers, where the distance of the lenses in front of the eyes is usually 10 to 18 mm, this implies that the exit pupil of the instrument must have an adequate eye clearance or eye relief (at least 20 mm and preferably 25 mm) to avoid contact between the spectacle lens and the eyepiece and allow the instrument's full field to be seen.

1. 4 OCULAR TRANSMITTANCE AND RETINAL ILLUMINANCE

The amount, spectral distribution, and polarization properties of the light reaching the retina are modified with respect to the original stimulus in a way that depends upon the pupil diameter and the transmittance characteristics of the eye.

Pupil Diameter

The circular opening in the iris, located approximately tangential to the anterior surface of the lens, plays the important role of aperture stop of the eye. It therefore controls the amount of light flux reaching the retina, as well as influencing retinal image quality through its effects on diffraction, aberration, and depth-of-focus (see Sec. 1.7). It may also affect the amount of scattered light reaching the retina, particularly in older eyes where cataract is present.

What is normally measured and observed is the image of the true pupil as viewed through the cornea, that is, the entrance pupil of the eye. This is some 13 percent larger in diameter than the true pupil. Although ambient lighting and its spatial distribution have the most important influence on entrance pupil diameter (Fig. 6) the latter is also affected by many other factors including age, accommodation, emotion, and drugs.[36,37] For any scene luminance, the pupils are slightly smaller under binocular conditions of observation.[38] The gradual constriction with age[36] helps to account for the poorer visual performance of older individuals under dim lighting conditions in comparison with younger individuals.[39]

The pupil can respond to changes in light level at frequencies up to about 4 Hz.[37] Shifts in pupil center of up to 0.6 mm may occur when the pupil dilates[40,41] and these may be of some significance in relation to the pupil-dependence of ocular aberration and retinal image quality.

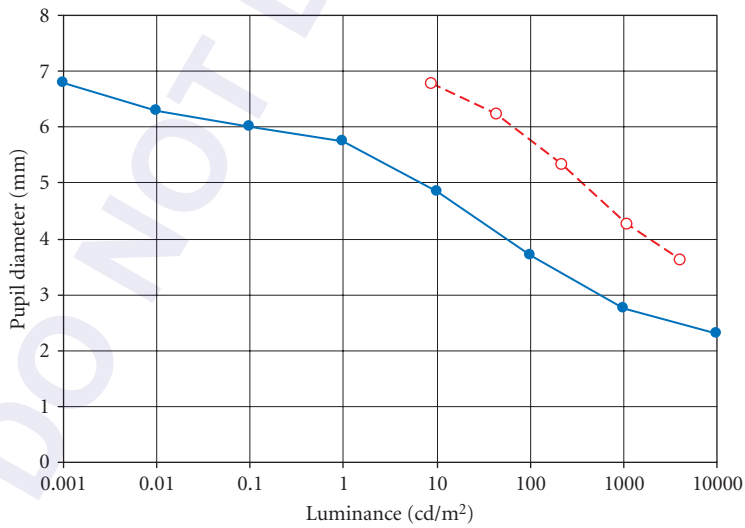

FIGURE 6 Entrance pupil diameter as a function of scene luminance for an extended visual field and young observers: the filled symbols and full curve show the weighted average of 6 studies. (*After Farrell and Booth.*[35]) Larger pupils are observed when the illuminated field is of smaller area: the dashed curve and open symbols show data for a 10 deg illuminated field. (*After Winn et al.*[36])

It has been suggested[42,43] that the major value of light-induced pupillary constriction is that it reduces retinal illuminance and hence prepares the eye for a return to darkness: following a change to a dark environment the dilation of the mobile pupil allows substantially better stimulus detection during the first few minutes of dark adaptation than would be found with a fixed pupil.

Transmittance

Light may be lost by spectrally varying reflection, scattering, and absorption in any of the media anterior to the retina.[44] Fresnel reflection losses are in general small, the maximum being 3 to 4 percent at the anterior cornea. Wavelength-dependent absorption and scattering are much more important: both tend to increase with age.

The measured transmittance[45–49] depends to some extent on the measuring technique, in particular on the extent to which scattered light is included, but representative data are shown in Fig. 7. The transmittance rises rapidly above about 400 nm, to remain high in the longer wavelength visible and near infrared. It then falls through several absorption bands, due mainly to water, to reach zero at about 1400 nm.

Although most of the absorption at ultraviolet wavelengths below 300 nm occurs at the cornea (where it may disrupt the surface cells, leading to photokeratitis, e.g., snow blindness or welder's flash, the lowest damage thresholds of about 0.4 $J \cdot cm^{-2}$ being at 270 nm[50]), there is also substantial absorption in the lens at the short wavelength (roughly 300–400 nm) end of the visible spectrum. This lenticular absorption increases markedly with age,[51–54] the lens becoming progressively yellower in appearance,[55] and can adversely affect color vision.[56,57] Most of the absorption occurs in the lens nucleus.[58] There is evidence that UV absorption in the lens may be a causative factor in some types of cataract.[59] Excessive visible light at the violet-blue end of the spectrum is thought to cause accelerated aging and resultant visual loss at the retinal level[60] so that lenticular absorption may have a protective function. (See also Chap. 7 by David H. Sliney.)

In the foveal region a thin layer of macular pigment, extending over the central few degrees of the retina[61,62] and lying anterior to the receptor outer segments[63,64] absorbs heavily at shorter wavelengths (Fig. 7). It has been argued that this absorption is helpful in reducing the blurring effects of longitudinal chromatic aberration[65] and in protecting the foveal receptors, which are responsible for detailed pattern vision, against blue-light damage.[66] It is, however, notable that the amount of macular pigment varies widely between individuals.[64]

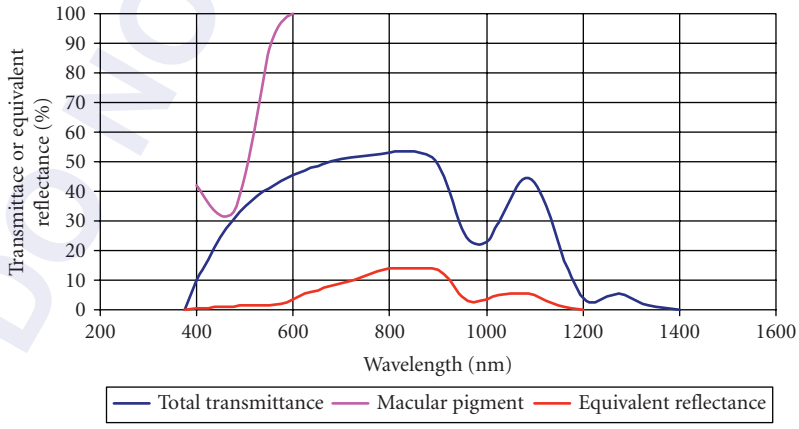

FIGURE 7 Spectral dependence of the overall transmittance of the ocular media[46] and the equivalent reflectance of the retina.[75–77] Also shown is the transmittance at the fovea of the macular pigment.[65]

Since the cornea, lens, and retinal nerve fibre layer all show birefringence, the polarization characteristics of the light entering the eye are modified before it reaches the outer segments of the retinal receptors. In general these effects are of little practical significance, although they can be demonstrated and measured by suitable methods.[67]

The Stiles-Crawford Effect

One complicating factor when considering the effectiveness of the light flux which enters the eye as a stimulus to vision is the Stiles-Crawford effect of the first kind SCEI.[68] (See also Chaps. 8 and 9 by Jay M. Enoch and Vasudevan Lakshminarayanan in this volume.) This results in light which enters the periphery of the entrance pupil to reach a given retinal location being less effective at stimulating the retina than light which passes through the pupil center (Fig. 8). The effect varies slightly with the individual and is not always symmetric about the center of the pupil. Under photopic conditions, giving cone vision, there is typically a factor of about 8 between the central effectiveness and that at the edge of a fully dilated 8-mm pupil; the effect is much weaker under rod-dominated, scotopic conditions (see Fig. 8).[69–71] In practice, unless pupil-dilating drugs are used, the natural pupil will only be large under scotopic conditions and will normally be constricted at photopic levels (see Fig. 6): the influence of SCE I is still significant, however.

Many equations have been proposed to fit photopic data of the type illustrated in Fig. 8. The simplest, due to Stiles,[72] can be written:

$$\log_{10}(\eta/\eta_{max}) = -\rho s^2 \tag{2}$$

where η/η_{max} is the relative luminous efficiency and s is the distance within the entrance pupil from the function peak (in mm). Values of the constant ρ equal to about 0.07 are typical, the value varying somewhat with wavelength.[72]

It is evident that the Stiles-Crawford effect of the first kind results in the photopic retinal stimulus being somewhat weaker than that predicted on the basis of visible pupil area. This can be accounted for by using an effective pupil area instead of the actual entrance pupil area. Moon and Spencer[73] suggested that the ratio P_A of the effective to the true pupil areas could be approximated by:

$$P_A = 1 - 0.0106d^2 + 0.0000417d^4 \tag{3}$$

where d is the pupil diameter in mm.

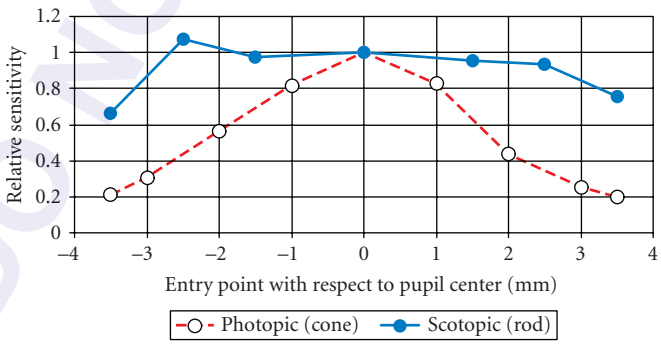

FIGURE 8 The Stiles-Crawford effect (SCE I) under photopic (open circles) and scotopic (filled circles) conditions for the same observer, measured at a position 6 deg from the fovea. The relative luminous efficiency is plotted as a function of the horizontal pupillary position of the beam. (*After van Loo and Enoch.*[69])

The Stiles-Crawford effect of the second kind (SCE II) involves a shift in the hue of monochromatic light as it enters different areas of the pupil.[70,72,74]

Although Fresnel reflection and lenticular absorption variations with pupil position may play minor roles, there seems little doubt that the Stiles-Crawford effects mainly involve the waveguide properties of the outer segments of the small-diameter receptors. (See Refs. 63 and 64, and Chap. 8 by Vasudevan Lakshminarayanan and Jay M. Enoch for reviews.) Effectively, the receptor can only trap light efficiently if the latter is incident in directions within a few degrees of the receptor axis. For this reason, the receptor outer segments must always be aligned toward the exit pupil of the eye, rather than perpendicular to the local surface of the eyeball. An obvious advantage of such directional sensitivity is that it helps to suppress the degrading effects of intraocular stray light. Such light will be ineffective at stimulating the receptors if it is incident at oblique angles on the retina. As will be discussed in Chap. 8, it appears that SCE I acts as an amplitude apodizing filter in its effects upon retinal image quality.

Retinal Reflectance

The function of the optical system of the eye is to deliver an image to the retina. Nevertheless, a significant amount of this light is reflected when it reaches the retina and underlying structures. Although such light does not contribute usefully to the process of vision, its existence allows the development of a variety of clinical instruments for examination of the retina, measurement of refraction, and other purposes.

Due to its double passage through the eye media, the emergent flux at any wavelength is proportional to the equivalent reflectance $T_E(\lambda)^2 R_R(\lambda)$, where $T_E(\lambda)$ is the total transmittance of the eye media and $R_R(\lambda)$ is the true retinal reflectance. Equivalent reflectance rises with wavelength across the visible spectrum, to become quite high in the near infrared.[62,75–78] Representative values are given Fig. 7. Absolute levels of equivalent reflectance are affected by the pigmentation of an individual eye. At the violet end of the visible spectrum the equivalent reflectance falls markedly with age,[79] due to the decreased transmittance of the lens. In the same spectral region, equivalent reflectance is usually lower within the immediate area of the fovea, due to the low transmittance of the macular pigment.

The high equivalent reflectance in the infrared is particularly useful in allowing measurements to be made of, for example, refraction or aberration, at wavelengths which are essentially invisible to the patient or subject. In practice, depending upon the wavelength, light may be reflected from structures anywhere between the anterior surface of the retina and the choroid/sclera interface. Although details of the nature of the reflections are still imperfectly understood, shorter visible wavelengths appear to penetrate less deeply before reflection occurs, while the infrared is reflected from the anterior sclera. At the shorter wavelengths the reflection is almost specular but becomes more diffuse at longer visible and infrared wavelengths.[79–81] Waveguiding effects within the receptors may play some role in determining the nature of the reflection and the angular distribution of the reflected light.[82–85]

Ocular Radiometry and Retinal Illuminance

If we confine ourselves to uniform object fields subtending at least 1 deg at the eye, so that blurring due to diffraction, aberration or defocus has little effect, the retinal image at moderate field angles would also be expected to be uniform across its area, except at the edges. Wyszecki and Stiles[37] show that the retinal irradiance in a wavelength interval $\delta\lambda$ corresponding to an external stimulus of spectral radiance $L_{e\lambda}(\theta,\phi)$ per unit wavelength interval per cm^2 per unit solid angle of emission, in a direction with respect to the eye given by the angular coordinates (θ,ϕ) is:

$$\frac{L_{e\lambda}(\theta,\phi)\cdot\delta\lambda\cdot p(\theta,\phi)\cdot t(\theta,\phi,\lambda)}{m(\theta,\phi,\lambda)} \tag{4}$$

where $p(\theta,\phi,\lambda)$ cm^2 is the apparent area of the pupil as seen from the direction (θ,ϕ); $t(\theta,\phi,\lambda)$ is the fraction of the incident radiant flux transmitted through the eye; and $m(\theta,\phi,\lambda)$ is an areal

magnification factor (cm^2) relating the area of the retinal image to the angular subtense of the stimulus at the eye, which will vary somewhat with the parameters of the individual eye. If required, the pupil area $p(\theta,\phi,\lambda)$ can be modified using Eq. (3) to take account of the Stiles-Crawford effect.

Use of Eq. (4) near to the visual axis is straightforward. In the peripheral field, however, complications arise. With increasing field angle the entrance pupil appears as an ellipse of increasing eccentricity and reduced area: the ratio of the minor diameter to the major diameter falls off somewhat more slowly than the cosine of the field angle.[86,87] Also, due to the retina lying on the curved surface of the quasi-spherical eyeball, both the distance between the exit pupil of the eye and the retina, and the retinal area corresponding to the image of an object of constant angular subtense diminish with field angle. Remarkably, theoretical calculations[88–91] show that these pupil and retinal effects tend to compensate one another, so that an extended field of constant luminance (i.e. a *Ganzfeld*) results in a retinal illuminance which is almost constant with peripheral field angle. This theoretical result is broadly confirmed by practical measurements,[91] showing that, from the photometric point of view, the design of the eye as a wide-angle system is remarkably effective.

A useful discussion of the photometric aspects of point and extended sources in relation to the eye is given by Wright.[92]

1.5 FACTORS AFFECTING IN-FOCUS RETINAL IMAGE QUALITY

The optical quality of the retinal image is degraded by the effects of diffraction, monochromatic and chromatic aberration, and scattering. The image is often further blurred by defocus, due to errors in refraction and accommodation. Under many conditions the latter may be the dominant cause of image degradation. It will, however, be convenient to consider the question of focus in a separate section.

The Aberration-Free (Diffraction-Limited) Eye

In the absence of aberration or variation in transmittance across the pupil, the only factors influencing the retinal image quality in monochromatic light at optimal focus would be the diffraction effects associated with the finite wavelength, λ, of the light and the pupil diameter, d. For such an eye, the point-spread function (PSF) is the well-known Airy diffraction pattern[93] whose normalized illuminance distribution, $I(z)$, takes the form:

$$I(z)=\left[\frac{2J_1(z)}{z}\right]^2 \tag{5}$$

where $J_1(z)$ is the Bessel function of the first kind of order 1 of the variable z. In the case of the eye, the dimensionless distance z has the value:

$$z=\frac{d\pi\cdot\sin\gamma}{\lambda} \tag{6}$$

γ is the angular distance from the center of the pattern, measured at the second nodal point, this being equal to the corresponding angular distance in the object space, measured at the first nodal point.[94,95] The angular resolution θ_{min} for two neighboring equally luminous incoherent object points, as given by the Rayleigh criterion is then:

$$\theta_{min}=\frac{1.22\,\lambda}{d}\,\text{rad} \tag{7}$$

θ_{min} is about 1 minute of arc when d is 2.3 mm and λ is 555 nm. Evidently the Rayleigh criterion is somewhat arbitrary, since it assumes that the visual system can just detect the 26 percent drop in irradiance between the adjacent image peaks; for small pupils actual visual performance is usually somewhat better than this limit.[96] The size of the PSF increases on either side of optimal focus.[97–99]

Images of more complex objects can be obtained by regarding the image as the summation of an appropriate array of PSFs, that is, by convolving the PSF with the object radiance distribution.[94] The in-focus line-spread function (LSF), the edge image,[100] and the modulation transfer function (MTF) also take standard forms. The phase transfer function (PTF) is always zero because the diffractive blur is rotationally symmetrical: this also makes the LSF, edge image, and MTF independent of orientation. Figure 9 shows the form of the MTF as a function of focus.[101] Extensive tables of numerical values are given by Levi.[102] Relative spatial frequencies, R_R, in Fig. 9 have been normalized in terms of the cutoff value beyond which the modulation transfer is always zero. Errors of focus have been expressed in what Levi calls "Rayleigh units," i.e., the number of quarter wavelengths of wavefront aberration at the edge of the pupil. Note from Fig. 9 that the modulation transfer is most sensitive to defocus at intermediate normalized spatial frequencies ($R_R \approx 0.5$).[103,104]

To convert the units of relative spatial frequency and Rayleighs to true spatial frequencies R c/deg and dioptric errors of focus ΔF respectively, the following relations may be used:

$$R = \frac{10^6 \times d \times R_R}{\lambda} \text{ c/rad}$$

$$= \frac{1.746 \times 10^4 \times d \times R_R}{\lambda} \text{ c/deg} \tag{8}$$

$$\Delta F = \frac{2 \times 10^{-3} \lambda g}{d^2} \text{ diopters} \tag{9}$$

where the entrance pupil diameter d is in mm, the wavelength λ is in nm, and g is the number of Rayleighs of defocus.

Figure 10 illustrates the variation in these parameters as a function of the ocular pupil diameter, d, for the case where $\lambda = 555$ nm. In such green light and with the typical photopic pupil diameter of 3 mm, the cutoff frequency imposed by diffraction is about 100 c/deg and one Rayleigh of defocus corresponds to about 0.12 D.

Sets of diffraction-limited ocular MTF curves for various specific combinations of pupil diameter, wavelength, and defocus have been illustrated by several authors (e.g., Refs. 105–111).

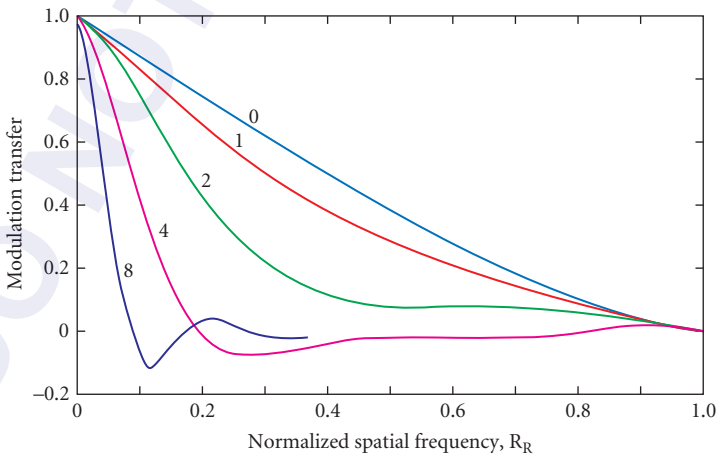

FIGURE 9 Modulation transfer functions for a diffraction-limited optical system with a circular pupil working in monochromatic light. It suffers from the errors of focus indicated. Defocus is expressed in Rayleighs, that is, the number of quarter-wavelengths of defocus wavelength aberration. (*Based on Levi.*[102])

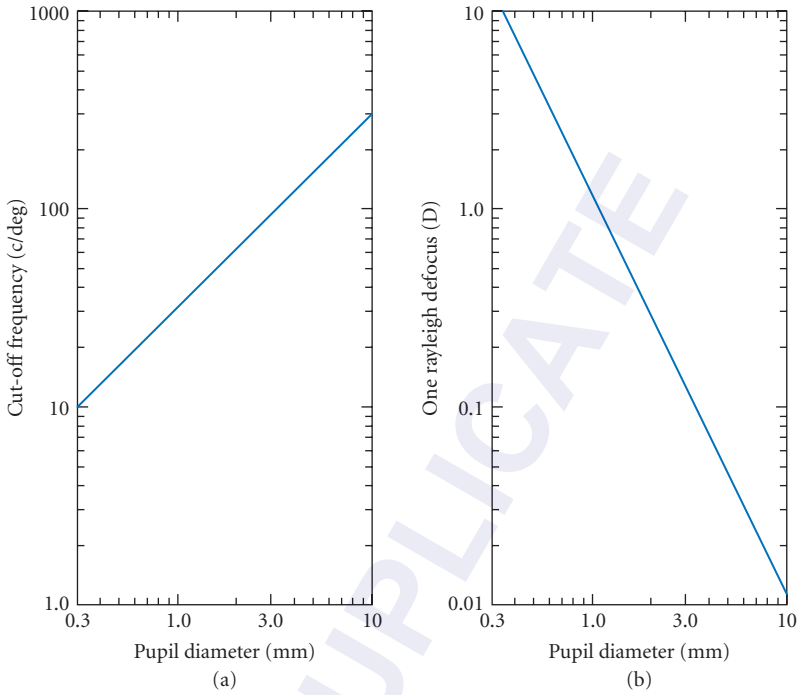

FIGURE 10 Values of (*a*) cutoff frequency $R_R = 1.0$ and (*b*) dioptric defocus equivalent to one Rayleigh, for a diffraction-limited eye working in monochromatic light of wavelength 555 nm.

When errors of focus become large, the geometric approximation in which the defocus PSF is a uniform blur circle becomes increasingly valid.[101,110,112–115] The angular diameter, β of the retinal blur circle for a pupil diameter d mm and error of focus ΔF diopters is

$$\beta = \frac{0.18 \cdot d \cdot \Delta F}{\pi} \text{ deg} \tag{10}$$

The corresponding geometrical optical MTF is

$$T(R) = \frac{2J_1(\pi\beta R)}{\pi\beta R} \tag{11}$$

where R is the spatial frequency (c/deg) and $J_1(\pi\beta R)$ is the Bessel function of the first kind of order 1 of $(\pi\beta R)$. Smith[114] gives detailed consideration to the range of ocular parameters under which the geometrical optical approximation may reasonably be applied and Chan et al.[115] have demonstrated experimentally that Eq. (10) usefully predicts blur circle diameters for pupils between 2 and 6 mm in diameter and defocus between 1 and 12 D.

Monochromatic Ocular Aberrations

In many early studies of ocular aberration, it was common to assume that the eye was symmetrical about a unique optical axis which differed only slightly from the visual axis. Thus it was expected that spherical aberration would dominate on axis, with oblique astigmatism, field curvature, and

coma becoming progressively more important as the field angle increased, although the curved surface of the retina would tend to reduce the impact of field curvature. The assumption was that the brain would adapt to any distortion, so that this aberration was not important. This simple picture has been progressively modified with the realisation that exact symmetry about a unique optical axis rarely occurs and that the fovea does not normally lie where the nominal optical axis intercepts the retina (the difference is usually a few degrees—see e.g., Refs. 116–118 for discussion of possible axes for eye). As a result, the patterns of both on- and off-axis aberrations are more complex than was expected on the basis of early, simple models of the eye.

Recent years have, in fact, seen an enormous expansion in the literature of the aberrations of the eye, fueled by the development of commercial aberrometers capable of measuring the characteristics of the individual eye within a few seconds[119,120] and the demands of refractive surgery, where it was recognized that although earlier techniques nominally corrected refractive error, they often resulted in poor visual outcomes due to higher than normal levels of residual aberration.[119] Currently, the optical defects of the eye are usually described in terms of its wavefront aberration under specified conditions, the overall level of aberration being expressed as the root-mean-square (RMS) wavefront error. Different types of aberration are quantified in terms of the coefficients of the corresponding Zernike polynomials of polar coordinates in the pupil (e.g., Refs. 119, 121–124, see also Chap. 11 by Virendra N. Mahajan in Vol. II as well as Chap. 4 by Virendra N. Mahajan and Chap. 5 by Robert Q. Fugate in Vol. V), defined according to OSA recommendations,[123,124] although this approach has been criticized as being inappropriate for eyes in which the wavefront aberration shows locally abrupt variation, as in, for example, some postsurgical cases.[125,126] In the recommended formulation, each Zernike coefficient gives the root-mean-square (RMS) wavefront error (in microns) contributed by the particular Zernike mode: the overall RMS error is given by the square root of the sum of the squares of the individual coefficients. The set of Zernike coefficients thus gives detailed information on the relative and absolute importance of the different aberrational defects of any particular eye for the specified conditions of measurement. In the Zernike description, first-order polynomials simply describe wavefront tilt (i.e. prismatic effects) and have no effect on image quality. Second-order polynomials describe the spherocylindrical errors of focus which can normally be negated by optical corrections, such as spectacles or contact lenses. It is the higher-order (third and greater) polynomials which represent the aberrations. The third-order modes include vertical and horizontal primary coma, and the fourth-order primary spherical aberration. Iskander et al.[127] have illustrated the effects of some of the individual Zernike aberrations on the retinal images of a selection of objects. The values of the Zernike coefficients for any particular eye will, of course, vary with pupil diameter, accommodation, and field angle.

Aberrations on the Visual Axis Several large-scale studies have addressed the question of the variation of aberrations between individuals.[128–133] Others have considered changes of aberration with such specific factors as pupil diameter,[134] age,[134–138] accommodation,[139–144] refractive error,[146,147] and time.[148–152]

Figure 11 shows recent mean data for the variation in total higher-order, axial, RMS wavefront error with pupil diameter for different age groups.[134] As would be expected, aberration levels tend to increase with pupil diameter: they also increase with age. The Maréchal criterion[153] suggests that near diffraction-limited performance will be given if the RMS error is less than $\lambda/14$, corresponding to about 0.04 microns in the green region of the spectrum. It can be seen that this level of aberration is typically present when the pupil diameter is about 3 mm in younger eyes. As illustrated in Fig. 9, such a pupil diameter is generally found under luminance conditions of a few hundred cd/m^2, corresponding to that occurring on cloudy days. Thus, in most eyes, wavefront aberration is likely to have only a minor impact on vision under daylight conditions.

To give some insight into the image degradation caused by any level of RMS wavefront aberration, we can roughly evaluate its blurring effects by equating them with those of an "equivalent defocus," that is the spherical error in focus which produces the same magnitude of RMS aberration for the same pupil size. The equivalent defocus is given by:

$$\text{Equivalent defocus (diopters)} = \frac{16.3^{1/2} \cdot \text{RMS error}}{d^2} \tag{12}$$

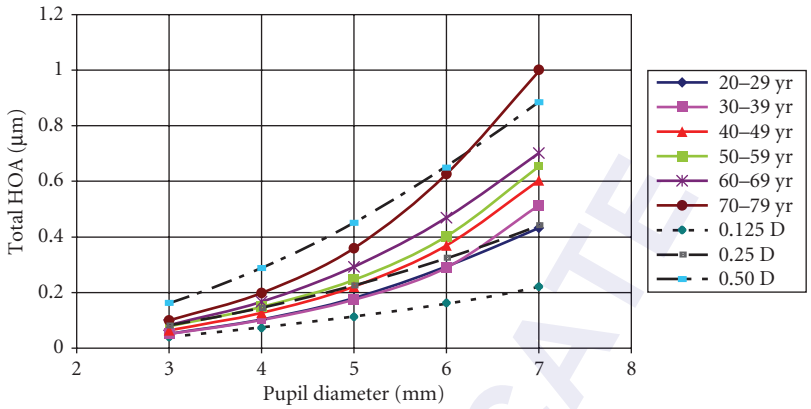

FIGURE 11 Plots of total mean RMS wave aberration as a function of pupil size for different age groups. (*After Applegate et al.*[134]) The dashed curves show levels of equivalent defocus of 0.125, 0.25, and 0.50 D.

where the RMS aberration is measured in microns and the pupil diameter, *d*, in mm. As examples, the dashed curves in Fig. 11 indicate equivalent defocus levels of 0.125, 0.25, and 0.50 D. For younger subjects (20–39 years), the mean HOA is always lower than an equivalent defocus level of 0.25 D, except at the largest, 7 mm, pupil diameter. For comparison, the reliability of clinical refractive techniques is around ±0.3 D.[154,155] Although the assumption that equal RMS errors produce equal degradation of vision is not completely justified,[156,157] it is evident that, in most younger, normal eyes, the impact on vision of optical blur due to axial monochromatic aberrations is likely to be modest under most conditions, although this may not be true for a minority of individuals.

When the coefficients of the individual Zernike polynomials are considered for eyes in which the accommodation is relaxed for distance vision, several large-scale studies involving many hundred normal individuals give very similar results.[128–134] As an example, the study by Applegate and his colleagues[134] generated mean values for the magnitudes of different types of third- and fourth-order aberration for different pupil sizes and ages (coefficients for still higher-order Zernike modes are usually much smaller). Table 1 gives examples of their values for different age groups. Note that,

TABLE 1 Mean Values of the Coefficients (μm) and Their Standard Deviations for Individual Third- and Fourth-Order Zernike Modes for 3- and 6-mm Pupils and Different Subject Age Groups*

Age (yrs)	Pupil Diameter (mm)	RMS WFE (μm) Trefoil	RMS WFE (μm) Coma	RMS WFE (μm) Tetrafoil	RMS WFE (μm) 2nd Astig.	RMS WFE (μm) Sph. ab.

*The third-order modes are third-order trefoil and coma, the fourth-order are tetrafoil, secondary astigmatism (2nd astig.) and spherical aberration (sph. ab.). The eyes are accommodated for distance vision.

Source: Applegate et al.[134]

where appropriate, the coefficients for similar, but differently oriented, polynomials have been combined. Evidently for smaller, 3-mm pupils, third-order coma and trefoil aberrations tend to dominate over fourth-order aberrations but spherical aberration becomes comparable to coma for the larger 6-mm pupil.

The results of another study[128] are shown in Fig. 12*a*, where in this case the second-order coefficients are included. Note that the second-order coefficients are much larger than those of the higher orders implying, not surprisingly, that the optical defects of many eyes are dominated by simple sphero cylindrical refractive errors.

A somewhat different picture emerges if we average the signed coefficients of the higher-order Zernike modes, rather than their absolute values (Fig. 12*b*). It is striking that the coefficients of most modes now have means close to zero, although individual eyes may have substantial aberration, as is shown by the relatively large standard deviations. A notable exception is the $j = 12$, Z_4^0 spherical aberration

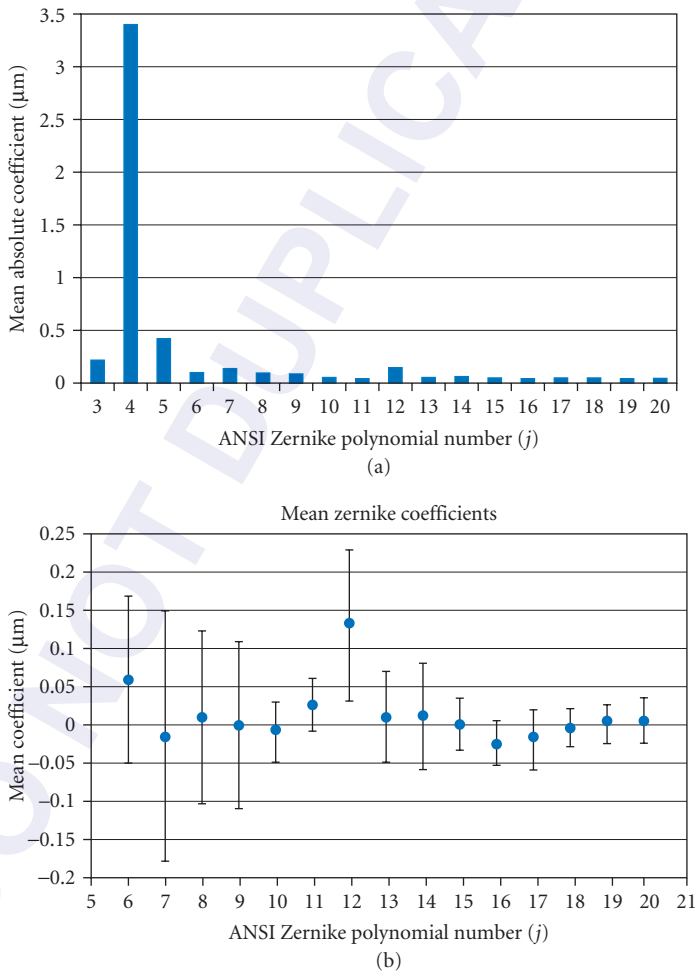

FIGURE 12 Typical data for the wavefront aberration of normal eyes with relaxed accommodation: 109 subjects, 5.7-mm pupil diameter. (*a*) Means of the absolute values of the coefficients of the Zernike modes from the second to the fifth orders. (*b*) Means of the signed values of each of the coefficients: among the higher-order coefficients, only that for $j = 12$ (C_4^0, spherical aberration) has a value which differs significantly from zero. (*Based on Porter et al.*[128])

mode, where the mean is positive and differs significantly from zero. Thus the picture that emerges is that most eyes have a central tendency to be free of all higher-order aberration, except for spherical aberration, which shows a significant bias toward slightly positive (under corrected) values. The Zernike coefficients of individual eyes vary randomly about these mean values in a way that presumably depends upon the idiosyncratic surface tilts, decentrations, and other asymmetries of the eye.

When the contributions made by the different optical components of the eye are considered, it appears that, with accommodation relaxed, the overall level of ocular aberration in the young adult is reduced by there being a balance between the contributions of the cornea and the lens. This is particularly the case for spherical aberration and horizontal coma,[158–162] although the compensation may not be found in young eyes with high levels of total aberration[163] or in older eyes.[164] The mechanism by which compensation might be achieved has been discussed by Artal and his colleagues.[2,165] It is interesting to note that there is at least some evidence that there may be additional neural compensation for the aberrations, this being specific to the individual.[166]

Since the shape and gradient index characteristics of the lens change with both accommodation and age, this affects the balance between the corneal and internal aberrations. As accommodation increases, spherical aberration tends to change from positive to negative.[139–145] With age, aberrations with relaxed accommodation at fixed pupil diameter also increase.[134–138] However, under normal conditions, the pupil diameter at constant light level decreases with age,[37] reducing the ocular aberration: image quality therefore remains almost constant with age, although retinal illuminance is lower.[135] Higher-order aberrations generally show, at most, only a very weak dependence on refractive error,[147,167] although the balance between the horizontal coma of the cornea and internal optics may be affected.[168]

Finally we note that measured higher-order aberrations of any individual eye show small fluctuations over time[148–152] with frequencies up to at least 20 Hz. Although the causes of these fluctuations remain to be fully elucidated, the lower-frequency components undoubtedly involve such factors as tear film changes and the cardiopulmonary system.[152,169,170] Lid pressures during such activities as reading may also produce longer-term changes.[171–173]

Off-Axis Aberrations Off-axis, on average increasing amounts of second-order aberration (defocus and astigmatism) are encountered (Fig. 13). These may show substantial variations with the individual and with the meridian under study, as may also the relationship between the tangential and sagittal image shells and the retinal surface.[174–187] While there is little systematic change in the mean oblique astigmatism with the axial refraction of the eye, myopes tend to have a relatively hyperopic peripheral mean-sphere refraction, while that in hyperopes tends to be relatively myopic.[177,178,183,185] There may be small changes in peripheral refraction with accommodation[181] and age.[186,187]

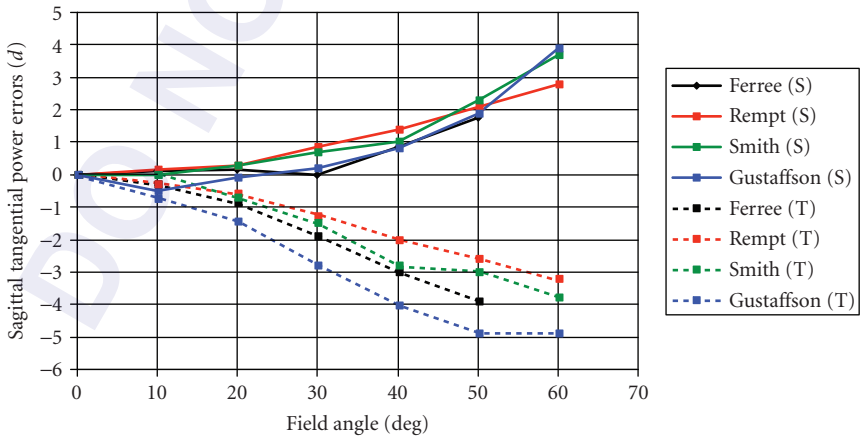

FIGURE 13 Oblique astigmatism in human eyes. T and S refer to the tangential and sagittal image shells, respectively. (*After Ferree et al.,*[124] *Jenkins,*[175] *Rempt et al.,*[176] *Smith et al.,*[181] *Gustafsonn et al.*[184])

Higher-order wave aberrations have been studied as a function of field angle by several groups.[188–192] They are generally much less important than the second-order defocus terms but third-order, coma-like terms rise with field angle to be considerably higher than those in axial vision.[188–192] As on axis, there appears to be a degree of balancing between the aberrations associated with the anterior cornea and those of the lens.[192] One problem in using Zernike polynomials to describe off-axis aberrations is that the associated entrance pupils are elliptical rather than circular as required if the Zernike approach is to be used: scaling methods to overcome this difficulty have been devised.[193–195]

Chromatic Aberration

Chromatic aberration arises from the dispersive nature of the ocular media, the refractive index, and hence the ocular power, being higher at shorter wavelengths. Constringence values for the ocular media are generally quoted[196] as being around 50, although there is evidence that this may need modification.[197,198] Atchison and Smith[199] have recently discussed the available data for the different media and recommend the use of Cauchy's equation to fit experimental values in the visible and allow extrapolation into the near infrared. Both longitudinal or axial chromatic aberration (LCA) and transverse or lateral chromatic aberration (TCA) occur (see, e.g., Refs. 200 and 201 for reviews). For LCA, what is normally measured experimentally is not the change in power of the eye across the spectrum but rather the change in its refractive error, or the chromatic difference of refraction. There are only minor differences in the results of different studies of LCA (e.g., Refs. 175, 202–205) and the basic variation in ocular refraction with wavelength, equivalent to about 2 D of LCA across the visible spectrum is well established (Fig. 14). Atchison and Smith[199] suggest that when the chromatic difference data are set to be zero at 590 nm they can be well fitted by the Cauchy equation

$$R_x(\lambda) = 1.60911 - 6.70941 \times \frac{10^5}{\lambda^2} + 5.55334 \times \frac{10^{10}}{\lambda^4} - 5.5998 \times \frac{10^{15}}{\lambda^6} \text{ diopters} \qquad (13)$$

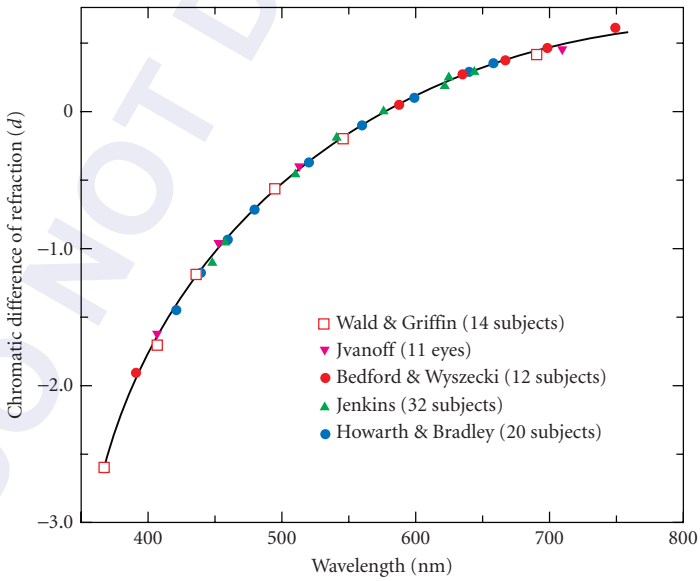

FIGURE 14 Representative sets of average data for the longitudinal chromatic aberration of the eye. The data for all subjects and studies have been displaced in power so that the chromatic aberration is always zero at 578 nm. (*Based on Jenkins,*[175] *Wald and Griffin,*[202] *Bedford and Wyszecki,*[204] *Howarth and Bradley.*[205])

where the wavelength is in nanometers and the difference in refraction, $Rx(\lambda)$, is in diopters. LCA has little effect on visual acuity for high-contrast objects in white light.[206] This appears to be because the spectral weighting introduced by the photopic luminosity curve, which is heavily biased toward the central region of the spectrum, results in the primary effect of the LCA being to degrade modulation transfer at intermediate spatial frequencies rather than at the high spatial frequencies involved in the high-contrast acuity limit.[107] Alternatively, McLellan et al.[207] have argued that it is the interaction between the monochromatic and chromatic aberrations of the eye that helps to minimize any change in image quality with wavelength across the spectrum.

TCA results in a wavelength-dependent change in magnification in the retinal image, the red image being larger than the blue. Thus in white light the image of an off-axis point is drawn out into a short radial spectrum whose length in a paraxial model increases with the field angle.[208] TCA therefore affects modulation transfer for tangentially oriented grating components of images.[201,209,210]

For a centered system, TCA would be zero on the optical axis. Since in the eye there is a ~5 deg difference (called angle α) in orientation between the visual axis joining the fixation point, nodal points and fovea of the eye, and the approximate optical axis, some foveal TCA might be expected. Remarkably, however, the center of the pupil in most eyes lies almost exactly on the visual axis[1,200,211] so that actual values of foveal TCA are typically only of the order of 0.7 min arc.[1,211] Although this value is less than predicted by simple eye models, it is still large enough to cause some orientation-dependent image degradation. This may be substantially increased if an artificial pupil is used which, for any reason, becomes decentered: such a situation may arise when using visual instrumentation having exit pupils which are much smaller than the entrance pupil of the eye.

With binocular viewing, the TCA associated with small decentrations of the natural pupils and of the foveas from the optical axis leads to the phenomenon of *chromostereopsis,* whereby objects of different colors placed at the same physical distance may appear to the observer to be at different distances.[212–218] The exact effect varies with the individual and, when artificial pupils are used, with the separation of the pupils. It is thus of some practical significance in relation to the design of instruments, such as binocular microscopes, in which interpupillary distance settings may not always be optimal for the observer.[216]

In the periphery, TCA may play a significant role in limiting the detection of tangential as opposed to radial gratings.[210,219] There is as yet no consensus as to its magnitude, although some measurements have been made.[220]

Intraocular Scattered Light and Lenticular Fluorescence

A variety of regular and irregular small-scale inhomogeneities exist within the optical media of the eye. These may serve to scatter light during its passage between the anterior cornea and the retinal receptors. Further stray light may arise for reflections at the various optical surfaces and the retina itself, and some light may also penetrate the nominally opaque iris and sclera to reach the internal eye (*diaphany*), particularly in eyes with low pigmentation, as in albinos. The main effect of such light is to reduce the contrast in the retinal image.

Quantitative studies of the effects of stray light on vision were pioneered by Holladay[221] and Stiles,[222] who expressed its impact in terms of an equivalent veiling luminance, L_{eq} cd·m^{-2}, that would produce the same masking effect as a glare source giving an illuminance E lux at the eye, as a function of the angular distance, ω deg, between the glare source and the fixation point. Vos et al.[223] have summarized more recent work by the approximate relationship:

$$L_{eq} = \frac{29E}{(\omega + 0.13)^{2.8}} \quad \text{where} \quad 0.15 \text{ deg} < \omega < 8 \text{ deg} \tag{14}$$

This expression relates to young adult eyes. Scattering increases throughout life by a factor of at least 2 to 3 times[224–227] and glare formulas can be modified to take account of this (e.g., Ref. 228). Roughly a quarter of the stray light comes from the cornea[229,230] and a further quarter from the retinal reflections.[231,232] The rest comes almost entirely from the lens,[233] there being little contribution from the aqueous or vitreous humors in normal healthy eyes.

Ohzu and Enoch[234] attempted to measure a retinal MTF which included the effects of forward scatter, by focusing grating images onto the anterior surface of an excised retina *in vitro* and measuring the image transfer to the far side. They argued that the receptor outer segments effectively act as a fiber optics bundle and that transmission through this bundle produces image degradation which supplements to the main optical elements of the eye. More recent psychophysical measurements[235,236] suggest, however, that forward scatter in the inner retina is negligible, implying that postmortem changes in the retina may have degraded Ohzu and Enoch's MTFs.

In addition to the general effects described above, a variety of more regularly organized, wavelength-dependent, scattering effects in the form of annular haloes or "star" patterns may occur (see e.g., Refs. 237 and 238 for reviews). These are most easily observed with point sources in an otherwise dark field, particularly if the pupil is large. Some of these result from diffraction due to ocular structures with quasi-regular spacing, for example, the corneal epithelial cells or lens fibers,[239,240] others relate to small-scale refractive irregularities or to higher-order aberrations.[241]

Forward scattering of light affects the precision of aberrometry,[137,241] while back scatter is of importance in allowing anterior ocular structures to be viewed by clinical examination techniques such as slit-lamp biomicroscopy and Scheimpflug photography.[242]

Stray light may also arise as a result of fluorescence in the crystalline lens. This increases with age and with the occurrence of cataract,[243] largely through the progressive accumulation of fluorogens. Under some circumstances, the emitted fluorescent light can cause a slight reduction in low-contrast acuity in older individuals[244] but in younger adults the effects are probably of little practical significance,[245] since the cornea absorbs most of the potentially activating short wavelength light.

1.6 FINAL RETINAL IMAGE QUALITY

Experimental estimates of the final quality of the retinal image can be made in three main ways: by calculation from wavefront aberration or similar data, by psychophysical methods, and by direct measurement of the light distribution on the retina using a double-pass ophthalmoscopic technique. Although each method has its limitations, the various methods yield compatible results in the same subjects and collectively produce a reasonably consistent picture of the changes in retinal image quality with pupil diameter, retinal location, and age.

Image Quality on the Visual Axis

Calculation from Aberration Data The optical transfer function (OTF) can be calculated by autocorrelation of the complex pupil function with its complex conjugate, using methods originally devised by Hopkins.[246] The pupil function gives the variation in amplitude and phase across the exit pupil of the system. The phase at each point can be deduced from the corresponding value of the wavefront aberration (each wavelength of aberration corresponds to 2π radians of phase). It is often assumed that the amplitude across the pupil is uniform but if imagery under photopic conditions is being considered, it may be more correct to take account of the Stiles-Crawford effect (SCE I) by including appropriate amplitude apodization, ideally on an individual basis:[209,247,248] this suggestion is supported by some experimental evidence.[249,250] The point- and line-spread functions can also be directly calculated from the wavefront aberration (see Chap. 4 by Glenn D. Boreman in Vol. I and Chap. 4 by Virendra N. Mahajan and Chap. 5 by Robert Q. Fugate in Vol. V) and appropriate software is often included with current commercial aberrometers.

The attractive feature of this approach is that it can allow the OTF (i.e., both the modulation and phase transfer functions) to be calculated for any orientation. On the other hand, it fails to include the effects of any scattered light and hence may give too optimistic a view of the final retinal image quality, particularly in older eyes in which scattering is high: high levels of intraocular scatter may have the additional effect of reducing the reliability and validity of the aberrometer estimates of wavefront aberration, the exact effects depending upon the design of the particular aberrometer.[251]

Van Meeteren[209] argued that it was appropriate to multiply the aberration-derived MTFs by the MTF derived by Ohzu and Enoch[234] for image transfer through the retina. When this is done, the results agree quite well with those found by the double-pass ophthalmoscope technique;[252] although, as noted earlier, the Ohzu and Enoch MTF may overestimate the effects of retinal degradation. A further problem with MTFs derived from wavefront measurements is that most aberroscopes estimate the form of the wavefront from measurements made at a limited number of points across the pupil.[253,254] Variations in aberration on a small spatial scale may therefore remain undetected, with consequent uncertainties in the derived OTFs; this problem was probably greatest with the early designs of aberroscope, such as the crossed cylinder device.[252]

Pyschophysical Comparison Method This method depends upon the comparison of modulation (contrast) thresholds for a normally viewed series of sinusoidal gratings of differing spatial frequencies with those for similar gratings which are produced directly on the retina by interference techniques.[256,257]

Suppose an observer directly views a sinusoidal grating of spatial frequency R. Then if the grating has modulation $M_0(R)$, the modulation of the retinal image will be $M_0(R) \cdot T(R)$, where $T(R)$ is the modulation transfer of the eye at this spatial frequency, under the wavelength and pupil diameter conditions in use. If now the modulation of the grating is steadily reduced until it appears to be just at threshold, the threshold modulation $M_{IT}(R)$ on the retina will be given by

$$M_{IT}(R) = M_{OT}(R) \cdot T(R) \tag{15}$$

where $M_{OT}(R)$ is the measured modulation of the external grating at threshold. The reciprocal of $M_{OT}(R)$ is the corresponding conventional contrast sensitivity and its measurement as a function of R corresponds to the procedure used to establish the contrast sensitivity function.

It is clear that $M_{IT}(R)$ corresponds to the threshold for the retina/brain portion of the visual system. If its value can be independently established, it will be possible to determine $T(R)$. $M_{IT}(R)$, in fact, can be measured by bypassing the dioptrics of the eye and their aberrations and forming a system of interference fringes directly on the retina. This procedure was originally suggested by Le Grand[256,257] and has since been progressively improved[258–264] (see Ref. 257 for review). Two mutually coherent point sources are produced close to the nodal points of the eye and the two resultant divergent beams overlap on the retina to generate a system of Young's fringes, whose angular separation, γ rads, is given by $\gamma = \lambda/a$, where λ is the wavelength and a is the source separation, both measured in air. If the sources have equal intensity, the fringes will nominally be of unit modulation. Fringe modulation can be controlled by varying the relative intensities of the two sources, by adding a uniform background, or by modulating the two sources with a temporal square-wave and introducing a phase difference between the two modulations. The contrast threshold $M_{IT}(R)$ for the retina brain can then be measured as a function of R, allowing the modulation transfer for the ocular dioptrics, $T(R)$, to be deduced from the relationship:

$$T(R) = \frac{M_{IT}(R)}{M_{OT}(R)} \tag{16}$$

There are some problems with this approach. Both sets of thresholds are affected by stray light, but in different ways. The determination of the external modulation threshold involves light entering the full pupil whereas for the interferometric measurements only two small regions of the pupil are used. There may also be problems in maintaining the same threshold criterion for the two types of grating, particularly when they may differ in color, field size, and possibly speckle characteristics. Lastly, although the method can in principle give ocular MTFs for any orientation, it yields no phase information and hence the PTF cannot be determined.

Some other psychophysical methods have been suggested[265] but as yet they have not been widely employed.

Ophthalmoscopic (Double-Pass) Methods When the image of an object is thrown on the retina, some of the light will be reflected back out of the eye and can be collected by an appropriate observing system

to form an external image. If, for example, the object is a narrow line, the external image will be the LSF for the double passage of the eye. It is usual to make the assumption that the retina acts as a diffuse reflector,[266] coherence of the image light being lost in the reflection. In this case, earlier workers assumed that the image suffered two identical stages of image degradation, so that the MTF deduced from the Fourier transform of the external LSF was the square of the single-pass MTF. Flamant's pioneering study[267] with this method used photographic recording, but later workers have all used electronic imaging methods, initially slit-scanning arrangements with photomultipliers to record LSFs, and latterly low-noise CCD cameras which allow PSFs to be recorded.[266,268–276] An important advance was the realization that in the simple form of the method as employed in earlier studies, when the same pupil acted as aperture stop for both the entering and exiting light paths, information on odd-order aberrations and on transverse chromatic aberration was lost.[274] While the estimates of MTF were potentially correct, the PTF could not be measured. This problem can be overcome for monochromatic aberrations by arranging the entering and exiting beams so that the entrance pupil is smaller than the exit pupil.[275,276] If the entrance pupil is small enough for the initial image to be effectively diffraction limited, the true single-pass OTF (i.e., both the MTF and the PTF) can be deduced from the double-pass PTF, at least up to the cutoff frequency imposed by the small entrance pupil. Some theoretical aspects of this problem have been discussed by Diaz-Santana and Dainty.[277]

The double-pass method has been used to explore the extent to which poorer retinal image quality contributes to the deterioration in visual performance that is observed in older eyes,[278] and to demonstrate the changes in retinal image quality with accommodation that are caused by aberrational change in the crystalline lens.[279] An adaptation allows the basic method to be used to determine an "index of diffusion" designed to characterize the optical deficit in eyes with age- and disease-related abnormalities of the anterior segment, using encircled energy measurements of the double-pass PSF.[280]

In all variations of the double-pass method, one problem is that light levels in the outer parts of any spread function are low, leading to possible truncation errors and to overestimation of the MTF.[281] Vos et al.[223] attempted to overcome the truncation problem by combining the opthalmoscopic estimates of the PSF with measurements of wider-angle entoptic stray light, to produce a realistic estimate of the full light profiles in the foveal white-light PSF. A vexing question which has yet to be fully answered is the identity of the layer or layers at which the retinal reflection occurs: it seems likely that this is wavelength dependent. If more than one layer is involved, the estimated MTF will be somewhat too low. However there is evidence that any effect of retinal thickness on the estimated MTF is small[282] and that scattered light from the choroid and deeper retina is guided through the receptors on its return through the pupil.[283]

Comparison between Methods Only a few direct comparisons of MTF measurements have been made by different techniques on the same eyes. Campbell and Gubisch[266] found that their double-pass MTFs were lower than those determined by the interferometric psychophysical method.[260] A similar result was found by Williams et al.,[284] who noted that agreement between the two techniques was better if green rather than red light was used for the double-pass measurements, presumably as a result of reduced retinal and choroidal scatter.[285] Although MTFs derived from early aberrometers, which only sampled the pupil at a small number of points, tended to be markedly higher than those derived by other methods, if green light is used with young eyes the three basic methods appear to yield very similar MTFs: increased entoptic scatter in older eyes may cause larger differences. Liang and Williams[286] give comparative MTF results obtained by the three techniques with three subjects with 3-mm pupils. The greatest discrepancies appear to be at intermediate spatial frequencies, where values of modulation transfer increase in the order double-pass, interferometric, and wave aberration derived.

Summary of Observed Optical Performance When the eye is corrected for any spherocylindrical refractive error, all investigators agree that, near the visual axis, the eye's performance in monochromatic light is reasonably close to the limit set by diffraction for pupil diameters up to 2 mm. As pupil size is increased further, aberration starts to play a more important role. The increasing impact of aberration is illustrated by a consideration of the changes in the Strehl intensity ratio,[287] the ratio of the maximum irradiance in the PSF to that which would be found in a truly diffraction-limited

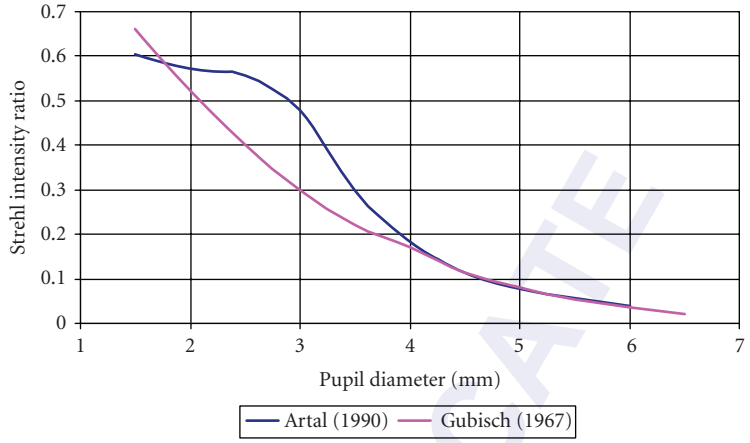

FIGURE 15 Changes in Strehl ration with pupil diameter. (*Based on data from Artal*[288] *and Gubisch.*[288])

system. Typical published values[89,288] are shown in Fig. 15. Although differences between individuals may be expected, the ratio falls steadily as the pupil diameter is increased, indicating the increasing impact of aberrations. For the smallest natural pupil diameters, the value approaches, but does not quite reach, the figure of 0.8 which is usually accepted as the minimum required for an optical system to closely approximate to being diffraction limited:[287] direct measures of the MTF for a 1.5-mm pupil in comparison with the diffraction-limited case support this finding.[276]

The changing balance between diffractive and aberrational effects results in optimal overall performance usually being achieved with pupil diameters of about 2.5 to 3 mm,[266,286,288,289] corresponding to the diameters of natural pupils under bright, photopic conditions. For still larger pupils, the degrading effects of aberration dominate and modulation transfer falls. Examples[286] of typical estimates of MTF, in this case based on wavefront measurements for different pupil diameters in young eyes, are shown in Fig. 16. The MTF at constant pupil diameter tends to deteriorate with

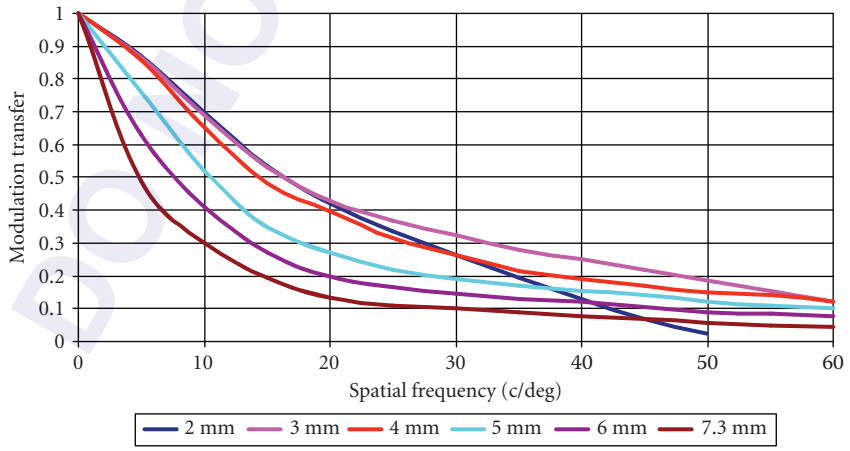

FIGURE 16 Examples of typical foveal MTFs in young, adult eyes for the pupil diameters indicated. (*After Liang and Williams.*[286])

age, due to both increased aberration and scatter.[278] It should be noted that, although transmission through the eye undoubtedly changes the polarization state of the incident light, the retinal image quality is apparently nearly independent of the initial state of polarization. However, quality as recorded by double-pass measurements may vary if polarizing elements are included in both the entering and exiting light paths.[290]

Effects of Aberration Correction on Visual Performance Early attempts[291] to improve axial visual performance by correction of monochromatic aberrations were failures, largely because it was assumed that spherical aberration was always dominant and the same in all eyes. Correction of longitudinal chromatic aberration also brought no improvement in acuity[292] although modest improvements at intermediate spatial frequencies could be demonstrated.[99] The advent of aberrometers capable of rapidly measuring the aberrations of an individual eye has refocused attention on the possibility that customized aberration correction might yield significantly enhanced vision (e.g., Refs. 293–298).

Several potential methods for correcting the monochromatic aberrations have been suggested. The most effective of these is adaptive optics.[299,300] This is impractical for everyday use but is being vigorously explored as a way of obtaining improved images of the retina for clinical diagnostic or research purposes(e.g., Ref. 301), since near diffraction-limited performance can be achieved through the full, 7 to 8 mm, drug-dilated eye pupil. For normal purposes, three methods have been suggested. In the first, spatially modulated excimer laser ablation of the cornea is used to correct the measured aberrations of the individual eye, as well as any second-order refractive error.[293–298] While such "wavefront-guided" ablation has been effective in reducing ocular aberrations consequent upon laser refractive surgery, it has yet to succeed in producing eyes which are completely aberration-free, largely because of factors such as subject-dependent variations in healing which influence the final level of aberration. The second possible method is the wearing of customized contact lenses, where the local thicknesses of the lens are manipulated to yield variations in path length which compensate for the ocular wavefront aberration.[302,303] The problem with this approach is that the lens must be stable against both rotation and decentration on the eye if aberration correction is to be maintained.[304–308] The limited control of lens movement occurring in practice means that adequate correction is difficult to achieve in normal eyes. Improved performance may, however, be given in clinically abnormal eyes with high levels of aberration, such as those of keratoconics.[307] The last suggested method, which has yet to be successfully demonstrated, is to incorporate the aberration correction in an intraocular lens: this has the theoretical advantage that the position of such a lens and its correction should be stable in the optical path.

Some of the potential benefits of aberration correction have been demonstrated by Yoon and Williams.[300] Figure 17 shows some of their results for eyes under cycloplegia. The contrast sensitivity function for either a 3- or a 6-mm pupil was measured under four conditions: white light with only spherocylindrical (second-order) refractive error corrected; with chromatic (but not monochromatic) aberration additionally removed by viewing through a narrow-band green filter; with monochromatic (but not chromatic) aberrations corrected using adaptive optics; with both monochromatic and chromatic aberrations corrected by using adaptive optics with a green filter. The retinal illuminances under the various conditions were kept constant with neutral density filters at 14.3 trolands for the 3-mm pupil and 57 trolands for the 6-mm pupil: these correspond to the lower end of the photopic range (a natural 6-mm pupil diameter is reasonably typical for this level of retinal illuminance). Yoon and Willliams[300] express their results in terms of the "visual benefit" at each spatial frequency, that is, the ratio of the contrast sensitivity under a particular condition to that achieved with white-light gratings and just the spherocylindrical refractive error corrected.

It can be seen that useful performance gains are given if both monochromatic and chromatic aberration can be corrected, particularly for the larger pupil. The benefits are less impressive (<2 at all spatial frequencies) if only monochromatic aberration is corrected, as would in practice be the case with corneal ablation, contact lens, or other corrections. It has been argued that these gains may be still smaller under real-life conditions, due to such factors as inaccurate accommodation, aberrational changes, and, at the larger natural pupil diameters occurring under mesopic and scotopic conditions, the limits to performance set by the neural parts of the visual system.[309,310] Although in principle

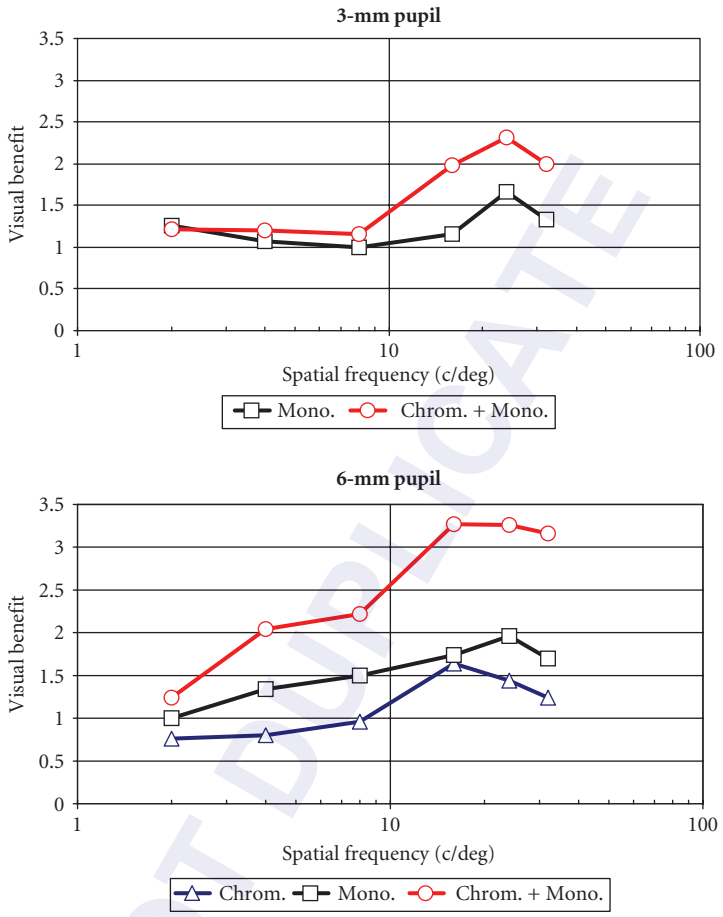

FIGURE 17 Visual benefit in contrast sensitivity for a subject with (*a*) a 3-mm pupil and (*b*) a 6-mm pupil. In all cases the eye has an optimal spherocylindrical refractive correction. The benefit is shown for (i) correction of chromatic aberration only (green light), (ii) correction of monochromatic aberration only (adaptive optics, white light), and (iii) correction of both chromatic and monochromatic aberration (adaptive optics, green light). (*Based on Yoon and Williams.*[300])

chromatic aberration of the eye can be corrected,[204,291,311–315] the required multielement lens systems are relatively bulky and decentration effects may mean that new problems arise in controlling transverse chromatic aberration.[316]

Off-Axis Image Quality

Fewer measurements have been made of off-axis image quality. Psychophysical measurements are difficult to carry out and aberration data, although available, do not yet appear to have been used to calculate MTFs. Most of the available measurements have therefore been made by the double-pass technique.[272, 317–319] As noted earlier, astigmatism usually increases with field angle, so that the PSFs

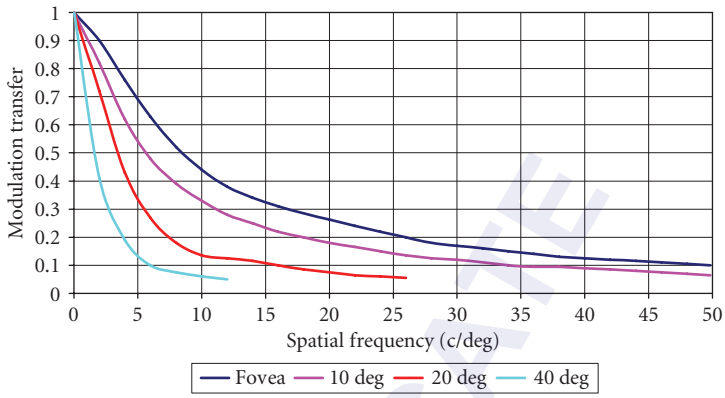

FIGURE 18 MTFs at different field angles for a 3-mm pupil. The position of focus is that corresponding to the circle of least confusion, with no correction for oblique astigmatism. (*Based on Williams et al.*[319])

normally lack rotational symmetry and different results for MTF and PTF are obtained at different orientations and levels of focus. Some representative data are shown in Fig. 18. The results shown are for the case when the circle of least confusion lies on the retina. Note that the MTF falls with field angle and that, for objects with strongly oriented structure, image quality will be improved if the appropriate focal line can be brought onto the retina, or if the peripheral astigmatism is corrected. Williams et al.[319] have suggested that the falloff in optical performance with field angle is advantageous in helping to prevent aliasing in peripheral vision.

Off-axis MTFs for different pupil diameters and field angles have been approximated as the sum of two exponential functions[318,319] or as a single exponential.[320]

Retinal Image Quality with Visual Instruments

When an object (e.g., a display screen) is observed with the naked eye, with no intervening optics, the spatial frequency spectrum of the retinal image is simply the spectrum of the object multiplied by the OTF of the eye under the observing conditions in use. The situation is, however, more complex when instruments such as microscopes, telescopes, or binoculars are used. In general, it is incorrect to assume that the OTF of the instrument-eye combination is simply the product of the individual OTFs. Instead, for any field position the aberrated wavefront from the instrument is modified by the wavefront aberrations of the eye, the two wavefronts being added together point by point across the common pupil. Under favorable circumstances where the component aberrations are of opposite sign, this *coherent coupling*[321–324] can obviously result in the summed aberration being smaller than the individual wavefront aberrations, and hence in performance being superior to that which would be expected on the basis of the product of the individual OTFs.

Two factors are of particular importance in this coupling: first, the size and positional relationship between the instrument's exit pupil and the ocular entrance pupil and, second, the state of focus of the eye. It is clear that if the entrance pupil of the eye is smaller than the exit pupil of the instrument (the two pupils coinciding) the eye pupil will constitute the aperture stop of the combined system. Movement of the smaller eye pupil within the instrument's exit pupil will sample different areas of the instrumental wavefront aberration and may therefore influence retinal image quality. Conversely, if the exit pupil is smaller than the eye pupil, the instrument's pupil provides the aperture stop and controls the aberrations. For example, with an exit pupil of 2-mm diameter or less centered on the eye pupil, the combined performance would be governed almost entirely by the instrumental aberrations,

since the eye aberrations would normally be small enough to make a negligible contribution to the combined wavefront aberration. Any focus error in the instrument or accommodation error in the observer will add an additional defocus term to the wavefront aberration. This may again be beneficial under some circumstances: for example, instrumental field curvature may be compensated for by changes in ocular accommodation (Refs. 325 and 326, and see later under "Vergence Input").

Considerations of this type mean that the MTF of any instrument alone may not be a very good guide to the visual performance that can be achieved with it.[327,328] One possible solution is to test the instrument in combination with a model eye which simulates as accurately as possible the aberrations and focus of the real eye.[329] Burton and Haig[330] explored the tolerance of the visual system to different levels and types of wavefront aberration (see also Ref. 331) and concluded that instrumental criteria based on the Strehl ratio may ultimately be more useful than MTF tests.[328] This suggestion has, however, been disputed by Mouroulis and Zhang[332] who feel that other criteria are more informative.

Chromatic aberrations are also of importance. The role of longitudinal chromatic aberration has been considered by Mouroulis and Woo,[332,323] who find that under some circumstances quite substantial amounts of instrumental LCA can be tolerated. Further studies support a tolerance of the order of 2.5 min arc for transverse chromatic aberration, with TCA having greater effects on contrast sensitivity than high-contrast resolution.[334] The general question of the design and testing of visual instruments is well reviewed in Mouroulis.[335]

1.7 DEPTH-OF-FOCUS AND ACCOMMODATION

In the foregoing it has been tacitly assumed that the eye is always optimally focused. In practice, since clear vision is required over a range of distances, exact focus may not always be achieved. It is of interest that, even if objects are at a fixed distance, small changes in focus may be required to optimize modulation transfer at different spatial frequencies in the presence of some types of aberration (e.g., spherical aberration[334–339]). With the increasing availability of aberrometers, considerable efforts are being devoted to establishing robust criteria for "best focus" (i.e., ocular refraction) from wavefront data.[340–342]

Ocular Depth-of-Focus

As in any optical system, very small changes in ocular focus have little effect on the retinal image but image quality deteriorates progressively as the error of focus increases (e.g., Fig. 9). For many practical purposes we would like to know how large the dioptric error of focus can be before image quality becomes unsatisfactory. However, this immediately raises the question of what we mean by "unsatisfactory." Atchison et al. have, for example, defined the concepts of "noticeable," "troublesome," and "objectionable" blur.[343] Noticeable blur is the defocus level at which blur of a set of letters first becomes detectable, troublesome blur is where the lack of clarity in the letters starts to be irritating, although the letters may still be readable, and objectionable blur is the level of blur which is unacceptable: the three dioptric limits of blur were found to be in the ratio of about 1.0:1.7:2.3, respectively. Ciuffreda et al. find very similar results when using minor variants of the same criteria.[344] In fact, as will be discussed below, values of depth-of-focus are strongly dependent upon the methodology and conditions used (see Ref. 345 for a recent review).

In the geometrical optical approximation, for an aberration-free eye the angular diameter of the retinal blur circle β degrees increases linearly with the error of focus ΔF diopters and pupil diameter d mm [Eq. (10)]. Thus the limits of the depth-of-focus correspond to the blur circle diameter reaching some assumed tolerable limit β_{tol} degrees: the corresponding value of ΔF_{tol} is then determined from [Eq. (10)] to yield for the total geometrical depth-of-focus DOF_{go}

$$DOF_{go} = 2\Delta F_{tol} = \frac{(34.9\beta_{tol})}{d} \text{ diopters} \tag{17}$$

The exact value obtained is, then, dependent on the assumed value of β_{tol}. If, say, a value of 2 min arc is taken, and the pupil diameter is 3 mm, the geometric DOF is about 0.4 D. Note that the geometric DOF is inversely dependent on the pupil diameter.

When the effects of physical optics are considered, for a diffraction-limited system it is conventional to use the Rayleigh criterion and to say that the limits of depth-of-focus are set by the requirement that the optical path difference between light from the center and edge of the pupil should not exceed a quarter-wavelength [one Rayleigh unit of defocus, see Eq. (9)]. For the eye, this implies that the total physical optical depth-of-focus (DOF_{po}) should correspond to 2 Rayleigh units, that is,

$$DOF_{po} = \frac{4.10^{-3}\lambda}{d^2} \text{ diopters} \tag{18}$$

where λ is in nm and d is in mm. Optimal focus will lie midway through this total depth-of-focus. Note that, unlike the geometrical approximation, [Eq. (18)] predicts that depth-of-focus will be inversely proportional to the square of the pupil diameter.

In reality, the ocular depth-of-focus depends on a variety of additional factors. From the purely optical point of view, even if the eye is diffraction-limited the rate of loss in modulation transfer with defocus is spatial-frequency-dependent (Fig. 9), so that the detectable error of focus is likely to depend upon the spatial-frequency content of the object under observation, as well as the pupil diameter. Low spatial frequencies are relatively insensitive to focus change.[94–96,346] Both monochromatic and chromatic aberrations will further modify the through-focus characteristics of the retinal image focus and, in general, will tend to increase the depth-of-focus.

Equally importantly, the perceptible focus changes will depend upon the neural characteristics of the visual system.[347] Under many conditions, the limited capabilities of the retina/brain system will mean that defocus tolerance may become larger than that expected on purely optical grounds. With larger pupils and photopic conditions, the Stiles-Crawford effect may play a role in reducing the effective pupil diameter and increasing the depth-of-focus (see "The Stiles-Crawford effect"). At low luminances, since only low spatial frequencies can be perceived[348] there is an increased tolerance to defocus blur:[349,350] a similarly increased tolerance is found in low-vision patients at photopic levels.[96]

Figure 19 shows a selection of experimental depth-of-focus data obtained by various techniques.[349,351–354] Although the exact results depend upon the methods and criteria used, it is clear that for larger pupils the visual depth-of-focus substantially exceeds the purely optical Rayleigh-limit predictions. Of more importance from the practical viewpoint, errors of focus in excess of about 0.2 to 0.5 D are likely to lead to perceptible image blur under photopic conditions with pupils of diameter 3 to 4 mm. Thus the eye must either change its focus (accommodate) for the range of distances that are of interest in everyday life (e.g., from infinity down to 0.2 m or less, corresponding to vergences from 0 to 5 D), or use some form of optical aid such as reading glasses.

It is of interest that Goss and Grosvenor[355] concluded from their review of the available clinical literature that conventional refraction is repeatable to within 0.25 D in approximately 75 percent of cases and to within 0.50 D in 95 percent of cases: errors in prescription of 0.25 D have been shown to produce dissatisfaction in many patients and a significant loss in both acuity and contrast sensitivity.[356]

The Accommodation Response

As with any focusing system, several aspects of accommodation are of interest: its range or amplitude, its speed, its stability, and its time-averaged steady-state characteristics. All of these are age-dependent and in most of what follows the behavior of young, adult (age around 15 to 35 years) eyes is described. Discussion of the response is complicated by the fact that, under normal binocular conditions of observation, accommodation (i.e., the focusing system) is intimately linked with the vergence system which ensures that the eyes converge appropriately to bring the images of any object of regard onto the foveas of the two eyes (see "Vergence Input" and "Movements of the Eyes"). Due to this linkage, accommodation can drive convergence and vice versa. The pupil usually contracts

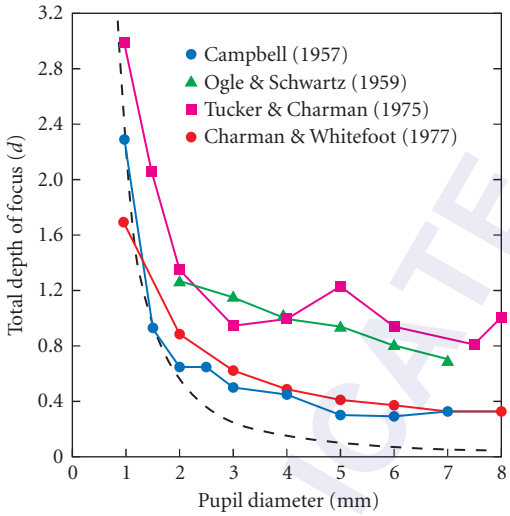

FIGURE 19 Examples of experimental measurements of photopic, total monocular depth-of-focus as a function of pupil diameter (optimal focus lies midway through the total depth-of-focus). The criteria for determining the depths-of-focus are Campbell[349]—just-perceptible blur for a small disc, one subject, white light; Ogle and Schwartz[351]—50-percent probability of resolving a 20/25 checkerboard, mean of three subjects, white light; Tucker and Charman[352]—80-percent probability of achieving 90 percent of the optimal Snellen acuity, mean of two subjects, white light; Charman and Whitefoot[353]—detectable movement of laser speckles, mean of six subjects, 633 nm. The dashed line gives the depth-of-focus based on Rayleigh's quarter-wavelength criterion for an aberration-free eye in 555-nm light.

during near vision (often called accommodative miosis), although it appears that such contraction is not directly driven by accommodation but is a comovement.[357–362] The three functions (accommodation, vergence, pupil) are sometimes known as the *near triad*. One important result of this linkage is that both the dynamic and static accommodation responses in the two eyes are always essentially the same, even when one eye is occluded.[363,364] Accommodation is driven by the responses of the cones of the retina and becomes progressively less effective as lighting levels are lowered from photopic levels through the mesopic region: at scotopic levels it is inoperative (see "Accuracy of Response").[365,366]

Although details of the neural and physiological mechanisms responsible for accommodation are beyond the scope of this section (see, e.g., Refs. 367–370 for reviews), it will be helpful to remember that, in simple terms, the crystalline lens is supported around its equator by a system (the zonule) of approximately radially oriented zonular fibres. The far ends of these fibres are anchored in the ciliary body or muscle and neighboring structures. The ciliary body effectively forms a ring surrounding the lens (Fig. 1). The lens and its thin enclosing capsule are elastic and, if the lens is free of the forces applied to it by the zonular fibres, its structure is such that its surfaces will naturally assume the relatively steep curvatures required for near vision.

Under conditions of distant viewing, the inner diameter of the ciliary ring is relatively large. This leads to a correspondingly high tension in the zonular fibers. These tensional forces when applied to

the periphery of the elastic lens and capsule cause the lens surfaces to flatten slightly, reducing the optical power to the value required for a clear distance focus. During active accommodation, the ciliary ring reduces in diameter. This relaxes the tension in the zonular fibres and allows the surfaces of the elastic lens to assume a steeper curvature and the power of the lens to increase. Attempts have been made to model this process (e.g., Refs. 371–374).

Dynamics of Response Typical records of a young subject's responses to abrupt changes in the position of an accommodation target are shown in Fig. 20. It can be seen that the change in position is followed by a short reaction time, or latency (about 0.4 s) during which the response remains unchanged. The response then progresses to its new level, the minimum response time typically being around 0.6 s.[360,375–380] Under conditions where there are plentiful cues to target distance this response usually occurs in a single sweep, but if binocular and other cues to target position apart from defocus blur are eliminated, the response may become uncertain and may initially be in the wrong direction, leading to longer response times.[381–383] The response times become larger for larger dioptric changes.[377–380]

Another way of characterizing the response dynamics is in terms of their frequency response characteristics.[384] These may be assessed by determining the gain and phase of the response obtained when a target is observed whose vergence is changing sinusoidally with time, as a function of the temporal frequency. It appears that when gain and phase are plotted as a function of the frequency both vary in an essentially linear fashion, with the cutoff frequency at which response no longer tracks the stimulus being about 2 Hz.[385] It should be stressed that these characteristics are not the output of a simple reflex system but depend upon higher-order involvement. They are strongly influenced by training and motivation,[386–389] and, with repetitive stimuli, by the knowledge that the required response has a predictable periodic form.[390] When the response to an abrupt unexpected step change in target vergence is analyzed in terms of the corresponding frequency response, much larger phase lags are given.[385,390] Thus the system does not behave linearly.[385]

The importance of perceptual factors in relation to accommodation is exemplified by studies in which the distance of the target (a Maltese cross) is kept constant but its lateral scale is varied sinusoidally.

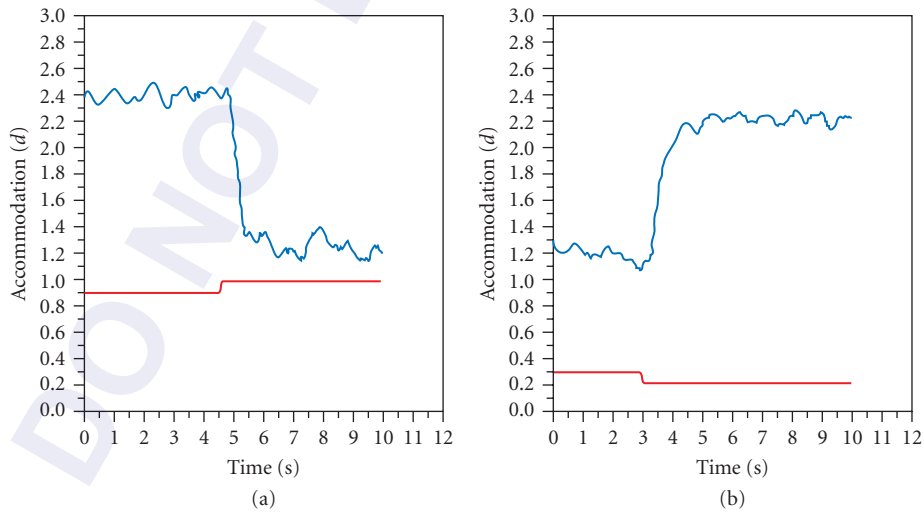

FIGURE 20 Examples of monocular accommodation responses to abrupt step changes in the vergence of an accommodation stimulus. Note the time interval (latency or reaction time) before each response starts to change and the time taken to complete the response (response time). Fluctuations in accommodation can be seen. The lower traces merely show the times at which the stimulus changes (between vergence levels of 2.38 and 1.33 D) occur.

Observers usually interpret this size variation at constant distance as a variation in distance of a target of constant linear size, and change their accommodation accordingly, even though this blurs the retinal image.[381] A similar effect is observed when binocular accommodation is stimulated by apparent depth elicited by pairs of stereograms at fixed distance.[392]

Stability of Response When a target at fixed distance is viewed with steady fixation, the accommodation response typically shows small fluctuations (~0.25 D) occurring at frequencies up to about 5 Hz (see Fig. 20): the fluctuations are correlated in the two eyes (see Refs. 393 and 394 for reviews). It appears that the lower frequency (0–0.6 Hz) components of the fluctuations may be under neural control but that higher frequencies (1.0–2.3 Hz) are related to physiological rhythms and other sources of noise.[395] The power in the low-frequency components increases as the target luminance is reduced, while that in the high-frequency components remains stable.[395,396] Similarly, the low-frequency components increase when the pupil is small and the depth-of-focus is large.[397] A peak in the frequency spectrum at frequencies of 1 to 2 Hz is often observed[398,399] and is correlated with the arterial pulse.[400,401] The fluctuations appear to have their origin in the crystalline lens and tend to increase in magnitude as the mean accommodation level increases,[397,402–404] although there is some suggestion that the higher-frequency components diminish at very high stimulus levels.[395] There is some disagreement on the exact nature of the changes with age.[395,405]

The possible role of these fluctuations in relation to accommodation control remains contentious. Some have argued that they simply represent plant noise[384,406] and are of no utility. Others suggest that they could both guide the initial direction of the response and help to maintain accurate focus,[101,399,407–411] the basic hypothesis being that if a fluctuation in one direction improves the clarity of the image the control system responds by moving the mean level of accommodation in that direction. Current opinion generally favors the concept that the high-frequency fluctuations represent plant noise and that any role in accommodation control is played by the lower-frequency components (below about 0.6 Hz), and that these would be primarily involved in the maintenance of the response at a steady level, rather than in rapid response changes.[410] In any case, under most circumstances the fluctuations appear to produce little variation in visual acuity,[412] although their effects can just be detected.[413,414]

Accuracy of Response Following pioneering work by Morgan,[415] numerous studies have shown that, rather than there being one-to-one matching between the dioptric stimulus level and the corresponding accommodation response, steady-state errors are an intrinsic part of the accommodation control system. This is true under both monocular and binocular conditions, although the magnitude of the errors differs in the two states.[415,416] These focus errors are often the major cause of foveal retinal image degradation, rather than the higher-order aberrations discussed earlier (see "Factors Affecting Retinal Image Quality"). Figure 21*a* illustrates a schematic response/stimulus curve. This emphasizes that the steady-state is usually characterized by overaccommodation (accommodative "lead") for distant objects and underaccommodation ("lag") for near objects. The range of stimulus vergence over which there is no noticeable image blur is termed the *subjective amplitude of accommodation*; it obviously includes depth-of-focus effects. The corresponding, somewhat smaller, range of actual accommodation response is the *objective amplitude of accommodation*. Note that a clinically "emmetropic" or "corrected" subject is usually left with a small myopic refractive error for objects at infinity, ocular depth-of-focus being relied upon to give clear vision under these circumstances.

The slope of the quasi-linear region of the curve depends upon the observing conditions, including target form and contrast,[100,101,417–426] ocular pupil diameter,[427–429] luminance level,[350,365,366,417] and the acuity of the observer.[418,430–433] The common feature is that, as the quality of the stimulus available to the visual system degrades, the slope of the central region of the response/stimulus curve diminishes (see, e.g., Fig. 21*b*, where the slope falls as the luminance is reduced and cone vision and visual acuity are gradually lost). To a close approximation, for any individual, as the stimulus degrades the curve pivots about the point for which stimulus and response are equal, that is, where the curve crosses the ideal one-to-one stimulus/response line. It is of interest that in many studies it appears that there is

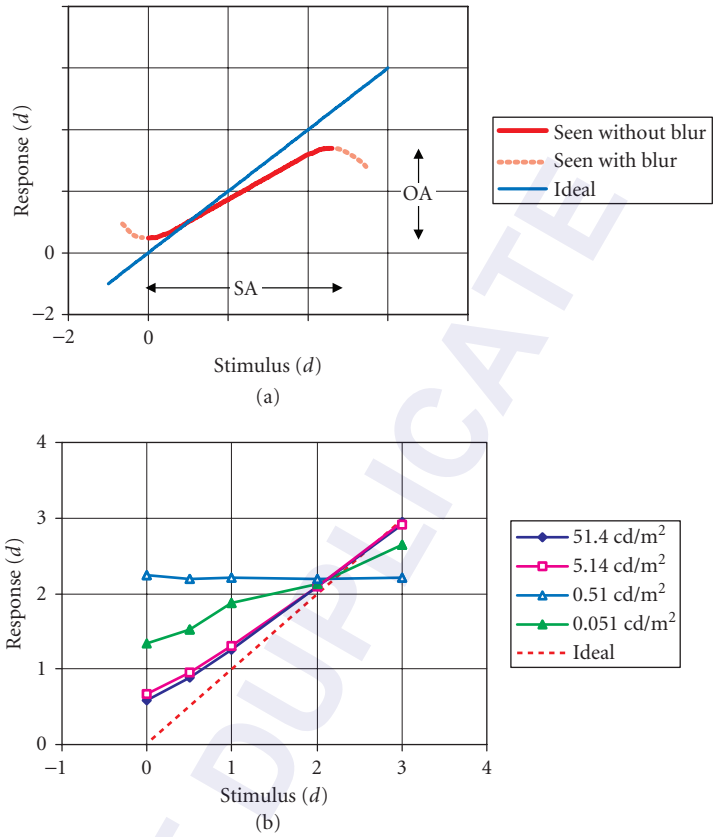

FIGURE 21 (*a*) Schematic appearance of a typical accommodation response/stimulus curve under photopic conditions. The black portion of the curve represents the range over which the target is seen without noticeable blur, the grey portions where the lags or leads exceed the ocular depth-of-focus and the target appears blurred. OA is the objective amplitude of accommodation and SA the subjective amplitude. The "ideal" line corresponds to equal response and stimulus values. (*b*) Typical changes in the lower part of the response/stimulus curve with target luminance. (*Based on Johnson*[366]) Target luminances are as indicated and the independently measured dark focus for the same subject is 2.0 D, corresponding closely to the cross-over point of the two curves.

a linear relationship between the slope of the central region of the response/stimulus curve and the eye's minimum angle of resolution under the target and observing conditions in use.[434]

The extreme case in this process is where the stimulus is either a uniform photopic field completely lacking in detail (a Ganzfeld), or the field is completely dark. In both cases no spatial information is available to the accommodation control system and the response/stimulus curve becomes completely flat. The response remains constant at the somewhat myopic value at which, under normal photopic conditions with a structured target, response equals stimulus (see, e.g., Fig. 21*b*). The refractive states under these stimulus-free, light and dark conditions are known as *empty field myopia* and *dark focus* respectively, and for any individual these states are essentially the same.[435–438]

These observations have led to the concept that this intermediate myopic level of accommodation is, in fact, the *tonic* level of accommodation (sometimes called the resting state or equilibrium level)

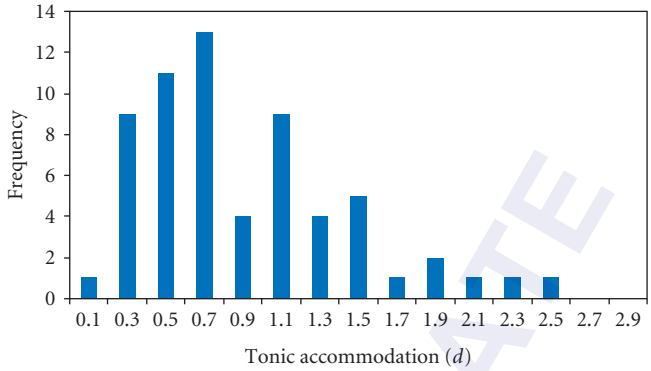

FIGURE 22 Frequency distribution of tonic accommodation as estimated by the dark focus. The values shown represent the difference in autorefractor measurements of refraction in photopic conditions and in darkness. (*After McBrien and Millodot*.[439]) The mean value of tonic accommodation and its standard deviation are 0.91 ± 0.53 D (62 young adult subjects).

to which the system returns in the absence of an adequate stimulus. This implies that accommodation must actively change from this level to view both distant and near targets. The tonic level varies somewhat with the individual (Fig. 22) but appears to have a mean value of around 1 D.[437,439]

Current theories suggest that these characteristics are dictated by the balance between the sympathetic and parasympathetic innervations to the system.[368,440–442]

Vergence Input As noted earlier, the convergence required to maintain single vision of a near object during binocular observation provides an input to the control system which supplements that due to pure defocus blur. This may be particularly useful in stimulating accommodation under conditions when the accommodation stimulus alone is relatively ineffective, for example, under mesopic night-driving conditions where the onset of *night* (*or twilight*) *myopia* is delayed when viewing is binocular.[443]

Control system models for the combined accommodation-convergence system, involving both fast feedback loops and slow adaptive elements, have been proposed by various authors (see, e.g., Refs. 368, 440, 444–446).

Application to Instrumentation From the practical point of view, it is evident that errors in accommodation and the resultant degradation in retinal image quality will be minimized if targets such as displays which are viewed by the naked eye are placed at vergences which approximately match the typical tonic levels of observers, that is, distances of about 1 m. Acuity will then be optimal[366] and the accommodative effort, and hence potential fatigue, will be minimized. With color displays, the longitudinal chromatic aberration of the eye means that more accommodative effort is required for red/black symbol combinations than for blue/black combinations. Only minor variations in response have, however, been reported when two-color isoluminant symbol/background combinations are used:[447–450] there is no evidence that viewing multichromatic targets results in a less stable response than that for black-and-white targets.[451]

It is of interest that, when focusing visual instruments, most observers set the focus so that the light leaving the eyepiece is slightly divergent, that is, they prefer to accommodate slightly when viewing the instrumental image.[452] This *instrument myopia*[453] correlates closely with the empty field myopia and dark focus of the individual observer,[435–438] suggesting that these myopic states (the anomalous myopias) have a common origin and that the instrument focus is selected to minimize

accommodative effort. This implies that fixed-focus visual instruments should not be designed to have parallel light leaving their eyepieces but that focus should be set so that the image appears at a vergence of about –1 D.[452] In any binocular instrument where the imagery is at infinity and the optical axes are arranged to be parallel, proximal (psychic) convergence and accommodation often occur, that is most young users tend to converge and accommodate slightly, leading to a loss in visual performance.[454,455] This is presumed to be due to the perception that the targets lie within the "black box" constituted by the instrument. Smith et al.[456] have discussed the various problems that arise when the focus of binocular instruments is not compatible with the angle between the eyepiece tubes.

Many visual instruments display field curvature and, provided that the vergences involved are negative, this can be at least partly compensated for by accommodation by the observer as the field is scanned.[325,326]

Age-Dependent Changes in Accommodation As the lens ages and thickens, its elastic constants change. This, in combination with other ocular changes, causes the efficiency of the accommodation system to diminish (see, e.g., Refs. 367–370 for reviews).

The most obvious change is in the amplitude of accommodation (Fig. 23). The mean subjective amplitude declines steadily from the age of about 10, to reach a small, constant level of about 1 D by the age of 50–55.[457] This residual subjective amplitude represents depth-of-focus rather than true accommodation and the corresponding objective amplitude is zero.[458] Longitudinal measurements of objective amplitudes suggest that the decline for any individual is linear with age.[459–461] Although the exact values of the constants depend upon the individual subject and the method of measurement, the amplitude changes might typically be described by an equation of the form

$$\mathrm{OA} = 12.7 - 0.27\ (\mathrm{age}) \tag{19}$$

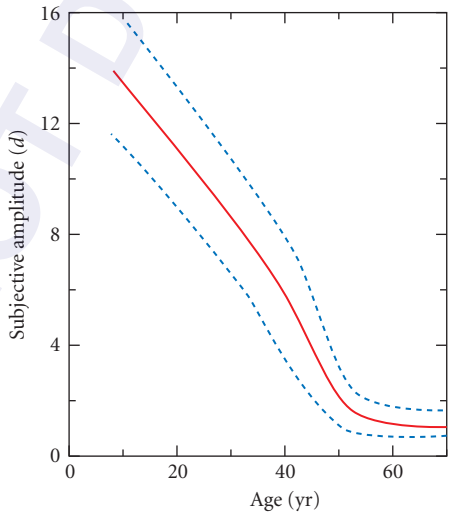

FIGURE 23 Transverse data for the changes in subjective amplitude of accommodation with age. (*After Duane.*[456]) The full curve represents the mean result, the dashed curves the limit of the range found at each age. The data refer to 4200 eyes, amplitudes being measured at the spectacle point 14 mm anterior to the cornea.

where OA is the objective amplitude in diopters and the age is in years.[461] Note that the conventional use of a value of 250 mm (i.e., an amplitude of accommodation of 4 D) for the "least distance of distinct vision" in the calculation of the nominal magnification of eyepieces and other devices is unlikely to reflect the effective magnification obtained by the individual user.

Apart from the change in amplitude, the general characteristics of the response/stimulus curve remain robust against age change up to about 35 years, when the slope starts to decline.[362,462,463] The frequency response of the accommodation system maintains its cutoff value at around 2 Hz up to the age of about 40 but at any lower frequency the gain tends to decrease and the phase lag to increase with age. There are also changes in the time constants of the responses to step changes in stimulus.[360,465–467]

The loss in amplitude becomes of practical significance when it declines sufficiently to begin to make it difficult to read at normal reading distances (around 1/3 m). It is tiring to exercise the full available amplitude of accommodation, so that problems usually start to arise at around the age of 40 when the subjective amplitude has fallen to about 5 D. These difficulties steadily increase as the amplitude declines further. Initially these problems may be eased by increases in reading distance, or the use of high light levels to increase depth-of-focus by constricting the pupil, but by the age of about 45 all emmetropes or corrected ametropes inevitably require some form of optical correction for near work. (See Chap. 14 by John S. Werner, Brooke E. Schefrin, and Arthur Bradley.)

1.8 EYE MODELS

Optical models of the eye have long been used in attempts to better understand its imaging characteristics, the development of refraction, and the optical effects of spectacle and contact lenses (see, e.g., Refs. 468–470 for reviews). More recently such models have assumed additional importance in relation to the effects of a variety of surgical procedures for modifying the optics of the eye, such as corneal refractive surgery and intraocular lens implantation.[471] They have also been used in the evaluation of retinal radiation hazards.[472,473] The earlier models were usually limited to describing behavior in the paraxial region, where rays make small angles with the axis: surfaces were assumed to be spherical. However recent years have seen the development of a succession of increasingly sophisticated paraxial and wide-angle models, incorporating such features as aspheric surfaces, gradient index optics, and accommodation.

Paraxial Models

Figure 24 shows examples of three typical types of paraxial model with spherical refracting surfaces and media characterized by single values of refractive index, the relevant parameters being given in Table 2. These paraxial models are useful for predicting the approximate dimensions of paraxial images (1 deg in the visual field corresponds to about 0.29 mm on the retina) and their changes with accommodation and correcting lenses. However, they are of more doubtful value in indicating retinal image quality on axis or in describing images in the peripheral field, and cannot predict the aberrations of real eyes.

In constructing such models, the values of the parameters are normally selected to be reasonably representative of those found in real eyes but are then adjusted slightly to make the eye emmetropic. In *schematic eyes*, the cornea and lens are each represented by a pair of surfaces (although sometimes the lens is divided into central nuclear and outer cortical regions, these being assigned different refractive indices). In the *simplified schematic eye* a single surface is used for the cornea. It can be seen in Fig. 24 that in both these eyes the two nodal points are very close together, as also are the two principal points. This has encouraged the development of *reduced eye* models, containing a single refractive surface, where each pair of nodal and principal points collapses to a single point. The cardinal points of reduced eyes are very close to those of the more complex paraxial models. Accommodation has been incorporated into several schematic eyes,[469,476–478] some of which incorporate aspheric surfaces and lenticular index gradients.

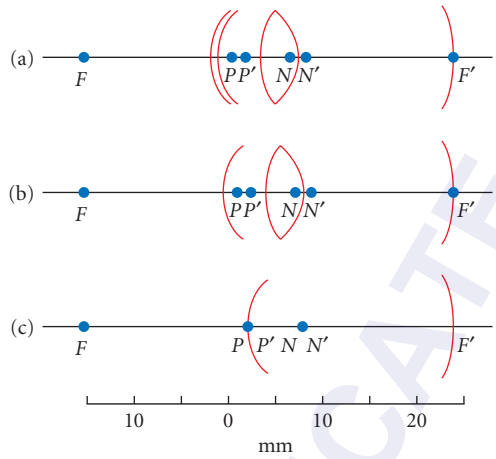

FIGURE 24 Examples of paraxial eye models of the human eye. In each case F,F'; P,P'; N,N' represent the first and second focal, principal, and nodal points respectively. (*a*) Unaccommodated schematic eye with four refracting surfaces. (*Le Grand and El Hage.*[474]) (*b*) Simplified schematic eye with three refracting surfaces. (*Emsley.*[475]) (*c*) Reduced eye with a single refracting surface. (*Emsley.*[475]) Note that progressive reduction in the number of surfaces used in the model produces only minor changes in the positions of the cardinal points.

TABLE 2 Parameters of Some Paraxial Models of the Human Eye

		Schematic Eye[474]	Simplified Schematic Eye[475]	Reduced Eye[475]
Radii of surfaces (mm)	Anterior cornea	7.80	7.80	5.55
	Posterior cornea	6.50	-	-
	Anterior lens	10.20	10.00	-
	Po st erior lens	–6.00	–6.00	-
				-
Distances from anterior cornea (mm)	Posterior cornea	0.55	-	-
	Anterior lens	3.60	3.60	-
	Posterior lens	7.60	7.20	-
	Retina	24.20	23.90	-
	1st principal point P	1.59	1.55	0
	2nd principal point P′	1.91	1.85	0
	1st nodal point N	7.20	7.06	5.55
	2nd nodal point N′	7.51	7.36	5.55
	1st focal point F	–15.09	–14.99	–16.67
	2nd focal point F′	24.20	23.90	22.22
Refractive indices	Cornea	1.3771	-	4/3
	Aqueous humour	1.3374	1.333	4/3
	Lens	1.4200	1.416	4/3
	Vitreous humour	1.3360	1.333	4/3

Wide-Angle Models

Following gradual advances in our knowledge of the form of the aspheric surfaces of the cornea and lens, together with the lenticular gradients of refractive index, several authors have produced sophisticated wide-angle eye models and have attempted to validate them by comparing the model predictions with the off-axis aberrations of real eyes.[478–487] It is of interest that a very simple reduced eye model with a single aspheric refracting surface and a suitably placed pupil (the "Indiana Eye") can simulate the chromatic, spherical, and oblique astigmatic aberrations typically found in real eyes.[488–491]

As yet, none of these models is completely successful, but progressive refinement in the experimental data should lead to corresponding improvements in the modeling of the eye's overall optical performance. Since, as discussed earlier, there are wide variations in both the on- and off-axis performance of individual eyes, it may be that "personalized" eye models, incorporating parameters as measured for the particular eye, will eventually prove to be of greatest value for use in predicting the outcomes of refractive surgery.

1.9 TWO EYES AND STEREOPSIS

Although binocular vision confers a variety of advantages, ranging from an extension of the field of view to a lowering of contrast thresholds,[492] attention here will be largely confined to its relevance for stereopsis and stereoscopic instruments. The relationship between the typical monocular and the binocular fields within which stereopsis can occur is shown in Fig. 25.

Just as the second-order wavefront errors (ocular refractions) of the two eyes are usually broadly similar, recent evidence suggests that the higher-order aberrations tend to show mirror symmetry between the two eyes:[128–132,286,493] cone directionality (SCE I) also appears to be mirror symmetric.[494] In cases where marked interocular differences in image quality occur, it is possible that the brain can make selective use of the better of the two retinal images under any particular set of observing conditions due to some form of probability summation. Certainly the apparently drastic technique of monovision contact or intraocular lens correction, in which one eye of a presbyopic observer receives a distance correction and the other a near correction, appears to work well for many patients and to yield acceptable vision over a range of distances.[495–497] It may be the studies of monocular performance that can sometimes give an unduly pessimistic view of the optical information available under binocular conditions.

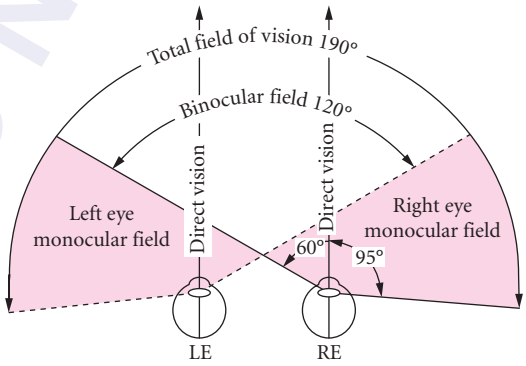

FIGURE 25 Approximate horizontal angular extents of the monocular and binocular fields of vision.

Basics of Stereoscopic Acuity

Due to the lateral separation of the eyes in the head, the apparent angular separations of objects at differing distances are slightly different for the two eyes. The resultant disparities between the two retinal images can be used by the visual system to estimate the relative distances of the objects, although absolute judgment is usually much more dependent upon such monocular cues as perspective and size constancy.

In Fig. 26*a*, suppose that the observer can just detect that the two object points A and B lie at different distances, l and $l + \delta l$, respectively. Then the corresponding stereo acuity $\delta\theta$ is given by:

$$\delta\theta = \theta_R - \theta_L = \alpha_1 - \alpha_2$$

Approximating all angles as being small [i.e., $l >> \delta l$, p, where p is the lateral separation of the nodal points of the two eyes, or interpupillary distance (IPD)], and using the binomial expansion with omission of higher-order terms in δl yields:

$$\delta\theta = \frac{p \cdot \delta l}{l^2} \qquad \text{or} \qquad \delta l = \frac{l^2 \cdot \delta\theta}{p} \tag{20}$$

where $\delta\theta$ is in radians. Thus the minimum detectable difference in object distance is directly proportional to the square of the viewing distance and inversely proportional to the separation between the eyes (see, e.g., Schor and Flom[498] for a more detailed analysis).

Figure 26*b* plots this approximate predicted value of the just-detectable difference in distance as a function of the distance l, on the assumption that $p = 65$ mm and $\delta\theta = 10$ sec arc. Note that discrimination of depth becomes very poor at distances in excess of about 500 m.

The interpupillary distance (IPD) varies somewhat between individuals and population groups.[499] Typical distributions for men and women are illustrated in Fig. 27. Values range between about 50 and 76 mm. In the real world, of course, binocular cues to distance are supplemented by

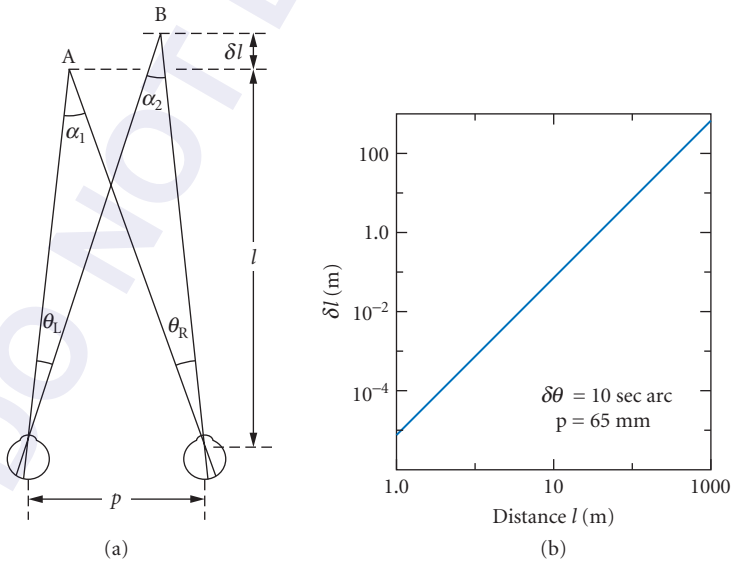

FIGURE 26 (*a*) Geometry of stereopsis. It is assumed that points A and B can just be discriminated in depth. (*b*) Theoretical just discriminable distance δl as a function of the object distance l for the assumed values of p and $\delta\theta$ indicated.

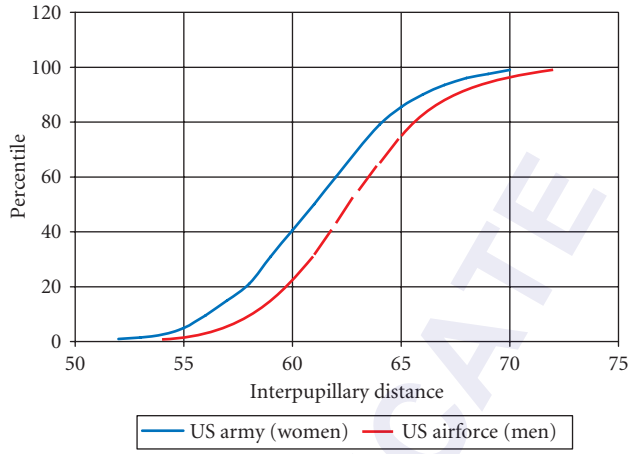

FIGURE 27 Typical cumulative frequency distributions of interpupillary distance for men and women.[499]

a variety of monocular cues such as perspective, overlay (interposition), size constancy, texture, motion parallax, etc.[500]

For any observer, $\delta\theta$ varies with such parameters as the target luminance and angular distance from fixation, and the observation time allowed (e.g., Refs. 501–504), being optimal close to fixation, with high luminance and extended observation times.[505] Values also vary with the nature of the task involved. Clinical tests of stereoacuity (e.g., Refs. 506 and 507) which are usually carried out at a distance of 40 cm and are calibrated for an assumed IPD, p, of 65 mm, typically yield normal stereoacuities of about 20 to 40 sec arc (see Fig. 28).[508] Two- or three-needle[509] or similar tests carried out at longer distances usually give rather smaller values, of around 5 to 10 sec arc.

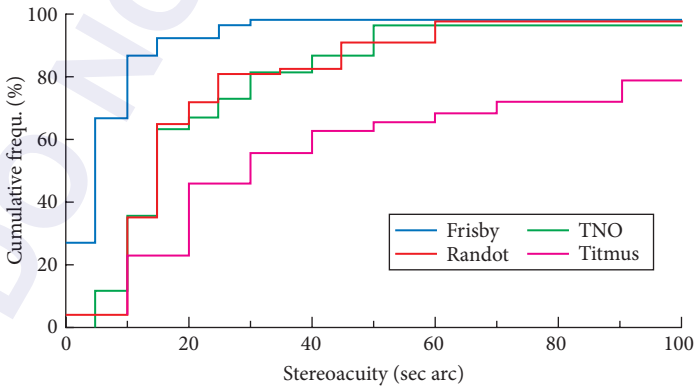

FIGURE 28 Cumulative frequency distribution for stereoscopic acuity, as measured by various clinical tests at a viewing distance of 400 mm, based on a sample of 51 adult subjects with normal binocular vision.[508]

Stereoscopic and Related Instruments

The stereoscopic acuity of natural viewing can be enhanced both by extending the effective IPD from p to Np with the aid of mirrors or prisms and by introducing transverse magnification M into the optical paths before each eye. This nominally has the effect of changing the just-detectable distance to

$$\delta l = \frac{l^2 \cdot \delta\theta}{MNp} \tag{21}$$

although in practice this improvement in performance is not always fully realized. Such changes will in general vary the spatial relationships in the perceived image, so that the object appears as having either enhanced or reduced depth in proportion to its lateral scale. If, for example, the magnification M is greater than one but N is unity, the object appears nearer but foreshortened. Simple geometrical predictions of such effects are, however, complicated by a variety of factors such as the reduced depth-of-field of magnifying system (see, e.g., Refs. 501, 510–512).

As a result of the range of IPD values encountered among different potential users (Fig. 27), it is important that adequate adjustment of IPD be provided (preferably covering 46 to 78 mm), with a scale so that users can set their own IPD. Convergence should be appropriate to the distance at which the image is viewed, that is, the angle between the visual axes should be approximately 3.7 deg for each diopter of accommodation exercised.[513]

Tolerances in Binocular Instrumentation and the Problem of Aniseikonia

In the foregoing, it has been assumed that the images available to the two eyes can be successfully fused to yield full binocular vision. Although this does not demand exact alignment of the two images, since, for example, horizontal misalignment can be compensated for by appropriate convergence or divergence between the visual axes of the user's eyes, such compensation is only possible over a limited range. Several authors have suggested instrumental tolerances appropriate to different circumstances (particularly duration of use) for vertical misalignment, convergence error, divergence error, magnification difference, and rotation in the images presented to the eyes by binocular instruments (see, e.g., Refs. 513–515 for reviews). Recommended tolerances on divergence and vertical misalignment (usually around 3 to 10 min arc) are smaller than those on convergence (around 10 to 20 min arc). These tolerances relate to the eyes: evidently if, for example, an afocal binocular instrument provides lateral magnification, the tolerances on the alignment of the tubes of the right- and left-eye optical systems will be reduced accordingly. Cyclofusion to compensate for relative image rotation is difficult to maintain on a sustained basis: any tolerance is independent of magnification.

Particular interest attaches to the possibility of a magnification difference between the two images (*aniseikonia*).[516] In practice, such magnification differences are probably most likely to occur as a result of refractive spectacle corrections in patients with markedly different refractions in the two eyes (*anisometropia*).[517] Strictly speaking we are not concerned with the retinal images as such but with the corresponding perceived images, since it is possible that these may differ in size as a result of neural as well as purely optical factors. It is conventional to express the relevant magnification differences in percentage terms. As a rough guide, magnification differences less than 1 percent usually present no problems and those greater than 5 percent often make it difficult to maintain fusion, leading to diplopia or suppression. It is the range between about 1 and 5 percent of perceived size difference where disturbing problems in spatial perception may arise but binocular vision is still possible. These may in turn lead to symptoms such as eyestrain, nausea, and headaches.

In eyes demanding a correction for both spherical and astigmatic errors, size differences may vary in different meridians, depending upon the axes of the correcting cylinders. The spatial distortions resulting from horizontal and vertical size differences are different in nature but, in general, objects may appear tilted and unpleasant instabilities in the perception of space may arise as the head or eyes turn. To give a rough estimate of the conditions under which significant aniseikonia may occur, we make use of the crude approximation that the spectacle magnification, expressed in percentage terms

is about $100aF$, where a mm is the distance of the spectacle lens from the eye and F diopter is its power. Thus the spectacle magnification is around 1.5 percent per diopter (positive for converging lenses, negative for diverging lenses). Thus, with a spectacle correction, problems may begin to arise even with quite modest degrees of anisometropia: these are reduced with contact lenses,[518] which give much lower spectacle magnification since $a \approx 0$. Even for ametropic patients without significant anisometropia, size differences will arise if one eye is corrected with, for example, corneal refractive surgery and the other with a spectacle lens. Similarly, correction of one eye with an intraocular lens following cataract surgery while the other eye remains spectacle corrected may also cause difficulties.[516] Methods for measuring aniseikonia and for its control are discussed in Refs. 516 and 517; fortunately many patients adapt to modest image size differences.

1.10 MOVEMENTS OF THE EYES

Movements of the eyes are of significance in relation to visual optics from two major points of view. First, since under photopic conditions both optical and neural performance are optimal on the visual axis, the eye movement system must be capable of rapidly directing the eyes so that the images of the detail of interest fall on the central foveas of both eyes, where visual acuity is highest (*gaze shifting* leading to *fixation*). A scene is explored through a series of such fixational movements (*saccades*) between different points within the field.[519,520] Second, the system must be capable of maintaining the images on the two foveas both when the object is fixed in space (*gaze holding*) and, ideally, when it is moving. Any lateral movement of the images with respect to the retina is likely to result in degraded visual performance, due to the limited temporal resolution of the visual system and the falloff in acuity with distance from the central fovea.

These challenges to the eye movement control system are further complicated by the fact that the eyes are mounted in what is, in general, a moving rather than a stationary head. Movements of the eyes therefore need to be linked to information derived from the vestibular system or labyrinth of the inner ear, which signals rotational and translational accelerations of the head. The compensatory *vestibulo-ocular responses* take place automatically (i.e., they are reflex movements) whereas the fixational changes required to foveate a new object are voluntary responses. Details of the subtle physiological mechanisms which have evolved to meet these requirements will be found in Refs. 521–524.

Basics

Each eye is moved in its orbit by the action of three pairs of extraocular muscles attached to the outside of the globe. Their action rotates the eye about an approximate center of rotation lying some 13.5 mm behind the cornea, although there is in fact no unique fixed point within the eye or orbit around which the eye can rotate to all possible positions that it can assume.[521,523] In particular, the "center of rotation" for vertical eye movements lies about 2 mm nearer the cornea than that for horizontal eye movements (mean values 12.3 mm and 14.9 mm, respectively).[525]

Although the two eyes can scan a field extending about 45 deg in all directions from the straight-ahead or *primary* position, in practice eye movements rarely exceed about 20 deg, fixation on more peripheral objects usually being achieved by a combination of head and eye movements.

If the angle between the two visual axes does not change during the movement, the latter is described as a *version* (or conjugate) movement. However, the lateral separation of the eyes in the head implies the need for an additional class of movements to cope with the differing convergence requirements of objects at different distances. These movements, which involve a change in the angle between the visual axes, are called *vergence* (or disjunctive) movements. Fixational changes may in general involve both types of movement, which appear to be under independent neurological control.[526]

Characteristics of the Movements

The version movements involved in bringing a new part of the visual field onto the fovea (saccades) are very rapid, being completed in around 100 ms with angular velocities often reaching more than 700 deg/s, depending upon the amplitude of the movement[527,528] (see Fig. 29*a*): the saccadic latency is about 200 ms.[529] Note that the larger saccades tend initially to be inaccurate. Interestingly, it appears that during the saccade, when the image is moving very rapidly across the retina, vision is largely, although not completely, suppressed. This saccadic suppression (or perhaps, more appropriately, saccadic attenuation) results in, for example, the retinal thresholds for brief flashes of light being elevated, the elevation commencing some 30 to 40 ms before the actual saccadic movement starts. The subject is normally unaware of this temporary impairment of vision and the exact mechanisms responsible for it remain controversial,[522,529] although an explanation may lie in the masking effect of the clear images available before and after the saccade.[530]

Smooth voluntary pursuit movements of small targets which are moving sinusoidally in a horizontal direction are accurate at temporal frequencies up to a few hertz. Their peak velocities range up to about 25 deg/s. In practice, when a small moving target is tracked, the following movements usually consist of a mixture of smooth movements and additional corrective saccades (e.g., Ref. 531; see Fig. 29*b*). With repetitive or other predictable stimuli, tracking accuracy tends to improve markedly with experience, largely through the reduction of the phase lag between target and eye.

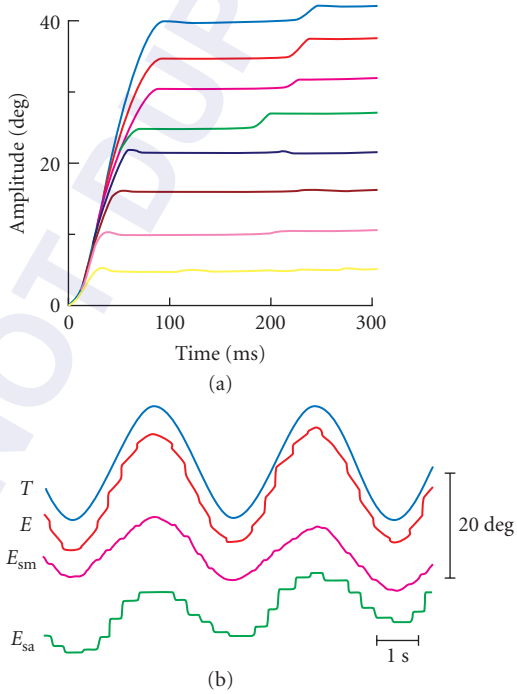

FIGURE 29 (*a*) Time course of saccades of different sizes. (*After Robinson.*[527]) The traces have been superimposed so that the beginning of each saccade occurs at time zero. (*b*) Separation of smooth (E_{sm}) and saccadic (E_{sa}) components of foveal tracking. (*After Collewijn and Tamminga.*[531]) T is the target position and E is the eye position.

When the image of a substantial part of the visual field moves uniformly across the retina, the eyes tend to rotate in a following movement to approximately stabilize the retinal image, until eventually the gaze is carried too far from the primary position, when a rapid anticompensatory flick-back occurs. Thus a continuously moving visual scene, such as the view from a train, causes a series of slow following movements and fast recoveries, so that a record of the eye movements takes a quasi-regular sawtooth form. At slow object speeds, the angular velocity of the slow phase is close to that of the field, but as the field velocity rises, greater lags in eye velocity occur, until at about 100 deg/s the following movements break down. Although this *optokinetic nystagmus* is basically a reflex, it can be influenced by any instructions given to the subject.

The angular speeds of the vergence eye movements (about 5 to 10 deg/s per degree of vergence[532]) are usually described as being much lower than those for version movements. However, studies with more natural 3-D targets suggest that it is possible for speeds to be much higher (up to 200 deg/s for 35-deg vergence movements[533,534]). Vergence movements typically follow a quasi-exponential course with a time constant of about 300 ms. Their latency is about 200 ms. Although the primary stimulus for vergence movements is disparity, that is, the difference in position of the images in the two eyes with respect to their foveas, vergence movements can also be driven by accommodation (see "The Accommodation Response") and by perceptual factors such as perspective in line drawings.[535]

The vergence system is primarily designed to cope with the differences in the directions of the visual axes of the two eyes which arise from their horizontal separation in the head. However, some vertical vergence movements and relative torsional movements about the approximate direction of the visual axis can also occur. Such fusional movements can compensate for corresponding small relative angular misalignments in the eyes or in the optical systems of binocular or biocular instruments. The maximum amplitude of these movements is normally small (about 1 deg for vertical movements and a few degrees for cyclofusional movements, see, e.g., Ref. 336). They also take longer to complete than horizontal vergence movements (some 8 to 10 s as compared to about 1 s). Due to the limited effectiveness of vertical and torsional vergence movements, it is typically recommended that in instruments where the two eyes view an image through separate optical systems a 10 min arc tolerance be set for vertical misalignment and a 30 min arc limit be set for rotational differences between the two images (see "Tolerances in Binocular Instrumentation").

Stability of Fixation

When an observer attempts to maintain fixation on a stationary target, it is found that the eyes are not steady, but that a variety of small-amplitude movements occur. These *miniature eye movements* can be broken down into three basic components: tremor, drift, and microsaccades. The frequency spectrum of the tremor falls essentially linearly with the logarithm of the frequency above 10 Hz, extending to about 200 Hz.[537] The amplitude is small (probably less than the angle subtended at the nodal point of the eye by the diameter of the smallest foveal cones, i.e., about 24 sec arc). Drift movements are much larger and slower, with amplitudes of about 2 to 5 min arc at velocities around 4 min/s.[538] The errors in fixation brought about by the slow drifts (which are usually disassociated in the two eyes) are corrected microsaccades: these are correlated in the two eyes. There are large intersubject differences in both mean microsaccade amplitude (from 1 to 23 min arc) and intersaccadic interval (from about 300 ms to 5 s),[539] which probably reflect voluntary control under experimental conditions.

The overall stability of fixation can be illustrated by considering the statistical variation in the point of fixation (Fig. 30).[540,541] For most of the time the point of regard lies within a few minutes of arc of the target. Although it has been suggested that these small eye movements could have some role in reducing potential aliasing problems,[542] experiments measuring contrast sensitivity for briefly presented interference fringes on the retina suggest that this is unlikely.[543] Interestingly, when a suitable optical arrangement is used to counteract these small changes in fixation and stabilize the image on the retina, the visual image may fragment or even disappear completely,[538] so that these small movements are important for normal visual perception. Fincham's suggestion[381] that small eye movements are of importance to the ability of the eye to respond correctly to a change in accommodation stimulus has never been properly explored.

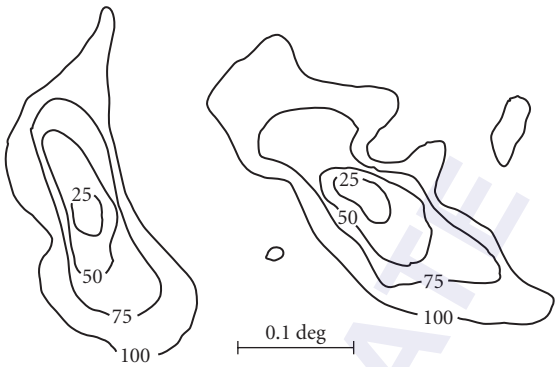

FIGURE 30 Stability of fixation for two subjects. The contours define areas within which the point of fixation was to be found for 25, 50, 75, and 100 percent of the time. (*After Bennet-Clark.*[541])

1.11 CONCLUSION

Recent years have seen considerable advances in our understanding of the aberrations of the eye and their dependence on factors such as pupil size, age, and field angle. The refractive index distribution of the lens remains to be fully elucidated, although substantial progress has been made. In general, it appears that the optical characteristics of the eye are such that the natural retinal image quality under different conditions of lighting, field, and age is well matched to the corresponding needs of the neural parts of the visual system. Those aberrations which are present may well be useful in such roles as guidance of the accommodation response, expansion of the depth-of-focus, and control of aliasing.

2.1 GLOSSARY

A	amplitude
a	interpupillary distance
A_p	effective area of the entrance pupil
C	contrast
c_o	maximum concentration of photopigment
d	horizontal disparity
d_e	distance from the image plane to the exit pupil of an optical system
d_θ	average disparity between two points and the convergence point
$E(\lambda)$	photopic spectral illuminance distribution
$E_e(\lambda)$	spectral irradiance distribution
f	spatial frequency of a sinusoid
I_o	half-bleaching constant
J_o	maximum photocurrent
l	length of outer segment
$L(\lambda)$	photopic spectral luminance distribution
$L_e(\lambda)$	spectral radiance distribution
m	magnificaton of the exit pupil relative to the actual pupil
N	total effective photons absorbed per second
n_r	index of refraction of the media where the image plane is located
$n(\lambda)$	spectral photon-flux irradiance distribution
p	proportion of unbleached photopigment
t_o	time constant of photopigment regeneration
$t(\lambda)$	transmittance function of the ocular media
$V(\lambda)$	standard photopic spectral sensitivity function of the human visual system

$\alpha(\lambda)$	absorptance spectrum
ΔC	contrast increment or decrement
Δf	frequency increment or decrement
Δz	distance between any pair of points in the depth dimension
ε	retinal eccentricity
$\varepsilon(\lambda)$	extinction spectrum
θ	convergence angle of the eyes
θ	orientation of a sinusoid
κ	collection area, or aperture, of a photoreceptor
λ	wavelength of the light in a vacuum
ξ	isomerization efficiency
Σ	covariance matrix for a gaussian noise process
σ_o	half-saturation constant
τ	time interval
τ_{opt}	optimum time interval
$\Phi(\cdot)$	cumulative standard normal probability function
ϕ	phase of a sinusoid

2.2 INTRODUCTION

Physiological optics concerns the study of (1) how images are formed in biological eyes, (2) how those images are processed in the visual parts of the nervous system, and (3) how the properties of image formation and neural processing manifest themselves in the perceptual performance of the organism. The previous chapter reviewed image formation; this chapter briefly describes the neural processing of visual information in the early levels of the human visual system, and summarizes, somewhat more extensively, what is known about human visual performance.

An enormous amount of information about the physical environment is contained in the light reaching the cornea of the eye. This information is critical for many of the tasks the human observer must perform, including identification of objects and materials, determination of the three-dimensional structure of the environment, navigation through the environment, prediction of object trajectories, manipulation of objects, and communication with other individuals. The performance of a human observer in a given visual task is limited by the amount of information available in the light at the cornea and by the amount (and type) of information encoded and transmitted by the successive stages of visual processing. This chapter presents a concise description of visual performance in a number of fundamental visual tasks. It also presents a concise description of the physiological and psychological factors believed to underlie performance in those tasks. Two major criteria governed the selection of the material to be presented. First, we attempted to focus on quantitative data and theories that should prove useful for developing rigorous models or characterizations of visual performance. Second, we attempted to focus on data and theories that have a firm empirical basis, including at least some knowledge of the underlying biological mechanisms.

2.3 OPTICS, ANATOMY, PHYSIOLOGY OF THE VISUAL SYSTEM

Image Formation

The processing of visual information begins with the optics of the eye, which consists of three major components: the cornea, pupil, and lens. The optical components are designed to form a sharp image at the layer of the photoreceptors in the retina. Neil Charman (Chap. 1) discusses many of

the details concerning how these optical components affect image quality. We briefly describe a few of the most useful formulas and methods for computing the approximate size, location, quality, and intensity of images formed at the photoreceptors. Our aim is to provide descriptions of image formation that might prove useful for developing models or characterizations of performance in perceptual tasks.

The sizes and locations of retinal images can be found by projecting points on the objects along straight lines through the image (posterior) nodal point until they intersect the retinal surface. The intersections with the retinal surface give the image locations corresponding to the points on the objects. The angles between pairs of projection lines are *visual angles*. Image locations are usually described in terms of the visual angles that projection lines make with respect to a reference projection line (the *visual axis*), which passes through the nodal point and the center of the fovea. The radial visual angle between a projection line from an object and the visual axis is the object's *eccentricity*. Image sizes are often described by the visual angles between key points on the object. For purposes of computing the size and location of images, it is usually sufficient to use a simplified model of the eye's optics, such as the *reduced eye*, which consists of a single spherical refracting surface (radius of curvature = 5.5 mm) and a retinal surface located 16.7 mm behind the nodal point (see Fig. 2*c*, Chap. 1).

A general method for computing the quality of retinal images is by convolution with a point-spread function $h(x, y)$. Specifically, if $o(x, y)$ is the luminance (or radiance) of the object, and $i(x, y)$ is the image illuminance (or irradiance), then

$$i(x,y) = o(x,y) ** h(x,y) \tag{1}$$

where ** represents the two-dimensional convolution operator. The shape of the point-spread function varies with wavelength and with retinal location. The precise way to deal with wavelength is to perform a separate convolution for each wavelength in the spectral luminance distribution of the object. In practice, it often suffices to convolve with a single point-spread function, which is the weighted average, across wavelength, of the monochromatic point-spread functions, where the weights are given by the shape of the spectral luminance distribution. To deal with retinal location, one can make use of the fact that the human point-spread function changes only gradually with retinal eccentricity out to about 20 deg;[1] thus, a large proportion of the visual field can be divided into a few annular regions, each with a different point-spread function.

Calculation of the point-spread function is normally accomplished by finding the transfer function, $H(u, v)$.[2,3] (The point-spread function can be obtained, if desired, by an inverse Fourier transform.) The transfer function is given by the autocorrelation of the generalized pupil function followed by normalization to a peak value of 1.0:

$$T(u,v) = p(x,y)e^{iW(x,y,\lambda)} \otimes\otimes p(x,y)e^{-iW(x,y,\lambda)}\Big|_{\mathbf{x}=(\lambda d_e/mn_r)u, y=(\lambda d_e/mn_r)v} \tag{2}$$

$$H(u,v) = \frac{T(u,v)}{T(0,0)} \tag{3}$$

where λ is the wavelength of the light in a vacuum, n_r is the index of refraction of the media where the image plane is located, d_e is the distance from the image plane to the exit pupil of the optical system, and m is the magnification of the exit pupil relative to the actual pupil. The generalized pupil function is the product of the simple pupil function, $p(x, y)$ (transmittance as a function of position within the actual pupil), and the aberration function, $e^{iW(x,t,\lambda)}$. The exit pupil is the apparent pupil, when viewed from the image plane. The size of and distance to the exit pupil can be found by ray-tracing a schematic eye. For the Le Grand eye, the relevant parameters are approximately as follows: $m = 1.03$, $d_e = 20.5$ mm, and $n = 1.336$. Average values of the monochromatic and chromatic aberrations are available (see Chap. 1) and can be used as estimates of $W(x, y, \lambda)$.

Equation (3) can be used to compute approximate point-spread functions (and hence image quality) for many stimulus conditions. However, for some conditions, direct measurements (or psychophysical measurements) of the point-spread function are also available (see Chap. 1), and are easier to deal with. For broadband (white) light and a well-accommodated eye, the axial point-spread functions directly measured by Campbell and Gubisch[4] are representative. A useful set

of monochromatic point-spread functions was measured at various eccentricities by Navarro et al.[1] These point-spread functions can be used directly in Eq. (1) to compute approximate image quality.

The approximate retinal irradiance for extended objects is given by the following formula:

$$E_e(\lambda) = \frac{A_p}{278.3} L_e(\lambda) t(\lambda) \tag{4}$$

where $E_e(\lambda)$ is the retinal spectral irradiance distribution (watts $\cdot$ m^{-2} $\cdot$ nm^{-1}), $L_e(\lambda)$ is the spectral radiance distribution of the object (watts $\cdot$ m^{-2} $\cdot$ sr^{-1} $\cdot$ nm^{-1}), $t(\lambda)$ is the transmittance of the ocular media (see Chap. 1), and A_p is the effective area of the entrance pupil (mm^2). [Note, $A_p = \iint p(x/m', y/m')\, dx\, dy$, where m' is magnification of the entrance pupil relative to the actual pupil; the entrance pupil is the apparent size of the pupil when viewed from outside the eye.]

Photopic retinal illuminance, $E(\lambda)$ (candelas $\cdot$ nm^{-1}), is computed by an equivalent formula where the spectral radiance distribution, $L_e(\lambda)$, is replaced by the spectral luminance distribution, $L(\lambda)$ (candelas $\cdot$ m^{-2} $\cdot$ nm^{-1}), defined by

$$L(\lambda) = 683\, V(\lambda) L_e(\lambda) \tag{5}$$

where $V(\lambda)$ is the standard photopic spectral sensitivity function of the human visual system.[5]

In theoretical calculations, it is often useful to express light levels in terms of photon flux rather than in terms of watts. The photon-flux irradiance on the retina, $n(\lambda)$ (quanta $\cdot$ sec^{-1} $\cdot$ deg^{-2} $\cdot$ nm^{-1}) is computed by multiplying the retinal irradiance, $E_e(\lambda)$, by 8.4801×10^{-8} which converts m^2 to deg^2 (based upon the *reduced eye*), and by λ/ch which converts watts into quanta/sec (where c is the speed of light in a vacuum, and h is Planck's constant). Thus,

$$n(\lambda) = 1.53 \times 10^6 A_p L_e(\lambda) t(\lambda) \lambda \tag{6}$$

and, by substitution of Eq. (5) into Eq. (6),

$$n(\lambda) = 2.24 \times 10^3 A_p \frac{L(\lambda)}{V(\lambda)} t(\lambda) \lambda \tag{7}$$

Most light-measuring devices report radiance, $L_e(\lambda)$, or luminance, $L(\lambda)$; Eqs. (6) and (7) allow conversion to retinal photon-flux irradiance, $n(\lambda)$. For more details on the calculation of retinal intensity, see Wyszecki and Stiles.[5]

Image Sampling by the Photoreceptors

The image formed at the receptor layer is described by a four-dimensional function $n(x, y, t, \lambda)$, which gives the mean photon-flux irradiance (quanta $\cdot$ sec^{-1} $\cdot$ deg^2 $\cdot$ nm^{-1}) as a function of space (x, y), time (t), and wavelength (λ). This four-dimensional function also describes the photon noise in the image. Specifically, photon noise is adequately described as an inhomogeneous Poisson process; thus, the variance in the number of photons incident in a given interval of space, time, and wavelength is equal to the mean number of photons incident in that same interval.

The photoreceptors encode the (noisy) retinal image into a discrete representation in space and wavelength, and a more continuous representation in time. The image sampling process is a crucial step in vision that can, and often does, result in significant information loss. The losses occur because physical and physiological constraints make it impossible to sample all four dimensions with sufficiently high resolution.

As shown in the schematic diagram in Fig. 1, there are two major types of photoreceptors: rods and cones. They play very different functional roles in vision; rods subserve vision at low light levels and cones at high light levels. There are three types of cones, each with a different spectral sensitivity (which is the result of having different photopigments in the outer segment). The "long" (L), "middle" (M), and "short" (S) wavelength cones have peak spectral sensitivities at wavelengths of approximately 570, 540, and 440 nm, respectively. Information about the spectral wavelength distribution of

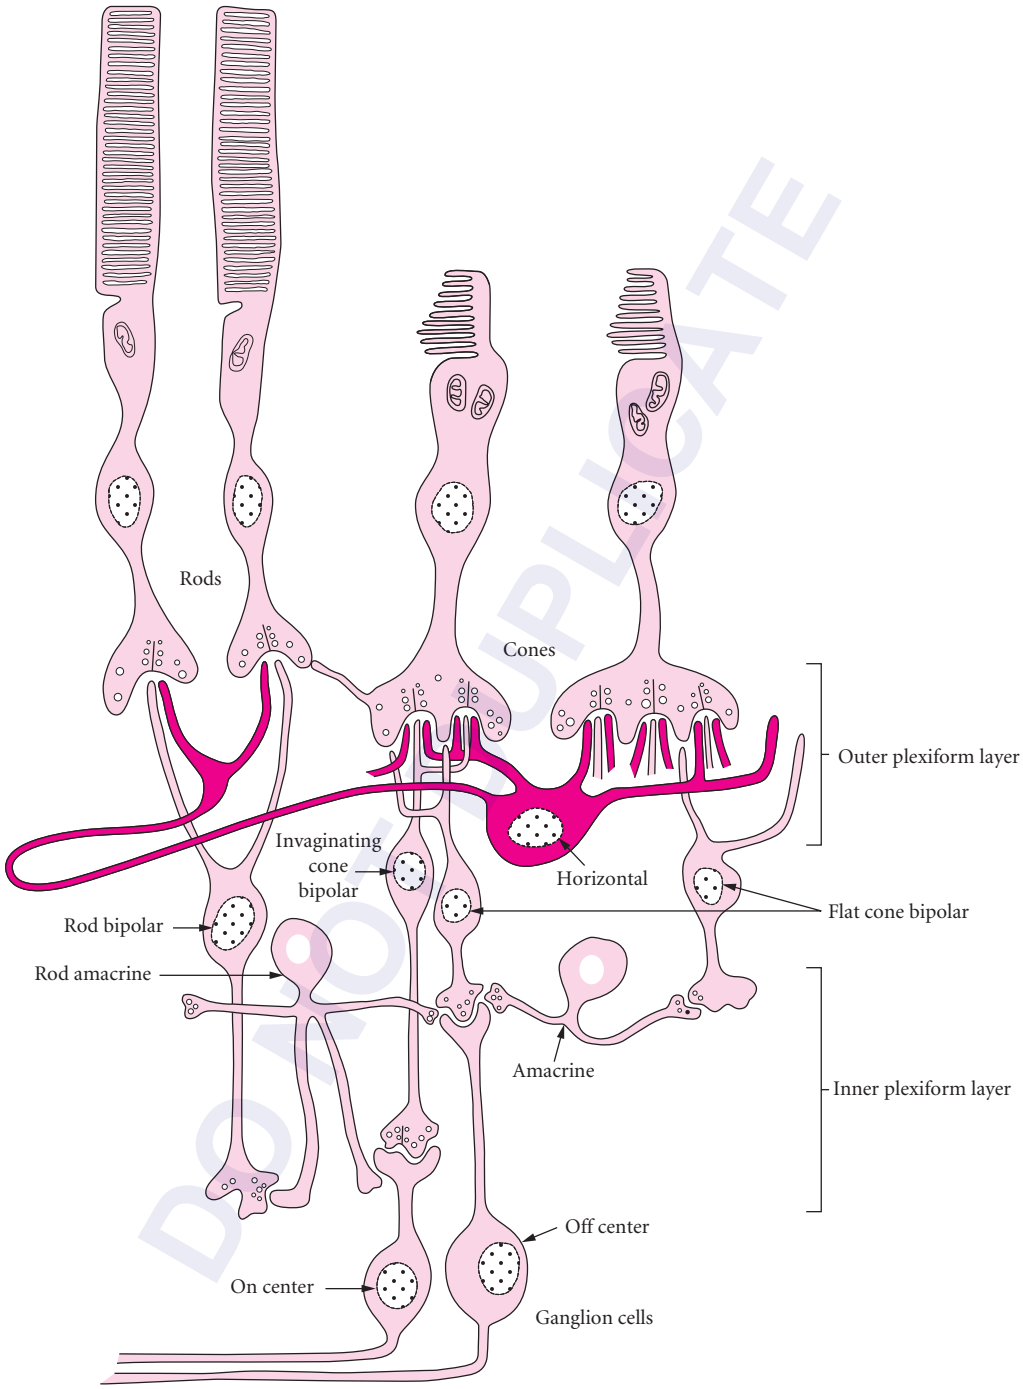

FIGURE 1 Schematic diagram of the retinal neurons and their major synaptic connections. Note that rods, rod bipolar cells, and rod amacrine cells are absent in the fovea. (*From Ref. 263.*)

the light falling on the retina is encoded by the relative activities of the L, M, and S cones. All rods have the same spectral sensitivity (and the same photopigment), peaking at about 500 nm.

The quality of spatial, temporal, and wavelength information encoded by the photoreceptors depends upon: (1) the spatial distribution of the photoreceptors across the retina, (2) the efficiency with which individual photoreceptors absorb light at different wavelengths (the absorptance spectrum), (3) the area over which the individual photoreceptors collect light (the receptor aperture), and (4) the length of time over which the individual photoreceptors integrate light.

The spatial distribution of cones and rods is highly nonuniform. Figure 2*a* shows the typical density distribution of rod and cone photoreceptors across the retina (although there are individual differences; e.g., see Ref. 6). Cone density decreases precipitously with eccentricity; rods are absent in the fovea and reach a peak density at 20 deg. If the receptor lattice were perfectly regular, the highest unambiguously resolvable spatial frequency (the Nyquist limit), would be half the linear density (in cells · deg^{-1}). Under normal viewing conditions, the Nyquist limit does not affect vision in the fovea because the eye's optics eliminate spatial frequencies at and above the limit. However, the

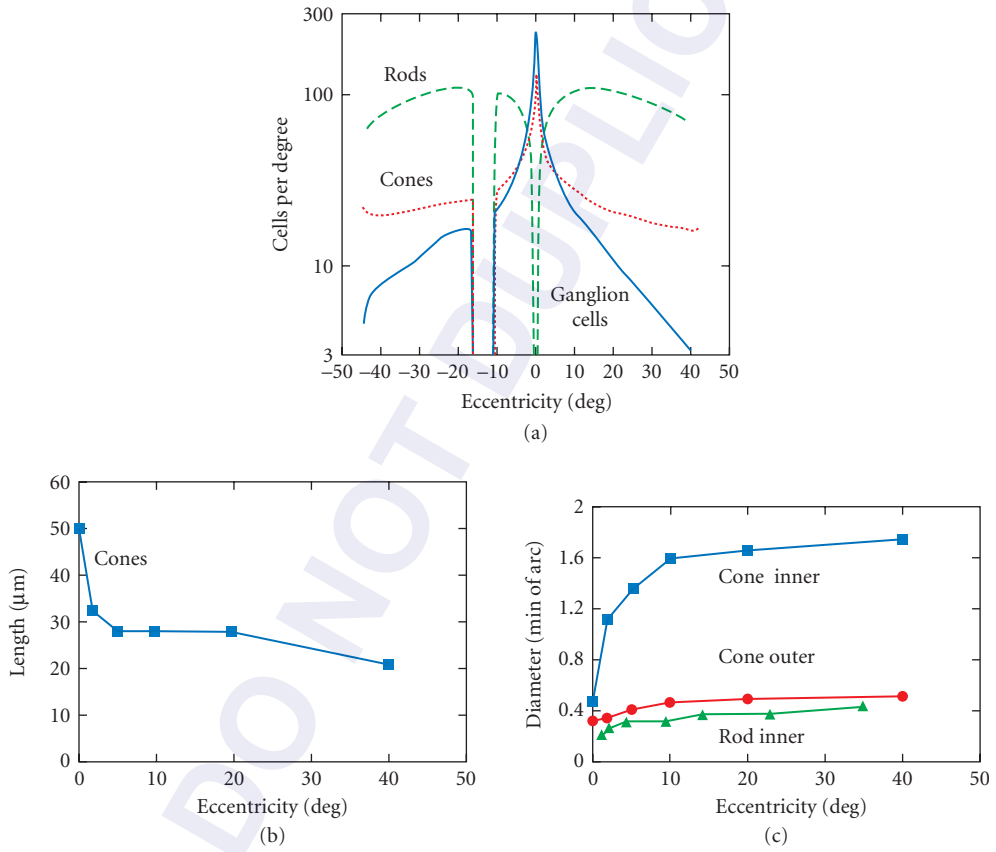

FIGURE 2 (*a*) Linear density of cones, rods, and ganglion cells as a function of eccentricity in the human retina. (*The data were modified from Refs. 6 and 32.*) Conversion from cells/mm^2 to cells/deg^2 was computed assuming a posterior nodal point 16.68 mm from the retina, and a retinal radius of curvature of 12.1 mm. Conversion to cells/deg was obtained by taking the square root of areal density. Ganglion cell density in the central 10 deg was derived assuming a 3:1 ratio of ganglion cells to cones in the fovea.[32] (*b*) Human cone outer segment length. (*Modified from Ref. 125.*) (*c*) Human cone inner segment, cone outer segment, and rod diameter as a function of eccentricity. (*Modified from Ref. 125.*)

presentation of interference fringes (which avoid degradation by the eye's optics) yields visible spatial aliasing for spatial frequencies above the Nyquist limit.[7–9]

The densities and retinal distributions of the three cone types are quite different. The S cones form a rather regular lattice comprising less the 2 percent of cones in the central fovea and somewhat less than 10 percent of the cones elsewhere;[10–12] they may be absent in the central 20′ to 25′ of the fovea.[13] It is much more difficult to distinguish individual L and M cones anatomically, so their densities and distributions are less certain. Psychophysical evidence indicates that the ratio of L to M cones is approximately 2:1,[14,15] but the available physiological data in monkey suggest a ratio closer to 1:1.[16,17]

From the Beer-Lambert law, the absorptance spectrum of a receptor depends upon the concentration of the photopigment, $c_o p$, in the receptor outer segment, the length of the outer segment, l, and the extinction spectrum, $\varepsilon(\lambda)$, of the photopigment,

$$\alpha(\lambda) = 1 - 10^{-lc_o p\varepsilon(\lambda)} \tag{8}$$

where c_o is the concentration of photopigment in the dark-adapted eye and p is proportion of unbleached photopigment. The specific absorptance spectra for the different classes of receptor are described in Chap. 11 by Andrew Stockman and David H. Brainard. At the peak wavelength, the photoreceptors absorb approximately 50 percent of the incident photons (although there are some variations with eccentricity).

Because of photopigment bleaching and regeneration processes within the photoreceptor, the absorption spectra of the photopigments change depending upon the history of photon absorptions. For example, prolonged exposure to high intensities depletes a significant fraction of the available photopigment, reducing the overall optical density. Reflection densitometry measurements[18–20] have shown, to first approximation, that the proportion p of available photopigment at a given point in time is described by a first-order differential equation:

$$\frac{dp}{dt} = \frac{n(\lambda)\xi(1 - 10^{-lc_o\varepsilon(\lambda)p})}{lc_o} + \frac{1-p}{t_o} \tag{9}$$

where $n(\lambda)$ is the photon-flux irradiance distribution (quanta $\cdot$ sec^{-1} $\cdot$ deg^{-2} $\cdot$ nm^{-1}), t_o is the exponential time constant of regeneration, and ξ is the isomerization efficiency (which is believed to be near 1.0). For broadband light, Eq. (9) simplifies and can be expressed in terms of retinal illumination:[19]

$$\frac{dp}{dt} = -\frac{Ip}{Q_e} + \frac{(1-p)}{t_o} \tag{10}$$

where I is the retinal illumination (in trolands*) and Q_e is the energy of a flash (in troland $\cdot$ sec) required to reduce the proportion of unbleached photopigment to $1/e$. For the cone photopigments, the time constant of regeneration is approximately 120 sec, and Q_e (for broadband light) is approximately 2.4×10^6 troland $\cdot$ sec. For rods, the time constant of regeneration is approximately 360 sec, and Q_e is approximately 1.0×10^7 scotopic troland $\cdot$ sec. Equation (10) implies that the steady-state proportion of available photopigment is approximately

$$p(I) = \frac{I_o}{I_o + I} \tag{11}$$

where $I_o = Q_e/t_o$. (I_o is known as the *half-bleaching constant*.) Equation (11) is useful when computing photon absorptions at high ambient light levels; however, photopigment bleaching is not significant at low to moderate light levels. Equation (7) also implies that bleaching and regeneration can produce changes in the shapes of the absorptance spectra (see Chap. 10).

The lengths of the photoreceptor outer segments (and hence their absorptances) change with eccentricity. Figure 2*b* shows that the cone outer segments are longer in the fovea. Rod outer segments are approximately constant in length. If the dark-adapted photopigment concentration, c_o, is constant

*The troland is defined to be the retinal illumination produced by viewing a surface with a luminance of 1 cd/m^2 through a pupil with an area of 1 mm^2.

in a given class of photoreceptor (which is likely), then increasing outer segment length increases the amount of light collected by the receptor (which increases signal-to-noise ratio).

The light collection area of the cones is believed to be approximately 70 to 90 percent of the cross-sectional area of the inner segment at its widest point (see Fig. 1), although direct measurements are not available (see Refs. 21 and 22). The collection area of the rod receptors is equal to the cross-sectional area of the inner and outer segments (which is the same). Figure 2*c* plots inner-segment diameter as a function of eccentricity for cones and rods. As can be seen, the cone aperture increases with eccentricity, while the rod aperture is fairly constant. Increasing the cone aperture increases the light collected (which increases signal-to-noise ratio), but slightly reduces contrast sensitivity at high spatial frequencies (see later).

The data and formulas above [Eqs. (6) to (10)] can be used to compute (approximately) the total effective photons absorbed per second, N, in any receptor, at any eccentricity:

$$N = \int \kappa \xi \alpha(\lambda) n(\lambda) d\lambda \tag{12}$$

where κ is the collection area, or aperture, of the receptor (in deg^2).

Photons entering through the pupillary center have a greater chance of being absorbed in the cones than photons entering through the pupillary margins. This phenomenon, known as the Stiles-Crawford effect, can be included in the above calculations by modifying the pupil function [Eqs. (3) and (4); also see Chaps. 1 and 8]. We also note that the cones are oriented toward the exit pupil.

The temporal response properties of photoreceptors are more difficult to measure than their spatial integration properties. Figure 3 shows some physiological measurements of the photocurrent

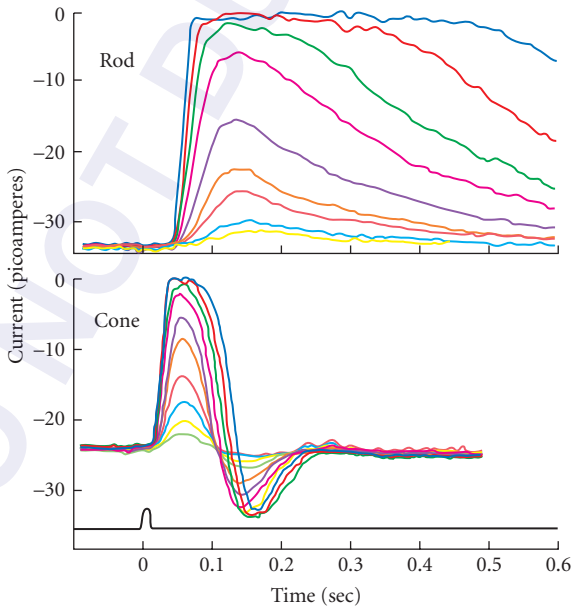

FIGURE 3 Photocurrent responses of macaque rod and cone photoreceptors to flashes of light. Each trace represents the response to a different intensity level. The flash intensities were varied by factors of two. (*From Ref. 23. Copyright © 1989 by Scientific American, Inc. All rights reserved.*)

responses of primate (macaque) rods and cones at low and moderate light levels.[23] Rods integrate photons over a substantially longer duration than cones do. In addition, rods produce reliable responses to single photon absorptions, but cones do not.

Photoreceptors, like all neurons, have a limited dynamic range. Direct recordings from receptors in macaque have shown that the peak responses of photoreceptors to brief flashes of light are adequately described by either a modified Michaelis-Menton function

$$f(z)=\frac{J_o z^n}{z^n+\sigma_o^n} \tag{13}$$

or an exponential function

$$f(z)=J_o(1-2^{-z^n/\sigma_o^n}) \tag{14}$$

where J_o is the maximum photocurrent, σ_o is the half-saturation constant (the value of z that produces exactly half the maximum response), and n is an exponent that has a value near 1.0.[17,24,25] As the above equations imply, the photoreceptors respond approximately linearly to transient intensity changes at low to moderate light levels, but respond nonlinearly (ultimately reaching saturation) at higher light levels. Recent electroretinogram (ERG) measurements suggest that the flash response of human photoreceptors is similar to those of the macaque.[26]

The nonlinear response saturation suggests that the receptors should not be able to encode high image intensities accurately (because any two intensities that saturate receptor response will be indistinguishable). However, the cones avoid saturation effects under many circumstances by adjusting their gain (σ_o) depending upon the ambient light level; the rods do not adjust their gain nearly as much. The gain adjustment is accomplished in a few ways. Photopigment depletion (see earlier) allows multiplicative gain changes, but only operates at very high ambient light levels. Faster-acting mechanisms in the phototransduction sequence are effective at moderate to high light levels.[27] At this time, there remains some uncertainty about how much gain adjustment (adaptation) occurs within the cones.[17,24,28]

Retinal Processing

The information encoded by the photoreceptors is processed by several layers of neurons in the retina. The major classes of retinal neuron in the primate (human) visual system and their typical interconnections are illustrated schematically in Fig. 1. Although the retina has been studied more extensively than any other part of the nervous system, its structure and function are complicated and not yet fully understood. The available evidence suggests that the primate retina is divided into three partially overlapping neural pathways: a *rod pathway*, a *cone parvo pathway*, and a *cone magno pathway* (for reviews see Refs. 29–31). These pathways, illustrated in Fig. 4, carry most of the information utilized in high-level visual processing tasks. There are other, smaller pathways (which will not be described here) that are involved in functions such as control of the pupil reflex, accommodation, and eye movements. Although Fig. 4 is based upon the available evidence, it should be kept in mind that there remains considerable uncertainty about some of the connections.

Retinal Anatomy As indicated in Fig. 4, the photoreceptors (R, C) form electrical synapses (gap-junctions) with each other, and chemical synapses with *horizontal* cells (H) and *bipolar cells* (RB, MB+, MB−, DB+, DB−). The electrical connections between receptors are noninverting* and hence produce simple spatial and temporal summation. The dendritic processes and the axon-terminal processes of the horizontal cells provide spatially extended, negative-feedback connections from cones onto cones and from rods onto rods, respectively. It is likely that the horizontal cells play an important role in creating the surround response of ganglion cells. Rod responses probably do not influence cone responses (or vice versa) via the horizontal cells.

*By *noninverting* we mean that changes in the response of the presynaptic neuron, in a given direction, produce changes in the response of the postsynaptic neuron in the same direction.

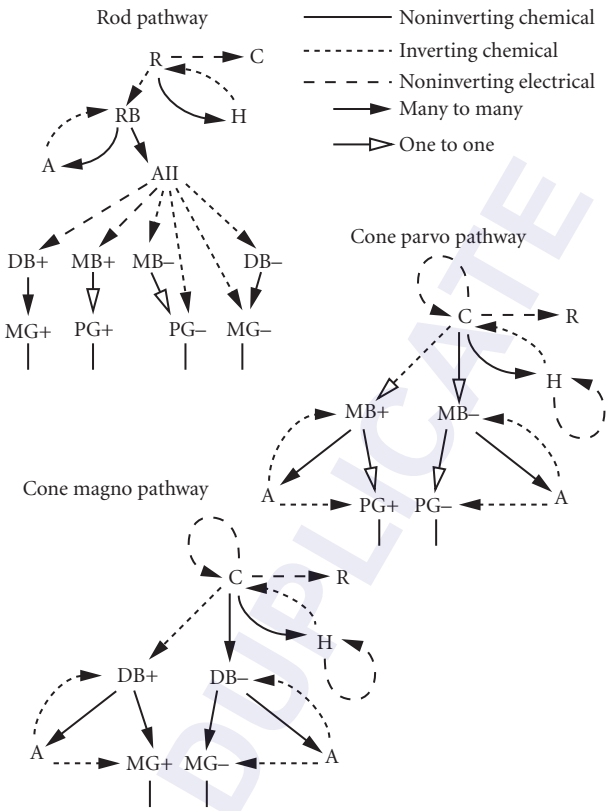

FIGURE 4 Schematic diagram of neural connections in the primate retina. R (rod), C (cone), H (horizontal cell), RB (rod bipolar), MB+ (midget on-bipolar), MB– (midget off-bipolar), DB+ (diffuse on-bipolar), DB– (diffuse off-bipolar), A (amacrine), AII (rod amacrine), PG+ (P or midget on-center ganglion cell), PG– (P or midget off-center ganglion cell), MG+ (M or parasol on-center ganglion cell), MG– (M or parasol off-center ganglion cell).

In the rod pathway, rod bipolar cells (RB) form noninverting chemical synapses with *amacrine* cells (AII, A). The rod amacrine cells (AII) form electrical (noninverting) synapses with the on-center bipolar cells (MB+, DB+), and form chemical (inverting) synapses with off-center bipolar cells (MB–, DB–) and with off-center ganglion cells (PG–, MG–). Other amacrine cells (A) form reciprocal negative-feedback connections to the rod bipolar cells.

In the cone pathways, on-bipolar cells (MB+, DB+) form chemical synapses with amacrine cells (A) and with on-center *ganglion* cells (PG+, MG+).* Off-bipolar cells (FMB, FDB) form chemical synapses with amacrine cells and off-center ganglion cells (PG–, MG–).

The ganglion cells are the output neurons of the retina; their myelinated axons form the optic nerve. In the fovea and parafovea, each P ganglion cell (PG+ , PG–) forms synapses with only one midget bipolar cell (MB+ , MB–), and each midget bipolar cell forms synapses with only one cone;

*The parvo ganglion cells and magno ganglion cells are also referred to as *midget ganglion cells* and *parasol ganglion cells*, respectively.

however, each cone makes contact with a midget on-bipolar and a midget-off bipolar. Thus, the P pathway (in the fovea) is able to carry fine spatial information. Current evidence also suggests that the P pathway carries most of the chromatic information (see Chap. 11). The M ganglion cells (MG+, MG−) form synapses with diffuse bipolar cells (DB+, DB−), and each diffuse bipolar cell forms synapses with many cones. Thus, the M pathway is less able to carry fine spatial information. However, the larger spatial summation (and other boosts in gain) give the M pathway greater sensitivity to changes in contrast. Furthermore, the larger sizes of neurons in the M pathway provide somewhat faster responses and hence somewhat faster transmission of information.

Figure 2*a* shows the density of ganglion cells as a function of eccentricity in the human retina;[32] for macaque retina, see Ref. 33. At each eccentricity, the P cells (PG+, PG−) comprise approximately 80 percent of the ganglion cells and the M cells (MG+, MG−) approximately 10 percent. Half the P and M cells are on-center (PG+ and MG+) and half are off-center (PG− and MG−). Thus, the approximate densities of the four major classes of ganglion cells can be obtained by scaling the curve in Fig. 2*a*. As can be seen, ganglion cell density decreases more quickly with eccentricity than does cone density, but in the fovea there are at least 2 to 3 ganglion cells per cone (a reasonable assumption is that there are two P cells for every cone). The Nyquist limit of the retina would appear to be set by the cone density in the fovea and by the ganglion cell density in the periphery.

Retinal Physiology Ganglion cells transmit information to the brain via action potentials propagating along axons in the optic nerve. The other retinal neurons transmit information as graded potentials (although amacrine cells generate occasional action potentials). Much remains to be learned about exactly how the computations evident in the responses of ganglion cells are implanted within the retinal circuitry.*

The receptive fields† of ganglion cells are approximately circular and, based upon their responses to spots of light, can be divided into a center region and an antagonistic, annular, surround region.[34] In on-center ganglion cells, light to the center increases the response, whereas light to the surround suppresses the response; the opposite occurs in off-center ganglion cells.

For small to moderate contrast modulations around a steady mean luminance, most P and M cells respond approximately linearly, and hence their spatial and temporal response properties can be usefully characterized by a spatiotemporal transfer function. The spatial components of the transfer function are adequately described as a difference of gaussian functions with separate space constants representing the center and surround;[35–37] see Fig. 5*a*. The available data suggest that the surround diameter is typically 3 to 6 times the center diameter.[37] The temporal components of the transfer function have been described as a cascade of simple feedback and feed-forward linear filters (e.g., Ref. 38; see Fig. 5*b*). There also appears to be a small subset of M cells that is highly nonlinear, similar to the Y cells in cat.[39]

The response amplitude of M and P cells as a function of sinewave contrast is reasonably well described by a Michaelis-Menton function [i.e., by Eq. (14)], but where z and σ_o are contrasts rather than intensities. As indicated by Fig. 5, the M ganglion cells are (over most spatial and temporal frequencies) about 4 to 10 times more sensitive than the P ganglion cells; in other words, σ_o is 4 to 10 times smaller in M cells than P cells.

When mean (ambient) light level increases, the high-frequency falloffs of the temporal transfer functions of M and P cells shift toward higher frequencies, corresponding to a decrease in the time constants of the linear filters.[38,40] The effect is reduction in gain (an increase in σ_o), and an increase in temporal resolution.

Relatively little is known about how the spatial transfer functions of primate ganglion cells change with mean light level. In cat, the relative strength of the surround grows with mean luminance, but the space constants (sizes) of the center and surround components appear to change relatively little.[41,42]

*In this subsection we describe the electrophysiology of M and P cells. This description is based on a composite of data obtained from ganglion cells and geniculate cells. The response properties of M and P ganglion cells and M and P geniculate cells are very similar.

†The receptive field of a neuron is defined to be the region of the visual field (or, equivalently, of the receptor array) where light stimulation has an effect on the response of the neuron.

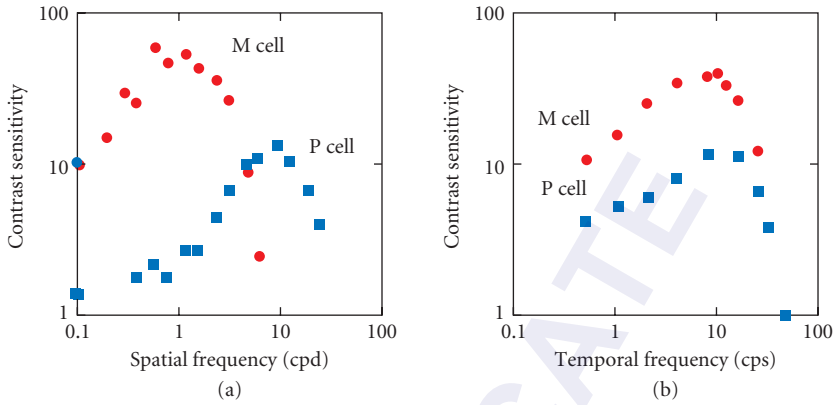

FIGURE 5 Typical spatial and temporal contrast sensitivity functions of P and M ganglion cells. (*a*) Spatial contrast sensitivity functions for sinusoidal gratings with a mean intensity of 1400 td, drifting at 5.2 cps. The symbols are modulation thresholds for a uniform field flickering sinusoidally at 5.2 cps. The threshold criterion was approximately 10 extra impulses per second. (*Adapted from Ref. 37.*) (*b*) Temporal contrast sensitivity functions for drifting sinusoidal gratings with mean intensities of 4600 td (P cell) and 3600 td (M cell), and spatial frequencies of 3 cpd (P cell) and 1.6 cpd (M cell). The threshold criterion was approximately 10 extra impulses per second. (*Adapted from Ref. 38.*)

The major effect of increasing adaptation luminance is an increase in the magnitude of the low-frequency falloff of the spatial transfer function.

The center diameters of both P and M cells increase with eccentricity,[42,43] roughly in inverse proportion to the square root of ganglion-cell density (cf., Fig. 2*a*). However, the precise relationship has not been firmly established because of the difficulty in measuring center diameters of ganglion cells near the center of the fovea, where the optical point-spread function is likely to be a major component of center diameter.[37]

Central Visual Processing

Most of the information encoded in the retina is transmitted via the optic nerve to the lateral geniculate nucleus (LGN) in the thalamus. The neurons in the LGN then relay the retinal information to the primary visual cortex (V1). Neurons in V1 project to a variety of other visual areas. Less is known about the structure and function of V1 than of the retina or LGN, and still less is known about the subsequent visual areas.

Central Anatomy The LGN is divided into six layers (see Fig. 6); the upper four layers (the parvocellular laminae) receive synaptic input from the P ganglion cells, the lower two layers (the magnocellular laminae) receive input from the M ganglion cells. Each layer of the LGN receives input from one eye only, three layers from the left eye and three from the right eye. The LGN also receives input from other brain areas including projections from the reticular formation and a massive projection (of uncertain function) from layer 6 of V1. The total number of LGN neurons projecting to the visual cortex is slightly larger than the number of ganglion cells projecting to the LGN.

The segregation of M and P ganglion cell afferents into separate processing streams at the LGN is preserved to some extent in subsequent cortical processing. The magnocellular neurons of the LGN project primarily to neurons in layer 4cα in V1, which project primarily to layer 4b. The neurons in layer 4b project to several other cortical areas including the middle-temporal area (MT) which appears to play an important role in high-level motion processing (for reviews see Refs. 44–46).

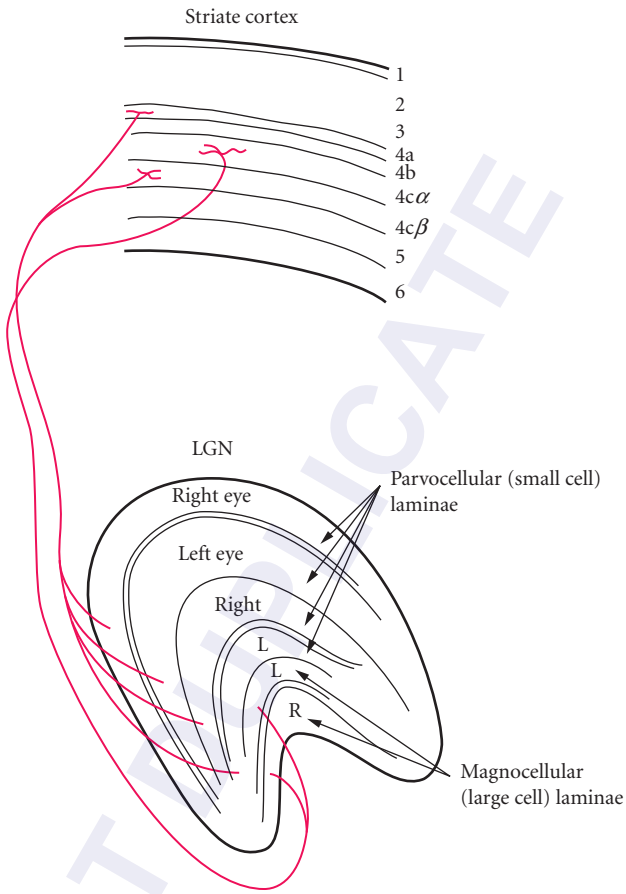

FIGURE 6 Schematic diagram of a vertical section through the lateral geniculate nucleus and through striate cortex (V1) of the primate visual system. (*Reproduced from Ref. 49.*)

The parvocellular neurons of the LGN project to layers 4a and 4cβ in V1. The neurons in layers 4a and 4cβ project to the superficial layers of V1 (layers 1, 2, and 3), which project to areas V2 and V3. Areas V2 and V3 send major projections to area V4 which sends major projections to IT (inferotemporal cortex). The superficial layers of V1 also send projections to layers 5 and 6.

It has been hypothesized that the magno stream subserves crucial aspects of motion and depth perception and that the parvo stream subserves crucial aspects of form and color perception. However, current understanding of the areas beyond V1 is very limited; it is likely that our views of their functional roles in perception will change substantially in the near future. For reviews of cortical functional anatomy see, for example, Refs. 46–49.

Central Physiology The receptive field properties of LGN neurons are quite similar to those of their ganglion-cell inputs.[50–52] LGN neurons have, on average, a lower spontaneous response rate than ganglion cells, and are more affected by changes in alertness and anesthetic level, but otherwise display similar center/surround organization, and similar spatial, temporal, and chromatic response properties (however, see Ref. 53).

The receptive-field properties of neurons in the primary visual cortex are substantially different from those in the retina or LGN; V1 neurons have elongated receptive fields that display a substantial degree of selectivity to the size (spatial frequency), orientation, direction of motion of retinal stimulation, and binocular disparity.[54–56] Thus, the probability that a cortical neuron will be activated by an arbitrary retinal image is much lower than for retinal and LGN neurons.

Each region of the visual field is sampled by cortical neurons selective to the full range of sizes, orientations, directions of motion, and binocular disparities. When tested with sinewave gratings, cortical neurons have a spatial-frequency bandwidth (full width at half height) of 1 to 1.5 octaves and an orientation bandwidth of 25 to 35 degrees.[57,58] The number of neurons in area V1 is more than two orders of magnitude greater than the number of LGN neurons;[59] thus, there are sufficient numbers of cortical neurons in each region of the visual field for their receptive fields to tile the whole spatial-frequency plane transmitted from retina to cortex several times. However, the number of cortical cells encoding each region of the spatial-frequency plane is still uncertain. The temporal frequency tuning of V1 neurons is considerably broader than the spatial-frequency tuning with peak sensitivities mostly in the range of 5 to 10 cps.[60] The direction selectivity of V1 neurons varies from 0 to 100 percent with an average of 50 to 60 percent.[57*] Early measurements of disparity tuning in primate suggested that cortical neurons fall into three major categories: one selective to crossed disparities, one selective to uncrossed disparities, and one tuned to disparities near zero.[56] Recent evidence[61] in agreement with evidence in cat cortex[62,63] suggests a more continuous distribution of disparity tuning.

The chromatic response properties of V1 neurons are not yet fully understood.[49] There is some evidence that discrete regions in the superficial layers of V1, called cytochrome oxidase "blobs," contain a large proportion of neurons responsive to chromatic stimuli;[64] however, see Ref. 65.

The spatial-frequency tuning functions of cortical cells have been described by a variety of simple functions including Gabor filters, derivatives of gaussian filters, and log Gabor filters (e.g., Ref. 66). The temporal-frequency tuning functions have been described by difference of gamma filters. The full spatiotemporal tuning (including the direction-selective properties of cortical cells) has been described by quadrature (or near quadrature) pairs of separable spatiotemporal filters with spatial and temporal components drawn from the types listed above (e.g., Ref. 67).

Essentially all V1 neurons display nonlinear response characteristics, but can be divided into two classes based upon their nonlinear behavior. *Simple cells* produce approximately half-wave rectified responses to drifting or counterphase sinewave gratings; *complex cells* produce a large unmodulated (DC) response component with a superimposed half-wave or full-wave rectified response component.[68] Simple cells are quite sensitive to the spatial phase or position within the receptor field; complex cells are relatively insensitive to position within the receptive field.[54]

Most simple and complex cells display an accelerating response nonlinearity at low contrasts and response saturation at high contrasts, which can be described by a Michaelis-Menton function [Eq. (11)] with an exponent greater than 1.0.[69] These nonlinearities impart the important property that response reaches saturation at approximately the same physical contrast independent of the spatial frequency, orientation, or direction of motion of the stimulus. The nonlinearities sharpen the spatiotemporal tuning of cortical neurons while maintaining that tuning largely independent of contrast, even though the neurons often reach response saturation of 10 to 20 percent contrast.[70,71]

Unlike retinal ganglion cells and LGN neurons, cortical neurons have little or no spontaneous response activity. When cortical cells respond, however, they display noise characteristics similar to retinal and LGN neurons; specifically, the variance of the response is approximately proportional to the mean response;[72,73] unlike Poisson noise, the proportionality constant is usually greater than 1.0.

2.4 VISUAL PERFORMANCE

A major goal in the study of human vision is to relate performance—for example, the ability to see fine detail—to the underlying anatomy and physiology. In the sections that follow, we will discuss some of the data and theories concerning the detection, discrimination, and estimation of contrast,

*Direction selectivity is defined as $100 \times (R_p - R_n)/R_p$, where R_p is the magnitude of response in the preferred direction and R_n is the magnitude of response in the nonpreferred direction.

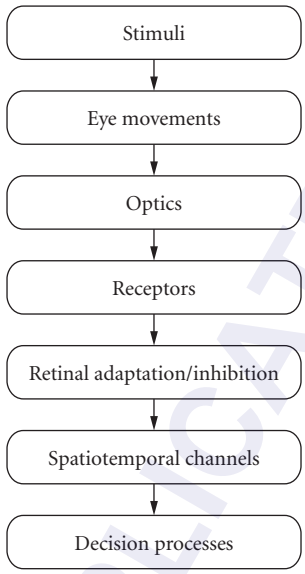

FIGURE 7 Simple information-processing model of the visual system representing the major factors affecting contrast detection and discrimination.

position, shape, motion, and depth by human observers. In this discussion, it will be useful to use as a theoretical framework the information-processing model depicted in Fig. 7. The visual system is represented as a cascade of processes, starting with eye movements, that direct the visual axis toward a point of interest, proceeding through a number of processing stages discussed in the previous sections and in Chaps. 1 and 11, and ending with a decision. When a human observer makes a decision about a set of visual stimuli, the accuracy of this decision depends on all the processes shown in Fig. 7. Psychophysical experiments measure the performance of the system as a whole, so if one manipulates a particular variable and finds it affects observers' performance in a visual task, one cannot readily pinpoint the responsible stage(s). The effect could reflect a change in the amount of information the stimulus provides, in the fidelity of the retinal image, in representation of the stimulus among spatiotemporal channels, or in the observer's decision strategy. Obviously, it is important to isolate effects due to particular processing stages as well as possible.

We begin by discussing the decisions a human observer might be asked to make concerning visual stimuli. Humans are required to perform a wide variety of visual tasks, but they can be divided into two general categories: *identification tasks and estimation tasks*.* In an identification task, the observer is required to identify a visual image, sequence of images, or a part of an image, as belonging to one of a small number of discrete categories. An important special case is the *discrimination task* in which there are only two categories (e.g., Is the letter on the TV screen an *E* or an *F*?). When one of the two categories is physically uniform, the task is often referred to as a *detection task* (e.g., Is there a letter *E* on the screen or is the screen blank?). In the estimation task, the observer is required to estimate the value of some property of the image (e.g., What is the height of the letter?). The distinction between estimation and identification is quantitative, not qualitative; strictly speaking, an estimation task can

*Visual tasks can also be categorized as *objective* or *subjective*. Objective tasks are those for which there is, in principle, a precise physical standard against which performance can be evaluated (e.g., a best or correct performance). The focus here is on objective tasks because performance in those tasks is more easily related to the underlying physiology.

be regarded as an identification task with a large number of categories. There are two fundamental measures of performance in visual tasks: the *accuracy* with which the task is performed, and the *speed* at which the task is performed. For further discussion of methods for measuring visual performance, see Chap. 3 by Denis G. Pelli and Bart Farell.

Referring again to the information-processing model of Fig. 7, we note that it is difficult to isolate the decision strategy; the best one can do is to train observers to adhere as closely as possible to the same decision strategy across experimental conditions. So, whether the experiment involves simple identification tasks, such as discrimination or detection procedures, or estimation tasks, observers are generally trained to the point of using a consistent decision strategy.

The stimulus for vision is distributed over space, time, and wavelength. As mentioned earlier, we are primarily concerned here with spatial and temporal variations in intensity; variations in wavelength are taken up in Chap. 11.

Before considering human visual performance, we briefly describe *ideal-observer theory* (e.g., Refs 74 and 75), which has proven to be a useful tool for evaluating and intepreting visual performance.

Ideal-Observer Theory

In attempting to understand human visual performance, it is critically important to quantify performance limitations imposed by the information contained in the stimulus. There is a well-accepted technique, based on the theory of ideal observers,[75] for so doing. As applied to vision (see Refs. 76–79), this approach is based on comparing human observers' performance to that of an ideal observer for the same stimuli. Ideal observers have three main elements: (1) a precise description of the stimuli, including any random variation or noise; (2) descriptions of how the stimuli are modified by the visual stages of interest (e.g., optics, receptors); and (3) an optimal decision rule. Such observers specify the best possible level of performance (e.g., the smallest detectable amount of light) given the variability in the stimulus and information losses in the incorporated visual stages. Because ideal observer performance is the best possible, the thresholds obtained are a measure of the information available in the stimulus (to perform the task) once processed by the incorporated stages. Poorer performance by the human observer must be due to information losses in the unincorporated stages. Thus, ideal-observer theory provides the appropriate physical benchmark against which to evaluate human performance.[75,80] One can, of course, use models of anatomical and physiological mechanisms to incorporate various processing stages into an ideal observer (as shown in Fig. 7); comparisons of human and ideal observer performance in such cases can allow one to compute precisely the information transmitted and lost by mechanisms of interest. This allows assessment of the contributions of anatomical and physiological mechanisms to overall visual performance.[78]

It is important to recognize that ideal-observer theory is not a theory of human performance (humans generally perform considerably below ideal); thus, the theory is not a substitute for psychophysical and physiological modeling. However, the theory is crucial for understanding the stimuli and the task. In many ways, measuring and reporting the information content of stimuli with an ideal observer is as fundamental as measuring and reporting the basic physical dimensions of stimuli.

To illustrate the concepts of ideal-observer theory, consider an identification task with response alternatives (categories) α_1 through α_m, where the probability of a stimulus from category α_j equals q_j. Suppose, further, that the stimuli are static images, with an onset at some known point in time. (By a static image, we mean there is no temporal variation within a stimulus presentation except for photon noise.) Let $\mathbf{Z}$ be the list of random values (e.g., photon counts) at each sample location (e.g., photoreceptor) in some time interval τ for a single presentation of a stimulus:

$$\mathbf{Z} = (Z_1, \ldots, Z_n) \tag{15}$$

where Z_i is the sample value at the ith location.

Overall accuracy in an identification task is always optimized (on average) by picking the most probable stimulus category given the sample data and the prior knowledge. Thus, if the goal is to

maximize overall accuracy in a given time interval τ, then the maximum average percent correct (PC_{opt}) is given by the following sum:

$$PC_{opt}(\tau)=\sum_{z} q_{*} p_{\tau}(\mathbf{z}|\alpha_{*}) \tag{16}$$

where $p_{\tau}(\mathbf{z}|\alpha_{*})$ is the probability density function associated with $\mathbf{Z}$ for stimulus category α_{j}, and the subscript $_{*}$ represents the category j for which the product $q_{*}\, p_{\tau}(\mathbf{z}|\alpha_{*})$ is maximum. (Note, $\mathbf{Z}$ is a random vector and $\mathbf{z}$ is a simple vector.)

Suppose, instead, that the goal of the task is to optimize speed. Optimizing speed at a given accuracy level is equivalent to finding the minimum stimulus duration, $\tau_{opt}(\varepsilon)$, at a criterion error rate ε. The value of $\tau_{opt}(\varepsilon)$ is obtained by setting the left side of Eq. (16) to the criterion accuracy level $(1-\varepsilon)$ and then solving for τ.

For the detection and discrimination tasks, where there are two response categories, Eq. (16) becomes

$$PC_{opt}(\tau)=\frac{1}{2}+\frac{1}{2}\sum_{z}|q_{1}p_{\tau}(\mathbf{z}|\alpha_{1})-(1-q_{1})p_{\tau}(\mathbf{z}|\alpha_{2})| \tag{17}$$

[The summation signs in Eqs. (16) and (17) are replaced by an integral sign if the probability density functions are continuous.]

Because the sums in Eqs. (16) and (17) are overall possible vectors $\mathbf{z}=(z_{1},\ldots,z_{n})$, they are often not of practical value in computing optimal performance. Indeed, in many cases there is no practical analytical solution for ideal-observer performance, and one must resort to Monte Carlo simulation.

Two special cases of ideal-observer theory have been widely applied in the analysis of psychophysical discrimination and detection tasks. One is the ideal observer for discrimination or detection tasks where the only source of stimulus variability is photon noise.[77,81,82] In this case, optimal performance is given, to close approximation, by the following formulas:[83,84]

$$PC_{opt}(\tau)=q+1(1-q)\Phi\left(\frac{c}{d'}+\frac{d'}{2}\right)-q\Phi\left(\frac{c}{d'}-\frac{d'}{2}\right) \tag{18}$$

where $c=\ln[(1-q)/q]$, $\Phi(\cdot)$ is the cumulative standard normal probability distribution, and

$$d'=\frac{\tau^{1/2}\sum_{i=1}^{n}(b_{i}-a_{i})\ln(b_{i}/a_{i})}{\left[\sum_{i=1}^{n}(b_{i}+a_{i})\ln^{2}(b_{i}/a_{i})\right]^{1/2}} \tag{19}$$

In Eq. (19), a_{i} and b_{i} are the average numbers of photons per unit time at the ith sample location, for the two alternative stimuli (α_{1} and α_{2}). For equal presentation probabilities ($q=0.5$), these two equations are easily solved to obtain $\tau_{opt}(\varepsilon)$.[85,86] In signal-detection theory[75] the quantity d' provides a criterion-independent measure of signal detectability or discriminability.

Figure 8 provides an example of the use of ideal-observer theory. It compares human and ideal performance for detection of square targets of different areas presented briefly on a uniform background. The symbols show the energy required for a human observer to detect the target as a function of target area. The lower curve shows the absolute performance for an ideal observer operating at the level of photon absorption in the receptor photopigments; the upper curve shows the same curve shifted vertically to match the human data. The differences between real and ideal performance represent losses of information among neural processes. The data show that neural efficiency, $[d'_{real}]^{2}/[d'_{ideal}]^{2}$, for the detection of square targets is approximately 1/2 percent for all but the largest target size.

Another frequently applied special case is the ideal observer for detection and discrimination tasks where the signal is known exactly (SKE) and white or filtered gaussian noise (i.e., image or pixel noise) has been added. Tasks employing these stimuli have been used to isolate and measure central mechanisms that limit discrimination performance[80,87,88] to evaluate internal (neural) noise levels in

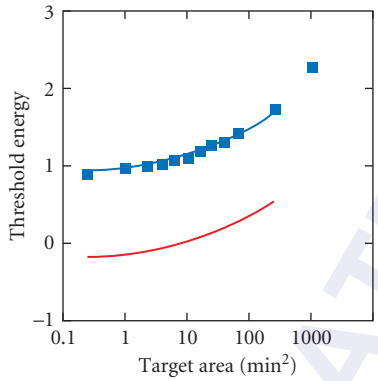

FIGURE 8 Comparison of real and ideal performance for detection of square targets on a uniform background of 10 cd/m^2 (viewed through a 3-mm artificial pupil). The symbols represent human thresholds as a function of target area. Threshold energy is in units of cd/m^2 × min^2 × sec. The lower curve is ideal performance at the level of the photoreceptors; the upper curve is the ideal performance shifted vertically to match the human data. (*Adapted from Ref. 264.*)

the visual system,[79,89] and to develop a domain of applied psychophysics relevant to the perception of the noisy images, such as those created by radiological devices and image enhancers.[90–92] For the gaussian-noise-limited ideal discriminator, Eq. (18) still applies, but d' is given by the following:

$$d' = \frac{E(L|\alpha_2) - E(L|\alpha_1)}{\sqrt{VAR(L)}} \tag{20}$$

where

$$L = [\mathbf{m}_2 - \mathbf{m}_1]' \Sigma^{-1} \mathbf{Z} \tag{21}$$

In Eq. (21), Z is the column vector of random values from the sample locations (e.g., pixels), $[\mathbf{m}_2 - \mathbf{m}_1]'$ is a row vector of the differences in the mean values at each sample point (i.e., $b_1 - a_1, \ldots, b_n - a_n$), and Σ is the covariance matrix resulting from the gaussian noise (i.e., the element $\sigma_{i,j}$ of Σ is the covariance between the ith and jth sample location). In the case of white noise, Σ is a diagonal matrix with diagonal elements equal to σ^2, and thus,*

$$d' = \frac{1}{\sigma}\sqrt{\sum (b_i - a_i)^2} \tag{22}$$

As an example, Fig. 9 compares human and ideal performance for amplitude discrimination of small targets in white noise as a function of noise spectral power density (which is proportional to σ^2). The solid black line of slope 1.0 shows the absolute performance of an ideal observer operating at the level of the cornea (or display screen); thus, the difference between real and ideal performance represents all losses of information within the eye, retina, and central visual pathways. For these conditions, efficiency for amplitude discrimination of the targets ranges from about 20 to 70 percent, much

*It should be noted that the performance of the photon-noise-limited oberver [Eq. (19)] becomes equivalent to an SKE white noise observer [Eq. (22)] for detection of targets against intense uniform backgrounds.

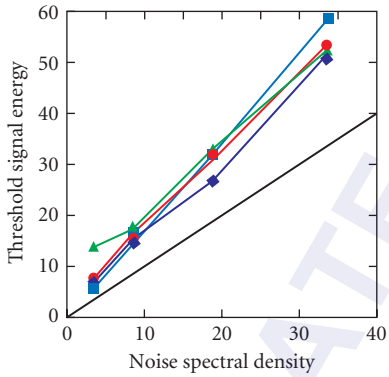

FIGURE 9 Comparison of real (symbols) and ideal (solid black line) performance for contrast discrimination of spatially localized targets in white noise backgrounds with a mean luminance of 154 cd/m^2. Noise spectral density and target signal energy are in units of 10^{-7} deg^2 (the arrow indicates a noise standard deviation of 26 percent contrast per pixel). (■) Gaussian target (standard deviation = 0.054 deg); (●) Gaussian damped sinewave target (9.2 cpd, standard deviation = 0.109 deg); (▲) Gaussian damped sinewave target (4.6 cpd, standard deviation = 0.217 deg); (◆) Sinewave target (4.6 cpd, 0.43 × 0.43 deg). *(Adapted from Ref. 87.)*

higher than for detecting targets in uniform backgrounds (cf., Fig. 8). Efficiencies are lower in Fig. 8 than in Fig. 9 primarily because, with uniform backgrounds, internal (neural) noise limits human, but not ideal, performance; when sufficient image noise is added to stimulus, it begins to limit both real and ideal performance.

The following sections are a selective review of human visual performance and underlying anatomical and physiological mechanisms. The review includes spatial and temporal contrast perception, light adaptation, visual resolution, motion perception, and stereo depth perception, but due to space limitations, excludes many other active areas of research such as color vision (partially reviewed Chaps. 10 and 11), eye movements,[93] binocular vision,[94,95] spatial orientation and the perception of layout,[96,97] pattern and object recognition,[96–99] visual attention,[100] visual development,[101,102] and abnormal vision.[103]

Contrast Detection

The study of contrast detection in the human visual system has been dominated for the last 20 years by methods derived from the concepts of linear systems analysis. The rationale for applying linear systems analysis in the study of visual sensitivity usually begins with the observation that a complete characterization of a visual system would describe the output resulting from any arbitrary input. Given that the number of possible inputs is infinite, an exhaustive search for all input-output relationships would never end. However, if the system under study is linear, then linear systems analysis provides a means for characterizing the system from the measurement of a manageably small set of input-output relationships. Of course, the visual system has important nonlinearities, so strictly speaking, the assumptions required by linear systems analysis are violated in general. Nonetheless, there have been several successful applications of linear systems analysis in vision.

In the case of spatial vision, linear systems analysis capitalizes on the fact that any spatial retinal illumination distribution, $I(x, y)$ can be described exactly by the sum of a set of basis functions, such as the set of sinusoids. Sinusoids are eigenfunctions of a linear system, which implies that the system response to a sinusoidal input can be completely characterized by just two numbers; an amplitude change and a phase change. Indeed, it is commonly assumed (usually with justification) that spatial phase is unaltered in processing, so only one number is actually required to describe the system response to a sinusoid. Linear systems analysis provides a means for predicting, from such characterizations of system responses to sinusoids, the response to any arbitrary input. For these reasons, the measurement of system responses to spatial sinusoids has played a central role in the examination of human spatial vision. We will begin our discussion with the spatial sinusoid and the system response to it.

A spatial sinusoid can be described by

$$I(x,y) = A\sin[2\pi f(x\cos(\theta) + y\sin(\theta)) + \phi] + \bar{I} \tag{23}$$

where $\bar{I}$ is the space-average intensity of the stimulus field (often expressed in trolands), A is the amplitude of the sinusoid, f is the spatial frequency (usually expressed in cycles · deg^{-1} or cpd), θ is the orientation of the pattern relative to axes x and y, and ϕ is the phase of the sinusoid with respect to the origin of the coordinate system. The contrast C of a spatial sinewave is defined as $(I_{max} - I_{min})/(I_{min} + I_{min})$, where I_{max} is the maximum intensity of the sinusoid and I_{min} is the minimum; thus $C = A/\bar{I}$. When the sinusoid is composed of vertical stripes, θ is zero and Eq. (23) reduces to

$$I(x,y) = A\sin[2\pi fx + \phi) + \bar{I} \tag{24}$$

When the contrast C of a sinusoidal grating (at a particular frequency) is increased from zero (while holding $\bar{I}$ fixed), there is a contrast at which it first becomes reliably detectable, and this value defines the contrast detection threshold. It is now well-established that contrast threshold varies in a characteristic fashion with spatial frequency. A plot of the reciprocal of contrast at threshold as a function of spatial frequency constitutes the *contrast sensitivity function* (CSF). The CSF for a young observer with good vision under typical indoor lighting conditions is shown in Fig. 10 (blue squares).

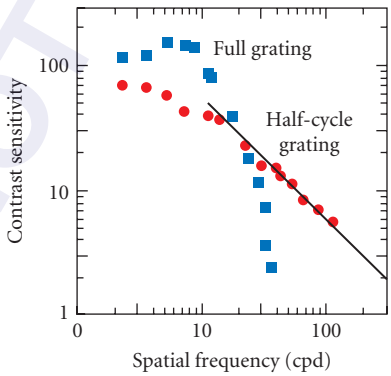

FIGURE 10 Contrast sensitivity as a function of spatial frequency for a young observer with good vision under typical indoor lighting conditions. The blue squares represent the reciprocals of contrast at detection threshold for sinusoidal grating targets. The red circles represent the reciprocals of contrast thresholds for half-cycle sinusoids. The solid line represents the predicted threshold function for half-cycle gratings for a linear system whose CSF is given by the blue squares. (*Adapted from Ref. 193.*)

The function is bandpass with a peak sensitivity at 3 to 5 cpd. At those spatial frequencies, a contrast of roughly 1/2 percent can be detected reliably (once the eye has adapted to the mean luminance). At progressively higher spatial frequencies, sensitivity falls monotonically to the so-called high-frequency cutoff at about 50 cpd; this is the finest grating an observer can detect when the contrast C is at its maximum of 1.0. At low spatial frequencies, sensitivity falls as well, although (as we will see) the steepness of this low-frequency rolloff is quite dependent upon the conditions under which the measurements are made. It is interesting that most manipulations affect the two sides of the function differently, a point we will expand later.

The CSF is not an invariant function; rather the position and shape of the function are subject to significant variations depending on the optical quality of the viewing situation, the average luminance of the stimulus, the time-varying and chromatic qualities of the stimulus, and the part of the retina on which the stimulus falls. We will examine all of these effects because they reveal important aspects of the visual processes that affect contrast detection.

Before turning to the visual processes that affect contrast detection, we briefly describe how CSF measurements and linear systems analysis can be used to make general statements about spatial contrast sensitivity. Figure 10 plots contrast sensitivity to targets composed of extended sinusoids and to targets composed of one half-cycle of a cosinusoid. Notice that sensitivity to high spatial frequencies is much higher with the half-cycle cosinusoids than it is with extended sinusoids.

The half-cycle wave forms can be described as cosinusoids multiplied by rectangular functions of widths equal to one-half period of the cosinusoid. The truncating rectangular function causes the frequencies in the pattern to "splatter" to higher and lower values than the nominal target frequency. Multiplication of the Fourier transforms of the half-cycle targets by the CSF obtained with extended sinusoids yields an estimate of the visual system's output response to the half-cycle targets. From there, use of a simple decision rule allows one to derive predicted half-cycle contrast sensitivities for a linear system. One expects to find greater visibility to high spatial frequencies with half-cycle gratings. The quantitative predictions are represented by the solid line in Fig. 10 and they match the observations rather well. There are numerous cases in the literature in which the CSF yields excellent predictions of the visibility of other sorts of patterns, but there are equally many cases in which it does not. We will examine some of the differences between those two situations later.

All of the information-processing stages depicted in Fig. 7 affect the CSF, and most of those effects have now been quantified. We begin with eye movements.

Eye Movements Even during steady fixation, the eyes are in constant motion, causing the retina to move with respect to the retinal images.[104] Such motion reduces retinal image contrast by smearing the spatial distribution of the target, but it also introduces temporal variation in the image. Thus, it is not obvious whether eye position jitter should degrade or improve contrast sensitivity. It turns out that the effect depends on the spatial frequency of the target. At low frequencies, eye movements are beneficial. When the image moves with respect to the retina, contrast sensitivity improves for spatial frequencies less than about 5 cpd.[105,106] The effect of eye movements at higher spatial frequencies is less clear, but one can measure it by presenting sinusoidal interference fringes (which bypass optical degradations due to the eye's aberrations) at durations too short to allow retinal smearing and at longer durations at which smearing might affect sensitivity.[107] There is surprisingly little attenuation due to eye position jitter; for 100-ms target presentations, sensitivity at 50 cpd decreases by only 0.2 to 0.3 log units relative to sensitivity at very brief durations. Interestingly, sensitivity improves at long durations of 500 to 2000 ms. This may be explained by noting that the eye is occasionally stationary enough to avoid smearing due to the retina's motion.

Thus, the eye movements that occur during steady fixation apparently improve contrast sensitivity at low spatial frequencies and have little effect at high frequencies. This means that with steady fixation there is little need for experimenters to monitor or eliminate the effects of eye movements in measurements of spatial contrast sensitivity at high spatial frequencies.

Optics The optical tranfer function (OTF) of an optical system describes the attenuation in contrast (and the phase shift) that sinusoidal gratings undergo when they pass through the optical system. As shown in Chap. 1 the human OTF (when the eye is well accommodated) is a low-pass function

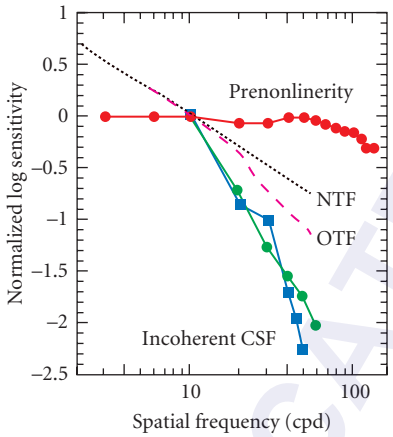

FIGURE 11 The contrast sensitivity function (CSF) and the transfer functions for various visual processing stages. All functions have been normalized to a log sensitivity of 0.0 at 10 cpd. The blue squares represent the CSF measured in the conventional way using incoherent white light.[22] The red circles represent the transfer function of the prenonlinearity filter measured.[22] The dotted line represents the neural transfer function that results from a bank of photon-noise-limited spatial filters of constant bandwidth.[122] The dashed line represents the optical transfer function for a 3.8-mm pupil.[4] The green circles are the product of the three transfer functions.

whose shape depends on pupil size and eccentricity. The dashed curve and the blue squares in Fig. 11 show the foveal OTF and the foveal CSF, respectively, for a pupil diameter of 3.8 mm. At high spatial frequencies, the foveal CSF declines at a faster rate than the foveal OTF. Thus, the OTF can only account for part of the high-frequency falloff of the CSF. Also, it is obvious that the OTF (which is a low-pass function) cannot account for the falloff in the CSF at low spatial frequencies.

Receptors Several receptor properties affect spatial contrast sensitivity and acuity. As noted earlier, the receptors in the fovea are all cones, and they are very tightly packed and arranged in a nearly uniform hexagonal lattice. With increasing retinal eccentricity, the ratio of cones to rods decreases steadily (see Fig. 2*a*) and the regularity of the lattice diminishes.

Several investigators have noted the close correspondence between the Nyquist frequency and the highest-detectable spatial frequency[108–111] and have argued that the geometry of the foveal cone lattice sets a fundamental limit to grating acuity. However, more importance has been placed on this relationship than is warranted. This can be shown in two ways. First, grating acuity varies with several stimulus parameters including space-average luminance, contrast, and temporal duration. For example, grating acuity climbs from about 5 cpd at a luminance of 0.001 cd/m^2 to 50 to 60 cpd at luminances of 100 cd/m^2 or higher.[112] Obviously, the cone lattice does not change its properties in conjunction with changes in luminance, so this effect has nothing to do with the Nyquist limit. The only conditions under which the Nyquist limit might impose a fundamental limit to visibility would be at high luminances and contrasts, and relatively long target durations. Second, and more importantly, several investigators have shown that observers can actually detect targets whose frequency components are well above the Nyquist limit. For example, Williams[113] presented high-frequency sinusoidal gratings using laser inter-ferometry to bypass the contrast reductions that normally occur in passage through the eye's optics. He found that observers could detect gratings at frequencies as high as 150 cpd, which

is 2.5 times the Nyquist limit. Observers did so by detecting the gratings' "aliases," which are Moiré-like distortion products created by undersampling the stimulus.[114] The CSF under these conditions is smooth with no hint of a loss of visibility at the Nyquist limit. The observer simply needs to switch strategies above and below the Nyquist limit; when the targets are below the limit, the observer can detect the undistorted targets, and when the targets are above the limit, the observer must resort to detecting the targets' lower frequency aliases.[7] On the other hand, when the task is to resolve the stripes of a grating (as opposed to detecting the grating), performance is determined by the Nyquist limit over a fairly wide range of space-average luminances.[115]

In addition to receptor spacing, one must consider receptor size in the transmission of signals through the early stages of vision. As noted earlier, the prevailing model of cones holds that the inner segment offers an aperture to incoming photons. In the fovea, the diameter of the inner segment is roughly 0.5 min[6,21] (see Fig. 2*c*). Modeling the cone aperture by a cylinder function of this diameter, one can estimate the low-pass filtering due to such an aperture from the cylinder's Fourier transform, which is a first-order Bessel function whose first zero occurs at 146 cpd. However, the entrance to a structure only a few wavelengths of light wide cannot be described accurately by geometric optics,[116] so the receptor aperture is generally modeled by a gaussian function whose full width at half height is somewhat smaller than the anatomical estimates of the aperture diameter.[22]

The modulation transfer of the neural stages prior to a compressive nonlinearity (thought to exist in the bipolar cells of the retina or earlier) has been measured in the following way.[22] Laser interferometry was used to bypass the contrast reductions that normally occur as light passes through the eye's optics. The stimuli were two high-contrast sinusoids of the same spatial frequency but slightly different orientations; these created a spatial "beat" of a different orientation and frequency than the component gratings. Passing two sinusoids through a compressive nonlinearity, like the ones known to exist early in the visual system, creates a number of distortion products at various frequencies and orientations. MacLeod et al.[22] varied the orientations and frequencies of the components so as to create a "beat" at 10 cpd, and then measured contrast sensitivity to the "beat." Because the "beat" was always at the same spatial frequency, the filtering properties of postnonlinearity stages could not affect the measurements and, therefore, any effect of component frequency on contrast sensitivity had to be due to the filtering properties of prenonlinearity stages. Observers were able to detect the "beat" produced by component gratings of frequencies as high as 140 cpd. This implies that the prenonlinearity filter has exceptionally large bandwidth. By inverse Fourier transformation of these data, one can estimate the spatial extent of the filter; it appears to have a full width at half height of about 16 arcsec, which is a bit smaller than current estimates of the cone aperture. Thus, the early neural stages are able to pass information up to extremely high spatial frequencies once the optics are bypassed.

The red circles in Fig. 11 display the estimate of the transfer function of the prenonlinearity neural filter for foveal viewing. Notice that it is virtually flat up to 140 cpd. Also shown (blue squares) is the CSF obtained in the conventional manner with incoherent white light from a CRT display. This function represents the product of the optics and the prenonlinearity and postnonlinearity spatial filters. As can be seen, the bandwidth of the conventional CSF is much smaller than the bandwidth of the prenonlinearity filter. Thus, optics and postnonlinearity filtering are the major constraints to contrast sensitivity at higher spatial frequencies.

As mentioned earlier, the transfer function of the optics is shown as the dashed line. The product of the optical transfer function and the prenonlinearity transfer function would be very similar to the dashed line because the prenonlinearity function is virtually flat. Thus, the product of optics and prenonlinearity filter does not match the observed CSF under conventional viewing conditions at all; the postnonlinearity filter must also contribute significantly to the shape of the CSF. The mismatch between the dashed line and the CSF is obvious at low and high spatial frequencies. We consider the high-frequency part first; the low-frequency part is considered later under "Adaptation and Inhibition."

Spatial Channels Spatial filters with narrow tuning to spatial frequency have been demonstrated in a variety of ways.[117,118] For example, the visibility of a sinusoidal target is reduced by the presence of a narrowband noise masker whose center frequency corresponds to the spatial frequency of the sinusoid, but is virtually unaffected by the presence of a masker whose center frequency is more than

1.5 octaves from the frequency of the sinusoid (Ref. 119; see "Contrast Discrimination and Contrast Masking" later in chapter). These spatial mechanisms, which have been described mathematically by Gabor functions and other functions,[120] correspond to a first approximation with the properties of single neurons in the visual cortex.[58] They seem to have roughly constant bandwidths, expressed in octaves or log units, regardless of preferred frequency.[58,117] As a consequence, mechanisms responding to higher spatial frequencies are smaller in vertical and horizontal spatial extent than mechanisms responding to lower frequencies.[121,122] Thus, for a given stimulus luminance, a higher-frequency mechanism receives fewer photons than does a lower-frequency mechanism. The mean number of photons delivered to such a mechanism divided by the standard deviation of the number of photons—the signal-to-noise ratio—follows a square root relation,[123] so the signal-to-noise ratio is inversely proportional to the preferred frequency of the mechanism. The transfer function one expects for a set of such mechanisms should be proportional to $1/f$ where f is spatial frequency.[122] This function is represented by the dotted line in Fig. 11. If we use that relation for describing the postnonlinearity filter, and incorporate the measures of the optical and prenonlinearity filters described above, the resultant is represented by the green circles. The fit between the observed CSF and the resultant is good, so we can conclude that the filters described here are sufficient to account for the shape of the high-frequency limb of the human CSF under foveal viewing conditions.

By use of the theory of ideal observers (see earlier), one can calculate the highest possible contrast sensitivity a system could have if limited by the optics, photoreceptor properties, and constant bandwidth spatial channels described above. As can be seen (green circles), the high-frequency limb of the CSF of such an ideal observer is similar in shape to that of human observers,[122,124] although the rate of falloff at the highest spatial frequencies is not quite as steep as that of human observers.[124] More importantly, the absolute sensitivity of the ideal observer is significantly higher. Some of the low performance of the human compared to the best possible appears to be the consequence of processes that behave like noise internal to the visual system and some appears to be the consequence of employing detecting mechanisms that are not optimally suited for the target being presented.[79,89] The high detection efficiencies observed for sinewave grating patches in the presence of static white noise (e.g., Ref. 87; Fig. 9) suggest that poor spatial pooling of information is not the primary factor responsible for the low human performance (at least when the number of cycles in the grating patches are kept low).

Optical/Retinal Inhomogeneity The fovea is undoubtedly the most critical part of the retina for numerous visual tasks such as object identification and manipulation, reading, and more. But, the fovea occupies less than 1 percent of the total retinal surface area, so it is not surprising to find that nonfoveal regions are important for many visual skills such as selecting relevant objects to fixate, maintaining posture, and determining one's direction of self-motion with respect to environmental landmarks. Thus, it is important to characterize the visual capacity of the eye for nonfoveal loci as well.

The quality of the eye's optics diminishes slightly from 0 to 20 deg of retinal eccentricity and substantially from 20 to 60 deg;[1] see Chap. 1. As described earlier and displayed in Fig. 2, the dimensions and constituents of the photoreceptor lattice and the other retinal neural elements vary significantly with retinal eccentricity. With increasing eccentricity, cone and retinal ganglion cell densities fall steadily and individual cones become broader and shorter. Given these striking variations in optical and receptoral properties across the retina, it is not surprising that different aspects of spatial vision vary greatly with retinal eccentricity. Figure 12 shows CSFs at eccentricities of 0 to 40 deg. With increasing eccentricity, contrast sensitivity falls off at progressively lower spatial frequencies. The high-frequency cutoffs range from approximately 2 cpd at 40 deg to 50 cpd in the fovea. Low-frequency sensitivity is similar from one eccentricity to the next. There have been many attempts to relate the properties of the eye's optics, the receptors, and postreceptoral mechanisms to contrast sensitivity and acuity. For example, models that incorporate eccentricity-dependent variations in optics and cone lattice properties, plus the assumption of fixed bandwidth filters (as in Ref. 122), have been constructed and found inadequate for explaining the observed variations in contrast sensitivity; specifically, high-frequency sensitivity declines more with eccentricity than can be explained by information losses due to receptor lattice properties and fixed bandwidth filters alone.[125] Adding a low-pass filter to the model representing the convergence of cones onto retinal ganglion cells[32] (i.e., by incorporating variation in receptive field center diameter) yields a reasonably accurate account of eccentricity-dependent variations in contrast sensitivity.[125]

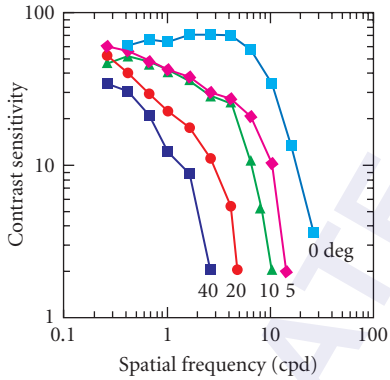

FIGURE 12 CSFs at different retinal eccentricities. *(Adapted from Ref. 125.)*

Adaptation and Inhibition Contrast sensitivity is also dependent upon the space-average intensity (i.e., the mean or background luminance) and the prior level of light adaptation. The blue symbols in Fig. 13 show how threshold amplitudes for spatial sinewaves vary as a function of background luminance for targets of 1 and 12 cpd.[126] [Recall that sinewave amplitude is contrast multiplied by background intensity; see discussion preceding Eq. (24).] The backgrounds were presented continuously and the observer was allowed to become fully light-adapted before thresholds were measured. For the low-spatial-frequency target (blue circles), threshold increases linearly with a slope of 1.0 above the low background intensities (1 log td). A slope of 1.0 in log-log coordinates implies that

$$A_T = k\bar{I} \tag{25}$$

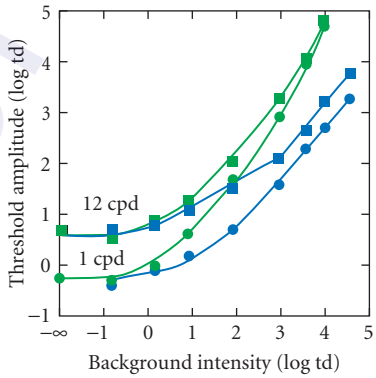

FIGURE 13 Amplitude threshold for gaussian-damped sinusoidal targets with 0.5-octave bandwidths as a function of background intensity. The targets were presented for 50 ms. The green symbols are thresholds measured at the onset of backgrounds flashed for 500 ms in the dark-adapted eye. The blue symbols are thresholds measured against steady backgrounds after complete adaptation to the background intensity. The difference between the green and blue symbols shows the effect of adaptation on contrast sensitivity. (*Adapted from Ref. 126.*)

where A_T is the amplitude threshold (or equivalently, it implies that contrast threshold, C_T, is constant). This proportional relationship between threshold and background intensity is known as *Weber's law*. For the higher spatial-frequency target (blue squares), threshold increases linearly with a slope of 0.5 at intermediate background intensities (0 to 3 log td) and converges toward a slope of 1.0 at the highest background intensities. A slope of 0.5 implies that

$$A_T = k\sqrt{I} \tag{26}$$

(or equivalently, that contrast threshold, C_T, decreases in inverse proportion to the square root of background intensity). This relationship between amplitude threshold and the square root of background intensity is known as the *square root law* or the *DeVries-Rose law*. As suggested by the data in Fig. 13, the size of the square root region gradually grows as spatial frequency is increased. The effect on the CSF is an elevation of the peak and of the high-frequency limb relative to the low-frequency limb as mean luminance is increased, thereby producing a shift of the peak toward higher spatial frequencies.[127,128] This result explains why humans prefer bright environments when performing tasks that require high spatial precision.

The visual system is impressive in its ability to maintain high sensitivity to small contrasts (as produced, for example, by small changes in surface reflectance) over the enormous range of ambient light levels that occur in the normal environment. In order to have high sensitivity to small contrasts, the response gain of visual neurons must be kept high, but high gain leaves the visual system vulnerable to the effects of response saturation (because neurons are noisy and have a limited response range). The visual system's solution to this "dynamic-range problem" is threefold: (1) use separate populations of receptors (rods and cones) to detect contrasts in the lower and upper ranges of ambient intensity, (2) adjust the retinal illumination via the pupil reflex, and (3) directly adjust the sensitivity of individual receptors and neurons (e.g., Refs. 129, 130). All three components are important, but the third is the most significant and is accomplished within the receptors and other neurons through photochemical and neural adaptation. The combined effect of the photochemical and neural adaptation mechanisms on foveal contrast detection is illustrated by the difference between the open and solid data points in Fig. 13 (all the data were obtained with a fixed pupil size). The green symbols show cone detection threshold for the 1- and 12-cpd targets on a background flashed in the dark-adapted eye (i.e., there was no chance for light adaptation) as a function of background intensity. The difference between the green and blue symbols shows the improvement in detection sensitivity due to photochemical and neural adaptation within the cone system.

The pupil reflex and photopigment depletion (see "Image Sampling by the Photoreceptors") are *multiplicative adaptation* mechanisms; they adjust the sensitivity of the eye by effectively scaling the input intensity by a multiplicative gain factor that decreases with increasing average intensity. The pupil reflex operates over most of the intensity range (see Chap. 1); photopigment depletion is only effective in the cone system above about 4 log td (see Fig. 13) and is ineffective in the rod system, at least over the range of relevant intensities (see earlier discussion). There is considerable psychophysical evidence that a substantial component of the remaining improvement in sensitivity illustrated in Fig. 12 is due to multiplicative neural adaptation mechanisms.[129,131–134] However, multiplicative adaptation alone cannot reduce threshold below a line of slope 1.0, tangent to the threshold curve in dark-adapted eye.[129,134] The remaining improvements in sensitivity (the difference between the tangent lines and the blue symbols) can be explained by neural *subtractive adaptation* mechanisms.[134,135] There is evidence that the multiplicative and subtractive adaptation mechanisms each have fast and slow components.[134–137] Threshold functions, such as those in Fig. 13, can be predicted by simple models consisting of a compressive (saturating) nonlinearity [Eq. (13)], a multiplicative adaptation mechanism, a subtractive adaptation mechanism, and either constant additive noise or multiplicative (Poisson) neural noise.

A common explanation of the low-frequency falloff of the CSF (e.g., Fig. 12) is based on center/surround mechanisms evident in the responses of retinal and LGN neurons. For example, compare the CSFs measured in individual LGN neurons in Fig. 5 with the human CSF in Fig. 12. The center and surround mechanisms are both low-pass spatial filters, but the cutoff frequency of the surround is much lower than that of the center. The center and surround responses are subtracted neurally, so

at low spatial frequencies, to which center and surround are equally responsive, the neuron's response is small. With increasing spatial frequency, the higher resolution of the center mechanism yields a greater response relative to the surround, so the neuron's response increases.

While the center/surround mechanisms are undoubtedly part of the explanation, they are unlikely to be the whole story. For one thing, the time course of the development of the low-frequency falloff is slower than one expects from physiological measurements.[105] Second, the surround strength in retinal and LGN neurons is on average not much more than half the center strength;[37] this level of surround strength is consistent with the modest low-frequency falloffs observed under transient presentations, but inconsistent with the steep falloff observed for long-duration, steady-fixation conditions. Third, there is considerable evidence for slow subtractive and multiplicative adaptation mechanisms, and these ought to contribute strongly to the shape of the low-frequency limb under steady fixation conditions.[137–139] Thus, the strong low-frequency falloff of the CSF under steady viewing conditions may reflect, to some degree, slow subtractive and multiplicative adaptation mechanisms whose purpose is to prevent response saturation while maintaining high contrast sensitivity over a wide range of ambient light levels. The weaker low-frequency falloff seen for brief presentations may be the result of the fast-acting surround mechanisms typically measured in physiological studies; however, fast-acting local multiplicative and subtractive mechanisms could also play a role.

Temporal Contrast Detection Space-time plots of most contrast-detection stimuli (plots of intensity as a function of x, y, t) show intensity variations in both space and time; in other words, most contrast detection stimuli contain both spatial and temporal contrast.

The discussion of contrast detection has, so far, emphasized spatial dimensions (e.g., spatial frequency), but there is, not surprisingly, a parallel literature emphasizing temporal dimensions (for a recent review see Ref. 140). Figure 14 shows de Lange's[141] measurements of temporal contrast sensitivity

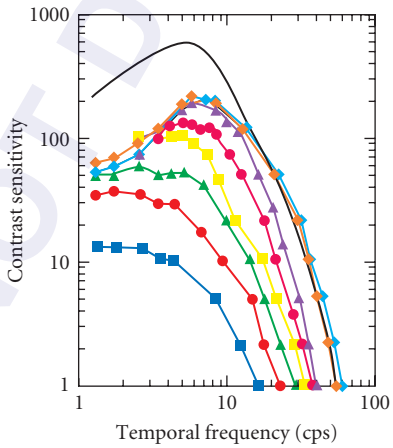

FIGURE 14 Temporal contrast sensitivity functions measured in the fovea at several mean luminances for a 2° circular test field. The test field was modulated sinusoidally and was imbedded in a large, uniform background field of the same mean luminance. Mean luminance: (■) 0.375 td, (●) 1 td, (▲) 3.75 td, (■) 10 td, (●) 37.5 td, (▲) 100 td, (◆) 1000 td, (◆) 10,000 td. (*Data from Ref. 141.*) The black curve is the MTF derived from the impulse response function of a single macaque cone reported by Schnapf et al.[17] The cone MTF was shifted vertically (in log-log coordinates) for comparison with the shape of the high-frequency falloff measured psychophysically.

functions at several mean luminances for uniform discs of light modulated in intensity sinusoidally over time. The major features of these results have been confirmed by other researchers.[142,143] Like spatial CSFs, temporal CSFs typically have a bandpass shape. At high mean luminances, the peak contrast sensitivity occurs at approximately 8 cycles per second (cps) and the cutoff frequency (also known as the critical flicker frequency) at approximately 60 cps. Contrast sensitivity increases with increasing mean luminance, larger increases (in log-log coordinates) being observed at middle and high temporal frequencies. For low temporal frequencies (below 6 cps), contrast sensitivity is nearly constant (i.e., Weber's law is observed) for mean intensities greater than 10 td or so.

The entire temporal CSF can be fit by a weighted difference of linear low-pass filters, where one of the filters has a relatively lower cutoff frequency, and/or where one of the filters introduces a relatively greater time delay (see Ref. 140). However, to fit the temporal CSFs obtained under different stimulus conditions, the time constants and relative weights of the filters must be allowed to vary. The low-frequency falloff may be partly due to the biphasic response of the photoreceptors (see Fig. 3), which appears to involve a fast subtractive process.[17] Surround mechanisms, local subtractive mechanisms, and local multiplicative mechanisms also probably contribute to the low-frequency falloff.

The factors responsible for the high-frequency falloff are not fully understood, but there is some evidence that much of the high-frequency falloff is the result of temporal integration within the photoreceptors.[144,145] The black curve in Fig. 14 is the MTF of the macaque cone photocurrent response derived from measured impulse-response functions[17] (see Fig. 3). The impulse responses were obtained in the linear response range by presenting brief, dim flashes on a dark background. Although the background was dark, there appears to be little effect of light adaptation on cone responses until background intensity exceeds at least a few hundred trolands;[17,24] thus, the cone impulse-response functions measured in the dark ought to be valid up to moderate background intensities. Following Boynton and Baron,[144] we have shifted the MTF vertically in order to compare the shape of the cone high-frequency falloff to that of the temporal CSF. The shapes are similar, lending support to the hypothesis that cone temporal integration is responsible for the shape of the high-frequency limb of the temporal CSF.

It is well established that a pulse of light briefer than some critical duration will be just visible when the product of its duration and intensity is constant. This is *Bloch's law*, which can be written:

$$I_T T = k \quad \text{for} \quad T < T_c \tag{27}$$

where k is constant, T_c is the critical duration and I_T is the threshold intensity at duration T. Naturally, Bloch's law can also be stated in terms of contrasts by dividing the intensities in the above equation by the background intensity. Below the critical duration, log-log plots of threshold intensity versus duration have a slope of −1. Above the critical duration, threshold intensity falls more slowly with increasing duration than predicted by Bloch's law (slope between −1 and 0) and, in some cases, it even becomes independent of duration (slope of 0).[76,146] It is sometimes difficult to determine the critical duration because the slopes of threshold-versus-duration plots can change gradually, but under most conditions Bloch's critical duration declines monotonically with increasing background intensity from about 100 ms at 0 log td to about 25 ms at 4 log td.

Bloch's law is an inevitable consequence of a linear filter that only passes temporal frequencies below some cutoff value. This can be seen by computing the Fourier transform of pulses for which the product $I_T T$ is constant. The amplitude spectrum is given by $I_T \sin(T\pi f)/\pi f$ where f is temporal frequency; this function has a value $I_T T$ at $f = 0$ and is quite similar over a range of temporal frequencies for small values of T. Indeed, to a first approximation, one can predict the critical duration T_c from the temporal CSFs shown in Fig. 14, as well as the increase in T_c with decreasing background intensity.[140]

The shape of the temporal sensitivity function depends upon the spatial frequency of the stimulus. Figure 15 shows temporal CSFs measured for spatial sinewave gratings whose contrast is modulated sinusoidally in time.[147] With increasing spatial frequency, the temporal CSF evolves from a bandpass function with high sensitivity (as in Fig. 14) to a low-pass function of lower sensitivity.[128,147] The solid curves passing through the data for the high spatial-frequency targets and the dashed curves passing through the data for the low spatial-frequency targets are identical except for vertical shifting. Similar behavior occurs for spatial CSFs at high spatial frequencies: changes in temporal frequency cause a vertical sensitivity shift (in log coordinates). Such behavior shows that the spatiotemporal CSF is separable at high temporal and spatial frequencies; that is, sensitivity can be predicted from the product

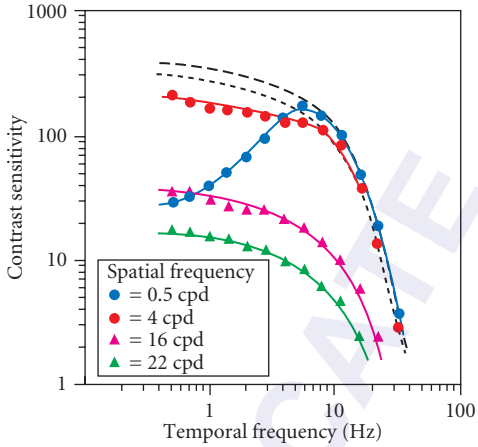

FIGURE 15 Temporal contrast sensitivity functions measured for several different spatial frequencies. The contrast of spatial sinewave gratings were modulated sinusoidally in time. The solid curves passing through the data for the high spatial-frequency targets and the dashed curves passing through the data for the low-frequency targets are identical except for vertical shifting. (*Reproduced from Ref. 147.*)

of the spatial and temporal CSFs at the appropriate frequencies. This finding suggests that the same anatomical and physiological mechanisms that determine the high-frequency slope of spatial and temporal CSFs determine sensitivity for the high-frequency regions of the spatiotemporal CSF.

The spatiotemporal CSF is, however, clearly not separable at low spatial and temporal frequencies, so an explanation of the underlying anatomical and physiological constraints is more complicated. The lack of spatiotemporal separability at low spatiotemporal frequencies has been interpreted by some as evidence for separate populations of visual neurons tuned to different temporal frequencies[143,148] and by others as evidence for different spatiotemporal properties of center and surround mechanisms within the same populations of neurons.[147,149] It is likely that a combination of the two explanations is the correct one. For a review of the evidence concerning this issue prior to 1984, see Ref. 140; for more recent evidence, see Refs. 150, 151, and 152.

The available evidence indicates that the temporal CSF varies little with retinal eccentricity once differences in spatial resolution are taken into account.[153,154]

Chromatic Contrast Detection The discussion has, so far, concerned luminance contrast detection (contrast detection based upon changes in luminance over space or time); however, there is also a large literature concerned with chromatic contrast detection (contrast detection based upon changes in wavelength distribution over space or time). Although the focus of this chapter is on achromatic vision, it is appropriate to say a few words about chromatic contrast sensitivity functions. A chromatic spatial CSF is obtained by measuring thresholds for the detection of sinewave gratings that modulate spatially in wavelength composition, without modulating in luminance.* This is typically accomplished by adding two sinewave gratings of different wavelength distributions but the

*The standard definition of luminance is based upon "the $V(\lambda)$ function" [see Eq. (5)] which is an average of spectral sensitivity measurements on young human observers. Precision work in color vision often requires taking individual differences into account. To do this a psychophysical procedure, such as flicker photometry, is used to define luminance separately for each observer in the study. For more details, see Ref. 5 and Chap. 11.

same luminance amplitude. The two gratings are added in opposite spatial phase so that the mean luminance is constant across the pattern; such a pattern is said to be *isoluminant*. Formally, an isoluminant sinewave grating can be defined as follows:

$$I(x,y)=(A\sin(2\pi fx)+\bar{I}_1)+(-A\sin(2\pi fx)+\bar{I}_2) \tag{28}$$

where the first term on the right represents the grating for one of the wavelength distributions, and the second term on the right for the other distribution. The terms $\bar{I}_1$ and $\bar{I}_2$ are equal in units of luminance. Contrast sensitivity at spatial frequency f is measured by varying the common amplitude, A. (Note that $I(x, y)$ is constant independent of A, and that when $A = 0.0$ the image is a uniform field of constant wavelength composition.) Chromatic contrast is typically defined as $C=2A/(\bar{I}_1+\bar{I}_2)$.

The green circles in Fig. 16 are an isoluminant CSF for a combination of red and green gratings.[155] The squares are a luminance (isochromatic) CSF measured with the same procedure, on the same subjects. As can be seen, there are three major differences between luminance and chromatic CSFs:[156] (1) the high-frequency falloff of the chromatic CSFs occurs at lower spatial frequencies (acuity is worse); (2) the chromatic CSF has a much weaker (or absent) low-frequency falloff, even under steady viewing conditions; and (3) chromatic contrast sensitivity is greater than luminance contrast sensitivity at low spatial frequencies.

Two of the factors contributing to the lower high-frequency limb of the chromatic (red/green) CSF are the large overlap in the absorption spectra of the L (red) and M (green) cones, and the overlap (when present) of the wavelength distributions of the component gratings. Both of these factors reduce the effective contrast of the grating at the photoreceptors. A precise way to quantify these effects (as well as those of the other preneural factors) is with an ideal-observer analysis (e.g., Refs. 78,124,157). For example, one can physically quantify the equivalent luminance contrast of a chromatic grating by (1) computing the detection accuracy of an ideal observer, operating at the level of the photoreceptor photopigments, for the chromatic grating at the given chromatic contrast, and then (2) computing the equivalent luminance contrast required to bring the ideal observer to the same accuracy level.[124,158] The magenta circles in Fig. 16 are the chromatic CSF data replotted in terms

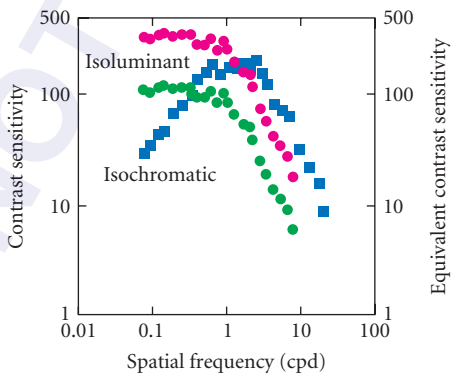

FIGURE 16 Isoluminant and isochromatic contrast sensitivity functions. The blue squares are isochromatic (luminance) CSFs for a green grating (526 nm). The green circles are isoluminant (chromatic) CSFs for gratings modulating between red (602) and green (526 nm). The magenta circles are the isoluminant data replotted as equivalent luminance contrast sensitivity (right axis). The isochromatic CSF plots the same on the left and right axes. (*Data from Ref. 155.*)

of equivalent luminance contrast. (The luminance CSF data are, of course, unaffected and hence are the same on both scales.) If the differences between the high-frequency falloffs of the luminance and chromatic CSFs were due to preneural factors alone, then the high-frequency limbs (magenta circles and blue squares) would superimpose. The analysis suggests that there are also neural factors contributing to the difference between high-frequency limbs.

One difficulty in interpreting the high-frequency limb of chromatic CSFs is the potential for luminance artifacts due to chromatic aberration.[156] Recently Sekiguchi et al.[124] eliminated chromatic aberration artifacts by producing isoluminant gratings with a laser interferometer which effectively bypasses the optics of the eye. Their results are similar to those in Fig. 16.

Comparison of the magenta circles and blue squares in Fig. 16 shows that the neural mechanisms are considerably more efficient at detecting chromatic contrast than luminance contrast at spatial frequencies below 2 cpd. One possible explanation is based upon the receptive-field properties of neurons in the retina and LGN (e.g., see Refs. 48 and 159). Many retinal ganglion cells (and presumably bipolar cells) are chromatically opponent in the sense that different classes of photoreceptors dominate the center and surround responses. The predicted CSFs of linear receptive fields with chromatically opponent centers and surrounds are qualitatively similar to those in Fig. 16.

Chromatic temporal CSFs have been measured in much the same fashion as chromatic spatial CSFs except that the chromatic sinewaves were modulated temporally rather than spatially [i.e., x represents time rather than space in Eq. (28)]. The pattern of results is also quite similar:[94,156,160] (1) the high-frequency falloff of chromatic CSFs occurs at lower temporal frequencies, (2) the chromatic CSF has a much weaker low-frequency falloff, and (3) chromatic contrast sensitivity is greater than luminance contrast sensitivity at low temporal frequencies. Again, the general pattern of results is qualitatively predicted by a combination of preneural factors and the opponent receptive field properties of retinal ganglion cells (e.g., see Ref. 48).

Contrast Discrimination and Contrast Masking

The ability to discriminate on the basis of contrast is typically measured by presenting two sinusoids of the same spatial frequency, orientation, and phase, but differing contrasts. The common contrast C is referred to as the *pedestal contrast* and the additional contrast ΔC in one of the sinusoids as the *increment contrast*. Figure 17 shows typical *contrast discrimination functions* obtained from such measurements. The increment contrast varies as a function of the pedestal contrast. At low

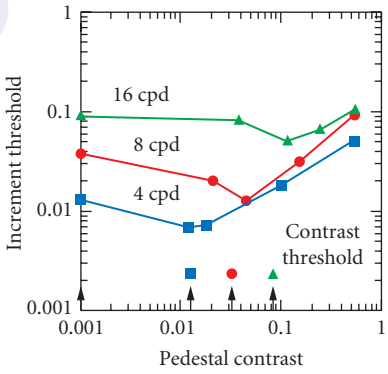

FIGURE 17 Contrast discrimination functions at different spatial frequencies. The just-discriminable contrast increment is plotted as a function of the contrast common to the two targets. The arrows indicate contrast thresholds at the indicated spatial frequencies. (*Adapted from Ref. 78.*)

pedestal contrasts, ΔC falls initially and then at higher contrasts becomes roughly proportional to $C^{0.6}$. Because the exponent is generally less than 1.0, Weber's law does not hold for contrast discrimination. Ideal observer calculations show that pedestal contrast has no effect on discrimination information; therefore, the variations in threshold with pedestal contrast must be due entirely to neural mechanisms. The dip at low pedestal contrasts has been modeled as a consequence of an accelerating nonlinearity in the visual pathways (e.g., Ref. 161) or the consequence of observer uncertainty (e.g., Ref. 162). The evidence currently favors the former.[89] Contrast discrimination functions at different spatial frequencies[78,163] and at different eccentricities[164] are, to a first approximation, similar in shape; that is to say, the functions can be superimposed by shifting the data along the log pedestal and log increment axes by the ratio of detection thresholds.

A generalization of the contrast-discrimination experiment is the contrast-masking experiment in which the increment and pedestal differ from one another in spatial frequency, orientation and/or phase. In contrast-masking experiments, the increment and pedestal are usually referred to as the *target* and *masker*, respectively. Figure 18*a* shows typical contrast-masking functions obtained for sinewave maskers of different orientations. The orientation of the sinewave target is vertical (0 deg); thus, when the orientation of the masker is also vertical (squares), the result is just a contrast discrimination function, as in Fig. 17. For suprathreshold maskers (in this case, maskers above 2 percent contrast), the threshold elevation produced by the masker decreases as the difference between target and masker orientation increases; indeed, when the target and masker are perpendicular (diamonds), there is almost no threshold elevation even at high masker contrasts. Also, the slope of the contrast-masking function (in log-log coordinates) decreases as the difference in orientation increases. Finally, notice that threshold enhancement at low masking contrasts occurs only when the masker has approximately the same orientation as the target.

Figure 18*b* shows a similar set of masking functions obtained for sinewave maskers of different spatial frequencies. The effect of varying masker spatial frequency is similar to that of varying masker orientation: with greater differences in spatial frequency between masker and target, masking is reduced, the slope of the contrast-masking function is reduced, and the threshold enhancement at low masker contrasts becomes less evident.

The substantial variations in threshold seen as a function of masker spatial frequency and orientation provide one of the major lines of evidence for the existence of multiple orientation and spatial-frequency-tuned channels in the human visual system;[119,165] for a review, see Ref. 166. Masking data (such as those in Fig. 18) have been analyzed within the framework of specific multiple-channel models in order to estimate the tuning functions of the spatial channels (e.g., Ref. 167). In one popular model, each channel consists of an initial linear filter followed by a static (zero memory) nonlinearity

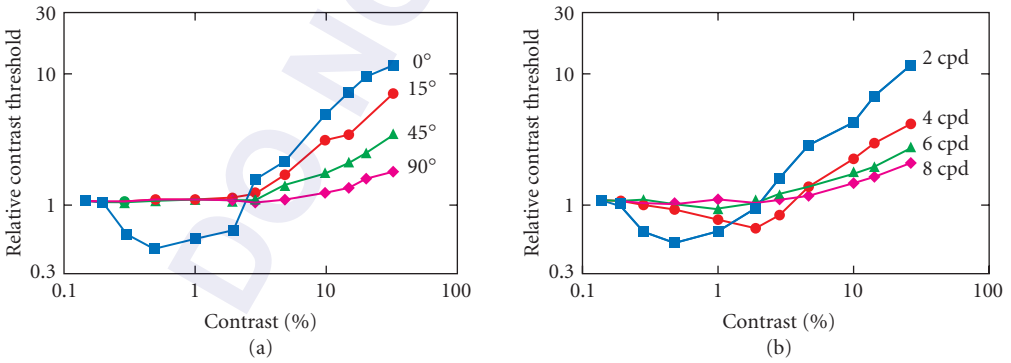

FIGURE 18 Contrast masking functions for sinewave-grating maskers of various orientations and spatial frequencies. The target was a 2-cpd sinewave grating. (*a*) Contrast-masking functions for 2-cpd maskers of various orientations. (*b*) Contrast-masking functions for 0° (vertical) maskers of various spatial frequencies. (*Adapted from Ref. 265.*)

that is accelerating at low contrasts and compressive at high contrasts (e.g., Refs. 161, 167, 168). Wilson and colleagues have shown that the spatial-channel tuning functions estimated within the framework of this model can predict discrimination performance in a number of different tasks (for a summary, see Ref. 169). However, recent physiological evidence[70,71] and psychophysical evidence[169,170] suggests that the compressive component of the nonlinearity is a broadly tuned, multiplicative gain mechanism, which is fundamentally different from the accelerating component. The full implications of these findings for the psychophysical estimation of channel-tuning functions and for the prediction of discrimination performance are not yet known.

Masking paradigms have also been used to estimate the tuning of temporal channels.[151,171]

Contrast Estimation

We have argued that the differential visibility of coarse and fine patterns can be understood from an analysis of information losses in the early stages of vision: optics, receptor sampling, the inverse relation between the preferred spatial frequency and size of tuned spatial mechanisms, and retinal adaptation mechanisms. It is important to note, however, that the differential visibility described by the CSF in Fig. 11 does not relate directly to perceptual experience. For example, if you hold this page up close and then at arm's length, the apparent contrast of the text does not change appreciably even though the spatial frequency content (in cycles per degree) does. This observation has been demonstrated experimentally by asking observers to adjust the contrast of a sinusoidal grating of one spatial frequency until it appeared to match the contrast of a sinusoid of a different frequency.[172] For example, consider two gratings, one at 5 cpd and another at 20 cpd; the former is near the peak of the CSF and the latter is well above the peak so it requires nearly a log unit more contrast to reach threshold. The 5-cpd target was set to a fixed contrast and the observer was asked to adjust the contrast of the 20-cpd target to achieve an apparent contrast match. When the contrast of the 5-cpd target was set near threshold, observers required about a log unit more contrast in the higher-frequency target before they had the same apparent contrast. The most interesting result occurred when the contrast of the 5-cpd grating was set to a value well above threshold. Observers then adjusted the contrast of the 20-cpd grating to the same physical value as the contrast of the lower-frequency target. This is surprising because, as described above, two gratings of equal contrast but different spatial frequencies produce different retinal image contrasts (see Chap. 1). In other words, when observers set 5- and 20-cpd gratings to equal physical contrasts, they were accepting as equal in apparent contrast two gratings whose retinal image contrast differed substantially. This implies that the visual system compensates at suprathreshold contrasts for the defocusing effects of the eye's optics and perhaps for the low-pass filtering effects of early stages of processing. This phenomenon has been called *contrast constancy*; the reader might recognize the similarity to deblurring techniques used in aerial and satellite photography (e.g., Ref. 173).

Visual Acuity

The ability to perceive high-contrast spatial detail is termed *visual acuity*. Measurements of visual acuity are far and away the most common means of assessing ocular health[174] and suitability for operating motor vehicles.[175] The universal use of visual acuity is well justified for clinical assessment,[176] but there is evidence that it is unjustified for automobile licensing (e.g., Ref. 177).

As implied by the discussion of contrast sensitivity, eye movements, optics, receptor properties, and postreceptoral neural mechanisms all conspire to limit acuity; one factor may dominate in a given situation, but they all contribute. To assess acuity, high-contrast patterns of various sizes are presented at a fixed distance. The smallest pattern or smallest critical pattern element that can be reliably detected or identified is taken as the threshold value and is usually expressed in minutes of arc. Countless types of stimuli have been used to measure visual acuity, but the four illustrated in Fig. 19 are most common.

Gratings are used to measure minimum angle of resolution (MAR); the spatial frequency of a high-contrast sinusoidal grating is increased until its modulation can no longer be perceived. The

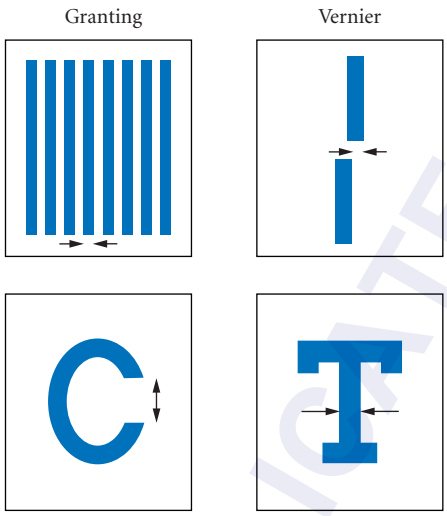

FIGURE 19 Targets commonly used to assess visual acuity. The dimension of the target that is taken as the acuity threshold is indicated by the arrows.

reader should note that this measurement is equivalent to locating the high-frequency cutoff of the spatial CSFs shown in previous sections. Under optimal conditions, the finest detectable grating bars are about 30 arcsec wide.[112]

The Landolt ring target is a high-contrast ring with a gap appearing in one of four positions. Threshold is defined as the smallest gap that can be correctly located. Under optimal conditions, threshold is again about 30 arcsec or slightly smaller.[112]

The most common test in clinical and licensing situations is the letter acuity task. The stimuli are a series of solid, high-contrast letters, varying in size. Threshold is defined by the smallest identifiable stroke width which, under optimal conditions, is nearly 30 arcsec.

Finally, the vernier acuity task involves the presentation of two nearly aligned line segments. Threshold is defined by the smallest visible offset from colinearity. Under optimal conditions, vernier acuity is about 5 arcsec.[178,179] The special label, *hyperacuity*, has been provided for spatial thresholds, like vernier acuity, that are smaller than the intercone distance.[180]

In practice, testing environments can vary widely along dimensions that affect visual acuity. These dimensions include illumination, the care chosen to correct refractive errors, and more. The National Academy of Sciences (1980) has provided a set of recommended standards for use in acuity measurements including use of the Landolt ring.

Although these various acuity tasks are clearly related, performance on the four tasks is affected differently by a variety of factors and, for this reason, one suspects that the underlying mechanisms are not the same.[110,181] Figure 20 shows how grating and vernier acuities vary with retinal eccentricity. It is obvious from this figure that no single scaling factor can equate grating and vernier acuity across retinal eccentricities; a scaling factor that would equate grating acuity, for example, would not be large enough to offset the dependence of vernier acuity on retinal eccentricity.

Indeed, there have been several demonstrations that the two types of acuity depend differently on experimental conditions. For example, grating acuity appears more susceptible to optical defects and contrast reductions, whereas vernier, Landolt, and letter acuities are more susceptible to a visual condition called *amblyopia*.[182] There are numerous models attempting to explain why different types

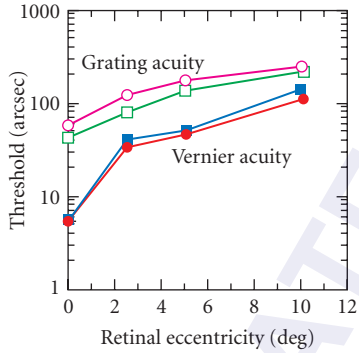

FIGURE 20 Grating and vernier acuity as a function of retinal eccentricity. The open symbols represent the smallest detectable bar widths for a high-contrast grating. The filled symbols represent the smallest detectable offset of one line segment with respect to another. Circles and squares are the data from two different observers. (*Adapted from Ref. 110.*)

of acuity are affected dissimilarly by experimental conditions, particularly eccentric viewing (e.g., Refs. 183 and 184).

The explanation of spatial discrimination thresholds smaller than the distance between photoreceptors, such as vernier acuity, has become a central issue in contemporary models of spatial vision. One view is that the fine sensitivity exhibited by the hyperacuities[179] reveals a set of local spatial primitives or features that are encoded particularly efficiently in the early stages of vision.[185–187] The other view is that hyperacuity can be understood from an analysis of information processing among the spatially tuned mechanisms described in the earlier sections.[183,188,189] Evidence favoring the second view is manifold. It has been shown, for example, that offset thresholds smaller than the grain of the photoreceptor lattice are predicted from measurements of the linear filtering and signal-to-noise properties of retinal ganglion cells.[188] Likewise, human vernier thresholds can be predicted in many situations from measurements of contrast discrimination thresholds.[190] Also, ideal-observer analysis has demonstrated that the information available at the level of the photoreceptors predicts better performance in hyperacuity tasks than in acuity (resolution) tasks,[191] suggesting that any relatively complete set of spatially tuned mechanisms should produce better performance in the hyperacuity tasks. The remaining puzzle for proponents of the second view, however, is why vernier acuity and the other hyperacuities diminish so strikingly with increasing retinal eccentricity.

Pattern Discrimination

An important aspect of spatial vision is the ability to distinguish one pattern from another. In this section, we consider the ability to distinguish simple, suprathreshold patterns that vary along a single dimension. The dimensions considered are orientation, size or spatial frequency, and position or phase.

The detectability of a pattern varies to some degree with orientation. For most observers, for example, targets are most visible when oriented vertically or horizontally and least when oriented obliquely.[192] This *oblique effect* is demonstrable for periodic and aperiodic targets and is largest for fine-detail targets. The cause of the effect appears to be differential sensitivity among orientation-tuned mechanisms, presumably in the visual cortex.[193] The ability to discriminate gratings differing in orientation depends on several stimulus parameters including target length, contrast, and

spatial frequency, but observers can generally discriminate extended, high-contrast targets that differ by 1 deg or less.

The ability to discriminate gratings differing in spatial frequency or aperiodic stimuli differing in size depends critically on the reference frequency or size. That is to say, the ratio of the frequency discrimination threshold, Δf, to the reference frequency, f, is roughly constant at about 0.03 for a wide range of reference frequencies;[194] similarly, the ratio of size discrimination threshold to reference size is roughly constant for a variety of reference sizes, except when the reference is quite small.[179]

The encoding of spatial phase is crucial to the identification of spatial patterns. Its importance is demonstrated quite compellingly by swapping the amplitude and phase spectra of two images; the appearance of such hybrid images corresponds to a much greater degree with their phase spectra than with their amplitude spectra.[195] The conventional explanation is that the phase spectrum determines the spatial structure of an image, but this is perhaps too simplistic because the amplitude spectra of most natural images are much more similar to one another than are the phase spectra (e.g., Refs. 196 and 197). Also, given that the result was obtained using global Fourier transforms, it does not have direct implications about the relative importance of phase coding within spatially localized channels.[198] Nonetheless, such demonstrations illustrate the important relationship between the encoding of spatial phase and pattern identification.

In phase discrimination tasks, the observer distinguishes between patterns—usually periodic patterns—that differ only in the phase relationships of their spatial frequency components. The representation of spatial phase in the fovea is very precise: observers can, for instance, discriminate relative phase shifts as small as 2 to 3 deg (of phase angle) in compound gratings composed of a fundamental and third harmonic of 5 cpd;[199] this is equivalent to distinguishing a positional shift of about 5 arcsec. Phase discrimination is much less precise in extrafoveal vision.[200–202] There has been speculation that the discrimination anomalies observed in the periphery underlie the diminished ability to distinguish spatial displacements,[110] to segment textures on the basis of higher-order statistics,[203,204] and to identify complex patterns such as letters,[205] but detailed hypotheses linking phase discrimination to these abilities have not been developed.

One model of phase discrimination[206] holds that local energy computations are performed on visual inputs and that local energy peaks are singled out for further analysis. The energy computation is performed by cross-correlating the waveform with even- and odd-symmetric spatial mechanisms of various preferred spatial frequencies. The relative activities of the even- and odd-symmetric mechanisms are used to represent the sort of image feature producing the local energy peak. This account is supported by the observation that a two-channel model, composed of even- and odd-symmetric mechanisms, predicts many phase discrimination capabilities well (e.g., Refs. 207–209). The model also offers an explanation for the appearance of illusory Mach bands at some types of edges and not others.[206] For this account to work, however, one must assume that odd-symmetric, and not even-symmetric, mechanisms are much less sensitive in the periphery than in the fovea because some relative phase discriminations are extremely difficult in extrafoveal vision and others are quite simple[202,209,210] (but see Ref. 211).

Motion Detection and Discrimination

The ability to discriminate the form and magnitude of retinal image motion is critical for many fundamental visual tasks, including navigation through the environment, shape estimation, and distance estimation. There is a vast literature on motion perception (some representative reviews from somewhat different perspectives can be found in Refs. 45, 212, 213). Here, we briefly discuss simple motion discrimination in the frontoparallel plane, and (as an example of more complicated motion processing) observer heading discrimination.

Detection and/or discrimination of motion in the frontoparallel plane is influenced by a number of factors, including contrast, wavelength composition, spatial-frequency content, initial speed, and eccentricity. For simplicity, and for consistency with the other sections in this chapter, we consider here only experiments employing sinewave-grating or random-dot stimuli.

Contrast sensitivity functions for detection of moving (drifting) sinewave-grating targets have the interesting property that they are nearly shape invariant on a log spatial-frequency axis; furthermore,

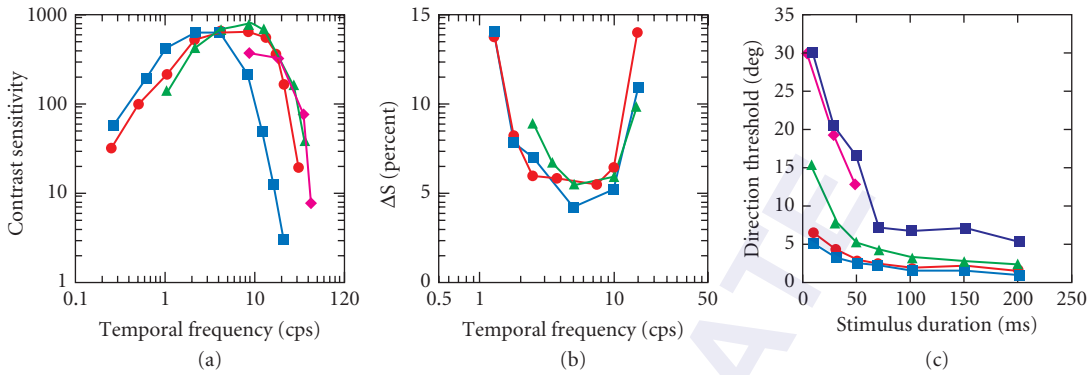

FIGURE 21 Motion detection and discrimination thresholds. (*a*) Contrast sensitivity for drifting sinewave gratings plotted as a function of temporal frequency. Each curve is for a different drift speed; (■) 1 deg/s (●) 10 deg/s, (▲) 100 deg/s; (◆) 800 deg/s. (*Adapted from Ref. 214.*) (*b*) Speed discrimination thresholds plotted as a function of temporal frequency. Each curve is for a different drift speed; (●) 5 deg/s, (■) 10 deg/s, (▲) 20 deg/s. (*Adapted from Ref. 215.*) (*c*) Direction threshold for random dot patterns as a function of stimulus duration. Each curve is for a different drift speed; (■) 1 deg/s, (▲) 4 deg/s, (●) 16 deg/s, (■) 64 deg/s, (◆) 256 deg/s. (*Adapted from Ref. 216.*)

as shown in Fig. 21*a*, they are nearly superimposed at high speeds and low spatial frequencies, when plotted as a function of temporal frequency.[106,214*] This latter result corresponds to the fact (mentioned earlier) that spatial CSFs are relatively flat at low spatial frequencies and high temporal frequencies.[128,147] In interpreting Fig. 21*a*, it is useful to note that the velocity (V) of a drifting sinewave grating is equal to the temporal frequency (f_t) divided by the spatial frequency (f_s):

$$V = \frac{f_t}{f_s} \tag{29}$$

Measurements of CSFs for moving stimuli provide relatively little insight into how the visual system extracts or represents motion information. For example, in one common paradigm[106] it is possible for subjects to perform accurately without "seeing" any motion at all. Greater insight is obtained by requiring the observer to discriminate between different aspects of motion such as speed or direction.

Representative measurements of speed discrimination for drifting sinewave grating targets are shown in Fig. 21*b*. The figure shows the just-detectable change in speed as a function of temporal frequency; each curve is for a differential initial or base speed. Similar to the motion CSFs, speed discrimination is seen to be largely dependent upon the temporal frequency and relatively independent of the speed.[215] As can be seen, the smallest detectable changes in speed are approximately 5 percent, and they occur in the temporal frequency range of 5 to 10 cps, which is similar to the temporal frequency where contrast sensitivity for drifting gratings is greatest (cf., Fig. 21*a*). Interestingly, 5 to 10 cps is the temporal frequency range of strongest response for most neurons in the macaque's primary visual cortex.[60] For random-dot patterns, the smallest detectable change in speed is also approximately 5 percent.[216]

Representative measurements of direction discrimination for drifting random-dot patterns are shown in Fig. 21*c*, which plots direction threshold in degrees as a function of stimulus duration for a wide range of speeds. Direction discrimination improves with duration and is a U-shaped function of dot speed. Under optimal conditions, direction discrimination thresholds are in the neighborhood of 1 to 2°.[216,217]

The available evidence suggests that direction and speed discrimination improve quickly with contrast at low contrasts but show little improvement when contrast exceeds a few percent.[215,218,219] Motion discrimination is relatively poor at isoluminance.[220,221] The variations in motion discrimination with eccentricity can be largely accounted for by changes in spatial resolution.[222]

*The temporal frequency of a drifting grating is the number of stripes passing a fixed reference point per unit time (seconds).

Psychophysical evidence suggests that there are at least two mechanisms that can mediate motion discrimination—a *short-range mechanism* which appears to be closely associated with motion-selective neurons in the early levels of cortical processing, and a *long-range mechanism* which appears to be associated with more "inferential" calculations occurring in later levels of cortical processing. Clear evidence for this view was first observed in an apparent motion paradigm in which observers were required to judge the shape of a region created by laterally displacing a subset of random dots in a larger random-dot pattern.[223] (These patterns are examples of *random-dot kinematograms*, the motion analog to random-dot stereograms.) Observers could accurately judge the shape of the region only if the displacements (1) were less than approximately 15 minarc ($D_{max} = 15$ min); (2) occurred with a delay of less than approximately 100 ms; and (3) occurred within the same eye (i.e., dichoptic presentations failed to produce reliable discrimination). These data suggest the existence of motion-sensitive mechanisms that can only detect local, monocular correlations in space-time.

The fact that motion-selective neurons in the early levels of the cortex can also only detect local spatiotemporal correlations suggests that they may be the primary source of neural information used by the subsequent mechanisms that extract shape and distance information in random-dot kinematograms. The receptive fields of motion-selective neurons decrease in size as a function of optimal spatial frequency, and they increase in size as a function of retinal eccentricity. Thus, the hypothesis that motion-selective neurons are the substrate for shape extraction in random-dot kinematograms is supported by the findings that D_{max} increases as spatial-frequency content is decreased via low-pass filtering,[224] and that D_{max} increases as total size of the kinematogram is increased.[225]

Accurate shape and motion judgments can sometimes be made in apparent-motion displays where the stimulation is dichoptic and/or the spatiotemporal displacements are large. However, in these cases the relevant shape must be clearly visible in the static frames of the kinematogram. The implication is that higher-level, inferential analyses are used to make judgments under these circumstances. A classic example is that we can infer the motion of the hour hand on a clock from its long-term changes in position even though the motion is much too slow to be directly encoded by motion-selective cortical neurons.

The evidence for short-term and long-term motion mechanisms raises the question of what mechanisms actually mediate performance in a given motion discrimination task. The studies described above (e.g., Fig. 21) either randomized stimulus parameters (such as duration and spatial frequency) and/or used random-dot patterns; hence, they most likely measured properties of the short-range mechanisms. However, even with random-dot patterns, great care must be exercised when interpreting discrimination experiments. For example, static pattern-processing mechanisms may sometimes contribute to motion discrimination performance even though performance is at chance when static views are presented at great separations of space or time. This might occur because persisting neural responses from multiple stimulus frames merge to produce "virtual" structured patterns (e.g., Glass patterns[226]). Similar caution should be applied when interpreting discrimination performance with random-dot stereograms (see below).

The discussion of motion perception to this point has focused on the estimation of velocities of various stimuli. Such estimation is importantly involved in guiding locomotion through and estimating the three-dimensional layout of cluttered environments. Motion of an observer through a rigid visual scene produces characteristic patterns of motion on the retina called the *optic flow field*.[227,228] Observers are able to judge the direction of their own motion through the environment based upon this optical flow information alone.[229,230] In fact, accurate motion perception is possible even for random-dot flow fields, suggesting that the motion-selective neurons in the early levels of the visual cortex are a main source of information in perceiving self-motion. But, how is the local motion information provided by the motion-selective neurons used by subsequent mechanisms to compute observer motion?

Gibson[227,228] proposed that people identify their direction of self-motion with respect to obstacles by locating the source of flow: the focus of expansion. Figure 22*a* depicts the flow field on the retina as the observer translates while fixating ahead. Flow is directed away from the focus of expansion and this point corresponds to the direction of translation. Not surprisingly, observers can determine their heading to within ±1 deg from such a field of motion.[230]

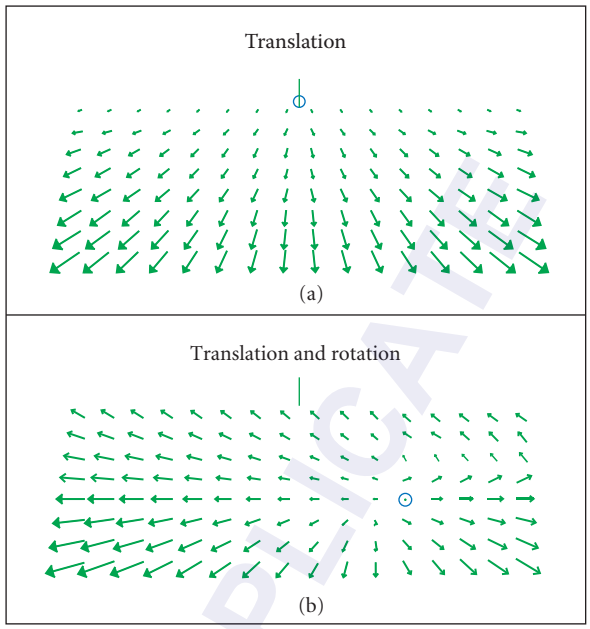

FIGURE 22 Optic flow fields resulting from forward translation across a rigid ground plane. (*a*) Flow field in the retinal image when the observer translates straight ahead while maintaining constant eye and head position; the heading is indicated by the small vertical line. (*b*) Retinal flow field when the observer translates straight ahead while making an eye movement to maintain fixation on the circle; again the heading is indicated by the small vertical line. (*Adapted from Ref. 231.*)

The situation becomes much more complicated once eye/head movements are considered. Figure 22*b* illustrates this by portraying the flow resulting from forward translation while the observer rotates the eyes to maintain fixation on a point off to the right. This motion does not produce a focus of expansion in the image corresponding to the heading; the only focus corresponds to the point of fixation. Consequently, heading cannot be determined by locating a focus (or singularity) in the retinal flow field. Nonetheless, human observers are able to locate their heading to within ±1.5 deg.[231]

Recent theoretical efforts have concentrated on this problem of computing heading in the presence of rotations due to eye/head movements. There are two types of models. One holds that observers measure the rotational flow components due to eye/head movements by means of an extraretinal signal; that is, the velocity of rotations is signaled by proprioceptive feedback from the extraocular and/or neck muscles or by efferent information.[232–236] The rotational flow components are then subtracted from the flow field as a whole to estimate the heading. The other type of model holds that people determine heading in the presence of rotations from retinal image information alone (e.g., Refs. 233–236). These models hypothesize that the visual system decomposes the flow field into rotational and translational components by capitalizing on the fact that flows due to translation and rotation depend differently on the scene geometry. Once the decomposition is performed, the heading can be estimated from the translational components (see Fig. 22*a*).

Current experimental evidence favors the extraretinal signal model,[237,238] but there is also evidence supporting the retinal-image model when the eye-head rotations are slow.[231]

The optic flow field also contains information specifying the relative depths of objects in the visual scene: The velocities of retinal image motions are, to a first approximation, proportional to the inverse depths of the corresponding objects.[239] Human observers are quite sensitive to this depth

cue as evidenced by the fact that they perceive depth variation for differential motions of as small as $\frac{1}{2}-\frac{1}{3}$ arcsec per s.[240]

Binocular Stereoscopic Discrimination

Light from the three-dimensional environment is imaged onto the two-dimensional array of photoreceptors, so the dimension associated with distance from the eye is collapsed in the two-dimensional retinal image. The images in the two eyes generally differ, however, because the eyes are separated by 6 to 7 cm. The differences between the images, which are called *binocular disparities*, are used by the visual system to recover information about the distance dimension. The depth percept that results from binocular disparity is called *stereopsis*. Binocular disparity (stereo) information is formally equivalent to the monocular information that results from a step translation of one eye by 6 to 7 cm. This observation implies a close theoretical connection between the computation of distance from motion and distance from binocular disparity. As indicated in an earlier section, the extraction of stereo and motion information presumably begins in the early stages of cortical processing (i.e., in V1 of the macaque), where many neurons are selective for disparity and direction of motion.

The geometry of stereopsis is described in Chap. 1, Fig. 25. Here, we briefly consider the nature of the information available for computing distance from disparity. The distance between any pair of points in the depth dimension (Δz) is related to the horizontal disparity (d) and the horizontal convergence angle of the eyes (θ) by the following formula:*

$$\Delta z = \frac{ad}{(\theta + d_\theta + d/2)(\theta + d_\theta - d/2)} \tag{30}$$

where d_θ is the average disparity between the two points and the convergence point, and a is the interpupillary distance (the distance between the image nodal points of the eyes). If d_θ is zero, then the points are centered in depth about the convergence point. The locus of all points where the disparity d equals zero is known as the (Vieth-Müller) *horopter*. As Eq. (30) indicates, the computation of absolute distance between points from horizontal disparity requires knowledge of the "eye parameters" (the interpupillary distance and the angle of convergence). However, relative distance information is obtained even if the eye parameters are unknown (in other words, Δz is monotonic with d). Furthermore, absolute distance can be recovered in principle without knowing the angle of convergence from use of horizontal and vertical binocular disparities (e.g., Refs. 241 and 242).

Under optimal conditions, the human visual system is capable of detecting very small binocular disparities and hence rather small changes in distance. In the fovea, disparities of roughly 10 arsec can be detected if the test objects contain sharp, high-contrast edges and if they are centered in depth about a point on or near the horopter ($d_\theta = 0.0$).[178,243] At a viewing distance of 50 cm, 10 s corresponds to a distance change of about 0.02 cm, but at 50 m, it corresponds to a distance change of about 2 m.

In measuring stereoscopic discrimination performance, it is essential that the task cannot be performed on the basis of monocular information alone. This possibility can be assessed by measuring monocular and binocular performance with the same stimuli; if monocular performance is substantially worse than binocular performance, then binocular mechanisms per se are used in performing the stereoscopic task.[243,244] Random-dot stereograms[244,245] are particularly effective at isolating binocular mechanisms because discriminations cannot be performed reliably when such stereograms are viewed monocularly.[244,246]

Stereopsis is affected by a number of factors. For example, the contrast required to produce a stereoscopic percept varies with the spatial frequency content of the stimulus. This result is quantified by the contrast sensitivity function for stereoscopic discrimination of spatially filtered random-dot stereograms; the function is similar in shape to CSFs measured for simple contrast detection,[247] but

*This formula is an approximation based on the assumption of relatively small angles and object location near the midsagittal plane; it is most accurate for distances under a few meters.

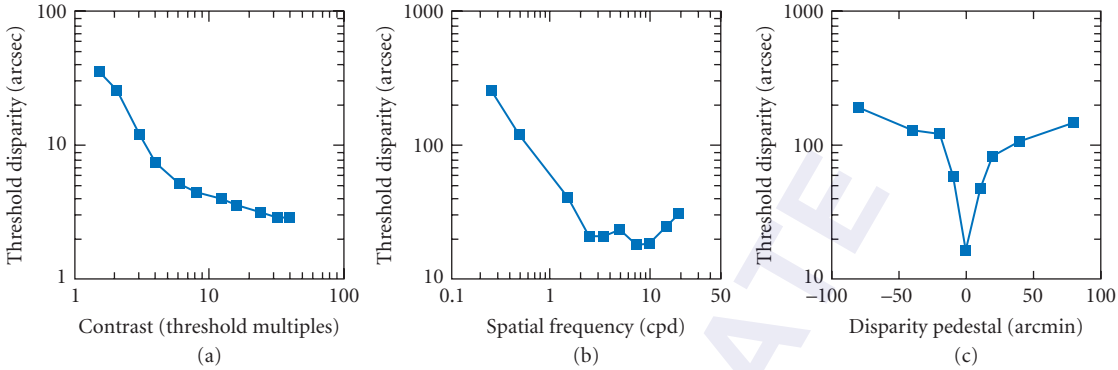

FIGURE 23 Disparity discrimination thresholds as a function of contrast, spatial frequency, and pedestal disparity. (*a*) Disparity threshold as a function of luminance contrast (in contrast threshold units) for dynamic random-dot stereograms. (*Adapted from Ref. 256.*) (*b*) Disparity threshold as a function of spatial frequency for sinewave-grating stereograms. (*Adapted from Ref. 255.*) (*c*) Disparity threshold as a function of the disparity pedestal (distance from the convergence plane) for difference-of-gaussian (DOG) stereograms. (*Adapted from Ref. 258.*).

detection occurs at lower contrasts than stereopsis occurs. In other words, there is a range of contrasts that are clearly detectable, but insufficient to yield a stereoscopic percept.[247]

The fact that the CSFs for contrast detection and stereoscopic discrimination have similar shapes suggests that common spatial-frequency mechanisms are involved in the two tasks. This hypothesis receives some support from masking and adaptation experiments demonstrating spatial-frequency tuning[248–251] and orientation tuning[252] for stereo discrimination, and from electrophysiological studies demonstrating that cortical cells selective for binocular disparity are also usually selective for orientation[55,56,62] and spatial frequency.[253]

The smallest detectable disparity, which is called *stereoacuity*, improves as luminance contrast is increased.[254–256] As shown in Fig. 23*a*, stereoacuity improves approximately in inverse proportion to the square of contrast at low contrasts, and in inverse proportion to the cube root of contrast at high contrasts. Stereoacuity is also dependent upon spatial frequency; it improves in inverse proportion to target spatial frequency over the low spatial-frequency range, reaching optimum near 3 cpd (Fig. 23*b*).[255] Both the inverse-square law at low contrasts and the linear law at low spatial frequencies are predicted by signal-detection models that assume independent, additive noise and simple detection rules.[255,256]

Stereoacuity declines precipitously as a function of the distance of the test objects from the convergence plane (Fig. 23*c*).[257,258] For example, adding a disparity pedestal of 40 minarc to test objects reduces acuity by about 1 log unit. This loss of acuity is not the result of losses of information due to the geometry of stereopsis; it must reflect the properties of the underlying neural mechanisms. [Note in Eq. (30) that adding a disparity to both objects is equivalent to changing the value of d_θ.]

Much like the spatial channels described earlier under "Spatial Channels," there are multiple channels tuned to different disparities, but it is unclear whether there are a small number of such channels—"near," "far," and "tuned"[259]—or a continuum of channels.[56,63,260,261] Models that assume a continuum of channels with finer tuning near the horopter predict both the sharp decline in stereoacuity away from the horopter[261,262] and the shapes of tuning functions that have been estimated from adaptation and probability summation experiments.[260,261]

3.1 INTRODUCTION

Psychophysical methods are the tools for measuring perception and performance. These tools are used to reveal basic perceptual processes, to assess observer performance, and to specify the required characteristics of a display. We are going to ignore this field's long and interesting history,[1] and much theory as well.[2,3] Here we present a formal treatment, emphasizing the theoretical concepts of psychophysical measurement. For practical advice in setting up an experiment, please turn to our user's guide.[4] Use the supplied references for further reading.

Consider the psychophysical evaluation of the suitability of a visual display for a particular purpose. A home television to be used for entertainment is most reasonably assessed in a "beauty contest" of subjective preference,[5] whereas a medical imaging display must lead to accurate diagnoses[6,7] and military aerial reconnaissance must lead to accurate vehicle identifications.[8] In our experience, the first step toward defining a psychophysically answerable question is to formulate the problem as a task that the observer must perform. One can then assess the contribution of various display parameters toward that performance. Where precise parametric assessment is desired it is often useful to substitute a simple laboratory task for the complex real-life activity, provided one can either demonstrate, or at least reasonably argue, that the laboratory results are predictive.

Psychophysical measurement is usually understood to mean measurement of behavior to reveal internal processes. The experimenter is typically not interested in the behavior itself, such as pressing a button, which merely communicates a decision by the observer about the stimulus.* This chapter reviews the various decision tasks that may be used to measure perception and performance and evaluates their strengths and weaknesses. We begin with definitions and a brief review of visual stimuli. We then explain and evaluate the various psychophysical tasks, and end with some practical tips.

*Psychophysical measurement can also be understood to include noncommunicative physiological responses such as pupil size, eye position, electrical potentials measured on the scalp and face, and even BOLD fMRI responses in the brain, which might be called "unintended" responses. (These examples are merely suggestive, not definitive. Observers can decide to move their eyes and, with feedback, can learn to control many other physiological responses. Responses are "unintended" only when they are not used for overt communication by the observer.) Whether these unintended responses are called psychophysical or physiological is a matter of taste. In any case, decisions are usually easier to measure and interpret, but unintended responses may be preferred in certain cases, as when assessing noncommunicative infants and animals.

3.2 DEFINITIONS

At the highest level, an *experiment* answers a question about how certain "experimental conditions" affect observer performance. *Experimental conditions* include stimulus parameters, observer instruction, and anything else that may affect the observer's state. Experiments are usually made up of many individual measurements, called "trials," under each experimental condition. Each trial presents a stimulus and collects a response—a decision—from the observer.

There are two kinds of decision tasks: judgments and adjustments. It is useful to think of one as the inverse of the other. In one case the experimenter gives the observer a stimulus and asks for a classification of the stimulus or percept; in the other case the experimenter, in effect, gives the observer a classification and asks for an appropriate stimulus back. Either the experimenter controls the stimulus and the observer makes a *judgment* based on the resulting percept, or the observer *adjusts* the stimulus to satisfy a perceptual criterion specified by the experimenter (e.g., match a sample). Both techniques are powerful. Adjustments are intrinsically subjective (because they depend on the observers' understanding of the perceptual criterion), yet they can often provide good data quickly and are to be preferred when applicable. But not all questions can be formulated as adjustment tasks. Besides being more generally applicable, judgments are often easier to analyze, because the stimulus is under the experimenter's control and the task may be objectively defined. Observers typically like doing adjustments and find judgments tedious, partly because judgment experiments usually take much longer.

An obvious advantage of adjustment experiments is that they measure physical stimulus parameters, which may span an enormous dynamic range and typically have a straightforward physical interpretation. Judgment tasks measure human performance (e.g., frequency of seeing) as a function of experimental parameters (e.g., contrast). This is appropriate if the problem at hand concerns human performance per se. For other purposes, however, raw measures of judgment performance typically have a very limited useful range, and a scale that is hard to interpret. Having noted that adjustment and judgment tasks may be thought of as inverses of one another, we hasten to add that in practice they are often used in similar ways. Judgment experiments often vary a stimulus parameter on successive trials in order to find the value that yields a criterion judgment. These "sequential estimation methods" are discussed in Sec. 3.6. The functional inversion offered by sequential estimation allows judgment experiments to measure a physical parameter as a function of experimental condition, like adjustment tasks, while retaining the judgment task's more rigorous control and interpretation.

Distinguishing between judgment and adjustment tasks emphasizes the kind of response that the observer makes. It is also possible to subdivide tasks in a way that emphasizes the stimuli and the question posed. In a *detection* task there may be any number of alternative stimuli, but one is a blank, and the observer is asked only to distinguish between the blank and the other stimuli. Slightly more general, a *discrimination* task may also have any number of alternative stimuli, but one of the stimuli, which need not be blank, is designated as the reference, and the observer is asked only to distinguish between the reference and other stimuli. A decision that distinguishes among more than two categories is usually called an *identification* or *classification*.[9] All decision tasks allow for alternative responses, but two alternatives is an important special case.[10]

As normally used, the choice of term, *detection* or *discrimination*, says more about the experimenter's way of thinking than it does about the actual task faced by the observer. This is because theoretical treatments of detection and discrimination usually allow for manipulation of the experimental condition by introduction of an extraneous element, often called a "mask" or "pedestal," that is added to every stimulus. Thus, one is always free to consider a discrimination task as detection in the presence of a mask. This shift in perspective can yield new insights (e.g., Refs. 11–15). Since there is no fundamental difference between detection and discrimination,[16] we have simplified the presentation below by letting detection stand in for both. The reader may freely substitute "reference" for "blank" (or suppose the presence of an extraneous mask) in order to consider the discrimination paradigm.

The idea of "threshold" plays a large role in psychophysics. Originally deterministic, *threshold* once referred to the stimulus intensity above which the stimulus was always distinguishable from blank, and below which it was indistinguishable from blank. In a discrimination task one might refer to a "discrimination threshold" or a "just-noticeable difference." Nowadays the idea is statistical; we know that the observer's probability of correct classification rises as a continuous function of stimulus

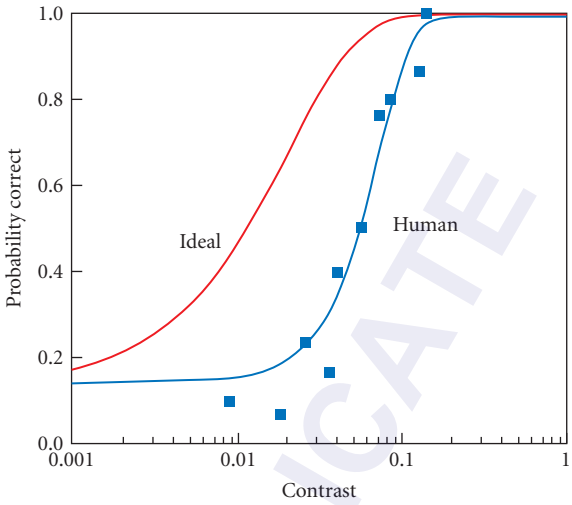

FIGURE 1 Probability of correctly identifying a letter in noise, as a function of letter contrast. The letters are bandpass filtered. Gaussian noise was added independently to each pixel. Each symbol represents the proportion correct in 30 trials. The solid curve through the points is a maximum likelihood fit of a Weibull function. The other curve represents a similar maximum likelihood fit to the performance of a computer program that implements the ideal letter classifier.[40] Efficiency, the squared ratio of threshold contrasts, is 9 percent. (*Courtesy of Joshua A. Solomon.*)

intensity (see Fig. 1). Threshold is defined as the stimulus intensity (e.g., contrast) corresponding to an arbitrary level of performance (e.g., 82 percent correct). However, the old intuition, now called a "high threshold," still retains a strong hold on everyone's thinking for the good reason that the transition from invisible to visible, though continuous, is quite abrupt, less than a factor of two in contrast.

Most psychophysical research has concentrated on measuring thresholds. This has been motivated by a desire to isolate low-level sensory mechanisms by using operationally defined tasks that are intended to minimize the roles of perception and cognition. This program is generally regarded as successful—visual detection is well understood (e.g., Ref. 17)—but leaves most of our visual experience and ability unexplained. This has stimulated a great deal of experimentation with suprathreshold stimuli and nondetection tasks in recent years.

3.3 VISUAL STIMULI

Before presenting the tasks, which are general to all sense modalities (not just vision), it may be helpful to briefly review the most commonly used visual stimuli. Until the 1960s most vision research used a spot as the visual stimulus (e.g., Ref. 18). Then cathode ray tube displays made it easy to generate more complex stimuli, especially sinusoidal gratings, which provided the first evidence for multiple "spatial frequency channels" in vision.[19] Sinusoidal grating patches have two virtues. A sinusoid at the display always produces a sinusoidal image on the retina.* And most visual mechanisms are selective in space and in spatial frequency, so it is useful to have a stimulus that is restricted in both domains.

*This is strictly true only within an isoplanatic patch, i.e., a retinal area over which the eye's optical point spread function is unchanged.

Snellen,[20] in describing his classic eye chart, noted the virtue of letters as visual stimuli—they offer a large number of stimulus alternatives that are readily identifiable.[21,22] Other commonly used stimuli include annuli, lines, arrays of such elements, and actual photographs of faces, nature, and military vehicles. There are several useful texts on image quality, emphasizing signal-to-noise ratio.[23–26] Finally, there has been some psychophysical investigation of practical tasks such as reading,[27] flying an airplane,[28] or shopping in a supermarket.[29]

The stimulus alternatives used in vision experiments are usually parametric variations along a single dimension, most commonly contrast, but frequently size and position in the visual field. *Contrast* is a dimensionless ratio: the amplitude of the luminance variation within the stimulus, normalized by the background luminance. Michelson contrast (used for gratings) is the maximum minus the minimum luminance divided by the maximum plus the minimum. Weber contrast (used for spots and letters) is the maximum deviation from the uniform background divided by the background luminance. RMS contrast is the root-mean-square deviation of the stimulus luminance from the mean luminance, divided by the mean luminance.

3.4 ADJUSTMENTS

Adjustment tasks require that the experimenter specify a perceptual criterion to the observer, who adjusts the stimulus to satisfy the criterion. Doubts about the observer's interpretation of the criterion may confound interpretation of the results. The adjustment technique is only as useful as the criterion is clear.

Threshold

Figure 2 shows contrast sensitivity (the reciprocal of the threshold contrast) for a sinusoidal grating as a function of spatial and temporal frequency.[30] These thresholds were measured by what is probably the most common form of the adjustment task, which asks the observer to adjust the stimulus contrast up and down to the point where it is "just barely detectable." While some important studies have collected their data in this way, one should bear in mind that this is a vaguely specified criterion. What should the observer understand by "barely" detectable? Seen half the time? In order to adjust to threshold, the observer must form a subjective interpretation and apply it to the changing percept. It is well known that observers can be induced (e.g., by coaching) to raise or lower their criterion, and when comparing among different observers it is important to bear in mind that social and personality factors may lead to systematically different interpretations of the same vague instructions. Nevertheless, these subjective effects are relatively small (about a factor of two in contrast) and many questions can usefully be addressed, in at least a preliminary way, by quick method-of-adjustment threshold settings. Alternatively, one might ignore the mean of the settings and instead use the standard deviation to estimate the observer's discrimination threshold.[31]

Nulling

Of all the many kinds of adjustments, nulling is the most powerful. Typically, there is a simple basic stimulus that is distorted by some experimental manipulation, and the observer is given control over the stimulus and asked to adjust it so as to cancel the distortion (e.g., Ref. 32). The absence of a specific kind of distortion is usually unambiguous and easy for the observer to understand, and the observer's null setting is typically very reliable.

Matching

Two stimuli are presented, and the observer is asked to adjust one to match the other. Sometimes the experiment can be designed so that the observer can achieve a perfect match in which the stimuli are utterly indistinguishable, which Brindley[33] calls a "Class A" match. Usually, however, the stimuli

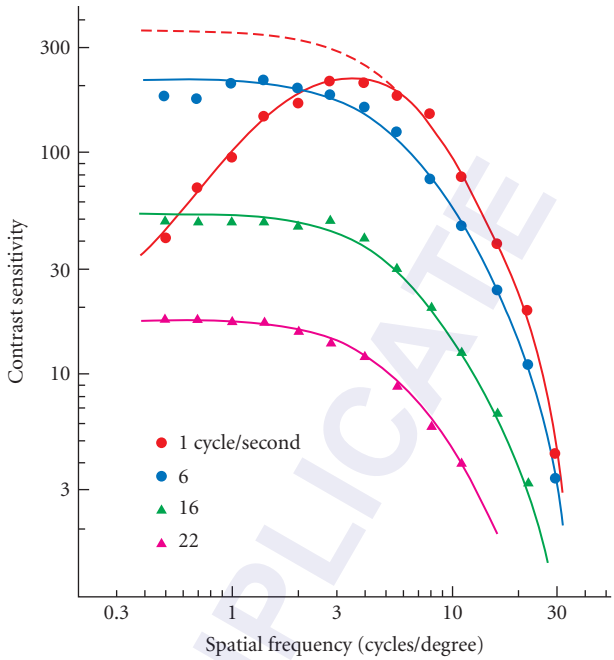

FIGURE 2 Spatial contrast sensitivity (reciprocal of threshold contrast) functions for sinusoidal gratings temporally modulated (flickered) at several temporal frequencies. The points are the means of four method-of-adjustment measurements and the curves (one with a dashed low-frequency section) differ only in their positions along the contrast-sensitivity scale. (*From Robson.*[30])

are obviously different and the observer is asked to match only a particular aspect of the stimuli, which is called a "Class B" match. For example, the observer might be shown two grating patches, one fine and one coarse, and asked to adjust the contrast of one to match the contrast of the other.[34] Or the observer might see two uniform patches of different colors and be asked to match their brightnesses.[35] Observers (and reviewers for publication) are usually comfortable with matching tasks, but, as Brindley points out, it is amazing that observers can seemingly abstract and compare a particular parameter of the multidimensional stimuli in order to make a Class B match. Matching tasks are extremely useful, but conclusions based on Class B matches may be less secure than those based on Class A matches because our understanding of how the observer does the task is less certain.

Magnitude Production

The observer is asked to adjust a stimulus to match a numerically specified perceptual criterion, e.g., "as bright as a 60-watt light bulb." The number may have a scale (watts in this case) or be a pure number.[2] The use of pure numbers, without any scale, to specify a perceptual criterion is obviously formally ambiguous, but in practice many experimenters report that observers seem comfortable with such instructions and produce stable results that are even reasonably consistent among different observers. Magnitude production, however, is rarely used in visual psychophysics research.

3.5 JUDGMENTS

Judgment tasks ask the observer to classify the stimulus or percept. They differ primarily in the number of alternative stimuli that may be presented on a given trial and the number of alternative responses that the observer is allowed.

The Ideal Observer

When the observer is asked to classify the stimulus (not the percept) it may be useful to consider the mathematically defined ideal classifier that would yield the most accurate performance using only the information (the stimuli and their probabilities) available to the observer.[36–42] Obviously this would be an empty exercise unless there is some known factor that makes the stimuli hard to distinguish. Usually this will be visual noise: random variations in the stimulus, random statistics of photon absorptions in the observer's eyes, or random variations in neural processes in the observer's visual system. If the stimuli plus noise can be defined statistically at some site—at the display, as an image at the observer's retinae, as a pattern of photon absorptions, or as a spatiotemporal pattern of neural activity—then one can solve the problem mathematically and compute the highest attainable level of performance. This ideal often provides a useful point of comparison in thinking about the actual human observer's results. A popular way of expressing such a comparison is to compute the human observer's efficiency, which will be a number between 0 and 1. For example, in Fig. 1 at threshold the observer's efficiency for letter identification is 9 percent. As a general rule, the exercise of working out the ideal and computing the human observer's efficiency is usually instructive but, obviously, low human efficiencies should be interpreted as a negative result, suggesting that the ideal is not particularly relevant to understanding how the human observer does the task.

Yes-No

The best-known judgment task is yes-no. It is usually used for detection, although it is occasionally used for discrimination. The observer is either asked to classify the stimulus, "Was a nonblank stimulus present?" or classify the percept, "Did you see it?" The observer is allowed only two response alternatives: yes or no. There may be any number of alternative stimuli. If the results are to be compared with those of an ideal observer, then the kind of stimulus, blank or nonblank, must be unpredictable.

As with the method-of-adjustment thresholds discussed above, the question posed in a yes-no experiment is fundamentally ambiguous. Where is the dividing line between yes and no on the continuum of internal states between the typical percepts generated by the blank and nonblank stimuli? Theoretical considerations and available evidence suggest that observers act as if they reduced the percept to a "decision variable," a pure magnitude—a number if you like—and compared that magnitude with an internal criterion that is under their conscious control.[40,43] Normally we are not interested in the criterion, yet it is troublesome to remove its influence on the results, especially since the criterion may vary between experimental conditions and observers. For this reason, most investigators no longer use yes-no tasks.

As discussed next, this pesky problem of the observer's subjective criterion can be dealt with explicitly, by using "rating scale" tasks, or banished, by using unbiased "two-alternative forced choice" (2afc) tasks. Rating scale is much more work, and unless the ratings themselves are of interest, the end result of using either rating scale or 2afc is essentially the same.

Rating Scale

In a rating scale task the observer is asked to rate the likelihood that a nonblank stimulus was presented. There must be blank and nonblank stimulus alternatives, and there may be any number of alternative ratings—five is popular—but even a continuous scale may be allowed.[44] The endpoints of

the rating scale are "The stimulus was definitely blank" and "The stimulus was definitely nonblank," with intermediate degrees of confidence in between. The results are graphed as a receiver operating characteristic, or ROC, that plots one conditional probability against another. The observer's ratings are transformed into yes-no judgments by comparing them with an external criterion. Ratings above the criterion become "yes" and those below the criterion become "no." This transformation is repeated for all possible values of the external criterion. Finally, the experimenter plots—for each value of the criterion—the probability of a yes when a nonblank stimulus was present (a "hit") against the probability of a yes when a blank stimulus was present (a "false alarm"). In medical contexts the hit rate is called "sensitivity" and one minus the false alarm rate is called "specificity." Figure 3 shows an ROC curve for a medical diagnosis;[45] radiologists examined mammograms and rated the likelihood that a lesion was benign or malignant.

In real-life applications the main value of ROC curves is that they can be used to optimize yes-no decisions based on ratings, e.g., whether to refer a patient for further diagnosis or treatment. However, this requires knowledge of the prior stimulus probabilities (e.g., in Fig. 3, the incidence of disease in the patient population), the benefit of a hit, and the cost of a false alarm.[6,7] These conditions are rarely met. One usually can estimate prior probability and assess the cost of the wasted effort caused by the false alarms, but it is hard to assign a commensurate value to the hits, which may save lives through timely treatment.

The shape of the ROC curve has received a great deal of attention in the theoretical detection literature, and there are various mathematical models of the observer's detection process that can account for the shape.[46–48] However, unless the actual situation demands rating-based decisions, the ROC shape has little or no practical significance, and the general practice is to summarize the ROC curve by the area under the curve. The area is 0.5 when the observers' ratings are independent of the stimuli (i.e., useless guessing). The area can be at most 1—when the observer makes no mistakes. The

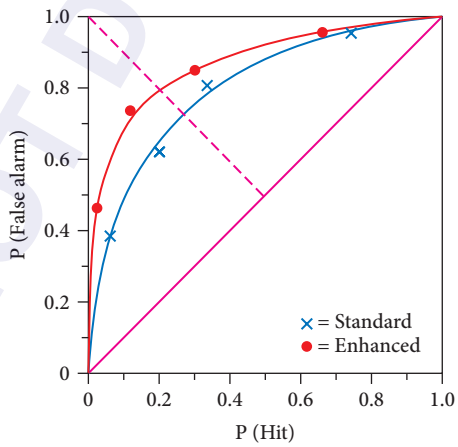

FIGURE 3 Example of an empirical ROC. Six radiologists attempted to distinguish between malignant and benign lesions in a set of 118 mammograms, 58 malignant and 60 benign, first when the mammograms were viewed in the usual manner ("standard"), and then—"enhanced"—when they were viewed with two aids, including a checklist of diagnostic features. The ratings were "very likely malignant," "probably malignant," "possibly malignant," "probably benign," and "very likely benign." The areas under the curves are 0.81 and 0.87. (*From Swets.*[45])

area can descend below 0.5 when the observer reverses the categories of blank and nonblank. We'll see in a moment that a result equivalent to ROC area can usually be obtained with much less effort by doing a two-alternative forced choice experiment instead.

Two-Alternative Forced Choice

This task is traditionally characterized by two separate stimulus presentations, one blank and one nonblank, in random order. The two stimuli may be presented successively or side by side. The observer is asked whether the nonblank stimulus was first or second (or on the left or right). We noted above that in yes-no tasks observers seem to reduce the stimulus to a decision variable, the magnitude upon which they base their decisions. The 2afc task is said to be "unbiased" because the observer presumably chooses the presentation that generated the higher magnitude, without referring to any subjective internal criterion. At the beginning of this section we said that all judgment tasks consist of the presentation of a stimulus followed by a judgment. In this view, we might consider the two presentations in the 2afc task to be a single stimulus. The two possible composite stimuli to be discriminated are reflections of one another, either in space or time. The symmetry of the two alternatives suggests that the observer's choice between them may be unbiased.

Other related tasks are often called "two-alternative forced choice" and are similarly claimed to be unbiased. There is some confusion in the literature over which tasks should be called "2afc." In our view, the "2afc" label is of little consequence. What matters is whether the task is unbiased, i.e., are the alternative stimuli symmetric for the observer? Thus a yes-no discrimination of blank and nonblank stimuli may be biased even though there are two response alternatives and the choice is forced, whereas it may be reasonable to say that the judgment of the orientation of a grating that is either horizontal or vertical is unbiased even though there is only a single presentation. We suggest that authors wishing to claim that their task is unbiased say so explicitly and state why. This claim might be based on a priori considerations of the symmetry between the stimuli to be discriminated, or on a post hoc analysis of relative frequencies of the observer's responses.

In theory, if we accept the assumptions that each stimulus presentation produces in the observer a unidimensional magnitude (one number, the decision variable), that the observer's ratings and 2afc decisions are based, in the proper way, on this magnitude, and that these magnitudes are stochastically independent between presentations, then the probability of a correct response on a 2afc trial must equal the area under the ROC curve.[47] Nachmias[43] compared 2afc proportion correct and ROC area empirically, finding that ROC area is slightly smaller, which might be explained by stimulus-induced variations in the observer's rating criteria.

MAGNITUDE ESTIMATION

In the inverse of magnitude production, a stimulus is presented and the observer is asked to rate it numerically.[2] Some practitioners provide a reference (e.g., a stimulus that rates 100), and some don't, allowing observers to use their own scale. Magnitude estimation and rating scale are fundamentally the same. Magnitude estimation experiments typically test many different stimulus intensities a few times to plot mean magnitude versus intensity, and rating-scale experiments typically test few intensities many times to plot an ROC curve at each intensity.

Response Time

In practical situations the time taken by the observer to produce a judgment usually matters, and it will be worthwhile recording it during the course of the experiment. Some psychophysical research has emphasized response time as a primary measure of performance in an effort to reveal mental processes.[49]

3.6 STIMULUS SEQUENCING

So far we have discussed a single trial yielding a single response from the observer. Most judgments are stochastic, so judgment experiments usually require many trials. An uninterrupted sequence of trials is called a *run* (or a *block*). There are two useful methods of sequencing trials within a run.

Method of Constant Stimuli

Experimenters have to worry about small, hard-to-measure variations in the observer's sensitivity that might contaminate comparisons of data collected at different times. It is therefore desirable to run the trials for the various conditions as nearly simultaneously as possible. One technique is to interleave trials for the various conditions. This is the classic "method of constant stimuli." Unpredictability of the experimental condition and equal numbers of trials for each condition are typically both desirable. These are achieved by using a randomly shuffled list of all desired trials to determine the sequence.

Sequential Estimation Methods

One can use the method of constant stimuli to measure performance as a function of a signal parameter—let us arbitrarily call it intensity—and determine, by interpolation, the threshold intensity that corresponds to a criterion level of performance.* This approach requires hundreds of trials to produce a precise threshold estimate. Various methods have been devised that obtain precise threshold estimates in fewer trials, by using the observer's previous responses to choose the stimulus intensity for the current trial. The first methods were simple enough for the experimenter to implement manually, but as computers appeared and then became faster, the algorithms have become more and more sophisticated. Even so, the requisite computer programs are very short.

In general, there are three stages to threshold estimation. First, all methods, implicitly or explicitly, require that the experimenter provide a confidence interval around a guess as to where threshold may lie. (This bounds the search. Lacking prior knowledge, we would have an infinite range of possible intensities. Without a guess, where would we place the first trial? Without a confidence interval, where would we place the second trial?) Second, one must select a test intensity for each trial based on the experimenter's guess and the responses to previous trials. Third, one must use the collected responses to estimate threshold. At the moment, the best algorithm is called ZEST,[50] which is an improvement over the popular QUEST.[51] The principal virtues of QUEST are that it formalizes the three distinct stages, and implements the first two stages efficiently. The principal improvement in ZEST is an optimally efficient third stage.

3.7 CONCLUSION

This chapter has reviewed the practical considerations that should guide the choice of psychophysical methods to quickly and definitely answer practical questions related to perception and performance. Theoretical issues, such as the nature of the observer's internal decision process, have been de-emphasized. The question of how well we see is answerable only after we reduce the question to measurable performance of a specific task. The task will be either an adjustment—for a quick answer when the perceptual criterion is unambiguous—or a judgment—typically to find threshold by sequential estimation.

*The best way to interpolate frequency-of-seeing data is to make a maximum likelihood fit by an S-shaped function.[52] Almost any S-shaped function will do, provided it has adjustable position and slope.[53]

The success of psychophysical measurements often depends on subtle details: the seemingly incidental properties of the visual display, whether the observers receive feedback about their responses, and the range of stimulus values encountered during a run. Decisions about these matters have to be taken on a case-by-case basis.

3.8 TIPS FROM THE PROS

We asked a number of colleagues for their favorite tips.

- Experiments often measure something quite different from what the experimenter intended. Talk to the observers. Be an observer yourself.
- Viewing distance is an often-neglected but powerful parameter, trivially easy to manipulate over a 100:1 range. Don't be limited by the length of your keyboard cable.
- Printed vision charts are readily available, offering objective measurement of visiblity, e.g., to characterize the performance of a night-vision system.[20,21,54,55]
- When generating images on a cathode ray tube, avoid generating very high video frequencies (e.g., alternating black and white pixels along a horizontal raster line) and very low video frequencies (hundreds of raster lines per cycle) since they are typically at the edges of the video amplifier's passband.[56]
- Liquid crystal displays (LCD) have largely replaced cathode ray tube (CRT) displays in the market place. LCDs are fine for static images, but have complicated temporal properties that are hard to characterize. Thus, CRTs are still preferable for presentation of dynamic images, as they allow you to know exactly what you are getting.[57]
- Consider the possibility of aftereffects, whereby past stimuli (e.g., at high contrast or different luminance) might affect the visibility of the current stimulus.[58–61]
- Drift of sensitivity typically is greatest at the beginning of a run. Do a few warm-up trials at the beginning of each run. Give the observer a break between runs.
- Allow the observer to see the stimulus once in a while. Sequential estimation methods tend to make all trials just barely detectable, and the observer may forget what to look for. Consider throwing in a few high-contrast trials, or defining threshold at a high level of performance.
- Calibrate your display before doing the experiment, rather than afterward when it may be too late.

3.9 ACKNOWLEDGMENTS

VISUAL ACUITY AND HYPERACUITY

Gerald Westheimer

Division of Neurobiology
University of California
Berkeley, California

4.1 GLOSSARY

Airy disk. Point-spread function in the image of a diffraction-limited optical instrument with a circular pupil.

Diffraction limit. Minimum dissipation of spatial information in the imaging of an optical system, due to the aperture restriction in the propagation of electromagnetic energy.

Fovea. Region in the center of the retina where receptor elements are most closely packed and resolution highest.

Hyperacuity. Performance in task where thresholds are substantially lower than the grain of the receiving layer.

Light. Visually evaluated radiant energy. In this chapter radiant and luminous energy terms are used interchangeably.

Optical-transfer function. Modulation in the transmitted images of spatial sinusoids, as a function of their spatial frequency; it is complex, that is, has amplitude and phase terms.

Psychophysics. Procedure for studying an observer's performance by relating the variables of physical stimuli to measurements of associated responses.

Point-spread function. Spatial distribution of energy in the image of a point object.

Snellen letters. Alphanumeric characters of defined size and shape used in standard clinical testing of visual acuity.

Spatial frequency. Number of cycles of a sinusoidal grating target per unit distance. Commonly cycles/degree visual angle.

Superresolution. Ability to garner knowledge of spatial details in an optical image based on previous available information, either by extrapolation or averaging.

Vernier acuity. Performance limit in the alignment of two abutting line segment; it is the prime example of hyperacuity.

Visual acuity. Performance limit in distinguishing spatial details in visual object.

Visual angle. Angle subtended by an object at the center of the eye's entrance pupil; it is a measure of distance in the retinal image.

Equation (1). Point-spread function of a purely diffraction-limited optical imaging system with a round pupil.

θ angular subtense of radius of Airy's disk
λ wavelength of radiation
a diameter of aperture

Equation (2). Specification of contrast in the spatial distribution.
L_{max}, L_{min} Luminance of maximum, minimum, respectively

4.2 INTRODUCTION

Visual acuity—literally sharpness—refers to the limit of the ability to discriminate spatial partitioning in the eye's object space. As a psychophysical measure, its analysis encompasses

- The physics—in this case optics—of the stimulus situation
- The anatomical and physiological apparatus within the organism that processes the external stimulus
- The operations leading to the generation of a response

Measurement of visual acuity involves the organism as a whole, even though it is possible to identify the performance limits of only a segment of the full operation, for example, the eyeball as purely an optical instrument, or the grain of the receptor layer of the retina, or neural activity in the visual cortex. But the term acuity is reserved for the behavioral essay and therefore necessarily includes the function of all components of the arc reaching from physical object space to some indicator of the response of the whole organism. It is a psychophysical operation. The fact that it includes a component that usually involves an observer's awareness does not preclude it from being studied with any desired degree of rigor.

4.3 STIMULUS SPECIFICATIONS

Specification of the stimulus is an indispensable preliminary. For this purpose, an Euclidean object space containing visual targets is best defined by a coordinate system with its origin at the center of the eye's entrance pupil and its three axes coinciding with those of the eye. The observer is usually placed to make the vertical (y) axis that of gravity, and the horizontal (x) axis orthogonal and passing through equivalent points in the two eyes; distances from the observer are measured along the z axis. When an optical device is associated with the eye, its principal axes should accord, either by positioning the device or the observer. On occasions when both eyes of an observer are involved, the origin of the coordinate system is located at the midpoint of the line joining the two eyes. More details of possible coordinate systems have been described elsewhere.[1]

The ocular structure most relevant to the spatial dissection of an observer's object world is the retina, and the inquiry begins with the quest for the most instructive way of relating the *distal* and *proximal* stimuli, that is, the actual objects and their retinal images. Here it is achieved by using the center of the entrance pupil of the eye as the origin of the coordinate system which has at least two advantages. First, while associated with the eye's imagery, it belongs to object space and hence is objectively determinable by noninvasive means. In a typical human eye, the entrance pupil is located about 3 mm behind the corneal vertex and is not far from round. Its center is therefore an operationally definable point. The second reason for choosing it as a reference point involves the nature of the eye's image-forming apparatus. As seen in Fig. 1, the bundle of rays from a point source converging toward the retina is centered on the ray emerging from the center of the eye's exit pupil, which is the optical conjugate of the center of the entrance pupil. Regardless of the position

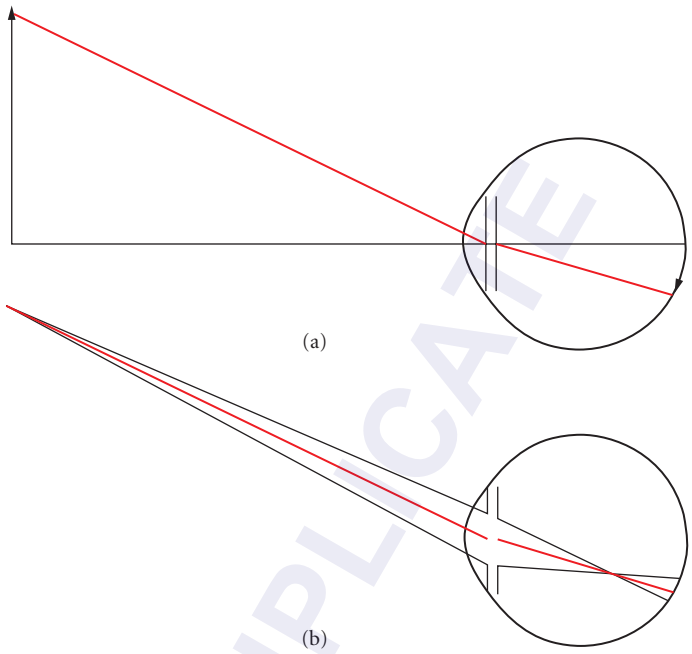

FIGURE 1 Schematic diagram of imaging in human eye. (*a*) The retinal image size of a target is represented by the angle it subtends at the eye's entrance pupil. (*b*) The position of the image of a point is most effectively demarcated by the intercept of the image-sided chief ray, which is the center of the light distribution even if the eye is out of focus.

of the geometrical image with respect to the retina, that is, regardless of the state of defocus, the center of the retinal image patch, blurred or sharp, will be defined by the intersection of that ray, called *chief ray,* with the retina. When two object points are presented to the eye, the retinal distance corresponding to their separation is given by the intercept of the chief rays from these objects. In this manner, the three-dimensional object space of the eye has been collapsed into the two-dimensional one of the retinal surface. What has been lost, and needs to be specified separately, is the object's distance from the eye along the chief ray. But all objects, in or out of focus, anywhere along a given chief ray share a single retinal location, or, to rephrase it, the coordinates on the retinal surface are homologous to angular coordinates within the object-sided sheaf of rays converging on the center of the eye's entrance pupil.

Hence in the specification of retinal distances it suffices to identify corresponding angles in the eye's object space, objectively determinable measures. Units of measurement are the radian, or, degrees or minutes of arc. At a distance of 57 cm, a 1-cm object subtends 1 deg, a 0.16-mm object 1 arcmin. At the standard eye-chart distance of 6 m (20 ft) the limb of a 20/20 letter is just under 2 mm wide.

The next specification to be considered is that of the luminous intensity impinging on the eye. One starts with the most elemental stimulus: the luminous intensity of a point source is given in the internationally agreed-on unit of candela (lumens · steradian^{-1}). This again is object-sided and objectively determinable. Extended sources are measured in terms of luminance (lumens · steradian^{-1} · unit area^{-1}, in practice cd · m^{-2}). Hence the specification of visual acuity targets in the eye's object space requires, apart from their observation distance, their spatial extent in angular measure at the eye's entrance pupil and the luminance of the background from which or against which they are formed. The luminous energy reaching the retina differs in that it depends on the pupil area, the absorption in the eye's

media, and retinal factors considered elsewhere. Attenuation in the passage through the ocular media will differ from one eye to another and is prominently age dependent (Chap. 1). (Polarization and coherence properties of the incoming luminous energy are generally not relevant, but see special conditions analyzed in Chap. 14). How this luminous energy is distributed on the retinal surface depends on the transfer characteristics of the eye's optics which will now be considered.

4.4 OPTICS OF THE EYE'S RESOLVING CAPACITY

The spatial distribution of energy reaching the retina will differ from that incident on the cornea by being subject to spread produced by the eye's imaging.

Light Spread in the Retinal Image and Limits of Resolution

The two modes of proceeding in this discussion, via the point-spread or the contrast-transfer functions, are equivalent (Fig. 2). So long as one remains in the realm of optics and does not enter that of neural and psychophysical processing where linearity is not guaranteed, it is permissible to transfer back and forth between the two.

Point-Spread Function When the object space is restricted to a single point, the spatial distribution of energy in the image is called the point-spread function and describes the spread introduced by passage through the eye's optics. Even in ideal focus, the spread depends on the eye's aperture and the wavelength of the electromagnetic energy; the object-sided distribution then has θ, that is, angle subtended by the distance from its center to the first zero, given by

$$\theta = \frac{1.22\lambda}{a} \tag{1}$$

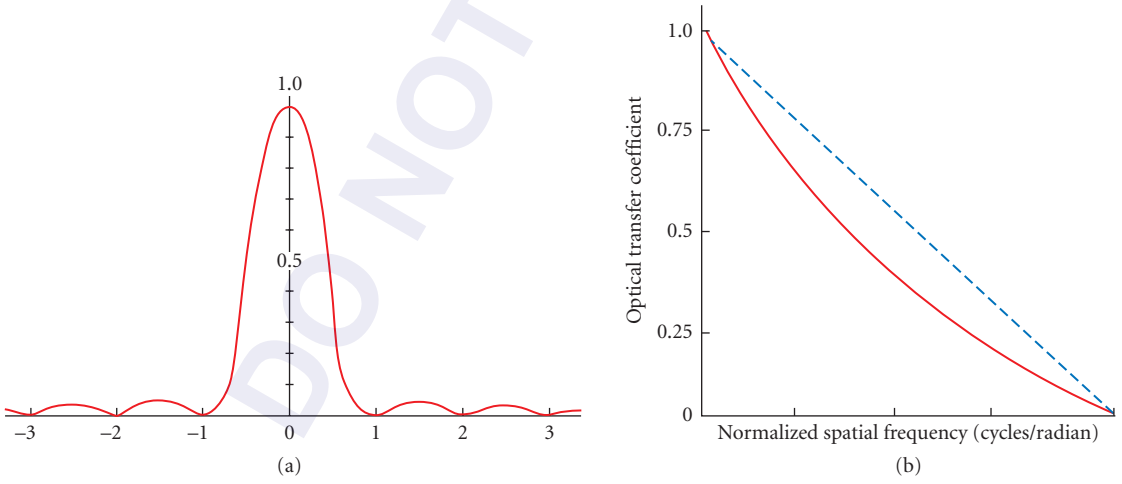

FIGURE 2 Retinal light distribution in an idealized optical system like the eye's. (*a*) Diffraction-limited point-spread function (Airy's disk). Unit distance is given by 1.22 λ/a in radians, where λ is the wavelength of light and a the diameter of the round pupil, both in the same units of length. (*b*) The optical contrast-transfer function for a square pupil (blue dashed line) and a round pupil (red solid line). It descends to zero at a spatial frequency equal to a/λ cycles/radian.

A point can never be imaged smaller than a patch of such a size; the light distribution for any object is the convolution of that of the points constituting it. In practice there are additional factors due to the aberrations and scattering in each particular eye.

Spatial-Frequency Coordinates and Contrast-Transfer Function A fundamental property of optical imagery in its application to the eye is its linearity. Hence a permissible description of light distributions is in terms of their spatial Fourier spectra, that is, the amplitudes and phases of those spatial sinusoidal intensity distribution in terms of their spatial frequency that, when superimposed, will exactly reconstruct the original distribution. The limit here is the cutoff spatial frequency at which the optical transfer coefficient of the eye reaches zero (Fig. 2*b*).

Either of the two descriptors of the optical transfer between the eye's object and image spaces, the point-spread function, that is, light spread in the image of a point, and the contrast-transfer function, that is, the change in amplitude and phase that the component sinusoids (as a function of spatial frequency in two angular dimensions) experience as they are transferred from the eye's object space to the retinal image, is complete and the transposition between the two descriptors in uncomplicated.

Because resolution relates to the finest detail that can be captured in an image, the interest is in the narrowness of the point-spread function (e.g., width at half-height) or, equivalently, the high-frequency end of the contrast-transfer function. The absolute limit imposed by diffraction gives a bound to these two functions but this is actually achieved only in fully corrected eyes with pupil diameters below about 3 mm, when other dioptric deficits are minimal. Concentrating on light of wavelength 555 nm, for which the visual system during daylight is most sensitive, Fig. 2, taken over directly from diffraction theory, illustrates the best possible performance that may be expected from a normal human eye under ordinary circumstances. The cutoff spatial frequency then is near 90 cycles/degree^{-1} and the diameter of Airy's disk about 1.5 arcmin.

A great deal of effort has gone into the determination of the actual point-spread functions of eyes which include factors such as aberrations. Only under very exceptional circumstances—and nowadays also with the aid of adaptive optics—does one get better imagery than what is shown in Fig. 2. When the pupil diameter is increased, theoretical improvement due to narrowing of the Airy disk is counteracted by aberrations which become more prominent as the outer zones of the pupil are uncovered. The effect of refractive errors on imaging can also be described in theory, but then phase changes in the contrast-transfer function enter because its complex nature (in the mathematical sense) can no longer be ignored (see under "Defocus").

4.5 RETINAL LIMITATIONS—RECEPTOR MOSAIC AND TILING OF NEURONAL RECEPTIVE FIELDS

Also amenable to physical analysis are the limitations imposed on the resolving capacity of the eye by the structure of the retina. All information that is handed on to the neural stages of vision is in the first place partitioned by the elements of the receptor layer, each of which has an indivisible spatial signature. The spacing of the receptors is not uniform across the retina, nor is the individuality of their local sign necessarily retained in further processing. Ultimately, the information transfer to the brain is confined by the number of individual nerve fibers emerging from the retina. Nevertheless it is instructive to inquire into the grain of the retina in the foveal region where there is certainly at least one optic nerve fiber for each receptor.

Figure 3 is a cross section of the layer of a primate retina and shows an approximately hexagonal array of cones, whose average spacing in the center is of the order of 0.6 arcmin. No matter what else is in play, human visual resolution cannot be better than is allowed by this structure. The center of the fovea is only about 0.5 deg in diameter; the further one proceeds into the retinal periphery the coarser the mosaic and the lower the ratio of receptors to optic nerve fibers. This explains the reason for our highly developed oculomotor system with its quick ability to transfer foveal gaze to different eccentric and even moving targets.

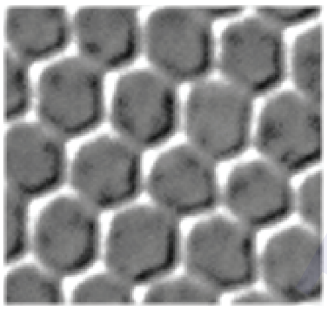

FIGURE 3 Histological cross section of the retinal mosaic in the primate fovea. Each receptor represents an object-sided angle of about 0.6 arcmin.

The neural elements of the retina are not passive transducers but actively rearrange the optical signals that reach the receptors. After transmission to the brain, processing of these neural signals involves interaction from other regions and modification as a result of such factors as attention and memory. As yet the neural circuitry interposed between the optical image on the retina and the individual's acuity response has not reached a level of understanding equivalent to that of the optical and receptor stages.

4.6 DETERMINATION OF VISUAL RESOLUTION THRESHOLDS

Awareness of the limitations imposed by the optics and anatomy of the eye is, of course, of value, but visual acuity is, in the end, a function of the operation of the whole organism: what are the finest spatial differences that can be distinguished? In answering this question, attention has to be paid to the manner of obtaining the measurements.

Since there is scatter in individual determinations, the number of trials will be controlled by the needed precision. The armamentarium of psychophysical procedures allows determination of a threshold with arbitrary precision. The standard optometric visual acuity chart, in use for 150 years, is a textbook case of effective employment of this approach. The ensemble of test symbols, the information content per symbol, the accepted answers, and the scaling of the steps and number of trials (letters in each row) have all been optimized for quick and reliable acuity identification.

A psychophysical threshold is a number along a scale of a variable (e.g., distance between double stars) at which a correct response is made in a predetermined proportion of trials. In a good experiment it is accompanied by a standard error. Thus if in a particular situation the two-star resolution threshold is found to be 0.92 ± 0.09 arcmin and the 50-percent criterion was employed, this means that on 50 percent of occasions when the separation was 0.92 inch the observer would say "yes" (the percentage increasing with increasing separation) and that the scatter of the data and the number of observations were such that if the whole experiment were repeated many times, the value would be expected to be between 0.83 inch and 1.01 inch in 19 out of 20 runs of data.

The distinction is often made between detection and discrimination thresholds. In sophisticated detection procedures, stimulus presentations are alternated randomly with blanks. A count is kept of the number of times the observer gives a "yes" answer when there was no stimulus, the so-called false positives. An elaborate analytical procedure can then be deployed to examine the internal

"noise" against which the incoming sensory signal has to compete.[2] This methodology is appropriate when there is a blank as one of the alternatives in the test, for example, in the measurement of the high spatial-frequency cutoff for grating resolution. In the bulk of acuity determinations the observer has to discriminate between at least two alternative configurations each presented well above detection threshold, and what has to be safeguarded against are bias errors.

It is the current practice in vision research to observe as many of these niceties of psychophysical methodology as possible (Chap. 3). However, in clinical and screening situations less time and observer engagement is available, with, as a consequence, diminished reliability and repeatability of findings.

4.7 KINDS OF VISUAL ACUITY TESTS

The common denominator of acuity tests is the determination of the finest detectable spatial partitioning, and this can be done in many ways. The closest to the optical concept of resolving power are the two-point or two-line patterns, whose minimum separation is measured at which they are seen as double (Fig. 4*a*). More popular are the two-bar experiments, most effectively implemented in a matrix of 3 × 3 elements, in which either the top and bottom rows, or the right and left columns

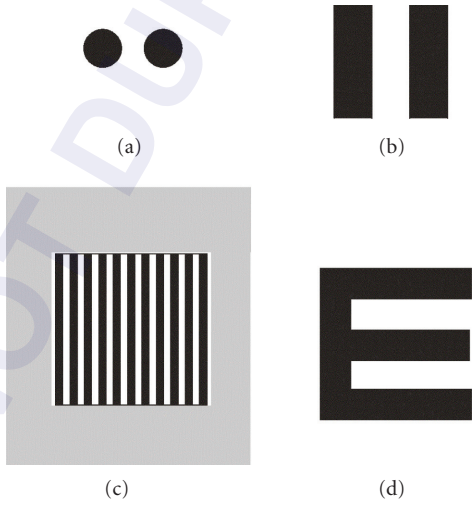

FIGURE 4 Patterns used in visual acuity tests and the associated response criteria: (*a*) Two point resolution. (*b*) Koenig bars in a 3 × 3 matrix. (*c*) Grating resolution. (*d*) Letters, as used in the clinical Snellen chart. Observers respond to these questions: You will be shown either a single or a double star. Was it "one" or "two?" (*a*). You will be shown a two-line pattern. Were the lines vertical or horizontal? (*b*). You will be shown a field that is either blank or contains vertical stripes? Was it "blank" or "striped?" (*c*). You will be shown an alphanumeric character. What letter or digit was it? (*d*).

have a different contrast than the middle row or column (Fig. 4*b*), the observer's responses being limited to "horizontal" and "vertical." The size of the matrix elements is increased to determine the observer's threshold. Overall size is no clue and the response is based on the detection of the internal image structure.

Some brightness variables are available to the experimenter. In the old days, the lines would be black on a white background whose luminance would be specified. With the advent of oscilloscopic displays this can now be white on black or, more generally, brighter and darker than a uniform background. Contrast is then a further variable, usually defined by the Michelson formula

$$\frac{(L_{\max} - L_{\min})}{(L_{\max} + L_{\min})} \tag{2}$$

With the advent of the Fourier approach to optics, grating targets have become popular. For the purposes of acuity, the highest spatial-frequency grating is determined at which, with 100-percent modulation, the field is just seen as striped rather than uniform (Fig. 4*c*). The phenomenon of spurious resolution, described below, makes this test inadvisable when focus errors may be at play. The role of grating targets in acuity measurements differs from that in modulation sensitivity tests, where gratings with a range of spatial periods are demodulated till they are no longer detectable. This process yields the modulation sensitivity curve, discussed below.

Since they were first introduced in the second half of the 19th century, the standard for clinical visual acuity are the Snellen letters—alphanumerical characters, each drawn within a 5×5 matrix, with limb thickness as the parameter (Fig. 4*d*). From the beginning it was accepted that the resolution limit of the human eye is 1 arcmin, and hence the overall size of the Snellen letter for normal acuity is 5 arcmin, or 9.5 mm at a distance of 6 m or 20 ft (optical infinity for practical purposes). When such letters can be read at 20 ft, visual acuity is said to be 20/20. Letters twice this size can normally be read at 40 ft; an observer who can only read such double-sized letters at 20 ft has 20/40 acuity. The charts are usually assembled in lines of about 8 letters for 20/20 and progressively fewer for the lower ratings, with just a single letter for 20/200. Because in acuity determinations the error is proportional to the size of the letters[3] and the sequence of letter sizes in charts is usually logarithmic.[4] Snellen acuity is often converted to a fraction, 20/20 becoming 1.0, 20/40 becoming 0.5, and so on. When some of the letters in a line are missed, say 2 in the 20/20 line, a score of 20/20 − 2 is recorded. For example, if there are 7 letters in the 20/25 (0.8) line of which 3 are missed, and the next line is 20/30 (0.67) a numerical value of 0.74 [0.8 − (3/7) (0.8 − 0.67)] can be entered for statistical purposes.

Snellen charts have been made available in many alphabets, but letters may not have equal legibility, even in English. Hence a stripped-down version of letter acuity is often used. A single letter E can be shown in four or even eight orientations and the observer asked to respond, perhaps by pointing a hand with outstretched fingers. The detection of the location of a gap in an annulus, that is, the distinction between the letter O and an oriented C, called the Landolt C test after its inventor is particularly useful. Both the E and Landolt C tests can be fitted into the tradition of Snellen letters by, for the 20/20 targets, generating them with 1′ line within a $5 \times 5'$ matrix, with progressive size increases to arrive at a solid numerical acuity value. These two tests make no demands on the subjects' literacy and have the virtue that the effect of guessing is a known quantity. Even here, a minor problem arises because of the "oblique effect," a small performance deficit in oblique orientations over the horizontal and vertical.

The development of the visual system in infants and the early detection of visual anomalies has sparked the design of infant visual acuity tests, usually depending on the observation of eye movements to targets of interest whose size can be progressively diminished.[5] Apart from this "preferential looking" technique, optokinetic nystagmus, that is, the involuntary eye tracking of large moving fields, can be effectively utilized to measure acuity by progressively diminishing the size of details until tracking fails.

As outlined so far, all the tests have in common the need for the subject to be aware and cooperative, though not necessary literate. When these conditions are absent, other procedures have to be adopted, for example, recording the signals from the eye into the central nervous system from the scalp. These are not further described here.

4.8 FACTORS AFFECTING VISUAL ACUITY

Visual acuity performance will be diminished whenever any of the contributing functions have not been optimized. Initial analysis concentrates on optical and retinal factors; not enough is known about the subsequent central neural stages to differentiate all the possible ways in which their operation can be encumbered or rendered inefficient. Such factors as attention, training, and task familiarity are clearly relevant. A treatment of the subject from the clinical point of view is available in textbooks.[6,7]

Pupil When the optical line-spread function has been widened for whatever reason, resolution will obviously suffer. This is the case when the pupil is too small—2 mm or less—when diffraction widens it or, in the presence of aberrated wavefronts, when it is very large—usually 6 mm or larger.

Defocus Focus errors are of particular interest, because one of the most ubiquitous applications of visual acuity testing is to ascertain the best refractive state of eyes for purposes of spectacle, contact lens, or surgical correction. Ever since the establishment of the current optometric routines in the late 19th century, rules of thumb have existed for the relationship between refractive error and unaided acuity. One of these is shown in Fig. 5. But this does not take into account a patient's pupil size which governs depth of focus, the possible presence of astigmatism, and higher-order aberrations, nor some complications arising from the nature of out-of-focus imagery. When a spherical wavefront entering the eye's image space does not have its center at the retina, the imagery can be described as having a phase error that increases as the square of the distance from the center of the aperture.[9] The contrast-transfer function, which is the Fourier transform of the complex (i.e., amplitude and phase) pupil aperture function, then does not descend to the cutoff spatial frequency monotonically, but shows oscillatory behavior (Fig. 6); in some regions in the spatial-frequency spectrum it dips below zero and the grating images have their black and white stripes reversed. This so-called spurious resolution means that if one views grating pattern under these conditions and gradually increases spatial frequency, stripes will first be visible, then disappear at the zero-crossing of the transfer function, then reappear with inverted contrast and so on. The seen image of objects like Snellen letters will undergo even more complex changes, with the possibility that "spurious" recognition is achieved with specific states of pupil size and defocus.

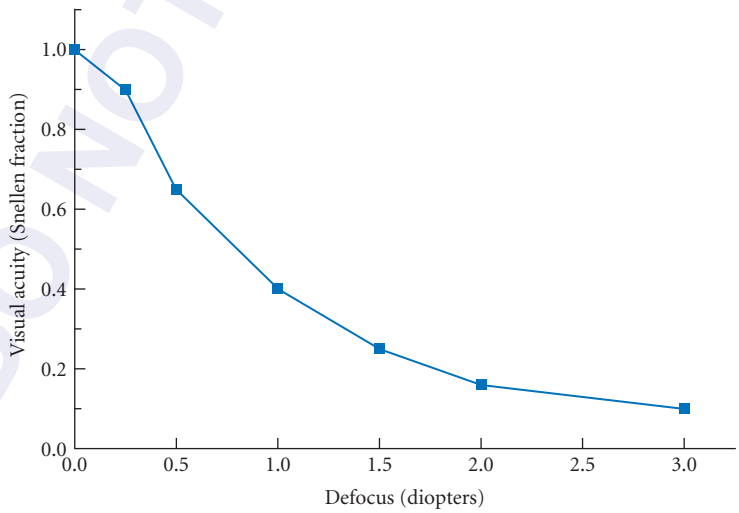

FIGURE 5 Visual acuity in a typical eye as a function of uncorrected spherical refractive error in diopters. (*Adapted from Laurance.*[8])

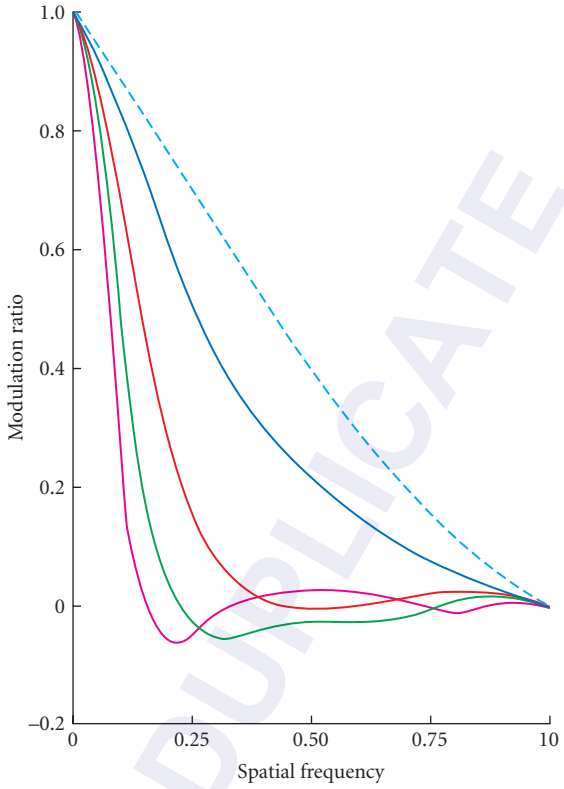

FIGURE 6 Normalized optical-transfer function for various degrees of defocus, showing regions of the spatial-frequency spectrum in which the coefficients are negative and the contrast of grating targets is reversed in the image compared to that in the object. (*Adapted from Hopkins.*[10]) For an eye with a 3-mm round pupil and wavelength 560 nm, the cutoff spatial frequency denoted by the normalized value 1.0 on the axis of abscissas is 1.53 cycles/arcmin and the five curves show the theoretical response for 0, 0.23, 0.31, 0.62, and 1 diopters defocus.

Color The diffraction equations have wavelength as an explicit variable. The width of the point-spread function varies inversely with wavelength. This is, however, only a minor factor where the effect of color on visual acuity is concerned. More immediately involved is the eye's chromatic aberration, giving defocus of about 1 diopter at the extremes of the visual spectrum, where also more energy is needed to compensate for the fact that the luminous efficiency of the eye peaks as 555 nm for the photopic and 500 nm for the scotopic (rod) system. In practice, therefore, each situation will have to be handled individually depending on the wavelength distribution of the particular stimulus.

Retinal Eccentricity Due to the coarsening of the grain of the anatomical connections in the peripheral retina, visual acuity falls off with increasing eccentricity (Fig. 7) and this is more pronounced in the extreme nasal than temporal field of view of each eye. In binocular vision, when

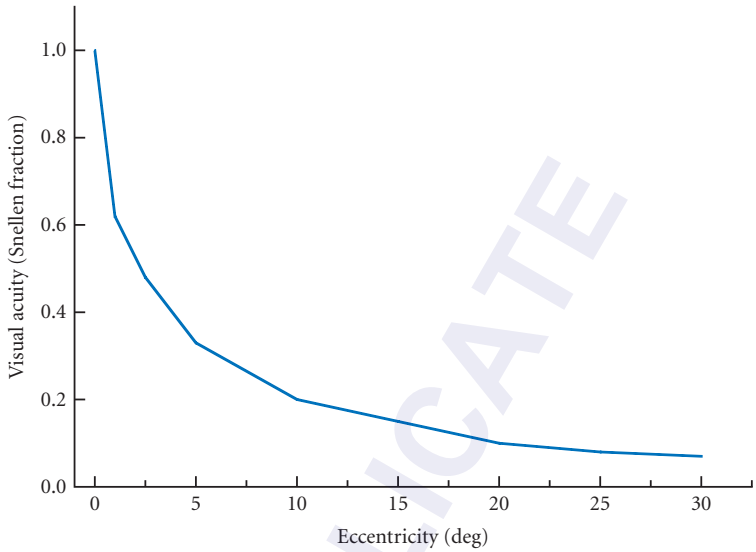

FIGURE 7 Expected visual acuity in various locations in the peripheral visual field. (*Adapted from Wertheim.*[11])

both eyes are in play, acuity is usually better than in monocular vision, not only because the better eye covers any possible deficiency of the other, but also because of probability summation due to the two retinas acting as independent detectors.

Luminance Acuity measured for black symbols against a white background, that is, for 100 percent contrast (Fig. 8) remains constant from about 10 $cd \cdot m^{-2}$ up. Below about 1 $cd \cdot m^{-2}$ the photopic system drops out and rods, which are absent in the fovea, take over. Their luminosity curve peaks at

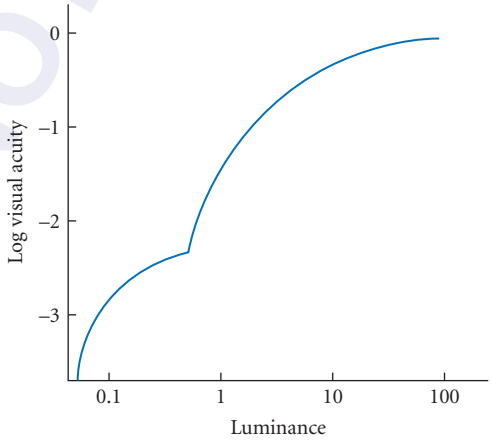

FIGURE 8 Visual acuity for targets as a function of their luminance. (*Adapted from Shlaer.*[12]) The rod-cone break occurs at a light level equivalent to that of a scene lit by full-moon light.

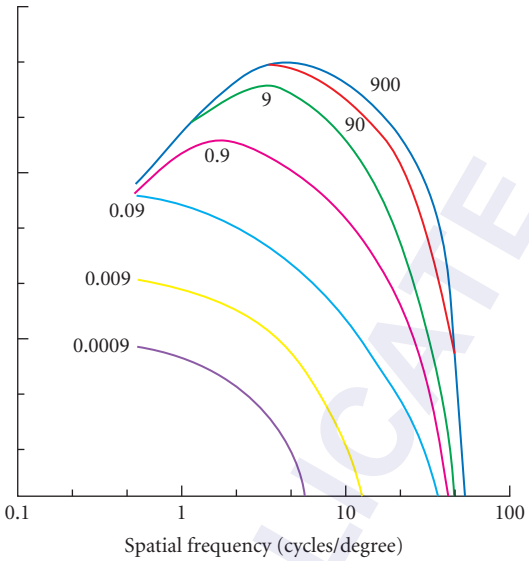

FIGURE 9 Modulation sensitivity (contrast detection) curve of the human visual apparatus as a function of spatial frequency at different light levels. (*From van Nes and Bouman.*[13]) Visual acuity is equivalent to the highest spatial frequency at which a response can still be obtained (intersection with the *x* axis) and the data here map well on those in Fig. 8.

about 500 nm. Also, they are color blind, and subject to considerable spatial summation and adaptation, that is, become more sensitive with increased time in the dark, up to as much as 30 to 45 min.

Contrast Most clearly shown with the use of grating stimuli, there is reduction in performance at both the low and high spatial frequency ends of the spectrum (Fig. 9). Because contrast sensitivity is lowered in various ocular abnormalities, particularly scatter of or absorption in the media, it has been found valuable to perform acuity measurements with low-contrast charts.[14,15] Reversing the contrast polarity, that is, presenting bright letters against a dark background, has virtue for eyes with a wide point-spread function and light scatter[16] and indeed improves acuity performance in some older eyes.[17]

Time Time is decidedly a factor in visual acuity. For very short presentations, about 20 ms or less, the eye integrates all the light flux, what matters then is the product of the intensity and the duration, in any combination. But acuity improves with duration in the several hundred millisecond range where light detection no longer depends on duration but only intensity (Fig. 10).

Surround A prominent effect in visual acuity is that of crowding, where the presence of any contour close to the resolution target interferes with performance (Fig. 11).

Practice Effects Surprisingly, in the fovea of normal observers, practice in the task does not confer any further advantage—it seems that optimum performance has been entrained through continuous exercise of the facility in everyday situation. Peripheral acuity can, however, be improved by training.[20,21]

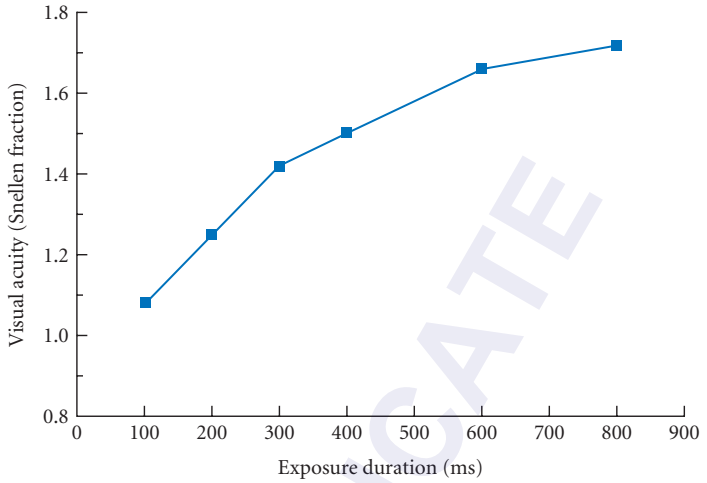

FIGURE 10 Visual acuity as function of exposure duration. (*From Baron and Westheimer.*[18])

Stage of Development and Aging Visual acuity shows a steep increase in the first few months of life and, if a secure measurement can be obtained, is not far from normal at least by the third year.[5] The aging eye is subject to a large number of conditions that impair acuity (Chap. 14); it is their presence or absence that determines any individual patient's status. Consequently age decrements of acuity can rage from none to severe.

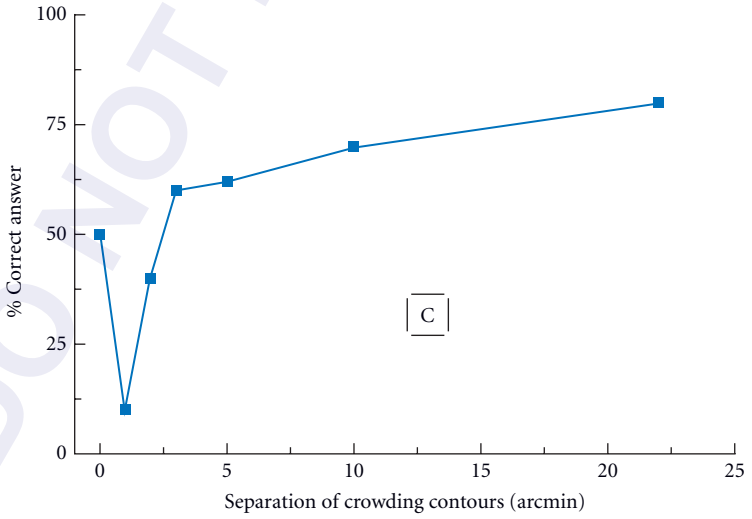

FIGURE 11 Data showing the "crowding" effect in visual acuity. A standard letter is surrounded by bars on all four sides and the performance drops when the bars are separated from the edge of the letter by the thickness of the letter's line-width. (*Adapted from Flom, Weymouth, and Kahneman.*[19])

4.9 HYPERACUITY

For a long time human spatial discriminations have been known where thresholds are markedly lower than the resolution limit. For vernier acuity, the foveal alignment threshold for two abutting lines is just a few arcsecs, as compared with the 1 arcmin or so of ordinary resolution limit.

Such high precision of localization is shared by many kinds of pattern elements, both in the direction joining them, in their alignment, and in deviations from rectilinearity (Fig. 12). The word hyperacuity is applied to this discrimination of relative position, in recognition that it surpasses by at least an order of magnitude the traditional acuity. Whereas the limitation of the latter are mainly in the resolving capacity of the eye's optics and retinal mosaic, hyperacuity depends on the neural visual system's ability to extract subtle differences within the spatial patterns of the optical image on the retina.

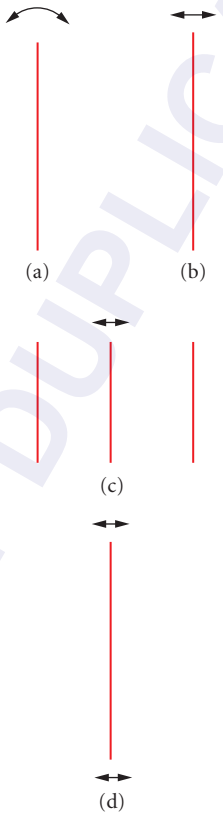

FIGURE 12 Configuration in which location differences can be detected with a precision higher than the resolution limit by up to an order of magnitude. These hyperacuity tasks do not contradict any laws of optics and are the result of sophisticated neural circuits identifying the centroids of light distributions and comparing their location. Thresholds are just a few arcsec in the foveal discrimination of these patterns from their null standards: (*a*) orientation deviation from the vertical of a short line; (*b*) alignment or vernier acuity; (*c*) bisection of a spatial interval; and (*d*) deviation from straightness of a short line.

Localization discriminations in the hyperacuity range are performed by identification of the centroid of the retinal light distributions[22] of the involved pattern components, for example, abutting lines in the vernier task. The information is available in the image and can be described equally well in the domains of light distribution and its Fourier spectrum. It is testimony of sophisticated neural processing to arrive at the desired decision. Resolution and localization acuity share many attributes, though usually not in the same numerical measure.

Like ordinary visual acuity, hyperacuity is susceptible to crowding and to the oblique effect, but the two classes of spatial discrimination do not share all the other attributes.[23] Specifically, hyperacuity is more robust to reduction in exposure duration and diminishes more steeply with retinal eccentricity. It therefore follows that the neural processing apparatus is different and involves subtly recognition of differences in the excitation state of a neural population. In this respect it is similar to a whole host of fine discriminations, for example, those in the visual domains of color and stereoscopic depth.

4.10 RESOLUTION, SUPERRESOLUTION, AND INFORMATION THEORY

The threshold difference between ordinary visual acuity and hyperacuity raises the question whether any fundamental physical principles are being disobeyed.[24]

Resolution and Superresolution

In the first instance, all of vision must satisfy the laws of physical optics according to which no knowledge can be acquired about an object that is contained in the region beyond the cutoff spatial frequency decreed by diffraction theory. Here the concepts associated with the term *superresolution* (Chaps. 3 and 4 in Vol. I) are relevant; they have been expanded since first formulated as involving an extrapolation: If the predominant features in which the spatial-frequency spectrum of two objects differ are located beyond the cutoff, but are always accompanied by a characteristic signature within it, then in principle it is possible to make the distinction between the two objects from detailed study of the transmitted spectrum and extrapolate from that to arrive at a correct decision. More recently the word has also been used to describe a procedure by which several samples of noisy transmitted spatial-frequency spectra from what is known to be the same object are superimposed and averaged. In both uses of the word, no diffraction theory limit has been broached; rather, knowledge is secured from detailed analyses of observed energy distributions on the basis of prior information—in the first case that the difference in the spatial-frequency spectrum inside the cutoff limit is always associated with those beyond it, in the second that the several spectra that are averaged arose from the same target.

Resolution and Information

Information theory has been of help in understanding some potentially knotty problems in defining resolution.[25] Traditionally, the resolving power of an ideal optical instrument is regarded to have been reached when two stars are separated by the width of the Airy disk, when the images of the two stars partially overlap and the dip between the two peaks is about 19 percent. This so-called Rayleigh criterion usually allows the receptive apparatus to signal the two peaks and the trough as separable features—provided its spatial grain is fine enough and the intensity difference detectable. It is then possible to decide, without prior knowledge, that there are two stars or that a spectral line is double. But when there is prior knowledge that the source can only be either single or double, and if double, what their relative intensity is, then the decision can be made for smaller separations, because the light distribution resulting from the overlapping images of two adjoining sources differs in predictable fashion from that of a single sources, even when the dip between the peaks is less than at the

Rayleigh limit and even when there is no dip at all. This specific example highlights how information theory, as first formulated by Shannon, enters the discussion: in quantifying the transmitted information, prior knowledge needs to be factored in.

The diffraction image of a point is an expression of the uncertainty principle: it describes the probability distribution of the location of the source of an absorbed photon. The larger the number of absorbed photons, the more secure the knowledge of the source's location *provided always that it is known that it has remained the same source as the photons are being accumulated.* With sufficient number of absorbed photons, and the assurance that they arose from the same source, it is possible to assign location with arbitrary precision. Hence, from the standpoint of optics, there is nothing mysterious about the precision of locating visual target that is now called hyperacuity. Rather it draws attention to the physiological and perceptual apparatus that enables this precision to be attained.

4.11 SUMMARY

The human visual system's capacity to discriminate spatial details is governed by the eye's optical imagery, by the grain of the retinal receiving layer, by the physiological apparatus of the retina and the central nervous system, and by methodological considerations of recording observers' responses. Overall, under the best conditions of ordinary viewing, the resolution limit is close to that governed by the diffraction theory for the involved optical parameters. Performance is impaired whenever any of the optical, anatomical, physiological, or perceptual components does not operate optimally. There is an additional class of visual threshold based not on resolution of spatial detail but on locating relative object position. Because thresholds then are at least one order of magnitude better, they are called hyperacuity. They do not contravene any laws of optics but are testimony to sophisticated neural processing that can identify the location of the centroid of retinal light distributions with high precision.

Robert H. Webb

The Schepens Eye Research Institute
Boston, Massachusetts

5.1 GLOSSARY

A	area
D	distance
E_r	illuminance at the retina (retinal illuminance)
f	focal length
f_e	focal length of the eye
L_s	intrinsic luminance of the source
td	troland (the unit of retinal illuminance)
x	position
Δ	change in position
Φ	flux (general)
Φ_p	flux at the pupil
τ	transmittance

We have also consistently used subscripted and/or subscripted versions of A and S for area, D for distance, f for focal lengths, x for positions, and Δ for changes in position.

5.2 INTRODUCTION

This chapter presents basic techniques for generating, controlling, and calibrating the spatial and temporal pattern of light on the retina (the visual stimulus). It deals with the optics of stimulus generation and the control of light sources used in the vision laboratory. Generation of stimuli by computer video displays is covered in detail in Chap. 22. Units for measuring radiation are discussed in Chap. 34, "Radiometry and Photometry," by Edward Zalewski and Chap. 37, "Radiometry and Photometry for Vision Optics," by Yoshi Ohno in Vol. II.

5.3 THE SIZE OF THE VISUAL STIMULUS

The size of a visual stimulus can be specified either in terms of the angle which the stimulus subtends at the pupil, or in terms of the physical size of the image of the stimulus formed at the retina, for most purposes vision scientists specify stimuli in terms of the angular subtense at the pupil. If an object of size h is viewed at distance D then we express its angular extent as

$$\text{Degrees visual angle} = 2\left(\tan^{-1}\left(\frac{h}{2D}\right)\right) \tag{1}$$

or, for angles less than about 10 deg

$$\text{Degrees visual angle} \cong \frac{360h}{2\pi D} = \frac{57.3h}{D} \tag{2}$$

In this chapter we specify stimuli in terms of the actual retinal area, as well as the angular extent. Angular extent has the advantage that it is independent of the eye, that is, it can be specified totally in terms of externally measurable parameters. However, an understanding of the physical dimensions of the retinal image is crucial for understanding the interrelation of eye size, focal length, and light intensity, all of which are part of the design of optical systems for vision research.

5.4 FREE OR NEWTONIAN VIEWING

There are two broad classes of optical systems that are used in vision research. Free viewing, or *newtonian* viewing, forms an image of a target on the retina with minimal accessory optics (Fig. 1*a*).

Retinal Illuminance

Photometric units incorporate the overall spectral sensitivity of the eye, but that is the only special property of this set of units. That is, there are no terms specific to color (for a discussion of colorimetry, see Chap. 10) and no allowances for the details of visual perception. The eye is treated as a linear detector which integrates across wavelengths. The retinal illuminance of an object in newtonian view is determined by the luminous intensity of the target and the size of the pupil of the eye. The luminous power at the pupil [dimensions are luminous power or energy per unit time, the SI units are lumens (lm)]

$$\Phi_P = L_s A_s \frac{A_p}{D^2} \tag{3}$$

where L_s is the luminance of the source [the SI units are lumens per meter squared per steradian (lm/m^2/sr) or candelas per meter squared (cd/m^2)], A_s is the source area, A_p is the area of the pupil, and D is the distance from the pupil to the source [so (A_p/D^2) is the solid angle the pupil subtends].

The area of the image element on the retina is

$$A'_R = A_s m^2 = A_s \left(\frac{f_e}{D}\right)^2 \tag{4}$$

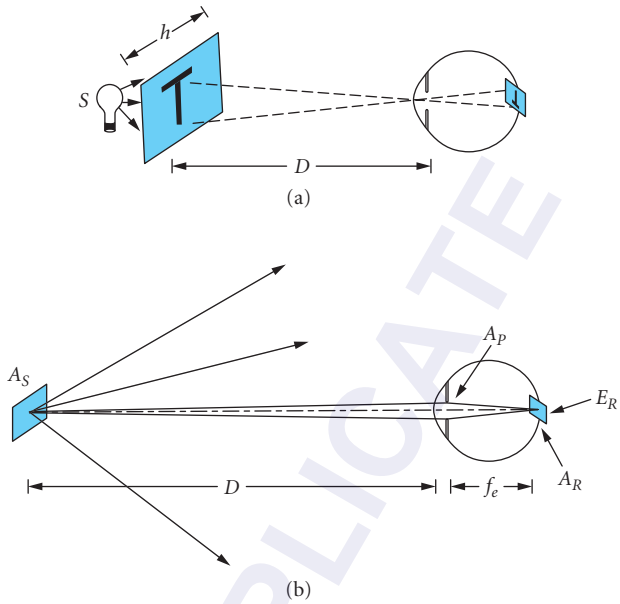

FIGURE 1 (*a*) In free viewing or newtonian viewing the eye's optics are used to image a target onto the retina. (*b*) Computation of the retinal illuminance in free-viewing. A_s the area of the source, D the distance between the source and the eye, A_p the area of the pupil, f_e the optical focal length of the eye, A_R the area of the image of the source on the retina, and E_R the retinal illuminance.

where m is the magnification of the eye and f_e is the effective focal length of the eye (Fig. 1*b*). From this we compute the illuminance at the retina as

$$E_R = \frac{\Phi_p}{A'_R} = \frac{A_p L_s}{(f_e)^2} \tag{5}$$

(The SI units of illuminance are lm/m^2). A typical value for f_e, is 16.67 mm.[1,2] Note that the retinal illuminance does not depend on the distance. That is, the retinal illuminance when viewing an extended source such as a video screen is independent of the viewing distance and is dependent only on the size of the eye's pupil, the luminance of the source, and the focal length of the eye. In most cases, the focal length of the viewer's eye is not known, but it is possible to measure the size of the pupil. For this reason a standard unit for specifying retinal illuminance was developed, the *troland*.

The Troland (td) The troland is a unit of illuminance (luminous power per unit area). The troland quantifies the luminous power per unit area at the retina (the retinal illuminance). One troland was defined as the illuminance at the retina when the eye observes a surface with luminance = 1 cd/m^2 through a pupil having an area of 1 mm^2. Using Eq. (5) and a standard f_e of 16.67 mm we find that the troland is defined by

$$1\,\text{td} = 0.0035\ \text{lumens/m}^2 \tag{6}$$

This definition ties the troland to the illuminance on the retina of a standard eye assuming no transmission loss in the ocular media at 555 nm. Thus, two observers with different-size eyes, different-size pupils, or different relative losses in the ocular media, viewing the same surface, will have different retinal illuminances. Wyszecki and Stiles[2] have recommended that the term *troland value* be used to distinguish the trolands computed for a standard eye from the actual retinal illuminance. General usage is that the retinal illuminance is determined simply by measuring the luminance of a surface in cd/m^2 and multiplying this value by the area of the pupil in mm^2.

Limitations of Free Viewing: An Example

There are two major limitations to newtonian view systems. The first is that the retinal illuminance is limited. For instance, a 60-W frosted incandescent bulb can produce a 120,000-td field, but to obtain a uniform 20 deg field it must be placed 17 inches from the observer's eye. This requires an accommodative effort that not all observers can make. A comparable illuminance at more realistic distances, or with variable focus, requires larger light sources or more elaborate optical systems. The second limitation of free viewing is that variations in pupil size are not readily controlled. This means that the experimenter cannot specify the retinal illuminance for different stimulus conditions or for different individuals. Maxwellian view optical systems solve these problems.

5.5 MAXWELLIAN VIEWING

Figure 2*a* shows a simple *Maxwellian* view system. The key factor that distinguishes the maxwellian view system is that the illumination source is made optically conjugate to the pupil of the eye. As a result, the target which forms the stimulus is not placed at the source, but rather at a separate plane optically conjugate to the retina. In the system of Fig. 2*a* the plane conjugate to the retina, where a target should be placed, lies at the focal point of lens L_{21}, between the source and the lens (see Chap. 6). Light from the source is diverging at this point, and slight changes in target position will cause changes in both the plane of focus and the magnification of the target. For this reason most real maxwellian view systems use multiple lenses. Figure 2*b* shows such a maxwellian view system where the single lens has been replaced by two lenses. The first lens collimates light from the source and the second forms an image of the source at the pupil. This places the retinal conjugate plane at the focal plane of L_1. We label the conjugate planes starting at the eye, so R_1 is the first plane conjugate to the retina and P_1 is the first plane conjugate to the pupil.

Control of Focus and the Retinal Conjugate Plane

The focus of the maxwellian view system is controlled by varying the location of the target.[3–5] Moving the target away from R_1 allows the experimenter either to adjust for ametropia or to require the observer to accommodate. To see this we compute where lens L_1 (Fig. 2*b*) places the image of the target relative to the eye. If the target is at the focal point of L_1, the image is at infinity, which means there is a real image in focus at the retina for an emmetropic eye. If we move the target toward lens L_1, the lens of an emmetrope must shorten the focus to bring the image back into focus on the retina. We quantify this required change in focus as the change in the dioptric power of the eye (or the optical system if spectacle correction is used) where the dioptric power is simply the inverse of the focal length measured in meters. If the target is displaced by Δ from the focal point of L_1 then using the newtonian form of the lens formula ($x'x = f^2$) we find that

$$\text{Change in dioptric power} = \frac{\Delta}{(f_1)^2} \tag{7}$$

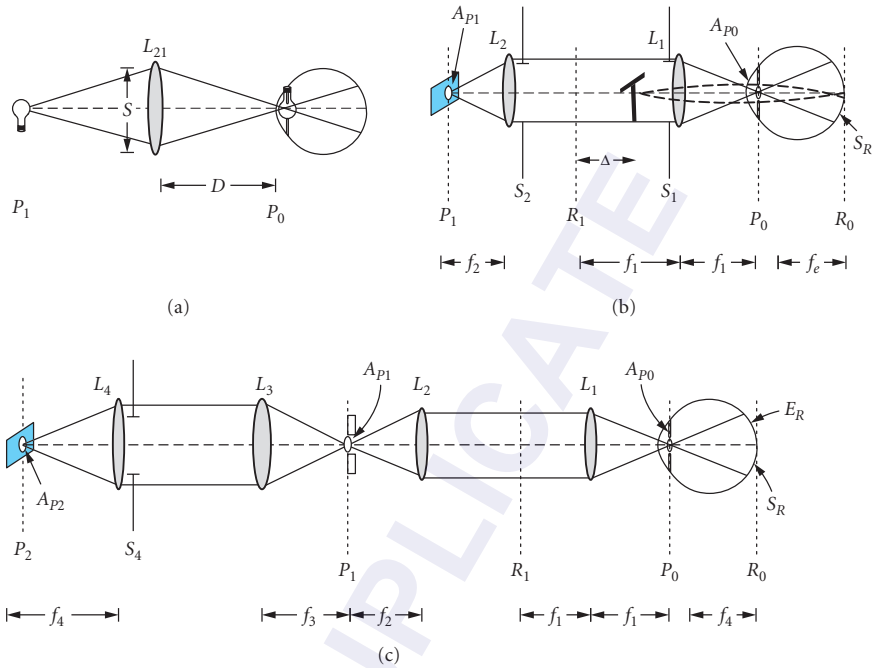

FIGURE 2 (*a*) In a minimal maxwellian view system a lens L_{21} images a source in the plane of the eye's pupil. The lens is shown at a distance D from the eye equal to twice its focal length. The field stop (S) in the aperture of L_{21}. (*b*) A maxwellian view optical system with an accessible retinal conjugate plane (R_1). Lens L_2 collects light from the source and collimates it. Lens L_1 images the source in the plane of the eye's pupil (P_0). Pupil conjugate planes (P_i) and retinal conjugate planes (R_i) are labeled starting at the eye. For an emmetrope lens L_1 images the retina (R_0) at R_1. This is the plane where a visual target will appear in best focus for an emmetropic observer. Moving the target away from R_1 a distance Δ changes the plane of focus of the retinal image, requiring the emmetrope to accommodate. The maximum size of the retinal image (S_R) is limited for this system to the aperture of lens L_2(S_2). The pupil is imaged at position P_1, where the light source is placed. (*c*) Shows a more complex system where a second set of pupil conjugate and retinal conjugate planes have been added. An artificial pupil (A_{P1}) is added at P_1. It is the image of this pupil at the source (A_{P2}) that limits the retinal illuminance produced in this optical configuration. Other symbols as above.

If the target move toward the lens L_1, this compensating power must be positive (the focal length of the eye or eye plus spectacle shortens). If the target moves from f_1 away from lens L_1, the required compensation is negative. If the eye accommodates to keep the target in focus on the retina, then the size of the retinal image is unchanged by the change in position.[3,4]

Size

For this system the area of the illuminated retinal field is determined by the limiting aperture in a retinal conjugate plane between the light source and the retina (the field stop S_2 in Fig. 2*b*) and is

$$S_R = \left(\frac{f_e}{f_1}\right)^2 S_2 \tag{8}$$

or for the schematic eye we use

$$S_R = \left(\frac{16.67}{f_1}\right)^2 S_2 \tag{9}$$

where f_e is the focal length of the eye (in mm) and f_1 is the focal length of lens L_1. This formula is used to compute the physical size of an image on the retina. Note that the linear magnification is (f_e/f_1) and the areal magnification is $(f_e/f_1)^2$. The angular subtense of the field is the same as in Eq. (1), substituting the diameter of S_2 for h and f_1 for the distance D. Also note that the angular extent is independent of details of the optics of the eye. This convenience is the main reason that angular extent is the most widely used unit for specifying the stimulus in vision research.

Retinal Illuminance

One of the *principal advantages* of a maxwellian view system is that it provides a large, uniformly bright field of view. This mode of illumination is called Kohler illumination in microscopy. The light available in a maxwellian view optical system is determined by two main factors, the luminance of the light source, and the effective pupillary aperture of the optical system being used. In Fig. 2*b* we see that lens L_2 collects light from the source. The amount of light collected is the maximum amount of light that can be presented to the eye and is[1,3]

$$\Phi = A_{P1} L_s \frac{S_2}{(f_2)^2} \tag{10}$$

where A_{P1} is the area of source being considered (or, equivalently, a unit area of the source), L_s is the luminance of the source (in lm/m^2/sr), S_2 is the aperture of lens L_2, and f_2 is the focal length of lens L_2. We have used the area of lens L_2, for this example, although in actual practice this area might be reduced by later field stops. This quantity will cancel out in the subsequent calculations. Finally, if all of the light collected by lens L_2 is distributed across the retina, then the retinal illuminance is

$$E_R = \frac{\Phi}{S_R} = A_s L_s \left(\frac{f_1}{f_2 f_e}\right)^2 \tag{11}$$

where S_R is obtained from Eq. (8). Note that only the luminance of the source, the source area, and the focal lengths of the optical elements are important in setting the retinal illuminance. Using different diameters for lens L_2 will change the amount of light collected and the size of the retinal area illuminated. Such a change will be reflected by changing the area parameter in both Eqs. (8) and (10), which cancel.

In Eq. (11) the area of the source image (A_{P1}) at the pupil is

$$A_{P0} = A_{P1} \left(\frac{f_1}{f_2}\right)^2 \tag{12}$$

If the eye's pupil (A_{P0}) is smaller than this source image then the eye's pupil is limiting and

$$E_R = \frac{A_{P0} L_s}{(f_e)^2} \tag{13}$$

Equation (13) for the maxwellian view system is identical to Eq. (5) which we obtained for the newtonian view system, but now the entire field is at the retinal luminance set by the source luminance. Thus, in maxwellian view a large, high retinal illuminance field can be readily obtained.

To control the size of the entry pupil rather than allowing it to fluctuate with the natural pupil, most maxwellian view systems use a pupillary stop. Figure 2*c* shows a system where a stop has been introduced at an intermediate pupil conjugate plane A_{P1}. This has the advantage of placing the pupillary stop of the system conjugate to the eye's pupil. The projection of A_{P1} at the source is A_{P2} and it is A_{P2} that limits the available luminous area of the source. Lenses L_3 and L_4 image the source onto the artificial pupil, and lenses L_1 and L_2 image the artificial pupil in the plane of the eye's pupil (A_{P0}). The retinal illuminance of this more complex system can be computed as follows: the field stop over which light is collected by lens L_4 is S_4 and can be computed by projecting the retinal area illuminated (S_R) back to lens L_4.

$$S_4 = S_R\left(\frac{f_1 f_3}{f_2 f_e}\right)^2 \tag{14}$$

A_{P2} is the area of the source which passes through the artificial pupil:

$$A_{P2} = \left(\frac{f_4}{f_3}\right)^2 A_{P1} \tag{15}$$

Therefore the total amount of usable light collected is

$$\Phi = L_s A_{P2}\frac{S_4}{(f_4)^2} = S_R L_s A_{P1}\left(\frac{f_1}{f_2 f_e}\right)^2 \tag{16}$$

and the retinal illuminance is

$$E_R = \frac{\Phi}{S_R} = L_s A_p\left(\frac{f_1}{f_2 f_3}\right)^2 \tag{17}$$

Note that, as in Eq. (13), $[A_{P1}(f_1/f_2)^2]$ is the size of the image of the aperture A_{P1} when measured at the exit pupil (A_{P0}). Thus, even in this more complex case we find that the retinal illuminance is dependent only on the source luminance, the pupillary area measured at P_0, and the focal length of the eye.

Advantages of Maxwellian Viewing: Example Revisited

The strength of a maxwellian view system is that properties of the target (focus, size, shape) can be controlled independently from retinal illuminance. If the source is larger than the limiting pupil, then the maximum retinal illuminance is the luminance of the source, scaled only by the exit pupil and eye size [Eqs. (13) and (17)]. The retinal illuminance is controlled by pupillary stops, and the target size, shape, and focus are controlled by retinal stops. Additionally, focus can be controlled independently of retinal illuminance and image size.

If we use the 60-W frosted bulb that we used in the example of newtonian viewing as a source in a maxwellian view optical system we find that we can produce the same maximum retinal illuminance for a given pupil size [Eqs. (5) and (13)]. However, with the maxwellian view system relatively inexpensive, achromat lenses will allow us to generate a field size greater than 20 deg. In addition, we can dispense with the frosted bulb (which was needed in free viewing to give a homogeneously illuminated target) and use an unfrosted tungsten halogen bulb to produce in excess of 1 million td.

Controlling the Spatial Content of a Stimulus

The spatial frequency content of a retinal image is usually measured in cycles per degree (of visual angle). The frequencies present in the retinal image are those present in the target, cut off by the limiting aperture of the pupillary stop—either the eye's pupil or an artificial pupil in a pupillary plane *between the target and the eye*.[25] Apertures placed on the source side of the target do nothing to the spatial frequency content of the retinal image, leaving the pupil of the eye controlling the image, not the artificial pupil. (For a more detailed treatment of the effects of pupils on the spatial content of images see Refs. 6–10. For a discussion of the spatial resolving power of the eye's optics see Chaps. 1 and 4 in this volume of the *Handbook*).

Positioning the Subject

One of the practical disadvantages in using maxwellian view systems is the need to position the eye's pupil at the focal point of the maxwellian lens (L_1 in Fig. 2*c*) and to maintain its position during an experimental session. One technique for stabilizing the position of the eye is to make a wax impression of the subject's teeth (a bite bar). By attaching the bite bar to a mechanism that can be accurately positioned in three dimensions (such as a milling machine stage) the eye can be aligned to the optical system and, once aligned, the eye position is maintained by having the subject bite loosely on the bite bar. Alignment of the eye can be achieved either by observing the eye, as described at the end of this chapter, or by using the subject to guide the alignment process as described in the following paragraphs.

The first step in alignment is to position the eye at the proper distance from lens L_1. This can be accomplished by noting that, when the eye's pupil is at the plane of the source image, slight movements of the head from side to side cause the target to dim uniformly. If the eye's pupil is not at the proper distance from lens L_1 then moving the head from side to side causes the target to be occluded first on one side, then the other. By systematically varying the distance of the eye from lens L_1, the proper distance of the eye can be determined. It is then necessary to precisely center the eye's pupil on the optical axis of the apparatus. There are several approaches to centering the eye.

1. The physical center of the pupil can be located by moving the translation stage such that the pupil occludes the target first on one side, then on the other. The center of these two positions is then the center (in one dimension) of the pupil. The process is then repeated for vertical translations.
2. The entry position that produces the optimum image quality of the target can be determined. One variant is to use a target that generates strong chromatic aberration (for instance, a red target on a blue background). The head can then be moved to minimize and center the chromatic fringes.[11] This process defines the achromatic axis of the eye.
3. The eye can be positioned to maximize the brightness of the target, which centers the Stiles-Crawford maximum in the pupil with respect to the exit pupil of the instrument.
4. A set of stimuli can be generated that enter the eye from different pupil positions. If the eye is centered, then all stimuli will be seen. If the eye is not centered, then the pupil occludes one of the pupil entry positions and part of the stimulus array disappears. In this case, the subject merely has to keep his or her head positioned such that all stimuli are visible.

5.6 BUILDING AN OPTICAL SYSTEM

Alternating Source Planes and Retinal Planes in a Controlled Manner

The separation of retinal and pupil conjugate planes in a maxwellian view system allows precise control over the spatial and temporal properties of the visual stimulus. By placing the light source conjugate to the pupil of the eye, every point on the source projects to every point in the retinal image

and vice versa. Thus, to control the whole retinal image, such as turning a light on and off, manipulation of a pupil conjugate plane is optimal. To control the shape of the retinal image without altering the entry pupil characteristics, variation at the retinal conjugate planes is required. However, there is an exception to this rule. Light from the edges of the image traverse the pupil conjugate plane at a higher angle than light from the center of the image. For small fields (<15-deg diameter) the angular dependence is minimal, but for larger fields it can be significant and filters should be placed in a collimated light path.

Combining Lights in an Optical System

To control aspects of the visual stimulus independently, different light sources and targets, each with its own set of filters and shutters, can be combined. We will call these separate "channels." Three different techniques allow for combining optical channels, beamsplitters, beam separators or reflective apertures, and diffusers. All three methods are demonstrated in Fig. 3.

Beamsplitters A beamsplitter both transmits and reflects a fraction of the incident light. Any surface with an index of refraction change can be a beamsplitter. In vision we generally use either a cube or a plate beamsplitter. By locating the beamsplitter in a collimated portion of the optical system (Fig. 3), but away from a retinal conjugate plane, two channels can be combined. For channels with different spectral compositions the beamsplitter can be dichroic, reflecting some wavelengths and transmitting others, usually by interference effects. Plate beamsplitters have the disadvantage

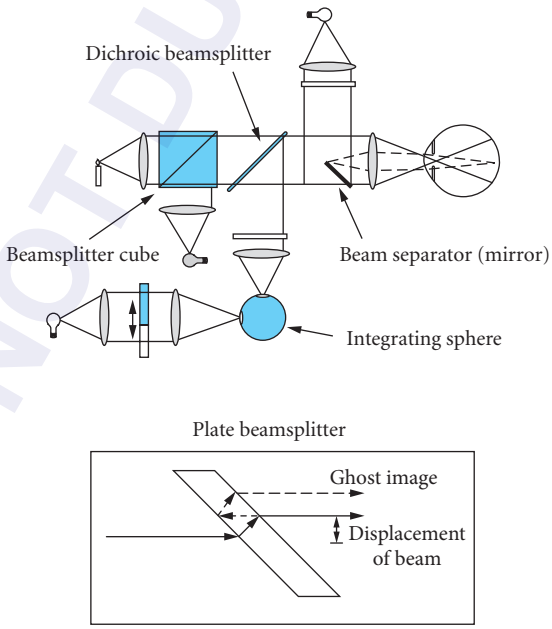

FIGURE 3 Techniques for combining light from different light sources or optical paths. The inset illustrates potential problems that need to be considered when using a plate style of beamsplitter. These problems are eliminated by the use of a cube beamsplitter or wedge beamsplitter.

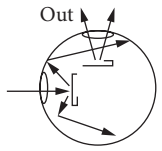
that there are secondary reflections, slightly displaced (inset, Fig. 3) from the main beam. In an image-carrying beam this produces "ghost" images, slightly displaced from the main image. The displacement decreases with decreasing thickness. A pellicle is simply a plate beamsplitter with negligible thickness. A wedge beamsplitter displaces a ghost image a long way, and Liebman has used this to design a tapered beamsplitter with no secondary reflections.[12] Unlike plate beamsplitters, the beamsplitter cube has the advantage that there is no lateral displacement of an image.

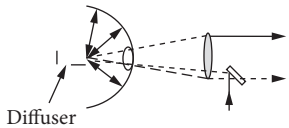
Beam Separators (or Reflective Apertures) A beam separator combines two optical channels into one, while keeping the light spatially distinct. For instance, a mirror placed halfway across the aperture at 45 deg combines two channels at 90 deg to each other. Such a separator in a retinal conjugate plane is imaged at the retina to produce a bipartite field (Fig. 3). The mirror must be oriented to hide the bevel from the subject and must have a high-quality edge. A transparent plate evenly silvered in a pattern and optically sandwiched between right angle prisms is a convenient beam separator with good edges.

Diffusers, Integrating Spheres, and Optical Fibers Diffusers also mix light. Diffusers are used when either the spatial uniformity of the final beam or thorough spatial mixing of light sources is important. The direction of light remitted from the diffuser is independent of the incident light, which simplifies the combination of sources. Both integrating spheres and integrating bars have been used to combine lights (Fig. 4*a* and *b*, respectively). Diffusers have been widely used in the construction of colorimeters.[2] In the La Jolla colorimeter[13] light is passed through a filter assembly with three monochromatic filters assembled edge to edge. Moving the filter assembly across the light path changes the relative proportions of the light impinging on each filter, which changes the average color of the light. An integrating sphere then completely mixes the colors producing a variable chromaticity light source without the spatial inhomogeneity of the filters. The major disadvantages of using diffusers are light loss, the need for careful optical baffling (since any light impinging on the diffuser gets mixed into the system) and the gradual deterioration of the diffuser due to dirt and dust. While the light loss from an

(a) Integrating bar



(b) Integrating sphere



(c) A reflective concentrator

FIGURE 4 An example of different types of beam combiners based on diffusers. In general it is critical that high-efficiency diffusing materials be used in all of these techniques.

integrating sphere is ideally very low, slight decreases in the efficiency of the diffusing surfaces cause large losses in the output. Collection of light from a simple diffuser can be increased by the use of a spherical mirror[14] (Fig. 4c). Similarly, a noncoherent fiber-optic bundle can be used to mix lights.

Mixing coherent light sources with diffusers requires movement to minimize interference (speckle) effects. Either liquid diffusers[15] which work by Brownian motion or moving diffusers[16] can be used.

Lenses

Lens orientation affects any optical system. For instance, the most curved surface of a lens should be toward the more collimated light. This makes both sides of the lens share the work of refraction and decreases aberrations. Achromats reduce both spherical and chromatic aberrations (they have three or more refracting surfaces) and are typically designed to form a collimated beam.

Typically, the goal in aligning an optical system is to place all lenses upon a common optical axis, oriented such that a ray of light traversing that axis is not deviated. A simple prescription is

1. Define the system axis using pinholes, pointers, or a laser beam, with all lenses removed. In a multichannel optical system it is often easiest to start from the position of the eye's pupil (P_0).
2. Introduce mirrors, beamsplitters, and other nonrefractive optics in their proper positions, being careful to keep the beam at the same height. A technique for ensuring a constant height, such as a movable pinhole, also helps.
3. Starting at the alignment source, set each lens, one at a time, such that its Boys points lie on the system axis. The Boys points are the focused reflections from the various curved surfaces of lenses (see Ref. 17 for a detailed discussion of using Boys points for alignment). When using a laser they are the "bull's eye" interference patterns. Lateral translation of the lens moves the first (brightest) Boys point and rotation moves the second, so convergence is rapid.
4. To determine the position of a lens along the optical axis, a photographic loop (a magnifying lens) and a target grid (graph paper) can be used. By placing the graph paper at a known location such as at the exit pupil, and then looking with the photographic loop into the system (turn off the laser first!) the exact position of the next pupil conjugate point can be determined. To position a lens to collimate light from a source, place a mirror in the collimated beam, reflecting the light back into the lens. When the lens is placed at one focal length from the source, the mirror causes the source to be imaged back onto itself (autocollimation).

Field Quality

The uniformity of the illumination of the retinal image is controlled by the size and emission characteristics of the source and by the uniformity of illumination of the target. Ideally, a source emits uniformly into all angles subtended by the collection lens (lens L_2 in Fig. 2). LEDs do not meet this requirement and produce inhomogeneous illumination unless the light is further diffused. Tungsten-halogen sources with coiled-coil filaments uniformly illuminate the collecting lens and can produce uniform retinal images. Problems arise if a retinal conjugate is placed too close to a pupil conjugate plane. This occurs most often when the target is placed at the end of a long collimated portion of the optical path. In this case, the structure of the source becomes visible at the retinal plane. In general, collimation lengths should be kept to less than roughly twice the focal length of the collimating lens. It is also important to control the pupillary conjugate points; in some cases multiple pupil conjugate apertures can help.[18]

Controlling Wavelength

Spectral composition of a light source can be varied either by absorbing the unwanted light (in a filter), or by redirecting it (by either interference of refraction). Table 1 presents techniques for controlling wavelength. Interference filters can have blocking filters that absorb wavelengths outside the specified transmission band. However, a blocking of 10^{-3} may not be sufficient for the human visual

TABLE 1 Controlling Wavelength

Technique	Properties	Advantages	Disadvantages/Comments
Absorption filters: aka dye, film, gel, or pigment filters	Available in both gels and glass forms. Generally broadband.	Can be extremely stable over time. Wide range of colors available. Reasonably priced.	Broadband, can be damaged by too much light, as encountered with lasers and focused beams. Most fluoresce.
Narrowband interference	Half-width about 10 nm, usually bonded to an absorption filter for blocking distant wavelengths.	Convenient, readily available, and moderately priced.	If not fully sealed, humidity can cause long-term degradation. Wavelength depends on angle of incidence. Need good blockers.
Broadband interference (see also dichroic beam splitters)	Half-width 40–100 nm.	Same as narrowband interference filters, less need for blocking filters.	
Grating monochromators	Tunable, bandwidth can be set by slits.	Can have low stray light.	Must match aperture of system to the interior grating to minimize stray light. Expensive.
Prism monochromators	Produces a spectrum by refraction.	High throughput.	Bulky.
Interference wedges (spatially varying interference filters)	Allow continuous change of wavelength by changing the position of light incidence.	Small, easy to use.	Some have more leakage than a monochromator, may not be adequately blocked for higher-order transmission. Must be placed at a pupil conjugate point to avoid chromatic wedging on the retina.
Special sources (Na, Cd, etc.)	Discharge sources that produce a few exactly specified spectral lines.	Many lines are available. Very pure wavelengths. Larger aperture sources are available.	Mostly replaced by lasers which are stable, cheap, and easier to use but are point sources (see Table 5).

system. For instance, a narrow 670-nm filter may transmit only 10^{-3} of the intensity at 555 nm, but the human visual system is about 30 times as sensitive to 555 nm as to 670 nm and can integrate over the entire visible spectrum. Thus, the visual effectiveness of the "blocked" light can be considerable. Monochromatic and narrowband light sources and lasers can also be used both to provide a specific wavelength and to calibrate the wavelength scale of monochromators.

Wavelength selection filters are best placed in a collimated beam to avoid changing the passband to shorter wavelengths. This shift is asymmetric, and the maximum transmission changes as the angle of incidence decreases from 90 deg.[2] Differently colored lights can be combined using broadband interference filters (dichroic filters) placed at an angle, but using narrowband filters designed for normal incidence at 45 deg can introduce unwanted polarization properties.[2] Filters designed for use at 45 deg are readily available.

Turning the Field On and Off

Light from an optical channel can be clocked entirely by a shutter. Shutters should generally be located at a pupil conjugate plane. At this position the source is focused to a small area and thus a smaller, faster shutter can be used. In addition, manipulation of a pupil plane changes the retinal image uniformly (see above). Parameters of interest are the speed, repetition rate (and duty cycle), and the transmission of the shutter in both its open and closed states. Table 2 summarizes details on common types of shutters. Shutters that work by means of polarization generally need to be placed in a collimated beam, and their extinction (transmission when off) and maximum transmission are wavelength-dependent.

Controlling Intensity

The visual system operates over about 11 log units of luminance (11 orders of magnitude, or 10^{11}), and within this range can make discriminations of 0.1 percent or better. This level of visual capability requires a two-stage control of retinal illuminance. The overall retinal illuminance is set by

TABLE 2 Types of Shutters

Shutter	Speed	Size of Aperture (mm)	T off/T on	Comments
Mechanical shutter	ms	1 mm and up	0	Larger apertures are slower. Most designs cannot run in a continuous mode, but these are ideal for low duty-cycle use.
Galvanometers	ms	A few mm for high speeds	0	Operating at high rates requires fairly careful driver design but they can be used to excellent effect and are commercially available with drivers. Can be run continuously.
Choppers	kHz	Variable	0	For continuous on-off flicker choppers are ideal. They have no attenuation when open and no transmission when closed. Small, feedback-controlled devices are available off the shelf. Stepper motors with vanes mounted on the shaft can also be used.
Acousto-optic modulator (AOM)	μs	<2 mm	~10^{-3}	AOMs have small aperture and high *f*-number and thus work best for lasers. They are inherently chromatic and orientation-sensitive. Polarization effects can be important.
LCD shutters	ms	A few cm	~10^{-2}	Speeds are increasing rapidly, works by polarization. Maximum transmission is less than 50 percent. Use in collimated beam.
LCD displays	μs	Work as video screens; individual pixels can be μm.	~10^{-2}	Work by polarization. Speed is increasing with development of displays for computer use.
Kerr cells	ps	cm	~10^{-2}	Require high voltages, work by polarization.

discrete neutral density filters, while smaller steps are set by either a variable density filter or an electronic system. Due to limited precision in most measuring instruments, it is hard to calibrate an individual filter with a density greater than 3.0.

Varying the Intensity of the Field The intensity of a channel can be varied by using fixed or variable filters, or by controlling the radiance of the source. For simple, relatively slow (1/min) changes in retinal illuminance, neutral density filters are appropriate. For faster changes, modulators or direct variation of the source radiance are typically required.

Filters Neutral density filters either have a uniform attenuation across their spatial extent (fixed filters) or vary in their attenuation characteristics depending on the spatial location (variable filters or "wedges"). Absorbing filters should be used in a collimated beam to avoid different path lengths through the filter. Wedges are used at a pupil conjugate plane to avoid imaging the density gradient on the retina. Fixed filters are typically used to set fixed parameters (such as the average luminance), variable filters to control the brightness continuously (for instance, in an increment threshold test). Table 3 presents some types of neutral density filters.

Modulators Passing linearly polarized light through a rotating polarizer produces sinusoidal modulation of the transmitted light. Careful optical design allows generation of an excellent variable modulation, flicker stimulus.[19,20] Acousto-optic modulators (AOM) can be used to vary a light rapidly, but have only a small aperture. Mechanical methods have also been used for temporally modulating a target.[21–23] For the most part, mechanical modulators and moving polarizers have been replaced by direct control of light sources by high-speed shutters and by video systems (see Chap. 22 in this volume of the *Handbook*).

TABLE 3 Neutral Density Filters

Method	Advantages	Disadvantages	Other Comments
Metal film neutral density filters	Readily available, stable, spectral neutrality is good.	Must be cleaned with care, pinholes can cause a problem. Interreflections between filters can cause deviations from density obtained when calibrated alone.	Silver and inconel are most common. Tilt to keep reflections out of the system.
Multilayer dielectric filters	Easier to clean.	Expensive, chromatic.	
Metal film "wedges"	Same as metal film filters.	Same as metal film filters.	Tilt to aim reflections out of the system. Use in a pupil conjugate plane to avoid spatial variation of image.
Absorbing gel filters	Less expensive, easily available at good photography stores.	They become brittle with age. Somewhat chromatic. Damaged by intense light.	Keep dry and away from a hot lamp. Use in a collimated light path.
Sector disk and mechanical devices (cams, variable slits, etc.)	Spectrally flat.	Must be used in a pupil plane to get desired results.	Use in a pupil conjugate (or in a uniform beam before an integrating sphere). Variable slits can be a simple, inexpensive way to control intensity.
Photographic film or film wedges	Cheap, easily made by flashing a film and developing.	Spectral neutrality will be poor in relation to commercial filters. Must be calibrated. Stability over time will depend on the film base used.	Best used with monochromatic light.

Varying the Source Varying the radiance of the light source is fast, and is particularly straightforward with electro-optical sources such as LEDs and diode lasers. However, control of the source is not limited to these devices and can be used with thermal sources (incandescent bulbs), xenon arcs, and fluorescent lights as well. There are four major problems to be overcome when directly varying a light source: (1) nonlinear current versus radiance characteristics, (2) changes in the current-radiance relation over time, (3) temporal hysteresis in the current-radiance relation, and (4) changes in the wavelength distribution of the source with changes in current.

For instance, LEDs have been considered ideal light sources by some investigators, yet they show the same deviations from ideal behavior common to other sources[24–29] (see Chap. 15, "Artificial Sources," by Anthony LaRocca, Chap. 17, "Light-Emitting Diodes," by Roland H. Haity, M. George Craford, and Robert M. Weissman, and Chap. 18, "High-Brightness Visible LEDs," by Winston V. Schoenfeld in Vol. II). The current/radiance relation of LEDs depends on the internal temperature of the device. Thus, the relation changes with both the measurable *temperature* (due to both the environment and to the time average current) and with the immediate current history (for instance, it was just driven at a high current). Finally, the temperature also affects the probability of electronic transitions in the semiconductor, which can change the *wavelength* emitted. For LEDs used in visual work this wavelength dependence has been measured to be on the order of a 1.6-nm change in dominant wavelength with variation of the duty cycle for an ultrabright red LED.[26] Thermal sources, such as a tungsten-halogen bulb, undergo especially large changes in spectral output with changes in current. With these sources, only a narrow spectral band should be used if the source is controlled. In addition, the thermal inertia of an incandescent source precludes rapid modulation, although slow modulation (~1 Hz) can be achieved. Even fluorescent sources which have been widely used in some areas of research show significant changes in spectral output with time.[30]

While heat sinks can help to stabilize the response characteristics of many devices, linear control still requires careful driver design. Drivers can use either an analog or binary design. Analog drivers control the source radiance by varying the current, while digital drivers turn the source either on or off, with the average radiance set by the proportion of time that the source is on (the duty cycle). An advantage of the binary scheme is that transistors dissipate less power in the on and off states than in intermediate states.

There are four major approaches to linearization:

1. Calibrate the current-luminance relation and build a driver with the inverse nonlinearity. For simple applications this technique is adequate. However, for demanding applications the driver becomes complex and the demands for stability in the driver raise new problems.
2. Calibrate the current-luminance relation and use an inverse nonlinearity in computer memory (a lookup table). This technique is quick and easy to implement. A static lookup table will not compensate for dynamic nonlinearities (hysteresis) but a variation of this approach, known as *delta modulation*, will. With delta modulation a linear detector is used to precalibrate the output of a binary driver to produce the desired waveform. By later playing back the binary sequence, the waveform can be re-created exactly. Thus, delta modulation can be used to compensate for all source nonlinearities except for changes in wavelength. The disadvantage is that the waveform must be precalibrated.
3. Vary the ratio of the on and off time periods (the duty cycle) of the source using a binary driver. With a fixed cycle time, the on time can be varied (pulse-width modulation or PWM). PWM works fairly well, but is sensitive to capacitance and nonlinear switching effects that can alter the waveform for either short on or off periods. A similar approach is to use fixed (short) pulses and vary the frequency of the pulses (pulse-frequency modulation or PFM). This approach has the advantage that every pulse is identical, thus capacitance and switching effects are minimized. PFM has been used to control the luminance of LEDs[27] and AOMs[16] linearly over a 1000:1 luminance range.
4. Detect the light with a linear photodetector and use feedback within the driver to linearize the output. By using a PIN photodiode in photovoltaic mode (see Chap. 24, "Photodectors," by Paul R. Norton in Vol. II), it is possible to construct a very linear circuit.[28,31] Light feedback can be used with either analog or binary drivers.

Generating Complex Temporal and Spatial Patterns

Any type of light source or visual stimulus, from video monitors to street scenes, can be integrated into an optical system, giving improved control of luminance and pupil position. Thus, almost anything can be used as a target. Stimuli can be moved without varying the position of light entry in the eye's pupil by (1) translating a target in the retinal plane, (2) using a cathode ray tube (CRT) or a liquid crystal display (LCD) in a retinal conjugate plane, or (3) rotating a mirror in a pupil conjugate plane.[22]

Rotating a mirror in a pupil conjugate plane changes the angle at which light enters the eye, but not the pupil entry position. This technique has been used for generating motion and counterphase gratings[21] and for decreasing the apparent inhomogeneity of a stimulus by moving the image at a rate above flicker fusion. Galvanometers are commonly used to generate the motion (Fig. 5).

Video Monitors and CRTs The combination of a video display with a maxwellian view optical system allows the experimenter the advantages of precise control of the pupil, use of a broad spectral range of backgrounds (provided by the traditional optics), and the fine spatial control available in a video system. The video monitor or CRT is placed at a retinal conjugate plane and the other optical channels are added to it. By passing the combined light path through an aperture at a pupil conjugate plane it is possible to control the pupil size for the video system, insert achromatizing lenses, and the like (see Fig. 8 later in the chapter).

Liquid Crystal Displays One type of video display that is of increasing utility is the liquid crystal display (LCD) (Chap. 22). LCDs, unlike video monitors, work by transmission or reflection; they are not self-luminous. Thus, while the wavelength composition of a monitor is determined by the characteristics of its phosphors, the LCD can be used with *any* light source. LCD displays work by changing the polarization state of local regions of the display (pixels). The pattern of pixels is controlled by a video signal or a computer. Like most polarization devices, the extinction ratio is wavelength-dependent and the proportion of light transmitted in the off state may be relatively high. With color versions of the newer active matrix LCDs it is possible to pass three wavelengths of monochromatic light through the color LCD and have a spatially controlled, high-intensity display with the maximum possible gamut. In this case the LCD is placed at a retinal conjugate plane.

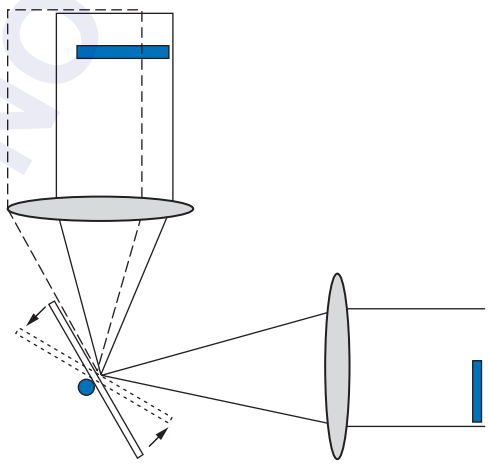


FIGURE 5 A movable mirror located in a pupil conjugate plane allows motion of the retinal image without moving the pupil conjugate images.

Calibration

There are several approaches to calibrating the retinal illuminance of a maxwellian view system. All depend on either a standard source of known luminance (a reference source) or a calibrated, linear[31,32] photodetector. In the past, calibration typically depended on referring the illuminance of an optical system to a carefully maintained standard light or by measuring the luminance of a diffuser. Well-calibrated photometers and radiometers are now readily available, and we will cover techniques based on using these (the reader is referred to Westheimer[3] for other approaches). We assume that all of the light arriving at the exit pupil of the instrument enters the eye and that the exit pupil can be adequately approximated as circular with a radius of r.

Measurement of Power at Exit Pupil With the first technique (Fig. 6*a*) a calibrated detector is placed at the exit pupil of the maxwellian view device. First, the total luminous power at the exit pupil is measured. Next, the retinal area illuminated is computed from the geometry of the stimulus [Eq. (12)]. From these two quantities the retinal illuminance can be computed. This calculation specifically assumes that all of the power is uniformly distributed across the retinal image. Conversion of retinal illuminance from lm/m^2 to trolands is achieved using Eq. (6).

Measurement of the Illuminance on a Detector In this technique the illuminance falling on a detector at a fixed distance from the exit pupil is measured (Fig. 6*b*; also see Ref. 33). A circular source of luminance L and radius r produces an illuminance E on a detector at distance d^2. If we assume that the source dimensions affect the calibration negligibly ($r < d/10$; $r < f_e/10$), then

$$E = \frac{L\pi r^2}{(d^2)} \tag{18}$$

We want to relate E as measured by the detector to E_R, the retinal illuminance, which is

$$E_R = \frac{L\pi r^2}{(f_e)^2} \tag{19}$$

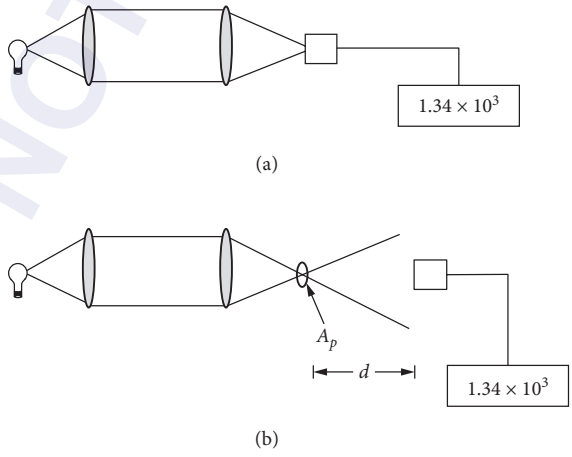

FIGURE 6 Techniques for calibrating an optical system. (*a*) Measure the luminous power of the exit pupil and assume that it is uniformly distributed in the retinal image. (*b*) Measure the illuminance produced by an exit pupil of radius r at a detector located at distance d from the exit pupil.

Combining Eqs. (18) and (19) we have

$$E_R = \frac{(d)^2}{(f_e)^2} E \tag{20}$$

If the radius of the exit pupil (r_p) cannot be ignored then we need to account for its properties as a light source. If the exit pupil is circular and can be approximated as a lambertian emitter, then the illumination on the detector [Eq. (18)] is

$$E = \frac{L\pi r^2}{(r_p^2 + d^2)} \tag{21}$$

(Ref. 2, Chap. 56, Table I(4.4)). Likewise, the retinal illuminance [Eq. (20)] is

$$E_R = \frac{(r_p^2 + d^2)}{(r_p^2 + (f_e)^2)} E \tag{22}$$

The troland value of E_R can be computed from Eq. (16).

5.7 LIGHT EXPOSURE AND OCULAR SAFETY

There are two main mechanisms by which light can damage the eye. The first is simply by heating: too much radiation burns the retina. The second mechanism is photochemical. Light, especially short-wavelength light, causes photochemical oxidation. The by-products of this oxidation are toxic to the retina (see Chap. 7).

Figure 7 shows the relation of the danger thresholds as defined by the ANSI 136 standard,[34] expressed in tds and lumens/m^2, for a 440-, a 550-, and a 670-nm light. These thresholds are for field sizes greater than 1 deg. The damage threshold for visible light is quite high, and thus lights capable of producing damage are intensely unpleasant. However, care should be taken to exclude IR and UV light. Most

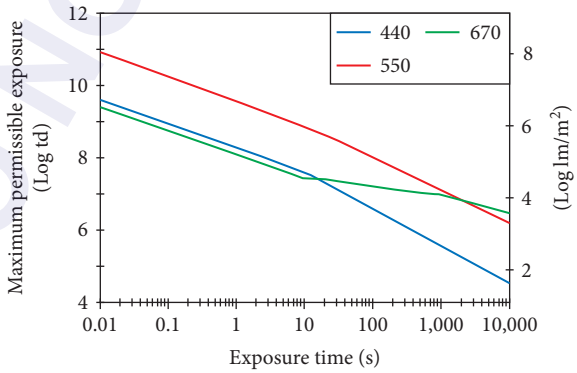

FIGURE 7 The maximum permissible retinal illuminance at different exposure times for 440 nm (blue line), 550 nm (red line), and 670 nm (green line) lights and extended fields according to the ANSI standards.

light sources emit considerable radiant energy in the infrared, and sources such as xenon arcs can emit ultraviolet radiation. Failures of blocking filters in these spectral regions may be visually undetectable. For safety it is advisable to have separate blocking filters to exclude unwanted radiation. It should also be noted that when using coherent light sources speckle can cause large focal variations in the retinal illuminance and the safety limits should be lowered by a factor of between 10 and 100 times.[35] Point sources and lasers have different safety standards that take into account the motion of the eye.

5.8 LIGHT SOURCES

Common light sources are presented in Table 4 and lasers are presented in Table 5 and in Chap. 15. Wyszecki and Stiles[2] present detailed discussions of light sources. The considerations for deciding on a light source are stability and uniformity of the luminous area, intrinsic luminosity of the source, and the spectral distribution of light from the source. Light sources of various types are discussed in Chaps. 15 to 23 in Vol. II.

5.9 COHERENT RADIATION

Coherent light sources can be used for generation of interference fringes,[36] a common use of lasers in vision research.[8–10] Light from the laser is directed into two similar channels. The light from the two channels arrives at the pupil of the eye separated by some distance *d*. Light spreading from the two beams then overlaps on the retina and creates an interference pattern in the intersection zone. The spacing of the interference pattern is controlled by the angle at which the beams intersect at the retina. The orientation of the pattern is controlled by the relative orientation of the two pupils. However, HeNe and easily controlled solid-state visible lasers are also excellent general-purpose light sources. The major drawback to their use is speckle.

Generation of Speckle Fields

Speckle arises when coherent light is reflected from an optically rough surface. The surface roughness causes variations in the path length between the retina and adjacent areas on the surface. This variation causes phase differences from point to point in the retinal image. The spatial frequency of

TABLE 4 Common Light Sources

Type	Properties	Comments
Tungsten	Broadband, thermal emitter.	Available in a number of filament and power choices, hotter bulbs are short-lived.
Tungsten-halogen	Broadband, thermal emitter.	Inclusion of halogen regeneration cycle allows tungsten-halogen to run hotter (more blue light and a higher luminance) at a longer rated life than tungsten. If running at below the rated wattage the bulbs can be inverted to extend the lifetime.
Xenon arcs	Nearly flat spectrum, high luminance, some emission lines are present.	UV light can create ozone which must be vented. Tendency for the arc to move relative to the electrodes, causing movement of the exit pupil in maxwellian view systems. Luminous area is fairly small.
Fluorescent tube	Broad spectral output with superimposed emission lines. Easily obtainable, efficient.	Can be modulated rapidly. But there may be problems with compound phosphors (see Ref. 28).
Light-emitting diodes (LEDs)	Small, cheap, efficient light sources. Easily controlled.	Can be modulated rapidly, come in a variety of wavelength and power ranges (see Chap. 13).

TABLE 5 Types of Lasers

Type	Most Common Visible Wavelengths	Comments	Typical Power	Typical Noise %
Argon	514, 488, (other lines are available, depending upon the design).	Power of each wavelength varies with particular laser design and cost. Most common wavelengths are 514 nm and 488 nm.	5 mW–5 W	1
HeCd	444 nm	Fairly expensive, have some high-frequency noise (>300 kHz) that may be important in scanning or short exposure applications.	0.5–50 mW	3
HeNe	543, 594, 632.8, also have orange lines.	Most common and least expensive gas laser. The 632.8-nm designs are easily available, inexpensive, and long-lived. Other wavelengths have many of the same advantages but power and beam options are limited and cost is higher.	0.1–20 mW	0.5
Krypton	588, 677.	Expensive, tend to be unstable, large.	50 mW–5 W	3
Dye lasers	Variable.	Expensive, need to be pumped by another laser. Require costly and toxic dyes to operate, not particularly stable.	50 mW–5 W	Depends on pump laser.
Slab diode lasers	~630 nm, ~670 nm, ~690 nm, some in blue.	Development is very rapid with new wavelengths and power options. The beam geometry is not ideal but they have great potential as light sources. Can be easily controlled using standard electronic techniques as are common with LEDs. Have high impedance and are easily damaged by static electricity. Rapid developments at shorter wavelengths.	0.2–100 mW	1 percent or better if temperature stabilized.
VCSELS vertical cavity lasers (microlasers)	Infrared.	These are under rapid development. They are solid-state lasers but have superior efficiency and beam properties as compared to slab lasers. Low impedance.	1 mW	
Frequency doubled YAG	532 nm.	Readily available, solid-state designs. Expensive.	5–50 mW	<1 percent.
Tunable solid-state and solid dye lasers	Variable, pumped by lasers.	An area of rapid development. By using materials that fluoresce, and tuning the laser cavity, the output wavelength can be varied while maintaining excellent beam qualities.	mW–W	Depends on pump laser.

speckle depends on pupil size, since the size of those adjacent areas is smaller for bigger pupils. Thus, for a very small pupil, speckles will be large. Speckle has been used to develop optometers,[37–39] and to generate a pattern on the retina in the presence of poor optic media.[40,41] However, when using lasers as general-purpose light sources, speckle needs to be minimized or eliminated. There are three ways to despeckle a source: *spatial filtering, temporal despeckling,* and *raster scanning*.

In spatial filtering[10] the light remains spatially coherent. A light source is imaged onto a pinhole which diffracts the light so that a spherical wave emerges from the pinhole. A lens is then used to collimate the light, resulting in a plane wave. Filtering should be restricted to those experiments that require the use of coherent light. The introduction of dust or even structure in the anterior segment of the eye can introduce undesirable diffraction effects.

Temporal despeckling[14,15] uses the temporal integration of the visual system to blur the speckle field. Since speckle arises as a result of surface irregularities at a very small scale, a small amount of motion can decrease speckle contrast considerably.

Scanning moves a diffraction-limited spot of light across the retina to create a visual pattern. Typically, the pattern is a raster pattern, like that of a television, and the stimulus is generated by temporal variation in the intensity of the beam.[42–44] Since at any one time only a single, diffraction-limited, retinal region is illuminated, then there is no opportunity for speckle.

5.10 DETECTORS

Detectors are used for measuring the light produced by an optical system. They can generally be characterized by their quantum sensitivity, their spectral response curve, and the temporal amplitude spectrum of their noise (see Ref. 45 and Chap. 24, "Photodetectors," by Paul R. Norton and Chap. 27, "Signal Detection and Analysis," by John R. Willison in Vol. II). For most purposes detectors can be treated as detecting all light power incident upon their active area, but there are limitations that make it advisable to use them for normally incident light whenever possible.[46] Table 6 presents the most common detectors (also see Chaps. 24 to 28 in Vol. II). At low light levels photomultiplier tubes (PMT)[47] or an avalanche photodiodes (APD)[48] can be used in a photon-counting mode (Chap. 26, "High-Speed Photodetectors," by John E. Bowers and Yih G. Wey in Vol. II).

5.11 PUTTING IT TOGETHER

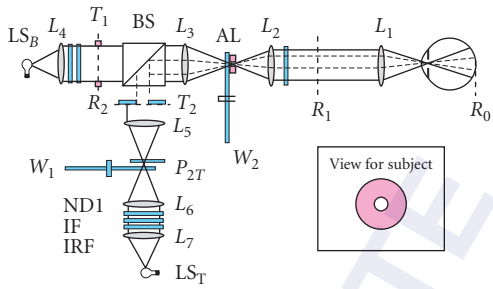
This section briefly describes construction of more complex maxwellian view systems. The goal is simply to help the researcher get started building an optical device by presenting real examples.

A Two-Channel Maxwellian View Apparatus

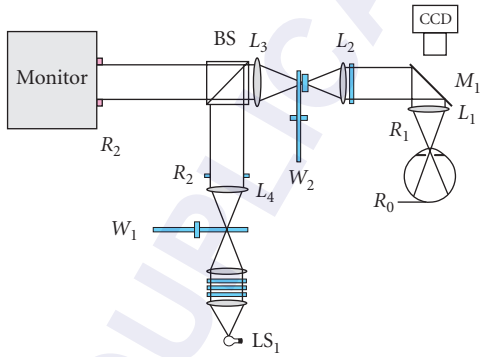
We first consider a simple two-channel maxwellian view device (Fig. 8*a*) for measuring the detectability of a small circular target on a large circular background. The background is provided via the straight optical channel. It has a light source LS_B followed by a lens L_4 that collimates the light from the source. A field stop (target T_1) controls the size of the background field. Adjacent to the target is a beamsplitter, followed by another lens L_3. L_3 creates a source image where we place a 2.0-log-unit circular neutral density wedge, a 2-mm (diameter) stop (artificial pupil) and an achromatizing lens AL. An achromatizing lens minimizes the effects of the chromatic aberrations of the eye.[49–51] The artificial pupil will be imaged at 1:1 in the pupil of the eye, thus providing a limiting pupil. Lenses L_2 and L_1 relay the artificial pupil to the pupil of the eye. The test channel is derived from the second light source LS_T. Light is collimated by L_7, passed through a heat-rejecting filter IRF, interference filter IF_1, and a neutral density filter ND_1. An image of LS_T is then formed at P_{2T} by L_6. In this plane we set an electromechanical shutter and a neutral density wedge. We then collimate

TABLE 6 Detectors

Detector	Sensitivity	Speed	Problems/Limitations
Photomultipliers	Best in the blue, extended multialkali cathodes extend sensitivity into the red and near IR. Many designs have very low noise.	Fast, MHz, capable of photon counting.	Low sensitivity in the red and infrared, can be damaged by high light levels, though recovery can be aided by leaving in the dark for a long time (months). Fragile. Require high voltage (kV).
Avalanche photodiodes	Have the silicon sensitivity curve, peaking in the near IR. Higher quantum efficiency than PMTs.	Fast MHz, capable of photon counting, better quantum efficiency than a PMT, but higher noise level.	Noise increases rapidly at avalanche voltage, light can affect the breakdown point. Higher noise level than PMTs, but the higher quantum sensitivity makes them better for video rate imaging. Small sensitive area.
CCDs, CIDs	Very linear, easy to use, sensitivity peaks in the near IR. These have a high quantum efficiency.	Variable, depending upon implementation, integrate between readings (kHz).	Blooming and charge spread can affect spatial properties at high radiances.[52] CID's are resistant to blooming.
PIN silicon photodiodes	Easy to use, sensitivity peaks in the near IR.	With care they can be operated at high rates (MHz); however, in most photometers the circuitry is specifically designed for low-noise, lower-frequency operation.	
Thermal (bolometers)	Measures energy, thus flat spectral responsivity.	Very slow <10 Hz.	The only real use for these devices in vision research is for calibration of the spectral sensitivity of another detector. In general, it is better to have the detector calibrated against an NIST standard by a manufacturer.
See also photoresistors, vacuum photodiodes, and phototransistors	Seldom used.		



(a) Two channel increment threshold apparatus



(b) Using a video display in a maxwellian view and monitoring eye position

FIGURE 8 (*a*) An example of a two-channel increment threshold maxwellian view device. Two light sources are used (LS$_B$ and LS$_T$) to form a background and a test channel respectively. The two channels are combined using a beamsplitter (BS). The intensity of the test field is controlled by a circular neutral density wedge W_1, and the intensity of both channels is controlled using wedge W_2. Additional details are provided in the text. (*b*) A similar apparatus, except now a video monitor is superimposed on a background derived from source LS$_1$. An infrared sensitive CCD camera is used to monitor the pupil through the back of a dichroic beamsplitter plate (M_1) which reflects visible light and transmits infrared light (cold mirror). Infrared illumination of the eye is provided by infrared LEDs (not shown).

the light with lens L_5, pass it through an aperture T_2 that creates the target, and combine it with the background light at the beamsplitter. In some cases it may be desirable to obtain both the test and background light from a single light source. This is readily achieved by the addition of mirrors and avoids the possibility that slight fluctuations in the sources might produce variability in the ratio of the target and background illuminances. When appropriate, use a single light source for multiple optical channels.

A similar optical design allows full spatial control of the stimulus by incorporating a video monitor (Fig. 8*b*) or an LCD (not shown). In general, the retinal image of the monitor will need to be minified. As shown, the size of the retinal image of the monitor is set by the ratio of the focal length of lenses L_1, L_2, and L_3 [Eq. (14)]. The main advantages of the hybrid system over free-viewing the monitor are the ability to control the pupil precisely, the ability to add spectrally pure backgrounds (and, if only low contrasts are needed, the background can be quite bright), and the ability to align an achromatizing lens precisely and to monitor the eye position. We show a simple monitoring system, where the eye is monitored by a CCD camera, through the back side of a "cold mirror" (M1). A cold mirror is a dichroic beamsplitter that reflects visible light and transmits infrared radiation. IR-emitting LEDS are used to illuminate the eye diffusely. Using the full aperture of the lens L_1 means that the depth of focus will be small, and the eye can be precisely positioned (or monitored) in three dimensions. The resolution of the camera can be relatively low.

To use an LCD in transmission mode rather than a video monitor we can simply introduce the display at the retinal conjugate plane (R_2) in Fig. 8*a*. Again, it will be desirable to decrease the magnification of the LCD on the retina by choosing L_3 to have a longer focal length than lenses L_1 and L_2.

An Interferometer

We next describe a research interferometer that was built using modern electro-optical components.[10] To study the spatial sampling of the photoreceptor matrix of the eye, this instrument needed to have the following properties: (1) generation of spatial patterns on the retina with a frequency content above that imaged by the optics of the eye, (2) rapid and precise control of the modulation (contrast) and frequency (spacing) of the spatial patterns, (3) minimization of speckle, and (4) control of the two entrance pupils of the interferometer to displace them symmetrically about the center of the eye's pupil. We outline below how these objectives were achieved. The researcher should refer to the original paper for a more detailed account.

Interference can be used to generate diffraction patterns on the surface of the retina. Two coherently related sources are imaged in the plane of the eye's pupil (Fig. 9*a*). The spacing of the resulting diffraction pattern depends on the separation of the two sources in the eye's pupil, and the orientation of the pattern depends on the relative position of the two sources. Williams[10] (see also Refs. 8 and 9 for other examples) constructed a modified Mach-Zender interferometer[52] (Fig. 9*b*) that satisfies the requirements outlined above.

Modulation of the interference pattern is controlled using AOMs. Each of the beams is either on or off, with a 50 percent duty cycle. If both beams are on at the same time (in phase), the interference pattern is seen at full contrast. If one is off when the other is on (counterphase), then there is no interference pattern. Intermediate phases of the two beams will cause intermediate contrasts of the interference pattern (Fig. 9*c*). Thus, both beams are always operated in the same state (avoiding luminance artifacts due to temporal nonlinearities), and all control of modulation is electronic. The use of an all-electronic design allows precise control of contrast without audible cues to the subject. Spatial masking from speckle is minimized by placing spatial filters in a pupil conjugate plane. The spacing of the interference pattern is controlled by a rotable cube. Each beam traverses the cube in opposite directions (Fig. 9*d*). As the cube is rotated the beams, and thus the images in the eye's pupil, are displaced symmetrically.

5.12 CONCLUSIONS

We have covered only some of the basics of stimulus generation. We urge the interested reader to look elsewhere in this *Handbook*. In addition, the following references are good general sources for this topic.

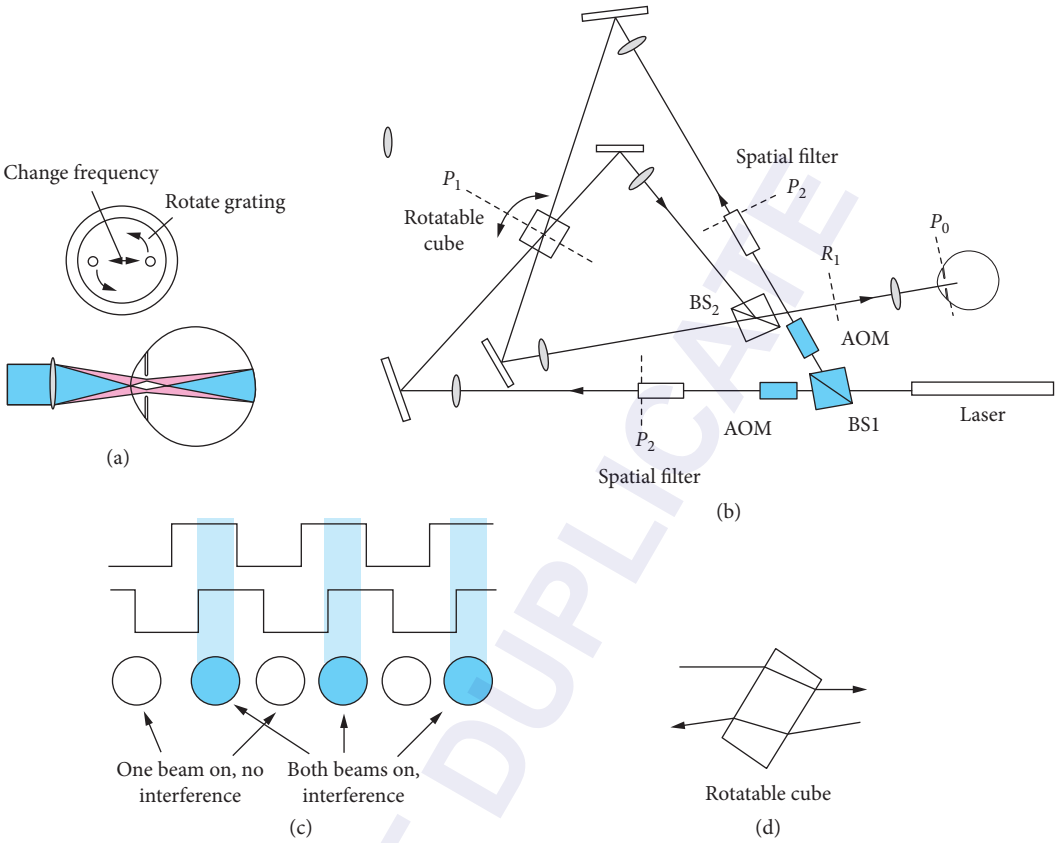

FIGURE 9 An example of a modern interferometer for vision research. (*Modified from Ref. 10.*) (*a*) Factors controlling the spacing and orientation of the interference pattern on the retina. Increasing the distance between the entry pupils decreases the spacing of the pattern (increases the spatial frequency in cycles per deg). It is also possible to change the orientation of the interference pattern by rotating the two entry pupil in the plane of the eye's pupil. (*b*) A schematic of William's interferometer. This is a modified Mach-Zender interferometer and includes acousto-optic modulators (AOM) to control the modulation of the interference pattern, spatial filters to reduce speckle, a rotatable cube to control spacing and beamsplitters to separate the two beams (BS1) and to recombine them (BS2). (*For additional details see Ref. 10.*) (*c*) Contrast of the interference pattern is controlled by electronically varying the phase of the signals from the two AOMs. Each AOM is square wave modulated. The interference pattern is produced only when both beams are on at the same time. Thus, varying the relative phase of the two beams varies the proportion of the time when both are on, and thus the contrast. (*d*) The spacing of the beams in the plane of the eye's pupil is varied by rotating a deviation plate. The two beams propagate through the glass plate in opposite directions. Thus, as the plate is rotated, the beams are displaced equal but opposite amounts, resulting in symmetric deviations of the beams about the center of the eye's pupil. The actual apparatus uses an anti-reflection coated cube.

THE MAXWELLIAN VIEW*† WITH AN ADDENDUM ON APODIZATION

Gerald Westheimer

Division of Neurobiology
University of California
Berkeley, California

Abstract—Optical questions arising in the so-called Maxwellian View method of illuminating the retina have been analyzed theoretically. Problems discussed in detail include those of photometry, of magnification, of focus, and finally of pupil size insofar as it relates to the transmission of spatial frequencies in coherent and incoherent illumination.

6.1 GLOSSARY

Diffraction theory. Formulation for calculating the distribution of electromagnetic energy when the propagation of radiation is restricted by apertures.

Emmetropia. Refractive state of eye in which the retina is conjugate to infinity. Its absence is called ametropia.

Fourier theory of optics. Object-image relationship in which the basic object structure is a sinusoidal grating and all other targets are described in their Fourier terms.

In the Fourier Theory of Optics, the complex amplitude of the electromagnetic vibrations in the plane of focus is the Fourier transform of that in the pupil plane.

Incoherent light sources. Sources for which light originating from different elements, when overlapping in forming the image, sums in intensity rather than by interference of the amplitudes of the electromagnetic vibrations.

Pupil of eye. Aperture stop, limiting the width of bundle of light entering the eye. The entrance pupil is the virtual aperture stop situated in the eye's object space; it can be directly measured and related to objects without further consideration of the eye's refracting apparatus.

Transfer function. Ratio of amplitudes of images to their generating objects for targets whose intensity changes sinusoidally, as a function of spatial frequency.

6.2 INTRODUCTION

In his experiments on color mixing, James Clerk Maxwell (1968) devised a way by which he could increase the quantity of monochromatic light reaching the retina of his eye. Using the sky as his source, he produced a spectrum by means of a prism and then isolated narrow regions of this spectrum with slits. He thus had monochromatic sources, but the special virtue of his approach is that he then imaged each slit on the pupil of his eye by a lens and saw the lens "uniformly illuminated with light." The procedure of imaging a light source in the eye's pupil, instead of looking at it directly, has since been applied widely and is now known as Maxwellian viewing. Its simplest form is illustrated schematically in Fig. 1, and compared there with ordinary viewing.

In the following discussion certain simplifying assumptions are used. (a) The eye is taken to be perfectly transparent; if the transmissivity of the ocular media is known, this can be multiplied into the final results. (b) The Stiles-Crawford effect is not taken into account. (c) No distinction is made between the plane of the eye's entrance pupil and its anterior principal plane—the error introduced is relatively unimportant here. (d) The eye is assumed to be accommodated for the object plane which is not necessarily at infinity. (e) Angles are regarded as small enough that the approximation $\cos\theta = 1$ is adequate.

In Fig. 1(a) and Fig. 1(b), the primary source of light is a small self-luminous patch of size $S(\mathrm{m}^2)$ and luminance $B(\mathrm{cd/m}^2)$; it is imaged directly on the retina in the case of Fig. 1(b), ordinary viewing, and it is imaged by a lens of aperture $L(\mathrm{m}^2)$ in the pupil of the eye, in the case of Maxwellian viewing, Fig. 1(a).

Concise discussions of the Maxwellian view can be found in Legrand (Vol. II) and in Walsh (1958). The present paper deals with several aspects of using the Maxwellian view in vision experiments.

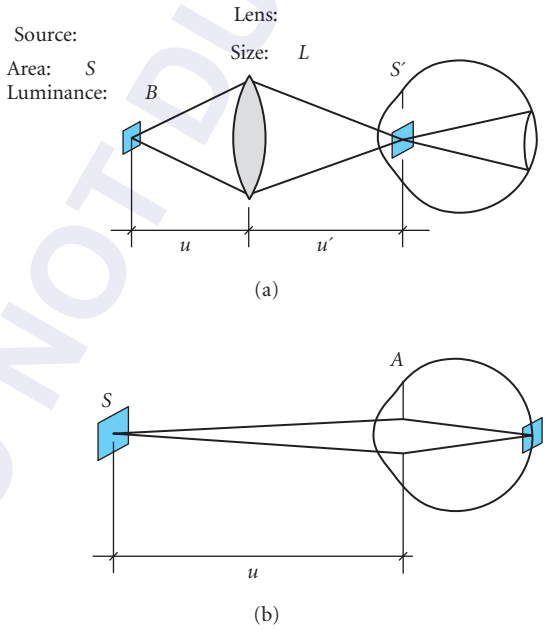

FIGURE 1 (a) Schematic diagram of the principles of Maxwellian viewing. A source of area S is imaged by a lens in the pupil of the eye. The image of the source has area $S' = Su'^2/u^2$. (b) Ordinary viewing of an extended source of area S placed at a distance from an eye whose entrance pupil has area A.

Retinal Illuminance

An immediate concern in any arrangement in which visual stimuli are presented, is the quantity of light reaching the subject's retina. The retinal illuminance should really be measured in terms of the luminous flux per unit area of retina. But there is the difficulty that, while we may be able to specify the light reaching the eye, additional assumptions are necessary to specify the retinal illuminance. The assumptions concern such things as the transmissivity of the ocular media and the size relationship between objects in front of the eye and their images on the retina. To obviate this, an approach is here adopted which retains, for as long as possible, all quantities in realistic units measurable in the eye's object space. For example, the size of the stimulated retinal area is expressed in terms of the object-sided visual angle, rather than square millimeters of retina. Knowledge of the dimension of the structures of the eye permits conversion of one set of units to others, but the advantage claimed for the present approach is that its validity is independent of the constants of a particular eye and it may be applied readily, therefore, to non-standard conditions, and to the eyes of other species.

Take the case of ordinary viewing first (Fig. 1*b*). A luminous surface [area $S(m^2)$, luminance $B(cd/m^2)$] is observed by an eye with an entrance pupil [area $A(m^2)$], directly facing the surface and at a distance $u(m)$ from it. The total luminous flux entering the eye is equal to the product of the flux emitted by the source per unit solid angle (BS) and the solid angle subtended by the eye's entrance pupil at the source (A/u^2). This flux ($B.S.A./u^2$) covers a retinal region represented in the eye's object space by the solid angle subtended by the source at the center of the entrance pupil (S/u^2). The measure of the retinal illuminance which retains all quantities in the eye's object space is luminous flux per unit solid visual angle and it is given by

$$E\,(\text{lm/sterad}) = B \cdot A \tag{1a}$$

where B is the source's luminance in cd/unit area and A is the eye's pupillary area. It is to be noted that the retinal illuminance is independent of the size of the source and the observation distance.

The most widely used unit of retinal illuminance, the troland, is defined by the condition in which a surface of luminance 1 cd/m^2 is observed by an eye with an entrance pupil area of 1 mm^2. A troland is thus equal to 10^{-6} lm/sterad visual angle. A steradian is not a convenient unit of solid visual angle. We are usually interested in much smaller areas, often of the order of magnitude of single retinal receptors. Thus, it may sometimes be better to give the luminous flux not in each steradian of visual angle, but in each square minute of arc of which there are $(60 \times 57.3)^2 = 11.8 \times 10^6$ per steradian. A useful unit in which to express the rate at which light is impinging on the eye then is luminous flux per square minute of arc visual angle for each square millimeter of entrance pupil area. When this pupillary area is A mm^2 and when the source has luminance $B cd/m^2$, we have

$$E\,(\text{trolands}) = B \cdot A \tag{1b}$$

or

$$E\,(\text{lm/sterad}) = 10^{-6} B \cdot A \tag{1c}$$

or

$$E\,(\text{lm/sq. min of arc}) = \frac{B \cdot A 10^{-6}}{11.8 \times 10^{-6}} = 0.85 \times 10^{-13} B \cdot A \tag{1d}$$

In the human eye, cones in the center of the fovea, and rods in an optimal region for scotopic vision (about 10° peripheral) are packed about 4 to a sq. min of arc, and thus the next kind of derived unit would be

$$E\,(\text{lm/receptor}) = 0.21 \times 10^{-13}\, B \cdot A \tag{1e}$$

Each scotopic lumen represents a flux of 1.46×10^{15} quanta (507 mμ) per second (Aguilar and Stiles, 1954) and hence we have yet another derived unit

$$E\,(\text{quanta (507)/receptor} \times \text{sec}) = 30\,B \cdot A \qquad (1f)$$

Note that in equations (1 b-f), B is the luminance of the extended source measured in cd/m^2, and A is the pupil area in square millimeters.

All the above units are still in the eye's object space, and before the number of quanta that are absorbed in each receptor per second can be computed, it is necessary to know the proportion of externally incident quanta that is transmitted by the ocular media, and the proportion of the latter that is absorbed by the visual pigment. Rushton (1956b) has given an estimate of 0.1 for these two factors combined for human rod vision.

Consider the case of Maxwellian viewing, i.e. in which the source is not imaged on the retina but in the eye's entrance pupil. We may distinguish two important categories, one in which the image of the source (area $S'' = S \cdot u'^2/u^2$) is larger than the pupil area (A) and the other in which it is smaller. In the former, it is A that limits the light entering the eye. The retinal area illuminated in each case is given, in steradians of visual angle, by (L/u'^2) where L is the area (m^2) of the clear aperture of the field lens, and u' is the distance between this lens and the eye. The total luminous flux reaching the image S'' is $B \cdot S \cdot L/u^2$. If the pupil area A is smaller than S'', the proportion of this total flux that can enter the eye is A/S'.

It is understood that when the pupil size remains constant, the retinal illuminance when viewing a Lambert surface is independent of observation distance. This is so because the angle subtended by an element of area increases when it is brought closer, but so does the angle the pupil subtends at the surface, and hence the fraction of the total radiation emitted by the source. The two effects exactly counterbalance each other.

A similar kind of invariance obtains when using an extended source in a Maxwellian view. So long as the image of the source is larger than the pupil, it is immaterial with what magnification the source is imaged in the pupil plane. The closer the source comes to the lens (i.e. the smaller u) the larger the flux per unit area there. Yet at the same time, for a portion of lens surface of given size to subtend a fixed angle at the eye, the distance between the lens and the eye has to be controlled and this in turn controls the lens power and the magnification of the image of the source in the pupil. The result is that the flux per unit angular size of lens surface per unit pupil area always remains constant, so long as all the available pupil area is occupied by the image of the source.

The actual flux entering the eye is either $S \cdot B \cdot L \cdot u^2$ for $S' < A$ and $S \cdot B \cdot L \cdot A/S'u^2$ for $S' > A$. In the latter case, i.e. when the source image is larger than the pupil, the flux is equal to $B \cdot L \cdot A/(u')^2$ which is spread over an angular area $L\,(u'^2)$: the flux incident per unit solid visual angle is, therefore,

$$E\,(\text{lm/sterad}) = B \cdot A$$

which is the same as that in the case of ordinary viewing.

The principal advantage of the Maxwellian view technique is here brought out; the retinal illuminance attainable is at most equal to that of ordinary viewing of the light source, but a larger area of the retina may be illuminated at that level. This is apparent in Fig. 1. When the pupil area is smaller than the image of the source at the pupil, the retinal illuminance, i.e. flux per unit retinal area, is the same in the two cases, only in the case of Maxwellian viewing the visual angle is equal to L/u'^2, while otherwise it is S/u^2.

When the image of the source is smaller than the pupil, the retinal illuminance will be smaller in proportion to the fraction of the pupil covered by the image of the source, i.e.

$$E\,(\text{lm/sterad}) = B \cdot A \qquad S'/A = B \cdot S' \qquad (2)$$

The determination of the retinal illuminance in an experimental arrangement employing Maxwellian viewing follows from the above consideration. When the effective entrance pupil of the eye (real or artificial) is completely covered by the image of the source, the retina is illuminated at the same flux/unit area as if the eye with that particular pupil were looking directly at the source—allowance having to be made for transmission losses in the optical system between the source and the eye.

When the image of the source is smaller than the pupil, an indirect method of determining the retinal illuminance may be employed, predicated by the fact that all the light coming towards the eye out of the Maxwellian view optical system enters the eye's pupil. The retinal illuminance in this case, by Eq. (2), is $B \cdot S'$ lm/sterad target area. Figure 1(*a*) shows how this retinal illuminance is in fact achieved by having the equivalent of a source emitting $B \cdot S'$ 1m/sterad, i.e. a source of $B \cdot S'$ candelas, imaged in the pupil. A good method* of measuring the resulting retinal illuminance is to find the number of candelas in the areal image of the source by measuring the luminance it produces when illuminating a perfectly diffusing surface placed at a given distance from it. One candela placed 1 m in front of a perfectly reflecting and diffusing surface gives it a luminance of 0.1 mL. When a small source placed at a distance x meters in front of a perfectly diffusing surface of reflectance r produces a luminance of $\bar{B}$ mL, the source has intensity 10 $\bar{B}x^2/r$ cd, and by equation (1*b*) such a source image in the plane of the pupil would give a retinal illuminance of 10 $\bar{B}x^2/r$ lm/sterad or 10^7 $\bar{B}x^2/r$ trolands.

The procedure for measuring the retinal illuminance in a Maxwellian view system where all the radiation passing through the instrument enters the pupil is:

1. Place a perfectly diffusing surface of reflectivity r at a distance x m beyond the source image that would ordinarily be in the plane of eye's pupil.
2. Measure the luminance of the surface with one of the standard instruments. Let it be $\bar{B}$ mL.
3. Calculate the retinal illuminance using the formula

$$\text{E (trolands)} = 10^7 \ \bar{B}x^2/r \tag{3}$$

Focus

Our discussion has so far concerned itself only with the retinal illuminance achievable with a Maxwellian view arrangement. Unless a uniform field of view is desired, a target is placed in the beam. In the typical experiment it is intended to stimulate the subject's retina in a certain way, for example, by illuminating certain areas and not others. The almost universally adopted way of creating a desired pattern of light stimulation on the retina, is to place in the object plane, conjugate to the retina, a target which is then imaged on the retina by the optics of the eye. (Rare exceptions to this approach may occur, for example, when setting up interference fringes on the retina, Westheimer, 1960.) In the arrangement of Fig. 1(*a*), a reasonable place for the target is just in front of or behind the lens L. Unfortunately, the resulting retinal image will only be clear when the eye is accommodated on L. This restriction is no longer necessary, however, if we re-arrange the optical system by splitting the lens L into two components, L_1 and L_2. In Fig. 1(*a*) it is seen that the function of L is to image the source in the pupil. Suppose this is done in two stages, first by using a lens, L_1, to produce a parallel beam of the light from the source, and then by having another lens, L_2, image this parallel beam in the pupil (Fig. 2). Because the beam in its passage between L_1 and L_2 is parallel, these two lenses may be separated by any desired distance without altering their effect of imaging the source in the pupil. But the target position can now be chosen so that the subject's accommodative state may be anything within a wide limit. For example, if the subject is emmetropic and is not to accommodate, the target would be placed at the first focal point of lens L_2, which then images it at infinity, and this is its situation relative to the subject's eye. If, on the other hand, the subject is 1 diopter myopic (or is emmetropic and is to accommodate 1 diopter) the target's place with respect to lens L_2 must be such that this lens images it at a distance of 1 m in front of the eye. Suppose the lens has focal length f_2. Let x be the distance of the object from the first focal point of lens L_2, and x' be the distance of the image from the second focal point of lens L_2 (which in our present arrangement is the eye's entrance pupil); then by Newton's lens formula we have the relationship

$$xx' = -f_2^2 \qquad \text{or} \qquad 1/x' = -x/f_2^2$$

*The author was introduced to this technique by W. A. H. Rushton, who had originally described in the literature (Rushton, 1956a) a related approach.

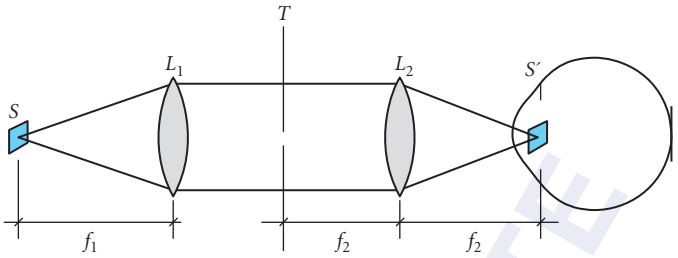

FIGURE 2 More versatile arrangement for Maxwellian view. The source S is placed at the first principal focal plane of lens L_1 and the target T is now trans-illuminated by a parallel beam. A laser may be substituted for S and L_1. For the image of the source to fall in the plane of the eye's entrance pupil, the latter should be in the second principal focal plane of lens L_2. If the observer is emmetropic, the target T should be placed at the first principal focal plane of lens L_2.

Now $1/x'$ is the reciprocal of the image distance from the eye, i.e., it is the desired accommodative state of an emmetropic eye (or the far point of an unaccommodated ametropic eye) in diopters. It follows that a linear relationship exists between x the displacement of the target from the first primary focal point of lens L_2, and the target focus with respect to the eye in diopters. Each diopter of target focus corresponds to a distance $x = f_2^2$ (x, f_2 in meters). For example, if the lens L_2 has a focal length of 0.20 m, each diopter of target focus as far as the eye is concerned is represented by 0.04 m displacement of the target from the first focal point of the lens L_2. The displacement is towards L_2 if the subject is accommodating, or is myopic, and is away from L_2 if he is hyperopic. The device clearly makes a good optometer, and was described in an arrangement for this purpose by Schmidt-Rimpler in 1877 (Emsley, 1939).

Field of View

Another important variable in setting up a vision experiment, in addition to the level of retinal illuminance and the state of focus, which were discussed above, is the area of retina illuminated. We shall follow the approach adopted throughout this paper of specifying retinal distances in angular measure in the eye's object space. The angle should be measured at the center of the entrance pupil, which is about 3 mm behind the corneal vertex; the specification of retinal distance is then more invariant with such factors as accommodation and out-of-focusness than if another reference point, e.g. nodal point, is used. For a typical human eye, 1 min of arc in the object space corresponds to a retinal distance of just under 5 μ, so that there arc about 3.4° in each millimeter of retinal distance.

If the target is placed in the plane of lens L_2 in Fig. 2, and if its diameter is c, its angular subtense is approximately c/f_2 rad. Here, c and f_2 should be measured in the same units. To convert to minutes of arc, it should be remembered that there are 3.44×10^3 min of arc in each radian. In a hypothetical situation where $f_2 = 20$ cm, and it is desired to present the eye with a stimulus 60 min of arc in diameter, its linear dimension must then be $c = 20 \times 60/3.44 \times 10^3$ cm = 0.3 cm. Clearly, if small targets have to be presented to the eye, the focal length of the lens L_2 should be long so that the linear size of the targets does not become too small. For example, if a lens of focal length 34.4 cm is chosen, each minute of arc of target size is 0.1 mm.

The above arguments hold identically if the target is not in the plane of L_2 but is placed anywhere in the parallel beam between lenses L_1 and L_2. The important property of the principle of placing the

second focal point of the lens L_2 in the plane of eye's entrance pupil, the so-called telecentric principle, is now apparent: for purposes of changing focus (Section "Focus") the target may be moved in the space between the two lenses L_1 and L_2, but such a move does not change either the retinal illuminance or the image size.

The maximum image size that can be achieved in the arrangement of Fig. 2 is one in which the apertures of lenses L_1 and L_2 remain unobscured. If the aperture of the smaller of the two lenses is c, the maximum field size is c/f_2 rad. If, for example, lens L_2 is filled and has an aperture of 50 mm and focal length 20 cm, the largest field is 5/20 = 1/4 rad. ≈ 14° in diameter.

Pupil Size

The effect of pupil size on the quantity of light entering the eye has already been discussed. The Stiles-Crawford effect has an influence, of course; whether it needs to be taken into consideration is a decision that depends on the particular application since, for example, the S-C effect does not show up in rod vision.

The pupil aperture also affects the quality of the retinal image. While in an important way everything to be said here will be modified by the optical aberrations of the particular eye to which it is applied, there still remains a substantial body of generally valid facts based on the diffraction theory of perfect optical instruments. Only under exceptional circumstances can an eye be expected to be as good as this, but our considerations allow us to set a bound to the best performance of any eye. In the present study no attempt will be made to go beyond this approach.

Incoherent Target[*] It used to be taught that the resolution limit of an eye with an entrance pupil diameter of a mm for light of wave length λ is 1.22 λ/a rad of visual angle in object space. This is at best an incomplete description of the situation, based on the fact that the diffraction-limited point-spread function, the Fraunhofer diffraction pattern, then has a radius (to its first zero) of 1.22 λ/a rad of visual angle. A fuller analysis of the performance limitation of the eye is afforded by Fourier theory. The fundamental description of the eye's imagery, which the above statement expresses in the space domain (a point object is imaged in the Fraunhofer diffraction spread pattern), may also be phrased in terms of the spatial frequency domain. A grating with sinusoidal intensity pattern with a period α min of arc visual angle may also be said to have repetition rate or spatial frequency of $1/\alpha$ c/min of arc. In the spatial frequency domain, the way of describing the performance limitation of an optical system is to state the demodulation experienced by a sinusoidal grating target in the process of being imaged. When this quantity is plotted against spatial frequency we have what is now called the modulation transfer function. Such curves for a hypothetical aberration-free eye with various entrance pupils are shown in Fig. 3. Their main feature is a progressive reduction in the modulation of the image (when the object grating retains constant contrast) as the spatial frequency is increased up to the cut-off spatial frequency, beyond which there is no indication in the image that the object contains any features of those repetition frequencies.

The above statement is based on the acceptable premise that optical imagery obeys the principles of linearity. When the target is self-luminous, as it is assumed to be the case with ordinary viewing, this is indeed the case. The following is a summary in mathematical language of the basic concepts of image formation for an incoherent target.

Let the two dimensions in the eye's object space be α,β; distances involving α refer to the horizontal direction, and β the vertical direction. Let distances in the two corresponding directions of the eye's entrance pupil be y_α, y_β. Let spatial frequencies in these two directions be denoted by ω_α, ω_β. For example a grating made up of vertical bars with period 10 min of arc has spatial frequency ω_α = 0.1 c/min of arc.

[*] An excellent introduction to the following discussions can be found in O'Neill (1963) or in Hopkins (1953).

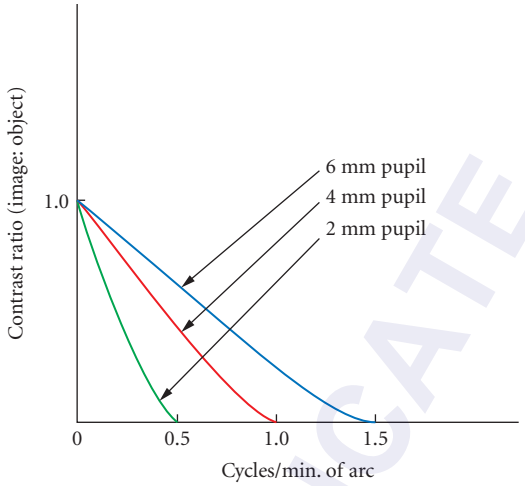

FIGURE 3 Contrast transfer functions (ratios of contrast in images and corresponding objects for sinusoidal light distributions) of optical system like that of the human eye but free from aberrations with round pupil of various diameters in monochromatic light of wavelength $\lambda = 555$ mμ.

Let the pupil aperture be described by the function $g(y_\alpha, y_\beta)$. For example, if the pupil is rectangular with a horizontal diameter of a, and vertical diameter b, and is quite unobstructed,

$$g(y_\alpha, y_\beta) = 1 \qquad \frac{-a}{2} \le y_\alpha \le \frac{+a}{2}$$

$$\frac{-b}{2} \le y_\beta \le \frac{+b}{2}$$

$$= 0 \qquad \text{elsewhere.}$$

If it is round,

$$g(y_\alpha, y_\beta) = 1 \qquad y_\alpha^2 + y_\beta^2 \le \left(\frac{a}{2}\right)^2$$

$$= 0 \qquad \text{elsewhere.}$$

The following theorems from diffraction theory are applicable:

1. Let the pupil function be expressed in terms of the variables $\omega_\alpha = y_\alpha/\lambda$ and $\omega_\beta = y_\beta/\lambda$ where λ is the wavelength of light. In this way we define the function $\hat{S}(\omega_\alpha, \omega_\beta) = g(y_\alpha, y_\beta)$. It is the Fourier transform of $\hat{s}(\alpha,\beta)$, the amplitude distribution of the disturbance in the image of a point object, that is to say

$$\hat{s}(\alpha,\beta) = \int_{-\infty}^{+\infty}\int g(y_\alpha, y_\beta) e^{-2\pi i(y_\alpha\alpha + y_\beta\beta)} dy_\alpha dy_\beta \tag{4}$$

2. The intensity distribution in the image of a point object, $s(\alpha,\beta)$ is the product of the amplitude distribution $\hat{s}(\alpha,\beta)$ and its complex conjugate $\hat{s}^*(\alpha,\beta)$. Thus

$$s(\alpha,\beta) = \hat{s}(\alpha,\beta) \cdot \hat{s}^*(\alpha,\beta) \tag{5}$$

3. The Fourier transform of the intensity distribution in the image of a point source $s(\alpha,\beta)$, is the modulation transfer function, $\tau(\omega_a,\omega_\beta)$. Thus

$$\tau(\omega_a,\omega_\beta)=\int_{-\infty}^{+\infty}\int s(\alpha,\beta)e^{-2\pi i(\alpha\omega_\alpha+\beta\omega_\beta)}d\alpha d\beta \tag{6}$$

4. The modulation transfer function is the self-convolution of the pupil function

$$\tau(\omega_a,\omega_\beta)=g(y_\alpha,y_\beta)\otimes g(y_\alpha,y_\beta) \tag{7}$$

In practice, the following steps can lead from the knowledge of the aperture function of an optical system to the detailed knowledge of the image intensity distribution:

1. The modulation transfer function is given by the self-convolution (auto-correlation) of the pupil aperture function, equation (7).
2. The product of the Fourier transform of the object intensity distribution with the modulation transfer function gives the Fourier transform of the image intensity distribution. In the space domain, the equivalent statement is that the image intensity distribution is the convolution of the object intensity distribution, with the intensity distribution in the image of a point source. These relationships, which are derived and discussed in considerable detail in the relevant texts (O'Neil, Born and Wolf) are summarized in Table 1.

The fundamental imaging property of an instrument like the eye is, therefore, contained in the modulation transfer function $\tau(\omega_\alpha,\omega_\beta)$ in the Fourier domain, and in the image intensity distribution of a point object $s(\alpha,\beta)$ in the space domain. This holds not only for purely diffraction-limited instruments but also for those afflicted with aberrations. In such cases the modulation transfer function will be lower (less transmission of spatial frequencies) and the point-spread function larger.

The application of this theory to imaging in the eye of incoherently illuminated objects has been discussed in a previous study (Westheimer, 1964).

Coherent Illumination The whole situation is radically altered if the target is transilluminated by light which has its origin in a single source, so that the radiation emitted from different portions of the target is capable of mutually interfering. This is realized in Maxwellian viewing when the source *S*

TABLE 1 Incoherent Imagery

	Object Space α,β Visual Angle	Pupil Plane y_α, y_β Distance	Fourier Domain $\omega_\alpha, \omega_\beta$ (c/min of arc)	Image Space α,β (min of arc)
Object	$o(\alpha,\beta)$		$O(\omega_\alpha, \omega_\beta)$	
Pupil aperture function		$g(y_\alpha,y_\beta)$		
Amplitude function in image of point object			$\hat{S}(\omega_\alpha,\omega_\beta)$	$\hat{s}(\alpha,\beta)$
Transfer function			$\tau(\omega_\alpha,\omega_\beta)=g(y_\alpha,y_\beta)\otimes g(y_\alpha,y_\beta)$	
Intensity function in image of point object				$s(\alpha,\beta)=\hat{s}(\alpha,\beta)\cdot\hat{s}^*(\alpha,\beta)$
Image intensity function			$I(\omega_\alpha,\omega_\beta)=\tau(\omega_\alpha,\omega_\beta)\cdot O(\omega_\alpha,\omega_\beta)$	$i(\alpha,\beta)=o(\alpha,\beta)\hat{s}^*(\alpha,\beta)$

See footnote to Table 2.

in Fig. 1(*a*) is very small, and monochromatic. Then the light after being collimated by lens L_1 may be regarded as perfectly coherent, and the following theory holds rigidly. (It also holds for targets illuminated by lasers which emit perfectly coherent light.†)

The following is a convenient way of visualizing the situation. Since the wavefront impinging on the target is plane, there will be formed in the plane of the *eye's* pupil the Fraunhofer diffraction pattern produced at the passage of the light through the target. The amplitude distribution in this diffraction image is the Fourier transform of the target amplitude function.

If $\delta(\alpha,\beta)$ is the distribution of amplitude in the object, the distribution of amplitude in the disturbance in the plane of the pupil is given by

$$O(\omega_a,\omega_\beta)=\int_{-\infty}^{+\infty}\int \delta(\omega_a,\omega_\beta)e^{-2\pi i(\omega_\alpha\alpha+\omega_\beta\beta)}d\alpha\,d\beta \tag{8}$$

Naturally, only that portion of $O(\omega_a,\omega_\beta)$ that is transmitted by the pupillary aperture can be effective in the formation of the image amplitude distribution $i(\alpha,\beta)$ which is again the Fourier transform of the pupil amplitude function. Thus

$$i(\alpha,\beta)=\iint_{\text{pupil}} O(\omega_a,\omega_\beta)e^{-2\pi i(\omega_\alpha\alpha+\omega_\beta\beta)}d\omega_\alpha\,d\omega_\beta \tag{9}$$

Finally, the image intensity distribution $i(\alpha,\beta)$ is the product of the image amplitude distribution with its complex conjugate:

$$i(\alpha,\beta)=i(\alpha,\beta)\cdot i^*(\alpha,\beta)$$

It is seen that the limitation to the fidelity of reproduction of the original target on the retina (aside from any aberrations that may be present) is the fact that the pupil aperture is necessarily finite, while for any finite target the diffraction image, or Fourier transform, that is formed in the pupillary plane will be infinite in extent. All portions of the diffraction image of the target that fall outside the pupil will be cut off. The diffraction limitation during Maxwellian viewing lies therefore in equation (9) which states that the range of integration in the Fourier re-synthesis of the image extends only over the pupil instead of going to infinity. Now there is a very simple relationship between the target's amplitude spatial frequencies (ω_a,ω_β), and the corresponding positions in the diffraction image in the pupil. Each spatial frequency ω is situated at a distance $y=\lambda\omega$ from the geometrical image of the source in the pupil. The pupil aperture function $g(y_\alpha,y_\beta)$, written in terms of the variables $\omega_\alpha=y_\alpha/\lambda, \omega_\beta=y_\beta/\lambda$, thus, gives us the amplitude transmission function $\tau(\omega_a,\omega_\beta)$. It is this function which, when multiplied with $O(\omega_a,\omega_\beta)$, the Fourier transform of the object amplitude function, gives $I(\omega_a,\omega_\beta)$ the Fourier transform of the image amplitude function. All this is also summarized in Table 2.

Two examples follow. Suppose that the disturbance issuing from the target plane has an amplitude distribution that is sinusoidal with spatial frequency ω, i.e.

$$O(\alpha,\beta)=1+\cos(2\pi\alpha\omega)$$

The associated amplitude distribution in the plane of the pupil is three delta functions, i.e. there is a concentration of disturbance in 3 spots in the pupillary plane and nowhere else. The three are:

(1) $\omega_a=0$, i.e. $y_a=\omega_\alpha\lambda=0$, i.e. at the center of the pupil and

(2 and 3) $\omega_a=\pm\omega$, i.e. $y_a=\pm\omega\lambda$

† A laser may be substituted for the source and lens L_1. It is to be noted that all the light from the laser is then focused in the eye's pupil. Obviously, precautions are necessary here, just as much as in using a laser and letting the eye's optical system focus its beam on the retina.

TABLE 2 Incoherent Imagery

	Object Space α,β Visual Angle	Pupil Plane y_α, y_β Distance	Spatial Frequency Domain ω (c/min of arc)	Image Space
Object amplitude function	$o(\alpha,\beta)$		$O(\omega_\alpha,\omega_\beta)$	
Aperture function		$g(y_\alpha, y_\beta)$		
Complex amplitude transmission function			$\tau(\omega_\alpha,\omega_\beta)$	
Image amplitude function			$I(\omega_\alpha,\omega_\beta)=\tau(\omega_\alpha,\omega_\beta)\cdot O(\omega_\alpha,\omega_\beta)$	$\hat{i}(\alpha,\beta)$
Image intensity function				$i(\alpha,\beta)=i(\alpha,\beta)i^*(\alpha,\beta)$

The relationship between variables is as follows:

1. Where quantities in 1st and 3rd columns are entered between a pair of horizontal lines, they are Fourier transforms:

$$o(\omega_\alpha,\omega_\beta)=\int_{-\infty}^{+\infty}\int O(\alpha,\beta)e^{-2\pi i(\alpha\omega_\alpha+\beta\omega_\beta)}d\alpha d\beta$$

where α, and β are visual angles in minutes of arc, ω_α, ω_β are spatial frequency in c/min of arc.

2. Distances y_α, y_β in plane of entrance pupil measured from its center are related to the spatial frequencies in the same orientation by the equations

$$y_\alpha=\omega_\alpha\lambda \qquad y_\beta=\omega_\beta\lambda$$

λ being the wavelength of light used. Functions in the second column (pupil space) are transferred directly to the third column, spatial frequency, by this change in variables.

The above example shows that the representation of a sinusoidal grating in the frequency domain consists of a d.c. term and a pair of a.c. terms which are physically placed in the pupillary plane in positions according to their spatial frequency. Frequencies higher than the one present at the edge of the pupil can clearly not be available to make up the image. If the pupil aperture has diameter *a,* this limit of sinusoidal components of amplitude is given by

$$\omega_\alpha = a/2\lambda$$

Another example: suppose the target is a trans-illuminated circular disk of diameter α_0 rad, centered on the optical system. This case has been dealt with in detail in a previous study (Westheimer, 1959). The amplitude distribution in the diffraction image in the pupil is here the familiar Airy disk, with the first zero at a distance from the center given by

$$y = 1.22\ \lambda/\alpha_0$$

y and λ being in the same units. For a disk 2.0 min of arc in diameter (0.00058 rad) and light of a representative wavelength, y = 1.2 mm. Thus, if the pupil diameter is smaller than 2.4 mm (or if an artificial pupil of smaller diameter than 2.4 mm is placed in front of the eye) only the center portion of the diffraction image of the disk is admitted into the eye. This constitutes a severe restriction of the "bandwidth" of spatial frequencies making up the original disk. The apparent anomaly of the situation is that most of the amplitude of the disturbance (>90 per cent) from the point source passing through the target disk, is contained in the central part of the diffraction image. Yet much of the "information" about the target-whether or not it is a sharply bounded disk and the position and exact nature of its edge-is contained in the higher spatial frequencies. They are imaged in the periphery of the eye's entrance pupil and could thus be screened out needlessly by an experimenter who, unaware of their information content, might stop them from entering the eye by placing too small an artificial pupil in front of an eye seeing the target in Maxwellian view.

It should be emphasized that the process of coherent imaging is linear in *amplitude* of the electromagnetic radiation, not in *intensity* as it is with incoherent targets. When a target is lit by coherent light, it is helpful to consider the amplitude of the disturbance emerging from the target plane as being focused in the pupil plane. The amplitude of the disturbance there, which is the Fourier

transform of that in the target plane, represents the spatial frequency content of the latter displayed at distances from the geometrical image of the source proportional to the spatial frequencies. Since the pupil necessarily cuts out all portions of the diffraction pattern further out than its radius, the disturbance entering the eye will now make up an image amplitude distribution on the retina that is restricted in bandwidth of its spatial frequencies. In addition, intraocular effects and aberrations may also superimpose inhomogeneities and phase shifts. Ultimately the amplitude distribution of the disturbance in the plane of the retina is subjected to a non-linear transformation, viz. squaring, and the resulting intensity distribution constitutes the retinal image. Once its origin is properly understood, the Stiles-Crawford effect can be allowed for in this series of transformations. The place of the non-linearity in coherent imagery—it occurs as the last step in the transformation—prevents the formulation of any general statements about the retinal image. All particular cases of target configurations, pupil openings (not to mention aberrations and defocusing) will give rise to their own kinds of imaging characteristics. For incoherent target illumination, the non-linearity occurs at a more convenient juncture in the sequence, for once the point-spread function, or in the Fourier domain, the modulation transfer function, has been fixed by the particulars of the pupil size, aberrations and focus errors, the image for any target can be readily determined.

When it is coherent, the amplitude of the electromagnetic disturbance emerging from the target plane is being spatially Fourier analyzed (displayed as a diffraction image in the plane of the pupil), filtered, and then resynthesized as a distribution of amplitude of electromagnetic disturbance in the retinal plane. Ultimately the amplitude is squared at each point in the image and this constitutes the image intensity pattern. It is seen that filtering the spatial frequency in the domain of the amplitude of the disturbance will lead to results which, when looked at in the realm of the intensity pattern, may be non-linear. As an example, consider the case of an amplitude distribution that is sinusoidal. When squared this becomes an intensity distribution that is also sinusoidal but has twice the frequency. Suppose that now a constant (d.c.) level is added in the realm of amplitude. The laws of linearity are observed, so that the new amplitude distribution is the sum of the a.c. and d.c. terms. But when this is squared to yield the intensity distribution, a result is obtained which is quite different from that obtained when the amplitude distribution due to the a.c. term alone is squared.

Partial Coherence

The theory of coherent imagery (Beran and Parrant, 1964; Born and Wolf, 1959) developed above is applicable when the source S is essentially a monochromatic point source. (A laser in place of source S and lens L_1 realizes this situation in practice.) It is then possible for light coming from a point on the target to interfere with all the light coming from all the other parts of the target. When the source is larger than that, a point on the target is transilluminated by light from a range of points on the source, and the capacity to subsequently interfere is limited. In the limit, when the source is quite extensive, the target may be regarded as incoherently illuminated. These effects are described by the theory of partial coherence, the chief theorem of which, the van Cittert–Zernike theorem, permits us to define the target region beyond which no significant degree of coherence exists.

Applied to the situation illustrated in Fig. 2, the van Cittert-Zernike theorem states that the degree of coherence in the target plane is distributed in the manner of the Fraunhofer pattern that would be produced in the hypothetical case due to diffraction at the aperture of the source S. Let the source be circular with linear diameter y_0, let the ratio of the focal lengths of the lens L_2 to that of lens L_1 (the magnification of the source in the plane of the pupil) be M. Then the separation of two points in the source for the first reduction of their mutual coherence to zero (i.e. the radius of the Fraunhofer diffraction pattern) expressed in terms of α, the angular distance at the eye, is

$$\alpha = 1.22\lambda/My_0$$

It is seen that for α to be, say, 1 min of arc, My_0 should be about 2.2 mm, i.e. the geometrical image of the source in the plane of the pupil should be 2.2 mm. This is an outer limit, since two points on the source separated by, say, half the radius of the Airy disk due to the source, would have a mutual coherence that is already small.

It is thus possible to lay down the following guidelines on whether a particular experimental situation calls for the application of the theory of coherent or incoherent imagery.

When the source has an image in the plane of the pupil larger than, say, 2.5 mm in diameter, the target may be regarded as incoherently illuminated. An artificial pupil can with advantage be employed and the approach to the light distribution in the retinal image would be by way of the modulation transfer function of the eye.

On the other extreme, one may wish to utilize the characteristics of coherent imagery for a particular purpose, such as spatial filtering. How small does the geometrical image of the source have to be for a satisfactory degree of coherence to be achieved? We have mentioned that the laser will do this, but all the essential ingredients are also present in a tungsten filament or mercury or xenon arc, provided that the angular subtense of the source at lens L_1 is small enough and the light has been restricted to a narrow enough wavelength band. If one wishes to ensure that the light coming from a 10 min of arc region of the visual field is at least, say, 90 per cent coherent, the geometrical image of the source in the pupil should be no larger than

$$My_0 = 0.32\lambda/2.9 \times 10^{-3} \qquad \text{i.e.} \qquad 0.06 \text{ mm}$$

When an interference filter is used to make the beam monochromatic, the resultant retinal illuminance cannot be very high. Nevertheless, a tungsten filament with a luminance of 10^3 cd/cm^2 can still give a few hundred trolands of quasi-monochromatic retinal illuminance with good coherence properties. With the use of a high-pressure mercury arc this can be increased by at least two orders of magnitude.

6.3 POSTSCRIPT (2008)

These supplementary remarks are informed by developments in the two intersecting topics which this article, written 45 years ago, covers: physical optics and dioptrics of the eye.

The Maxwellian view is a nontraditional way of generating the retinal image. In ordinary viewing, the energy over the whole bundle of rays—or the wavefront—reaching the entrance pupil is uniform.

The recent great advances in adaptive optics, that is, the modifying of the wavefront for purposes of neutralizing deviations caused by the eye's dioptric defects, deal only with the phase, not amplitude (Chap. 15 in this volume, and Chap. 5, "Adaptive Optics," by Robert Q. Fugate in Vol. V).

But it is precisely the amplitude of the electromagnetic disturbance across the entering wavefront that is in play in Maxwellian viewing. A simple way of formulating the eye's imaging is the statement that Fourier transformation relates the complex amplitude distributions of the electromagnetic disturbance in the planes of the exit pupil and the retinal image. The image intensity distribution is then the product of the amplitude with its complex conjugate—in practice squaring, once phase effects have been factored in. Hence in principle one can configure a desired retinal image by manipulating the incoming wavefront as it reaches the eye. In the most elementary case of Maxwellian viewing, the disturbance in the pupil plane is merely the diffraction pattern generated when a coherent beam passes through a transparent target comes to a focus there. But spatial amplitude and phase distributions can be created by other means. Limiting it to two points by a double prisms, for example, is a time-honored manner of producing interference fringes on the retina. If, a technology were available that allows both amplitude and phase modulation of a uniform plane wavefront incident on the eye—instead of only the phase as currently implementated in "adaptive optics"—an unprecedented control of the retinal image would be achieved in the absence of any physical objects. A start of this has already been made in attempts to measure the performance of the retinal mosaic by not just interference fringes but also in two-point separation acuity.[1]

The original paper discussed the always difficult problem of partial coherence. This is only appropriate, if for no other reason than that resolution measurements as a function of the degree of coherence had been performed in the first instance by visual observation[2]. In the early days of this research, generating a highly coherent light signal was quite difficult. It involved strictly monochromatic light, usually produced by mercury arcs limited to a single spectral line by narrow-band interference filters, focused on a pinhole aperture only a fraction of a millimeter in diameter. The possibility of coherence being only partial needed to be kept in mind, particularly since its mathematical handling involves delicate problems.

All this changed radically with the advent of the laser. This advance in technology took place in the interval between two papers devoted to measuring retinal resolution bypassing the eye's optics and illustrates how it allowed researchers to concentrate on the biology rather than the physics of the process.[3,4] As the result of the easy access to fully coherent beams, partial coherence is now of more theoretical than practical interest.

Utilizing lasers and sources other than incandescent ones has opened up a question that at one time occupied center stage in vision research: photon statistics at the absolute visual threshold. Hecht, Shlaer and Pirenne's epochal work,[5] done while the quantum theory of light was still novel, pointed to the physical basis of threshold fluctuation through the contention that a Poisson distribution was the governing rule when the number of absorbed photons was only a handful. Since then the subject of photon statistics has been opened more widely with the utilization of photon emission both from lasers[6,7] and from oscilloscope screens,[8] each of which are used in vision research.

In the process of estimating the retinal image by way of Fourier transformation of the complex amplitude distribution of the electromagnetic disturbance in the plane of the entrance pupil, the question cannot be skirted of how to factor in the Stiles-Crawford effect[9] (see Chaps. 8 and 9). The original measurement involved the reduction in luminous efficiency for a narrow bundle as it was moved from the center to the edge of the pupil. The most trivial explanation of absorption in the eye media was quickly eliminated by the fact that the phenomenon differs between rod and cone vision.

The problem arises when computing the light distribution in the image formed by the eye's optics as it is in turn is funneled into the receptors to form the immediate stimulus for the visual process leading to photoisomerizations of photopigment molecules in rods and cones. Most calculations make no particular assumptions about the uptake of radiation in retinal receptors, yet their properties in channeling and accepting radiation cannot be ignored, especially if that involves conditioning the impinging wavefront. There are two possible interpretations of the role of the Stiles-Crawford effect at the level just prior to the phototransduction:

a. The effect is an apodization phenomenon, where the entering wavefront near the edge of the pupil somehow is diminished in amplitude, perhaps as a result of waveguide properties of receptors (Chap. 9) or acceptance-lobe limitations at the molecular absorption levels. In such a case, the

calculation from pupil aperture to image distributions would have to fold in amplitude variations across the wavefront; in other words, the amplitude of the wavefront is in effect diminished toward the pupil periphery as the square root of the measured Stiles-Crawford effect, the latter measurements having been obtained in the intensity, not the amplitude domain of the electromagnetic disturbance.

b. The effect is a diminution of the Poynting vector of the electromagnetic disturbance as a function of its direction with respect to the orientation of the receptor cells. This would be implemented by physical light screening at the retina, for example, inter-receptor absorbing pigments.

The case for (a) has been made well enough by arguments in favor of retinal receptors acting as waveguides (Chap. 8) and resultant improvement in image quality through reducing the weight of the wavefront in the pupil periphery more prone to be afflicted by ocular aberrations. It is strengthened by the fact that the Stiles-Crawford effect is much more prominent in cone vision where light level is not an issue but image quality is, than in rod vision.[10]

But the alternative (b) cannot yet be dismissed. There is evidence that the photopigment pools reached by light entering at opposite edges of the pupil are not identical.[11] The situation has been laid out in greater detail elsewhere.[12,13]

An effective retinal image, that is, a pattern of intra-receptoral light absorption, based on proposition (a) will differ form one based on (b) and would lead to a rod-cone difference in spatial visual stimulus patterns.

Laser/Optical Radiation Program
Aberdeen Proving Ground, Maryland

7.1 GLOSSARY

Bunsen-Roscoe law of photochemistry. The reciprocal relation between irradiance (dose-rate) and exposure duration to produce a constant radiant exposure (dose) to produce an effect.

Coroneo effect. See *Ophthalmoheliosis*.

Erythema. Skin reddening (acute damage) such as that caused by UV radiation; sunburn.

Macula lutea. Yellowed-pigment central region (macular area) of the retina of the human eye.

Maxwellian view. A method for directing a convergent beam into the eye's pupil to illuminate a large retinal area.

Ophthalmoheliosis. The concentration of UV radiation upon the nasal region of the cornea (the limbus) and nasal equatorial region of the lens, thus contributing to the development of pterygium on the cornea and cataract in the lens beginning in these regions.

Photokeratitis. A painful inflammation of the cornea of the eye.

Photoretinitis. Retinal injury due to viewing the sun or other high-intensity light source arising from photochemical damage due to short, visible wavelengths (also termed *photic maculopathy*).

Pterygium. A fleshy growth that invades the cornea (the clear front "window" of the eye). It is an abnormal process in which the conjunctiva (a membrane that covers the white of the eye) grows into the cornea. A pterygium may be small or grow large enough to interfere with vision and commonly occurs on the inner (nasal) corner of the eye.

Solar retinopathy. Retinal injury caused from staring at the sun—photochemical damage produced by short, visible (blue) light (also referred to as *solar maculopathy*, since it normally occurs in the macula lutea).

*Note: The opinions or assertions herein are those of the author and should not be construed as official policies of the U.S. Department of the Army or Department of Defense.

7.2 INTRODUCTION

Optical radiation hazards to the eye vary greatly with wavelength and also depend upon the ocular exposure duration. Depending upon the spectral region the cornea, conjunctiva, lens, and/or retina may be at risk when exposed to intense light sources such as lasers and arc sources and even the sun. Photochemical damage mechanisms dominate in the ultraviolet (UV) end of the spectrum, and thermal damage mechanisms dominate at longer wavelengths in the visible and infrared (IR) spectral regions. Natural aversion responses to very bright light sources limit ocular exposure, as when one glances at the sun, but artificial sources may be brighter than the solar disk (e.g., lasers) or have different spectral or geometrical characteristics that overcome natural avoidance mechanisms, and the eye can suffer injury. Guidelines for the safe exposure of the eye from conventional light sources as well as lasers have evolved in recent decades. Because of special concerns about laser hazards, safety standards and regulations for lasers exist worldwide. However, the guidelines for exposure to conventional light sources are more complex because of the likelihood of encountering more than one type of ocular hazard from the broader emission spectrum.

The adverse effects associated with viewing lasers or other bright light sources such as the sun, arc lamps, and welding arcs have been studied for decades.[1–4] During the last three decades, guidelines for limiting exposure to protect the eye have evolved.[4–12] The guidelines were fostered to a large extent by the growing use of lasers and the quickly recognized hazard posed by viewing laser sources. Injury thresholds for acute injury in experimental animals for corneal, lenticular, and retinal effects have been corroborated for the human eye from accident data. Exposure limits are based upon this knowledge.[3] These safe exposure criteria were based not only upon studies aimed at determining thresholds in different ocular structures, but also upon studies of injury mechanisms and how the different injury mechanisms scaled with wavelength, exposure duration, and the area of irradiated tissue. The exposure guidelines also had to deal with competing damage to different ocular structures such as the cornea, lens, and retina, and how these varied with wavelength.[3–11] Although laser guidelines could be simplified to consider only the type of damage dominating for a single wavelength and exposure duration, the guidelines for incoherent, broadband sources were necessarily more complex.[11] To understand the guidelines for safe exposure, it is first necessary to consider the principal mechanisms of injury and which ocular structures may be injured under different exposure conditions.

7.3 INJURY MECHANISMS

For most exposure durations ($t > 1$ s), optical radiation injury to ocular structures is dominated by either photochemically or thermally initiated events taking place during or immediately following the absorption of radiant energy. At shorter durations, nonlinear optical interaction mechanisms may play a role.[12] Following the initial insult; biological repair responses may play a significant role in determining the final consequences of the event. While inflammatory, repair responses are intended to reduce the sequellae; in some instances, this response could result in events such as scarring, which could have an adverse impact upon biological function.[3]

Action Spectra

Photochemical and thermal effects scale differently with wavelength, exposure duration, and irradiated spot size. Indeed, experimental biological studies in humans and animals make use of these different scaling relationships to distinguish which mechanisms are playing a role in observed injury. Photochemical injury is highly wavelength dependent; thermal injury depends upon exposure duration.

Exposure Duration and Reciprocity

The Bunsen-Roscoe law of photochemistry describes the *reciprocity* of exposure rate and duration of exposure, which applies to any photochemical event. The product of the dose-rate (in watts per square centimeter) and the exposure duration (in seconds) is the exposure dose (in joules

per square centimeter at the site of absorption) that may be used to express an injury threshold. Radiometrically, the irradiance E in watts per square centimeter, multiplied by the exposure duration t, is the radiant exposure H in joules per square centimeter, as shown in Eq. (1).

$$H = E \cdot t \tag{1}$$

This reciprocity helps to distinguish photochemical injury mechanisms from thermal injury (burns) where heat conduction requires a very intense exposure within seconds to cause photocoagulation; otherwise, surrounding tissue conducts the heat away from the absorption site (e.g., from a retinal image). Biological repair mechanisms and biochemical changes over long periods and photon saturation for extremely short periods will lead to reciprocity failure.

Thermal injury is a *rate process* that is dependent upon the time-temperature history resulting from the volumic absorption of energy across the spectrum. The thermochemical reactions that produce coagulation of proteins and cell death require critical temperatures for detectable biological injury. The critical temperature for an injury gradually decreases with the lengthening of exposure duration. This approximate decrease in temperature varies over many orders of magnitude in time and deceases approximately as a function of the exposure duration t raised to the −0.25 power {i.e., $[f(t^{-0.25})]$}.

As with any photochemical reaction, the *action spectrum* should be known.[13] The action spectrum describes the relative effectiveness of different wavelengths in causing a photobiological effect. For most photobiological effects (whether beneficial or adverse), the full width at half-maximum is less than 100 nm and a long-wavelength cutoff exists where photon energy is insufficient to produce the effect. This is not at all characteristic of thermal effects; in which the effect occurs over a wide range of wavelengths where optical penetration and tissue absorption occur. For example, significant radiant energy can penetrate the ocular media and be absorbed in the retina in the spectral region between 400 and nearly 1400 nm; the absorbed energy can produce retinal thermal injury.

Although the action spectra for acute photochemical effects upon the cornea,[3,14–16] upon the lens[3,16] and upon the retina[3,17] have been published, the action spectra of some other effects appear to be quite imprecise or even unknown.[14] The action spectrum for neuroendocrine effects mediated by the eye is still only approximately known. This point to the need to specify the spectrum of the light source of interest as well as the irradiance levels if one is to compare experimental results from different experimental studies.

Although both E and H may be defined over the entire optical spectrum, it is necessary to employ an action spectrum for photochemical effects. The International Commission on Illumination (CIE) photopic $V(\lambda)$, UV hazard $S(\lambda)$, and blue-light hazard $B(\lambda)$ curves of Fig. 1 are examples of action spectra that may be used to spectrally weight the incident light. With modern computer spreadsheet programs, one can readily spectrally weight a lamp's spectrum by a large variety of photochemical action spectra. These computations all take the following form:

$$E_{\text{eff}} = \Sigma E_{\lambda} \cdot A(\lambda) \cdot \Delta(\lambda) \tag{2}$$

where $A(\lambda)$ may be any action spectrum (unitless) of interest. One can then compare different sources to determine the relative effectiveness of the same irradiance from several lamps for a given action spectrum.

7.4 TYPES OF INJURY

The human eye is actually quite well-adapted to protect itself against the potential hazards from optical radiation (UV, visible, and IR radiant energy) from most environmental exposures encountered from sunlight. However, if ground reflections are unusually high, as when snow is on the ground, reflected UV radiation may produce "snow blindness," that is, UV photokeratitis. Another example occurs during a solar eclipse, if one stares at the solar disc for more than 1 to 2 min without eye protection, the result may be an "eclipse burn" of the retina.[3,17] Lasers may injure the eye, and under unusual situations other artificial light sources, such as mercury-quartz-discharge lamps or arc lamps, may pose a potential ocular hazard. This is particularly true when the normal defense

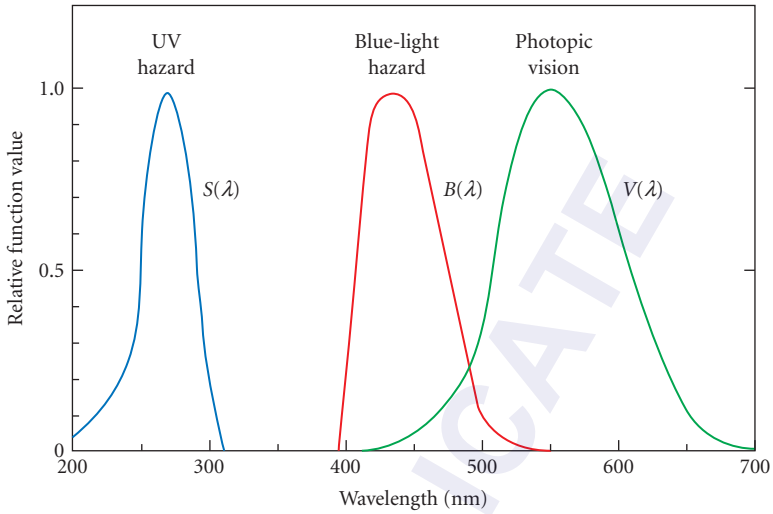

FIGURE 1 Action spectra. The ACGIH UV hazard function $S(\lambda)$ describes approximately the relative spectral risk for photokeratitis, and the blue-light hazard function $B(\lambda)$ describes the spectral risk for photoretinitis. For comparison, the CIE spectral sensitivity (standard observer) function $V(\lambda)$ for the human eye is also provided.

mechanisms of squinting, blinking, and aversion to bright light are overcome. Ophthalmic, clinical exposures may increase this risk if the pupil is dilated or the head is stabilized.

There are at least six separate types of hazards to the eye from lasers and other intense optical sources, and these are shown in Fig. 2 (along with the spectral range of responsible radiation):[3]

1. Ultraviolet photochemical injury to the cornea (photokeratitis); also known as "welder's flash" or "snow blindness" (180 to 400 nm)[3,15,16]
2. Ultraviolet photochemical injury to the crystalline lens (cataract) of the eye (295 to 325 nm, and perhaps to 400 nm)[16]
3. Blue-light photochemical injury to the retina of the eye (principally, 400 to 550 nm; unless aphakic, 310–550 nm)[3,4,17]
4. Thermal injury (photocoagulation) to the retina of the eye (400 to nearly 1400 nm) and thermoacoustic injury at very short laser exposure durations[3,4,12,18]
5. Near-IR thermal hazards to the lens (~800–3000 nm)[3,19]
6. Thermal injury (burns) of the cornea of the eye (~1300 nm to 1 mm)[3]

The potential hazards to the eye and skin are illustrated in Fig. 2, which shows how effects are generally dominant in specific CIE photobiological spectral bands, UV-A, -B, and -C and IR-A,-B, and -C.[20] Although these photobiological bands are useful shorthand notations, they do not define fine lines between no effect and an effect in accordance with changing wavelengths.

Photokeratitis

This painful but transient (1 to 2 d) photochemical effect normally occurs only over snow or open arc. The relative position of the light source and the degree of lid closure can greatly affect the proper calculation of this UV exposure dose. For assessing risk of photochemical injury, the spectral distribution of the light source is of great importance.

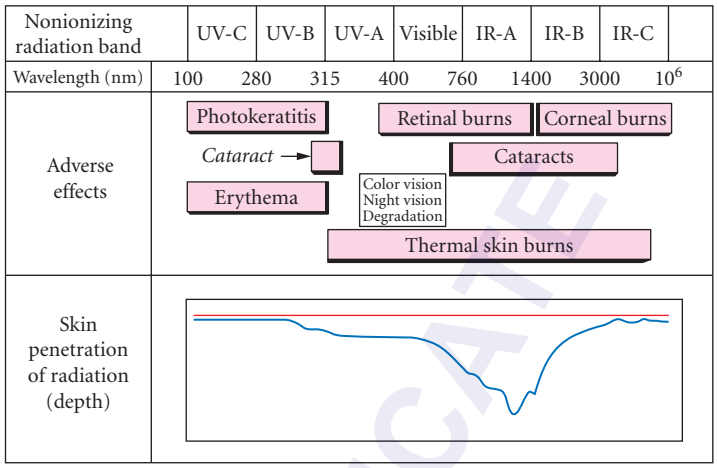

FIGURE 2 The separate types of hazards to the eye from lasers and other intense optical sources, along with the spectral range of responsible radiation.[3]

Cataract

Ultraviolet cataract can be produced from exposure to UV radiation (UVR) of wavelengths between 295 and 325 nm (and even to 400 nm). Action spectra can only be obtained from animal studies, which have shown that anterior, cortical, and posterior subcapsular cataract can be produced by intense exposure delivered over a period of days. Human cortical cataract has been linked to chronic, lifelong UV-B radiation exposure. Although the animal studies and some epidemiological studies suggest that it is primarily UV-B radiation in sunlight, and not UV-A, that is most injurious to the lens, biochemical studies suggest that UV-A radiation may also contribute to accelerated aging of the lens. It should be noted that the wavelengths between 295 and 325 nm are also in the wavelength region where solar UVR increases significantly with ozone depletion. Because there is an earlier age of onset of cataract in equatorial zones, UVR exposure has frequently been one of the most appealing of a number of theories to explain this latitudinal dependence. The UVR guideline, established by the American Conference of Governmental Industrial Hygienists (ACGIH) and the International Commission on Non-Ionizing Radiation Protection (ICNIRP) is also intended to protect against cataract.

Despite the collection of animal and epidemiological evidence that exposure of the human eye to UVR plays an etiological role in the development of cataract, this role in cataractogenesis continues to be questioned by others. Indeed, more recent studies would support a stronger role for ambient temperature as the primary environmental etiological factor in one type of cataract—nuclear cataract.[19]

Because the only direct pathway of UVR to the inferior germinative area of the lens is from the extreme temporal direction, it has been speculated that side exposure is particularly hazardous. For any greatly delayed health effect, such as cataract or retinal degeneration, it is critical to determine the actual dose distribution at critical tissue locations. A factor of great practical importance is the actual UVR that reaches the germinative layers of any tissue structure. In the case of the lens, the germinative layer where lens fiber cell nuclei are located is of great importance. The DNA in these cells is normally well-shielded by the parasol effect of the irises. However, Coroneo[21] has suggested that the focusing of very peripheral rays by the temporal edge of the cornea, those which do not even reach the retina, can enter the pupil and reach the equatorial region as shown in Fig. 3. He terms this effect, which can also produce a concentration of UVR at the nasal side of the limbus and lens, "ophthalmoheliosis." He also noted the more frequent onset of cataract in the nasal quadrant of the lens and the formation of pterygium in the nasal region of the cornea. Figure 4 shows the percentage of cortical cataract that

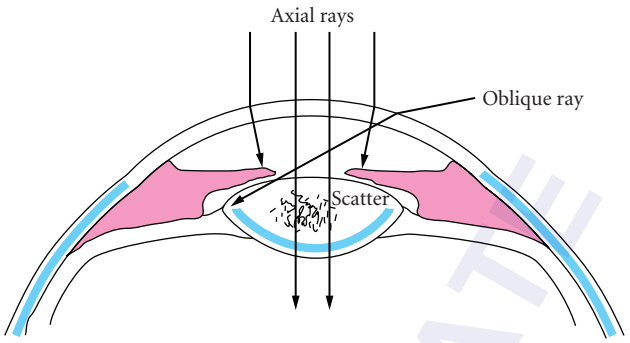

FIGURE 3 The Coroneo effect. Very oblique, temporal rays can be focused near the equator of the lens in the inferior nasal quadrant.

actually first appears in each quadrant of the lens from the data of Barbara Klein and her colleagues in their study of a population in the U.S. Midwest, in Beaver Dam, Wisconsin.[22] This relationship is highly consistent with the Coroneo hypothesis.

Pterygium and Droplet Keratopathies

The possible role of UVR in the etiology of a number of age-related ocular diseases has been the subject of many medical and scientific papers. However, there is still a debate as to the validity of these arguments. Although photokeratitis is unquestionably caused by UVR reflection from the snow,[3,23,24] pterygium and droplet keratopathies are less clearly related to UVR exposure.[24] Pterygium, a fatty growth over the conjunctiva that may extend over the cornea, is most common in ocean island residents (where both UVR and wind exposure is prevalent). Ultraviolet radiation

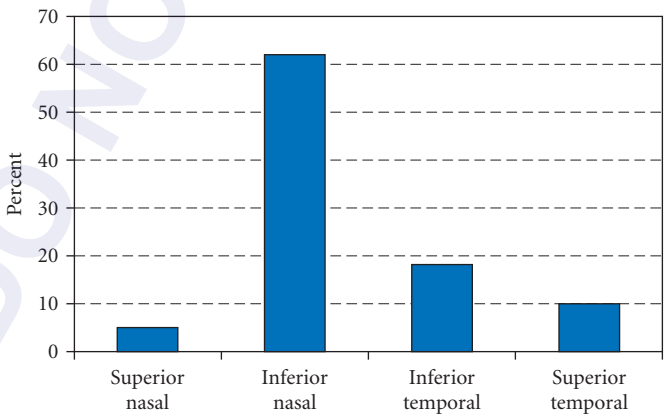

FIGURE 4 Distribution of cortical cataract by segment. The percentage of cortical cataract that actually first appears in each quadrant of the lens.[22]

is a likely etiological factor,[24,25] and the Coroneo effect may also play a role.[21,25] To better answer these epidemiological questions, far better ocular dosimetry is required. Epidemiological studies can arrive at erroneous conclusions if assignments of exposure are seriously in error, and assumptions regarding relative exposures have been argued to be incorrect.[25] Before one can improve on current epidemiological studies of cataract (or determine the most effective UVR protective measures), it is necessary to characterize the actual solar UVR exposure to the eye.

Photoretinitis

The principal retinal hazard resulting from viewing bright continuous-wave (CW) light sources is photoretinitis [e.g., *solar retinitis* with an accompanying scotoma ("blind spot"), which results from staring at the sun]. Solar retinitis was once referred to as "eclipse blindness" and associated "retinal bum." At one time, solar retinitis was thought to be a thermal injury, but it has been since shown conclusively (1976) to result from a photochemical injury related to exposure of the retina to shorter wavelengths in the visible spectrum (i.e., violet and blue light).[3,17] For this reason, it has frequently been referred to as the "blue-light" hazard. The action spectrum for photoretinitis peaks at about 445 nm in the normal phakic eye; however, if the crystalline lens has been removed (as in cataract surgery), the action spectrum continues to increase for shorter wavelengths into the UV spectrum, until the cornea blocks shorter wavelengths, and the new peak shifts down to nearly 305 nm.

As a consequence of the Bunsen-Roscoe law of photochemistry, blue-light retinal injury (photoretinitis) can result from viewing either an extremely bright light for a short time or a less bright light for longer periods. The approximate retinal threshold for a nearly monochromatic source at 440 nm is approximately 22 J/cm^2, hence a retinal irradiance of 2.2 W/cm^2 delivered in 10 s, or 0.022 W/cm^2 delivered in 1000 s will result in the same threshold retinal lesion. Eye movements will reduce the hazard, and this is particularly important for sources subtending an angle of less than 11 milliradians (mrad), because saccadic motion even during fixation is of the order of 11 mrad.[27]

Infrared Cataract

Infrared cataract in industrial workers appears only after lifetime exposures of the order of 80 to 150 mW/cm^2. Although thermal cataracts were observed in glassblowers, steelworkers, and others in metal industries at the turn of the century, they are rarely seen today. These aforementioned irradiances are almost never exceeded in modern industry, where workers will be limited in exposure duration to brief periods above 10 mW/cm^2, or they will be (should be) wearing eye protectors. Good compliance in wearing eye protection occurs at higher irradiances if only because the worker desires comfort of the face.[3]

7.5 RETINAL IRRADIANCE CALCULATIONS

Retinal irradiance (exposure rate) is directly related to source radiance (brightness). It is not readily related to corneal irradiance.[3] Equation (3) gives the general relation, where E_r is the retinal irradiance in watts per square centimeter, L_s is the source radiance in watts per square centimeter per steradian (sr), f is the effective focal length of the eye in centimeters, d_e is the pupil diameter in centimeters, and t is the transmittance of the ocular media:

$$E_r = \frac{(\pi \cdot L_s \cdot \tau \cdot d_e^{\,2})}{(4 f^2)} \tag{3}$$

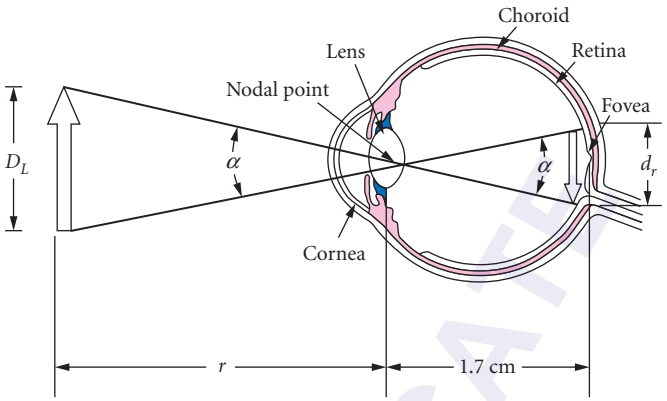

FIGURE 5 Retinal image size related to source size. The retinal image size can be calculated based upon the equal angular subtense of the source and the retinal image at the eye's nodal point (17 mm in front of the retina).

Equation (3) is derived by considering the equal angular subtense of the source and the retinal image at the eye's nodal point (Fig. 5). The detailed derivation of this equation is given elsewhere[3] and in Chap. 37 "Radiometry and Photometry for Vision Optics," by Yoshi Ohno in Vol. II. The transmittance t of the ocular media in the visible spectrum for younger humans (and most animals) is as high as 0.9 (i.e., 90 percent).[3] If one uses the effective focal length f of the adult human eye (Gullstrand eye), where $f = 1.7$ cm, one has

$$E_r = 0.27 \cdot L_s \cdot \tau \cdot d_e^{\,2} \tag{4}$$

All of the preceding equations assume that the iris is pigmented, and the pupil acts as a true aperture. In albino individuals, the iris is not very effective, and some scattered light reaches the retina. Nevertheless, imaging of a light source still occurs, and Eq. (4) is still valid if the contribution of scattered light (which falls over the entire retina) is added.

7.6 EXAMPLES

As an example, a typical cool-white fluorescent lamp has an illumination of 200 lx, and the total irradiance is 0.7 mW/cm^2. By spectral weighting, the effective blue-light irradiance is found to be 0.15 mW/cm^2. From measurement of the solid angle subtended by the source at the measurement distance,[3,11] the blue-light radiance is 0.6 mW/(cm^{2}sr) and the radiance is 2.5 mW/(cm^2 · sr). When fluorescent lamps are viewed through a plastic diffuser, the luminance and blue-light radiance are reduced.

As another example, a 1000-watt tungsten halogen bulb has a greater radiance, but the percentage of blue light is far less. A typical blue-light radiance is 0.95 W/(cm^2 · sr) compared with a total radiance of 58 W/(cm^2 · sr). The luminance is 2600 candelas (cd)/cm^2—a factor of 3000 times brighter than the cool-white fluorescent. However, because the retinal image is small, eye movements spread the exposure over a much larger area.

Once the source radiance, L or L_B, is known, the retinal irradiance E_r is calculated by Eq. (4). The preceding examples illustrate the importance of considering the size of a light source and the impact of eye movements in any calculation of retinal exposure dose. If one were exposed to a focal beam

of light (e.g., from a laser or LED) that was brought to focus in the anterior chamber (the aqueous humor), the pupil plane, or the lens, the light beam would diverge past this focal point and could be incident upon the retina as a relatively large image. This type of retinal illumination is frequently referred to as *Maxwellian view* and does not occur in nature. The retinal irradiance calculation in this case would be determined by the depth of the focal spot in the eye; the closer to the retina, the smaller the retinal image and the greater the irradiance.

Because the iris alters its diameter (and pupil center) dynamically, one must be alert to vignetting. The pupil aperture also diminishes with age. Near-sighted, or myopic, individuals tend to have larger pupils, and far-sighted, or hyperopic, individuals tend toward smaller pupils. Accommodation also results in a decrease in pupil diameter.

7.7 EXPOSURE LIMITS

A number of national and international groups have recommended occupational or public exposure limits (ELs) for optical radiation (i.e., UV, light, and IR radiant energy). Although most such groups have recommended ELs for UV and laser radiation, only one group has recommended for some time ELs for visible radiation (i.e., light). This one group is well-known in the field of occupational health—the American Conference of Governmental Industrial Hygienists (ACGIH).[5,6] The ACGIH refers to its ELs as *threshold-limit values* (TLVs); these are issued yearly, so there is an opportunity for a yearly revision. The current ACGIH TLVs for light (400 to 760 nm) have been largely unchanged for the last decade—aside from an increase in the retinal thermal limits in 2008. In 1997, with some revisions, the International Commission on Non-Ionizing Radiation Protection (ICNIRP) recommended these as international guidelines.[11] The ICNIRP guidelines are developed through collaboration with the World Health Organization (WHO) by jointly publishing criteria documents that provide the scientific database for the exposure limits.[4] The ACGIH TLVs and ICNIRP ELs are generally applied in product safety standards of the International Commission on Illumination (CIE), the International Electrotechnical Commission (IEC), the International Standardization Organization (ISO), and consensus standards from the American National Standards Institute and other groups. They are based in large part on ocular injury data from animal studies and data from human retinal injuries resulting from viewing the sun and welding arcs. All of the guidelines have an underlying assumption that outdoor environmental exposures to visible radiant energy is normally not hazardous to the eye except in very unusual environments such as snow fields, deserts, or out on the open water.

Applying the UV Limits

To apply the UV guideline, one must obtain the average spectrally weighted UV irradiance E_{eff} at the location of exposure. The spectrally weighted irradiance is

$$E_{\text{eff}} = \sum E_{\lambda} \cdot S(\lambda) \cdot \Delta(\lambda) \tag{5}$$

where the summation covers the full spectral range of $S(\lambda)$, which is the normalized "Ultraviolet Hazard Function" (a normalized action spectrum for photokeratitis). The maximum duration of exposure to stay within the limit t_{max} is determined by dividing the daily EL of 3 mJ · cm^{-2} by the measured effective irradiance to obtain the duration in seconds, as noted in Eq. (6):

$$t_{\text{max}} = \frac{3 \times 10^{-3}\ \text{J} \cdot \text{cm}^{-2}}{E_{\text{eff}}} \tag{6}$$

In addition to the $S(\lambda)$ envelope action spectrum-based EL, there has always been one additional criterion to protect the lens and to limit the dose rate to both lens and the skin from very high irradiances.

Initially, this was based only upon a consideration to conservatively protect against thermal effects. This was later thought essential not only to protect against thermal damage, but to also hedge against a possible unknown photochemical damage in the UV-A to the lens.

Sharply defined photobiological action spectra apply to the ultraviolet hazard function [$S(\lambda)$], the blue-light hazard function [$B(\lambda)$], and the retinal thermal hazard function [$R(\lambda)$]. These are shown in Fig. 1.

Guidelines for the Visible

The ocular exposure limits for intense visible and IR radiation exposure of the eye (from incoherent radiation) are several, because they protect against either photochemical or thermal effects to the lens or retina.

The two primary hazards that must be assessed in evaluating an intense visible light source are (1) the photoretinitis (blue-light) hazard and (2) the retinal thermal hazard. Additionally, lenticular exposure in the near IR may be of concern. It is almost always true that light sources with a luminance less than 1 cd/cm^2 (10^4 cd/m^2) will not exceed the limits, and this is generally a maximal luminance for comfortable viewing. Although this luminance value is not considered a safety limit, and may not be sufficiently conservative for a violet LED, it is frequently provided as a quick check to determine the need for further hazard assessment.[3,5]

The retinal thermal criteria, based upon the action spectrum $R(\lambda)$, applies to pulsed light sources and to intense sources. The longest viewing duration of potential concern is 10 s, because pupillary constriction and eye movements limit the added risk from greater exposure durations. The retinal thermal hazard EL is therefore not specified for longer durations.[12] Indeed, in 2008 ACGIH limited the changing value to 0.25 s. These retinal thermal limits are

$$\sum L_\lambda \cdot R(\lambda) \cdot \Delta\lambda \le 5/\alpha \cdot t^{0.25} \quad \text{W} \cdot \text{cm}^{-2} \cdot \text{sr}^{-1}, \quad 1\,\mu\text{s} < t < 10\,\text{s} \quad \text{(ICNIRP, 1997)} \tag{7}$$

$$\sum L_\lambda \cdot R(\lambda) \cdot \Delta\lambda \le 640/t^{0.25} \quad \text{W} \cdot \text{cm}^{-2} \cdot \text{sr}^{-1}, \quad 1\,\mu\text{s} < t < 0.625\,\text{ms} \quad \text{(ACGIH, 2008)} \tag{8a}$$

$$\sum L_\lambda \cdot R(\lambda) \cdot \Delta\lambda \le 16/t^{0.75} \quad \text{W} \cdot \text{cm}^{-2} \cdot \text{sr}^{-1}, \quad 0.625\,\text{ms} < t < 0.25\,\text{s} \quad \text{(ACGIH, 2008)} \tag{8b}$$

$$\sum L_\lambda \cdot R(\lambda) \cdot \Delta\lambda \le 45 \quad \text{W} \cdot \text{cm}^{-2} \cdot \text{sr}^{-1}, \quad t > 0.25\,\text{s} \quad \text{(ACGIH, 2008)} \tag{8c}$$

The blue-light photoretinitis hazard criteria were based upon the work of Ham et al.[6,11,17] The limit for time t is expressed as a $B(\lambda)$ spectrally weighted radiance:

$$\sum L_\lambda \cdot B(\lambda) \cdot t \cdot \Delta\lambda \le 100\ \text{J} \cdot \text{cm}^{-2} \cdot \text{sr}^{-1} \tag{8}$$

Applying IR Limits

There are two criteria in the near-IR region. To protect the lens against IR cataract, the EL that is applicable to IR-A and IR-B radiant energy (i.e., 780 to 3000 nm) specifies a maximal irradiance for continued exposure of 10 mW/cm^2 (average) over any 1000-s period, but not to exceed an irradiance of $1.8t^{-0.75}$ W/cm^2 (for times of exposure less than 1000 s). This is based upon the fact that IR cataract in workers appears only after lifetime exposure of 80 to 150 mW/cm.[2,3,6]

The second IR EL is to protect against retinal thermal injury from low-luminance IR illumination sources. This EL is for very special applications, where near-IR illuminators are used for night surveillance applications or IR LEDs are used for illumination or signaling. These illuminators have a very low visual stimulus and therefore would permit lengthy ocular exposure with dilated pupils. Although the retinal thermal limit [based upon the $R(\lambda)$ function] for intense, visible, broadband sources is not provided for times greater than 0.25 to 10 s because of pupillary constriction and the like, the

retinal thermal hazard—for other than momentary viewing—will only realistically occur when the source can be comfortably viewed, and this is the intended application of this special-purpose EL. The IR illuminators are used for area illumination for nighttime security where it is desirable to limit light trespass to adjacent housing. If directly viewed, the typical illuminator source may be totally invisible, or it may appear as a deep cherry red source that can be comfortably viewed. The EL is proportional to $1/\alpha$ and is simply limited to:

$$L_{\mathrm{NIR}} = \sum L_\lambda \cdot R(\lambda) \cdot \Delta\lambda \le 3.2/\alpha \cdot t^{0.25} \quad \mathrm{W \cdot cm^{-2} \cdot sr^{-1}} \quad t < 810\,\mathrm{s} \quad \text{(ACGIH, 2008)} \tag{10a}$$

$$L_{\mathrm{NIR}} = \sum L_\lambda \cdot R(\lambda) \cdot \Delta\lambda \le 0.6/\alpha \quad \mathrm{W \cdot cm^{-2} \cdot sr^{-1}} \quad t < 810\,\mathrm{s} \quad \text{(ACGIH, 2008)} \tag{10b}$$

It must be emphasized that this criterion is not applied to white-light sources, because bright light produces an aversion response and Eq. (8) or (9) would apply instead.

7.8 DISCUSSION

Exceeding the Exposure Limits

When deriving the ELs for minimal-image-size visible and infrared laser radiations, the ICNIRP generally includes a factor of 10 to reduce the 50-percent probability of retinal injury by a factor of 10. This is not a true "safety factor," because there is a statistical distribution of damage, and this factor was based upon several considerations. These included the difficulties in performing accurate measurements of source radiance or corneal irradiance, the measurement of the source angular subtense, as well as histological studies showing retinal changes occurring at the microscopic level at levels of approximately 2 below the ED-50 value.[3] In actual practice, this means that an exposure at two to three times the EL would not be expected to actually cause a physical retinal injury. At five times the EL, one would expect to find some injuries in a population of exposed subjects. The ELs are guidelines for controlling human exposure and should not be considered as fine lines between safe and hazardous exposure. By employing benefit-versus-risk considerations, it would be appropriate to have some relaxed guidelines; however, to date, no standards group has seen the need to do this.

Laser Hazards

The very high radiance (brightness) of a laser (MW and TW $\mathrm{cm^{-2}\ sr^{-1}}$) is responsible for the laser's great value in material processing and laser surgery, but it also accounts for its significant hazard to the eye (Fig. 6). When compared with a xenon arc or the sun, even a small He–Ne alignment laser is typically 10 times brighter (Fig. 7). A collimated beam entering the relaxed human eye will experience an increased irradiance of about 10^5 (i.e., 1 $\mathrm{W \cdot cm^{-2}}$ at the cornea becomes 100 $\mathrm{kW/cm^2}$ at the retina). Of course, the retinal image size is only about 10 to 20 μm, considerably smaller than the diameter of a human hair. So you may wonder: "So what if I have such a small lesion in my retina? I have millions of cone cells in my retina." The retinal injury is always larger because of heat flow and acoustic transients, and even a small disturbance of the retina can be significant. This is particularly important in the region of central vision, referred to by eye specialists as the *macula lutea* (yellow spot), or simply the *macula*. The central region of the macula, the fovea centralis, is responsible for your detailed 20/20 vision. Damage to this extremely small (about 150-μm diameter) central region can result in severe vision loss even though 98 percent of the retina is unscathed. The surrounding retina is useful for movement detection and other tasks but possesses limited visual acuity (after all, this is why your eye moves across a line of print, because your retinal area responsible for detailed vision has a very small angular subtense). Outside the retinal hazard region (400 to1400 nm), the cornea—and even the lens—can be damaged by laser beam exposure.

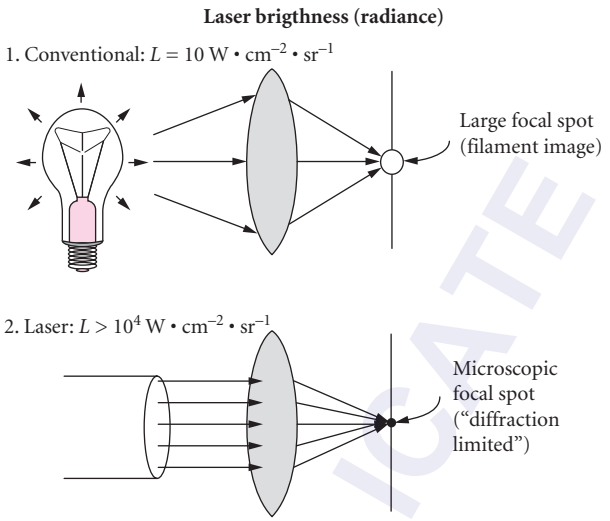

FIGURE 6 The radiance of a light source determines the irradiance in the focal spot. Hence, the very high radiance of a laser permits one to focus laser radiation to a very small image of very high irradiance.

Laser Safety Standards In the United States, the American National Standard, ANSI Z136.1-2000, *The Safe Use of Lasers*, is the national consensus standard for laser safety in the user environment. It evolved through several editions since 1973. Maximum permissible exposure (MPE) limits are provided as sliding scales, with wavelength and duration for all wavelengths from 180 nm to 1 mm and for exposure durations of 100 fs to 30 ks (8-h workday). Health and safety specialists want the simplest expression of the limits, but some more mathematically inclined scientists and engineers on standards committees argue for sophisticated formulas to express the limits (which belie the real level of biological uncertainty). These exposure limits (which are identical to those of ACGIH) formed the basis for the U.S. Federal Product Performance Standard (21 CPR 1040).[3] The latter standard regulates only laser manufacturers. On the international scene, the International Electrotechnical Commission Standard IEC 60825–1 Ed. 2 (2007) originally grew out of an amalgam of the ANSI standard for user control measures and exposure limits and the U.S. Federal product classification regulation. The ICNIRP, which has a special relationship with the WHO in developing criteria documents on laser radiation, now recommends exposure limits for laser radiation.[10] All of the aforementioned standards are basically in agreement.

Laser safety standards existing worldwide group all laser products into four general hazard classes and provide safe measures for each hazard class (classes 1 to 4).[4,5] The U.S. Federal Product Performance Standard (21 CFR 1040) requires all commercial laser products to have a label indicating the hazard class. Once one understands and recognizes the associated ocular hazards, the safety measures recommended in these standards are quite obvious (e.g., beam blocks, shields, baffles, eye protectors). The ocular hazards are generally of primary concern. Many laser products sold in the USA and worldwide, will also be certified to meet the corresponding standard of IEC 60825–1:2007.

Laser Accidents A graduate student in a physical chemistry laboratory is aligning a Nd:YAG-pumped optical parametric oscillator (OPO) laser beam to direct it into a gas cell to study photodissociation parameters for a particular molecule. Leaning over a beam director, he glances down over an upward, secondary beam and approximately 80 μJ enters his left eye. The impact produces a microscopic hole in his retina, a small hemorrhage is produced over his central vision, and he sees only red in his left eye. Within an hour, he is rushed to an eye clinic where an ophthalmologist tells him

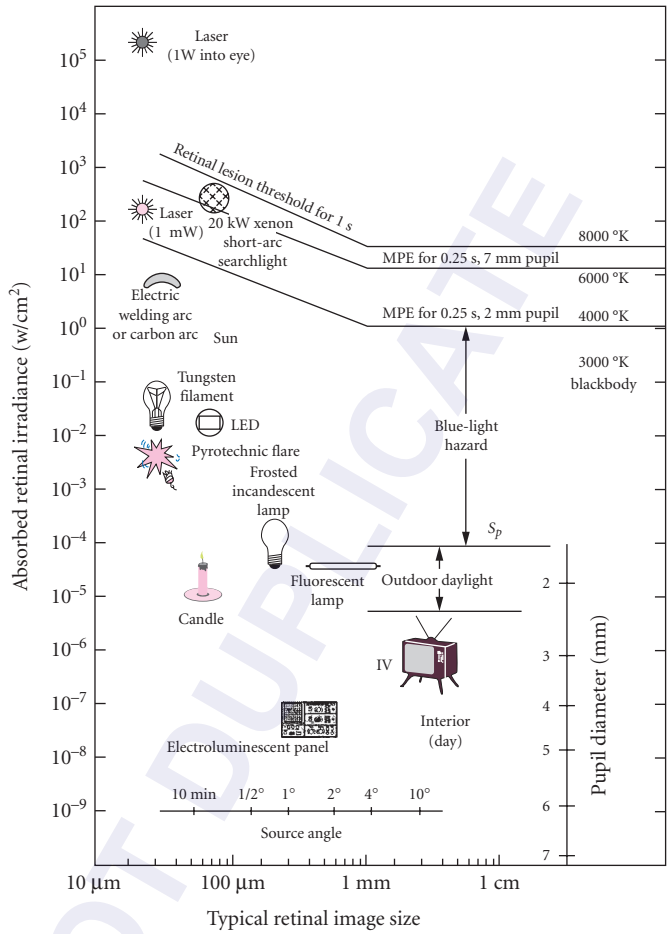

FIGURE 7 Relative retinal irradiances for staring directly at various light sources. Two retinal exposure risks are depicted: (1) retinal thermal injury, which is image-size dependent and (2) photochemical injury, which depends on the degree of blue light in the source's spectrum. The horizontal scale indicates typical image sizes. Most intense sources are so small that eye movements and heat flow will spread the incident energy over a larger retinal area. The range of photoretinitis (the "blue-light hazard") is shown to be extending from the normal outdoor light levels and above. The xenon arc lamp is clearly the most dangerous of nonlaser hazards.

he has only 20/400 vision. In another university, a physics graduate student attempts to realign the internal optics in a Q-switched Nd:YAG laser system—a procedure normally performed by a service representative that the student had witnessed several times before. A weak secondary beam reflected upward from a Brewster window enters the man's eye, producing a similar hemorrhagic retinal lesion with a severe loss of vision. Similar accidents occur each year and frequently do not receive publicity because of litigation or for administrative reasons.[3,26] Scientists and engineers who work with open-beam lasers really need to realize that almost all such lasers pose a very severe hazard to the eye if eye protection is not worn or if other safety measures are not observed![2–4]

A common element in most laser laboratory accidents is an attitude that "I know where the laser beams are; I do not place my eye near to a beam; safety goggles are uncomfortable; therefore, I do not need to wear the goggles." In virtually all accidents, eye protectors were available, but not worn. The probability that a small beam will intersect a 3- to 5-mm pupil of a person's eye is small to begin with, so injuries do not always happen when eye protectors are not worn. However, it is worthwhile to consider the following analogy. If these individuals were given an air rifle with 100 BBs to fire, were placed in a cubical room that measures 4 m on each side and is constructed of stainless-steel walls, and were told to fire all of the BBs in any directions they wished, how many would be willing to do this without heavy clothing and eye protectors?!! Yet, the probability of an eye injury is similar. In all fairness, there are laser goggles that are comfortable to wear. The common complaints that one cannot see the beam to align it are mere excuses that are readily solved with some ingenuity once you accept the hazard. For example, image converters and various fluorescent cards (such as are used to align the Nd: YAG l064-nm beam) can be used for visible lasers as well.

Laser Eye Protectors In the ANSI Z136.1 standard, there is broad general guidance for the user to consider factors such as comfort and fit, filter damage threshold, and periodic inspection, as well as the critical specification of wavelength and optical density (OD). However, there has never been any detailed U.S. specifications for standard marking and laboratory proofing (testing) of filters. By contrast, the approach in Germany (with DIN standards) and more recently in Europe (with CEN standards) has been to minimize the decision making by the user and place heavy responsibility upon the eyewear manufacturer to design, test, and follow standardized marking codes to label the eye protector. Indeed, the manufacturer had been required to use third-party test houses at some considerable expense to have type eyewear tested. Each approach has merit, and a new standard in the United States is now being developed for testing for standardized marking that is understandable to the wearer. The most important test of a protective filter is to measure the OD under CW, Q-switched, and mode-locked pulse irradiation conditions to detect saturable absorption-reversible bleaching.[28,29]

The marking of laser eye protection in an intelligible fashion to ensure that the user will not misunderstand and select the wrong goggle has been a serious issue, and there appears to be no ideal solution. Several eye injuries appear to have been caused by a person choosing the wrong protector. This is particularly likely in an environment where multiple and different laser wavelengths are in use, as in a research laboratory or a dermatological laser setting. A marking of OD may be clearly intelligible to optical physicists, but this is seldom understandable to physicians and industrial workers. Probably the best assurance against misuse of eyewear has been the application of customized labeling by the user. For example, "Use only with the model 12A," or "Use only for alignment of mode-locked YAG," or "Use only for port-wine stain laser." Such cautions supplement the more technical marking. The terms ruby, neodymium, carbon dioxide, and similar labels in addition to the wavelength can reduce potential confusion with a multiwavelength laser. Marking of broadband eye protection, such as welding goggles, does not pose a problem to the wearer. The welding shade number (e.g., WG-8), even if misunderstood by the welder, poses little risk. The simple suggestion to select the filter based upon visual comfort prevents the welder from being injured; wearing too light a shade such that the BL for blue light is exceeded is virtually impossible because of the severe disability glare that would result. The same is not true for laser eye protectors: One could wear a goggle that protects against a visible wavelength but that doesn't protect against the invisible l064-nm wavelength. Improved, standardized marking is certainly needed! Recently, a new standard in the ANSI Z136 series of standards was published: ANSI Z136.7:2008 (American National Standard for Testing and Labeling of Laser Protective Equipment), which provides more reasonable guidance.[28]

Lamp Safety Standards

Lamp safety is dealt with in ANSI/IESNA RP27.3-2005 [*Recommended Practice for Photobiological Safety for Lamps—Risk Group Classification & Labeling, and in CIE Standard S-009:2006*(IEC62471:2006) *Photobiological Safety for Lamps and Lamp Systems*. In addition, LEDs are also included in one laser safety standard: *American National Standard for the Safe Use of Lasers in Optical Fiber Communications Systems (OFCS)*], ANSI Zl36.2 (1997), since LEDs used in this special application may be viewed by

optical aids such as a microscope or eye loupe, and such viewing actually happens in realistic splicing conditions and the instrumentation to distinguish the narrow bandwidth of the laser from the wider, nominal 50-nm bandwidth of the LED is a needless burden. All current LEDs have a maximum radiance of about 12 $W \cdot cm^{-2} \cdot sr^{-1}$ and can in no way be considered hazardous, but for a period an IEC laser standard 60825-1 included LEDs (an inclusion dropped in 2007). Some observers of the IEC group accused the group of having an ulterior motive of providing test houses and safety delegates with greater business!

8.1 GLOSSARY

Apodization. Modification of the pupil function. In the present context, the Stiles-Crawford directional effect can be considered as an apodization, that is, variable transmittance across the pupil.

Bessel functions. These special functions, first defined by the mathematician Daniel Bernoulli and generalized by Friedrich Bessel, are canonical solutions of a particular differential equation called the Bessel differential equation. Bessel's equation arises when finding separable solutions to Laplace's equation and the Helmholtz equation in cylindrical or spherical coordinates systems. Bessel functions are therefore especially important for many problems of wave propagation, static potentials, such as propagation of electromagnetic waves in cylindrical waveguides, heat conduction in cylindrical objects, and the like. A specific form of the Bessel functions are called Hankel functions. These functions are very useful to describe waveguiding.

Born approximation. If an electromagnetic wave is expressed as the sum of an incident wave and the diffracted secondary wave, the scattering of the secondary wave is neglected. This neglect represents what is known as Born's first-order approximation.

Bruch's membrane. Inner layer of the choroid.

Cilia. Hair.

Cochlea. The spiral half of the labyrinth of the inner ear.

Coleoptile. The first true leaf of a monocotyledon.

Copepod. A subclass of crustacean arthropods.

Cotyledons. The seed leaf—the leaf or leaves that first appear when the seed germinates.

Ellipsoid. The outer portion of the inner segment of a photoreceptor (cone or rod). It is located between the myoid and the outer segment. It often contains oriented mitochondria for metabolic activity.

Fluence. A measure of the time-integrated energy flux usually given in units of Joules/cm^2. In biology, it is used as a measure of light exposure.

Helmholtz's reciprocity theorem. Also known as the reversion theorem. It is a basic statement of the reversibility of optical path.

Henle's fibers. Slender, relatively uniform fibers surrounded by more lucent Müller cell cytoplasm in the retina. They arise from cone photoreceptor bodies and expand into cone pedicles.

Hypocotyl. The part of the axis of the plant embryo that lies below the cotyledons.

Interstitial matrix. Space separating photoreceptors. It is of a lower refractive index than the photoreceptors and, hence, can be considered as "cladding."

Mesocotyl. The node between the sheath and the cotyledons of seedling grasses.

Mode. The mode of a dielectric waveguide is an electromagnetic field that propagates along the waveguide axis with a well-defined phase velocity and that has the same shape in any arbitrary plane transverse along that axis. Modes are obtained by solving the source-free Maxwell's equations with suitable boundary conditions.

Myoid. It is the inner portion of the inner segment of a photoreceptor (cone or rod), located between the ellipsoid and the external limiting membrane of the retina.

Organ of Corti. The structure in the cochlea of the mammals which is the principal receiver of sound; contains hair cells.

Pedicle. Foot of the cone photoreceptor; it is attached to a narrow support structure.

Phototropism. Movement stimulated by light.

Spherule. End bulb of a rod photoreceptor.

***V*-parameter.** Waveguide parameter [Eq. (3)]. This parameter completely describes the optical properties of a waveguide and depends upon the diameter of the guide, the wavelength of light used, and the indices of refraction of the inside (core) and outside (cladding) of the guide.

Equation (1). This is a statement of Snell's law.

- n_1 refractive index of medium 1; light is incident from this medium
- n_2 refractive index of medium 2; light is refracted into this medium
- θ_1 angle of incidence of light measured with respect to the surface normal in medium 1
- θ_2 angle of refraction of light in medium 2 measured with respect to the surface normal

Equation (2). This is an expression for the numerical aperture.

- n_1 refractive index of the inside of the dielectric cylinder (the "core")
- n_2 refractive index of the surround (the "cladding")
- n_3 refractive index of medium light is incident from before entering the cylinder
- θ_L limiting angle of incidence

Equation (3). Expression for the waveguide *V*-parameter.

- d diameter of the waveguide cylinder
- λ wavelength of incident light
- n_1 refractive index of core
- n_2 refractive index of cladding

8.2 INTRODUCTION

In this chapter, we will be studying two different types of biological waveguide model systems in order to relate the models' structures to the waveguide properties initiated within the light-guide construct. In these models, we will be discussing how these biological waveguides follow the Stiles-Crawford effect of the first kind, wavelength sensitivity of transmission, and Helmholtz's reciprocity theorem of optics. Furthermore, we will be investigating the different sources of biological waveguides such as vertebrate photoreceptors, cochlear hair cells (similar to cilia), and fiber-optic plant tissues, as well as considering their applications and comparing their light-guiding effects to the theoretical models. The emphasis will be on waveguiding in vertebrate retinal photoreceptors, though similar considerations apply to other systems.

8.3 WAVEGUIDING IN RETINAL PHOTORECEPTORS AND THE STILES-CRAWFORD EFFECT

Photoreceptor optics is defined as the science that investigates the effects of the optical properties of the retinal photoreceptors—namely, their size, shape, refractive index, orientation, and arrangement—on the absorption of light by the photopigment, as well as the techniques and instrumentation necessary to carry out such studies. It also explores the physiological consequences of the propagation of light within photoreceptor cells. The *Stiles-Crawford effect of the first kind*[1] (*SCE I*), discovered in 1933, represents a major breakthrough in our understanding of retinal physiology and the modern origin of the science of photoreceptor optics. The SCE I refers to the fact that visual sensitivity in normal eyes is greatest for light entering near the center of the eye pupil, and the response falls off roughly symmetrically from this peak. The SCE I underscores the fact that the retina is a complex optical processing system whose properties play a fundamental role in visual processing. The individual photoreceptors (rods and cones) behave as light collectors which capture the incident light and channel the electromagnetic energy to sites of visual absorption, the photolabile pigments, where the transduction of light energy to physicochemical energy takes place. The photoreceptors act as classic fiber-optic elements and the retina can be thought of as an enormous fiber bundle (a typical human retina has about 130×10^6 receptors). Some aspects of the behavior of this fiber optic bundle can be studied using the SCE I function, a psychophysical measurement of the directional sensitivity of the retina. The SCE I is an important index reflecting waveguide properties of the retina and is a psychophysical measurement of the directional sensitivity of the retina. The SCE I can be used to elucidate various properties, and the photodynamic nature, of the photoreceptors. The SCE I can also be used to indicate the stage and degree of various retinal abnormalities. The reader is referred to the literature for detailed discussion of various aspects of photoreceptor optics.[2–5] A collection of classic reprints on the Stiles-Crawford effect and photoreceptor optics has been published by the Optical Society of America.[6] The books by Dowling[7] and Rodieck,[8] for example, give good basic information on the physiology of the retina as well as discussions of the physical and chemical events involved in the early stages of visual processing. Additionally, there is a color effect, known as the Stiles-Crawford effect of the second kind (SCE II). Here, if the locus of entry of a beam in the entrance pupil of the eye is changed, it altered the perceived hue and saturation of the retinal image. The SCE II will not be dealt with in this chapter and the reader is referred to the literature.[9,10] Added features of the SCE are addressed in the following chapter.

8.4 WAVEGUIDES AND PHOTORECEPTORS

It appears as though there are two major evolutionary lines associated with the development of visual receptors: the ciliary type (vertebrates) and the rhabdomeric type (invertebrates). Besides being different in structure, the primary excitation processes also differ between these two types of detectors. Ciliary type (modified hair) detectors are found in all vertebrate eyes. They have certain common features with other sensory systems, for example, the hair cells of the auditory and vestibular systems. It is possible to say that all vertebrate visual detectors have waveguides associated with the receptor element. The incident light is literally guided or channeled by the receptor into the outer segment where the photosensitive pigments are located. In other words, the fiber transmits radiant energy from one point (the entrance pupil or effective aperture of the receptor) to other points (the photolabile pigment transduction sites). Given the myriad characteristics found in photoreceptors in both vertebrate and invertebrate eyes (including numerous superposition and apposition eyes), what is common in all species is the presence of the fiber-optic element. It appears as though fiber-optic properties evolved twice in the vertebrate and invertebrate receptors. This fact emphasizes the importance of these fiber-optic properties.

Like any optical device, the photoreceptor as a waveguide can accept and contain light incident within a solid angle about its axis. Therefore, all waveguides are directional in their acceptance of light and selection of only a certain part of the incident electromagnetic wavefront for transmittance to the transducing pigment.

The detailed analysis of optics and image formation in various forms of vertebrate and invertebrate eyes is beyond the scope of this chapter (see Refs. 11 and 12 as well as Chap. 1 in this volume for excellent reviews). However, all such eyes must share a common characteristic. That is, each detecting element must effectively collect light falling within its bound and each must "view" a slightly different aspect of the external world, the source of visual signal. Because of limitations of ocular imagery, there must be a degree of overlap between excitation falling on neighboring receptors; there is also the possibility of optical cross talk. It has been postulated that there is an isomorphic correspondence between points on the retina and a direction in (or points in) real (the outside world) space. A number of primary and secondary sources of light stimulus for the organism are located in the outside world. The organism has to locate those stimuli falling within its field of view and to relate those sensed objects to its own egocentric (localization) frame of reference. Let us assume that there is a fixed relationship between sense of direction and retinal locus. The organism not only needs to differentiate between different directions in an orderly manner, but it must also localize objects in space. This implies that a pertinent incident visual signal is identifiable and used for later visual processing. Further, directionality-sensitive rods and cones function most efficiently only if they are axially aligned with the aperture of the eye, that is, the source of the visual signal. Thus, it becomes necessary to relate the aperture of the receptor as a fiber-optic element relative to the iris aperture. The retinal receptor-waveguide-pupillary aperture system should be thought of as an integrated unit that is designed for optimization of light capture of quanta from the visual signal in external space and for rejection of stray light noise in the eye/image. A most interesting lens-aperture-photoreceptor system in the invertebrate world is that of a copepod, *Copilia.* The *Copilia* has a pair of image-forming eyes containing two lenses, a corneal lens and another lens cylinder (with an associated photoreceptor), separated by a relatively enormous distance. Otherwise, the photoreceptor system is similar to the insect eye. *Copilia* scans the environment by moving the lens cylinder and the attached photoreceptor. The rate of scan varies from about five scans per second to one scan per two seconds. This is like a mechanical television camera. There are other examples of scanning eyes in nature.[12]

The retina in the vertebrate eye is contained within the white, translucent, diffusing, integrating-sphere-like eye. It is important to realize that the retinal receptor "field of view" is not at all limited by the pupillary aperture. The nonimaged light may approach the receptor from virtually any direction. In Fig. 1 the larger of the two converging cones of electromagnetic energy is meant to portray (in a

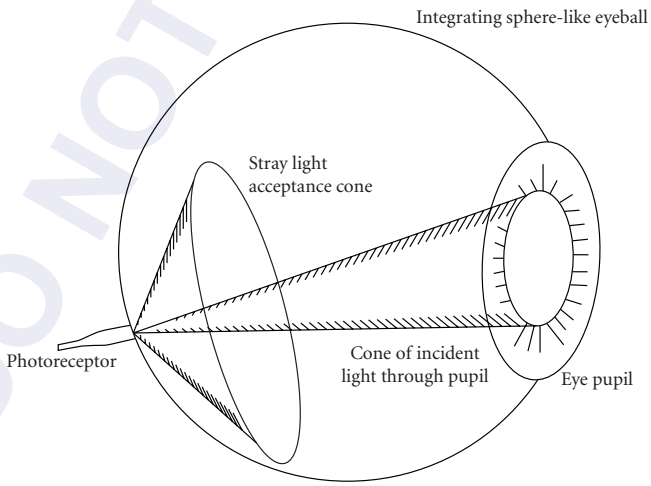

FIGURE 1 Schematic drawing showing light incidence at a single photoreceptor. Light incident on the retina has a maximum angle of incidence of about ±10° for a receptor at the posterior pole of the eye. Stray light may enter the receptor over a much larger acceptance angle (shown by the larger cone).

limited sense) the extent of the solid angle over which energy may impinge on the receptor. While stray light from any small part of this vast solid angle may be small, the total, when integrated over the sphere surrounding the receptor, may be quite a significant sum. To prevent such noise from destroying image quality, the organism has evolved specific mechanisms, including screening dark pigments in the choroid and pigment epithelium, morphological designs, photomechanical changes, aligned photolabile pigment and fiber-optic properties, and in a number of species, a tapetum.

Since the pupillary aperture is the source of the pertinent visual signal, the primary purpose of the retinal fiber-optic element, the receptor, is to be a directionally selective mechanism, which accepts incident light from only within a rather narrow solid angle. Given that the receptor has a rather narrow, limiting aperture, exhibits directionality, and favors absorption of light passing along its axis, this optical system will be most effective if it is aligned with the source of the signal, the pupillary aperture. This argument applies equally for cones and rods.

In order for a material to serve as a fiber-optic element, the material must be reasonably transparent and have a refractive index that is higher than the immediately surrounding medium. To reduce cross talk in an array of such fiber-optic elements, they must be separated by a distance approximately equal to or greater than a wavelength of light by a medium having a lower index of refraction than the fiber. The inner and outer segments of retinal photoreceptors and the separating interstitial matrix satisfy such condition. The index of refraction of biological materials is generally dependent on the concentration of large molecules of proteins, lipids, and lipoproteins. The receptor has a high concentration of such solids. These materials are in low concentrations in the surrounding interstitial matrix space. As examples, Sidman[13] has reported refractive index values of 1.4 for rod outer segments, 1.419 for foveal cone outer segments, and a value between 1.334 and 1.347 for the interstitial matrix in the primate retina. Enoch and Tobey[14] found a refractive index difference of 0.06 between the rod outer segment and the interstitial matrix in frogs. Photoreceptors are generally separated by about 0.51 μm. A minimum of about 0.5 μm (1 wavelength in the green part of the spectrum) is needed. Separation may be disturbed in the presence of pathological processes. This can alter waveguiding effects, transmission as a function of wavelength, directionality, cross talk, stray light, resolution capability, and the like.

8.5 PHOTORECEPTOR ORIENTATION AND ALIGNMENT

As noted above, Stiles and Crawford[1] found that radiant energy entering the periphery of the dilated pupil was a less effective stimulus than a physically equal beam entering the pupil center. Under photopic foveal viewing conditions, it was found that a beam entering the periphery of a pupil had to have a radiance of from 5 to 10 times that of a beam entering the pupil center to have the same subjective brightness. Stiles and Crawford plotted a parameter η, defined as the ratio of the luminance of the standard beam (at pupil center) to that of the displaced beam at photometric match point as a function of the entry portion of the displaced beam. The resultant curve has essentially a symmetric falloff in sensitivity (Fig. 2). This cannot be explained as being due to preretinal factors and this directional sensitivity of the retina is known as the Stiles-Crawford Effect of the first kind (SCE I). Later a chromatic effect (alteration of perceived hue and saturation of displaced beam) was also discovered that is called the *Stiles-Crawford Effect of the second kind.*[9.10] SCE I is unaffected by polarized light. Normative values of the parameters of this function describing the effect (as well as various mathematical descriptions) can be found in Applegate and Lakshminarayanan.[15]

The directionality of photoreceptors depends upon the acceptance angles of individual photoreceptors and on the variability of their orientation within the tested photoreceptor population. MacLeod[16] developed a selective adaptation technique to study the variability of photoreceptor orientations and concluded that foveal cones were aligned with great precision (similar results were shown, for example, Burns et al.[17] using reflectometry methods). Roorda and Williams[18] measured the orientations of individual cones and found the average disarray to be 0.17 mm in the pupil plane and point out that this disarray accounts for less than 1 percent of the breadth of the overall tuning function.

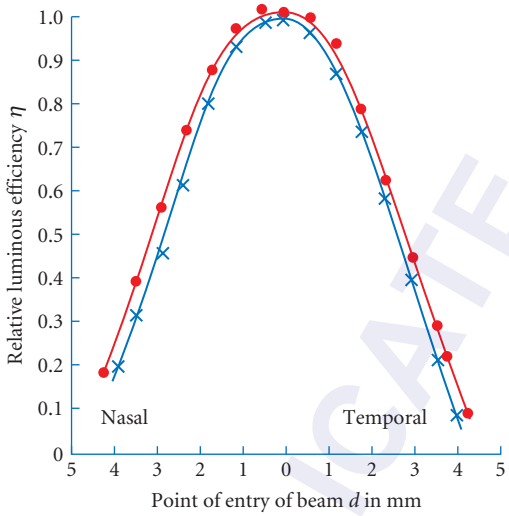

FIGURE 2 Psychophysically measured Stiles-Crawford function for left and right eyes of an observer. Nasal and temporal refer to direction with respect to pupil center. The observer's task is to match the brightness of a beam whose point of entry is varied in the pupil to a fixed beam coming in through the center of the pupil.

The directionality of photoreceptors is due to their structure that makes them act as optical fibers. Therefore, measurement of photoreceptor directionality is an important tool for testing the physical properties of photoreceptors in vivo. Much valuable information has been obtained from studies of patients with pathologies or conditions that affect the photoreceptor (and adjoining structures) layers. However clinical studies are limited by the fact that psychophysical methods are time consuming and require excellent cooperation from the subject. Therefore, different reflectometric methods have been developed.

Krauskopf[19] was the first to show a direct correspondence between the psychophysical SCE and changes in reflectivity when the entry and exit pupils are moved. There are three major methods to measure the directional properties of photoreceptors by reflectometry. They are: (a) Moving entry and exit pupils method—here the angles of incidence and reflection at the retina are changed in tandem. This method has been applied to design the photoreceptor alignment reflectometer[20] and a custom built Scanning Laser Ophthalmoscope.[21] (b) Moving exit pupil method—in this method the entrance pupil remains fixed and this desing was applied to the reflectometers of van Blokland[22,23] and Burns et al.[24] (c) Moving entrance pupil method[25]—Roorda and Williams[18] applied this method to sample fields as small as a single cone by means of the Rochester adaptive optics ophthalmoscope. (See Chap. 15 in this volume for a discussion of adaptive optics in vision science).

Histological and x-ray diffraction studies show that in many species, including human, photoreceptors tend to be oriented not toward the center of the eye, but toward an anterior point. This pointing tendency is present at birth. The directional characteristics of an individual receptor are difficult to assess, and cannot, as yet, be directly related to psychophysical SCE I data. If one assumes that there is a retinal mechanism controlling alignment and that the peak of the SCE I represents the central alignment tendencies of the receptors contained within the sampling area under consideration, it is possible to investigate where the peak of the receptor distribution is pointed at different loci tested across the retina and to draw conclusions relative to the properties of an alignment system or mechanism. Results of the SCE I functions studied over a wide area of the retina show that the overall pattern of receptor orientation is toward the approximate center of the exit pupil of the eye.

This alignment is maintained even up to 35° in the periphery. There is a growing evidence that receptor orientation is extremely stable over time in normal observers.[26]

Photoreceptor orientation disturbance and realignment of receptors following retinal disorders have also been extensively studied. A key result of these studies is that with remission of the pathological process, the system is often capable of recovering orientation throughout life. Another crucial conclusion from these studies is that alignment is *locally controlled* in the retina (e.g., Ref. 27). The stability of the system, as well as corrections in receptor orientation after pathology, implies the presence of at least one mechanism (possibly phototropic) for alignment. Even though the center-of-the-exit-pupil-of-the-eye receptor alignment characteristic is predominant, rare exceptions to this have been found. These individuals exhibit an approximate center-of-the-retinal-sphere-pointing receptor alignment tendency (Fig. 3).[28] Though certain working hypotheses have been made,[29] what maintains the receptor is an open unanswered question and is the subject of current research that is beyond the scope of this chapter. Eckmiller,[30] for example, has proposed that the alignment of photoreceptors is accomplished by a feedback controlled bending of the cell at the myoid. Some unspecified local changes are thought to occur within the myoid that activate molecular motors and induce local movements by cytoskeletal elements, and bending can be accomplished by a differential change in the myoid at different positions around the cell perimeter. To summarize, the resultant directionality must reflect the properties of the media, the waveguide properties of receptors, the alignment properties of photolabile pigments, and so forth. Mechanical tractional effects also affect receptor alignment (e.g., Refs. 31 and 32). Other factors could include stress due to microscars, traction or shear forces due to accommodation, inertial forces during saccades, local growth for example, in high myopia, and the like. The SCE I function obtained experimentally depends upon all these factors as well as the sum of photoreceptor alignment properties sampled in the retinal test area. The response is dominated by the receptor units most capable of responding in the test area and is affected by the level of light adaptation.

What are the functional visual consequences of SCE I? Recent studies have dealt with this question (e.g., Ref. 33). SCE is important in photometry and retinal image quality (see Chap. 9). Calculations for change in effective retinal illuminance were first given by Martin[34] and expanded on by Atchison et al.[35] Baron and Enoch,[36] used a half-sensitivity, half-width measurement of retinal directional sensitivity as the basis for integrating a parabolic approximation of the SCE over the pupillary area. It is possible to define an "effective" troland which takes into account the SCE compensated entrance pupil area. These studies show that increasing the pupil size from 2- to 8-mm diameter provides an increase in effective retinal illuminance of about 9 times rather than the 16 times increase in pupil area.

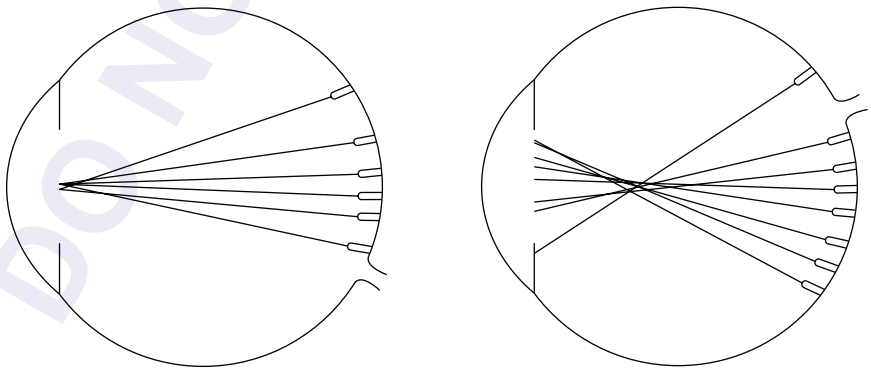

FIGURE 3 Inferred photoreceptor alignment from SCE measurements. (*a*) The more usual center-of-the-exit-pupil pointing tendency. (*b*) Center-of-the-retinal-sphere pointing tendency (rare).

The influence of the SCE on visual functions can be investigated by using filters based on the apodization model of the SCE.[37,38] Rynders et al.[39] developed SCE neutralizing filters, but provided few details. Following up, Scott et al.[40] have described construction of practical filters to achieve neutralization of the SCE. When light from the edge of a large pupil plays a significant role in degrading retinal image quality, attenuating this light by the effective SCE I apodization will, of course, improve image quality. In general, the magnitude of this improvement will depend on the magnitude of the SCE and the level of blur caused by marginal rays. The presence of aberrations influences the impact of the SCE apodization on defocused image quality. Since defocus of the opposite sign to that of the aberration can lead to well-focused marginal rays, attenuating these well-focused rays with apodization will not improve image quality.[41] In addition to generally attenuating the impact of defocus on image contrast, this apodization will effectively remove some of the phase reversals (due to zero crossings of the modulation transfer function) created by positive defocus. The displacement of phase reversals to higher spatial frequencies will have a direct impact on defocused visual resolution. Spatial tasks in which veridical phase perception is critical will be significantly more resistant to positive defocus because of the SCE. However, Atchison et al.[41,42] suggest that SCE has little effect on image quality when dealing with well centered pupils. Zhang et al.[33] have used a wave optics model to examine the effects of SCE and aberrations and have compared the results with psychophysical measurements of the effect of defocus on contrast sensitivity and perceived phase reversals. They found that SCE apodization had the biggest effect on defocused image quality only when defocus and spherical aberration have the same sign and conclude that SCE can significantly improve defocused image quality and defocused vision particularly for tasks that require veridical phase perception. It has been argued that measurements of the *transverse chromatic aberration* (*TCA*) can be affected due to SCE. Various studies show that the effect of the SCE on the amount of TCA varies strongly across individuals, and between eyes in the same individual. In conclusion, it is thought that aberrations and SCE modify the amount and direction of TCA, and SCE does not necessarily reduce the impact of TCA.[43] Longitudinal chromatic aberration, on the other hand, is only slightly affected by SCE I. It has also been shown that decentering the SCE produces an appreciable shift in subjective TCA for large pupil sizes.[42]

The wavelength dependence of the SCE has been explained by using a model of fundus reflectance developed by van de Kraats et al.[44] Berendschot et al.[45] showed that a there is a good fit between the model (based on geometrical optics) and experimental data, if self-screening and backscattered choroidal light are included in the model.

Is the retina an optimal instrument? To answer this question, Marcos and Burns[46] studied both wavefront aberration and cone directionality. They concluded that cone directionality apodization does not always occur at the optically best pupillary region and that in general ocular optics and cone alignment do not develop toward an optimal optical design.

8.6 INTRODUCTION TO THE MODELS AND THEORETICAL IMPLICATIONS

First, we need to explore the theoretical constructs or models of the biological waveguide systems based on the photoreceptors to get a full appreciation of how these models transmit light through their structure. There are two models of biological waveguide systems that will be discussed here. The first model, which is the retinal layer of rods and cones, is defined as beginning approximately at the *external limiting membrane* (*ELM;* Fig. 4), and it is from that boundary that the photoreceptors are believed to take their orientation relative to the pupillary aperture. In any local area within that layer, the photoreceptors are roughly parallel cylindrical structures of varying degrees of taper, which have diameters of the order of magnitude of the wavelength of light, and which are separated laterally by an organized lower refractive index substance, called the *interphotoreceptor matrix* (*IPM*). The photoreceptors thus form a highly organized array of optical waveguides whose longitudinal axes are, beginning at the ELM, aligned with the central direction of the pupillary illumination. The IPM serves as a cladding for those waveguides. We will assume that the ELM approximates the inner bound of the receptor fiber bundle for light that is incident upon the retina in the physiological

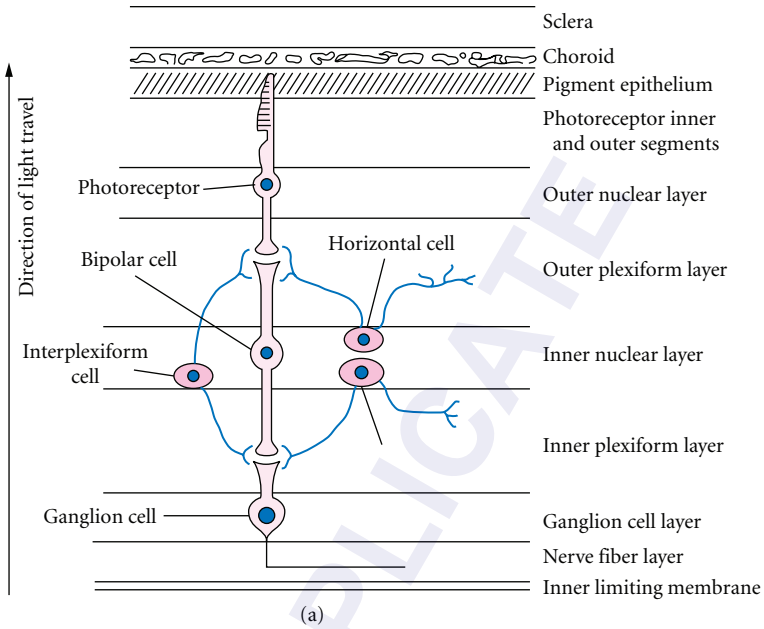

FIGURE 4 Schematic diagram of the retina and the photoreceptor. (*a*) Retinal layers. Note: the direction of light travel from the pupil is shown by the arrow.

direction.[47] Portions of the rod and cone cells that lie anterior to the ELM are not necessarily aligned with the pupillary aperture, and might be struck on the side, rather than on the axis, by the incident illumination. Some waveguiding is observed for a short distance into this region. However, these portions of the rod and cone cells anterior to the ELM would only be weakly excited by the incoming light.

Figure 5 shows the three-segment model that is generally used, denoting the idealized photoreceptor. All three segments are assumed to have a circular cross section, with uniform myoid and outer segment and a smoothly tapered ellipsoid. For receptors with equal myoid and outer segment radii, the ellipsoid is untapered. In this model, the sections are taken to be homogeneous, isotropic, and of higher refractive index than the surrounding near homogeneous and isotropic medium, which is the IPM. Both the myoid and the ellipsoid are assumed to be lossless, or nonabsorbing, since the cytochrome pigments in the mitochondria of the ellipsoids are not considered in this model. Absorption in the outer segments by the photolabile pigment molecules aligned within the closely packed disk membranes is described by the *Naperian absorption coefficient* (α). The aperture imposed at the ELM facilitates calculation of the equivalent illumination incident upon the receptor.

A number of assumptions and approximations have been made for these two models described above:

1. The receptor cross section is approximately circular and its axis is a straight line. This appears to be a reasonable assumption for the freshly excised tissue that is free of ocular diseases or pathology.
2. Ellipsoid taper is assumed to be smooth and gradual. Tapers that deviate from these conditions may introduce strong mode coupling and radiation loss.
3. Individual segments are assumed to be homogeneous. This is a first-order approximation, as each of the photoreceptor sections has different inclusions, which produce local inhomogeneities.

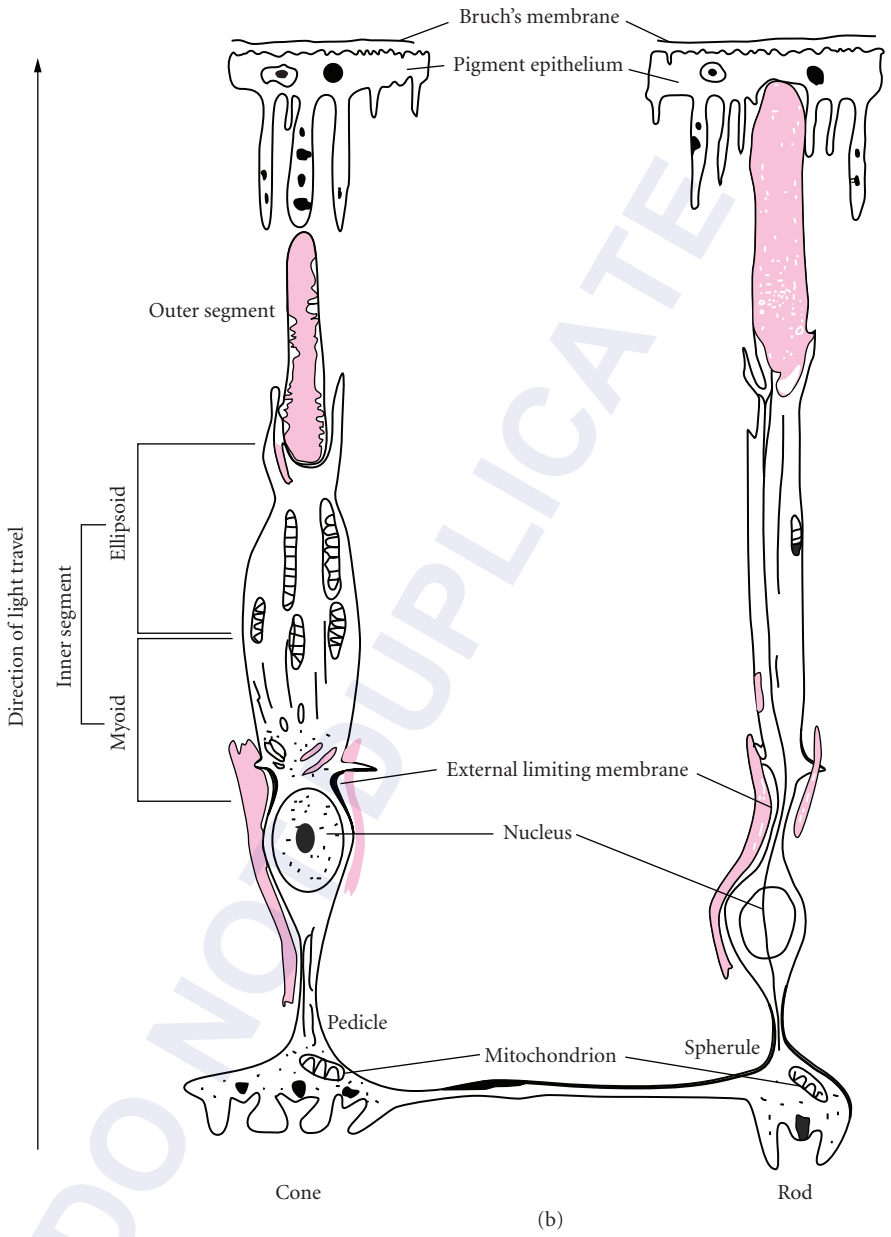

FIGURE 4 (*Continued*) (*b*) Structure of the cone and rod photoreceptor cells.

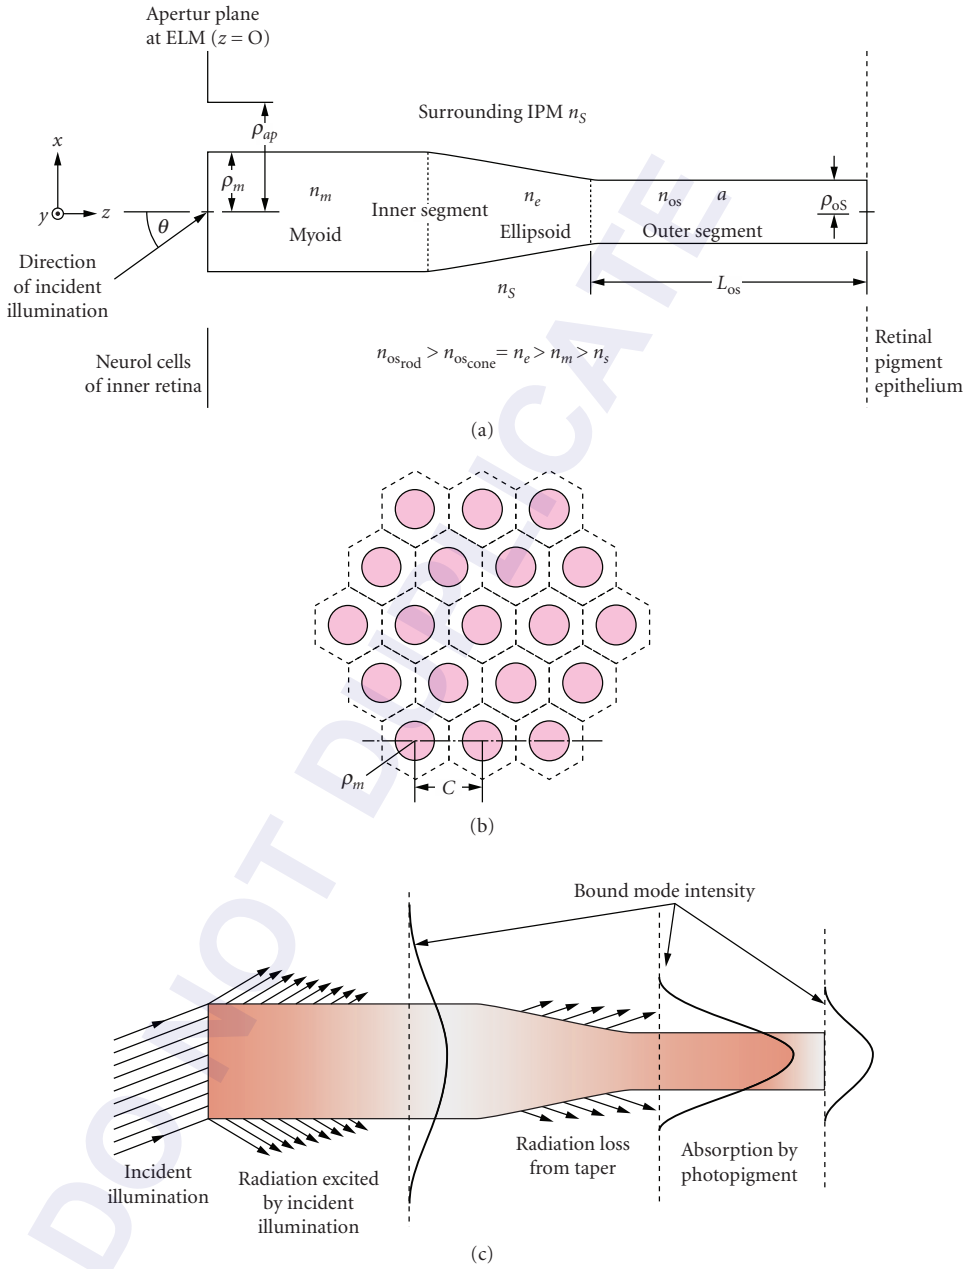

FIGURE 5 (*a*) Generalized three-segment model of an idealized photoreceptor. (*b*) View of retinal mosaic from the ELM (external limiting membrane), which is the aperture plane of the biological waveguide model for photoreceptors. The solid circles represent myoid cross sections. (*c*) Illustration of optical excitation of retinal photoreceptor showing radiation loss, funneling by ellipsoid taper, and absorption in the outer segment. Regions of darker shading represent greater light intensity.

4. Individual segments are assumed to be isotropic as a first-order approximation. However, in reality, the ellipsoid is packed with highly membranous mitochondria whose dimensions approach the wavelength of visible light, and which are shaped differently in different species. The mitochondrion-rich ellipsoid introduces light scattering and local inhomogeneity. The outer segment is composed of transversely stacked disks, having a repetition period an order of magnitude smaller than the wavelength of light; in addition, these outer segments contain photolabile pigment.
5. Linear media are assumed. Nonlinearities may arise from a number of sources. These could include the following:
   - Absorption of light is accompanied by bleaching of the photopigments and the production of absorbing photoproducts that have different absorption spectra from those of the pigments. Bleaching is energy and wavelength dependent and the bleached pigment is removed from the pool of available pigment, thus affecting the absorption spectrum. Under physiological conditions in the intact organism where pigment is constantly renewed, the relatively low illumination levels that result in a small percent bleach can be expected to be consistent with the assumed linearity. However, with very high illumination levels where renewal is virtually nonexistent, researchers must utilize special procedures to avoid obtaining distorted spectra (e.g., albino retina).
   - Nonlinearity may arise in the ellipsoid owing to illumination-dependent activity of the mitochondria, since it has been shown that mitochondria of ellipsoid exhibit metabolically linked mechanical effects. If such effects occurred in the retina, then illumination-driven activity could alter inner segment scattering.
   - Some species exhibit illumination-dependent photomechanical responses that result in gross movement of retinal photoreceptors. That movement is accompanied by an elongation or contraction of the myoid in the receptor inner segment and has been analyzed in terms of its action as an optical switch.[48] In affected species, rod myoids elongate and cone myoids shorten in the light, while rod myoids contract and the cone myoids elongate in the dark. In the light, then, the cones lie closer to the outer limiting membrane and away from the shielding effect of the pigment epithelial cell processes, and contain absorbed pigment, while the pigment granules migrate within the pigment epithelial processes.[49]
6. The refractive indices of the segment are assumed to be independent of wavelength, which completely contradicts the definition of the *refractive index,* which is $n = c/v$ where v (velocity) = f (frequency) $\cdot \lambda$ (wavelength), and v is proportional to wavelength because f is constant for all media. Therefore, a change in the velocity dependent on wavelength also changes the refractive index in real life.
7. The medium to the left of the external limiting membrane is assumed to be homogeneous. However, in reality, although the ocular media and inner (neural) retina are largely transparent, scattering does occur within the cornea, aqueous, lens, vitreous, and inner retina. Preparations of excised retina will be devoid of the ocular media, but the inner retina will be present. In turn, the preparations would account for light scattering upon light incidence.
8. It is assumed that the medium surrounding the photoreceptors is homogeneous and nonabsorbing. Again, this is an approximation. Microvilli originating in the Müller cells extend into the space between the inner segments, and microfibrils of the *retina pigment epithelium* (*RPE*) surround portions of the outer segments. Also, the assumption of homogeneity of the surround neglects the reflection and backscatter produced by the RPE, choroid, and sclera. Note that preparations of excised retinae that are used for observing waveguiding are usually (largely) devoid of interdigitating RPE.
9. In some species the outer segment is tapered. Gradual taper can be accommodated in the model. Sharp tapers, however, must be dealt with separately.
10. The exact location of the effective input plane to the retinal fiber optics bundle is not known; however, in early studies it was assumed that the ELM was the effective inner bound of the retinal fiber bundle. To date, though, universal agreement does not exist regarding the location of the effective input plane; some investigators assume it to be located at the outer segment level.

11. In species with double cones (e.g., goldfish), the two components may often not be of equal length or contain identical photolabile pigments.

Next, we will evaluate the electromagnetic validity of the preceding models based on the assumptions discussed above. An additional assumption is that meaningful results relating to the in situ properties of a retinal photoreceptor can be obtained by means of calculations performed upon a single photoreceptor model. Involved here are considerations regarding optical excitation, optical coupling between neighboring receptors, and the role of scattered light within the retina. These assumptions may be summarized as follows:

1. The illumination incident upon the single photoreceptor through the aperture in Fig. 5 is taken to be representative of that illumination available to an individual receptor located in the retinal mosaic. Figure 5*b* illustrates the cross section of a uniform receptor array as seen from the ELM. For a uniformly illuminated, infinitely extended array, the total illumination available to each receptor would be that falling on a single hexagonal area.
2. The open, or unbounded, transverse geometry of the dielectric waveguide supports two classes of modes, referred to as bound, guided, or trapped modes, and unbound, unguided, or radiation modes. Different behavior is exhibited by the two mode species. As their names suggest, the bound modes carry power along the waveguide, whereas the unbound or radiation modes carry power away from the guide into the radiation field (Fig. 5*c*). From a ray viewpoint, the bound modes are associated with rays that undergo total internal reflection and are trapped within the cylinder; unbound modes are associated with rays that refract or tunnel out of the cylinder. These modes are obtained as source-free solutions of Maxwell's equations and are represented in terms of Bessel and Hankel functions (for a cylindrical geometry). These mode shapes show a high degree of symmetry. A full discussion of waveguide theory can be found in Snyder and Love.[50]
3. Coherent illumination of the photoreceptors is assumed. Here, the equivalent aperture of the photoreceptor is defined to be the circle whose area is equal to that of the hexagon seen in Fig. 5*b* specified by the appropriate intercellular spacing and inner segment diameter.

The earliest analyses of light propagation within the retinal photoreceptors employed geometric optics. As early as 1843, Brucke discussed the photoreceptor's trapping of light via total internal reflection (as quoted by von Helmholtz),[51] but stopped just short of attributing a directionality to vision. In fact, Hannover had observed waveguide modes in photoreceptors,[52] but interpreted them as being cellular fine structure (Fig. 6). Interest resumed after the discovery of the Stiles-Crawford effect of the

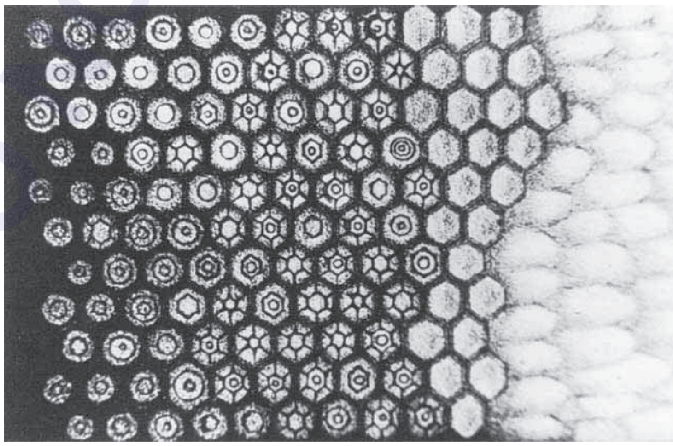

FIGURE 6 Drawing of frog outer segment viewed end-on. (*From Ref. 21.*)

first kind (SCE I). O'Brien[53] suggested a light-funneling effect produced by the tapered ellipsoids, and Winston and Enoch[54] employed geometric optics to investigate the light-collecting properties of the retinal photoreceptor.

Recall the behavior of rays incident upon the interface separating two dielectric media (see Fig. 7*a*). Rays incident from medium 1 at an angle θ_1 to the interface normal, will be refracted at an angle θ_2 in medium 2; the angles are related by Snell's law where:

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \tag{1}$$

where n_1 and n_2 are the refractive indices of media 1 and 2, respectively. As shown in Fig. 6*a,* the refracted rays are bent toward the interface, since the incidence is from a medium of greater refractive index toward a medium of lesser refractive index. In this situation, the limiting angle of incidence angle θ_L equals the critical angle of the total internal reflection, for which the refracted ray travels along the interface (angle $\theta_2 = 90°$); from Snell's law, the critical angle = arcsin (n_2/n_1). Rays incident at angles smaller than critical angle will undergo partial reflection and refraction; rays incident at angles equal to or larger than critical angle will undergo total internal reflection.

Let us now consider the pertinent geometry involved with a dielectric cylinder. A circular dielectric cylinder of refractive index n_1 is embedded in a lower-refractive-index surround n_2. Light is incident upon the fiber end face at an angle θ to the z or cylinder axis from a third medium of refractive index $n_3 < n_1$ (Fig. 7*b*). We consider the meridional rays, that is, rays which intersect the fiber axis. There are

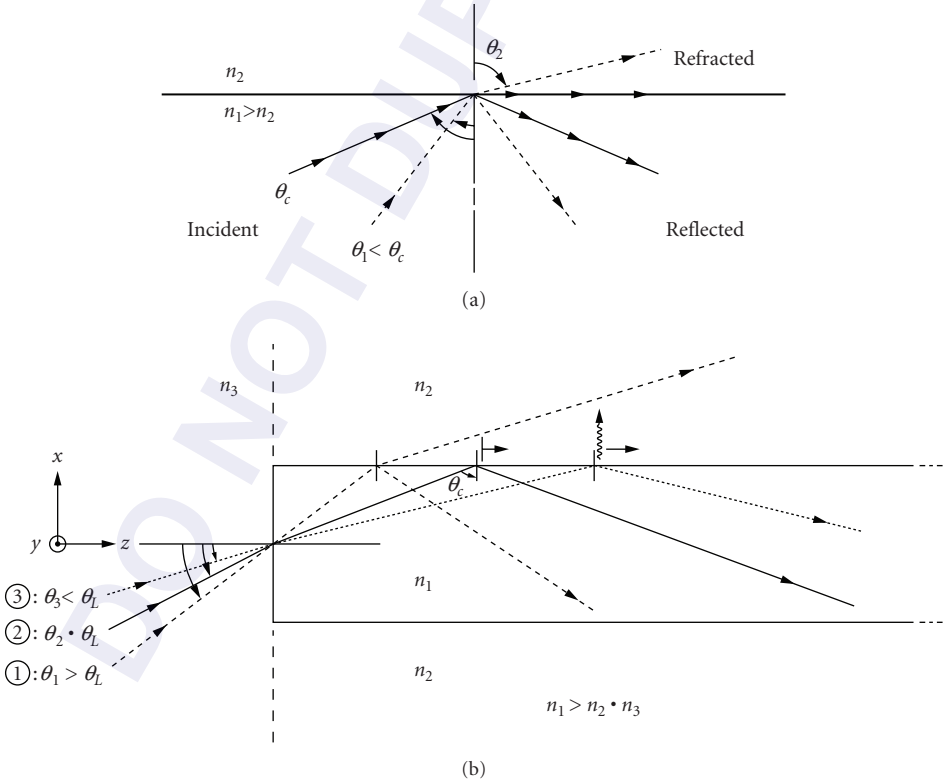

FIGURE 7 (*a*) Reflection and refraction of light rays incident upon an interface separating two different media. (*b*) Ray optics analysis of light incident on an idealized cylindrical photoreceptor (see text for details).

three possibilities for meridional rays, shown by rays 1 through 3. Once inside the cylinder, ray 1 is incident upon the side wall at an angle smaller than the critical angle, is only partially reflected, and produces, at each reflection, a refracted ray that carries power away from the fiber. Ray 2 is critically incident and is thus totally reflected; this ray forms the boundary separating meridional rays that are refracted out of the fiber from meridional rays that trapped within the fiber. Ray 3 is incident upon the side wall at an angle greater than the critical angle, and is trapped within the fiber by total internal reflection.

Ray optics thus predicts a limiting incidence angle θ_L, related to the critical angle via Snell's law, given by

$$n_3 \sin \theta_L = [(n_1)^2 - (n_2)^2]^{1/2} \tag{2}$$

for which incident meridional rays may be trapped within the fiber. Only those rays incident upon the fiber end face at angles $\theta <$ limiting angle θ_L are accepted; those incident at greater angles are quickly attenuated owing to refraction. The numerical aperture (NA) of the fiber is defined to be $n_3 \sin \theta_L$.

Application of meridional ray optics thus yields an acceptance property wherein only rays incident at $\theta < \theta_L$ are trapped within the fiber. One thing to note is that the greater the angle of incidence is, the faster the attenuation of light will be through the fiber. This result is consistent with results obtained with electromagnetic waveguide modal analysis, which show that the farther away from a cutoff a mode is, the more tightly bound to the cylinder it is, and the closer its central ray is to the cylinder axis.

Geometric optics predicts that an optical fiber can trap and guide light; however, it does not provide an accurate quantitative description of phenomena on fibers having diameters of the order of the wavelength of visible light, where diffraction effects are important. Also, taking a simplified electromagnetic analysis of the photoreceptor waveguide model, illumination is assumed to be monochromatic, and the first Born approximation[55]—which ignores the contribution of waves that are scattered by the apertures—is used to match the incident illumination in the equivalent truncating aperture to the modes of the lossless guide that represents the myoid. Modes excited on the myoid are then guided to the tapered ellipsoid. Some of the initially excited radiation field will have leaked away before the ellipsoid is reached. Each segment is dealt with separately; thus, the ellipsoid will guide or funnel the power received from the myoid to the outer segment. Since each segment is dealt with separately, and because the modes of those segments are identical to those of an infinitely extended cylinder of the same radius and refractive index, the dielectric structure is considered to have an infinite uniform dielectric cylinder of radius p and refractive index n_1 embedded in a lower-refractive-index surround n_2.

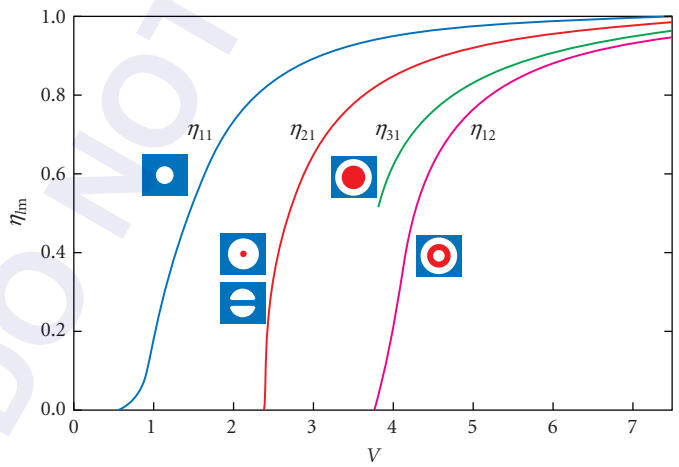
8.7 QUANTITATIVE OBSERVATIONS OF SINGLE RECEPTORS

The first observations of waveguide modal patterns in photoreceptors were made by Enoch.[47,56–58] Given that vertebrate photoreceptors act as waveguides, in order to treat the optics of a single receptor theoretically, it is modeled as a cylindrical waveguide of circular symmetry, with two fixed indices of refraction inside and outside the guide. Note that light is propagated along the guide in one or more of a set of modes, each associated with a characteristic three-dimensional distribution of energy density in the guide. In the ideal guide their distributions may be very nonuniform but will show a high degree of symmetry. Modes are grouped into orders, related to the number of distinct modal surfaces on which the electromagnetic fields go to zero. Thus, in Fig. 8, the lowest (first) order mode (designated HE_{11}) goes to zero only at an infinite distance from the guide axis. Note that for all modes the fields extend to infinity in principle. At the terminus of the guide the fiber effectively becomes an antenna, radiating light energy into space. If one observes the end of an optical waveguide with a microscope, one sees a more or less complex pattern of light which roughly approximates a cross section through the modes being transmitted.

Modal patterns

Designations	Nagative form	Cutoff
HE_{11}		0.0
TE_{01}, TM_{01}		2.405
HE_{21}		2.4+
(TE_{01} or TM_{o1}) + HE_{21}		2.4+
HE_{12}		3.812
EH_{11}		3.812
HE_{31}		3.8+
HE_{12} + (HE_{31} $\overset{+}{\text{or}}$ EH_{11})		3.8+
HE_{13} + EH_{11}		3.8+
EH_{21} or HE_{41}		5.2
TE_{02}, TM_{02}, HE_{22}		5.52
(TE_{02} or TM_{02}) + HE_{22}		5.52

(a)



(b)

FIGURE 8 (*a*) Some commonly observed modal patterns found in human photoreceptors; their designations and V values. (*b*) The fraction of transmitted energy as a function of the V parameter for some commonly observed modal patterns.

The optical properties of the ideal guide are completely determined by a parameter called the *waveguide parameter V,* defined by

$$V = (\pi d/\lambda)\ [(n_1)^2 - (n_0)^2]^{1/2} \tag{3}$$

where d is the diameter of the guide, λ the wavelength in vacuum, and n_1 and n_0 are the indices of refraction of the inside (core) and outside (cladding) of the fiber, respectively. For a given guide, V is readily changed by changing wavelength as shown above. With one exception, each of the various modes is associated with a cutoff value, V_c, below which light cannot propagate indefinitely along the fiber in that mode. Again, the lowest order, HE_{11}, mode does not have a cutoff value. V may be regarded as setting the radial scale of the energy distribution; for $V >> V_c$, the energy is concentrated near the axis of the guide with relatively little transmitted outside the core. As V approaches V_c, the energy spreads out with proportionally more being transmitted outside the guide wall. A quantity η (not to be confused with the relative luminous efficiency defined for SCE I) has been defined that represents the fraction of transmitted energy which propagates inside the guide wall. For a given mode or combination of modes and given V, η can be evaluated from waveguide theory. Figure 8*a* shows schematic representations of the mode patterns commonly observed in vertebrate receptors, cochlear hair cells, cilia (various), and the like, together with V_c for the corresponding modes. Figure 8*b* shows values of η as a function of V for some of the lower order modes.[59]

It is evident that an understanding of receptor waveguide behavior requires a determination of V for a range of typical receptors. An obvious straightforward approach is suggested, where if one could determine V at any one wavelength, it could be found for other wavelengths by simple calculation. How is this done? If one observes a flat retinal preparation illuminated by a monochromator so that the mode patterns are sharp, then by rapidly changing the wavelength throughout the visible spectrum, some of the receptors will show an abrupt change of the pattern from one mode to another. This behavior suggests that for these receptors V is moving through the value of V_c for the more complex mode resulting in a change in the dominant mode being excited. To be valid, this approach requires that the fraction of energy within the guide (η) should fall abruptly to zero at cutoff. In experimental studies, it has been shown that η does go to zero at cutoff for the second-order modes characterized by bilobed or thick annular patterns as shown in Fig. 8. These modes include HE_{12}, TE_{01}, TM_{01}, $TM_{01}(TE_{01} + HE_{21})$, and $(TM_{01} + HE_{21})$. Figure 9 displays some waveguide modes obtained in humans and monkeys, as well as variation with wavelength. In turn, it has been discovered that these second-order modal patterns are by far the most frequently observed in small-diameter mammalian receptors. Also, a detailed understanding of receptor-waveguide behavior requires accurate values for guide diameters. Another fact to note concerning parameter V is that the indices of refraction of the entire dielectric cylinder are fairly constant with no pronounced change in waveguide behavior as determined from past experimental studies. For reinforcement, considerable power is carried outside the fiber for low (above cutoff) values of V. In the limit as $V \rightarrow$ infinity, the mode's total power is carried within the fiber.

The most complete study of the electrodynamics of visible-light interaction with the outer segment of the vertebrate rod based on detailed, first-principles computational electromagnetics modeling using a direct time integration of Maxwell's equation in a two-dimensional space grid for both transverse-magnetic and transverse-electric vector field modes was presented by Piket-May, Taflove, and Troy.[60] Detailed maps of the standing wave within the rod were generated (Fig. 10). The standing-wave data were Fourier analyzed to obtain spatial frequency spectra. Except for isolated peaks, the spatial frequency spectra were found to be essentially independent of the illumination wavelength. This finding seems to support the hypothesis that the electrodynamic properties of the rod contribute little if at all to the wavelength specificity of optical absorption.[61] Frequency-independent structures have found major applications in broad band transmission and reception of radio-frequency and microwave signals. As Piket-May et al.[60] point out, it is conceivable that some engineering application of frequency-independent, retinal-rod-like structures may eventually result for optical signal processing.

8.8 WAVEGUIDE MODAL PATTERNS FOUND IN MONKEY/HUMAN RETINAL RECEPTORS

When a given modal pattern is excited, the wavelength composition of the energy associated with the propagation of that pattern in the retinal receptor (acting as a waveguide) may differ from the total distribution of energy at the point of incidence; for it is important to realize that the energy which is not transmitted is not necessarily absorbed by the receptor. It may be reflected and refracted out of the receptor. A distinct wavelength separation mechanism is seen to exist in those retinal

receptors observed. In some instances, one type of modal pattern was seen having a dominant hue. Where multiple colors were seen in a given receptor unit, those colors in some instances were due to changes in modal pattern with wavelength. The appearance of multiple colors, observed when viewing the outer segments, occurred in some receptors where mode coupling or interactive effects were present. There are differences in the wavelength distribution of the energy transmitted to the terminal end of the receptor. In addition, there are differences in the spatial or regional distribution of that energy within the outer segments as a function of wavelength due to the presence of different modal patterns and interactions governed by parameter V.[62]

If the same well-oriented central foveal receptors of humans are illuminated at three angles of obliquity of incident light, other changes are observed. It is observed subjectively that increased obliquity results in more red being transmitted, or less yellow and green being seen. Why does this occur? This phenomenon is dependent on the angle of incidence of light upon the receptor and the spectral sensitivity of the outer segment. First, the angle of incidence of light upon the receptor determines the amount of light transmitted through the receptor, as shown. Therefore, different values of V result in different amounts of light being collected for a fixed angle of incidence, as well as in different shapes, hence, in different widths, of the respective selectivity curves. Also, as the angle of incidence approaches the limiting angle, there is a decrease in the amount of bound-mode power of light transmitted through the receptor. In turn, absorption is greater for the larger-diameter receptors which, having higher V values, are more efficient at collecting light. So for higher amounts of light transmitted through the receptor with less contrast of different hues, the receptor has a high V value (large myoid diameter) and the light incident upon it is closer to normal to the myoid's surface versus its limiting angle. Another fact to note is that the absorption peak occurs at decreasing wavelengths for decreasing receptor radius, and the absorption curves broaden for decreasing radius of outer segment.

Also, since wavelength transmissivity, as well as total transmissivity, changes with obliquity of incidence, it may be further assumed that receptors that are not oriented properly in the retina will not respond to stimuli in the same manner as receptors that are oriented properly. In other words, disturbance in the orientation of receptors should result in some degree of anomalous color vision as well as visual acuity.[55,63–65]

It has been suggested that Henle fibers found in the retina may act as optical fibers directing light toward the center of the fovea.[66] Henle fibers arise from cone cell bodies, and turn horizontally to run radially outward from the center of the fovea, parallel to the retinal surface. At the foveal periphery, the Henle fibers turn again, perpendicular to the retinal surface, and expand into cone pedicules. Pedicules of foveal cones form an annulus around the fovea. Cone pedicules are located between 100 to 1000 μm from the center of the fovea and the Henle fibers connecting them to cone photoreceptor nuclear regions can be up to 300 μm long. If this hypothesis is correct, then Henle fiber-optic transmission could increase foveal irradiance, channeling short wavelength light from perifoveal pedicules to the central fovea and increasing the fovea's risk of photochemical damage from intense light exposure. This property has also been suggested as a reason for foveomacular retinitis burn without direct solar observation and could also be considered as a previously unsuspected risk in perifoveal laser photocoagulation therapy.

More recently, Franze et al.[67] investigated intact retinal tissue and individual Muller cells, which are radial glial cells spanning the entire thickness of the retina. Transmission and reflection confocal microscopy of retinal tissue in vivo and in vitro showed that these cells provide a low scattering passage for light from the retinal surface to the photoreceptors. In addition, using a modified dual beam laser trap, these researchers were able to demonstrate that these individual cells act as optical fibers. Their parallel array in the retina is analogous to fiberoptic plates used for low-distortion image transfer. It should be noted that these cells have an extended funnel shape, a higher refractive index than their surrounding tissue and are oriented along the direction of light propagation. Calculation of the V parameter showed that it varied from 2.6 to 2.9 (at 700 nm) for the different parts along the Muller cell, which is sufficiently high for low loss propagation of a few modes in the structure at this long wavelength. In the more intermediate wavelengths, the V varies from 3.6 to 4.0. Even though the refractive index and diameter of the cells change along their length, the V parameter and thus, their light guiding capability is very nearly constant. Unlike photoreceptors, muller cells do not have

the smooth cylindrical shape and have complex side branching processes. Their inclusion, using an "effective index" actually increases the *V* parameter. Therefore, even though Muller cells have a complex morphology, they can function as optical waveguides for visible light.

Modern theories of the Stiles-Crawford Effect I (SCE I) have used waveguide analysis to describe the effect. The most noteworthy is that of Snyder and Pask.[68] Snyder and Pask hypothesized an ideal "average" foveal cone with uniform dimensions and refractive indices. The cone is thought to be made up of two cylinders representing inner and outer segments. The response of a single cone is assumed to be a monotonically increasing function of absorbed light. The psychophysical response is assumed to be a linear combination of single-cone responses. Values of various parameters in the associated equations were adjusted to fit the wavelength variation of the SCE I reported by Stiles.[69] The model predicts the magnitude and trends of the experimental data (Fig. 11). The predictions, however, are highly dependent on the choice of refractive indices. Even small variations (~0.5%) produce enormous changes in the results. The model is based not upon the absorption of light, but upon transmitted modal power. Other waveguide models include those of, for example, Alpern,[70] Starr,[71] and Wijngaard et al.[72] These papers deal with SCE II, the color effect. Additionally, Goyal et al.[73] have proposed an inhomogeneous waveguide model for cones. Vohnsen and his colleagues[74,75] have modified the existing models by making an important assumption, namely that instead of assuming that the light that propagates as rays in the eye to/from photoreceptors are propagated as waves. This implies that diffraction of both the incoming beam and the light emanated by the photoreceptors has to be included in the analysis. The mode field is approximated as a Gaussian. This is an important modification, since diffraction effects in relation to waveguide coupling have not been considered in previous models. Using this model it is possible to derive analytical expressions for the directionality parameters. The model also approximates the overall wavelength variation of directionality.

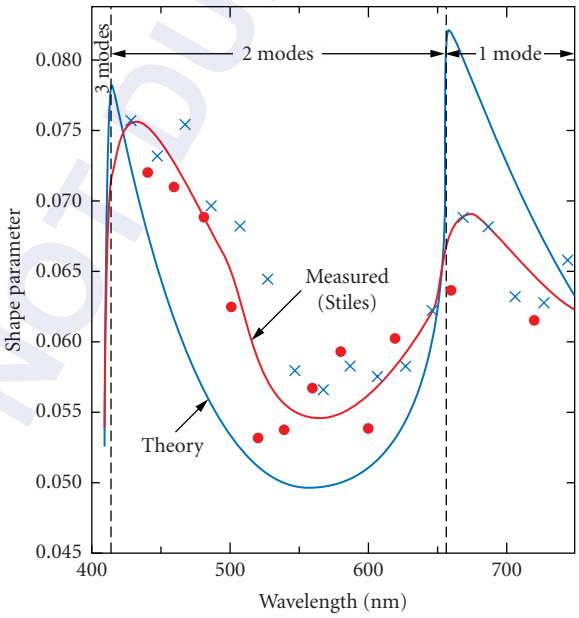

FIGURE 11 The idealized cone model of Snyder and Pask. (*From Ref. 31*) Here the magnitude of the shape parameter (the curvature of the SCE function) is plotted as a function of the wavelength. The blue curve is the theoretical prediction and the red curve is plotted through Stiles's experimental points. Note the qualitative agreement between theory and experiment.

When phase variations (say, due to aberrations) of the field incident at the photoreceptor aperture are considered, the model predicts that the finite width of photoreceptors not only leads to a slight broadening of the point spread function, but also reduces the impact of aberrations on the visual sensation that is produced. This may play a role in accommodation, since a defocused image couples less light.

A caveat when considering waveguide models is that attention must be given to the physical assumptions made. These, along with uncertainties in the values of various physical parameters (e.g., refractive index), can seriously affect the results and hence the conclusions drawn from these models.

A formalism for modal analysis in absorbing photoreceptor waveguides has been presented by Lakshminarayanan and Calvo.[76–78] Here, an exact expression for the fraction of total energy confined in a waveguide was derived and applied to the case of a cylindrically symmetric waveguide supporting both the zeroth- and first-order sets of excited modes. The fraction of energy flow confined within the cylinder can be decomposed into two factors, one containing a Z-dependence (Z is direction of cylinder axis) as a damping term and the second as a Z-dependent oscillatory term. It should be noted that because of non-negligible absorption, Bessel and Hankel functions with complex arguments have to be dealt with. Using this formalism, if it is found that, using physiological data, the attenuation of the fraction of confined power increased with distance, the energy is completely absorbed for a penetration distance $Z > 60$ μm.

More interesting results are obtained when two neighboring waveguides separated by a distance of the order of the wavelength (a situation found in the foveal photoreceptor mosaic) are considered. An incoherent superposition of the intensity functions in the two waveguides is assumed. The results are shown in Fig. 12. The radial distribution of transmitted energy for two values of core radius (0.45 μm

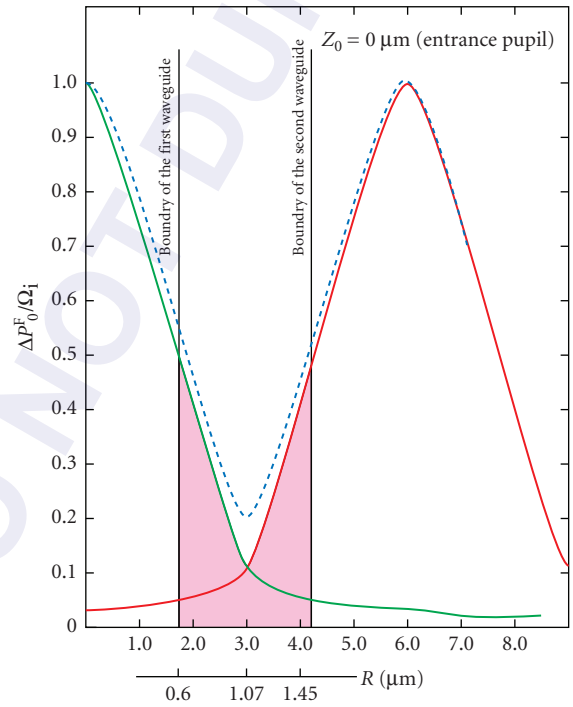

FIGURE 12 Effect of two neighboring absorbing waveguide photoreceptors on the fraction of confined power per unit area. The pink area denotes the region in which the energy of both wave-guides is "cooperative."

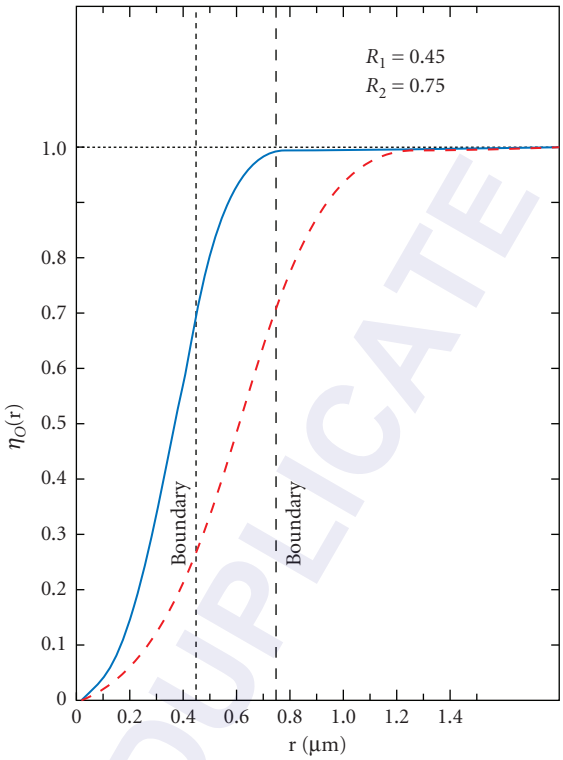

FIGURE 13 Flow of transmitted energy in a monomode absorbing waveguide for two value of the core radius (blue lines—0.45 μm; red line—0.75 μm) (see text for details).

and 0.75 μm) is shown in Fig. 13. It is seen that 70 percent of the energy is still confined within the waveguide boundary, with some percentage flowing into the cladding, producing an "efficient" waveguide with radius of the order of 0.75 μm and 0.95 μm in the two cases. This effect together with the incoherent superposition implies a mechanism wherein as light propagates along the waveguide, there is a two-way transverse distribution of energy from both sides of the waveguide boundary, providing a continuous energy flow while avoiding complete attenuation of the transmitted signal. Analysis also showed that for specific values of the modal parameters, some energy can escape in a direction transverse to the waveguide axis at specific points of the boundary. This mechanism, a result of the Z-dependent oscillatory term, also helps to avoid complete attenuation of the transmitted signal.

The spatial impulse response of a single-variable cross-section photoreceptor has been analyzed by Lakshminarayanan and Calvo.[79] The modal field propagating under strict confinement conditions can be shown to be written in terms of a superposition integral which describes the behavior of a spatially invariant system. Using standard techniques of linear systems analysis, it is possible to obtain the modulation transfer functions of the inner and outer segments. This analysis neglects scattering and reflection at the inner-outer segment interface. The transfer function depends on both the modal parameter defining the waveguide regime and spatial frequency (Fig. 14). It is seen that both inner and outer segments behave as low-pass filters, although for the outer segment a wide frequency range is obtained, especially for the longer wavelengths. Using a different analysis, Stacey and Pask[80,81] have shown similar results and conclude that photoreceptors themselves contribute to visual acuity

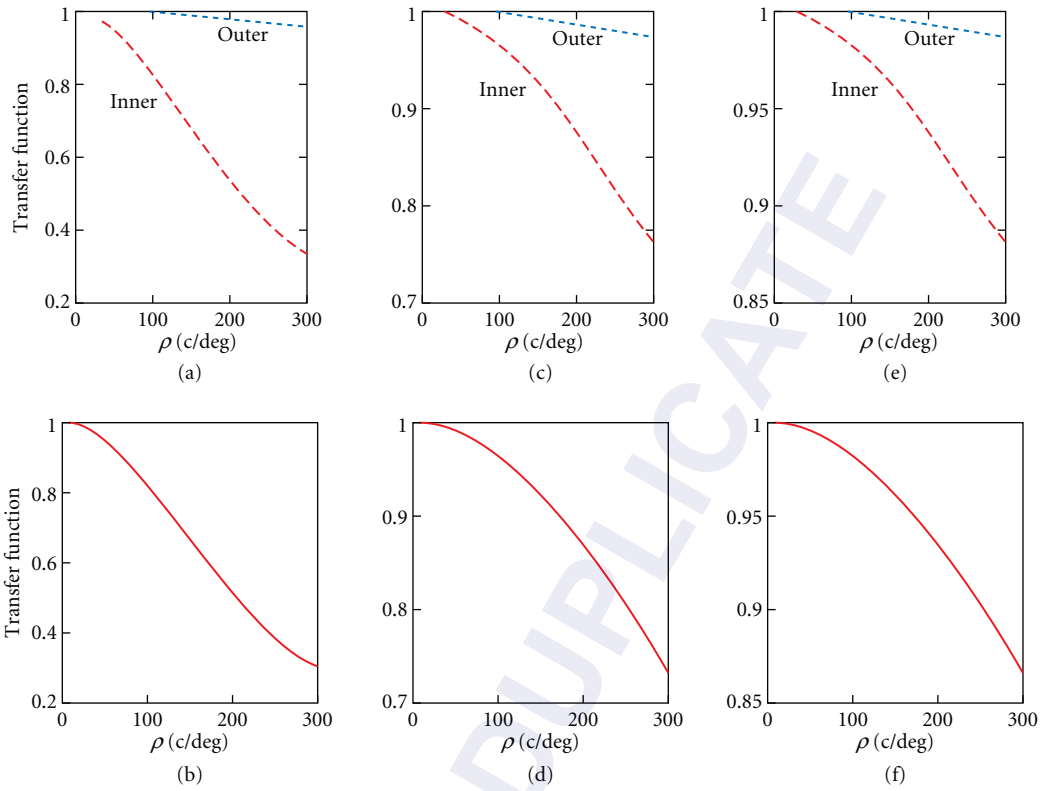

FIGURE 14 Transfer function of the inner and outer segments (top) and the total transfer function of the photoreceptor for three wavelengths: 680, 550, and 460 nm. The values of the modal parameters are fixed. Horizontal axis is in units of cycles/degree.

through a wavelength-dependent response at each spatial frequency and that the response is dependent on the coherence of the source. They have used this model to study the Campbell effect. (When measuring human visual acuity with an incoherent source, Campbell,[82] noticed that the response decreased markedly when an artificial pupil placed in front of the eye was displaced perpendicular to the test fringes. There was no observed reduction when the pupil was displaced parallel to the fringes.) They conclude[83] that the waveguiding properties of photoreceptors make them sensitive to obliquely incident exciting waves and this provides some support for the hypothesis that both the SCE and the Campbell effect are manifestations of the same underlying waveguide nature of the photoreceptors.[83,84]

8.9 LIGHT GUIDE EFFECT IN COCHLEAR HAIR CELLS AND HUMAN HAIR

The vibration of the organ of Corti in response to sound is becoming evident at the cellular level using the optical waveguide property of cochlear hair cells to study the motion of single hair cells. It has been reported that conspicuous, well-defined bright spots can be seen on the transilluminated organ of Corti. The spots are arranged in the mosaic fashion of hair cells known from surface views of the organ of Corti.[85] Thus, the hair cells appear to act as light guides. Also, a definite property of

biological waveguide requires the extracellular matrix or fluid to be lower in refractive index as compared to the fiber (in this case, cochlear hair cell), and this property has been elucidated by phase-contrast micrographs of cochlear hair cells.[86]

Cochlear hair cells are transparent, nearly cylindrical bodies with a refractive index higher than the surrounding medium. Inner hair cells are optically denser than the surrounding supporting cells, and outer hair cells are optically denser than the surrounding cochlear fluid. Therefore, in optical studies, hair cells may be considered as optical fibers and the organ of Corti as a fiber-optics array. Even though the significance of the function of the organ of Corti in audition is understood, the role of waveguiding in hair cells is not clearly established.

To check for light-guide action, a broad light is usually used so that many hair cells show up simultaneously as light guides. For broad beams the conditions of light entrance into individual cells are not specified. Light can enter hair cells along the cylindrical wall. Part of such light is scattered at optical discontinuities inside the cells. To a large extent scattered light is trapped in cells by total internal reflection. Thus, to maximize contrast for transillumination with broad beams, no direct light is allowed to enter the microscope. Areas with hair cells appear dark. However, the heads of hair cells appear brightly illuminated owing to the light-collecting effect of hair cells on scattered light. Also, the diameter of cochlear hair cells is from 5 to 9 μm, that is, 10 to 20 times the wavelength of light. In fiber optics, fibers with diameters larger than 10 to 20 times the wavelength are considered multimodal because they support a large number of characteristic modes of light-energy propagation. Fibers with diameters smaller than 10 to 20 times the wavelength support fewer modes, and discrete modes of light-energy propagation can be launched more readily. Because of this division, cochlear hair cells fall in between typically single-mode and multimode optical fibers.[87] Also, an important parameter for the evaluation of fibers with small diameters is the parameter *V.* Recall that the smaller parameter *V,* the smaller the number of discrete modes a given fiber is capable of supporting. In addition, parameter *V* is greater for cochlear hair cells than for retinal receptor cells mainly because they have larger diameters than retinal rods and cones (see above for parameter *V*).

Gross features of surface preparations of the organ of Corti can be recognized with the binocular dissecting microscope. When viewed, the rows of hair cells can be seen as strings of bright pearls. Bright spots in the region of hair cells are due to light transmission through hair cells. Bright spots disappear when hair cells are removed.

Helmholtz's reciprocity theorem of optics[55] (reversibility of light path) also applies to hair cells where exit radiation pattern is equivalent to entrance radiation pattern. There is no basic difference in light-guide action when the directions of illumination and observation are reversed compared to the normal directions. Obviously, Helmholtz's theorem applies to visual photoreceptors too, since they are just modified cilia.

It is also seen that the detection of light guidance is shown to strongly correlate with the viewing angle, where incident light hits the numerical aperture of the hair cell, which is 30 to 40°. When the incident light is normal to the numerical aperture of the hair cell, higher transmittance of light and contrast is observed; however, at more oblique angles to the numerical aperture of the hair cell, less contrast is observed because the angle of incident light is approaching the limiting angle, which is a limit to total internal reflection and more refraction or scattering of rays occurs through the fiber.

A useful tool for studying the quality and preservation of preparations of organ of Corti utilizes the concept that hair cells show little change in appearance under the light microscope for up to 20 to 40 min after the death of an animal. Consequently, poor fixation and preservation of the organ of Corti can be recognized immediately at low levels of magnification.

To study the modal light intensity distributions on single hair cells, researchers use a monocular microscope. Hair cells exercise relatively little mode selection, which is to be expected because of their relatively large diameters (large parameter *V*). As the monocular microscope is focused up and down individual hair cells, it is seen that the intensity distributions in different cross sections of hair cells may differ. Focusing above the exit of hair cells shows that the near-field radiation pattern may differ from the intensity distribution on the cell exit. Furthermore, other studies have shown that the modal distribution of light intensity can be changed drastically for individual cells by changing the angle of light incidence relative to the axis of hair cells. Also, several low-order patterns on the exit end of single hair cells are easily identifiable and are designated according to the customary notation.

As a note, since cochlear hair cells show relatively little mode selection, it is not always possible to launch a desired mode pattern on a given cell with ordinary light. In order to restrict the spectrum of possible modes, it is advantageous to work with monochromatic, coherent light, that is, laser light. However, the identification of patterns relative to the cells was found to be difficult. This is due to the fact that laser stray light is highly structured (speckled), which makes it difficult to focus the microscope and to recognize cell boundaries. Light guidance in cochlear hair cells may be considered to be a general research tool for cochlear investigations in situations where the organ of Corti can be transilluminated and where relatively low levels of magnification are desirable.

Furthermore, biological waveguide effects have also been shown to occur in human hair,[88] which are similar to cochlear hair cell waveguide effects. There is a reduction in light intensity with increased hair length, but by far the most important factor was hair color. Little or no light was transmitted by brown hair, while gray hair acts as a natural fiber optic which can transmit light to its matrix, the follicular epithelium, and to the dermis. Interestingly, whether light transmission down hairs affects skin and hair needs investigation. As pointed out by Enoch and Lakshminarayanan,[89] many major sensory systems incorporate cilia in their structure. In the eye, the invagination of the neural groove of the surface ectoderm of the embryo leads to the development and elaboration of the nervous system. The infolding and incorporation of surface tissue within the embryo accounts for the presence of ciliated cells within nervous tissue neurons, which after maturation form photoreceptors containing cilia, lining the outer wall of the collapsed brain ventricle that will form the retina (see Oyster[90] for a description of the embryology and growth of the retina). A study of the evolution of the relationships between cilia and specific sensory systems would be of great interest.

8.10 FIBER-OPTIC PLANT TISSUES

Dark-grown (etiolated) plant tissues are analogous to multiple fiber-optic bundles capable of coherent transfer of light over at least 20 mm; hence, they can transmit a simple pattern faithfully along their length. Each tissue examined can accept incident light at or above certain angles relative to normal as is expected of any optical waveguide. The peak of the curve that describes this angular dependence, the acceptance angle, and the overall shape of the curve appear to be characteristic of a given plant species and not of its individual organs.[91] Knowledge of this optical phenomenon has permitted localization of the site of photoreception for certain photomorphogenic responses in etiolated oats. Before the discussion of the fiber-optic properties of etiolated plant tissues, it is important to have a general idea of what plant structures are presently being discussed to get a full understanding of the structure to function relationship (Fig. 15). To define, the *epicotyl* is a region of shoot above the point of attachment of the cotyledons, often bearing the first foliage leaves. The *hypocotyl* is the part of the embryo proper below the point of attachment of the cotyledons; it will form the first part of the stem of the young plant. The *coleoptile* is a cylindrical sheath that encloses the first leaves of seedlings of grasses and their relatives.

Total internal reflection of light should be independent of fluence rate since this phenomenon is simply a special case of light scattering. The amount of light emerging from the tissue segment was measured first at the highest fluence rate available and then again when the incident light beam had been attenuated with one or more calibrated neutral density filters over a range of 4.5 absorbance units. The amount of light axially transmitted at a given fluence rate (expressed as a percentage of the amount transmitted at the highest fluence rate for individual tissue segments) decreased log-linearly as filters of increasing absorbance were used for oat, mung bean, and corn tissues. Therefore, light guiding in etiolated tissues is clearly fluencerate-independent over at least 4.5 orders of magnitude.[92]

Light guiding through segments of etiolated root, stem, and coleoptiles, plus primary leaves from several species, all display the spectral dependence expected of any light scattering agent, with low transmission in the blue relative to that in the far-red regions of the spectrum. As tissue length increases, the difference between transmissions in the blue and far-red regions of the spectrum increases.

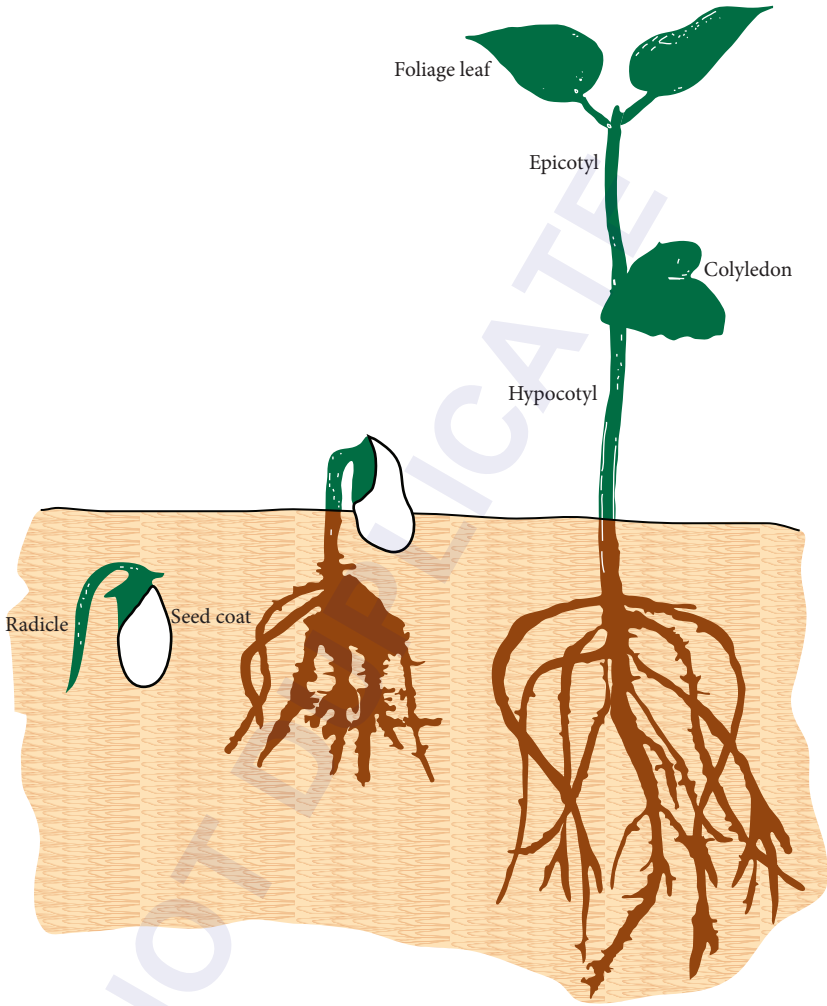

FIGURE 15 General structure of plant tissues.

It has been found that the spectra obtained when the incident beam of white light is applied to the side of the intact plant are indistinguishable from those obtained when the cut end of a tissue is irradiated. Spectra taken on tissue segments excised from different regions of the plant may show traces of certain pigments present only in those regions. Whereas there are no differences between spectra of the apical and basal portions of oat mesocotyls, the hook regions of mung bean hypocotyls contain small amounts of carotenoids, which is indicated as a small dip in the transmittance curve that is absent in spectra from the lower hypocotyl or hypocotyl-root transition zone. Oat coleoptilar nodes, which join the mesocotyl to the coleoptile, decrease light transmission from one organ to another when light is passed from the coleoptile to the mesocotyl or from the mesocotyl to the coleoptile, respectively, but show a spectral dependence which is independent of the direction of light transmission based on Helmholtz's reciprocity theorem of light. Older etiolated leaves do not transmit red light axially relative to the cylindrical coleoptile which sheaths them. Consequently, the presence or absence of the primary leaves does not alter the spectrum of the etiolated coleoptile.

Plant tissues mainly consist of vertical columns of cells. Light internally reflected through them passes predominantly along these columns of cells rather than across columns when the incident beam is at or above the tissue acceptance angle.[91] As optical fibers, the tissues are about 10 percent as effective as glass rods of comparable diameter, and about 1 percent as effective as commercial fiber optics.[92] Within a given cell, light could be traveling predominantly in the cell wall, the cytoplasm, the vacuole, or any combination of these three compartments. Observations of the cut ends of tissue segments that are light-guiding indicate that the cell wall does not transmit light axially but that the cell interior does. Also, plant cells contain pigments that are naturally restricted to the vacuole or to the cytoplasmic organelles. Mung bean hypocotyls contain carotenoids (absorption maxima near 450 nm), which are located in the etioplasts, organelles found only in the cytoplasm, whereas etiolated beet and rhubarb stems are composed of cells with clear cytoplasm and vacuoles containing betacyanin and/or anthocyania (absorption maxima near 525 to 530 nm). Spectra of the light guided through these tissues show that light guiding occurs both through the cytoplasm and the vacuole. The relative size of each compartment, the pigment concentration, and the refractive indices involved will largely determine the amount of light that a given compartment will transmit. As the seedlings are exposed to light and become green, troughs due to absorption by chlorophylls (near 670 nm) appear. Completely greened tissue has very little light-guiding capacity except in the far-red region of the spectrum.

Also, the red to far-red (R/FR) ratio determines the fraction of phytochrome in the active state in the plant cell.[93] This ratio plays an important role in the regulation of growth. Similarly, the blue to red (B/R) ratio may be important for responses mediated by phytochrome alone when transmission is low in the red relative to the blue, or for those mediated by both phytochrome and a pigment absorbing blue light. The R/FR ratio of the light emitted from several curved, etiolated plant tissues decreases as the tissue length increases. However, the patterns of change in the B/R ratio differ with each tissue examined. All B/R ratios presumably decrease along the first 20 mm of tissues but in mung hypocotyl (stem) this ratio then increases, whereas in oat mesocotyl it increases and then decreases further. Changes in the R/FR and B/R ratios also occur in a given length of tissue as it becomes green. The R/FR ratio does not change in tissues that remain white (i.e., oat mesocotyl) but decreases dramatically in those that synthesize pigments (i.e., oat coleoptile or mung bean, beet, and rhubarb stems). The B/R ratios, unlike the R/FR ratios, tend to increase as the tissues becomes green, reflecting a smaller decrease in transmission at 450 nm than 660 nm as pigments accumulate.

All of these results demonstrate certain properties of light-guiding effects in plants: the fluence-rate independence of light guiding in plants; an increase in tissue length showing a more pronounced difference between transmission in the blue and far-red regions of the spectra; and the effect of the greening status on the pertinent R/FR and B/R ratios for several species of plants grown under a variety of conditions. Certainly, both the B/R and the R/FR ratios change dramatically in light that is internally reflected through plants as etiolated tissue length is increased and as greening occurs. Finally, the sensitivity of etiolated plant tissues to small fluences of light and the inherent capacity of plants to detect and respond to small variations in the R/FR ratio indicate that light guiding occurring in etiolated plants beneath the soil and the concomitant spectral changes that occur along the length of the plant may be of importance in determining and/or fine-tuning the plant's photomorphogenic response.[94,95]

8.11 SPONGES

Recently, researchers at Bell Laboratories studied the fiber optical features of a deep sea organism, namely, the glass sponge (*Euplectella*, "venus flower basket").[96] The spicules of these sponges have some remarkable fiber optic properties. The skeleton of the hexactinellid class of sponges is constructed from amorphous hydrated silica. The sponge has a lattice of fused spicules that provide extended structural support. The spicules are 5 to 15 cm long and 40 to 70 μm in diameter. The spicules have a characteristic layered morphology and a cross-sectional variation in composition: a pure silica core of about 2 μm in diameter that enclosed an organic filament, a central cylinder with maximum organic material and a striated shell that has a gradually decreasing organic content.

The researchers conducted interferometric index profiling and found that corresponding to the three regions, there was a core with a high refractive index that is comparable to or higher than that of vitreous silica, a cylinder of lower refractive index that surrounds the core and an oscillating pattern with progressively increasing refractive index at the outer part of the spicule. These embedded spicules act as single or a few-mode waveguides. When light was coupled to free standing spicules, they functioned as multimode fibers.

These fibers are similar to commercial telecommunication fibers in that they are made of the same material and have comparable dimensions. They also function as efficient as single-mode, few-mode, or multi-mode, fibers depending upon optical launch conditions.

In addition, it is possible that these spicules in addition to providing structural anchorage support, could also act as a fiber optic network for distributing light in the deep sea environment. The fascinating aspect of these fibers is that they are made under ambient conditions, as opposed to commercial manufactured fibers which require very high temperatures (about 1700°C). Organic ligands at the exterior of the fiber seem to protect it and provide an effective crack-arresting mechanism and the fibers seem to be doped with specialized impurities that improve the refractive index profile and hence the waveguiding properties.

8.12 SUMMARY

In short, we have pointed out some similar relationships between the theoretical waveguide models and the actual biological waveguides such as vertebrate photoreceptors, cochlear hair cells of the inner ear, human hair (cilia), and fiber-optic plant tissues. The similar relationships between the theoretical model of waveguides and actual biological waveguides were demonstrated as (a) almost entirely following the Stiles-Crawford effect of the first kind (SCE-I) for vertebrate photoreceptors, (b) exhibiting wavelength sensitivity of transmission, and (c) conforming to Helmholtz's reciprocity theorem of optics. Of special interest is the fact that visual photoreceptors exhibit self-orientation. Similar phototropic self-orientation is exhibited by growing and fully-grown plants (e.g., sunflowers). For theoretical or possible applications, the light-guiding properties of biological waveguides can be used not only to determine the structure of such guides, but also to provide the basis for determining the functioning of other structures related to these guides. Lastly, these studies which give us greater insight into low temperature, biologically inspired processes could possibly result in better fiber optic materials and networks for commercial applications such as telecommunications.

9.1 GLOSSARY*

Aniridia. (Greek "an" = without; "iridia" = iris.) One or both eyes of a patient who is either born without an iris (usually this is a bilateral anomaly), or, for whatever reason the individual has no iris (e.g., as a result of disease, or trauma, or surgery, etc.). Note: In some cases, on examination, a very tiny remnant or very small iris nubbin may be present in congenital cases.

Aniseikonia. (Greek "anis" = unequal; "eikon or ikon" = image.) The result of aniseikonia, or the presence of unequal image sizes in the two eyes, is the formation of characteristic spatial distortions in binocular vision. If this anomaly is large enough, there is a loss of fusion of the two images.

Aphakia. (Greek "a" = not or without; "phakia" = lens.) The state of an eye after surgical removal of an eye lens. In some cases, the eye lens may become displaced rather than removed (this used to be seen commonly with an older form of cataract surgery), or for example, as a complication of certain diseases such as Marfan's syndrome. Today, the excised eye lens is commonly replaced with a plastic "intraocular lens" (see Chap. 21).

*Added useful Glossaries: please also refer to glossaries of Chap. 8, "Biological Waveguides" by Vasudevan Lakshminarayanan and Jay M. Enoch and Chap. 6, "The Maxwellian View with an Addendum on Apodization" by Gerald Westheimer in this volume and to Chap. 37, "Radiometry and Photometry for Vision Optics" by Yoshi Ohno in Vol. II.

Keratoconus. This is an anomaly of the cornea which results in a cone-like forward-projection of the central or near-central cornea (usually slightly decentered). It is also often accompanied by progressive thinning of the area within and surrounding the cone.

Stiles-Crawford Effect of the first kind (SCE-1). The directional sensitivity of the retina. SCE-1 is the result largely of photoreceptor waveguide properties (see Chap. 8). We test vision for beams of light entering the eye at different points in the entrance pupil of the eye, and then refracted to the retina by the optical system of the eye. *The SCE-1 affects perceived brightness of luminous objects.*

Stiles-Crawford Effect of the second kind (SCE-2). In addition to perceived brightness effects, there occur alterations in perceived hue and saturation of objects viewed. This is associated with the angle of incidence of the viewed beam at the retinal receptor (e.g., see Refs. 45 and 46).

Optical Stiles-Crawford effect. Distribution of reverse path (reflected) luminous energy distribution assessed in the entrance pupil of the eye by reverse path. It is radiant energy which had been transmitted to and through the retina and has been reflected back through the ocular media after having been reradiated after reflection by the photoreceptor waveguides. It is assumed that these retinal receptors are preferentially aligned with the exit pupil of the eye. Also present are back-reflected scattered and nonguided light, for example, see Refs. 25–27.

9.2 INTRODUCTION

The Troland

In the vision science literature, the stimulus to vision is defined as the product of (1) the luminance of the object of regard assessed in the plane of the entrance pupil of the eye, expressed in candelas/m^2, times (2) the area of the entrance pupil of the eye expressed in mm^2. These values are expressed in either photopic or scotopic "trolands." The unit is named after the late Dr. Leonard Troland.[1–3]

It Is Time for a Reasoned Reassessment of "the Troland," the Unit of Retinal Illuminance

Leonard Troland, 1889 to1932, died in a tragic accident as a relatively young man. He left behind a respectable body of research which led to the modern approach to assessment of retinal illuminance, the accepted unit used to specify the stimulus to vision.[1–3] Please also refer to Dr. Yoshi Ohno's discussion in Chap. 37 in the section on "Radiometry and Photometry for Vision Optics," in Vol. II. He discusses current practices. We also call attention to the recent paper by Cheung et al. which addresses the standard units of optical radiation.[4]

There remains, of course, the larger issue of considering whether the currently employed means of estimating/assessing the stimulus to vision (often expressed today as "the photopic or scotopic troland") might be improved and/or modified in order to bring this form of analysis, and measurement units employed, more effectively into parallel with other modern measures of radiometry and photometry.

Please note the spectral response of the eye, when exposed to brighter/more intense stimuli exciting the cone-dominant-*photopic*-visual-response-system (V_λ), differs from the rod-receptor-dominant-*scotopic*-visual-response-system (V'_λ). The latter determination(s) pertain to less intense visual stimuli. Readers are referred to the book by Wyszecki and Stiles for further discussion.[5]

An "equivalent troland" also has been defined. This unit makes use of specification of the SCE-1 in the entrance pupil where the stimulus has 50 percent effectiveness relative to the level of response determined at the SCE-1 peak location.[6–9] The more complete SCE-1 function, etc., can be inferred using data obtained with this approach.

The Photometric Efficiency Factor

For completeness, we call attention to another approach to integration of and utilization of SCE-1 data for photometric and other purposes. This is based on the photometric efficiency (PE) factor.[10,11] The PE is defined by the following ratio:

$$\frac{\textit{Effective light collected by pupil}}{\textit{Actual light collected through the pupil}} \tag{1}$$

This is an interesting concept, but it is not easy to compute.[10] What is sought here is determination of "an equivalent entrance pupil size" where all points in the entrance pupil of the eye would theoretically contribute equally to the visual stimulus. Particularly for photopic vision, this equivalent pupil, would be smaller than the measured entrance pupil of the eye.[10,11] By using this approach, an integrated "equivalent entrance pupil" of given diameter and area may be determined. In addition, an adjusted SCE-1 centrum[10,11] is provided by developing appropriate weighting factors for the asymmetries encountered. Please remember, for different size pupils, the center of the entrance pupil may change by as much as 0.5 mm with dilation of the pupil.[12] For the same dilation of the eye pupil, usually this centrum is quite stable.

Current Practice

The troland,[1–3] as it is ordinarily computed (also see Chap. 37, "Radiometry and Photometry for Vision Optics," by Yoshi Ohno in Vol. II), does not take into consideration the Stiles-Crawford effects, nor factors associated with existing blur of the retinal image, nor uncorrected blur encountered when large entrance pupil areas are included in the experimental design (using a large natural, or a dilated pupil of the eye, or a decentered eye pupil). It is in our collective interest to enhance the quality of determinations, to improve the precision of measurements, to reconsider units used, and to correct these deficiencies.

The Argument Presented in This Chapter

Here we address a number of aspects of these issues, and offer an approach to the solution of resultant photometric problems. We suggest incorporation of the integrated Stiles-Crawford effect of the first kind (SCE-1)[13–16] in photometric analyses *when degradation of images caused by peripheral portions of the optical elements of the eye (the cornea and the eye lens) are/have been effectively neutralized.* Even though this is still not a perfect solution to the specification of the visual stimulus, it does represent an advance relative to techniques employed today. This will allow us to move effectively toward a finer estimate of the magnitude of the visual stimulus seen either by the experimental subject or patient tested.

9.3 THE PROBLEM AND AN APPROACH TO ITS SOLUTION

Statement of the Problem

When one seeks to determine effective "visual stimulation induced by radiant energy" within the visible spectrum (i.e., *light*, the stimulus to vision),[9] and integrates all energy entering within the entrance pupil of the eye,[13] for example, one needs to consider the Stiles-Crawford effect of the first kind (SCE-1).[13–16] SCE-1 is also known as the directional sensitivity of the retina (see Chap. 8). The issues considered here have rarely been treated adequately in experimental procedures. *If one integrates data derived from point-by-point SCE-1 determinations* (*obtained by measuring responses obtained when using tiny apertures imaged at a number of different locations in the entrance pupil of the eye*)

the resultant integrated function may not predict properly the visual result obtained when different diameter areas in the entrance pupil of the eye are sampled (please see further arguments presented in this chapter).

Most modern assessments of the integrated SCE-1 are based on point-by-point measurements of SCE-1 determined experimentally at a number of discrete points across the entrance pupil of the eye in a number of meridians (commonly tested in two meridians, i.e., horizontal and vertical). These are then fitted by a parabolic function, proposed in 1937, by *both* Stiles (using a log base 10 relationship)[14,15] and Crawford (employing a $\log_e$ or ln base *e* equation),[16] and that function is then integrated around the entrance pupil. Other functions have been proposed, for example, a Gaussian function by Safir and Hyams,[17] Burns et al.[18] as well as the relationship used in figures in this chapter by Enoch.[19,20] A review of various analytical expressions used to fit SCE-1 data is discussed in Applegate and Lakshminarayanan.[21]

In his dissertation, Lakshminarayanan recorded SCE-1 functions in a unique patient. This was a young lady born aniridic (without an iris), and (importantly) she had developed only marginal nystagmus (i.e., approximately ¼ mm amplitude nystagmus—in others, it is almost always of greater amplitude). She had quite normal visual acuity. In this eye, not only was the SCE-1 recorded, but, in her case, it was possible to assess better the associated side lobes of SCE-1.[22–24] Assuming (1) her data correspond to characteristic population (central lobe) SCE-1 patterns in normal observers, (2) then none of the above cited equations adequately conforms to the SCE-1 coupled with *the side lobes recorded.*

Notes: (1) In most experiments measuring the SCE-1 performed in recent years, very small-size projections of the aperture stop of the test apparatus have been imaged in the plane of the observer's entrance pupil (i.e., they are usually less than 1 mm in diameter). (2) This discussion is limited to monocular testing. (3) Measured SCE-1 functions obtained vary with wavelength (see Fig. 8). (4) We do not consider here recent discussions of reflected, re-emitted, and projected light gathered from the retinal photoreceptor waveguides which can be assessed by reverse path irradiation/illumination. This relationship is commonly termed "the optical SCE-1" (see Glossary and Refs. 25–27).

Confounds

Fundamentally, when an observer views a display or a scene in an eye with a relatively large natural eye pupil, or with a dilated iris resulting in an enlarged pupil (for purposes considered here, let us say this occurs when the entrance pupil *diameter* is greater than 3 mm), one must consider *both the SCE-1 and additional blur effects* present in the peripheral portions of the cornea and the eye lens. These two factors affect perceived brightness of a stimulus!

For simplicity, assume we are testing at photopic levels, the refraction of the individual has been appropriately corrected for spherical and astigmatic errors (these are first- and second-order aberrations), and the observer is properly accommodated (or corrected visually) for the object viewed. When point-to-point assessments for SCE-1 in the entrance pupil of the eye are properly determined and analyzed, *the resultant uncertainty occurring is largely assignable to the remaining/residual blur of the retinal image* (see data and figures). And as will be seen, this uncertainty is associated with blur induced by peripheral corneal and eye lens aberrations. In discussions of related topics, the senior author has referred to this blur factor as *a dirty variable*, that is, this is an uncontrolled or poorly controlled factor both in vision research and in clinical practice. To further simplify this discussion, we do not address chromatic aberrations (these factors can be addressed/considered separately), nor the use of binocular stimuli. Similarly, here, we do not consider a variety of anomalous optical conditions encountered in clinical settings (e.g., keratoconus, cataracts, or aphakia, etc.), or decentered and/or misshapen irises/pupils, or intraocular lenses centered or decentered, refractive surgery and its complications, movements/decentration(s) of contact lenses, binocular anomalies, etc. (see Chaps. 13, 14, 16, 20, and 21).

Both the magnitude of blur encountered and the nature of a blurred image vary with accommodation of the eye, and, of course, with mismatches between the retinal plane and the plane of focus of the retinal image formed within the eye. We restate the point that the center of the entrance pupil of the eye varies naturally with pupillary dilation, and is virtually always decentered to some extent relative to the optical axis of the eye. Further, the optical axis of the cornea as best determined is not the

same as that of the eye lens (e.g., Refs. 28–30). Simply, the optical system of the eye is not a perfectly centric system. We also know that dilation does not affect the SCE-1 function, *per se* (e.g., Ref. 31). For radiometric and/or photometric purposes, we seek the very best result possible depending on the level of accuracy required for the task.

A Bit of History

When Walter "Stanley" Stiles and Brian "Hewson" Crawford first reported the SCE effect 75 years ago in 1933,[13] their results were based on data obtained from their own eyes. And it is apparent that, by chance, their eyes manifested little blur of the retinal image, and hence, the complications one often encounters during integration of SCE-1 in the entrance pupil of the eye were largely not encountered in their data.[13] In such relatively rare individuals, the point-by-point estimates obtained through SCE-1 studies predict well the results of integrating such data across the entrance pupil of the eye.[19,20] (For example, see the example given under "Sample Data from Enoch" in Sec. 9.4 for experimental subject B.W.)[19,20]

On the other hand, if there is meaningful degradation of the retinal image caused by peripheral corneal and lenticular aberrations of the eye resulting in image blur, this factor, on its own, can alter the effective integrated perceived luminance of the visual stimulus (e.g., Refs. 18, 19, 32–37). The results found need not be the same between eyes or individuals, nor as predictable as SCE-1.

Collectively, these points have been demonstrated in number of studies, particularly in those of Enoch and coworkers[18,19,32,33] and Drum.[34,35]

Today, A Solution of the Problem Is Possible by Using (in Addition) Adaptive Optics (AO) Techniques

What is needed is a joint test of the Stiles-Crawford function using a suitable SCE-1 apparatus (e.g., Ref. 38) *and* utilization of one of a number of modern adaptive optics (AO) devices (see Chap. 15) capable of determining and correcting the incident wavefront in order to deliver a corrected or a nearly corrected image at the retinal test locus sampled. By such an approach, we have the ability to determine more accurately the magnitude of the visual stimulus for the designated entrance pupil size. This is achieved by correcting blur (and higher-order aberrations), and adjusting or correcting for the SCE-1, and properly integrating the resultant data. Earlier, except for use of small entrance pupil diameters or imaged apertures in experiments (see Chap. 6), such corrections were not always possible. Note, devices utilizing adaptive optics are moving toward incorporation of means of correction for chromatic aberrations in their designs or overall experimental techniques.

If a Nonmonochromatic Stimulus to Vision Is Employed

For a more complete treatment of stimuli which are not monochromatic, one might use an achromatic approach/technique proposed by Powell[39] (see Chap. 15), or other special lens(es) such as designed and used by the late Gunter Wyszecki to correct the chromatic aberrations of the human eye (e.g., Ref. 5). Using the Wyszecki lens, JME made such adjustments in some of his earlier research, and found this approach quite useful. Please note, the Wyszecki lens must be aligned carefully with the optic axis.

A Reasonable Estimate Is Possible without Full Application of Adaptive Optics

By correcting refraction, *and* spherical aberration in annual zones within the eye pupil, and by using monochromatic stimuli, in 1956, Enoch was able to approximate a more complete correction of blur in the eyes of his experimental subjects.[19,20]

A rather similar research project to that of Enoch was conducted by Drum just a few years later.[34,35]

These added issues relate to image formation in the retinal plane, and the assumption is made (often implied, but rarely stated) that energy is transferred from a single plane into the rod and cone photoreceptor waveguides. Please realize that the living cell is a highly complex entity (e.g., Ref. 43). Cell morphology and dimensions (particularly cones) often alter quite a bit across small/modest distances on the retina. Clearly, diffraction and interference effects, as well as rapid changes occurring in the spatial retinal image itself, are occurring across small distances about the entrance to the photoreceptor waveguides. For example, it is useful to consider image alterations occurring over small distances about a plane of focus (both longitudinally and laterally) of the retinal image. As but one example, consider the contents of a paper by Bachinski and Bekkefi,[40] and data recorded by Enoch and Fry[41] in greatly enlarged and simplified rod and cone receptor models assessed in the microwave spectrum. Without addressing such issues further, here we suggest that a somewhat better estimate of the retinal stimulus to vision *per se* is achievable by incorporating the integrated SCE-1 function in a blur-corrected or blur-minimized retinal image. We argue that this provides a better assessment of the visual stimulus than that provided in what has become now a "classical" approach defined by the late Leonard Troland many years ago, and which is still used for assessing retinal illuminance.[2,3] See Chap. 37, "Radiometry and Photometry for Vision Optics," by Yoshi Ohno in Vol. II. So saying, there is more that needs consideration relative to this topic in future.

9.4 SAMPLE POINT-BY-POINT ESTIMATES OF SCE-1 AND INTEGRATED SCE-1 DATA

Sample Data from Stiles and Crawford, 1933

In this section, data are presented which demonstrate reasonably the magnitude and nature of the errors induced in calibration and measurement without correction of the defined errors encountered. While these are not extreme errors, *per se*, these are real effects, they are readily correctable, and should be considered in studies of vision.

Data here are taken from the dissertation of Enoch[19,20] and the function utilized for integrations of "relative directional sensitivity" here indicated as "η" (plotted as a $\log_{10}$ scale) are defined as

$$\eta = 0.25(1 + \cos 9.5\,\theta)^2 \tag{2}$$

η equals 1.0 at the peak of the SCE-1 curve; θ is the angle of incidence of the ray of light at the retinal plane. A 1-mm beam displacement at the entrance pupil of the eye alters the angle of incidence of the incident ray of light by 2.5° of oblique incidence at the retinal plane (based on computations using the constants of the Gullstrand schematic eye).[23]

This particular equation provides a bit better fit of SCE-1 data[13–16] than the Stiles', 1937 (log base 10) relationship[14] or Crawford's 1937 (ln base e) equation[16] for a parabola. It is used here to simplify transfer of the figures employed below. Because the improvements made when fitting SCE-1 data using this relationship were modest, the authors of this chapter have not used this format for some years, and, rather, have used the more broadly employed Stiles 1937 formulation[14] in its stead

$$\mathrm{Log}_{10}\,\eta = -\rho r^2 \tag{3}$$

In this equation "η" is the measured relative visual sensitivity of the stimulus to vision (in trolands, $\log_{10}$ scale); "ρ" is a constant defining the curvature of this parabolic function; and "r," in mm, is the distance of the point being sampled from the peak of the measured SCE-1 function in the plane of the entrance pupil of the eye.

SCE-1 data shown in Fig. 1 were taken from Stiles and Crawford[13] and were fitted by Eq. (2).

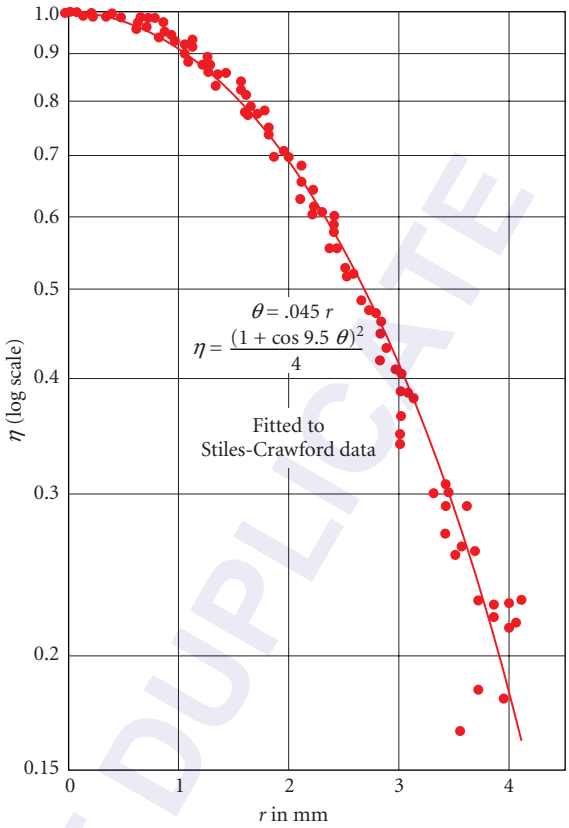

FIGURE 1 The 1933 SCE-1 data of W. S. Stiles and B. H. Crawford were adjusted such that the maxima of measured relative visual sensitivity functions were located at $r = 0.0$ mm in their entrance pupils, and were assigned a relative sensitivity value of 1.0 (at/as the peak of these data functions). Radial distance settings, "*r*," of the test beam in the entrance pupils of their eyes from the peaks of SCE-1 are displayed on the abscissa. The ordinate displays η ($\log_{10}$ scale). *Data used in this illustration originated in the paper of W. S. Stiles and B. H. Crawford, 1933.[13] (This illustration was copied from Fig. 1, Enoch, 1956, Dissertation; and Fig. 1, Enoch, 1958, J.O.S.A.[19,20] These figures in this paper are reproduced with permission of the author and the publisher of J.O.S.A.)*

In their initial study, Stiles and Crawford, 1933,[13] were seeking to measure precisely the area of the eye pupil (i.e., their instrument had been designed as a straightforward pupillometer). They assumed, at the outset, that energy passing through each part of the eye pupil contributed equally and proportionately to the retinal image and visual sensitivity. They discovered that the device gave results which were not consistent with their *à priori* assumption, and they properly interpreted their results to indicate that there was evidence for the presence of directional sensitivity of the retina, which became known as the Stiles-Crawford effect of the first kind (SCE-1).

Their instrument sought to assess the integrated visual response resulting from irradiating the entire entrance pupil, and for different size entrance pupils of the eye. *Since they had little image blur in their own eyes*, the integrated result gave little evidence that when the full pupil was measured, the resultant additivity (of the contributions of different parts of the pupil) might also be different in eyes where there were meaningful peripheral corneal and eye lens aberrations resulting in additional degradation (blur) of the retinal image. That is, they did not encounter other than near perfect additivity from integrating point-by-point SCE-1 determinations and comparing them to full eye-pupil assessments. Thus, we need to differentiate between (1) simple addition of the contributions of the entire eye pupil, versus (2) that sum adjusted for SCE-1, and (3) *the result obtained in eyes where there are meaningful aberrations in the periphery of the optical elements of the eye.*

Sample Data from Enoch

Data were obtained from three well-trained graduate student subjects.[19,20] Subject B.W. had an eye with fine optical properties. Both subjects R. V. and A. M. had greater peripheral ocular aberrations in their measured eyes than B. W.; with subject A. M. exhibiting somewhat greater image degradation than observer R. V. Note these are all photopic determinations. By avoiding scotopic measurements here, we simplify the argument.[42] Except for overall refractive correction, the single aberration measured independently as part of this dissertation (1955 to 1956) was spherical aberration. The latter was achieved by using a technique similar to one employed by Ivanoff.[43] That is, the pupil was divided into discrete nonoverlapping annular zones, and the required refractive correction was altered as needed within each annular zone. Table 1 provides values useful if one is performing the described integrations.

The SCE-1 was measured separately for both (1a) white light (obtained by using a ribbon filament lamp run at 16 amperes, with the beam passing through a heat filter), and paired neutral density filters, or (1b) by appropriately adding an interference filter having a near monochromatic green light band of light (peak $\lambda = 552$ mμ) into the same optical system.

A second variable was introduced in this experiment. There was the traverse of the test beam across the entrance pupil of the eye employing (2a) an instrument design where the ribbon-lamp-filament was imaged in the plane of the entrance pupil of the eye (a classic Maxwellian view instrument design) (see Chap. 6), and, alternatively (2b) the light source was imaged directly on the retina of the observer having passed through the same number of surfaces and by using the same dimension beam image in the entrance pupil of the eye, and the same viewed stimulus target. This was regarded as a non-Maxwellian–view illumination system. Each of these cases utilized a projected aperture which subtended slightly less than 1-mm diameter image in the entrance pupil of the eye. Differences in measured SCE-1 results encountered for these different test conditions were very modest for all three subjects. Direct comparisons were made using both (a) bipartite fields, and, separately, (b) flicker photometry.

TABLE 1 Area in the Entrance Pupil of the Human Eye Based on Gullstrand Schematic Eye

Ent. Pupil Area (Abscissa)*	Solve for Radius and Diameter of Entrance Pupil	
	Radius	Diameter
10 mm^2	1.78 mm	3.57 mm
20	2.52	5.05
30	3.09	6.18
40	3.57	7.14
50	3.99	7.98
60	4.37	8.74
70	4.72	9.44

* The Abscissas in Figs. 3 to 6 are plotted as $\log_{10}$ entrance pupil area.

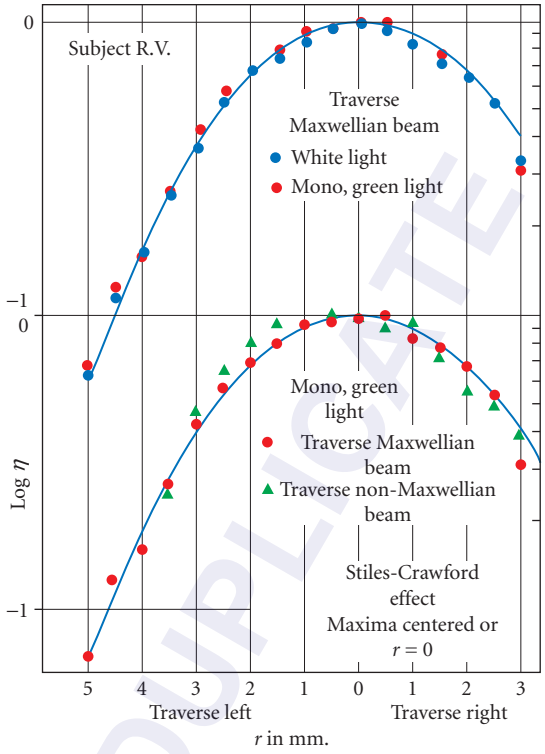

FIGURE 2 SCE-1 data for subject R. V. are presented as an example of the many data sets acquired. His SCE-1 maxima were set at $r = 0.0$ mm on the abscissa. *Top:* SCE-1 data obtained for both white light and monochromatic green light (552 mμ max.) are shown. *Bottom:* Both data sets were obtained using monochromatic light. Two different optical conditions were employed. That is, in one experiment, a Maxwellian beam traversed in the eye pupil, and in a second set of sessions, a non-Maxwellian beam was used to traverse the entrance pupil of the eye.[19,20] Also please refer to Chap. 6. These data are presented with Eq. (2) fitted to these data. (*This illustration was taken from Fig. 14, Enoch, 1956, Dissertation;*[19] *and Fig. 9, Enoch, 1958, J.O.S.A.*[19,20] *These figures are reproduced with permission of the author and the publisher of J.O.S.A.*)

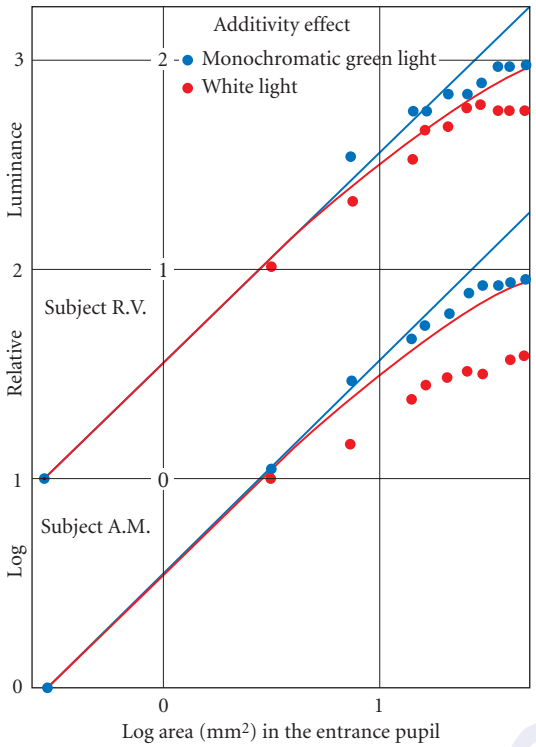
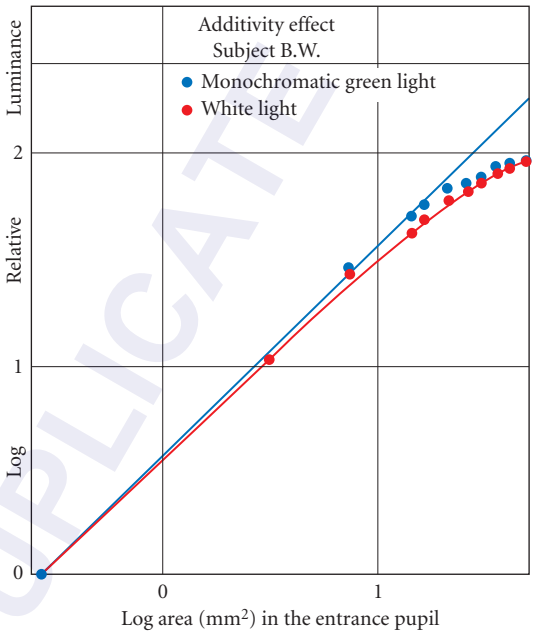
Figure 2 shows sample SCE-1 test data for subject R. V.[19,20] As is obvious, there were only small differences between measured SCE-1 functions for the stated conditions. These data are presented as an example of the many data sets acquired. The peaks of his SCE-1 maxima were set at $r = 0.0$ mm on the abscissa.

In Figs. 3 and 4, two different predictive additivity (integrated) plots are presented. The straight line on these double logarithmic plots assumes each point within the entrance pupil of the observer's eye contributes equally to the perceived visual stimulus. The modestly curved line represents the integrated SCE-1 function [here based on Eq. (2) above]. In Fig. 3, data for subjects A. M. and R. V. are presented, and in Fig. 4, data for subject B. W. appears. In Fig. 3 data for one observer were displaced by 1 log unit for clarity. For monochromatic green light [wavelength 522 mμ, (blue circles)] data obtained from all subjects show quite good agreement with the integrated SCE-1 function plot in





FIGURES 3 AND 4 These figures demonstrate the equivalent of integrated or "additivity" diagrams for excitation entering defined entrance pupil areas. The straight line would predict perfect additivity of luminous stimuli entering the entrance pupil of the eye tested of the designated subject. The curved line incorporates a correction for the integration of SCE-1 data about the entrance pupil of the eye. In Fig. 3 data for Subjects R. V. and A. M. are presented; in Fig. 4 data are presented for Subject B. W. (*This illustration was taken from Figs. 18 and 19, Enoch, 1956, Dissertation19; and Figs. 12,13, Enoch, 1958, J.O.S.A.20 These figures are reproduced with permission of the author and the publisher of J.O.S.A.*)

both Figs. 3 and 4 (blue circles). The performance of subjects R. V. and A. M. clearly was less good for white light (red circles). On the other hand, data obtained from the eye of B. W. (Fig. 4) shows remarkably good "additivity" for both monochromatic and white light stimuli. We can infer that ocular aberrations in B. W.'s eye exhibited lower amplitudes than those encountered in the eyes of A. M. and R. V. That is, the optical quality of the periphery of B. W.'s cornea and eye lens was better than that found in the peripheral portions of the ocular components of the other two observers. This difference is the result of factors contributing to both monochromatic and chromatic aberrations.

In each case, near monochromatic green stimuli more closely matched the integrated SCE-1 curve than did white light, and in the case of B. W. both data sets were in close approximation to the predicted result.[19,20]

The added chromatic aberrations apparently made little difference to B. W. (or he retained his focus about mid-spectrum?), while the chromatic aberrations noticeably affected performance of the two subjects, R. V. and A. M.

In Fig. 5, the additivity effect obtained when placing an added –1.00 diopter spherical (D.S.) lens (before the test eye of each subject) is shown for a limited number of different test aperture sizes projected into the entrance pupil of the eye, and this result is contrasted with the addition of a +2.00 D.S. lens placed in front of the same eye (with the –1.00 D.S. lens removed). The former lens (the –1.00 D.S.) makes that eye more hyperopic "far-sighted," while the +2.00 D.S. makes the same eye more myopic "near-sighted." The test eye could at least partially self-correct for the –1.00 D.S.

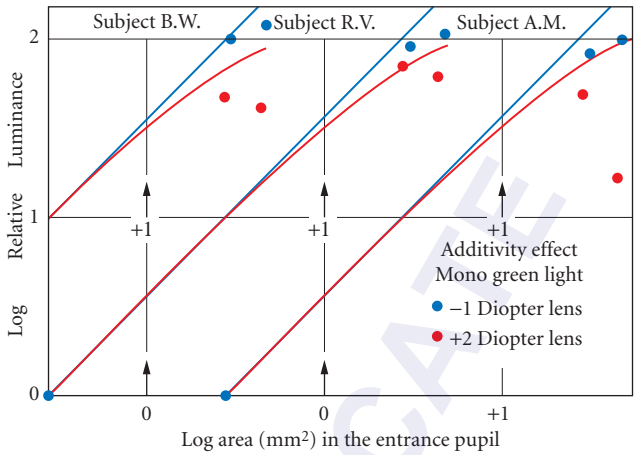


FIGURE 5 A comparison was made between the SCE additivity effect obtained when a –1.00 D.S. lens was placed in the apparatus before the eye of each observer's test eye, and (separately) for addition of a +2.00 D.S. lens. Two differing relatively large entrance pupil areas were selected for this test. These lenses slightly altered the area of the imaged aperture stop in the observer's entrance pupil. Hence, the +2 D.S. lens is shown as subtending a slightly smaller area in the entrance pupil (on the abscissa) than the –1.00 D.S. lens. (*This illustration was taken from Fig. 22, Enoch, 1956, Dissertation;*[19] *and Fig. 16, Enoch, 1958, J.O.S.A.*[20] *These figures are reproduced with permission of the author and the publisher of J.O.S.A.*)

lens by accommodating on the test target. That is, these were nonpresbyopic test subjects. That is, the pupil-dilating drops employed had only slight/modest effect on accommodation in these observers. All tests were monocular.

When a flicker photometric test method was employed,[19,20] *blur of the retinal image proved to have much less of an influence upon brightness matches made by the subjects* (note, observers were instructed to compare the apparent brightness of the central parts of the flickering fields). When this same technique was combined with use of monochromatic $\lambda = 552$ mμ stimuli, the matches of all three subjects proved to be similar and closely matched the integrated SCE-1 estimated curve. That is, all three subjects exhibited near perfect additivity approximately matching the SCE-1 predicted values (Fig. 6).[19,20]

Thus, by eliminating and/or minimizing blur effects on perceived brightness due to aberrations (i.e., both monochromatic and chromatic aberrations!), *the integrated SCE function* becomes a good estimate of visual performance for any given pupil aperture utilized. Use of such methods, now (today) are made more readily achievable by using modern adaptive optics techniques for nonchromatic image formation, and, thus, for visual stimulus control. Taking the defined steps allows a superior estimate to be made of perceived brightness, and for the specification of the visual stimulus.

Finally, please note, the factor rho (or ρ) is not a constant across the retina (i.e., it varies with eccentricity from the point of fixation (Fig. 7).[12,14,15,44,45] It also varies within the visual spectrum with test wavelength utilized (as implied in Fig. 8).[12] Here we do not consider the Stiles-Crawford effect of the second kind (SCE-2), that is, the alteration of perceived hue and saturation associated with variation of the angle of incidence at the retina.[14–16, 44–46] Separately, the SCE-1 is also affected to some degree by the distribution of and density of yellow (blue-absorbing) pigment in the eye lens.[47] The absorbance of this pigment also varies with wavelength. This factor is addressed in Fig. 8. See Chap. 3 in Ref. 12.

As noted above, Drum addressed some similar issues from a somewhat different point of view.[34,35] He also clearly demonstrated additivity of the SCE-1 to exist for all assessed tests and conditions. The simple fact is that SCE-1 and associated integrated results are rather robust under quite a variety of test conditions.

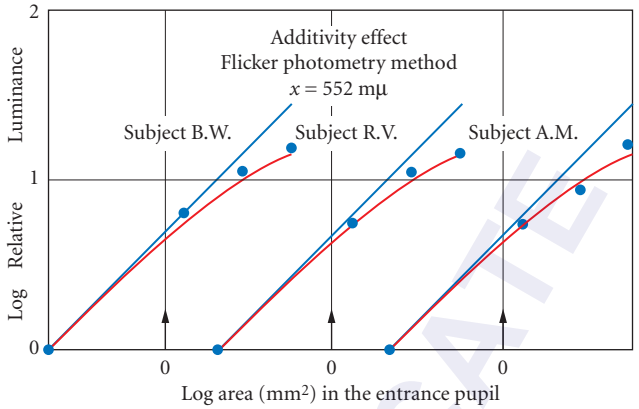

FIGURE 6 These are integrated additivity data for each of the three trained subjects. The flicker photometry method was used. Effects of peripheral corneal and eye lens blur of the observers were minimized by testing with (1) monochromatic light, and by employing (2) a photometric matching technique less influenced by blurred imagery. (*This illustration was taken from Fig. 25, Enoch, 1956, Dissertation;*[19] *and Fig. 19, Enoch, 1958, J.O.S.A.*[20] *These figures are reproduced with permission of the author and the publisher of J.O.S.A.*)

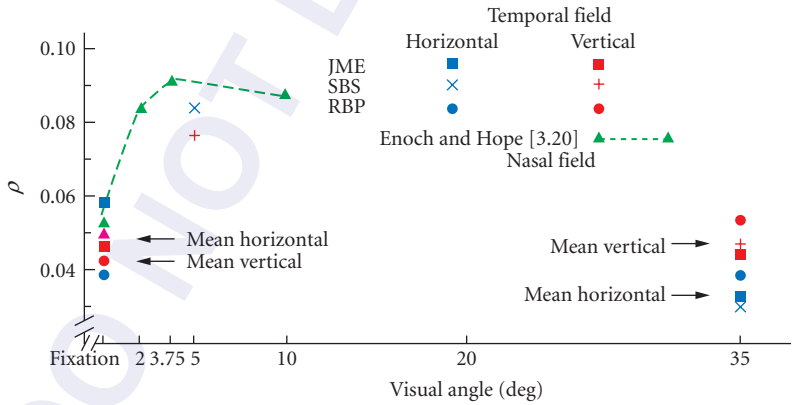

FIGURE 7 This figure addresses the variation of rho, ρ, with eccentricity from the point of fixation (assume this locus corresponds to the center of the fovea). This seemingly complex figure combines data from more than one paper on Stiles' ρ factor [Eq. (3)]. Tests were performed at fixation, in the para-foveal area, and separately at a test locus located 35° from the point of fixation. Horizontal and vertical in this figure refer to SCE-1 tests conducted in these two meridians within the entrance pupils of human eyes. (*This figure is reproduced from Fig. 3.8 in Enoch and Tobey, 1980, (see Ref. 12, p. 99), and Enoch and Hope, 1973.*[12,45] *It is printed with the permission of the authors and publishers.*)

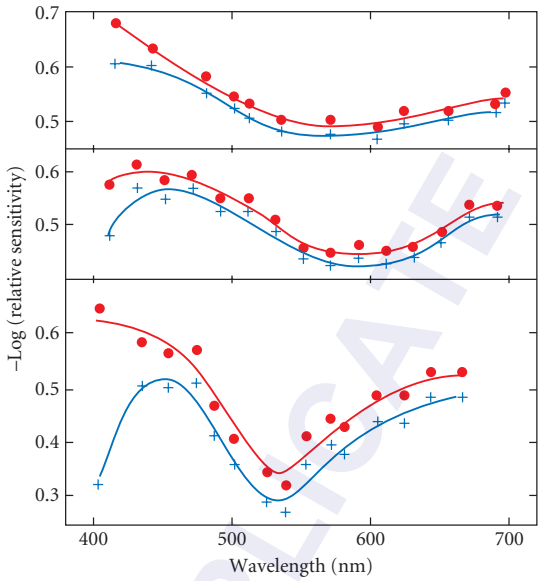

FIGURE 8 These data relate to values obtained from measured human foveal SCE-1 functions (see Ref. 12, Fig. 3.13 located on p. 109).[15,47] The upper curves present values of (–) log relative sensitivity for different subjects measured at a number of different wavelengths. The upper data curves presented were affected by the presence of yellow eye lens pigment(s), and the lower curves have been corrected for these pigment effects. Please be aware that the density of the yellow lens pigments increases with age. (*This illustration has origin in data of Stiles, 1939,[15] with additions obtained from the paper by Vos and Van Os, 1975.[47] These figures are reproduced with permission of the authors and the publishers.*)

9.5 DISCUSSION

When Do Matters Considered Here Warrant Consideration?

Like in all psychophysical studies, the demand for precision is greater the more sensitive the determination, and the more complex the problem encountered in the observer or patient. We think we would all agree that the approach argued here is indicated whenever large or dilated pupils are used, particularly for tests of photopic vision! If a pupil is not well centered, or even reasonably asymmetric, or relatively nonresponsive, or otherwise not normal, one needs to rule out any unnecessary variable. Similarly, if the SCE-1 is abnormal, or displaced from its natural centrum, then it is clearly advisable to pursue the matter further. Note, given retinal photoreceptor packing properties, that it is almost unheard of for rods to be normally aligned if cones are found to be disturbed in their orientations in a given retinal area, and vice versa.

Zwick and his coworkers (e.g., Ref. 48) have studied the effects of laser exposures on retinal survival, recovery, and/or lack thereof mainly in snakes. In their experiments on animals, Zwick et al. used (1) subthreshold laser exposures, (2) threshold burns, (3) above threshold burns, and (4) more severe exposures. These studies were backed up by assessments of individual humans who have been exposed to comparable laser burns. Such laser burns result in immediate and substantial disturbances in photoreceptor alignments (often extending for some distance about the burn site), resultant early and late sensitivity losses. Snake eyes have large photoreceptors visible directly through the animal's natural pupil in vivo, and are available for study. Snakes are relatively nonreactive when exposed

to high intensity laser light when sedated, and show relatively rapid recovery *if* there is a potential for recovery. A meaningful area of the retina is affected. These authors[48] have carefully documented recovery and failure to recover in their studies.

One must remember that alignment of photoreceptors with the center of the exit pupil of the eye is maintained normally throughout life, except in cases where there has been some retinal disorder or disease.[49,50] In a number of cases, the retina can recover if the inducing anomaly is corrected or self corrects (remits).[51,52] So saying, residual scar tissue, local adhesions, or other impediments to recovery can alter the result. If ever doubts exist, suitable tests are indicated.

As has been inferred above, and can be seen in Fig. 3 to 6, in the normal observer the smooth, integrated SCE-1 function curve differs only modestly from the linear additivity curve until there is about a 4- to 5-mm-diameter entrance pupil.

Once again, looking at Figs. 3 and 4, uncertainty enters with peripheral blur of the optical components of the eye. The effects are greater for white light than monochromatic light. Subject A. M. apparently manifests less aberrations in his peripheral eye lens and cornea than observer V. R., and subject B. W. exhibits virtually no effect due to aberrations. At the outset, it was pointed out that image blur or degradation enters as a "dirty variable." Without correction of these degrading peripheral lens blur factors, one introduces uncertainty. If one adds refractive error to the mix, the situation is made worse (see Fig. 5). If refractive and peripheral blur are corrected or at least meaningfully minimized, then a SCE correction applied to such data predict quite well the visual stimulus presented to the observer (see Fig. 6)!

Among other very interesting results, Makous and his coworkers,[53–58] and Applegate and Lakshminarayanan,[21] correctly point out, as can be inferred from comments made above, for small pupil apertures, certainly for 3-mm-diameter entrance pupils (1.5-mm radial distances) and perhaps a bit more, the two functions differ only slightly if refraction is well corrected, and the system is centered on the subject's entrance pupil. And Makous et al. have also addressed and thoughtfully considered issues regarding effects of coherence and noncoherence of imagery, loci of adaptation, quantum activation rates in photoreceptors, effects of cell obliquity on excitation processes, etc.

9.6 TELEOLOGICAL AND DEVELOPMENTAL FACTORS

In a sense, it is also useful to consider these visual functions from a teleological point of view. It is apparent that the ultimate purpose(s) of the SCE-1 and associated waveguide properties of retinal photoreceptors are to enhance the detection of critical visual signal, both photopic and scotopic, and to help suppress intraocular stray light "noise" present in the "integrating-sphere-like" eye (e.g., Ref. 12). The feedback mechanisms controlling receptor alignment (under normal circumstances) and their directional properties *together* serve to favor the detection of directed visual signal content passing through the center of the exit pupil in eyes of vertebrates. In many invertebrate species the eyes serve similarly, for example, octopus, etc.; or in a different (but effectively comparable) fashion in the vast number of other invertebrate species. These optical and anatomical features serve to enhance greatly visual processes, and, as such, play critical roles in vision and survival of species. This argument emphasizes the great importance exerted by such mechanisms in evolutionary processes.

Related to such matters, the attention of the reader is called to a *remarkable recent paper* by Detlev Arendt et al. in *Science* in 2004.[59] These authors located a primitive and ancient form of invertebrate aquatic worm which had the usual paired invertebrate eye structures *as well as vertebrate-type, cylindrically shaped photoreceptors* containing cilia located in its brain in that area which controlled circadian rhythms. And the latter cells were also shown to contain a cone-type of opsin![59]

9.7 CONCLUSIONS

There is a need to optimally correct and control the quality of the images formed in the eye, and/or the eye plus associated optical apparatuses. This is needed in order to define better the observer's stimulus to vision, and to understand, in a superior way, the observer's visual responses. This will include (1) a satisfactory correction of refraction, that is, lower-order aberrations, (2) correction

of higher-order monochromatic aberrations, and also (3) correction of chromatic aberrations. The totality can be aided by utilization of modern adaptive optics (AO) techniques. In radiometric and photometric studies, there is also need to include a factor which corrects for the Stiles-Crawford effect of the first kind (SCE-1), and that need increases with pupil diameter, particularly for photopic vision.

Note, because we do not wholly understand the nature of the stimulus to accommodation, we must be careful not to be too overly aggressive in seeking to eliminate *all* image blur.

And, as pointed out in the introductory remarks, it is time to reconsider the definition and units used to describe/define the troland.

Here, we only have considered monocular visual corrections. That is, in this discussion, we have not considered issues associated with maintenance of sustained and comfortable binocular vision (see Chap. 13) both in instrument design as well as in assessment and corrections of vision. For effective binocular results, it is clear that issues associated with maintaining an observer's comfort while performing extended binocular visual tasks need to be carefully addressed in both design and assessment of vision roles/function, including careful attention being paid to equating the sizes of the two retinal images (i.e., countering the effects of aniseikonia), and fusion of those images. That is, in design, we always need to address those additional factors affecting ocular motility and binocular fusion (Chap. 13).

The list of references appended to this chapter includes a number of citations which address additional aspects of issues considered here.[60–68]

10.1 GLOSSARY

Chromaticity coordinates. Tristimulus values normalized to sum to unity.

CIE. Commission Internationale de l'Éclairage or International Commission on Illumination. Organization that develops standards for color and lighting.

Color-matching functions (CMFs). Tristimulus values of the equal-energy spectrum locus.

Color space transformation matrix. Multiply a vector of tristimulus values for one color space by such a matrix to obtain tristimulus values in another color space.

Cone coordinates. Tristimulus values of a light with respect to the cone fundamentals.

Cone fundamentals. Estimates of the cone spectral sensitivities at the cornea. Equivalently, the CMFs that would result if primaries that uniquely stimulated the three cones could be and were used.

Linear model. Set of spectral functions that may be scaled and added to approximate other spectral functions. For example, the spectral power distributions of three monitor primaries are a linear model for the set of lights that can be emitted by the monitor.

Metamers. Two physically different lights that match in appearance to an observer.

Photopic luminosity function. Measure of luminous efficiency as a function of wavelength under photopic (i.e., rod-free) conditions.

Primary lights. Three independent lights (real or imaginary) to whose scaled mixture a test light is matched (actually or hypothetically). They must be independent in the sense that no combination of any two can match the third.

Standard observer. The standard observer is the hypothetical individual whose color-matching behavior is represented by a particular set of CMFs.

Tristimulus values. The tristimulus values of a light are the intensities of the three primary lights required to match it.

Visual angle. The angle subtended by an object in the external field at the effective optical center of the eye. Colorimetric data are typically specified for centrally fixated 2° or 10° fields of view.

10.2 INTRODUCTION

Scope

The goal of colorimetry is to incorporate properties of the human color vision system into the measurement and numerical specification of visible light. Thanks in part to the inherent simplicity of the initial stages of visual coding, this branch of color science has been quite successful. We now have effective quantitative representations that predict when two lights will appear identical to a human observer and a good understanding of how these matches are related to the spectral sensitivities of the underlying cone photoreceptors. Although colorimetric representations do not directly predict color sensation,[1–3] they do provide the foundation for the scientific study of color appearance. Moreover, colorimetry can be applied successfully in practical applications. Foremost among these is perhaps color reproduction.[4–6]

As an illustrative example, Fig. 1 shows an image processing chain. Light from an illuminant reflects from a collection of surfaces. This light is recorded by a color camera and stored in digital form. The digital image is processed by a computer and rendered on a color monitor. The reproduced image is viewed by a human observer. The goal of the image processing is to render an image with the same color appearance at each image location as the original. Although exact reproduction is not always possible with this type of system, the concepts and formulas of colorimetry do provide a reasonable solution.[4,7] To develop this solution, we will need to consider how to represent the spectral properties of light, the relation between these properties and color camera responses, the representation of the restricted set of lights that may be produced with a color monitor, and the way in which the human visual system encodes the spectral properties of light. We will treat each of these topics in this chapter, with particular emphasis on the role played by the human visual system.

Reference Sources

A number of excellent references are available that provide detailed treatments of colorimetry and its applications. Wyszecki and Stiles' comprehensive book[8] is an authoritative reference and

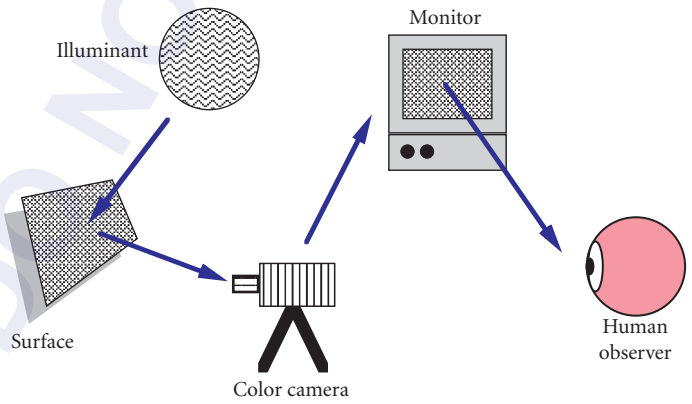

FIGURE 1 A typical image processing chain. Light reflects from a surface or collection of surfaces. This light is recorded by a color camera and stored in digital form. The digital image is processed by a computer and rendered on a color monitor. The reproduced image is viewed by a human observer.

provides numerous tables of standard colorimetric data. Smith and Pokorny[9] provide a treatment complementary to the one developed here. Several publications of the Commission Internationale de l'Éclairage (International Commission on Illumination, commonly referred to as the CIE) describe current international technical standards for colorimetric measurements and calculations.[10] The most recent CIE proposal is for a set of physiologically relevant color-matching functions or cone fundamentals based mainly on the results of human psychophysical measurements.[11] Other sources cover colorimetry's mathematical foundations,[12,13] its history,[14–16] its applications,[2,5,17,18] and its relation to neural mechanisms.[19–21] Chapters 3, 5, 11, and 22 in this volume, and Chap. 37, "Radiometry and Photometry for Vision Optics," by Yoshi Ohno in Vol. II of this *Handbook* are also relevant.

Chapter Overview

The rest of this chapter is organized into three main sections. Section 10.3, "Fundamentals of Colorimetry," reviews the empirical foundation of colorimetry and introduces basic colorimetric methods. In this section, we adhere to notation and development that is now fairly standard in the field.

Section 10.4, "Color Coordinate Systems," discusses practicalities of using basic colorimetric ideas and reviews standard coordinate systems for representing color data.

Desktop computers can easily handle all standard colorimetric calculations. In Sec. 10.5 we introduce vector and matrix representations of colorimetric data and formulas. This development enables direct translation between colorimetric concepts and computer calculations. Matrix algebra is now being used increasingly in the colorimetric literature.[4,22,23]

Section 10.6 uses the vector and matrix formulation developed in Sec. 10.5 to treat some advanced topics.

The appendix (Sec. 10.7) reviews the elementary facts of matrix algebra required for this chapter. Numerous texts treat the subject in detail.[24–27] Many software packages (e.g., MATLAB, S-Plus, R) provide extensive support for numerical matrix algebra.

10.3 FUNDAMENTALS OF COLORIMETRY

Introduction

We describe the light reaching the eye from an image location by its spectral power distribution. The spectral power distribution generally specifies the radiant power density at each wavelength in the visible spectrum. For human vision, the visible spectrum extends roughly between 400 and 700 nm (but see subsection "Sampling the Visible Spectrum" in Sec. 10.5). Depending on the viewing geometry, measures of radiation transfer other than radiant power may be used. These measures include radiance, irradiance, exitance, and intensity. The distinctions between these measures and their associated units as well as equivalent photometric measures are treated in Chaps. 34, 36, and 37 of Vol. II on this *Handbook* and are not considered here.

Color and color perception are limited at the first stage of vision by the spectral properties of the layer of light-sensitive *photoreceptors* that cover the rear surface of the eye (upon which an inverted image of the world is projected by the eye's optics). These photoreceptors transduce arriving photons to produce the patterns of electrical signals that eventually lead to perception. Daytime (photopic) color vision depends mainly upon the three classes of cone photoreceptor, each with different spectral sensitivity. These are referred to as long-, middle-, and short-wavelength-sensitive cones (L, M, and S cones), according to the part of the visible spectrum to which they are most sensitive (see Fig. 6). Night-time (scotopic) vision, by contrast, depends on a single class of photoreceptor, the rod.

TABLE 1 Glossary of Conventional Colorimetric Terms and Notation

Chromaticity coordinates	*x, y,* or in terms of the tristimulus values $X/(X+Y+Z)$ and $Y/(X+Y+Z)$, respectively (or *r, g* for *RGB* space, or *l, m* for *LMS* space).
Color-matching functions or CMFs	$\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$. Tristimulus values of the equal-energy spectrum locus.
Cone fundamentals	$\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ in CMF notation, or often $L(\lambda)$, $M(\lambda)$, and $S(\lambda)$. These are the CMFs that would result if primaries that uniquely stimulated the three cones could be used.
Photopic luminosity function	Photometric measure of luminous efficiency as a function of wavelength under photopic (*i.e.*, rod-free) conditions: $V(\lambda)$ or $\bar{y}(\lambda)$.
Primary lights	**R**, **G**, **B**, the three independent primaries (real or imaginary) to which the test light is matched (actually or hypothetically). They must be independent in the sense that no combination of two can match the third.
Standard observer	The standard observer is the hypothetical individual whose color-matching behavior is represented by a particular set of mean CMFs.
Tristimulus values	*R, G, B,* the amounts of the three primaries required to match a given stimulus.
Visual angle	The angle subtended by an object in the external field of view at the effective optical center of the eye. Colorimetric data are typically for centrally fixated 2 or 10° fields of view.

Conventional Colorimetric Terms and Notation

Table 1 provides a glossary of conventional colorimetric terms and notation. We adhere to these conventions in our initial development, in this section and in Sec.10.4. See also Table 3.1 of Ref. 28, and compare with the matrix algebra glossary in Table 2.

Trichromacy and Univariance

Normal human vision is *trichromatic*. With some important provisos (see subsection "Conditions for Trichomatic Color Matching" in Sec. 10.3), observers can match a test light of any spectral composition to an appropriately adjusted mixture of just three other lights. Consequently, colors can be defined by three variables: the intensities of the three primary lights with which they match. These are called *tristimulus values*.

The range of colors that can be produced by the additive combination of three lights is simulated in Fig. 2. Overlapping red, green, and blue lights produce regions that appear cyan, purple, yellow, and white. Other, intermediate, colors can be produced by varying the relative intensities of the three lights.

Human vision is *trichromatic* because there are only three classes of cone photoreceptor in the eye, each of which responds univariantly to the rate of photon absorption.[29,30] *Univariance* refers to the fact that the effect of a photon, once absorbed, is independent of wavelength. What varies with wavelength is the probability that a photon is in fact absorbed, and this variation is described by the photoreceptor's spectral sensitivity. Photoreceptors are, in effect, sophisticated photon counters the outputs of which vary according to the rate of absorbed photons. Changes in the absorption rate can result from a change in photon wavelength or from a change in the number of incident photons. This confound means that individual photoreceptors are effectively color blind. Normal observers are able to see color by comparing the outputs of the three, individually color-blind, cone types.

TABLE 2 Glossary of Notation Used in Matrix Algebra Development

		Link to Conventional Notation
λ	Wavelength	
N_λ	Number of wavelength samples	
b	Spectral power distribution; basis vector	
B	Linear model basis vectors	
a	Linear model weights	
N_b	Linear model dimension	
p	Primary spectral power distribution	
P	Linear model for primaries	
t	Tristimulus coordinates	$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix}$
T	Color-matching functions ($\bar{x}$, $\bar{y}$, and $\bar{z}$ are rows of **T**)	$\begin{bmatrix} \bullet & \bullet & \bullet & \bar{x} & \bullet & \bullet & \bullet \\ \bullet & \bullet & \bullet & \bar{y} & \bullet & \bullet & \bullet \\ \bullet & \bullet & \bullet & \bar{z} & \bullet & \bullet & \bullet \end{bmatrix}$
r	Cone (or sensor) coordinates	$\begin{bmatrix} L \\ M \\ S \end{bmatrix}$
R	Cone (or sensor) sensitivities ($\bar{l}$, $\bar{m}$, and $\bar{s}$ are rows of **R**)	$\begin{bmatrix} \bullet & \bullet & \bullet & \bar{l} & \bullet & \bullet & \bullet \\ \bullet & \bullet & \bullet & \bar{m} & \bullet & \bullet & \bullet \\ \bullet & \bullet & \bullet & \bar{s} & \bullet & \bullet & \bullet \end{bmatrix}$
v	Luminance	$[Y]$
V	Luminous efficiency function (V_λ is the single row of vector **v**)	$\begin{bmatrix} \bullet & \bullet & \bullet & V_\lambda & \bullet & \bullet & \bullet \end{bmatrix}$
M	Color space transformation matrix	

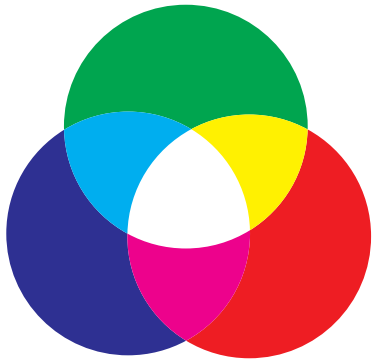

FIGURE 2 Additive color mixing. Simulated overlap of projected red, green, and blue lights. The additive combination of red and green is seen as yellow, red and blue as purple, green and blue as cyan, and red, green, and blue as white.

Color Matching

Trichromacy, together with other critical properties of color matching described in subsection "Critical Properties of Color Matching" in Sec. 10.3 mean that the color-matching behavior of an individual can be characterized as the intensities of three independent *primary lights* that are required to match a series of monochromatic spectral lights spanning the visible spectrum. Two experimental methods have been used to measure color matches: the maximum saturation method and Maxwell's method. Most standard color-matching functions have been obtained using the maximum saturation method, though it is arguably inferior.

Maximum Saturation Method The maximum saturation method was used by Wright[31] and Guild[32] to obtain the matches that form the basis of the CIE 1931 color-matching functions (see subsection "CIE 1931 2° Color Matching Functions" in Sec. 10.4). In this method, the observer is presented with a half field illuminated by a monochromatic test light of variable wavelength λ as illustrated in Fig. 3*a* and an abutting half field illuminated by a mixture of red (**R**), green (**G**), and blue (**B**) primary lights.

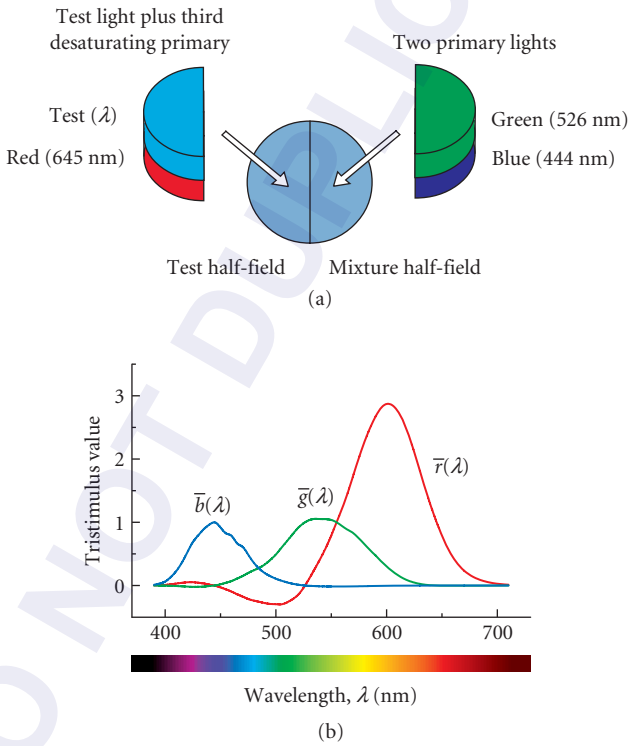

FIGURE 3 (*a*) Maximum saturation method of color matching. A monochromatic test field of wavelength λ can be matched using a mixture of red (645 nm), green (526 nm), and blue (444 nm) primary lights, one of which must usually be added to the test field to complete the match. (*b*) Color-matching functions. The amounts of each of the three primaries required to match equal energy monochromatic lights spanning the visible spectrum are known as the red $\bar{r}(\lambda)$, green $\bar{g}(\lambda)$, and blue $\bar{b}(\lambda)$, CMFs. These are shown as the red, green, and blue lines respectively. A negative sign means that primary must be added to the target to complete the match. (*Based on Fig. 2.6 of Stockman and Sharpe.*[21] *The data are from Stiles and Burch.*[33])

(Note that in this section of the chapter, bold uppercase symbols denote primary lights, not matrices.) Often the primary lights are chosen to be monochromatic, although this is not necessary. For each test wavelength λ, the observer adjusts the intensities and arrangement of the three primary lights to make a match between the half field containing the test light and the adjacent half field. Generally, one of the primary lights is admixed with the test, while the other two are mixed together in the adjacent half field. Figure 3*b* shows the mean $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ color-matching functions (hereafter abbreviated as CMFs) obtained by Stiles and Burch[33] for primary lights of 645, 526, and 444 nm. Notice that one of the CMFs is usually negative. There is no "negative light." Negative values mean that the primary in question has been added to the test light in order to make a match. Matches using real primaries result in negative values because the primaries do not uniquely stimulate single cone photoreceptors, the spectral sensitivities of which overlap throughout the visible spectrum (see Fig. 6). Although color-matching functions are generally plotted as functions of wavelength, it is helpful to keep in mind that they represent matches, not light spectral power distributions.

The maximum saturation match between $\mathbf{E}_\lambda$, a monochromatic constituent of the equal unit energy stimulus of wavelength λ, and the three primary lights (**R**, **G**, and **B**) is denoted by

$$\mathbf{E}_\lambda \sim \bar{r}(\lambda)\mathbf{R} + \bar{g}(\lambda)\mathbf{G} + \bar{b}(\lambda)\mathbf{B} \tag{1}$$

where $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ are the three CMFs, and where negative CMF values indicate that the corresponding primary was mixed with the test to make the perceptual match. CMFs are usually defined for a stimulus, **E**, which has equal unit energy throughout the spectrum. However, in practice the spectral power of the test light used in most matching experiments is varied with wavelength. In particular, longer-wavelength test lights are typically chosen to be intense enough to saturate the rods so that rods do not participate in the matches (see, e.g., Ref. 34). CMFs and the spectral power distributions of lights are always measured and tabulated as discrete functions of wavelength, typically defined in steps of 1, 5, or 10 nm.

We use the symbol $\sim$ in Eq. (1) to indicate that two lights are a perceptual match. Perceptual matches are to be carefully distinguished from physical matches, which are denoted by the = symbol. Of course, when two lights are a physical match, they must also be a perceptual match. Two lights that are a perceptual match but not a physical match are referred to as metameric color stimuli or metamers. The term metamerism is often used to refer to the fact that two physically different lights can appear identical.

The color-matching functions are defined for equal energy monochromatic test lights. More generally any test light, whether monochromatic or not, may be matched in the color-matching experiment. As noted above, we refer to the primary weights *R*, *G*, and *B* required to match any light as its tristimulus values. As with CMFs, tristimulus values may be negative, indicating that the corresponding primary is mixed with the test to make the match. Once the matching primaries are specified, the tristimulus values of a light provide a complete description of its effect on the human cone-mediated visual system, subject to the caveats discussed below. In addition, knowledge of the color-matching functions is sufficient to compute the tristimulus values of any light (see subsection "Tristimulus Values for Arbitrary lights" in Sec. 10.3).

Conditions for Trichromatic Color Matching There are a number of qualifications to the empirical generalization that it is possible for observers to match any test light by adjusting the intensities of just three primaries. Some of these qualifications have to do with ancillary restrictions on the experimental conditions (e.g., the size of the bipartite field and the overall intensity of the test and matching lights). The other qualifications have to do with the choice of primaries and certain conventions about the matching procedure. First the primaries must be chosen so that it is not possible to match any one of them with a weighted superposition of the other two. Second, the observer sometimes wishes to increase the intensity of one or more of the primaries above its maximum value. In this case, we must allow him to scale the intensity of the test light down. We follow the convention of saying that the match was possible and scale up the reported primary weights by the same factor. Third, as discussed in more detail above, the observer sometimes wishes to decrease the intensity of one or more of the primaries below zero. This is always the case when the test light is a spectral light unless its wavelength is equivalent to one of the primaries. In this case, we must allow the observer

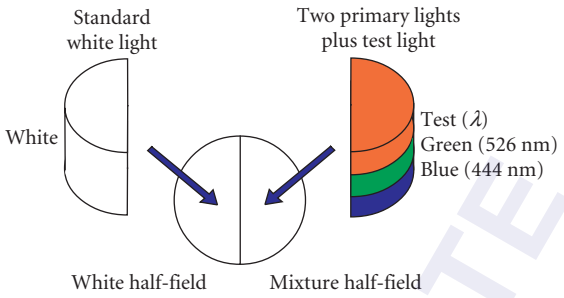

FIGURE 4 Maxwell's method of color matching. A monochromatic test field of wavelength λ replaces the primary light to which it is most similar, and a match is made to the white standard by adjusting the intensities of the two remaining primaries and the test field. (*Based on Fig. 3 of Stockman.*[206])

to superimpose each such primary on the test light rather than on the other primaries. We follow the convention of saying that the match was possible but report with negative sign the intensity of each transposed primary.

With these qualifications, matching with three primaries is always possible for small fields. For larger fields, spatial inhomogeneities may make it impossible to produce a match simultaneously across the entire field (see subsections "Specifity of CMFs" and "Tristimulus Values for Arbitrary Lights" in Sec. 10.3).

Maxwell's Matching Method It is of methodological interest to note that the maximum saturation method is not the only way to instrument the color-matching experiment. Indeed the first careful quantitative measurements of color matching and trichromacy were made by Maxwell.[35] In Maxwell's method, which is illustrated in Fig. 4, the matched fields always appear white, so that at the match point the eye is always in the same state of adaptation whatever the test wavelength (in contrast to the maximum saturation method in which the chromaticity of the match varies with wavelength). In the experiment, the subject is first presented with a white standard half-field, and is asked to match it with the three primary lights. The test light then replaces the primary light to which it is most similar and the match is repeated. Grassmann's laws are invoked to convert the two empirical matches to the form of Eq. (1).

Critical Properties of Color Matching Color-matching data are usually obtained for monochromatic test lights. Such data are useful in general only if they can be used to predict matches for other lights with arbitrary spectral power distributions, and by extension the matches that would be made for other sets of primary lights. For this to be possible, the color-matching experiment must exhibit a number of critical properties. We review these properties briefly below. Given that they hold, it is possible to show that tristimulus values provide a complete representation for the spectral properties of light as these affect human vision. Krantz provides a detailed formal treatment.[12]

Grassmann's laws Grassmann's laws describe several of the key properties of color matching. They are:[8,12]

1. *Symmetry*: If light **X** matches light **Y**, then **Y** matches **X**.
2. *Transitivity*: If light **X** matches light **Y** and **Y** matches light **Z**, then **X** matches **Z**.
3. *Proportionality*: If light **X** matches light **Y**, then n**X** matches n**Y** (where n is a constant of proportionality).
4. *Additivity:* If **W** matches **X** and **Y** matches **Z**, then the combination of **W** and **Y** matches the combination of **X** and **Z** (and similarly the combination of **X** and **Y** matches **W** and **Z**).

These laws have been tested extensively and hold well.[8,19] To a first approximation, color matching can be considered to be linear and additive.[12,36]

Uniqueness of color matches The tristimulus values of a light should be unique. This is equivalent to the requirement that only one weighted combination of the apparatus primaries produces a match to any given test light. The uniqueness of color matches ensures that tristimulus values are well-defined. In conjunction with transitivity, uniqueness also guarantees that two lights that match each other will have identical tristimulus values. It is generally accepted that, apart from variability, trichromatic color matches are unique for color normal observers.

Persistence of color matches The above properties concern color matching under a single set of viewing conditions. By viewing conditions, we refer to the properties of the image surrounding the bipartite field and the sequence of images viewed by the observer before he made the match. An important property of color matching is that lights that match under one set of viewing conditions continue to match when the viewing conditions are changed. This property is referred to as the persistence or stability of color matches.[8, 19] It holds to good approximation (but see subsection "Limits of Color Matching Data" in Sec. 10.4). The importance of the persistence law is that it allows a single set of tristimulus values to be used across viewing conditions.

Consistency across observers Finally, for the use of tristimulus values to have general validity, it is important that there should be agreement about matches across observers. For the majority of the population, there is good agreement about which lights match. We discuss individual differences in color matching in section "Limits of Color-Matching Data."

Specificity of CMFs Color-matching data are specific to the conditions under which they were measured, and strictly to the individual observers in whom they were measured. By applying the data to other conditions and using them to predict other observer's matches, some errors will inevitably be introduced.

An important consideration is the area of the retina within which the color matches were made. Standard color matching data (see section "Color-Matching Functions" in Sec. 10.4) have been obtained for centrally viewed fields with diameters of either 2° or 10° of visual angle. The visual angle refers to the angle subtended by an object in the external field at the effective optical center of the eye. The size of a circular matching field used in colorimetry is defined as the angular difference subtended at the eye between two diametrically opposite points on the circumference of the field. Thus, matches are defined according to the retinal size of the matching field *not* by its physical size. A 2° diameter field is known as a *small field*, whereas a 10° one as a *large field*. (One degree of visual angle is roughly equivalent to the width of the fingernail of the index finger held at arm's length.) Color matches vary with retinal size and position because of changes in macular pigment density and photopigment optical density with visual angle (see section "Limits of Color-Matching Data").

Standardized CMFs are mean data that are also known as *standard observer* data, in the sense that they are assumed to represent the color-matching behavior of a hypothetical typical human observer. The color matches of individual observers, however, can vary substantially from the mean matches represented by standard observer CMFs. Individual differences in lens pigment density, macular pigment density, photopigment optical density, and in the photopigments themselves can all influence color matches (see section "Limits of Color-Matching Data").

Tristimulus Values for Arbitrary Lights Given that additivity holds for color matches, the tristimulus values, R, G, and B for an arbitrarily complex spectral radiant power distribution $P(\lambda)$ can be obtained from the $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ CMFs by:

$$R = \int P(\lambda)\bar{r}(\lambda)d\lambda, \qquad G = \int P(\lambda)\bar{g}(\lambda)d\lambda, \qquad \text{and} \qquad B = \int P(\lambda)\bar{b}(\lambda)d\lambda \tag{2}$$

Since spectral power distributions and CMFs are usually discrete functions, the integration in Eq. (2) is usually replaced by a sum.

Transformability of CMFs The $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ CMFs shown in Fig. 3 are for monochromatic RGB (red-green-blue) primaries of 645, 526, and 444 nm. These CMFs can be transformed to other sets of real primary lights, and to CMFs for imaginary primary lights, such as the CIE **X, Y,** and **Z** primaries, or to CMFs representing the *LMS* cone spectral sensitivities (*cone fundamentals*). These transformations are illustrated in Fig. 5.

Each transformation of CMFs is accomplished by multiplying the CMFs, viewed as a column vector at each wavelength, by a 3×3 matrix. For now we simply assert this result, as our key point here is to note that such transformation is possible to enable a discussion of commonly used tristimulus representations. See Sec. 10.5 or Sec. 3.2.5 of Ref. 8 for more details about transformations between primaries.

The primaries selected by the CIE produced $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ CMFs that are always positive. The $\bar{y}(\lambda)$ CMF is also the luminosity function (see section "Brightness Matching and Photometry" and also Chap. 11) thus incorporating luminosity information into the CMFs, and linking colorimetry and photometry.

The primaries that yield the cone fundamentals $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ as CMFs are three imaginary primary lights that would uniquely stimulate each of the three classes of cones. Although $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ cannot be obtained directly from color matches, they are strongly constrained by color-matching data since they should be a linear transformation of any other set of CMFs. Derivation of cone fundamentals is discussed in the section "Cone Fundamentals."

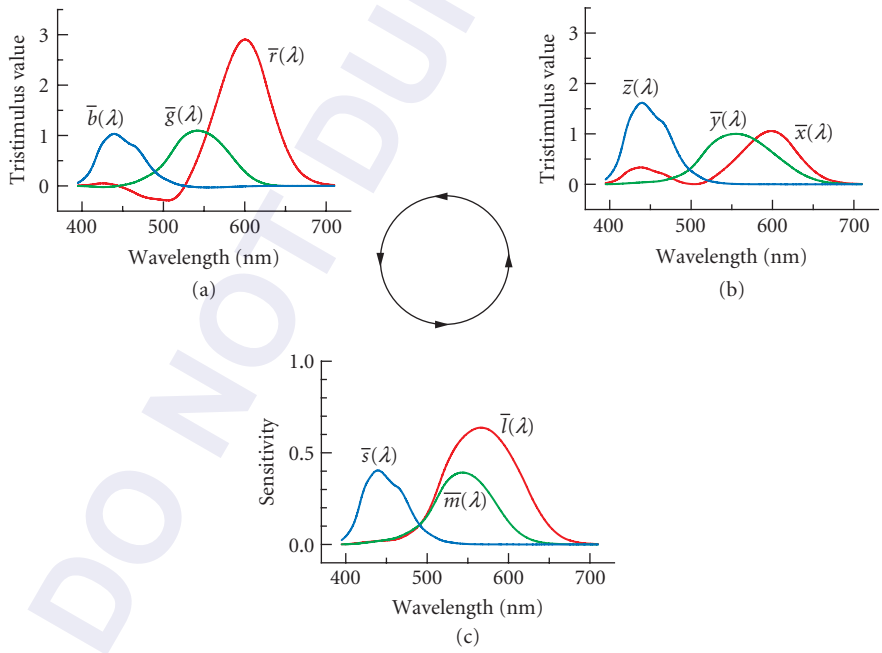

FIGURE 5 CMFs can be linearly transformed from one set of primaries to another. Illustrated here are CMFs for **R**, **G**, and **B** primaries (*a*), for the imaginary **X**, **Y**, and **Z** primaries (*b*), and the cone fundamental **L**, **M**, and **S** primaries (*c*). The CMFs shown in (*a*) and (*b*) are Judd-Vos modified CIE 1931 *RGB* and *XYZ* functions, respectively (see subsection "Judd-Vos Modified 2° Color-Matching Functions" in Sec. 10.4) and those shown in (*c*) are the Smith-Pokorny cone fundamentals (see section "Cone Fundamentals"). (*Based on Fig. 4 of Stockman.*[206])

10.4 COLOR COORDINATE SYSTEMS

Overview

For the range of conditions where the color-matching experiment obeys the properties described in the previous sections, tristimulus values (or cone coordinates) provide a complete and efficient representation of human color vision. When two lights have identical tristimulus values, they are indistinguishable to the visual system and may be substituted for one another. When two lights have tristimulus values that differ substantially, they can be distinguished by an observer with normal color vision.

The relation between spectral power distributions and tristimulus values depends on the choice of primaries used in the color-matching experiment. In this sense, the choice of primaries in colorimetry is analogous to the choice of unit (e.g., foot versus meter) in the measurement of length. We use the terms *color coordinate system* and *color space* to refer to a representation derived with respect to a particular choice of primaries. We will also use the term *color coordinates* as synonym for tristimulus values.

Although the choice of primaries determines a color space, specifying primaries alone is not sufficient to compute tristimulus values. Rather, it is the color-matching functions that characterize the properties of the human observer with respect to a particular set of primaries. As noted in section "Fundamentals of Colorimetry" above and developed in detail in Sec. 10.5, "Matrix Representations and Calculations," knowledge of the color-matching functions allows us to compute tristimulus values for arbitrary lights, as well as to derive color-matching functions with respect to other sets of primaries. Thus in practice we can specify a color space either by its primaries or by its color-matching functions.

A large number of different color spaces are in common use. The choice of which color space to use in a given application is governed by a number of considerations. If all that is of interest is to use a three-dimensional representation that accurately predicts the results of the color-matching experiment, the choice revolves around the question of finding a set of color-matching functions that accurately capture color-matching performance for the set of observers and viewing conditions under consideration. From this point of view, color spaces that differ only by an invertible linear transformation are equivalent. But there are other possible uses for color representation. For example, one might wish to choose a space that makes explicit the responses of the physiological mechanisms that mediate color vision. We discuss a number of commonly used color spaces based on CMFs, cone fundamentals, and transformations of the cone fundamentals guided by assumptions about color vision after the photoreceptors.

Many of the CMFs and cone fundamentals are available online in tabulated form at URL http://www.cvrl.org/.

Stimulus Spaces

A stimulus space is the color space determined by the primaries of a particular apparatus. For example, stimuli are often specified in terms of the excitation of three monitor phosphors. Stimulus color spaces have the advantage that they provide a direct description of the physical stimulus. On the other hand, they are nonstandard and their use hampers comparison of data collected in different laboratories. A useful compromise is to transform the data to a standard color space, but to provide enough side information to allow exact reconstruction of the stimulus. Often this side information can be specification of the apparatus primaries.

Color-Matching Functions

Several sets of standard CMFs are available for the central 2° or the central 10° of vision. For the central 2° (the small-field matching conditions), they are the CIE 1931 CMFs,[37] the Judd-Vos modified 1931 CMFs,[38,39] and the Stiles and Burch CMFs.[33] For the central 10° (the large-field matching conditions), they are the 10° CMFs of Stiles and Burch,[34] and the related 10° CIE 1964 CMFs. CIE functions are available as $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ for the real primaries **R**, **G**, and **B**, or as $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ for the imaginary primaries **X**, **Y**, and **Z**. The latter are more commonly used in applied colorimetry.

CIE 1931 2° Color-Matching Functions In 1931, the CIE integrated a body of empirical data to determine a standard set of CMFs.[37,40] The notion was that the CIE 1931 color-matching functions would characterize the results of a color-matching experiment performed on an "average" or "standard" color-normal human observer known as the CIE 1931 standard observer. They are available in both $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ and $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ form.

The empirical color-matching data used to construct the 1931 standard observer were those of Wright[41] and Guild,[32] which provided only the ratios of the three primaries required to match spectral test lights. Knowledge of the absolute radiances of the matching primaries is required to generate CMFs, but this was unavailable. The CIE reconstructed this information by assuming that a linear combination of the three unknown CMFs was equal to the 1924 CIE $V(\lambda)$ function.[37,42] In addition to uncertainties about the validity of this assumption,[43] the $V(\lambda)$ curve that was used as the standard is now known not to provide an accurate description of typical human performance; it is far too insensitive at short wavelengths (see Fig. 2.13 of Ref. 44).

More generally, there is now considerable evidence that the color-matching functions standardized by the CIE in 1931 differ from those of the average human observer[21,33,34,38,39] and the CIE has recently recommended[11] a new set of color-matching functions based on estimates of the cone photoreceptor spectral sensitivities and the Stiles and Burch 10° CMFs.[34] A large body of extant data is available only in terms of the CIE 1931 system, however, and many colorimetric instruments are designed around it. Therefore it seems likely that the CIE 1931 system will continue to be of practical importance for some time. Its inadequacy at short-wavelengths is well-known, and is often taken into account in colorimetric and photometric applications.

Judd-Vos Modified 2° Color-Matching Functions In 1951, Judd reconsidered the 1931 CMFs and came to the conclusion that they could be improved.[38] He increased the sensitivity of $V(\lambda)$ used to reconstruct the CIE CMFs below 460 nm, and derived a new set of CMFs [see Table 1 (5.5.2) of Ref. 8, which were later slightly modified by Vos,[39] see his Table 1].

The modifications to the $V(\lambda)$ function introduced by Judd had the unwanted effect of producing CMFs that are relatively insensitive near 460 nm (where they were unchanged). Although this insensitivity can be roughly characterized as being consistent with a high macular pigment density,[33,45,46] the CMFs are somewhat artificial and thus removed from real color matches. Nevertheless, in practice the Judd-Vos modifications lead to a set of CMFs that are probably more typical of the average human observer than the original CIE 1931 color-matching functions. These functions were never officially standardized. However, they are widely used in practice, especially in vision science, because they are the basis of a number of estimates of the human cone spectral sensitivities, including the recent versions of the Smith-Pokorny cone fundamentals.[47]

Stiles and Burch (1955) 2° CMFs The assumption used to construct the CIE 1931 standard observer, namely that $V(\lambda)$ is a linear combination of the CMFs is now unnecessary, since current instrumentation allows CMFs to be measured in conjunction with absolute radiometry. The Stiles and Burch 2° CMFs[33] are an example of directly measured functions. Though referred to by Stiles as "pilot" data, these CMFs are the most extensive set of directly measured color-matching data for 2° vision available, being averaged from matches made by 10 observers. Even compared in relative terms, there are real differences between the CIE 1931 and the Stiles and Burch[33] 2° color-matching data in the range between 430 and 490 nm. These CMFs are seldom used.

Stiles and Burch (1959) 10° CMFs The most comprehensive set of color-matching data are the large-field, centrally viewed 10° CMFs of Stiles and Burch.[34] Measured in 49 subjects from approximately 390 to 730 nm (and in nine subjects from 730 to 830 nm), these data are probably the most secure set of existing CMFs. Like the Stiles and Burch 2° functions,[33] the 10° functions represent directly measured CMFs, and so do not depend on measures of $V(\lambda)$. These CMFs are the basis of the Stockman and Sharpe[46] cone fundamentals (see section "Cone Fundamentals") and thus the recent CIE proposal for a set of physiologically relevant CMFs.[11]

1964 10° Color-Matching Functions In 1964, the CIE standardized a second set of CMFs appropriate for larger field sizes. These CMFs take into account the fact that human color matches depend on

the size of the matching fields. The CIE 1964 10° color-matching functions are an attempt to provide a standard observer for these larger fields. The use of 10° color-matching functions is recommended by the CIE when the sizes of the regions under consideration are larger than 4°.[10] The large field CIE 1964 CMFs are based mainly on the 10° CMFs of Stiles and Burch[34] and to a lesser extent on the arguably inferior and possibly rod-contaminated 10° CMFs of Speranskaya.[48] These functions are available as $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ and $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$.

While the CIE 1964 CMFs are similar to the 10° CMFs of Stiles and Burch functions, they differ in several ways that compromise their use as the basis for cone fundamentals.[46] The CIE[11] has now recommended a new set of 10° color-matching functions that are more tightly coupled to estimates of the cone spectral sensitivities and are based on the original Stiles and Burch 10° data.

Cone Fundamentals

An important goal in color science since the establishment of trichromatic color theory,[49–52] has been the determination of the linear transformation between $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ and the three cone spectral sensitivities, $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$.

A match between the test and mixture fields in a color-matching experiment is a match at the level of the cone photoreceptors. The response of each cone class to the mixture of primaries equals the response of that cone class to the test light. Put more formally, the following equations must hold for each unit energy test light:

$$\begin{aligned} \bar{l}_R\bar{r}(\lambda)+\bar{l}_G\bar{g}(\lambda)+\bar{l}_B\bar{b}(\lambda)&=\bar{l}(\lambda)\\ \bar{m}_R\bar{r}(\lambda)+\bar{m}_G\bar{g}(\lambda)+\bar{m}_B\bar{b}(\lambda)&=\bar{m}(\lambda)\\ \bar{s}_R\bar{r}(\lambda)+\bar{s}_G\bar{g}(\lambda)+\bar{s}_B\bar{b}(\lambda)&=\bar{s}(\lambda) \end{aligned} \tag{3}$$

where $\bar{l}_R$, $\bar{l}_G$, and $\bar{l}_B$ are, respectively, the L-cone sensitivities to the **R**, **G**, and **B** primary lights, $\bar{m}_R$, $\bar{m}_G$, and $\bar{m}_B$ are the M-cone sensitivities to the primary lights, and $\bar{s}_R$, $\bar{s}_G$, and $\bar{s}_B$ are the S-cone sensitivities.

Since the S cones are now known to be insensitive to long wavelengths, it can be assumed that $\bar{s}_R$ is effectively zero for a long-wavelength **R** primary. There are therefore eight unknowns required, and we can rewrite Eq. (3) as a linear transformation:

$$\begin{pmatrix} \bar{l}_R & \bar{l}_G & \bar{l}_B \\ \bar{m}_R & \bar{m}_G & \bar{m}_B \\ 0 & \bar{s}_G & \bar{s}_B \end{pmatrix} \begin{pmatrix} \bar{r}(\lambda) \\ \bar{g}(\lambda) \\ \bar{b}(\lambda) \end{pmatrix} = \begin{pmatrix} \bar{l}(\lambda) \\ \bar{m}(\lambda) \\ \bar{s}(\lambda) \end{pmatrix} \tag{4}$$

Moreover, since we are often more concerned about the relative $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ cone spectral sensitivities, rather than their absolute values, the eight unknowns become five:

$$\begin{pmatrix} \bar{l}_R/\bar{l}_B & \bar{l}_G/\bar{l}_B & 1 \\ \bar{m}_R/\bar{m}_B & \bar{m}_G/\bar{m}_B & 1 \\ 0 & \bar{s}_G/\bar{s}_B & 1 \end{pmatrix} \begin{pmatrix} \bar{r}(\lambda) \\ \bar{g}(\lambda) \\ \bar{b}(\lambda) \end{pmatrix} = \begin{pmatrix} k_l\,\bar{l}(\lambda) \\ k_m\bar{m}(\lambda) \\ k_s\,\bar{s}(\lambda) \end{pmatrix} \tag{5}$$

Note that the constants k_l, k_m, and k_s remain unknown. Their values are typically chosen to scale the three cone fundamentals to meet some side criterion: for example, so that $k_l\bar{l}(\lambda)$, $k_m\bar{m}(\lambda)$, and $k_s\bar{s}(\lambda)$ peak at unity. Smith and Pokorny[53] assume that $k_l\bar{l}(\lambda)+k_m\bar{m}(\lambda)$ sum to $V(\lambda)$, the luminous efficiency function. Care should be taken when drawing conclusions that depend on the scaling chosen.

The five unknowns in the left of Eq. (5) can be estimated by fitting linear combinations of CMFs to cone spectral sensitivity measurements made in dichromatic observers and in normal observers under special conditions that isolate the responses of single cone types. They can also be estimated by comparing

color matches made by normal and dichromatic observers. Estimates from dichromats depend on the "loss," "reduction," or "König" assumption that dichromatic observers lack one of the three cone types, but retain two that are identical in spectral sensitivity to the normal counterparts.[35,54] The identity of the two remaining cone types means that dichromats accept all color matches set by normal trichromats. The loss hypothesis now has a firm empirical foundation, because it has become possible to sequence and identify the photopigment opsin genes of normal, dichromatic and monochromatic observers.[55,56] As a result, individuals who conform to the loss assumption can be selected by genetic analysis. Thanks to the longer wavelength part of the visible spectrum being effectively dichromatic, because of the insensitivity of the S cones to longer wavelength lights, the unknown value, $\overline{s}_G / \overline{s}_B$, can also be derived directly from normal color-matching data (see Refs. 57 and 58 for details).

Several authors have estimated LMS cone spectral sensitivities using the loss hypothesis.[8,53,59–66] Figure 6 shows estimates by Smith and Pokorny[53] and Stockman and Sharpe.[46] The Smith-Pokorny estimates are a transformation of the Judd-Vos corrected CIE 1931 functions (see earlier). The Stockman-Sharpe estimates are a transformation of the Stiles and Burch 10° (see earlier) adjusted to 2° (see Ref. 21 for further information).

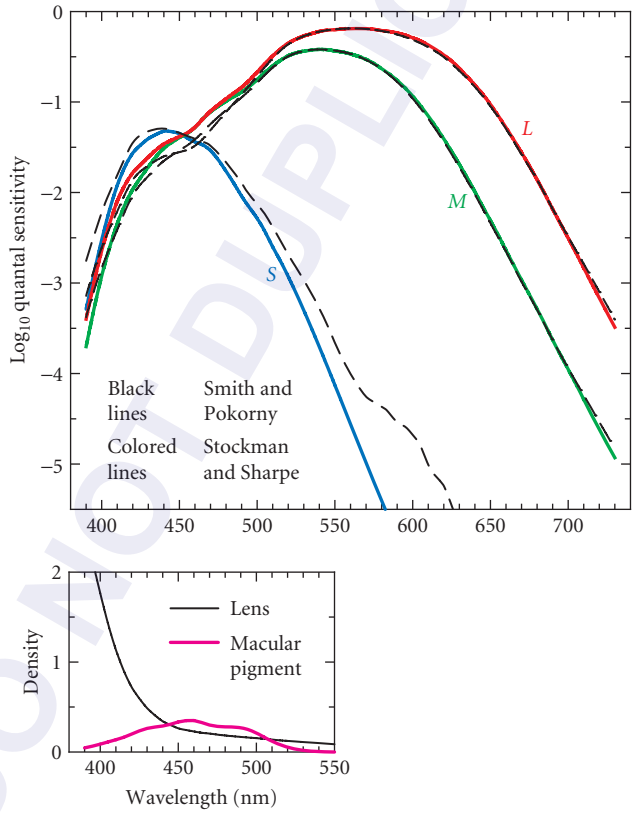

FIGURE 6 *S*-, *M*-, and *L*-cone spectral sensitivity estimates of Stockman and Sharpe[46] (colored lines) compared with the estimates of Smith and Pokorny[53] (dashed black lines). The lower inset shows the lens pigment optical density spectrum (black line) and the macular pigment optical density spectrum (magenta line) from Stockman and Sharpe.[46] Note the logarithmic vertical scale—commonly used in such plots to emphasize small sensitivities. (*Based on Fig. 5 of Stockman.*[206])

Limits of Color-Matching Data

Specifying a stimulus using tristimulus values depends on having an accurate set of color-matching functions. The CMFs and cone fundamentals discussed in preceding sections are designed to be representative of a standard observer under typical viewing conditions. A number of factors limit the precision to which a standard color space can predict the individual color matches. We describe some of these factors below. Wyszecki and Stiles[8] provide a more detailed treatment.

For most applications, standard calculations are sufficiently precise. However, when high precision is required, it is necessary to tailor a set of color-matching functions to the individual and observing conditions of interest. Once such a set of color-matching functions or cone fundamentals is available, the techniques described in other sections may be used to compute corresponding color coordinates.

Standard sets of color-matching functions are summaries or means of color-matching results for a number of color-normal observers. There is small but systematic variability between the matches set by individual observers, and this variability limits the precision to which standard color-matching functions may be taken as representative of any given color-normal observer. A number of factors underlie the variability in color matching. Stiles and Burch carefully measured color-matching functions for 49 observers using 10° fields.[33,34] Webster and MacLeod analyzed individual variation in these color-matching functions.[67] They identified five primary factors that drive the variation in individual color matches. These are macular pigment density, lens pigment density, photopigment optical density, amount of rod intrusion into the matches, and variability in the absorption spectra of the L, M, and S cone photopigments.

Macular Pigment Density Light must pass through the ocular media before reaching the photoreceptors. At the fovea this includes the macula lutea, which contains macular pigment. This pigment absorbs lights of shorter wavelengths covering a broad spectral region centered on 460 nm (see inset of Fig. 6). There are large individual differences in macular pigment density, with peak densities at 460 nm ranging from 0.0 to about 1.2.[68–70]

Lens Pigment Density Light is focused on the retina by the cornea and the yellow pigmented crystalline lens. The lens pigment absorbs light mainly of short wavelengths (see inset of Fig. 6). Individual differences in lens pigment density range by as much as ±25 percent of the mean density in young observers (<30 years old).[71] Lens pigment also increases with age,[72,73] resulting in systematic differences in color-matching functions between populations of different ages.[74]

Photopigment Optical Density The axial optical density of the photopigment in the photoreceptor outer segment depends on several factors, including the underlying photopigment extinction or absorbance spectra, outer segment length, and the photopigment concentration within the outer segment. All these factors can vary between individuals,[75–82] and within individuals. Photoreceptor outer segment length, and thus axial photopigment optical density, decreases with retinal eccentricity.[83,84] Although changes in photopigment optical density are typically neglected, they can become important under circumstances where very intense adapting fields (which dilute the photopigment by bleaching) are employed or where fixation is eccentric. See section "Adjusting Cone Spectral Sensitivities for Individual Differences" for corrections that account for changes in photopigment optical density.

Variability in Photopigment λ_{max} Genetic and behavioral evidence shows that there are multiple versions of the human L- and M-cone photopigments.[56,85–89] This multiplicity is known as cone polymorphism. The most common genetic polymorphism is the substitution of alanine for serine at position 180 of the L-cone photopigment gene. This substitution produces a shift in the L-cone photopigment spectral sensitivity of several nanometers, with the A180 variant shifted toward shorter wavelengths relative to the S180 variant (see Ref. 89 for a review of shift estimates). In applications where precise knowledge of an individual's cone spectral sensitivities is important, genotyping can now help provide key information.[46,90] Some individuals possess more than one variant of the L- or M- cone photopigment gene.[55, 91–93]

Color-Deficient Observers A class of color-deficient individuals, known as anomalous red-green trichromats, are trichromatic but set color matches substantially different from color-normal observers. Anomalous red-green trichromacy is caused by the spectral sensitivity of either the L- or the M-cone photopigment being shifted from its normal location to an anomalous position that lies closer to the location of the spectral sensitivity function of the remaining normal M- or L-cone photopigment (for a review, see Ref. 89). These shifts result from the inheritance of hybrid LM- or ML-cone photopigment opsin genes, which are fusion genes produced by intragenic crossing over, containing the coding sequences of both L- and M-cone pigment genes. Measurements of the absorbance spectrum peaks of the hybrid pigments made *in vitro*[87,94] and *in vivo*[95,96] reveal a wide range of possible anomalous spectra that lie between the normal L- and M-cone spectra. The peak absorbances of the LM hybrid pigments cluster within about 8 nm of the peak absorbance of the normal M-cone pigment, while those of the ML hybrid pigments cluster within about 12 nm of the peak absorbance of the normal L-cone pigment (see Table 1 of Ref. 97). In protanomalous trichromats, one of the two polymorphic variants of the normal L-cone pigment has been replaced with a hybrid LM pigment, whereas in deuteranomalous trichromats one of the two polymorphic variants of the normal M-cone pigment has been replaced with a hybrid ML pigment.

Our development of colorimetric calculations in Sec. 10.5 can be used to tailor color specification in a particular application for color anomalous individuals, if their color-matching functions are known. Estimates of the cone sensitivities of color anomalous observers are available.[47,98] Estimates of the A180 and S180 variants of the Stockman and Sharpe 2° functions are tabulated in Table A of Ref. 99. Details of how to adjust cone fundamentals for different λ_{max} values are discussed in section "Adjusting Cone Spectral Sensitivities for Individual Differences" (see also section "Photopigment Optical Density Spectra" of Ref. 21).

Some individuals require only two primaries in the color-matching experiment (i.e., they are dichromats) or in rare cases only one primary (i.e., they are monochromats). Dichromats, like anomalous trichromats, are referred to as color deficient. Monochromats are, however, truly color blind (except for rod-cone interactions at mesopic levels in single cone monochromats[100]). Most forms of monochromacy and dichromacy can be understood by assuming that the individual lacks one or more of the normal three types of cone photopigment.[35,101] Individuals who lack the L-, M-, or S-cone photopigments are known, respectively, as protanopes, deuteranopes, or tritanopes. Protanopes and deuteranopes are much more common than tritanopes.[89] Some protanopes and deuteranopes have only one of the two normal longer wavelength cone photopigments, and so are true loss dichromats. Some, however, have a single hybrid ML- or LM-cone photopigment, which is intermediate in spectral position between M and L, while others have two cone photopigments with identical or nearly identical spectral sensitivities. For dichromatic and monochromatic individuals with normal cone photopigments (i.e., those without hybrid photopigments), the use of standard color coordinates will produce acceptable results, since a match for all three cone types will also be a match for any subset of these types. In very rare cases, an individual has no cones at all and his vision is mediated entirely by rods. His visual matches can be predicted by the CIE scotopic luminosity function [see Table I (4.3.2) of Ref. 8].

Simple standard tests exist for identifying color-deficient and color-anomalous individuals. These include the Ishihara pseudoisochromatic plates,[102] the Farnsworth 100 hue test,[103] and the Rayleigh match.[104] For coverage of the available clinical tests see Ref. 105. Genetic analysis may also be used to identify the variants of cone pigments likely to be expressed by a given individual.[46]

Retinal Inhomogeneity Most standard colorimetric systems are based on color-matching experiments where the bipartite field was either 2° or 10° in diameter and viewed foveally. The distribution of photoreceptors is not homogeneous across the retina, however, and both macular pigment and photopigment optical density decline with eccentricity. Thus, CMFs that are accurate for the fovea do not necessarily describe color matching in the extra fovea. The CIE 1964 10° *XYZ* color-matching functions are designed for situations where the colors being judged subtend a large visual angle. Stockman and Sharpe[46] provide both 2° and 10° cone fundamentals.

Another consideration is that the absence of S cones in approximately the central 25-min diameter of vision makes color matches confined to that small region tritanopic.[106–109]

Rod Intrusion Both outside the fovea and at low light levels, rods can play a role in color-matching. Under conditions where rods play a role, there is a shift in the color-matching functions due to the contribution of rod signals. Wyszecki and Stiles[8] discuss approximate methods for correcting standard sets of color-matching functions when rods intrude into color vision.

Chromatic Aberrations By some standards, even the small (roughly 2°) fields used as the basis of most color coordinate systems are rather coarse. The optics of the eye contain chromatic aberrations which cause different wavelengths of light to be focused with different accuracy. These aberrations can cause a shift in the color-matching functions if the stimuli being matched have fine spatial structure. Two stimuli which are metameric at low spatial frequencies may no longer be so at high spatial frequencies. Such effects can be quite large.[110–112] It is possible to correct color coordinates for chromatic aberration if enough side information is available. Such correction is rare in practice but can be important for stimuli with fine spatial structure. Some guidance is available from the literature.[111,113] Another strategy available in the laboratory is to correct the stimulus for the chromatic aberration of the eye.[114]

Adjusting Cone Spectral Sensitivities for Individual Differences

Adjustments from Corneal to Photoreceptor Sensitivities Cone spectral sensitivities and CMFs are measured with respect to light entering the observers' cornea. However, between the cornea and photoreceptor, the light passes through the pigmented crystalline lens, and in the fovea through the macula lutea. Both of these filters markedly reduce the observers' sensitivity to short-wavelength lights (see Fig. 6).

In the first part of this section, we describe how to adjust the cone spectral sensitivities back to their values at the photoreceptor. A related adjustment is to correct cone spectral sensitivities and CMFs for individual differences in lens and macular pigment densities.

The calculation of photoreceptor sensitivities is straightforward given the lens $[d_{\text{lens}}(\lambda)]$ and macular $[d_{\text{mac}}(\lambda)]$ density spectra, as well as the respective scaling constants, k_{lens} and k_{mac}, by which each should be multiplied. Beginning with the *quantal* corneal spectral sensitivity of, for example, the L cones $[\bar{l}(\lambda)]$, the filtering by the lens pigment $[k_{\text{lens}}d_{\text{lens}}(\lambda)]$ and the macular pigment $[k_{\text{mac}}d_{\text{mac}}(\lambda)]$ is removed:

$$\log_{10}[\bar{l}_r(\lambda)] = \log_{10}[\bar{l}(\lambda)] + k_{\text{lens}}d_{\text{lens}}(\lambda) + k_{\text{mac}}d_{\text{mac}}(\lambda) \tag{6}$$

to give $\bar{l}_r(\lambda)$, the spectral sensitivity of the cones at the photoreceptor. The mean or standard $d_{\text{lens}}(\lambda)$ and $d_{\text{mac}}(\lambda)$ spectra that are assumed appropriate for the Stockman and Sharpe 2° cone fundamentals are tabulated in Table 2 of their paper.[46] These densities correspond to a macular density of 0.35 at 460 nm, and a lens density of 1.765 at 400 nm. For the standard 2° observer, the values of k_{lens} and k_{mac} are set to 1, but should be adjusted appropriately for individual observers or groups of observers with different lens and macular densities. For the mean 10° observer of Stockman and Sharpe, the values of k_{lens} and k_{mac} are assumed to be 1 and 0.27, respectively.

To calculate back from photoreceptor to corneal sensitivities, the filtering by the lens and macular pigments is added back:

$$\log_{10}[\bar{l}(\lambda)] = \log_{10}[\bar{l}_r(\lambda)] - k_{\text{lens}}d_{\text{lens}}(\lambda) - k_{\text{mac}}d_{\text{mac}}(\lambda) \tag{7}$$

Again, k_{lens} and k_{mac} should be adjusted as appropriate.

Macular pigment density can be estimated psychophysically from the differences between spectral sensitivities measured centrally and peripherally (in the macular-free area). Note, however, that such estimates can be affected by other changes between the two locations, such as photopigment optical density (see Fig. 2.5 of Ref. 21). Relative estimates of lens density can be obtained psychophysically by measuring spectral sensitivities in a macular-free area of the retina, and then comparing them with

mean spectral sensitivity data. Typically, rod spectral sensitivities are measured[115] and then compared with mean rod data, such as the data for 50 observers measured by Crawford[72] to obtain the mean standard rod spectral sensitivity function, $V'(\lambda)$. Absolute lens density estimates can be obtained by comparing spectral sensitivities with photopigment spectra. See Ref. 21 for discussion.

Adjustments for Photopigment Optical Density As noted above, decreases and increases in photopigment optical density result in a narrowing or broadening, respectively, of the cone spectral sensitivity curves. Corrections for these changes are most easily applied to the cone fundamentals.

The photopigment optical density or absorbance spectra $[\bar{l}_{OD}(\lambda)]$ can be calculated from photoreceptor spectral sensitivity $[\bar{l}_r(\lambda)]$ given the value of D_{peak}, the peak optical density of the photopigment, thus:

$$\bar{l}_{OD}(\lambda) = \frac{-\log_{10}[1-\bar{l}_r(\lambda)]}{D_{peak}} \tag{8}$$

Note that $\bar{l}_r(\lambda)$ should be scaled before applying Eq. (8) for $\bar{l}_{OD}(\lambda)$ to peak at 1. Stockman and Sharpe[46] assume L-, M-, and S-cone D_{peak} of 0.5, 0.5, and 0.4, respectively, for their mean 2° observer, and values of 0.38, 0.38, and 0.3 for their mean 10° observer.

The spectral sensitivity at the photoreceptor, $\bar{l}_r(\lambda)$, can be calculated from the normalized photopigment optical density spectrum, $\bar{l}_{OD}(\lambda)$, by the inversion of Eq. (8) (see Ref. 116):

$$\bar{l}_r(\lambda) = 1 - 10^{-D_{peak}\bar{l}_{OD}(\lambda)} \tag{9}$$

Calculations from corneal spectral sensitivities to retinal photopigment optical densities ignore changes in spectral sensitivity that may result from the structure of the photoreceptor or other ocular structures and pigments (unless they are incorporated in estimates of the lens or macular pigment density spectra).

Photopigment optical density can be estimated from the differences between spectral sensitivities or color matches obtained when the concentration of the photopigment is dilute and those obtained when it is in its normal concentration. This can be achieved psychophysically by comparing data obtained under bleached versus unbleached conditions or for obliquely versus axially presented lights. Bleaching measurements yield mean peak optical density values in the range 0.3 to 0.6, those that depend on oblique presentation in the range 0.7 to 1.0 and objective measures in the range 0.35 to 0.57. See Ref. 21 for discussion.

Adjustments for Changes in Photopigment λ_{max} Adjustments in the spectral position of the photopigment spectra can be affected by shifting them along an appropriate spectral scale before applying Eq. (7) to restore the prereceptoral filtering, the appropriate scale being one that preserves the shapes of photopigment spectra, in general, as λ_{max} changes (i.e., their shape should be invariant). An early proposal was by Dartnall[117] who proposed a "nomogram" or template shape for photopigment spectra that was invariant when shifted along frequency or wavenumber ($1/\lambda$, in units of cm^{-1}) scale. Shape invariance, however, is better preserved when spectra are plotted as a function of log frequency or log wavenumber $[\log(1/\lambda)]$,[118–120] which is equivalent to log wavelength $[\log(\lambda)]$ or normalized frequency (λ_{max}/λ). Barlow[121] has also proposed an abscissa of the fourth root of wavelength ($\sqrt[4]{\lambda}$). A recent nomogram proposed by Govardovskii et al.[122] is seeing considerable use. See also Eq. (8) of Ref. 46 for human photopigment nomograms. Linear wavelength scales (λ) should not be used to shift pigment templates unless the spectral shift is quite small.

Opponent and Contrast Spaces

Cone coordinates are useful because they make explicit the responses of the initial physiological mechanisms thought to mediate color vision. A number of investigators have begun to use representations that attempt to represent the responses of subsequent postreceptoral mechanisms. Two basic

ideas underlie these representations. The first is the general opponent processing model described in companion chapter (Chap. 11) in this volume. We call representations based on this idea opponent color spaces. The second idea is that stimulus contrast is more relevant than stimulus magnitude.[123] We call spaces that are based on this second idea modulation or contrast color spaces. Some color spaces are both opponent and contrast color spaces.

Cone contrast space To derive coordinates in the cone contrast color space, the stimulus is first expressed in terms of its cone coordinates. The cone coordinates of a white point are then chosen. Usually these are the cone coordinates of a uniform adapting field or the spatio-temporal average of the cone coordinates of the entire image sequence. The cone coordinates of the white point are subtracted from the cone coordinates of the stimulus and the resulting differences are normalized by the corresponding cone coordinates of the white point.

The DKL color space Derrington, Krauskopf, and Lennie[124] introduced an opponent modulation space that is now widely used. This space is closely related to the chromaticity diagram suggested by MacLeod and Boynton[125] (see also Ref. 126). To derive coordinates in the DKL color space, the stimulus is first expressed in cone coordinates. As with cone contrast space, the cone coordinates of a white point are then subtracted from the cone coordinates of the stimulus of interest. The next step is to reexpress the resulting difference as tristimulus values with respect to a new choice of primaries that are thought to isolate the responses of post-receptoral mechanisms.[127,128] The three primaries are chosen so that modulating two of them does not change the response of the photopic luminance mechanism (see section "Brightness Matching and Photometry"). The color coordinates corresponding to these two primaries are often called the constant B and constant R and G coordinates. Modulating the constant R and G coordinates of a stimulus modulates only the S cones. Modulating the constant B coordinate modulates both the L and M cones but keeps the S-cone response constant. Because the constant R and G coordinates are not allowed to change the response of the photopic luminance mechanism, the DKL color space is well-defined only if the S cones do not contribute to luminance. The third primary of the space is chosen so that it has the same relative cone coordinates as the white point. The coordinate corresponding to this third primary is called the luminance coordinate. Flitcroft[110] and Brainard[129] provide detailed treatments of the DKL color space.

Caveats The basic ideas underlying the use of opponent and modulation/contrast color spaces seem to be valid. On the other hand, there is not a general agreement about how signals from cones are combined into opponent channels, about how this combination depends on adaptation, or about how adaptation affects signals originating in the cones. Since a specific model of these processes is implicit in any opponent or modulation/contrast color space, coordinates in these spaces must be treated carefully. This is particularly true of contrast spaces, where the relation between the physical stimulus and coordinates in the space depends on the choice of white point. As a consequence, radically different stimuli can have identical coordinates in a contrast space. For example, 100 percent contrast monochromatic intensity gratings are all represented by the same coordinates in contrast color spaces, independent of their wavelength. Nonetheless, such stimuli appear very different to human observers. Identity of coordinates in a contrast color space does not imply identity of appearance across different choices of white points. See Ref. 129 for more extended discussion.

Visualizing Color Data

A challenge facing today's color scientist is to produce and interpret graphical representations of color data. Because color coordinates are three-dimensional, it is difficult to plot them on a two-dimensional page. Even more difficult is to represent a dependent measure of visual performance as a function of color coordinates. We discuss several approaches.

Three-Dimensional Approaches One strategy is to plot the three-dimensional data in perspective. In many cases the projection viewpoint may be chosen to provide a clear view of the regularities of

interest in the data. In Fig. 7*a* the spectrum locus is shown in the LMS tristimulus space. The three-dimensional structure of the data may be emphasized by the addition of various monocular depth cues to such figures, such as shading or drop lines. A number of computer graphics packages now provide facilities to aid in the preparation of three-dimensional perspective plots. Often these programs allow variation of the viewpoint and automatic inclusion of monocular depth cues.

Computer display technology also provides promise for improved methods of viewing three-dimensional data. For example, it is now possible to produce computer animations that show plots that vary over time. Such plots have the potential for representing multidimensional data in a manner that is more comprehensible to a human viewer than a static plot. Other interesting possibilities include the use of stereo depth cues and color displays. Online publication is making the use of such technologies more widely available for archival purposes.

Another approach to showing the three-dimensional structure of color data is to provide multiple two-dimensional views, as in a draftsman's sketch. This is illustrated in Fig. 7.

Chromaticity Diagrams A second strategy for plotting color data is to reduce the dimensionality of the data representation. One common approach is through the use of chromaticity coordinates. Chromaticity coordinates are defined so that any two lights with the same relative color coordinates have identical chromaticity coordinates. That is, the chromaticity coordinates of a light are invariant with respect to intensity scaling. Because chromaticity coordinates have one fewer degree of freedom than color coordinates, they can be described by just two numbers and plotted in a plane. We call a plot of chromaticity coordinates a chromaticity diagram. A chromaticity diagram eliminates all information about the intensity of a stimulus.

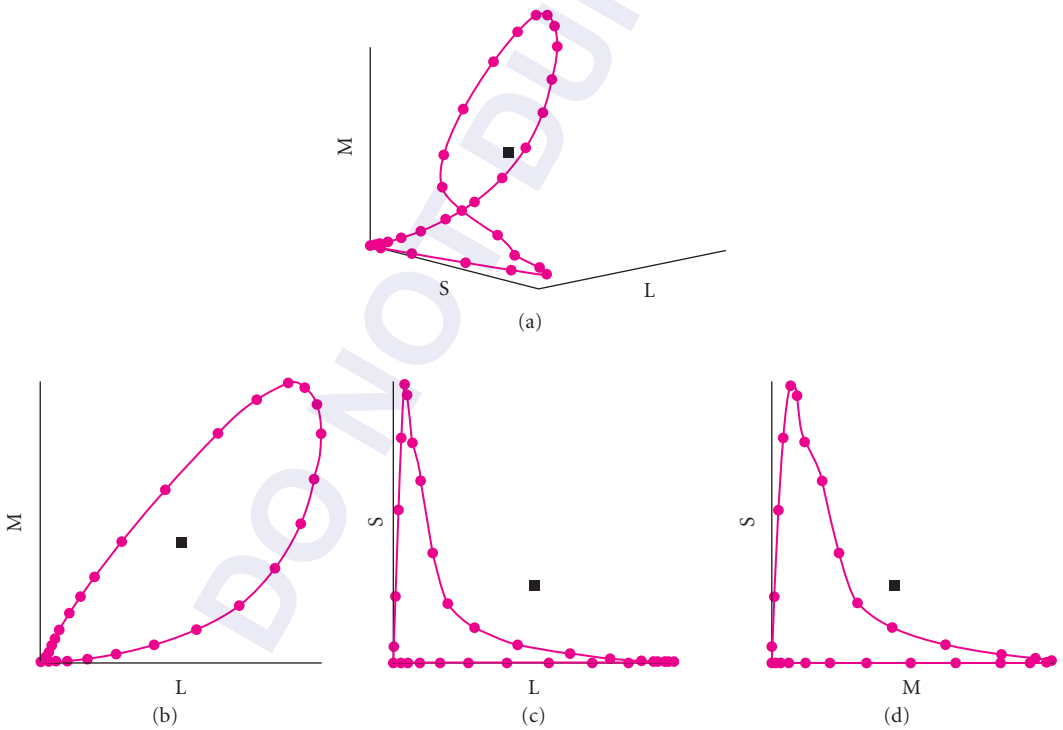

FIGURE 7 Three-dimensional views of color data. The figure shows the color coordinates of an equal energy spectrum in color space defined by the human cone sensitivities (connected closed circles) and the color coordinates of CIE daylight D65 (closed squares). (*a*) The data in perspective. (*b*, *c*, and *d*) Three two-dimensional views of the same data.

There are many ways to normalize color coordinates to produce a set of chromaticity coordinates. In general, the chromaticity coordinates $[r(\lambda), g(\lambda), \text{and } b(\lambda)]$ of the spectrum locus are related to the CMFs $[\bar{r}(\lambda), \bar{g}(\lambda), \text{and } \bar{b}(\lambda)]$ as follows:

$$r(\lambda) = \frac{\bar{r}(\lambda)}{\bar{r}(\lambda)+\bar{g}(\lambda)+\bar{b}(\lambda)}$$

$$g(\lambda) = \frac{\bar{g}(\lambda)}{\bar{r}(\lambda)+\bar{g}(\lambda)+\bar{b}(\lambda)} \quad \text{and} \tag{10}$$

$$b(\lambda) = \frac{\bar{b}(\lambda)}{\bar{r}(\lambda)+\bar{g}(\lambda)+\bar{b}(\lambda)}$$

Given $r(\lambda)+g(\lambda)+b(\lambda)=1$, only $r(\lambda)$ and $g(\lambda)$ are typically plotted, since $b(\lambda)$ is $1-[r(\lambda)+g(\lambda)]$.

For the special case of the 1931 CMFs, we have:

$$x(\lambda) = \frac{\bar{x}(\lambda)}{\bar{x}(\lambda)+\bar{y}(\lambda)+\bar{z}(\lambda)} \quad \text{and}$$

$$y(\lambda) = \frac{\bar{y}(\lambda)}{\bar{x}(\lambda)+\bar{y}(\lambda)+\bar{z}(\lambda)} \tag{11}$$

Figure 8 shows the spectrum locus in the 1931 CIE *x, y* chromaticity space with an approximate representation of the colors associated with each coordinate.

Neither *r, g* nor *x, y* chromaticity diagrams provide a strong visual connection between the data representation and the underlying cone mechanisms. For this reason, there is increasing use of chromaticity diagrams defined by the cone fundamentals. Figure 9 shows the spectrum locus plotted in *l, m* chromaticity coordinates.

A useful property of most chromaticity diagrams is that the chromaticity coordinates of the mixture of two lights is always a weighted combination of chromaticity coordinates of the individual lights. This is easily verified for the CIE 1931 chromaticity diagram by algebraic manipulation. Thus the chromaticity of a mixture of lights will plot somewhere on the chord connecting the chromaticities of the individual lights. Wyszecki and Stiles[8] review a number of standard chromaticity diagrams not discussed here.

Implicit in the use of chromaticity coordinates is the assumption that scalar multiplication of the stimuli does not affect the visual performance being plotted. If the overall intensity of the stimuli matter, then the use of chromaticity coordinates can obscure important regularities. For example, the shape of color discrimination contours (see "Color Discrimination" in Sec. 10.6 and the Chap. 11) depends on how the overall intensity of the stimuli covaries with their chromaticities. Yet these contours are often plotted on a chromaticity diagram. This practice can lead to misinterpretation of the discrimination data. We recommend that plots of chromaticity coordinates be treated with some caution.

Functions of Wavelength Color data are often represented as functions of wavelength. The wavelength spectrum parameterizes a particular path through the three-dimensional color space. The exact path depends on how overall intensity covaries with wavelength. For an equal energy spectrum, the path is illustrated by Fig. 7.

Wavelength representations are particularly useful in situations where knowing the value of a function for the set of monochromatic stimuli provides a complete characterization of performance. Color-matching functions, for example, are usefully plotted as functions of wavelength because these functions may be used to predict the tristimulus values of any light. Plots of detection threshold

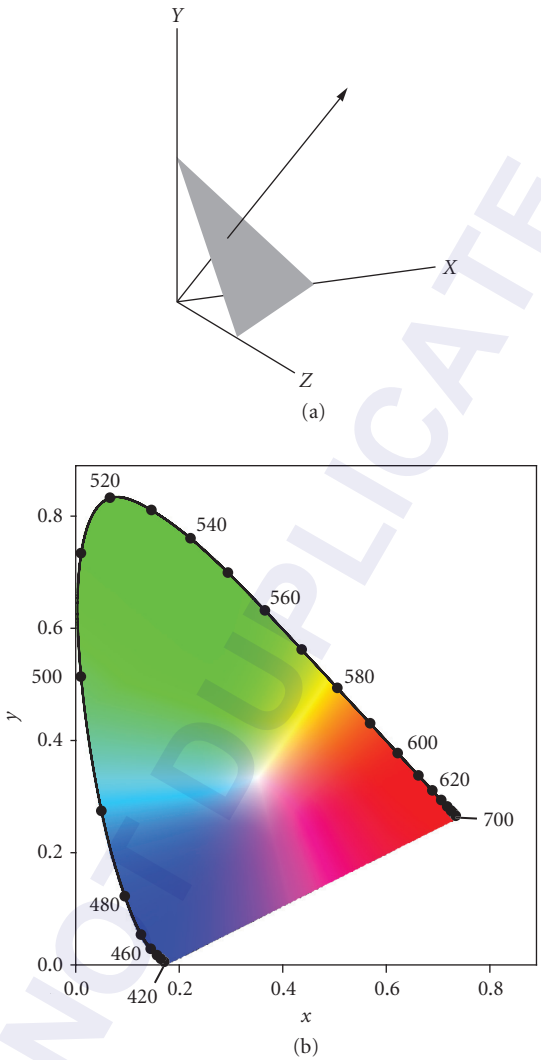

FIGURE 8 CIE 1931 *xy* chromaticity diagram. (*a*) A perspective view of the CIE 1931 *XYZ* tristimulus space. The ray shows a locus of points with constant chromaticity coordinates. The actual chromaticity coordinates for each ray are determined by where the ray intersects the plane described by the equation $X + Y + Z = 1$. This plane is indicated. The *X* and *Y* tristimulus values at the point of intersection are the *x* and *y* chromaticity coordinates for the ray. (*b*) The chromaticity coordinates of an equal energy spectrum with the interior colored to provide a rough indication of the color appearance of a stimulus of each chromaticity when viewed in a neutral context.

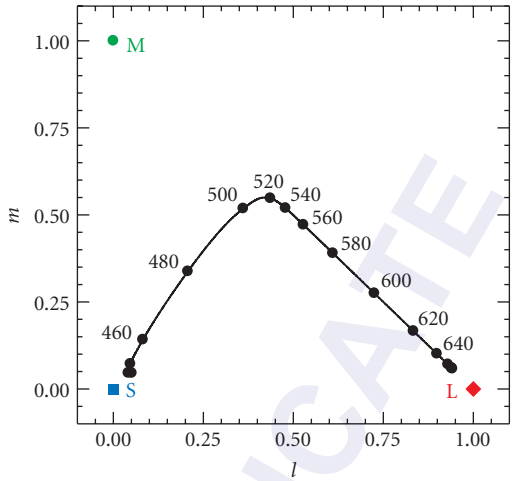

FIGURE 9 Spectrum locus (continuous line) and selected wavelengths (filled circles) plotted in the Stockman and Sharpe[46] 2° *l*, *m* cone chromaticity space. The L- (red diamond), M- (green circle), and S- (blue square) cone fundamentals plot at (1,0), (0,1), and (0,0), respectively.

versus wavelength, on the other hand, cannot be used to predict the detection threshold for arbitrary lights.[130] Just as the chromaticity diagram tends to obscure the potential importance of manipulating the overall intensity of light, wavelength representations tend to obscure the potential importance of considering mixtures of monochromatic lights.

Colorimetric Measurements

To apply the formulas described in this chapter, it is often necessary to measure the colorimetric properties of stimuli. The most general approach is to measure the full spectral power distribution of the stimuli. Often, however, it is not necessary to know the full spectral power distribution; knowledge of the tristimulus values (in some standard color space) is sufficient. For example, the color space transformations summarized in Table 3 depend on the full spectral power distributions of the primaries only through their tristimulus values.

Specialized instruments, called colorimeters, can measure tristimulus values directly. These instruments typically operate using the same principles as photometers with the exception that they have three calibrated filters rather than just one. Each filter mimics the spectral shape of one of the color-matching functions. Wyszecki and Stiles discuss the basics of colorimeter design.[8] Colorimeters are generally less expensive than radiometers and are thus an attractive option when full spectral data are not required.

Two caveats are worth noting. First, it is technically difficult to design filters that exactly match a desired set of color-matching functions. Generally, commercial colorimeters are calibrated so that they give accurate readings for stimuli with broadband spectral power distributions. For narrow band stimuli (e.g., the light emitted by the red phosphor of many color monitors) the reported readings may be quite inaccurate. Second, most colorimeters are designed according to the CIE 1931 standard. This may not be an optimal choice for the purpose of predicting the matches of an average human observer.

TABLE 3 Color Space Transformations

Spectral Functions Known			
Source	Destination	M	Notes

CMFs stands for color matching functions.
The table summarizes how to form the matrix **M** that transforms color coordinates between two spaces.

10.5 MATRIX REPRESENTATIONS AND CALCULATIONS

Introduction

In the remainder of the chapter we move away from the conventional representation of colorimetric data and formulae as continuous functions of wavelength to their representation as vectors and matrices. Matrix algebra greatly simplifies the implementation of colorimetry on digital computers. Although a discrete representation provides only samples of the underlying function of wavelength, the information loss caused by this sampling can be made arbitrarily small by sampling at smaller intervals.

Notation for Matrix Calculations The conventional notation used in colorimetry does not lend itself easily to matrix and vector representations, and at the risk of some confusion between the notation used in Secs. 10.3 "Fundamentals of Colorimetry" and 10.4 "Color Coordinate Systems" and that used here and in Sec. 10.6 "Topics," we now switch notational conventions. Table 2 provides a glossary of the major symbol usage for the matrix formulation. The following notational conventions are used: (a) scalars are denoted with italic symbols, (b) vectors are denoted with lowercase bold symbols, and (c) matrices are denoted with uppercase bold symbols. Symbols used in the appendix are generic.

Stimulus Representation

Vector Representation of Spectral Functions Suppose that spectral power density has been measured at N_λ discrete sample wavelengths $\lambda_1 \ldots \lambda_{N_\lambda}$, each separated by an equal wavelength step $\Delta\lambda$. As shown in Fig. 10, we can represent the measured spectral power distribution using an N_λ dimensional column vector **b**. The nth entry of **b** is simply the measured power density at the nth sample wavelength multiplied by $\Delta\lambda$. Note that the values of the sample wavelengths $\lambda_1 \ldots \lambda_{N_\lambda}$ and wavelength step $\Delta\lambda$ are not explicit in the vector representation. These values must be provided as side information when they are required for a particular calculation. In colorimetric applications, sample wavelengths are typically spaced evenly throughout the visible spectrum at steps of 1, 5, or 10 nm. We follow the convention that the entries of **b** incorporate $\Delta\lambda$, however, so that we need not represent $\Delta\lambda$ explicitly when we approximate integrals over wavelength.

Manipulation of Light Intensity scaling is an operation that changes the overall power of a light at each wavelength without altering the relative power between any pair of wavelengths.

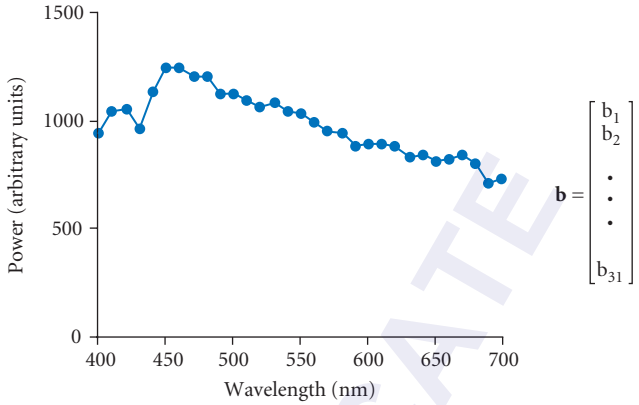

FIGURE 10 The vector representation of functions of wavelength. The plot shows a spectral power distribution measured at 10-nm intervals between 400 and 700 nm. Each point on the plot represents the power at a single sample wavelength. The vector **b** on the right depicts the vector representation of the same spectral power distribution. The *n*th entry of **b** is simply the measured power density at the *n*th sample wavelength times $\Delta\lambda$. Thus b_1 is derived from the power density at 400 nm, b_2 is derived from the power density at 410 nm, and b_{31} is derived from the power density at 700 nm.

The superposition of two lights is an operation that produces a new light whose power at each wavelength is the sum of the power in the original lights at the corresponding wavelength. The effects of both manipulations may be expressed using matrix algebra.

We use scalar multiplication to represent intensity scaling. If a light $\mathbf{b}_1$ is scaled by a factor a, then the result **b** is given by the equation $\mathbf{b} = \mathbf{b}_1 a$. The expression $\mathbf{b}_1 a$ represents a vector whose entries are obtained by multiplying the entries of the vector $\mathbf{b}_1$ by the scalar a. Similarly, we use vector addition to represent superposition. If we superimpose two lights $\mathbf{b}_1$ and $\mathbf{b}_2$, then the result **b** is given by the equation $\mathbf{b} = \mathbf{b}_1 + \mathbf{b}_2$. The expression $\mathbf{b}_1 + \mathbf{b}_2$ represents a vector whose entries are obtained by adding the entries of the vectors $\mathbf{b}_1$ and $\mathbf{b}_2$ component by component. Figures 11 and 12 depict both of these operations.

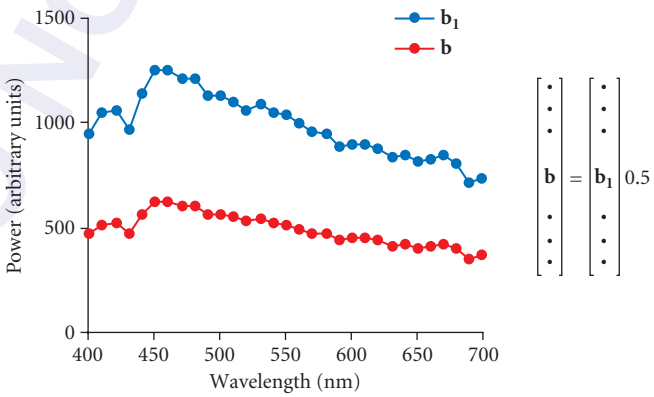

FIGURE 11 Representation of intensity scaling. Suppose that light **b** is created by reducing the power in light $\mathbf{b}_1$ by a factor of 0.5 at each wavelength. The result is shown graphically in the plot. The vector representation of the same relation is given by the equation $\mathbf{b} = \mathbf{b}_1 0.5$.

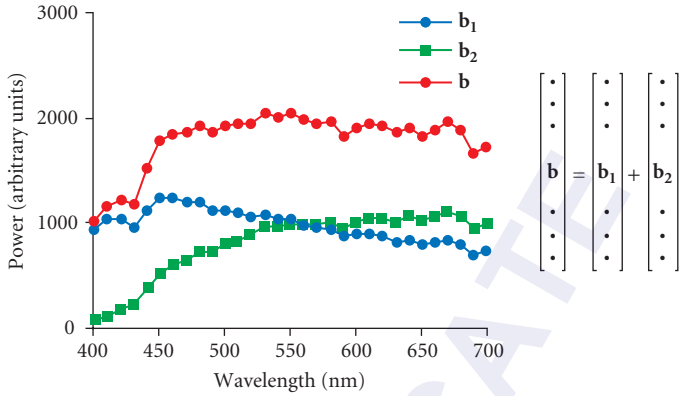

FIGURE 12 Representation of superposition. Suppose that light **b** is created by superimposing two lights $\mathbf{b}_1$ and $\mathbf{b}_2$. The result is shown graphically in the plot. The vector representation of the same relation is given by the equation $\mathbf{b} = \mathbf{b}_1 + \mathbf{b}_2$.

Linear Models for Spectral Functions Intensity scaling and superposition may be used in combination to produce a wide range of spectral functions. Suppose that we have a set of N_b lights that we can individually scale and superimpose. Let the vectors $\mathbf{b}_1 \ldots \mathbf{b}_{N_b}$ represent the spectral power distributions of these lights. In this case, we can produce any spectral power distribution **b** that has the form

$$\mathbf{b} = \mathbf{b}_1 a_1 + \cdots + \mathbf{b}_{N_b} a_{N_b} \tag{12}$$

Now suppose we know that a spectral function **b** is constrained to have the form of Eq. (12) where the vectors $\mathbf{b}_1 \ldots \mathbf{b}_{N_b}$ are known. Then we can specify **b** completely by providing the values of the scalars $a_1 \ldots a_{N_b}$. If the number of primaries N_b is less than the number of sample wavelengths N_λ, then this specification is more efficient (i.e., requires fewer numbers) than specifying the entries of **b** directly. We say that the spectral functions that satisfy Eq. (12) are described by (or lie within) a linear model. We call N_b the dimension of the linear model. We call the vectors $\mathbf{b}_1 \ldots \mathbf{b}_{N_b}$ the basis vectors for the model. We call the scalars $a_1 \ldots a_{N_b}$ required to construct any particular spectral function the model weights for that function.

Matrix Representation of Linear Models Equation (12) can be written using vector and matrix notation. Let **B** be an N_λ by N_b dimensional matrix whose columns are the basis vectors $\mathbf{b}_1 \ldots \mathbf{b}_{N_b}$. We call **B** the basis matrix for the linear model. The composition of the basis matrix is shown pictorially on the left of Fig. 13. Let **a** be an N_b dimensional vector whose entries are the weights $a_1 \ldots a_{N_b}$. Figure 13 also depicts the vector **a**. Using **B** and **a** we can re-express Eq. (12) as the matrix multiplication

$$\mathbf{b} = \mathbf{B}\mathbf{a} \tag{13}$$

The equivalence of Eqs. (12) and (13) may be established by direct expansion of the definition of matrix multiplication (see App. A). A useful working intuition for matrix multiplication is that the effect of multiplying a matrix times a vector (e.g., **Ba**) is to produce a new vector (e.g., **b**) that is a weighted superposition of the columns of the matrix (e.g., **B**), where the weight for column $\mathbf{b}_i$ is given by the *i*th weight, a_i, in **a**.

Use of Linear Models When we know that a spectral function is described by a linear model, we can specify it by using the weight vector **a.** The matrix **B**, which is determined by the basis vectors, specifies the side information necessary to convert the vector **a** back to the discrete wavelength

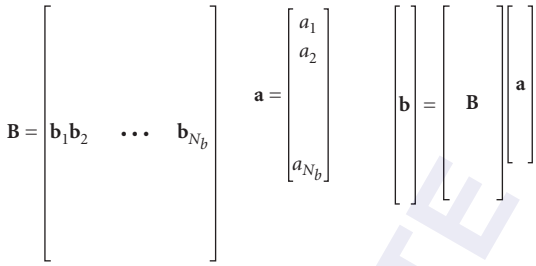

FIGURE 13 Vector representation of linear models. The matrix **B** represents the basis vectors of the linear model. The vector **a** represents the model weights required to form a particular spectral power distribution **b**. The relation between **b**, **a**, and **B** is given by Eq. (13) and is depicted on the right of the figure.

representation **b**. When we represent spectral functions in this way, we say that we are representing the functions within the specified linear model.

Representing spectral functions within a small-dimensional linear model places strong constraints on the form of functions. As the dimension of the model grows, linear models can represent progressively wider classes of spectral power distributions. In many cases of interest, there is prior information that allows us to assume that spectra are indeed described by a linear model. A common example of this situation is the light emitted from a computer controlled color monitor. Such a monitor produces different spectral power distributions by scaling the intensity of the light emitted by three different types of phosphor (see Chap. 22). Thus the emitted light lies within a three-dimensional linear model whose basis vectors are given by the emission spectra of the monitor's phosphors. Linear model constraints also turn out to be useful for describing naturally occurring surface and illuminant spectra.

Note that representing spectral functions within linear models is a generalization of, rather than an alternative to, the more traditional wavelength representation. To understand this, we need to only note that we can choose the basis vectors of the linear model to be discrete delta functions centered at each sample wavelength. We refer to this special choice of basis vectors as the identity basis or wavelength basis. We refer to the corresponding linear model as the identity model. For the identity model, the basis matrix **B** is the (square) N_λ by N_λ identity matrix, where N_λ is the number of sample wavelengths. The identity matrix contains ones along its main diagonal and zeros elsewhere. Multiplying the identity matrix times any vector simply results in the same vector. From Eq. (13), we can see that when **B** is the identity matrix, the representation of any light **b** within the linear model is simply **b** = **a**.

Sampling the Visible Spectrum To use a discrete representation for functions of wavelength, it is necessary to choose a sampling range and sampling increment. Standard practice varies considerably. The Commission Internationale de l'Éclairage (International Commission on Illumination, commonly referred to as the CIE) provides recommendations on the sampling of the visible spectrum.[10] For many applications, using 5-nm increments between 380 and 780 nm is sufficient, and coarser sampling at 10 nm between 400 and 700 nm is not uncommon. In cases where a subset of the spectral data required for a calculation is not available, interpolation or extrapolation may be used to estimate the missing values.

Vector Representation of Colorimetric Data

The Basic Color-Matching Experiment In the maximum saturation experiment color matching (see Fig. 3), observer's task is to adjust the spectral power distribution $\mathbf{b}_m$ of the matching light on one side of the bipartite field to match the appearance of the spectral power distribution $\mathbf{b}_t$ of the

test light on the other side of the field. As described above, the matching light's spectral power distribution is described completely by a three-dimensional linear model whose basis vectors are the primary lights' spectral power distributions. The tristimulus values of a test light are precisely the linear model weights required to form the matching light. We denote the primary spectral power distributions by the vectors $\mathbf{p}_1 \ldots \mathbf{p}_3$. The associated linear model matrix **P** contains these vectors in its three columns. We denote the tristimulus values of a light using the three-dimensional vector **t.** Thus we can use the tristimulus values of any test light **b** to reconstruct a matching light **Pt** such that:

$$\mathbf{b} \sim \mathbf{Pt} \tag{14}$$

We emphasize that in general that **Pt** will not be equal to **b.**

Grassmann's Laws Revisited In vector notation, the proportionality law states

if $$\mathbf{b}_1 \sim \mathbf{b}_2$$

then $$\mathbf{b}_1 a \sim \mathbf{b}_2 a \tag{15}$$

where a is a scalar that represents any intensity scaling. The additivity law states

if $$\mathbf{b}_1 \sim \mathbf{b}_2 \quad \text{and} \quad \mathbf{b}_3 \sim \mathbf{b}_4$$

then $$\mathbf{b}_1 + \mathbf{b}_3 \sim \mathbf{b}_2 + \mathbf{b}_4 \tag{16}$$

The proportionality law allows us to determine the relation between the tristimulus values of a light and the tristimulus values of a scaled version of that light. Suppose that $\mathbf{b} \sim \mathbf{Pt}$. Applying the proportionality law, we conclude that for any scalar a, we have $\mathbf{b}a \sim (\mathbf{P}\,\mathbf{t})\,a$. Because matrix multiplication is associative, we can conclude that

if $$\mathbf{b} \sim \mathbf{Pt}$$

then $$\mathbf{b}a \sim \mathbf{P}\,(\mathbf{t}a) \tag{17}$$

This means that the tristimulus values of a light $\mathbf{b}a$ may be obtained by scaling the tristimulus values **t** of the light **b**. A similar argument shows that the additivity law determines the relation between the tristimulus values of two lights and the tristimulus values of their superposition

if $$\mathbf{b}_1 \sim \mathbf{Pt}_1 \quad \text{and} \quad \mathbf{b}_2 \sim \mathbf{Pt}_2$$

then $$\mathbf{b}_1 + \mathbf{b}_2 \sim \mathbf{P}\,(\mathbf{t}_1 + \mathbf{t}_2) \tag{18}$$

Implication of Grassmann's laws If the tristimulus values of the basis vectors for a linear model are known, then Grassmann's laws allow us to determine the tristimulus values of any light within the linear model. Let $\mathbf{t}_1 \ldots \mathbf{t}_{N_b}$ be the tristimulus values corresponding to the model basis vectors and let $\mathbf{T}_B$ be the 3 by N_b matrix whose columns are $\mathbf{t}_1 \ldots \mathbf{t}_{N_b}$. For any light **b** within the linear model, we can write that $\mathbf{b} = \mathbf{Ba}$ where **a** now represents the vector of weights to be applied to each basis vector to produce **b**. By expanding this matrix product and applying Eqs. (17) and (18), it is possible to show that the tristimulus values of **b** are given by the matrix product

$$\mathbf{t} = \mathbf{T}_B\mathbf{a} \tag{19}$$

Equation (19) is very important. It tells how to compute the tristimulus values for any light within a linear model from the tristimulus values for each of the basis vectors. Thus a small number of color matches (one for each of the basis vectors) allow us to predict color matches for a large number of lights, that is, any light within the linear model.

Color-Matching Functions and Cone Fundamentals Let **T** be the matrix of tristimulus values for the basis vectors of the identity model (i.e., equal energy monochromatic lights). In this case **T** has

dimensions 3 by N_λ, where N_λ is the number of sample wavelengths. Each column of **T** is the tristimulus values for a monochromatic light. Within the identity model, the representation of any light **b** is simply **b** itself. From Eq. (19) we conclude directly that the tristimulus values for any light are given by

$$\mathbf{t} = \mathbf{T}\mathbf{b} \tag{20}$$

Once we know the tristimulus values for a set of monochromatic lights centered at each of the sample wavelengths, we can use Eq. (20) to compute the tristimulus values of any light. Equation (20) is the matrix algebra version of Eq. (2).

We can regard each of the rows of **T** as a function of wavelength, and in doing so we can identify these as the standard color-matching functions obtained with respect to the primaries used in the matching experiment.

We can similarly represent the spectral sensitivity functions of the three classes of cones by the rows of a 3 by N_λ matrix **R**. Let **r** be a three-dimensional vector whose entries are the cone quantal absorption rates of an arbitrary light represented by **b**. We can compute the absorption rates through the matrix equation

$$\mathbf{r} = \mathbf{R}\mathbf{b} \tag{21}$$

This computation accomplishes the wavelength-by-wavelength multiplication and summation for each cone class.

We use the term cone coordinates to refer to the vector **r**. We can relate cone coordinates to tristimulus values in a straightforward manner. Suppose that in a color-matching experiment performed with primaries **P** we find that a light **b** has tristimulus values **t**. From our mechanistic explanation of color matching in terms of the cones, we have that

$$\mathbf{r} = \mathbf{R}\mathbf{b} = \mathbf{R}\mathbf{P}\mathbf{t} \tag{22}$$

Recall that the matrix **P** holds the power spectrum of the three primaries used in a matching experiment. If we define the matrix $\mathbf{M}_{T,R} = (\mathbf{R}\mathbf{P})$, we see that the tristimulus values of a light are related to its cone coordinates by the linear transformation

$$\mathbf{r} = \mathbf{M}_{T,R}\mathbf{t} \tag{23}$$

By comparing Eq. (20) with Eq. (22) and noting that these equations hold for any light **b**, we derive

$$\mathbf{R} = \mathbf{M}_{T,R}\mathbf{T} \tag{24}$$

Equation (24) has the key implication, which we took advantage of in Sec. 10.4 "Color Coordinate Systems" [Eqs. (3) and (4)], that the color-matching experiment determines the cone sensitivities up to a free linear transformation, the matrix $\mathbf{M}_{T,R}$ of Eq. (24).

Transformations between Color Spaces

Because of the large number of color spaces currently in use, the ability to transform data between various color spaces is of considerable practical importance. The derivation of such transformations depends on what is known about the source and destination color spaces. Below we discuss cases where both the source and destination color space are derived from the same underlying observer (i.e., when the source and destination color spaces both predict identical color matches). Table 3 summarizes these transformations. When the source and destination color spaces are characterized by a different underlying observer (e.g., if they are based on different CMFs) the transformation is more difficult and often cannot be done exactly. We discuss possible approaches in section "Color Cameras and Other Visual Systems."

Source Primaries and Destination Color-Matching Functions Known Let $\mathbf{P}_1$ be the matrix representing the spectral power distributions of a set of known primaries, with one primary in each column. Let $\mathbf{T}_2$ be the matrix representing a known set of color-matching functions (e.g., the CIE 1931 *XYZ* color-matching functions), with one function in each of its three rows. We would like to determine a transformation between the color coordinate system specified by $\mathbf{P}_1$ and that specified by $\mathbf{T}_2$. For example, linearized frame buffer values input to a computer-controlled color monitor may be thought of as tristimulus values in a color space defined by the monitor's phosphor emission spectra. The transformation we seek allows computation of the CIE 1931 tristimulus values from the linearized frame buffer values.

We start by using Eq. (20) to compute the tristimulus values, with respect to $\mathbf{T}_2$, for the three primary lights specified by $\mathbf{P}_1$. Each of these primaries is contained in a column of $\mathbf{P}_1$, so that we may perform this calculation directly through the matrix multiplication

$$\mathbf{M}_{P,T} = \mathbf{T}_2\mathbf{P}_1 \tag{25}$$

Let the matrix $\mathbf{P}_2$ represent the destination primaries. We do not need to know these explicitly, only that they exist. The meaning of Eq. (25) is that

$$\mathbf{P}_1 \sim \mathbf{P}_2\mathbf{M}_{P,T} \tag{26}$$

where we have generalized the symbol "~" to denote a column-by-column visual match for the matrices on both sides of the relation. This relation follows because the columns of $\mathbf{M}_{P,T}$ specify how the destination primaries should be mixed to match the source primaries. Equation (26) tells us that we can substitute the three lights represented by the columns of $\mathbf{P}_2\,\mathbf{M}_{P,T}$ for the three lights represented by the columns of $\mathbf{P}_1$ in any color matching experiment. In particular, we may make this substitution for any light $\mathbf{b}$ with tristimulus values $\mathbf{t}_1$ in the source color coordinate system. We have

$$\mathbf{b} \sim \mathbf{P}_1\mathbf{t}_1 \sim \mathbf{P}_2\mathbf{M}_{P,T}\mathbf{t}_1 \tag{27}$$

By inspection, this tells us that the three-dimensional vector

$$\mathbf{t}_2 = \mathbf{M}_{P,T}\mathbf{t}_1 \tag{28}$$

is the tristimulus values of $\mathbf{b}$ in the destination color coordinate system.

Equation (28) provides us with the means to transform tristimulus values from a coordinate system where the primaries are known to one where the color-matching functions are known. The transformation matrix $\mathbf{M}_{P,T}$ required to perform the transformation depends only on the known primaries $\mathbf{P}_1$ and the known color-matching functions $\mathbf{T}_2$. Given these, $\mathbf{M}_{P,T}$ may be computed directly from Eq. (25).

Source Color-Matching Functions and Destination Primaries Known A second transformation applies when the color-matching functions in the source color space and the primaries in the destination color space are known. This will be the case, for example, when we wish to render a stimulus specified in terms of CIE 1931 tristimulus values on a calibrated color monitor.

Let $\mathbf{T}_1$ represent the known color-matching functions and $\mathbf{P}_2$ represent the known primaries. By applying Eq. (28) we have that the relation between source tristimulus values and the destination tristimulus values is given by $\mathbf{t}_1 = \mathbf{M}_{P,T}\mathbf{t}_2$. This is a system of linear equations that we may solve to find an expression for $\mathbf{t}_2$ in terms of $\mathbf{t}_1$. In particular, as long as the matrix $\mathbf{M}_{P,T}$ is nonsingular, we can convert tristimulus values using the relation

$$\mathbf{t}_2 = \mathbf{M}_{T,P}\mathbf{t}_1 \tag{29}$$

where we define

$$\mathbf{M}_{T,P} = (\mathbf{M}_{P,T})^{-1} = (\mathbf{T}_1\mathbf{P}_2)^{-1} \tag{30}$$

Source and Destination Primaries Known A third transformation applies when the primaries of both the source and destination color spaces are known. One application of this transformation is to generate matching stimuli on two different calibrated monitors.

Let $\mathbf{P}_1$ and $\mathbf{P}_2$ represent the two sets of primaries. Let $\mathbf{T}$ represent a set of color-matching functions for any human color coordinate system. (There is no requirement that the color-matching functions be related to either the source or the destination primaries. For example, the CIE 1931 *XYZ* color-matching functions might be used.) To do the conversion, we simply use Eq. (28) to transform from the color coordinate system described by $\mathbf{P}_1$ to the coordinate system described by $\mathbf{T}$. Then we use Eq. (29) to transform from the coordinates system described by $\mathbf{T}$ to the coordinate system described by $\mathbf{P}_2$. The overall transformation is given by

$$\mathbf{t}_2 = \mathbf{M}_{P,P}\,\mathbf{t}_1 = (\mathbf{M}_{T,P_2})(\mathbf{M}_{P_1,T})\,\mathbf{t}_1 = (\mathbf{T}\mathbf{P}_2)^{-1}\,(\mathbf{T}\mathbf{P}_1)\mathbf{t}_1 \tag{31}$$

It should not be surprising that this transformation requires the specification of a set of color-matching functions. These color-matching functions are the only source of information about the human observer in the transformation equation.

Source and Destination Color-Matching Functions Known Finally, it is sometimes of interest to transform between two color spaces that are specified in terms of their color-matching functions. An example is transforming between the space defined by the Stiles and Burch 10° color-matching functions[34] and the space defined by the Stockman and Sharpe 10° cone fundamentals.[46]

Let $\mathbf{T}_1$ and $\mathbf{T}_2$ represent the source and destination color-matching functions. Our development above assures us that there is some three-by-three transformation matrix, call it $\mathbf{M}_{T,T}$, that transforms color coordinates between the two systems. Recall that the columns of $\mathbf{T}_1$ and $\mathbf{T}_2$ are themselves tristimulus values for corresponding monochromatic lights. Thus $\mathbf{M}_{T,T}$ must satisfy

$$\mathbf{T}_2 = \mathbf{M}_{T,T}\mathbf{T}_1 \tag{32}$$

This is a system of linear equations where the entries of $\mathbf{M}_{T,T}$ are the unknown variables. This system may be solved using standard regression methods. Once we have solved for $\mathbf{M}_{T,T}$, we can transform tristimulus values using the equation

$$\mathbf{t}_2 = \mathbf{M}_{T,T}\mathbf{t}_1 \tag{33}$$

The transformation specified by Eq. (33) will be exact as long as the two sets of color-matching functions $\mathbf{T}_1$ and $\mathbf{T}_2$ characterize the performance of the same observer. One sometimes wishes, however, to transform between two color spaces that are defined with respect to different observers. For example, one might want to convert CIE 1931 *XYZ* tristimulus values to Judd-Vos modified tristimulus values. Although the regression procedure described here will still produce a transformation matrix in this case, the result of the transformation is not guaranteed to be correct.[4] We will return to this topic in section "Color Cameras and Other Visual Systems."

Interpreting the Transformation Matrix It is useful to interpret the rows and columns of the matrices derived in the preceding sections. Let $\mathbf{M}$ be a matrix that maps the color coordinates from a source color space to a destination color space. Both source and destination color spaces are associated with a set of primaries and a set of color-matching functions. From our derivations above, we can conclude that the columns of $\mathbf{M}$ are the coordinates of the source primaries in the destination color space [see Eq. (25)] and the rows of $\mathbf{M}$ provide the destination color-matching functions with respect to the linear model whose basis functions are the primaries of source color space (see subsection "Use of Linear Modes" in Sec. 10.5). Similarly, the columns of $\mathbf{M}^{-1}$ are the coordinates of the destination primaries in the source color-matching space and the rows of $\mathbf{M}^{-1}$ are the source color-matching functions with respect to the linear model whose basis functions are the primaries of the destination color space. Thus in many cases it is possible to construct the matrix $\mathbf{M}$ without full knowledge of the spectral functions. This can be of practical importance. For example, monitor manufacturers often specify the CIE 1931 tristimulus values of their monitors' phosphors. In addition, colorimeters that measure tristimulus values directly are often more readily available than spectral radiometers.

Transforming Primaries and Color-Matching Functions We have shown that color coordinates in any two color spaces may be related by applying a linear transformation **M**. The converse is also true. If we pick any nonsingular linear transformation **M** and apply it to a set of color coordinates we have defined a new color space that will successfully predict color matches. The color-matching functions for this new space will be given by $\mathbf{T}_2 = \mathbf{M}\mathbf{T}_1$. A set of primaries for the new space will be given by $\mathbf{P}_2 = \mathbf{P}_1\mathbf{M}^{-1}$. These derived primaries are not unique. Any set of primaries that match the constructed primaries will also work.

The fact that new color spaces can be constructed by applying linear transformations has an important implication for the study of color. If we restrict attention to what we may conclude from the color-matching experiment, we can only determine the psychological representation of color up to a free linear transformation. There are two attitudes one can take toward this fact. The conservative attitude is to refrain from making any statements about the nature of color vision that depend on a particular choice of color space. The other is to appeal to experiments other than the color-matching experiment to choose a privileged representation.

10.6 TOPICS

Surfaces and Illuminants

As shown in Fig. 1, the light reaching the eye is often formed when light from an illuminant reflects from a surface. Illuminants and surfaces are of interest in color reproduction applications involving inks, paints, and dyes and in lighting design applications.

Reflection Model Illuminants are specified by their spectral power distributions. We will use the vector **e** to represent illuminant spectral power distributions. In general, the interaction of light with matter is quite complex. For many applications, however, a rather simple model is acceptable. Using this model, we describe a surface by its surface reflectance function. The surface reflectance function specifies, for each sample wavelength, the fraction of illuminant power that is reflected to the observer. We will use the vector **s** to represent surface reflectance spectra. Each entry of **s** gives the reflectance measured at a single sample wavelength. Thus the spectral power distribution **b** of the reflected light is given by the wavelength-by-wavelength product of the illuminant spectral power distribution and the surface reflectance function.

The most important consideration neglected in this formulation is viewing geometry. The relation between the radiant power emitted by a source of illumination, the material properties of a surface, and the radiant power reaching an observer can depend strongly on the viewing geometry. In our formulation, these geometrical factors must be incorporated implicitly into the specification of the illuminant and surface properties, so that any actual calculation is specific to a particular viewing geometry. Moreover, the surface reflectance must be understood as being associated with a particular image location, rather than with a particular object. A topic of current research in computer graphics is to find accurate and efficient ways to specify illuminants and surfaces for rendering,[131,132] and parallel work in human vision seeks to understand how the reflectance of spatially complex objects is perceived.[133–136] A second complexity that we neglect is fluorescence.

Computing the Reflected Light The relation between the surface reflectance function and the reflected light spectral power distribution is linear if the illuminant spectral power distribution is held fixed. We form the N_λ by N_λ diagonal illuminant matrix **E** whose diagonal entries are the entries of **e.** This leads to the relation $\mathbf{b} = \mathbf{E}\mathbf{s}$. By substituting into Eq. (20), we arrive at an expression for the tristimulus values of the light reflected from a surface:

$$\mathbf{t} = (\mathbf{T}\mathbf{E})\mathbf{s} \tag{34}$$

where **T** holds the colour matching functions in its three rows. The matrix (**TE**) in this equation plays exactly the same role as the color-matching functions do in Eq. (20). Any result that holds for spectral

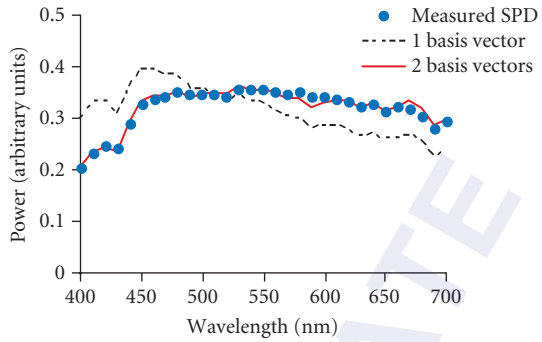

FIGURE 14 The figure shows a daylight spectral power distribution and its approximation using the CIE linear model for daylight. For this particular illuminant, only two basis functions were required to provide a very good fit.

power distributions may thus be directly extended to a result for surface reflectance functions when the illuminant is known and held fixed (see subsection "Color Coordinates of Surfaces" in Sec. 10.6).

Linear Model Representations for Surfaces and Illuminants Judd, MacAdam, and Wyszecki[137] measured the spectral power distributions of a large number of naturally occurring daylights. They determined that a four-dimensional linear model provided a good description of their spectral measurements. Consideration of their results and other daylight measurements led the CIE to standardize a three-dimensional linear model for natural daylights.[10] Figure 14 depicts a daylight spectral power distribution measured by the first author and its approximation using the first two basis vectors of the CIE linear model for daylight.

Cohen[138] analyzed the reflectance spectra of a large set of Munsell papers[139,140] and concluded that a four-dimensional linear model provided a good approximation to the entire data set. Maloney[141] reanalyzed these data, plus a set of natural spectra measured by Krinov[142] and confirmed Cohen's conclusion. More recently, reflectance measurements of the spectra of additional Munsell papers and natural objects[143,144] have been described by small-dimensional linear models. Figure 15 shows a measured surface reflectance spectrum (red cloth, measured by the first author) and its approximation using Cohen's four-dimensional linear model.

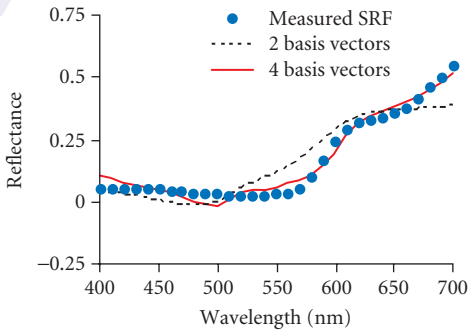

FIGURE 15 The figure shows a measured surface reflectance function and a fit to it using Cohen's four-dimensional linear model.[138]

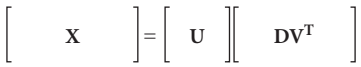
It is not yet clear why natural illuminant and surface spectra are well-approximated by small-dimensional linear models nor how general this conclusion is. Maloney[141] provides some speculations. None the less, the assumption that natural spectra do lie within small-dimensional linear models seems reasonable in light of the currently available evidence. This assumption makes possible a number of interesting practical calculations, as we illustrate in some of the following sections.

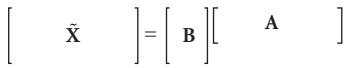
Determining a Linear Model from Raw Spectral Data Given a set of spectral measurements, it is possible, for any integer N_b, to find the N_b dimensional linear model that best approximates the spectral data set (in a least squares sense). Suppose that the data set consists of N_{meas} spectra, each of which is represented at N_λ sample wavelengths. Let $\mathbf{X}$ be an N_λ by N_{meas} data matrix whose columns represent the individual spectral measurements. The goal of the calculation is to determine the N_λ by N_b matrix $\mathbf{B}$ and an N_b by N_{meas} matrix of coefficients $\mathbf{A}$ such that the linear model approximation $\tilde{\mathbf{X}} = \mathbf{BA}$ is the best least squares approximation to the data matrix $\mathbf{X}$ over all possible choices of $\mathbf{B}$ and $\mathbf{A}$.

The process of finding the matrix $\mathbf{B}$ is called one mode components analysis.[145,146] It is very closely related to the principle components analysis technique discussed in most multivariate statistics texts.[147] One mode 1 components analysis may be accomplished numerically through the use of the singular value decomposition.[27,148] We define the singular value decomposition in Sec. 10.7 "Appendix—Matrix Algebra." To see how the singular value decomposition is used to determine an N_b dimensional linear model for $\mathbf{X}$, consider Fig. 16. Figure 16*a* depicts the singular value decomposition of an N_λ by N_{meas} matrix $\mathbf{X}$ for the case $N_{\text{meas}} > N_\lambda$, where the two matrices $\mathbf{D}$ and $\mathbf{V}^{\text{T}}$ have been collapsed. This form makes it clear that each column of $\mathbf{X}$ is given by a linear combination of the columns of $\mathbf{U}$. Furthermore, for each column of $\mathbf{X}$, the weights needed to combine the columns of $\mathbf{U}$ are given by the corresponding column of the matrix $\mathbf{DV}^{\text{T}}$. Suppose we choose an N_b dimensional linear model $\mathbf{B}$ for the data in $\mathbf{X}$ by extracting the first N_b columns of $\mathbf{U}$. In this case, it should be clear that we can form an approximation $\tilde{\mathbf{X}}$ to the data $\mathbf{X}$ as shown in Fig. 16*b*. Because the columns of $\mathbf{U}$ are orthogonal, the matrix $\mathbf{A}$ consists of the first N_b rows of $\mathbf{DV}^{\text{T}}$. The accuracy of the approximation depends on how important the columns of $\mathbf{U}$ excluded from $\mathbf{B}$ were to the original expression for $\mathbf{X}$. Under certain assumptions, it can be shown that choosing $\mathbf{B}$ as above produces a linear model that minimizes the squared error of the approximation, for any choice of N_b.[145] Thus computing the singular value decomposition of $\mathbf{X}$ allows us to find a good linear model of any desired dimension for $N_b < N_\lambda$. Computing linear models from data is quite feasible on modern desktop computers.

Although the above procedure produces the linear model that provides the best least squares fit to a data set, there are a number of additional considerations that should go into choosing a linear



(a)



(b)

FIGURE 16 (*a*) The figure depicts the singular value decomposition (SVD) of an N_λ by N_{meas} matrix $\mathbf{X}$ for the case $N_{\text{meas}} > N_\lambda$. In this view we have collapsed the two matrices $\mathbf{D}$ and $\mathbf{V}^{\text{T}}$. To determine an N_b dimensional linear model $\mathbf{B}$ for the data in $\mathbf{X}$ we let $\mathbf{B}$ consist of the first N_b columns of $\mathbf{U}$. (*b*) The linear model approximation of the data is given by $\hat{\mathbf{X}} = \mathbf{BA}$, where $\mathbf{A}$ consists of the first N_b rows of $\mathbf{DV}^{\text{T}}$.

model. First, we note that the choice of linear model is not unique. Any nonsingular linear combination of the columns of **B** will produce a linear model that provides an equally good account of the data. Second, the least squares error measure gives more weight to spectra with large amplitudes. In the case of surface spectra, this means that the more reflective surfaces will tend to drive the choice of basis vectors. In the case of illuminants, the more intense illuminants will tend to drive the choice. To avoid this weighting, the measured spectra are sometimes normalized to unit length before performing the singular value decomposition. The normalization equalizes the effect of the relative shape of each spectrum in the data set.[141] Third, it is sometimes desired to find a linear model that best describes the variation of a data set around its mean. To do this, the mean of the data set should be subtracted before performing the singular value decomposition. When the mean of the data is subtracted, one mode components analysis is identical to principle components analysis. Finally, there are circumstances where the linear model will be used not to approximate spectra but rather to approximate some other quantity (e.g., color coordinates) that depend on the spectra. In this case, more general techniques, closely related to those discussed here, may be used.[149]

Approximating a Spectrum with Respect to a Linear Model Given an N_b dimensional linear model **B**, it is straightforward to find the representation of any spectrum with respect to the linear model. Let **X** be a matrix representing the spectra of functions to be approximated. These spectra do not need to be members of the data set that was used to determine the linear model. To find the matrix of coefficients **A** such that $\widetilde{\mathbf{X}} = \mathbf{BA}$ best approximates **X** we use simple linear regression. Regression routines to solve this problem are provided as part of any standard matrix algebra software package.

Digital Image Representations If in a given application illuminants and surfaces may be represented with respect to small-dimensional linear models, then it becomes feasible to use point-by-point representations of these quantities in digital image processing. In typical color image processing, the image data at each point are represented by three numbers at each location. These numbers are generally tristimulus values in some color space. In calibrated systems, side information about the color-matching functions or primary spectral power distributions that define the color space is available to interpret the tristimulus values. It is straightforward to generalize this notion of color images by allowing the images to contain N_b numbers at each point and allowing these numbers to represent quantities other than tristimulus values.[7] For example, in representing the image produced by a printer, it might be advantageous to represent the surface reflectance at each location.[150] If the gamut of printed reflectances can be represented within a small-dimensional linear model, then representing the surface reflectance functions with respect to this model would not require much more storage than a traditional color image.[7] The basis functions for the linear model only need be represented once, not at each location. But by representing reflectances rather than tristimulus values, it becomes possible to compute what the tristimulus values reflected from the printed image would be under any illumination. We illustrate the calculation in the next section. Because of the problem of metamerism (see subsection "Computing the Reflected Light"), this calculation is not possible if only the tristimulus values are represented in the digital image. To avoid this limitation, hyperspectral images record full spectra at each image location.[151–153]

Simulation of Illuminated Surfaces Consider the problem of producing a signal on a monitor that has the same tristimulus values as a surface under a variety of different illuminants. The solution to this problem is straightforward and is useful in a number of applications. These include rendering digitally archived paintings,[154,155] generating stimuli for use in psychophysics,[156] and producing photorealistic computer-generated imagery.[17] We show the calculation for the data at a single image location. Let **a** be a representation of the surface reflectance with respect to an N_b dimensional linear model **B**. Let **E** represent the illuminant spectral power distribution in diagonal matrix form. Let **T** represent the color-matching functions for a human observer, and **P** represent the primary phosphor spectral power distributions for the monitor on which the surface will be rendered. We wish to determine tristimulus values **t** with respect to the monitor primaries so that the light emitted from the monitor will appear identical to the light reflected from the simulated surface under the

simulated illuminant. From Eqs. (13) (cast as **s** = **Ba**), (34), (29), and (30) we can write directly the desired rendering equation

$$\mathbf{t} = [(\mathbf{TP})^{-1}(\mathbf{TE})\mathbf{B}]\mathbf{a} \tag{35}$$

The rendering matrix $[(\mathbf{TP})^{-1}(\mathbf{TE})\mathbf{B}]$ has dimensions 3 by N_b and maps the surface weights directly to monitor tristimulus values. It is quite general, in that we may use it for any calibrated monitor and any choice of linear models. It does not depend on the particular surface being rendered and may be computed once for an entire image. Because the rendering matrix is of small dimension, rendering of this sort is feasible, even for very large images. As discussed in subsection "Transformations between Color Spaces" in Sec. 10.5, it may be possible to determine the matrix $\mathbf{M}_{T,P} = (\mathbf{TP})^{-1}$ directly. A similar shortcut is possible for the matrix $(\mathbf{TE})\mathbf{B}$. Each column of this matrix is the tristimulus values of one linear model basis vector under the illuminant specified by the matrix **E**.

Color Coordinates of Surfaces Our discussion thus far has emphasized describing the color coordinates of lights. In many applications of colorimetry, it is desirable to describe the color properties of reflective objects. One efficient way to do this, as described above, is to use linear models to describe the full surface reflectance functions. Another possibility is to specify the color coordinates of the light reflected from the surface under standard illumination. This method allows the assignment of tristimulus values to surfaces in an orderly fashion.

The CIE has standardized several illuminant spectral power distributions that may be used for this purpose (see the next section). Using the procedures defined above, one can begin with the spectral power distribution of the illuminant and the surface reflectance function and from there calculate the desired color-matching coordinates.

The relative size of the tristimulus values assigned to a surface depend on its spectral reflectance function and on the illuminant chosen for specification. To factor the intensity of the illuminant out of the surface representation, the CIE specified a normalization of the color coordinates for use with 1931 *XYZ* tristimulus values. This normalization consists of multiplying the computed tristimulus values by the quantity $100/Y_0$, where Y_0 is the Y tristimulus value for the illuminant.

The tristimulus values of a surface provide enough information to match the surface when it is viewed under the illuminant used to compute those coordinates. It is important to bear in mind that two surfaces that have the same tristimulus values under one illuminant do not necessarily share the same tristimulus values under another illuminant. A more complete description can be generated using the linear model approach described above.

Standard Sources of Illumination The CIE has standardized a number of illuminant spectral power distributions.[157] These were designed to be typical of various common viewing conditions and are useful as specific choices of illumination when the illuminant cannot be measured directly. CIE Illuminant A is designed to be representative of tungsten-filament illumination. CIE Illuminant D65 is designed to be representative of average daylight. Other CIE standard daylight illuminants may be computed using the CIE principle components of daylight as basis vectors and the formulas specified by the CIE.[10] Spectra representative of fluorescent lamps and other artificial sources are also available.[8,10]

Metamerism

Recovering Spectral Power Distributions from Tristimulus Values It is not possible in general to recover a spectral power distribution from its tristimulus values. If some prior information about the spectral power distribution of the color signal is available, however, then recovery may be possible. Such recovery is of most interest in applications where direct spectral measurements are not possible and where knowing the full spectrum is important. For example, the effect of lens chromatic aberrations on cone quantal absorption rates depends on the full spectral power distribution.[110]

Suppose the spectral power distribution of interest is known to lie within a three-dimensional linear model. We may write **b** = **Ba**, where the basis matrix **B** has dimensions N_λ by 3. Let **t** be the

tristimulus values of the light with respect to a set of color-matching functions **T**. We can conclude that $\mathbf{a} = (\mathbf{TB})^{-1}\mathbf{t}$, which implies

$$\mathbf{b} = \mathbf{B}(\mathbf{TB})^{-1}\mathbf{t} \tag{36}$$

When we do not have a prior constraint that the signal belongs to a three-dimensional linear model, we may still be able to place some linear model constraint, of dimension higher than three, on the spectral power distribution. For example, when we know that the signal was produced by the reflection of daylight from a natural object, it is reasonable to assume that the color signal lies within a linear model of dimension that may be as low as nine.[158] In this case, we can still write $\mathbf{b} = \mathbf{Ba}$, but we cannot apply Eq. (36) directly because the matrix (**TB**) will be singular. To deal with this problem, we can choose a reduced linear model with only three dimensions. We then proceed as outlined above, but substitute the reduced model for the true model. This will lead to an estimate for the actual spectral power distribution **b**. If the reduced linear model provides a reasonable approximation to **b**, the estimation error may be quite small. The estimate will have the property that it is a metamer of **b**. The techniques described above for finding linear model approximations may be used to choose an appropriate reduced model.

Finding Metamers of a Light It is often of interest to find metamers of a light. We discuss two approaches here. Wyszecki and Stiles[8] treat the problem in considerable detail.

Using a linear model If we choose any three-dimensional linear model we can combine Eq. (36) with the fact the fact that $\mathbf{t} = \mathbf{Tb}$ [Eq. (20)] to compute a pair of metameric spectral power distributions **b** and $\hat{\mathbf{b}}$

$$\hat{\mathbf{b}} = \hat{\mathbf{B}}(\mathbf{T}\hat{\mathbf{B}})^{-1}\mathbf{Tb} \tag{37}$$

Each choice of $\hat{\mathbf{B}}$ will lead to a different metamer. Figure 17 shows a number of metameric spectral power distributions generated in this fashion.

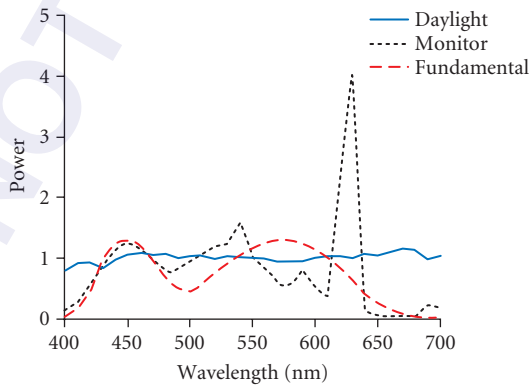


FIGURE 17 The figure shows three metameric color signals with respect to the CIE 1931 standard observer. The three metamers were computed using Eq. (37). The initial spectral power distribution **b** (not shown) was an equal energy spectrum. Three separate linear models were used: one that describes natural daylights, one typical of monitor phosphor spectral power distributions, and one that provides Cohen's "fundamental metamer."[207]

Metameric blacks Another approach to generating metamers is to note that there will be some spectral power distributions $\mathbf{b}_0$ that have the property $\mathbf{Tb}_0 = \mathbf{0}$. Wyszecki referred to such distributions as metameric blacks, since they have the same tristimulus values as no light at all.[159] Grassmann's laws imply that adding a metameric black $\mathbf{b}_0$ to any light $\mathbf{b}$ yields a metamer of $\mathbf{b}$. Given a linear model $\mathbf{B}$ with dimension greater than three it is possible to find a second linear model $\mathbf{B}_0$ such that (a) all lights that lie in $\mathbf{B}_0$ also lie in $\mathbf{B}$ and (b) all lights in $\mathbf{B}_0$ are metameric blacks. We determine $\mathbf{B}_0$ by finding a linear model for the null space of the matrix $\mathbf{TB}$. The null space of a matrix consists of all vectors that are mapped to $\mathbf{0}$ by the matrix. Finding a basis for the null space of a matrix is a standard operation in numerical matrix algebra. If we have a set of basis vectors $\mathbf{N}_0$ for the null space of $\mathbf{TB}$, we can form $\mathbf{B}_0 = \mathbf{BN}_0$. This technique provides a way to generate a large list of metamers for any given light $\mathbf{b}$. We choose a set of weights $\mathbf{a}$ at random and construct $\mathbf{b}_0 = \mathbf{B}_0\mathbf{a}$. We then add $\mathbf{b}_0$ to $\mathbf{b}$ to form a metamer. To generate more metamers, we simply repeat with new choices of weight vector $\mathbf{a}$.

Surface and Illuminant Metamerism The formal similarity between Eq. (20) (which gives the relation between spectral power distributions and tristimulus values) and Eq. (34) (which gives the relation between surface reflectance functions and tristimulus values when the illuminant is known) makes it clear that our discussion of metamerism can be applied to surface reflectance spectra. Two physically different surfaces will appear identical if the tristimulus values of the light reflected from them is identical. This fact can be used to good purpose in some color reproduction applications. Suppose that we have a sample surface or textile whose color we wish to reproduce. It may be that we are not able to reproduce the sample's surface reflectance function exactly because of various limitations in the available color reproduction technology. If we know the illuminant under which the reproduction will be viewed, we may be able to determine a reproducible reflectance function that is metameric to that of the desired sample. This will give us a sample whose color appearance is as desired. Applications of this sort make heavy use of the methods described earlier to determine metamers.

But what if the illuminant is not known or if it is known to vary? In this case there is an additional richness to the topic of determining metamers. We can pose the problem of finding surface reflectance functions that will be metameric to a desired reflectance under multiple specified illuminants or under all of the illuminants within some linear model. The general methods developed here have been extended to analyze this case.[158,160] Similar issues arise in lighting design, where we desire to produce an artificial light whose color-rendering properties match those of a specified light (such as natural daylight). When wavelength by wavelength matching of the spectra is not feasible, it may still be possible to find a spectrum so that the light reflected from surfaces within a linear model is identical for the two light sources. Because of the symmetric role of illuminants and surfaces in reflection, this problem may be treated by the same methods as used for surface reproduction.

Color Cameras and Other Visual Systems

We have treated colorimetry from the point of view of specifying the spectral information available to a human observer. We have developed our treatment, however, in such a way that it may be applied to handle other visual systems. Suppose that we wish to define color coordinates with respect to some arbitrary visual system with N_{device} photosensors. This visual system might be an artificial system based on a color camera or scanner, a nonhuman biological visual system, or the visual system of a color anomalous human observer. We assume that the sensitivities of the visual system's photosensors are known up to a linear transformation. Let $\mathbf{T}_{\text{device}}$ be an N_{device} by N_λ matrix whose entries are the sensitivities of each of the device's sensors at each sample wavelength. We can compute the responses of these sensors to any light $\mathbf{b}$. Let $\mathbf{t}_{\text{device}}$ be a vector containing the responses of each sensor type to the light. Then we have $\mathbf{t}_{\text{device}} = \mathbf{T}_{\text{device}}\,\mathbf{b}$. We may use $\mathbf{t}_{\text{device}}$ as the device color coordinates of $\mathbf{b}$.

Transformation between Color Coordinates of Different Visual Systems Suppose that we have two different visual systems and we wish to transform between the color coordinates of each.

A typical example might be trying to compute the CIE 1931 *XYZ* tristimulus values of a light from the responses of a color camera. Let N_s be the number of source sensors, with sensitivities specified by $\mathbf{T}_s$. Similarly, let N_d by the number of destination sensors with sensitivities specified by $\mathbf{T}_d$. For any light $\mathbf{b}$ we know that the source device color coordinates are given by $\mathbf{t}_s = \mathbf{T}_s\mathbf{b}$ and the destination device color coordinates $\mathbf{t}_d = \mathbf{T}_d\mathbf{b}$. We would like to transform between $\mathbf{t}_s$ and $\mathbf{t}_d$ without direct knowledge of $\mathbf{b}$.

If we can find an N_d by N_s matrix $\mathbf{M}$ such that $\mathbf{T}_d = \mathbf{M}\mathbf{T}_s$ then it is easy to show that the matrix $\mathbf{M}$ may be used to compute the destination device color coordinates from the source device color coordinates through $\mathbf{t}_d = \mathbf{M}\mathbf{t}_s$. We have already considered this case (in a less general form) in subsection "Transformations between Color Spaces." The extension here is that we allow the possibility that the dimensions of the two color coordinate systems differ. When a linear transformation between $\mathbf{T}_s$ and $\mathbf{T}_d$ exists, it can be found by standard regression methods.

Horn demonstrated that when no exact linear transformation between $\mathbf{T}_s$ and $\mathbf{T}_d$ exists, it is not in general possible to transform between the two sets of color coordinates.[4] The reason for this is that there will always exist a pair of lights that have the same color coordinates for the source device but different color coordinates for the destination device. The transformation will therefore be incorrect for at least one member of this pair. When no exact linear transformation exists, it is still possible to make an approximate transformation. One approach is to use linear regression to find the best linear transformation $\mathbf{M}$ between the two sets of color-matching functions in a least squares sense. This transformation is then applied to the source color coordinates as if it were exact.[4] Although this is an approximation, in many cases the results will be acceptable. In the absence of prior information about the spectral power distribution of the original light $\mathbf{b}$, it is a sensible approach.

A second possibility is to use prior constraints on the spectral power distribution of the light to guide the transformation.[22] Suppose that we know that the light is constrained to lie within an N_b dimensional linear model $\mathbf{B}$. Then we can find the best linear transformation $\mathbf{M}$ between the two matrices $\mathbf{T}_s\mathbf{B}$ and $\mathbf{T}_d\mathbf{B}$. This transformation may then be used to transform the source color coordinates to the destination color coordinates. It is easy to show that the transformation will be exact if $\mathbf{T}_d\mathbf{B} = \mathbf{M}\mathbf{T}_s\mathbf{B}$. Otherwise it is a reasonable approximation that takes the linear model constraint into account.

A number of recent papers present more elaborated methods for color correction.[161–163]

Computational Color Constancy An interesting application is the problem of estimating surface reflectance functions from color coordinates. This problem is of interest for two reasons. First, it appears that human color vision makes some attempt to perform this estimation, so that our percept of color is more closely associated with object surface properties than with the proximal properties of the light reaching the eye. Second, an artificial system that could estimate surface properties would have an important cue to aid object recognition. In the case where the illuminant is known, the problem of estimating surface reflectance properties is the same as the problem of estimating the color signal, because the illuminant spectral power distribution can simply be incorporated into the sensor sensitivities. In this case the methods outlined in the preceding section for estimating color signal spectral properties can be used.

The more interesting case is where both the illuminant and the surface reflectance are unknown. In this case, the problem is more difficult. Considerable insight has been gained by applying linear model constraints to both the surface and illuminant spectral power distributions. A number of approaches have been developed for recovering surface reflectance functions or otherwise achieving color constancy.[158,164–172] Each approach differs (1) in the additional assumptions that are made about the properties of the image and (2) in the sophistication of the model of illuminant surface interaction and scene geometry used. A thorough review of all of these methods is beyond the scope of this chapter. It is instructive, however, to review one of the simpler methods, that of Buchsbaum.[165] See Ebner[173] for a discussion of many current algorithms.

Buchsbaum assumed that in any given scene, the average reflectance function of the surfaces in the scene is known. This is commonly called the "gray world" assumption. He also assumed that the illuminant was diffuse and constant across the scene and that the illuminants and surfaces in the scene are described by linear models with the same dimensionality as the number of sensors.

Let $\mathbf{S}_{avg}$ be the spectral power distribution of the known average surface, represented in diagonal matrix form. Then it is possible to write the relation between the space average of the sensor responses and the illuminant as

$$\mathbf{t}_{avg} = \mathbf{T}\mathbf{S}_{avg}\mathbf{B}_e\mathbf{a}_e \tag{38}$$

where $\mathbf{a}_e$ is a vector containing the weights of the illuminant within the linear model representation $\mathbf{B}_e$. Because we assume that the dimension $N_e = N_t$, the matrix $\mathbf{T}\mathbf{S}_{avg}\mathbf{B}_e$ will be square and typically may be inverted. From this we recover the illuminant as $\mathbf{e} = \mathbf{B}_e(\mathbf{T}\mathbf{S}_{avg}\mathbf{B}_e)^{-1}\mathbf{t}_{avg}$. If we let $\mathbf{E}$ represent the recovered illuminant in matrix form, then at each image location we can write

$$\mathbf{t} = \mathbf{T}\mathbf{E}\mathbf{B}_s\mathbf{a}_s \tag{39}$$

where $\mathbf{a}_s$ is a vector containing the weights of the surface within the linear model representation $\mathbf{B}_s$. Proceeding exactly as we did for the illuminant, we may recover the surface reflectance from this equation.

Although Buchsbaum's method depends on rather strong assumptions about the nature of the scene, subsequent algorithms have shown that these assumptions can be relaxed.[22,166,172] Several authors treat the relation between computational color constancy and the study of human vision.[174–178]

Color Discrimination

Measurement of Small Color Differences Our treatment so far has not included any discussion of the precision to which observers can judge identity of color appearance. To specify tolerances for color reproduction, it would be helpful to know how different the color coordinates of two lights must be for an observer to reliably distinguish between them. A number of techniques are available for measuring human ability to discriminate between colored lights. We review these briefly here as an introduction to the topic of uniform color spaces. A more extended discussion of color discrimination and its relation to postreceptoral mechanisms is presented in the companion chapter (Chap. 11).

One experimental method, employed in seminal work by MacAdam,[179,180] is to examine the variability in individual color matches. That is, if we have observers set matches to the same test stimulus, we will discover that they do not always set exactly the same values. Rather, there will be some trial-to-trial variability in the settings. MacAdam and others[181,182] used the sample covariance of the individual match tristimulus values as a measure of observers' color discrimination.

A second approach is to use more direct psychophysical methods (see Chap. 3) to measure observers' thresholds for discriminating between pairs of colored lights. Examples include increment threshold measurements for monochromatic lights[183] and thresholds measured systematically in a three-dimensional color space.[184,185]

Measurements of small color differences are often summarized with isodiscrimination contours. An isodiscrimination contour specifies the color coordinates of lights that are equally discriminable from a common standard light. Figure 18 shows an illustrative isodiscrimination contour. Isodiscrimination contours are often modeled as ellipsoids[184,185] and the figure is drawn to the typical ellipsoidal shape. The well-known MacAdam ellipses[179] are an example of representing discrimination data using the chromaticity coordinates of a cross-section of a full three-dimensional isodiscrimination contour (see the legend of Fig. 18). Chapter 11 provides a more extensive discussion of possible models of discrimination contours. Under some experimental conditions, the measured contour may not be ellipsoidal.

CIE Uniform Color Spaces Figure 19 shows chromaticity plots of theoretical isodiscrimination contours. A striking feature of the plots is that the size and shape of the contours depends on the standard stimulus. For this reason, it is not possible to predict whether two lights will be discriminable solely on the basis of the Euclidean distance between their color coordinates. The heterogeneity of the isodiscrimination contours must also be taken into account.

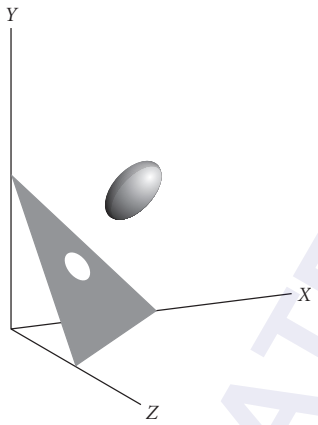

FIGURE 18 Isodiscrimination contour. The plotted ellipsoid shows a hypothetical isodiscrimination contour in the CIE *XYZ* color space. This contour represents color discrimination performance for the standard light whose color coordinates are located at the ellipsoid's center. Isodiscrimination contours such as the one shown are often summarized by a two-dimensional contour plotted on a chromaticity diagram (see Fig. 19). The two-dimensional contour is obtained from a cross section of the full contour, and its shape can depend on which cross section is used. This information is not available directly from the two-dimensional plot. A common criterion for choice of cross section is isoluminance. The ellipsoid shown in the figure is schematic and does not represent actual human performance.

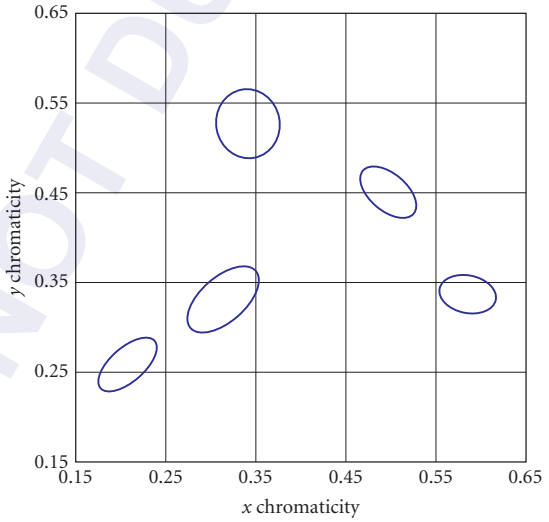

FIGURE 19 Isodiscrimination contours plotted in the chromaticity diagram. These were computed using the CIE L*a*b* uniform color space and ΔE^*_{ab} difference metric. They provide an approximate representation of human performance. For each standard stimulus, the plotted contour represents the color coordinates of lights that differ from the standard by 15 ΔE^*_{ab} units but that have the same luminance as the standard. The choice of 15 ΔE^*_{ab} units magnifies the contours compared to those that would be obtained in a threshold experiment. The contours shown are a projection of isodiscrimination contours computed for isoluminant color differences. The luminance of the white point used in the CIELAB computations was set at 1000 cd/m^2, while the discriminations were around stimuli with a luminance of 500 cd/m^2.

The CIE[10] provides formulas that may be used to predict the discriminability of colored lights. The most recent recommendations are based on the CIE 1976 $L^*a^*b^*$ (CIELAB) color coordinates. These are obtained by a nonlinear transformation from CIE 1931 *XYZ* color coordinates. The transformation stretches the *XYZ* color space so that the resulting Euclidean distance between color coordinates provides an approximation to the how well lights may be discriminated. The $L^*a^*b^*$ system is referred to as a uniform color space. There is also a CIE 1976 $L^*u^*v^*$ (CIELUV) system, but this is now less widely used than the $L^*a^*b^*$ system and its derivatives.

Transformation to CIELAB coordinates The CIE 1976 $L^*a^*b^*$ color coordinates of a light may be obtained from its CIE *XYZ* coordinates according to the equations

$$L^* = \begin{cases} 116\left(\dfrac{Y}{Y_n}\right)^{1/3} - 16 & \dfrac{Y}{Y_n} > 0.008856 \\ 903.3\left(\dfrac{Y}{Y_n}\right) & \dfrac{Y}{Y_n} \le 0.008856 \end{cases}$$

$$a^* = 500\left[f\left(\frac{X}{X_n}\right) - f\left(\frac{Y}{Y_n}\right)\right] \tag{40}$$

$$b^* = 200\left[f\left(\frac{Y}{Y_n}\right) - f\left(\frac{Z}{Z_n}\right)\right]$$

where the function $f(s)$ is defined as

$$f(s) = \begin{cases} (s)^{1/3} & s > 0.008856 \\ 7.787(s) + \dfrac{16}{116} & s \le 0.008856 \end{cases} \tag{41}$$

The quantities X_n, Y_n, and Z_n in the equations above are the tristimulus values of a white point. Little guidance is available as to how to choose an appropriate white point. In the case where the lights being judged are formed when an illuminant reflects from surfaces, the tristimulus values of the illuminant may be used. In the case where the lights being judged on a computer-controlled color monitor, the sum of the tristimulus values of the three monitor phosphors stimulated at their maximum intensity may be used.

Distance in CIELAB space The Euclidean distance between the $L^*a^*b^*$ coordinates of two lights provides a rough guide to their discriminability. The symbol ΔE^*_{ab} is used to denote distance in the uniform color space and is defined as

$$\Delta E^*_{ab} = \sqrt{(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2} \tag{42}$$

where the various quantities on the right represent the differences between the corresponding coordinates of the two lights. Roughly speaking, a ΔE^*_{ab} value of 1 corresponds to a color difference that can just be reliably discerned by a human observer under optimal viewing conditions. A ΔE^*_{ab} value of 3 is sometimes used as an acceptable tolerance in industrial color reproduction applications.

The CIE color difference measure ΔE^*_{ab} provides only an approximate guide to the discriminability between two lights. There are a number of reasons why this is so. The first is that the relatively simple nonlinear transformation between CIE *XYZ* and CIE $L^*a^*b^*$ coordinates does not completely capture the empirical data on color discrimination between two samples. In part this is because the formulae were designed to predict not only discrimination data but also certain suprathreshold judgments of color appearance.[186] Second, color discrimination thresholds depend heavily on factors other than the tristimulus values. These factors include the adapted state of the observer,[183] the spatial and temporal structure of the stimulus,[187–189] and the task demands placed on the observer.[190–193] Therefore, the complete specification of a uniform color space must incorporate these factors. The CIE has now recommended a more involved method of computing small color differences from the CIE $L^*a^*b^*$ coordinates that attempts to provide better prediction of small color differences.[10,194] The resultant computed difference is referred to as ΔE_{00}. The details of the computation of ΔE_{00} are provided and discussed in a CIE technical report.[194] The reader considering using ΔE_{00} is encouraged to study Wyszecki and Stiles's[8(pp. 584–586)] insightful discussion of color vision models.

Effect of Errors in Color-Matching Functions

Given that there is some variation between different standard estimates of color-matching functions, between the color-matching functions of different individuals, and between the color-matching functions that mediate performance for different viewing conditions, it is of interest to determine whether the magnitude of this variation is of practical importance. There is probably no general method for making this determination, but here we outline one approach.

Consider the case of rendering a set of illuminated surfaces on a color monitor. If we know the spectral power distribution of the monitor's phosphors, it is possible to compute the appropriate weights on the monitor phosphors to produce a light metameric to each illuminated surface. The computed weights will depend on the choice of color-matching functions. Once we know the weights, however, we can find the $L^*a^*b^*$ coordinates of the emitted light. This suggests the following method to estimate the effect of differences in color-matching functions. First we compute the $L^*a^*b^*$ coordinates of surfaces rendered using the first set of color-matching functions. Then we compute the corresponding coordinates when the surfaces are rendered using the second set of color-matching functions. Finally, we compute the ΔE^*_{ab} difference between corresponding sets of coordinates. If the ΔE^*_{ab} are large, then the differences between the color-matching functions are important for the rendering application.

We have performed this calculation for a set of 462 measured surfaces[139,140] rendered under CIE Illuminant D_{65}. The two sets of color-matching functions used were the 1931 CIE *XYZ* color-matching functions and the Judd-Vos modified *XYZ* color-matching functions. The monitor phosphor spectral power distributions were measured by the first author. The results are shown in Fig. 20. The plot shows a histogram of the differences. The median difference is 1.2 units. This difference is quite close to discrimination threshold and for many applications, the differences between the two sets of color-matching functions will probably not be of great consequence.

Brightness Matching and Photometry

The foundation of colorimetry is the human observer's ability to judge identity of color appearance. It is sometimes of interest to compare certain perceptual attributes of lights that do not, as a whole, appear identical. In particular, there has been a great deal of interest in developing formulas that predict when two lights with different relative spectral power distributions will appear equally bright. Colorimetry provides a partial answer to this question, since two lights that match in appearance must appear equally bright. Intuitively, however, it seems that it should be possible to set the relative intensities of any two lights so that they match in brightness.

In a heterochromatic brightness matching experiment, observers are asked to scale the intensity of a matching light until its brightness matches that of an experimentally controlled test light. Although

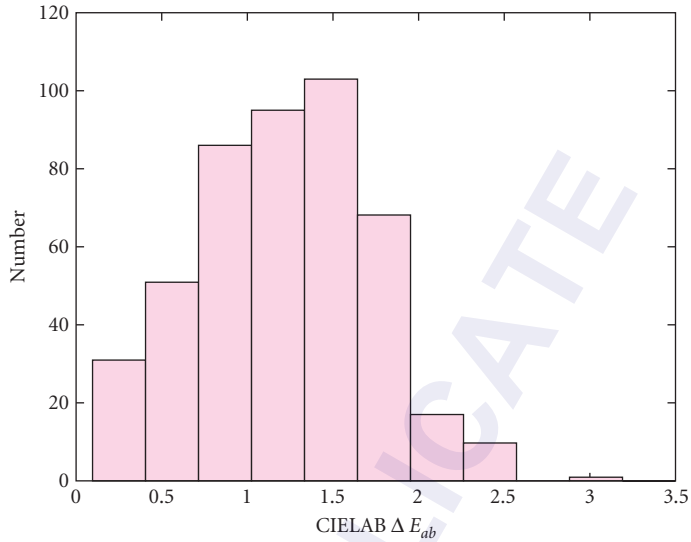

FIGURE 20 Effect of changes in color-matching functions. The plot shows a histogram of the ΔE^*_{ab} differences between two sets of lights, each of which is a monitor rendering of the same set of illuminated surfaces. The two renderings were computed using different sets of color-matching functions. The white point used in the CIELAB transformations was the *XYZ* coordinates of the illuminant used to compute the renderings, CIE D65.

observers can perform the heterochromatic brightness matching task, they often report that it is difficult and their matches tend to be highly variable.[8] Moreover, the results of brightness-matching experiments are not additive.[43,195] For photometry to be as practicable as radiometry, the measured luminous efficiency of any mixture of lights must equal the sum of the luminous efficiencies of the component lights. Such additivity is known as obedience to Abney's law.[196,197] For this reason, more indirect methods for equating the overall effectiveness of lights at stimulating the visual system have been developed.[8,195,198–203] The most commonly used method is that of flicker photometry. In a flicker photometric experiment, two lights of different spectral power distributions are presented alternately at the same location. At moderate flicker rates (about 20 Hz), subjects are able to adjust the overall intensity of one of the lights to minimize the apparent flicker. The intensity setting that minimizes apparent flicker is taken to indicate that the two lights match in their effectiveness as visual stimuli. Two lights equated in this way are said to be equiluminant or to have equal luminance.

Because experiments for determining when lights have the same luminance obey linearity properties similar to Grassmann's laws, it is possible to determine a luminous efficiency function that allows the assignment of a luminance value to any light. A luminous efficiency function specifies, for each sample wavelength, the relative contribution of that wavelength to the overall luminance. We can represent a luminous efficiency function as an N_λ dimensional row vector **v**. Each entry of the matrix specifies the relative luminance of light at the corresponding sample wavelength. The luminance v of an arbitrary spectral power distribution **b** may be computed by the equation

$$v = \mathbf{vb} \tag{43}$$

The CIE has standardized four luminous efficiency functions by definition. The most commonly used of these is the standard photopic luminous efficiency function $V(\lambda)$. This is identical by definition to the 1931 *XYZ* color-matching function $\overline{y}\lambda$. For lights that subtend more than 4° of visual angle, a luminous efficiency function $V_{10}(\lambda)$ given by the 1964 10° *XYZ* color-matching functions is

preferred. More recently, the Judd-Vos modified color matching function has been made a supplemental standard.[204] A final standard luminous efficiency function is available for use at low light levels when the rods are the primary functioning photoreceptors. A new luminous efficiency function will be incorporated into the new CIE proposal for a set of physiologically relevant color-matching functions. The notation V_λ or $V(\lambda)$ is often used in the literature to denote luminous efficiency functions. Note that Eq. (43) allows the computation of luminance in arbitrary units. Ref. 8 discusses standard measurement units for luminance.

It is important to note that luminance is a construct derived from flicker photometric and related experiments. As such, it does not directly predict when two lights will be judged to have the same brightness. The relation between luminance and brightness is quite complicated.[8,205]

It is also worth noting that there is considerable individual variation in flicker photometric judgments, even among color-normal observers. For this reason, it is a common practice in psychophysical experiments to use flicker photometry to determine isoluminant stimuli for individual subjects with the stimuli of interest.

10.7 APPENDIX—MATRIX ALGEBRA

This appendix provides a brief introduction to matrix algebra. The development emphasizes the aspects of matrix algebra that are used in this chapter and is somewhat idiosyncratic. In addition, we do not prove any of the results we state. Rather, our intention is to provide the reader unfamiliar with matrix algebra with enough information to make this chapter self-contained.

Basic Notions

Vectors and Matrices A vector is a list of numbers. We use lowercase bold letters to represent vectors. We use single subscripts to identify the individual entries of a vector. The entry a_i refers to the ith number in $\mathbf{a}$. We call the total number of entries in a vector its dimension.

A matrix is an array of numbers. We use uppercase bold letters to represent matrices. We use dual subscripts to identify the individual entries of a matrix. The entry a_{ij} refers to the number in the ith row and jth column of $\mathbf{A}$. We sometimes refer to this as the ijth entry of $\mathbf{A}$. We call the number of rows in a matrix its row dimension. We call the number of columns in a matrix its column dimension. We generally use the symbol N to denote dimensions.

Vectors are a special case of matrices where either the row or the column dimension is 1. A matrix with a single column is often called a column vector. A matrix with a single row is often called a row vector. By convention, all vectors used in this chapter should be understood to be column vectors unless explicitly noted otherwise.

It is often convenient to think of a matrix as being composed of vectors. For example, if a matrix has dimensions N_r by N_c, then we may think of the matrix as consisting of N_c column vectors, each of which has dimension N_r.

Addition and Multiplication A vector may be multiplied by a number. We call this scalar multiplication. Scalar multiplication is accomplished by multiplying each entry of the vector by the number. If $\mathbf{a}$ is a vector and b is a number, then $\mathbf{b} = \mathbf{a}b = b\mathbf{a}$ is a vector whose entries are given by $c_j = ba_j$.

Two vectors may be added together if they have the same dimension. We call this vector addition. Vector addition is accomplished through entry-by-entry addition. If $\mathbf{a}$ and $\mathbf{b}$ are vectors with the same dimension, the entries of $\mathbf{c} = \mathbf{a} + \mathbf{b}$ are given by $c_j = a_j + b_j$.

Two matrices may be added if they have the same row and column dimensions. We call this matrix addition. Matrix addition is also defined as entry by entry addition. Thus if $\mathbf{A}$ and $\mathbf{B}$ are matrices with the same dimension, the entries of $\mathbf{C} = \mathbf{A} + \mathbf{B}$ are given by $c_{ij} = a_{ij} + b_{ij}$. Vector addition is a special case of matrix addition.

A column vector may be multiplied by a matrix if the column dimension of the matrix matches the dimension of the vector. If **A** has dimensions N_r by N_c and **b** has dimension N_c, then $\mathbf{c} = \mathbf{Ab}$ is an N_r dimensional vector. The ith entry of **c** is related to the entries of **A** and **b** by the equation:

$$c_i = \sum_{j=1}^{N_c} a_{ij} b_j \tag{44}$$

It is also possible to multiply a matrix **B**, by another matrix, **A** on the left, if the column dimension of **A** matches the row dimension of **B**. If **A** has dimensions N_r by N and **B** has dimensions N by N_c, then $\mathbf{C} = \mathbf{AB}$ is an N_r by N_c dimensional matrix. The ikth entry of **C** is related to the entries of **A** and **B** by the equation:

$$c_{ik} = \sum_{j=1}^{N} a_{ij} b_{jk} \tag{45}$$

By comparing Eqs. (44) and (45) we see that multiplying a matrix by a matrix is a shorthand for multiplying several vectors by the same matrix. Denote the N_c columns of **B** by $\mathbf{b}_1, \ldots, \mathbf{b}_{N_c}$ and the N_c columns of **C** by $\mathbf{c}_1, \ldots, \mathbf{c}_{N_c}$. If $\mathbf{C} = \mathbf{AB}$, then $\mathbf{c}_k = \mathbf{Ab}_k$ for $k = 1, \ldots, N_c$.

It is possible to show that matrix multiplication is associative. Suppose we have three matrices **A**, **B**, and **C** whose dimensions are such that the matrix products (**AB**) and (**BC**) are both well-defined. Then $(\mathbf{AB})\mathbf{C} = \mathbf{A}(\mathbf{BC})$. We often write **ABC** to denote either product. Matrix multiplication is not commutative. Even when both products are well-defined, it is not in general true that **BA** is equal to **AB**.

Matrix Transposition The transpose of an N_r by N_c matrix **A** is an N_c by N_r matrix **B** whose ijth entry is given by $b_{ij} = a_{ji}$. We use the superscript "T" to denote matrix transposition: $\mathbf{B} = \mathbf{A}^T$. The identity $(\mathbf{AB})^T = \mathbf{B}^T\mathbf{A}^T$ always holds.

Special Matrices and Vectors A diagonal matrix **D** is an N_r by N_c matrix whose entries d_{ij} are zero if $i \neq j$. That is, the only nonzero entries of a diagonal matrix lie along its main diagonal. We refer to the nonzero entries of a diagonal matrix as its diagonal entries.

A square matrix is a matrix whose row and column dimensions are equal. We refer to the row and column dimensions of a square matrix as its dimension.

An identity matrix is a square diagonal matrix whose diagonal entries are all one. We use the symbol $\mathbf{I}_N$ to denote the N by N identity matrix. Using Eq. (45) it is possible to show that for any N_r by N_c matrix **A**, $\mathbf{AI}_{N_c} = \mathbf{I}_{N_r}\mathbf{A} = \mathbf{A}$.

An orthogonal matrix **U** is a square matrix that has the property that $\mathbf{U}^T\mathbf{U} = \mathbf{U}\mathbf{U}^T = \mathbf{I}_N$, where N is the dimension of **U**.

A zero vector is a vector whose entries are all zero. We use the symbol $\mathbf{0}_N$ to denote the **N** dimensional zero vector.

Linear Models

Linear Combinations of Vectors Equation (44) is not particularly intuitive. A useful way to think about the effect of multiplying a vector **b** by matrix **A** is as follows. Consider the matrix **A** to consist of N_c column vectors $\mathbf{a}_1, \ldots, \mathbf{a}_{N_c}$. Then from Eq. (44) we have that the vector $\mathbf{c} = \mathbf{Ab}$ may be obtained by the operations of vector addition and scalar multiplication by

$$\mathbf{c} = \mathbf{a}_1 b_1 + \cdots + \mathbf{a}_{N_c} b_{N_c} \tag{46}$$

where the numbers $b_1, \ldots, b_{N_c}$ are the entries of **b**. Thus the effect of multiplying a vector by a matrix is to form a weighted sum of the columns of the matrix. The weights that go into forming the sum are the entries of the vector. We call any expression that has the form of the right hand side of Eq. (46) a linear combination of the vectors $\mathbf{a}_1, \ldots, \mathbf{a}_{N_c}$.

Independence and Rank Consider a collection of vectors $\mathbf{a}_1, \ldots, \mathbf{a}_{N_c}$. If no one of these vectors may be expressed as a linear combination of the others, then we say that the collection is independent. We define the rank of a collection of vectors $\mathbf{a}_1, \ldots, \mathbf{a}_{N_c}$ as the largest number of linearly independent vectors that may be chosen from that collection. We define the rank of a matrix $\mathbf{A}$ to be the rank of the vectors $\mathbf{a}_1, \ldots, \mathbf{a}_{N_c}$ that make up its columns. It may be proved that the rank of a matrix is always less than or equal to the minimum of its row and column dimensions. We say that a matrix has full rank if its rank is exactly equal to the minimum of its row and column dimensions.

Linear Models When a vector $\mathbf{c}$ has the form given in Eq. (46), we say that $\mathbf{c}$ lies within a linear model. We call N_c the dimension of the linear model. We call the vectors $\mathbf{a}_1, \ldots, \mathbf{a}_{N_c}$ the basis vectors for the model. Thus an N_c dimensional linear model with basis vectors $\mathbf{a}_1, \ldots, \mathbf{a}_{N_c}$ contains all vectors $\mathbf{c}$ that can be expressed exactly using Eq. (46) for some choice of numbers $b_1, \ldots, b_{N_c}$. Equivalently, the linear model contains all vectors $\mathbf{c}$ that may be expressed as $\mathbf{c} = \mathbf{Ab}$ where the columns of the matrix $\mathbf{A}$ are the vectors $\mathbf{a}_1, \ldots, \mathbf{a}_{N_c}$ and $\mathbf{b}$ is an arbitrary vector. We refer to all vectors within a linear model as the subspace defined by that model.

Simultaneous Linear Equations

Matrix and Vector Form Matrix multiplication may be used to express a system of simultaneous linear equations. Suppose we have a set of N_r simultaneous linear equations in N_c unknowns. Call the unknowns $b_1, \ldots, b_{N_c}$. Conventionally we would write the equations in the form

$$\begin{aligned} a_{11}b_1 + \cdots + a_{1N_c}b_{N_c} &= c_1 \\ a_{21}b_1 + \cdots + a_{2N_c}b_{N_c} &= c_2 \\ &\cdots \\ a_{N_r1}b_1 + \cdots + a_{N_rN_c}b_{N_c} &= c_{N_r} \end{aligned} \tag{47}$$

where the a_{ij} and c_i represent known numbers. From Eq. (44) it is easy to see that we may rewrite Eq. (47) as a matrix multiplication

$$\mathbf{Ab} = \mathbf{c} \tag{48}$$

In this form, the entries of the vector $\mathbf{b}$ represent the unknowns. Solving Eq. (48) for $\mathbf{b}$ is equivalent to solving the system of simultaneous linear equations of Eq. (47).

Solving Simultaneous Linear Equations A fundamental topic in linear algebra is finding solutions for systems of simultaneous linear equations. We will rely on several basic results in this chapter, which we state here.

When the matrix $\mathbf{A}$ is square and has full rank, it is always possible to find a unique matrix $\mathbf{A}^{-1}$ such that $\mathbf{AA}^{-1} = \mathbf{A}^{-1}\mathbf{A} = \mathbf{I}_N$. We call the matrix $\mathbf{A}^{-1}$ the inverse of the matrix $\mathbf{A}$. The matrix $\mathbf{A}^{-1}$ is also square and has full rank. Algorithms exist for determining the inverse of a matrix and are provided by software packages that support matrix algebra.

When the matrix $\mathbf{A}$ is square and has full rank, a unique solution $\mathbf{b}$ to Eq. (48) exists. This solution is given simply by the expression $\mathbf{b} = \mathbf{A}^{-1}\mathbf{c}$. When the rank of $\mathbf{A}$ is less than its row dimension, then there will not in general be an exact solution to Eq. (48). There will, however, be a unique vector $\mathbf{b}$ that is the best solution in a least squares sense. We call this the least squares solution to Eq. (48). Finding the least squares solution to Eq. (48) is often referred to as linear regression. Algorithms exist for performing linear regression and are provided by software packages that support matrix algebra.

A generalization of Eq. (48) is the matrix equation

$$\mathbf{AB} = \mathbf{C} \tag{49}$$

where the entries of the matrix **B** are the unknowns. From our interpretation of matrix multiplication as a shorthand for multiple multiplications of a vector by a matrix, we can see immediately that this type of equation may be solved by applying the above analysis in a columnwise fashion. If **A** is square and has full rank, then we may determine **B** uniquely as $\mathbf{A}^{-1}\mathbf{C}$. When the rank of **A** is less than its row dimension, we may use regression determine a matrix **B** that satisfies Eq. (49) in a least squares sense.

It is also possible to solve matrix equations of the form $\mathbf{BA} = \mathbf{C}$ where the entries of **B** are again the unknowns. An equation of this form may be converted to the form of Eq. (49) by applying the transpose identity (see subsection "Matrix Transposition"). That is, we may find **B** by solving the equation $\mathbf{A}^T\mathbf{B}^T = \mathbf{C}^T$ if $\mathbf{A}^T$ meets the appropriate conditions.

Null Space When the rank of a matrix **A** is greater than its row dimension N_r, it is possible to find nontrivial solutions to the equation

$$\mathbf{Ab} = \mathbf{0}_{N_r} \tag{50}$$

Indeed, it is possible to determine a linear model such that all vectors contained in the model satisfy Eq. (50). This linear model will have dimension equal to the difference between N_r and the rank of the matrix A. The subspace defined by this linear model is called the null space of the matrix A. Algorithms to find the basis vectors of a matrix's null space exist and are provided by software packages that support matrix algebra.

Singular Value Decomposition

The singular value decomposition allows us to write any N_r by N_c matrix **X** in the form

$$\mathbf{X} = \mathbf{UDV}^T \tag{51}$$

where **U** is an N_r by N_r orthogonal matrix, **D** is an N_r by N_c "diagonal" matrix, and **V** is an N_c by N_c orthogonal matrix.[148] The diagonal entries of **D** are guaranteed to be nonnegative. Some of the diagonal entries may be zero. By convention, the entries along this diagonal are arranged in decreasing order. We illustrate the singular value decomposition in Fig. 21. The singular value decomposition has a large number of uses in numerical matrix algebra. Routines to compute it are generally provided as part of software packages that support matrix algebra.

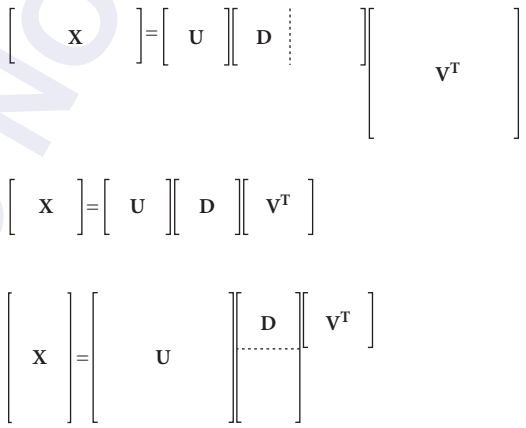

FIGURE 21 The figure depicts the singular value decomposition (SVD) of an N by M matrix **X** for three cases: $N_c > N_r$, $N_c = N_r$, and $N_c < N_r$.

11.1 GLOSSARY

Achromatic mechanism. Hypothetical psychophysical mechanisms, sometimes equated with the luminance mechanism, which respond primarily to changes in intensity. Note that achromatic mechanisms may have spectrally opponent inputs, in addition to their primary nonopponent inputs.

Bezold-Brücke hue shift. The shift in the hue of a stimulus toward either the yellow or blue invariant hues with increasing intensity.

Bipolar mechanism. A mechanism, the response of which has two mutually exclusive types of output that depend on the balance between its two opposing inputs. Its response is nulled when its two inputs are balanced.

Brightness. A perceptual measure of the apparent intensity of lights. Distinct from luminance in the sense that lights that appear equally bright are not necessarily of equal luminance.

Cardinal directions. Stimulus directions in a three-dimensional color space that silence two of the three "cardinal mechanisms." These are the isolating directions for the L+M, L–M, and S–(L+M) mechanisms. Note that the isolating directions do not necessarily correspond to mechanism directions.

Cardinal mechanisms. The second-site bipolar L–M and S–(L+M) chromatic mechanisms and the L+M luminance mechanism.

Chromatic discrimination. Discrimination of a chromatic target from another target or background, typically measured at equiluminance.

Chromatic mechanism. Hypothetical psychophysical mechanisms that respond to chromatic stimuli, that is, to stimuli modulated at equiluminance.

Color appearance. Subjective appearance of the hue, brightness, and saturation of objects or lights.

Color-appearance mechanisms. Hypothetical psychophysical mechanisms that mediate color appearance, especially as determined in hue scaling or color valence experiments.

Color assimilation. The phenomenon in which the hue of an area is perceived to be closer to that of the surround than to its hue when viewed in isolation. Also known as the von Bezold spreading effect.

Color constancy. The tendency of objects to retain their color appearance despite changes in the spectral characteristics of the illuminant, or, more generally, despite changes in viewing context.

Color contrast. The change in the color appearance of an area caused by the presence of a colored surround. The color change, unlike assimilation, is usually complementary to the surround color.

Color-discrimination mechanisms. Hypothetical psychophysical mechanisms that determine performance in chromatic detection or discrimination tasks. Assumed in some models to correspond to cone-opponent mechanisms.

Color spaces. Representations of lights either in terms of the responses of some known or hypothetical mechanisms thought to underlie the perception of color (such as cone or postreceptoral mechanisms), or in terms of the projection of the lights onto stimulus-based vectors (such as monochromatic primaries or mechanism-isolating vectors).

Color valence. A measure of the color of a light in terms of the amount of a cancelling light required to null one of the hue sensations produced by that light. Thus, if a light appears red it is cancelled by light that appears green, and the amount of this green light is its red valance. In opponent-colors theory, color appearance depends on the relative red-green and blue-yellow valences.

Cone contrast. The contrast (or relative change in quantal or energy catch) presented to each cone photoreceptor: $\Delta L/L$, $\Delta M/M$, and $\Delta S/S$.

Cone contrast space. A color space where the position along each axis represents the contrast of one cone class.

Cone mechanisms. Hypothetical psychophysical mechanisms, the performances of which are limited at the cone photoreceptors.

Cone-opponent mechanism. Hypothetical psychophysical mechanisms with opposed cone inputs.

Derrington Krauskopf Lennie (DKL) space. Color space, the axes of which are the stimulus strengths in each of the three cardinal mechanism directions. Closely related to the spaces proposed by Lüther[85] and MacLeod and Boynton.[86] In some accounts of this space the axes are defined in a different way, in terms of the three vectors that isolate each of the three cardinal mechanisms.

Detection surface or contour. Detection thresholds measured in many directions in color space form a detection surface. Confined to a plane, they form a contour. The terms threshold surface and threshold contour are synonymous with detection surface and detection contour, respectively.

Field method. A method in which the observer's sensitivity for detecting or discriminating a target is measured as a function of some change in context or in the adapted state of the mechanism of interest.

First-site adaptation. Adaptation, usually assumed to be cone-class specific, occurring at or related to the photoreceptor level.

Habituation. Loss of sensitivity caused by prolonged adaptation to chromatic and/or achromatic stimulus modulations, also known as contrast adaptation.

Incremental cone-excitation space. A color space in which the axes represent the deviations of each of the three classes of cones from a background. Deviations can be negative (decrements) as well as increments.

Intensity. Generic term to denote variation in stimulus or modulation strength when chromatic properties are held constant. In the particular context of modulations around a background, the vector length of a modulation may be used as a measure of intensity.

Invariant hue. A stimulus produces an invariant hue if that hue is independent of changes to stimulus intensity. Generally studied in the context of monochromatic stimuli.

Isolating direction. Direction in a color space that isolates the response of a single mechanism.

Linear visual mechanisms. Hypothetical mechanisms that behave linearly, usually with respect to the cone isomerization rates, but in some models with respect to the cone outputs after von Kries adaptation or contrast coding.

Luminance. A measure of the efficiency (or effectiveness) of lights often linked to the assumed output of the achromatic mechanism.

Mechanism direction. Stimulus color direction along which a specified mechanism is most sensitive. Note that the mechanism direction is not, in general, the same as the isolating direction for the same mechanism.

Noise masking. Threshold elevations caused by superimposing targets in noise.

Nonlinear visual mechanisms. Hypothetical mechanisms that behave nonlinearly either with respect to the cone inputs or with respect to their own (assumed) inputs.

Opponent-colors theory. A color theory that accounts for color appearance in the terms of the perceptual opposition of red and green (R/G), blue and yellow (B/Y), and dark and light (W/B).

Pedestal effects. Changes in sensitivity that occur when a target is superimposed on another stimulus, called the pedestal, which may have either identical or different spatio-chromatic-temporal characteristics to the target.

Second-site desensitization. Adaptation or sensitivity losses that act on the outputs of second-site cone-opponent and achromatic mechanisms, and thus on the combined cone signals processed by each mechanism.

Test method. A method in which the sensitivity for detecting or discriminating a target is measured as a function of some target parameter, such as wavelength, size, or temporal frequency.

Threshold surface or contour. Synonyms for detection surface or contour.

Unique hues. Hues that appear perceptually unmixed, such as unique blue and unique yellow (which appear neither red nor green).

Unipolar mechanism. A mechanism that responds to only one pole of bipolar cone-opponent excursions, thought to be produced by half-wave rectification of bipolar signals.

Univariant mechanism. A mechanism, in which the output varies unidimensionally, irrespective of the characteristics of its inputs.

von Bezold spreading. See Color assimilation.

von Kries adaptation. Reciprocal sensitivity adjustment in response to changing light levels assumed to occur independently within each of the three cone mechanisms.

Weber's law. $\Delta I/I$ = constant. The sensitivity to increments (ΔI) is inversely proportional to the adaptation level (I).

11.2 INTRODUCTION

The first stage of color vision is now well understood (see Chap. 10). When presented in the same context under photopic conditions, pairs of lights that produce the same excitations in the long-, middle-, and short-wavelength-sensitive (L-, M-, and S-) cones match each other exactly in appearance. Moreover, this match survives changes in context and changes in adaptation, provided that the changes are applied equally to both lights. Crucially, however, while the match survives such manipulations, the shared appearance of the lights does not. Substantial shifts in color appearance can be caused both by changes in context and by changes in chromatic adaptation. The identity of lights matched in this way reflects univariance at the cone photoreceptor level, whereas their changed appearance reflects the complex activity of postreceptoral mechanisms acting on the outputs of the cone photoreceptors. Figure 1 shows examples of how color contrast and color assimilation can affect the color appearance of pairs of lights that are physically identical.

In addition to affecting color appearance, postreceptoral mechanisms play a major role in determining the discriminability of color stimuli. Indeed, measurements of color thresholds (detection and discrimination) are critical in guiding models of postreceptoral mechanisms. Models of color discrimination are also important in industrial applications, for instance, in the specification tolerances for color reproduction (see subsection "CIE Uniform Color Spaces" in Sec. 10.6, Chap. 10).

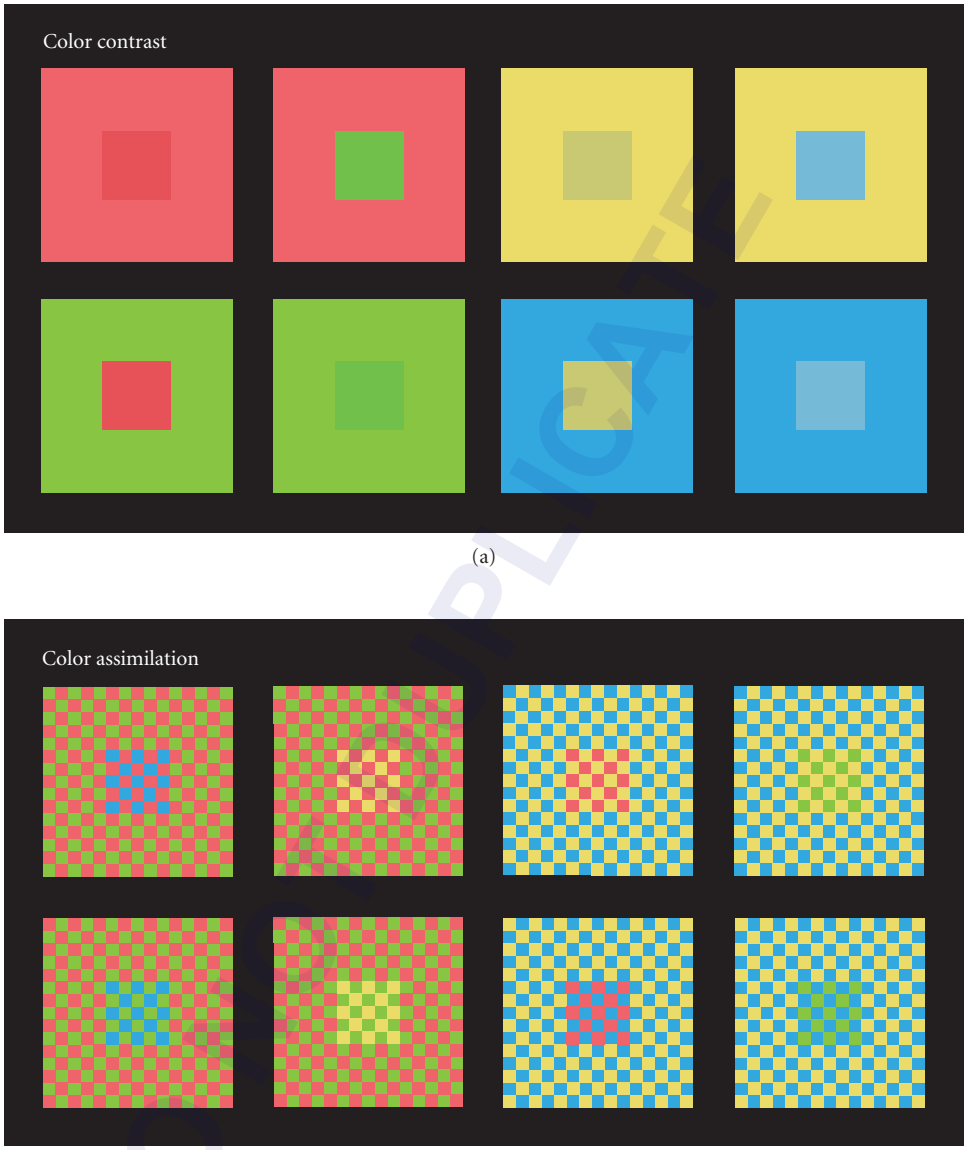

FIGURE 1 (*a*) Color contrast: The pairs of smaller squares in each of the four vertical columns are physically the same, but their color appearances are very different. The differences arise because of the surrounding areas, which induce complementary color changes in the appearance of the central squares.[473] Comparable examples of color contrast have been produced by Akiyoshi Kitaoka,[474] which he attributed to Kasumi Sakai.[475] (*b*) Color assimilation or the von Bezold spreading effect:[476] The tiny squares that make up the checkerboard patterns in each of the four columns are identical, except in the square central areas. In those central areas, one of the checkerboard colors has been replaced by a third color. The replacement color is the same in the upper and lower patterns, but the colors of the checkers that it replaces are different. The result is that the replacement color is surrounded by a different color in the upper and lower patterns. Although the replacement color is physically the same in each column, it appears different because of the color of the immediately surrounding squares. Unlike color contrast, the apparent color change is toward that of the surrounding squares.

The Mechanistic Approach

This chapter is about color vision after the photoreceptors. In the development, we adopt a mechanistic approach. The idea is to model color vision as a series of stages that act on the responses of the cones. Within the mechanistic approach, the central questions are: how many stages are needed, what are the properties of the mechanisms at each stage, and how are the mechanisms' outputs linked to measured performance? We focus on psychophysical (perceptual) data. Nonetheless, we are guided in many instances by physiological and anatomical considerations. For reviews of color physiology and anatomy, see, for example, Gegenfurtner and Kiper,[1] Lennie and Movshon[2], and Solomon and Lennie.[3] A useful online resource is Webvision at http://webvision.med.utah.edu/.

The distinction between color encoded at the photoreceptors and color encoded by postreceptoral mechanisms was anticipated by two theories that have dominated color vision research since the late nineteenth century. First, in the Young-Helmholtz trichromatic theory,[4,5] color vision is assumed to depend on the univariant responses of the three fundamental color mechanisms (see Chap. 10). Color vision is therefore trichromatic. Trichromacy allows us to predict which mixtures of lights *match*, but it does not address how those matches *appear*, nor the discriminability or similarity of stimuli that do not match.

Second, in Hering's[6,7] opponent colors theory, an early attempt was made to explain some of the phenomenological aspects of color appearance, and, in particular, the observation that under normal viewing conditions some combinations of colors, such as reddish-blue, reddish-yellow, and greenish-yellow, are perceived together, but others, such as reddish-green or yellowish-blue, are not. This idea is illustrated in Fig. 2. Hering proposed that color appearance arises from the action of three signed mechanisms that represent opposing sensations of red versus green, blue versus yellow, and light versus dark.[6,7] A consequence of this idea is that opposing or opponent pairs of sensations are exclusive, since they cannot both be simultaneously encoded. In this chapter, we will use the term "color-appearance mechanisms" to refer to model-constructs designed to account for the appearance of stimuli, and in particular the opponent nature of color appearance.

Early attempts to reconcile trichromacy with the opponent phenomenology of color appearance suggested that the color-appearance mechanisms reflect a postreceptoral stage (or "zone") of color processing that acts upon the outputs of the three Young-Helmholtz cone mechanisms. Modern versions of the two-stage theory explicitly incorporate the cone's characteristics as a first stage as well as

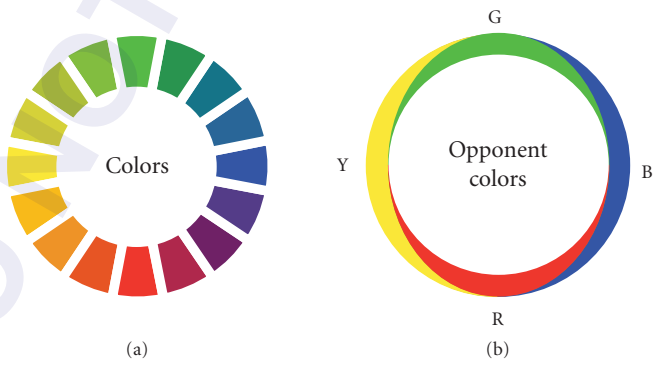

FIGURE 2 Hering's opponent-colors diagram. A diagrammatic representation of opponent-colors theory. The ring on the left (*a*) shows a range of colors changing in small steps from green at the top clockwise to blue, red, yellow, and back to green. The ring on the right (*b*) shows the hypothetical contributions of each of the color-opponent pairs [red (R) vs. green (G), and blue (B) vs. yellow (Y)] to the appearance of the corresponding colors in (*a*). In accordance with opponent-colors theory, the opposed pairs of colors are mutually exclusive. (*Redrawn from Plate 1 of Ref. 7*).

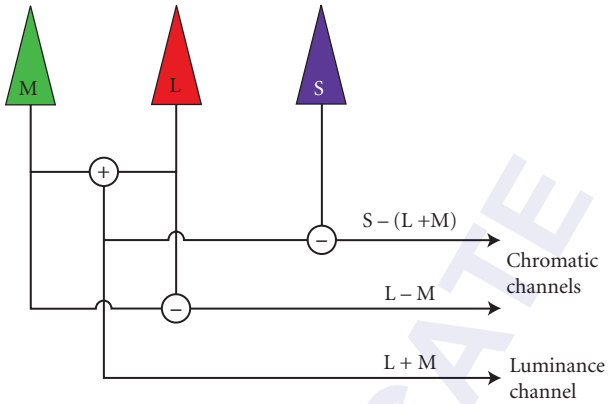

FIGURE 3 Model of the early postreceptoral stages of the visual system. The signals from the three cone types, S, M, and L, are combined to produce an achromatic or luminance channel, L+M, and two cone-opponent channels, L–M and S–(L+M). Note that there is assumed to be no S-cone input to the luminance channel. (*Based on Fig. 7.3 of Ref. 15*).

a second stage at which signals from the separate cone classes interact (e.g., Refs. 8–14). A familiar version of the two-zone model from Boynton[15] with chromatic, L–M and S–(L+M), and achromatic, L+M, postreceptoral mechanisms is shown in Fig. 3.

Interestingly, the particulars of many modern two-stage models were formulated not to account for color appearance, but rather to explain threshold measurements of the detection and discrimination of visual stimuli. As Fig. 3 indicates, the opponent mechanisms in these models take on a simple form, represented as elementary combinations of the outputs of the three cone classes. We refer to opponent mechanisms that are postulated to explain threshold data as "color-discrimination mechanisms," to distinguish them from color-appearance mechanisms postulated to explain appearance phenomena. Here we use the omnibus term color-discrimination to refer both to detection (where a stimulus is discriminated from a uniform background) and discrimination (where two stimuli, each different from a background, are discriminated from each other.)

The distinction between color-appearance and color-discrimination mechanisms is important, both conceptually and in practice. It is important conceptually because there is no a priori reason why data from the two types of experiments (appearance and threshold) need be mediated by the same stages of visual processing. Indeed, as we will see below, the theory that links measured performance to mechanism properties is quite different in the two cases. The distinction is important in practice because the mechanism properties derived from appearance and discrimination data are not currently well reconciled.

The discrepancy between color-discrimination and color-appearance mechanisms has been commented on by recent authors,[11,14,16–22] but the discrepancy is implicit in early versions of the three-stage Müller zone theories,[23,24] Judd's version of which[24] was discussed again some years later in a more modern context (see Fig. 6. of Ref. 25). It is remarkable that models with separate opponent stages for the two types of data were proposed well before the first physiological observation of cone opponency in fish[26] and primate.[27]

Figure 4 illustrates a modern version of Judd's three-stage Müller zone theory, which is described in more detail in the subsection "Three Stage Zone Models" in Sec. 11.6. The figure shows the spectral sensitivities of each of the three stages. The spectral sensitivities of Stage 1 correspond to the cone spectral sensitivities of Stockman and Sharpe,[28] those of Stage 2 to the spectral sensitivities of

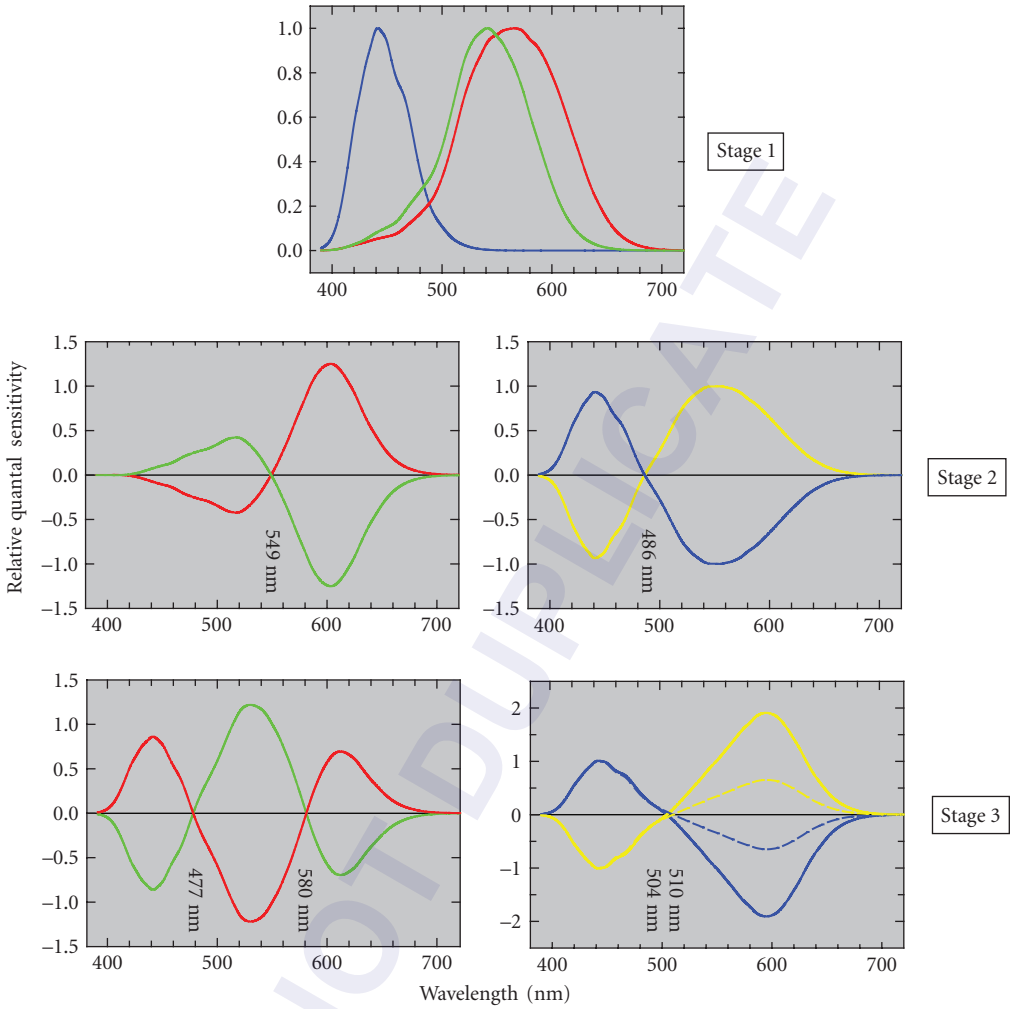

FIGURE 4 Version of the three-stage Müller zone model with updated spectral sensitivities. The panels shows the assumed spectral sensitivities of the color mechanisms at Stages 1 (upper panel), 2 (middle panels), and 3 (lower panels). *Stage 1:* L- (red line), M- (green line), and S- (blue line) cone fundamental spectral sensitivities.[28] *Stage 2:* L–M (red line), M–L (green line), S–(L+M) (blue line), and (L+M)–S (yellow line) cone-opponent mechanism spectral sensitivities. *Stage 3:* R/G (red line), G/R (green line), B/Y (blue line), Y/B (yellow line) color-opponent spectral sensitivities. Our derivation of the cone-opponent and color-opponent spectral sensitivities is described in the subsection "Three-Stage Zone Models" in Sec. 11.6. The dashed lines in the lower right panel are versions of the B/Y and Y/B color-opponent spectral sensitivities adjusted so that the Y and B spectral sensitivity poles are equal in area. The wavelengths of the zero crossings of the Stage 2 and Stage 3 mechanisms are given in the figure. The spectral sensitivities of the achromatic mechanisms have been omitted.

color-discrimination mechanisms as suggested by threshold data, and those of Stage 3 to the spectral sensitivities of color-appearance mechanisms as suggested by appearance data.

Figure 4 sets the scene for this chapter, in which we will review the theory and data that allow derivation of the properties of color-discrimination and color-appearance mechanisms, and discuss the relation between the two. According to some commentators, one of the unsolved mysteries of color vision is how best to understand the relation between mechanisms referred to as Stages 2 and 3 of Fig. 4.

Nomenclature

One unnecessary complication in the literature is that discrimination and appearance mechanisms are frequently described using the same names. Thus, the terms red-green (R/G), blue-yellow (B/Y), and luminance are often used to describe both types of mechanisms. We will attempt in this chapter to maintain a distinct nomenclature for distinct mechanisms.

It is now accepted that cones should be referred to as long-, middle-, and short-wavelength-sensitive (L-, M-, and S-), rather than red, green, and blue, because the color descriptions correspond neither to the wavelengths of peak cone sensitivity nor to the color sensations elicited by the excitation of single cones.[30] However, it is equally misleading to use color names to refer to color-discrimination mechanisms. Stimulation of just one or other side of such a mechanism does not necessarily give rise to a simple color sensation. Indeed, current models of opponent color-discrimination mechanisms have the property that modulating each in isolation around an achromatic background produces in one case a red/magenta to cyan color variation and in the other a purple to yellow/green variation.[31,32] Consequently, the perception of blue, green, and yellow, and to a lesser extent red, requires the modulation of *both* cone-opponent discrimination mechanisms (see subsection "Color Appearance and Color Opponency" in Sec. 11.5). We therefore refer to chromatic color-discrimination mechanisms according to their predominant cone inputs: L–M and S–(L+M). Although this approach has the unfortunate consequence that it neglects to indicate smaller inputs, usually from the S-cones (see subsection "Sensitivity to Different Directions of Color Space" in Sec. 11.5.), it has the advantage of simplicity and matches standard usage in much of the literature. We refer to the nonchromatic color discrimination mechanism as L+M. Note also that this nomenclature is intended to convey the identity and sign of the predominant cone inputs to each mechanism, but not the relative weights of these inputs.

In contrast, the perception of pure or "unique" red, green, yellow, and blue is, by construction of the theory, assumed to result from the responses of a single opponent color-appearance mechanism, the response of the other mechanism or mechanisms being nulled or in equilibrium (see subsection "Opponent-Colors Theory" in Sec. 11.5). We refer to opponent color-appearance mechanisms as R/G and B/Y, according to the color percepts they are assumed to generate. We refer to the nonopponent appearance mechanism as brightness.

Guiding Principles

Behavioral measurements of color vision reflect the activity of an inherently complex neural system with multiple sites of processing that operate both in series and in parallel. Moreover, these sites are essentially nonlinear. The promise of the mechanistic approach lies in two main areas. First, in terms of developing an overall characterization of postreceptoral color vision, the hope is that it will be possible to identify broad regularities in the behavior of the system that can be understood in terms of models that postulate a small number of relatively simple mechanism constructs. Second, in terms of using psychophysics to characterize the behavior of particular neural sites, and to link behavior to physiology, the hope is that specific stimulus conditions can be identified for which the properties of the site of interest dominate the measured performance. In the conceptual limit of complexity, where a mechanistic model explicitly describes the action of every neuron in a given visual pathway, these models can, in principle, predict performance. But as a practical matter, it

remains unclear the degree to which parsimonious mechanistic models derived from behavioral measurements will succeed. Given the complexity of the underlying neural system, it is apparent that the mechanistic approach is ambitious.

In this context, several points are worth bearing in mind. First, the concept of a psychophysical mechanism will have the most utility when it can be shown to have an existence that extends beyond the particular stimulus and task conditions from which it was derived. Thus, we regard a mechanism as a theoretical construct whose usefulness depends on the range of data it can explain parsimoniously. This is a broader consideration than those sometimes used to determine the value of a mechanism.[33,34] In Secs. 11.3 and 11.4, we review two broad mechanism concepts that satisfy this criterion: opponency and adaptation.

Second, while some psychophysical techniques may emphasize the contribution of particular stages of the system, it is, with the exception of color matching, a simplification to ignore the contributions of earlier and/or later stages. For example, an often made but usually implicit assumption is that the cone quantal absorption rates are transmitted directly to postreceptoral mechanisms, as if the photoreceptors had no role other than to pass on a linear copy of their inputs. An interesting future direction for mechanistic models is to account for interactions between different stages of processing more fully.

Finally, in spite of our concerns, we have written this chapter primarily from the point of view of psychophysics. We readily acknowledge that over the past 50 years, results from molecular genetics, anatomy, and physiology have helped propel many psychophysical theories from intelligent speculation to received wisdom, particularly in the cases of cone spectral sensitivities and early retinal visual processing. Physiology and anatomy have also provided important evidence about color coding at different levels of the early visual system (e.g., Refs. 35–37), crucial information that is hard to obtain psychophysically. Obversely, as the increasing complexity of the visual system at higher levels of processing begins to limit the utility of a mechanistic psychophysical approach, it also constrains how much can be understood from a knowledge of the properties of the component neurons in the processing chain, the majority of which have yet to be characterized.

Chapter Organization

The rest of this chapter is organized as follows: In the next two sections, we describe how mechanism concepts allow us to understand important features of both color discrimination and color appearance. Our treatment here is illustrative. We review a small selection of experimental data, and emphasize the logic that leads from the data to constraints on the corresponding models. In Sec. 11.3 we discuss discrimination data; in Sec. 11.4 we turn to appearance data. Two broad mechanistic concepts emerge from this initial review: those of color opponency and of adaptation. The initial review provides us with a basic model for postreceptoral color vision. Although this model is clearly oversimplified, it serves as the point of departure for much current work, and understanding it is crucial for making sense of the literature. The remainder of the chapter (Secs. 11.5 and 11.6) is devoted to a discussion of advanced issues that push the boundaries of the basic model.

11.3 BASICS OF COLOR-DISCRIMINATION MECHANISMS

What Is a Mechanism?

Given the central role of the mechanism concept in models of color vision, one might expect that this concept is clearly and precisely defined, with a good consensus about its meaning. Our experience, however, is that although there are precise definitions of what constitutes a mechanism,[33,34] these are generally specific to a particular model and that the term is often used fairly loosely. In keeping with this tradition, we will proceed to discuss mechanisms through examples without attempting a rigorous definition.

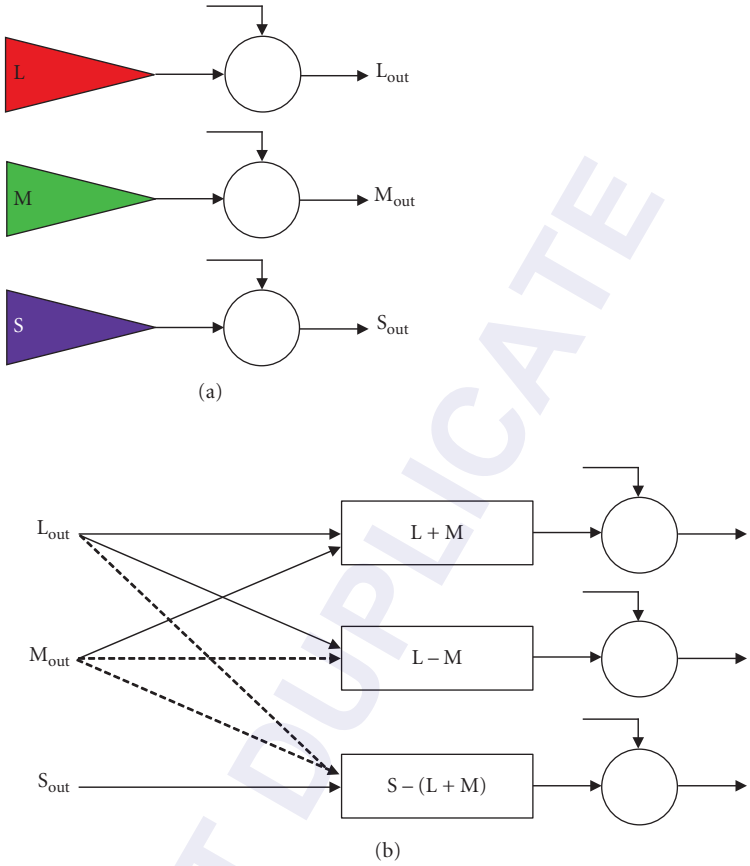

FIGURE 5 Basic mechanisms. (*a*) First-stage cone mechanisms: L, M, and S. The cone outputs are subject to some form of gain control (open circles), which can, in principle, be modified by signals from the same or from different cone mechanisms. (*b*) Second-stage color-discrimination mechanisms: L+M, L–M, and S–(L+M). The inputs to these mechanisms are the adapted cone outputs from the cone mechanisms. As with the cone mechanisms, the outputs of the second-stage mechanism are subject to some gain control, which can be modified by signals from the same or from different second-stage mechanisms. Dashed arrows indicate inhibitory outputs.

Figure 5 illustrates the broad mechanism concept. Figure 5*a* shows the L, M, and S cones. Each of these cones is a mechanism and satisfies several key properties. First, we conceive of each cone mechanism as providing a spatiotemporal representation of the retinal image, so that the mechanism output may be regarded as a spatial array that changes over time. Second, at a single location and time, the output of each cone mechanism is univariate and conveys only a single scalar quantity. This means that the output of a single cone mechanism confounds changes in the relative spectrum of the light input with the overall intensity of the spectral distribution. Third, the relation between mechanism input and output is subject to adaptation. This is indicated in the figure by the open circle along the output pathway for each cone mechanism. Often the adaptation is characterized as a gain control, or a gain control coupled with a term that subtracts steady-state input (e.g., Refs. 38 and 39).

Key to the mechanism approach is that the behavior of the mechanism can be probed experimentally with adaptation held approximately fixed. This may be accomplished, for example, by presenting brief, relatively weak, flashes on spatially uniform backgrounds. In this case, the state of adaptation is taken to be determined by the background alone; that is, it is assumed that the weak flashes do not measurably perturb the state of adaptation and thus that the state of adaptation is independent of the flash.

The arrows pointing into each circle in Fig. 5 indicate that the signals that control the state of adaptation can be quite general, and need to be specified as part of the model. In the classical (von Kries) mechanism concept, however, these signals are assumed to arise entirely within the array of signals from the same cone mechanism.[33] For example, the gain (or adaptation) applied to the L-cone signals at a location would be taken to be determined entirely by the array of L-cone responses, and be independent of the responses of M and S cones. Adaptation that acts on the output of the cones is referred to as "first-site" adaptation.

Figure 5*b* shows a simple model of three second-stage color-discrimination mechanisms with the same basic wiring diagram as Fig. 3. These mechanisms have a similar structure to the cone mechanisms, in the sense that they are assumed to provide a spatial array of univariate responses. In addition, as with the cone mechanisms, the second-stage mechanisms can adapt. An important difference between these second-stage mechanisms and the cone mechanisms is the nature of their input. Where the cone mechanisms transduce light into a neural signal, the second-stage mechanisms take the adapted cone responses as their input. As shown in the Fig. 5, each of the postreceptoral mechanisms can be thought of as computing a weighted combination of cone signals. The three mechanisms are labeled by the manner in which they combine cone inputs. The first mechanism, (L+M), which is often referred to as the luminance mechanism, adds inputs from the L and M cones. The second mechanism, (L–M), takes a difference between L and M cone signals. And the third mechanism, S–(L+M), takes a difference between S-cone signals and summed L- and M-cone signals.

Although not necessary as part of the mechanism definition, making the input to the mechanism be a linear function of the output of the preceding stage simplifies the model, and enables it to make stronger predictions; whether the cone combinations are actually linear is an empirical question. Adaptation that acts on the outputs of the second-stage postreceptoral mechanisms is usually referred to as "second-site" adaptation or desensitization.

The cone mechanisms used in color vision models represent the action of a well-defined neural processing stage (the cone photoreceptors). The connection between postreceptoral mechanisms and neurons is not as tight. Although the cone inputs to different classes of retinal ganglion cells are similar to those used in models, these models often do not incorporate important features of real ganglion cells, such as their spatial receptive field structure (but see subsection "Multiplexing Chromatic and Achromatic Signals" in Sec. 11.5), cell-to-cell variability in cone inputs, and the fact that ganglion cells come in distinct ON and OFF varieties that each partially rectify their output (but see "Unipolar vs. Bipolar Chromatic Mechanisms" in Sec. 11.6).

Psychophysical Test and Field Methods

Broadly speaking, two principal psychophysical techniques have been used to investigate the properties of color-discrimination mechanisms.[40–42] In the "test" (or "target") sensitivity method, the observer's sensitivity for detecting or discriminating a target is measured as a function of some target parameter, such as its wavelength, size, or temporal frequency. As noted above, implicit in the use of this method is the assumption that the presentation of the target does not substantially alter the properties or sensitivity of the detection mechanism, so that targets are usually presented against a background and kept near visual threshold.

In the "field" sensitivity method, the observer's sensitivity for detecting or discriminating a target is measured as a function of some change in the adaptive state of the mechanism. Field methods complement test methods by explicitly probing how contextual signals control adaptation. On the assumption that the control of adaptation occurs solely through signals within the mechanism mediating detection, the spectral properties of that mechanism can be investigated by, for example,

superimposing the target on a steady adapting field and changing the adapting field chromaticity and/or radiance, by habituating the observer to backgrounds temporally modulated in chromaticity and/or luminance just prior to the target presentation, or by superimposing chromatic and/or luminance noise on the target.

Both test and field methods have obvious limitations. In the test method, it is difficult to ensure that a target is detected by a single mechanism when the target parameters are varied, with the result that multiple mechanisms typically mediate most sets of test sensitivity measurements. As we discuss below, assigning different portions of chromatic detection contours to different mechanisms is problematic (see subsection "Sensitivity to Different Directions of Color Space" in Sec. 11.5). In the field method, it is often easier to ensure that a target is detected by a single mechanism. However, the assumption that adaptation is controlled entirely by signals from within the mechanism mediating detection is a strong one, and interpretation of results becomes much more complicated under conditions where this assumption is not secure. More generally, without an explicit and accurate model about the properties of the mechanism, both test and field sensitivity data may be uninterpretable.

How Test Measurements Imply Opponency

In the next three sections, we introduce color-discrimination mechanisms. These are characterized by opponent recombination of cone signals at a second site (as shown in Fig. 5*b*), by adaptation in cone specific pathways (first-site adaptation, Fig. 5*a*), and by adaptation after the opponent recombination (second-site adaptation, Fig. 5*b*).

We begin with evidence from test sensitivity measurements that some sort of opponent recombination occurs. In the canonical test sensitivity experiment, a small test stimulus is presented against a uniform background. We denote the L-, M-, and S-cone excitations of the background by L_b, M_b, and S_b. If we fix the background, the test stimulus may be characterized by how much the cone excitations it produces deviate from the background. Denote these deviations by ΔL, ΔM, and ΔS, so that the overall cone excitations of the test are given by $L = L_b + \Delta L$, $M = M_b + \Delta M$, and $S = S_b + \Delta S$. Note that the deviations ΔL, ΔM, and ΔS may be positive or negative.

For any background, we can consider a parametric family of test stimuli whose L-, M-, and S-cone deviations are in the same proportion. That is, we can define a test *color direction* by a triplet of deviations ΔL_d, ΔM_d, and ΔS_d, normalized so that $\sqrt{\Delta L_d{}^2 + \Delta M_d{}^2 + \Delta S_d{}^2} = 1$. Test stimuli that share the same color direction have the form $\Delta L = c\Delta L_d$, $\Delta M = c\Delta M_d$, and $\Delta S = c\Delta S_d$. We refer to the constant c as the *intensity* of the test stimulus along the given color direction. Figure 6*a* illustrates the test color direction and intensity concept for two vectors in the ΔL, ΔM plane.

If the background and color direction of a test stimulus are held fixed, an experimenter can vary the test intensity and determine the psychophysical threshold for detection. This is the lowest intensity at which the observer can just see the test, and its value can be found experimentally using a variety of procedures.[43] The experiment can then be repeated for different choices of color direction, and the threshold intensity can be determined for each one.

Figure 6*b* plots one way in which the data from a threshold experiment might come out. For simplicity, we assume that ΔS_d was set to zero, and show data only in the ΔL, ΔM plane. Each point in the plot represents the results of a threshold measurement for one color direction. The set of threshold points together trace out a "detection contour" (or "threshold contour"), since each point on the contour leads to an equal level of detection performance (the "threshold"). The two points that lie directly on the ΔL axis represent threshold for increments and decrements that drive only the L cones and leave the M cones silent; that is, these targets produce zero change in the M cones. Similarly two points that lie directly on the ΔM axis represent increments and decrements that produce only changes in the M cones. The other points on the contour show thresholds obtained when L- and M-cone signals are covaried in various ratios.

Understanding how threshold contours inform us about color-discrimination mechanisms is a key idea in the theory we present in this chapter. It is useful to begin by asking how the contour would come out if the visual system had a single color-discrimination mechanism consisting of, say,

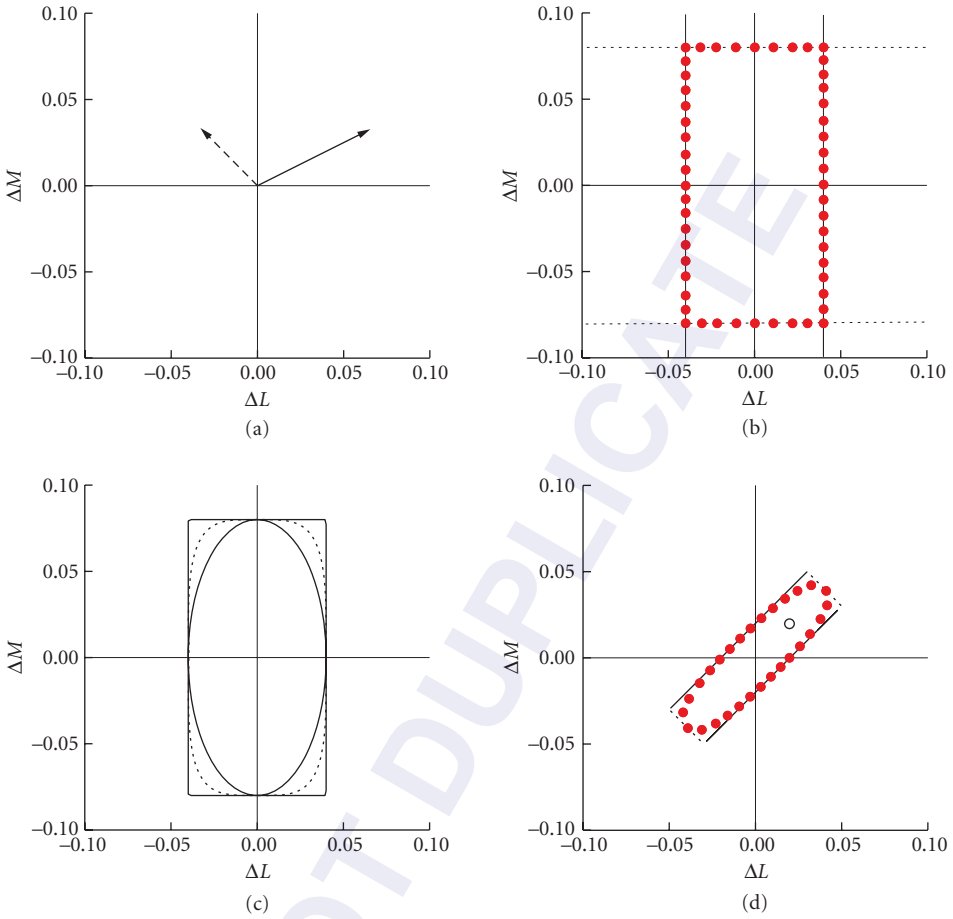

FIGURE 6 Basic thresholds. (*a*) Two vectors plotted in the ΔL, ΔM plane that represent two lights of different color directions and different intensities. (*b*) Incremental and decremental thresholds determined by an L-cone mechanism (vertical black lines) or by an M-cone mechanism (black, horizontal dotted lines). The points define the contour expected if threshold is determined independently and with no interactions between L- and M-cone detection mechanisms. (*c*) The joint detection contours when the L- and M-cone detection mechanisms show different degrees of summation. The inner, middle, and outer contours are for summation exponents of $k = 2$, 4, and 1000, respectively. (*d*) Idealized detection contours (red solid points) for thresholds determined by chromatic L–M (solid lines at 45°) and achromatic L+M (dotted lines at –45°) mechanisms. The single open circle shows the threshold expected in the $\Delta L_d = \Delta M_d$ direction if the threshold was determined by the cone mechanisms (i.e., by the thresholds along the axes $\Delta L_d = 0$ and $\Delta M_d = 0$).

only the L cones. In this case, only the ΔL component of the test modulation would affect performance, and the threshold contour would consist of two lines, both parallel to the ΔM axis. One line would represent threshold for incremental tests with a positive ΔL value, while the other would represent threshold for decremental tests with a negative ΔL value. This hypothetical detection contour is shown as two solid vertical lines in Fig. 6*b*. If there were no other mechanisms, the threshold contour would simply continue along the extensions of the solid vertical lines. The contour would not be closed, because modulations along the M-cone isolating direction produce ΔL values of zero and thus are invisible to the L-cone mechanism.

We can also consider a visual system with only an M-cone discrimination mechanism. By reasoning analogous to that used for the L-cone case above, the threshold contour for this system would consist of the two horizontal dotted lines also shown in the figure.

Finally, we can consider a system with independent L- and M-cone mechanisms and a threshold determined when either its ΔL or ΔM component reached the threshold for the corresponding mechanism. This would lead to a closed rectangular detection contour formed by the intersecting segments of the solid vertical and dotted horizontal lines shown in Fig. 6*b*. The threshold data plotted as solid red circles in the panel correspond to this simple model.

When signals from both L- and M-cone mechanisms mediate detection, the measured detection contour would be expected not to reach the corners of the rectangular contour shown in Fig. 6*b*. This is because even if the L- and M-cone mechanisms are completely independent, detection is necessarily probabilistic, and in probabilistic terms the likelihood that L, M, or both L and M together will signal the test is greater than the likelihood of either cone mechanism doing so alone even when the mechanisms are independent, especially when L and M are both near threshold. This "probability summation" will reduce thresholds in the corners where L and M signals are of similar detectability, rounding them. A number of simple models of how mechanisms outputs might combine in the presence of neural noise predict such rounding, with the exact shape of the predicted contour varying across models.

A convenient parametric form for a broad class of summation models is that test threshold is reached when the quantity $\Delta = \sqrt[k]{\sum_{i=1}^{N} |\Delta_i|^k}$ reaches some criterion value. In this expression, N is the number of mechanism whose outputs are being combined, Δ_i is the output of the ith mechanism, and the exponent k determines the form of summation. When $k = 2$, the quantity Δ represents the Euclidean vector length of the mechanism outputs. When $k \rightarrow \infty$, Δ represents the output of the mechanism whose output is greatest.

Figure 6*c* shows expected threshold contours for the output of the L and M mechanisms for three values of k. The outer rectangular contour (solid lines) shows the contour for $k = 1000$. Here there is effectively no summation, and the contour has the rectangular shape shown in Fig. 6*b*. The inner contour (solid line) shows the case for $k = 2$. Here the contour is an ellipse. The middle contour (dotted line) shows the case for $k = 4$. Determining the value of k that best fits experimental data is a topic of current interest, as the answer turns out to have important implications for how to reason from sensitivity contours to mechanism properties (see subsection "Sensitivity to Different Directions of Color Space" in Sec. 11.5). Here, however, the key point is that we expect actual experimental data to show more rounded threshold contours than the one depicted in Fig. 6*b*. Under conditions where sensitivity is determined by the output of the L- and M-cone mechanisms, the expected shape of the threshold contour is a closed form whose major axes are aligned with the ΔL and ΔM axes.

Figure 6*d* shows an idealized representation of how the data actually come out when thresholds are measured against a neutral background (see also Fig. 20). Actual data deviate clearly from the predictions shown in Fig. 6*c*, which were based on the assumption that the color-discrimination mechanisms are the responses of the L and M cones. Instead, the data lie near an elongated ellipsoid whose axes are rotated intermediate to the ΔL and ΔM axes. The deviations from the predictions of the Fig. 6*c* are large and robust. In particular, note the location of the open circle in the figure. This circle shows an upper bound on threshold in the $\Delta L_d = \Delta M_d$ color direction; if the color-discrimination mechanisms were the L and M cones and they operated without summation, then threshold would be given by the open circle. If there was also summation between L- and M-cone mechanisms, then threshold would lie between the open circle and the origin, with the exact location depending on the degree of summation. Thresholds in this direction vastly exceed the bound shown by the open circle. This observation demonstrates unequivocally that the outputs of different cone mechanisms must be postreceptorally recombined.

A natural interpretation of the threshold contour shown in Fig. 6*d* is indicated by the rotated rectangle shown on the plot. The parallel solid lines represent the threshold contour that would be observed if detection were mediated by a single mechanism that computed as its output the difference between the L- and M-cone excitations to the test, and if threshold depended on $|\Delta L - \Delta M|$ reaching some criterion threshold level. Similarly, the dotted lines represent the threshold contours of a mechanism that sums the L- and M-cone excitations of the test. The idealized threshold data

shown is thus consistent with the first two color-discrimination mechanisms illustrated in Fig. 5*b*, with some amount of summation between mechanism outputs accounting for the quasi-ellipsoidal shape of the overall contour.

Logic similar to that shown, applied to data where ΔS is varied, leads us to postulate a third color-discrimination mechanism whose output is given by a weighted opposition of ΔS on the one hand and ΔL and ΔM on the other. Figure 21, later, shows detection contours in the equiluminant plane partially determined by the S–(L+M) mechanism.

Although it is straightforward to predict detection contours if the spectral properties of the underlying detection mechanisms and the interactions between them are known, it is harder, as we shall see below, to infer unequivocally the exact mechanism properties (e.g., the exact weights on signals from each cone class) from the contours.

First-Site Adaptation

Weber's law and contrast coding The measurements described in the previous section assess sensitivity under conditions where the state of adaptation was held fixed. We now turn to how input signals from the cones depend on the conditioning or adapting background. The key idea here is that the cone excitations are converted to a contrast representation. Here we use L cones as an example and take the L-cone contrast of the test, C_L, to be given by $C_L = \Delta L/L_b$, where ΔL is (as above) the difference between the L-cone excitations produced by the test and background, and L_b is the L-cone excitation produced by the background. Similar expressions apply for the M and S cones.

The conversion of raw cone excitations (photoisomerizations) to a contrast code implies an important adaptive function. The range of cone excitation rates encountered in the environment can be greater than 10^6. This range greatly exceeds the limitations imposed by the individual neurons in the visual pathway, many of which have dynamic ranges of no more than about 10^2 from the level of noise—their spontaneous firing rate in the absence of light stimulation—to their response ceiling.[44,45] If there were no adaptation, the cone visual response would often convey no useful information, either because it was too small to rise above the noise at the low end of the stimulus range or because it was saturated at the maximum response level and thus unable to signal changes. For adaptation to protect the cone-mediated visual system from overload as the light level increases, the primary mechanisms of sensitivity regulation are likely to be early in the visual pathways, most likely in the cone photoreceptors themselves.[46,48] Indeed, the molecular mechanisms of adaptation acting within the photoreceptor are now fairly well understood.[49–52]

The idea that signals leaving the cones are effectively converted to a contrast code makes a specific prediction about how thresholds should depend on the background. Suppose we consider test stimuli that only stimulate the L cones, and that we manipulate the L-cone component of the background, L_b. Because of the cone-specific adaptation, increasing L_b will produce a proportional decrease in the contrast signal fed to the postreceptoral detection mechanisms. On the assumption that the noise limiting discrimination behavior remains constant across the change of background (see "Sites of Limiting Noise" in Sec. 11.3), this decrease means that the differential signal, ΔL, required to bring a test stimulus to threshold will increase in proportion to L_b. This sort of behavior is often described as obedience to Weber's law; predictions of Weber's law models are shown by the blue line in Fig. 7*a*. Figure 7*a* shows a log-log plot of increment threshold ΔL against background component L_b. The predicted thresholds increase with a slope of unity on the log-log plot.

A feature of contrast-coding predictions that is clearly not realistic is that the threshold ΔL should decrease toward zero in complete darkness. A generalized and more realistic form of contrast coding is given by $C_L = \Delta L/(L_b + L_o)$, where L_o is a constant. The dashed line in Fig. 7*a* shows a prediction of this form, which has the feature that thresholds approach a constant nonzero value as L_b decreases below L_o. The value of L_o may be thought of as the hypothetical excitation level—sometimes called a "dark light"—produced internally within the visual system in the absence of light that limits performance at low background levels.

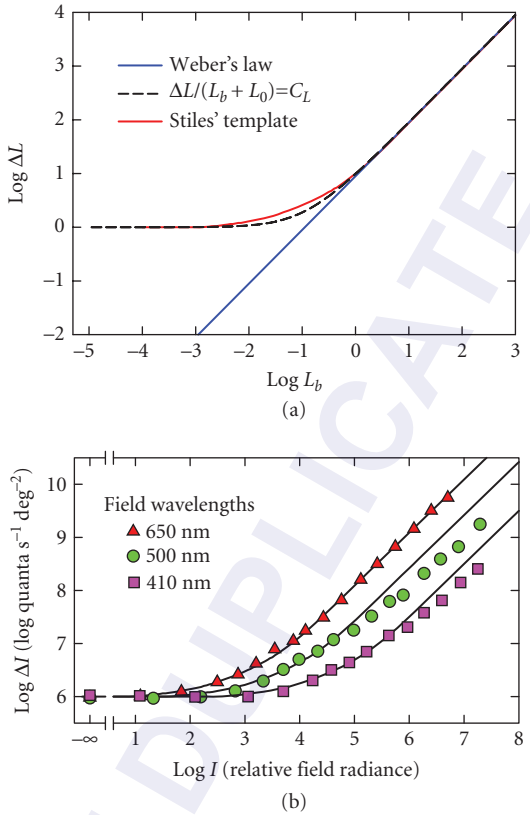

FIGURE 7 Weber's law and increment thresholds. (*a*) Predictions of three first-site adaptation models for test lights detected by an L-cone mechanism as a function of background intensity. (*b*) Increment threshold data attributed to the L-cone mechanism (π_5, see subsection "Stiles' π Mechanisms" in Sec. 11.5) replotted from Fig. 2 (Observer: EP) of Sigel and Pugh[54] obtained using a 200-ms duration, 667-nm target presented on background fields of 650 nm (red triangles), 500 nm (green circles), and 410 nm (purple squares). The solid lines aligned with each data set at low background radiances are Stiles' standard template [Table 1(7.4.3) of Ref. 53]. The horizontal position of the data is arbitrary.

Stiles' template shape [see Table 1(7.4.3) of Ref. 53], shown as the red line in Fig. 7*a*, has a form similar to that predicted by generalized contrast coding (dashed line). This template was derived to account for increment threshold data obtained under a variety of conditions (see subsections "Sensitivity to Spectral Lights" and "Stiles' π Mechanisms" in Sec. 11.5). Figure 7*b* shows increment threshold data measured by Sigel and Pugh,[54] for three different background wavelengths under conditions where the L-cone mechanism is thought to dominate detection. These data fall approximately along Stiles' template, although deviations are clear at high background radiances for two of the three spectral backgrounds shown. The deviations are consistent with contributions of postreceptoral mechanisms to detection performance.[54,55] Data like these speak to the difficulties of distinguishing the contributions of different mechanisms from even the simplest data. Stiles, for example, accounted for the same sort of deviations by proposing an additional cone mechanism.[33]

The signals reaching the second site Although increment threshold data suggest a roughly Weber-type gain control, they do not by themselves determine whether the signal transmitted to the second site is of the contrast form $\Delta L/(L_b + L_o)$, as we have written above, or of the simpler form $L/(L_b + L_o)$, where to recap $L = \Delta L + L_b$. We cannot, in other words, determine from detection thresholds alone whether the adapted signal generated by the background is partially or wholly subtracted from the signal transmitted to the postreceptoral mechanisms.

To understand the ambiguity, define the gain g as $g = 1/(L_b + L_o)$. In a gain control only model (with no background subtraction), the signal transmitted from the L cones in response to the background plus test would be $L' = gL$, where L represents the combined cone excitations to the background plus test. Similarly, under this model, the gain adjusted response to the background alone would be $L_b' = gL_b$. If we assume that threshold requires the difference in response to background plus test on the one hand and background alone on the other to reach some criterion level, then the threshold will depend on $(L' - L_b') = g(L - L_b) = (L - L_b)/(L_b + L_o) = \Delta L/(L_b + L_o) = C$, which is the contrast form. Thus, predictions about detection threshold are independent of whether a constant is subtracted from the signals leaving the cones.

To deduce the need for a subtractive term (i.e., to differentiate contrast-like coding from gain control alone) from threshold data requires discrimination experiments, in which threshold is measured not just for detecting a test against the background, but also for detecting the test (often referred to as a probe in this context) presented against an incremental flash, both of which are presented against a steady background. In these experiments, the threshold intensity for the probe depends on the flash intensity, and changes in this dependence with the background may be used to infer the nature of the adaptive processes. We will not review these experiments or their analysis here; other papers provide detailed descriptions (e.g., Refs. 56–59). The conclusion drawn by these authors is that to account for steady-state adaptation a subtractive term is required in addition to multiplicative gain control.

Second-Site Adaptation

The final piece of the basic model of color-discrimination mechanisms is a second stage of adaptation that modifies the output of the second-stage mechanisms (Fig. 5*b*). First-site adaptation is postulated to remove the effects of steady, uniform backgrounds by converting signals to a contrast representation; second-site adaptation is postulated to be driven by contrast signals in the background (see subsection "Field Sensitivities" in Sec. 11.5). Before proceeding, however, we should add two caveats. First, even with uniform, steady fields, first-site adaptation is usually incomplete. Were it complete, detection thresholds expressed as contrasts would be independent of background chromaticity, which they clearly are not (see Fig. 8 and subsection "Field Sensitivities" in Sec. 11.5). Second, first-site adaptation is not instantaneous. If it were, then in the extreme case of complete first-site adaptation being local to the photoreceptor as well as being instantaneous, neither local nor global changes in contrast would be transmitted to the second-site. In the less extreme case of complete, instantaneous adaptation being more spatially extended, then global changes in contrast would not be transmitted—with the result that large uniform field or Ganzfeld flicker should be invisible, which is not the case.[60] To understand the basic logic that connects threshold experiments to second-site contrast adaptation or desensitization, we first consider the effects of steady backgrounds and then the effects of habituation.

Second-site desensitization by steady fields Because first-site adaptation is incomplete, steady chromatic backgrounds can desensitize second-site mechanisms. The effect of this type of desensitization on detection contours is illustrated in Fig. 8. The colored circles in Fig. 8*a* show segments of detection contours in the $\Delta L/L$, $\Delta M/M$ plane of cone contrast space for two background chromaticities. The contours have a slope of 1, which is consistent with detection by a chromatic L–M mechanism with equal and opposite L- and M-cone contrast weights. If the background chromaticity is changed and adaptation at the first site follows Weber's law, then the contours plotted in cone contrast units should not change. What happens in practice, when for example, a field is changed

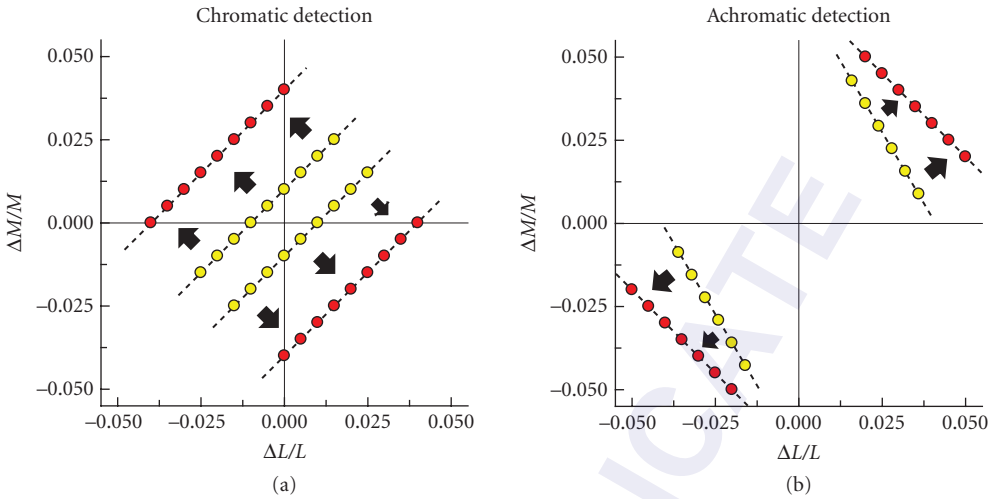

FIGURE 8 Changes in contrast threshold caused by second-site adaptation to steady fields. (*a*) Hypothetical contours for detection mediated by the L–M mechanism plotted in cone contrast space before (yellow circles) and after (red circles) second-site desensitization (caused by, e.g., a change in background chromaticity from yellow to red). The L–M mechanism is assumed to have equal and opposite L-cone contrast weights at its input, and this equality is assumed to be unaffected by the desensitization. (*b*) Hypothetical detection contours for detection by the L+M mechanism before (yellow circles) and after (red circles) a change in background chromaticity from yellow to red. Initially, the L+M mechanism is assumed to have an L-cone contrast weight 1.7 times greater than the M-cone contrast weight. Changing the field to red suppresses the L-cone contrast weight, causing a rotation of the contour, as indicated by the arrows and the red circles.[63]

in chromaticity from spectral yellow to red, is that the contours move outward,[61] as indicated by the arrows and the red circles in Fig. 8*a*. (Actual data of this type are shown in Fig. 28.)

The constant slope of the L–M detection contours with changing background chromaticity is consistent with Weber's law operating at the first site. The loss of sensitivity in excess of Weber's law is most naturally interpreted as a second-site desensitization that depends on background chromaticity and acts on the joint L–M signals. Experimental evidence also supports the idea that first-site adaptation is in the Weber regime under conditions where supra-Weber desensitization is observed.[62]

The effect of second-site chromatic adaptation on the L+M luminance mechanism is different. The yellow circles show partial detection contours with a slope of –1.7, which is consistent with detection by an achromatic L+M mechanism with an L-cone contrast weight 1.7 times greater than the M-cone contrast weight (this choice is arbitrary, but, in general, the L-cone weight is found to be greater than the M-cone weight, see subsection "Luminance" in Sec. 11.5). If the background chromaticity is again changed from spectral yellow to red, the detection contours rotate, as indicated by the arrows and the yellow circles.[63] In this case, the rotation is due to a suppression by the long-wavelength field of the L-cone contribution to luminance detection relative to the M-cone contribution.[63,64] Given first-site adaptation that follows Weber's law independently in the L- and the M-cones, first-site adaptation should affect L- and M-cone inputs equally in all postreceptoral mechanisms. The fact that the L–M measurements show an equal effect on the L- and M-cone contrast inputs, whereas the L+M measurements show a differential effect, is most easily explained by positing adaptation effects at a second-site. The idea that the cone inputs to luminance and chromatic mechanisms undergo adaptation that is specific to each type of mechanism was framed by Ahn and MacLeod.[65] The same idea is also explicit in the earlier work of Stromeyer, Cole, and Kronauer.[61,63] The effects of steady fields on the L+M mechanism are discussed further in subsection "Achromatic Direction and Chromatic Adaptation" in Sec. 11.5.

Second-site habituation The effects of steady backgrounds at the second site are comparatively small because the background signals are attenuated by adaptation at the first site. Second-site effects can be enhanced by temporally modulating the chromaticity or luminance of the background as in an habituation experiment. Figure 9*a* shows an idealized threshold contour for detection thresholds

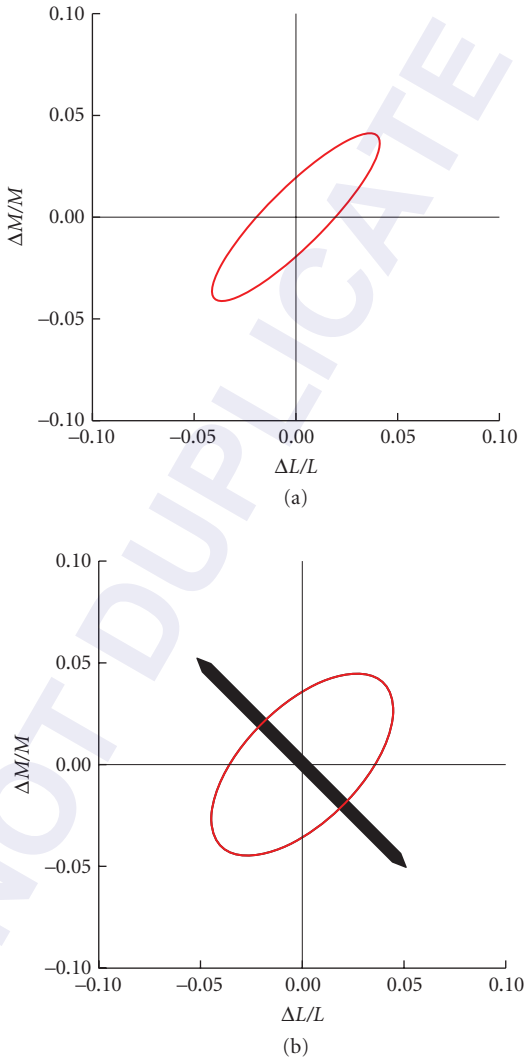

FIGURE 9 Habituation predictions. (*a*) Hypothetical threshold contour under conditions where detection is mediated by second-site mechanisms. The contour is plotted in a cone contrast representation, and shows the contour in the $\Delta L/L$, $\Delta M/M$ contrast plane. The S-cone contrast is taken to be zero, so that thresholds are mediated by the L+M and L–M mechanisms. The contour was computed on the assumption that the gain of the L–M mechanism was four times that of the L+M mechanism, using a summation model with an exponent of 2. (*b*) Corresponding contour after habituation has reduced the gain of the L–M mechanism by a factor of 2 and left the L+M mechanism gain unchanged. The habituating direction is indicated by the black arrow. The result is the threshold contour becomes more elongated along the negative diagonal in the cone contrast plot.

in the $\Delta L/L$, $\Delta M/M$ plane obtained against a uniform background. This is the same type of data shown in Fig. 6*d*, but plotted on cone contrast axes. Detection is assumed to be mediated by L–M and L+M mechanisms with L–M being four times more sensitive to cone contrast than L+M. The elliptical contour reflects a summation exponent of 2, which we assume here for didactic purposes. If the same experiment is repeated after the subject has been habituated to contrast modulated in the L–M direction (as indicated by the black arrow Fig. 9*b*), the basic second-site model predicts that thresholds will be elevated for test stimuli that are modulated in that direction. On the other hand, for test stimuli modulated in the L+M direction, thresholds should be unaffected. Finally, for stimuli in intermediate directions, thresholds will be elevated to the extent that the L–M opponent mechanism contributes to detection. Figure 9*b* shows the predicted threshold contour, computed on the assumption that the L–M habituation cuts the gain of the L–M mechanism in half while leaving that of the L+M mechanism unaffected.

The data shown in Fig. 9 may be replotted by taking the difference of the post- and prehabituation threshold stimuli, for each color direction. Figure 10*a* shows an habituation effect plot of this sort. In this plot, the distance from the origin to the contour in each direction shows the threshold increase produced by the L–M habituation for test stimuli modulated in that color direction. The radius is large in the L–M test direction, and drops to zero for the L+M test direction.

Figure 10*b* and *c* show idealized habituation effect plots for habituation in the L+M direction and to an intermediate color direction, as shown by the black arrows. What the figure makes clear is that the effect of habituation on detection threshold should have a characteristic signature for each habituation direction.

Figure 11 replots the parts of Fig. 10 on axes that represent not cone contrast but rather stimulus directions that isolate the L+M and L–M discrimination mechanisms. These axes have been normalized so that a unit step along each axis direction corresponds to a threshold stimulus (without any habituation) for the corresponding mechanism. We discuss in more detail in subsection "Color Data Representations" in Sec. 11.5 the advantages and disadvantages of using an opponent representation of this type, but introduce it here to allow direct comparison of the idealized predictions of the basic model to the data reported by Krauskopf, Williams, and Heeley.[14] These authors made measurements of how habituation in different color directions affected threshold contours. Their data for observer DRW, as shown in Fig. 29 in subsection "Habituation or Contrast Adaptation Experiments" in Sec. 11.5, agree qualitatively with the predictions shown in Fig. 11, and provide fairly direct evidence to support habituation at a second site. As with other aspects of the basic model, we return below to discuss more subtle features of the data that deviate from its predictions.

Sites of Limiting Noise

Before proceeding to color-appearance mechanisms, we pause to discuss a fundamental theoretical issue. This is the question of how the properties of a mechanism at an early stage of the visual processing chain could directly mediate observed detection thresholds, given that the signals from such a site must pass through many additional stages of processing before a perceptual decision is made. This question parallels one often asked in the context of colorimetry, namely, how it is that the very first stage of light absorption can mediate the overall behavior observed in color matching (see Chap. 10). Both questions have the same underlying answer, namely, that information lost at an early stage of visual processing cannot be restored at subsequent stages. The difference is the nature of the information loss. In the case of color matching, the information loss occurs because of the univariant nature of phototransduction. In the case of color thresholds, the information loss occurs because of noise in the responses of visual mechanisms. These sources of noise, relative to the signal strength, set the limits on visual detection and discrimination.

The link between thresholds and noise is well developed under the rubric of the theory of signal detection.[43,66–68] Here we introduce the basic ideas. Consider a test stimulus of intensity c in the $\Delta L_d = 1$, $\Delta M_d = 0$ color direction. Only the L-cone mechanism responds to this stimulus, so for this initial example we can restrict attention to the L-cone response. If we present this same stimulus over many trials, the response of the L-cone mechanism will vary from trial-to-trial. This is indicated

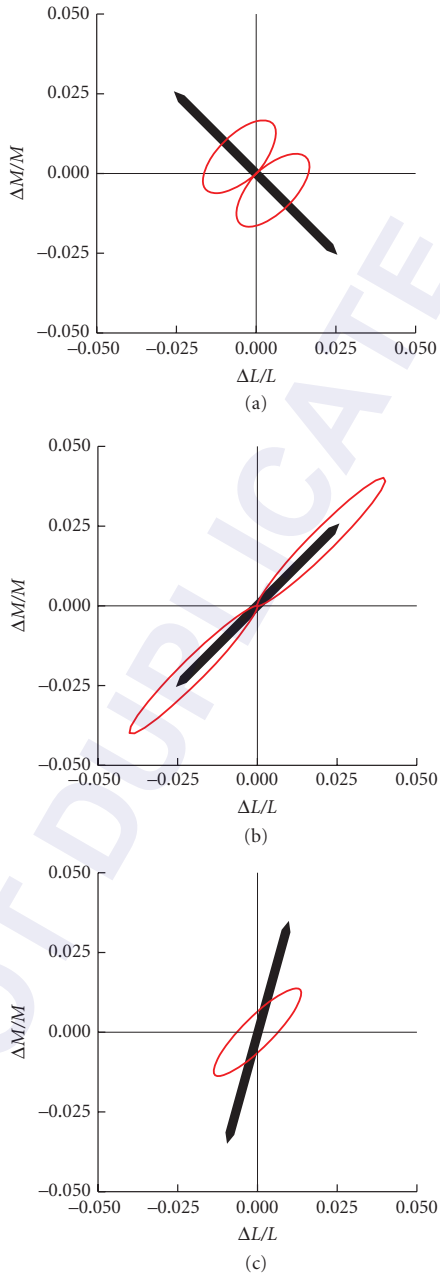

FIGURE 10 Changes in contrast threshold caused by habituation. It is conventional to report the results of a habituation experiment using a plot that shows the change in threshold caused by habituation. (*a*) Depiction of the hypothetical data shown in Fig. 9 in this fashion. For each direction in the cone contrast plot, the distance between the origin and the contour shows the increase in threshold caused by habituation for tests in that color direction. For the example shown, there is no change in threshold in the L+M contrast direction, and the contour returns to the origin for this direction. (*b*) Changes in threshold that would be produced by a habituating stimulus that decreases the gain of the L+M mechanism by a factor of 2 and leaves the gain of the L–M mechanism unchanged. (*c*) Changes in threshold that would be produced by a habituating stimulus that decreases the gain of both mechanisms equally by a factor of 1.33. The habituating directions are indicated by the black arrows.

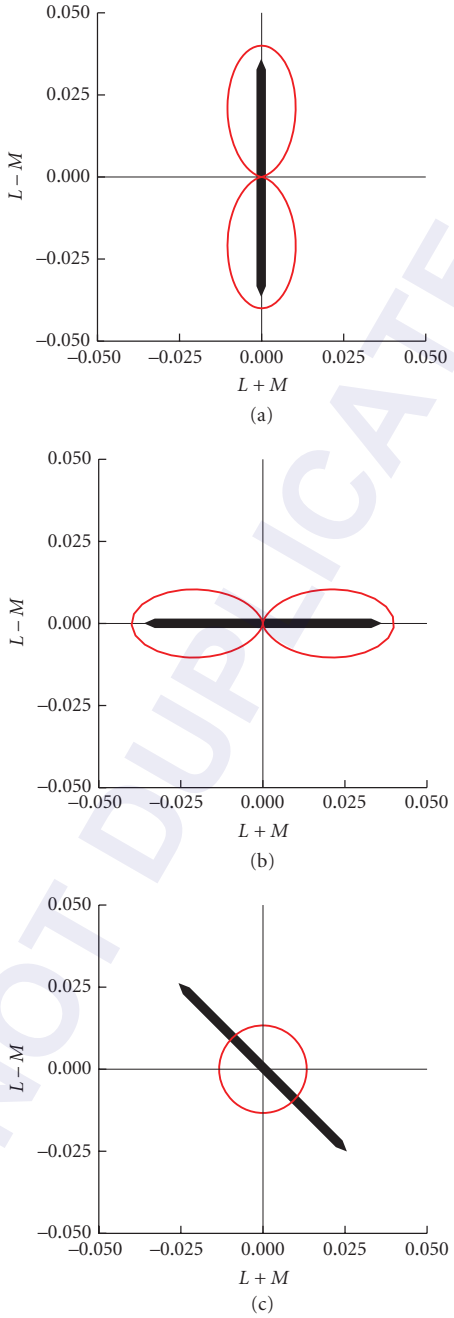

FIGURE 11 Changes in L+M and L–M sensitivity caused by habituation. Panels (*a*) to (*c*) replot the threshold changes shown in the corresponding panels of Fig. 10. Rather than showing the effects in cone-contrast space, here the results are shown in a space where the axes correspond to the L+M and L–M color directions. In addition, the units of each of these rotated axes have been chosen so that detection threshold for tests along the axis is 1. This representation highlights the canonical pattern of results expected when habituation along each axis reduces sensitivity for only the corresponding mechanism, and where habituation along the 45° direction reduces sensitivity equally for the two mechanisms. The habituating directions are indicated by the black arrows.

by the probability distribution (solid red line) in Fig. 12*a*. Although the mean response here is 0.06, sometimes the response is larger and sometimes smaller. Similarly, the mechanism response to the background alone will also fluctuate (probability distribution shown as dotted blue line).

It can be shown[43,69] that optimal performance in a detection experiment occurs if the observer sets an appropriate criterion level and reports "background alone" if the response falls below this criterion

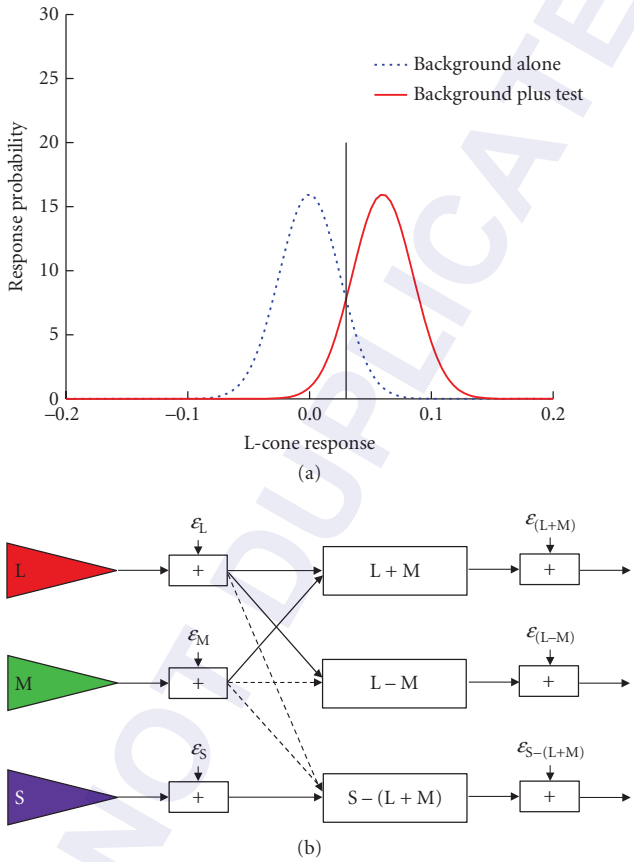

FIGURE 12 Thresholds and noise. (*a*) The theory of signal detection's account of how noise determines thresholds, for a single mechanism. When the background alone is presented, the mechanism's responses vary somewhat from trial-to-trial because of additive response noise. The response variation is illustrated by the probability distribution centered on zero and shown by the dotted blue line. When the background and test are presented together, the average response increases but there is still trial-to-trial variability. This is illustrated by the probability distribution shown by the solid red line. When the two types of trial are presented equally often and the magnitudes of the costs associated with correct and incorrect responses are equal, it can be shown that the observer maximizes percent correct by reporting that the test was present whenever the mechanism response exceeds the criterion value shown in the figure by the vertical line. Different costs and prior probabilities simply move the location of this criterion. Even when this optimal criterion is used, there will still be some incorrect trials, those on which the response to background alone exceeds the criterion and those on which the response to background and test falls below the criterion. Threshold is reached when the test is intense enough that the observer is correct on a sufficient percentage of trials. How much the average response to background plus test must exceed that to background alone is determined by the magnitude of the noise. (*b*) The two-stage model of color-discrimination mechanisms, drawn in a manner that emphasizes that noise (ε) may be added both to the output of the first-site mechanisms and to the output of the second-site mechanisms. A full signal detection theoretic model of detection takes into account the response gain at each stage (which determines the separation of the average response to background and to background plus test) and the magnitude of noise at each stage. It also replaces the simple criterion shown in (*a*) with an optimal multivariate classifier stage.[70]

and "background plus test" otherwise. The plot shows the location of the optimal criterion (vertical line) for the special case when background-plus-test and background-alone events are presented equally often and when the benefits associated with both sorts of correct response (hits and correct rejections) have the same magnitude as the costs associated with both sorts of incorrect response (false alarms and misses). Note that even the optimal strategy will not lead to perfect performance unless the intensity of the test is large enough that the two distributions become completely separated. In this sense, the magnitude of response noise (which determines the widths of the distributions), relative to the effect of the test on the mean mechanism response, is what limits performance. More generally, the theory of signal detection allows computation of the probability of the observer performing correctly in the detection experiment as a function of the noise magnitude and test intensity.

With this idea in mind, we can turn to understanding how threshold measurements can reveal properties of early mechanisms, despite later processing by subsequent mechanisms. Figure 12*b* shows the basic model of color-discrimination mechanisms from Fig. 5, but without the adaptation stages shown explicitly. What is shown here, however, is that noise (ε) is added to the response of each mechanism. At the first stage, the cone responses are noisy. The noisy cone responses are then transformed at the second-site, and more noise is added. Thus the responses of the second-site mechanisms are subject both to noise that propagates from the first site, in addition to noise injected directly at the second site. For simplicity, we consider the noise added to each mechanism at each site to be independent; note that even with this assumption the noise at the opponent site will be correlated across the three color-discrimination mechanisms as a result of the way the first-site noise is transformed.

This model allows us to compute the expected shape of the threshold contours for a visual system that makes optimal use of the output of the second-site mechanisms. The computation is more involved than the simple unidimensional signal detection example illustrated in Fig. 12*a*, because optimal performance makes use of the output of all three second-site mechanisms and must take into account the correlated nature of the noise at this stage. Nonetheless, the ideas underlying the computation are the same as in the simple example, and the theory that allows the computation is well worked out.[70] We can thus ask how the expected discrimination contours, computed on the basis of the output at the second site, vary with the properties of the noise added at each stage.

Figure 13 shows threshold contours computed for three choices of noise. Figure 13*a* shows a case where the standard deviation of the noise injected at the first site is 5 times larger than that at the second site. The derived contour has the properties expected of detection by cone mechanisms, with the major axes of the contour aligned with the L- and M-cone contrast axes (see Fig. 6*b* and *c*). Figure 13*c* on the other hand, shows the opposite situation where the noise injected at the second site is 5 times larger than that at the first site. Simply changing the noise magnitude has major effects on the observed contour; the shape of the contour shown in Fig. 13*c* is the expected result for detection mediated by second-site mechanisms (see Fig. 6*d*). Finally, Fig. 13*b* shows an intermediate case, with equal noise injected at the two sites. Here the result is intermediate between the two other cases.

This example lets us draw a number of important conclusions. First, the result in Fig. 13*a* shows explicitly how, in a two-stage visual system, threshold contours can reveal properties of the first-stage mechanism. The necessary condition is that the noise added before the transformation to the second stage be large enough to dominate the overall performance. When a situation like this holds, we say that the first stage represents the *site of limiting noise*. As long as subsequent processing does not add significant additional noise, it is the site of limiting noise whose properties will be reflected by threshold measurements. Although Fig. 13*a* shows an example where the cones were the site of limiting noise, the fact that detection contours often have the shape shown in Fig. 13*c* suggests that often the second site limits performance, and that subsequent processing at sites past the second site do not add significant additional noise. As an aside, we note that much of threshold psychophysics is concerned with arranging auxiliary stimulus manipulations that manipulate mechanism properties so as to move the site of limiting noise from one stage of processing to another, or to shift it across mechanisms within a stage (e.g., to change the relative contribution of L+M and L–M mechanisms to performance), with the goal of enabling psychophysical probing of individual mechanisms at different stages of processing. Generally, the stimulus manipulations are thought to

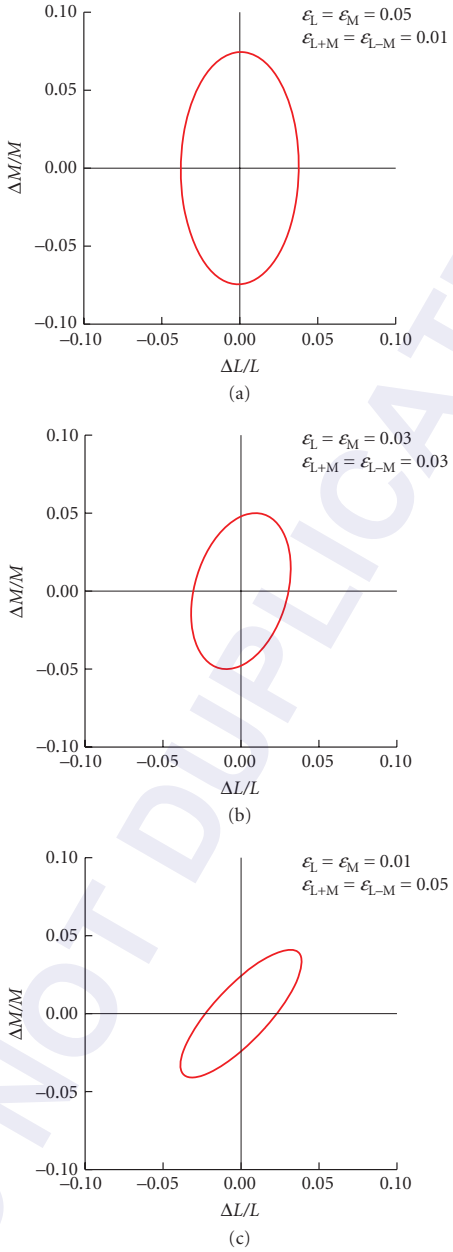

FIGURE 13 Threshold predictions from signal detection theoretical model. The figure shows threshold contours predicted using the model shown in Fig. 12*b*, for various choices of noise amplitude. In all cases, only the L+M and L–M mechanisms were considered. The gain on L-cone contrast was set at 2, while the gain on M-cone contrast was set at 1. The gain of the L+M mechanism was set at 1, while that of the L–M mechanism was set at 4. The noise added at each site was assumed to be Gaussian, and for each test color direction and choice of noise magnitude, the test intensity that led to optimal classification performance of 75 percent was determined. (*a*) Resulting contour when the noise at the first site is five times that of the noise at the second site. In this case, the detection contour has the shape expected for the first-site mechanisms, because little additional information is lost at the second-site mechanisms. (*c*) Contour when the magnitude of the noise at the second site is five times that of the first. In this case, the properties of the second-site mechanisms dominate measured performance. (*b*) Contour when the noise at the two sites is of comparable magnitude, and here the result is itself intermediate between that expected from the properties of first- and second-site mechanisms.

act by changing the gains applied to mechanism outputs. This changes the effect of the stimulus relative to the noise, rather than the noise magnitude itself.

A second important point can be drawn from Fig. 13*b*. It is not unreasonable to think that noise at different stages of visual processing will be of a comparable magnitude, and Fig. 13*b* shows that in such cases observed performance will represent a mixture of effects that arise from mechanisms properties at different stages. This is a more formal development of a point we stressed in the introduction, namely, that in spite of our attempt to attribute performance under any given experimental conditions primarily to the action of a small number of mechanisms, this is likely to be a highly simplified account. Eventually, it seems likely that models that explicitly account for the interactions between mechanisms at different stages will be needed. The theory underlying the production of Fig. 13, which explicitly accounts for the role of noise at each stage, would be one interesting approach toward such models.

Finally, note that the development of Fig. 13 is in the tradition of ideal-observer models, where performance is derived from an explicit model of a set of stages of visual processing, followed by the assumption that further processing is optimal.[71–74] Although the assumption of optimal processing is unlikely to be exactly correct, ideal-observer models are useful because they can provide theoretical clarity and because cases where the data deviate from the predictions of such a model highlight phenomena that require further exploration and understanding. For example, the rounded shape of threshold contours, which we initially described using a descriptive vector length account, emerges naturally from the ideal-observer analysis. Indeed, for the ideal observer the predicted shape of the threshold contours is essentially ellipsoidal (summation exponent of 2). This prediction is another reason why careful assessment of the observed shape of threshold contours is of theoretical interest.

In subsection "Noise-Masking Experiments" in Sec. 11.5, we consider the effects of adding external noise to the system.

11.4 BASICS OF COLOR-APPEARANCE MECHANISMS

We now turn to consider how a different class of observations can inform us about mechanisms. These are measurements that assess not the observer's ability to detect or discriminate stimuli, but rather measurements of how stimuli look to observers. More specifically, we will consider measurements of color appearance.

As with threshold measurements, color-appearance measurements may be divided into two classes, those that assess the appearance of test stimuli as some function of those stimuli (test measurements) and those that assess how the color appearance of a test stimulus depends on the context in which it is viewed (field measurements). We review how both sorts of measurements can inform a model of color-appearance mechanisms. This treatment parallels our development for color-discrimination mechanisms in order to highlight similarities and differences between models that account for the two types of data.

Appearance Test Measurements and Opponency

As described in the introduction, one of the earliest suggestions that the output of the cone mechanisms were recombined at a second site came from Hering's observation that certain pairs of color sensations (i.e., red and green, blue and yellow) are mutually exclusive. Hurvich and Jameson elaborated this observation into a psychophysical procedure known as hue cancellation (see subsection "Spectral Properties of Color-Opponent Mechanisms" in Sec. 11.5). Hue cancellation can be performed separately for the red/green opponent pair and the blue/yellow opponent pair.

In the red/green hue-cancellation experiment, the observer is presented with a test stimulus, which is usually monochromatic, and asked to judge whether its appearance is reddish or greenish. The results may be used to derive the properties of an opponent mechanism, under the "linking

hypothesis" that when the mechanism's response is of one sign the stimulus appears reddish, while when it is of the opposite sign the stimulus appears greenish. That is, color-appearance measurements are used to derive mechanism properties on the assumption that the mechanism output provides an explicit representation of the sensation experienced by the observer.

To understand the hue-cancellation procedure in more detail, imagine that the experimenter picks a fixed monochromatic reference light that in isolation appears greenish to the observer. The experimenter then chooses a series of monochromatic test lights of unit intensity, each of which appears reddish in isolation. The observer judges mixtures of each test light and the reference light. If the mixture appears reddish, the intensity of the greenish reference light is increased. If the mixture appears greenish, the intensity of the greenish reference light is decreased. Repeating this procedure allows the experimental determination of a balance or equilibrium point for the red-green mechanism, where the result of the mixture appears neither reddish nor greenish. (Depending on the test stimulus, the balanced mixture will appear either as yellow or blue or achromatic.) Colored stimuli that appear neither reddish nor greenish are referred to as "unique yellow" or "unique blue." The intensity of the green reference light in the balanced mixture may be taken as a measure of the amount of redness in the test stimulus, in the same way that the amount of weight added to one side of a balance scale indexes the weight on the other side when the balance is even (see Krantz's "force table" analogy.[75])

A similar procedure may be used to determine the amount of greenness in test stimuli that have a greenish component, by choosing an adjustable reference stimulus that appears reddish. Moreover, the units of redness and greenness may be equated by balancing the two reference stimuli against each other. Figure 14*a* and *b* show prototypical results of such measurements for spectral test lights, as well as results for an analogous procedure used to determine the amount of blueness and yellowness in the same set of spectral test lights. Such data are referred to as "chromatic valence" data.

Krantz[75,76] showed that if the amount of redness, greenness, blueness, and yellowness in any test light is represented by the output of two opponent color-appearance mechanisms, and if these mechanisms combine cone signals linearly, then the spectral hue-valence functions measured in the cancellation experiment must be a linear transformation of the cone spectral sensitivities. Although the linearity assumption is at best an approximation (see subsection "Linearity of Color-Opponent Mechanisms" in Sec. 11.5), Krantz's theorem allows derivation of the cone inputs from the data shown in Fig. 14. Such fits are shown in Fig. 14*a* and *b*, and lead to the basic wiring diagram shown in Fig. 14*c*. This shows two opponent color-appearance mechanisms, labeled R/G and B/Y. The cone inputs to these mechanisms are similar to those for the opponent color-discrimination mechanisms, with one striking difference: the S cones make a strong R contribution to the R/G appearance mechanism. By contrast, the S-cone input to the L–M discrimination mechanism is small at most. Another difference, which we address later, is that the M-cone contribution to B/Y in some models is of the same sign as the S-cone contribution (see "Three-Stage Zone Models" in Sec. 11.6).

Although the hue-cancellation procedure may be used to derive properties of opponent-appearance mechanisms, it is less suited to deriving the properties of a third mechanism that signals the brightness of colored stimuli. This aspect of color appearance may be assessed using heterochromatic brightness matching, where subjects are asked to equate the brightness of two stimuli, or scaling methods, where observers are asked to directly rate how bright test stimuli appear (see subsection "Luminance and Brightness" in Sec. 11.5).

Appearance Field Measurements and First-Site Adaptation

It is also possible to make field measurements using appearance judgments. A common method is known as asymmetric matching, which is a simple extension of the basic color-matching experiment (see Chap. 10). In the basic color-matching experiment, the observer adjusts a match stimulus to have the same appearance as a test stimulus when both are seen side-by-side in the same context. The asymmetric matching experiment adds one additional variable, namely that the test and match are each seen in separate contexts. As illustrated in Fig. 1, when an identical test patch is presented

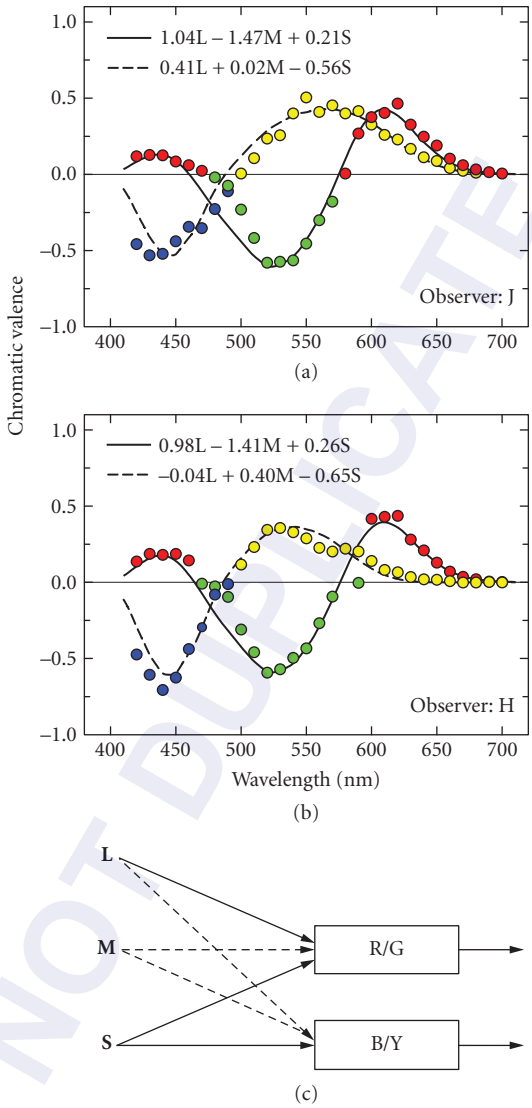

FIGURE 14 Chromatic valence data and wiring. (*a*) and (*b*) Valence data (colored symbols) replotted from Figs. 4 and 5 of Jameson and Huryich[279] for observers "J" (*a*) and "H" (*b*) fitted with linear combinations of the Stockman and Sharpe[28] cone fundamentals (solid and dashed curves). The best-fitting cone weights are noted in the key. (*c*) Wiring suggested by this (*a*) and subsequent color valence data. In the diagram, the sign of the M-cone contribution to B/Y is shown as negative (see subsection "Spectral Properties of Color-Opponent Mechanisms" in Sec. 11.5).

against two different surrounds, it can appear quite different. In the asymmetric matching experiment, the observer compares test patches seen in two different contexts (e.g., against different adapting backgrounds) and adjusts one of them until it matches the other in appearance. The cone coordinates of the match test patches typically differ, with the shift being a measure of the effect of changing from one context to the other.

Figure 15*a* plots asymmetric matching data from an experiment of this sort reported by MacAdam.[77] The filled circles show the L- and S-cone coordinates of a set of test stimuli, seen in a region of the retina adapted to a background with the chromaticity of a typical daylight. The open circles show a subset of the corresponding asymmetric matches seen in a region of the retina adapted to a typical tungsten illuminant. The change in adapting background produces a change in test appearance, which observers have compensated for in their adjustments.

Asymmetric matching data can be used to test models of adaptation. For example, one can ask whether simple gain control together with subtractive adaptation applied to the cone signals can account for the matches. Let (L_1, M_1, S_1), (L_2,M_2,S_2), . . ., (L_N,M_N,S_N) represent the L-, M-, and S-cone coordinates of N test stimuli seen in one context. Similarly, let (L'_1,M'_1,S'_1), (L'_2,M'_2,S'_2), . . ., (L'_N,M'_N,S'_N) represent the cone coordinates of the matches set in the other context. If the data can be accounted for by cone-specific gain control together with subtractive adaptation, then we should be able to find gains g_L, g_M, g_S, and subtractive terms L_0, M_0, S_0 such that $L'_i \approx g_L\, L_i - L_0$, $M'_i \approx g_M\, M_i - M_0$, and $S'_i \approx g_S\, S_i - S_0$ for all of the N matches. The asterisks plotted in Fig. 15*a* show predictions of this gain control model in the L,-S cone plane. Figure 15*b*, *c*, and *d* show predicted shifts against the measured shifts for all three cone classes. The model captures the broad trends in the data, although it misses some of the detail. The first-site adaptation captured by this model is often taken to be the same adaptation revealed by sensitivity experiments.[78]

Appearance Field Measurements and Second-Site Adaptation

Asymmetric matching may also be used to investigate the effect of contrast adaptation on color appearance. In a series of experiments, Webster and Mollon[32,79] investigated the effect of contrast adaptation (or habituation) on the color appearance of suprathreshold lights (see also Refs. 80 and 81). Observers habituated to a background field that was sinusoidally modulated at 1 Hz along various color directions. The habituating field was interleaved with a stimulus presented at the same location. The observer's task was to adjust the chromaticity and luminance of a match stimulus so that its appearance matched that of the test field. Webster and Mollon found that habituation affected the appearance of the test stimulus.

The motivation behind these experiments was to test whether or not the changes in color appearance caused by contrast adaptation were consistent with the type of second-site adaptation that characterizes sensitivity experiments, namely independent adaptation of three cardinal mechanisms with cone inputs: L–M, L+M, and S–(L+M). The prediction for this case is that the appearance effects should always be greatest along the color axis corresponding to the mechanism most adapted by the habituating stimulus, and least along the axis corresponding to the mechanism least adapted by the stimulus—and this pattern should be found whatever the chromatic axis of the habituating stimulus. Thus the *relative* changes in chromaticity and/or luminance caused by habituation should be roughly elliptical with axes aligned with the mechanism axes.

The results showed that the sensitivity changes did not consistently align with the axes of the cardinal mechanisms. Instead, the largest selective sensitivity losses in the equiluminant plane, for two out of three subjects, aligned with the adapting axis, while the smallest losses aligned with an axis approximately 90° away. Comparable results were found when the habituating and test stimuli varied in color and luminance in either the plane including the L−M and L+M+S axes or the plane including the S and L+M+S axes. Thus, contrast adaptation produces changes in color appearance that are, in general, selective for the habituating axis rather than selective for the purported underlying mechanism axes. Nevertheless, greater selectivity was found for habituation along the three cardinal axes, which suggests their importance. See Ref. 32 for further details.

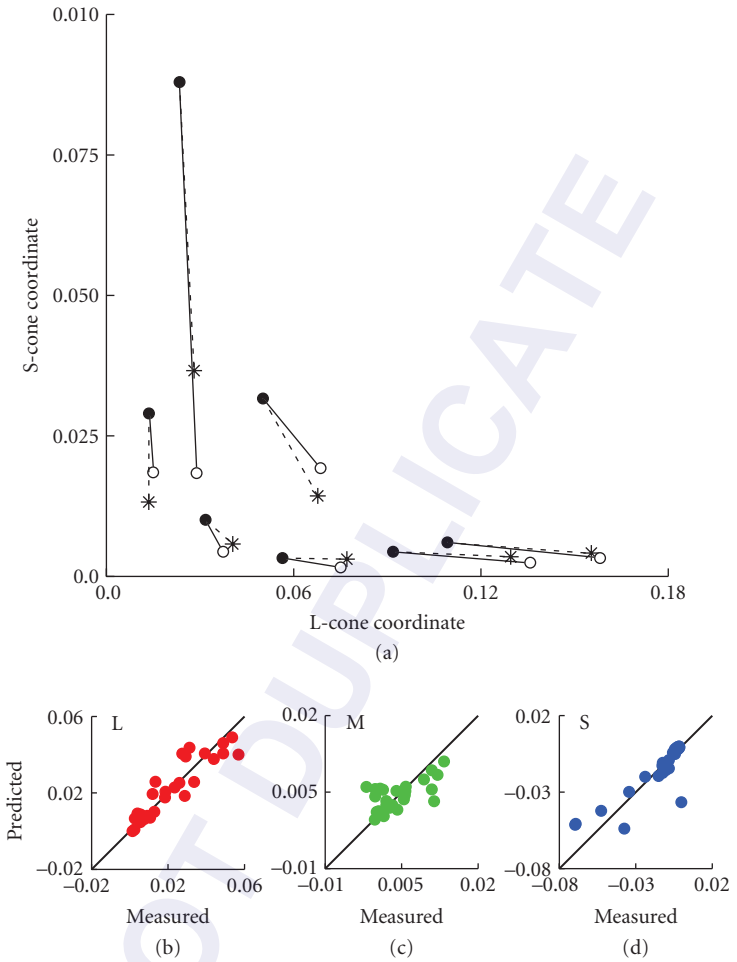

FIGURE 15 Analysis of asymmetric matching data. (*a*) Subset of the data from Observer DLM reported by MacAdam.[77] The closed circles show L- and S-cone coordinates of tests viewed on part of the retina adapted to a background with the chromaticity of daylight. The connected open circles show the asymmetric matches to these tests, when the matching stimulus was viewed on part of the retina adapted to the chromaticity of a tungsten illuminant. The star symbols show the predictions of a model that supposes first-site gain control and subtractive adaptation, operating separately within each cone mechanism. (*b*), (*c*), and (*d*) Model predictions for the full set of 29 matches set by Observer DLM. Each panel shows data for one cone class. The *x* axis shows the measured difference between the test and match, and represents the size of the asymmetric matching effect. The *y* axis shows the corresponding predicted difference. If the model were perfect, all of the data would lie along the positive diagonals. The model captures the broad trend of the data, but misses in detail.

Webster and Mollon[32] conclude that the changes in color appearance following habituation are inconsistent with models of color vision that assume adaptation in just three independent postreceptoral channels. Given, however, that the properties of the color-appearance mechanisms as revealed by test methods differ from those of color-discrimination mechanisms, this result is hardly surprising. Also note that comparisons between sensitivity measurements made for test stimuli near detection threshold and appearance measurements made for suprathreshold tests are complicated by the presence of response nonlinearities at various stages of processing. See Refs. 78 and 82 for discussion.

11.5 DETAILS AND LIMITS OF THE BASIC MODEL

Sections 11.3 and 11.4 introduce what we will refer to as a "basic model" of color-discrimination and color-appearance mechanisms. There is general agreement that the components incorporated in this model are correct in broad outline. These are (1) first-site, cone specific, adaptation roughly in accord with Weber's law for signals of low temporal frequency, (2) a recombination of cone signals that accounts for opponent and nonopponent postreceptoral second-site signals, (3) second-site desensitization and habituation, and (4) the necessity for distinct mechanistic accounts of discrimination and appearance.

In the earlier sections, we highlighted example data that strongly suggest each feature of the basic model. Not surprisingly, those data represent a small subset of the available experimental evidence brought to bear on the nature of postreceptoral color vision. In this section we provide a more detailed review, with the goal of highlighting both data accounted for by the basic model, as well as data that expose the model's limitations. Current research in the mechanistic tradition is aimed at understanding how we should elaborate the basic model to account parsimoniously for a wider range of phenomena, and at the end of this chapter we outline approaches being taken toward this end.

Sections "Test Sensitivities" through "Color Appearance and Color Opponency" follow the same basic organization as the introductory sections. We consider discrimination and appearance data separately, and distinguish between test and field methods. We begin, however, with a discussion of color data representations.

Color Data Representations

Over the past 50 years, color vision research has been driven in part by the available technology. Conventional optical systems with spectral lights and mechanical shutters largely restricted the volume of color space that could be easily investigated to the 1/8 volume containing positive, incremental cone modulations. When such data are obtained as a function of the wavelength of monochromatic stimuli, a natural stimulus representation is to plot the results as a function of wavelength (e.g., Fig. 14*a* and *b*). This representation, however, does not take advantage of our understanding of the first stage of color processing, transduction of light by the cone photoreceptors. Moreover, with the availability of color monitors and other three-primary devices, stimuli are now routinely generated as a combination of primaries, which makes increments, decrements, and mixtures readily available for experimentation. Spectral plots are not appropriate for such stimuli, which instead are represented within some tristimulus space (see Chap. 10).

Our estimates of the human cone spectral sensitivities have become increasingly secure over the past 30 years (see Chap. 10). This allows stimulus representations that explicitly represent the stimulus in terms of the L-, M-, and S-cone excitations and which therefore connect data quite directly to the first-stage color mechanisms. Such representations are called "cone-excitation spaces," and an example of this sort of representation is provided in Fig. 7 of Chap. 10.

An extension of cone-excitation space is one in which the cone excitations are converted to increments and decrements of each cone type relative to a background. Thus, the three axes are the changes in cone excitations: $\pm\Delta L$, $\pm\Delta M$, and $\pm\Delta S$. We introduced such spaces in Fig. 6; they are useful when

the stimulus is most naturally conceived as a modulation relative to a background, and where the properties of the background per se are of less interest. We will use the shorthand "incremental cone spaces" to refer to this type of representation, although clearly they allow expression of both increments and decrements.

Closely related to incremental cone spaces are "cone contrast spaces," in which the incremental/decremental changes in cone excitations produced by the target are divided by the cone excitations produced by the background.[61,83] Here, the three axes are dimensionless cone contrasts: $\Delta L/L_b$, $\Delta M/M_b$, and $\Delta S/S_b$. If Weber's law holds independently for each cone type then $\Delta L/L_b$, $\Delta M/M_b$, and $\Delta S/S_b$ all remain constant. Thus a particular advantage of this space is that it factors out the gross effects of first-site cone-specific adaptation, which tends to follow Weber's law at higher intensities (see subsection "First-Site Adaptation" in Sec. 11.3). Plots in cone contrast space help to emphasize desensitization that occurs after the receptors, and, to the extent that Weber's law holds, provide an explicit representation of the inputs to postreceptoral mechanisms. (We introduced a cone contrast representation in Fig. 8 exactly for this reason.)

At lower adaptation levels, when adaptation falls short of Weber's law (see Fig. 7) or under conditions where Weber's law does not hold (such as at high spatial and temporal frequencies; see, e.g., Ref. 84), cone contrast space is less useful. However, for targets of low temporal and spatial frequencies, Weber's law has been found to hold for chromatic detection down to low photopic levels.[62]

A final widely used color space is known as the "Derrington-Krauskopf-Lennie" (DKL) space[36,85,86] in which the coordinates represent the purported responses of the three second-site color-discrimination mechanism, L+M, L–M, and S–(L+M). In this context, modulation directions that change the response of one of these mechanisms while leaving the response of the other two fixed are referred to as "cardinal directions."[14] The DKL representation was introduced in Fig. 11 and is further illustrated in Fig. 16. See Ref. 87 for further discussion of color spaces and considerations of when each is most appropriately used.

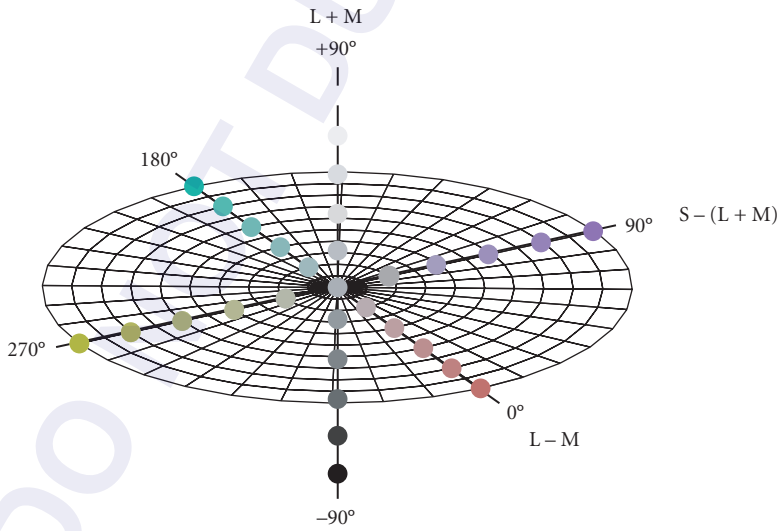

FIGURE 16 Derrington-Krauskopf-Lennie (DKL) color space. The grid corresponds to the equiluminant plane, which includes the L–M (0°–180°) and S–(L+M) (90°–270°) cardinal mechanisms axes. The vertical axis is the achromatic L+M axis (–90° – +90°). The colors along each axis are approximate representations of the appearances of lights modulated along each cardinal axis from an achromatic gray at the center. Notice that the unique hues do not appear. The axes are labeled according to the mechanisms that are assumed to be uniquely excited by modulations along each cardinal axis. (*Figure provided by Caterina Ripamonti.*)

Although the conceptual ideas underlying the various color spaces discussed here are clear enough, confusion often arises when one tries to use one color space to represent constructs from another. The confusion arises because there are two distinct ways to interpret the axes of a three-dimensional color space. The first is in terms of the responses of three specified mechanisms, while the second is in terms of how the stimulus is decomposed in terms of the modulation directions that isolate the three mechanisms. To understand why these are different, note that to compute the response of a particular mechanism, one only needs to know its properties (e.g., that it is an L–M mechanism). But, in contrast, the stimulus direction that isolates that same mechanism is the one that silences the responses of the other two mechanisms. The isolating stimulus direction depends not on the properties of the mechanism being isolated but on those of the other two. For this reason, it is important to distinguish between the *mechanism direction*, which is the stimulus direction that elicits the maximum positive response of a given mechanism per unit intensity, and the *isolating direction* for the same mechanism, which produces no response in the other two mechanisms. For the triplet of mechanisms L+M, L–M, and S–(L+M), the mechanism and isolating directions align (by definition) in DKL space, but this property does not hold when these directions are plotted in the antecedent incremental cone space or cone contrast space. Note that in some descriptions of DKL space, the axes are defined in terms of the cone modulations that isolate mechanisms rather than in terms of the mechanism responses. These conflicting definitions of DKL space have led to a good deal of confusion. See Chap. 10 and Refs. 87–89 for further discussion of transformations between color spaces and the relation between mechanism sensitivities, mechanism directions, and isolating directions.

Caveats Crucial for the use of any color space based on the cone mechanisms either for generating visual stimuli or for interpreting the resulting data is that the underlying cone spectral sensitivities are correct. Our estimates of these are now secure enough for many applications, but there are uncertainties that may matter for some applications, particularly at short wavelengths. These are compounded by individual differences (see Chap. 10), as well as issues with some of the sets of color-matching functions used to derive particular estimates of cone spectral sensitivities (again see Chap. 10, and also Ref. 90 for further discussion).

Such concerns are magnified in the use of postreceptoral spaces like the DKL space, because as well as the cone spectral sensitivities needing to be correct, the rules by which they are combined to produce the spectral sensitivities of the postreceptoral mechanisms must also be correct. For example, to silence the L+M luminance mechanism it is necessary to specify exactly the relative weights of the M and L cones to this mechanism. However, these weights are uncertain. As discussed in subsection "Luminance" in Sec. 11.5, the M- and L-cone weights show large individual differences. Furthermore, the assumption typically used in practice, when constructing the DKL space, is that luminance is a weighted sum of M and L cones and that the S cones therefore do not contribute to luminance. This may not always be the case.[91–94] Luminous efficiency also varies with chromatic adaptation, the spatial and temporal properties of the stimulus, and the experimental task used to define luminous efficiency. Lastly, the standard 1924 CIE $V(\lambda)$ luminous efficiency function, which determines candelas/m^2, and has been used by several groups to define the spectral sensitivity of the luminance mechanism, seriously underestimates luminous efficiency at shorter wavelengths (see Ref. 90).

One final note of caution is that it is useful to keep in mind that independently representing and manipulating the responses of mechanisms at a particular stage of visual processing only makes sense if there are three or fewer mechanisms. If there are more than three photopic mechanisms at the second stage of color processing (see also subsection "Low-Level and Higher-Order Color-Discrimination Mechanisms" in Sec. 11.6), independently manipulating all of them is not possible because of the inherent three-dimensionality of the first stage.

These caveats are not meant to discourage entirely the use of physiologically motivated color spaces for data representation; on the contrary we believe such representations offer important advantages if used judiciously. It is crucial, however, to bear in mind that such spaces usually assume particular theories of processing, and that interpreting data represented within them should be done in the context of a clear understanding of the limitations of the corresponding theories.

Test Sensitivities

The most direct method of studying the chromatic properties of color mechanisms is the test method. Variations of this method have been tailored to investigate the properties of different visual mechanisms, including cone, chromatic, and achromatic (or luminance) mechanisms.

Sensitivity to Spectral Lights Perhaps the most influential chromatic detection data have been the two-color threshold data of Stiles,[41,42,95–98] so called because the threshold for detecting a target or test field of one wavelength is measured on a larger adapting or background field usually of a second wavelength (or mixture of wavelengths). These data were collected within the context of an explicit model of color mechanisms, referred to as "π-mechanisms," and how they adapt. Enoch[99] provides a concise review of Stiles' work.

An important limitation of Stiles' model is that it did not allow for opponency: the π-mechanisms had all-positive spectral sensitivities and interactions between them were required to be summative. In some instances, the deviations caused by opponency were accommodated in Stiles' model by the postulation of new π-mechanisms, such as π_5' (see Refs. 54 and 55). As data in the two-color tradition accumulated, this limitation led to the demise of the π-mechanism framework and the development of the basic model we introduced in Sec. 11.3. Nonetheless, any correct model must be consistent with the experimental data provided by the two-color threshold technique, and we review some key aspects in the context of current thinking.

Two-color threshold test spectral sensitivity measurements obtained on steady backgrounds as a function of target wavelength have characteristic peaks and troughs that depend on the background wavelength (see Fig. 1 of Ref. 98). These undulations were interpreted as the envelope of the spectral sensitivities of the underlying cone mechanisms (or "π-mechanisms," see Fig. 23), but crucially they are now known also to reflect opponent interactions between mechanisms.[100]

The shape of test spectral sensitivity functions depend not only on background wavelength but also on the type of target used in the detection task. Detection by second-site opponent color-discrimination mechanisms is generally favored by targets comprised mainly of low temporal and spatial frequency components, whereas detection by achromatic mechanisms, which sum cone signals, is favored by targets with higher temporal and spatial frequency components.[83,101,102] Stiles typically used a flashed target of 1° in visual diameter and 200 ms in duration, which favors detection by chromatic mechanisms. When Stiles' two-color threshold experiments are carried out using brief, 10-ms duration targets, the results are more consistent with detection being mediated by achromatic mechanisms.[103]

Detection by chromatically opponent mechanisms is most evident in test spectral sensitivity functions measured using targets of low temporal and/or spatial frequency. Measured on neutral fields, chromatic detection is characterized by peaks in the spectral sensitivity curves at approximately 440, 530, and 610 nm that are broader than the underlying cone spectral sensitivity functions and separated by pronounced notches.[102,104–108] The so-called "Sloan notch"[109] corresponds to the loss of sensitivity when the target wavelength is such that the target produces no chromatic signal (e.g., when the L- and M-cone inputs to the L−M chromatic mechanism are equal), so that detection is mediated instead by the less-sensitive achromatic mechanism. By contrast, the broad peaks correspond to target wavelengths at which the target produces a large chromatic signal.[101,102,105–108,110,111] Examples of detection spectral sensitivities with strong contributions from opponent mechanisms are shown in Fig. 17*a* and Fig. 18*a*. Those shown as circles in Fig. 17 and Fig. 18 were measured on a white background. The other functions in Fig. 17 were measured on backgrounds of 560 nm (green squares), 580 nm (yellow triangles), and 600 nm (orange triangles).

The nature of the mechanisms responsible for the spectral sensitivity data in Fig. 17*a* can be seen clearly by replotting the data as cone contrasts, as illustrated in Fig. 17*b* for the three chromatic backgrounds (from Ref. 89). As indicated by the straight lines fitted to each set of data, the detection contours have slopes close to one in cone contrast space, which is consistent with detection by L–M chromatic mechanisms with equal cone contrast weights (see subsection "Sensitivity to Different Directions of Color Space" in Sec. 11.5). Note also that the contours move outward with increasing field wavelength. This is consistent with second-site desensitization (see Fig. 8). The dependence

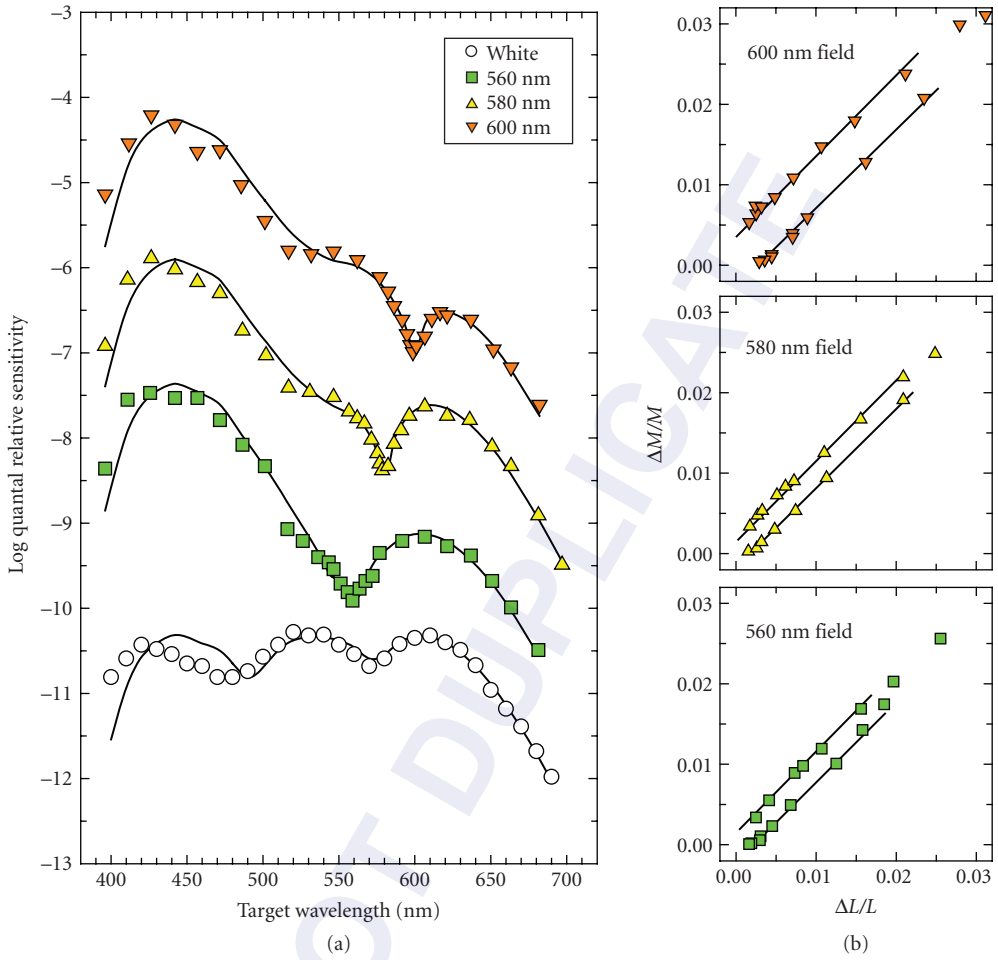

FIGURE 17 Sloan notch and chromatic adaptation. The three data sets in (*a*) are spectral sensitivity data replotted from Fig. 1 of Thornton and Pugh[107] measured on 10^{10} quanta sec^{-1} deg^{-2} fields of 560 nm (green squares), 580 nm (yellow triangles), and 600 nm (orange inverted triangles) using a long duration (one period of a 2-Hz cosine), large (3° diameter, Gaussian-windowed) target. The lowest data set in (*a*) are data replotted from Fig. 4 (Observer JS) of Sperling and Harwerth[105] measured on 10,000 td, 5500 K, white field (open circles) using a 50-ms duration, 45-min diameter target. The data have been modeled (solid lines) by assuming that the spectral sensitivities can be described by $b|aL - M| + c|M - aL| + d|S - e(L + 0.5M)|$, where L, M, and S are the quantal cone fundamentals[28] normalized to unity peak, and a–e are the best-fitting scaling factors. These fits are comparable to the ones originally carried out by Thornton and Pugh[107] using different cone fundamentals. Notice that the Sloan notch (on colored backgrounds) coincides with the field wavelength. The detection contours in (*b*) have been replotted from Fig. 18.4B of Eskew, McLellan, and Giulianini.[89] The data are the spectral sensitivities measured on 560 nm (green squares), 580 nm (yellow triangles), and 600 nm (orange inverted triangles) fields already shown in (*a*), but transformed and plotted in cone-contrast space. Only data for target wavelengths ≥ 520 nm are shown. As indicated by the straight lines fitted to each set of data, the detection contours have slopes close to one in cone contrast space, which is consistent with detection by L–M chromatic mechanisms with equal L- and M-cone contrast weights.

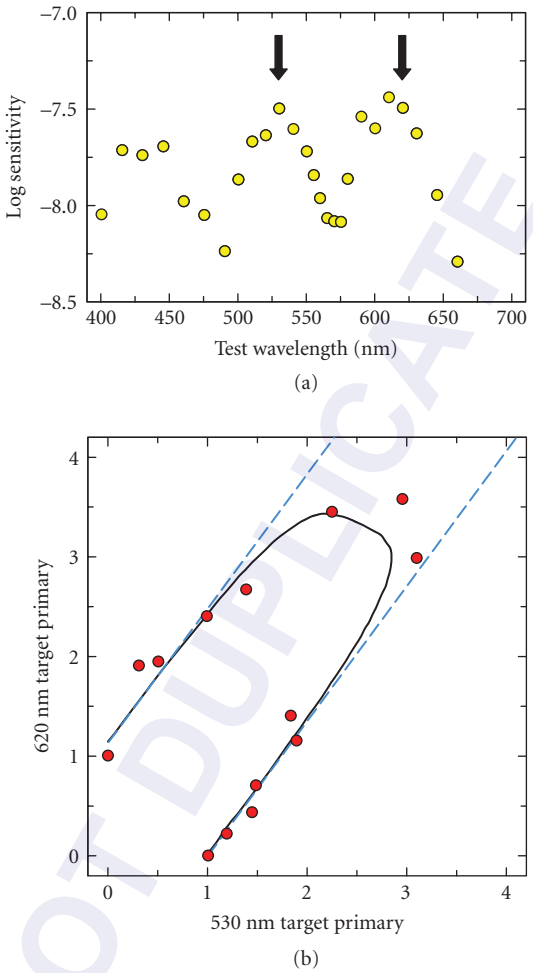

FIGURE 18 Test additivity. (*a*) Spectral sensitivity for the detection of a low frequency target measured on a 6000 td xenon (white) background (yellow circles). The shape is characteristic of detection by chromatic channels. The arrows indicate the wavelengths of the two primaries used in the test additivity experiment shown in (*b*). (*b*) Detection thresholds measured on the same field for different ratios of the two primaries. Data and model fits replotted from Fig. 2 of Thornton and Pugh.[164] The solid curve is the fit of a multi-mechanism model comprising an achromatic (L+M) and chromatic mechanisms (L–M and M–L with the same but opposite weights). The sensitivities of the chromatic mechanisms are shown by the dashed blue line. (See Ref. 164 for details.)

of the spectral position of the Sloan notch on background wavelength is discussed in subsection "Chromatic Adaptation and the Sloan Notch" in Sec. 11.5.

Luminance

Luminous efficiency The target parameters (and the experimental task) can also be chosen to favor detection by achromatic mechanisms. For example, changing the target parameters from a 200-ms duration, 1° diameter flash to a 10 ms, 0.05° diameter flash presented on a white background changes the spectral sensitivity from a chromatic one to an achromatic one, with chromatic peaks at approximately 530- and 610-nm merging to form a broad peak near 555 nm.[102] Measurements that favor detection by achromatic mechanisms have been carried out frequently in the applied field of photometry as a means of estimating scotopic (rod), mesopic (rod-cone), or photopic (cone) "luminous efficiency" functions.

Luminous efficiency was introduced by the CIE (Commission Internationale de l'Éclairage) to provide a perceptual analog of radiance that could be used to estimate the visual effectiveness of lights. The measurement of luminous efficiency using tasks that favor achromatic detection is a practical solution to the requirement that luminous efficiency should be additive. Additivity, also known as obedience to Abney's law,[112,113] is necessary in order for the luminous efficiency of a light of arbitrary spectral complexity to be predictable from the luminous efficiency function for spectral lights, $V(\lambda)$.

Some of the earlier luminous efficiency measurements[114–117] incorporated into the original 1924 CIE photopic luminous efficiency function, $V(\lambda)$, used techniques that are now known to fail the additivity requirement. Techniques that satisfy the additivity requirement, and depend mainly on achromatic or luminance mechanisms, include heterochromatic flicker photometry (HFP), heterochromatic modulation photometry (HMP), minimally distinct border (MDB), and minimum motion (MM). Details of these techniques can be found in several papers.[28,53,90,118–124]

In visual science, $V(\lambda)$ or its variants, has often been assumed to correspond to the spectral sensitivity of the human postreceptoral achromatic or "luminance" mechanism, which is assumed to add positively weighted inputs from the L and M cones.[125] As a result, estimates of luminous efficiency have taken on an important theoretical role in studies of the opponent mechanisms, because they are used to produce stimulus modulations that produce no change in the purported luminance mechanism. In this context, the $V(\lambda)$ standard is often overinterpreted, since it obscures a number of factors that affect actual measurements of luminous efficiency. These include (1) the strong dependence of luminous efficiency on the mean state of chromatic adaptation (see subsection "Achromatic Detection and Chromatic Adaptation" in Sec. 11.5), (2) the sizeable individual differences in luminous efficiency that can occur between observers (see below), and (3) the fact that luminous efficiency is affected both by the spatial properties of the target, as well by where on the retina it is measured.

A more fundamental problem is that the CIE photopic 1924 $V(\lambda)$ function seriously underestimates luminous efficiency at short wavelengths, because of errors made in its derivation. Consequently, $V(\lambda)$ is seldom used in visual science, except for the derivation of troland values (with the result that luminance is often underestimated at short wavelengths). Attempts to improve $V(\lambda)$[126,127] have been less than satisfactory,[28,90] but are continuing in the form of a new estimate referred to as $V^*(\lambda)$.[128,129] The $V^*(\lambda)$ (green line) and the CIE 1924 $V(\lambda)$ (green circles) luminous efficiency functions for centrally viewed fields of 2° in visual diameter, and the $V_{10}{}^*(\lambda)$ (orange line) and the CIE 1964 $V_{10}(\lambda)$ (orange squares) luminous efficiency functions for centrally viewed fields of 10° in visual diameter can be compared in Fig. 19. The functions differ mainly at short wavelengths. The $V^*(\lambda)$ and $V_{10}{}^*(\lambda)$ functions have been recommended by the CIE for use in "physiologically relevant" colorimetric and photometric systems.[130]

In general, luminous efficiency functions can be approximated by a linear combination of the L-cone $[\bar{l}(\lambda)]$ and M-cone $[\bar{m}(\lambda)]$ spectral sensitivities, thus: $V(\lambda)=a\bar{l}(\lambda)+\bar{m}(\lambda)$, where a is the L-cone weight relative to the M-cone weight. Luminous efficiency shows sizeable individual differences even after individual differences in macular and lens pigmentation have been taken into account. For example, under neutral adaptation, such as daylight D65 adaptation, the L-cone weight in a group of 40 subjects, in whom 25-Hz HFP spectral sensitivity data were measured on a 3 log td white D65 background, varied from 0.56 to 17.75, while the mean HFP data were consistent with an L-cone weight of 1.89.[128,129]

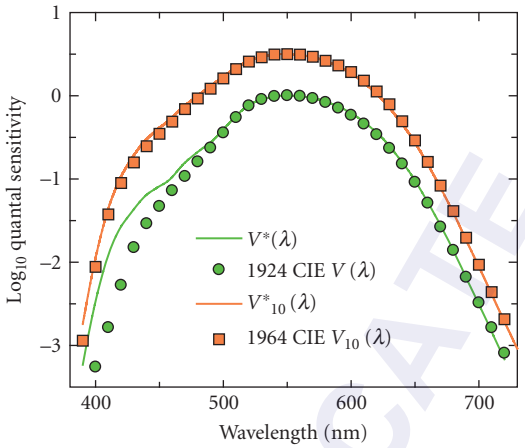

FIGURE 19 Luminous efficiency functions for 2° and 10° central viewing conditions. The lower pair of curves compare the CIE 1924 2° $V(\lambda)$ function (green circles) with the 2° $V^*(\lambda)$ function[128,129] (green line). The upper pair of curves compare the CIE 1964 10° $V_{10}(\lambda)$ function (orange squares) with the 10° $V^*(\lambda)$ function (orange line). The main discrepancies are found at short wavelengths.

Cone numerosity On the assumption that the variation in L:M cone contribution to luminous efficiency is directly related to the variation in the ratio of L:M cone numbers in the retina, several investigators have used luminous efficiency measurements to estimate relative L:M cone numerosity.[125,131–141] It is important to note, however, that luminous efficiency depends on factors other than relative L:M cone number, and is affected, in particular, by both first-site and second-site adaptation.[63,64,142] Indeed, the L:M contribution to luminous efficiency could in principle have little or nothing to do with the relative numbers of L and M cones, but instead reflect the relative L- and M-cone contrast gains set in a manner independent of cone number. Such an extreme view seems unlikely to hold, however. Population estimates of relative L:M cone numerosity obtained using luminous efficiency, correlate reasonably well with estimates obtained using direct imaging,[30] flicker ERG,[143,144] and other methods.[134,137–139,145–148] More precise delineation of the relation between luminous efficiency and relative L:M cone numerosity awaits further investigation. Note that an important piece of this enterprise is to incorporate measurements of individual variation in L- and M-cone spectral sensitivity.[128,144,146]

Multiple luminance signals As developed later in subsection "Multiplexing Chromatic and Achromatic Signals" in Sec. 11.5, cone-opponent, center-surround mechanisms that are also spatially opponent, such as parvocellular or P-cells, encode not only chromatic information, but also luminance information (see Fig. 38). The fact that P-cells transmit a luminance signal suggests that there may be two distinct "luminance" signals at the physiological level: one generated by P-cells and another by magnocellular or M-cells, a possibility which has been discussed in several papers by Ingling and his coworkers.[149–152] The need for a P-cell-based luminance system is also suggested by the fact that the retinal distribution of M-cells is too coarse to support the observed psychophysical spatial acuity for luminance patterns[153] (but see Ref. 154). Others have also suggested that multiple mechanisms might underlie luminance spectral sensitivity functions.[124]

Luminance mechanisms based on M-cell and P-cells should have different spatial and temporal properties. Specifically, the mechanism more dependent on M-cell activity, which we refer to as $(L+M)_M$, should be more sensitive to high temporal frequencies, whereas the mechanism more dependent on

P-cell activity, which we refer to as $(L+M)_P$, should be more sensitive to high spatial frequencies. If, as has been suggested,[149–152] $(L+M)_P$ is multiplexed with L–M, we might also expect the interactions between $(L+M)_P$ and L–M to be different from those between $(L+M)_M$ and L–M. Similarly, chromatic noise may have a greater effect on $(L+M)_P$ than on $(L+M)_M$. Note, however, that if the stimulus temporal frequency is high enough for the spatially opponent surround to become synergistic with the center (i.e., when the surround delay is half of the flicker period), the P-cell will, in principle, become sensitive to any low spatial frequency luminance components of the stimulus.[151,155]

Psychophysical evidence for multiple luminance mechanisms is relatively sparse. Given the likely difference in the M- and L-cone weights into $(L+M)_M$, the conventional luminance mechanism, and into L-M, the chromatic mechanism [from which $(L+M)_P$ is assumed to derive], the spectral sensitivities for spatial acuity tasks, which favor $(L+M)_P$, and for flicker tasks, which favor $(L+M)_M$, should be different. However, little difference in spectral sensitivity is actually found.[122,156–158] Ingling and Tsou[152] speculate that this similarity is found despite there being different luminance mechanisms, because the spatial acuity task may depend on P-cell centers rather than on centers and surrounds. Averaged over many cells, the P-cell *center* spectral sensitivity may be similar to the M-cell sensitivity, particularly if the latter depends on relative cone numerosity (see previous subsection).

Webster and Mollon[17] looked at the effect of correlated chromatic and luminance contrast adaptation on four different measures of "luminous efficiency." They found that lightness settings and minimum-motion settings for 1-Hz counter-phase gratings were strongly biased by contrast adaptation, but that flicker settings and minimum-motion settings for 15-Hz counter-phase gratings were unaffected. On the face of it, these results are consistent with the idea that different luminance mechanisms mediate low- and high-temporal frequency tasks.

We speculate that some of the discrepancies found between the detection contours measured in the L,M plane might be related to detection being mediated by different luminance mechanisms under different conditions. Conditions chosen to favor the conventional luminance channel (e.g., the presence of chromatic noise and/or the use of targets of high temporal frequency) are likely to favor detection by $(L+M)_M$. Perhaps, under these conditions the $(L+M)_M$ luminance contours appear as distinct segments, because there is relatively little threshold summation with L–M (e.g., $k = 4$). Examples of such segments are shown by the dashed lines in Fig. 20*c*. Conditions *not* specially chosen to favor the conventional luminance channel (e.g., the use of targets of high spatial and/or low temporal frequencies) may favor instead detection by $(L+M)_P$. Perhaps, under these conditions the luminance $(L+M)_P$ contours form elliptical contours with L–M ($k = 2$). Examples of such contours are shown in Fig. 20*d*. Noorlander, Heuts, and Koenderink,[83] however, reported that elliptical contours were found across all spatial and temporal frequencies.

Sensitivity to Different Directions of Color Space Before considering results obtained using trichromatic test mixtures, we first consider earlier results obtained using bichromatic mixtures.

Sensitivity to bichromatic test mixtures The use of spectral lights restricts the range of measurements to the spectrum locus in color space, thus ignoring the much larger and arguably environmentally more relevant volume of space that includes desaturated colors, achromatic lights, and extra-spectral colors (such as purples). Measuring detection sensitivity for mixtures of spectral targets probes the inner volume of color space. Studying these "bichromatic mixtures," moreover, can provide a direct test of the additivity of a mechanism. For example, under conditions that isolate a univariant linear mechanism, pairs of lights should combine additively, so that the observer should be more sensitive to the combination than to either light alone. For a cone-opponent mechanism, on the other hand, pairs of lights that oppositely polarize the mechanism should combine subadditively, so that the observer is less sensitive to the mixture than to either component (as illustrated in Fig. 6*d*). If different mechanisms detect the two targets, then other potential interactions include probability summation or gating inhibition (winner takes all). Boynton, Ikeda, and Stiles[100] found a complex pattern of interactions between various test fields that included most of the possible types of interactions.

Several workers have demonstrated subadditivity for mixtures of spectral lights that is consistent with either L–M or S–(L+M) cone opponency.[100,106,120,159–165] Clear examples of subadditivity were

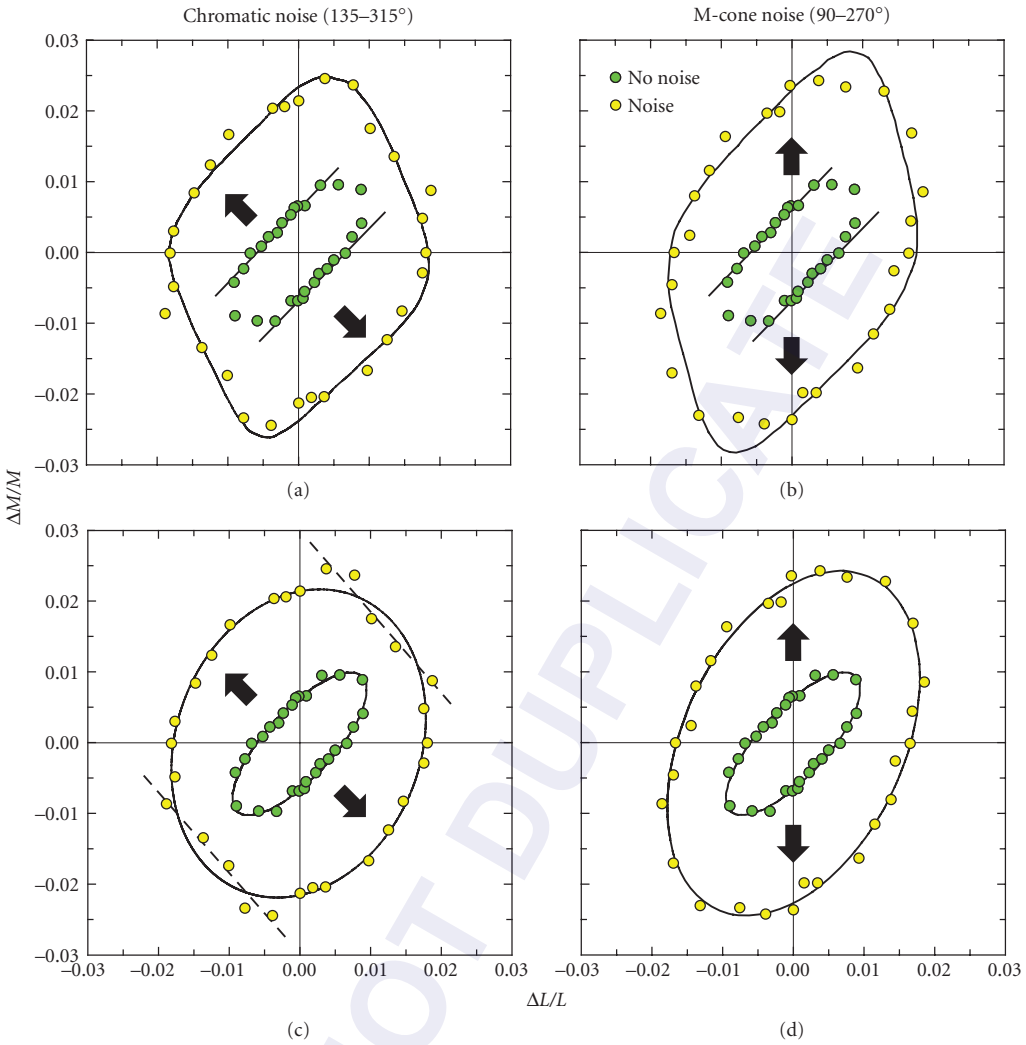

FIGURE 20 Detection contours in the $\Delta L/L$, $\Delta M/M$ plane. Detection thresholds for a 1-cpd Gabor replotted from Fig. 5 of Giulianini and Eskew[175] obtained with (yellow circles) or without (green circles) noise made up of superposed flickering rings modulated along the $\Delta L/L = -\Delta M/M$ (chromatic) axis (*a* and *c*) or the $\Delta M/M$ (M-cone) axis (*b* and *d*). The arrows indicate the noise directions. (*a*) and (*b*). Model fits (solid lines) by Giulianini and Eskew[175] in which L–M chromatic detection is assumed to be mediated by a mechanism with relative cone contrast weights of 0.70 $\Delta L/L$ and 0.72 $\Delta M/M$ of opposite sign, while L+M achromatic detection is mediated by a mechanism with relative weights of 0.90 $\Delta L/L$ and 0.43 $\Delta M/M$ of the same sign. Without chromatic noise, the detection data are consistent with detection solely by the chromatic mechanism (as indicated by the parallel lines) except along the luminance axis. With added chromatic noise, the sensitivity of the chromatic mechanism is reduced, revealing the achromatic mechanism in the first and third quadrants. In the presence of noise, the data are consistent with detection by both chromatic and achromatic mechanisms (as indicated by the rounded parallelogram). The combination exponent for the two mechanisms, *k*, was assumed to be 4 (see subsection "How Test Measurements Imply Opponency" in Sec. 11.3). (*c*) and (*d*) Alternative fits to the data using elliptical contours, which provide a surprisingly good fit to the detection data, except in the achromatic direction with chromatic noise (*c*). The ellipse fitted to the yellow circles in (*c*) has the formula $3332x^2 + 2021y^2 + 873xy = 1$ (major axis 73.16°), while that fitted to the green circles has the formula $27{,}191x^2 + 24{,}842y^2 + 43{,}005xy = 1$ (major axis 46.56°), where $x = \Delta L/L$ and $y = \Delta M/M$. Those data with noise that are poorly accounted for by the ellipse have been fitted with a straight line of best-fitting slope –1.14 (dashed line). The ellipse fitted to the yellow circles in (*d*) has the formula $3648x^2 + 1959y^2 + 1992xy = 1$ (major axis 65.15°), while that fitted to the green circles has the formula $26{,}521x^2 + 23{,}587y^2 + 38{,}131xy = 1$ (major axis 47.20°).

obtained by Thornton and Pugh,[164] who presented targets chosen to favor chromatic detection on a white (xenon-arc) background. Figure 18*a* shows the test spectral sensitivity obtained on the white field characteristic of chromatic detection. The spectral positions of the test mixture primaries used in the additivity experiment are indicated by the arrows. Figure 18*b* shows the results of the text mixture experiment. Detection contours aligned with the parallel diagonal contours (dashed blue lines) is consistent with chromatic detection by an L–M mechanism, whereas detection along the 45° vector (parallel to the contours) is consistent with achromatic detection by an L+M mechanism. Thornton and Pugh[164] also used test primaries of 430 and 570 nm, which were chosen to favor detection by the S cones and by luminance (L+M), respectively. Although less clear than the L–M case shown here, they found evidence for inhibition between the 430- and 570-nm target consistent with detection by an S–(L+M) cone-opponent mechanism.

Guth and Lodge[11] and Ingling and Tsou[12] both used models that incorporated opponency to analyze bichromatic and spectral thresholds. Both found that the threshold data could be accounted for by two opponent-color mechanisms [which can be approximated to the basic cone-opponent discrimination mechanisms, L+M and S–(L+M)], and a single nonopponent mechanism (L+M). Both also developed models that could better account for "suprathreshold" data, such as color valence data, by modifying their basic models. These modifications took the form of an increase in the contribution of the S–(L+M) mechanism and either inhibition between the two cone-opponent mechanisms[11] or addition of an S-cone contribution to the L-cone side of the L–M mechanism.[12] These suprathreshold models are related to the color-appearance models discussed in subsection "Color Appearance and Color Opponency" in Sec. 11.5. It is worth noting that Guth and Lodge acknowledge that modulations of their cone-opponent discrimination mechanisms do not produce strictly red-green or yellow-blue appearance changes, but rather yellowish-red versus blue-green and greenish-yellow versus violet. That is, their threshold discrimination mechanisms do not account for unique hues (see subsection "Spectral Properties of Color-Opponent Mechanisms" in Sec. 11.5).

Kranda and King-Smith[106] also modeled bichromatic and spectral threshold data, but they required four mechanisms: an achromatic mechanism (L+M), two L–M cone-opponent mechanisms of opposite polarities (L–M and M–L), and an S-cone mechanism (S). The main discrepancy from the previous models is that they found no clear evidence for an opponent inhibition of S by L+M. Two opposite polarity, L–M mechanisms were required because Kranda and King-Smith assumed that only the positive lobe contributed to detection, whereas previous workers had assumed that both negative and positive lobes could contribute. This presaged the unipolar versus bipolar mechanism debate (see "Unipolar versus Bipolar Chromatic Mechanisms" in Sec. 11.6).

With the exception of Boynton, Ikeda, and Stiles,[100] most of the preceding studies used incremental spectral test lights, which confined the measurements to the eighth volume of color space in which all three cone signals increase. To explore other directions in color space, both incremental and decremental stimuli must be used.

Detection contours in the L,M plane The first explicit use of incremental and decremental stimuli in cone contrast space was by Noorlander, Heuts, and Koenderink,[83] who made measurements in the L,M plane. They fitted their detection contours with ellipses, and found that the alignment of the minor and major axes depended on temporal and spatial frequency. At lower frequencies, the minor and major axes aligned with the chromatic ($\Delta M/M = -\Delta L/L$) and achromatic ($\Delta M/M = \Delta L/L$) directions, respectively. By contrast, at higher frequencies, the reverse was the case. Such a change is consistent with relative insensitivity of chromatic mechanisms to higher temporal and spatial frequencies (see subsection "Spatial and Temporal Contrast Sensitivity Functions" in Sec. 11.5).

If the individual detection contours are truly elliptical in two-dimensional color space or ellipsoidal in three, then the vectors of the underlying linear detection mechanisms cannot be unambiguously defined. This ambiguity arises because ellipses or ellipsoids can be linearly transformed into circles or spheres, which do not have privileged directions.[165] Consequently, whether or not detection contours are elliptical or ellipsoidal has become an important experimental question. Knoblauch and Maloney[166] specifically addressed this question by testing the shapes of detection contours measured in two color planes. One plane was defined by modulations of the red and green phosphors of their display (referred to by them as the ΔR, ΔG plane), and the other by the modulations of the red and green phosphors together and the blue phosphor of their display (referred to as the ΔY, ΔB plane). The

detection contours they obtained did not differ significantly in shape from an elliptical contour.[166] Note, however, that a set of multiple threshold contours, each ellipsoidal but measured under related conditions, can be used to identify mechanisms uniquely, given a model about how the change in conditions affects the contours (see, e.g., Ref. 167; discussed in subsection "Spatial and Temporal Contrast Sensitivity Functions" in Sec. 11.5).

Deviations from an ellipse, if they do occur, are most likely to be found under experimental conditions that maximize the probability that different portions of the contour depend on detection by different mechanisms. Such a differentiation is unlikely to be found under the conditions used by Knoblauch and Maloney.[166] At lower temporal frequencies (1.5-Hz sine wave or a Gaussian-windowed, $\sigma = 335$ ms, 1.5-Hz cosine wave), the detection contour in the $\Delta R, \Delta G$ phosphor space is likely to be dominated by the much more sensitive L–M mechanisms, whereas the contour in $\Delta Y, \Delta B$ space is likely to depend upon detection by all three mechanisms [L–M, L+M, and S–(L+M)]. A comparable conclusion about the shape of threshold contours was reached by Poirson, Wandell, Varner, and Brainard,[168] who found that color thresholds could be described well by ellipses, squares, or parallelograms. Again, however, they used long duration (a Gaussian envelope lasting 1 s, corresponding to +5 to –5 standard deviations) and large (2° diameter) target that would favor detection by L–M.

The relatively high sensitivity of the L–M mechanism to foveally viewed, long-duration flashed targets[169–171] means that the L–M mechanism dominates the detection contours unless steps are taken to expose the L+M luminance mechanisms, such as by the use of flickering targets,[63,172] very small targets,[173] or chromatic noise (see subsection "Noise-Masking Experiments" in Sec. 11.5). Detection threshold contours measured in the L,M plane that expose both L–M and L+M contours are arguably better described by a parallelogram with rounded corners rather than an ellipse, with the parallel sides of positive slope corresponding to detection by the L–M chromatic mechanism and those of negative slope corresponding to detection by the L+M luminance mechanism.[61,63,173,174] Examples of detection contours that appear nonelliptical include parts of Figs. 3 and 4 of Ref. 63; Fig. 3, 5, and 7 of Ref. 175; and Fig. 2 of Ref. 176.

Figure 20 shows the detection data replotted from Fig. 5 of Ref. 175. The data are shown twice: once in the upper panels (a, b) and again in the lower panels (c, d). The data shown as green circles were measured without noise. The data shown as yellow circles in Fig. 20*a* and *c* were measured in the presence of chromatic noise, while those in Fig. 20*b* and *d* were measured in the presence of M-cone noise. The noise directions are indicated by the black arrows.

If, for the sake of argument, we accept that the mechanism vectors of the detection mechanisms can be unambiguously defined from detection contours (as illustrated in Fig. 20*a* and *b*), it is possible to estimate their cone weights and therefore their spectral sensitivities. The chromatic L–M detection contours in Fig. 20*a* and *b* obtained without noise (green circles) have been fitted with lines of parallel slopes of approximately 1.0, which indicates that the L–M chromatic mechanism responds to the linear difference of the L- and M-cone *contrast* signals; $|c\Delta L/L - d\Delta M/M| = \text{constant}$, where $c = d$.[61,63,173,174] The equality of the L- and M-cone weights, unlike the underlying relative L-and M-cone numerosities (e.g., Ref. 30), shows a remarkable lack of individual variability across observers (see Ref. 89). Similarly, color appearance settings (see subsection "Color Appearance and Color Opponency" in Sec. 11.5) in the form of unique yellow settings show much less variability than would be expected if unique yellow depended on the relative number of L and M cones in the retina.[146]

As suggested by the yellow circles in Fig. 20*a* and *c*, the use of a high frequency flickering target in chromatic noise exposes more of the L+M contour in the first and third quadrants. Unlike the L–M contour, the L+M contour has a negative slope, which indicates that the L+M achromatic chromatic mechanism responds to the linear sum of the L- and M-cone *contrast* signals; $|a\Delta L/L + b\Delta M/M| = \text{constant}$, where a is typically greater than b.[61,63,89,173,174]

Mechanism interactions The shapes of the detection contours when two or more postreceptoral mechanisms mediate threshold depends upon the way in which those mechanisms interact (see Fig. 6*c*). In principle, such interactions can range from complete summation, through probability summation to exclusivity (winner takes all) and inhibition (see Ref. 100). The usual assumption is that L–M, S–(L+M), and L+M are stochastically independent mechanisms that combine by probability summation. That is, if two or three mechanisms respond to the target, then the threshold will be lower than if only one responds to it. How much the threshold is lowered depends upon the

underlying frequency-of-seeing curve for each mechanism. Steep frequency-of-seeing curves result in a relatively small drop in threshold, whereas shallow curves result in a larger drop. Several groups have mimicked probability summation by using the summation rule introduced in "How Test Measurements Imply Opponency" in Sec. 11.3. The summation exponent can be varied to mimic the effects of probability summation for psychometric functions with different slopes (see Refs. 174 and 89). A closely related geometrical description of the threshold contours was used by Sankeralli and Mullen.[172] For the fits in Fig. 20*a* and *b*, the summation exponent was assumed to be 4, which produces a contour shaped like a rounded parallelogram.[89,175]

The superiority of a rounded parallelogram over an ellipse (summation exponent of 2) is not always clear. For example, Fig. 20*c* and *d* show the same detection data as the *a* and *b*. In *c* and *d*, the data have been fitted with ellipses. As can be seen, each set of data is well fitted by an ellipse, except perhaps for a small part of the contour measured in the presence of chromatic noise shown in Fig. 20*c*. In this region, we have fitted a straight line plotted as the dashed line. Changing the direction of the noise from L–M chromatic to M cone between Fig. 20*c* and *d* rotates the ellipse slightly anticlockwise. The L–M data along the opponent diagonals clearly follow an elliptical rather than a straight contour in both cases. As previously noted, when an elliptical representation underlies the data, it does not uniquely determine the inputs to the underlying mechanisms.

Support for the summation exponent of 4 used to fit the data in Fig. 20*a* and *b* is also lacking from estimates of the slopes of the underlying psychometric functions, which are consistent with much smaller exponents.[171,177,178]

Detection in the other planes An investigation of mechanisms other than L–M and L+M (as well as information about whether or not there are S-cone inputs into those mechanisms) requires the measurement of responses outside the L,M plane of color space. Two systematic investigations have been carried out that include S-cone modulations. Cole, Hine, and McIlhagga[174] made measurements on a roughly 1000 log td white background using a Gaussian-blurred 2°, 200-ms spot that favors chromatic detection. Their data were consistent with three independent mechanisms: an L–M mechanism with equal and opposite L- and M-cone inputs but no S-cone input; an L+M mechanisms with unequal inputs and a small positive S-cone input, and an S–(L+M) mechanism. Sankeralli and Mullen[172] used three types of gratings with spatiotemporal properties chosen to favor either the chromatic L–M (1 cpd, 0 Hz), chromatic S–(L+M) (0.125 cpd, 0 Hz), or the achromatic L+M mechanism (1 cpd, 24 Hz). They confirmed that L–M had equal and opposite L- and M-cone inputs, but found a small S-cone input of about 2 percent added to either the L or the M cones for different observers. In addition, they found a small 5 percent S-cone input into the luminance mechanism that opposed the L+M input (see also Ref. 92). The S–(L+M) mechanism was assumed to have balanced opposed inputs.[172] Eskew, McLellan, and Giulianini[89] provide a separate analysis of both these sets of data (see Table 18.1 of Ref. 89).

Figure 21 shows chromatic detection data measured in the L–M,S plane by Eskew, Newton, and Giulianini.[179] The central panel shows detection thresholds with (filled circles) and without (open squares) L–M chromatic masking noise. Detection by the relatively insensitive S-cone chromatic mechanisms becomes apparent when detection by L–M chromatic mechanism is prevented by chromatic noise. The nearly horizontal portions of the black contour reflect detection by S–(L+M), while the vertical portions reflect detection by L–M (the model fit is actually of the unipolar mechanisms |L–M|, |M–L|, |S–(L+M)|, and |(L+M)–S|, see Ref. 34 for details; also "Unipolar versus Bipolar Chromatic Mechanisms" in Sec. 11.6).

The question of whether or not the S cones make a small contribution to the L–M detection mechanisms remains controversial. Boynton, Nagy, and Olsen[180] found that S cones show summation with L–M (+S with L–M, and –S with M–L) in chromatic difference judgments. Stromeyer et al.[181] showed that S-cone flicker facilitated detection and discrimination of L–M flicker, with +S facilitating L–M and –S facilitating M–L. Yet, the estimated S-cone contrast weight was only approximately 1/60th of the L- and M-cone contrasts weight into L–M (see p. 820 of Ref. 181). In general, in detection measurement the S-cone signal adds to redness (L–M) rather than greenness (M–L)—as expected from color-opponent theory (see Sec. 11.4), but the size of the contribution is much less than expected. Eskew and Kortick,[20] however, made both hue equilibria and detection measurements and estimated that the S-cone contrast weight was about 3 percent that of the L- and

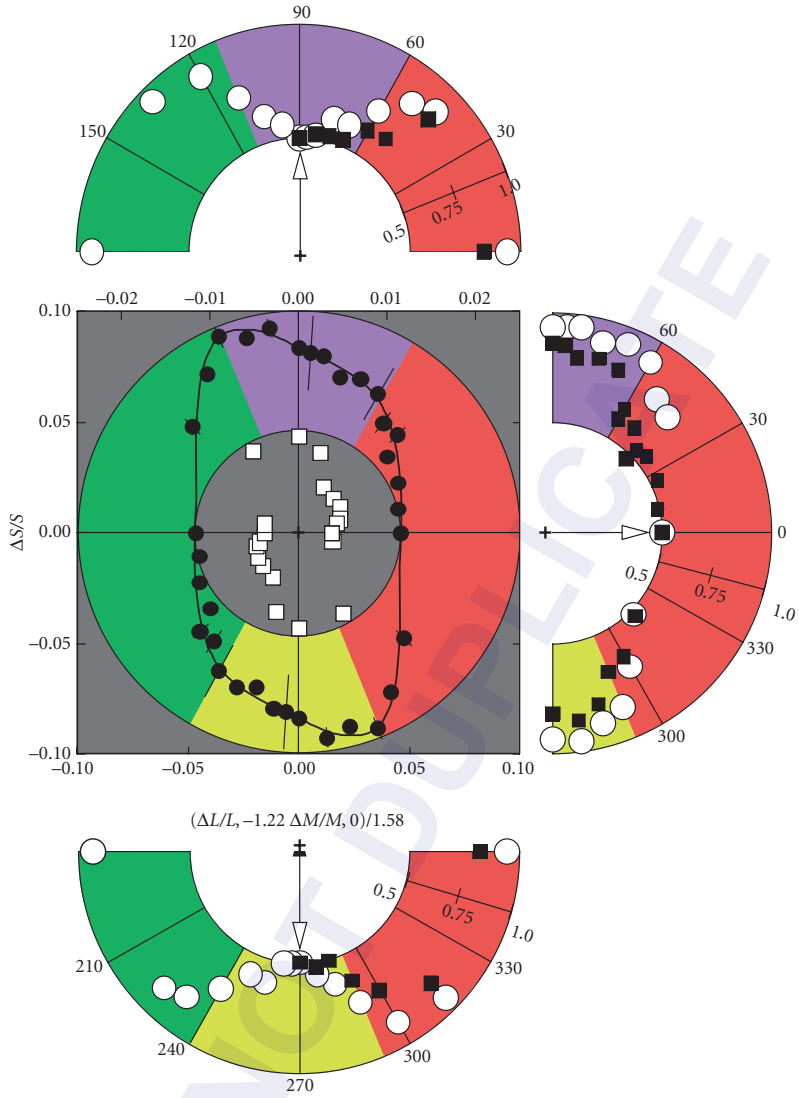

FIGURE 21 Detection and discrimination contours in the equiluminant plane. This figure is a reproduction of Fig. 5 from Eskew.[34] The central panel shows thresholds for the detection of Gabor patches with (filled circles) and without (open squares) L–M chromatic masking noise (0°/180° color direction). For clarity, the horizontal scale for the no-noise thresholds (open squares) has been expanded as indicated by the upper axis. Data are symmetric about the origin due to the symmetric stimuli. Detection by the relatively insensitive S-cone chromatic mechanisms becomes apparent when detection by the L–M chromatic mechanism(s) is suppressed by L–M chromatic noise. The black contour fitted to the filled circles is the prediction of a model in which detection is mediated by probability summation between four symmetric unipolar linear mechanisms |L–M|, |M–L|, |S–(L+M)|, and |(L+M)–S|, (see subsection "Unipolar versus Bipolar Chromatic Mechanisms" Sec. 11.6). The three outlying semicircular polar plots are discriminability data (filled squares), in which the angular coordinate corresponds to the same stimuli, at the same angles, as in the detection data. The radial coordinate gives the discriminability between 0.5 (chance) and 1.0 (perfect discriminability) of the given test color angle relative to the standard color angle indicated by the arrow. The open circles are predictions of a Bayesian classifier model that takes the outputs of the four mechanisms fitted to the detection data as its inputs. Colored regions indicate bands of poorly discriminated stimuli, and are redrawn on the detection plot for comparison. These results suggest that just four univariant mechanisms are responsible for detection and discrimination under these conditions. See Ref. 34 for further details. [*Figure adapted by Eskew*[34] *from Fig. 4 (Observer JRN) of Ref. 179 Reprinted from The Senses: A Comprehensive Reference, Volume 2: Vision II, Fig. 5* from R. T. Eskew, Jr., "Chromatic Detection and *Discrimination," pp. 109–117. Copyright (2008), with permission from Elsevier.*]

M-cone contrast weights for both tasks. Yet, although test methods support an S-cone contribution to L–M, field methods do not (see Ref. 34). Changes in the S-cone adaptation level have little effect on L–M detection[182] or on L–M mediated wavelength discrimination.[183]

Given the uncertainties about cone spectral sensitivities and luminous efficiency at short wavelengths, as well as the substantial individual differences in prereceptoral filtering between observers (see, e.g., Ref. 90), evidence for small S-cone inputs should be treated with caution.

Spatial and Temporal Contrast Sensitivity Functions The test method can also be used to determine the temporal and spatial properties of visual mechanisms. These properties are traditionally characterized by temporal and spatial "contrast sensitivity functions" (CSFs). These are sometimes incorrectly called "modulation transfer functions" (MTFs)—incorrectly because MTFs require phase as well as amplitude specifications.

In a temporal CSF determination, the observer's sensitivity for detecting sinusoidal flicker is measured as a function of temporal frequency. Generally, the chromatic mechanisms have a lowpass temporal frequency response with typically greater temporal integration and a poorer response to higher temporal frequencies than the more band-pass achromatic mechanism.[94,102,184–190] A lowpass CSF means that the temporal response is approximately independent of frequency at low frequencies but falls off at higher frequencies, whereas a band-pass CSF means that the response peaks at an intermediate frequency and falls off at both lower and higher frequencies.

On the grounds that different chromatic flicker frequencies can be discriminated near threshold, Metha and Mullen[190] suggest that at least two chromatic mechanisms with different temporal CSFs must underlie the measured chromatic CSF, one with a band-pass CSF and the other with a lowpass CSF. They argue that two mechanisms must operate, because a single *univariant* flicker mechanism will confound changes in contrast and flicker frequency, making frequency identification impossible. However, the assumption that flicker is encoded univariantly may be flawed. At low frequencies, flicker may be encoded as a moment-by-moment variation that matches the flicker frequency.[191]

In a spatial CSF determination, the observer's sensitivity for detecting sinusoidal gratings is measured as a function of their spatial frequency. Generally, the chromatic mechanisms have a lowpass spatial frequency response with greater spatial integration and a poorer response to higher spatial frequencies than the usually more band-pass achromatic mechanisms.[102,192–197]

Spatial CSFs are degraded by sensitivity losses introduced by the optics of the eye. In one study, laser interference fringes were used to project gratings directly on the retina, thereby effectively bypassing the MTF of the eye's optics.[198,199] However, because the red and green equiluminant interference fringes could not be reliably aligned to produce a steady artifact-free chromatic grating, they were drifted in opposite directions at 0.25 Hz. Thus, the gratings continuously changed from a red-green chromatic (equiluminant) grating to a yellow-black luminance (equichromatic) grating. The subject's task was to set the contrast threshold separately for the different spatial phases, which was apparently possible.[199] One concern about this method, however, is that the close juxtaposition of chromatic and luminance gratings in time and space might produce facilitation or interference (see subsection "Pedestal Experiments" in Sec. 11.5). For S-cone detection, a single grating was used.

The results for equiluminant, chromatic (red circles) and equichromatic, achromatic (blue circles) fringes are shown for three observers in the upper panels of Fig. 22. As expected, there is a steeper fall-off in high spatial-frequency sensitivity for chromatic gratings than for luminance gratings. By estimating the sensitivity losses caused by known factors such as photon noise, ocular transmission, cone-aperture size, and cone sampling, Sekiguchi, Williams, and Brainard[198] were able to estimate an ideal observer's sensitivity at the retina. Any additional losses found in the real data are then assumed to be due to neural factors alone. Estimates of the losses due to neural factors are shown in the lower panels of Fig. 22. Based on these estimates, the neural mechanism that detects luminance gratings has about 1.8 times the bandwidth of the mechanisms that detect chromatic gratings. Interestingly, the neural mechanisms responsible for the detection of equiluminant L–M gratings and S-cone gratings have strikingly similar (bandpass) contrast sensitivities, despite the very different spatial properties of their submosaics.[200] This commonality may have important implications for color processing (see "Three-Stage Zone Models" in Sec. 11.6).

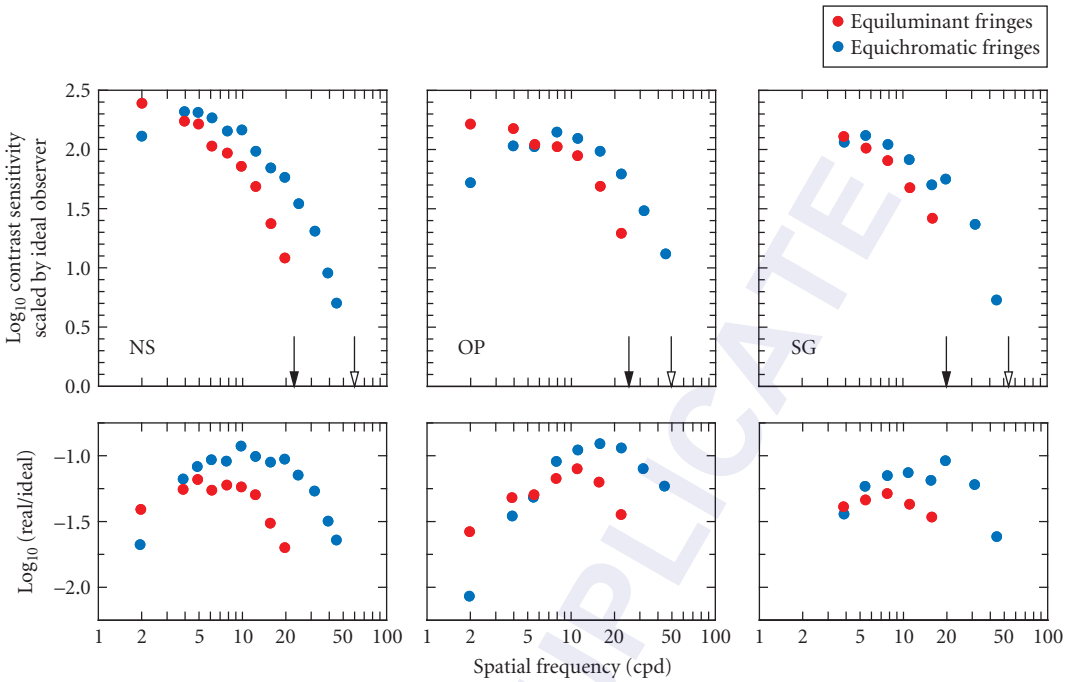

FIGURE 22 Spatial equiluminant and equichromatic contrast sensitivity functions. Top panels: Foveal CSFs for equiluminant (red circles) and equichromatic (blue circles) interference fringes for three observers. Filled and open arrows represent the foveal resolution limit for the equiluminant and the equichromatic stimuli, respectively. Bottom panels: The ratio of the ideal to the real observer's contrast sensitivity for detecting equiluminant (red circles) and equichromatic (blue circles) stimuli. (*Based on Figure 9 of Ref. 199.*)

Poirson and Wandell[167] measured spatial CSFs along the two cardinal directions and along intermediate directions in color space; that is, they effectively measured threshold contours for a series of grating spatial frequencies. They fitted the contours with an ellipsoidal model, but added a constraint of pattern-color separability; that is, they assumed that the effect of pattern operated independently in each of three second-site mechanisms. This constraint resolves the mechanism ambiguity inherent in fitting ellipsoidal contours to the individual data, and allowed Poirson and Wandell to estimate the sensitivities of three underlying mechanisms by jointly analyzing the contours across spatial frequency. They found two opponent and one nonopponent mechanisms, with sensitivities consistent with the cardinal mechanisms, L+M, L–M, and S–(L+M) (see Fig. 6 of Ref. 167).

We next consider results obtained using the field method.

Field Sensitivities

Stiles' π-Mechanisms Stiles used the field sensitivity method to define the spectral sensitivities of the π-mechanisms, which are illustrated in Fig. 23. The tabulated field sensitivities can be found in Table 2 (7.4.3) of Ref. 53 and Table B of Ref. 33. The field sensitivities are the reciprocals of the field radiances (in log quanta s^{-1} deg^{-2}) required to raise the threshold of each isolated π-mechanism by one log unit above its absolute threshold. The tabulated data are average data for four subjects: three females aged 20 to 30 and one male aged 51.

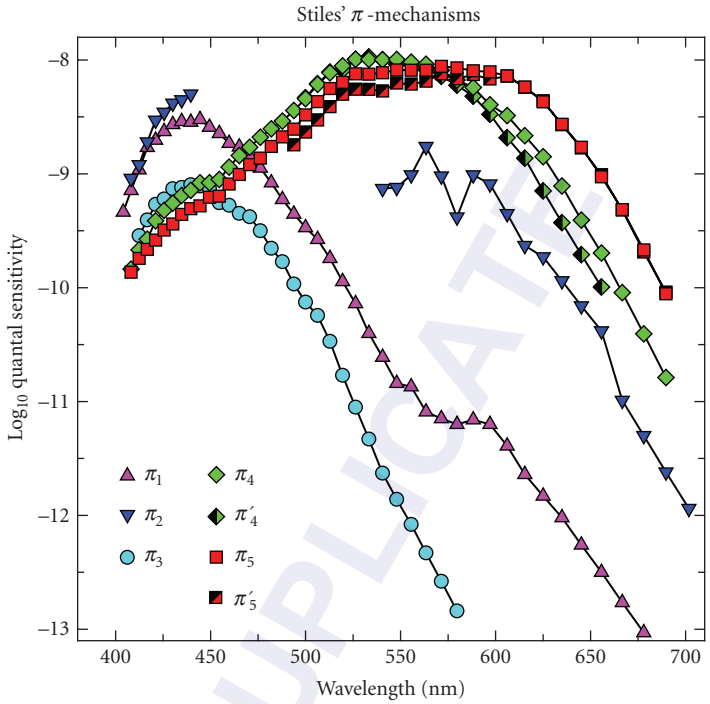

FIGURE 23 Stiles' π-mechanisms. Field spectral sensitivities of the seven photopic π-mechanisms: π_1 (purple triangles), π_2 (dark blue inverted triangles), π_3 (light blue circles), π_4 (green diamonds), π'_4 (green half-filled diamonds), π_5 (red squares), π'_5 (red half-filled squares). The field sensitivities are the reciprocals of the field radiances (in log quanta s^{-1} deg^{-2}) required to raise the threshold of each "isolated" π-mechanism by one log unit above its absolute threshold. The results were averaged across four subjects: three females aged 20 to 30 and one male aged 51. Details of the experimental conditions can be found on p. 12 of Stiles' book.[33] (*Data from Table 2(7.4.3) of Wyszecki and Stiles.*[53])

Through field sensitivity measurements, and measurements of threshold versus background radiance for many combinations of target and background wavelength, Stiles identified seven photopic π-mechanisms: three predominately S-cone mechanisms (π_1, π_2, and π_3), two M-cone (π_4 and π_4'), and two L-cone (π_5 and π_5'). Although it has been variously suggested that some of the π-mechanisms might correspond to cone mechanisms,[97,201–203] it is now clear that all reflect some form of postreceptoral cone interaction. The surfeit of π-mechanisms and their lack of obvious correspondence to cone mechanisms or simple postreceptoral mechanisms led to the demise of Stiles' model. Its usefulness, however, was prolonged in the work of several investigators, who used failures of Stiles' model as a way of investigating and understanding the properties of chromatic mechanisms (see "Field Additivity" in this section). But, as noted in the parallel discussion in the context of test sensitivity, the potential ongoing value of the π-mechanism field sensitivities is that they provide an empirical database that may be used to constrain current models.

Achromatic Detection and Chromatic Adaptation Achromatic spectral sensitivity (or luminous efficiency) is strongly dependent on chromatic adaptation.[63,64,142,204–210] Figure 24*a* shows the changes in luminous efficiency caused by changing background field wavelength from 430 to 670 nm and Fig. 24*b* shows the changes caused by mixing 478- and 577-nm adapting fields in different luminance

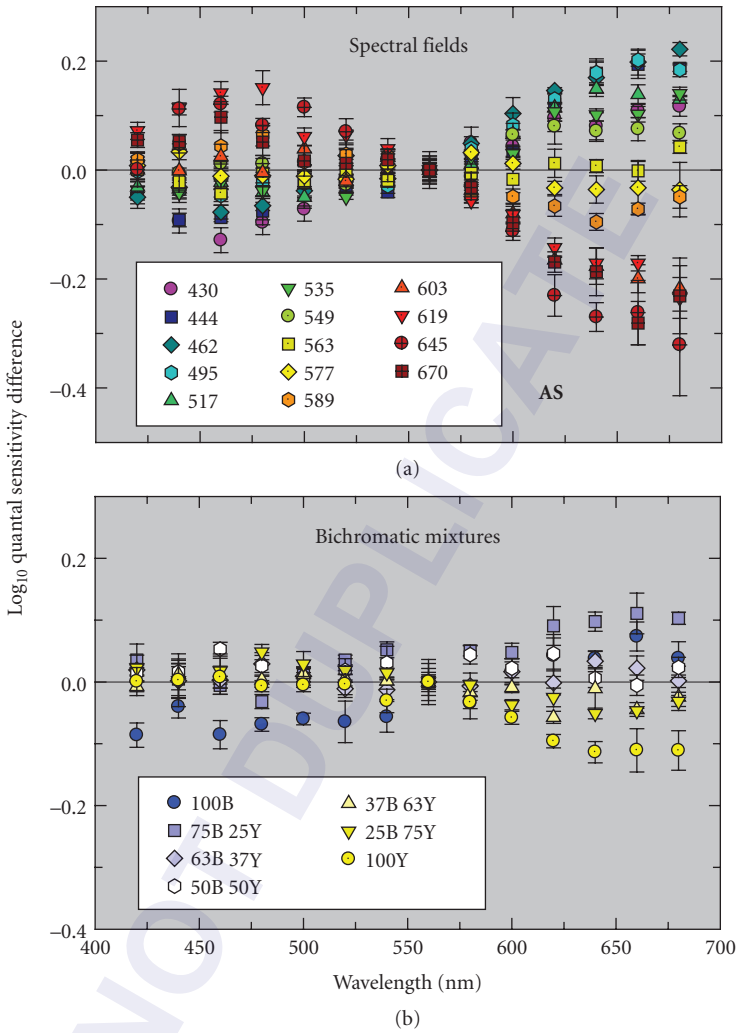

FIGURE 24 Dependence of luminous efficiency on chromatic adaptation. Changes in quantal luminous efficiency caused by changes in adapting field chromaticity plotted relative to the mean luminous efficiency. Data from Observer S1 of Stockman, Jägle, Pirzer and Sharpe.[129] Measurements were made using 25-Hz heterochromatic flicker photometry (HFP) on 1000-td backgrounds. (*a*) HFP changes on fourteen 1000-td spectral adapting fields from 430 to 670 nm and (*b*) changes on seven 1000 td bichromatic, 478(B) + 577(Y)-nm adapting field mixtures that varied from 100 percent B to 100 percent Y.

ratios. These changes are consistent with selective adaptation reducing L-cone sensitivity relative to M on longer wavelength fields, and reducing M-cone sensitivity relative to L on shorter wavelength fields. Between about 535 and 603 nm the selective changes are roughly consistent with Weber's law ($\Delta I/I$ = constant). Consequently, plotted in cone contrast space, the sensitivity contour for the achromatic mechanism should remain of constant slope between field wavelengths of 535 and 603 nm, *unlike* the example shown in Fig. 8*b*. For background wavelengths shorter than 535 nm,

on the other hand, the changes in spectral sensitivity are consistent with a relative loss of M-cone sensitivity in excess of that implied by Weber's law (for details, see Ref. 129). This is consistent with other evidence that also shows that the luminance contribution of the L- or M-cone type more sensitive to a given chromatic field can be suppressed by more than Weber's law implies.[63,64,142] Such supra-Weber suppression, illustrated in Fig. 8*b* for the L-cone case, causes the luminance sensitivity contours in cone contrast space to rotate away from the axis of the more suppressed cone.

Multiple cone inputs There is now good psychophysical evidence that the standard model of the luminance channel as an additive channel with just fast L- and M-cone inputs (referred to here as *+fL+fM*) is incomplete. According to this model, pairs of sinusoidally alternating lights that are "luminance-equated" and detected solely by the luminance channel should appear perfectly steady or nulled whatever their chromaticities (equating alternating lights to produce a null is known as heterochromatic flicker photometry or HFP). And, indeed, such nulls are generally possible, but sometimes only if moderate to large phase delays are introduced between the pairs of flickering lights.[184,211–215] Moreover, these large phase delays are often accompanied by substantial frequency-dependent changes in the spectral sensitivity of flicker detection and modulation sensitivity.[216–218] From the phase delays and sensitivity changes, it is possible to infer that, in addition to the faster *+fM+fL* signals, sluggish *+sM–sL*, *+sL–sM*, and *–sS* signals also contribute to the luminance-signal nulls in a way that depends on adapting chromaticity and luminance.[94,215–223]

Figure 25 shows examples of large phase delays that are found for M- and L-cone-detected flickering lights on four increasingly intense 658 nm fields. In these plots, 0° means that the two lights cancelled when they were physically in opposite phase (i.e., when they were alternated), while ± 180° means that they cancelled when they were actually in the same phase. The differences between the plotted M- and L-cone phase delays therefore show the delays between the M- and L-cone signals introduced *within* the visual system. As can be seen, some of the phase delays are substantial even at moderately high temporal frequencies, particularly for the M-cone signals. Such delays are inconsistent with the standard model of luminance, which, except for phase differences caused by the selective adaptation of the L cones by the long-wavelength field, predicts that no phase adjustments should be required. Notice also the abrupt changes in phase *between* intensity levels 3 and 4.

The continuous lines in Fig. 25 are fits of a vector model, in which it was assumed that sluggish and fast signals both contribute to the resultant M- and L-cone signals, but in different ratios depending on the cone type and intensity level. At levels 1 to 3, the dominant slow and fast signals are *+sL–sM* and *+fL+fM*, respectively, as illustrated in the lower neural circuit diagram of Fig. 25, whereas at level 4 they are *–sL+sM* and *+fL+fM*, as illustrated in the upper neural circuit diagram. According to the model, the polarities of the both the slow M- and the slow L-cone signals reverse between levels 3 and 4.

Note that although the sluggish signals *+sM–sL* and *+sL–sM* are spectrally opponent, they produce an achromatic percept that can be flicker photometrically cancelled with luminance flicker, rather than producing an R/G chromatic percept.

Chromatic Adaptation and the Sloan Notch Thornton and Pugh[107] measured test spectral sensitivity functions on fields of 560, 580, and 600 nm using a target that strongly favors chromatic detection. As illustrated in Fig. 17*a*, they found that the local minimum in spectral sensitivity, or Sloan notch, coincides with the field wavelength (i.e., it occurs when the target and background wavelengths are the same; i.e., homochromatic). As discussed in subsection "Sensitivity to Spectral Lights" in Sec. 11.5, the notch is thought to correspond to the target wavelength that produces a minimum or null in the L–M chromatic channel, so that the less-sensitive, achromatic channel takes over detection. For the notch to occur at the homochromatic target wavelength means that adaptation to the field has shifted the zero crossing or null in the cone-opponent mechanism to the field wavelength. Such a shift is consistent with reciprocal (von Kries) adaptation occurring independently in both the M and the L cones. This type of adaptation is plausible given that Weber's law behavior for detection will have been reached on the fairly intense fields used by Thornton and Pugh.[33] If first-site adaptation had fallen short of the proportionality implied by Weber's Law, then the Sloan notch would not have shifted as far as the homochromatic target wavelength.

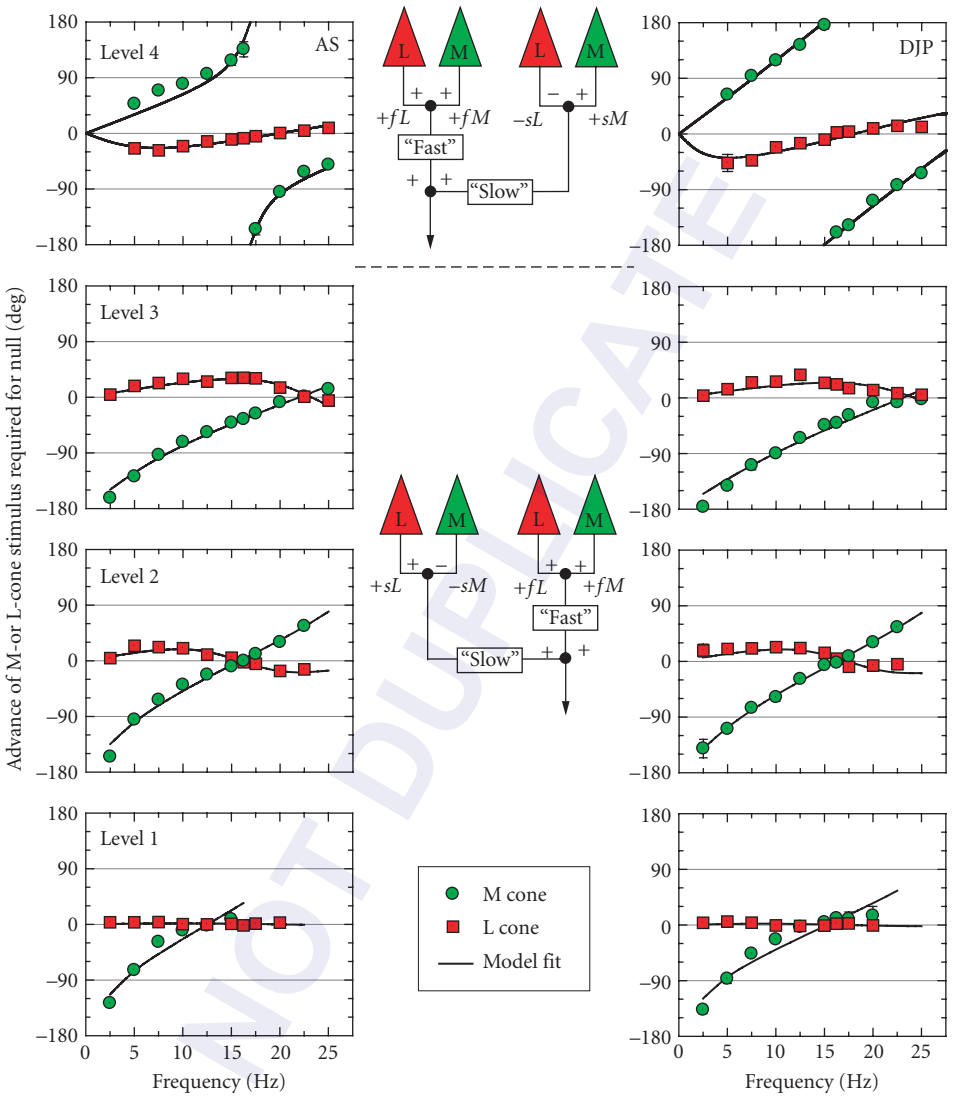

FIGURE 25 Large phase delays in the "luminance" channel. Phase advances of M-cone (green circles) or L-cone (red squares) stimuli required to flicker-photometrically null a 656-nm target for observers AS (left panels) and DJP (right panels) measured on 658-nm backgrounds of 8.93 (*Level 1*), 10.16 (*Level 2*), 11.18 (*Level 3*), or 12.50 (*Level 4*) $\log_{10}$ quanta s^{-1} deg^{-2}. The M-cone stimuli were alternating pairs of L-cone-equated 540 and 650 nm targets; and the L-cone stimuli were pairs of M-cone-equated 650- and 550-nm targets. The continuous lines are fits of a model in which the L- and M-cone signals are assumed to be the resultant of a fast signal (*f*) and a delayed slow signal (*s*) of the same or opposite sign. The predominant signals at each level are indicated by the wiring diagrams in the central insets (see Ref. 223).

As noted in Sec. 11.3, the idea that the zero or null point of an opponent second site always corresponds to the background field wavelength is due to von Kries adaptation is clearly an oversimplification. Were that the case, chromatic detection contours measured in cone contrast units would be independent of field wavelength, which they clearly are not (see subsection "Detection Contours and Field Adaptation" in Sec. 11.5). Similarly, chromatic sensitivity would be independent of field chromaticity at intensities at which Weber's law had been reached, which is also not the case in field additivity experiments (see next). In general, if first-site adaptation was precisely inversely proportional to the amount of background excitation, second-site opponent desensitization would play little or no role in adaptation to steady fields. It would, of course, still play an important role in contrast adaptation; that is, in adaptation to excursions around the mean adapting level.

Field Additivity By using mainly spectral backgrounds (but sometimes with fixed-wavelength auxiliary backgrounds), Stiles restricted his measurements to the spectrum locus of color space. Some of the most revealing failures of his model, however, occur in the interior volume of color space when two spectral backgrounds are added together in different intensity ratios. Given the expectation in Stiles' model that π-mechanisms should behave univariantly, bichromatic field mixtures should raise the threshold of a π-mechanism simply in accordance with the total quantum catch generated by those fields in that mechanism. For a linear mechanism, the effects of mixed fields, in other words, should be additive whenever only a single π-mechanism is involved. However, failures of field additivity can be subadditive, the mixed fields have less than the expected effect, or superadditive, when they have more than the expected effect. Subadditivity is an indication of opponency, and cases of subadditivity are thus another way that field experiments provide evidence of opponency.

Arguably the most interesting failures of field additivity occur under conditions that isolate Stiles' S-cone mechanisms, π_1 and π_3, as illustrated in Fig. 26. On a blue, 476-nm background, the threshold for a 425 nm target rises faster than Weber's law predicts (leftmost data set, dashed vs continuous lines), this is superadditivity and is consistent with S-cone saturation.[224,225] However, when a yellow, 590-nm background is added to the blue background, additivity typically fails. For lower 476-nm radiances (open circles, dashed vs continuous lines), superadditivity is found again,[226] whereas for higher 476-nm radiances (open and filled squares, open triangles) subadditivity is found.[227,228] Comparable failures of field additivity are found for the L-cone mechanism or π_5,[55,188] but less clearly for the M-cone mechanisms or π_4.[188,196,229,230]

First- and Second-Site Adaptation Pugh and Mollon[231] developed a model to account for the failures of field additivity and other "anomalies" in the S-cone pathway, which has been influential. They assumed that the S-cone signal can be attenuated by gain controls at two sites. Gain at the first site is cone-specific, being controlled in the case of π_1 and π_3 solely by excitation in the S cones. By contrast, gain at the cone-opponent second-site is controlled by the net difference between signals generated by the S cones and those generated by the two other cone types. Excursions at the second site either in the S-cone direction or in the L+M-cone direction reduce the gain of that site, and thus attenuate the transmitted S-cone signal. Sensitivity at the second site is assumed to be greatest when the S-cone and the L+M-cone signals are balanced. Superadditivity occurs when attenuation at the first and second sites work together, for example on a blue spectral background. Subadditivity occurs when the addition of a background restores the balance at the second site, for example when a yellow background is added to a blue one. The original version of the Pugh and Mollon[231] model is formalized in their Eqs. (1) to (3). Another version of the model in which the second-site "gain" is implemented as a bipolar static nonlinearity (see Fig. 6 of Ref. 227) is illustrated in Fig. 27. The nonlinearity is a sigmoidal function that compresses the response and thus reduces sensitivity if the input is polarized either in the +S or –(L+M) direction or in the L+M or –S direction. The presence of a compressive nonlinearity in the output of mechanisms is now generally accepted as an important extension of the basic model. Such nonlinearities form a critical piece of models that aim to account for discrimination as well as detection data (see subsection "Pedestal Experiments" in Sec. 11.5).

There is an inconsistency in the Pugh and Mollon scheme for steady-state adaptation. In order for first-site adaptation to be consistent with Weber's law ($\Delta I/I$ = constant), sensitivity adjustment is assumed to be reciprocal—any increase in background radiance is compensated for by a reciprocal

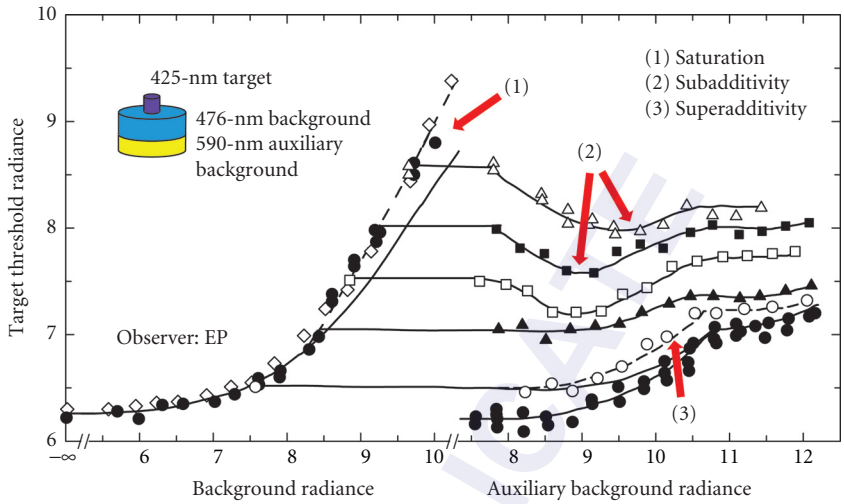

FIGURE 26 Field additivity failures. S-cone threshold data replotted from Fig. 1A of Pugh and Larimer.[228] The data are increment thresholds for a 425 nm, 200-ms duration, 1° diameter foveal target presented in the centre of 476-nm fields (filled circles and open diamonds, left curves), 590-nm fields (filled circles, right curves), and various bichromatic mixtures of the two. (A 590-nm field of at least 8.0 $\log_{10}$ quanta s^{-1} deg^{-2} was always added to the 476-nm field.) In the bichromatic mixture experiments a series of increasingly intense 590-nm fields, the intensities of which are indicated along the abscissa on the right, were added to a fixed intensity 476-nm field, the intensity of which corresponds to the abscissa associated with the dashed curve at target threshold radiance values corresponding to the data points at the lowest auxiliary background radiances. The shape of solid curves associated with the filled circles and open diamonds on the left and with the filled circles on the right is the standard Stiles threshold-versus-increment (tvi) template shape. The data provide examples of saturation (1), when the threshold elevation grows faster than Weber's law,[224,225] subadditivity (2), when the threshold elevation of the bichromatic mixture falls short of the additivity prediction,[227] and superadditivity (3), when the threshold elevation exceeds the additivity prediction.[226] Figure design based on Figs. 1A and 2 of Pugh and Larimer.[228] Units of radiance are log quanta sec^{-1} deg^{-2}.

decrease in gain. Consequently, the signal that leaves the first site (and potentially reaches the second site) should be independent of background radiance (see also "First-Site Adaptation" in Sec. 11.3). However, for the Pugh and Mollon model (and comparable models of first- and second-site adaptation) to work requires that the cone signals reaching the second site continue to grow with background radiance. To achieve this in their original model, they decrease the S-cone gain at the second site in proportion to the background radiance raised to the power n (where n is 0.71, 0.75, or 0.82 depending on the subject) rather than in proportion to the background radiance as at the first site ($n = 1$). Thus, the S-cone signal at the input to the second site continues to grow with background radiance, even though the signal at the output of the first site is constant. This scheme requires that the cone signal at second site somehow bypasses first-site adaptation, perhaps depending on signals at the border of the field[89] or on higher temporal frequency components, which are not subject to Weber's law.[52]

A now mainly historical issue is how much adaptation occurs at the cone photoreceptors. Although some evidence has suggested that relatively little adaptation occurs within photoreceptors until close to bleaching levels,[232,233] other compelling evidence suggests that significant adaptation occurs at much lower levels.[46–48] Measures of adaptation in monkey horizontal cells show that light adaptation is well advanced at or before the first synapse in the visual pathway, and begins at levels as low as 15 td.[234,235] Moreover, psychophysically, local adaptation has been demonstrated to occur with the resolution of single cones.[236–238] The available evidence supports a receptoral site of cone adaptation.

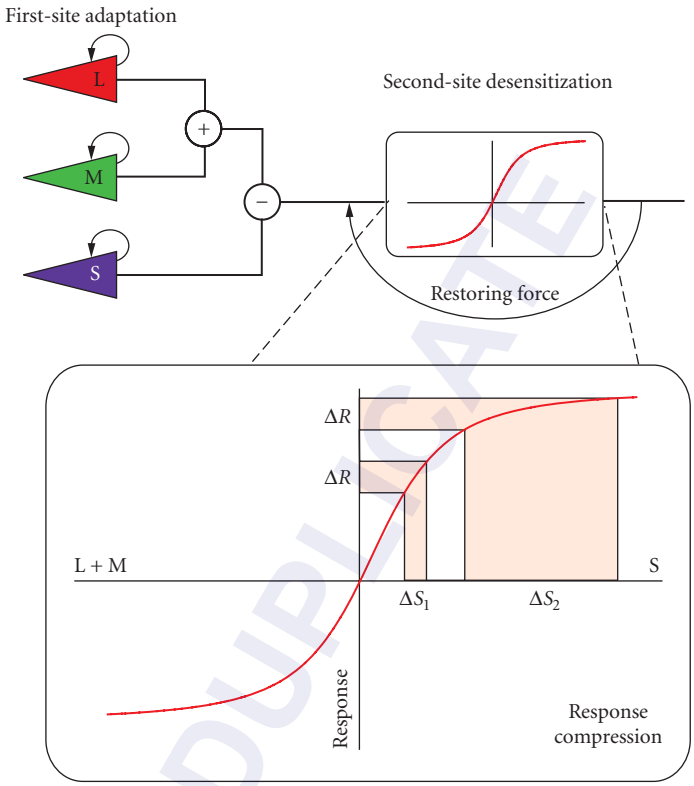

FIGURE 27 Pugh and Mollon cone-opponent model. Version of the Pugh and Mollon model[231] in which the cone-opponent, second-site desensitization is implemented at a bipolar static nonlinearity.[227] The nonlinearity is a sigmoidal function that compresses the response as the input is polarized either in the +S [or –(L+M)] direction or in the L+M or (–S) direction. The effect of the nonlinearity can be understood by assuming that the system needs a criterion change in response (ΔR) in order for a change in the input to be detected. At smaller excursions along the +S direction, a smaller change in the S-cone signal, ΔS_1, is required to produce the criterion response than the change in signal, ΔS_2, required at greater excursions. Sensitivity should be greatest when the polarization is balanced, and the system is in the middle of its response range.

Detection Contours and Field Adaptation Stromeyer, Cole, and Kronauer[61] measured cone contrasts in the L,M-cone plane (the plane defined by the $\Delta L/L$ and $\Delta M/M$ cone contrast axes, which includes chromatic L–M and achromatic L+M excursions) on spectral green, yellow, and red adapting backgrounds. Changing background wavelength moved the parallel chromatic contours for the detection of 200-ms flashes either outward (reducing sensitivity) or inward (increasing sensitivity). In general, background field wavelength strongly affects chromatic detection with sensitivity being maximal on yellow fields, declining slightly on green fields, and declining strongly on red fields. Since the slopes of the contours in contrast space are unaffected by these changes, the results again show that chromatic adaptation does not alter the relative weights of the M- and L-cone contrast inputs to the chromatic mechanism, but does change the sensitivity of the chromatically opponent second site. These data should be compared with the predictions shown in Fig. 8*a*. S-cone stimulation did not affect the L–M chromatic detection contours.[61]

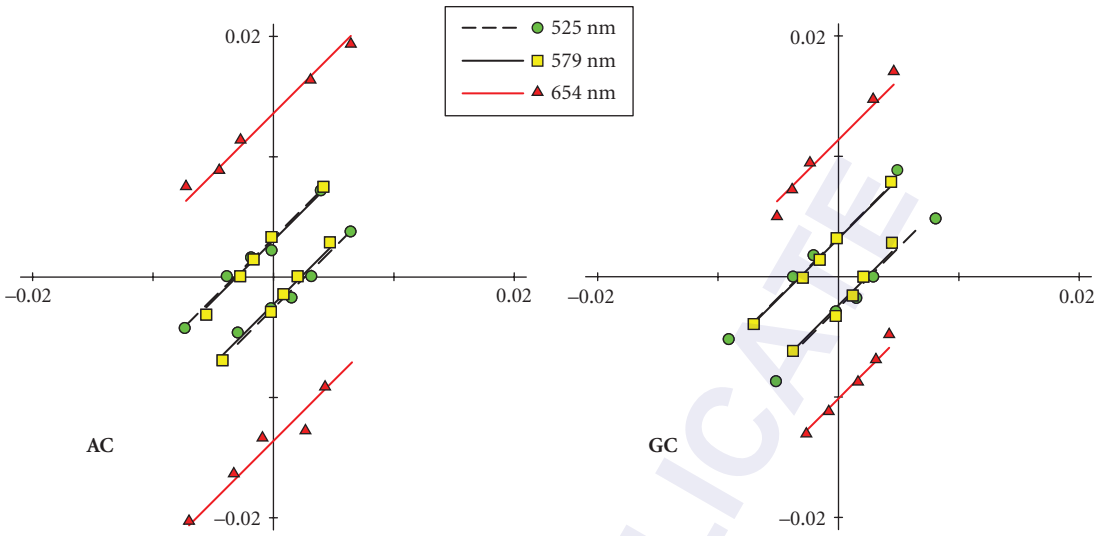

FIGURE 28 Second-site desensitization of L–M by steady fields. L–M detection contours in cone contrast space for two subjects measured by Chaparro, Stromeyer, Chen, and Kronauer[62] on 3000-td fields of 525 nm (green circles), 579 nm (yellow squares), and 654 nm (red triangles) replotted from their Fig. 4. $\Delta M/M$ is plotted along the ordinate and $\Delta L/L$ along the abscissa. The straight contours fitted to thresholds have slopes of 1, consistent with detection by an L–M mechanism with equal and opposite L- and M-cone contrast weights. Constant relative L- and M-cone weights are a characteristic of von Kries first-site adaptation. The displacement of the contour from the origin on the 654 nm field is characteristic of second-site adaptation.

Figure 28 shows a clear example of the effect of changing the background wavelength of 3000 td fields from 525 to 579 to 654 nm from Fig. 4 of Ref. 62. Consistent with Stromeyer, Cole, and Kronauer,[61] the L–M chromatic detection contours have positive unity slopes, and move outward from the origin as the wavelength lengthens to 654 nm.

The relation between these detection contours and spectral sensitivity data is nicely illustrated by replotting the spectral sensitivity data as cone contrasts. Figure 17*b*, shows the spectral sensitivity data of Thornton and Pugh[107] replotted in cone contrast space by Eskew, McLellan, and Giulianini.[89] The replotted spectral sensitivity data have the same characteristics as the detection contours shown in Fig. 28.

Habituation or Contrast Adaptation Experiments The extent of second-site desensitization produced by steady backgrounds is fundamentally limited by first-site adaptation. A natural extension of the field sensitivity method is to temporally modulate the chromaticity or luminance of the background around a mean level, so partially "bypassing" all but the most rapid effects of first-site adaptation and enhancing the effects of second-site desensitization. Moreover, if the spectral properties of the postreceptoral detection mechanisms are known, one mechanism can be selectively desensitized by adapting (or habituating) to modulations along a cardinal axis, which are invisible or "silent" to the other mechanisms (see Ref. 239 for a review of silent substitution methods and their origins).

In an influential paper, Krauskopf, Williams, and Heeley[14] used habituation (the loss of sensitivity following prolonged exposure, in this case, to a temporally varying adapting stimulus) to investigate the properties of what they referred to as the "cardinal mechanisms" (see also Ref. 240). They used a 50 td, 2° diameter field made up of 632.5-, 514.5-, and 441.6-nm laser primaries. Following habituation to 1-Hz sinusoidal modulations (a 30-s initial habituation, then 5-s top-ups between test presentations) that were either chromatic (in the L–M, or S directions at equiluminance), or achromatic (L+M+S), or intermediate between these three directions, the detection sensitivity for Gaussian target pulses ($\sigma = 250$ ms) was measured in various directions of color space.

Figure 29 shows the results for observer DRW. The red circles show the losses of sensitivity and the black circles the increase in sensitivity following habituation to stimuli modulated in the directions of the orange arrows shown in all panels. These results should be compared with the predictions shown in Fig. 11. In their original paper, Krauskopf, Williams, and Heeley[14] concluded that their results showed that habituation occurred independently along each of the three cardinal mechanism axes: L–M, S, and L+M. Thus, the sensitivity losses to habituation along one axis were mainly confined to targets modulated along the same axis, whereas the losses to habituation along axes intermediate to the cardinal ones involved losses in both mechanisms.

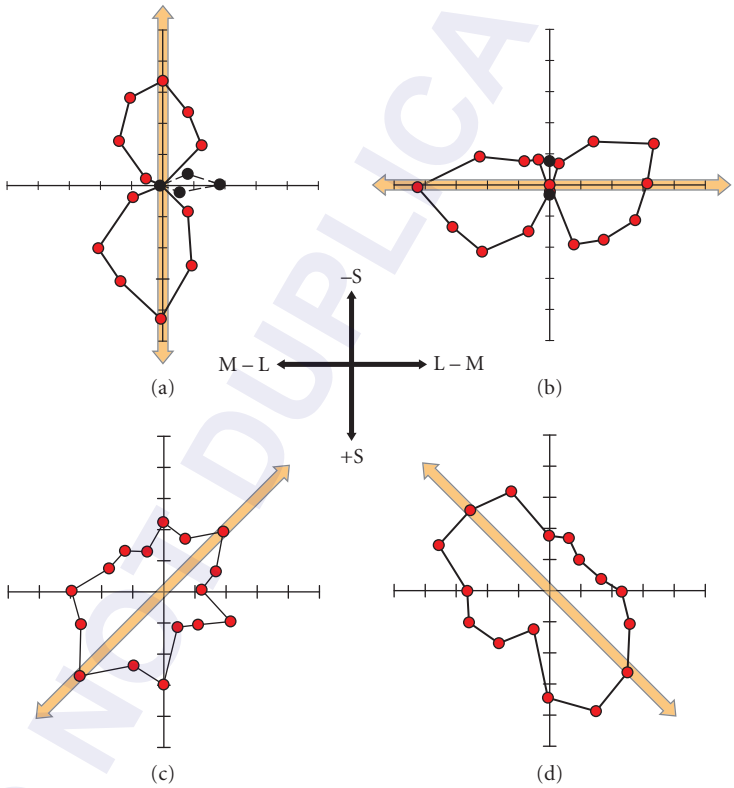

FIGURE 29 Habituation. Data from Fig. 6 of Krauskopf, Williams, and Heeley[14] plotted in the canonical format shown in Fig. 11. These data are for stimuli that silence the L+M mechanism and reveal the properties of the L–M and S–(L+M) mechanisms plotted in a color space in which the horizontal axis corresponds to stimuli that only stimulate the L–M mechanism and the vertical axis corresponds to stimuli that only stimulate the S–(L+M) mechanism (by modulating S). (*a*) and (*b*) Results for habituation stimuli oriented along the horizontal and vertical axes, respectively. (*c*) and (*d*) Threshold changes for habituation stimuli along intermediate directions. The pattern of results is in qualitative agreement with the predictions developed in Figs. 9 to 11, and provides evidence for second-site adaptation in two opponent-discrimination mechanisms. The red circles plot increases in threshold following habituation, whereas the black circles plot cases where threshold was slightly decreased, rather than increased, by habituation.

Three years later, after a more rigorous analysis using Fourier methods, Krauskopf, Williams, Mandler, and Brown[241] concluded instead that the same data showed that habituation could desensitize multiple "higher-order" mechanisms tuned to intermediate directions in the equiluminant plane between the L–M and S cardinal directions. Yet, in terms of the magnitude of the selective losses, those along the intermediate axes are very much second-order effects compared with those found along the cardinal L–M or S axes. These second-order effects are not particularly compelling evidence for the existence of higher-order mechanisms, because they might also be due to more mundane causes, such as the visual distortion of the habituating stimuli or low-level mechanism interactions. The strong conclusion that can be drawn from the habituating experiments is that selective losses are largest when the habituating stimuli are modulated along the S, L–M, or L+M+S cardinal axes. The evidence for higher-order mechanisms along intermediate axes is secondary. Other workers have suggested that instead of there being multiple mechanisms, the cardinal mechanisms adapt to decorrelate the input signals so that their mechanism vectors rotate.[242–244]

Noise-Masking Experiments Another field method used to investigate visual mechanisms is the introduction of masking noise to raise detection threshold. The spectral properties of the underlying mechanisms can then be investigated by varying either the chromaticity and/or luminance of the target (which, if the noise is held constant, is strictly speaking a test method) or by varying the chromaticity and/or luminance of the noise. As with habituating stimuli, the noise stimuli can be fashioned to excite one or other receptoral or postreceptoral mechanism. However, whereas habituation is assumed to have little effect at the first site, noise masking can potentially raise thresholds at both the first and the second sites. Although it is possible to selectively excite different first-stage cone mechanisms by modulating the noise along cone-isolating vectors or to selectively excite different second-stage color-discrimination mechanisms by modulating the noise along cardinal vectors, each noise stimulus inevitably excites both first- and second-stage mechanisms. As described in section "Sites of Limiting Noise" in Sec. 11.3 with respect to internal noise (see Figs. 12 and 13), changing the balance of noise at the first and second sites has the potential of rotating the detection contours in color space. Consequently, the discovery of detection contours for some noise vectors that do not align with the assumed low-level mechanism axes does not necessarily imply the existence of high-order mechanisms.

Gegenfurtner and Kiper[245] measured thresholds for a 1.2-cpd Gabor patch ($\sigma = 0.8°$ in space and 170 ms in time) in the presence of noise modulated in different directions around white in the L,M plane of DKL space. The target was either modulated in the L–M or L+M+S directions or in an intermediate direction along which the target color appeared to change between bright red and dark green. For all three directions masking was maximal when the noise was in the target direction, and minimal when it was in the orthogonal direction, even if the target direction did not lie along a cardinal axis. These findings suggested to the authors that there must be multiple mechanisms, some tuned to axes other than the cardinal ones.

The mechanisms derived by Gegenfurtner and Kiper, however, combined cone inputs nonlinearly. In a linear mechanism, the effectiveness of the noise should depend on the cosine between the cardinal direction and the noise direction, but Gegenfurtner and Kiper[245] found mechanisms that were more narrowly tuned. Curiously, when square rather than Gabor patches were used, evidence for multiple mechanisms was not found.

The central findings of Gegenfurtner and Kiper have been contradicted in other papers, some of which used comparable techniques. Sankeralli and Mullen[246] found evidence for only three mechanisms in $\Delta L/L$, $\Delta M/M$, $\Delta S/S$ cone contrast space using a 1-cpd semi-Gabor patch ($\sigma = 1.4°$ vertically, and 4° horizontally with sharp edges in space, and $\sigma = 170$ ms in time). Mechanism tuning was found to be linear in cone contrast units with a cosine relationship between the noise effectiveness and the angle between the mechanism and noise vectors. Giulianini and Eskew[175] working in the $\Delta L/L$, $\Delta M/M$ cone contrast plane using 200-ms circular Gaussian blobs ($\sigma = 1°$) or horizontal Gabor patches (1 cpd, $\sigma = 1°$) similarly found evidence for only two mechanisms in that plane. Their results were consistent with a linear L–M mechanism with equal cone contrast weights, and a linear L+M mechanism with greater L-than M-cone weights.

Some of Giulianini and Eskew's[175] results from their Fig. 5 are shown in Fig. 20, for noise masks in the chromatic direction (Fig. 20*a* and *c*) and in the M-cone direction (Fig. 20*b* and *d*). Their interpretation

of the data is shown by the solid contours in Fig. 20*a* and *b*. Their model is consistent with detection by two mechanisms with roughly constant L–M contours across the two noise directions, but L+M contours that rotate slightly away from the M-cone axis in the presence of M-cone noise. However, as our elliptical fits in Fig. 20*c* and *d* show, other interpretations of their data are also plausible; most of the data in the presence of chromatic and M-cone noise can be described by ellipses, but the major axes of the ellipses do not align with the noise directions.

Subsequently, Eskew, Newton, and Giulianini[179] extended these measurements to include S-cone modulations in the equiluminant plane, and again found no evidence for higher-order mechanisms in detection or near-threshold discrimination tasks. Some of their results are shown in Fig. 21. These data seem more consistent with a rounded parallelogram than an ellipse. All three studies just described, in contradiction to Gegenfurtner and Kiper,[245] found that the directions at which noise masking was maximal more closely aligned with the expected mechanism directions than with the noise directions. However, see also Hansen and Gegenfurtner.[247]

In a related study, D'Zmura and Knoblauch[248] did find evidence for multiple mechanisms within the equiluminant plane of DKL space. They used "sectored" noise made up of noise centered on the signal direction combined with noise of various strengths in the orthogonal direction. Contrast thresholds for "yellow," "orange," "red," and "violet" signals ($\sigma = 2.4°$ in space and 160 ms in time) were independent of the strength of the orthogonal noise, which suggests the existence of linear broad-band mechanisms tuned to each of the signal directions (for which the orthogonal direction is a null direction). Like Gegenfurtner and Kiper[245] multiple mechanisms were found, but they were broadly rather than narrowly tuned. D'Zmura and Knoblauch[248] argued that narrow tuning can result from off-axis looking in which subjects switch among multiple linear broad-band detection channels to reduce the noise and maximize the detectability of the signal.

An important caveat about D'Zmura and Knoblauch's experiments is that they used the 1924 $V(\lambda)$ function to equate luminance (see p. 3118 of Ref. 248). Because $V(\lambda)$ substantially underestimates luminous efficiency at short wavelengths, modulations of their blue phosphor will produce a luminance signal in their nominally equiluminant plane, which could complicate the interpretation of their results. For example, nominally S-cone modulations might have superimposed and cancelling L+M modulations, and some signal directions might be luminance-detected (and therefore artifactually independent of chromatic noise in the orthogonal direction). Nonetheless, Monaci et al.[249] using a related technique, but a better definition of luminous efficiency, came to the same conclusion.

Most recently, Giulianini and Eskew[250] used noise masking to investigate the properties of the S–(L+M) mechanism, and, in particular, whether or not the mechanism responds linearly to noises in different directions of cone contrast space. Though the effects of noise on the L–M mechanism are linear, for both polarities of the S–(L+M) mechanism (i.e., for +S and –S detection) its effects are nonlinear.[250]

Chromatic Discrimination

Basic Experiments Chromatic discrimination is the ability to distinguish the difference between two test lights that differ in chromaticity. The prototypical set of chromatic discrimination data are the discrimination ellipses of MacAdam[251] originally plotted as CIE *x,y* chromaticity coordinates, and thus in a color space that is not especially conducive to understanding the underlying mechanisms. These ellipses were determined from the variability of repeated color matches made at 25 different reference chromaticities in the CIE color space. Le Grand[252] reanalyzed MacAdam's data and found that much of the variability between the ellipses could be accounted for by considering variability along the tritan (S) dimension and along the cone-opponent (L–M) dimension. Interpretation of MacAdam's data is complicated by the fact that each ellipse was measured for a different state of adaptation, namely that determined by the mean match whose variability was being assessed.

Boynton and Kambe[253] made a series of discrimination measurements in the equiluminant plane along the important S and L–M color directions. They found that discrimination along the S axis depended on only S-cone excitation level; specifically that $\Delta S/S+S_0 = \text{constant}$, where S is the background excitation and S_0 is an "eigengrau" or "darklight" term. At high S-cone excitation levels, as S_0 becomes less significant, Weber's law holds (i.e., $\Delta S/S$ is approximately constant).[254–256] A similar

conclusion was reached by Rodieck[257] in his reanalysis of MacAdam's[251] data (see Figs. XXIII-10 and XXIII-11 of Ref. 257). When plotted in a normalized cone excitation diagram, chromaticity ellipses for individual subjects have similar shapes regardless of the reference chromaticity.[258]

Chromatic Discrimination Near Detection Threshold Under conditions that isolate the chromatic mechanisms, near-threshold lights can be indistinguishable over fairly extended spectral or chromaticity ranges. On a white background using 0.75° diameter, 500-ms duration test discs, Mullen and Kulikowski[197] found that there were four indistinguishable wavelength ranges that corresponded to the threshold lights appearing orange (above 585 nm), pale yellow (566–585 nm), green (c. 490– 566 nm), and blue (c. 456–490 nm), and that there was weaker evidence for a fifth range that appeared violet (< c. 456 nm). Importantly, too, these boundaries were independent of the wavelength *differences* between pairs of lights, which suggests that each mechanism is univariant. These results suggest the existence of four or five distinct unipolar mechanisms at threshold.[197] Unlike the bipolar mechanisms (L–M) and S–(L+M), a unipolar mechanism responds with only positive sign. The bipolar (L–M) mechanism, for example, may be thought of as consisting of two unipolar mechanisms |L–M| and |M–L|, each of which is half-wave rectified (see "Unipolar versus Bipolar Chromatic Mechanisms" in Sec. 11.6).

Eskew, Newton, and Giulianini[179] looked at discrimination between near-threshold Gabor patches modulated in various directions in the equiluminant plane. Noise masking was used to desensitize the more sensitive L–M mechanism and thus reveal more of the S-cone mechanism, and perhaps higher-order mechanisms. Despite the presence of noise they found evidence for only four color regions within which lights were indiscriminable. These regions corresponded to detection by the four poles of the classical cone-opponent mechanisms |L–M|, |M–L|, |S–(L+M)|, and |(L+M)–S|. Some of their results are shown in Fig. 21. The four colors shown in the three outer arcs of the figure correspond to the four regions within which lights were indiscriminable. The data in each semicircular polar plot (filled squares) show the discriminability of a given chromatic vector from the standard vector shown by the arrow. The open circles are model predictions (see legend). There is no evidence here for higher-order color mechanisms. In a later abstract, Eskew, Wang, and Richters[259] reported evidence also from threshold level discrimination measurements for a fifth unipolar mechanism, which from hue-scaling measurements they identified as generating a "purple" hue percept (with the other four mechanisms generating blue, green, yellow, and red percepts).

Thus, the work of both Mullen and Kulikowski[197] and Eskew et al.[179,259] may be consistent with five threshold-level color mechanisms. By contrast, Krauskopf et al.[241] found evidence for multiple mechanisms. They measured the detection and discrimination of lights that were 90° apart in the equiluminant DKL plane and modulated either along cardinal or intermediate axes. No difference was found between data from the cardinal and noncardinal axes, which should not be the case if only cardinal mechanisms mediate discrimination. The authors argued that stimuli 90° apart modulated along the two cardinal axes should always be discriminable at threshold, because they are always detected by different cardinal mechanisms. In contrast, stimuli 90° apart modulated along intermediate axes will only be discriminable if they are detected by different cardinal mechanisms, which will not always be the case. Care is required with arguments of this sort, because angles between stimuli are not preserved across color space transformations (i.e., they depend on the choice of axes for the space and also on the scaling of the axes relative to each). More secure are conclusions based on an explicit model of the detection and discrimination process. Note that this caveat applies not just here but also to many studies that rely on intuitions about the angular spacing of stimuli relative to each other.

Clearly, colors that are substantially suprathreshold and stimulate more than one color mechanism should be distinguishable. However, the range of suprathreshold univariance can be surprisingly large. Calkins, Thornton, and Pugh[111] made chromatic discrimination and detection measurements in the red-green range from 530 to 670 nm both at threshold and at levels up to 8 times threshold. Measurements were made with single trough-to-trough periods of a 2-Hz raised-cosine presented on a yellow field of 6700 td and 578 nm. The observers' responses were functionally monochromatic either for wavelengths below the Sloan notch (between 530 and 560 nm) or for wavelengths above the Sloan notch (between 600 and 670 nm); that is, any two wavelengths within each range were indistinguishable at some relative intensity. The action spectra for indiscriminability above threshold

and for detection at threshold were consistent with an L–M opponent mechanism. Discrimination for pairs of wavelengths either side of the Sloan notch was very good, and between stimuli near the notch and stimuli further away from the notch was also good. The good discriminability near the notch is consistent with a diminution of |L–M| as the signals become balanced and with the intrusion of another mechanism, which between 575 and 610 nm has a spectral sensitivity comparable with the photopic luminosity function [although whether or not this corresponds to luminance or the L+M lobe of S–(L+M) is unclear]. For full details, see Ref. 111.

The results reviewed in this section are especially important because they suggest that each color mechanism is not only univariant, but behaves like a "labeled line." As Calkins et al. note on their p. 2365 "Phenomenologically speaking, the discrimination judgments [in the monochromatic regions] are based upon variation in perceptual brightness."

Pedestal Experiments Discrimination experiments, sometimes called "pedestal experiments" can be used to investigate the properties of mechanisms over a range of contrasts both above and below the normal detection threshold. In a typical pedestal experiment, an observer is presented with two identical but brief "pedestal" stimuli, separated either in space or in time, upon one of which a test stimulus is superimposed. The observer's task is to discriminate in which spatial or temporal interval the test stimulus occurred. By presenting the test and pedestal stimuli to the same mechanism (sometimes called the "uncrossed" condition), it is possible to investigate the properties of chromatic and luminance mechanisms separately. By presenting the test and pedestal stimuli to different mechanisms (sometimes called the "crossed" condition), it is possible to investigate interactions between them. The presentation of the pedestals causes a rapid shift away from the mean adapting state. The transient signals produced by these shifts will be affected by instantaneous or rapid adaptation mechanisms, such as changes in the response that depend on static transducer functions, but not by more sluggish adaptation mechanisms.

When pedestal and test stimuli are both uncrossed and of the *same* sign, the discrimination of the test stimulus typically follows a "dipper" function as the pedestal contrast is increased. As the pedestal contrast is raised from below its contrast threshold, the threshold for detecting the test stimulus falls by a factor of about two or three, reaching a minimum just above the pedestal threshold, after which further increases in pedestal contrast hurts the detection of the test.[260–265] Facilitation has been explained by supposing there is a transducer (input-output) function that accelerates at lower contrasts, thus causing the difference in output generated by the pedestal and test-plus-pedestal to increase with pedestal contrast (e.g., Refs. 263, 266). Alternatively, it has been explained by supposing that the pedestal, because it is a copy of the test, reduces detection uncertainty.[267] The dipper function is found both for uncrossed luminance and uncrossed chromatic stimuli, and has similar characteristics for the two mechanisms.[169,268,269] When pedestals and test stimuli are uncrossed but of the *opposite* sign, increases in pedestal contrast first raise threshold—consistent with subthreshold cancellation between the pedestal and test. As the pedestal approaches its own threshold, however, discrimination threshold abruptly decreases, after which further increases in pedestal contrast hurt detection of the test for both uncrossed luminance and uncrossed chromatic conditions.[169] The increase followed by decrease in threshold has been referred to as a "bumper" function.[270] The dipper and bumper functions found under uncrossed conditions show clear evidence of subthreshold summation or cancellation. Figure 30*a* shows examples of the dipper (upper right and lower left quadrants) and bumper functions (upper left and lower right quadrants) for uncrossed L–M chromatic pedestals and targets from Cole, Stromeyer, and Kronauer.[169]

Presenting the pedestals and test stimuli to different mechanisms in the crossed conditions is a potentially powerful way of investigating how the luminance and chromatic mechanisms interact. For example, if the two mechanisms interact before the hypothesized accelerating transducer, then the crossed and uncrossed dipper and bumper functions should be comparable and should also show evidence for subthreshold interactions. If the chromatic and luminance mechanisms are largely independent until later stages of visual processing, then subthreshold effects should be absent, but given the uncertainty model suprathreshold facilitation might still be expected.

The results obtained with crossed test and pedestal stimuli, however, remain somewhat equivocal. Luminance square-wave gratings or spots have been shown to facilitate chromatic discrimination.[194,271]

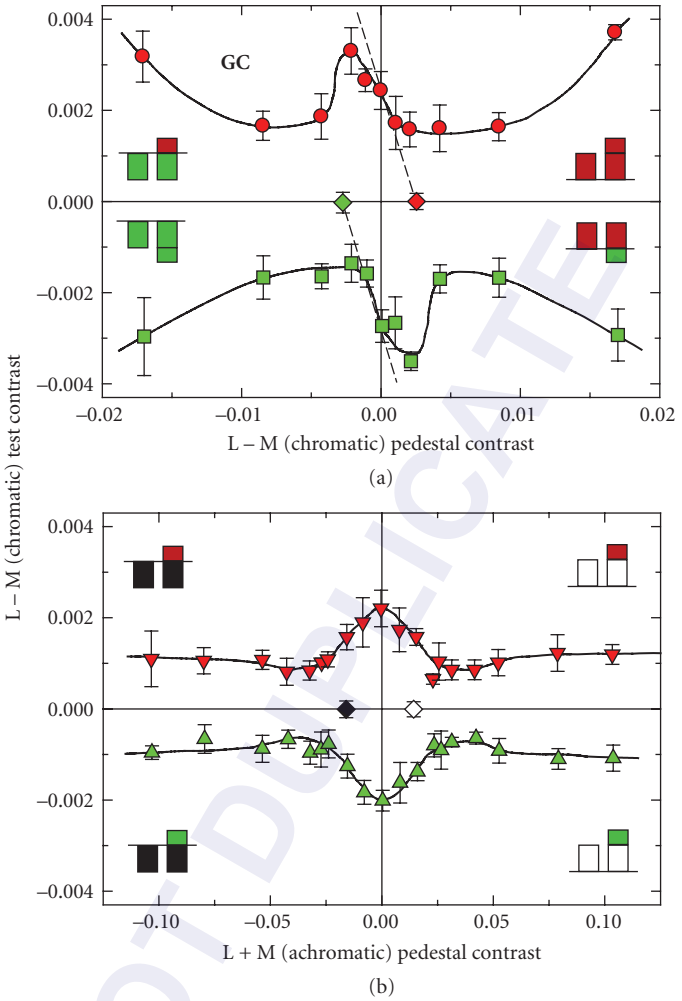

FIGURE 30 Pedestal effects. (*a*) Detection of chromatic L–M tests on chromatic L–M pedestals. As indicated by the icons in each quadrant, the data points are the thresholds for detecting red chromatic targets (red circles) on either red (upper right quadrant) or green (upper left quadrant) chromatic pedestals, or for detecting green chromatic targets (green squares) on either red (lower right quadrant) or green (lower left quadrant) pedestals. The diamonds show the thresholds for detecting the red (red diamond) or green (green diamond) chromatic pedestals alone. The dashed lines show predictions that the discrimination of the presence of the test depends only on the intensity of the test plus the pedestal (which implies that pedestal alone is ineffectual). (*b*) Detection of chromatic L–M tests on achromatic L+M pedestals. As indicated by the icons, the data are the thresholds for detecting red chromatic targets (red inverted triangles) on incremental (upper right quadrant) or decremental (upper left quadrant) luminance pedestals, or for detecting green chromatic targets (green triangles) on incremental (lower right quadrant) or decremental (lower left quadrant) luminance pedestals. The diamonds show the thresholds for detecting the incremental (open diamond) or decremental (filled diamond) luminance pedestals alone. (*Data replotted from Figs. 4 and 5 of Cole, Stromeyer, and Kronauer.*[169] *Design of the figure based on Fig. 18.10 of Eskew, McLellan, and Giulianini.*[89])

Using sine-wave gratings, De Valois and Switkes[265] and Switkes, Bradley, and De Valois[268] found that crossed facilitation and masking was asymmetric: for luminance pedestals and chromatic tests they found facilitation and no masking, but for chromatic pedestals and luminance tests they found no facilitation and strong masking. This curious asymmetry has not always been replicated in subsequent measurements. Using spots, Cole, Stromeyer, and Kronauer[169] obtained equivalent results for crossed luminance pedestals and chromatic tests and for crossed chromatic pedestals and luminance tests. They found in both cases that increasing the contrast of the crossed pedestal had little effect on test threshold until the pedestal approached or exceeded its own threshold by a factor of two or more, and that further increases in pedestal contrast had little or no masking effect.[169] Figure 30*b* shows examples of their crossed luminance and chromatic results. Similarly, Mullen, and Losada[269] found facilitation for both types of crossed pedestals and tests when the pedestal was suprathreshold, but unlike Cole, Stromeyer, and Kronauer[169] they found crossed masking for higher pedestal contrasts. Chen, Foley, and Brainard,[272] however, obtained results that were more consistent with De Valois and Switkes[265] and Switkes, Bradley, and De Valois.[268] They used spatial Gabors (1 cpd, 1° standard deviation) with a Gaussian temporal presentation (40-ms standard deviation, 160-ms total duration), and investigated the effects of targets and pedestals presented in various directions of color space. They found masking for all target-pedestal pairs and facilitation for most target-pedestal pairs. The exceptions were that (1) equiluminant pedestals did not facilitate luminance targets, and (2) tritan (blue/yellow) pedestals facilitated only tritan targets.

So, what does all this mean? The fact that the crossed facilitation, when it is found, occurs mostly with suprathreshold pedestals[169,268,269] suggests that the interaction occurs after the stages that limit the thresholds in the chromatic and luminance mechanisms. This is surprising, given that center-surround L–M neurons respond to both chromatic and luminance gratings (see subsection "Multiplexing Chromatic and Achromatic Signals" in Sec. 11.5). This early independence is supported by findings with gratings that the crossed facilitation is independent of the spatial phase of the gratings.[268,269] However, the facilitation is not found with crossed dichoptic pedestals and tests. The finding that crossed facilitation survives if the luminance pedestal is replaced with a thin ring[169] suggests that it might be due to uncertainty reduction. However, yes-no psychometric functions and receiver operating characteristics show clearly that the facilitation of chromatic detection by luminance contours is inconsistent with the uncertainty model.[177] To explain their results, Chen, Foley, and Brainard[273] presented a model made up of three postreceptoral channels with separate excitatory inputs (producing facilitation), but each with divisive inhibition aggregated from all channels (producing masking).

Krauskopf and Gegenfurtner[255] performed a series of experiments in which chromatic discrimination was measured after an abrupt change in chromaticity away from an equal-energy-white adapting light (see also Refs. 274, 275). The change in chromaticity was effected by simultaneously presenting four 36-min diameter discs for 1 s. Three of the discs were of the same chromaticity, but the fourth was slightly offset from the others. The observer's task was to identify which disc was different. The task can be thought of as the presentation of three stimuli defined by a "pedestal" color vector from the white point with the fourth stimulus being defined by the vector sum of the pedestal vector plus a "test" vector.[89] The experiments were carried out in the DKL equiluminant plane at a luminance of 37 cd/m^2. The discrimination of a test vector along one of the cardinal axes was found to deteriorate if the pedestal vector was along the same axis, but was relatively unaffected if the pedestal vector was along the other axis. Color discrimination, therefore, depended primarily on the L–M and S–(L+M) mechanisms nominally isolated by modulations along the cardinal axes.[255] A more detailed determination of the shapes of chromatic discrimination ellipses for pedestal and test vectors along 16 color directions was also consistent with discrimination being determined by the cardinal mechanisms, but there was also evidence for another mechanism orientated along a blue-green to orange axis, from 135 to 315° in the DKL space.[255] This might reflect the existence of a higher-level mechanism, but it might also be consistent with other explanations. Maintaining the phosphors at 37 cd/m^2 [a photometric measure defined by the discredited CIE $V(\lambda)$ function that underestimates luminous efficiency in the blue and violet] results in modulation of the blue phosphor at nominal "equiluminance" producing a luminance (L+M) axis close to the blue-green axis. The effect of such a signal is hard to predict, but could affect the sensitivity of the S–(L+M) mechanism by

cancelling S, or it could be detected by L+M. Another possibility is that the evidence for an additional mechanism might instead reflect a small S-cone contribution to L–M, which would rotate the L–M mechanism axis.[89]

Color Appearance and Color Opponency

When viewed in isolation (i.e., in the "aperture" mode), monochromatic lights have characteristic color appearances. Across the visible spectrum hues vary from violet through blue, blue-green or cyan, green, yellow-green, yellow, orange, and red.[276] Yet, however compelling these colors might seem, they are private perceptions. Consequently, to investigate them, we must move away from the safer and more objective psychophysical realms of color matching, color detection, and color discrimination, and rely instead on observers' introspections about their perceptual experiences (see Ref. 277 for a related discussion of "Class A" and "Class B" observations). Experiments that depend upon introspection are an anathema to some psychophysicists, yet they represent one of the few methods of gaining insights into how color is processed beyond the early stages of the visual system. As long as the limitations of the techniques are recognized, such experiments can be revealing. In addition, it is of interest to understand color appearance per se, and to do so requires the use of subjective methods in which observers report their experience.

Physiological measurements of the spectral properties of neurons in the retina and LGN are generally inconsistent with the spectral properties of color-appearance mechanisms, which suggests that color appearance is likely to be determined by cortical processes (see, e.g., Ref. 18). Relative to the input at the photoreceptors, the relevant neural signals that eventually determine color appearance will have undergone several transformations, likely to be both linear and nonlinear, before they reach the cortex. Despite this many models of color appearance are based on the assumption that appearance can be accounted for by mechanisms that linearly combine cone inputs (see Sec. 11.4). As we will see later, this is at best an approximation, at least for some aspects of color appearance. One reason for the failures of linearity may be that the suprathreshold test stimuli used to probe appearance are often adapting stimuli that intrude significantly on the measurements. That is, unlike in detection experiments where near-threshold tests can reasonably be assumed not to perturb the adapted state of the visual system very much, nonlinear adaptive processes cannot be ignored even for nominally steady-state color-appearance measurements, except perhaps under some contrived experimental conditions (see subsection "Linearity of Color-Opponent Mechanisms" in Sec. 11.5).

Opponent-Colors Theory Color appearance is often conceptualized in terms of Hering's opponent-color theory; that is, in terms of the perceptual opposition of red and green (R/G), blue and yellow (B/Y), and dark and light. In many versions of the model, the opponent mechanisms are assumed, either explicitly or implicitly, to combine their inputs from cones in a linear fashion.[11,12,18,19,29,76,278–282] Stage 3 of Fig. 4 represents a version of the linear model derived by the simple combinations of cone-opponent mechanisms (see subsection "Three-Stage Zone Models" in Sec. 11.6 for details).

The assumption of linearity constrains and simplifies the predicted properties of the color-opponent mechanisms. For example, under this assumption each opponent mechanism is completely characterized by its spectral response. As a function of wavelength, the R/G opponent mechanism responds R at both short and long wavelengths, corresponding to the red constituent in the appearance of both short- and long-wavelength lights, and responds G at middle wavelengths. The B/Y mechanism responds B at shorter wavelengths and Y at longer wavelengths. Each response (R, G, Y, or B) is univariant, and the responses of opposed poles (R vs. G, and B vs. Y) are mutually exclusive. The colors of lights detected solely by the same pole of a given mechanism cannot be distinguished at threshold, but lights detected by different poles can. In the model, color appearance depends on the relative outputs of the color-opponent appearance mechanisms. The individual mechanisms signal one opponent color or the other (e.g., redness or greenness) in different strengths, or a null.

The wavelength at which the opponent response of a mechanism changes polarity is a zero crossing for that mechanism, at which its response falls to zero. These zero crossings correspond to the unique hues. Unique blue and yellow are the two zero crossings for the R/G mechanism, and unique green and red are the two zero crossings for the Y/B mechanism. Unique red does not appear in plots

of valence against wavelength because it is extra-spectral (i.e., it has no monochromatic metamer and can only be produced by a mixture of spectral lights). Another extra-spectral color is white, which corresponds to an "equilibrium color" for *both* the R/G and B/Y mechanisms. A property of opponent-color mechanisms is that both the R/G and the Y/B mechanisms do not respond to a suitably chosen broadband white stimulus (such as an equal energy white). Thus, the sum of the outputs of the positive and negative lobes of each mechanism in response to such stimuli should be zero.

Tests of the assumptions of linearity of opponent-colors mechanisms are discussed below (see subsection "Linearity of Color-Opponent Mechanisms" in Sec. 11.5). See also Hurvich[283] for more details of opponent colors theory.

Spectral Properties of Color-Opponent Mechanisms Several techniques have been used to investigate the spectral properties of the color-opponent mechanisms. Most rely on the assumption that opponent-color mechanisms can be nulled or silenced by lights or combinations of lights that balance opposing sensations. The null may be achieved experimentally by equating two lights so that their combination appears to be in equilibrium (see section "Appearance Test Measurements and Opponency" in Sec. 11.4). A closely related alternative is to find single spectral lights that appear to be in equilibrium for a particular mechanism (e.g., that appear neither red nor green, or neither blue nor yellow). Another related technique is hue scaling, in which lights are scaled according to how blue, green, yellow, or red they appear. Thus, lights that are rated 100 percent blue, green, yellow, or red are equilibrium or unique hues.

Hue scaling Despite the variety of color terms that could be used to describe the colors of lights, observers require only four—red, yellow, green, and blue—to describe most aspects of color appearance.[6,7] Other colors such as orange can be described as reddish-yellow, cyan as bluish-green, purple as reddish-blue, and so on. The need for just four color terms is consistent with opponent-colors theory. By asking observers to scale how blue, green, yellow, and blue spectral lights appear, hue scaling can be used to estimate the spectral response curves of the opponent mechanisms.[21,284–286] A cyan, for example, might be described as 50-percent green, 50-percent blue, and an orange as 60-percent red and 40-percent yellow. Figure 31 shows hue scaling data obtained by De Valois et al.,[21] who instead of using spectral lights used equiluminant modulations in DKL space, the implications of which are discussed below. Hue-scaling results have been reported to be consistent with hue-cancellation valence functions,[286] but inconsistencies have also been reported.[287]

Color-opponent response or valence functions As introduced in section "Appearance Test Measurements and Opponency," the phenomenological color-opponency theory of Hering[6] was given a more quantitative basis by the hue-cancellation technique.[279,280,288] Jameson and Hurvich (see Fig. 14 for some of their data) determined the amount of particular standard lights that had to be added to a spectral test light in order to cancel the perception of either redness, greenness, blueness, or yellowness that was apparent in the test light, and so produced "valence" functions. Figure 32 shows additional R/G valence data from Ingling and Tsou[12] and B/Y valence data from Werner and Wooten.[286] Individual lobes of the curves show the amounts of red, green, blue, or yellow light required to cancel the perception of its opposing color in the test light. The zero crossings are the "unique" colors of blue, green, and yellow.

These types of judgments are, of course, highly subjective because the observer must abstract a particular color quality from color sensations that vary in more than one perceptual dimension. In valence settings, the color of the lights at equilibrium depends on the wavelength of the spectral test light. Lights that are in red/green equilibrium vary along a blue-achromatic-yellow color dimension, while those in yellow/blue equilibrium vary along a red-achromatic-green color dimension. To reduce the need for the observer to decide when a light is close enough to the neutral point to accept the adjustment, some authors have used techniques in which the observer judges simply whether a presented light appears, for example, reddish or greenish, to establish the neutral points of each mechanism.[289]

Unique hues and equilibrium colors The equilibrium points of the R/G color opponent mechanism correspond to the unique blue and unique yellow hues that appear neither red nor green,

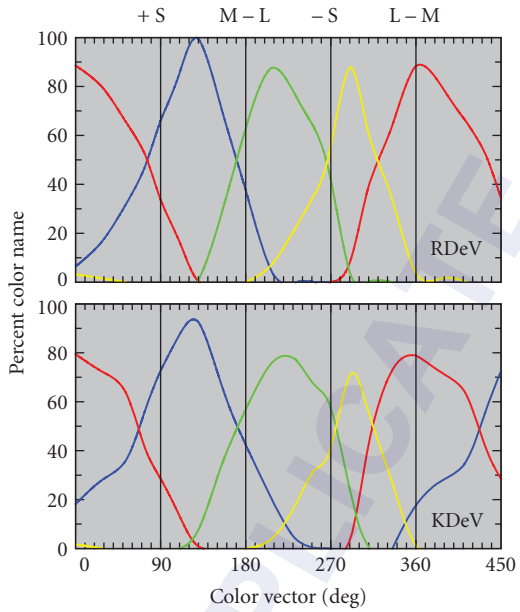

FIGURE 31 Hue scaling. Data replotted from Fig. 3 (Observers: RDeV and KDeV) of De Valois, De Valois, Switkes, and Mahon.[21] The data show the percentage of times that a stimulus with a given color vector in the equiluminant plane of DKL space was called red (red lines), yellow (yellow lines), green (green lines), or blue (blue lines). The vertical lines indicate the cardinal axes at 90/450° (+S), 180° (M–L), 270° (–S), and 0/360° (L–M). With the exception perhaps of the red function for RDeV, the other hue naming functions do not align with the cardinal axes.

whereas those of the B/Y mechanism correspond to the unique green and unique red hues that appear neither blue nor yellow. These hues are "unique" in the sense that they appear phenomenologically unmixed.[290]

Measurements of the spectral positions of the unique hues have been made in several studies.[281,290–296] Kuehni[297] provides a useful summary of the unique hue settings from 10 relatively recent studies. For unique yellow, the mean and standard deviation after weighting by the number of observers in each study are 577.8 and 2.9 nm, respectively; for unique green, 527.2 and 14.9 nm; and for unique blue, 476.8 and 5.2 nm. Studies that generate colors either on monitors[22,289,298] or in print,[299,300] and therefore use desaturated, nonspectral colors, are not necessarily comparable with the results obtained using spectral lights, since perceived hue depends upon saturation.[301] The mean unique yellow, green, and blue wavelengths taken from Table of Kuehni[297] *excluding* those obtained by extrapolation from desaturated, nonspectral equilibrium lights are 576.3, 514.8, and 478.0 nm, respectively. Although unique hues show sizable individual differences, the settings within observers are generally quite precise.[302,303] Dimmick and Hubbard[290] review historical estimates.

Dimmick and Hubbard[290] reported, nearly 70 years ago, that unique blue and yellow and unique red and green are not complementaries (see also Ref. 304). By extending unique hue settings to include nonspectral colors it is possible to determine the equilibrium vectors of the opponent mechanisms in two dimensions or the equilibrium planes in three dimensions. Valberg[305] determined unique blues, greens, yellows, and reds as a function of saturation. Although not commented on in the original paper, two important features of his results were that (1) the unique red and green vectors plotted

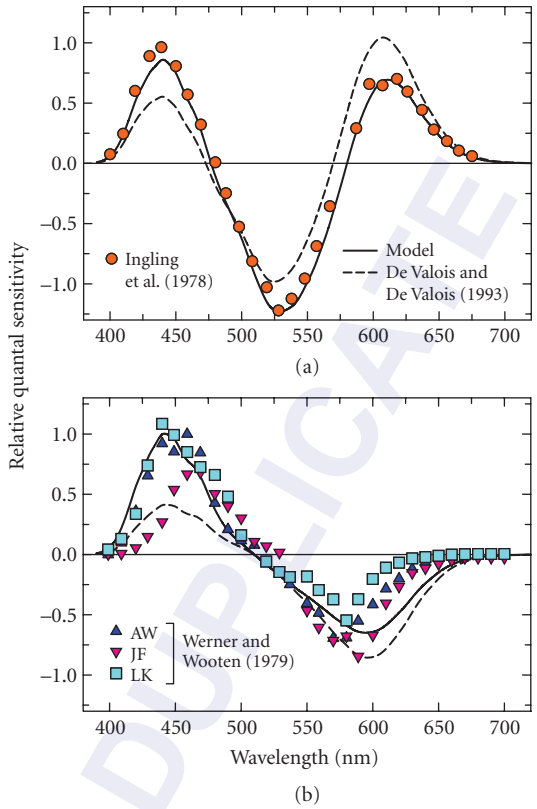

FIGURE 32 Color valence data. (*a*) R/G valence data (red circles) replotted from Fig. 2A of Ingling, Russell, Rea, and Tsou.[314] (*b*) B/Y valence data for observers AW (dark blue triangles), JF (purple inverted triangles) and LK (light blue squares) replotted from Fig. 9 of Werner and Wooten.[286] The continuous lines are the spectral sensitivity predictions of Stage 3 of the Müller-zone model outlined in the text (see section "Three-Stage Zone Models" in Sec. 11.6). Each set of valence data has been scaled to best fit the spectral sensitivity predictions. For comparison, the spectral sensitivity predictions of the model proposed by De Valois and De Valois[18] are also shown as dashed lines, in each case scaled to best fit the Müller-zone model predictions.

in a CIE *x,y* chromaticity diagram were not colinear, and (2) unique yellow and blue vectors, though continuous through the white point, were slightly curved. Burns et al.[16] in a comparable experiment confirmed that the unique green and red vectors were not colinear, and that the unique blue vector was curved, but found that the unique yellow and green vectors were roughly straight.
