Another key technology used extensively for filtering in IO is gratings. By periodically modulating the index profile of a waveguide, typically done by corrugating the boundaries of the guide through etching technology, Bragg reflection can be achieved. Such reflectors typically exhibit a relatively flat passband with a width dependent upon the strength and length of the periodic perturbation. Using such a filter inside a laser resonator provides a highly frequency-selective resonator and forms the basis for distributed feedback (DFB) and distributed bragg reflector (DBR) lasers. By cascading sections of grating, reflectors with a periodic sequence of peaks can be achieved. Such designs have been used as the basis for wavelength selective reflectors in widely tunable lasers. Gratings are critical to PICs containing semiconductor lasers because they allow for on-chip resonators without the need for reflecting facets on the chip edge which would constrain the PIC chip size and component layout.

Active Devices

Active IO devices are those capable of having their state altered by an external applied voltage, current, or other stimulus. This may include electro-optic devices, or devices that generate, amplify, or detect light. Active IO devices in non-semiconducting dielectrics generally depend on the linear electro-optic effect, or Pockels effect,[24] which produces a change of the index of refraction of a material upon the application of an electric field as discussed earlier. Typical values for a variety of materials is about 10^{-4} for a field of 10^4 V/cm. This results in a phase change for light propagating in the field region and is the basis for a large family of modulators.

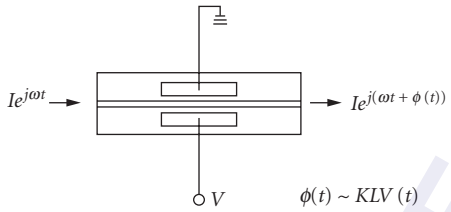

FIGURE 13 Top-down view of a typical $LiNbO_3$ phase modulator. Field is applied laterally across the guide by surface electrodes on each side.

The fundamental guided-wave modulator is a phase modulator, as illustrated in Fig. 13. In this device, electrodes are placed along side the waveguide and the lateral electric field determines the modulation. In other modulator designs, the vertical field component is used. For the geometry shown, the phase shift is *KLV*, where *K* is a constant, *L* is the electrode length, and *V* is the applied voltage. For $LiNbO_3$, $K = \pi n^3 r_{63} \Gamma/g\lambda$ for the preferred orientation of field along the *z* (optic) axis and propagation along the *y* axis. Here, *n* is the index r_{63} is the electro-optic coefficient, λ is the wavelength, *g* is the electrode gap, and Γ is the overlap of the electrical and optical fields. In general the value of *K* is anisotropic and is determined by the electro-optic tensor.[24] It should be noted that modulators are often characterized by their V_π value. This is the voltage required for a pi-radian phase shift; in this nomenclature phase shift is written as $\Phi = \pi \cdot V/V_\pi$ where $V_\pi \equiv \pi/KL$. Due to the requirement that the optical field be aligned with a particular crystal axis (e.g., in $LiNbO_3$ and III-V semiconductors), the input fiber on modulators is generally polarization maintaining.

Modulators in $LiNbO_3$ typically have efficiencies at 1.3 μm of 50 °/V, cm, a V_π of 5 V for a 1-GHz 3-dB bandwidth, and a fiber-to-fiber insertion loss of 2 to 3 dB. In semiconductors, modulation efficiencies can be significantly higher if one designs a tightly guided mode (i.e., one well suited for on-chip laser coupling, but having a relatively high fiber-to-chip mismatch coupling loss).

The modulation bandwidth of phase and intensity modulators is determined by the dielectric properties of the electro-optic material and the electrode geometry. For structures in which the electrode length is comparable to or shorter than a quarter RF wavelength, it is reasonable to consider the electrodes as lumped and to model the modulator as a capacitor with a parasitic resistance and inductance. In this case, the bandwidth is proportional to $1/L$. For most IO materials, lumped-element modulators have bandwidths less than 5 GHz to maintain reasonable drive voltages. For larger bandwidths, the electrodes are designed as transmission lines and the RF signal copropagates with the optical wave. This is referred to as a *traveling wave modulator*. The microwave performance of this type of structure is determined by the degree of velocity match of the optical and RF waves, the electrode microwave loss, the characteristic impedance of the electrodes and a variety of microwave packaging considerations. In general, semiconductor and polymer modulators fundamentally have better velocity match than $LiNbO_3$ and thus are attractive for highest frequency operation. Techniques and structures have been developed to substantially improve the velocity match in $LiNbO_3$, however, intensity modulators with 50 GHz have been reported.[94]

To achieve intensity modulation, it is generally necessary to incorporate a phase modulator into a somewhat more complex guided-wave structure. The two most common devices are the Mach-Zehnder and the directional coupler modulator. Figure 14 illustrates the MZ modulator. This device is the guided-wave analog of the classical MZ interferometer. The input and output Y junctions serve as 3-dB splitters and modulation is achieved in a push-pull manner by phase modulating both arms of the interferometer. The interferometer arms are spaced sufficiently that there is no coupling between them. When the applied voltage results in a pi-radian phase shift in light propagating in the two arms when they recombine at the output junction, the resultant odd field distribution corresponds to a second-order mode that cannot be guided and light radiates into the substrate. The output intensity *I*

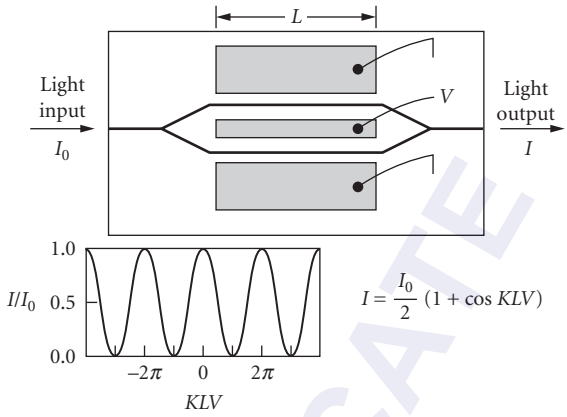

FIGURE 14 Geometry of lumped-element Mach-Zehnder modulator and transfer characteristic.

of this device is given by $I = I_0/2[1+\cos(KLV)]$. The sinusoidal transfer characteristic is unique in IO modulators and provides the unique capability to "count fringes" by applying drive signals that are multiples of V_π. This feature has been exploited in a novel analog-to-digital converter.[95] The device can be operated about its linear bias point $\pi/2$ for analog applications and can also be used as a digital switch. A variation on this device is a balanced bridge modulator. In this structure the two Y junctions are replaced by 3-dB directional couplers. This structure retains a sinusoidal transfer characteristic, but can function as a 2×2 switch.

A directional coupler switch is shown in Fig. 15. In the embodiment illustrated, a set of electrodes is positioned over the entire coupler region. The coupler is chosen to be L_c, a coupling length long, so that in the absence of an applied voltage, all light incident in one guide will

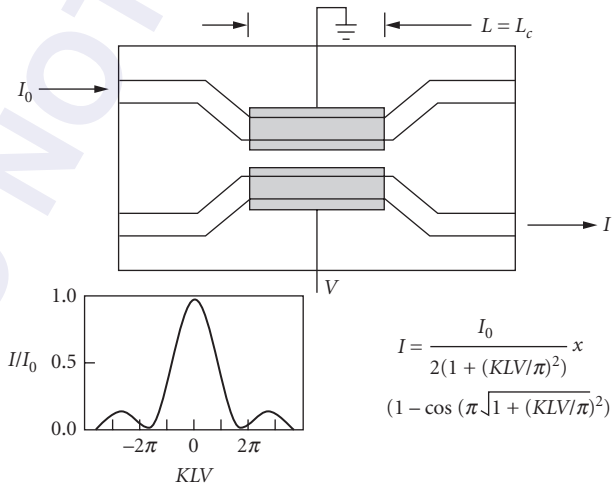

FIGURE 15 Geometry of lumped-element directional coupler switch and transfer characteristic.

cross over and exit the coupled guide. The performance of the directional coupler switch can be modeled by coupled mode theory. The application of an electric field spoils the synchronism of the guides, resulting in reduced coupling, and a shorter effective coupling length. For application of a voltage such that $KLV = \pi\sqrt{3}$, all light will exit the input guide. In general, the transfer characteristic is given by

$$I = \frac{I_0}{2(1+(KLV/\pi)^2)} \cdot \left[1 - \cos\left(\pi\sqrt{1+(KLV/\pi)^2}\right)\right] \tag{15}$$

Directional coupler switches can also be used for analog or digital modulation. They have also been fabricated in matrix arrays for applications in $N \times N$ switch arrays (see Sec. 21.6). To increase the fabrication tolerance of directional coupler switches, designs based on reversing the sign of index change (delta beta) periodically along the coupler have been developed. The most common device consists of a device one to two coupling lengths long and a single reversal of the voltage formed by a two-section electrode.

Both Mach-Zehnder and directional coupler devices have been developed in semiconductors, $LiNbO_3$ and polymers. Devices are commercially available in $LiNbO_3$. Drive voltages and bandwidths achieved are similar to the values quoted above for phase modulators. Additional effort has been focused in $LiNbO_3$ to make devices that are polarization insensitive so that they are compatible with conventional single-mode fiber.[96] Mach-Zehnder modulators have also been formed in glass waveguides. Here a resistive pad is heated to vary the index of the waveguide via the thermo-optic effect.

Another important IO component is the TE-to-TM mode converter. This device, illustrated in Fig. 16, depends on an off-diagonal component r_{51} of the electro-optic tensor in $LiNbO_3$ to convert incident TE (TM) light to TM (TE) polarization. In the converter a periodic electrode structure is used to create a periodic index change along the waveguide to provide phase matching, and thus coupling, between the TE and TM wave. The period Λ of this index change is given by $\Lambda = \lambda/(n_{TE} - n_{TM})$. The coupling efficiency at the phase-matched wavelength is given by $\sin^2(\kappa L)$ where $\kappa = \pi n^3 r_{51} E/\lambda$ and E is the applied field. This type of device can be used for polarization control. In a polarization controller, a phase modulator is placed before and after the converter so that signals of arbitrary input polarization can be converted into any desired output polarization. The converter also serves as the basis for a tunable wavelength filter.[97]

There are numerous other types of IO intensity modulators that have been reported. These include a crossing channel switch, a digital optical switch, an acousto-optic tunable wavelength switch, and a cutoff modulator. The first two devices depend on modal interference and evolution effects. The acousto-optic switch utilizes a combination of acoustically induced TE-to-TM mode

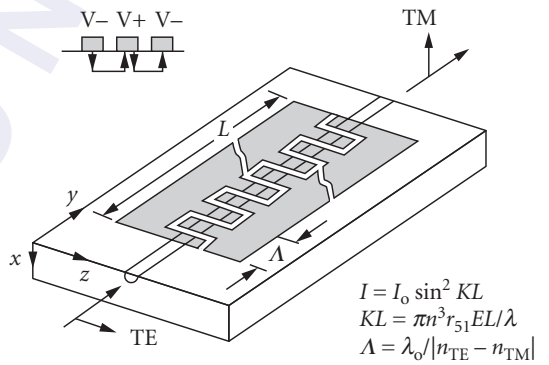

FIGURE 16 TE-TM mode converter using periodic electrodes to achieve phase matching.

conversion and TE-TM splitting couplers to switch narrow-optical-band signals. The cutoff modulator is simply a phase modulator designed near the cutoff of the fundamental mode such that an applied field effectively eliminates the guiding index change between the guide and the substrate. This results in light radiating into the substrate.

In addition to the electro-optic devices described above, another common modulation technique employed in III-V materials employs the electroabsorption or electrorefraction effects discussed in Sec. 21.3. Here the bandgap energy of a bulk medium or an appropriately engineered quantum-well medium is chosen to be somewhat higher than the energy of the propagating photons. An applied field directly induces absorption, or a large index shift associated with the change in absorption at higher energy. The latter effect is used interferometrically in directional couplers, Mach- Zehnder modulators, or other designs as an enhanced substitute for the conventional electro-optic effect. The former is used as a single-pass absorptive waveguide modulator.

To achieve low operating voltages, such modulators are usually designed with small waveguide dimensions for tight confinement of the optical mode. This usually leads to a significant insertion loss of approximately 2 to 3 dB/cm when coupling to optical fibers. However, the tight waveguide mode is very similar to the waveguides employed in semiconductor lasers, and hence one of the primary appeals of waveguide electroabsorption modulators lies in their potential for integration with semiconductor lasers on a single PIC chip.[98]

A particular implementation used by Soda et al.,[99] is shown schematically in Fig. 17. A 1.55-μm DFB laser structure is mated to an electroabsorption modulator with an InGaAsP core layer having a photoluminescence wavelength of λ_{PL} approximately 1.40 μm. The entire structure uses a buried heterostructure waveguide with semi-insulating InP lateral cladding to provide good current blocking with low capacitance for high modulator bandwidth. Optimization of the modulator core $\lambda_{PL}$is very important in this device. With proper design, devices have yielded a good compromise between high output power and high modulator extinction ratios with low voltage drive. Typical device designs exhibit milli watt-level fiber-coupled output power with a −10-dB extinction ratio at drive levels of 2 to 4 V.

Semiconductor lasers comprise one of the most highly developed implementations of integrated optics and are the subject of Chap. 19 in Vol. II, "Semiconductor Lasers." Semiconductor lasers are routinely combined in PICs with other IO elements such as filters, modulators, amplifiers, and detectors. Common to most laser, detector or waveguide PICs is the inclusion of a guide containing an amplifying or gain medium, or an absorptive medium for detection, and the requirements of

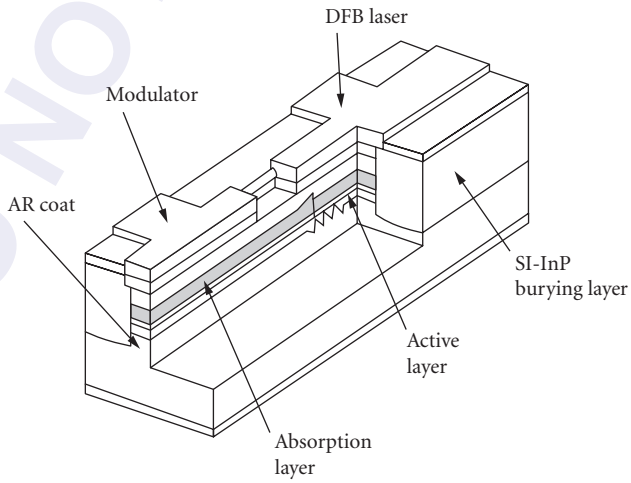

FIGURE 17 Integrated semiconductor laser/electorabsorption modulator PIC.

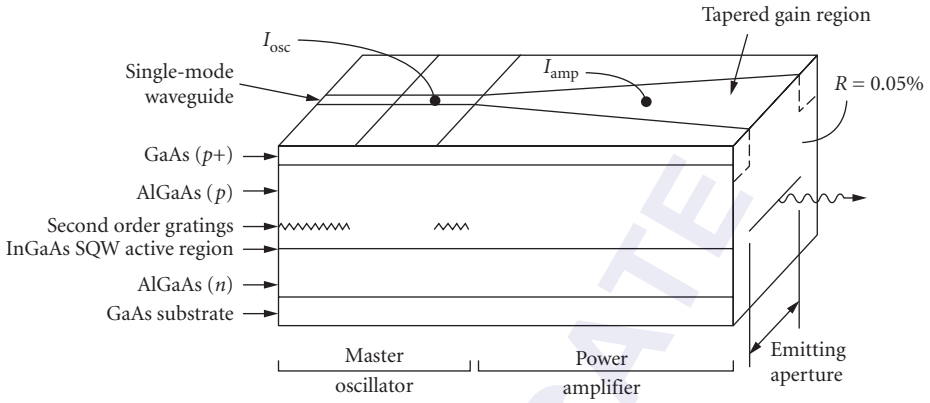

FIGURE 18 Integrated semiconductor master oscillator/power amplifier (MOPA) PIC.

current drive or extraction. The design and processing associated with these guided-wave components relies heavily on a relatively mature technology associated with semiconductor lasers.[100]

The gain section of a semiconductor laser is usually fabricated in a buried heterostructure guide, as shown in Fig. 2*a,* and is driven through a forward biased *p-n* junction where the layers are usually doped during the crystal growth. With zero or reverse bias, this same structure can function as a waveguide photodetector. In a DFB laser or a distributed Bragg reflector (DBR) laser, this feature can be used to provide an integrated detector, on the back end of the device external to the cavity, for monitoring laser power. Alternatively, a separate gain medium external to the laser cavity can be located external to the cavity on the *output* side to function as an integrated power amplifier for the laser. Such a structure is shown in Fig. 18, where an array of DBR laser is followed by a fan-shaped amplifier to keep the amplifier medium at a relatively constant state of saturation. These PICs are termed master-oscillator/power-amplifiers (MOPAs), and can provide watt-level single-frequency, diffraction-limited output beams from a single chip.[101]

The challenge of laser integration is to fabricate other guided-wave components without compromising the intricate processing sequence required to make high-performance lasers. Figure 19 shows an early implementation of a sophisticated PIC providing a balanced heterodyne receiver that might be used for coherent optical communications links.[102] Here a tunable local oscillator is tuned to an optical frequency offset by a predetermined amount from one of potentially many incoming signals. The beat signal are generated in the integrated photodetectors, and whose signals can be subtracted for noise reduction, and then electrically amplified, filtered, and fed to a decision circuit This PIC combines five different types, and a total of seven, guided-wave optical devices: two tunable Bragg reflection filters, an MQW optical gain section, an electrically adjustable phase shifter, a zero-gap directional coupler switch, and two MQW waveguide photodetectors. It also demonstrates self-aligned connections between the buried heterostructure guides, which offer current access and semi-insulating InP lateral current blocking, and the low-loss semi-insulating InP-clad rib guides used in the S-bends and input port. The processing sequence for PICs of this complexity has been described in some detail in the literature, and can be carried out following most of the same steps used in commercial semiconductor laser fabrication.[103]

Tuning of the DBR lasers, as used in the PIC above, is accomplished by injecting current into the (transparent) Bragg reflectors, shifting their index via the plasma and anomalous dispersion effects discussed under Sec. 21.3. This shifts the wavelength of peak Bragg reflectivity, thereby selecting different longitudinal modes for the laser. The laser can also be *continuously* tuned by shifting the frequency of any particular longitudinal mode by injecting current to provide an index shift in the (transparent) phase section of the laser. Detectors in PICs of this type often employ for absorption the same layers used for gain in the laser, and typically have a capacitance of several picofarads dominated by the contact pads rather than the depletion capacitance of the *p-n* junction.

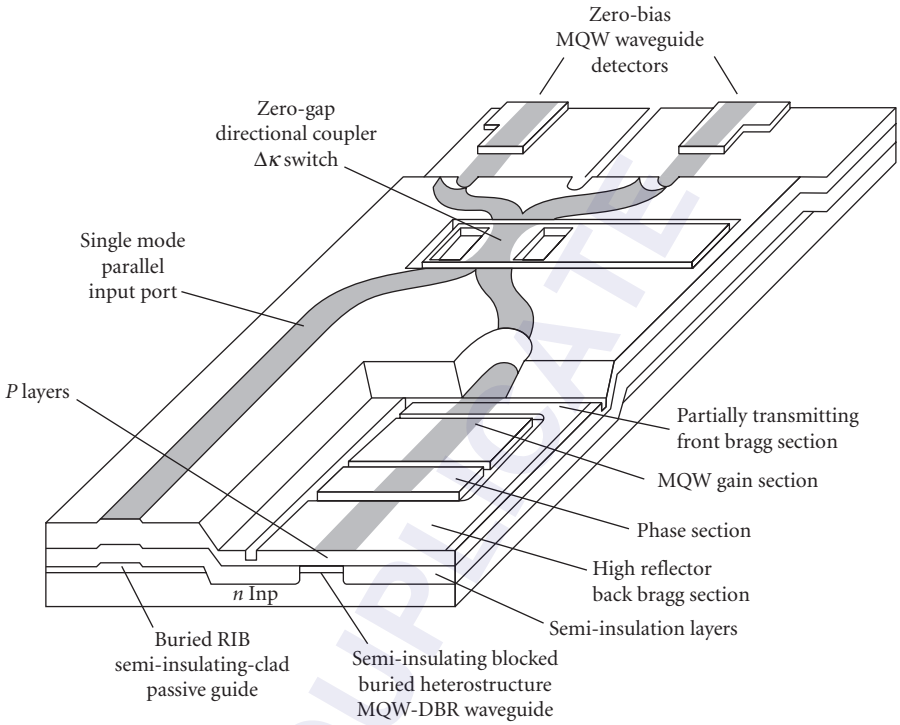

FIGURE 19 Integrated balanced heterodyne receiver PIC.

Early experimental prototypes of PICs of this type have demonstrated total on-chip losses including propagation losses, bending losses, radiation losses at the coupler and at the active/passive detector transitions, and any departures from 100 percent quantum efficiency in the detectors, of approximately 4 dB, providing encouragement for even more complex integrations. This PIC demonstrated error-free heterodyne reception of frequency-shift-keyed digital signals with sensitivities of –40 dBm at 200 Mb/s measured in free-space outside the chip. PICs such as this may in the future offer a cost-effective pathway for the efficient use of the optical spectrum via electrical filtering and encoding techniques, much in the same way cell phone systems operate today.

21.6 APPLICATIONS OF INTEGRATED OPTICS

Digital Transmission

The performance metric in digital optical fiber transmission is the ability of a transmitter to deliver a signal to the receiver an the end of the link in a manner such that the receiver can clearly distinguish between the "0" and "1" state in each time period or bit slot. Binary amplitude-shift-keyed transmission (ASK) is by far the most common format in commercial systems, but high performance systems today also employ differential phase-shift-keyed (DPSK) formats. A decision circuit at the receiver must distinguish between "0" and "1," and this circuit will be more susceptible to noise when the "0" and "1" level difference is reduced, or when the time over which this difference is maintained is reduced below the full bit period.

The performance of a transmitter is thus governed by its rise and fall times, and its modulation bandwidth or flatness of response to avoid pattern-effects and its output power. Furthermore, the spectral characteristics of its optical output can impair transmission. Examples of the latter include unnecessary optical bandwidth, as might be present in an LED or a multilongitudinal-mode laser, that can produce pulse spreading of the digital pulses due to dispersion in the transmission fiber. While transmission sources include current-modulated LEDs, for speeds higher than approximately 100 Mb/s semiconductor lasers are used, and IO technology has played a fundamental role in the evolution of semiconductor laser technology. In very high-speed systems (typically > 1 Gb/s), dispersive pulse distortion can cause severe degradation with directly modulated lasers unless devices which emit only one longitudinal mode are employed. The incorporation of gratings in DFB and DBR lasers has produced sources with exceptional spectral purity and allow multi-gigabit per second transmission over intermediate distances (< 100 km) in conventional fiber.

The advent of fiber amplifiers has enabled longer transmission spans without digital regeneration, and here the unavoidable frequency excursions that result from directly modulating even a single-longitudinal-mode laser again lead to pulse spreading and distortion. In these instances, a continuous wave (CW) laser followed by an external modulator is a preferred source. The integrated DFB/electroabsorption modulator, as discussed in Sec. 23.5, provides such a source. These PICs have demonstrated error-free transmission in excess of 500 km in dispersive fiber at 2.5 Gb/s.[104] However, even these devices impose a small residual dynamic phase shift on the signal due to electrorefractive effects accompanying the induced absorption in the modulator. This can be especially problematic with typical percent-level antireflection coatings on the output facet, since this will provide phase-varying optical feedback into the laser and further disrupt its frequency stability.

The highest performance digital transmission has been achieved using external $LiNbO_3$ Mach-Zehnder modulators to encode a CW semiconductor laser. Modulators similar to that in Fig. 14 have been constructed to allow separate traveling-wave voltages to be applied to each arm of the modulator in a push-pull configuration. This device design can produce a digitally encoded signal with *zero* residual phase shift or chirp.[105] Such a source has only its information-limited bandwidth and generally provides nearly optimized performance in a dispersive environment. The Mach-Zehnder can also be driven to intentionally provide positive or negative chirping to optimize transmission characteristics in dispersive links.[106] Semiconductor lasers have also been monolithically integrated with Mach-Zehnder modulators using electrorefraction from the QCSE.[107]

Recently there has been significant focus on using phase modulation formats such as DPSK, and higher level formats such as differential quadrature phase-shift keyed (DQPSK) modulation where each bit period can contain 2 bits of information. Such formats not only allow higher spectral efficiency, or information per unit bandwidth in the fiber, but also offer advantages in robustness against impairments from fiber nonlinearity which can seriously degrade the performance of long-distance amplified WDM systems. Just as in the case of the simpler integrated laser-modulator, PIC technology provides a powerful vehicle for the precision control of the pathlengths or phase delays required to encode and decode such formats in transmitters and receivers.[108,109]

Analog Transmission

A second application area that is expected to use a large number of IOCs is analog fiber optic links. Analog fiber optic links are currently being used to transmit cable television (CATV) signals at the trunk and supertrunk level. They are also being used for both commercial and military antenna remoting. Analog fiber optic links are being fielded for these applications because of their low distortion, low loss, and low life-cycle cost when compared to more conventional coaxial cable-based transmission systems.

An analog fiber optic link using IOCs is typically configured as shown in Fig. 20. A high-power CW solid-state laser, such as a 150-mW diode-pumped YAG laser operating at 1319 nm, is typically used as the source in order to maximize dynamic range, carrier-to-noise ratio, and link gain. An interferometric modulator, such as a Mach-Zehnder interferometer or a Y-fed balanced bridge modulator, is typically used to modulate the light with the applied RF or microwave signal

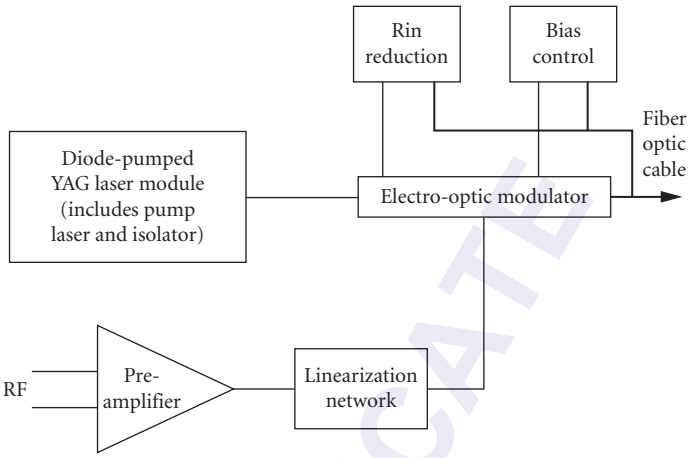

FIGURE 20 Standard configuration for externally modulated analog fiber optic link.

via the linear electro-optic effect. Current analog links for CATV signal distribution utilize a 1-GHz Y-fed balanced bridge modulator biased at the quadrature point (linear 3-dB point).[110,111] A predistortion circuit is required to minimize third-order distortion associated with the interferometric modulator response. The CATV-modulated signal can be transmitted on both output fibers of the device. Analog links for antenna remoting typically fit into one of two categories. Certain applications require relatively narrow passbands in the UHF region while other microwave-carrier applications require very broadband (several GHz) performance. Y-fed balanced bridge modulators biased at the quadrature point are again used to perform the electrical-to-optical conversion, with the electrode structure tailored to the application. In both narrowband and broadband applications, 20- to 30-dB preamplifiers are typically utilized to minimize the noise figure and maximize the RF gain of the link.

Two important modulator parameters are the insertion loss and the half-wave drive voltage which both impact the link gain and dynamic range. Fully packaged Y-fed balanced bridge modulators with 2.5 to 4.0 dB insertion loss are now readily achieved in production for both UHF and microwave bandwidths. A trade-off typically needs to be made between half-wave voltage and bandwidth for both lumped-element and traveling-wave electrode structures. Commercially available lumped-element $LiNbO_3$ interferometric modulators typically have half-wave voltages of approximately 5 V for 600-MHz, 1-dB bandwidths. Commercially available traveling-wave $LiNbO_3$ interferometric modulators typically have half-wave voltages of approximately 8 V for 12-GHz, 3-dB bandwidths. The half-wave voltages of $LiNbO_3$ traveling-wave modulators can be reduced by more than a factor of two using a velocity-matched electrode structure as described in Ref. 93.

In order to be used in practical systems, it is critical that the integrated optical modulators have well-behaved, flat frequency responses in the band of interest. Modulators for CATV signal transmission and UHF antenna remoting typically required that the amplitude response and the phase response be flat to ± 0.25 dB and ± 2°, respectively. The frequency response of an integrated optical modulator is a function of both the device design and packaging parasitics. Care must be exercised in designing modulators since $LiNbO_3$ is both a piezoelectric and an acousto-optic material. Early $LiNbO_3$ modulators typically had 1 to 3 dB of ripple in the passband due to acoustic mode excitation. When packaging lumped-electrode devices, it is also critical to keep terminating resistors close and wire bonds short to minimize stray inductance and capacitance . When packaging traveling-wave modulators, it is critical to control the impedance of the launch, the transitions, the device, and the termination. Through proper device design and packaging, it is possible to achieve well-behaved frequency responses in both lumped-electrode and traveling-wave devices as shown in Fig. 21.

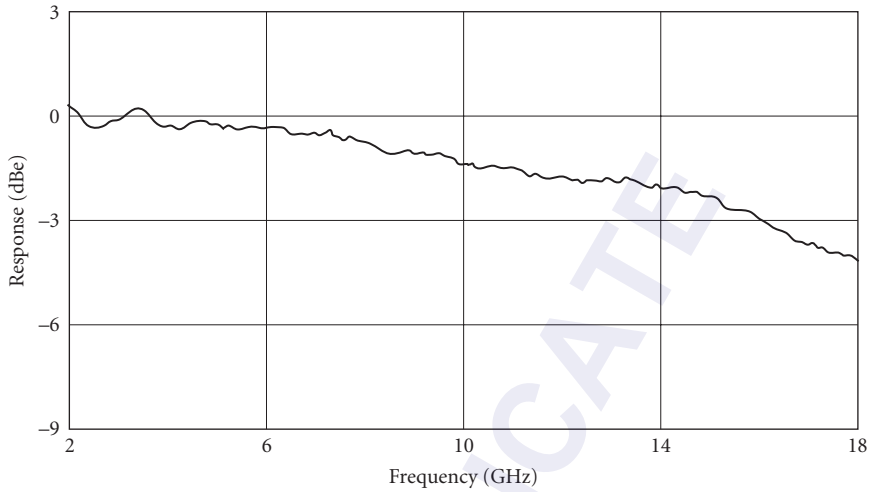

FIGURE 21 Frequency response of APE LiNbO3 microwave interferometric modulator for broadband antenna remoting.

An additional issue that impacts IOC modulator design for analog links is harmonic and intermodulation distortion. Most modulators used in analog links are interferometric in nature with a sinusoidal transfer function. By operating the device precisely at the quadrature point, all even harmonics can be suppressed. Second-harmonic distortion less than −75 dBc is easily achieved using an electronic feedback loop for modulator bias. Alternative techniques are being investigated to laser trim one leg of a Mach-Zehnder to bring the modulator to quadrature. Third-order distortion due to the sinusoidal transfer function of the interferometric modulator also poses a problem, but the transfer functions are very well-behaved and predictable, and this distortion can be suppressed to acceptable levels using electronic predistortion or feed-forward techniques.

Forty- and eighty-channel CATV transmitters operating at 1300-nm wavelengths with APE $LiNbO_3$ modulators are currently being fielded. Compared to coaxial transmission which requires transmitters every 500 m, the fiber optic systems can transmit over distances up to 50 km without repeaters. Similarly, externally modulated analog fiber optic links are currently being fielded for military and commercial applications. UHF links with 115 dB/$Hz^{2/3}$ dynamic range, 4-dB noise figure, and unity gain have been demonstrated using commercially available hardware. These systems will maintain this quality of transmission over temperature ranges of −25 to +50°C. Microwave links with 2 to 18 GHz frequency response, 114-dB/$Hz^{2/3}$ spurious-free dynamic range, and input noise figure of 22 dB can also be achieved using commercially available hardware.

Switching

Arrays of IO switches have been proposed and demonstrated for a variety of space switching and time-multiplexed switching (TMS) applications. In space switching, it is generally necessary to formulate the switches in a nonblocking geometry and the reconfiguration time can be relatively slow (seconds or longer). This requirement led to the development of cross-bar switches in which an N × N switch contains N^2 IO switches and 2N − 1 stages and from 1 to 2N −1 cross points. Typically $N = 4$ in $LiNbO_3$ and in InP. More recently, much attention in IO switch arrays has shifted to the dilated Benes architecture which is only rearrangeably nonblocking but reconfigurable in short (ns) times suitable for TMS, and has the advantage of requiring substantially fewer switches and a constant number $2 \log_2 N$ of cross points.

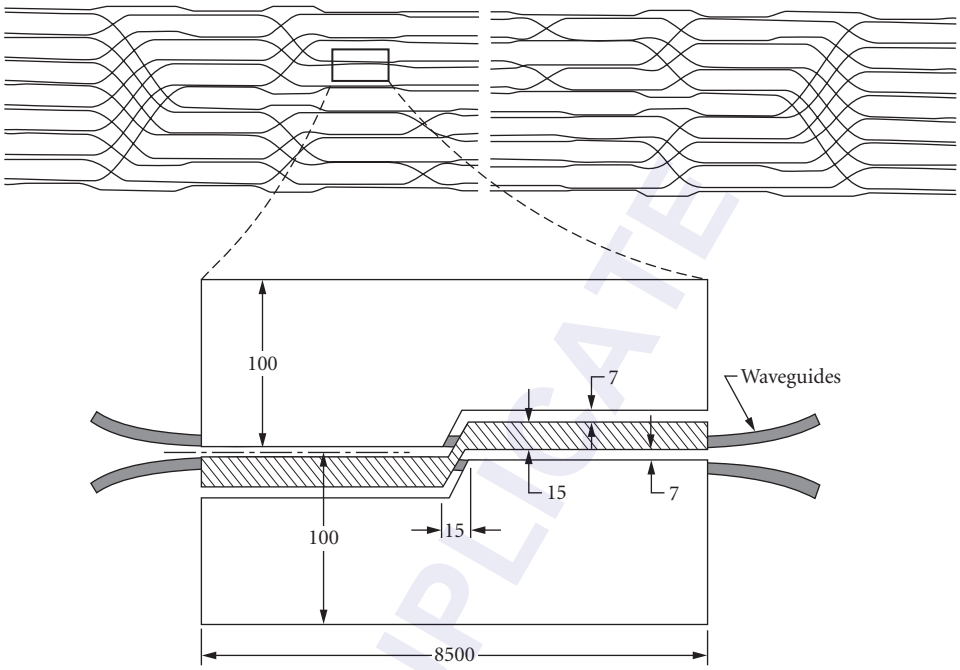

FIGURE 22 Architecture of 8 × 8 dilated Benes directional coupler switch array.

A schematic of a two-chip 8 × 8 dilated Benes switch making extensive use of crossovers is shown in Fig. 22.[112] The performance of switch arrays of the dilated Benes architecture are much more forgiving than crossbar switches to the degradation of individual switches. The device shown contains 48 delta beta switches driven by a single-voltage arrangement. The switching voltage at 1.3 μm was 9.4 + −0.2 V, the insertion loss varied from −8 to −11 dB (93 percent of the 256 paths through the switch were within ±1 dB), the cross-talk levels in individual switches ranged from −22 to −45 dB, and the reconfiguration time was 2.5 ns. Larger 16 × 16 switches have also been demonstrated.[113]

An advantage of these types of IO switch arrays is that they are data rate transparent. That is, once the switch is reconfigured, the data stream through the device is simply the passage of light and can easily be multi-gigabit. Crossbar switches are now commercially available and other types of arrays continue to be explored.

Fiber Optic Gyroscopes

Another application that may require large quantities of integrated optical circuits is the fiber optic gyroscope (FOG)[114–119]. A FOG is one form of a Sagnac interferometer, in which a rotation rate results in a phase shift between clockwise- and counterclockwise-propagating optical fields. The most frequently utilized FOG configuration, which was first proposed by workers at Thomson CSF in the mid 1980s,[120] is presented in Fig. 23.

FOG IOCs are typically fabricated in $LiNbO_3$ using the annealed proton exchange (APE) process[66] although titanium-diffused IOCs with surface plasmon polarizers have also been utilized. The IOC performs four primary functions in the fiber gyroscope. First, the Y-junction serves as the loop coupler splitting and recombining the clockwise- and counterclockwise-propagating optical fields. Second, the IOC functions as a high-quality polarizer. Third, a 90° phase dither (at the eigen frequency of the fiber coil) is typically applied to one of the integrated optical phase modulators.

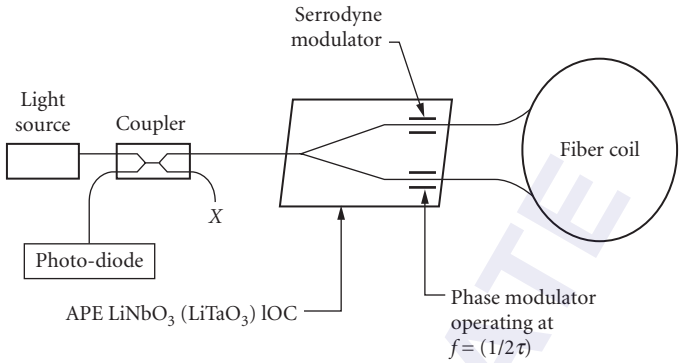

FIGURE 23 Standard configuration for fiber optic gyroscope incorporating a three-port integrated optical circuit.

This approach keeps the Sagnac interferometer biased at the 3-dB point where it is linear and most sensitive to rotation. Finally, in a closed-loop FOG configuration, one of the phase modulators functions as a frequency shifter. A serrodyne signal (saw-tooth wave) is applied to the phase modulator to effectively cancel the shift due to the rotation.

The output signal from a fiber gyro at rest is the sum of white receiver noise, primarily dependent on the amount of optical power arriving at the detector, and an additional long-term drift of the mean value. The long-term drift in a FOG associated with a residual lack of reciprocity typically limits the sensitivity of the FOG to measure low rotation rates. Another important characteristic of a gyro is the scale factor, which is a measure of the linearity between the actual rotation rate and the gyro response. The critical performance parameters for a FOG IOC are presented in Table 1. The performance of 800- and 1300-nm APE $LiNbO_3$ FOG IOCs that are currently in production is also presented in this table.

One application of the FOG is inertial guidance, requiring a FOG with a bias drift < 0.01°/h and a scale factor accuracy < 5 ppm. A 1300-nm LED or an erbium-doped fiber is typically used as the light source. A large coil of polarization-maintaining fiber (typically 1 km of fiber wound in a 15 to 20 cm diameter coil) and precise source spectral stability are required to achieve the desired sensitivity. The fiber is typically wound in a quadrupole configuration to minimize sensitivity to temperature gradients. With recent improvements in optical sources, integrated optics, and fiber coil-winding technology, it is now possible to achieve inertial grade FOG performance over a temperature range of −55 to +95°C.

TABLE 1 Critical Performance Parameters for 800- and 1300-nm APE $LiNbO_3$ FOG IOCs. Listed Values Are Maintained over a Temperature Range of −55 to +95°C and during Vibration up to 15 Grms.

Performance Parameter	1300-nm IOCs	800-nm IOCs
Insertion loss (pigtailed)	3 dB	4 dB
Polarization extinction	70 dB	60 dB
Y-junction split ratio (pigtailed)	48/52 to 52/48	45/55 to 55/45
Polarization crosstalk at fiber-waveguide interfaces	< −30 dB	< −25 dB
Optical back reflection	< −65 dB	< −65 dB
Half-wave voltage	4.5 V	3.5 V
Residual intensity modulation	0.02%	0.05%

A second tactical-grade FOG design is more typical to aerospace applications, with bias drift and scale factor accuracy requirements ranging from 0.1 to 10°/h and 10 to 1000 ppm, respectively. These systems are typically designed for operation at 810 to 830 nm to make use of low-cost multimode 830-nm AlGaAs laser diodes as used in consumer electronic products. These systems typically utilize 2- to 5-cm-diameter fiber coils with 100 to 200 m of either polarization-maintaining or single-mode fiber. A third very low-cost, low-grade FOG design for automotive navigation is also nearing production. The required bias drift is only 1000°/h, and a closed-loop configuration is unneccessary since the scale factor accuracy is only 0.1 percent. Current designs to achieve low cost include low-performance IOCs, laser, and fiber couplers, fully automated FOG assembly and test procedures, and only approximately 50 m of single-mode fiber. More advanced IOCs, including four-port designs that integrate the source/detector coupler into the IOC, are also being considered to reduce component count.

WDM Systems

Wavelength division multiplexing (WDM), by encoding parallel data streams at different wavelengths on the same fiber, offers a technique to increase transmission capacity, or increase networking or switching flexibility, without requiring higher speed electronics to process each channel. As noted earlier, IO is an enabling technology in WDM demultiplexer design. However, due to the large number of component interconnections at the transmit and receive end of a WDM link, PIC technology offers great promise in cost reduction for both WDM transmitters and receivers by additionally eliminating separate packages for lasers, amplifiers, detectors, and the like.

One key application of PICs for WDM systems is the stable and efficient longitudinal connection of optical elements required to form a tunable laser. The tunable Bragg laser was briefly discussed earlier in the description of the balanced heterodyne receiver PIC. Figure 24 below shows a more complex sampled-grating distributed Bragg reflector PIC. Here the reflectivity of a grating with

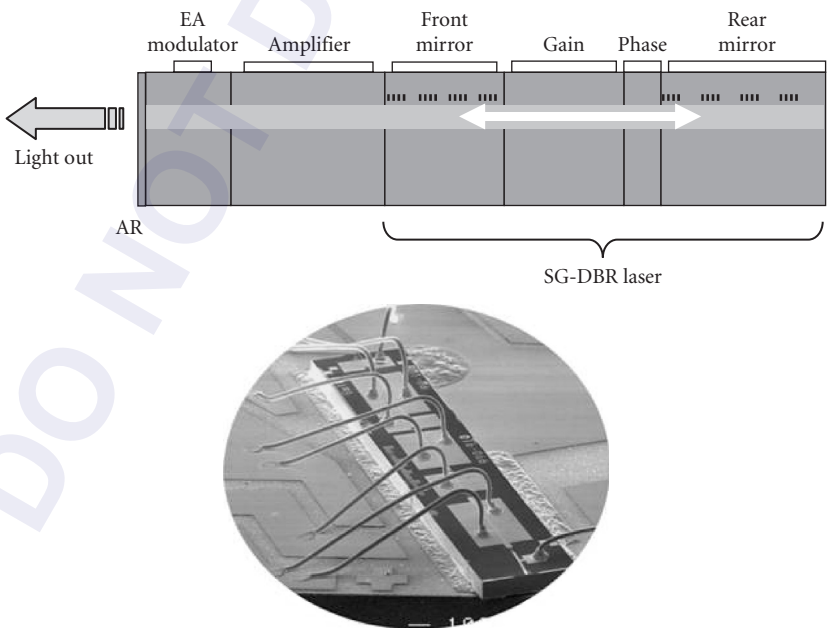

FIGURE 24 Tunable sampled-grating distributed Bragg reflector (SG-DBR) laser with integrated semiconductor optical amplifier and electroabsorption modulator.

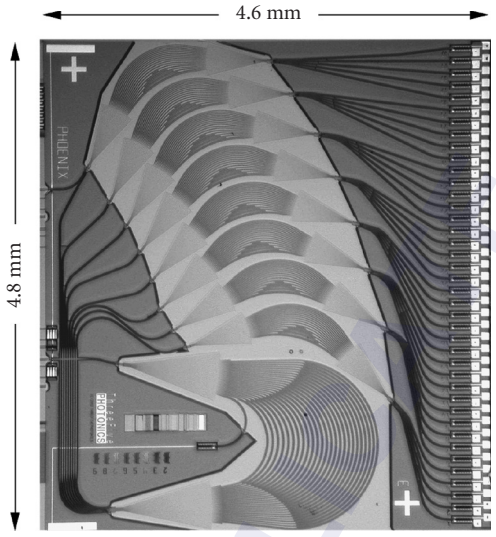

FIGURE 25 Integrated 40-channel optical channel monitor, comprising 9 different AWG demultiplexers and 40 photodetectors. (*By III-V Photonics, Inc.*)

sections periodically omitted provides a comb of reflection bands, and if the front and back combs have different spacings in frequency, the laser can tune over a wide range with a small index change because the laser will operate only at a frequency where the front and back reflection bands coincide in frequency.[121] Tuning is accomplished by changing the index of the front or back section by current injection, for example.

Because the InP materials system readily allows detectors as well as high-quality passives, the AWG demultiplexer discussed earlier can be combined with an integrated detector for each wavelength output port to make a single-chip WDM receiver. Figure 25 illustrates a 40-channel WDM receiver PIC, comprising nine different AWG demultiplexers and 40 photodetectors within a 4.6×4.8 mm chip.[122] This PIC had only 4-dB on-chip loss and provided less than 35-dB cross talk between different wavelength channels.

Figure 26 shows the layout of a WDM transmission PIC, which is perhaps the most sophisticated example of commercially deployed active IO demonstrated to date.[123] Following the concept initially introduced by Aiki et al.[124] in combining multiple DFB lasers, this PIC includes 10 frequency tunable DFB lasers with wavelength locking function, 10 electroabsorption modulators, 10 monitor detectors, 10 adjustable attenuators, an AWG for low-loss, frequency-selective combining into a single waveguide output port. This PIC provides a 100-Gb/s transmission capacity from a single chip, and together with a matching 10-channel WDM receiver PIC has been commercially deployed in telecommunication networks worldwide.[123] These PICs have demonstrated remarkable performance, and offer significant improvements in cost, size, power, and reliability compared to discrete component solutions.

Silicon Photonics Transceivers

As noted in the earlier discussions of IO materials, silicon has gained significant attention in recent years due to its ability to harness highly advanced CMOS fabrication technologies, combined with the very high index contrast available and effective modulation using the plasma index change from free carriers. This modulation is most effectively done at high speed using either a reverse-biased P-N junction, or using a structure similar to a field-effect-transistor (FET) where charge can accumulate on a gate oxide within the optical mode. Both of these designs have been demonstrated

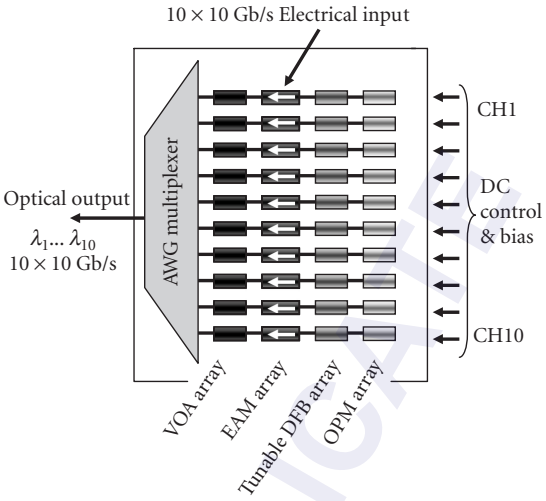

FIGURE 26 Chip architecture for commercially implemented PIC with nearly 50 elements, including 10 frequency tunable DFB lasers with wavelength-locking function, 10 electroabsorption modulators, 10 monitor detectors, 10 adjustable attenuators, and an integrated AWG combiner.

by several organizations[125,126] and commercialized with fabrication conducted within a CMOS electronics foundry using nearly standard IC fabrication steps. PICs have been demonstrated that include 10 Gb/s transmitters and recievers, and the ability to include CMOS electronics has also allowed for on-chip modulator drivers, preamplifiers, clock and data-recovery circuits, and even pseudo-random bit-stream generators for on-chip testing.[46] Commercial silicon photonics transceivers have demonstrated low-power operation, and also 40-Gb/s data rates using integration to achieve parallelism with only one laser source.

21.7 FUTURE TRENDS

Shift from R&D to Manufacturing

Integrated optical circuit technology has now advanced from R&D into manufacturing as noted in the examples given. $LiNbO_3$ modulators and integrated DFB/electroabsorption modulators have been critical, high-volume products for more than a decade. There are now several companies producing more complex IO and PIC products in $LiNbO_3$, Si/SiO_2, and InP in moderate volumes (several thousand devices each per year) with considerable success in reducing manufacturing costs and achieving high reliability.

The majority of the $LiNbO_3$ devices described in this chapter can be fabricated using either existing or slightly modified semiconductor processing equipment. Clean room requirements are not nearly as tight as what is required for VLSI and MMIC wafer fabrication. Production yields of $LiNbO_3$ integrated optical circuits have been obtained well in excess of 95 percent. The majority of the defects were initially mechanical in nature (probes scratching electrodes or fibers damaging polished end faces), but these have been minimized as the processes have become more automated. At this time, it appears that all wafer-processing operations should be easily scalable to wafer batch processing, including the end-face optical polishing. The majority of the cost of an integrated optical circuit is currently associated with fiber attachment, packaging, and final testing. While these operations are

not fundamentally expensive, the limited production volumes do not always justify the capital expenditure required to fully automated processes with robotics and machine vision.

The second area that has seen improvement is device reliability. First-generation commercial integrated optic products were plagued by premature failures and poor performance over temperature. The majority of these problems resulted from poor fiber attachment and packaging techniques. These problems have been remedied by carefully selecting compatible material systems and incorporating proven hybrid electronic packaging techniques. For example, commercially available $LiNbO_3$ integrated optical circuits can be thermally cycled hundreds of times from −65 to +125 °C with less than 1 dB variation in insertion loss. The devices can also withstand 30 Grms random vibration testing. Long-term aging effects have been addressed by identifying potential failure mechanisms and then by developing physical models of these failures. $LiNbO_3$ integrated optical circuit reliability has now achieved a level where devices can be certified for operational lifetimes in excess of 25 years for properly designed, fabricated, and assembled devices. Obviously, this level of performance can only be guaranteed by fabricating the devices in well-controlled, well-documented production environments.

In the semiconductor area, reliability certification technology for PICs borrows heavily from the more mature level models and aging methodologies developed for semiconductor lasers. This includes sequences of purges at high currents or voltages combined with high temperatures, together with extended accelerated aging to identify activation energies and aging rates for various degradation mechanisms. Integrated laser modulators have been deployed in high volume with outstanding reliability, also easily in excess of 25 years including wavelength stability for WDM lasers. More complex PICs have also shown extremely high reliability, and as with the $LiNbO_3$ IO devices, any failures that do occur are most often associated with poorly designed packaging of the device rather than the PIC chip itself. This again points to one of the fundamental advantages of PICs, where many individual component packages are eliminated by lithographic connections and only one package is required for the final PIC or IO device.

Advanced Integration and New PIC Applications

The most active areas of IO and PIC research today are in telecommunications, datacom, and sensor applications. In InP materials, for example, there has been extensive work on all-optical networking technologies where wavelength-converter PICs have been demonstrated that encode incoming data onto a new wavelength determined by an on-chip tunable laser in conjunction with nonlinear Mach-Zehnder interferometers with SOA gain elements.[127,128] The complexity, speed, and wavelength count of high speed WDM transmit and receive PICs continues to grow, with research demonstrations of 1.6 Tb/s from a single chip combining 40 tunable DFB lasers with 40 electroabsorption modulators running at 40 Gb/s each.[129] As transmission technology continues to evolve in sophistication and spectral efficiency, work on advanced modulation formats moves forward aggressively. A resurgence of interest in heterodyne-detection technology has shown that many system impairments can be effectively removed in the electronic domain when the information is received linearly in the optical electric field. It is quite likely that information coding in the optical domain will progress to a level that is now commonplace in the world of RF and cell phone technology.

Silicon photonics has made remarkable progress in a short period, and whereas true OEIC integration with electronics has only had very limited penetration in III-V materials, the potential for including sophisticated electronics in silicon has provided a strong incentive to explore and commercialize this technology. In datacom, for example, the proximity of driver circuits and modulator devices allows for low power by obviating the usual electrical transmission line and terminating resistor approaches. For sensors, the ability to combine preamplification, analog-to-digital converters, and digital signal processors is extremely compelling, and biochem sensors that can detect frequency shifts in suitably sensitized resonators are now emerging. It is also likely that the mapping of photonic functions into commercial CMOS electronics foundries will become more common, and if suitable design tools become more widely available, the reduced barriers to using silicon photonics solutions may lead to a growth of new market applications.

Analogies with massively repetitive logic gates in electronics integration are not particularly good, but there is indeed now a proliferation of applications where stable designs have emerged that require significant numbers of interconnected optical components. In these areas, the improvements in size, cost, power, and reliability are extremely compelling, and today it is safe to say that IO and PIC technologies have earned a secure footing in the world of optics.

22.1 GLOSSARY

A, B, C, D	constants
$A(r, z)$	converging spherical wavefront
c	curvature
D	diffusion constant
d	diffusion depth
EFL	effective focal length
f	focal length
g	gradient constant
h	radial distance from vertex
i	imaginary
k	conic constants
k	wave number
LA	longitudinal aberration
l_0	paraxial focal length
M	total number of zones
NA	numerical aperture
n	refractive index
r	radial distance from optical axis
r_{mask}	mask radius
r_m	radius of the mth zone
t	fabrication time
$\overline{u}$	slope
W_{ijk}	wavefront function
X	shape factor

x, y	Cartesian coordinates
y	height
Z	sag
z	optical axis
Δ	relative refractive difference
ρ	propagation distance
λ	wavelength
$\bar{\sigma}$	$\sigma_{rms}/2y$
σ_{rms}	rms wavefront error
Φ	phase
ψ	special function
FOV	field of view

22.2 INTRODUCTION

Optical components come in many sizes and shapes. A class of optical components that has become very useful in many applications is called micro-optics. We define micro-optics very broadly as optical components ranging in size from several millimeters to several hundred microns. In many cases, micro-optic components are designed to be manufactured in volume, thereby reducing cost to the customer. The following paragraphs describe micro-optic components that are potentially useful for large-volume applications. The discussion includes several uses of micro-optics, design considerations for micro-optic components, molded glass and plastic lenses, distributed-index planar lenses, micro-Fresnel lenses, laser printing, grayscale lithography, diamond turning and micromilling, and liquid tunable lenses. For further information the reader is directed to Refs. 1–3.

22.3 USES OF MICRO-OPTICS

Micro-optics are becoming an important part of many optical systems. This is especially true in systems that demand compact design and form factor. Some optical fiber-based applications include fiber-to-fiber coupling, laser diode-to-fiber connections, LED-to-fiber coupling, and fiber-to-detector coupling. Microlens arrays are useful for improving radiometric efficiency in focal-plane arrays, where relatively high numerical aperture (NA) microlenslets focus light onto individual detector elements. Microlens arrays can also be used for wavefront sensors, where relatively low-NA lenslets are required. Each lenslet is designed to sample the input wavefront and provide a deviation on the detector plane that is proportional to the slope of the wavefront over the lenslet area. Micro-optics are also used for coupling laser diodes to waveguides and collimating arrays of laser diodes. An example of a large-volume application of micro-optics is data storage, where the objective and collimating lenses are only a few millimeters in diameter.[4] Recently micro-optics is also widely used in medical applications like endo-microscopy including confocal, multiphoton microscopy and optical coherence tomography (OCT). It also has a strong position in consumer market in applications like cell phone cameras, Blu-Ray readers, etc.

22.4 MICRO-OPTICS DESIGN CONSIDERATIONS

Conventional lenses made with bulk elements can exploit numerous design parameters, such as the number of surfaces, element spacings, and index/dispersion combinations, to achieve performance requirements for NA, operating wavelength, and field of view. However, fabricators of micro-optic

lenses seek to explore molded or planar technologies, and thus the design parameters tend to be more constrained. For example, refractive microlenses made by molding, ion exchange, mass transport process resemble single-element optics. Performance of these lenses is optimized by manipulating one or possibly two radii, the thickness, and the index or index distribution. Index choices are limited by the available materials. Distributed-index and graded-index lenses have a limited range of index profiles that can be achieved. Additional performance correction is possible by aspherizing one or both surfaces of the element. This is most efficiently done with the molding process, but molded optics are difficult to produce when the diameter of the lens is less than 1.0 mm. In general, one or two aberrations may be corrected with one or two aspheres, respectively.

Due to the single-element nature of microlenses, insight into their performance may be gained by studying the well-known third-order aberrations of a thin lens in various configurations. Lens bending and stop shift are the two parameters used to control aberrations for a lens of a given power and index. Bending refers to distribution of power between the two surfaces, i.e., the shape of the lens, as described in R. Barry Johnson's Chap. 17, "Lenses." The shape is described by the shape factor X that is

$$X = \frac{C_1 + C_2}{C_1 - C_2} \tag{1}$$

where C_1 and C_2 are the curvatures of the surfaces. The third-order aberrations as a function of X are shown in Fig. 1. These curves are for a lens with a focal length of 10.0 mm, an entrance pupil diameter of 1.0 mm, field angle $\overline{u} = 20°$, an optical index of refraction of 1.5, λ = 0.6328 μm, and the object at infinity. For any given bending of the lens, there is a corresponding stop position that eliminates coma,[5] and this is the stop position plotted in the figure. The stop position for which coma is zero is referred to as the *natural* stop shift, and it also produces the least curved tangential field for the given bending. Because the coma is zero, these configurations of the thin lens necessarily satisfy the Abbe sine condition. When the stop is at the lens (zero stop shift), the optimum shape to eliminate coma is approximately convex-plano (X = +l) with the convex side toward the object. The optimum shape is a function of the index, and the higher the index, the more the lens must be bent into a meniscus. Spherical aberration is minimized with the stop at the lens, but astigmatism is near its maximum. It is interesting to note that biaspheric objectives for data storage tend toward the convex-plano shape.

Astigmatism can be eliminated for two different lens-shape/stop-shift combinations, as shown in Fig. 1. The penalty is an increase in spherical aberration. Note that there is no lens shape for which

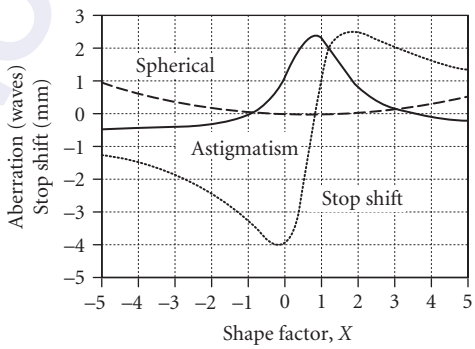

FIGURE 1 Third-order aberrations as a function of the shape factor, or bending, of a simple thin lens with focal length 10.0 mm, entrance pupil diameter of 1.0 mm, field angle 20°, n = 1.5, and object at infinity. The stop position shown is the *natural* stop shift, that is, the position that produces zero coma.

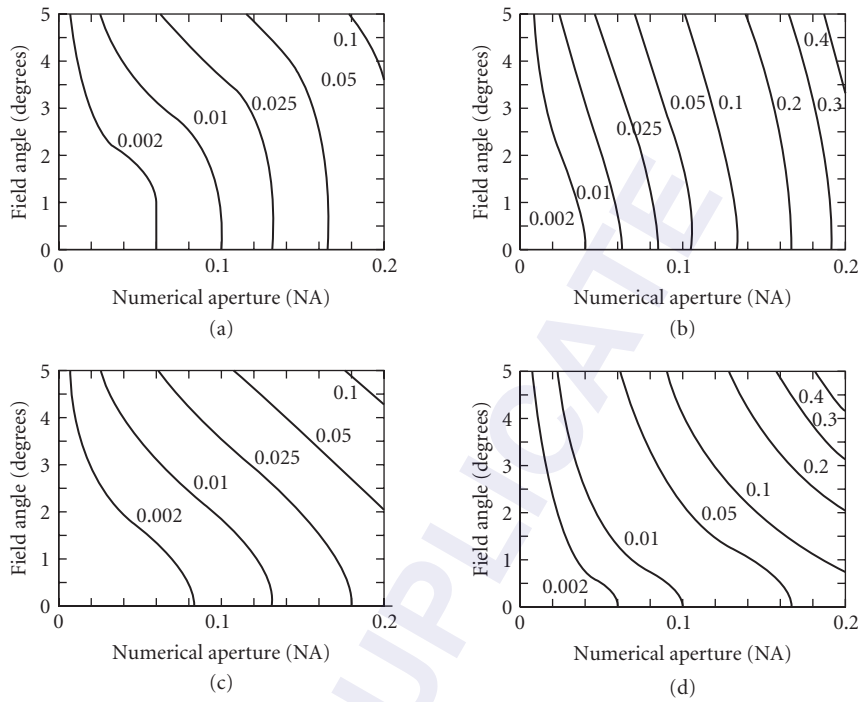

FIGURE 2 Contours of normalized rms wavefront deviation, $\bar{\sigma} = 1000\lambda\sigma_{rms}/2y$, versus field angle and NA, where $2y$ is the diameter of the stop. The stop is located at the lens. The focus is adjusted to give minimum rms deviation of the wavefront, so effects of Petzval curvature are not included. (*a*) $X = 1$, $n = 1.5$; (*b*) $X = -1$, $n = 1.5$; (*c*) $X = 1$, $n = 3.0$; (*d*) $X = -1$, $n = 3.0$.

spherical, coma, and astigmatism are simultaneously zero in Fig. 1, that is, there is no aplanatic solution when the object is at infinity. The aplanatic condition for a thin lens is only satisfied at finite conjugates.

The plano-convex shape ($X = -1$) that eliminates astigmatism is particularly interesting because the stop location is in front of the lens at the optical center of curvature of the second surface. All chief rays are normally incident at the second surface. Thus, the design is monocentric.[6] (obviously, the first surface is not monocentric with respect to the center of the stop, but it has zero power and only contributes distortion.)

Two very common configurations of micro-optic lenses are $X = +1$ and $X = -1$ with the stop at the lens. Typically, the object is at infinity. In Fig. 2, we display contours of normalized rms wavefront deviation, $\bar{\sigma} = \sigma\lambda_{rms}/2y$, versus $\bar{u}$ and NA, where $2y$ = diameter of the stop. Aberration components in σ_{rms} include third-order spherical, astigmatism, and coma. The focus is adjusted to give minimum rms deviation of the wavefront, so effects of Petzval curvature are not included. Tilt is also subtracted. As NA or field angle is increased, rms wavefront aberration increases substantially. The usable field of view of the optical system is commonly defined in terms of Maréchal's criterion[7] as field angles less than those that produce $2y\bar{\sigma}/1000\lambda \le 0.07$ wave. For example, if the optical system operates at $2y = 1.0$ mm, $\lambda = 0.6328$ μm, NA = 0.1, $X = +1$, $n = 1.5$, and $\bar{u} = 2°$, the wavefront aberration due to third-order contributions is

$$\sigma_{rms} = \frac{2y\bar{\sigma}}{1000\lambda} \approx \frac{(1.0\times10^{-3}\,\text{m})(0.015)}{(10^3)(0.6328\times10^{-6}\,\text{m/wave})} = 0.024 \text{ wave} \tag{2}$$

which is acceptable for most situations. Note that the configuration for $X = -1$ yields $\sigma_{rms} \approx 0.079$ wave, which is beyond the acceptable limit. When large values of σ_{rms} are derived from Fig. 2, care must be taken in interpretation of the result because higher-order aberrations are not included in the calculation. Also, if field curvature is included in the calculation, the usable field of view is significantly reduced.

Coma and astigmatism are only significant if the image field contains off-axis locations. In many laser applications, like laser diode collimators, the micro-optic lens is designed to operate on axis with only a very small field of view. In this case, spherical aberration is very significant. A common technique that is used to minimize spherical aberration is to aspherize a surface of the lens. Third-, fifth-, and higher orders of spherical aberration may be corrected by choosing the proper surface shape. In some lens design codes, the shape is specified by

$$Z = \frac{ch^2}{1+\sqrt{1-(1+k)c^2h^2}} + Ah^4 + Bh^6 + Ch^8 + Dh^{10} \tag{3}$$

where Z is the sag of the surface, c is the base curvature of the surface, k is the conic constant ($k = 0$ is a sphere, $k = -1$ is a paraboloid, etc.), and $h = \sqrt{x^2 + y^2}$ is the radial distance from the vertex. The A, B, C, and D coefficients specify the amount of aspheric departure in terms of a polynomial expansion in h.

When a plane-parallel plate is inserted in a diverging or converging beam, such as the window glass of a laser diode or an optical disk, spherical aberration is introduced. The amount of aberration depends on the thickness of the plate, the NA of the beam, and to a lesser extent the refractive index of the plate,[8] as shown in Fig. 3. The magnitude of all orders of spherical aberration is linearly proportional to the thickness of the plate. The sign is opposite that of the spherical aberration introduced by an $X = +1$ singlet that could be used to focus the beam through the plate. Therefore, the aspheric correction on the singlet compensates for the difference of the spherical aberration of the singlet and the plate. This observation follows the fact that minimum spherical aberration without aspheric correction is achieved with the smallest possible air gap between the lens and the plate. For high-NA singlet objectives, one or two aspheric surfaces are added to correct the residual spherical aberration.

Considerations on High-Performance Miniature Systems

In recent years, several designs of high-performance miniature optics were implemented.[9–13] Since one of the major applications is miniature microscopy, many systems have similar characteristics. The diameter of miniature objectives is in the range of 1 to 8 mm, consists of multiple lenses (upto 10), NA is 0.4–1.0 and field of view (FOV) 250 to 500 μm. All these parameters place high requirements on system assembly and fabrication technologies. Examples of manufacturing techniques

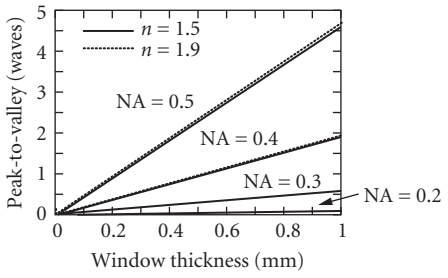

FIGURE 3 Effect of a window on wavefront distortion at $\lambda = 830$ nm.

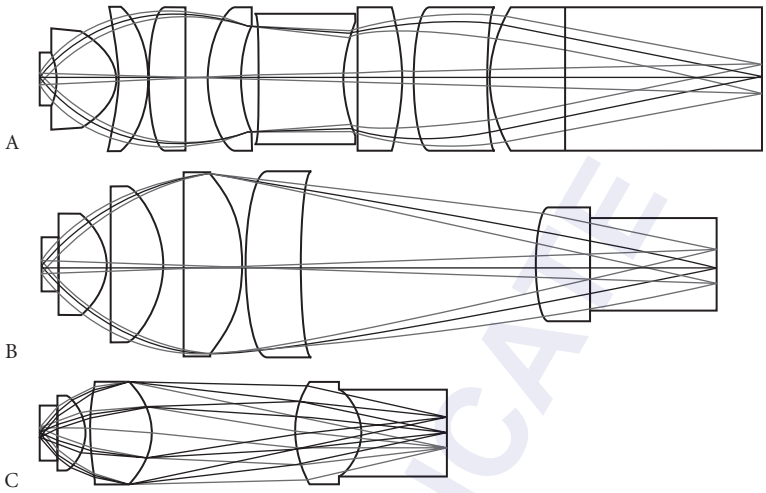

FIGURE 4 Comparison of designs of miniature NA = 1.0, 205 μm FOV microscope objectives. Design A[10] is an all glass, spherical lenses system. Design B[11] uses a plastic injection molded objective lens made in Zeonex. Design C[13] consists of a leading spherical glass lens followed by two aspehrical Zeonex plastic lenses.

include (1) grinding and polishing methods, (2) injection glass and plastic molding, (3) grayscale lithography, and (4) direct diamond turning/micromilling. Grinding and polishing in glass is the most costly technique and requires a large number of components to provide good system correction (lenses are usually spherical). All other mentioned technologies allow easy application of aspherical lenses that significantly reduces the number of parts. On the other hand, these methods often rely on application of photosensitive polymers, solgels, or plastics, which limits selection of materials with different Abbe numbers. This limitation makes correction for chromatic aberrations more difficult.

An example of an effective approach is to build a high NA system as a combination of glass spherical lenses and aspherical plastic/polymer lenses. A comparison of three optical designs with single wavelength, NA = 1.0, FOV = 250 μm is shown in Fig. 4. Design A[10] is an all glass, spherical lenses system. Design B[11] uses aspheric plastic injection molded lenses made in Zeonex. Design C[13] consists of a leading spherical glass lens followed by two aspherical Zeonex plastic lenses, which can be injection molded or diamond turned. All objectives in Fig. 4 are presented in scale and the clear aperture of the smallest design (C) is 2.75 mm. These designs show progressive decrease of complexity based on material and surface shape choices.

A common method used for tolerance analysis of multicomponent systems is Monte Carlo (MC) simulation that statistically adjusts design parameters like radius error, thickness error, surface form error, surface decenter, surface tilt, and refractive index tolerances.[11,13] MC can apply a normal distribution of errors and then evaluate the performance of the system based on the rms spot size or wavefront error. Possible compensation parameters can include the object position, image position, and object shape which is for three-dimensional volume imaging in biological applications. The acceptance criteria can be defined based on the percentage of results that have a rms spot size equal to or less than the diffraction limited Airy disk spot size.

As mentioned above, one of the most significant issues in building high-performance miniature systems is precision assembly. Several alignment-free approaches were recently proposed to simplify the manufacturing process. They include techniques like: micro-optical table (MOT),[14] fabrication of kinematic mechanical features embedded in optical components,[11,15,16] and self centering mounts.[13] All these techniques rely on a zero-alignment concept. In practical terms, the

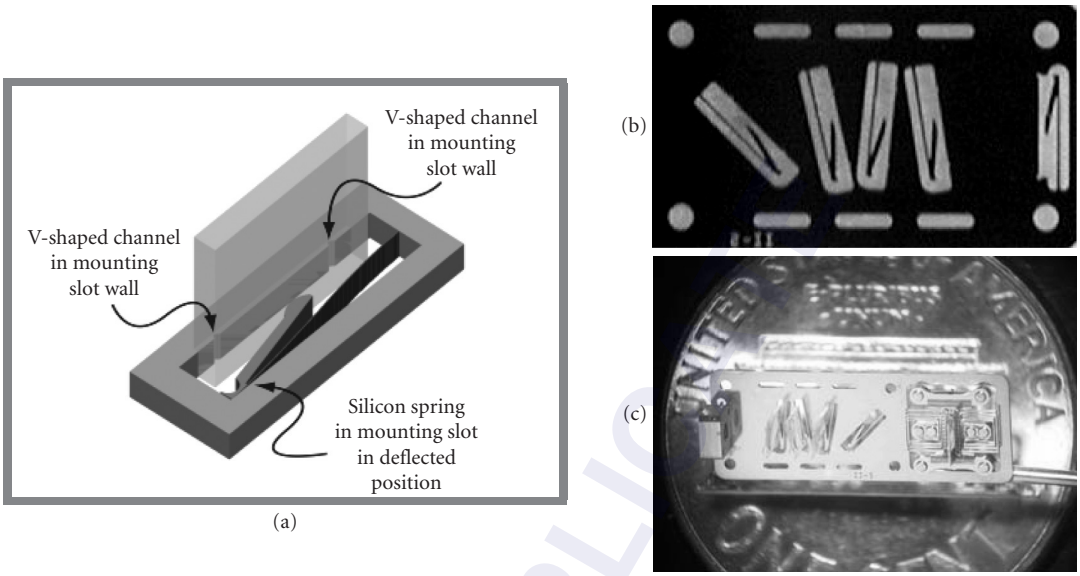

FIGURE 5 (*a*) Concept of MOT assembly;[14] (*b*) MOT platform made with DXRL process; and (*c*) NA = 0.4 miniature microscope assembled on MOT platform.[19]

zero-alignment concept translates into assembly errors that are smaller than the tolerances on the performance of the optical system. Very low assembly errors are achieved through positioning features on each optomechanical and optical component. One technology to fabricate mechanical components is deep reactive ion etching (DRIE)[17] in silicon. A less expensive and more robust alternative is deep x-ray lithography (DXRL).[18] An example of MOT platform fabricated using DXRL technology in nickel-steel alloy is shown in Fig. 5*b*. The DXRL technology delivers submicron assembly precision and helps with packaging. Spring and grove features in MOT shown in the figure allow inserting optical components fabricated with grayscale lithography on thin glass substrates. Positioning precision is provided by assembly features on both MOT and optics. (Grayscale lithography allows fabrication of lens and mechanical features in one step.) Figure 5 shows (*a*) the MOT assembly concept, (*b*) MOT platform made with DXRL process, and (*c*) assembled NA = 0.4 miniature microscope.[19] Table 1 provides assembly precision for MOT technology with DRIE and lithographically fabricated opto-mechanics.[14] These parameters must be accommodated in optical design.

The principle of a kinematic mount fabricated with injection molding or a lithographic process is shown in Fig. 6. Note that V- or U-shaped grooves can be made in the same process as a lens. Precision spheres are then used for stacking consecutive lenses or lens layers, stops, and spacer

TABLE 1 Assembly Precision for MOT Technology with DRIE and Lithographically Fabricated Optomechanics[14]

components.[11] Figure 6*a* shows the concept of kinematic mount and Fig. 6*b* shows NA = 1.0 microscope objective assembled using kinematic mounts embedded in plastic injection molded lenses.[11] (The design of the system is presented in Fig. 4*b*.)

A kinematic approach was also used to build arrays of complex optical systems. Examples of applications include microchemical chips using microlens arrays[16] (used for illumination and detection) and array of high NA microscopes for high throughput digital telepathology.[15]

Another method to position lens components in the objective is to use a self-centering ring, which engages the lens surface, flexing away as it makes contact, while centering the lens with respect to its optical axis.[14] This self-centering ring eliminates any decentration associated with manufacturing error and allows looser lens tolerance. Figure 7 shows a model self-centering lens spring. This approach was used for assembly of NA = 1.0 plastic-glass objective[13] (see also Fig. 4*c*).

22.5 MOLDED MICROLENSES

Molded micro-optic components have found applications in several commercial products, which include compact disk players, bar-code scanners, and diode-to-fiber couplers. Molded lenses become especially attractive when one is designing an application that requires aspheric surfaces.

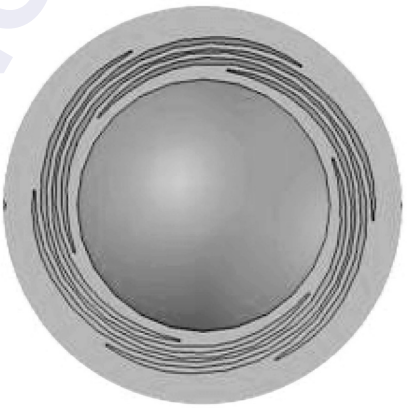

FIGURE 7 Model self-centering lens spring for lens alignment.

Conventional techniques for polishing and grinding lenses tend to be time-expensive and do not yield good piece-to-piece uniformity. Direct molding, on the other hand, eliminates the need for significant grinding or polishing. Another advantage of direct molding is that useful reference surfaces can be designed directly into the mold. The reference surfaces can take the form of flats.[20] The reference flats are used to aid in aligning the lens element during assembly into the optical device. Therefore, in volume applications that require aspheric surfaces, molding becomes a cost-effective and practical solution. The molding process utilizes a master mold, which is commonly made by single-point diamond turning and postpolishing to remove tooling marks and thus minimize scatter from the surface. The master can be tested with conventional null techniques, computer-generated null holograms,[21] or null Ronchi screens.[22] Two types of molding technology are described in the following paragraphs. The first is molded glass technology. The second is molded plastic technology.

Molded Glass

One of the reasons glass is specified as the material of choice is thermal stability. Other factors include low birefringence, high transmission over a broad wavelength band, and resistance to harsh environments.

Several considerations must be made when molding glass optics. Special attention must be made to the glass-softening point and refractive index.[23] The softening point of the glass used in molded optics is lower than that of conventional components. This enables the lenses to be formed at lower temperatures, thereby increasing options for cost-effective tooling and molding. The refractive index of the glass material can influence the design of the surface. For example, a higher refractive index will reduce the surface curvature. Smaller curvatures are generally easier to fabricate and are thus desirable.

An illustration is Coming's glass molding process.[23] The molds that are used for aspheric glass surfaces are constructed with a single-point diamond turning machine under strict temperature and humidity control. The finished molds are assembled into a precision-bored alignment sleeve to control centration and tilt of the molds. A ring member forms the outside diameter of the lens, as shown in Fig. 8. The glass material, which is called a preform, is inserted between the molds. Two keys to accurate replication of the aspheric surfaces are forming the material at high glass viscosity and maintaining an isothermal environment. After the mold and preform are heated to the molding temperature, a load is applied to one of the molds to press the preform into shape. After molding, the assembly is cooled to below the glass transformation point before the lens is removed. Optical performance characteristics of the finished lens are determined by the quality of the mold surfaces, the glass material, and the preform volume, which also determines the thickness of the lens when pressed.

An alternative process is used at Kodak, Inc., where molded optics are injection molded and mounted into precision lens cells.[24] In this process, a tuned production mold can reproduce intricate

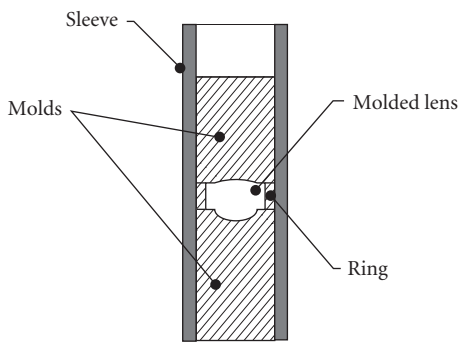

FIGURE 8 Mold for glass optics.

TABLE 2 Preferred and Possible Tolerances for Molded Glass Components[24]

	Preferred	Possible
Center thickness (mm)	10.00 max 0.40 min ±0.030 tol	25.00 0.35 ±0.015
Diameter (mm)	25.00 max 4.00 min ±0.10 tol	50.00 2.00 ±0.01
Diameter of lens beyond clear aperture (mm)	2.00	0.50
Surface quality	80–50	40–20
Axis alignment	3×10^{-3} rad	2×10^{-3} rad
Radius (mm)—best fit sphere	5 to ∞	2 to ∞
Slope (λ/mm)	50 max	100 max
Wavelengths (λ) departure from BFS	≤250	≤500

mounting datum features and extremely well-aligned optics. It can also form a stop, baffle, or a film-plane reference in the system. Table 2 lists preferred and possible tolerances for molded glass components. The Kodak process has been tested with over 50 optical glasses, which include both crowns and flints. This provides a wide index-of-refraction range, $1.51 < n < 1.85$, to choose from.

Most of the molded glass microlenses manufactured to date have been designed to operate with infrared laser diodes at $\lambda = 780$ to 830 nm. The glass used to make the lenses is transparent over a much broader range, so the operating wavelength is not a significant factor if designing in the visible or near infrared. Figure 9 displays a chart of the external transmission of several optical materials versus wavelength. LaK09 (curve B) is representative of the type of glass used in molded optics. The external transmission from 300 to over 2200 nm is limited primarily by Fresnel losses due to the relatively high index of refraction ($n = 1.73$). The transmission can be improved dramatically with antireflection coatings. Figure 10 displays the on-axis operating characteristics of a Corning 350110 lens, which is used for collimating laser diodes. The rms wavefront variation and effective focal length (EFL) are shown versus wavelength. The highest aberration is observed at shorter wavelengths. As the wavelength increases, the EFL increases, which decreases the NA slightly. Table 3 lists several optical properties of molded optical materials. The trend in molded glass lenses is to make smaller, lighter, and higher NA components.[25] Reduction in mass and size allows for shorter access times in optical data storage devices, and higher NA improves storage density in such devices.

Molded Plastic

Molded plastic lenses are an inexpensive alternative to molded glass. In addition, plastic components are lighter than glass components. However, plastic lenses are more sensitive to temperatures and environmental factors. The most common use of molded plastic lenses is in compact disk (CD) players.

Precision plastic microlenses are commonly manufactured with injection molding equipment in high-volume applications. However, the classical injection molding process typically leaves some inhomogeneities in the material due to shear and cooling stresses.[26] Improved molding techniques can significantly reduce variations, as can compression molding and casting. The current state of the art in optical molding permits master surfaces to be replicated to an accuracy of roughly one fringe

1 = lowest / 5 = highest.

per 25 mm diameter, or perhaps a bit better.[27] Detail as small as 5 nm may be transferred if the material properties and processing are optimum and the shapes are modest. Table 4 lists tolerances of injection-molded lenses.[28] The tooling costs associated with molded plastics are typically less than those associated with molded glass because of the lower transition temperature of the plastics. Also, the material cost is lower for polymers than for glass. Consequently, the costs associated with manufacture of molded plastic microlenses are much less than those for molded glass microlenses. The index of refraction for the plastics is less than that for the glass lenses, so the curvature of the surfaces must be greater, and therefore harder to manufacture, for comparable NA.

The glass map for molded plastic materials is shown in Fig. 11. The few polymers that have been characterized lie mainly outside the region containing the optical glasses and particularly far from the flint materials.[29] Data on index of refraction and Abbe number are particularly difficult to obtain for molded plastic. The material is supplied in pelletized form, so it must first be molded into a form suitable for measurement. The molding process subjects the material to a heating and annealing cycle that potentially affects the optical properties. Typically, the effect of the additional thermal history is to shift the dispersion curve upward or downward, leaving the shape unchanged. A more complete listing of optical plastics and their properties is given in Ref. 26. Additional information

TABLE 4 Injection Molding Tolerances for Plastic Lenses

Focal length	±0.5%
Radius of curvature	±0.5%
Spherical power	2 to 5 f*
Surface quality	60/40 (40/20 possible)
Vertex thickness (in)	±0.0005
Diameter (in per in DIA.)	±0.002–0.0005
Repeatability lens-to-lens	0.1–0.3%

*Tolerances given in optical fringes abbreviated by "f".
Vertex-to-edge thickness ratio
4:1 Difficult to mold
3:1 Moderately easy to mold
2:1 Easy to mold

can be obtained from the *Modern Plastics Encyclopedia,*[30] the *Plastics Technology*, *Manufacturing Handbook and Buyer's Guide,*[31] and in John D. Lytle's Chap. 3, "Polymeric Optics," in Vol. IV.

Changes in dimension or refractive index due to thermal variations occur in both molded glass and molded plastic lenses. However, the effect is more pronounced in polymer optical systems because the thermal coefficients of refractive index and expansion are ten times greater than for optical glasses, as shown in Table 3. When these changes are modeled in a computer, a majority of the optical systems exhibit a simple defocus and a change of effective focal length and corresponding first-order parameters. An experimental study[32] was made on an acrylic lens designed for a focal length of 6.171 mm at $\lambda = 780$ nm and 20°C. At 16°C, the focal length changed to 6.133 mm. At 60°C, the focal length changed to 6.221 mm. Thermal gradients, which can introduce complex aberrations, are a more serious problem. Therefore, more care must be exercised in the design of athermalized mounts for polymer optical systems.

The transmission of two common optical plastics, polystyrene and polycarbonate, are shown in Fig. 9. The useful transmittance range is from 380 to 1000 nm. The transmission curve is severely degraded above 1000 nm due to C-H vibrational overtone and recombination bands, except for windows around 1300 nm and 1500 nm. Sometimes, a blue dye is added to the resins to make the manufactured part appear "water clear," instead of slightly yellowish in color. It is recommended that resins be specified with *no* blue toner for the best and most predictable optical results.[26]

The shape of the lens element influences how easily it can be manufactured. Reasonable edge thickness is preferred in order to allow easier filling. Weak surfaces are to be avoided because surface-tension forces on weak surfaces will tend to be very indeterminate. Consequently, more strongly curved surfaces tend to have better shape retention due to surface-tension forces. However, strongly curved surfaces are a problem because it is difficult to produce the mold. Avoid clear apertures that are too large of a percentage of the physical surface diameter. Avoid sharp angles on flange surfaces. Use a center/edge thickness ratio less than 3 for positive lenses (or 1/3 for negative lenses). Avoid cemented interfaces. Figure 12 displays a few lens forms. The examples that mold well are C, E, F, and H. Form A should be avoided due to a small edge thickness. Forms A and B should be avoided due to weak rear surfaces. Form D will mold poorly due to bad edge/center thickness ratio. Form G uses a cemented interface, which could develop considerable stress due to the fact that thermal differences may deform the pair, or possibly even destroy the bond.

The plastic injection-molding process may cause flow-induced birefringence in molded optics and significantly reduce system performance, as it creates highly localized regions of refractive

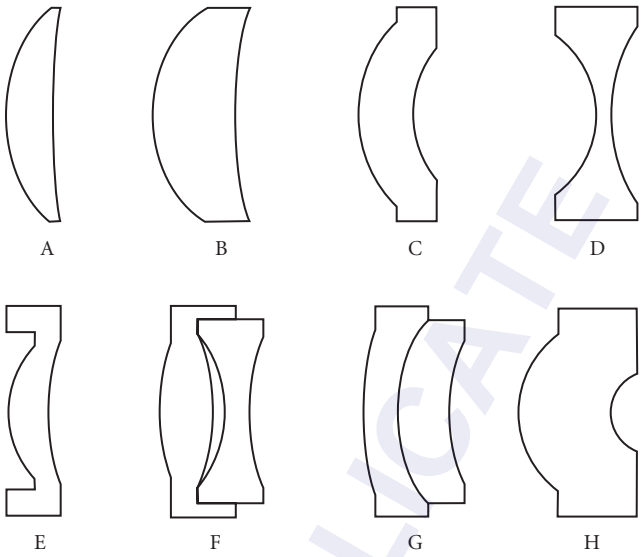

FIGURE 12 Example lens forms for molded plastic lenses. Forms C, E, F, and H mold well. Form A should be avoided due to small edge thickness. Forms A and B should be avoided due to weak rear surfaces. Form D will mold poorly due to bad edge/center ratio. Form G uses a cemented interface, which could develop stress.[29]

index changes. The effect is more likely for high-power components with small edge thickness. Plane polariscope images of injection-molded lenses are presented in Fig. 13. The very left image is for a lens fabricated in a standard injection-molding process, while the center and right images are for the same lens type but after lowering fill speed and first-stage packing pressure. The center and right image had the same molding parameters, but the position of the optical molding insert pin was corrected. Figure 13 shows how significant birefringence effects may occur in the fabrication process. It also shows that it is possible to reduce birefringence effects through parameter adjustment. These effects should be taken into considerations during lens form design. Note that CA in the picture marks clear aperture of the fabricated lenses.

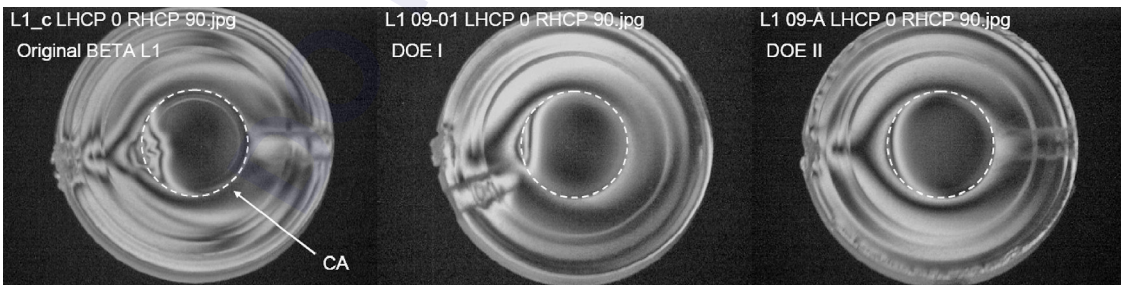

FIGURE 13 Plane polariscope images of injection-molded lenses. The lens edge thickness is 0.5 mm. The very left lens was fabricated in standard injection-molding process. Center and right lenses were fabricated with lower fill speed and lower first-stage packing pressure. CA is clear aperture of the lens.[33]

Since polymers are generally softer than glass, there is concern about damage from ordinary cleaning procedures. Surface treatments, such as diamond films,[34] can be applied that greatly reduce the damage susceptibility of polymer optical surfaces.

A final consideration is the centration tolerance associated with aspheric surfaces. With spherical optics, the lens manufacturer is usually free to trade off tilt and decentration tolerances. With aspheric surfaces, this tradeoff is no longer possible. The centration tolerance for molded aspherics is determined by the alignment of the mold halves. A common specification is 4 to 6 μm, although 3 to 4 μm is possible.

22.6 DIAMOND TURNING

Ultra precision diamond tool machining is an important technology for fabrication of miniature optical systems. It can be used in two ways: (1) producing molds for glass and plastic injection molding, and (2) for direct part manufacturing. Diamond turning was originally developed for large-scale aspherical optics (reflective and IR optics) for astronomy and military applications.[35] Recently, it took an important place in prototyping and fabrication of small-scale systems. Currently diamond turning is capable of fabricating parts with diameters from a fraction of millimeter to over 500 mm.

Diamond tool machining is a technology using monocrystal diamond-cutting tools assembled on an ultraprecision numerically controlled lathe. Diamond tools have nanometer precision edges, which allow cutting a variety of materials and produce molds for injection molding (in metals) or components like mirrors (metals) and lenses (infrared materials and plastics). The depth of a single cut can be below 1 μm. Depending on the material, rough passes have cuts of 10 μm (metals) to approximately 100 μm (plastics). The finishing cut is usually in the 1 to 5 μm range. Modern diamond-turning instruments use air bearings and high-pressure oil bearings to eliminate direct contact of moving parts. After application of a counter-balancing mass, it is possible to achieve exceptionally high precision machining. Optical interpolators assembled on current instruments allow for 1-nm position monitoring. Effective positioning precision is in the range 10 to 50 nm. Therefore, the process is capable of producing submicrometer form precision and nanometer range roughness.

An important performance parameters is form error which is usually in the range 0.05 to 5 μm, while roughness (Ra) is between 1 and 10 nm. The lowest roughness can be reached for metals, where for high-purity aluminum and nickel-plated aluminum Ra is 1 to 5 nm. Slightly worse Ra of 5 to 10 nm can be obtained for plastics (PMMA. Zeonex), while Ra for infrared crystals is few tens of nanometers. Specifications for diamond-turning machines (for example, UPL 250 from Nanotech) guarantee form error of 0.125 μm over a 75-mm diameter part, and surface roughness of 3 nm (Ra) is achieved for spherical component made with high-purity aluminum. While these parameters are manufacturer specific, it is possible to reach values better than 0.05 μm form error and 1.2 nm roughness (Ra). No polishing is required after diamond cutting, and both form error and roughness depends greatly on the surface size, shape, and material.

While diamond-machining technology has many advantages, it also has two major limitations. One drawback is a periodic character of surface roughness of the fabricated part. Improper surface fabrication may result in diffractive effects. Small cutting depth and low feed rate help to mitigate this issue. A second disadvantage is due to material limitations. Diamond turning can machine nonferrous metals, infrared crystals, and selected polymers. It is not possible to machine glass, due to material microcracking. The list of diamond-turnable materials is shown in Table 5.

Current diamond-turning machines have up to 5° of freedom to position the part/tool. They are all called (in machining jargon axes) *X*, *Y*, *Z*, *C,* and *B. X*, *Y*, and *Z* correspond to linear translation of the tool in reference to the part. *C* axis relates to the angular coordinate of a spindle and in consequence angular position of a machined part. The *B* axis controls the angular position of the diamond tool. The variety of axes allows producing aspherical and nonrotational arbitrary

TABLE 5 Summary of Diamond Turnable Materials[1]

Material Category	Material Name	Refractive Index[36,37]	Abbe Number[36,37]	Transmission[2] (μm)[36,37]	Comments
Metals	Aluminum alloys				
	Brass				
	Copper				
	Gold				
	Nickel				Electroplated
	Silver				
Polymers	Acetyl				
	Acrylic (PMMA)	1.491	57.4	0.35–2.1	
	Fluoroplastic	1.320	92		
	Polycarbonate	1.586	30.1	0.30–2.1	Damages tool quickly

[1]Values in the table are approximate and a general guidance.
[2]For IR Crystals transmission is given as a wavelength range of 1-mm-thick sample at 300 K, assuming that the value is larger than 10 percent.[36] For polymers transmission is given for 3.2-mm thick sample and at least 10 percent transmission. Note that polymers with listed transmission range have at least 80 percent (3.2-mm sample) transmission in 400 to 1100 nm wavelengths.

optical components, like Alvarez plates[38] or arrays of lenses. A diagram of a five-axis diamond machine geometry is presented in Fig. 14.

Only *X* and *Z* axes are required for machining aspherical and axially symmetrical parts. For this two-axis mode, the part is mounted on the vacuum chuck of the rotation spindle, while the diamond tool is mounted on the *Z*-axis stage. While the spindle rotates with constant speed, *X* and *Z* move to provide proper surface height (*Z*) for the related radius coordinate (*X*). An example of Zeonex aspherical lenses made for a NA = 1.0 miniature microscope cut in this two-axis mode is presented in Fig. 15. The diameter of the lenses is 2.75 mm.

Arbitrary (free) form machining can be obtained in two cutting modes: diamond turning with *C* axis (*X*, *Z*, *C* configuration) and micromilling (*X, Y, Z*). The *B* axis is used for changing tool angle and, in effect, allows increasing optical power of the fabricated components. Diamond turning using the *C* axis is based on moving the diamond-turning tool in the *Z* direction synchronously with the rotation

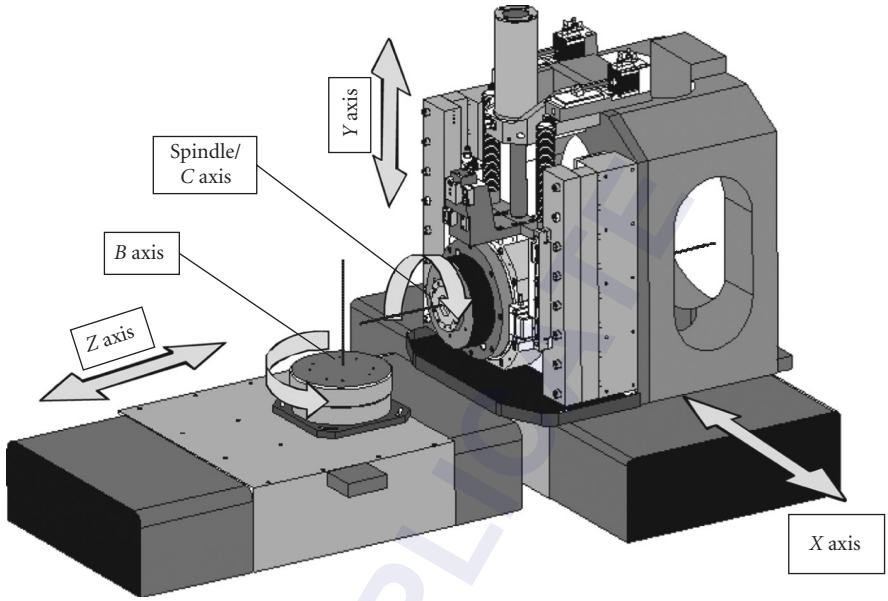

FIGURE 14 A geometry of five-axis diamond-turning machine. (Courtesy of *Moore Nanotechnology System, LLC.*)

angle of the part controlled with spindle controller (*C* axis). The *C* axis is used to change the spindle rate during the cutting process. *C*-axis machining can be used in slow-slide servo and fast servo modes. The slow-slide servo mode uses the *Z* stage of the machine to move the diamond tool. Fast-tool servo requires the diamond tool to be mounted on a piezo or voice-coil controller (the controller is placed on the *Z* stage) and move it with high frequency and small *Z* amplitude synchronously with angular position of spindle (*C* axis). The fast-tool servo, depending on the particular design, works at 100 to 700 Hz frequency and within the *Z* range of approximately 50–70 μm to 500 μm (Precitech, Moore Nanotechnology Systems). Large scanning range of ±3000 μm is possible at low 20-Hz rate (Moore Nanotechnology Systems). The fast-tool servo allows higher fabrication speeds compared with slow-slide servo mode, which in some cases slows the spindle down (during process) below 1 rpm. Depending on the particular machine, spindle-rotation rates can reach upto 10,000 rpm. Common diamond-turning rates are 1000 to 3000 rpm. An example of a lens array fabricated with slow-slide servo

FIGURE 15 Zeonex aspherical lenses made for a NA = 1.0 miniature microscope cut in this two-axis mode.

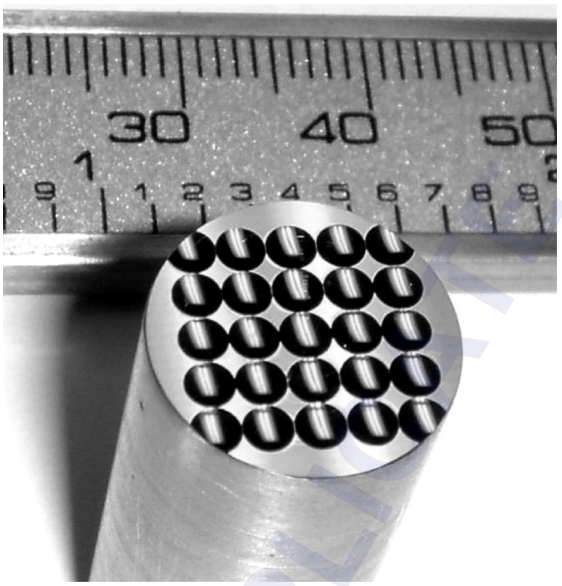

FIGURE 16 An example of a lens array fabricated with slow-slide servo *C*-axis machining.[39]

C-axis machining is presented in Fig. 16.[39] There is a limitation on the slope angle for diamond turning of array components in *C*-axis mode. It depends on the primary clearance angle of the diamond tool. For a standard diamond-cutting tool the slope angle limit is aproximately 20°. Some manufactures can supply tools with angles up to 32°, but these tools are very fragile. Note that the slope angle limitation can be mitigated with *B* axis or in micromilling mode.

Micromilling technology requires the diamond tool to be mounted on the spindle and the part now on the *Z*-axis stage. While the spindle (tool) rotates, it can be moved in *X*, *Y*, *Z* directions in reference to the fabricated part. The cutting time of free-form surfaces with diamond micromilling is significantly longer than for diamond turning in *C*-axis mode. For that reason, it is more appropriate for small optic applications. On the other hand, micromilling is very effective for fabrication of parts that conform to the shape of the tool. For example, making arrays of spherical lenses can be very fast (1-μm cutting depth/revolution) and deliver high surface quality. Micromilling spindle rates are usually faster than for normal diamond-turning applications and typically are 6000 to 8000 rpm. An example of a lens array cut with micromilling is shown in Fig. 17. Micromilling can produce high-power components, like hemispherical lenses or arrays of such lenses.

Research on fabrication of aspherically shaped tools is currently being pursued.[40] If successful, it will provide tremendous benefits for micromilling fabrication and will allow fast production of arrays of high-power aspherical lenses.

22.7 LITHOGRAPHY FOR MAKING REFRACTIVE COMPONENTS

In recent years lithographic techniques became important for micro-optics fabrication. Since lithography is designed for making small, planar components it is more appropriate for fabrication of miniature and micro components rather than for large optics. While entire micro-optics systems can be made with lithographic processes, fabrication of large-scale devices is limited to phase

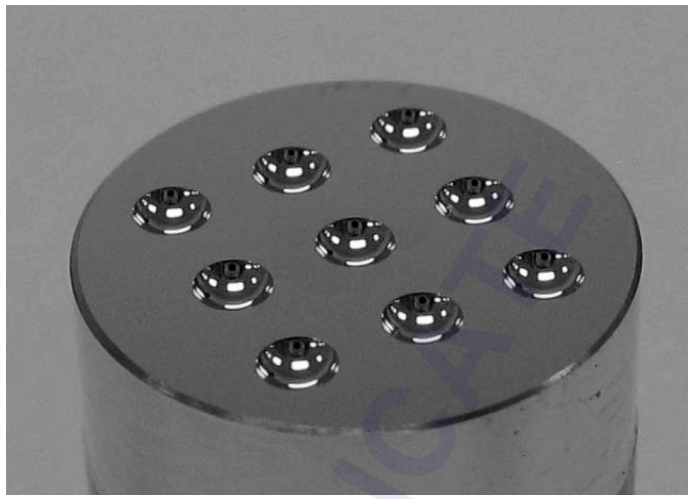

FIGURE 17 A lens array cut with diamond micromilling. *(Courtesy of Moore Nanotechnology Systems, LLC.)*

correctors/plates. As lithography was derived from electronics, it allows producing components in large quantities (parts can be diced out of the wafer) or arrays of systems. Additional benefits are obtained with use of grayscale lithography, which allows making components of arbitrary shape. In this process, fabrication of aspherical surfaces is as easy as making spherical ones (no rotational symmetry is necessary) and it gives the designer enormous work freedom. One example application of grayscale lithography for making arbitrary surfaces was proposed by J. Rogers in the design of miniature microscope.[41] The goal of the design was to remove ghost reflections through lens tilts and to at the same time maintain high performance of NA = 0.4 optics. Shapes of lens surfaces made with grayscale lithography corrected for aberrations originating from tilts. Another benefit of using grayscale lithography is making optomechanical (assembly) features in the same process as optics. This combination can significantly improve assembly precision (see also Sec. 22.4).

While lithography has many advantages, it also has lens sag limitations (in effect limits lens power) currently between 100 and 150 μm.[42] To improve lens parameters research on higher refractive index materials (for example, solgel) is currently being pursued.

Grayscale lithography can be divided into two major categories: (1) direct printing and (2) lithography using grayscale masks. Direct printing can be performed using laser, x-ray or e-beam writing in photosensitive material. In this chapter we will concentrate on fabrication using laser direct writing.

Laser Direct Write Fabrication of Micro-optical Elements

The maskless optical lithography technique referred to in this section is laser direct write (LDW) technology. Most LDW phototools have been developed by modulating a single laser spot focused by a microscope objective. The exposure media is moved under the single focused spot using a translation stage, as shown in Fig. 18.[43] Both rectilinear raster scan and rotational scan techniques have been studied. The rotational scan spins the media on a rotary table, and the objective translates across a radius, as shown in Fig. 19.[44] Rectilinear raster scan by means of a translating *X*-*Y* stage allows patterning of nonrotational profiles with the advantage of patterning more than one element.[43] This method adds a nonrotational pattern structure to the final image.

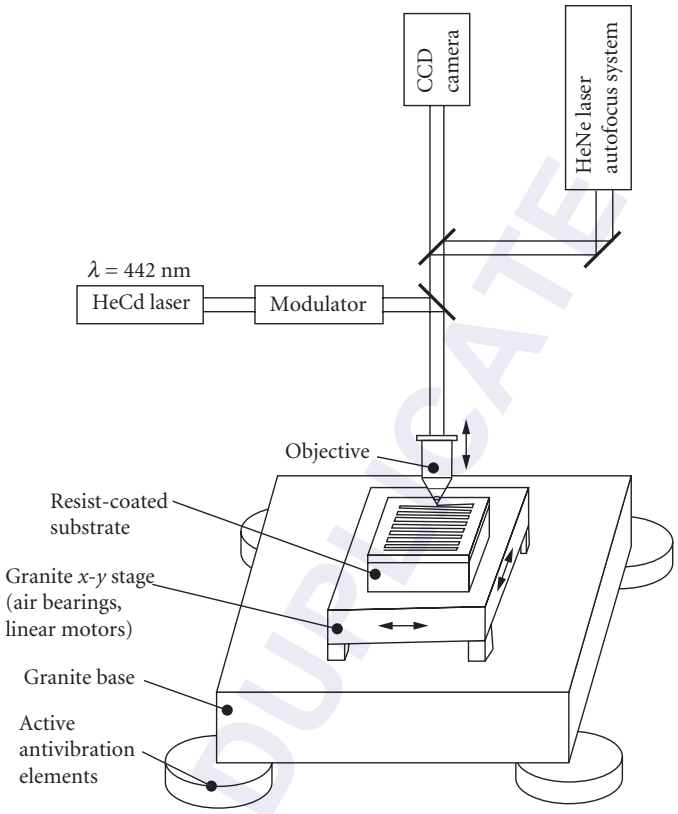

FIGURE 18 Typical laser direct write (LDW) system employing a stable base and *x-y* scan stage with a modulated laser to expose the photosensitive surface at each scan point.[43]

The process steps used in a typical application using LDW technology are

1. Calculate the desired two-dimensional surface sag matrix in the lens material, based on the optical wavefront desired in transmission or reflection. In transmission, properties of the optical material used for the micro-optical element must be considered at the design wavelength. Exposure into simple photoresist is often sufficient for many applications, but the pattern may also be milled or etched into an underlying substrate, like fused silica or GaP.
2. If all other process steps are linear, the surface sag matrix is directly proportional to the depth of material removed with a positive-tone photoresist, which is the most common type of photoresist.
3. However, these process steps are rarely linear. Typically, the designer must compensate the surface sag by the nonlinear properties of the photoresist and the etching or milling processes. Nonlinear properties of the photoresist are best calibrated directly on the LDW phototool immediately before exposure. A calibration ramp is shown in Fig. 20, where responses of the exposure system and photoresist to a linear input ramp show a strongly nonlinear behavior. Depending on the milling or etching technique used, the additional correction for differential milling rate (etch rate of the optical material divided by the etch rate of the resist) must be accommodated. In dry-etch system, the differential etch rate is typically 6:1, but may be as high as 100:1 or as low as 1:1.

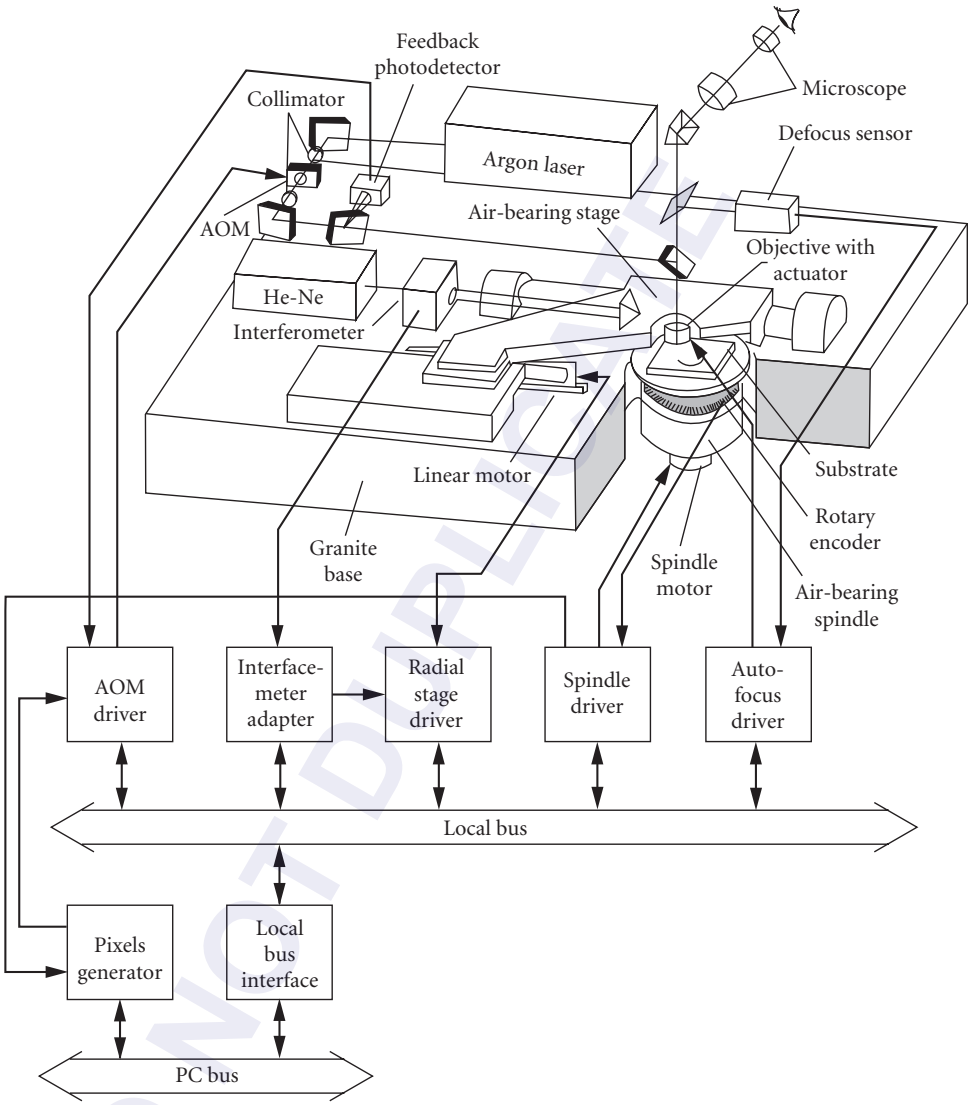

FIGURE 19 Polar coordinate writer for fabrication of micro-optical components.[44] The substrate rotating on the spindle is exposed with a focused and modulated laser beam along a diameter. A translation stage moves the focused beam along the spindle radius to expose different diameters. Good synchronization between the spindle and laser modulation can produce arbitrary gray-scale profiles.

4. Resist layer is deposited on the substrate, exposed and developed according to the compensated exposure profile. Certain photoresist process steps are required, such as prebake to remove residual solvents and postbake or postdevelop bake, which depend on the chemistry being used. If resist is used as the optical material, there are no more process steps required.
5. If the pattern is transferred into the substrate material, the substrate must be mounted into the milling chamber or etch bath for further processing.

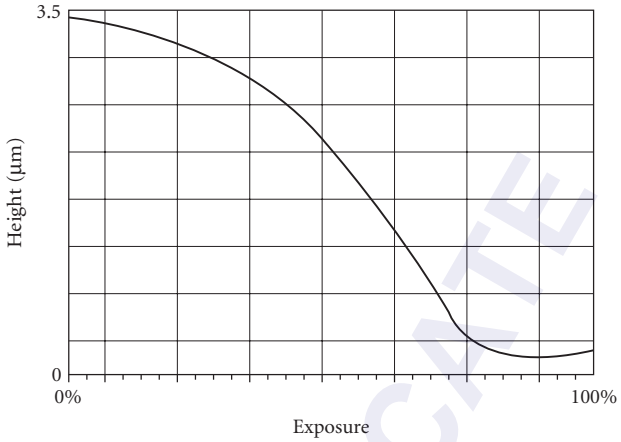

FIGURE 20 Response curve of positive-tone photoresist to a linearly increasing exposure signal (0 to 100 percent laser power) that takes into account nonlinearities of the exposure system and the photoresist.

Although exposure in photoresist is the most common method, other materials may be used for direct laser writing. For example, Poleshchuk et al. use a polar coordinate writer to change the absorption of amorphous silicon as a function of position for fabrication of gray-scale masks, as shown in Fig. 21.[44] The reduction in optical absorption is caused by an induced crystallization of the amorphous silicon.

Other types of LDW phototools have also been proposed. A system using *x-y* galvanometer mirrors has been constructed to fabricate micro-optical components by photodeposition of amorphous

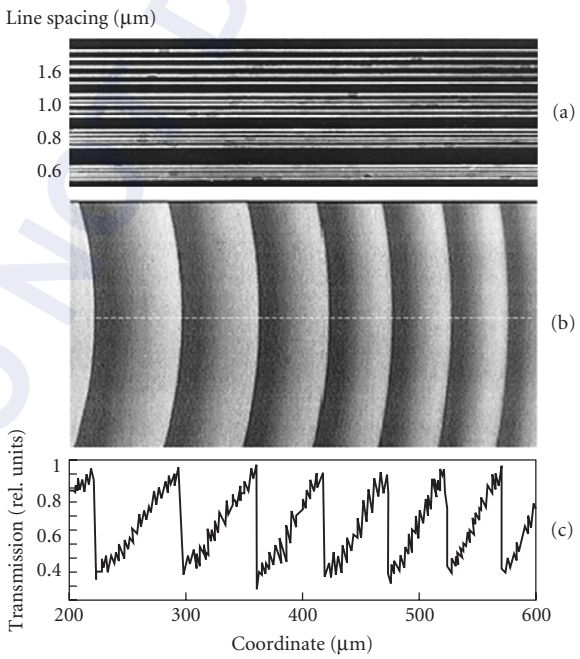

FIGURE 21 Directing laser writing of gray-scale patterns in amorphous silicon films using a polar coordinate writer.[44]

selenium (a-Se).[45] The galvanometer mirrors are used instead of *x-y* stages to move the focused laser spot across the sample. Yet another system uses digital multi-micromirror device (DMD) array with a 10:1 lithographic reduction camera to expose micro-optical patterns.[46] In this system, the DMD is illuminated with a He g-line (436 nm) illumination system, and pixels of the DMD are turned "on" or "off" to direct light into or away from, respectively, the projection camera. A full image of the DMD array is exposed at one time with this system, thus increasing throughput. Pixels in the "on" state expose the resist. Still another system under development is the high-speed maskless lithography tool (MLT) at the University of Arizona.[47] In this system, an 8-bit modulated 370-nm laser beam is reflected from a rotating polygon and focused to a scan line (*x* dimension) in the photoresist. As the polygon rotates, the photoresist-coated sample is slowly translated with a linear stage perpendicular (*y* dimension) to the scan line. By the time the scan line is complete, the stage has moved a *y* distance corresponding to the width of 1 pixel in that dimension and is ready for the next scan line. A twelve-sided polygon rotating at 3000 rpm provides 12,000 pixels across one scan line. Pixel dimensions are 2.1 μm square, and the spot size is approximately 2.5 μm. The length of the written pattern in the *y* direction depends on the range of the stage and the size of the computer buffer memory. One 25 mm × 25 mm substrate can be exposed in approximately 12 seconds.

Lithography with Gray-Scale Masks

Lithography with use of gray-scale masks is a three step process:

1. Substrate is coated with photoresist, polymer, or solgel glass.
2. Sample is exposed with UV light through gray-scale mask.
3. Sample is developed to create refractive lens component.

For transferring lens shape into glass, an additional step of deep reactive ion etching (DRIE) is required. A conceptual graph presenting the gray-scale lithography process is shown in Fig. 22. The process requires two critical components, which are a gray-scale mask and a photosensitive material with linear relationship between optical density and level of polymerization so the lens height will directly relate to energy delivered to the sample. Note that a nonlinear relation is also possible to use,

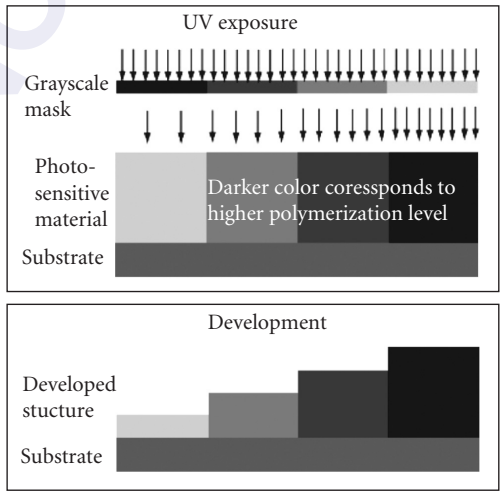

FIGURE 22 Principle of gray-scale lithography process.

TABLE 6 Comparison of Achievable Resolution for Different Type of Gray-Scale Mask[3]

Mask Type	Minimum Feature Size
Photographic masks	<5 μm
Halftoning	≅8 μm
HEBS masks	<1 μm

but it requires a careful calibration process for the mask fabrication, exposure, and development process. Examples of technologies to make gray-scale masks include[3]

- Photographic masks—can be made with photoreduction on photosensitive emulsion or with variable laser intensity writing.
- Halftoning—gray levels are obtained by different density and size of binary structure.
- HEBS masks—high energy beam sensitive glass is used to fabricate masks with e-beam writing.

Comparison of parameters for these mask techniques is presented in Table 6.

During the lithography process negative-tone photosensitive material (solgel, photoresist) is polymerized with UV light and immersed in developer. Regions less exposed to UV radiations dissolve more quickly and create variable height components. An example of structure height as a function of optical density is shown in Fig. 23.[48]

Especially interesting is the gray-scale lithography process with thick solgel and photoresist materials, as it allows higher optical power and larger components. It is especially important for miniature imaging systems (miniature microscopes, endoscopes, cameras). These devices need to obtain large FOV and therefore their size cannot be too small. High-film thicknesses is a prerequisite to optical elements of greater optical power, that is, shorter focal length. Small root-mean-square (rms) surface roughness is demanded to minimize undesired scattering from lithographically

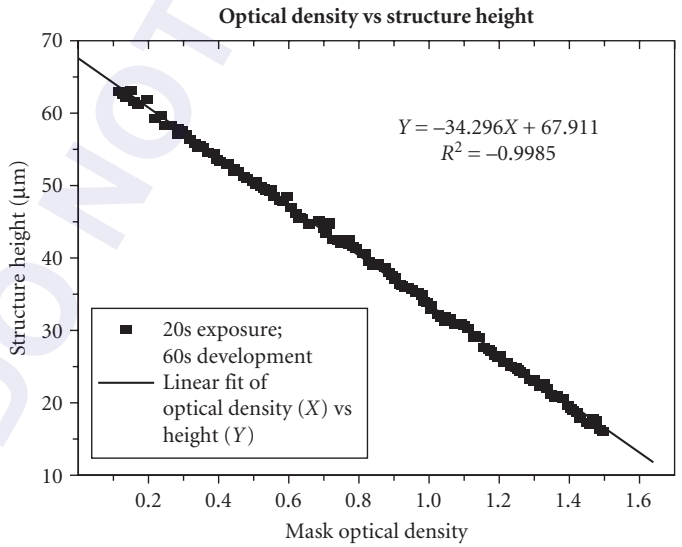

FIGURE 23 Optical component surface height as a function of optical density for hybrid solgel glass.[48]

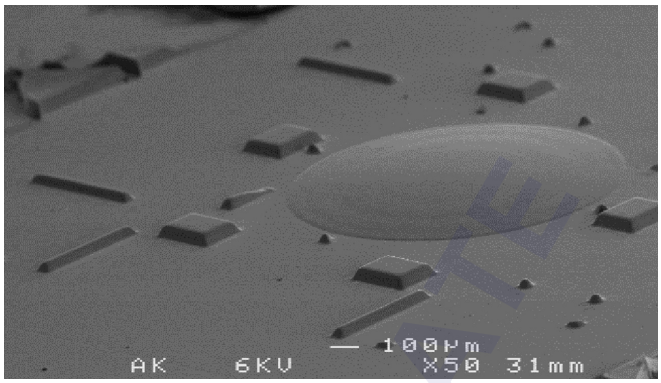

FIGURE 24 SEM image of the lens fabricated using solgel and gray-scale HEBS photomasks.[48]

fabricated optical elements. Values of large thickness (up to 135 μm) at a low *rms* roughness of 10 nm were reported.[42] An example of a solgel lens fabricated with gray-scale process is shown in Fig. 24.[48] Features around the lens were designed for optomechnical assembly and work in the MOT setting. (For more details refer to Sec. 22.4.)

22.8 MONOLITHIC LENSLET MODULES

Monolithic lenslet modules (MLMs) are micro-optic lenslets configured into close-packed arrays. Lenslets can be circular, square, rectangular, or hexagonal. Aperture sizes range from as small as 25 μm to 1.0 mm. Overall array sizes can be fabricated up to 68 × 68 mm. These elements, like those described in the previous section, are fabricated from molds. Unlike molded glass and plastic lenses, MLMs are typically fabricated on only one surface of a substrate, as shown in the wavefront sensing arrangement of Fig. 25. An advantage of MLMs over other microlens array techniques is that the fill factor, which is the fraction of usable area in the array, can be as high as 95 to 99 percent.

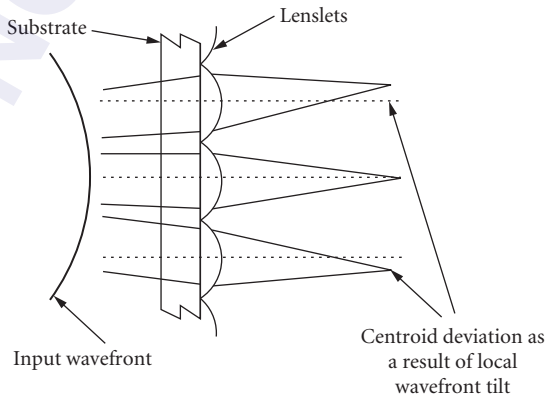

FIGURE 25 Monolithic lenslet modules (MLMs) configured for wavefront sensing.[57]

Applications for MLMs include Hartman testing,[49] spatial light modulators, optical computing, video projection systems, detector fill-factor improvement,[50] and image processing.

There are three processes that are used to construct MLMs.[51] All three techniques depend on using a master made of high-purity annealed and polished material. After the master is formed, a small amount of release agent is applied to the surface. In the most common fabrication process, a small amount of epoxy is placed on the surface of the master. A thin glass substrate is placed on top. The lenslet material is a single-part polymer epoxy. A slow-curing epoxy can be used if alignment is necessary during the curing process.[52] The second process is injection molding of plastics for high-volume applications. The third process for fabrication of MLMs is to grow infrared materials, like zinc selenide, on the master by chemical vapor deposition. Also, transparent elastomers can be used to produce flexible arrays.

MLMs are advertised[53] to be diffraction-limited for lenslets with NA < 0.10. Since the lens material is only a very thin layer on top of the glass substrate, MLMs do not have the same concerns that molded plastic lenses have with respect to birefringence and transmission of the substrate. For most low-NA applications, individual lenslets can be analyzed as plano-convex lenses. Aspheres can be fabricated to improve imaging performance for higher NAs. Aspheres as fast as NA = 0.5 have been fabricated with spot sizes about twice what would be expected from a diffraction-limited system. The residual error is probably due to fabrication imperfections observed near the edges and corners of the lenslets.[54]

22.9 DISTRIBUTED-INDEX PLANAR MICROLENSES

A distributed-index planar microlens, which is also called a Luneberg lens,[55] is formed with a radially symmetric index distribution. The index begins at a high value at the center and decreases to the index value of the substrate at the edge of the lens. The function that describes axial and radial variation of the index is given by[56]

$$n(r, z) \approx n(0, 0)\sqrt{1 - g^2 r^2 - \frac{2g\Delta n^2(0, 0)}{d} z^2} \tag{4}$$

where r is the radial distance from the optical axis, z is the axial distance, $n(0, 0)$ is the maximum index at the surface of the lens, g is a constant that expresses the index gradient, d is the diffusion depth, and $\Delta = (n(0, 0) - n_2)/n(0, 0)$, where n_2 is the substrate index. Typical values are $\Delta = 0.05$, $d = 0.4$ mm, $r_{max} = 0.5$ mm, $n_2 = 1.5$, and $g = \sqrt{2\Delta}/r_{max} = 0.63$ mm^{-1}. These lenses are typically fabricated on flat substrates and yield hemispherical index profiles, as shown in Fig. 26. Two substrates placed together will produce a spherical lens. Several applications of light coupling with distributed-index microlenses have recently been demonstrated.[57] These include coupling laser diodes to fibers, LEDs to fibers, fibers to fibers, and fibers to detectors. In the future, arrays of lenslets might aid in parallel communication systems.

One way to introduce the index gradient is through ion exchange.[58] As shown in Fig. 26, a glass substrate is first coated with a metallic film. The film is then patterned with a mask that allows ions to diffuse from a molten salt bath through open areas of the mask. Ions in the glass substrate are exchanged for other ions in the molten salt at high temperatures. The diffused ions change the refractive index of the substrate by an amount that is proportional to their electric polarizability and concentration. To increase the index, diffusing ions from the salt bath must have a larger electronic polarizability than that of the ions involved in the glass substrate. Since ions that have larger electron polarizability also have larger ionic radius, the selective ion exchange changes the index distribution and creates local swelling where the diffusing ion concentration is high. The swelling can be removed with polishing for a smooth surface. Alternatively, the swelling can be left to aid in the lensing action of the device. To obtain the proper index distribution, the mask radius and diffusion time must be chosen carefully.[59] If the mask radius, r_{mask}, is small compared to the diffusion depth, the derivative of the index distribution with respect to radial distance r monotonically

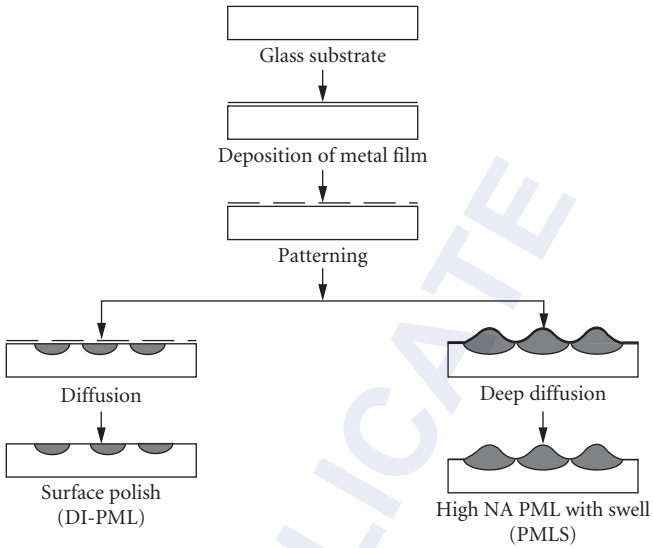

FIGURE 26 Planar distributed-index microlens array and fabrication process.[57]

decreases. Since the curvature of a light ray passing through the medium is proportional to the gradient of the logarithm of the refractive index, the rays tend not to focus. A suitable combination of diffusion time t and mask radius is given by $Dt/r_{\text{mask}}^2 \approx 0.4$, where D is the diffusion constant of the dopant in the substrate. Table 7 displays the diffusion time necessary for making a planar microlens with a radius of 0.5 mm. Typically, the paraxial focal length in the substrate is $l_0 \approx 20\ r_{\text{mask}}$, and the numerical aperture is NA $\approx n_2/20$.

Other fabrication techniques can also be used. Planar lens arrays in plastics are fabricated with monomer-exchange diffusion.[60,61] Plastics are suitable for making larger-diameter lenses because they have large diffusion constants at relatively low temperatures (100°C). The electromigration technique[62] is more effective for creating devices with short focal length. For example, by applying an electric field of 7 V/mm for 8 hours, it is possible to obtain a planar microlens with radius of 0.6 mm and focal length of 6.8 mm.[59] A distributed-index microlens array using a plasma chemical vapor deposition (CVD) method has also been reported.[63] In this process, hemispherical holes are etched into a planar glass substrate. The holes are filled with thin layers of a combination of SiO_2 and Si_2N_4. These materials have different indices of refraction, and the composition is varied from the hemispherical outside shell to the center to provide a Luneburg index distribution.

TABLE 7 Summary of Diffusion Times for Planar DI Lenses[61]

Materials	W_n/n	D (m²/s)	t (s)*
Plastics (DIA-MMA)	0.05	3×10^{-10}	3×10^2
Glass (TI) ion-exchange	0.05	4×10^{-13}	9×10^4
Glass (TI) electromigration	0.05	—	$3 \times 10^{4\dagger}$

*$t = (r_m^2/D) \times 0.4$.
†Experimental data with radius of 0.6 mm.

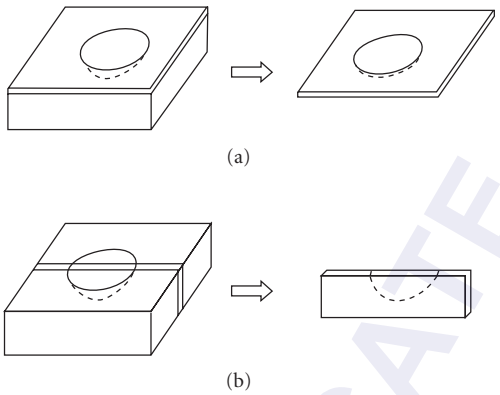

FIGURE 27 Slicing a lens to obtain a thin sample for interferometric characterization.[59] (*a*) Lateral slice and (*b*) longitudinal slice.

Shearing interferometry can be used to measure the index distribution from thinly slieed samples of lenslets. Samplets are acquired laterally or longitudinally, as shown in Fig. 27. Results of the measurement on a lateral section are shown in Fig. 28 for the ion-exchange technique. The solid line is the theoretical prediction, and the dotted line corresponds to measured data. The large discrepancy between measured and theoretical results is probably due to concentration-dependent diffusion or the interaction of the dopants. Figure 29 shows the two-dimensional index profile resulting from a deep electromigration technique.[64] These data correspond much more closely to the theoretical values in Fig. 28.

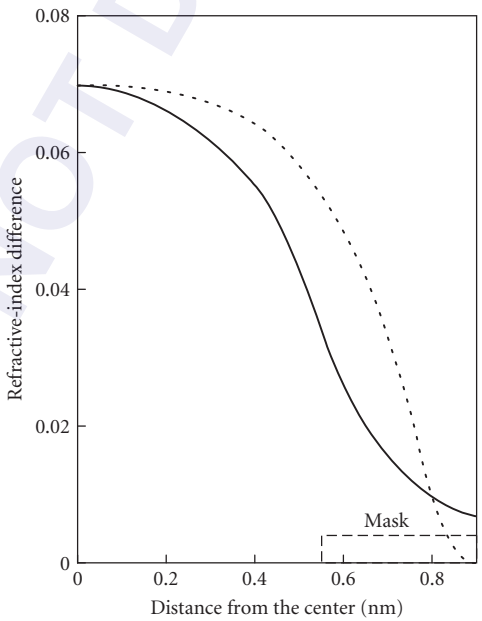

FIGURE 28 Surface index distribution of a planar microlens. Theoretical (——) and experimental (···).[107]

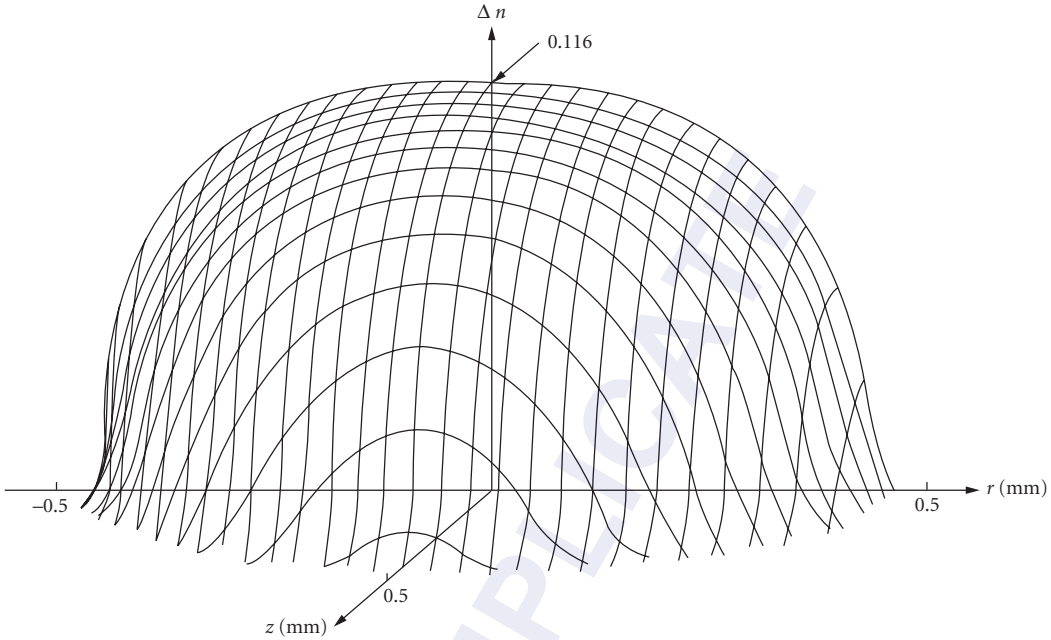

FIGURE 29 Two-dimensional index distribution of a distributed-index planar microlens prepared with the deep electromigration technique.[64]

The ray aberration of a distributed-index lens is commonly determined by observing the longitudinal aberration at infinite conjugates, as shown in Fig. 30. The paraxial focusing length, l_0, is given by

$$l_0 = d + \frac{\sqrt{1-2\Delta}}{g} \cot\left[\frac{gd \sin^{-1}\sqrt{2\Delta}}{\sqrt{2\Delta}}\right] \tag{5}$$

The amount of longitudinal aberration is defined by LA = $(l - l_0)/l_0$, where l is the distance at which a ray crosses the optical axis. LA increases with the radius r of the ray. In order to display the effects of different Δ and n_2 parameters, we define a normalized numerical aperture that is given by

$$\overline{\text{NA}} = \frac{\text{NA}}{n_2\sqrt{2\Delta}} \tag{6}$$

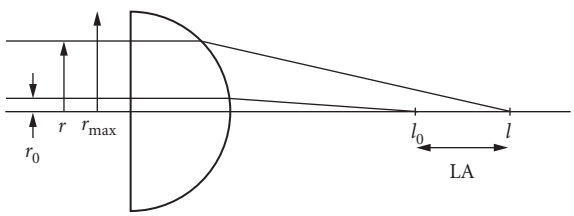

FIGURE 30 Longitudinal ray aberration, LA, of a distributed-index planar microlens. The object is at infinity. l_0 is the paraxial focal distance. LA increases with r.

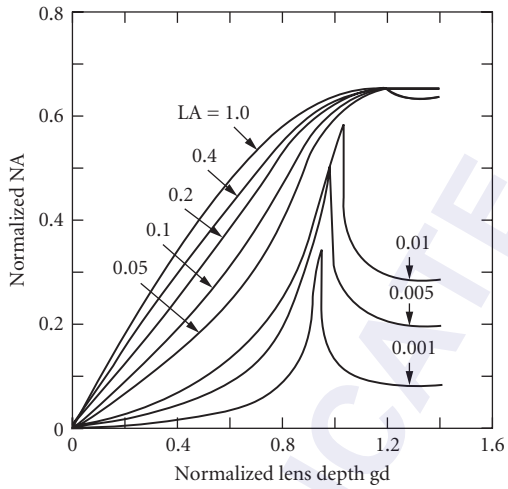

FIGURE 31 Normalized NA versus normalized depth of the distributed index region at several values of LA.[56]

and is plotted in Fig. 31 versus diffusion depth for several values of LA. Notice that, for small values of LA, the maximum $\overline{NA}$ occurs at a diffusion depth of $d \approx 0.9/g$.

Wave aberration of a planar distributed index microlens is shown in Fig. 32. The large departure at the maximum radius indicates severe aberration if used at full aperture. Swelled-structure lenses can exhibit much improved performance.[65] It has been determined that the index distribution contributes

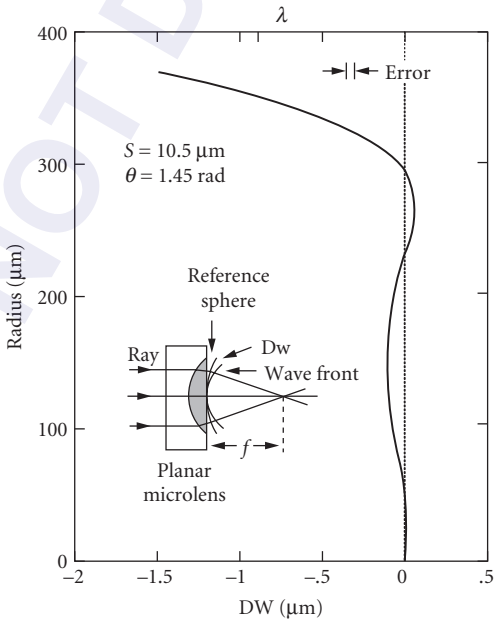

FIGURE 32 Wave aberration of a distributed-index planar microlens.[108]

TABLE 8 Fundamental Characteristics of the Planar DI Microlens[28]

	Diameter (μm)	NA	Focal Length (μm)
Planar	10–1000	0.02–0.25	20–4000
Swelled	50–400	0.4–0.6	55–500

very little to the power of the swelled-surface element. Most of the focusing power comes from the swelled surface-air interface. A few characteristics of ion-exchanged distributed-index microlenses are shown in Table 8.

22.10 MICRO-FRESNEL LENSES

The curvature of an optical beam's wavefront determines whether the beam is converging, diverging, or collimated. A bulk lens changes the wavefront curvature in order to perform a desired function, like focusing on a detector plane. The micro-Fresnel lens (MFL) performs the same function as a bulk lens, that is, it changes the curvature of the wavefront. In a simple example, the MFL converts a plane wavefront into a converging spherical wavefront, $A(x, y, z)$, as shown in Fig. 33. The difference between an MFL and a bulk lens is that the MFL must change the wavefront over a very thin surface.

A Fresnel lens is constructed of many divided annular zones, as shown in Fig. 34. Fresnel lenses are closely related to Fresnel zone plates.[66,67] Both zone patterns are the same. However, unlike a Fresnel zone plate, the Fresnel lens has smooth contours in each zone, which delay the phase of the optical beam by 2π radians at the thickest point. In the central zone, the contour is usually smooth enough that it acts as a refractive element. Toward the edges, zone spacing can become close to the wavelength of light, so the Fresnel lens exhibits diffractive properties. Also, due to the quasi-periodical nature of the zones and the diffractive properties, Fresnel lenses have strong wavelength dependencies.

Advantages of the Fresnel lens are that they can be made small and light compared to bulk optical components. Note that binary optics, which are described in Michael W. Farn and Wilfrid B. Veldkamp's Chap. 23, "Binary Optics," are stepped approximations to the MFL smooth-zone contour.

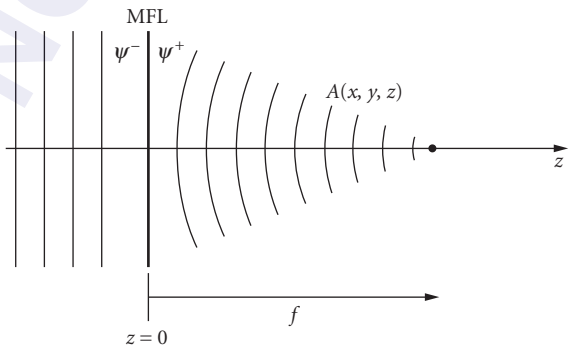

FIGURE 33 A micro-Fresnel lens (MFL) is often used to convert a planar wavefront into a converging spherical wave, $A(x, y, z)$, which focuses a distance f away from the MFL. The phase of the light in a plane on either side of the MFL is described by $\psi^-$and ψ^+.

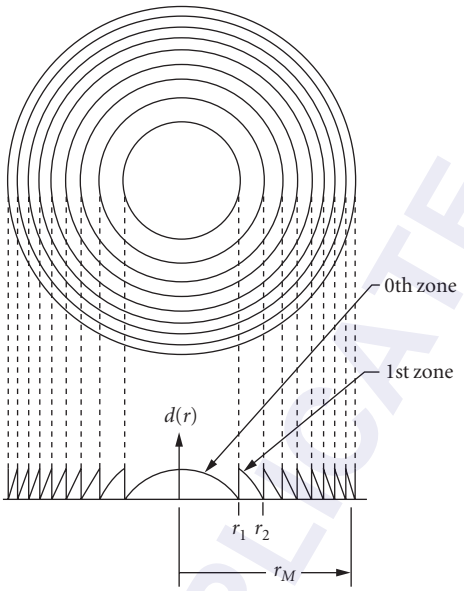

FIGURE 34 Fresnel lens construction. M-divided annular zones occur at radii r_i in the same manner as a Fresnel zone plate. The profiles of each zone are given by $d(r)$, and they are optimized to yield the maximum efficiency in the focused beam.

To understand the zonal profiles of the MFL, we return to our example problem illustrated in Fig. 33. Our development is similar to that described by Nishihara and Suhara.[68] The converging spherical wavefront is given by

$$A(r, z)=\frac{A_0}{\rho}\exp\left[-i(k\rho+\omega t)\right]=\frac{A_0}{\rho}\exp\left[i\phi(r, z)\right] \tag{7}$$

where A_0 is the amplitude of the wave, $\rho^2=(z-f)^2+r^2$, $r=\sqrt{x^2+y^2}$, f is the focal length, and $k=2\pi/\lambda$. The phase of $A(x, y, z)$ at $t=0$ and in a plane just behind the MFL is given by

$$\phi(x, y, 0^+)=-k\sqrt{f^2+r^2} \tag{8}$$

We could add a constant to Eq. (8) and not change any optical properties other than a dc phase shift. Let

$$\psi^+(r)=\phi(x, y, 0^+)+kf+2\pi=2\pi+k(f-\sqrt{f^2+r^2}) \tag{9}$$

Zone radii are found by solving

$$k(f-\sqrt{f^2+r_m^2})=-2\pi m \tag{10}$$

where $m=1, 2, 3, \ldots$ is the zone number. The result is

$$r_m=\sqrt{2\lambda fm+(\lambda m)^2} \tag{11}$$

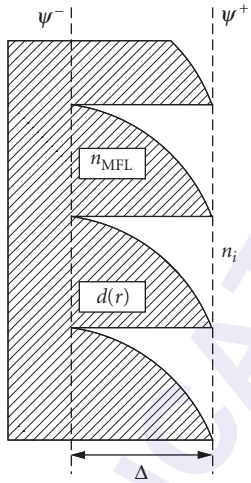

FIGURE 35 Portion of a Fresnel lens profile showing the thickness variation of the pattern. The thickness at any radius is given by $d(r)$, where r is the radial distance from the center of the lens. The phase shift that is added to wavefront ψ^- is determined by $d(r)$, the index of refraction of the substrate, n_{MFL}, and the index of refraction of the image space, n_i. The maximum thickness of the pattern is given by Δ. The resulting phase in a plane just after the MFL is given by ψ^+.

Equation (9) becomes

$$\psi_m^+(r) = 2\pi(m+1) + k(f - \sqrt{f^2 + r^2}) \tag{12}$$

The job of the MFL is to provide a phase change so that the incident wavefront phase, $\psi^-(r)$, is changed into $\psi^+(r)$. The phase introduced by the MFL, $\psi_{MFL}(r)$, must be

$$\psi_{MFL}(r) = \psi^+(r) - \psi^-(r) \tag{13}$$

A phase change occurs when a wave is passed through a plate of varying thickness, as shown in Fig. 35. $\psi^+(r)$ is given by

$$\begin{aligned} \psi^+(r) &= \psi^-(r) + kn_{MFL}\, d(r) + kn_i[\Delta - d(r)] \\ &= \psi^-(r) + k(n_{MFL} - n_i)d(r) + kn_i\Delta \end{aligned} \tag{14}$$

where $d(r)$ is the thickness profile, n_i, is the refractive index of the image space, n_{MFL} is the refractive index of the substrate, and Δ is the maximum thickness of the MFL pattern. $d(r)$ is found by substituting Eq. (14) into Eq. (12). Note that the factor Δ is a constant and only adds a constant phase shift to Eq. (14). Therefore, we will ignore Δ in the remainder of our development. If $n_i = 1$, the result is

$$d_m(r) = \frac{\lambda(m+1)}{n_{MFL} - 1} - \frac{\sqrt{f^2 + r^2} - f}{n_{MFL} - 1} \tag{15}$$

where we have arbitrarily set $\psi^{-}(r) = 0$. The total number of zones M for a lens of radius r_M is

$$M = \frac{r_M(1-\sqrt{1-\mathrm{NA}^2})}{\lambda \mathrm{NA}} \tag{16}$$

The minimum zone period, $\Lambda_{\min}$, occurs at the outermost part of the lens and is given by

$$\Lambda_{\min} = r_M - r_{M-1} = r_M\left(1-\sqrt{1-\frac{2\lambda f+(2M-1)\lambda^2}{2M\lambda f+(M\lambda)^2}}\right) \tag{17}$$

The following approximations may be used without significant error if NA < 0.2 and $M \gg 1$:

$$d_m(r) \approx \frac{m\lambda f - 0.5r^2}{f(n_{\mathrm{MFL}}-1)} \tag{18}$$

$$r_m \approx \sqrt{2m\lambda f} \tag{19}$$

$$M \approx \frac{r_M}{2\lambda}\mathrm{NA} \tag{20}$$

and

$$\Lambda_{\min} \approx \frac{\lambda}{\mathrm{NA}} \tag{21}$$

The consequence of using Eqs. (18) and (19) for NA > 0.2 is that a small amount of spherical aberration is introduced into the system.

The aberration characteristics of the MFL and the Fresnel zone plate are very similar. Aberrations of Fresnel zone plates have been discussed by Young.[69] For convenience, we describe a zone plate with the stop at the lens that is illuminated with a plane wave at angle α. For an MFL made according to Eq. (15) and used at the proper conjugates, there will be no spherical aberration or distortion. Coma, astigmatism, and field curvature are given by $W_{131} = \alpha r_M^3/2\lambda f^2$, $W_{222} = \alpha^2 r_M^2/2\lambda f$, and $W_{220} = \alpha^2 r_M^2/4\lambda f$, respectively. When M ≫ 1 and α is small, the dominant aberration is coma, W_{131}. If the substrate of the zone plate is curved with a radius of curvature equal to the focal length, coma can be eliminated.[70] Chromatic variations in the focal length of the MFL are also similar to a Fresnel zone plate. For NA < 0.2,

$$\lambda f \approx \frac{r_M^2}{2M} \tag{22}$$

A focal-length-shift versus wavelength comparison of a Fresnel (hologram) lens and some single-element bulk-optic lenses are shown in Fig. 36. Note that the dispersion of the MFL is much greater than the bulk lens, and the dispersion of the MFL is opposite in sign to that of the bulk lenses. These facts have been used to design, hybrid achromats by combining bulk lenses and diffractive lenses into the same system.[71] The thermal variations in MFLs primarily result in a change of focal length given by[72]

$$\Delta f = 2f\alpha_g \Delta T \tag{23}$$

where f is the nominal focal length, α_g is the coefficient of thermal expansion for the substrate material, and ΔT is a uniform temperature change of the element. For most optical glasses, α_g ranges from 5×10^{-4} °C^{-1} to 10×10^{-4} °C^{-1}.

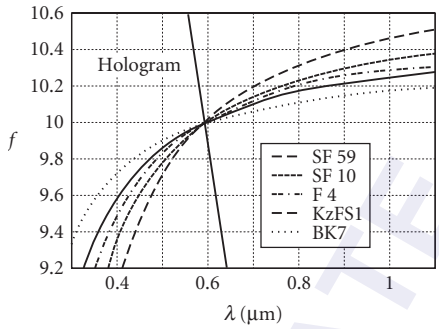

FIGURE 36 Single-element dispersions for a Fresnel (hologram) lens and refractive singlets. The focal lengths (arbitrary units) of thin lenses are plotted versus wavelength for refractive lenses of various optical glasses. Each lens was constructed to have a focal length of 10 at $\lambda_g = 0.5876$ μm.[71]

The diffraction efficiency, η, of an MFL is defined as the ratio of the power in the focused spot to the power in the unfocused beam transmitted through the lens. At best, Fresnel zone plates exhibit $\eta = 40.5$ percent.[73] Blazing the grating profile can significantly increase the efficiency of the lens. Theoretically, η of an MFL can be 100 percent with the proper profile. However, there are several process parameters that limit η, as shown in Fig. 37, where a perfect zone profile has width T and height $d_{MAX} = \lambda/(n_{MFL}-1)$. Variation of film thickness, overetching, and swell all exhibit sinc-squared

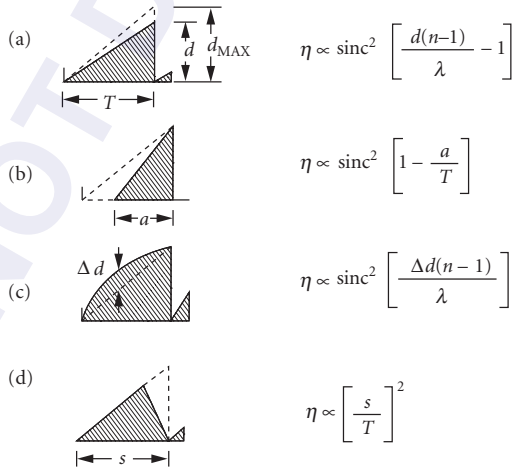

FIGURE 37 Four parameters that influence the diffraction efficiency of MFLs are: (*a*) film thickness variation; (*b*) overetching; (*c*) swell of the resist; and (*d*) imperfection of the shoulders. A profile of one zone is illustrated for each parameter. The ideal profile is shown as a dotted line, where d_{MAX} is the ideal height and T is the ideal period. The diffraction efficiency η of each profile is determined from extrapolating the result obtained from an infinite blazed grating.[75]

dependency on the errors. Shoulder imperfection is the most critical parameter, with η proportional to (s/T).[2] For $\eta > 90$ percent, $s/T \geq 0.95$, which implies that the falling edge of the zone profile must take no more than 5 percent of the grating period. This is possible with low NA systems, where the zone spacing is large compared to the resolution of the exposure system, but it becomes difficult in high NA systems, where the zone spacing is on the order of several microns. Analysis of the three remaining parameters indicates fairly loose tolerances are acceptable. For $\eta > 98$ percent, tolerance on individual parameters are: $|d(n-1)/\lambda - 1| < 0.25$, $a/T > 0.50$, and $\Delta d(n-1)/\lambda < 0.50$. Due to the increasing difficulty in fabricating correct zone profiles with decreasing zone width, most MFLs exhibit a variation in diffraction efficiency versus radius. In the center of the zone pattern, where the zone spacing is large, the measured diffraction efficiency can be in excess of 90 percent. At the edge of the zone pattern, where the zone spacing can be on the order of a few wavelengths, the measured diffraction efficiency is much lower. One possible solution to this problem is to use "superzone" construction,[74] in which the zone radii are found from a modified form of Eq. (10), that is

$$k(f - \sqrt{f^2 + r_M^2}) = 2\pi N m \tag{24}$$

where N is the superzone number. This results in a maximum thickness of $d_{MAX} = N\lambda/(n_{MFL} - 1)$. Note that $N = 1$ corresponds to the standard MFL. $N = 2$ implies that zones are spaced at every 4π phase transition boundary instead of at every 2π phase transition boundary. Although this makes the zones wider apart, the surface relief pattern must be twice as thick.

Molding provides a potentially valuable process for fabricating large quantities of MFLs economically. MFLs can be produced with conventional injection molding, but due to the large thermal expansion coefficient of polymers, the lenses are sensitive to thermal variations. An alternative MFL molding process is shown in Fig. 38, where a glass substrate is used to avoid large thermal effects.

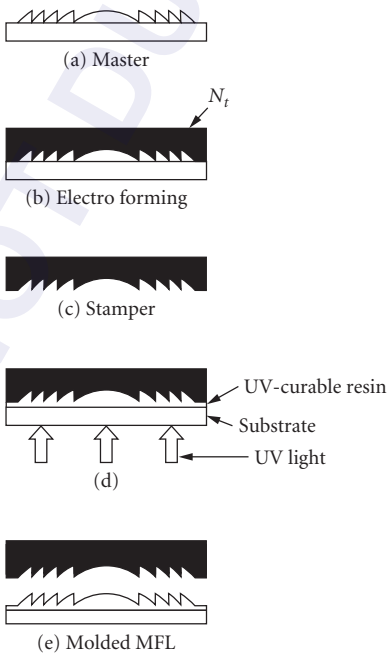

FIGURE 38 Molding process for a MFL on a glass substrate. First, a master is made by electron-beam lithography, then a stamper is electroformed from the master. MFLs are molded by potting a UV-curable resin between the stamper and the substrate and then exposing through the substrate.[53]

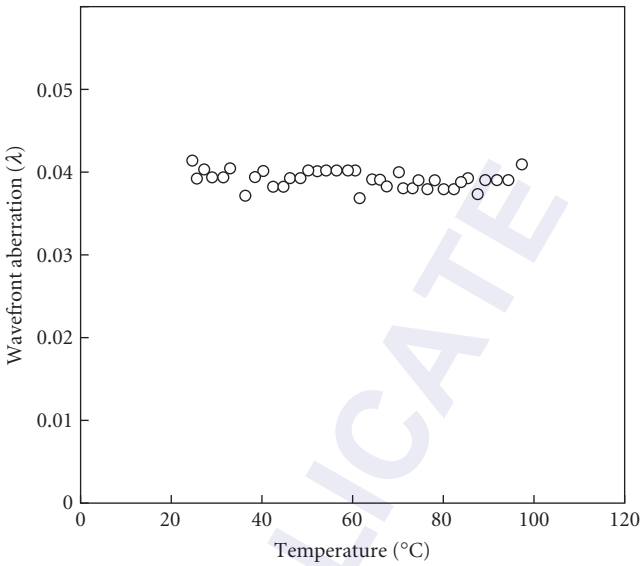

FIGURE 39 Wavefront aberration versus substrate temperature for a 0.25 NA molded MFL on a glass substrate designed to operate at $\lambda = 780$ nm.[78]

First, a master lens is formed with electron-beam or laser writing. A stamper is prepared using conventional nickel electro-forming methods.[76] After potting a UV-curable resin between the stamper and the glass substrate, the replica lenses are molded by the photopolymerization (2P) process.[77] The wavefront aberration versus temperature for a $\lambda = 780$ nm, NA = 0.25, diameter = 0.5 mm lens formed with this technique is shown in Fig. 39.[78] A variation on this technique is to use the stamper as a substrate in an electron-beam evaporation device.[79] Inorganic materials of various refractive indices can be deposited on the stamper, resulting in a thin lens of high refractive index. The high refractive index of a material like ZnS ($n = 2.35$) can be used to lower the maximum thickness requirement of the lens, which makes fabrication of the master with electron-beam writing easier.

22.11 LIQUID LENSES

Integrated micro and miniature systems are often limited by fixed geometry, difficult realignment, and tuning capabilities. Therefore, extensive research was performed to develop miniature optical components with adjustable optical power. Even though zoom solutions, like applications of Alvarez-Humphrey plates mounted on microelectro mechanical system (MEMS) actuators, were recently suggested,[80] the most successful tunable miniature optic components are based on principles of liquid lenses or liquid crystals. In general, the concept of liquid lenses arises from the fact that it is possible to change the shape of the liquid volume and provide an optical power change. This power change can be done in several ways, including electrowetting,[81,82] pressure,[83–85] or temperature change.[86] Liquid crystal lenses[87] are based on changing an electric field to create different crystal orientations and, in consequence, refractive index distribution. One of the most successful approaches for tunable miniature lenses is the concept of an electrowetting lens.[81] It was developed primarily for consumer market applications, like cell phone or credit card cameras. The limited amount of space and relatively high cost does not permit using traditional motor-driven systems in these products. Another application of electrowetting lenses is Blu-Ray Disk (BD) recording systems for dual layer disks.

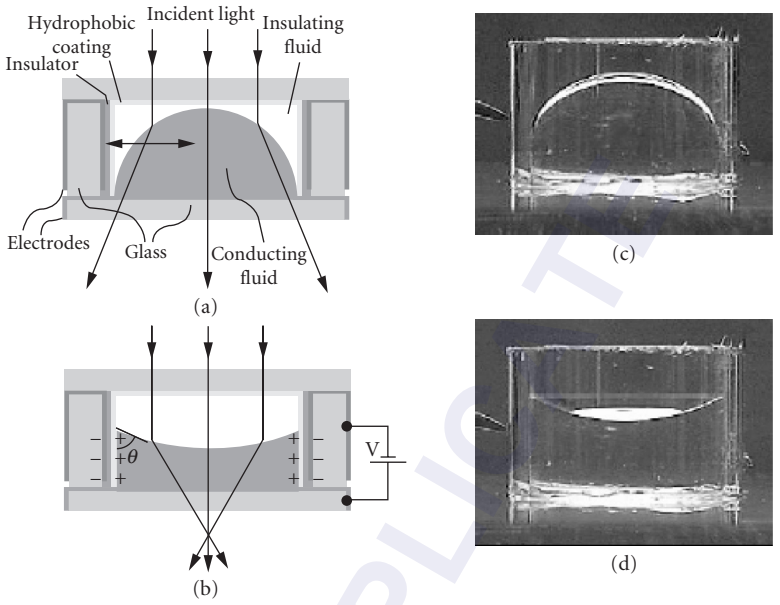

FIGURE 40 A-B schematic cross section of electrowetting lens for convex and concave lens, respectively. C-D photographs of electrowetting lenses.[81]

The principle of an electrowetting lens is presented in Fig. 40.[81] It relies on using two nonmixable liquids, where one is conductive and one nonconductive. An example of conductive liquid is salted water, while a nonconductive example is nonpolar oil. Both liquids must have significantly different refractive index (typically $\Delta n = 0.15$–0.20) and similar density. Refractive index difference is required to provide optical power, while similar density makes the lens insensitive to vibrations and shocks. Liquid is placed in a cylinder where the cylinder wall and bottom are metal coated and act as two electrodes. Note that the cylinder wall is separated from the conductive liquid by an insulating layer. Changing potential between these two electrodes influences the shape of the conductive liquid and creates either a convex or a concave refractive lens.

An example of electrowetting camera lens from Philips is presented in Fig. 41.[81] The outer diameter of the lens (Fig. 40) is 4 mm, inner diameter is 3 mm, and height 2.2 mm. Typical switching voltage is in range of 50 to 120 V. Note that a concave lens is a natural state when no voltage is applied (voltage application allows to decrease negative power or obtaining convex lenses). The switching time is about 10 ms. The Philips lens can achieve maximum negative power of −100 dioptres, and positive of +50 dioptres. This corresponds to focus lengths of −10 mm and 20 mm, respectively. Optical power D can be described as

$$D = \Delta nC \tag{25}$$

where C is lens curvature (reciprocal of lens radius).

Electrowetting lenses can provide sufficiently good optical performance. The main imperfections arise from asymmetric cylinder shape and nonuniform coating. Major wave aberrations in the lens are coma and astigmatism. It has been shown that they can be within diffraction limit of 0.07λ wavefront error[81] within their operating range. Note that work on aspherical, asymmetric electrowetting optical components[82] and reconfigurable lens arrays[88,89] is currently an active research area. For the purpose of this chapter, however, we limit our discussion of electrowetting to a principle level analysis only.

FIGURE 41 A prototype of camera module with electrowetting liquid lens.[81]

Another tunable lens concept is based on using liquids/gels and a pressure change to adjust optical power.[83,84,85] In this case diameter of the cylinder containing the gel or liquid is covered with an elastic membrane (most often polydimethylsiloxane [PDMS]). The membrane is pushed out or pulled in by an increase/decrease of liquid pressure, respectively, and can create convex or concave lenses. The principle of the pressure-based liquid lens is presented in Fig. 42.

Depending on the liquid and lens diameter, pressure change lenses can obtain approximately 1.0 to 10 mm and −1.0 to −10 mm focal lengths. If the membrane is sufficiently thin, the same equation as used for electrowetted lenses can be used to estimate lens power. The pressure change technique allows easy population of lenses in micro fluidic systems and fabrication of tunable lens arrays.[83,84,85] An array of 200-μm (diameter) lenses made on a substrate glass in PDMS is shown in Fig. 43.[83]

Note that membrane lenses are subject to spherical aberrations, since the membrane shape produces an aspherical form due to lower membrane stiffness in the middle area of a lens that creates a nonuniform curvature. Liquid material used for an array prototype (Fig. 42) was a microscope immersion oil ($n = 1.51$) or UV-curable polymers (Norland 63, $n = 1.56$), but other materials are also possible.

While the majority of applications for pressure-based liquid lenses are "lab on a chip" use, they were also recently prototyped for use in optical coherence tomography (OCT). An example of liquid lens and complete head of an OCT probe is shown in Fig. 44.[90]

Tunable lenses can also implement thermal change of the liquid volume.[85] This method is suitable for small millimeter or submillimeter components. It is due to the fact the volume change $\Delta V = \beta V \Delta T$.

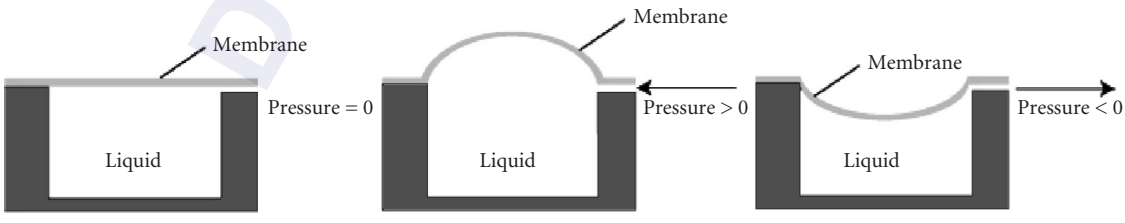

FIGURE 42 The principle of the pressure-based liquid lens.

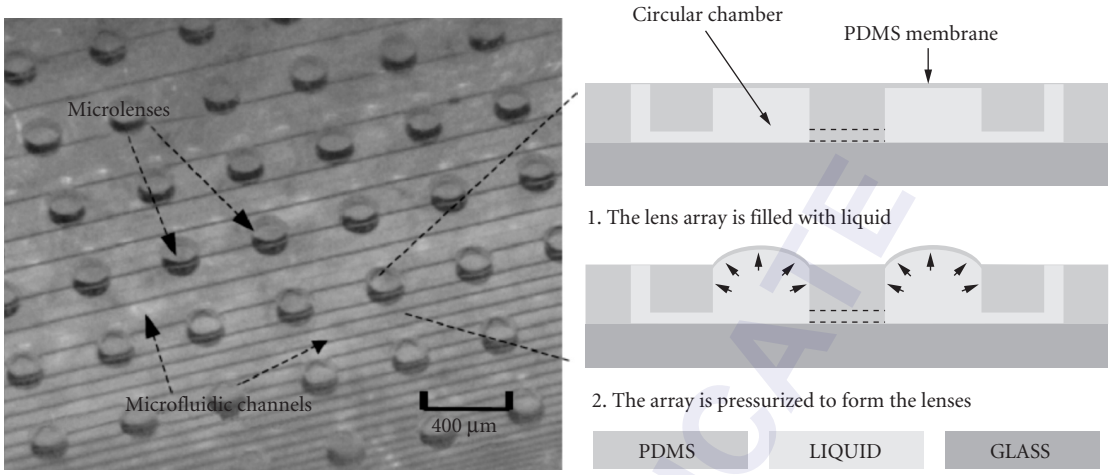

FIGURE 43 (*a*) Picture of the pressure base microfluidic lens array. (*b*) Schematic of the microlens array.[83]

Larger masses require in linear proportion more heat energy. Therefore, this method is more effective for small liquid volumes. Note that β denotes volume expansion coefficient, V and ΔV material volume and volume change, respectively, and ΔT is the introduced temperature change. An example of a thermally controlled liquid lens is presented in Fig. 45.[86] The liquid chamber is covered with PDMS lens (gives system an initial optical power) made in a two-step replication process. PDMS was applied as a flexible and easily stretchable material. This lens has 1.9-mm clear aperture. The entire package is 8.5 mm × 6.5 mm × 1.5 mm. The lens requires voltage change (for thermal actuation) of 0 to 14 V, which corresponds to temperature change from about 20 to 50°C. In effect, focal length changes from 14.7 to 2.8 mm.

Entirely different technology for making tunable lenses is based on the liquid crystal principle[87] in which it is possible to create a continuously changing electric field that causes axially symmetric

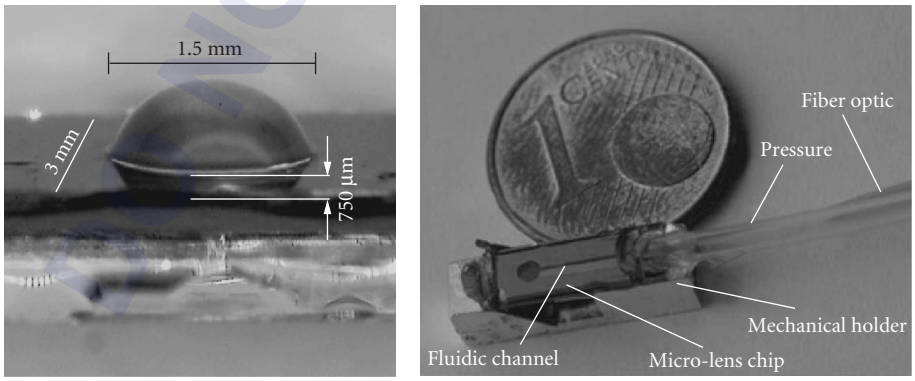

FIGURE 44 (*a*) Microfluidic pressure lens and (*b*) picture of entire OCT head.[90]

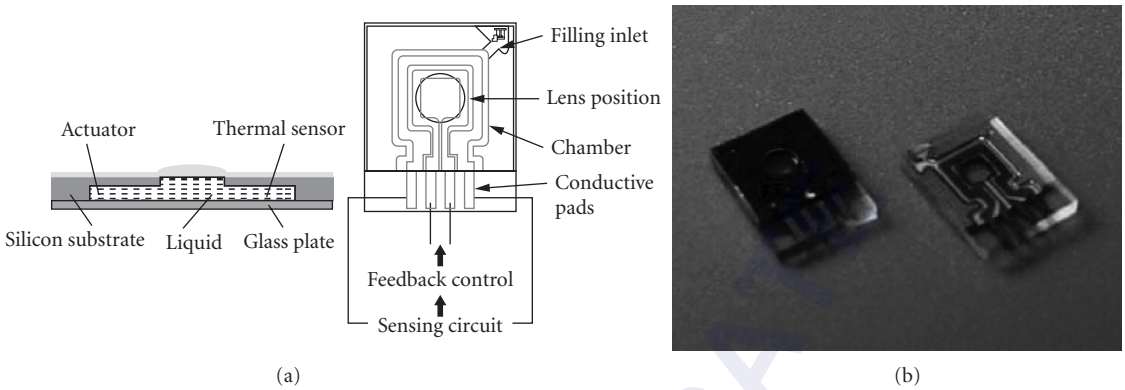

FIGURE 45 (*a*) Schematic of an integrated thermal volume change lens. (*b*) Photo of a complete packaged lens.[86]

orientation changes of liquid crystals (LC). The crystal orientations results in a distribution of refractive index similar to that obtained in gradient index (GRIN) lenses. LC lenses are being used in machine vision, photonics, and eyeglasses.

The LC lens principle can be described following Naumov et al.[87] and his design of a liquid crystal lens. The LC is placed between two transparent electrodes deposited on glass substrates. One is the control electrode with distributed resistance much higher than the distributed resistance of the ground electrode. The LC layer placed between these two electrodes acts as a capacitor. In case of application of AC voltage to the single circular contact at the control electrode, the active impedance of the control electrode and the reactive impedance of the capacitor create a distributed voltage divider. This divider results in a distributed AC voltage over the layer of LC relatively close to a parabolic distribution. In consequence the axially symmetric distribution of liquid crystals provides a change of optical power. It is also possible to build cylindrical lenses by using two line contacts at the control electrode. LC lenses are very convenient, due to the fact that they are electrically controlled integrated components. Switching voltage of LC lenses, depending on design, is usually in 0–100 V range. Their major drawback arises from relatively low optical power and polarization effects due to the crystal structure.

Liquid crystal lens research is a very broad area. For the purpose of this discussion we concentrate on selected examples. One group of miniature liquid lenses includes relatively large components of 5 to 10 mm in diameter and quite low optical power with focal length between few hundred millimeters and infinity.[87] Multilayer liquid crystal lenses[91] can increase optical power and obtain a range of 93 to 1230 mm. Examples of negative lenses with a glass lens embedded between liquid crystal layers were also demonstrated.[92] Most recently, research on aspheric liquid crystal components (like axicons) is also being pursued.[93] A second group of liquid crystal lenses are microlenses[94] and arrays of microlenses.[95,96] The diameter of a single lens is usually few hundred microns (200 to 600 μm) and these lenses can achieve short focal lengths in range ±2 to ±10 mm.

To compare various techniques for making tunable miniature or microlenses, a summary of parameters of various lens types are presented in Table 9. Values from literature are rounded to show achievable range rather than detailed numbers. Note that it is possible to find examples of systems going outside values summarized in Table 9.

Other tunable liquid lens approaches can be found in literature including adaptive liquid microlenseses activated with different stimuli.[97] The optical power of these lenses may potentially be designed in a way so it will adapt to the environment, which means that optical power will change depending on conditions (PH, temperature, etc.). Detailed discussions of these quite new approaches are omitted, as they are in initial research stages.

TABLE 9 Comparison of Parameters of Different Tunable Lenses

Technique	Common Size of Clear Aperture	Focal Range	Possible Shapes	Range of Tuning Parameter	Switching Time
Electrowetted	0.2–5.0 mm	20 mm–∞ −10 mm–∞	Convex Concave	Voltage 50–120 V	10 ms
Pressure change	0.2–2 mm	1.0–10.0 mm −1.0–−10 mm	Convex Concave	Pressure 0–50 KPa	500 ms– few seconds
Volume change	~2.0 mm, possible Decrease to 300 μm	2.0–15.0 mm	Convex	Temperature 20–50°C	50 seconds
Liquid crystal	5–10 mm 0.2–0.6 mm	100 mm–∞ 2–10 mm −2–−10 mm	Convex Convex Concave	Voltage 0–100 V	500 ms– few seconds

22.12 OTHER TECHNOLOGIES

There are several other technologies that are potentially valuable for micro-optic components. Four particularly interesting technologies are melted-resin arrays,[98] laser-assisted chemical etching,[99] mass transport,[100] and drawn preform cylindrical lenses.[98]

Melted-resin arrays of hemispherical ball lenses are formed with the process shown in Fig. 46. First, an Al film is deposited on a quartz substrate and patterned with holes that serve as aperture

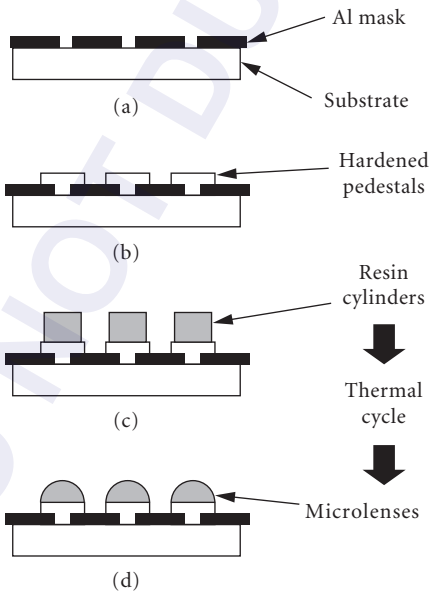

FIGURE 46 Process used to form melted-resin microlenses: (*a*) an AL film is deposited on the substrate and patterned with holes to serve as aperture stops for the array; (*b*) circular pedestals are formed on top of the aperture holes and hardened; (*c*) cylinders of resin are developed of the pedestals; and (*d*) pedestals are melted to form spherical surfaces.[98]

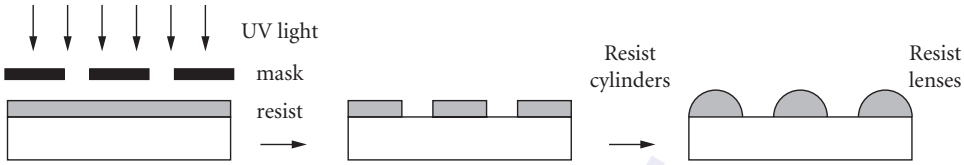

FIGURE 47 Principle of fabrication of microlens arrays using photoresist reflow technique.[16]

stops for the array. Next, circular pedestals are formed on top of the aperture holes. The pedestals are hardened so that they are insoluble and stable for temperatures in excess of 180°C. Cylinders of resin are then developed on top of the pedestals. The device is heated to 140°C to melt the resin. The pedestals serve to confine the melting resin. The lenses form into hemispherical shapes due to surface tension forces. Lens diameters have been demonstrated at 30 μm with good wavefront performance and uniformity.[98]

Similar to the process for making melted resin arrays is fabrication of reflow lenses.[3,16] The graphical representation of reflow process is presented in Fig. 47.[16] Figure 48 shows example of fabricated lenslet array.[16]

Fabrication of reflow lenses consists of two major steps: (1) A layer of photoresist or solgel is exposed through lithographic binary mask and then developed; (2) photoresist cylinders are melted to create surfaces close to spherical shape. The third step of reactive ion etching[3,16] or plasma etching[101] can be added to transfer lens shapes into a substrate. For the melting step, the sample is heated to the glass temperature of the resist, which is in range of 150 to 200°C. After Sinzinger and Jahns,[3] the focal length equation in Eq. (26) of the obtained lens is

$$f = \frac{r_c}{n-1} \tag{26}$$

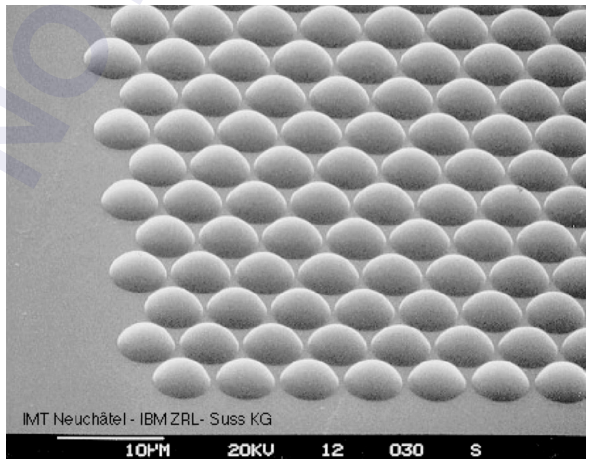

FIGURE 48 SEM picture of 5-μm diameter microlenses packed hexagonally.[16] Lenses were made using reflow process in photoresist.

where r_c is radius of curvature derived from properties of binary cylinders:

$$r_c = \frac{h^2 + \frac{D^2}{4}}{2h} \tag{27}$$

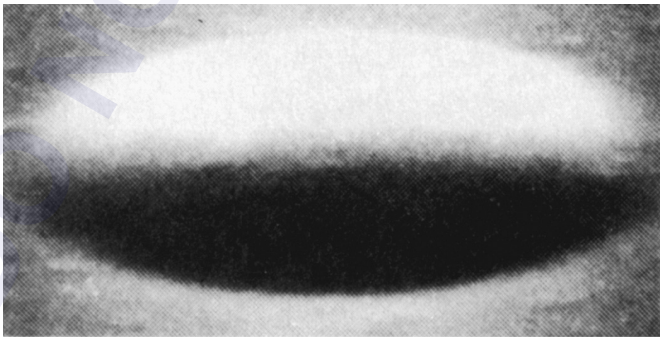
Note that h is the height of the droplet and corresponds to lens sag and D is diameter of the cylinder.

Knowledge of cylinder volume allows also to find a relation between cylinder thickness and the droplet height (sag),[3]

$$t = \frac{h}{6}\left(3 + 4\frac{h^2}{D^2}\right) \tag{28}$$

Reflow lenses require very careful selection of photosensitive material (high viscosity, e.g., Hoechst AZ 4562), cylinder diameter, and its height. If the cylinder structure is too shallow, the melting process may create lenses deviating significantly from a sphere. The ratio between cylinder height and diameter is usually in range of 0.04 to 0.5. To improve quality of fabricated lenses, preshaping of

(a)



(b)

FIGURE 49 SEM photographs showing perspective views of (*a*) etched multilevel mesa structure and (*b*) the microlens formed after mass transport.[100]

photoresist can be applied. It is also possible to fabricate asymmetric lenses using either preshaping or noncircular masks.

The reflow technique can be further extended and combined with a molding process.[102,103] After exposure, developing, and melting steps the lens array can be coated with PDMS and cured. In result, one obtains the negative impression of the photoresist array. Due to the fact that PDMS is hydrophobic and elastic such a created mold easily comes of the substrate and can be used in additional steps to create solgel (or other polymer) lens arrays.[103]

The quality of reflow fabricated lenses is high, resulting in surface roughness in the range of Ra = 1 nm and deviation from perfect sphere of $\lambda/10$ (RMS) can be achieved. By application of aforementioned method[103] large sag and NA values can be obtained.

Diameters of reflow lenses usually vary between 5 and 2000 μm^3[3,16] and their sag is within 2.5 and 60 to 70 μm. Reported focal lengths were few and 9000 μm^3 where longer focal lengths were obtained for larger lens diameters.

Laser-assisted chemical etching (LACE) can be used to make arrays of F/0.7–F/10 lenslets with spacings of 50 to 300 μm. Microlenses have been fabricated in glass, silicon, CdTe, and sapphire with 95 percent fill factors and figure quality better than 1/10th wave.[99] In the LACE process, a focused laser beam is scanned over a thick layer of photoresist. The irradiance of the laser beam is modulated in order to vary the exposure and thus the thickness of the developed resist. With the proper irradiance mapping, accurate lens profiles can be produced in the developed resist. If lenslet material other than photoresist is required, a pattern can be exposed in the photoresist and transferred into the new material by ion milling.

Our discussion of the mass-transport process follows discussion presented in Ref. 100. In the mass-transport process, a multilevel mesa structure is first etched into a semiconductor, as shown in Fig. 49*a*. The semiconductor must be a binary compound in which the evaporation rate of one element is negligible compared to that of the other. For example, InP has been used successfully. The mesa structure is placed in a furnace at an elevated temperature. Since some surface decomposition occurs with InP, a minimum phosphorus vapor pressure must be maintained in the gas ambient to prevent the sample from being transformed into metallic In. The decomposition produces free In atoms located at the crystal surface, which are in equilibrium with phosphorus in the vapor and InP in the crystal. The concentration of In in the vapor is negligible. The equilibrium concentration of free In atoms increases with increasing positive surface curvature, since the higher surface energy of the high-curvature regions translates into a lower bonding energy in the decomposition process. Consequently, a variation in curvature across the surface will result in diffusion of free In atoms from regions of high positive curvature, where the concentrations are high, to low-curvature regions, where the In-diffused atoms exceed the equilibrium concentration and have to be reincorporated into the crystal by reaction with P to form InP. (The diffusion of P in the vapor phase is presumably much faster than the diffusion of free In atoms on the surface. The latter is therefore assumed to be the rate-limiting process.) The mass transport of InP, resulting from decomposition in high-curvature regions, will continue until the difference in curvature is completely eliminated. After mass transport, a smooth profile is obtained, as shown in Fig. 49. The design of the mesa structure can result in very accurate control of the lens profile, as shown in Fig. 50. Mass-transport lens arrays have been used to collimate arrays of laser diodes, with diffraction-limited performance at NA ~0.5.

Very accurate cylindrical lenses can be drawn from performs.[104] An SEM photo of an elliptical cylindrical lens is shown in Fig. 51. The first step in the process is to make a preform of a suitable glass material. Since the cross-sectional dimensions of the preform are uniformly reduced (typtically ~50 to 100×) in the fiber drawing process, small manufacturing errors become optically insignificant. Therefore, standard numerically controlled grinding techniques can be utilized to generate a preform of any desired shape. Besides maintaining the preform shape, the drawing process also polishes the fiber. Results are presented[98] that demonstrate a 200-μm-wide elliptical cylindrical lens. The SFL6 preform was about 0.75 cm wide. The lens has a nominal focal length of 220 μm at λ = 800 μm. The lens is diffraction-limited over about a 150-μm clear aperture, or NA ~0.6. The application is to collimate the fast axis of laser diodes.

BINARY OPTICS

Michael W. Farn and Wilfrid B. Veldkamp

MIT/Lincoln Laboratory
Lexington, Massachusetts

23.1 GLOSSARY

A	aspheric
C	describes spherical aberration
C_m	Fourier coefficients
c	curvature
$c(x, y)$	complex transmittance
D	local period
f	focal length
k, l	running indices
l_i	paraxial image position
L, M	direction cosines
m	diffraction order
P	partial dispersion
s	spheric
t	thickness
V_d	Abbe number
x, y, z	Cartesian coordinates
λ	wavelength
η	diffraction efficiency
ξ_i	paraxial image height
$\phi(x, y)$	phase

23.2 INTRODUCTION

Binary optics is a surface-relief optics technology based on VLSI fabrication techniques (primarily photolithography and etching), with the "binary" in the name referring to the binary coding scheme used in creating the photolithographic masks. The technology allows the creation of new, unconventional optical elements and provides greater design freedom and new materials choices for conventional elements. This capability allows designers to create innovative components that can solve problems in optical sensors, optical communications, and optical processors. The technology has advanced sufficiently to allow the production of diffractive elements, hybrid refractive-diffractive elements, and refractive micro-optics which are satisfactory for use in cameras, military systems, medical applications, and other demanding areas.

The boundaries of the binary optics field are not clearly defined, so in this chapter, the concentration will be on the core of the technology: passive optical elements which are fabricated using VLSI technology. As so defined, binary optics technology can be broadly divided into the areas of optical design and VLSI-based fabrication. Optical design can be further categorized according to the optical theory used to model the element: geometrical optics, scalar diffraction theory, or vector diffraction theory; while fabrication is composed of two parts: translation of the optical design into the mask layout and the actual micromachining of the element. The following sections discuss each of these topics in some detail, with emphasis on optical design. For a more general overview, the reader is referred to Refs. 1 for many of the original papers, 2 and 3 for a sampling of applications and research, and 4 to 6 for a lay overview.

Directly related areas which are discussed in other chapters but not in this one include micro-optics and diffractive optics fabricated by other means (e.g., diamond turning, conventional manufacturing, or optical production), display holography (especially computer-generated holography), mass replication technologies (e.g., embossing, injection molding, or epoxy casting), integrated optics, and other micromachining technologies.

23.3 DESIGN—GEOMETRICAL OPTICS

In many applications, binary optics elements are designed by ray tracing and "classical" lens design principles. These designs can be divided into two classes: broadband and monochromatic. In broadband applications, the binary optics structure has little optical power in order to reduce the chromatic aberrations and its primary purpose is aberration correction. The device can be viewed as an aspheric aberration corrector, similar to a Schmidt corrector, when used to correct the monochromatic aberrations and it can be viewed as a material with dispersion an order of magnitude greater than and opposite in sign to conventional materials when used to correct chromatic aberrations. In monochromatic applications, binary optics components can have significant optical power and can be viewed as replacements for refractive optics.

In both classes of designs, binary optics typically offers the following key advantages:

- Reduction in system size, weight, and/or number of elements
- Elimination of exotic materials
- Increased design freedom in correcting aberrations, resulting in better system performance
- Generation of arbitrary lens shapes (including micro-optics) and phase profiles

Analytical Models

Representation of a Binary Optics Element As with any diffractive element, a binary optics structure is defined by its phase profile $\phi(x, y)$ (z is taken as the optical axis), design wavelength λ_0, and the surface on which the element lies. For simplicity, this surface is assumed to be planar for the remainder of this chapter, although this is commonly not the case. For example, in many refractive/diffractive systems,

the binary optics structure is placed on a refractive lens which may be curved. The phase function is commonly represented by either explicit analytical expression or decomposition into polynomials in x and y (e.g., the HOE option in CODE V).

Explicit analytic expressions are used in simple designs, the two most common being lenses and gratings. A lens used to image point (x_o, y_o, z_o) to point (x_i, y_i, z_i) at wavelength λ_0 has a phase profile

$$\phi(x, y) = \frac{2\pi}{\lambda_0}\left[z_o\left(\sqrt{(x-x_o)^2/z_o^2 + (y-y_o)^2/z_o^2 + 1} - 1\right) - z_i\left(\sqrt{(x-x_i)^2/z_i^2 + (y-y_i)^2/z_i^2 + 1} - 1\right)\right] \tag{1}$$

where z_o and z_i are both taken as positive to the right of the lens. The focal length is given by the gaussian lens formula:

$$1/f_0 = 1/z_i - 1/z_o \tag{2}$$

with the subscript indicating that f_0 is the focal length at λ_0. A grating which deflects a normally incident ray of wavelength λ_0 to the direction with direction cosines (L, M) is described by

$$\phi(x, y) = \frac{2\pi}{\lambda_0}(xL + yM) \tag{3}$$

Axicons are circular gratings and are described by

$$\phi(x, y) = \frac{2\pi}{\lambda_0}(\sqrt{x^2 + y^2}\, L) \tag{4}$$

where L now describes the radial deflection.

For historical reasons, the polynomial decomposition of the phase profile of the element commonly consists of a spheric term and an aspheric term:

$$\phi(x, y) = \phi_S(x, y) + \phi_A(x, y) \tag{5}$$

where

$$\phi_A(x, y) = \frac{2\pi}{\lambda_0}\sum_k \sum_l a_{kl} x^k y^l$$

and the spheric term $\phi_S(x, y)$ takes the form of Eq. (1). Since the phase profiles produced by binary optics technology are not constrained to be spheric, $\phi_S(x, y)$ is often set to zero by using the same object and image locations and the aspheric term alone is used to describe the profile. The binary optics element is then optimized by optimizing the polynomial coefficients a_{kl}. If necessary, the aspheric term can be forced to be radially symmetric by constraining the appropriate polynomial coefficients.

It is possible to describe the phase profile of a binary optics element in other ways. For example, $\phi(x, y)$ could be described by Zernike polynomials or could be interpolated from a two-dimensional look-up table.

Ray Tracing by the Grating Equation A binary optics element with phase $\phi(x, y)$ can be ray traced using the grating equation by modeling the element as a grating, the period of which varies with position. This yields

$$L' = L + \frac{m\lambda}{2\pi}\frac{\partial\phi}{\partial x} \tag{6}$$

$$M' = M + \frac{m\lambda}{2\pi}\frac{\partial\phi}{\partial y} \tag{7}$$

where m is the diffracted order, L, M are the direction cosines of the incident ray, and L', M' are the direction cosines of the diffracted ray.[7] In geometrical designs, the element is usually blazed for the first order ($m = 1$). Note that it is the phase gradient $\nabla\phi(x, y)$ (a vector quantity proportional to the local spatial frequency) and not the phase $\phi(x, y)$ which appears in the grating equation. The magnitude of the local period is inversely proportional to the local spatial frequency and given by

$$D(x, y) = 2\pi/|\nabla\phi| \tag{8}$$

where || denotes the vector magnitude. The minimum local period determines the minimum feature size of the binary optics structure, a concern in device fabrication (see "Fabrication" later in this chapter).

Ray Tracing by the Sweatt Model The Sweatt model,[8] which is an approximation to the grating equation, is another method for ray tracing. The Sweatt approach models a binary optics element as an equivalent refractive element and is important since it allows results derived for refractive optics to be applied to binary optics. In the Sweatt model, a binary optics element with phase $\phi(x, y)$ at wavelength λ_0 is replaced by a refractive equivalent with thickness and refractive index given by

$$t(x, y) = \frac{\lambda_0}{n_0 - 1}\frac{\phi(x, y)}{2\pi} + t_0 \tag{9}$$

$$n(\lambda) - 1 = \frac{\lambda}{\lambda_0}(n_0 - 1) \tag{10}$$

Here, t_0 is a constant chosen to make $t(x, y)$ always positive and n_0 is the index of the material at wavelength λ_0. The index n_0 is chosen by the designer and as $n_0 \to \infty$, the Sweatt model approaches the grating equation. In practice, a value of $n_0 = 10{,}000$ is sufficiently high for accurate results.[9]

In the special case of a binary optics lens described by Eq. (1), the more accurate Sweatt lens[10] can be used. In this case, the element is modeled by two surfaces of curvature

$$c_o = 1/[(1 - n_0)z_o] \tag{11}$$

$$c_i = 1/[(1 - n_0)z_i] \tag{12}$$

and conic constant $-n_0^2$, with the axis of each surface passing through the respective point source. The refractive index is still modeled by Eq. (10).

Aberration Correction

Aberrations of a Binary Optics Singlet As a simple example of a monochromatic imaging system, consider a binary optics singlet which is designed to image the point $(0, 0, z_o)$ to the point $(0, 0, z_i)$

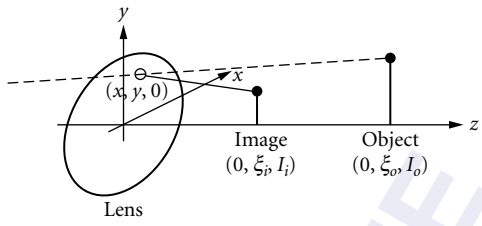

FIGURE 1 Primary aberrations of a binary optics lens.[7]

at wavelength λ_0. The phase profile of this lens can be derived from Eq. (1) and the focal length f_0 from Eq. (2). Now consider an object point of wavelength λ located at $(0, \xi_o, l_o)$. The lens will form an image at $(0, \xi_i, l_i)$ (see Fig. 1), with the paraxial image position l_i and height ξ_i given by[7]

$$\frac{1}{l_i} = \frac{\lambda}{f_0 \lambda_0} + \frac{1}{l_0} \tag{13}$$

$$\xi_i / l_i = \xi_o / l_o \tag{14}$$

Note that the first equation is just the gaussian lens law but using a wavelength-dependent focal length of

$$f(\lambda) = f_0 \frac{\lambda_0}{\lambda} \tag{15}$$

The focal length being inversely proportional to the wavelength is a fundamental property of diffractive lenses. In addition, due to the wavelength shift and position change of the object point, the lens will form a wavefront with a primary aberration of[7]

$$\begin{aligned} W(x, y) = {} & \frac{1}{8}\left[\left(\frac{1}{l_i^3} - \frac{1}{l_o^3}\right) - \frac{\lambda}{\lambda_0}\left(\frac{1}{z_i^3} - \frac{1}{z_o^3}\right)\right](x^2 + y^2)^2 \\ & - \frac{1}{2l_i}\left(\frac{1}{l_i^2} - \frac{1}{l_o^2}\right)\xi_i y(x^2 + y^2) \\ & + \frac{3}{4l_i^2}\left(\frac{1}{l_i} - \frac{1}{l_o}\right)\xi_i^2 y^2 + \frac{1}{4l_i^2}\left(\frac{1}{l_i} - \frac{1}{l_o}\right)\xi_i^2 x^2 \end{aligned} \tag{16}$$

where the ray strikes the lens at (x, y). The first term is spherical aberration, the second is coma, and the last two are tangential and sagittal field curvature. As noted by Welford, all the off-axis aberrations can be eliminated if and only if $l_i = l_o$, a useless configuration. In most systems of interest, the limiting aberration is coma.

The performance of the binary optics singlet can be improved by introducing more degrees of freedom: varying the stop position, allowing the binary optics lens to be placed on a curved surface, using additional elements, etc. For a more detailed discussion, see Refs. 1, 7, and 11.

Chromatic Aberration Correction Binary optics lenses inherently suffer from large chromatic aberrations, the wavelength-dependent focal length [Eq. (15)] being a prime example. By themselves,

they are unsuitable for broadband imaging and it has been shown that an achromatic system consisting only of diffractive lenses cannot produce a real image.[12]

However, these lenses can be combined successfully with refractive lenses to achieve chromatic correction (for a more detailed discussion than what follows, see Refs. 4, 13, and 14). The chromatic behavior can be understood by using the Sweatt model, which states that a binary optics lens behaves like an ultrahigh index refractive lens with an index which varies linearly with wavelength [let $n_0 \to \infty$ in Eq. (10)]. Accordingly, they can be used to correct the primary chromatic aberration of conventional refractive lenses but cannot correct the secondary spectrum. For the design of achromats and apochromats, an effective Abbe number and partial dispersion can also be calculated. For example, using the *C*, *d*, and *F* lines, the Abbe number is defined as $V_d = [n(\lambda_d) - 1]/[n(\lambda_F) - n(\lambda_C)]$. Substituting Eq. (10) and letting $n_0 \to \infty$ yields

$$V_d = \lambda_d/(\lambda_F - \lambda_C) = -3.45 \tag{17}$$

In a similar fashion, the effective partial dispersion using the *g* and *F* lines is

$$P_{gF} = (\lambda_g - \lambda_F)/(\lambda_F - \lambda_C) = 0.296 \tag{18}$$

By using these effective values, the conventional procedure for designing achromats and apochromats[15] can be extended to designs in which one element is a binary optics lens.

Figure 2 plots the partial dispersion P_{gF} versus Abbe number V_d for various glasses. Unlike all other materials, a binary optics lens has a negative Abbe number. Thus, an achromatic doublet can be formed by combining a refractive lens and a binary optics lens, both with positive power. This significantly reduces the lens curvatures required, allowing for larger apertures. In addition, the binary optics lens has a position in Fig. 2 which is not collinear with the other glasses, thus also allowing the design of apochromats with reduced lens curvatures and larger apertures.

Monochromatic Aberration Correction For a detailed discussion, the reader is referred to Refs. 1 and 11. As a simple example,[4] consider a refractive system which suffers from third-order spherical aberration and has a residual phase given by

$$\phi_r(x, y) = \frac{2\pi}{\lambda} C(x^2 + y^2)^2 \tag{19}$$

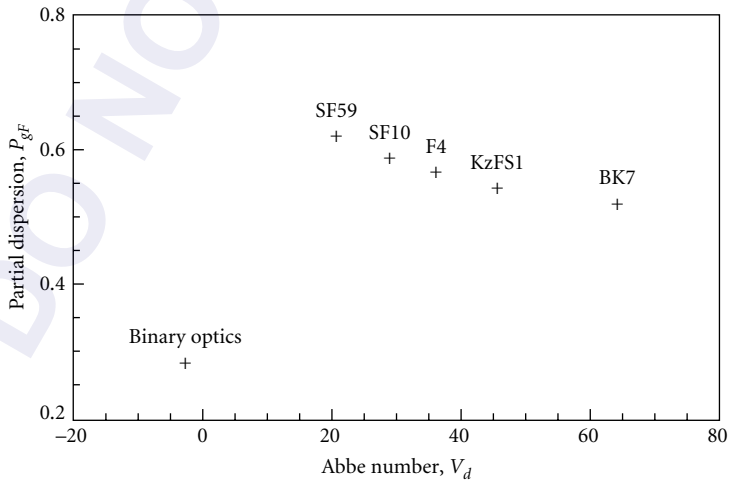

FIGURE 2 Partial dispersion vs. Abbe number.[14]

where C describes the spherical aberration. Then, a binary optics corrector with phase

$$\phi_b(x, y) = -\frac{2\pi}{\lambda_0} C(x^2 + y^2)^2 \tag{20}$$

will completely correct the aberration at wavelength λ_0 and will reduce the aberration at other wavelengths to

$$\phi_r + \phi_b = \frac{2\pi}{\lambda} C(1 - \lambda/\lambda_0)(x^2 + y^2)^2 \tag{21}$$

The residual aberration is spherochromatism.

Micro-Optics

Binary optics technology is especially suited for the fabrication of micro-optics and micro-optics arrays, as shown in Fig. 3. The advantages of binary optics technology include the following:

- *Uniformity and coherence.* If desired, all micro-optics in an array can be made identical to optical tolerances. This results in coherence over the entire array (see Fig. 4).
- *Refractive optics.* Binary optics is usually associated with diffractive optics. This is not a fundamental limit but results primarily from fabrication constraints on the maximum achievable depth (typically, 3 μm with ease and up to 20 μm with effort). However, for many micro-optics, this is sufficient to allow the etching of refractive elements. For example, a lens of radius R_0

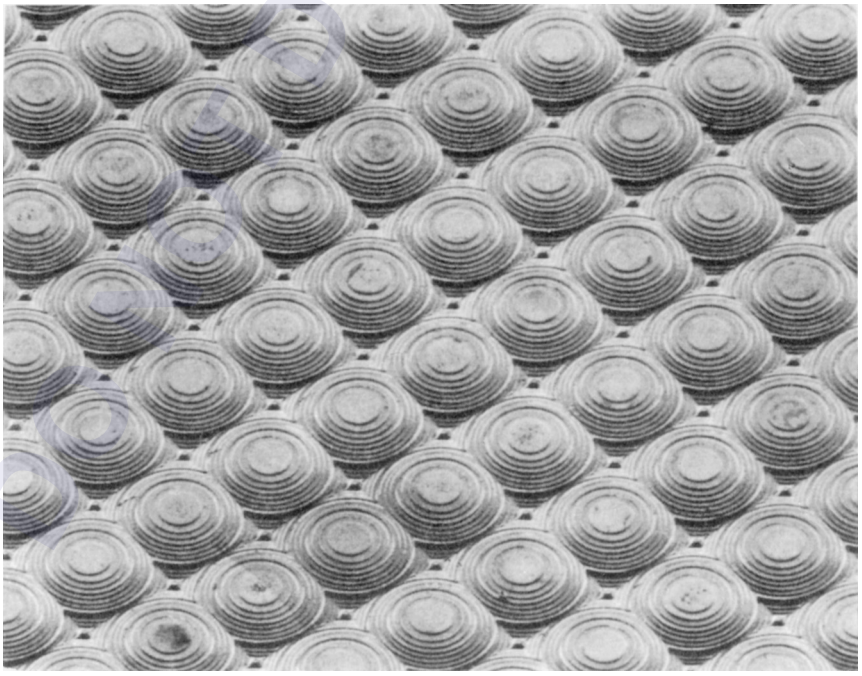

FIGURE 3 96 × 64 array of 51 × 61 μm CdTe microlenses.

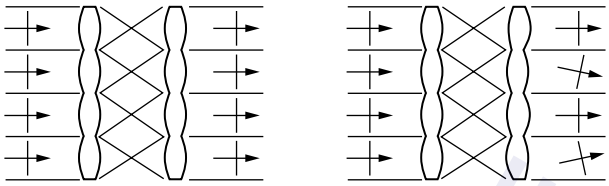

FIGURE 4 Micro-optic telescope using (*a*) coherent arrays and (*b*) incoherent arrays.

which is corrected for spherical aberration[15] and focuses collimated light at a distance z_0 (see Fig. 5) has a thickness of

$$t_{\max} = n\left[\sqrt{R_0^2 + z_0^2} - z_0\right]/(n-1) \tag{22}$$

where n is the index of the material.

- *Arbitrary phase profiles.* Binary optics can produce arbitrary phase profiles in micro-optics just as easily as in macro-optics. Fabricating arrays of anamorphic lenses to correct the astigmatism of semiconductor lasers, for example, is no more difficult than fabricating arrays of conventional spherical lenses.
- *100 percent fill factor.* While many technologies are limited in fill factor (e.g., round lenses on a square grid yield a 79 percent fill factor), binary optics can achieve 100 percent fill factor on any shape grid.
- *Spatial multiplexing.* Each micro-optic in an array can be different from its neighbors and the array itself can compose an arbitrary mosaic rather than a regular grid. For example, a binary optics array of individually designed micro-optics can be used to optimally mode-match one-dimensional laser arrays to laser cavities or optical fibers.[16]

Optical Performance

Wavefront Quality The wavefront quality of binary optics components is determined by the accuracy with which the lateral features of the element are reproduced. Since the local period (typically several μm) is usually much larger than the resolution with which it can be reproduced (of order 0.1 μm), wavefront quality is excellent. In fact, wavefront errors are typically limited by the optical quality of the substrate rather than the quality of the fabrication.

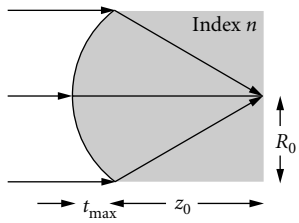

FIGURE 5 Thickness of a refractive lens.[15]

Diffraction Efficiency The diffraction efficiency of a device is determined by how closely the binary optics stepped-phase profile approximates a true blaze. The theoretical efficiency at wavelength λ of an element with I steps designed for use at λ_0 is[4]

$$\eta(\lambda, I) = \left| \operatorname{sinc}(1/I) \frac{\sin(I\pi\alpha)}{I \sin \pi\alpha} \right|^2 \tag{23}$$

where $\operatorname{sinc}(x) = \sin(\pi x)/(\pi x)$ and $\alpha = (\lambda_0/\lambda - 1)/I$.

This result is based on scalar theory, assumes perfect fabrication, and neglects any material dispersion. Figure 6 plots the efficiency $\eta(\lambda, I)$ for different numbers of steps I; while Table 1 gives the average efficiency over the bandwidth $\Delta\lambda$ for a perfectly blazed element ($I \to \infty$).[4] The efficiency equation is asymmetric in λ but symmetric in $1/\lambda$.

The use of scalar theory in the previous equation assumes that the local period $D(x, y)$ [see Eq. (8)] is large compared to the wavelength. As a rule of thumb, this assumption begins to lose validity when the period dips below 10 wavelengths (e.g., a grating with period less than $10\lambda_0$ or a lens faster than $F/5$) and lower efficiencies can be expected in these cases. For a more detailed discussion, see Ref. 17.

The efficiency discussed here is the diffraction efficiency of an element. Light lost in this context is primarily diffracted into other diffraction orders, which can also be traced through a system to determine their effect. As with conventional elements, binary optics elements will also suffer reflection losses which can be minimized in the usual manner.

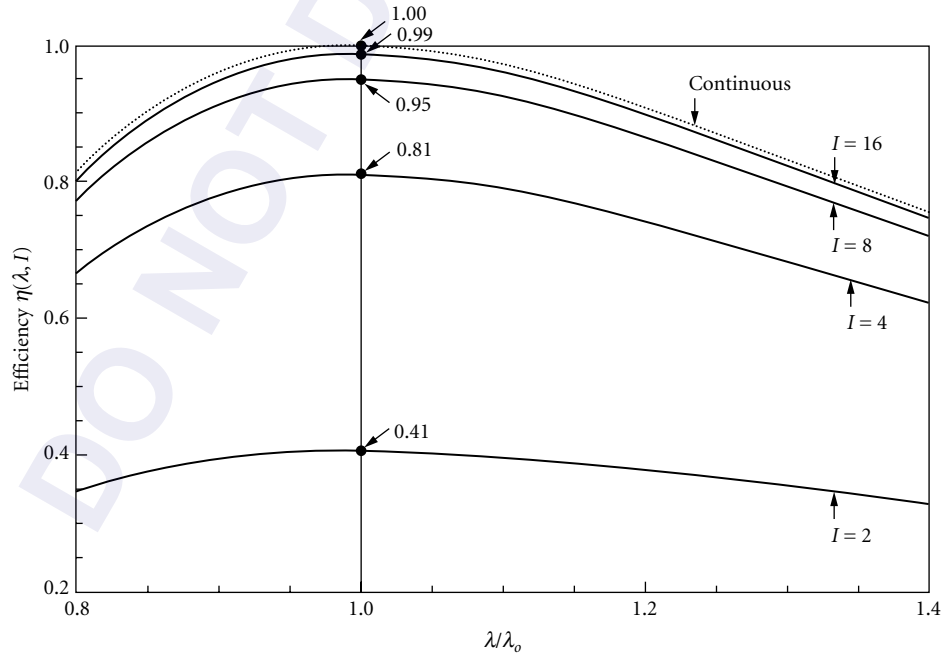

FIGURE 6 Diffraction efficiency of binary optics.[4]

TABLE 1 Average Diffraction Efficiency for Various Bandwidths[4]

$\Delta\lambda/\lambda_0$	$\bar{\eta}$
0.00	1.00
0.10	1.00

0.30	0.98
0.40	0.96
0.50	0.93
0.60	0.90

23.4 DESIGN—SCALAR DIFFRACTION THEORY

Designs via scalar diffraction theory are based on the direct manipulation of the phase of a wavefront. The incident wavefront is generally from a coherent source and the binary optics element manipulates the phase of each point of the wavefront such that the points interfere constructively or destructively, as desired, at points downstream of the element. In this regime, binary optics can perform some unique functions, two major applications being wavefront multiplexing and beam shaping.

Analytical Models

In the scalar regime, the binary optics component with phase profile $\phi(x, y)$ is modeled as a thin-phase screen with a complex transmittance of

$$c(x, y) = \exp[j\phi(x, y)] \tag{24}$$

The phase screen retards the incident wavefront and propagation of the new wavefront is modeled by the appropriate scalar formulation (e.g., angular spectrum, Fresnel diffraction, Fraunhofer diffraction) for nonperiodic cases, or by Fourier series decomposition for periodic cases.

The design of linear gratings is an important problem in the scalar regime since other problems can be solved by analogy. A grating with complex transmittance $c(x)$ and period D can be decomposed into its Fourier coefficients C_m, where

$$C_m = \frac{1}{D}\int_0^D c(x)\exp(-j2\pi mx/D)\,dx \tag{25}$$

$$c(x) = \sum_{m=-\infty}^{\infty} C_m \exp(j2\pi mx/D) \tag{26}$$

The relative intensity or efficiency of the mth diffracted order of the grating is

$$\eta_m = |C_m|^2 \tag{27}$$

Due to the fabrication process, binary optics gratings are piecewise flat. The grating transmission in this special case can be expressed as $c(x) = c_i$ for $x_i < x < x_{i+1}$, where c_i is the complex transmission of step i of I total steps, $x_0 = 0$, and $x_I = D$. The Fourier coefficients then take the form

$$C_m = \sum_{i=0}^{I-1} c_i \delta_i \exp(-j2\pi m\Delta_i)\,\mathrm{sinc}(m\delta_i) \tag{28}$$

where $\delta_i = (x_{i+1} - x_i)/D$ and $\Delta_i = (x_{i+1} + x_i)/(2D)$.

The sinc term is due to the piecewise flat nature of the grating. If, in addition to the above, the grating transition points are equally spaced, then $x_i = iD/I$ and Eq. (28) reduces to

$$C_m = \exp(-j\pi m/I)\ \mathrm{sinc}\ (m/I)\left[\frac{1}{I}\sum_{i=0}^{I-1} c_i \exp(-j2\pi mi/I)\right] \tag{29}$$

The bracketed term is the FFT of c_i, which makes this case attractive for numerical optimizations. If the complex transmittance is also stepped in phase by increments of ϕ_0, then $c_i = \exp(ji\phi_0)$ and Eq. (29) further reduces to[18]

$$C_m = \exp\{j\pi[(I-1)\alpha - m/I]\}\ \mathrm{sinc}\ (m/I)\frac{\sin(I\pi\alpha)}{I\sin\pi\alpha} \tag{30}$$

where $\alpha = \phi_0/(2\pi) - m/I$. This important case occurs whenever a true blaze is approximated by a stepped-phase profile. The efficiency equation [Eq. (23)] is a further specialization of this case.

Wavefront Multiplexers

Grating Designs Grating multiplexers (also known as beam-splitter gratings) split one beam into many diffracted beams which may be of equal intensity or weighted in intensity.[19] Table 2 shows some common designs. In general, the designs can be divided into two categories: continuous phase and binary. Continuous phase multiplexers generally have better performance, as measured by the total efficiency and intensity uniformity of the diffracted beams, while binary multiplexers are easier to fabricate (with the exception of several naturally occurring continuous phase profiles). Upper bounds for the efficiency of both continuous and binary types are derived in Ref. 20.

If the phase is allowed to be continuous or nearly continuous (8 or 16 phase levels), then the grating design problem is analogous to the phase retrieval problem and iterative techniques are commonly used.[21] A generic problem is the design of a multiplexer to split one beam into K equal intensity beams. Fanouts up to 1:50 with perfect uniformity and efficiencies of 90–100 percent are typical.

The complex transmittance of a binary grating has only two possible values [typically +1 and −1, or $\exp(j\phi_0)$ and $\exp(-j\phi_0)$], with the value changing at the transition points of the grating. By nature, the response of these gratings has the following properties:

- The intensity response is symmetric; that is, $\eta_m = \eta_{-m}$.
- The relative intensities of the nonzero orders are determined strictly by the transition points. That is, if the transition points are held constant, then the ratios η_m/η_n for all m, $n \neq 0$ will be constant, regardless of the actual complex transmittance values.
- The complex transmittance values only affect the balance of energy between the zero and nonzero orders.

TABLE 2 Grating Multiplexers of Period D, $0 < x < D$

Phase Profile	η_{-1}	η_0	η_1	Remarks
$\phi(x, y) = \begin{cases} 0 & x < D/2 \\ \pi & D/2 < x \end{cases}$	0.41	0	0.41	Binary 1:2 splitter
$\phi(x, y) = \begin{cases} 0 & x < D/2 \\ 2.01 & D/2 < x \end{cases}$	0.29	0.29	0.29	Binary 1:3 splitter
$\phi(x, y) = \pi x/D$	×	0.41	0.41	Continuous 1:2 splitter
$\phi(x, y) = \arctan[2.657 \cos(2\pi x/D)]$	0.31	0.31	0.31	Continuous 1:3 splitter

Binary gratings are usually designed via the Dammann approach or search methods and tables of binary designs have been compiled.[22,23] Efficiencies of 60–90 percent are typical for the 1:K beam-splitter problem.

Multifocal Lenses The concepts used to design gratings with multiple orders can be directly extended to lenses and axicons to design elements with multiple focal lengths by taking advantage of the fact that while gratings are periodic in x, paraxial lenses are periodic in $(x^2 + y^2)$, nonparaxial lenses in $\sqrt{x^2+y^2+f_0^2}$, and axicons in $\sqrt{x^2+y^2}$. For gratings, different diffraction orders correspond to plane waves traveling in different directions, but for a lens of focal length f_0, the mth diffraction order corresponds to a lens of focal length f_0/m. By splitting the light into different diffraction orders, a lens with multiple focal lengths (even of opposite sign if desired) can be designed.

As an example, consider the paraxial design of a bifocal lens, as used in intraocular implants. Half the light should see a lens of focal length f_0, while the other half should see no lens. This is a lens of focal length f_0, but with the light split evenly between the 0 and +1 orders. The phase profile of a single focus lens is given by $\phi(r) = -2\pi r^2/(2\lambda_0 f_0)$, where $r^2 = x^2 + y^2$. This phase, with the 2π ambiguity removed, is plotted in Fig. 7*a* as a function of r and in Fig. 7*b* as a function of r^2, where the periodicity in r^2 is evident. To split the light between the 0 and +1 orders, the blaze of Fig. 7*b* is replaced by the 1:2 continuous splitter of Table 2, resulting in Fig. 7*c*. This is the final design and the phase profile is displayed in Fig. 7*d* as a function of r.

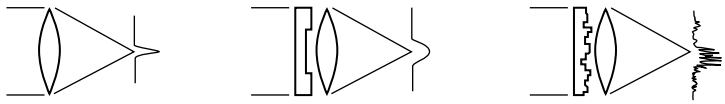

FIGURE 8 Reshaping a focused beam: (*a*) gaussian focus; (*b*) deterministic beam-shaper; and (*c*) statistical diffuser.

Beam Shapers and Diffusers

In many cases, the reshaping of a laser beam can be achieved by introducing the appropriate phase shifts via a binary optics element and then letting diffraction reshape the beam as it propagates. If the incoming beam is well characterized, then it is possible to deterministically design the binary optics element.[24] For example, Fig. 8*a* shows the focal spot of a gaussian beam without any beam-forming optics. In Fig. 8*b*, a binary optics element flattens and widens the focal spot. In this case, the element could be designed using phase-retrieval techniques, the simplest design being a clear aperture with a π phase shift over a central region. If the beam is not well-behaved, then a statistical design may be more appropriate.[25] For example, in Fig. 8*c*, the aperture is subdivided into randomly phased subapertures. The envelope of the resulting intensity profile is determined by the subaperture but is modulated by the speckle pattern from the random phasing. If there is some randomness in the system (e.g., changing laser wavefront), then the speckle pattern will average out and the result will be a design which reshapes the beam and is robust to variations in beam shape.

Other Devices

Other Fourier optics-based applications which benefit from binary optics include the coupling of laser arrays via filtering in the Fourier plane or other means[26] the fabrication of phase-only components for optical correlators,[27] and the implementation of coordinate transformations.[16,28] In all these applications, binary optics is used to directly manipulate the phase of a wavefront.

23.5 DESIGN—VECTOR DIFFRACTION THEORY

Binary optics designs based on vector diffraction theory fall into two categories: grating-based designs and artificial index designs.

Grating-based designs rely on solving Maxwell's equations for diffraction by the element. This is practical for periodic structures. Two major methods for this analysis are the expansion in terms of space harmonics (coupled wave theory) and the expansion in terms of modes (modal theory).[29] In this category, optical design is difficult since it can be both nonintuitive and computationally intensive.

Artificial index designs are based on the following premise. When features on the component are small compared to the wavelength, then the binary optics element will behave as a material of some average index. Two common applications are shown in Fig. 9. In Fig. 9*a*, the device behaves as an antireflection coating (analogous to anechoic chambers) since, at different depths, the structure has a different average index, continuously increasing from n_1 to n_2. In Fig. 9*b*, the regular, subwavelength structure exhibits form birefringence.[30] For light polarized with the electric vector perpendicular to the grooves, the effective index is

$$\frac{1}{n_{\text{eff}}^2} = p\frac{1}{n_1^2} + (1-p)\frac{1}{n_2^2} \tag{31}$$

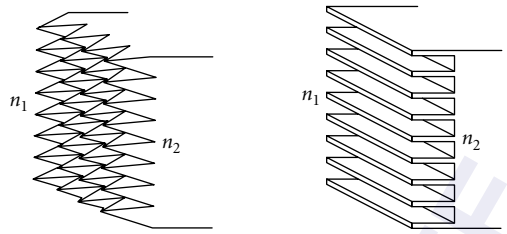

FIGURE 9 Artificial index designs: (*a*) antireflection layer and (*b*) form birefringence.

where p is the fraction of total volume filled by material 1. However, for light polarized with the electric vector parallel to the grooves,

$$n_{\text{eff}}^2 = pn_1^2 + (1-p)n_2^2 \tag{32}$$

In both these cases, the period of the structure must be much less than the wavelength in either medium so that only the zero order is propagating.

23.6 FABRICATION

Mask Layout

At the end of the optical design stage, the binary optics element is described by a phase profile $\phi(x, y)$. In the mask layout process, this profile is transformed into a geometrical layout and then converted to a set of data files in a format suitable for electron-beam pattern generation. From these files, a mask maker generates the set of photomasks which are used to fabricate the element.

The first step is to convert the phase profile $\phi(x, y)$ into a thickness profile (see Fig. 10*a* and *b*) by the relation

$$t(x, y) = \frac{\lambda_0}{2\pi(n_0 - 1)}(\phi \bmod 2\pi) \tag{33}$$

where λ_0 is the design wavelength and n_0 is the index of the substrate at λ_0. The thickness profile is the surface relief required to introduce a phase shift of $\phi(x, y)$. The thickness varies continuously from 0 to t_0, where

$$t_0 = \lambda_0/(n_0 - 1) \tag{34}$$

is the thickness required to introduce one wave of optical path length difference.

To facilitate fabrication, $t(x, y)$ is approximated by a multilevel profile $t'(x, y)$ (Fig. 10*c*), which normally would require one processing cycle (photolithography plus etching) to produce each thickness level. However, in binary optics, a binary coding scheme is used so that only N processing cycles are required to produce

$$I = 2^N \tag{35}$$

thickness levels (hence the name binary optics).

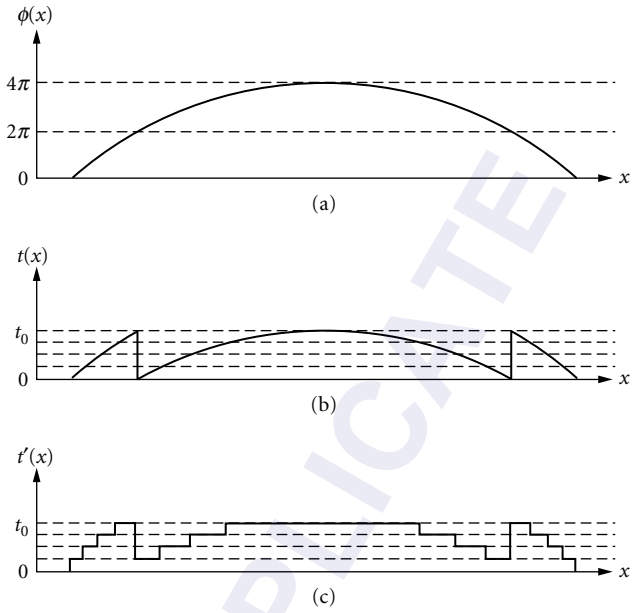

FIGURE 10 Translation from $\phi(x, y)$ to micromachined surface: (*a*) phase $\phi(x, y)$; (*b*) thickness $t(x, y)$; and (*c*) binary optics profile $t'(x, y)$.

The photomasks and etch depths required for each processing cycle are determined from contours of the thickness $t(x, y)$ or equivalently the phase $\phi(x, y)$, as shown in Table 3. The contours can be generated in several ways. For simple phase profiles, the contours are determined analytically. Otherwise, the contours are determined either by calculating the thickness at every point on a grid and then interpolating between points[31] or by using a numerical contouring method,[32] analogous to tracing fringes on an interferogram.

To generate the photomasks, the geometrical areas bounded by the contours must be described in a graphics format compatible with the mask vendor (see Fig. 11*a* and *b*). Common formats are GDSII and CIF,[33] both of which are high-level graphics descriptions which use the multisided polygon (often limited to 200 sides) as the basic building block. Hierarchical constructions (defining structures in terms of previously defined structures) and arraying of structures are also allowed.

The photomasks are usually written by electron-beam generators using the MEBES (moving electron beam exposure system) format as input. Most common high-level graphics descriptions can be translated or "fractured" to MEBES with negligible loss in fidelity via existing translation routines. Currently, commercial mask makers can achieve a minimum feature size or "critical dimension" (CD) of 0.8 μm with ease, 0.5 μm with effort, and 0.3 μm in special cases. The CD of a

3	$0 < t \bmod (t_0/4) < t_0/8$	$0 < \phi \bmod \pi/2 < \pi/4$	$t_0/8$
4	$0 < t \bmod (t_0/8) < t_0/16$	$0 < \phi \bmod \pi/4 < \pi/8$	$t_0/16$

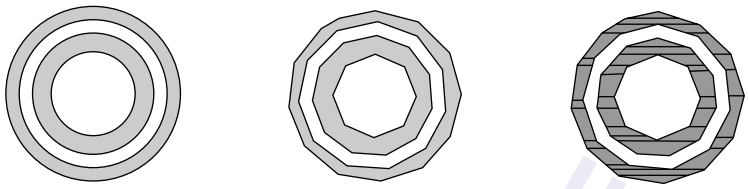

FIGURE 11 Mask layout descriptions: (*a*) mathematical description based on thickness contours; (*b*) high-level graphics description; and (*c*) MEBES.

binary optics element is determined by the minimum local period [see Eq. (8)] divided by the number of steps, $D_{\min}/I$. For lenses,

$$D_{\min} \doteq 2\lambda_0 F \tag{36}$$

where F is the F-number of the lens; while, for gratings, $D_{\min}$ is the period of the grating.

In MEBES, all geometrical shapes are subdivided into trapezoids whose vertices lie on a fixed rectangular grid determined by the resolution of the electron-beam machine (see Fig. 11*c*). The resolution (typically 0.05 μm) should not be confused with the CD achievable by the mask maker.

In summary, the description of the photomask begins as a mathematical description based on contours of the thickness profile and ends as a set of trapezoids whose vertices fall on a regular grid (see Fig. 11). This series of translations results in the following artifacts. First, curves are approximated by straight lines. The error introduced by this approximation (see Fig. 12) is

$$\delta = R(1-\cos\theta/2) \doteq R\theta^2/8 \tag{37}$$

Normally, the maximum allowable error is matched to the electron-beam resolution. Second, all coordinates are digitized to a regular grid. This results in pixelization artifacts (which are usually negligible), analogous to the ziggurat pattern produced on video monitors when plotting gently sloped lines. Finally, the MEBES writing process itself has a preferred direction since it uses electrostatic beam deflection in one direction and mechanical translation in the other.

In addition to the digitized thickness profile, photomasks normally include the following features which aid in the fabrication process. Alignment marks[34] are used to align successive photomasks, control features such as witness boxes allow the measurement of etch depths and feature sizes without probing the actual device, and labels allow the fabricator to easily determine the mask name, orientation, layer, etc.

Micromachining Techniques

Binary optics uses the same fabrication technologies as integrated circuit manufacturing.[34,35] Specifically, the micromachining of binary optics consists of two steps: replication of the photomasks

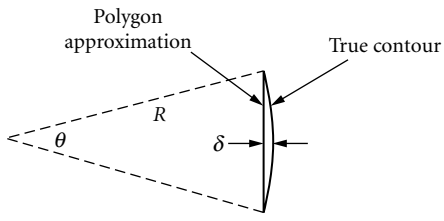

FIGURE 12 Quantization angle.

pattern into photoresist (photolithography) and the subsequent transfer of the pattern into the substrate material to a precise depth (etching or deposition).

The replication of the photomasks onto a photoresist-covered substrate is achieved primarily via contact, proximity, or projection optical lithography. Contact and proximity printing offer lower equipment costs and more flexibility in handling different substrate sizes and substrate materials. In contact printing, the photomask is in direct contact with the photoresist during exposure. Vacuum-contact photolithography, which pulls a vacuum between the mask and photoresist, results in the highest resolution (submicron features) and linewidth fidelity. Proximity printing, which separates the mask and photoresist by 5 to 50 μm, results in lower resolution due to diffraction. Both contact and proximity printing require 1:1 masks. In projection printing, the mask is imaged onto the photoresist with a demagnification from 1× to 20×. Projection printers are suitable for volume manufacturing and can take advantage of magnified masks. However, they also require expensive optics, strict environmental controls, and can only expose limited areas (typically 2 cm × 2 cm).

Following exposure, either the exposed photoresist is removed (positive resist) or the unexposed photoresist is removed (negative resist) in a developer solution. The remaining resist serves as a protective mask during the subsequent etching step.

The most pertinent etching methods are reactive ion etching (RIE) and ion milling. In RIE, a plasma containing reactive neutral species, ions, and electrons is formed at the substrate surface. Etching of the surface is achieved through both chemical reaction and mechanical bombardment by particles. The resulting etch is primarily in the vertical direction with little lateral etching (an anisotropic etch) and the chemistry makes the etch attack some materials much more vigorously than others (a selective etch). Because of the chemistry, RIE is material-dependent. For example, RIE can be used to smoothly etch quartz and silicon, but RIE of borosilicate glasses results in micropatterned surfaces due to the impurities in the glass. In ion milling, a stream of inert gas ions (usually Ar) is directed at the substrate surface and removes material by physical sputtering. While ion milling is applicable to any material, it is usually slower than RIE.

For binary optics designed to be blazed for a single order (i.e., designs based on geometrical optics), the major effect of fabrication errors is to decrease the efficiency of the blaze. There is little or no degradation in the wavefront quality. Fabrication errors can be classified as lithographic errors, which include alignment errors and over/underexposure of photoresist, and etching errors, which include depth errors and nonuniform etching of the substrate. As a rule of thumb, lithographic errors should be held to less than 5 percent of the minimum feature size ($<0.05\ D_{\min}/I$), which can be quite challenging; while etching errors should be held to less than 5 percent of t_0, which is usually not too difficult. For binary optics designed via scalar or vector diffraction theory, manufacturing tolerances are estimated on a case-by-case basis through computer simulations.

a, b	constants
g	constant
h_i	constants
n	refractive index
r	radius
V_{ij}	Abbe numbers
z	Cartesian coordinate (optical axis direction)
Φ	power

24.2 INTRODUCTION

Gradient index (GRIN) optics[1] refers to the field of optics in which light propagates along a curved path. This contrasts with normal homogeneous materials in which light propagates in a rectilinear fashion. Other terms that have been used to describe this field are inhomogeneous optics, index of refraction gradients, and distributed index of refraction. The most familiar example of a gradient index phenomenon is the mirage when a road appears to be wet on a hot summer day. This can be understood by the fact that the road is absorbing heat, thus slightly raising the temperature of the air relative to the temperature a few meters above the surface. By the gas law, the density decreases, and therefore the index of refraction decreases. Light entering this gradient medium follows a curved path. The ray path, as shown in Fig. 1, is such that the ray propagates downward toward the road and then gradually upward to the observer's eye. The observer sees two images. One is the normal image propagating through the homogeneous material and the second is an image that is inverted and appears below the road surface. Thus, the index of refraction gradient acts as a mirror by gradual light refraction rather than reflection.

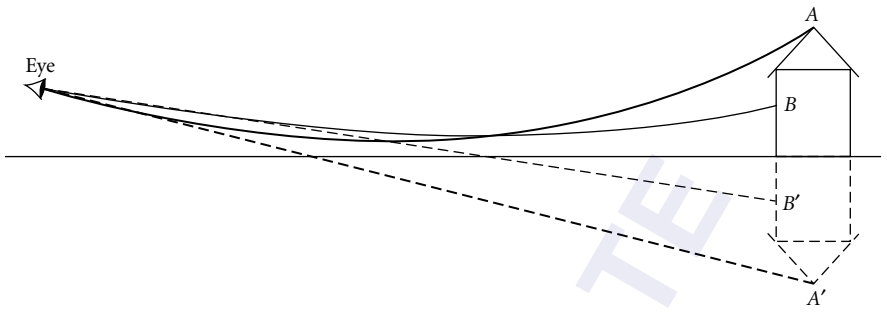

FIGURE 1 Light from point *A* emits or reflects in all directions. Light propagating several meters above the heated road travels in a straight line. Light passing through the lower index of refraction region near the road undergoes a bending. This light appears to have come from below the road.

24.3 ANALYTIC SOLUTIONS

Over the approximately 150 years that gradient index optics has been studied, a wealth of very interesting analytic solutions has been published.[2] A classic example was published by James Clerk Maxwell in 1850. Maxwell[3] showed through geometrical optics that the ray paths in a spherically symmetric material whose index of refraction is given by

$$n(r) = a/(b^2 + r^2) \tag{1}$$

are circles. The object and the image lie on the surface of the sphere but, otherwise, the imaging is perfect between the conjugate points on the sphere. The medium between the object and the image is continuous with no discreet surfaces. A century later, Luneburg[4] modified the system to allow for discontinuities of the index of refraction. While these have not been implemented in ordinary optical systems, they have, however, been shown to be useful in integrated optics.[5]

A final example of a numerical solution is that of a radial (cylindrical) gradient in which the index of refraction varies perpendicular to a line. In 1954, Fletcher[6] showed that if the index of refraction is given by

$$n(r) = n_o\, sech(ar^2) \tag{2}$$

then the ray paths inside the material in the meridional plane are sinusoidal. Nearly 50 years earlier, Wood[7] had shown experimentally that the paths appeared to be sinusoidal. This solution has several important commercial applications. It is the basis of the Selfoc lens used in arrays for facsimile and photocopying machines and in endoscopes used for medical applications.

24.4 MATHEMATICAL REPRESENTATION

Most of the gradient index profiles are represented by a polynomial expansion. While these expansions are not necessarily the most desirable from the gradient materials manufacturing standpoint, they are convenient for determining the aberrations of systems embodying GRIN materials. There are basically two major representations for gradient index materials. The first, used by the Nippon Sheet Glass, is used exclusively by representing radial gradient components. In this case, the index of refraction is written as a function of the radial coordinate *r*

$$N(r) = N_0(1 - \mathrm{A}r^2/2 + h_4 r^4 + h_6 r^6 + \cdots) \tag{3}$$

The second method of representing index of refraction profiles is a polynomial expansion in both the radial coordinate r and the optical axis coordinate z. In this case, the representation is

$$N(r, z) = \sum_{j=0} \sum_{i=0} N_{ij} r^{2i} z^j \tag{4}$$

where the coefficients N_{ij} are the coefficients of the index of refraction polynomial. A pure axial gradient (in the z direction) has coefficients only in the form of N_{0j} and those in the radial would be of the form of N_{i0}. These representations for the index of refraction polynomial have been the basis of the aberration theory which was first developed for gradient index materials with discreet surfaces by Sands.[8] These coefficients are wavelength dependent and are typically defined at three wavelengths. A gradient dispersion is defined by using a general Abbe number

$$V_{ij} = N_{ij,d} / (N_{ij,F} - N_{ij,C}) \tag{5}$$

except for i and j both equal to zero. In the case for $i = j = 0$, then the Abbe number becomes the standard form, namely

$$V_{00} = (N_{00,d} - 1) / (N_{00,F} - N_{00,C}) \tag{6}$$

The subscripts d, F, and C refer to the wavelengths 0.5876, 0.4861, and 0.6563 μm, respectively. Unlike the normal dispersion of glasses where V_{00} is between 20 and 90, the V_{ij} can have negative and positive values or can be infinite (implying that the gradient is the same as both the red and the blue portions of the spectrum).

24.5 AXIAL GRADIENT LENSES

When the index of refraction varies in the direction of the optical axis (the z direction), the bending of the light within the material is very small. Thus, the main feature of an axial gradient is its ability to correct aberrations rather than to add power to the lens. Sands showed that the effect of an axial gradient on monochromatic aberrations is exactly equivalent to that of an aspheric surface. In fact, one could convert any aspherical surface to an axial gradient with a spherical surface and have the same image performance to the third-order approximation. There is, however, one very important difference between aspheric surfaces and axial gradients, i.e., the variation of the index of refraction profile with wavelength. Since an aspheric is the same for all wavelengths, its effect on spherochromatism is established once the aspheric has been determined. Further, an asphere has no effect on paraxial axial or lateral chromatic aberrations. This is not the case for axial gradients. Since the index of refraction profile varies with wavelength, it is possible to significantly modify the spherochromatism of the lens and, in the case where the gradient extends from the front to the back surface, to affect the paraxial chromatic aberrations. Depending upon the dispersion of the gradient index material, the spherochromatism can be increased or decreased independent of the monochromatic correction. The effect of an axial gradient on paraxial axial chromatic aberration is best understood by placing a surface perpendicular to the optical axis in the middle of a single lens dividing it into two parts. The gradient dispersion implies that the medium will have one dispersion at the front surface and a different dispersion at the second surface. Thus, if one were to design a material in which the dispersion of the front surface is 60 and at the rear surface is 40, then the combination of a positive (convex surface on the front) and negative lens (concave surface on the back), reduces the chromatic aberration. This can only be done if the lens is meniscus. In that case, the theoretical front lens is plano-convex while the back one is plano-concave. If the negative element has the higher dispersion (lower V numbers), then it is possible to chromatize the lens by a proper bending of the lens surfaces. This was first shown in the infrared part of the spectrum using a zinc sulfide-zinc selenide gradient material.[9]

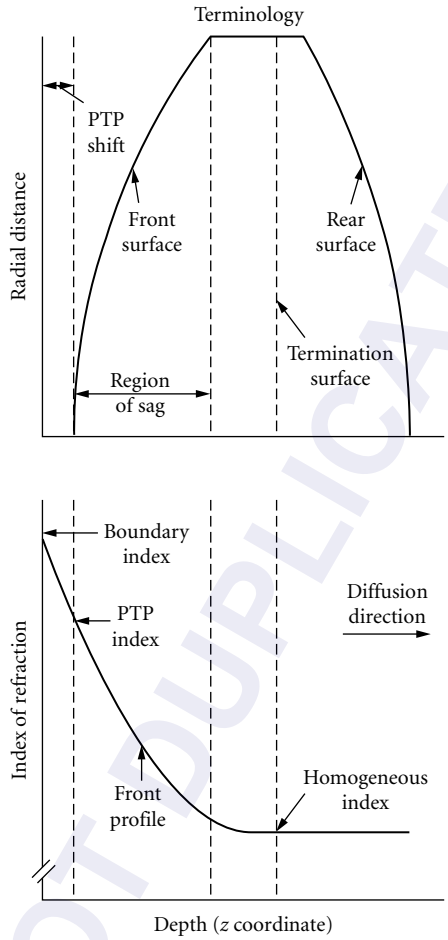

FIGURE 2 Diagram of axial gradient terminology. The effective region of the gradient is in the "region of sag."

The simplest example of an axial gradient is the linear profile in which the index of refraction is written as

$$N(z) = N_{00} + N_{01}z \tag{7}$$

The coefficient N_{01} is an additional degree of freedom which can be used to correct any of the third-order monochromatic aberrations except Petzval curvature of field. There are two ways to approach the design of these lenses. In the case where the index of refraction profile does not continue to the rear surface (see Fig. 2), a simple formula can be used to relate the amount of index change to the *F*-number of the lens surface if the third-order spherical aberration and coma are to be correct to zero,[10] namely,

$$\Delta n = (0.0375/(N_{00} - 1)^2)/f\#^2 \tag{8}$$

in this formula, the important parameters are the index of refraction of the base material, N_{00}, the change in index of index of refraction, Δn, from the polar tangent to the maximum sag point, and

the *F*-number of the lens. One sees that if the *F*-number of the lens is doubled, then the amount of index change necessary to correct the spherical aberration and coma to zero increases by a factor of 4. Thus, while it is possible to correct the spherical aberration of the singlet operating at F/4 with an index change of only 0.0094, that same lens operating at *F*/1 will require an index change of 0.15. In most lenses, one never corrects the spherical aberration of individual elements to zero, but corrects the total amount of spherical aberration of all lens elements to zero.

Axial gradients have been used in a number of lens designs. Most of the work in this field has occurred in photographic objectives.[11,12] In these cases, they offer a slight advantage over aspherics because of the chromatic variation of the gradient.

24.6 RADIAL GRADIENTS

In the most generalized case for radial gradients (one in which all coefficients are nonzero), it is possible not only to use the gradient for aberration correction, but also to modify the focal length of the lens. Independent of which representation is used, the coefficient of the parabolic term [Eq. (2) or Eq. (3)] dictates the amount of power that is introduced by the radial gradient component. Assuming only a radial gradient component, Eq. (4) can be expanded as

$$N(r) = N_{00} + N_{01}r^2 + N_{02}r^4 + \cdots \tag{9}$$

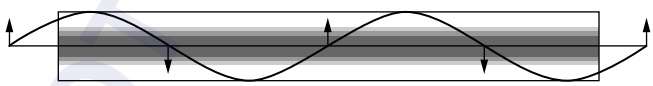
Equating the terms in Eq. (3) and Eq. (9) gives

$$N_{00} = N_0 \quad \text{and} \quad N_{10} = -N_0 A/2 \tag{10}$$

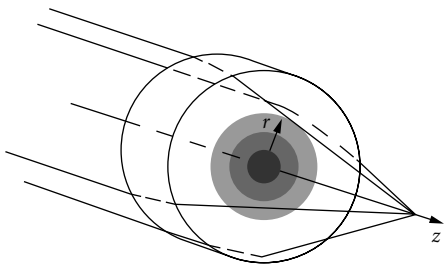
In the most general form, the power ϕ, due to the radial gradient component, is written as

$$\phi = -N_0 A^{0.5} \sin(A^{0.5} t) \tag{11}$$

From Eq. (11), the length of the material t determines the focal length of the system. In fact, depending on the choice of length, the power can be positive, negative, or zero. See Fig. 3*a*. A convenient variation



(a)



(b)

FIGURE 3 Diagram of radial gradient: (*a*) a long radial gradient lens illustrating period ray path and (*b*) wood lens.

on this formula is to determine the length at which light entering the material collimated will be focused on the rear surface. This length is called the quarter pitch length of the rod and is given by

$$P_{1/4} = (\pi/2)(-N_{00}/(2N_{10}))^{0.5} \tag{12}$$

The full period length of the rod is simply four times Eq. (12).

For the case where the focal length (the reciprocal of the power) is long compared to its thickness, this can be approximated by the formula (see Fig. 3*b*)

$$\phi = -2N_{10}t \tag{13}$$

This simplifying formula was derived by the entomologist Exner[13] in 1889 while he was analyzing insect eyes and found them to have radial gradient components. Since the dispersion of a gradient material can be positive, negative, or infinity, the implication is that the paraxial axial chromatic aberration can be negative, positive, or zero. This leads to the possibility of an achromatized singlet with flat surfaces; or, by combining the dispersion of the gradient with that of the homogeneous materials, to single element lenses with curved surfaces that are color-corrected.

The radial gradient lens with flat surface is a very important example, both from a theoretical and a commercial standpoint. Consider such a lens with an object of infinity where the lens is thin relative to its focal length. As has already been shown, the value of N_{10} and the thickness determine the focal length of such a lens. According to third-order aberration theory,[8] the only other term that can influence the third-order monochromatic aberrations is the coefficient N_{20}. This term can be used to correct any one of the third-order aberrations except Petzval curvature of field. The coefficient N_{20} is normally used to correct the spherical aberration; however, once this choice is made, there are no other degrees of freedom to reduce other aberrations such as coma. It can be shown that the coma in such a single element lens is very large if the lens is used at infinite conjugates. Of course, if such a lens is used at unit magnification in a system which is symmetric about the aperture stop, the coma (as well as the distortion and paraxial lateral color) is zero. As the length of the rod increases, the approximation for the focal length becomes inaccurate and the more rigorous formula given by Eq. (11) is appropriate. However, the rules governing the aberration correction remain the same. That is, the choice of the value of N_{20}, or in the Nippon sheet glass representation, in h_4 coefficient, corrects the third-order spherical aberration to zero. In Fletcher's original paper, he showed that rays propagating in a material whose index of refraction is given by Eq. (2) would focus light in the meridional plane periodically with no aberration along the length of such a rod. If one expands a hyperbolic secant in a polynomial expansion, one obtains

$$N_{20} = 5N_{10}^2/6N_{00} \tag{14}$$

The implication is that if N_{20} is chosen according to Eq. (14), then not only is the spherical aberration corrected, but so is the tangential field (that is, the sum of three times the astigmatism plus the field curvature). Rawson[14] showed that a more appropriate value for N_{20} was $3N_{10}^2/2N_{00}$. This is a compromise for the correction of sagittal and tangential fields.

The second limiting case is to use these rods with arbitrary length but at unit magnification. This has important commercial applications in photocopying and fax machines, for couplers for single-mode fibers, and in relays used in endoscopes. In all of these systems, the magnification is ±1 and thus there is no need to correct the coma, the distortion, or the lateral color. Thus, the choice of N_{20} can be used to either correct the spherical aberration or to achieve a compromise between the tangential and sagittal fields.

In one of the most common applications, a series of lenses is assembled to form an array (see Fig. 4). In this case, the magnification between the object and the image must be a +1 with an inverted image halfway through the gradient index rods. Light from an object point is imaged through multiple GRIN rods depending on the numerical aperture of each of the rods. The effective numerical aperture of the array is significantly higher than that of a single rod. Theoretically, a full two-dimensional array can be constructed to image an entire two-dimensional object. In practice, to reduce costs the object is scanned by moving the object across the fixed lens array with either a charged couple device or a transfer drum used to record the image.

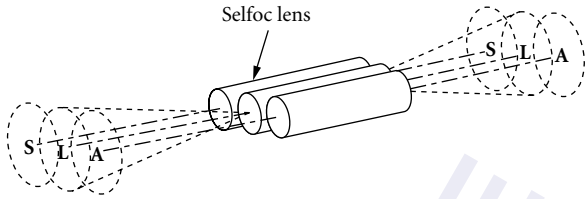


FIGURE 4 An array of radial gradient lenses (only three shown) can be used to form an image of an extended object. This principle is used in photocopying and fax machines.

24.7 RADIAL GRADIENTS WITH CURVED SURFACES

While the radial gradient with flat surfaces offers tremendous commercial applications today, it has limited applications because of the large amount of coma that is introduced unless the lens system is used at unit magnification. Thus, it is often desirable to introduce other degrees of freedom that may improve the imagery. The simplest way to do this is to make one or both of the end cases curved. The ability to chromatize such a lens is not lost so long as the power resulting from the curved surfaces and that of the radial gradient maintain the same ratio (but with opposite sign) as that of the Abbe number of homogeneous material and the Abbe number of N_{10}. Thus, the lens shape can be determined to reduce the coma to zero and the value of the N_{20} coefficient is chosen to eliminate the spherical aberration. An example of a curved lens with a radial gradient was developed by Nippon Sheet Glass for a compact disc player.[15] In that case, it is not necessary to achromatize the lens since the source is a monochromatic laser diode, but it was necessary to extend the field and reduce the amount of spherical aberration simultaneously. It is also often desirable to place part of the power on the curvature rather than using the gradient to refract all of the light. This reduces the magnitude of the index change and makes the lens easier to manufacture.

In a radial gradient material with curved surfaces, it is possible to eliminate four out of five monochromatic aberrations,[16] and any four can be chosen. However, these lenses tend to be very sensitive to slight manufacturing errors, as they require a very delicate balance between the coefficients of the gradient profile and typically have very large amounts of higher-order aberrations.

24.8 SHALLOW RADIAL GRADIENTS

An interesting compromise between an axial gradient and a radial gradient with power is the shallow radial gradient (SRGRIN). In this type of gradient, there is no power generated by the gradient (i.e., $N_{10} = 0$). Like the axial gradient, it has no effect on Petzval curvature of field, but its aberration correction is significantly different than that of axial gradients. Sands[8] showed that in the case of an axial gradient, the important parameter is the differential refraction of the ray at the surface which causes an additional surface contribution. In the shallow radial gradient there is no surface contribution, since the N_{10} coefficient is zero. All of the aberration correction is from the transfer contribution through the material.[8] The implication of this fact is that the thickness of the shallow radial gradient is very important and, in fact, the most important parameter is the product of the thickness and the N_{20} coefficient. Thus, if only a small index change can be manufactured, the same amount of aberration correction can be achieved by increasing the thickness of the element. The other significant difference between this gradient and a normal radial gradient is the sign of the index change. In most lenses designed to date, the index of refraction of a conventional radial gradient should be lower at the periphery than it is at the center, thus creating a positive lens. However, in the shallow radial gradient, the index of refraction should be higher at the periphery than at the center. This has also normally

been the case in the axial gradient in which the index of refraction should be higher at the polar tangent plane than at the maximum sag point. This has important implications for the manufacturing process. Furthermore, the amount of index change necessary for shallow gradient correction is usually very small compared to the amount of index change needed in a regular radial gradient.

24.9 MATERIALS

While several materials systems have been proposed for forming gradient index materials, gradients have only been made for commercial applications in glasses and polymers. However, research has been conducted in zinc selenide-zinc sufilde,[17] and germanium-silicon[18] for the infrared portion of the spectrum, and in fluoride materials for the ultraviolet.[19] However, none of these have reached the stage, at this writing, which can be commercialized. For glasses, several processes have been proposed. The most common method of making gradient index materials is by the ion exchange process. In this case, a glass containing a single valence ion (such as sodium, lithium, or potassium) is placed in a molten salt bath at temperatures between 400 and 600°C. The molten salt bath contains a different ion than that in the glass. The ions from the salt diffuse into the glass and exchange for an ion of equal valence in the glass. The variation in composition leads to a variation in index of refraction. The variation in index of refraction occurs due to the change of polarizability between the two ions and the slight change in the density of the material. In some cases, these two phenomena can cancel one another, producing a composition variation, but no corresponding change in index of refraction. A model for predicting the index refraction change as well as the chromatic variation of the gradient has been developed.[20] In this system, it is clear that the maximum index change is limited by the changes in the properties of single valence ions. While very large index changes have been made (approaching 0.27), these gradients suffer from large amounts of chromatic aberration. In axial gradients, a large amount of chromatic aberration is desirable, as it normally improves the spherochromatism. In the case of radial gradients, however, it creates large paraxial axial chromatic aberration which is normally not desirable.

The manufacturing method is quite simple. If one wishes to make axial gradients, a sheet of glass is placed in a molten salt bath. Typical times for diffusion are a few days for diffusion depths of 3 to 7 mm at temperatures around 500°C. The higher the temperature, the faster the diffusion; however, at high temperature the glass will begin to deform. Lower temperatures increase the diffusion times. For radial gradients, one simply starts with glass with cylindrical symmetry and places the rods inside an ion exchange bath. In order to form good parabolic profiles, it is necessary for the ions to diffuse through the center.

Two other methods have been proposed for making gradients in glass. In the first, the gradient is formed by leaching or by stuffing in a sol-gel formed glass. This system has only shown to be applicable to radial gradients. After the glass is formed by the sol-gel (solution gelatin process), the glass is in a porous state where one of the components can be dissolved out in an acid bath[21] or molecules can be stuffed into the glass to form the index of refraction gradient.[22] By the leaching method, gradients have been formed in either titanium or zirconium. Index changes of up to 0.03 have been formed by this method. Alternatively, the glass can be stuffed with ions such as lead. The lead precipitates on the walls of the porous material whereupon it is included in the glass during the sintering step. While it is possible to get much larger changes using the method based on lead, both of these techniques suffer from large amounts of chromatic aberration.

A new method shown to be very useful for axial gradients is based on the fusion of glass slabs.[23] The index of refraction of each slab is slightly different than its adjacent slab. Very large index of refraction changes can be formed by this technique ($\Delta n = 0.4$). Further, these materials can be made in apertures up to 100 mm.

Two basic methods for manufacturing of polymers for gradient index have been demonstrated. In the first, an exchange of one monomer for a monomer in a partially polymerized material forms a profile in the same way as the ion exchange method.[24] In the second, ultraviolet light is used to induce photocopolymerization to form an index of refraction in the material.[25]

HDTV	high definition television
IR	infrared
IRED	infrared emitting diode
FP	film plane
LCD	liquid crystal display
LP	line pairs
SLR	single lens reflex
MT	mount

25.2 INTRODUCTION

Thanks to technical progress and vigorous competition, the camera buyer faces a difficult challenge in making a choice. This chapter will attempt to reduce the difficulty by asking the buyer to consider the final image; its purpose, its audience, and its appearance.

Next, some of the more recent technical features are discussed. These include the intriguing ability to select objects in a scene for focus and/or exposure measurement by tracking the position of the user's eye. Finally, various types of cameras and their accessories are described.

In terms of technical sophistication, a moderately priced 35-mm snapshot camera made today would astonish a photographer who was suddenly time shifted from the 1950s. Consider the automation of exposure, focus, film loading, winding, rewinding, plus flash exposures from a tiny integral electronic flash unit no bigger than a spare roll of film.

The net result, for the snapshooter, is a higher percentage of "good" pictures per roll of film than ever before. The specialist also profits, particularly when the basis and limits of the feature are understood.

A good share of these technical features have been incorporated in the more advanced cameras; sometimes just because it can be done. Looking beyond this, the most basic technical camera ever made, the view camera, remains virtually unchanged for the past century. It is to photography what the wooden match is to fire making.

Portions of this chapter are adapted from the author's book, *Camera Technology: The Dark Side of The Lens* (Academic Press, 1992). The author acknowledges, with thanks, the permission granted by Academic Press to use certain material from that book in this chapter.

25.3 BACKGROUND

Imagine the first camera as nothing more than a tent with a small hole in the side casting an image upon the opposite wall. From this accidental version of a "pinhole" camera to today's "smart" cameras, we find a cornucopia of ingenuity embracing optics, mechanics, electronics, and chemistry.

The variety of cameras ranges from one tiny enough to be concealed in a man's ring to one large enough for several people to walk around it without obscuring the image. The price range of cameras stretches from few dollars for a disposable model (complete with film) to several thousand dollars (without film).

Cameras have recorded images of the deepest ocean trenches and the surface features of Jupiter's moons. There are cameras that can freeze a bullet in midair or compress the germination of an acorn into a few minutes. From intimate portraits of bacteria to a 360° panoramic view of the Grand Canyon, there's a camera for any task.

Nonetheless, there is a common denominator: all cameras produce an image. This image may be the end product, or it may be converted in some way to the final image intended for viewing, as shown in Fig. 1. To choose the best camera for a given task, the properties of this final image should be determined first.

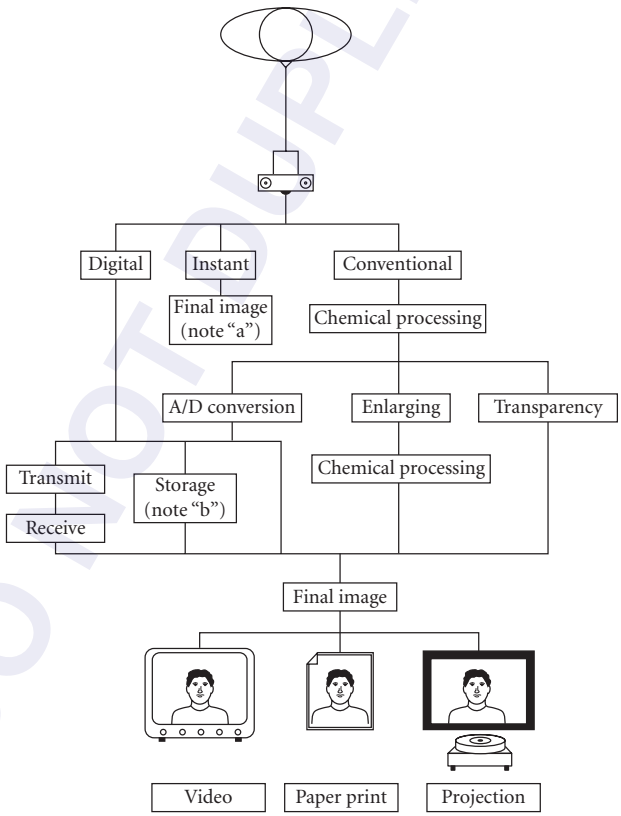

FIGURE 1 Final image flow chart. (a) Many instant photos can be manipulated just as the digital and conventional types, but are treated here in their primary use. (b) Storage means include magnetic tape and disks, optical disks, etc.

25.4 PROPERTIES OF THE FINAL IMAGE

1. Appearance
   - *a.* Black-and-white
   - *b.* Color
   - *c.* High contrast
   - *d.* Continuous tone
2. Smallest detail to be resolved
3. Type of display
   - *a.* Audience population
   - *b.* Viewing conditions
     - (1) Viewing distance
       - (*a*) Minimum
       - (*b*) Maximum
     - (2) Ambient illumination
   - *c.* Display choices
     - (1) Print
     - (2) Projection
     - (3) Self-luminous
4. Distribution

By considering the properties listed, we're obliged to visualize the final image through the viewer's eyes. Esthetics aside, we'll assume that the prime purpose of the final image is to convey information to the viewer.

25.5 FILM CHOICE

The appearance of the final image affects the choice of a camera by the kind of film required to produce that appearance. There are some films that are not available in all sizes. Other films are available in certain sizes only by special order. The availability of some films in some sizes changes over time, so check with your supplier before you select a camera for which film may be scarce.

Most film makers will be glad to send you their latest data on their current films, but be prepared for changes, because this is a very competitive field. New 35-mm color films in particular seem to come out with every change in the seasons.

25.6 RESOLVING FINE DETAIL

If the information in the final image is to be of any use, it must be legible to its detector, which we'll assume to be the human eye. Figure 2 shows that for high-contrast detail viewed under at least 50 foot-candles (office lighting), the eye has an angular resolution of about 1 minute of arc. This means that we can resolve about seven line-pairs per millimeter (LP/mm) at a distance of 250 mm. Since most photographic images exhibit moderate contrast and are viewed in moderate light, a more conservative limit of resolution would be 3.4 minutes of arc, which is good enough to resolve a pattern of 2 LP/mm at 250 mm.

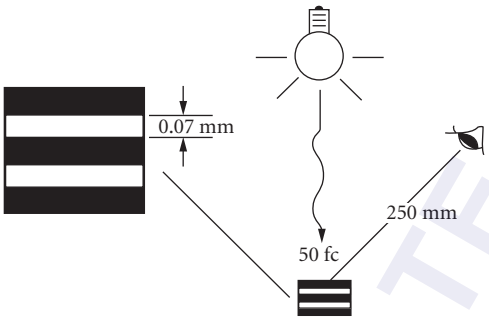

FIGURE 2 Visual resolution. Under ideal viewing conditions, we can resolve seven line-pairs per millimeter.

In most cases, the final image is a magnification of the primary image formed in the camera. All else being equal, there is a practical limit to the extent of this magnification, after which the structure of the film, residual lens aberrations, focus inaccuracy, and/or diffraction effects begin to obscure fine image details.

Suppose then, that for some film we set a practical limit of magnification at 10×. Based on the visual resolution limit given previously, the smallest detail in the primary image could be 20 LP/mm, each line 0.025 mm wide.

Looking at it another way, if you want to photograph fine details and display the image legibly at a distance of 250 mm from the viewer, choose a film that will clearly resolve at least 20 LP/mm and is capable of being enlarged 10 diameters without its grain or other structure obscuring the image. Most films in common use today easily satisfy this criterion.

25.7 FILM SIZES

In terms of the widest variety of films available, 35-mm ranks number one. The most common format for this film is 24×36 mm. Although seldom used today, other 35-mm formats include 18×24 mm and 24×24 mm.

Next in line for a broad choice of film types is known as *medium-format* and is sold in 61.5-mm-wide rolls. The shortest rolls are paper-backed and are called 120. Many cameras that accept 120 film will also accept 220 film, which has an opaque paper leader and trailer, but no paper backing over the film. This permits a longer strip of film (more exposures per roll) and better film flatness than 120.

Common formats include (nominal dimensions) 45×60 mm, 60×60 mm, 60×70 mm, and 60×90 mm. Some medium-format cameras also accept 70-mm film that has a row of sprocket holes along each edge and may be loaded in special cassettes for use in the camera's large capacity, motorized, interchangeable film magazine.

The large formats, commonly referred to by their sheet film sizes in inches include 4×5, 5×7, and 8×10, to name the most well known. They may not offer as broad a choice of film as the smaller formats, but the most essential films are available for them.

25.8 DISPLAY

Choosing the best type of display for the final image should start with the number of people in the viewing audience. For large groups, a projected transparency has the advantage of being visible to the entire audience simultaneously. This is especially important if you want to use a pointer to single out detail in the image. Image detail should be clearly resolved by everyone in the audience, from

the front row (image not too grainy) to the last row (image detail within the visual limits). In some cases, the best display is both a projected transparency that the lecturer can refer to with a pointer and a print for each viewer to examine closely, regardless of his position in the audience.

For the best viewing of projected images, the only light striking the screen should be that coming through the transparency. In other words, the room should be pitch black. Unless this condition is met, there is no possibility of reproducing the full tonal range, from deepest black to sparkling white, that the image could contain.

When this condition is difficult to satisfy, a self-luminous display may be best. One or more video monitors located at strategic points can provide good image contrast even under office illumination. The type of monitor may be the conventional cathode ray tube (CRT) or liquid crystal display (LCD). Of the two, the CRT produces a brighter image and is the least expensive. But it is bulky and fragile. The LCD has the virtue of minimal thickness; it's a flat screen display that can be hung on a wall like a framed photo.

At present, neither type can equal the fine detail and subtle color reproduction of a high-grade projected transparency viewed under the proper conditions. However, the gap in image quality is closing, especially now that high-definition television (HDTV) are widely available.

25.9 DISTRIBUTING THE IMAGE

For many applications, the ease and speed with which an image can be distributed is crucial. Thanks to scanners, fax machines, modems, color photocopy machines, rapid photofinishing plants, self-processing "instant" films, etc., we can send practically any image to practically anyone who wants it in a matter of minutes. At present, our ability to do this depends on transforming the analog information in the subject into digital information for transmission, reception, manipulation, analysis, storage, and/or display, as indicated in Fig. 1.

25.10 VIDEO CAMERAS

If speed of acquisition and distribution is most important, we can capture the image on the charge coupled device (CCD) of the widely available camcorder, whose video and audio output signals are available in real time. These video cameras are versatile and moderately priced.

The still-picture counterpart to the camcorder seems to have come to a fork in the road. One path goes to a complete camera system, designed from scratch around the CCD chip and incorporating a miniature magnetic disk drive. The second path leads to a special video back, designed to replace the standard back of a conventional (film) camera. The video back contains a CCD chip and associated circuitry. In some cases the video back and the recorder, in which hundreds of images can be stored, require an "umbilical" cord between them. Some of the newer designs have integrated the back and recorder into a single (cordless) unit. Some of these backs can store up to 50 images internally.

As the capacity for image storage and/or manipulation grows, we see the emergence of systems within systems, where black box A converts black box B to communicate with computer C as long as you have the right adapter cables D, E, and F. This is typical of many rapidly expanding technologies.

Users of a video back on a conventional film camera will notice an unusually narrow angle of view for the lens in use if the light-sensitive area of the CCD chip is smaller than that of the film normally used in the camera. The reason is that only the central region of the camera's format is used. The result is that the camera's lenses perform as though their focal lengths have been "stretched" compared to their performance with conventional film that covers the whole format.

For example, Kodak's DCS 200 replaces the back of an unmodified 35-mm SLR camera, the Nikon N8008s. The "normal" lens for this camera's 24×36 mm film format has a 50-mm focal length, producing a (diagonal) angle of view of about 47°. The same lens used with the video back produces an angle of view of 37° because the CCD measures only 9.3×14 mm. To duplicate the 47° angle of view for this size CCD, a 19.3-mm focal length lens should be used.

Concerning the resolution from CCD images, Kodak's data for the DCS 200 gives a count of 1.54 million (square) pixels, arranged in a 1012×1524 pixel array that measures 9.3×14 mm. This gives a pixel spacing of 0.018 mm, which theoretically can resolve 54.4 monochromatic LP/mm. The color version uses a checkerboard pattern of red, green, and blue filters over the array, so divide the monochrome figure by three to come up with a color resolution of 18.1 LP/mm.

This is quite close to the criterion, discussed earlier, of 2 LP/mm for a 10× enlargement viewed at 250 mm. A 10× enlargement of the CCD image just described would measure 93×140 mm, about the size of a typical snapshot.

25.11 INSTANT PICTURES

For many applications, instant, self-processing film is the best choice. A familiar example is the oscilloscope camera loaded with high-speed film. With minimum, moderately priced equipment, a transient waveform on the scope screen can be captured on the film. Seconds later the print can be examined.

Polaroid dominates this field, which they spawned in 1948. Their range of camera models goes from snapshot to trucksize. They also have special backs which can be used on various cameras to adapt them for use with Polaroid films.

These films range from 35-mm color transparency to 8×10 in (and larger) color print. Included in this variety are black-and-white sheet films that yield both a positive print and a negative. The negative must be stabilized, then washed and dried before being placed in an enlarger or contact printer.

25.12 CRITICAL FEATURES

In many cases, the availability of an accessory such as a Polaroid and/or digital image back is important enough to dictate the choice of a camera. Other factors that may tip the scales in favor of one camera over another might not be discovered until the chosen camera is used for some time.

For example, it may be very useful to have the kind of exposure automation that measures the light reflected from the film plane, before and during the exposure, thus being capable of responding instantly to any change in the scene luminance. There are some cameras that have this capability, yet they lack another feature that may be more valuable for some kinds of photography: the ability to observe the image through the viewfinder of an SLR not just before, but during the exposure.

Most SLRs employ a mirror that swings out of the way just before the exposure begins. This allows the image-forming light to reach the film, but it also blacks out the viewfinder, so that during the crucial instant of the exposure the photographer is momentarily blind. Figure 3 illustrates that by using a beam splitter instead of a conventional mirror in an SLR, the problem is eliminated.

When the advantages of a beam-splitting system are considered, it seems strange that the feature isn't used more widely. Eliminating the swinging mirror reduces the noise and vibration generated each time an exposure is made. This can be crucial when the camera is attached to a microscope or telescope. Some SLRs provide for the mirror to be locked in its raised (shooting) position when desired.

25.13 TIME LAG

Even more important for some types of photography, substituting a beam splitter for a moving mirror in an SLR should reduce the camera's time lag. This is the interval between pressing the camera's trip button and the beginning of the exposure. It's a characteristic shared by all cameras and is rarely mentioned in a manufacturer's specifications of a camera. With few exceptions, time lag has increased in step with camera automation.

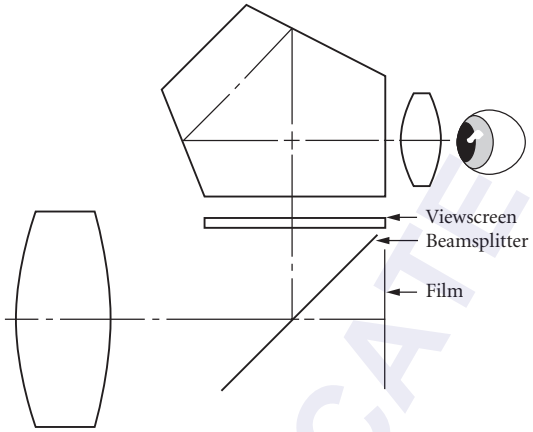

FIGURE 3 Beam-splitter SLR. The beam splitter eliminates the moving mirror, resulting in shorter time lag, reduced noise and vibration, plus the ability to monitor exposure and other image properties in real time.

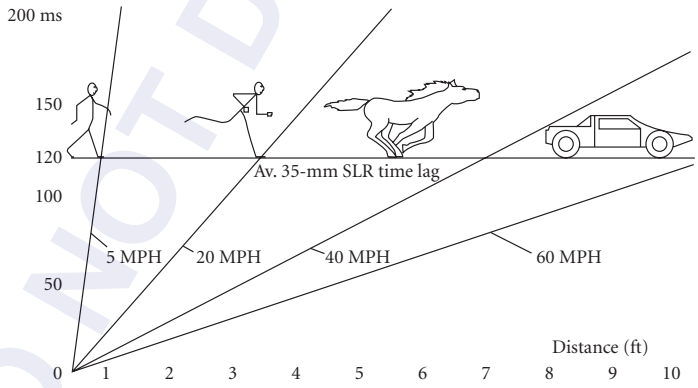
Testing 40 different 35-mm SLRs for their time lag resulted in a broad range, with the minimum of 46 ms and the maximum of 230 ms. The average was 120 ms. Figure 4 shows that during this interval, a walker moves about 0.8 ft, a runner about twice as far, a galloping horse about 7.0 ft, and a car going 60 mph moves 10.6 ft.



Distance traveled (ft)

Time ms		20	40	60	80	100	120	140	160	180	200
Motion	MPH										
Walker	5	0.1	0.3	0.4	0.6	0.7	0.8	1.0	1.1	1.3	1.4
Runner	20	0.6	1.2	1.7	2.3	2.9	3.5	4.1	4.6	5.2	5.8
Horse	40	1.2	2.4	3.5	4.6	5.8	7.0	8.1	9.3	10.4	11.6
Car	60	1.8	3.5	5.3	7.0	8.8	10.6	12.3	14.1	15.4	17.6
Car	80	2.3	4.7	7.0	9.4	11.7	14.0	16.4	18.7	21.1	23.4

FIGURE 4 Time and motion.

Various other cameras were also tested for their time lag, with these results:

Minox 35 EL (35-mm ultracompact): 8 ms
Leica M3 (35-mm coupled range finder classic): 17 ms
Hasselblad 500C (6×6 cm SLR classic): 82 ms
Kodak Disk 4000 (subminiature snapshot): 270 ms
Polaroid SX-70 Sonar (autofocus instant SLR): 600 ms

25.14 AUTOMATION

Camera automation has taken full advantage of the miniaturization and economy of electronic devices, making two features, autoexposure and autofocus, available in all but the least expensive cameras. This increases the percentage of (technically) good photos per roll of film exposed by the typical amateur.

It's the amateur photographer that is first served when it comes to most of the significant camera automation features. Curious as this may seem, camera makers prefer to introduce a new concept by offering it first in a model intended for the casual snapshooter. This generally means large numbers will be produced. If problems with the feature show up, improvements are made and a "new, improved" model follows. Typically, the feature will be scoffed at by the more seasoned photographer who has learned to overcome the difficulties of making a technically good photograph with the most basic equipment. In time, the new feature is mature enough to be included in the camera maker's premier model. Eventually, even those that scoffed at the feature in its infancy learn to love it, but only after they discover how to recognize and compensate for its weaknesses, if any.

Autoexposure

Early autoexposure systems measured the average luminance of a scene with a selenium photocell, then regulated the shutter speed and/or f-stop based on the deflection of a galvanometer connected to the photocell. These were known as trapped needle systems and were successful in their prime mission: to produce acceptable exposures in snapshot cameras with the just-available color films, whose exposure error tolerance is much smaller than that of black-and-white film.

Most of the first generation autoexposure cameras using the trapped needle system relied on brute force, requiring a long, hard push to trip the camera. This caused camera motion, resulting in a (correctly exposed) smeared image. Nonetheless, many resourceful photographers used these early autoexposure cameras, bolted together with an intervalometer and electromagnetic tripping system, to create an unmanned camera for surveillance, traffic studies, etc.

Amateur movie cameras eagerly adopted autoexposure systems, which proved to be at least as much, if not more, of an improvement for them as they were in still cameras. The movie camera autoexposure systems work by regulating the lens opening (the f-stop), either with a galvanometer or a servomotor. With autoexposure, the movie maker can follow the subject as it moves from bright sunshine to deep shade without the distraction of manually adjusting the f-stop.

This same freedom to follow action without the distraction of manually resetting camera and/or lens controls explains the need for autofocus, a feature whose introduction enjoyed greater enthusiasm from amateur movie makers than from still photographers. Once again, the amateur models were the first to incorporate the feature, but in far less time than it took for autoexposure's acceptance, autofocus became a standard feature in both the amateur and front-line models from most of the makers of 35-mm cameras.

There are similarities between the automation of exposure and focusing. Both have become increasingly sophisticated as user expectations increase. Paradoxically, in the effort to perfect the making of a routine snapshot, some of the more sophisticated automation intrudes on the process by offering the

user certain choices. Instead of simplifying photography, these technological marvels require the user to select a mode of operation from several available modes. For example, many cameras with autoexposure offer factory-programmed combinations of shutter speed and f-stop that favor

- *Action*: fast shutter speed, wide f-stop
- *Maximum depth of field*: small f-stop, slow shutter speed
- *Average scenes*: midway between the first two
- *Fill-flash*: to illuminate portraits made against the light (backlit)

It comes down to this: if you know enough about photographic principles to choose the best autoexposure program, you will rarely need any of them. But when an unexpected change in the subject occurs, such as a cloud moving across the sun, some form of autoexposure can be valuable.

One of the more helpful refinements of autoexposure is the automatic shift of shutter speed with the focal length setting of a zoom lens. This is based on the time-honored guide that gives the slowest shutter speed that may be used without objectionable image motion from normal body tremor. The rule of thumb is to use the shutter speed given by the reciprocal of the lens's focal length. For example, if you're using a 35- to 105-mm zoom lens, the slowest shutter speed for arresting body tremor will shift as you zoom, from 1/35 to 1/105 s (nominal). If the focal length's reciprocal doesn't coincide with a marked shutter speed, use the next faster speed. This guide applies to a handheld camera, not for a camera mounted on a tripod.

Another autoexposure refinement combines a segmented silicon or gallium photocell with a microprocessor to automatically select the best exposure based on the distribution of light reflected from the subject. It amounts to making a series of narrow-angle "spot" readings of the subject, then assigning weighting factors to the different readings according to their relative importance. The weighting factors are determined by the camera maker based on the analysis of thousands of photographs.

Reduced to its most spartan form, a segmented photocell could have a very small central region, surrounded by a broad field. The user can flip a switch to select the desired reading—the center segment for spot readings, the broad segment for full field readings, or both segments for center-weighted full field readings.

To ensure optimum exposure for a subject, seasoned photographers "bracket" exposure settings by making at least three exposures of the subject. The first exposure obeys the meter's reading. The next two are one exposure step less and one greater than the first. This exposure bracketing, with some variations, has been incorporated as an on-demand automatic feature in some cameras.

Autofocus

Autofocus (AF), in one form or another, has become a standard feature in camcorders and in most 35-mm cameras. The latter can be divided into two main types: (1) the snapshot "point–and–shoot," also known as "PHD" (press here, dummy) and (2) the SLR, spanning a wide range in price and sophistication. In between, there are several models which can be thought of as "PHDs on steroids." They have zoom lenses and elaborate viewfinders, making them too bulky to fit easily into a shirt pocket.

There are two main types of autofocus systems, the active and the passive. The active type emits a signal toward the subject and determines the subject's distance by measuring some property of the reflected signal. The passive type measures subject distance by analyzing the subject's image.

Active Autofocus Systems Nearly every active system uses two windows, spaced some distance apart. The user centers the subject in the viewfinder's aiming circle and presses the shutter trip button. Figure 5 shows how a narrow infrared (IR) beam is projected from one of the windows, strikes the subject, and is reflected back to the second window. A photocell behind this window detects the reflected beam. The photocell is sensitive to the position of the beam on its surface and relays this information to its associated circuitry to regulate the camera's focus setting.

Initially, this was a straight-forward triangulation system, using a single infrared beam. But too many users were getting out-of-focus pictures of the main subject when it wasn't in the center of

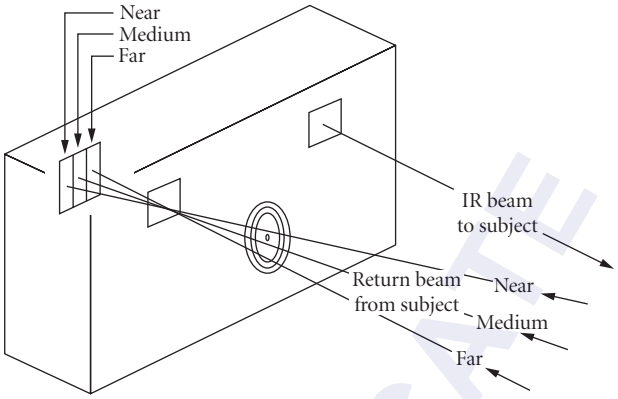


FIGURE 5 Active autofocus. Subject distance determines the angle of the reflected IR beam. The segmented photocell detects this angle, the AF system translates the angle to distance, moves the lens accordingly.

the picture. The camera's instruction book gives the solution: center the main subject in the finder's aiming circle, press the trip button halfway down, and hold it there, then recompose the scene and press the trip button all the way to make the exposure. This requires a fair amount of concentration and discipline, so it contradicted the purpose of having an automatic camera—to be free of cumbersome details, relying on the camera to make properly exposed, sharp photos.

A big improvement was made by projecting three beams from the camera, instead of one. The beams are divergent and the center beam coincides with the finder's aiming circle. Focus is set on the object closest to the camera.

A very different type of active autofocus is the ultrasonic system used by Polaroid in several models. Basically, it's a time-of-flight device that's been compared to sonar and bats. It uses an electrostatic transducer to emit an ultrasonic "chirp" toward the subject. Based on a round-trip travel time of about 5.9 ms/m, the time it takes for the chirp to reach the subject and be reflected back to the camera is translated into subject distance and a servomotor sets the focus accordingly.

A significant advantage of the active autofocus systems just described is their ability to work in total darkness. On the minus side is their inability to focus through a pane of glass or on a subject with an oblique glossy surface that reflects the signal away from the camera.

Passive Autofocus Systems Passive autofocus systems can be broadly characterized as acquiring two views of the subject, each view coming from a slightly different position, then focusing the lens to make the two views match. In this sense, the system operates just like a coincidence-type of optical range finder, but there are important differences.

With an optical range finder we rely on our ability to see when the two images are perfectly superimposed, so our focusing accuracy depends on our visual acuity. In a passive autofocus system, we relieve our eye of this burden and let the tireless electro-optical technology take over.

For the point-and-shoot camera, a passive autofocus system uses two windows, one whose line of sight coincides with that of the viewfinder's, and a second window, spaced some distance from the first. A simple, symmetrical optical system behind the windows includes a CCD for each window. The signal from the first CCD is taken as the reference against which the second CCD's signal is compared. Differences in the light distribution and/or differences in the relative location of the waveforms causes the control circuit to change the focus setting.

Autofocus SLRs Instead of the two windows just described, autofocus SLRs use two bean-shaped segments on opposite sides of the camera lens's exit pupil. Figure 6 shows how this is done. Two small lenslets are located a short distance behind the geometric equivalent of the camera's film

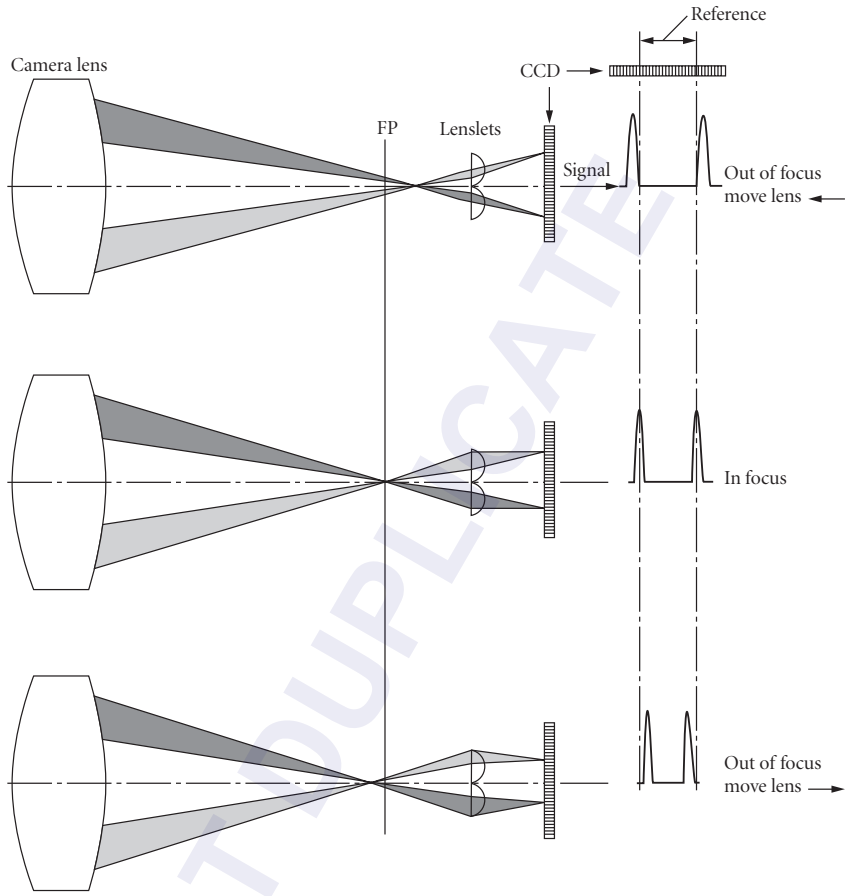

FIGURE 6 Autofocus SLR.

plane. Each lenslet receives light only from its side of the exit pupil and projects it onto a CCD line array, one for each lenslet. The relative position of each image on its CCD strip is analyzed by the system's microcomputer which is programmed to recognize the focus condition as a function of the CCD's signals. If the signals deviate from the programmed values, the microcomputer issues the appropriate command to the focus motor.

For off-center subjects, it's necessary to prefocus on them by pressing the trip button halfway, holding it there as you recompose the scene, then pressing all the way on the trip button to make the exposure. This is asking too much of a photographer shooting any sort of action, and many of them mistrusted their autofocus SLRs. In response, camera makers offered new models with broader CCD arrays to provide a larger central region of autofocus sensitivity. Some of these can be switched between narrow and broad sensitivity regions.

Other refinements to SLR autofocusing include

- Optimization of camera settings to maximize depth of field
- Prediction of moving subject's distance at instant of exposure
- Accommodation for horizontal and vertical subject detail
- Focus priority according to position of user's eye

To optimize depth of field, the user aims the camera at the near point and presses the trip button halfway. This is repeated for the far point. Then the scene is recomposed in the viewfinder and the exposure is made with the actual focus set automatically to some midpoint calculated by the camera's microcomputer.

For predicting the distance of a moving subject, the subject's motion should be constant, both in direction and velocity. Under these conditions, the autofocus sensor's signals can be used to calculate where the subject will be when the exposure is made. The calculation must consider the camera's inherent time lag.

Early AFSLRs used focus sensors that were shaped to respond to vertical image detail, with diminishing response as the detail approached the horizontal, where they were unable to respond. One solution incorporates three sets of lenslets and their CCD detector arrays. One set is laid out horizontally to respond to vertical detail, while the other two sets are vertical and straddle the first to form the letter "H." The two vertical sets respond to horizontal detail. Another solution has the individual, rectangular, detector segments (pixels) slanted to respond to both horizontal and vertical details.

By combining information from the autofocus detector and the focal length tracer in a zoom lens, some AFSLRs can maintain the image size (within the limits of the zoom range) chosen by the user, even as the subject distance changes.

Eye Tracking Figure 7 shows how Canon's model EOS A2E overcomes the need for the subject to be centered in the viewfinder in order to be in focus. Canon devised an eye tracking system that detects what portion of the viewscreen the user is looking at. Using low-power infrared emitting diodes (IREDs) to illuminate the eye, the system is matched to the user by having him/her look at the extremities of the five autofocus aiming patches in the viewfinder's center. The reflections from the eye are detected by a 60×100 pixel CCD array and the resulting signals are stored in the camera's

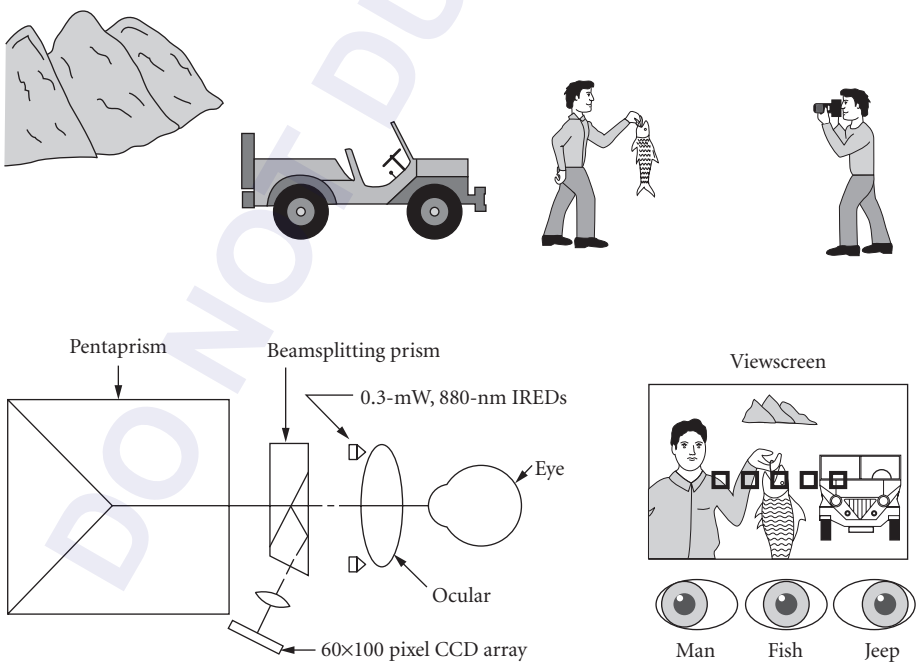

FIGURE 7 Canon's Eye Tracking SLR. The user's eye, illuminated by IREDs, is imaged on a CCD array. The resulting signal shifts in step with eye movements, causing a corresponding focus patch on the viewscreen to glow, indicating where the camera should focus.

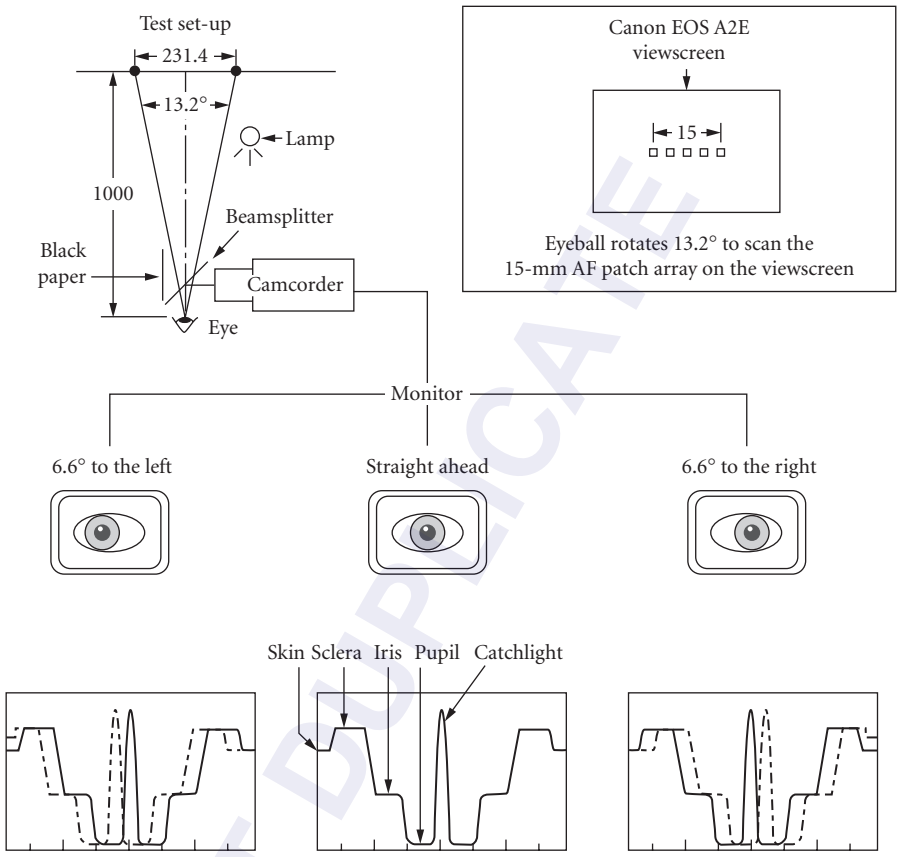

FIGURE 8 Eye tracking experiment. Line scan of the monitor's image at half screen height. (Dashed lines indicate image shift.)

memory. The five aiming patches occupy a 15-mm horizontal strip at the center of the finder. As it is, the camera's 16 user-selectable operational modes include one in which both the autofocus and autoexposure systems are commanded by the eye-tracking feature.

If the user wants to preview the depth of field, all that's necessary is to look at a small patch near the finder's upper left corner (not shown here). This brief glance causes the lens to close down to the f-stop chosen by the autoexposure system.

Because this eye-tracking feature is in an SLR, the user can see if it's working as expected just by looking at the viewscreen image. This indicates if, but not how, it works. To see how it works, I set up a simple experiment to measure the distribution of the light reflected from my eye as I shifted my gaze between two marks on a wall. The separation between the marks and their distance from my eye were chosen to duplicate the angle swept by the eye when looking from one side to the other of the 15-mm focus patch array on the Canon EOS A2E viewscreen. As indicated by Fig. 8, the format was nearly filled with the image of my eye. Consistent eye placement was assured with a chin and head rest. Once the image of my eye was recorded on tape, I could play back and pause at any point, then select a line at half screen height and store its waveform in a storage oscilloscope. By superimposing line scan waveforms from the frames showing my gaze from one side to the other, I could easily see the difference and dismissed my skepticism. This novel feature has intriguing possibilities.

25.15 FLASH

Many 35-mm cameras feature a built-in electronic flash unit. Some are designed to flash every time the shutter is tripped, unless the user switches off the flash. Others fire only when the combination of scene luminance and film speed calls for flash. In some of the more advanced models with zoom lenses, the beam angle emitted by the flash changes in step with the focal length setting of the lens.

Red Eye

In the interest of compactness, the majority of cameras with built-in flash units have the flash close to the lens. The resulting flash photos of people frequently exhibit what is commonly known as "red eye," which describes the eerie red glow in the image of the pupils of a subject's eyes. The red glow is the light reflected from the retina, which is laced with fine blood vessels. Young, blue-eyed subjects photographed in dim light seem to produce the most intense red-eye images.

The effect is reduced by (1) increasing the angle subtended to the subject's eye by the separation between the centers of the lens and the flash; (2) reducing the subject's pupil diameter by increasing the ambient brightness or having the subject look at a bright light for a few seconds before making the exposure.

Examples of how some camera makers fight red eye include Kodak's Cobra Flash, used on several of their point-and-shoot models, and the "preflash," used on many different camera makes and models. The Cobra Flash describes a flash unit whose flashlamp/reflector unit is hinged at the camera's top. When the camera is not in use, the flash is folded down, covering the lens. To use the camera, the flash is swung up, positioning it further from the lens than would be possible if it had been contained in the camera's main body. One of their most compact cameras featuring the Cobra Flash is the Cameo motordrive model, which slips easily into a dress shirt pocket when the flash is folded down. When opened for use, the flash is 72 mm above the lens. Test shots were free of red eye when the subject was no more than 7 ft away.

Another Kodak approach to the elimination of red eye is their single-use Fun Saver Portrait 35, whose integral electronic flash unit points upward, instead of forward. To use the camera, a simple white plastic panel, hinged at the camera's top rear edge above the flash is pulled open. It latches at a 45° angle to switch the flash circuit on and direct the light from the flash forward. The result is a diffused beam that appears to originate from a point 100 mm above the lens.

Other makes and models have integral flash units that pop up at short distance when put into play. This may only gain several millimeters of lens-to-flash separation, but my experiments indicate that, as sketched in Fig. 9, for every extra millimeter of separation between the lens and the flash, the (red-eye-free) subject distance can be increased about 30 mm.

Several 35-mm cameras use the *preflash* method to reduce red eye by emitting a brief, rapid burst of low intensity flashes just before the main flash goes off for the exposure. A variation uses a steady beam from an incandescent lamp in the flash unit. The beam switches on shortly before the flashlamp fires for the exposure. The purpose in both methods is to make the subject's pupils close down, reducing the light reflected from the eye during the exposure.

The preflash approach has two drawbacks: (1) it drains energy from the camera's battery, reducing the number of pictures per battery; (2) many times the subject reacts to the preflash and blinks, just in time for the exposure.

25.16 FLEXIBILITY THROUGH FEATURES AND ACCESSORIES

The seemingly endless combinations of operating modes with a camera like the Canon EOS A2E might be taken as an attempt to be all things to all photographers. Another way to look at it is to see it as a 3-lb Swiss army knife: you'll never use all of the tools all of the time, but if there's the need for some tool, even just once, it might be nice to know you have it.

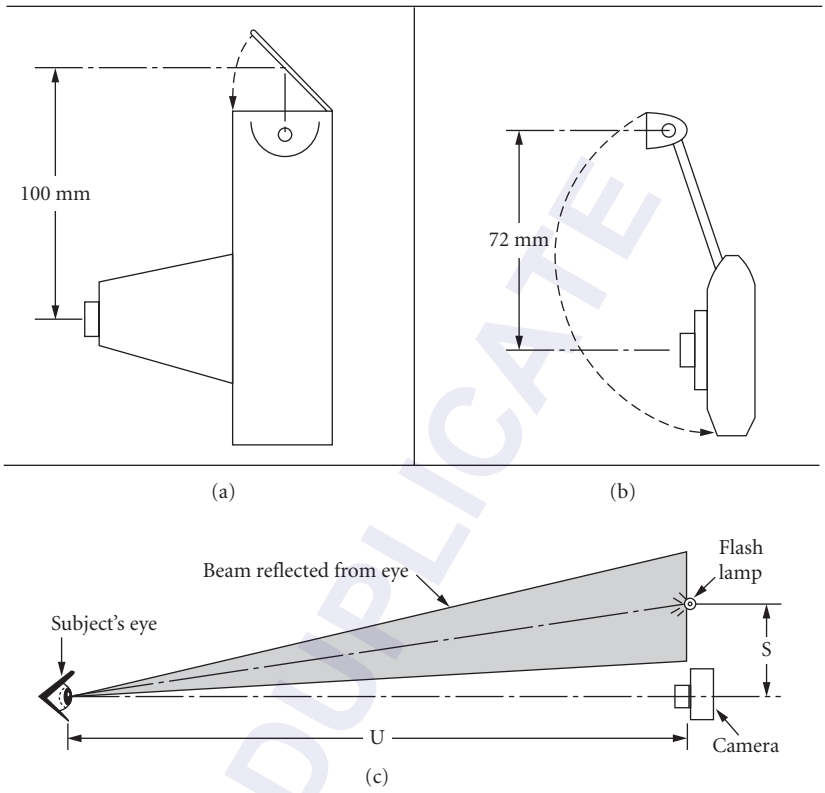

FIGURE 9 (*a*) Kodak's "Fun Saver Portrait 35" bounces its flash from a folding reflector. (*b*) Kodak's "Cameo Motordrive" uses the folding "Cobra Flash." (*c*) A beam reflected from the subject's eye misses the lens when the subject's distance "U" is not more than 20 S.

Many cameras have long lists of accessories. A typical camera system can be thought of as a box with an open front, top, and rear. For the front, the user may choose from as many as 40 different lenses. For the top, there may be three or more viewfinder hoods. For the back, choose one of perhaps five image receptacles.

Then there are the other groups, shown in Fig. 10: flash units, motor drives, close-up hardware, carrying cases, neck straps, lens hoods, filters, remote control cables, transmitters and receivers, mounting brackets, eyepiece magnifiers, corrective eyepiece lenses, cold weather heavy-duty battery packs, and more.

No matter how varied your photographic needs may be, the camera maker wants you to find everything you need in his or her catalog. Possibly, the availability of just one accessory, such as a wide-angle lens with tilt-shift controls for perspective correction, can decide which camera you choose.

25.17 ADVANTAGES OF VARIOUS FORMATS

In terms of versatility through a broad range of accessories plus the camera's intrinsic capabilities, it's hard to beat one of the major brands of 35-mm SLRs. No other type of camera has had as much ingenuity and as many refinements lavished on it for so many years. It's one of the most highly evolved consumer-oriented products.

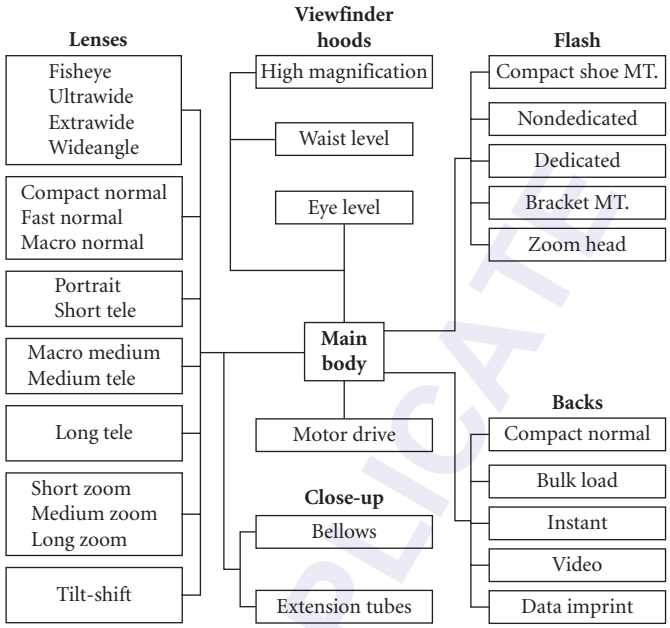

FIGURE 10 Camera system.

Accompanying the evolution in optics, mechanics, and electronics, film emulsions have improved over the years, making the 35-mm format just as able as the larger formats for most applications. Even so, all else being equal, there is no substitute for "real estate"—the precious additional square millimeters of emulsion offered by the many 120-size medium formats. As the data in Fig. 11 shows, some of these are SLRs with systems as extensive as their 35-mm counterparts.

25.18 LARGE FORMAT: A DIFFERENT WORLD

When you make the jump from medium-format to large-format, you're in a different world. You use individual sheets of film, not rolls. Your camera will be used on a tripod or copy stand most of the time. Your photography will be contemplative, careful, and unhurried—perhaps better.

Scene composition and focusing are done with the lens at full aperture. Then the lens is stopped down, the shutter closed, the film holder inserted, its dark slide pulled, the shutter tripped, the dark slide replaced, and the film holder removed.

In a short time you'll realize that the large-format (view) camera can be thought of as a compact optical bench. As such, it lends itself to special applications that could be difficult for the smaller formats.

View Camera Versatility

To illustrate, suppose you need a picture of a picket fence at some obliquity, with every picket board, from near to far, in sharp focus and with the lens wide open. This calls for the use of the "Scheimpflug condition," shown in Fig. 12. It requires that the planes containing the lensboard, film, and subject all intersect on a common line. When this condition is satisfied, the entire surface of the subject plane will be in focus, even with the lens wide open.

Camera type	5 MM	Medium format	Large format
Format sizes	18×24 mm	45×60 mm	2-1/4×3-1/4”
	24×24 mm	60×60 mm	3-1/4×4-1/4”
	24×36 mm	60×70 mm	4×5”, 5×7”
		60×90 mm	8×10”
Viewfinder	Galilean, SLR	Galilean, TLR, SLR	Galilean, FP
Focusing	CRF, SLR, AF	CRF, TLR, SLR	CRF, FP
Exposure	Manual, AE, TTL	Manual, AE, TTL	Manual
Options	Mot, Bulk, Pol, Dig, Data, Hood, Lens, Pgm, DEF	Mot, Bulk, Pol, Dig, Data, Hood Lens, DEF	Pol, Lens

Abreviations:

AE = autoexposure, AF = autofocus, Bulk = bulk film back, CRF = coupled rangefinder, Data = data recording, DEF = dedicated electronic flash, Dig = digital image detector, FP = film plane, Hood = interchangeable viewfinder hoods, Lens = interchangeable lenses, Mot = motor drive, Pgm = programable AE, AF, other functions, Pol = polaroid film back, SLR = single lens reflex, TLR = twin lens reflex, TTL = through the lens metering.

FIGURE 11 Major camera features.

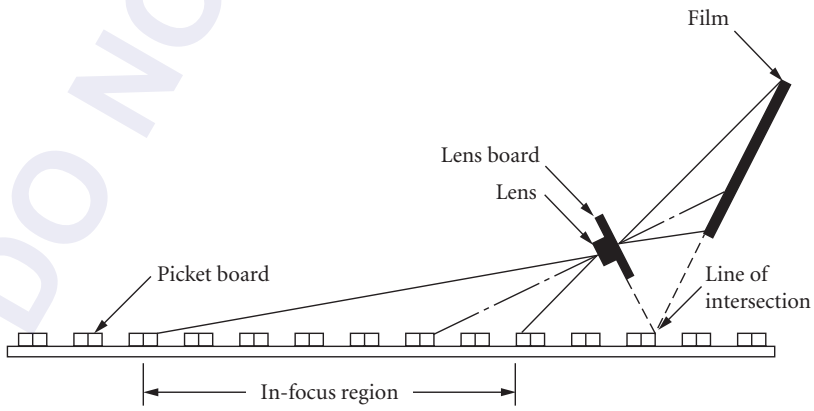

FIGURE 12 Scheimpflug condition. All of the picket boards within the field of view will be in focus when the planes of the lens board, film, and picket boards intersect on a common line.

The necessary camera movements, involving lensboard and film plane, are standard features of even the most Spartan view cameras. These movements are known as swings and tilts. They take just a few seconds to adjust on a view camera and the job doesn't require a special lens. You can do it with a smaller format camera too, but you'll need one of their special (expensive) tilt-shift lenses or a bellows unit with articulated front and rear panels, plus a lens with a large enough image circle. The resulting combination may not retain all of the small-format camera's features, such as exposure metering, autofocus, etc.

The view camera's fully articulated front and rear provide for swing, tilt, rise, fall, and left-right shift. Thanks to this flexibility, objects such as boxes and buildings can be photographed without distortion, and distracting detail near the image borders can be omitted.

It takes first-time users a while to get used to the inverted and reversed image seen on the view camera's groundglass screen. This can be annoying when shooting a portrait, since an upside-down smile looks like a frown until you accept the fact that even though you understand the basic camera optics, it doesn't mean you have to enjoy coping with it. Worse, you'll need to drape a dark cloth over the back of the camera and over your head in order to see the image if you're working in bright light. If you're claustrophobic, this may bother you.

On the plus side, large-format negatives are frequently contact-printed or only slightly enlarged for the final image. Because the image is large, depth of field and other image properties can be examined easily on the groundglass viewscreen with a small magnifier of modest power—a 4× loupe works well. The large negative has another attribute: it lends itself to retouching, masking, and other image manipulations, but these may be lost arts now that clever computer programs are available for doing the same things, provided your image is in digital form.

25.19 SPECIAL CAMERAS

Some photographic tasks call for cameras with special features, such as the ability to form images in near-total darkness or inside of a crowded mechanism. Among the long list of special cameras, we find

- Aerial
- Clandestine
- Endoscopic
- High-speed
- Periphery
- Sewer
- Stereo (3-D)
- Streak
- Thermal imaging
- Underwater
- Wide-angle

Aerial Cameras

Aerial cameras come in a variety of sizes and features. Among the more common features are image motion compensation, where focal length, speed, and altitude are factored into the movement of the film during the exposure; a vacuum back to hold the film flat during the exposure; and a calibrated lens so that any rectilinear distortion can be factored into the measurements made of the image.

Clandestine Cameras

Clandestine or "spy" cameras have been with us since photography was invented. In the broadest sense, any camera that is not recognized as such by the subject being photographed might be considered a successful spy camera. Many early box cameras were dubbed "detective" cameras because they were much smaller and more drab than a "real" camera with its prominent bellows and sturdy stand.

Cameras have been disguised as books, rings, binoculars, cigarette packs and lighters, matchboxes, portable radios, briefcases, canes, cravats, hats, even revolvers. Among them, the classic Minox is probably the best known. It can be concealed in an adult's fist, focuses down to eight inches, and is nearly silent. Its smooth exterior and gently rounded corners have inspired the belief among many that it was designed to be concealed in a body cavity with minimal discomfort.

Endoscopic Cameras

Endoscopic cameras use a tiny, short-focal-length lens to form an image that's transferred by a coherent, flexible fiber-optic bundle to a relay system that forms the image on the detector (film or CCD) in the camera. To illuminate the subject, the coherent bundle may be surrounded by an incoherent ring of fibers optically coupled to a light source at its free end, close to the camera.

Often fitted with a 90° prism on its tip, these cameras are used to photograph inside humans and machines. Another application is shown in Fig. 13: getting close-up views of architectural models from "ground" level. Variations include those without illumination optics but having a very small diameter image bundle to fit inconspicuously in some object for surveillance photography.

High-Speed Cameras

High-speed cameras were once defined as being able to make exposures of less than 1/1000 s. Today this would include many 35-mm SLRs which have a top speed of 1/10,000 s, a speed equaled by several consumer-grade camcorders. When shorter exposures are called for, a common, low-cost electronic flash unit can give flash durations as short as 1/32,000 s.

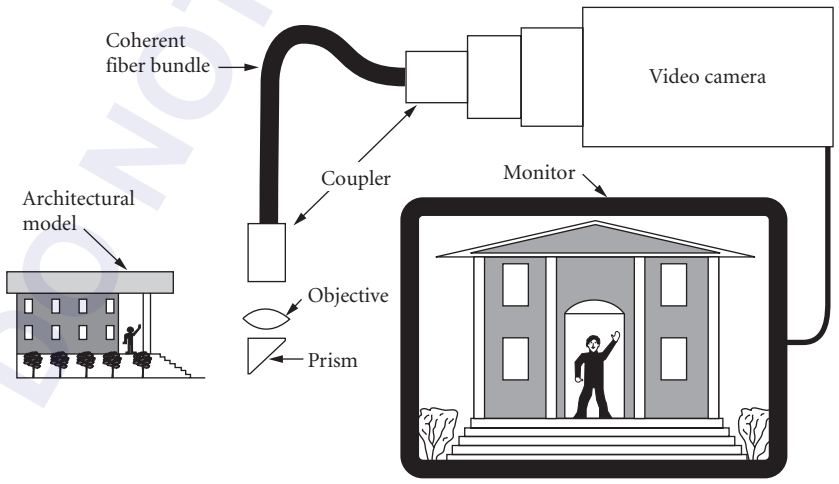

FIGURE 13 Endoscopic camera. While most often used for medical purposes, the endoscopic camera's properties make it valuable for photographing miniature scenes from the perspective of a miniature photographer.

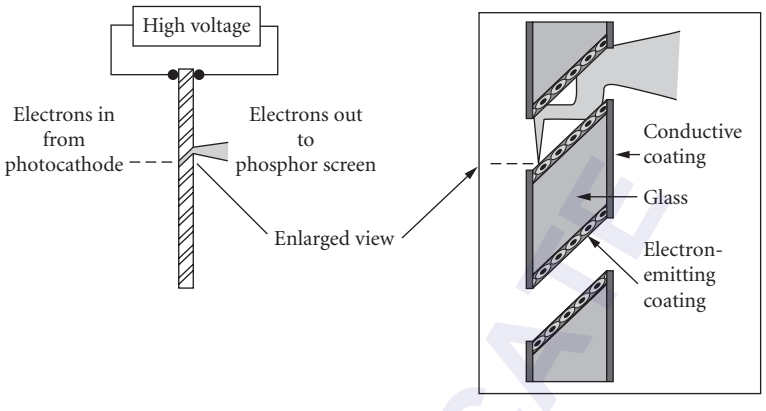

FIGURE 14 Microchannel plate.

The next step includes the Kerr cell and Faraday shutters, both of which work by discharging a high-voltage capacitor across a medium located between crossed polarizers. This produces a momentary rotation of the plane of polarization within the medium, permitting light to pass through to the detector. Exposure times are in the nanosecond range for these electro-optical/magneto-optical devices.

For exposures in the picosecond range accompanied by image intensification, there's the electronic image tube. When a lens forms an image on the photocathode at the front of this tube, electrons are emitted. Their speed and direction are controlled by electrodes within the tube. A secondary image is formed by the electrons as they strike the phosphor screen at the rear of the tube. This image may be photographed, or, if the tube has a fiber-optic faceplate behind the screen, the image can be directly transferred to a film held against the faceplate.

By placing a microchannel plate in front of the phosphor screen, the image can be intensified by a factor of 10,000 or more. A microchannel plate is a thin glass disk riddled with microscopic holes that pierce the disk at an angle. In Fig. 14 the wall surface of each hole is coated with a substance that reacts to the impact of an electron by emitting more electrons. A high voltage across the disk accelerates the stream of electrons. For every electron that enters one of the angled holes, about 100,000 electrons emerge to strike the phosphor screen.

Periphery Cameras

A periphery camera is used to make photos of objects like gas engine pistons, bullets, and other cylindrical objects whose surface detail must be imaged as though the surface was "unrolled" and laid out flat before the camera. Depending on the size of the subject, either it or the camera is rotated about its longitudinal axis at a constant angular velocity. The image strikes the film moving behind a slit that's parallel to the axis of rotation. The film's velocity matches that of the image unless deliberate image compression or elongation is desired.

Sewer Cameras

A sewer camera is designed to photograph the inside of pipes, tunnels, etc. It may be thought of as a small underwater camera on a sled. The camera's lens is encircled by an electronic flashtube and reflector to illuminate the scene. Pictures are made at regular intervals, as judged by distance marks on the cable attached to the sled. Other cables attached to the camera convey signals to and from

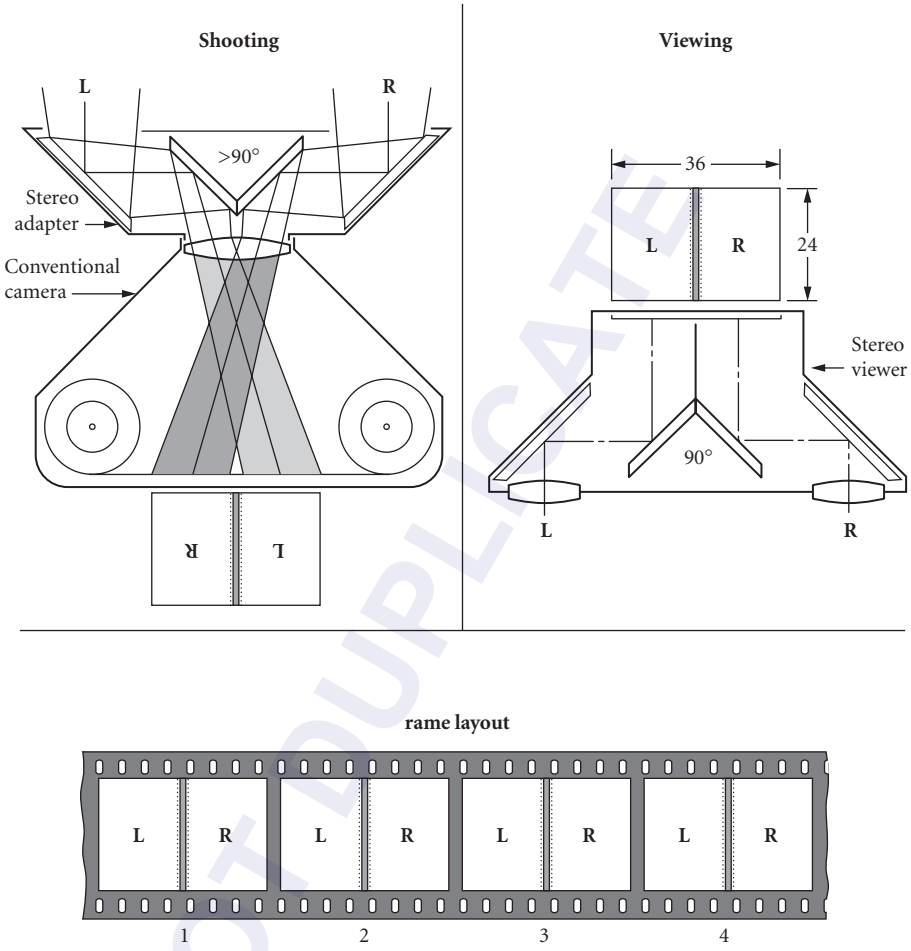

FIGURE 15 Stereo adapter set.

the camera. With the miniaturization of video cameras, they have taken over this task, except where maximum resolution is required. This is where film cameras have excelled.

Stereo Cameras

Stereo cameras seem to come in and out of vogue with some mysterious rhythmic cycle. The root idea has been around since the dawn of photography and is based on the parallax difference between the views of our left and right eyes. The classic stereo camera mimics nature by using two lenses spaced about 65 mm apart to form two images of the subject.

The two images can be made in other ways. A simple reflection system using four small mirrors or an equivalent prism system placed in front of a normal camera's lens will form two images of the subject, as shown in Fig. 15. Another method requires that the subject be stationary because two separate exposures are made, with the camera being shifted 65 mm between exposures. In aerial stereo photography, two views are made of the ground, some seconds apart.

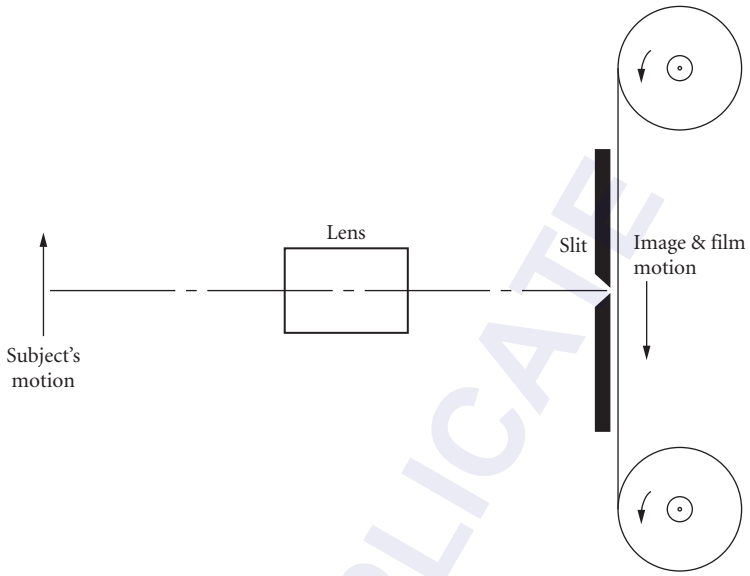

FIGURE 16 Streak camera. When film motion matches image motion, image will be free of distortion. If the film moves too fast, the image will be stretched. If the film moves too slow, the image will be compressed.

When the images are viewed in a manner that restricts the left and right images to their respective eye, the stereo effect is achieved. Various methods for viewing stereo pairs include projection, where the left and right views are polarized at 90° to each other. The viewer wears glasses with polarizing filters oriented to let each eye see the view intended for it.

Another viewing system is called a *parallax stereogram.* It (optically) slices the left and right images into narrow, interlaced strips. When viewed through a series of vertical lenticular prisms with a matching pitch, the 3-D effect is seen.

Streak Cameras

Streak cameras are useful for studying relative motion between the subject and camera. They share certain characteristics with the periphery camera described previously, insofar as they match the movement of the film to that of the image coming through a slit at the film plane. Exposure time is determined by how long it takes for a point on the film's surface to travel across the slit's width.

The basics of the streak camera are shown in Fig. 16. It would be pointless to use a streak camera without some relative motion between the image and film. Some photographers use a streak camera for creative effects, such as depicting motion tack-sharp at its beginning, then gradually elongating or compressing it, and ending in a smear. This is done by varying the relative velocity between the image and the film during the exposure, either by moving the camera, the subject, or the film, These motions may be made singly or in combination. Varying the focal-length setting of a zoom lens with the film moving also produces unusual images.

A streak camera's format has a width defined by the film it uses, but each picture has its own length, limited only by the length of the roll of film. One of the more critical factors to look for in a streak camera is freedom from *cogging*, a local density variation in exposure while the film is moving at a fixed velocity. The result of periodic or intermittent speed variations, the cause may be improperly meshed gears, a bad bearing, poor fit between the film drive sprocket teeth and the film's sprocket perforations, or the magnetic pole effects of the drive motor.

Thermal Image Cameras

Thermal imaging cameras convert the intrinsic heat of a subject into a visible image. Among their many applications are detection of heat losses from buildings, blood circulation disorders, and surveillance. Some of these cameras produce false color images, in which each color represents a different temperature.

Among the various methods to form visible images of temperature variations, the most direct way is to use a normal camera loaded with film that's sensitive to the infrared portion of the electromagnetic spectrum.

In a more elaborate system, a moving mirror scans the subject and, line-by-line, projects its image onto a heat-sensitive semiconductor device whose output is proportional to the IR intensity. The output is used to modulate a beam of light focused on the surface of a conventional film.

Another version uses the semiconductor to modulate a stream of electrons striking a phosphor screen in an image converter tube. The image can then be photographed.

Underwater Cameras

Underwater cameras come in a wide variety of sophistication, from the inexpensive disposable to the expensive high-tech versions. In between, there are dozens of underwater housings designed for specific cameras. Typically, these housings permit the user to change the camera's settings through watertight couplings. Most of the cameras used in such housings have motorized film advance, autoexposure, and autofocus, so the only external control needed is a pushbutton at one end of a simple electrical switch.

External attachments include flashguns, viewfinders, and ballast weights. The flashgun connections should be carefully examined because they are one of the leading sources of problems. In general, the simpler the connector, the better.

Wide-Angle Photography

There are several 35-mm and medium-format cameras designed specifically for wide-angle photography. These include straightforward types which use lenses designed for wide-angle views on larger-format cameras. Essentially these cameras use only a rather long horizontal strip of the broad image circle the lens produces. This type of camera is uncomplicated and rugged.

Panoramic Cameras A special kind of wide-angle camera is known as a panoramic camera, and there are two main types: one where the entire camera rotates; the other, where just the lens rotates.

The rotating camera type is capable of a full 360° vista. As the camera turns on its vertical axis, the film is moved past a narrow, stationary slit at the center of the film plane. The motion of the film is matched to that of the image. Because these cameras rotate slowly, a common prank in photos of large groups is for the prankster to stand at the edge of the group that's exposed first, then dash behind the group to the opposite edge in time for its exposure, with the result that the same person appears twice in the same photo, once at either edge of the group.

The rotating lens type shown in Fig. 17 produces images of about 140°. It works by rotating its lens on a vertical axis coinciding with its real nodal point. The image is swept across the film through a tubular image tunnel at the rear of the lens. The tunnel extends almost to the film surface and has a narrow slit at its end. The slit is parallel to the axis of rotation and extends over the width of the film. During the exposure the film is held stationary against a cylindrical film gate whose radius equals the focal length of the lens. The slit width, the rotating speed, and the lens opening may be adjusted for exposure control.

The panoramic cameras described here regulate their speed of rotation with precision governing systems to ensure edge-to-edge uniformity of exposure, so they should be kept as clean as possible. Also, to avoid unpleasant distortion, use care in leveling them and always use the best single camera accessory money can buy: a good, solid tripod.

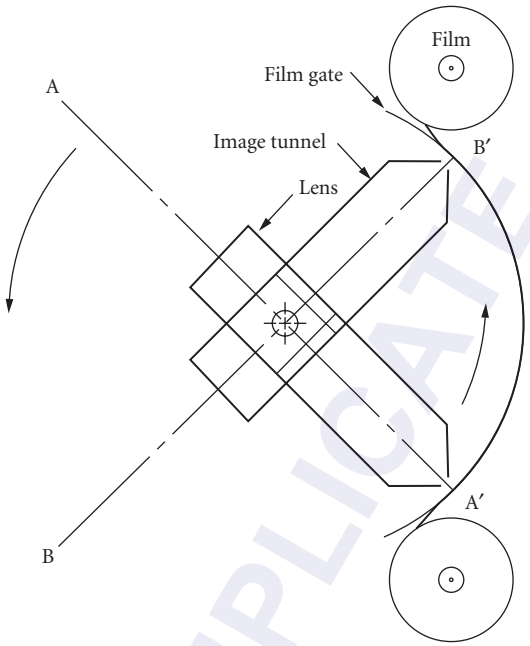

FIGURE 17 Panoramic camera. The lens rotates about its rear nodal point from A to B. Image-forming light reaches the film from A′ to B′ through a slit at the end of the image tunnel.

26.1 GLOSSARY

Quantity	Definition	Unit
A_D	photosensitive area of a detector	m^2
c	speed of light	3×10^8 m/s
C	sense node capacitance	F
$E_{e\text{-faceplate}}(\lambda)$	spectral radiant incidance	W μm^{-1} m^{-2}
$E_{q\text{-faceplate}}(\lambda)$	spectral photon incidance	photons s^{-1} μm^{-1} m^{-2}
d	detector size	mm
d_{CCH}	detector pitch	mm
D	aperture diameter	m
DR_{array}	array dynamic range	numeric
DR_{camera}	camera dynamic range	numeric
fl	focal length	m
F	f-number	numeric
G	source follower gain	numeric
h	Planck's constant	6.626×10^{-34} J s^{-1}
M_e	radiant exitance	W/m^2
$M_q(\lambda)$	spectral photon exitance	photons s^{-1} μm^{-1} m^{-2}
m_{optics}	optical magnification	numeric
M_v	photometric exitance	lumen m^2
n_{dark}	number of dark current electrons	numeric
n_{PE}	number of photoelectrons	numeric
n_{well}	charge well capacity	numeric
q	electronic charge	1.6×10^{-19} C
R_{eq}	equivalent resolution	mm

$\mathfrak{R}_e(\lambda)$	detector responsivity	A/W
$\mathfrak{R}_{ave}$	average detector responsivity	V/(J cm^{-2})
t_{int}	integration time	s
U	nonuniformity	numeric
V_{max}	maximum output voltage	V
V_{signal}	voltage created by photoelectrons	V
$<n_{floor}>$	noise created by on-chip amplifier	rms electrons
$<n_{pattern}>$	pattern noise	rms electrons
$<n_{PRNU}>$	photoresponse nonuniformity noise	rms electrons
$<n_{shot}>$	shot noise	rms electrons
$<n_{sys}>$	total array noise	rms electrons
η	image space horizontal spatial frequency	cycles/mm
η_C	optical cutoff in image space	cycles/mm
η_N	Nyquist frequency in image space	cycles/mm
η_S	sampling frequency in image space	cycles/mm
$\eta_{(\lambda)}$	spectral quantum efficiency	numeric
λ	wavelength	μm

26.2 INTRODUCTION

The heart of the solid-state camera is the solid-state array. It provides the conversion of light intensity into measurable voltage signals. With appropriate timing signals, the temporal voltage signal represents spatial light intensities. When the array output is amplified and formatted into a standard video format, a solid-state camera is created. Because charge-coupled devices (CCDs) were the first solid-state detector arrays, cameras are popularly called CCD cameras even though they may contain charge injection devices (CIDs) or complementary metal-oxide semiconductors (CMOS) as detectors.

Boyle and Smith[1] and Amelis et al.[2] invented CCDs in 1970. Then came considerable literature[3-11] on CCD physics, fabrication, and operation. A CCD refers to a semiconductor architecture in which charge is transferred through storage areas. This architecture has three basic functions: (1) charge collection, (2) charge transfer, and (3) the conversion of charge into a measurable voltage. The basic building block of the CCD is the metal-insulator semiconductor (MIS) capacitor. The most important MIS is the metal-oxide semiconductor (MOS). Because the oxide of silicon is an insulator, it is a natural choice.

Charge generation is often considered as the initial function of the CCD. With silicon photodetectors, each absorbed photon creates an electron-hole pair. Either the electrons or holes can be stored and transferred. For frame transfer devices, charge generation occurs under an MOS capacitor (also called a photogate). For some devices (notably interline transfer devices), photodiodes create the charge.

The CID does not use a CCD for charge transfer. Rather, two overlapping silicon MOS capacitors share the same row and column electrode. Column capacitors are typically used to integrate charge while the row capacitors sense the charge after integration. With the CID architecture, each pixel is addressable (i.e., it is a matrix-addressable device).

Active pixel sensors (APSs) are fabricated with CMOS technology. The advantage is that one or more active transistors can be integrated into the pixel. As such, they become fully addressable (to read selected pixels) and can perform on-chip image processing.

Devices may be described functionally according to their architecture (frame transfer, interline transfer, etc.) or by application. To minimize cost, array complexity, and electronic processing, the architecture is typically designed for a specific application. For example, astronomical cameras typically use full-frame arrays, whereas video systems generally use interline transfer devices.

The separation between general imagery, machine vision, scientific devices, and military devices becomes fuzzy as technology advances.

26.3 IMAGING SYSTEM APPLICATIONS

Cameras for the professional broadcast television and consumer camcorder markets are designed to operate in real time with an output that is consistent with a standard broadcast format. The resolution, in terms of array size, is matched to the bandwidth that is recommended by the standard. An array that provides an output of 768 horizontal by 484 vertical pixels creates a satisfactory image for conventional (U.S.) television. Eight bits (256 gray levels) provide an acceptable image in the broadcast and camcorder industry.

In its simplest version, a machine vision system consists of a light source, camera, and computer software that rapidly analyzes digitized images with respect to location, size, flaws, and other preprogrammed data. Unlike other types of image analysis, a machine vision system also includes a mechanism that immediately reacts to an image that does not conform to parameters stored in the computer. For example, defective parts are taken off a production line conveyor belt.

For scientific applications, low noise, high responsivity, large dynamic range, and high resolution are dominant considerations. To exploit a large dynamic range, scientific cameras may digitize the signal into 12, 14, or 16 bits. Scientific arrays may have 5000×5000 detector elements.[12] Theoretically, the array can be any size, but manufacturing considerations ultimately limit it.

Although low-light-level cameras have many applications, they tend to be used for scientific applications. There is no industrywide definition of a low-light-level imaging system. To some, it is simply a solid-state camera that can provide a usable image when the lighting conditions are less than 1 lux (lx). To others, it refers to an intensified camera and is sometimes called a low-light-level television (LLLTV) system. An image intensifier amplifies a low-light-level image that can be sensed by a solid-state camera. The image intensifier/CCD camera combination is called an intensified CCD (ICCD). The image intensifier provides tremendous light amplification but also introduces additional noise. The spectral response of the ICCD is governed by the image intensifier.

The military is interested in detecting, recognizing, and identifying targets at long distances. This requires high-resolution, low-noise sensors. Target detection is a perceptible act. A human determines if the target is present. The military uses the minimum resolvable contrast (MRC) as a figure of merit.[13]

26.4 CHARGE-COUPLED DEVICE ARRAY ARCHITECTURE

Array architecture is driven by its application. Full-frame and frame transfer devices tend to be used for scientific applications. Interline transfer devices are used in consumer camcorders and professional television systems. Linear arrays, progressive scan, and time delay and integration (TDI) are used for industrial applications. Despite an ever-increasing demand for color cameras, black-and-white cameras are widely used for many scientific and industrial applications.

The basic operation of linear, full-frame, frame transfer, and interline transfer devices is described in Chap. 32, "Visible Array Detectors," by Timothy J. Tredwell in Vol. II. This section describes some additional features.

Full-Frame Arrays

In full-frame arrays, the number of pixels is often based upon powers of 2 (e.g., 512×512 or 1024×1024) to simplify memory mapping. Scientific arrays have square pixels and this simplifies image-processing algorithms.

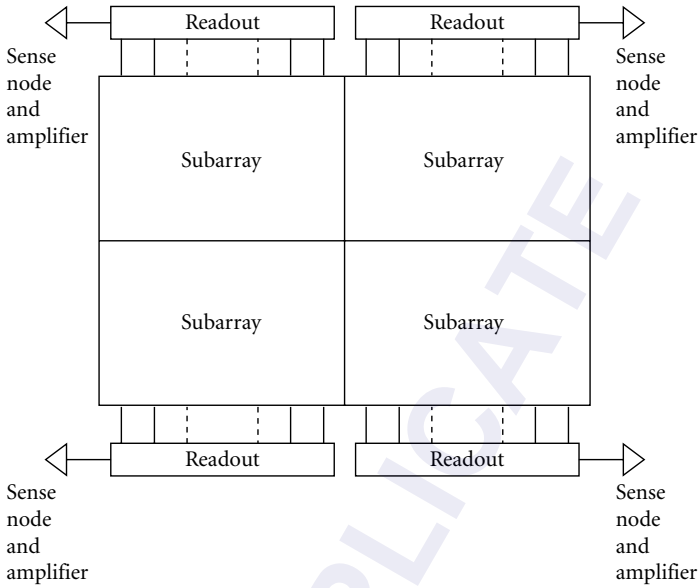

FIGURE 1 A large array divided into four subarrays. Each subarray is read out simultaneously to increase the effective data rate. Very large arrays may have up to 32 parallel outputs.

Data rates are limited by the amplifier bandwidth and, if present, the conversion capability of the analog-to-digital converter. To increase the effective readout rate, the array can be divided into subarrays that are read out simultaneously. In Fig. 1, the array is divided into four subarrays. Because they are all read out simultaneously, the effective clock rate increases by a factor of 4. Software then reconstructs the original image. This is done in a video processor that is external to the CCD device where the serial data are decoded and reformatted.

Interline Transfer

The interline transfer array consists of photodiodes separated by vertical transfer registers that are covered by an opaque metal shield (Fig. 2). Although photogates could be used, photodiodes offer higher quantum efficiency. After integration, the charge that is generated by the photodiodes is transferred to the vertical CCD registers in about 1 μs. The main advantage of interline transfer is that the transfer from the active sensors to the shielded storage is quick. There is no need to shutter the incoming light. The shields act like a venetian blind that obscures half the information that is available in the scene. The area fill factor may be as low as 20 percent. Because the detector area is only 20 percent of the pixel area, the output voltage is only 20 percent of a detector that would completely fill the pixel area. A microlens can optically increase the fill factor.

Because interline devices are most often found in general imagery products, most transfer register designs are based upon standard video timing. Figure 3 illustrates a four-phase transfer register that stores charge under two gates. With 2:1 interlace, both fields are collected simultaneously but are read out alternately. This is called frame integration. With EIA 170 (formerly called RS 170), each field is read every 1/60 s. Because the fields alternate, the maximum integration time is 1/30 s for each field.

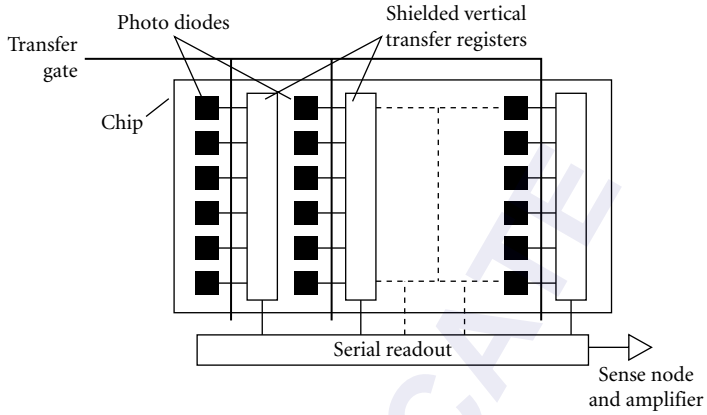

FIGURE 2 Interline transfer architecture. The charge is rapidly transferred to transfer registers via the transfer gate. Interline transfer devices can also have a split architecture similar to that shown in Fig. 1.

Pseudointerlacing (sometimes called field integration) is shown in Fig. 4. Changing the gate voltage shifts the image centroid by one-half pixel in the vertical direction. This creates 50 percent overlap between the two fields. The pixels have twice the vertical extent of standard interline transfer devices and therefore have twice the sensitivity. An array that appears to have 240 elements in the vertical direction is clocked so that it creates 480 lines. However, this reduces the vertical modulation transfer function (MTF). With some devices, the pseudointerlace device can also operate in a standard interlace mode.

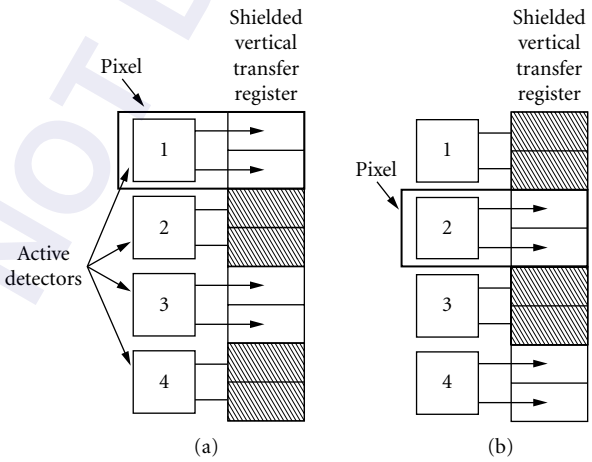

FIGURE 3 Detailed layout of the 2:1 interlaced array. (*a*) The odd field is clocked into the vertical transfer register and (*b*) the even field is transferred. The vertical transfer register has four gates and charge is stored under two wells. The pixel is defined by the detector center-to-center spacing, and it includes the shielded vertical register area. The transfer gate is not shown.

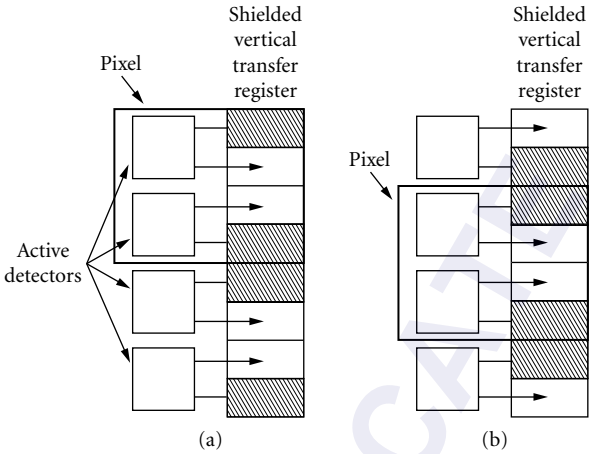

FIGURE 4 Pseudointerlace. By collecting charge from alternating active detector sites, the pixel centroid is shifted by one-half pixel. (*a*) Odd field and (*b*) even field.

26.5 CHARGE INJECTION DEVICE

A CID consists of two overlapping MOS capacitors sharing the same row and column electrode. Figure 5 illustrates the pixel architecture. The nearly contiguous pixel layout provides a fill factor of 80 percent or greater. Charge injection device readout is accomplished by transferring the integrated charge from the column capacitors to the row capacitors. After this nondestructive signal readout, the charge moves back to the columns for more integration or is injected (discarded) back into the silicon substrate.

Although the capacitors are physically orthogonal, it is easier to understand their operation by placing them side by side. Figure 6 illustrates a functional diagram of an array, and Fig. 7 illustrates the pixel operation. In Fig. 7*a*, a large voltage is applied to the columns, and photogenerated carriers (usually holes) are stored under the column gate. If the column voltage is brought to zero, the charge transfers to the row gate (Fig. 7*b*). The change in charge causes a change in the row gate potential that is then amplified and outputted. If V_1 is reapplied to the columns, the charge transfers back to the column gate. This is nondestructive readout and no charge is lost. By suspending charge injection,

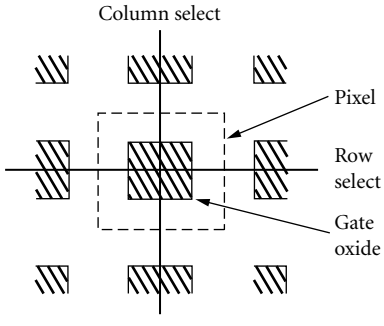

FIGURE 5 CID pixel architecture.

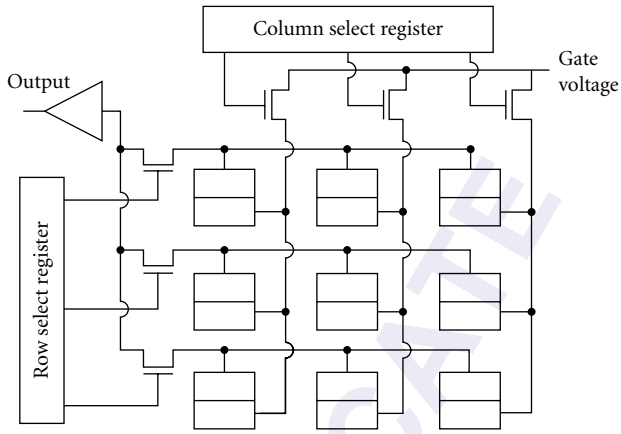

FIGURE 6 Functional layout of a 3 × 3 CID array. The row and column select registers are also called decoders. The select registers and readout electronics can be fabricated with CMOS technology.

multiple-frame integration (time-lapse exposure) is created. In this mode, the observer can view the image on a display as the optimum exposure develops. Integration may proceed for up to several hours. Reset occurs by momentarily setting the row and column electrodes to ground. This *injects* the charge into the substrate (Fig. 7*c*).

The conversion of charge into voltage depends upon the pixel, readout line, and amplifier capacitance. The capacitance is high because all the pixels on a given row are tied in parallel. Therefore, when compared with a CCD, the charge conversion is small, yielding a small signal-to-noise ratio (SNR). Because the readout is nondestructive, it can be repeated numerous times. The multiple reads are averaged together to improve the SNR.

Because each pixel sees a different capacitance, CIDs tend to have higher pattern noise compared with CCDs. However, off-chip algorithms can reduce the amount of pattern noise. With no charge transfer, CIDs are not sensitive to charge transfer efficiency effects. Without multiple gates, CIDs have larger well capacities than comparably sized CCDs. Charge injection devices inherently have antibloom capability. Because charge is limited to a single pixel, it cannot overflow into neighboring pixels. Perhaps the greatest advantage of CIDs is random access to any pixel or pixel cluster. Subframes and binned pixels can be read out at high frame rates.

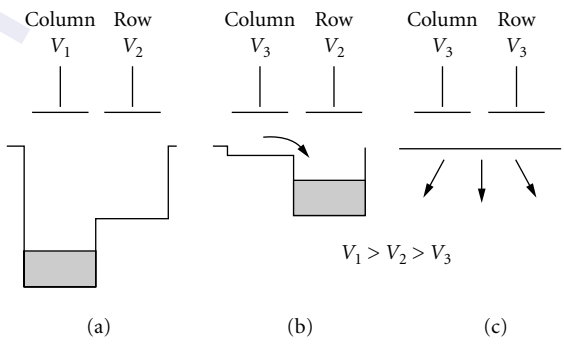

FIGURE 7 CID pixel operation. (*a*) Integration, (*b*) readout, and (*c*) injection.

26.6 COMPLEMENTARY METAL-OXIDE SEMICONDUCTOR

With the APS approach, highly integrated image sensors are possible.[14] By placing processing on the chip, a CMOS camera can be physically smaller than a CCD camera that requires clocks, image reformatting, and signal processing in separate hardware. A sophisticated APS array can create[15] a "camera on a chip." It is possible to build a frame transfer device where pixels can be binned to enhance the SNR and provide variable resolution imaging.[16]

In 1993, Fossum[17] described state-of-the-art active pixel concepts such as the double-gate floating surface transistor, charge modulation device, bulk charge modulation device, based-stored image sensor, and the static induction transistor. See also Ref. 14.

The APS contains a photodiode, row select transistor, and a reset transistor. As shown in Fig. 8, by activating a row, the data from the pixels in that row are simultaneously copied into the columns. Each column will have a load transistor, a column select switch, and a sampling switch. The chip may also have an analog-to-digital converter and provide correlated double sampling. The pixels are then reset and a new integration is started. The APS does not rely upon charge transfer. Rather, the photodiode drives a capacitance line. The total capacitance limits the chip speed. APSs can be fully addressable and subarrays can be read out at high frame rates just like CIDs.

Complementary metal-oxide semiconductor devices tend to have higher dark currents due to the highly doped silicon used. Therefore, CMOS sensors will not replace CCDs for low-noise scientific applications. Because the active devices often take up real estate, the area for the photosensor is reduced. This leads to reduced sensitivity that can be partially offset by a microlens. Because each pixel has its own amplifier, pattern noise is larger. However, more logic can be added to each pixel

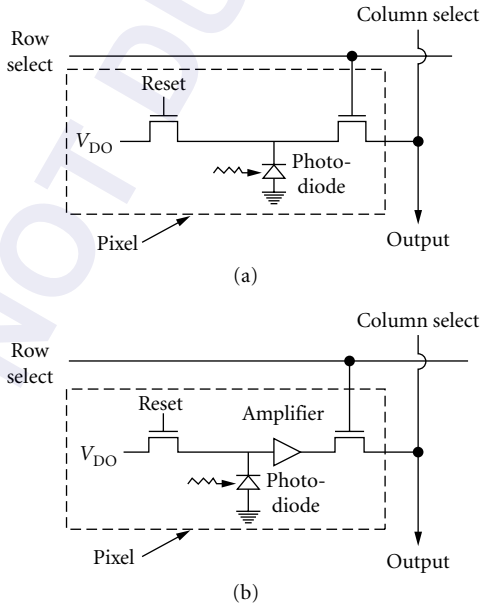

FIGURE 8 (*a*) Passive pixel device and (*b*) APS. Charge-coupled devices and CIDs are regarded as passive pixel sensors. Charge injection devices use photo-gates; CCDs use either photogates or photodiodes; CMOS devices typically use photodiodes.

for on-chip signal processing that suppresses pattern noise.[18] With charge limited to a single pixel, it cannot overflow into neighboring pixels and create blooming as seen with CCDs.

A further advantage of APS is its low power consumption. It can operate from a 5-V battery or less (compared with 10 to 15 V for a CCD). CMOS may compete with CCDs in the general video marketplace where weight, size, and power consumption are deciding factors.

26.7 ARRAY PERFORMANCE

The most common array performance measures are responsivity, read noise, and charge well capacity. From these the minimum signal, maximum signal, SNR, and dynamic range can be calculated. Full characterization includes quantifying the various noise sources, charge transfer efficiency, spectral quantum efficiency, linearity, and pixel nonuniformity.[19] These additional metrics are necessary for the most critical scientific applications.

Signal

Device specifications depend, in part, upon the application. Arrays for general video applications may have responsivity expressed in units of volts per lux. For scientific applications, the units may be in V/(J cm^{-2}) or, if a digital output is available, DN/(J cm^{-2}) where DN refers to a digital number. For example, in an 8-bit system, the digital numbers range from 0 to 255. These units are incomplete descriptors unless the device spectral response and source spectral characteristics are furnished.

The number of photoelectrons created by a detector is

$$n_{\mathrm{PE}} = A_D \int_{\lambda_1}^{\lambda_2} E_{q-\mathrm{faceplate}}(\lambda)\eta(\lambda)t_{\mathrm{int}}d\lambda \tag{1}$$

where A_D is the effective photosensitive area, t_{INT} is the integration time, $\eta(\lambda)$ is the spectral quantum efficiency, and $E_{q\text{-faceplate}}(\lambda)$ is the spectral photon incidance in unit of photons s^{-1} μm^{-1} m^{-2} (discussed further in Sec. 26.8). Some arrays have a transparent window protecting the array. The faceplate is the front surface of that window. With this approach, the array quantum efficiency includes the transmittance of the window.

For CCDs, charge is converted to a voltage by a floating diode or floating diffusion. The diode, acting as a capacitor, is precharged at a reference level. The capacitance, or sense node, is partially discharged by the amount of negative charge transferred. The difference in voltage between the final status of the diode and its precharged value (reset level) is linearly proportional to the number of photoelectrons. The signal voltage after the source follower is

$$V_{\mathrm{signal}} = V_{\mathrm{reset}} - V_{\mathrm{out}} = n_{\mathrm{PE}}\frac{qG}{C} \tag{2}$$

The gain, G, of a source follower amplifier is approximately unity, and q is the electronic charge (1.6×10^{-19} C). The charge conversion is q/C. The output gain conversion is qG/C. It typically ranges from 0.1 to 10 μV/e$^-$. The signal is then amplified and processed by electronics external to the CCD sensor.

Responsivity The spectral quantum efficiency is important to the scientific and military communities. When the array is placed into a general video or industrial camera, it is convenient to specify the output as a function of incident flux density or energy density averaged over the spectral response of the array.

The faceplate spectral photon incidance can be converted into the spectral radiant incidence by

$$E_{e\text{-faceplate}}(\lambda) = \frac{hc}{\lambda}E_{q\text{-faceplate}}(\lambda)\frac{W}{\mu\mathrm{m\ m}^2} \tag{3}$$

where h is Planck's constant (6.626×10^{-34} J s^{-1}) and c is the speed of light (3×10^{8} m s^{-1}). Quantities associated with power (watts) have the subscript e, and those associated with photons have the subscript q. The quantum efficiency can be converted to amperes per watt by

$$\Re_e(\lambda) = \frac{q\lambda}{hc}\eta(\lambda) \tag{4}$$

Then, the array output voltage (after the source follower amplifier) is

$$V_{\text{signal}} = \frac{G}{C} A_D \int_{\lambda_1}^{\lambda_2} E_{e\text{-faceplate}}(\lambda)\Re_e(\lambda) t_{\text{int}} d\lambda \tag{5}$$

It is desirable to express the responsivity in the form

$$V_{\text{signal}} = \Re_{\text{ave}} \left[\int_{\lambda_1}^{\lambda_2} E_{e\text{-faceplate}}(\lambda) t_{\text{int}} d\lambda \right] \tag{6}$$

The value $\Re_{\text{ave}}$ is an average responsivity that has units of V/J cm^2 and the quantity in the brackets has units of J/cm^2. Combining the two equations provides

$$\Re_{\text{ave}} = \frac{G}{C} A_D \frac{\int_{\lambda_1}^{\lambda_2} E_{e\text{-faceplate}}(\lambda)\Re_e(\lambda) d\lambda}{\int_{\lambda_1}^{\lambda_2} E_{e\text{-faceplate}}(\lambda) d\lambda} \text{ V/(J cm}^{-2}) \tag{7}$$

The value $\Re_{\text{ave}}$ is an average responsivity that depends upon the source characteristics and the spectral quantum efficiency. While the source can be standardized (e.g., CIE illuminant A or illuminant D_{6500}), the spectral quantum efficiency varies by device. Therefore, extreme care must be exercised when comparing devices solely by the average responsivity.

If a very small wavelength increment is selected, $E_{e\text{-faceplate}}(\lambda)$ and $\Re_e(\lambda)$ may be considered as constants and Eq. (7) can be approximated as

$$\Re_{\text{ave}} = \frac{G}{C} A_D \Re_e(\lambda_0) \tag{8}$$

Minimum Signal The noise equivalent exposure (NEE) is an excellent diagnostic tool for production testing to verify noise performance. NEE is a poor array-to-array comparison parameter and should be used cautiously when comparing arrays with different architectures. This is so because it depends on array spectral responsivity and noise. The NEE is the exposure that produces a SNR of one. If the measured root-mean-square (rms) noise on the analog output is V_{noise}, then the NEE is calculated from the radiometric calibration:

$$\text{NEE} = \frac{V_{\text{noise}}}{\Re_{\text{ave}}} \text{ J/cm}^2 \text{ rms} \tag{9}$$

When expressed in electrons, NEE is simply the noise value in rms electrons. The absolute minimum noise level is the noise floor, and this value is used most often to calculate the NEE. Although noise is an rms value, the notation "rms" is often omitted.

Maximum Signal The maximum signal is that input signal that saturates the charge well and is called the saturation equivalent exposure (SEE). It is

$$\text{SEE} = \frac{V_{\max}}{\Re_{\text{ave}}} \text{ J/cm}^2 \tag{10}$$

The total number of electrons that can be stored is the well capacity, n_{well}. The well size varies with architecture, number of phases, and pixel size. It is approximately proportional to pixel area. Small

pixels have small wells. If an antibloom drain is present, the maximum level is taken as the white clip level. The maximum signal is

$$V_{\max} = \frac{qG}{C}(n_{\text{well}} - n_{\text{dark}}) \tag{11}$$

For back-of-the-envelope calculations, the dark current is often considered negligible ($n_{\text{dark}} \approx 0$).

Dynamic Range The array dynamic range is

$$\text{DR}_{\text{array}} = \frac{n_{\text{well}} - n_{\text{dark}}}{\langle n_{\text{sys}} \rangle} \tag{12}$$

where $<n_{\text{sys}}>$ is the overall rms noise. The array noise consists of dark current, shot, pattern, and readout noise (noise floor). In the absence of light and with negligible dark current, the dynamic range is most often quoted as

$$\text{DR}_{\text{array}} = \frac{n_{\text{well}}}{\langle n_{\text{floor}} \rangle} \tag{13}$$

Noise

Many books[4–8] and articles[20–23] have been written on noise sources. The level of detail used in noise modeling depends on the application. The noise sources include shot noise, reset noise, pattern noise, on-chip amplifier noise, and quantization noise. It is customary to specify all noise sources in units of equivalent rms electrons at the detector output.

Reset noise can be reduced to a negligible level with correlated double sampling (CDS). CDS also reduces the source follower 1/*f* noise. The off-chip amplifier is usually a low-noise amplifier such that its noise is small compared with the on-chip amplifier noise. The use of an analog-to-digital converter that has more bits reduces quantization noise.

On-chip amplifier noise may be called readout noise, mux noise, noise-equivalent electrons, or the noise floor. The value varies by device and manufacturer. For most system analyses, it is sufficient to consider

$$\langle n_{\text{sys}} \rangle = \sqrt{\langle n_{\text{shot}}^2 \rangle + \langle n_{\text{floor}}^2 \rangle + \langle n_{\text{pattern}}^2 \rangle} \tag{14}$$

where $<n^2>$ is the noise variance and $<n>$ is the standard deviation measured in rms electrons.

Shot Noise Both photoelectrons and dark current contribute to shot noise. These follow Poisson statistics so that the variance is equal to the mean:

$$\langle n_{\text{shot}}^2 \rangle = n_{\text{PE}} + n_{\text{dark}} \tag{15}$$

While the dark current average value can be subtracted from the output to provide only the signal due to photoelectrons, the dark current noise cannot. Cooling the array can reduce the dark current to a negligible value and thereby reduce dark current noise to a negligible level.

Pattern Noise Pattern noise refers to any spatial pattern that does not change significantly from frame to frame. Pattern noise is not noise in the usual sense. This variation appears as spatial noise to the observer. Fixed-pattern noise (FPN) is caused by pixel-to-pixel variations in dark current.[24,25] As a signal-independent noise, it is additive to the other noise powers. Fixed-pattern noise is due to differences in detector size, doping density, and foreign matter getting trapped during fabrication.

Photoresponse nonuniformity (PRNU) is the variation in pixel-to-pixel responsivities and, as such, is a signal-dependent noise. This noise is due to differences in detector size, spectral response, and thickness in coatings. Photoresponse nonuniformity can be specified as a peak-to-peak value or an rms value referenced to an average value. This average value may either be full well or one-half

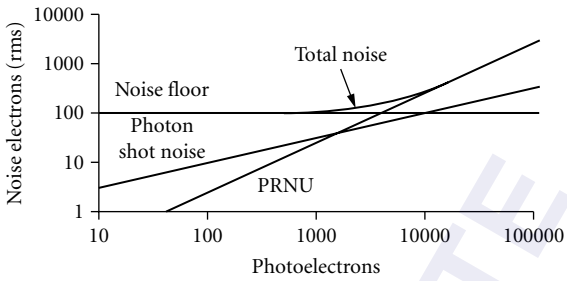

FIGURE 9 Photon transfer curve when U = 2.5 percent. The charge well capacity is 100,000 electrons and the noise floor is 100 e^- rms to produce a dynamic range of 60 dB. The noise floor, photon shot noise, and PRNU have slopes of 0, 0.5, and 1, respectively. Dark noise is considered negligible.

full well value. That is, the array is uniformly illuminated and a histogram of responses is created. The PRNU can be the rms of the histogram divided by the average value or the peak-to-peak value divided by the average value. The definition varies by manufacturer so that the test conditions must be understood when comparing arrays.

Because dark current becomes negligible when the array is sufficiently cooled, PRNU is the dominant pattern component for most arrays. As a multiplicative noise, PRNU is traditionally expressed as a fraction of the total number of charge carriers. If U is the fixed pattern ratio or nonuniformity, then

$$\langle n_{\text{pattern}} \rangle \approx \langle n_{\text{PRNU}} \rangle = U n_{\text{PE}} \tag{16}$$

Frame averaging will reduce all the noise sources except FPN and PRNU. Although FPN and PRNU are different, they are sometimes collectively called scene noise, pixel noise, pixel nonuniformity, or simply pattern noise.

Photon Transfer For many applications it is sufficient to consider photon shot noise, noise floor, and PRNU. The simplified noise model provides

$$\langle n_{\text{sys}} \rangle = \sqrt{n_{\text{PE}}^2 + \langle n_{\text{floor}}^2 \rangle + (U n_{\text{PE}})^2} \tag{17}$$

Recall that the mean square photon fluctuation is equal to the mean photon rate. Either the rms noise or noise variance can be plotted as a function of signal level. The graphs are called the photon transfer curve and the mean-variance curve, respectively. Both graphs convey the same information.

For very low photon fluxes, the noise floor dominates. As the incident flux increases, the photon shot noise dominates. For very high flux levels, the noise may be dominated by PRNU. Figure 9 illustrates the rms noise as a function of photoelectrons when the dynamic range ($n_{\text{well}}/<n_{\text{floor}}>$) is 60 dB. With large signals and small PRNU, the total noise is dominated by photon shot noise. When PRNU is large, U dominates the array noise at high signal levels. General video and industrial cameras tend to operate in high-signal environments, and cooling will have little effect on performance. A full SNR analysis is required before selecting a cooled camera.

26.8 CAMERA PERFORMANCE

Camera performance metrics are conceptually the same as array metrics. The camera is limited by the array noise and charge well capacity. The camera's FPN and PRNU may be better than the array pattern noise when correction algorithms are present. Frame averaging and binning can reduce the

random noise floor and thereby appear to increase the camera's dynamic range. If the camera does not introduce any additional noise, modify the noise bandwidth, or minimize the maximum output, the camera SNR and DR_{camera} will be identical to the array values.

Camera Formula

The number of photoelectrons created by an object is

$$n_{PE} = \int_{\lambda_1}^{\lambda_2} \eta(\lambda) \frac{M_q(\lambda)}{4F^2(1+m_{optics})^2} A_D t_{int} \tau_{optics}(\lambda) d\lambda \tag{18}$$

where $M_q(\lambda)$ is the object's spectral photon exitance in photons/s μm m^2 and $\tau_{optics}(\lambda)$ is the lens system transmittance. The *f*-number has the usual definition ($F = fl/D$), and the optical magnification is $m_{optics} = R_2/R_1$. Here, R_1 and R_2 are related to the system's effective focal length, fl, by

$$\frac{1}{R_1} + \frac{1}{R_2} = \frac{1}{fl} \tag{19}$$

As the target moves to infinity ($R_1 \to \infty$), m_{optics} approaches zero.

Electronic still cameras are matched to conventional photographic cameras. In photography, shutter speeds (exposure times) vary approximately by a factor of two (e.g., 1/30, 1/60, 1/125, 1/250, etc.). Thus, changing the shutter speed by one setting changes n_{PE} approximately by a factor of 2. F-stops have been standardized to 1, 1.4, 2, 2.8, 4, 5.6, 8, ... The ratio of adjacent F-stops is $\sqrt{2}$. Changing the lens speed by one F-stop changes the *f*-number by a factor of $\sqrt{2}$. Here, also, the n_{PE} changes by a factor of 2.

The measurement of faceplate illumination [see Eq. (1)] is usually performed with a calibrated lens. The value M_q is measured with a calibrated radiometer or photometer, and then $E_{q\text{-faceplate}}$ is calculated according to

$$E_{q\text{-faceplate}} = \frac{M_q}{4F^2(1+m_{optics})^2} \tau_{optics} \tag{20}$$

Minimum Signal

The maximum and minimum signals depend on the spectral output of the source and the spectral response of the detector. The source color temperature is not always listed but is a critical parameter for comparing systems. Although the CIE illuminant A is used most often, the user should not assume that this was the source used by the camera manufacturer.

Based on signal detection theory, the minimum illumination would imply that the SNR is one. However, the definition of minimum illumination is manufacturer dependent. Its value may be (a) when the video signal is, for example, 30 IRE units, (b) when the SNR is one, or (c) when an observer just perceives a test pattern. Because of its incredible temporal and spatial integration capability, the human visual system can perceive SNRs as low as 0.05. Therefore, comparing cameras based on "minimum" illumination should be approached with care.

The voltage signal [Eq. (5)] exists at the output of the array. This voltage must be amplified by the camera electronics (gain = G_{camera}) to a value that is consistent with video standards. The minimum signal provided with gain "on" (G_{camera} greater than one) is usually calculated due to the difficulty of performing accurate, low-level radiometric and photometric measurements. These values may be provided at 30, 50, or 80 percent video levels. That is, the illumination that is given produces an output video that gives 30, 50, or 80 IRE units, respectively. Although a higher-gain amplifier could provide 100 percent video, the user can optimize the image by adjusting the gain and level of the display. That is, the display's internal amplifiers can be used for additional gain. In this context, the camera *system* consists of the camera and display.

If G_{camera} is expressed in decibels, it must be converted to a ratio. The scene illumination that creates a 30 percent video signal is

$$M_v(30\%\ \text{video}) = \frac{0.3 M_v(\max \text{video})}{G_{\text{camera}}} \tag{21}$$

where M_v (max video) is the scene illumination that produces the maximum output. The subscript v indicates photometric units, which are usually lux. For 50 and 80 percent video, the factor becomes 0.5 and 0.8, respectively. The input signal that produces a SNR of one is

$$M_v(\text{SNR} = 1) = M_v(\max \text{video}) 10^{-\frac{DR_{\text{camera-dB}}}{20}} \tag{22}$$

where the camera's dynamic range is expressed in decibels (dB). Although photometric units are used most often, radiometric quantities can be used in Eqs. (21) and (22).

Dynamic range depends on integration time, binning, and frame integration. In addition, the spectral content of the source and the array spectral responsivity affect the camera output voltage. Thus, the camera dynamic range can be quite variable depending on test conditions.

Although the theoretical maximum signal just fills the charge wells, the manufacturer may limit the maximum output voltage to a lower stored-charge value. Because the dynamic range is often expressed in decibels,

$$\text{DR}_{\text{camera-dB}} = 20 \log\left(\frac{\text{V}_{\max}}{\text{V}_{\text{noise}}}\right) \tag{23}$$

Many camera manufacturers list the dynamic range as the signal-to-noise ratio. This value should not be confused with the actual SNR. With most cameras, the noise level is approximately equivalent to the array read noise. The electronics may increase the camera noise and image-processing techniques may reduce it somewhat. Usually the dynamic range is calculated from the measured signal and noise. Because the read noise is amplifier white noise, it is appropriate to include the bandwidth as part of the measurements. For standard video-compatible cameras, the bandwidth is equal to the video format bandwidth.

26.9 MODULATION TRANSFER FUNCTION

The MTF of the camera is the product of all the subsystem MTFs. Usually, the electronics MTF does not significantly affect the overall MTF. Therefore, it is often adequate to consider only the optics and detector MTFs.

The MTF of a single rectangular detector in image space is

$$\text{MTF}_{\text{detector}}(u) = \left|\frac{\sin(\pi d \eta)}{(\pi d \eta)}\right| \tag{24}$$

where d is the horizontal extent of the photosensitive surface and η is the image-space horizontal spatial frequency variable (in cycles/mm). The detector size may be different in the horizontal and vertical directions, resulting in different MTFs in the two directions.

The MTF for a circular, clear-aperture, diffraction-limited lens is

$$\text{MTF}_{\text{optics}}(\eta) = \frac{2}{\pi}\left[\cos^{-1}\left(\frac{\eta}{\eta_C}\right) - \frac{\eta}{\eta_C}\sqrt{1-\left(\frac{\eta}{\eta_C}\right)^2}\right] \tag{25}$$

The optical cutoff is $\eta_C = D/(\lambda_{\text{ave}}\text{fl})$, where D is the aperture diameter and λ_{ave} is the average wavelength.

26.10 RESOLUTION

Detector arrays are specified by the number of pixels, detector size, and detector pitch. These are not meaningful until an optical system is placed in front of the array. The most popular detector resolution measure is the detector angular subtense. In object space, it is

$$\text{DAS} = \frac{d}{\text{fl}} \text{ mrad} \tag{26}$$

and in image space, the detector size, d, becomes the measure of resolution.

Perhaps the most popular measure of optical resolution is Airy disk size. It is the bright central spot of the diffraction pattern produced by an ideal optical system. In the focal plane of the lens, the Airy disk diameter is

$$d_{\text{airy}} = 2.44\frac{\lambda}{D}\text{fl} = 2.44\lambda F \tag{27}$$

While often treated independently, the camera resolution depends upon both the optical and detector resolutions.

Shade created a metric for system performance. As reported by Lloyd,[26] Sendall modified Shade's equivalent resolution such that

$$R_{\text{eq}} = \frac{1}{2\int_0^\infty |\text{MTF}_{\text{sys}}(\eta)|^2 \, d\eta} \tag{28}$$

As a summary metric, R_{eq} provides a better indication of system performance than a single metric, such as the detector size or blur diameter. R_{eq} cannot be directly measured. It is a mathematical construct simply used to express overall performance. As the MTF increases, R_{eq} decreases and the resolution "improves" (smaller is better). As an approximation, the system resolution may be estimated from the subsystem equivalent resolutions by

$$R_{\text{eq}} \approx \sqrt{R_{\text{optics}}^2 + R_{\text{detector}}^2} \tag{29}$$

Substituting the diffraction-limited MTF into Eq. (28) provides

$$R_{\text{optics}} = 1.845\lambda F \tag{30}$$

Note that Shade's approach provides a value that is smaller than the Airy disk diameter. Recall that R_{eq} is only a mathematical construct used to analyze system performance. When R_{optics} dominates R_{eq}, we say the system is optics-limited.

Substituting the detector MTF into Eq. (28) provides

$$R_{\text{detector}} = d \tag{31}$$

Here, Shade's resolution matches the common method of describing detector performance: The smallest target that can be discerned is limited by the detector size. When R_{detector} dominates R_{eq}, we say the system is detector-limited.

Using Eq. (29) to estimate the composite resolution in image space,

$$R_{\text{eq}} \approx d\sqrt{\left(\frac{1.845\lambda F}{d}\right)^2 + 1} \tag{32}$$

As $\lambda F/d$ decreases, R_{eq} approaches d. For large values of $\lambda F/d$, the system becomes optics-limited and the equivalent resolution increases.

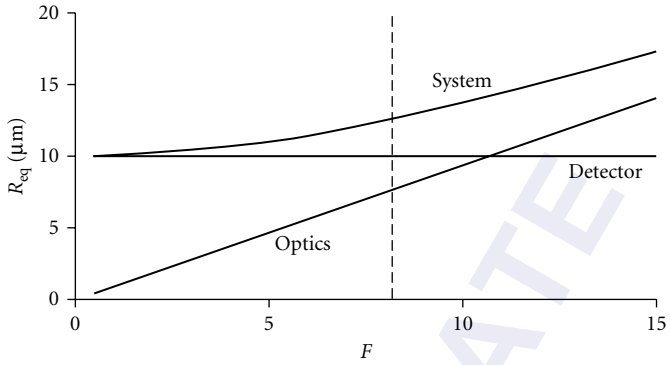

FIGURE 10 Resolution of a typical 1/2-inch-format CCD camera as a function of *f*-number. $\lambda = 0.5$ μm. The vertical line at $F = 8.20$ separates optics-limited from detector-limited operation. It occurs when the Airy disk size is equal to the detector size.

The more common 1/2-inch-format CCD arrays have detectors that are about 10 μm in size. Figure 10 illustrates R_{eq} as a function of *f*-number. Reducing the *f*-number below 5 does not improve resolution because the system is in the detector-limited region.

For most CCD camera applications, it is assumed that the camera is operating in the detector-limited region. This is only valid if $\lambda F/d$ is small. If $\lambda F/d$ is large, then the minimum discernable target size is definitely affected by the optics resolution.

We live in a world where "smaller is better." Detector sizes are shrinking. This allows the system designer to create physically smaller cameras. Replacing a 1/2-in-format array with a 1/4-in-format array (typical detector size is 5 μm) implies a 2× improvement in resolution. However, this is only true if the system is operating in the detector-limited region. As *d* decreases, the *f*-number must also decrease to stay within the detector-limited region. Further, the *f*-number must also decrease to maintain the same signal intensity [Eq. (18)]. Reducing the *f*-number can place a burden on the optical designer.

26.11 SAMPLING

Sampling is an inherent feature of all electronic imaging systems. The scene is spatially sampled in both directions due to the discrete locations of the detector elements. The horizontal sample rate is

$$\eta_S = \frac{1}{d_{\text{CCH}}} \text{ cycles/mm} \tag{33}$$

Staring arrays can faithfully reproduce signals up to the Nyquist frequency:

$$\eta_N = \frac{\eta_S}{2} = \frac{1}{2d_{\text{CCH}}} \text{ cycles/mm} \tag{34}$$

The pitch in the horizontal and vertical directions, d_{CCH} and d_{CCV}, respectively, may be different and, therefore, the sampling rates will be different. Any input frequency above the Nyquist frequency will be aliased to a lower frequency (Fig. 11). After aliasing, the original signal can never be recovered. Diagonal lines appear to have jagged edges, or "jaggies," and periodic patterns create moiré patterns. Periodic structures are rare in nature and aliasing is seldom reported when viewing natural scenery, although aliasing is always present. Aliasing may become apparent when viewing periodic targets such as test patterns, picket fences, plowed fields, railroad tracks, and Venetian blinds. It becomes bothersome when the scene geometric properties must be maintained as with mapping. It

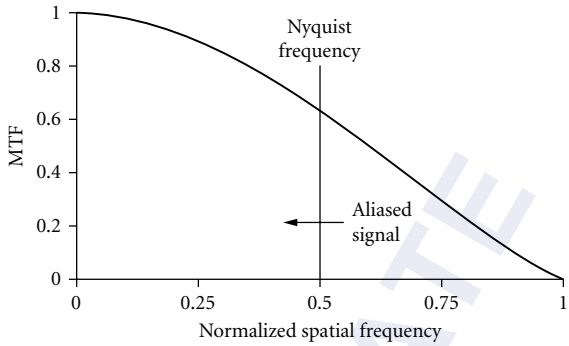

FIGURE 11 Signals above Nyquist frequency are aliased down to the base band. $\eta_S = 1$ and $\eta_N = 0.5$. The area bounded by the MTF above η_N may be considered as an "aliasing" metric.[27]

affects the performance of most image-processing algorithms. While this is a concern for scientific and military applications, it typically is of little consequence to the average professional television broadcast and consumer markets.

We have become accustomed to the aliasing in commercial televisions. Periodic horizontal lines are distorted due to the raster. Cloth patterns, such as herringbones and stripes, produce moiré patterns. Cross-color effects occur in color imagery (red stripes may appear green or blue). Many videotape recordings are undersampled to keep the price modest, and yet the imagery is considered acceptable when observed at normal viewing distances.

Because the aliasing occurs at the detector, the signal must be band limited by the optical system to prevent it. Optical band limiting can be achieved by using small-diameter optics, blurring the image, or by inserting a birefringent crystal between the lens and array. The birefringent crystal changes the effective detector size and is found in almost all single-chip color cameras. Unfortunately, these approaches also degrade the MTF (reduce image sharpness) and are considered unacceptable for scientific applications.

If a system is Nyquist frequency-limited, then the Nyquist frequency is used as a measure of resolution. Because no frequency can exist above the Nyquist frequency, many researchers represent the MTF as zero above the Nyquist frequency (Fig. 12). This representation may be too restrictive for modeling purposes.

The fill factor can vary from 20 percent for interline transfer devices to nearly 100 percent for frame transfer devices. In the detector-limited region, the detector MTF determines the potential

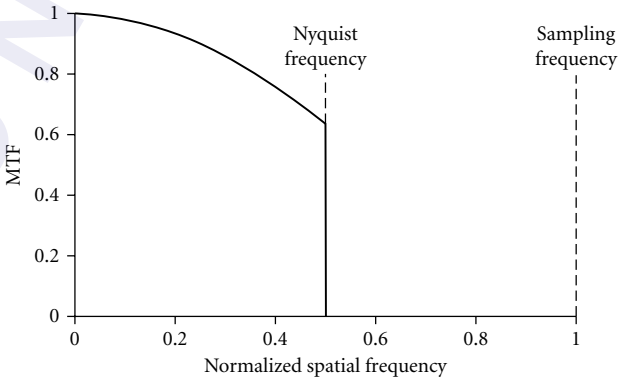

FIGURE 12 MTF representation of an undersampled system. $\eta_s = 1$ and $\eta_N = 0.5$. This restrictive representation erroneously suggests that there is no response above η_N.

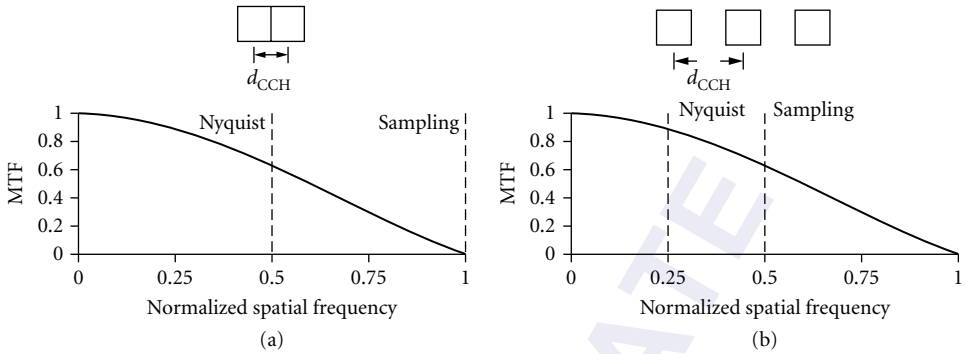

FIGURE 13 Two arrays with different horizontal center-to-center spacings. The detector size, d, is the same for both. (*a*) $d/d_{CCH} = 1$. This typifies frame transfer devices. (*b*) $d/d_{CCH} = 0.5$. This is representative of an ideal interline transfer CCD array. The detector MTF is plotted as a function of ηd.

spatial frequencies that can be reproduced. The center-to-center spacing uniquely determines the Nyquist frequency (Fig. 13). A microlens will increase the effective detector size, but it does not affect the center-to-center spacing. The absolute value of the Nyquist frequency ($1/2d_{CCH}$) does not change. By increasing the detector size, the detector cutoff decreases. The *relative* locations of the sampling and Nyquist frequencies change. The figures in this text use relative (normalized) frequency scales.

Less-expensive color cameras contain only a single CCD chip. A color filter array (CFA) is placed over the chip to create red, green, and blue pixels. Figure 20 in Chap. 32, "Visible Array Detectors," in Vol. II, provides a variety of CFA patterns. In many sensors, the number of detectors that are devoted to each color is different. The basic reason is that the human visual system (HVS) derives its detail information primarily from the green portion of the spectrum. That is, luminance differences are associated with green, whereas color perception is associated with red and blue. The HVS requires only moderate amounts of red and blue to perceive color. Thus, many sensors have twice as many green as either red or blue detector elements. An array that has 768 horizontal elements may devote 384 to green, 192 to red, and 192 to blue. This results in an unequal sampling of the colors (Fig. 14).

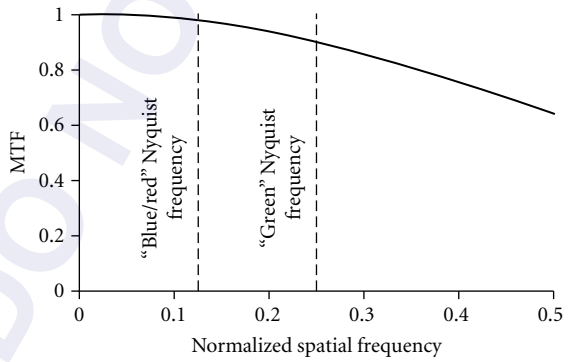

FIGURE 14 Horizontal detector MTF normalized to ηd. Unequally spaced red-, green-, and blue-sensitive detectors create different array Nyquist frequencies. This creates different amounts of aliasing and black-and-white scenes may break into color. The spacing between the red and blue detectors is twice the green detector spacing.

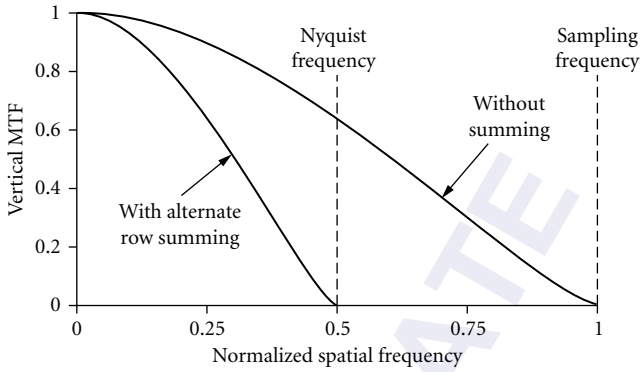

FIGURE 15 Alternate detector summing (pseudointerlacing) can reduce aliasing in the vertical direction. Vertical MTF with and without summing normalized to ηd.

The output R, G, and B signals are created by interpolation of the sparse data (sparse pixels). The output signals *appear* as if there are 768 red, green, and blue pixels. This interpolation does not change the Nyquist frequency of each color. A birefringent crystal[28] inserted between the lens and the array effectively increases the detector sizes. A larger detector will have reduced MTF and this reduces aliasing. It also reduces edge sharpness.

Pseudointerlacing (Fig. 4) doubles the size of the detector. This reduces the detector cutoff and makes it equal to the Nyquist frequency (Fig. 15). From an aliasing point of view, aliasing has been significantly reduced. However, the MTF has also been reduced, and this results in reduced-edge sharpness.

26.12 STORAGE, ANALYSIS, AND DISPLAY

Chapter 32, "Visible Array Detectors," in Vol. II describes the physics of CCD detectors. This chapter has described some additional features of CCDs and introduced CID and CMOS detectors. These solid-state devices are the basic building blocks of the solid-state array. Certain array architectures lend themselves to specific applications. Once the camera is fabricated, the user selects an optical system. The minimum signal, maximum signal, and resolution discussed in this chapter include the lens *f*-number. It would appear that with all this knowledge, it would be easy to select a camera. A camera only becomes operational when its output is analyzed. Analysis is performed by an observer (general video) or a computer (machine vision).

For general video, the camera output must be formatted into a data stream consistent with the display device. The monochrome standard is often called EIA 170 (originally called RS 170) and the color format is simply known as NTSC (originally called EIA 170A or RS 170A). Worldwide, three color broadcast standards exist: NTSC, PAL, and SECAM. For higher vertical resolution, more lines are required. EIA 343A (originally RS 343A) is a high-resolution monochrome standard used for closed-circuit television cameras (CCTV). Although the standard encompasses equipment that operates from 675 to 1023 lines, the recommended values are 675, 729, 875, 945, and 1023 lines per frame.

These standards are commonplace. Monitors that display these formats are readily available. For computer analysis of this imagery, frame grabbers that accept multiple standards are easily obtained. The output of most general video cameras is an analog signal, and the frame grabber digitizes this signal for computer processing.

In principle, the clock rate of an analog-to-digital converter within the frame grabber can be set at any rate. However, to conserve on memory requirements and minimize clock rates, some frame grabbers tend to just satisfy the Nyquist frequency of a standard video signal. That is, if the highest frequency of the video bandwidth is f_{BW}, then the frame grabber sampling clock operates at $2f_{BW}$.

Some frame grabbers have an internal antialias filter. This filter ensures that the frame grabber does not produce any additional aliasing. The filter cutoff is linked to the frame grabber clock and is not related to the camera output. Once aliasing has occurred in the camera, the frame grabber antialias filter cannot remove it. If the filter does not exist, the frame grabber may create additional aliasing.[29] On the other hand, some frame grabbers have antialiasing filters that significantly limit the analog signal bandwidth and thereby reduce resolution. The number of digital samples is simply related to the frame grabber clock rate and is not necessarily equal to the number of detector elements. Even if the number of digital samples matches the number of detector elements, phasing effects will corrupt the resolution. Image-processing algorithms operate on the digitized signal and the image-processing specialist must be aware of the overall resolution of the system. The frame grabber is an integral part of that system. These issues are mitigated when the camera output is in digital form and the frame grabber can accept digital signals.

As society moves toward digital television [high-definition television (HDTV) or advanced television system (ATS)], new demands are placed upon displays and frame grabbers. New standards also require new video-recording devices. This creates storage, frame grabber, and display problems. New standards do not impose any difficulties on camera design. The solid-state array can be made any size and appropriately designed electronics can support any video format.

Industrial and scientific applications require some forethought. The camera output is no longer a conventional format. Web inspection cameras may contain a linear array with as many as 4096 elements. Split architecture (Fig. 1) may have as many as 32 parallel outputs. Charge injection devices and CMOS cameras may offer variable-sized subframes at variable frame rates. Finding suitable frame grabbers is a challenge for these applications. Nonstandard formats (even after digitization) are not easy to display.

27.1 INTRODUCTION

Camera lenses have been discussed in a large number of books and articles. The approach in this chapter is to concentrate on modern types and to describe imaging performance in detail both in terms of digital applications and in terms of the optical transfer function. By modern types, we mean lens forms that were found on cameras in 1992. The chapter deals almost entirely with lenses for the 35-mm (24 × 36 mm) format. This limitation is unfortunate but not really inappropriate, given the widespread use of this format. Moreover, the different lens types that are described are used for applications ranging from 8-mm video to 6 × 9 cm roll film.

We have not included any specific design examples of lenses for large-format cameras, but the imaging capabilities of these lenses are described in terms of digital applications. By digital applications we mean the comparison of different lens types in terms of total pixels and pixels per unit solid angle. It is hoped that this feature will make comparisons between radically different imaging systems possible and also help to classify lenses in terms of information capability. See "Further Reading" at the end of this chapter for related information about photographic lenses, particularly with respect to older design types.

27.2 IMPOSED DESIGN LIMITATIONS

There are some limitations that are imposed on the design of camera lenses. The most significant ones are listed as follows.

Microprism focusing in single lens reflex cameras (SLRs) is difficult at apertures smaller than about F/4.5. Recent advances permit the use of microprisms at apertures down to F/5.6 and this is usually the smallest maximum aperture permitted in the specification of a lens for the SLR camera.

Depending on the camera type, there is a maximum rear lens opening allowable at the flange on SLR lenses. The limitation is approximately 33 to 36-mm diameter at flange to film plane distances of 40.5 to 46 mm. This affects the maximum possible aperture on normal lenses (typically to F/1.2) and also requires appropriate design of the exit pupil location on long-focal-length and high-speed retrofocus lenses in order to avoid excessive vignetting.

The minimum back focal length (BFL) allowable on SLR lenses (because of the swinging mirror) is about 38.5 mm. The BFL cannot be too short on non-SLRs because of in-focus dust or cosmetic problems on optical surfaces close to the film plane. The actual limitation depends on the minimum relative aperture that would be used but is rarely less than 4 mm and usually more than 8 mm.

Since most lens accessories such as filters and lens-shades are mounted on the front of a lens, there is a practical limitation to the allowable front diameter of most lenses. Filter sizes larger than 72 mm are not desirable, and smaller is always preferred. The actual clear aperture at the front of a lens is considerably smaller than the filter size, depending on the angular field and the mounting details of the filter. Obviously there are lenses such as 600-mm F/4 telephotos for which the 72-mm limitation is not possible. In these cases, the lens can be designed to use internal filters that are incorporated into the design.

Mechanical cams are still in widespread use for the practical realization of the required motions in zoom lenses. This technology requires that the motions themselves be controlled at the design stage to be reasonably monotonic and often to have certain mutual relationships. These requirements are particularly severe for the so-called "one-touch" zoom and focus manual control found on many SLR zoom lenses.

In general, size and weight restrictions pose the biggest problems for the designer of most camera lenses. Almost any lens can be designed if there are no physical limitations. These limitations are sometimes a consequence of ergonomic considerations but can equally be an effort to achieve a marketing advantage. Size restrictions almost always adversely affect the design, and exceptionally small lenses (for a given specification) should be regarded with suspicion.

27.3 MODERN LENS TYPES

Normal (with Aspherics) and Variations

Thirty-five-mm SLR normal lenses are invariably Double-Gauss types. Refer to Fig. 1. This lens form is characterized by symmetry about a central stop to facilitate the correction of coma, distortion, and lateral color. These lenses are relatively easy to manufacture and a user can expect good quality in a production lens. Total angular coverage of about 45° is typical, and speeds as fast as F/l are achievable. Extremely good optical performance is possible, particularly if the angular field and speed are reduced somewhat. Image quality generally deteriorates monotonically from axis to corner and improves dramatically as the lens aperture is reduced by about two F-numbers. With the addition of a fixed rear group, conjugate stability can be achieved over a wide range. Refer to Fig. 2.

Wide-Angle

An interesting new wide-angle lens type is a four-component form found commonly on the so-called compact 35-mm cameras. This lens is characterized by a triplet construction followed by a rear element that is strongly meniscus-shaped, convex to the image plane. This lens has much less astigmatism than either conventional triplets or Tessars and can cover total fields of up to 75° at speeds of around F/4. Faster speeds are possible if the angular field is reduced. Most importantly, the rear meniscus component takes the burden of field flattening away from the triplet front part. This results in considerably lower individual element powers and correspondingly lower sensitivities to tilts and decentrations of the elements. It is this problem that makes conventional triplets extremely difficult to manufacture. Refer to Fig. 3.

Inverted Telephoto (Retrofocus)

These lens types, characterized by a long back focal length, are typically used for wide-angle applications for single lens reflex cameras having a swinging viewing mirror behind the lens. Inverted telephoto implies a front negative group followed by a rear positive group, just the reverse of a

telephoto construction. This type of construction tends to result in relatively large front aperture sizes, and it is not easy to design small lenses without compromising on image quality. Retrofocus designs sometimes have a zone of poorer image quality in a field area between the axis and the corner. This zone is a by-product of the struggle to balance lower- and higher-order aberrations so that the outer parts of the field have acceptable image quality. These lenses have particularly good relative illumination both because the basic construction results in an exit pupil quite far from the image plane and also because it is possible for the size of the pupil to increase with field angle. In order to achieve conjugate stability, it is necessary to employ the use of so-called "floating elements" or variable airspaces that change with focusing. However, this feature does result in additional optomechanical complexity.

The newer forms of this lens type fall into four broad subcategories.

Very Compact Moderate Speed These include six-element 35-mm F/2.8 with a front negative element and seven-element 28-mm F/2.8 with a leading positive element. Refer to Figs. 4 and 5, respectively. These relatively simple constructions are suitable for speeds of F/2.8 or slower and total angular coverages of up to 75°.

Highly Complex Extreme Speed As the complexity of both the front and rear groups is increased, the inverted telephoto form can be designed to achieve speeds of F/1.4 and angular fields of 90°. The use of aspherical surfaces is essential in order to achieve these specifications. Refer to Figs. 6, 7, 8, and 9.

Highly Complex Extreme Wide-Angle with Rectilinear Distortion Correction

These are inverted telephoto designs covering total fields of up to 120°, often with speeds as fast as F/2.8. Distortion correction is rectilinear. The chromatic variations of distortion, astigmatism, and coma are usually the limiting aberrations and are virtually impossible to correct beyond a certain point. Refer to Figs. 10 and 11.

Extreme Wide-Angle with Nonrectilinear Distortion (*"*Fish-Eye Lenses*"*) Without the requirement of rectilinear correction of distortion, inverted telephoto designs can be achieved quite readily with total angular fields exceeding 180°. For these lenses, the image height h and focal length f are often related by $h = f \cdot \theta$, where θ is the semifield angle. See, for example, USP 4,412,726.

Telephoto Lenses

The term *telephoto* strictly applies to lenses having a front vertex length less than the focal length (telephoto ratio less than one). The classic telephoto construction has a front positive group followed by a rear negative group. This can lead to telephoto ratios that are as short as 0.7 or less. The term telephoto is often loosely used to refer to any long-focal-length lens and one sometimes sees references made to the telephoto ratio of a wide-angle lens.

Two significant advances characterize the newer types of telephoto lenses, particularly those used for 35-mm SLR cameras. The first is the use of small internal groups for focusing, sometimes in conjunction with the front group. This feature has also led to significant improvement in the performance of these lenses with change of conjugate. This has been a problem with telephoto lenses, particularly with respect to attaining close focus with good optical quality. Internal focusing of a long-focal-length lens also has considerable advantages in terms of mechanical simplicity because a smaller mass is being moved over a significantly shorter distance.

The second advance is the employment of optical glasses having anomalous dispersion for the correction of chromatic aberrations. These newer glasses have anomalous dispersion characteristics similar to those of calcium fluorite, but with physical and chemical properties that make their use practical. These glasses are still expensive and more difficult to use than ordinary ones, but they do

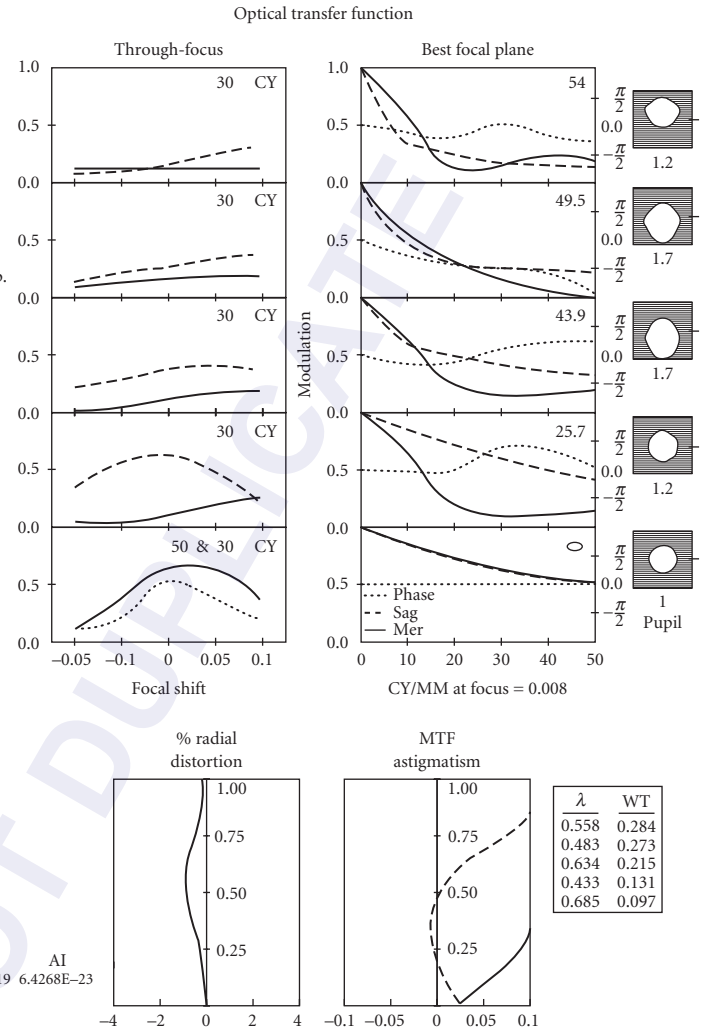

FIGURE 10 15-mm F/2.8 for 35-mm SLR.

offer significant advantages in terms of reducing the chromatic aberrations that otherwise severely limit the imaging potential of all long-focal-length refracting optics. Typical available versions of these glass types are the FK Schott, FCD Hoya, FPL Ohara, and PFC Corning series of glasses.

These design types offer outstanding optical correction together with remarkable specifications, resulting in considerable size and cost. Commercial embodiments include 300-mm F/2 and 400-mm F/2.8 for 35-mm. They are widely used for sports and wildlife photography. Since secondary color increases as the front vertex distance is reduced, it is advisable to regard excessively short all-refractive telephotos with some caution. Refer to Figs. 12 and 13. The letter *z* in the thickness column in Fig. 12 (later in Figs. 14, 16, and 17) represents the zooming or variable space between the lenses.

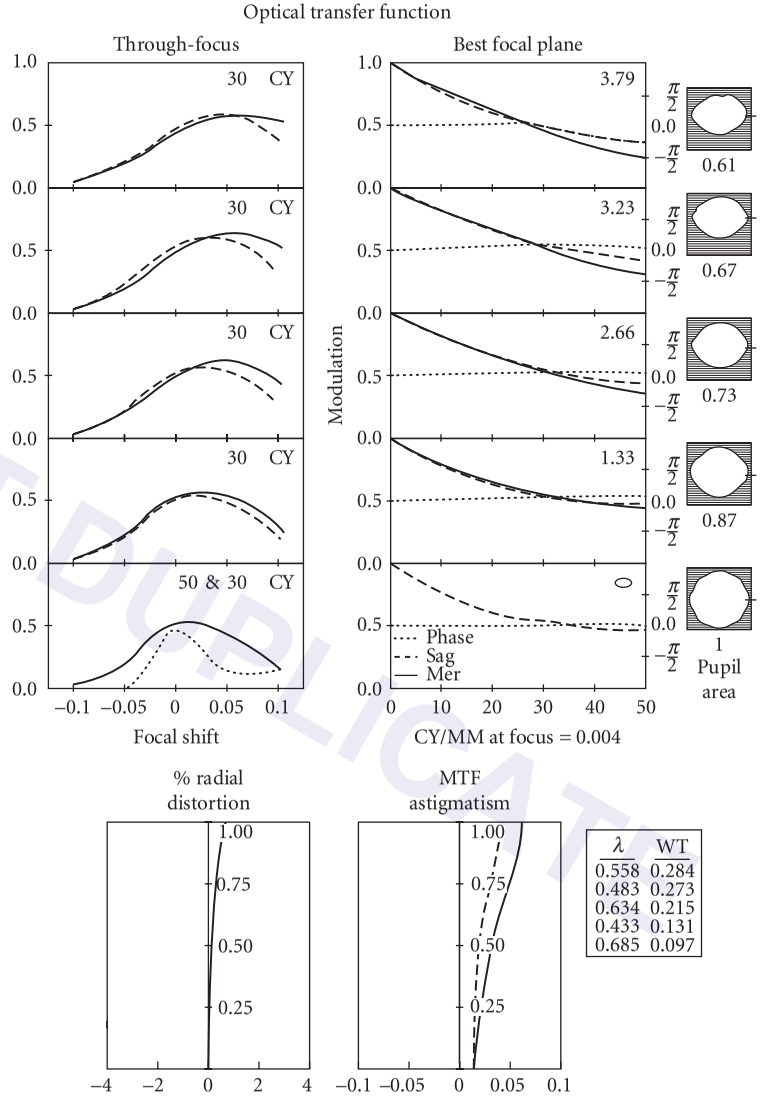

FIGURE 13 300-mm F/2 for 35-mm SLR.

Zoom Lenses

Zoom lenses have evolved significantly in the past 20 years. In the early 1970s, there was basically only the classic four-group type of zoom lens. This four-group zoom has two moving groups between a front group used only for focusing and a stationary rear (*master*) group. This type is still found on consumer video cameras. Figures 14 and 15 show a variation of this form with the rear group also moving for zooming. The master group could often be changed to yield a different zoom with the same ratio over a different range.

The second basic form, originating in the mid 1970s, was the two-group wide-angle zoom, typically 24 to 48 mm and 35 to 70 mm for the 35-mm format. Both the front negative group and the rear positive group move for zooming, and the front group is also used for focusing. This lens type has an inherently long back focal length, making it eminently suitable for the SLR camera. See, for example, USP 4, 844, 599. The maximum zoom range is about 3 : 1.

In order to achieve lens types such as a 28- to 200-mm zoom for 35-mm, new ideas had to be employed. The resulting lenses have up to five independent motions, including that of the diaphragm. These degrees of freedom allow for the location of the entrance pupil to be near the front of the lens at the short-focal-length position and also for the exit pupil to be located near the rear, particularly at the long-focal-length setting. These conditions result in acceptably small size. The extra zooming motions permit a large focal-length range to be achieved without any one motion being excessively long. There is a constant struggle in the design of these zooms to minimize the diameter of the front of the lens. This is not only to reduce size and weight, but also to permit the use of acceptably small filters. Some designs do have problems with relative illumination at the wide-angle end.

In the past, these lenses have been focused either by moving the front group or by moving the entire lens, the latter option leading to the so-called varifocal zoom. However, more recent developments in miniature electromechanical and autofocusing systems have led to the evolution of extended range zooms in which the distinction between a focusing and a compensating group has become academic. As a result, small internal zooming groups can serve a dual function as focusing groups under the control of an autofocusing system. Refer to Figs. 16, 17, and 18.

A recent new development in zooms is one for the so-called compact 35-mm camera. In its most basic form, this type can have as few as three elements and is characterized by having a front positive component and a rear negative component. This lens has an inherently short back focal length at the wide end, making it not suitable for SLR cameras with swinging mirrors. In more complicated versions, this idea can be extended to 28 to 160 mm or further, the main limitation being a small relative aperture at the long-focal-length end. A recent practical embodiment is a four-element 38- to 90-mm F/3.5 to 7.7 having three aspherical surfaces. See, for example, USP 4, 936, 661.

Zoom lenses are also found on most consumer video cameras. The classic fixed front-and rear-group type (with the aperture stop in the rear group) is still commonly used because the very small format sizes can permit acceptably small lenses. This lens form is also used for motion picture and television zooms. In many of these applications, it is desirable to have an exit pupil position that does not change with zooming. Telecentricity of the exit pupil is also sometimes required. In addition, the motion picture industry still prefers zoom lenses that have conventional front-group focusing in order to easily calibrate tape-measure focus measurements.

Very long range television zooms (often 30 : 1 or more) are also of the fixed front and rear type, with a succession of cascading zooming groups in between.

27.4 CLASSIFICATION SYSTEM

A wide variety of camera lenses has been classified in Table 1 in terms of total pixel capability P and pixels per steradian AD. Pixels are defined as digital resolution elements relative to a specified modulation level and are calculated as follows:

The polychromatic optical transfer function of each lens is calculated and the spatial frequencies at which the modulation falls to 0.5 and 0.2 is noted at each of five field points. The lower of the meridional and sagittal values is used.

D—image diameter in mm
P_m—pixels × 10^6 at modulation level m
F-no—F-number of the lens
W—semifield angle in degrees
AD_m—pixels × 10^6 per steradian at modulation level m
EFL—effective focal length of the lens in mm

The image field of the lens, assumed to be circular with diameter D, is divided into four annular regions. The outer boundaries of each region correspond, respectively, to $0.35H$, $0.7H$, $0.85H$, and $1.0H$, where H is the maximum field height. The area of each region is computed.

The average of the inner and outer boundary-limiting spatial frequency values is assigned to each region. This is done for both the 0.5 and 0.2 modulation levels.

The area of each annular region, in square millimeters, is multiplied by the square of the spatial frequency values from the previous step to yield regional pixel counts for both 0.5 and 0.2 modulation levels.

The pixel counts are summed over all regions to yield the D data in Table 1.

The AD data in Table 1 are obtained by dividing the total pixel values by the solid angle of the lens in object space. The solid angle S is given by the following formula:

$$S = 2\pi(1-\cos W)$$

where W is the semifield angle of the lens in degrees.

In general, for a given image diameter D, a larger P implies higher image quality or greater information-gathering capability. A lens designed for a smaller D will have a lower P than a lens of similar quality designed for a larger D. These same generalizations hold for AD except that, in addition, a lens designed for a smaller field angle and a given D will have a larger AD than a lens of similar image quality designed to cover a wider field for the same D. In other words, for the same image-quality level and format size, wide-angle lenses have lower AD values than do narrow angle lenses.

27.5 LENS PERFORMANCE DATA

A wide variety of camera lenses has been selected to show typical performance characteristics. In most cases, the data have been derived from the referenced published U.S. patents. The authors have taken the liberty of reoptimizing most of the data to arrive at what would, in our judgment, correspond to production-level designs. All performance data have been shown at maximum aperture. It is important to realize that photographic lenses are invariably designed so that optimum performance is achieved at F-numbers at least 2 stops slower than maximum. A general explanation of the data page follows.

The lens drawing shows the marginal axial rays together with the upper and lower meridional rays for seven-tenths and full field.

The lens prescription and all other data are in millimeters. Glass catalogs are Hoya, Ohara, and Schott. Distances to the right of a surface are positive. A positive radius means that the center of curvature is to the right of the surface. The thickness and glass data indicate the distance and medium immediately following the particular surface.

The optical transfer function (OTF) plots show the through-focus modulation transfer function (MTF) on the left and the OTF at best axial focus on the right. The data are shown for five field points, viz., the axis, $0.35H$, $0.70H$, $0.85H$, and $1.0H$, where H is the maximum field angle in object space. The actual field angles are indicated in the upper-right-hand corner of each best-focus OTF block and are in degrees. The through-focus data are at the indicated spatial frequency in cycles per millimeter with an additional frequency on-axis (dotted curve). Both the through-focus and best-focus data indicate meridional (solid curves) and sagittal (dashed curves) MTF. The modulus scale is on the left of each block and runs from zero to one. The phase of the OTF is shown as a dotted curve in the best-focus plots. The scale for the phase is indicated on the right of each best-focus block and is in radian measure. All the OTF data are polychromatic. The relative weights and wavelengths used appear in the lower-right-hand corner of each page. The wavelengths are in micrometers and the weights sum to one. The axial focus shift indicated beneath the best-focus plots is relative to the zero position of the through-focus plots. The best-focus plane is at the peak of the additional axial through-focus plot (dotted curve).

Vignetting for each field angle is illustrated by the relative pupil area plots on the right-hand side of each page. The distortion plots shows the percentage of radial distortion as a function of fractional field height. The MTF astigmatism plot shows the loci of the through-focus MTF peaks as a function of fractional field height. The data can be readily determined directly from the through-focus MTF plots.

Certain acronyms are used in the system first-order properties:

Effective focal length (EFL)

Back focal length (BFL)

Front vertex distance (FVD)

Barrel length (BRL)

Entrance pupil distance (ENP)

Exit pupil distance (EXP)

The ENP and EXP data are measured from the front and rear vertices of the lens, respectively. A positive distance indicates that the pupil is to the right of the appropriate vertex.

27.6 ACKNOWLEDGMENTS

The authors would like to acknowledge data provided by R. Mühlschlag of Jos. Schneider Optische Werke and C. Marcin of Schneider Corporation of America. We also appreciate permission granted by Panavision Corporation to use data pertaining to the Primo zoom lens.

28.1 GLOSSARY

f	focal length
M	magnification
n	refractive index
NA	numerical aperture
z	distance along optical axis
λ	wavelength of light
I	irradiance, sometimes called intensity

28.2 INTRODUCTION

The optical principles and basic lens design needed to generate a diffraction-limited, highly magnified image with the light microscope were already essentially perfected a century ago. Ernst Abbe demonstrated how a minimum of two successive orders of diffracted light had to be captured in order for a particular spacing to be resolved (see historical sketch about Abbe principle[1]). Thus, he explained and demonstrated with beautiful experiments the role of the wavelength of the imaging light and the numerical aperture (NA = $n \sin \Theta$, Fig. 1)[2] of the objective and condenser lenses on the resolving power of the microscope. In general, the minimum spacing δ for line gratings that can just be resolved cannot be smaller than

$$\delta = \frac{\lambda}{2\,\mathrm{NA}} \tag{1}$$

when the NA of the condenser is equal to the NA of the objective.

For generating an image, contrast is just as important as resolution. Much of the early use of the light microscope depended on the relatively high image contrast that could be generated by differential absorption, scattering, reflection, birefringence, and the like due to specimen composition

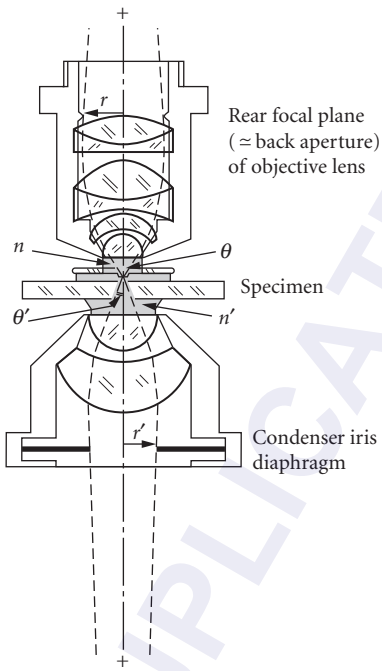

FIGURE 1 Definition of numerical aperture of objective ($NA_{obj} = n \sin\Theta$) and condenser ($NA_{cond} = n \sin\Theta'$).[2]

or structure. Specimens, such as unstained living cells and other transparent objects introducing small optical path differences, were generally not amenable to direct microscopic observation for they would not produce detectable image contrast when brought to exact focus.

These impediments were removed by Zernike who showed how contrast in the microscope image is generated by interference between the light waves that make up the direct rays (that are undeviated by the specimen) and those that were scattered and suffered a phase difference by the presence of the specimen. Using this principle, Zernike invented the phase-contrast microscope.[3] For the first time it became possible to see, in focus, the image of small, nonabsorbing objects. Zernike's revelations, together with Gabor's further contributions,[4] not only opened up opportunities for the design of various types of interference-dependent image-forming devices but, even more importantly, improved our understanding of the basic wave optics involved in microscope image formation.

About the same time as Zernike's contributions, perfection of the electron microscope made it possible to image objects down to the nanometer range, albeit necessitating use of a high-vacuum environment and other conditions compatible with electron imaging. Thus, for four decades following World War II, the light microscope in many fields took a back seat to the electron microscope.

During the last decades, however, the light microscope has reemerged as an indispensable, powerful tool for investigating the submicron world in many fields of application. In biology and medicine, appropriate tags, such as fluorescent tags, are used to signal the presence and location of selected molecular species with exceptionally high sensitivity. Dynamic behaviors of objects far below the limit of resolution are visualized by digitally enhanced video microscopy directly in their natural (e.g., aqueous) environment. Very thin optical sections are imaged by video microscopy, and even more effectively with confocal optics. Quantitative measurements are made rapidly with the aid of digital image analysis.

At the same time, computer chips and related information-processing and storage devices, whose availability in part has spurred the new developments in light microscopy, are themselves miniaturized to microscopic dimensions and packaged with increasingly higher density. These electronic and photonic devices in turn call for improved means for mass manufacturing and inspection, both of which require advanced microscope optics.

Driven by the new needs and aided in part by computerized ray tracing and the introduction of new optical materials, we see today another epochal advance in the quality of lens design. The precision and remote control capabilities of mechanical components are also steadily improving. Furthermore, we may expect another surge of progress, hand-in-hand with development of improved electro-optical and electromechanical devices, in regulated image filtration, contrast-generating schemes, as well as in optical manipulation of the specimen employing microscope optics.

There are a number of excellent review articles and books discussing the optical principles of light microscopes[1,5,6] and microscopic techniques,[2,7–10] and their applications.[11–14] Among the many resources on microscopy available on the Internet, the Molecular Expressions website (http://www.microscopy.fsu.edu/index.html) stands out for its comprehensive treatment, beautiful illustrations, and interactive tutorials on the subject.

The present chapter is intended in part to bridge the territories of the manufacturer and the user of the microscope, including those who incorporate microscope optics into other equipment or apply them in unconventional ways. In this revision for the third edition of the *Handbook of Optics,* we reorganized the material, expanded the description of techniques that are typically covered only in passing by recent reviews and books on microscopy (e.g. interference and polarization microscopy), and added brief descriptions of imaging modes that are based on new optical concepts or new approaches to extract quantitative information from traditional imaging modes.

Many of the optical concepts and techniques, which are introduced here in the context of microscopy, are discussed in more detail in other chapters of this *Handbook*. On general optical considerations consult the *Handbook* chapters in this volume, "General Principles of Geometrical Optics" (Chap. 1) and on optical elements, such as "Lenses" (Chap. 17), "Polarizers" (Chap. 13), as well as chapters on physical optics for wave phenomena such as "Interference" (Chap. 2), "Diffraction" (Chap. 3), "Coherence Theory" (Chaps. 5 and 6), and "Polarization" (Chap. 12) which, as phenomena, are essential to the workings of the various contrast modes of the microscope. Material on image detection and processing can be found in *Handbook* chapters on vision in Vol. III, imaging detectors in Vol. II, and optical information and image processing in Chap. 11 of this volume.

28.3 OPTICAL ARRANGEMENTS, LENSES, AND RESOLUTION

Optical Arrangements

Geometric Optical Train, Magnification, Conjugate Planes In the optical train of a compound microscope (Fig. 2) invented by Galileo around 1610, the objective lens L_{ob} projects an inverted, real, magnified image O' of the specimen O (or object plane) into the intermediate image plane (or primary image plane). The intermediate image plane is located at a fixed distance $f' + z'$ behind L_{ob}, where f' is the back focal length of L_{ob} and z' is the optical tube length of the microscope. In general, O' is an aerial image for which an ocular L_{oc} (or the eyepiece) acts as a magnifier in front of the eye. Since L_{oc}, coupled with the corneal surface and lens of the eye, produces an erect image O'' of O on the retina, the object appears inverted to the observer. The ocular may also be used to project the image onto a screen. The aerial image at O' can also be exposed directly onto conventional film or an electronic sensor.

Continuing with the schematic diagram in Fig. 2, using thin-lens approximations, O is placed at a short distance z just outside of the front focal plane of L_{ob}, such that $z + f = a$, where f is the front focal length of L_{ob} and a is the distance between O and L_{ob}. O' is formed at a distance $b = (z' + f')$ behind L_{ob}. For a height y of O, the image height $y' = y \times b/a$. Thus, L_{ob} magnifies O by $M_{ob} = b/a$.

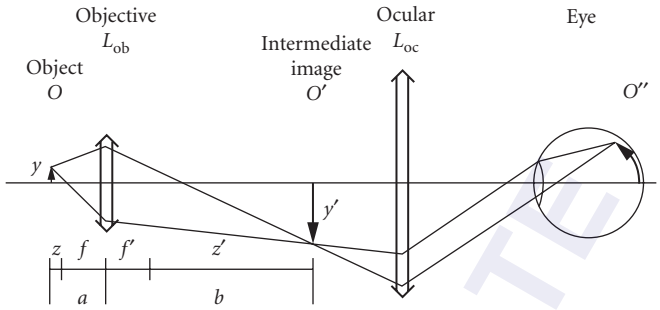

FIGURE 2 Ray path in the microscope from object to observer's eye (see text).

Also, $M_{ob} = f/z = z'/f'$. M_{ob} is the transverse or lateral magnification of L_{ob}. In the case of an infinity-corrected objective (Fig. 3), M_{ob} is the ratio f_{tb}/f, with f_{tb} the focal length of the specific tube lens L_{tb}. In turn, y' is magnified by L_{oc} by a factor $M_{oc} = 25\text{ cm}/f_{oc}$, where f_{oc} is the focal length of the ocular (in cm) and 25 cm is the so-called near distance from the observer's eye (see Vol. II of this *Handbook*). Thus, the total transverse magnification of the microscope $M_{tot} = M_{ob} \times M_{oc}$.

Note that most microscope objectives are corrected for use only within a narrow range of image distances, and, in case of older style objectives, only in conjunction with specific groups of oculars. M_{ob}, which is the magnification inscribed on the barrel of the objective lens, is defined for its specified tube length (for high-power objectives, $M_{ob} = z'/f$) or, in case of infinity-corrected objectives, when used together with its specified tube lens. These factors, as well as those mentioned under "Microscope Lenses, Aberrations," must be kept in mind when a microscope objective is used as a magnifying lens, or in reverse as a high-numerical-aperture reducing lens, to form a truly diffraction-limited image.

Continuing the optical train back to the light source in a transilluminating microscope, Fig. 4*a* shows the ray paths and foci of the waves that focus on an on-axis point in the specimen. In Köhler illumination, the distance between the specimen and the condenser are adjusted so that the image of the field diaphragm in the illuminator is superimposed with the focused region of the specimen, and the lamp collector lens is adjusted so that the source image is focused in the plane of the condenser aperture diaphragm. Thus, $\bar{O}$, O, O' and O'' all lie in image planes that are conjugate with each other.

Tracing the rays emitted from a point in the light source (Fig. 4*b*), the rays are parallel between the condenser and the objective lenses. This situation arises because in Köhler illumination the light

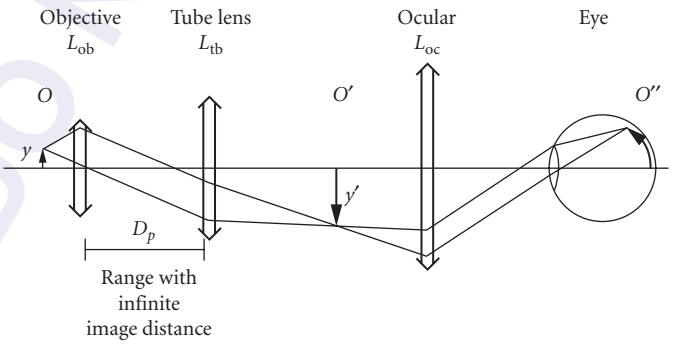

FIGURE 3 Ray path in microscope with infinity-corrected objective and tube lens.

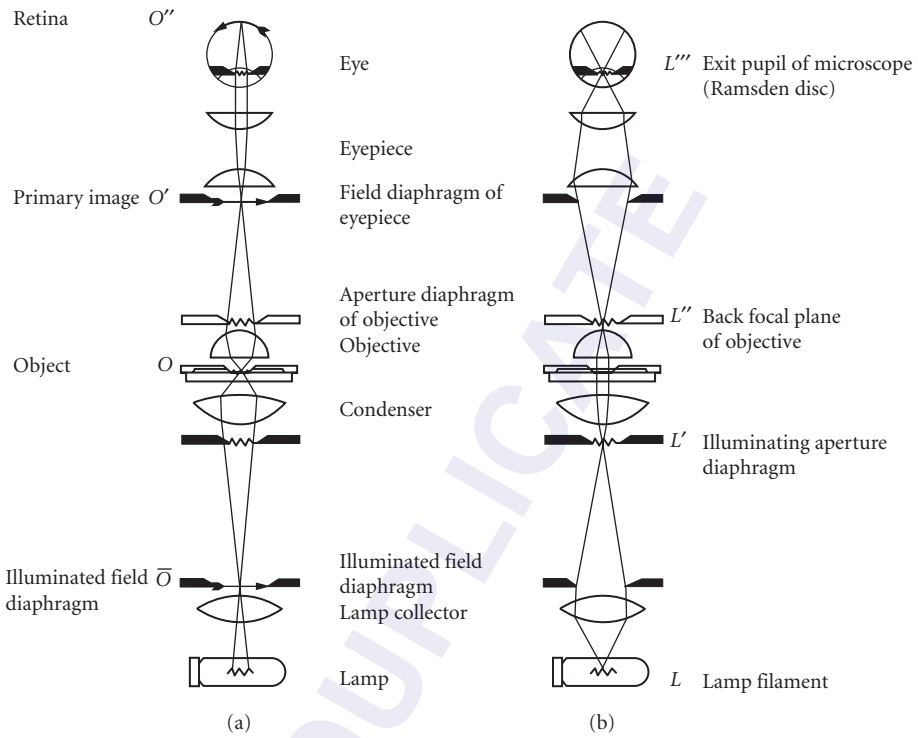

FIGURE 4 Ray paths in a transmitted light microscope adjusted for Köhler illumination. Two sets of conjugate planes are shown: set O in (*a*) is conjugate with the object O and with the field diaphragm planes; set L in (*b*) is conjugate with the lamp filament L and with aperture diaphragm planes.[15]

source (the filament of an incandescent bulb or the bright arc of a discharge lamp) is projected into the front focal plane of the condenser. Also, since the pupil of an (experienced) observer's eye is placed at the eyepoint or back focal plane of the ocular, the four aperture planes L, L', L'', and L''' are again conjugate to each other.

As inspection of Fig. 4*a* and *b*[15] shows, the field planes and aperture planes are in reciprocal space relative to each other throughout the whole optical system. This reciprocal relationship explains how the various diaphragms and stops affect the cone angles, paths, and obliquity of the illuminating and image-forming rays, and the brightness, uniformity, and size of the microscope field. More fundamentally, a thorough grasp of these reciprocal relationships is needed to understand the wave optics of microscope image formation and for designing various contrast-generating devices and other microscope optical systems.

Transillumination The full impact of the illumination system on the final quality of the microscope image is often not appreciated by the microscope user or designer. Undoubtedly, part of this neglect arises from a lack of understanding of the roles played by these components, in particular the condenser, and the common practice of closing down the condenser iris diaphragm to adjust image contrast for comfortable viewing. Regardless of the conventional view, critical examination of the microscope image or point spread function reveals the importance of the alignment, focus, tilt, NA, and effective aperture function of the condenser. The effects are especially noticeable when contrast is enhanced, e.g., by video microscopy. A further illustration of the importance of the illumination on the resolving power of the light microscope can be found in the section on "Structured Illumination."

Ernst Abbe was the first to systematically analyze the resolving power of microscope optics by fabricating precision line gratings and imaging them in the microscope. As indicated earlier, a grating is resolved if the objective lens captures at least two successive diffraction orders which are typically the zero- and first-order diffraction. Abbe summarized his results in a simple expression, relating the minimum resolvable pitch δ to the numerical aperture of the objective and condenser lens:

$$\delta = \frac{\lambda}{\mathrm{NA}_{\mathrm{obj}} + \mathrm{NA}_{\mathrm{cond}}} \tag{2}$$

with λ the wavelength of light used. This formula can be derived by considering the diffraction of linear gratings that are illuminated obliquely. In the limiting case of zero condenser NA, the grating is illuminated coherently by a collimated beam of light that is parallel to the microscope's optical axis. The minimum resolvable pitch is proportional to the wavelength and inversely proportional to the objective NA. By increasing the condenser NA, oblique rays are added to the illuminating light, increasing the angular span between diffraction orders captured by the same objective lens, and thus decreasing the minimum resolvable pitch. By making the condenser and objective NA equal, the grating is effectively illuminated incoherently and Eq. (2) reduces to Eq. (1).

The influence of the condenser NA on resolving two nearby point objects was considered by Hopkins and Barham.[16] They applied the Rayleigh criterion for resolving two pinholes that are equally bright and illuminated incoherently ($\mathrm{NA}_{\mathrm{cond}} = \mathrm{NA}_{\mathrm{obj}}$) and found a minimally resolved distance $d = 0.61\lambda/\mathrm{NA}_{\mathrm{obj}}$ (Fig. 5, $m = 1$).[17] Distance d is a factor 1.22 larger than the limiting pitch of a grating illuminated and imaged by the same condenser and objective lens [Eq. (1)]. However, for the case of coherent illumination ($\mathrm{NA}_{\mathrm{cond}} = 0$), the minimal distance of two resolved points only increases by 40 percent instead of 100 percent, as is the case for gratings. Hopkins and Barham calculated a maximum resolution (minimal d) for $\mathrm{NA}_{\mathrm{cond}} = 1.5 \times \mathrm{NA}_{\mathrm{obj}}$. Such high $\mathrm{NA}_{\mathrm{cond}}$ is usually not achievable for high-NA objective lenses, and, in addition, with most objectives, flare due to internal reflection would reduce image contrast to an extent possibly unsalvageable even with video contrast enhancement. Again, reduction of $\mathrm{NA}_{\mathrm{cond}}$, generally achieved by closing down the condenser iris diaphragm, tends

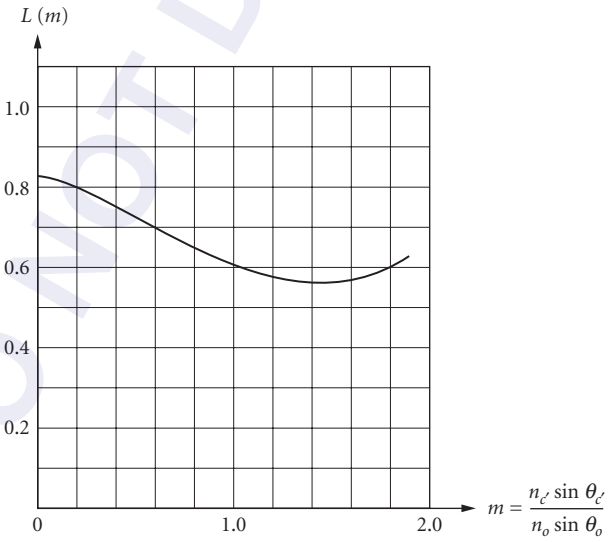

FIGURE 5 Effect of the condenser aperture on the resolution of two pinholes of equal brightness. m is the ratio of the numerical apertures of condenser to objective. L is the minimum resolved distance between the pinholes (Rayleigh criterion) in units of the wavelength divided by the objective aperture.[17]

to raise image contrast so that even experienced microscopists tend to use an $NA_{cond} \approx (0.3, \ldots, 0.5) \times NA_{obj}$ to obtain a compromise between resolution and visibility. With video and other modes of electronic enhancement, the loss of contrast can be reversed so that improved lateral, and especially axial, resolution is achieved by using an NA_{cond} that equals, or nearly equals, the NA_{obj}.

Under optimum circumstances, the light source and condenser should be focused for Köhler illumination (Fig. 4) to minimize flare and to improve the homogeneity of field illumination. Alternately, image brightness, especially in the middle of the field, can be maximized by *critical illumination* where the condenser is somewhat defocused from Köhler illumination to produce an image of the source rather than the field diaphragm superimposed on the specimen. Either mode of illumination can yield resolution approximately as given by Eq. (2).

The aperture function of the microscope can become nonuniform, or limited, for a number of reasons. These include misalignment between the objective and condenser lenses; misalignment of the condenser iris (relative to the condenser lens elements); misalignment of the illuminator and condenser axes; tilted objective or condenser lenses or lens elements; nonuniform illumination of the condenser aperture; limited source size; nonuniform intensity distribution in the source; and improper choice, or focusing, of the condenser or source collector. Whether intentional or accidental, these conditions can reduce the effective NA_{cond} and/or induce oblique illumination, thus sacrificing resolution and image quality. An improvement, using a single optical fiber light scrambler, which allows the filling of the full condenser aperture with uniform illumination and little loss of field brightness (especially when using concentrated arc lamps) was introduced by Ellis[18] (also see Figs. 3-13, 3-14 in Ref. 2).

Epi-Illumination In the epi-illumination mode, a beam splitter, part-aperture-filling mirror, or wavelength-discriminating dichromatic (unfortunately often called dichroic) mirror, placed behind the objective lens diverts the illuminating beam (originating from a light source placed in the side arm of the microscope) into the objective lens, which also acts as the condenser (Fig. 6).[19] Alternatively, a second set of lenses and a beam-diverting mirror (both of whose centers are bored out and are arranged coaxially around the objective lens) can provide a larger NA-illuminating beam, much as in dark field illumination in the transillumination mode.

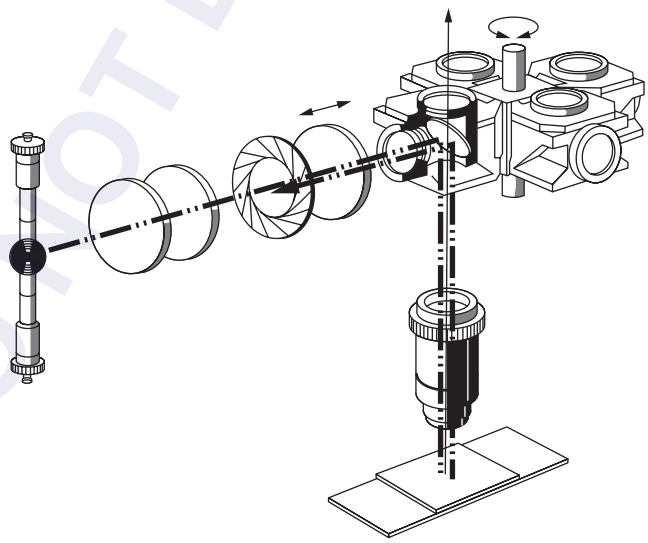

FIGURE 6 Schematic of epi-illuminating light path. The rotatable set of filter cubes with excitation filters, dichromatic mirrors, and barrier filters matched to specific fluorochromes are used in epifluorescence microscopy.[19]

This latter approach limits the maximum NA of the objective lens to around 1.25, but has the advantage that the illuminating beam traverses a path completely isolated from the image-forming beam. When the two beams do pass through the same objective lens, as is the case with most epi-illuminating systems, the lens elements must be carefully designed (by appropriate choice of curvature and use of highly efficient antireflection coating) to reduce hot spots and flare introduced by (multiple) reflection at the lens surfaces. Modern microscope objectives for metallurgical and industrial epi-illuminating systems in particular are designed to meet these qualities. In addition, circular polarizers (linear polarizer plus $\lambda/4$ wave plate) and appropriate stops are used to further exclude light reflected from the surfaces of lens elements, cover glass, and the like. For epi-illumination fluorescence microscopy, dichromatic beam splitters, and barrier filters can reduce background contamination that arises from the exciting beam to less than one part in 10^4.

Orthoscopic versus Conoscopic Imaging The common mode of observation through a microscope is by orthoscopic observation of the focused image. For certain specific applications, particularly with polarizing microscopes, examination of the aperture plane, or conoscopic observation, sheds valuable complementary information.

Conoscopic observation can be made either by replacing the regular ocular with a telescope that brings the aperture plane into focus or by inserting a Bertrand lens (that serves as a telescope objective) in front of a regular ocular. Conversely, one can observe the aperture plane simply by removing the ocular and looking down the microscope body tube (in the absence of a Bertrand lens) or by examining the Ramsden disk above the ocular with a magnifier. Levoy and Oldenbourg used a microlens array for generating a hybrid image that consists of an array of small conoscopic images, each sampling a different object area.[20,21]

The polar coordinates of each point in the aperture plane, that is the radius r and azimuth angle α are related to the rays traversing the specimen by: $r = \sin\theta$ and $\alpha =$ azimuth orientation of the ray projected onto the aperture plane (Fig. 7). Thus, conoscopic observation provides a plane projection of all of the rays traversing the specimen in three-dimensional space. For specimens, such as single crystal flakes or polished mineral sections in which a single crystal is illuminated (optically isolated)

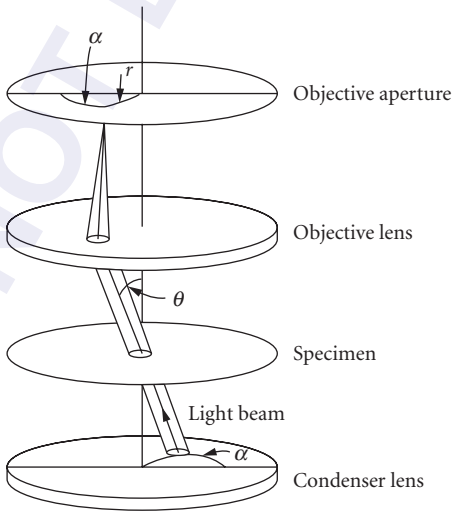

FIGURE 7 Parallel rays with inclination θ and azimuth orientation α traversing the specimen plane, and focused by the objective lens at a point with radius r and same azimuth angle α in the aperture plane.

by closing down the field diaphragm, the conoscopic image reveals whether the crystal is uniaxial or biaxial, its optic axis angle and directions, as well as sign and strength of birefringence and other anisotropic or optically active properties of the crystal.[22]

Conoscopic observation also reveals several attributes of the condenser aperture plane and its conjugate planes (e.g., in Köhler illumination, the plane of the condenser iris diaphragm and the illuminating source). Thus, conoscopy can be used for checking the size, homogeneity, and alignment of the illuminating light source as well as the size and alignment of the condenser iris diaphragm and phase-contrast annulus (located at the front focal plane of the condenser) relative to the objective exit pupil or the phase ring (located at the back focal plane of the objective). It also reveals the state of extinction in polarized light and interference-contrast microscopy and provides a visual estimate of the aperture transfer function for the particular optical components and settings that are used.

The aperture plane of the microscope is also the Fourier plane of the image, so that diffraction introduced by periodic textures in the specimen can be visualized in the aperture plane by conoscopic observation. Depending on the NA of the objective and the spatial period in the specimen, the pattern of diffraction up to many higher orders can be visualized in the aperture plane when the condenser iris is closed down to illuminate the specimen with a parallel beam of light. Closing down the condenser iris restricts the zero-order light to a small area in the aperture plane and higher-order diffraction maxima produce additional images of the diaphragm displaced in the directions of the periodic texture in the specimen.

Microscope Lenses, Aberrations

Objective Lenses With few exceptions, microscope objective lenses are designed to form a diffraction-limited image in a specific image plane that is located at a fixed distance from the objective lens (or from the tube lens in the case of an infinity-focus system). The field of view is often quite limited, and the front element of the objective is placed close to the specimen with which it must lie in optical contact through a medium of defined refractive index n, usually air ($n = 1$, dry objectives), water ($n = 1.33$, water immersion objectives), oil ($n = 1.52$, oil immersion objectives) or other high refractive index media.

Depending on the degree of correction, objectives are generally classified into achromats, fluorites, and apochromats with a plan designation added to lenses with low curvature of field and distortion (Table 1). Some of these characteristics are inscribed on the objective lens barrel, such as Plan Apo 60/1.40 oil 160/0.17, meaning 60 power/1.40 NA Plan Apochromatic objective lens designed to be used with oil immersion between the objective front element and the specimen, covered by an 0.17-mm-thick coverslip, and used at a 160-mm mechanical tube length. Another example might be Epiplan-Neofluar 50×/0.85 ∞/0, which translates to Plan "Fluorite" objective designed for epi-illumination (i.e., surface illumination of specimen through the objective lens rather than through a separate condenser) with a 50× magnification and 0.85 NA to be used in air (i.e., without added immersion medium between the objective front element and coverslip or specimen), with no coverslip, and an (optical) tube length of infinity. "Infinity-corrected" objectives require the use of

TABLE 1 Objective Lens Types and Corrections

Type	Spherical	Chromatic	Flatness
Achromat	*	2λ	No
F-achromat	*	2λ	Improved
Neofluar	3λ	$< 3\lambda$	No
Plan-neofluar	3λ	$< 3\lambda$	Yes
Plan apochromat	4λ	$> 4\lambda$	Yes

* = corrected for two wavelengths at two specific aperture angles.
2λ = corrected for blue and red (broad range of visible spectrum).
3λ = corrected for blue, green, and red (full range of visible spectrum).
4λ = corrected for dark blue, blue, green, and red.

TABLE 2 Common Abbreviations Designating Objective Lens Types

DIC, NIC	Differential (Nomarski) interference contrast
L, LL, LD, LWD, ELWD, ULWD	Long working distance (extra-) (ultra-)
FL, FLUOR, NEOFLUOR, FLUOTAR	With corrections as with "fluorite" objectives but no longer implies the inclusion of fluorite elements
PHASE, PHACO, PC, PH 1, 2, 3, etc.	Phase contrast, using phase condenser annulus 1, 2, 3, etc.
DL, DM, PLL, PL, PM, PH, NL, NM, NH	Phase contrast: dark low, dark medium, positive low low, low, medium, high contrast (regions with higher refractive index appear darker); negative low, medium, high contrast (regions with higher refractive index appear lighter)
PL, PLAN; EF	Flat field; extended field (larger field of view but not as high as with PLAN, achromats unless otherwise desginated)
PLAN APO	Flat field apochromat
NPL	Normal field of view plan
P, PO, POL	Low birefringence, for polarized light
UV	UV transmitting (down to approx. 340 nm), for UV-excited epifluorescence
ULTRAFLUAR	Fluorite objective for imaging down to approx. 250 nm in UV as well as in the visible range
CORR, W/CORR	With correction collar
I, IRIS, W/IRIS	Adjustable NA, with iris diaphragm built into back focal plane
M	Metallographic
NC, NCG	No coverslip
EPI	Surface illumination (specimen illuminated through objective lens), as contrasted to dia- or transillumination
BD, HD	For use in bright or darkfield (hell, dunkel)
CF	Chrome-free (Nikon: objective independently corrected longitudinal chromatic aberrations at specified tube length)
ICS	Infinity color-corrected system (Carl Zeiss: objective lens designed for infinity focus with lateral and longitudinal chromatic aberrations corrected in conjunction with a specified tube lens)
OIL, HI, H; WATER, W; GLY	Oil immersion, Homogeneous immersion, water immersion, glycerol immersion
U, UT	Designed to be used with universal stage (magnification/NA applies for use with glass hemisphere; divide both values by 1.51 when hemisphere is not used)
DI; MI; TI Michelson	Interferometry: noncontact; multiple-beam (Tollanski)
ICT; ICR	Interference contrast: in transillumination; in reflected light

a designated tube lens to eliminate residual aberrations and to bring the rays to focus into the image plane. Several other codes are inscribed or color-coded on microscope objectives (Tables 2 and 3).

Older style objective lenses are designed to be used with a specified group of oculars or tube lenses that are placed at specific distances in order to remove residual errors. For example, compensation oculars were used in conjunction with apochromatic and other high-NA objectives to eliminate lateral chromatic aberration and improve flatness of field. However, modern style objectives together with their tube lenses are typically fully corrected so as not to require additional chromatic or other type corrections.

Coverslip Correction For objective lenses with large NAs, the optical properties and thicknesses of the media lying between its front element and the specimen critically affect the calculations

TABLE 3 Color-Coded Rings on Microscope Objectives

Color code (narrow colored ring located near the specimen end of objective)	
Black	Oil immersion
Orange	Glycerol immersion
White	Water immersion
Red	Special
Magnification color code (narrow band located further away from specimen than immersion code)	
Color	**Magnification**
Black	1, 1.25, 1.5
Brown	2, 2.5
Red	4, 5
Yellow	10
Green	16, 20
Turquoise blue	25, 32
Light blue	40, 50
Cobalt (dark) blue	60, 63
White (cream)	100 and higher

needed to satisfy the aplanatic and sine conditions and otherwise to correct for image aberrations. For homogeneous immersion objectives (that are designed to be used with the refractive indices and dispersion of the immersion oil, coverslip, and medium imbibing the specimen, all matched to that of the objective lens front element), the calculation is straightforward since all the media can be considered an extension of the front lens element.

However, with nonimmersion objectives, the cover glass can become a source of chromatic aberration, which is worse the larger the dispersion and the greater the thickness of the cover glass. The spherical aberration is also proportional to the thickness of the cover glass. In designing objectives not to be used with homogeneous immersion, one assumes the presence of a standard cover glass and other specific optical media between the front lens element and the specimen. As one departs from these designated conditions, spherical aberration (and also coma) increases with the NA of the lens, since the difference between the tangent and sine of the angle of incidence is responsible for departure from the needed sine condition.

It should also be noted that oil immersion objectives fail to provide full correction, or full NA, when the specimen is mounted in an imbibing medium with a different refractive index, for example aqueous media, even with the objective and cover glass properly oil-contacted to each other. With such an arrangement, the diffraction image can degrade noticeably as one focuses into the specimen by as little as a few micrometers.[23] Special water immersion objectives (e.g., Nikon Plan Apo 60×/1.2 NA and short-wavelength transmitting Fluor 40×/1.0 NA, both with collar to correct coverslip thickness deviation from 0.17 mm) overcome such aberrations, even when the specimen is imaged through an aqueous medium of 200-μm thickness.

For lenses that are designed to be used with a standard coverslip of 0.17-mm thickness (and n_D = 1.515), departure from standard thickness is not overly critical for objectives with NA of 0.4 or less. However, for high-NA, nonhomogeneous immersion lenses, the problem becomes especially critical so that even a few micrometers' departure of the cover glass thickness degrades the image with *high-dry objectvies* (i.e., nonimmersion objectives with high NA) of NA above 0.8 (Fig. 8).[24] To compensate for such error, well-corrected, high-dry objectives are equipped with correction collars that adjust the spacing of their intermediate lens elements according to the thickness of the cover glass. Likewise, objective lenses that are made to be viewed through layers of silicon or plastic, or of different immersion media (e.g., water/glycerol/oil immersion lenses), are equipped with correction collars.

The use of objective lenses with correction collars does, however, demand that the observer is experienced and alert enough to reset the collar using appropriate image criteria. Also, the focus tends to shift, and the image may wander, during adjustment of the correction collar. Figure 9 shows an

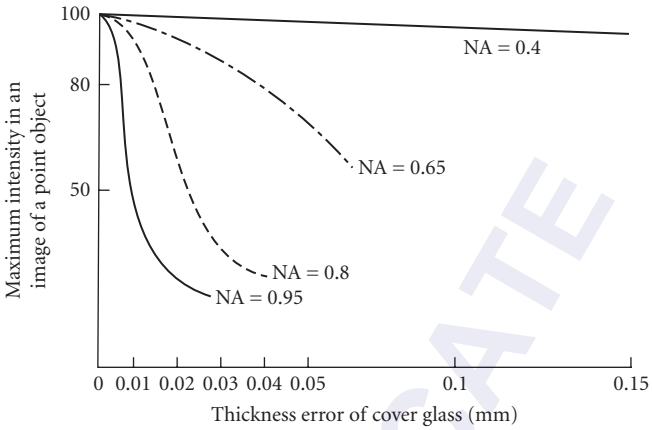

FIGURE 8 Calculated maximum intensity in the image of a point object versus the deviation of the coverglass thickness from the ideal thickness.[24]

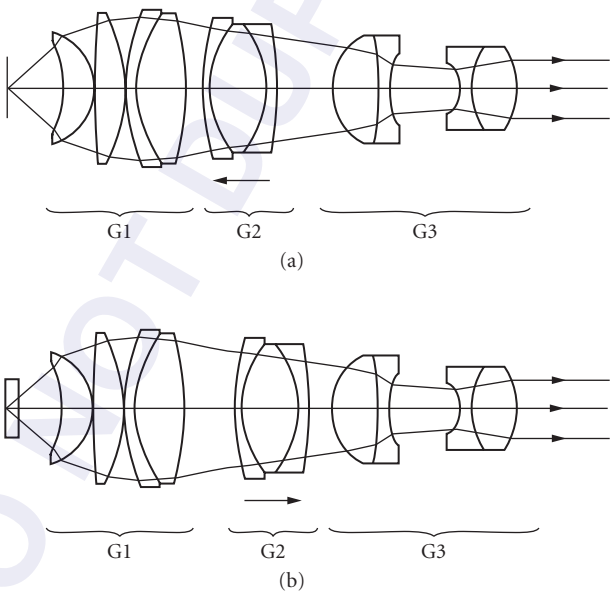

FIGURE 9 High-dry objective lens (60×/0.7 NA) equipped with a correction collar for (*a*) focusing at the surface or (*b*) through plane glass of up to 1.5-mm thickness. The lens group G_2 is moved forward to enhance the spherical and chromatic correction by G_1 and G_2 when focused on the surface, while it is moving backward to compensate for the presence of the glass layer when focusing deeper through the glass.[24] (*U.S. Patent 4666256.*)

TABLE 4 Reference Focal Lengths for Infinity-Focused Objective Lenses

Leica	200 mm	B, M

Carl Zeiss	164.5 mm	B, M
Nikon	200 mm	B, M

B = biological, M = metallurgical.

example of a 60/0.7 objective lens equipped with a correction collar for focusing at the surface or through a cover glass of up to 1.5-mm thickness without altering the focal setting of the lens.

Tube Lengths and Tube Lenses for Which Microscope Objectives Are Corrected For finite-focused "biological" objective lenses, most manufacturers had standardized the mechanical tube length to 160 mm. More recently most manufacturers have switched to infinity focus for their biomedical and metallurgical microscopes.

For infinity-focused objective lenses, the rays emanating from a given object point are parallel between the objective and tube lens. Since the physical distance (D_p, Fig. 3) and optical path length between the objective and tube lens are not critical, optical plane-parallel components, such as compensators, analyzers, and beam splitters, can be inserted in this space without altering the objective's corrections. The tube lens focuses the parallel rays onto the intermediate image plane.

The magnification of an infinity-focused objective lens is calculated by dividing the focal length of the tube lens (also called reference focal length) by the focal length of the objective lens. The reference focal lengths adopted by several manufacturers are listed in Table 4.

Working Distance Microscope objectives are generally designed with a short free working distance, that is the distance from the front element of the objective lens to the surface of the cover glass or, in the case of lenses that are designed to be used without cover glass, to the specimen surface. For some applications, however, a long free working distance is indispensable, and special objectives are designed for such use despite the difficulty involved in achieving large numerical apertures and the needed degree of correction.

Field Size, Distortion The diameter of the field in a microscope is expressed by the field-of-view number, or simply field number, which is the diameter of the field in millimeters measured in the intermediate image plane. The field size in the object plane is obviously the field number divided by the magnification of the objective. While the field number is often limited by the magnification and field stop of the ocular, there is clearly a limit that is also imposed by the design of the objective lens. In early microscope objectives, the maximum usable field diameter tended to be about 18 mm or considerably less, but with modern plan apochromats and other special flat field objectives, the maximum usable field can be as large as 28 mm or more. The maximum useful field number of objective lenses, while available from the manufacturers, is unfortunately not commonly listed in microscope catalogs. Acknowledging that these figures depend on proper combination with specific tube lenses and oculars, we should encourage listing of such data together with, for example, UV transmission characteristics (e.g., as the wavelength at which the transmission drops to 50 percent, or some other agreed upon fraction).

Design of Modern Microscope Objectives Unlike earlier objective lenses in which the reduction of secondary chromatic aberration or curvature of field were not stressed, modern microscope objectives that do correct for these errors over a wide field tend to be very complex. Here we shall examine two examples, the first a 60/1.40 Plan Apochromat oil-immersion lens from Nikon (Fig. 10).[24]

Starting with the hyperhemisphere at the front end (left side of Fig. 10) of the objective, this aplanatic element is designed to fulfill Abbe's sine condition in order to minimize off-axis spherical aberration and coma, while providing approximately half the total magnifying power of the objective (Fig. 11). In earlier designs, the hyperhemisphere has been made with as small a radius

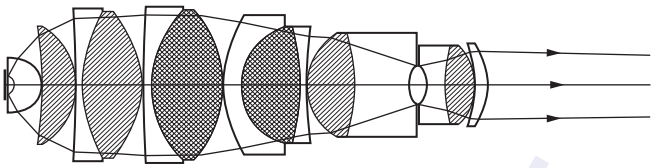

FIGURE 10 Design of Nikon Plan Apochromat oil-immersion objective with 60× magnification and 1.40 NA.[24]

as possible in order to maximize its magnifying power and to minimize its spherical and chromatic aberrations, since these aberrations increase proportionally with the focal length of the lens. Modern demands for larger field size and reduced curvature of field, however, introduce a conflicting requirement, namely, the need to maintain as large a radius as practical in order to minimize the hyperhemisphere's contribution to the Petzval sum (the algebraic sum of the positive and negative curvatures multiplied by the refractive indices of the lens elements).[25] The hyperhemisphere in these Plan Apochromats is made with a high-index, low-dispersion material to compensate for the greater radius. Additionally, a negative meniscus is generated in the front surface of the hyperhemisphere to which is cemented a minute, plano-convex lens. The negative curvature in the hyperhemisphere contributes to the reduction of the Petzval sum. At the same time the minute plano-convex lens protects the material of the hyperhemisphere which is less resistant to weathering. Index matching between the minute plano-convex lens and immersion oil eliminates or minimizes the refraction and reflection at the lens-oil interface and provides maximum transmission of the all-important high-NA rays into the objective lens. The index matching also reduces the influence of manufacturing errors of this minute lens element on the performance of the objective.

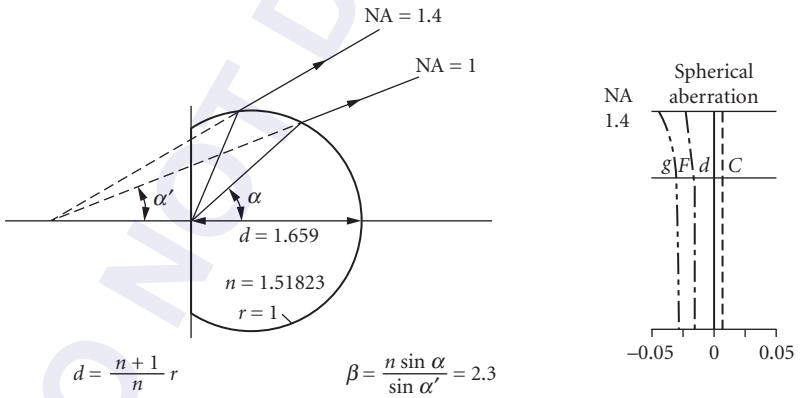

FIGURE 11 Aplanatic condition of the hyperhemisphere placed at the front end of an oil-immersion objective. The front lens has the same refractive index as the coverglass and immersion oil. The aplanatic condition describes the necessary relationship between refractive index n, distance d between object and spherical surface, and radius r of the spherical surface, in order to make all rays emanating from an object point on the axis leave the hemispherical surface after refraction without introducing spherical aberration. According to the sine condition, the magnification β has to be constant for all angles α. On the right, the small amount of longitudinal spherical aberration and chromatic deviation due to dispersion from the ideal focus point of the hyperhemisphere is shown for different wavelengths (λ_C = 656 nm, λ_d = 588 nm, λ_F = 486 nm, λ_g = 436 nm). Abscissa: longitudinal deviation on lens axis. Ordinate: numerical aperture from 0 (lens axis) to 1.4 NA.[24]

The low-dispersion-glass singlet behind the aplanatic hyperhemisphere further reduces the cone angle of the rays entering the doublets that follow, allowing these and the subsequent lenses to concentrate on correcting axial and lateral chromatic aberration as well as curvature of field. These errors, as well as residual spherical aberrations, are corrected by inclusion of low-dispersion positive and high-dispersion negative lens elements, use of thick-lens elements, appropriate placement of positive and negative lens curvatures, and through extensive ray tracing. Near the exit pupil, the height of the ray paths through the concave surfaces is reduced in order to generate additional negative values that minimize the Petzval sum (to complement the inadequate negative contribution made by the concave surface in the hyperhemisphere), so that field flatness can be improved without overly reducing the objective lens' magnifying power or adding to its spherical aberration.

In reality, the Petzval sum of the objective as a whole is made somewhat negative in order to compensate for the inevitable positive Petzval sum contributed by the ocular. Thus, the image at the intermediate image surface, especially the sagittal surface of modern objectives, bows away from the object. Unless the image area is relatively small, one needs to use specified oculars in order to attain maximum field flatness combined with optimum correction otherwise.

Unlike earlier objective lenses whose design did not appreciably vary from one manufacturer to another, the design of lenses in modern microscope objectives can vary considerably. For example, compare the Nikon Chrome Free 60/1.4 Plan Apo objective discussed above and the Zeiss Infinity Color-Corrected Systems 63/1.4 Plan Apo objective in Fig. 12. Both are excellent, state-of-the-art lenses. But in addition to general design philosophy, including the decision to avoid or to use tube lenses to achieve full chromatic corrections, other factors such as choice of optical elements with special dispersion characteristics; degrees of UV transmission; freedom from fluorescence, birefringence, aging loss of transmittance, and the like all affect the arrangement of choice.

While a modern research-grade microscope is corrected to keep the aberrations from spreading the image of a point source beyond the Airy disk, geometrical distortion of the image formed by microscope objectives tends not to be as well-corrected (e.g., compared to photographic objectives at the same picture angle). Thus, in objectives for biological use, pincushion distortions of up to 1 percent may be present. However, in objectives that are designed for imaging semiconductors, the distortion may be as low as 0.1 percent and they can be considered nearly distortion-free. To reduce stray light and flare, modern microscope objectives contain lens elements with carefully tuned, antireflection coatings, and lens curvatures are selected to minimize ghost images arising from multiple reflections.

Given the sophisticated design to provide a wide flat field, with spherical aberrations corrected over a broad wavelength range, and with low longitudinal as well as chromatic aberrations corrected at high NA, the aberration curves of these modern microscope objectives no longer remain simple cubic curves, but turn into complex combinations of higher-order curves (Fig. 13).

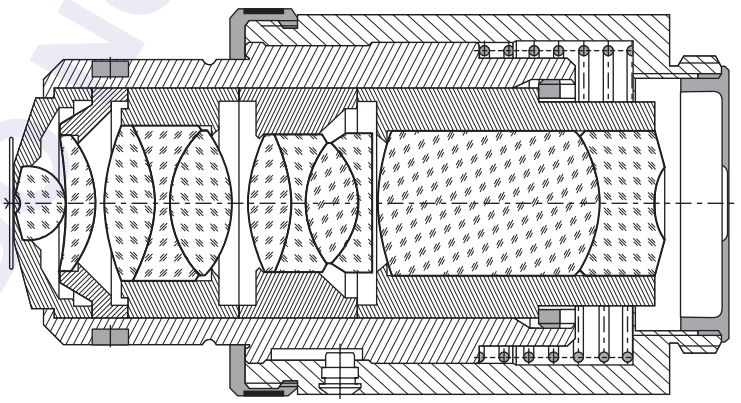

FIGURE 12 Carl Zeiss Infinity Color-Corrected 63/1.4 Plan Apo objective. (*Courtesy of E. Keller, Carl Zeiss, N.Y.*)

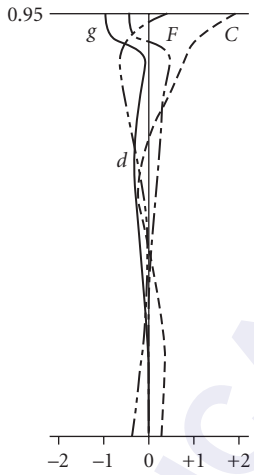

FIGURE 13 Spherical aberration curves for spectral lines (*C, d, F,* and *g*) of a highly corrected modern microscope objective with a high numerical aperture.[24] Ordinate: numerical aperture from 0 (lens axis) to NA = 0.95. Abscissa: longitudinal deviation of focal distance on lens axis indicated in millimeters. (The depth of focus for a 40×/0.95 NA apochromatic objective is approximately 1 mm which corresponds to a depth of field of 0.6 um in specimen space.)

Oculars As conventionally illustrated, the ocular in a light microscope further magnifies the primary (intermediate) image formed by the objective lens (Figs. 2 and 3). The ocular can also be viewed as the front elements of a macro (relay) lens system made up of the ocular plus the refractive elements of the viewer's eye (Fig. 4*a*) or a video or photographic camera lens. Special video and photo oculars combine these functions of the ocular plus the video or photo lenses into single units.

The intermediate image plane (that lies between the lenses in many ocular types or precedes the lens elements in the Ramsden-type oculars), or its conjugate plane is used to place field-limiting stops, iris diaphragms, reticles, micrometer scales, comparator beam splitters, and the like that need to appear in the same focal plane as the specimen.

The Ramsden disk, the exit pupil of the objective lens imaged by the ocular, generally appears a short distance above the ocular (Fig. 4*b*). Since the Ramsden disk should lie in the observer's pupil, special high-eye-point oculars are provided for the benefit of observers wearing corrective eye glasses (especially those for astigmatism). High-eye-point oculars are also used for inserting beam-deviating devices (such as the scanning mirrors in laser scanning confocal microscopes) or aperture-modifying devices (such as aperture occluders for stereo viewing through single objective binocular microscopes[2]).

The magnification of an ocular is defined as 25 cm divided by the ocular's focal length. On the ocular, the magnification and field number are inscribed (e.g., as 10×/20, meaning 10-power or 25-mm focal length with a field of view of 20-mm diameter), together with manufacturer's name and special attributes of the ocular such as chromatic-aberration-free (CF), wide-field (W, WF, EWF), plan (P, Pl), compensation (Comp, C, K), high-eye-point (H, picture of glasses), with cross hair and orientation stub for crystallography (pol), projection (pro), photographic (photo), video (TV), and the like. Also, special oculars provide larger and flatter fields of view (designated wide field, extra wide field, plan, periplan, hyperplan, etc., some with field numbers ranging up to 28 mm).

Compared to microscope objective lenses, fewer design standards have been adopted and fewer standard abbreviations are used to designate the performance or function of the oculars. Two physical parameters of the oculars have, however, become more or less standardized. The outside diameter of the ocular is either 23.2 mm or 30.0 mm, and the reference distance, or the parafocalizing distance of the ocular (i.e., the location of the intermediate image plane below the flange of the ocular) is now generally set to 10 mm.

In the past, oculars with wide ranges of incremental magnifications were provided to adjust the total image magnification of the microscope, but this practice is now replaced by the use of much fewer, better-corrected oculars coupled with a telan magnification changer in the microscope's body tube, or a zoom projection ocular.

Factors affecting choice of ocular focal length and magnification include optimizing the microscope total magnification and image resolution to match the MTF characteristics of the detector and to adjust the available field coverage. In video-enhanced fluorescence, differential interference contrast, polarizing, dark field, and the like microscopy, the total magnification often needs to be raised beyond the classical "empty magnification" limit, in order to be able to visualize minute objects whose diameters lie well below the limit of microscope resolution.[2] However, depending on the MTF characteristics, sensitivity, and total pixels available in the sensor, conflicts may arise between the need for greater magnification, image brightness, and field coverage. To optimize the total image magnification, fine trimming of the ocular magnification may be needed, in addition to choosing an objective with the appropriate magnification and NA-to-magnification ratio. Zoom oculars are especially suited for fine-tuning the magnification to optimize S/N ratio and image integration time in video microscopy. For very low light level images, for example in photon-counting imaging, ocular magnifications of less than one may be needed in order to sufficiently elevate the S/N ratio, albeit at a sacrifice to spatial resolution.

In addition to adjusting image magnification and placing the microscope's exit pupil at a convenient location, the ocular compensates for the aberrations that have not been adequately corrected in the objective and tube lens. Huygens oculars combined with lower-power achromatic objectives, and compensating oculars combined with higher-NA achromatic and apochromatic objectives, correct for lateral chromatic aberration. Some higher-NA achromatic objectives are purposely designed to provide residual aberrations (including field curvature) that are similar to those in the apochromats, so that the same compensation oculars can be used to compensate for both types of objectives.

Modern objectives used with the appropriate tube lens are sufficiently well corrected to require minimum or no compensatory correction by the oculars. In research-grade microscopes, the image projected by the objective and tube lens is often recorded directly by placing an electronic image sensor into the intermediate image plane. With objectives that are designed to produce well-corrected intermediate images, oculars themselves are made independently free of lateral and longitudinal chromatic and some spherical aberrations. Regardless of the degree of correction relegated to the ocular, modern microscopes provide images with color corrections, fields of view, and flatness of field much superior to earlier models.

Resolution

Airy Disk and Lateral Resolution Given a perfect objective lens and an infinitely small point of light residing in the specimen plane, the image formed in the intermediate image plane by the objective lens is not another infinitely small point, but a diffraction image with a finite spread (Fig. 14*a*). This Airy diffraction image is the Fraunhofer diffraction pattern formed by the exit pupil of the objective lens from which spherical waves converge to the focal point. The distribution of irradiance of the diffraction image (Fig. 14*b*)[26] is given by an expression containing the first-order Bessel function $J_1(v)$:

$$I(v) = I_0\left(\frac{2J_1(v)}{v}\right)^2 \tag{3}$$

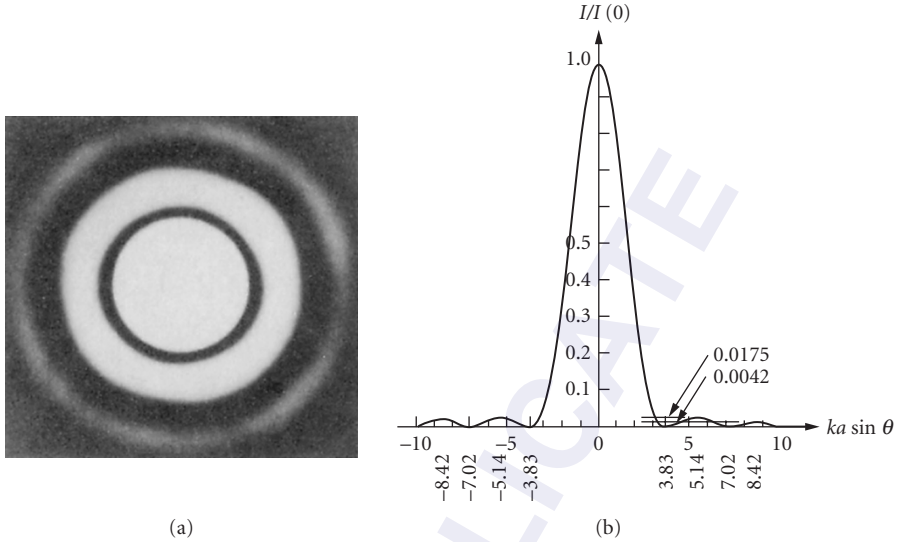

FIGURE 14 Airy pattern of circular aperture: image (*a*) of central Airy disk, first dark ring and subsidiary maximum and graph (*b*) of radial intensity distribution.[26]

with v proportional to the diffraction angle. If the irradiance is calculated as a function of radius measured from the center of the Airy diffraction pattern located in the intermediate image plane, v takes on the form

$$v = 2\pi \frac{\text{NA}}{M\lambda} r_i \tag{4}$$

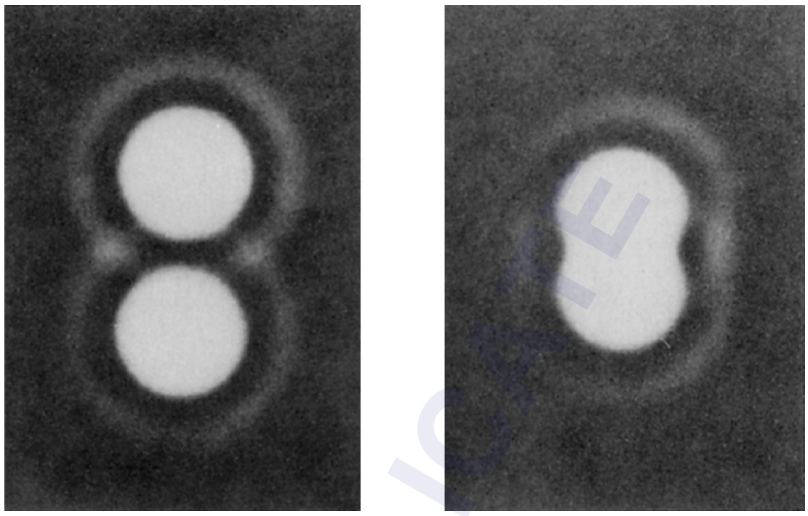
where NA is the numerical aperture and M the magnification of the objective lens, λ the wavelength of light, and r_i the radial distances measured in the intermediate image plane. If we express r_i as a distance r_o in the object plane, with $r_i = M\, r_o$, we obtain the more familiar relationship:

$$v = 2\pi \frac{\text{NA}}{\lambda} r_o \tag{5}$$

The central bright disk of the diffraction image is known as the Airy disk, and its radius (the radius from the central peak to the first minimum of the diffraction image) in object plane units is given by

$$r_{\text{Airy}} = 0.61 \frac{\lambda}{\text{NA}} \tag{6}$$

When there exist two equally bright, self-luminous points of light separated by a small distance d in object space, that is the specimen plane, their diffraction images lie side by side in the image plane. The sum of the two diffraction images, assuming the two points of light were mutually incoherent, appears as in Fig. 15*a*. As d becomes smaller so that the first minimum of one diffraction image overlaps with the central maximum of the neighboring diffraction image ($d = r_{\text{Airy}}$, Fig. 15*b*),[26] their sum (measured along the axis joining the two maxima) still contains a dip of 26.5 percent of the peak intensities that signals the twoness of the source points (the Rayleigh criterion). Once d becomes less than this distance, the two diffraction images rapidly pass a stage where instead of a small dip, their sum shows a flat peak (the Sparrow criterion) at $d = 0.78\, r_{\text{Airy}}$, and thereafter the sum of the diffraction images appears essentially indistinguishable from one arising from a single point source instead of two. In other words, we can no longer resolve the image of the two points once they are closer than the Rayleigh criterion, and we loose all cues of the twoness at spacings below



(a) (b)

FIGURE 15 Overlapping Airy patterns: (*a*) clearly resolved and (*b*) center of Airy patterns separated by $d = r_{Airy}$, Rayleigh criterion.[26]

the Sparrow criterion. Since the diameter of the Airy diffraction image is governed by NA_{obj} and the wavelength of the image-forming light λ, this resolution limit normally cannot be exceeded (for exceptions, see the section "Beyond the Diffraction Limit" later in this chapter).

The consideration given here for two-point sources of light applies equally well to two absorbing dots, assuming that they were illuminated incoherently. (Note, however, that it may, in fact, be difficult or impossible to illuminate the two dots totally incoherently since their spacing may approach the diameter of the diffraction image of the illuminating wave. For the influence of the condenser NA on resolution in transillumination, refer to the section on "Transillumination" earlier in this chapter. Also, the contrast of the diffraction images of the individual absorbing dots diminishes rapidly as their diameters are decreased, since the geometrical size of such small dots would occupy a decreasing fraction of the diameter of their diffraction images. For further detail see.)[27]

The image of an infinitely small point or line thus acquires a diameter equal to that of the Airy disk when the total magnification of the image becomes sufficiently large so that we can actually perceive the diameter of the Airy disk. In classical microscopy, such a large magnification was deemed useless and defined as empty magnification. The situation is, however, quite different when one is visualizing objects smaller than the limit of resolution with video microscopy. The location of the Airy disk can, in fact, be established with very high precision. Distances between lines that are clearly isolated from each other can, therefore be measured to a precision much greater than the resolution limit of the microscope. Also, minute movements of nanometer or even Ångstrom steps have been measured with video-enhanced light microscopy using the center of gravity of the highly magnified diffraction image of marker particles (see "Beyond the Diffraction Limit" later in this chapter).

Three-Dimensional Diffraction Pattern, Axial Resolution, Depth of Focus, Depth of Field The two-dimensional Airy pattern that is formed in the image plane of a **point object** is, in fact, a cross section of a three-dimensional pattern that extends along the optical axis of the microscope. As one focuses an objective lens for short distances above and below exact focus, the brightness of the central spot periodically oscillates between bright and dark as its absolute intensity also diminishes. Simultaneously, the diameters of the outer rings expand, both events taking place symmetrically above and below the plane of focus in an aberration-free system (Fig. 16).[28]

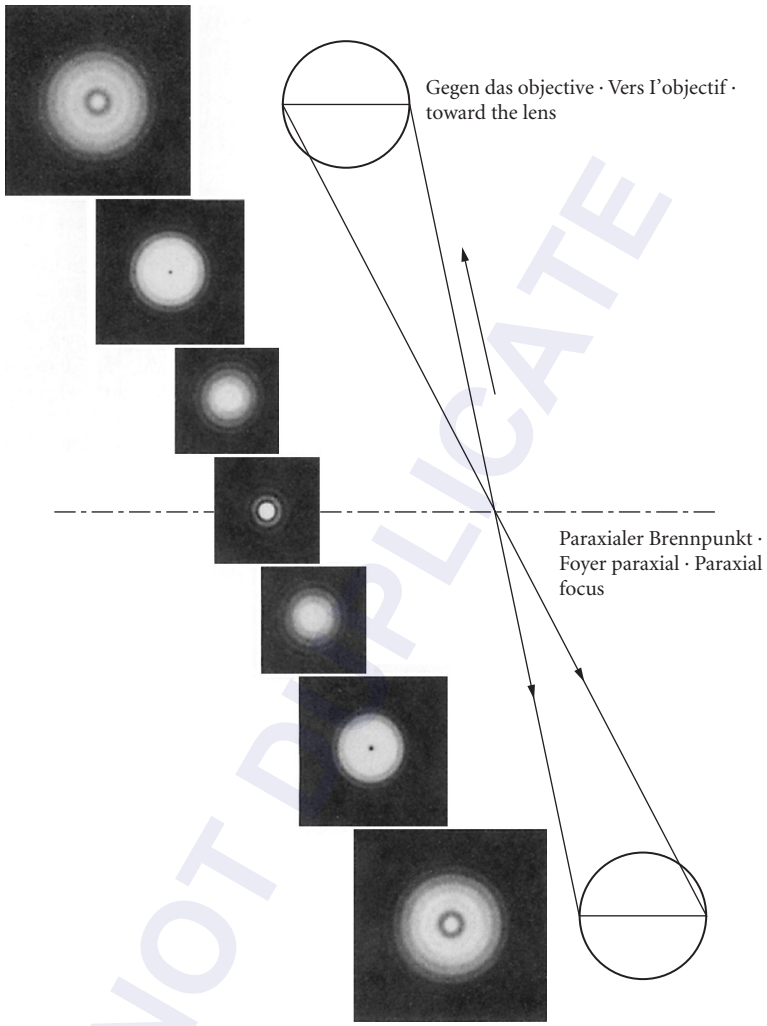


FIGURE 16 The evolution of the diffraction image of a circular aperture with differing planes of focus in an aberration-free system.[28]

Figure 17 shows an isophote (lines of equal brightness) of the longitudinal section of this three-dimensional diffraction image. The relationship between v and the lateral distance r_i is given by Eq. (4). The axial distance z_i, oriented perpendicular to the image plane, is related to u by

$$u = 2\pi \frac{\mathrm{NA}^2}{M^2 \lambda} z_i \tag{7}$$

In the graph we recognize at $v = 1.22\pi$ (and $u = 0$, focal plane) the first minimum of the Airy pattern which we discussed in the preceding section. The intensity distribution along u perpendicular to the focal plane has its first minima at $u = \pm 4\pi$ and $v = 0 (\pm z_1$ in Fig. 17*a*). To find the actual extent of the three-dimensional diffraction pattern near the intermediate plane of the microscope, we express the dimensionless variables v and u of Fig. 17*c* as actual distances in image space.

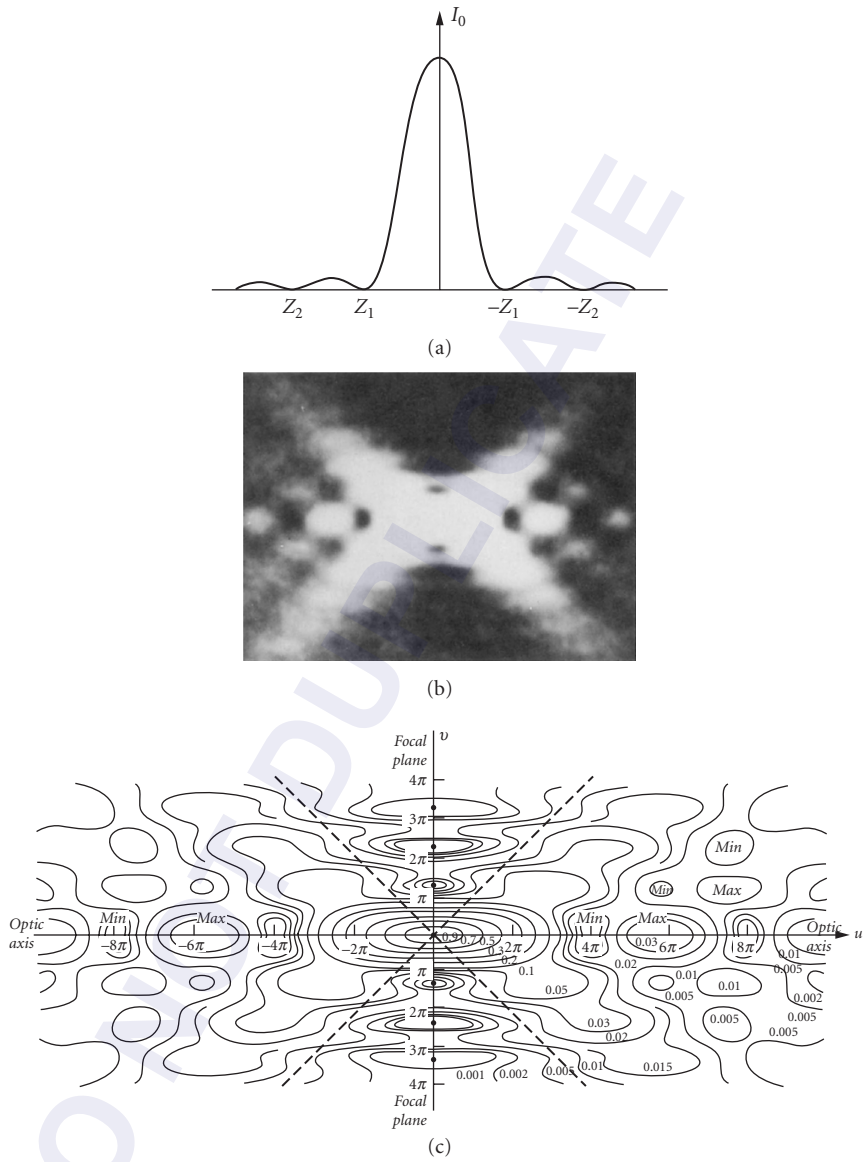

FIGURE 17 (*a*) Axial intensity distribution of irradiance near focal point;[23] (*b*) meridional section through diffraction pattern near focal point of a point source of light focused by lens with a uniform circular aperture;[23] and (*c*) contour plot (isophote) of the same cross section as in (*b*).[17,23,29] The three-dimensional diffraction pattern is obtained by rotating the meridional section around the optic axis. The three-dimensional diffraction pattern is also called the intensity point spread function.

The first minimum ($u = 4\pi$) is at a distance $z_1 = (2M^2\lambda)/\mathrm{NA}^2$. To transfer distance z_i in image space to distance z_o in object space, we use the relationship $z_i = z_o M^2/n$. (Note that for small axial distances, to a close approximation, the axial magnification is the square of the lateral magnification M divided by the refractive index n of the object medium.) The distance from the center of the three-dimensional diffraction pattern to the first axial minimum in object space is then given by:

$$z_{\min} = 2\frac{\lambda n}{\mathrm{NA}^2} \tag{8}$$

$z_{\min}$ corresponds to the distance by which we have to raise the microscope objective in order to change from exact focus of a small pinhole to the first intensity minimum in the center of the observed diffraction pattern (see Fig. 16).

In correspondence to the lateral resolution limit, which is taken as the Airy disk radius r_{Airy} [Eq. (6)], we can use $z_{\min}$ as a measure of the limit of *axial resolution* of microscope optics. Note that the ratio of axial to lateral resolution ($z_{\min}/r_{\mathrm{Airy}} = 3.28\ n/\mathrm{NA}$) is inversely proportional to the numerical aperture of the objective lens.

The axial resolution of the microscope is closely related to the depth of focus, which is the axial depth on both sides of the *image* plane within which the image remains acceptably sharp (e.g., when a focusing screen at the image plane is displaced axially without moving the object or objective). The *depth of focus D* is usually defined as 1/4 of the axial distance between the first minima above and below focus of the diffraction image of a small pinhole. In the intermediate image plane, this distance is equal to $z_1/2$, with z_1 defined earlier. The depth of focus defined by z_1 is the *diffraction-limited*, or physical, depth of focus.

A second and sometimes dominating contribution to the total depth of focus derives from the lateral resolution of the detector used to capture the image. This geometric depth of focus depends on the detector resolution and the geometric shape of the light cone converging to the image point. If the detector is placed in the intermediate image plane of an objective with magnification M and numerical aperture NA, the geometrical depth of focus D is given by

$$D = \frac{M}{\mathrm{NA}}e \tag{9}$$

with e the smallest distance resolved by the detector (e is measured on the detector's face plate).

The depth in *specimen* space that appears to be in focus within the image, without readjustment of the microscope focus, is the depth of field (unfortunately often also called the depth of focus). To derive expressions for the depth of field, we can apply the same arguments as outlined above for the depth of focus. Instead of moving the image plane in and out of focus, we keep the image plane in the ideal focus position and move the small pinhole in object space. Axial distances in object space, however, are a factor n/M^2 smaller than corresponding distances in image space. Therefore, we apply this factor to the expression for the geometrical depth of focus [Eq. (9)] and add the physical depth of field [derived from Eq. (8)] for the total depth of field d_{tot}:

$$d_{\mathrm{tot}} = \frac{\lambda n}{\mathrm{NA}^2} + \frac{n}{M\mathrm{NA}}e \tag{10}$$

Notice that the diffraction-limited depth of field shrinks inversely proportionally with the square of the NA, while the lateral limit of resolution is reduced inversely proportionally to the first power of the NA. Thus, the axial resolution and thinness of optical sections that can be attained are affected by the system NA much more so than is the lateral resolution of the microscope.

These values for the depth of field, and the distribution of intensities in the three-dimensional diffraction pattern, are calculated for incoherently illuminated (or emitting) point sources (i.e., $\mathrm{NA}_{\mathrm{cond}} \geq \mathrm{NA}_{\mathrm{obj}}$). In general, the depth of field increases, up to a factor of 2, as the coherence of illumination increases (i.e., as $\mathrm{NA}_{\mathrm{cond}} \to 0$). However, the three-dimensional point spread function with partially coherent illumination can depart in complex ways from that so far discussed when

the aperture function is not uniform. In a number of phase-based, contrast-generating modes of microscopy, the depth of field may turn out to be unexpectedly shallower than that predicted from Eq. (9) and may yield extremely thin optical sections.[30]

Beyond the Diffraction Limit In recent years the microscope's limit of resolution, as stated in Eq. (1), has been exceeded by different means, relying either on optical, photophysical, photochemical, or computational methods, or a combination thereof. Here we briefly refer to some of the schemes that rely on photonic properties of the specimen, while later in this chapter we will touch on schemes that rely on far-field optical methods, such as structured illumination and confocal microscopy.

Driven by the success of fluorescence microscopy in biomedical research and the need for higher resolution to understand the molecular machinery of the living cell, several methods were devised that exploit the photophysical and photochemical nature of fluorescent molecules. Most of these "super-resolving" methods take advantage of the fact that the position of a single fluorescent molecule (or point of light) can be determined to a much higher precision than the optical resolution of an imaging system. While the resolution of a traditional microscope, as described by Eq. (1), typically does not exceed 200 nm, the same microscope can be used to determine the position of a single fluorophore to 20 nm or better, depending on the number of photons captured and the mobility of the fluorescent molecule.[31,32] Here we briefly describe those methods that have become prominent and are recognized by their acronyms. For a more detailed discussion we refer to a number of excellent reviews[33–36] and to the original publications cited below.

Fluorescence imaging with one nanometer accuracy (FIONA) was introduced to measure the detailed stepping motion of a molecular motor (myosin V) along an immobilized track (filamentous actin).[37] The detailed, hand-over-hand motion was determined by measuring the location of a single fluorophore, attached to the motor-protein, with a spatial resolution of 1.5 nm and a temporal resolution of 0.5 s. The challenge here included the recording of a sufficient number of photons, within the 0.5 s time window, to localize a single fluorophore that also needed to be photostable enough to allow its observation over several minutes.

Photo-activated localization microscopy (PALM) was introduced to localize immobilized fluorophores at nanometer spatial resolution.[38] To this end, fluorophores are used that have to be photoactivated to become fluorescent. A low dose of typically short wavelength light activates a small, random subset of fluorophores that are spaced far enough for their point spread functions to not overlap. The locations of activated fluorophores are measured at nanometer precision and during the measurement process fluorophores become irreversibly bleached. The cycle of low-dose activation and subsequent position measurements is repeated many times and the aggregate position information from all cycles is assembled into a single, super-resolution image.

Stochastic optical reconstruction microscopy (STORM) uses similar principles as PALM but exploits photo-switchable fluorophores that can be turned on and off by exposing them to light pulses of differing wavelengths.[39]

Single molecule high-resolution colocalization (SHREC) takes advantage of separating the fluorescence of two or more single fluorophores by their spectral characteristics.[40] By using chromatically differing fluorescent molecules as probes, the probes can approach each other closer than the Rayleigh limit and still be distinguished. The technique is typically used to measure intramolecular distances of 10 nm or more in doubly labeled macromolecules or molecular complexes.

Fluorescence resonance energy transfer or Förster resonance energy transfer (FRET) refers to a photophysical effect that transfers the excitation energy of a fluorescent donor molecule to a nearby fluorescent acceptor molecule. The appropriately chosen donor and acceptor molecules have to be less than 10 nm apart for the radiationless transfer to be effective. For example, FRET can be used to analyze the conformational change of a protein that brings two molecular subunits closer together or farther apart, resulting in enhanced or reduced acceptor fluorescence, respectively. Hence, FRET is a ratiometric method that allows measurement of the internal distance in the molecular frame rather than in the laboratory frame, which makes it largely immune to instrumental noise and drift. While regular FRET reveals the population distributions of interdye distances, single molecule FRET is used to monitor single molecules for long stretches of time.[41,42]

Stimulated emission depletion (STED) provides a means of point spread function engineering to improve the optical resolution beyond the diffraction limit. A typical single-point scanning STED microscope uses a regularly focused excitation beam that is superimposed by a doughnut-shaped STED beam that instantly quenches excited molecules at the periphery of the excitation spot, thus confining fluorescence emission to the doughnut zero. Saturated quenching results in a fluorescent spot far below diffraction whose scanning across the sample yields a subdiffraction-resolution image.[34,43]

All the above methods rely on fluorescence microscopy. A general approach to improve resolution was proposed by Harris[44] who argued that the diffraction pattern in the Fourier plane can be extrapolated beyond the spatial frequency that is cut off by the NA of the objective lens—in other words, that the limit of resolution can be exceeded by computational extrapolation of the diffraction orders as long as the specimen is illuminated in a narrowly limited field.

The field of illumination can be reduced beyond that defined by diffraction by placing the minute exit aperture of a tapered light guide or a minute pinhole closely adjacent to the specimen. By scanning such an aperture relative to the specimen, one obtains a proximity-scanned image whose resolution is no longer limited by the diffraction orders captured by the objective lens. Instead, only the size of the scanning pinhole and its proximity to the specimen limit the resolution.[45]

For nonoptical microscopes, for example in scanning tunneling, force, and other proximity-scanning microscopes, resolution down to atomic dimensions can be obtained on images that reflect topological, electronic, ionic, and mechanical properties of the specimen surface.[46] In these types of proximity-scanning microscopes, a fine-tipped probe, mounted on a piezoelectric transducer that provides finely controlled *x, y*, and *z* displacements of the probe, interacts with specific properties of the specimen surface (alternatively, the probe may be fixed and the sample mounted to the transducer). The resulting interaction signal is detected and fed back to the *z*-axis transducer, which generally induces the probe tip to rise and fall with the surface contour (that reflects the particular electrical or mechanical property of the surface) as the probe is scanned in a raster fashion along the *x* and *y* directions over an area several tens of angstroms to several tens of micrometers wide. A highly magnified contour image of the atomic or molecular lattices is generated on a monitor that displays the *z* signal as a function of the *x, y* position.

28.4 CONTRAST AND IMAGING MODES

In microscopy, the generation of adequate and meaningful contrast is as important as providing the needed resolution. Many specimens are practically transparent and differ from their surroundings only by slight changes in refractive index, absorbance, reflectance, or optical anisotropy such as birefringence and dichroism. Most objects that are black or show clear color when reasonably thick become transparent or colorless when their thickness is reduced to a few tenths of a micrometer (since absorption varies exponentially with thickness). Additionally, in microscopy the specimen is often illuminated using a highly convergent beam to maximize resolution, thus reducing shadows and other contrast cues that aid detection of objects in macroscopic imaging. Furthermore, contrast is reduced at high spatial frequency because of an inherent fall-off of the contrast transfer function.

Many modes of contrast generation are used in microscopy partly to overcome these limitations and partly to measure, or detect, selected optical characteristics of the specimen. Thus, in addition to simply raising contrast to make an object visible, the introduction of contrast that reflects a specific physical or chemical characteristic of the specimen may impart particularly important information.

As a quantitative measure of expected contrast generation as functions of spatial frequencies, the modulation transfer functions (MTFs, of sinusoidal gratings) can be calculated theoretically for various contrast-generating modes assuming ideal lenses (Figs. 18 and 19),[47,48] or on the basis of measured point or line spread functions.[49] Alternatively, the contrast transfer function (CTF, of square wave gratings) can be measured directly using test targets made by electron lithography (Fig. 20).[50]

The rapid advance of electronic imaging and digital image processing in recent years made the quantitative evaluation of microscope images much more practical. Many computerized image-processing platforms provide standard functions to characterize the morphology and geometric

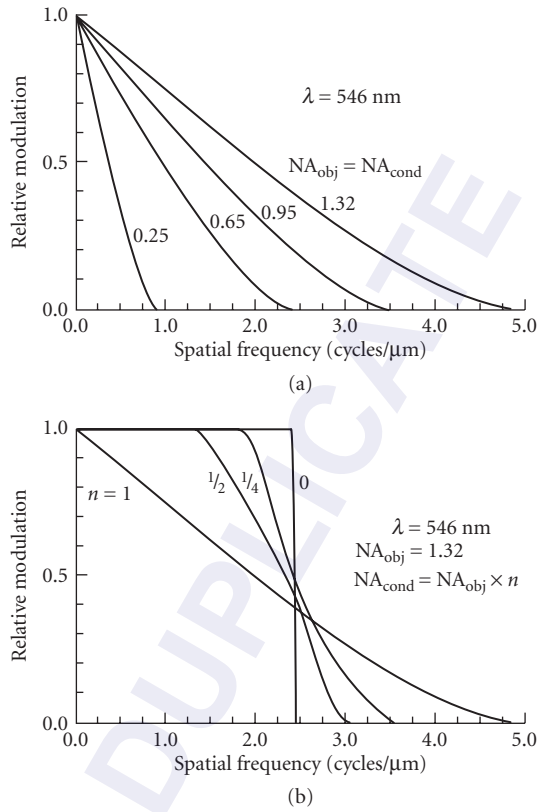

FIGURE 18 Modulation transfer function (MTF) curves for microscope lenses, calculated for periodic specimens in focus: (*a*) each curve represents a different numerical aperture (NA), which is the same for the objective and condenser lens in these curves. (*b*) These MTF curves all represent an objective lens of 1.32 NA, but with different condenser NAs; the conditions are otherwise the same as in (*a*). (*Courtesy of Dr. G. W. Ellis.*)[2]

relationship between image features. In addition, specialized systems that provide computer control of microscope components and settings in conjunction with quantitative image analysis provide advanced imaging modalities and new contrast modes that can no longer be viewed through the ocular, but can only be displayed on a computer screen. These hybrid contrast modes usually build on a traditional imaging mode and extend it through exact control and quantitation of image content. Therefore, in the following section we will present traditional imaging modes and give brief descriptions of related hybrid contrast modes.

Bright Field

Whether on an upright or inverted microscope, bright field is the prototypic illumination mode in microscopy (Fig. 4). In transmission bright-field illumination, image contrast commonly arises from absorption by stained objects, pigments, metal particles, etc., that possess exceptionally high extinction

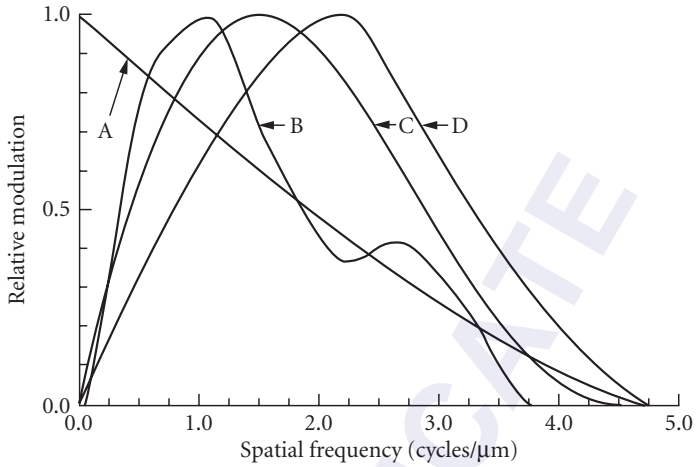

FIGURE 19 Modulation transfer function curves calculated for different modes of microscope contrast generation. A = bright field, B = phase contrast, C = differential interference contrast, and D = single-sideband edge enhancement. The curves are plotted with their peak modulation normalized to 1.0. (*Courtesy of Dr. G. W. Ellis.*)[2]

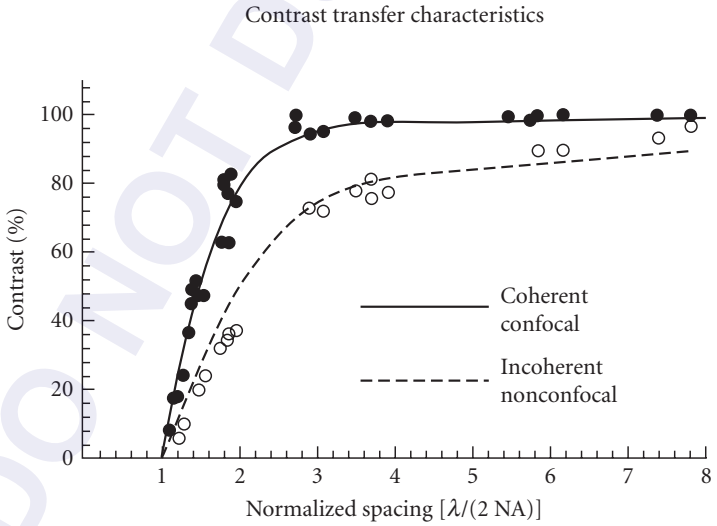

FIGURE 20 Measured contrast transfer values plotted as a function of spatial period in Airy disk diameter units, to normalize the values measured with different lenses and wavelengths. Data points were obtained with a laser spot scan microscope operating in the confocal reflection mode (*solid points*) and the nonconfocal transmission mode (*circles*). Curves are calculated contrast transfer values for the coherent confocal and the incoherent nonconfocal imaging mode.[50]

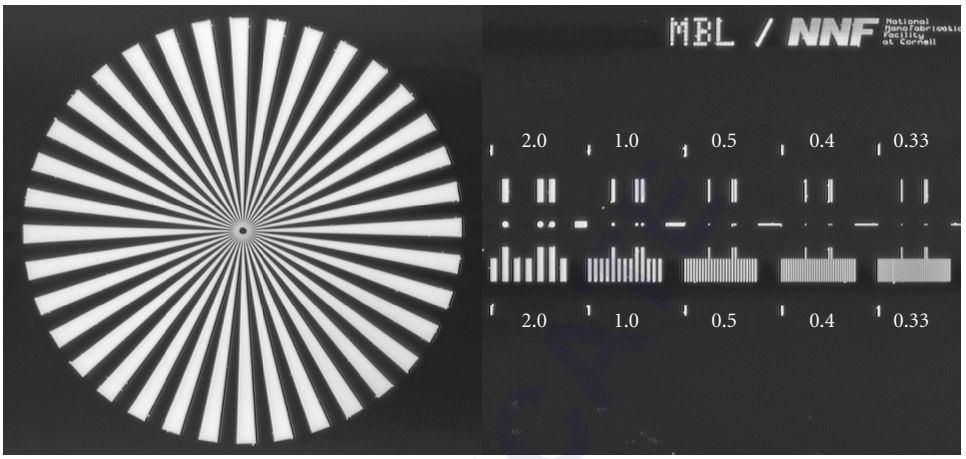

FIGURE 21 Siemens star, line and dot patterns that are part of the MBL/NNF test target imaged in bright field using transmitted light and a 60×/1.4 NA Plan Apo oil immersion objective lens (Nikon Inc.) and matching condenser. The dark background is due to the low transmittance of the 50-nm-thick aluminum film. Bright features were edged into the film using electron lithography. Numbers above and below bar gratings show period in microns. The Siemens star consists of 36 wedge pairs, with an outer diameter of 75 μm. The period near the outer edge is 6.5 μm, decreasing continuously toward the center. The smallest period is 0.1 μm near the inner black disk, which has a diameter of 1.2 μm.

coefficients (Fig. 21). Transparent objects only generate very weak contrast based on Becke lines introduced by refraction at object boundaries that are slightly out of focus. (The dark Becke line, which is used for immersion determination of refractive index of particles,[51] surrounds, or lies just inside, a boundary with a sharp gradient of refractive index when the boundary is slightly above or below focus. The Becke line disappears altogether when a thin boundary is exactly in focus.)

To gain additional contrast, especially in bright-field microscopy, the condenser NA is commonly reduced by closing down its iris diaphragm. This practice results in loss of resolution and superimposition of diffraction rings, Becke lines, and other undesirable optical effects originating from regions of the specimen that are not exactly in focus. The various modes of optical contrast enhancement discussed in following sections obviate this limitation and provide images with improved lateral and axial resolution as well as improved contrast.

Before the advent of phase-contrast and differential interference-contrast (DIC) microscopy, oblique illumination (that can be attained by off-centering a partially closed condenser iris diaphragm) was used to generate contrast of transparent objects. While this particular approach suffered from the problems listed in the previous paragraph, combination of oblique illumination at large condenser NA with video contrast enhancement proves to be an effective method for generating DIC-like thin optical sections.[52]

Recently, the optical phenomenon that leads to the formation of the Becke line has been explored more thoroughly, from a theoretical and an experimental point of view.[53–56] The goal is to retrieve phase information from images of objects that affect the phase of transmitted or reflected light, but not necessarily its amplitude. Usually, phase information is gained from specially designed setups that enhance interference effects between light waves that have different optical paths through the specimen. The following sections on phase-contrast, polarized light, and interference microscopy give examples of these specialized imaging modes. Streibl,[53] on the other hand, proposed to use a regular bright field microscope and the phenomenon of the Becke line to retrieve phase information of weakly scattering objects. He presented a theoretical framework based on the intensity transport equation and demonstrated the enhancement of phase objects based on images that were recorded at slightly different focus positions. Nugent and collaborators[55–57] have refined the theory and developed a practical implementation called *quantitative phase microscopy*.

In reflection bright-field microscopy, the image is formed by the reflected or backscattered light of the specimen, which is illuminated through the objective (see the section "Epi-illumination"). Reflection contrast is used primarily for opaque and thick samples, especially for metals and semiconductors. Reflection contrast is also finding increasing applications in autoradiography and in correlative light and electron microscopy for detecting the distribution of colloidal gold particles that are conjugated to antibodies and other selective indicators.

Total frustrated reflection microscopy[58] generates contrast due to objects that are present in a low-refractive-index medium located within the evanescent wave that extends over a distance only a fraction of a wavelength from the microscope coverslip surface. Regions of the specimen whose refractive index differs from its milieu produce interference fringes whose contrast sensitively reflects the refractive index difference and distance from the coverslip surface.

Dark Field

In dark field microscopy the illuminating beam is prevented from entering the image-forming ray paths. The background of the field is dark, and only light scattered by optical discontinuities in the specimen is designed to appear in the image as bright lines or dots. Thus, contrast can become extremely high, and diffraction images can be detected as bright points or lines even when the diameter of the scattering object becomes vanishingly small compared to the microscope's limit of resolution.[8,27,30,59]

For small objects that are not obscured by other light-scattering particles (a condition rather difficult to achieve) and are free in a fluid substrate, Brownian motion of the object and the time constant and sensitivity of the detector, rather than the object's absolute size, are more likely to set a lower limit to the size of the object that can be clearly visualized with dark field microscopy.

Phase-Contrast and Other Aperture-Modifying Contrast Modes

Microscopic objects, distinguished from their surround only by a difference of refractive index, lose their Becke line and disappear altogether when brought exactly into focus. Nevertheless, light diffracted by the small object still suffers a $\lambda/4$ phase shift relative to the undeviated background wave by the very act of being scattered (by a nonabsorbing object; the phase shift upon scattering by an absorbing object is $\lambda/2$).[60] As shown in Fig. 22, light *s* scattered by the small object and the undeviated light *u*, both originating from a common small point *A* of the condenser aperture, traverse different regions of the objective lens aperture. At the objective aperture, the undeviated light traverses only point *B* that is conjugate to *A*, while the scattered light passes those regions of the aperture defined by the spatial periods of the object.

Since light waves *s* and *u* arise from the same points in object space but traverse regions that are spatially separated in the objective aperture plane, a *phase plate* introduced in that plane can be used to modify the relative phase and amplitudes of those two waves. The phase plate is configured to subtract (or add) a $\lambda/4$ phase to *u* relative to *s* so as to introduce a $\lambda/2$ (or zero) phase difference between the two and, in addition, to reduce the amplitude of the *u* wave so that it approximates that of the *s* wave. Thus, when the two waves come to focus together in the image plane, they interfere destructively or constructively to produce a darker or brighter in-focus image of the small, transparent object against a dark gray background (positive and negative phase contrast).

As generally implemented, an annulus replaces the pinhole in the condenser aperture, and a complementary phase ring in the objective aperture plane or its conjugates (covering a somewhat larger area than the undisturbed image of the annulus in order to handle the *u* waves displaced by out-of-focus irregularities in the specimen) replaces the simple phase disk. Figure 23 shows an example of a phase object that was imaged using phase-contrast optics as described above. The object is a Siemens star that was etched into a thin layer of silica and imaged using a Olympus 100 × /1.3NA Plan Apo objective and condenser with complementary phase rings.

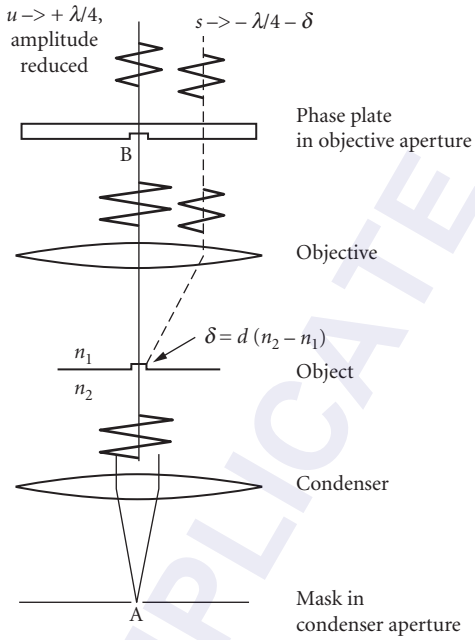

FIGURE 22 Optical principle of phase-contrast microscopy illustrating the phase relationships between waves of the light *s* scattered by the specimen and the undeviated light *u* (see text).

In the Polanret system, the phase retardation and effective absorbance of the phase ring can be modified by use of polarization optical components so that the optical path difference of a moderately small object can be measured by seeking the darkest setting of the object.[61,62] Similarly, the Polanret system can be used to accentuate color or low contrast due to slight absorption by the object.

Several modes of microscopy, including phase contrast, take advantage of the facts that (1) the front condenser and back objective lens apertures are conjugate planes, (2) the illuminating beam arising out of each point of the condenser aperture is variously deviated by the specimen structure according to its spatial frequency, and (3) the back objective aperture is the Fourier plane of the specimen plane.

In Hoffman modulation contrast microscopy, the condenser aperture contains a slit mask with the slit placed toward the edge of the aperture. The objective aperture holds a second, complementary mask, called a modulator, which consists of two parts (Fig. 24).[63] The dark part covers the smaller sector to one side of the projected slit and the gray part covers the slit area. The objective mask thus attenuates the zero-order light undeviated by the specimen and removes the light diffracted by the specimen to one side of the zero-order beam. The light deviated by specimen structure away from the dark sector of the mask passes unchanged, while the light deviated toward the dark sector is blocked. Thus, the image becomes shadow-cast, similar in appearance to DIC that reflects gradients of refractive indices or of optical path differences in the specimen.

Developed by Gordon W. Ellis in 1978[64] single-sideband edge enhancement microscopy (SSEE) generates directional image contrast of phase objects, with greater modulation transfer than by phase-contrast or DIC microscopy at high spatial frequencies (Fig. 19). SSEE is also capable of generating exceptionally thin optical sections (Fig. 25). (In 1988, Ellis also devised aperture-scanning phase-contrast microscopy, a method which generates full resolution phase-contrast images with virtually no halos;[65] see Fig. 2-47 in Ref. 2.)

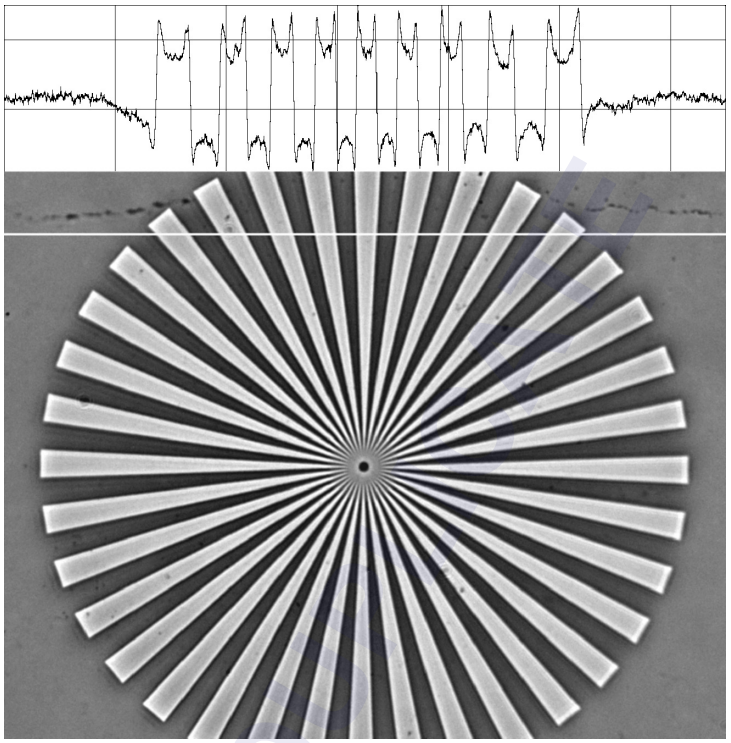

FIGURE 23 Siemens star etched into 90-nm-thick SiO_2 layer and imaged with phase contrast. The dimensions of the star pattern are the same as the one described in Fig. 21. The wedges that were etched away appear bright in this image. Light that has passed through the etched wedges is phase-advanced with respect to light that has passed through the rest of the pattern. (The SiO_2 layer was deposited on a 170-μm-thick coverglass, etched using electron lithography, and mounted on a microscope slide, leaving an air gap between slide and silica layer; 100×/1.3NA oil immersion Plan Apo objective.) The intensity profile along a horizontal line near the top illustrates deviations from the step function of the corresponding optical path difference. The accentuation of the edge contrast in this profile is an artifact of the phase-contrast method commonly implemented in form of an illumination ring in the condenser aperture and a complementary phase ring in the objective aperture.

SSEE takes advantage of the fact that illuminated by a condenser whose aperture is half masked, the two side bands (shifted by specimen diffraction to the left and right) are both phase shifted relative to the illuminating light (carrier wave) by $\lambda/4$, but with opposite signs. (As shown by Zernike,[60] the image contrast of a phase grating viewed with a bright field microscope disappears at exact focus, since the two side bands are in opposite phase.)

In the SSEE microscope, contrast is generated by interference between the attenuated carrier wave and one of the side bands (Fig. 26). Alternately, both side bands may be used with one of the side bands phase shifted by $\lambda/2$ (and appropriately attenuated) relative to the other. Interference between the attenuated carrier wave and the side band generates a high-contrast, high-resolution, in-focus image of the specimen's phase boundaries proportional to their orientation perpendicular to the straight edge of the half mask in the condenser.

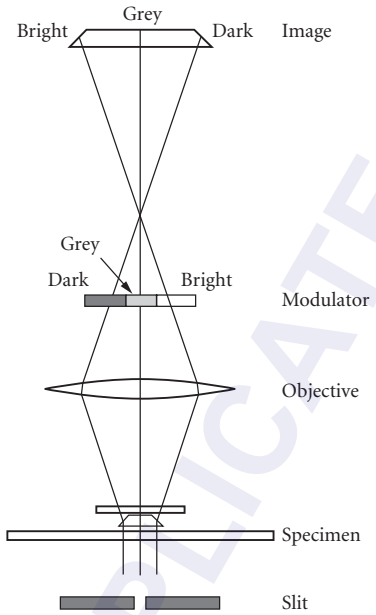

FIGURE 24 Schematic diagram indicating regions of the modulator that modify light from phase gradients in the object to enhance contrast.[63]

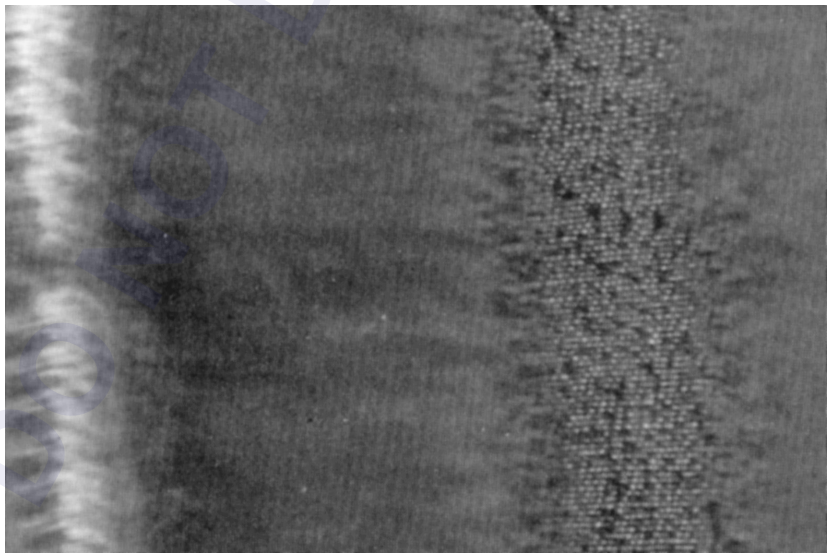

FIGURE 25 Optical section of the silicate shell of a diatom (*Surirella gemma*) observed with SSEE. The tiny pores are in focus over only a highly limited region of the shell due to the highly effective optical sectioning capability of SSEE. (*Image copied and cropped from Fig. 2-50 in Ref. 2. FIGURE 26 Schematic diagram of the edge enhancement single-sideband microscope (SSEE).[64]

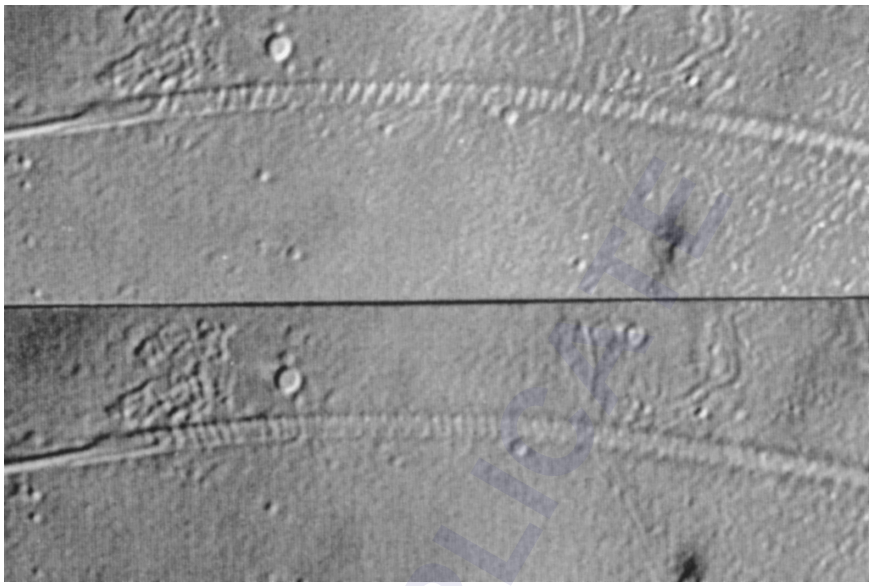

FIGURE 27 Gyres of chromosomes in live sperm head of cave cricket. The images were obtained with SSEE using selected e-vectors as described in the text. Besides rectified polarization microscopy (Fig. 36), few contrast-generating methods besides SSEE have been able to distinctly display these chromosome gyres. (*Image copied from Fig. 2-51 in Ref. 2. Original image courtesy of Dr. Gordon W. Ellis, University of Pennsylvania.*)

In SSEE, polarizing elements placed *after* the specimen attenuate and phase shift the carrier wave relative to the side bands (Fig. 26). Thus by adjusting the azimuth of the polarizer immediately following the specimen, one can capture exceptionally high resolution images reflecting the birefringence distribution and axes in the specimen (Fig. 27). Also, since the specimen is not sandwiched between crossed polarizers, image contrast in SSEE is not affected by birefringence of the specimen chamber as is the case with polarization and DIC microscopy.

Interference

While all modes of contrast generation in light microscopy in fact depend on interference phenomena, a group of instruments is nevertheless known separately as interference microscopes. These microscopes form part of an interferometer, or contain an interferometer, that allows direct measurements of optical path difference (or generation of contrast) based on interference between the waves passing the specimen and a reference wave. The interferometric and polarization microscopy techniques, which are considered below, generate complementary phase images of the specimen: distribution of refractive index and distribution of refractive index anisotropy, respectively.

Many interference microscopes employ amplitude-dividing beam splitters for setting up the two-beam interference scheme. Instead of amplitude division, division of wavefront can also be used to create both beam paths, especially when using a laser light source. Among the many designs that have been proposed and manufactured, amplitude division interference microscopes can be classified into three major groups: (1) the two-arm type with two separate beam paths, one containing the sample, the other for controlling the reference beam, with separate microscope optics in both arms or microscope optics only in the sample arm; (2) the beam-shearing type in which the reference wave is generated by displacing a beam laterally within the field of a single microscope; and

(3) the dual focus type in which the reference wave is focused to a different level than the specimen plane, again in a single microscope. All schemes can be implemented in transmission or reflection mode.[66,67]

The image in an interferometric microscope is created by the superposition of a probe and a reference beam. We denote the intensities in the probe and reference beam as I_p and I_r, and their respective phases as ϕ_p and ϕ_r. The intensity that results from superimposing the probe and reference beam can be expressed as described in[17,26]

$$I = I_p + I_r + 2|\gamma_{pr}|\sqrt{I_p I_r}\cos(\phi_p - \phi_r) \tag{11}$$

where $|\gamma_{pr}|$ is the modulus of the normalized mutual coherence function or the degree of coherence between the probe and reference image. This equation does not include polarization effects and assumes that both interfering beams have the same polarization. For quasi-monochromatic light the optical path difference (OPD) that is associated with the phase angle difference is given by

$$\text{OPD} = \frac{\bar{\lambda}}{2\pi}(\phi_p - \phi_r) \tag{12}$$

where $\bar{\lambda}$ is the center wavelength.

We note that in Eq. (11) I can stand for an array of intensity values representing the pixels of a digital image that was recorded with an appropriate camera attached to an interference microscope.

When using white light, each wavelength produces its own interference picture. White light interference pictures are only observed when the optical path difference between the probe and the reference beam is less than a few wavelengths. Let's assume that in a uniform image region the OPD is zero, hence the interference of each wavelength is constructive and the recorded spectrum in that region is white. However, if the OPD is finite, the wavelength that is twice the OPD is suppressed due to destructive interference and therefore that wavelength is missing from the spectrum recorded in the region. When systematically increasing the OPD from 0 to 2000 nm, for example, a characteristic change in spectrum is observed in the region, transitioning from white (OPD = 0), to blue (OPD = 300 nm), to yellow (OPD = 600 nm), to indigo (OPD = 900 nm), to a greenish yellow (OPD = 1600 nm), and bluish grey (OPD = 2000 nm).[68] As the OPD increases above 1000 nm, colors become less saturated and approach white again for OPDs of several thousand nanometers.

In some interferometric schemes there is an additional achromatic half-wave phase shift, for instance, due to polarization transformation, reflection, and the like. In this case, a zero optical path difference produces destructive interference at all wavelengths and a uniform image region with zero OPD appears black. For small OPDs (< 200 nm) the destructive interference is relaxed for all wavelengths simultaneously and the brightness of the region increases, first with a white spectral composition. With increasing OPD, the region becomes colored due to constructive and destructive interference of specific wavelengths leading to the following color sequence: light yellow (OPD = 300 nm), indigo (OPD = 600 nm), yellow (OPD = 900 nm), grey blue (OPD = 1600 nm), and whitish grey (OPD = 2000 nm). This sequence of interference colors is reproduced in the Michel-Lévy chart (see Fig. 28), which is used to rapidly estimate the OPD based on the observed color of a uniform region. When the OPD increases above 2000 nm, the interference colors turn white and can no longer be used to reliably determine the OPD.

Both interference schemes are implemented. The scheme with destructive interference at 0 OPD is more sensitive (higher signal to noise ratio) for measuring small OPDs, because the background of 0 OPD is black (ideally) and doesn't carry any shot noise, while the white light intensity of constructively interfering beams is subject to shot noise.

When using monochromatic light, the optical path difference between the probe and reference beam can be determined precisely by measuring the intensity in a uniform image region [see Eq. (11)]. However, measurements of OPDs that are larger than the wavelength λ of the monochromatic light result in an apparent OPD that is between 0 and λ. This ambiguity is often referred to as the order of the OPD. The order can be determined by making measurements with two or more wavelengths.

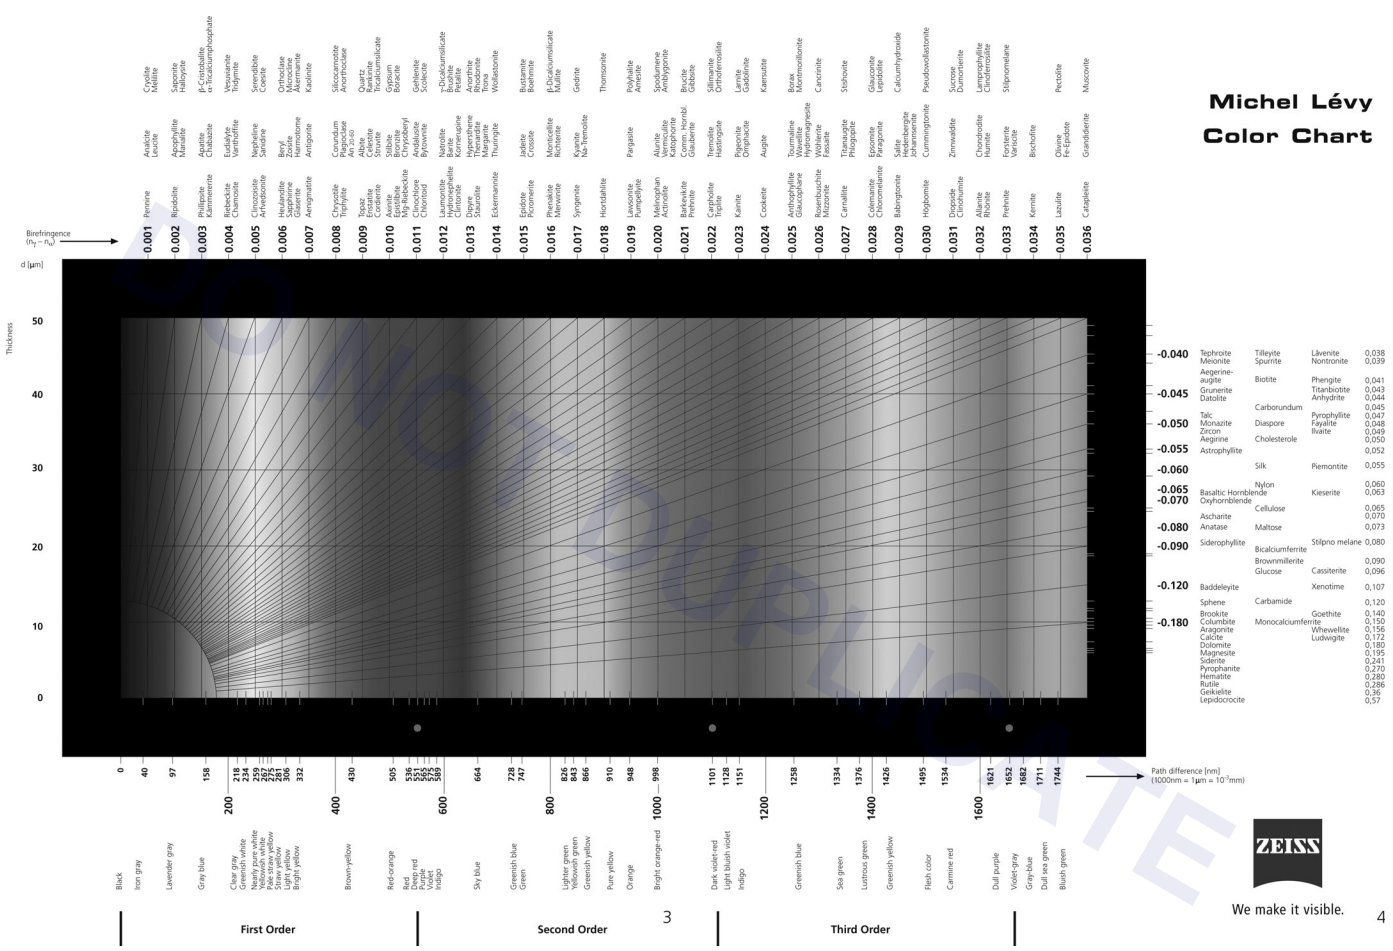

FIGURE 28 Michel Lévy Color Chart of interference colors. The horizontal sequence of colors is associated with the interference of two beams of white light whose mutual path difference increases from 0 (left, black for destructive interference) to more than 1700 nm (right, pale green). By comparing an experimentally observed color with the colors of this chart, one can estimate the path difference caused, for example, by the partial reflection off a thin dielectric film (e.g., soap bubble) or transmission through a thin birefringent sheet (e.g., mica) sandwiched between crossed polarizers. For birefringent materials, the path difference is the product of the birefringence (indicated along the upper and right edge) and the thickness (left edge) of the material. The diagonal lines assist in estimating one of the quantities (birefringence or thickness) from the observed color, if the other quantity is known. This brightness/color sequence is specific to interference phenomena that result in destructive interference for zero path difference (e.g., birefringent sheet between crossed polarizers). A complementary color sequence applies to interference phenomena that result in constructive interference at zero path difference (e.g., birefringent sheet between parallel polarizers). (See also color insert.) (*The chart was generously provided by Rudi Rottenfusser and Becky Hohman of Carl Zeiss MicroImaging Inc.*)

Further improvement in measuring the OPD can be achieved by controlling the phase of the reference beam. For example, we can measure the probe plus reference image four times, each time changing the phase of the reference image by a quarter wavelength. According to Eqs. (11) and (12) we find

$$\begin{aligned} I &= I_p + I_r + 2|\gamma_{pr}|\sqrt{I_p I_r}\cos\left(\frac{2\pi}{\lambda}\mathrm{OPD}\right) \\ I &= I_p + I_r - 2|\gamma_{pr}|\sqrt{I_p I_r}\sin\left(\frac{2\pi}{\lambda}\mathrm{OPD}\right) \\ I &= I_p + I_r - 2|\gamma_{pr}|\sqrt{I_p I_r}\cos\left(\frac{2\pi}{\lambda}\mathrm{OPD}\right) \\ I &= I_p + I_r + 2|\gamma_{pr}|\sqrt{I_p I_r}\sin\left(\frac{2\pi}{\lambda}\mathrm{OPD}\right) \end{aligned} \tag{13}$$

Assuming all other factors constant we can compute the OPD based on the four intensity measurements:

$$\mathrm{OPD} = \frac{\lambda}{2\pi}\arctan\left(\frac{I_4 - I_2}{I_1 - I_3}\right) \tag{14}$$

The last expression relates the OPD to a ratio of intensity differences. Hence, the OPD is measured independent of an intensity offset (because only intensity differences are entered) and independent of a gain factor that is common to all four intensity values (because only an intensity ratio is entered).

As noted earlier, $I_1, \ldots, I_4$ can be interpreted as arrays of intensity values representing the pixels of four digital images. In this case, the expression for OPD represents an image arithmetic operation that generates a map of the spatial variations of the measured optical path differences. This or similar image-processing schemes can be implemented using various interference microscope designs after adding appropriate equipment for electronic imaging and phase control.

Mach-Zehnder Interference Microscope The classical two-arm interference microscope with identical optics in both arms is the Mach-Zehnder interference microscope as designed by Horn (Leitz of Wetzlar) in the 1950s (Fig. 29). The intricate and sturdy design earned it the nickname "Rolls Royce of the microscopes,"[69] including its cost, which was comparable to that of an electron microscope of the time. The microscope, while straightforward in principle, requires close matching of the optics in the two interferometer arms and a mechanical design that provides exceptional precision and stability. Thus, in addition to using matched pairs of objectives and condensers and inserting a blank slide (that is similar to the specimen-containing slide) into the reference arm, one needs to carefully adjust the built-in beam deviators, path equalizers, and wedge components to reduce the difference in optical path length between the two arms to less than the coherence length of the quasi-monochromatic light. (The coherence length of light with a center wavelength $\bar{\lambda}$ and a bandwidth of $\Delta\lambda$ is $\bar{\lambda}^2/\Delta\lambda = 30\,\mu\mathrm{m}$ for $\bar{\lambda} = 550\,\mathrm{nm}$, $\Delta\lambda = 10\,\mathrm{nm}$.) While unfortunately no longer manufactured, this type of microscope permits precise interferometric measurements of microscopic objects both in the uniform field mode and the fringe displacement mode, and can even be used to generate holograms.[2]

Linnik Interference Microscope In 1933, V.P. Linnik proposed a two-arm reflective-type interference microscope with two matching objectives and a single ocular.[70] The optical scheme, also called the Linnik microinterferometer, is shown in Fig. 30*a*. The illumination is split and recombined by the same beam splitter before the microscope objective lens where the beam has low divergence. The probe beam and reference beam then pass through separate but matching objectives and reflect off the specimen and reference mirror, respectively. The objectives can have high NA and short working distance, but require close matching for efficient interference of the probe and reference beams in the common image plane or behind the ocular. Closely matched objectives reduce the influence

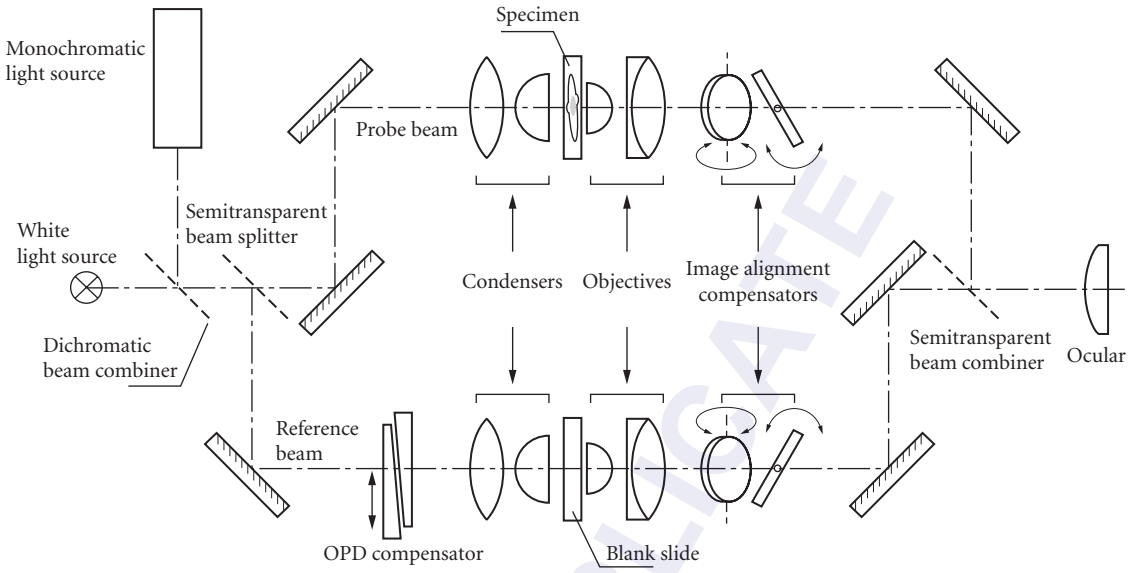

FIGURE 29 Designed by Horn the Mach-Zehnder-type interference microscope with two complete sets of microscope optics, one in each arm of a Mach-Zehnder interferometer.

of chromatic dispersion and other optical aberrations on the interference image. This is essential if a broad-band light source is used, because the dispersion and the optical path length must be closely matched across the entire useful field in each arm. Linnik type interference microscopes are still manufactured by LOMO, Russia.

The original Linnik design can be modified as proposed here by Michael Shribak and shown in Fig. 30*b*. The modification replaces the regular beam splitter with a polarizing one and adds

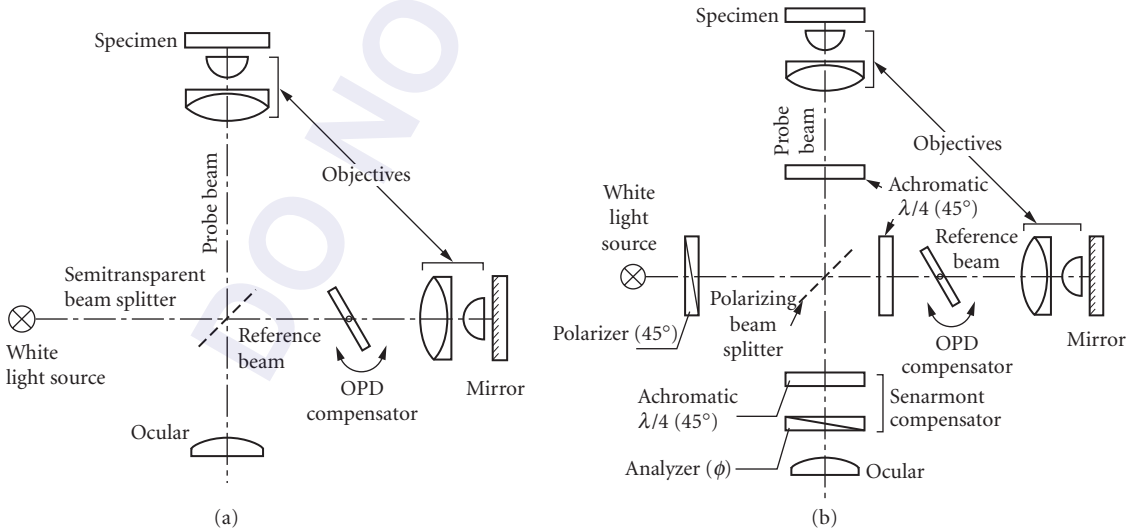

FIGURE 30 The Linnik-type interference microscope with two identical objectives, one in each arm.

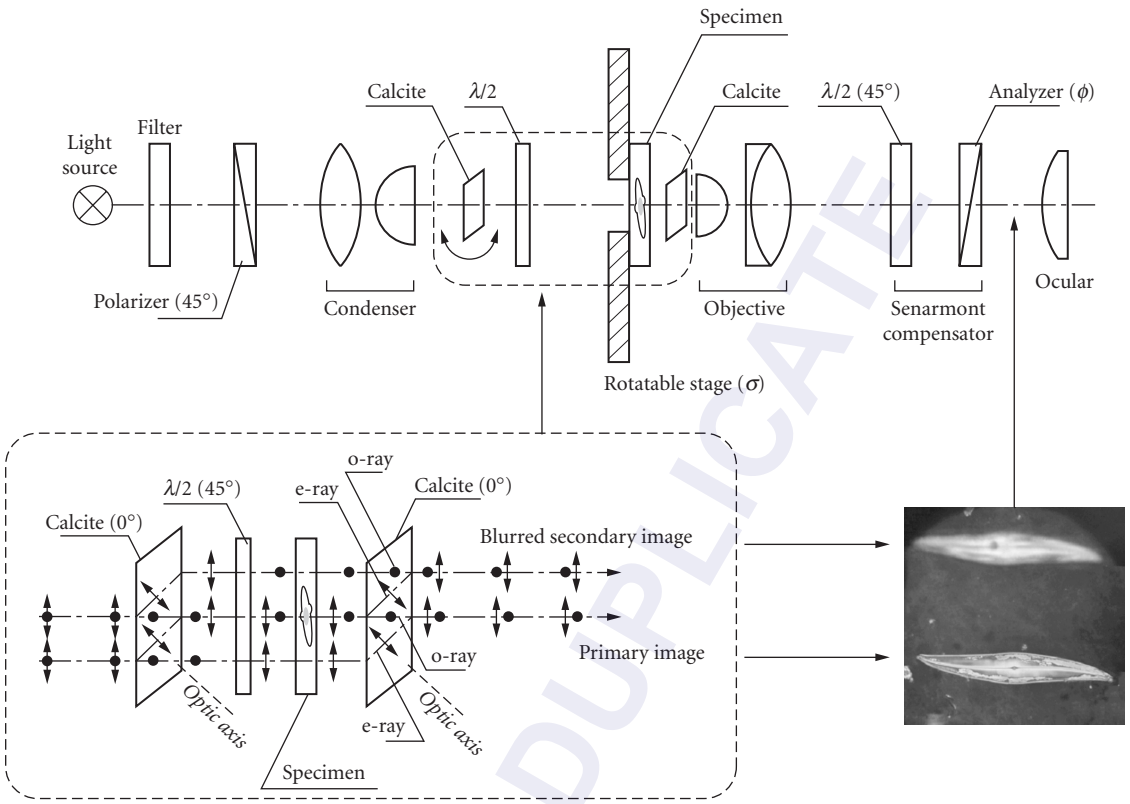

FIGURE 31 The Jamin-Lebedev type interference microscope.

quarter-wave plates to improve sensitivity and to provide a convenient way of measuring the phase. Its enhanced features include a rotatable polarizer, which is used to balance the intensities of the probe and reference beam. The quarter-wave plates following the beam splitter create circularly polarized light, which is reflected by the specimen/reference surface. The reflection induces an inversion of the circularity of the two beams, which causes them to be combined after the beam splitter in the arm with the Senarmont compensator and ocular. The compensator consists of a quarter-wave plate at azimuth 45° and a rotatable analyzer at azimuth ϕ. Image regions with different phase angles can be brought to extinction by rotating the analyzer to different angles. The phase difference Φ between two regions with extinction angles ϕ_1 and ϕ_2 is $\Phi = 2(\phi_2 - \phi_1)$. Other compensation schemes can be used, including liquid crystal devices, and a camera can be added for quantitative imaging.

Jamin-Lebedev Interference Microscope The first interference microscope was constructed by Lebedev in 1930[71–73] using a beam-shearing design based on the two-beam polarization interference scheme introduced by Jamin in 1868.[74] The optical scheme of the Jamin-Lebedev interference microscope is shown in Fig. 31.

In this instrument, a small plane-parallel plate of calcite is cut at 45° to the optic axis and cemented to the front of the objective lens. An identical calcite plate is cemented to the front of the condenser, with an additional half-wave plate facing the specimen. The axes of the two calcite plates are parallel, and at 45° to the axes of the half-wave plate. The specimen under investigation is placed between the half-wave plate and the calcite plate fixed to the objective. The plate fixed to the objective

produces the necessary lateral separation between the probe and reference beams in the intermediate image plane of the microscope. Thanks to the calcite and half-wave plate placed next to the condenser, the path difference of the interfering rays does not vary with the inclination of the rays. This compensation permits quite large openings of the substage condenser diaphragm.

In the beam-shearing Jamin-Lebedev microscope, the probe and reference beam travel a common physical path except along the short distance between the two calcite plates. Because of the common path many design criteria, including mechanical stability and duplication of optical components, can be significantly relaxed in this beam shearing microscope, compared to the dual-arm Mach-Zehnder design. The compromise lies in the lateral shear distance between probe and reference beam, which is limited by the field size and the requirement for telecentric paths for both probe and reference beam. Because both, the probe and reference beam pass through the same specimen slide, the observer has to be wary of ghost images introduced by the reference beam.

The design shown in Fig. 30 was manufactured in the 1960s by Carl Zeiss, Oberkochen, West Germany. The calcite plate next to the objective lens can be slightly rotated to align the shear planes of the two calcite plates. An additional calcite plate introduces a bias in the optical path difference adjusted by a small tilt of the plate. The microscope comes with three pairs of matched condenser and objective lenses, with the objectives designated as 10×/0.22NA, 40×/0.65NA, and 100×/1.0NA Oil. Their shear distances are 500, 170, and 50 μm, respectively. Optical path differences of less than one wavelength are measured using monochromatic light and a Senarmont compensator. For measuring higher path differences, white light and a Michel-Levy chart (Fig. 28) can be used.

Differential Interference-Contrast Microscope Differential interference-contrast (DIC) microscopy is used extensively in materials research and the life sciences for observing microscopic particles and structures that are associated with refractive index and thickness changes in the specimen. A DIC microscope is a beam-shearing interferometer in which the reference beam is sheared by only a small amount, generally by less than the diameter of the Airy disk that is associated with the imaging optics. The technique produces a shadow-cast image that displays the local gradients of the optical path length. A region of the specimen where the optical path length increases along a reference direction appears brighter (or darker), while a region where the optical path length decreases appears in reverse contrast. As the gradient of the optical path grows steeper, image contrast is increased. Another important feature of the DIC technique is that it produces effective optical sectioning. This is particularly obvious when high numerical aperture (NA) objectives are used together with high NA condenser illumination. The thin optical section is a consequence of the small shear between the interfering beams, which are appreciably separated only in a thin layer around the focal plane.

The DIC technique was invented by F. H. Smith in 1947.[75,76] He placed between a pair of polarizers one Wollaston prism at the front focal plane of the condenser and a second one in the back focal plane of the objective lens (Fig. 32). The first Wollaston prism splits the linearly polarized input beam into two orthogonally polarized beams that are separated by a small angle ε_1. The condenser lens converts the angular split in the focal plane into a small spatial shear in the object plane. The objective lens joins the two beams again in the back focal plane where the second Wollaston prism deviates the beams to form two parallel beams again. While parallel, the two beams are orthogonally polarized and therefore cannot interfere. Therefore, a linear analyzer is needed after the second Wollaston prism to create a common polarization and to enable the beams to interfere. The interference generates the typical relief image representing the optical path gradients in the specimen (see inset in Fig. 32).

The small angular split ε_1 and ε_2 in the condenser and objective focal planes are related to the shear amount d in the object plane and the focal lengths of the condenser (f_c) and objective (f_{ob}) lenses by

$$f_c \varepsilon_1 = f_{ob} \varepsilon_2 = d \tag{15}$$

This optical configuration creates a polarizing shearing interferometer, by which one visualizes optical path gradients of the specimen under investigation.

In conventional medium- to high-NA objective lenses, the back focal plane is located inside the lens system and therefore not available for insertion of a Wollaston prism. If the Wollaston prism

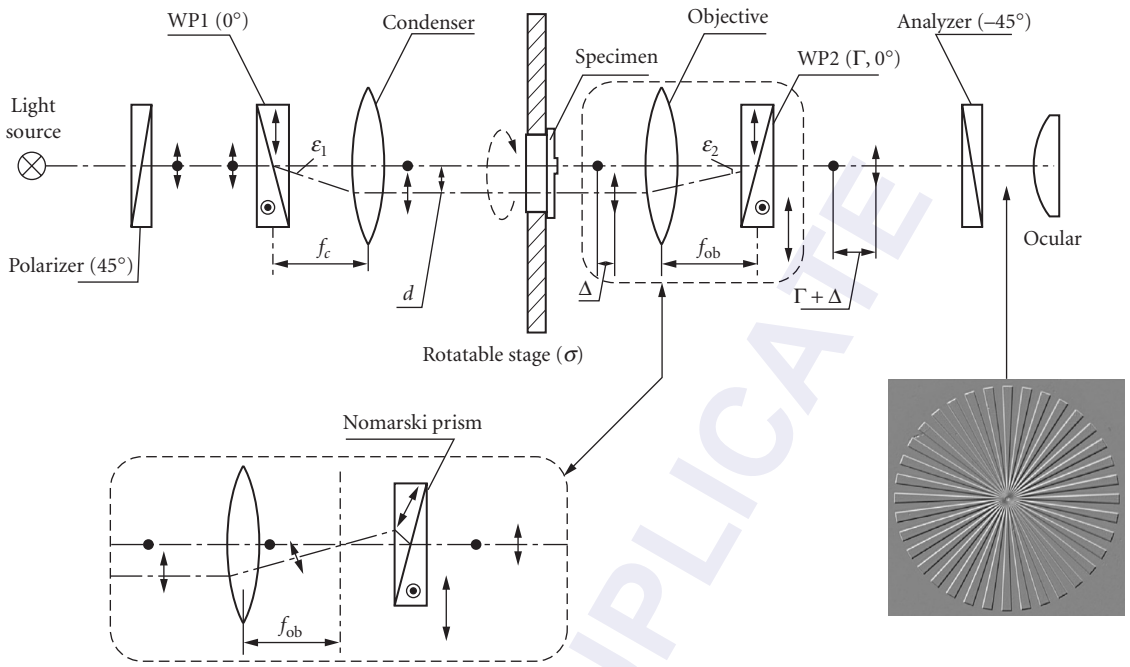

FIGURE 32 DIC microscope setup: polarizer at 45° azimuth; WP1: first Wollaston prism at 0° azimuth; ε_1: splitting angle; f_c: condenser lens focal distance; d: shear amount; Δ: optical path difference introduced by specimen under investigation; σ: azimuth of rotatable stage; f_{ob}: objective lens focal distance; WP2: second Wollaston prism at 0° azimuth (the second prism introduces bias Γ); ε_2: splitting angle; analyzer at –45° azimuth; Wollaston prism can be replaced by Nomarski prism.

is placed far from the back focal plane, the prism produces parallel beams, but the beams are spatially displaced and hence are not recombined. Therefore, the Smith DIC system requires specially designed objective lenses that allow the insertion of a Wollaston prism.

In 1952 G. Nomarski proposed a special prism, the Nomarski prism, which simultaneously introduced spatial displacement and angular deviation of two orthogonally polarized beams[77,78] (see inset in Fig. 31). The prism can therefore be placed outside the objective lens. By using crystal wedges with appropriately oriented axes, the Nomarski prism recombines the two beams that were separated by the condenser Wollaston prism, as though a regular Wollaston prism were located in the back aperture plane of the objective lens. The Nomarski DIC scheme can therefore be used with regular high NA microscope objectives.

A DIC image can be modeled as the superposition of one image over an identical copy that is displaced by a small amount d and phase shifted by a bias Γ. The intensity distribution $I(x, y)$ of the combined image depends on the specimen orientation and varies proportionally with the cosine of the angle between the gradients azimuth θ and the relative direction of wavefront shear σ:[79]

$$I(x, y) = \frac{1}{2} I_0 \left(1 - \cos\left(\frac{2\pi}{\lambda} (\Gamma + \gamma(x, y)\, d \cos(\theta(x, y) - \sigma)) \right) \right) \tag{16}$$

where I_0 is the initial beam intensity, $\gamma(x, y)$ and $\theta(x, y)$ are the gradient magnitude and azimuth. (For a theoretical framework of DIC imaging see Refs. 8, 79–81.)

Thus, regular DIC techniques show the two-dimensional distribution of optical path or phase gradients projected onto the shear direction. It is therefore prudent to examine unknown objects at several azimuth orientations.

Video-enhanced DIC (VE-DIC), in addition to providing images with improved contrast, allows the removal of unwanted background signal (such as shading and fixed image noise due to dust particles or other imperfections in the optical system) by subtraction of a reference image with no specimen.[82] Salmon and Tran gave a comprehensive description of the VE-DIC method.[83] They indicate that the best optical contrast of microscopic, lowly refractile particles can be achieved with a bias of 1/15-1/20 the wavelength.

A further increase in sensitivity and sectioning capability was achieved by video-enhanced DIC microscopy with retardation modulation.[84–87] By switching the polarization of the incident light in alternate video frames with a computer-controlled liquid crystal variable retarder, the contrast signal is increased by a factor of 2, relative to "standard" video-enhanced DIC. The modulator switches image highlights into shadows and vice versa. By subtracting alternate frames, a difference DIC image is created in which contrast is doubled while image defects and noise tend to be cancelled.

Recently, Carl Zeiss introduced a "C-DIC" technique for reflective-type microscopes, which avoids the need to rotate the specimen. Instead, the new system uses a single, mechanically rotatable Nomarski prism that is shared between the illumination and imaging path.[88]

Even in a transmission-type microscope one can obtain a DIC image using only one Wollaston or Nomarski prism placed in the imaging path, if the illumination beam is made spatially coherent. Pluta described a DIC setup with a slit condenser diaphragm.[8] A similar system is currently manufactured by Carl Zeiss called a "PlasDIC." In the latter case the specimen is illuminated with unpolarized light using a condenser that has a slit in its aperture plane. Only a single polarizer is used and placed behind the Nomarski prism that follows the objective. The system is less sensitive to birefringence of the specimen, can be used with plastic dishes, and does not require strain-free optics. Disadvantages include a reduced illumination intensity caused by the slit (instead of a fully open aperture) and a deterioration of the optical sectioning capability.

The contrast in DIC images is proportional to the scalar product between the phase gradient in the specimen and the shear generated in the microscope's prisms. Based on the phase gradient it is possible to restore the phase information using computational methods. The restored phase image shows the refractive index (dry mass) distribution within a thin layer of the specimen. Compared to a conventional phase-contrast image, the DIC-based phase image provides better sectioning due to the intrinsic sectioning capability of the DIC method.

The DIC phase image can be obtained by computing the line integral parallel to the shear direction.[79,89] Other techniques use iterative phase computation,[90] noniterative Fourier phase integration,[91] or nonlinear optimization using hierarchical representations.[92] Axelrod et al. used two phase-shifted DIC images to reconstruct the phase based on linearized expressions of interference.[93] Biggs developed an iterative deconvolution approach for computation of phase images, based on the same principles as deconvolution techniques normally used to remove out-of-focus haze.[94]

Dyson and Mirau Interference Microscopes A third group of interference microscopes, in which the reference wave is focused to a different level than the specimen plane, are represented by the Dyson and Mirau interference microscopes.

In 1950, J. Dyson designed a double-focus system for transmitted light (Fig. 33*a*).[95] In this system, the initial transparent beam-dividing surface is formed on the upper side of the first glass plate mounted normally to the optical axis of the microscope immediately beneath the specimen slide. The illuminating beam, convergently directed through this upper surface by the substage condenser, is then partially reflected back to the lower surface of the plate, which has a small opaquely silvered, reflecting central spot. The lower surface of the first plate therefore reflects this second beam back through the upper surface of the plate. As a result, the specimen area is illuminated by two beams, one of which is focused on the specimen after direct transmission through the plate while the other reaches the specimen in a defocused condition due to internal reflection within the plate. A similar plate between the specimen and the objective lens functions in much the same way, so that the portion of the second defocused beam, which passes directly through it becomes combined with a portion of the first focused beam internally reflected within it.

The image formed by the microscope objective consequently consists of a correctly focused image of the specimen area seen in interferometric comparison with a strongly defocused image of it.

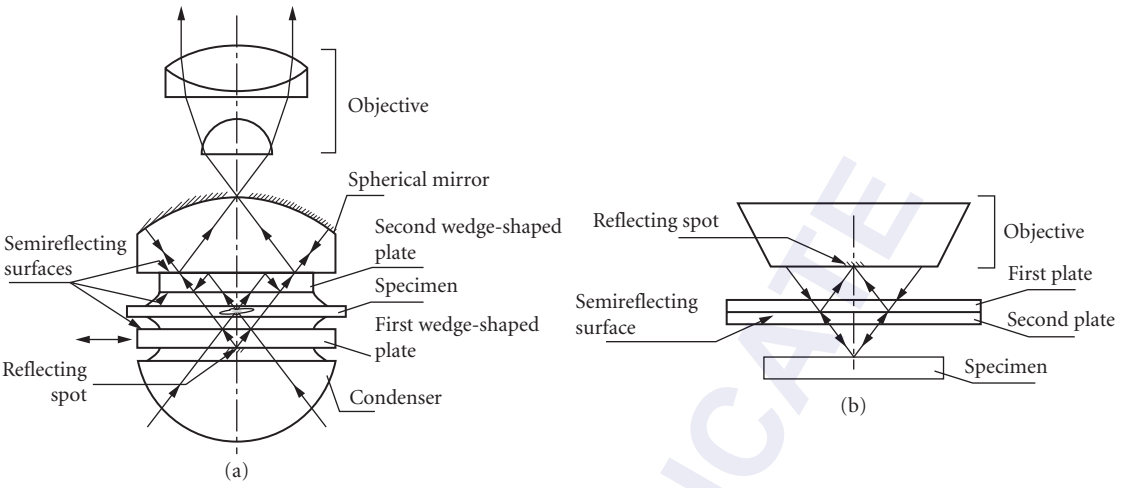

FIGURE 33 (*a*) Dyson and (*b*) Mirau's interference microscope. In (*b*), the incident light beam, emerging from the objective O_1, is split in two parts in the semireflective surface. One part is transmitted to the object *P* and the other is reflected to the reference area *R* extending over a small portion of the objective front surface. The wavefronts reflected by *R* and *P* are recombined at *G* to produce the interference pattern.[5]

A glass block with an upper spherical surface, which is fully reflecting apart from a central totally transmitting spot is included between the second plate and the objective to allow medium- and high-power objective lenses to focus through to the specimen. The two plates are made slightly wedge-shaped so that the optical path difference can be manually adjusted by traversing the condenser plate in a direction parallel to the principal section of the wedge across the optical axis of the microscope. This operation varies the effective thickness difference between the two plates and thereby controls the optical path difference. By calibrating this movement the optical path difference can be determined.

Mirau introduced a single objective reflecting system.[96] In this design (Fig. 33*b*) a flat, semireflecting beam-dividing surface is placed midway between the front of the objective and the specimen surface. A small central area of the front surface of the objective is silvered to form a miniature mirror, a reflected image of which becomes superimposed on the normal image of the specimen surface by virtue of the intervening semireflecting beam divider. To maintain the required degree of optical path similarity, the beam-dividing surface is formed on the internal side of one of a pair of identical plates, which are cemented together.

Holographic Soon after its invention the laser was employed for holographic imaging in microscopy. In the early 1960s, Gordon Ellis built one of the first holographic microscopes.[97] He used a helium-neon laser as light source and photographic film for recording the hologram. After development of the film, the hologram allowed to reconstruct images using a divergent laser beam.

In digital holographic microscopy (DHM), the hologram of interfering wave fronts is recorded with an electronic sensor (e.g. CCD chip, Fig. 34)[98] and images are digitally reconstructed by a computer. A digitized hologram represents a three-dimensional record of the optical features of the specimen. Based on a single hologram, several images can be reconstructed that correspond to specific focus planes in the specimen. Furthermore, the digital reconstruction allows to simulate different contrast modes, such as phase contrast and dark field imaging.[99–101] In addition to the specimen, the hologram can also contain information on the rest of the optical path, depending on the coherence length of the light source. For example, a hologram can provide the opportunity to correct for lens aberrations.[102]

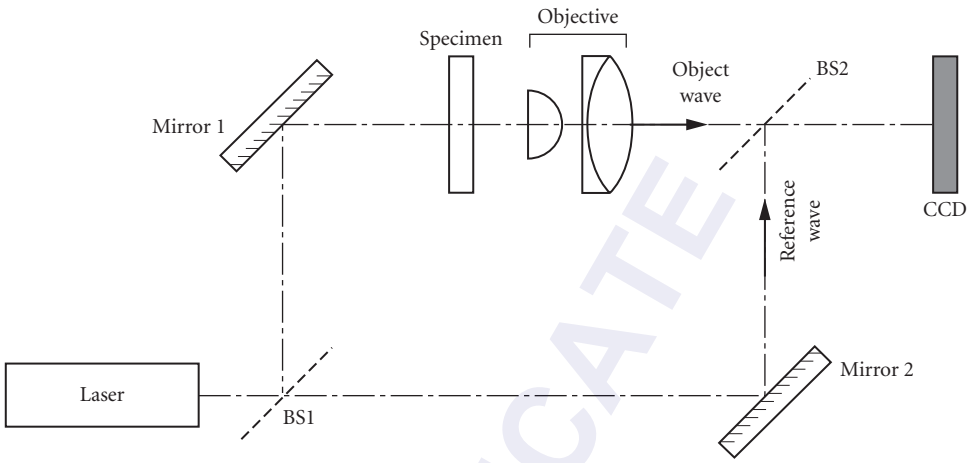

FIGURE 34 Optical principle of a holographic microscope. A collimated laser beam is divided by the beamsplitter BS1. One beam passes through the specimen and the microscope objective lens and forms the object wave. The second beam is the reference wave and is recombined on-axis with the first beam behind the objective lens. The interference pattern (hologram) of the object and reference wave is recorded by a CCD camera that is located near a conjugate plane of the backfocal plane of the objective lens. Other optical setups are possible, including for reflective-type specimens and for using an off-axis interference arrangement.[98]

The digital analysis of a set of holograms, each recorded with a beam that illuminates the sample from a different direction, allows to emulate an objective with a larger numerical aperture than actually employed, leading to a corresponding enhancement in image resolution.[103]

Optical Coherence Tomography Optical coherence tomography (OCT) is an imaging method that performs depth-resolved imaging of various turbid media. At the core of the OCT technique is a low-coherence, two-arm interferometer, which works in reflection mode.[104,105] The low-coherence interferometer is used to select only a small volume named the "coherence gate" that determines the depth in the sample from where the back-reflected or back-scattered signal is processed. The depth of the coherence gate is defined and controlled by matching the optical path in the probe and reference interferometer arms. A variable delay line in one of the arms changes the gate position. In addition to its depth-selectivity feature, the low coherence interferometer is used to "amplify" very weak signals back-scattered by the sample.

In OCT, the coherence length is shortened to a distance of several micrometers, thanks to the use of a broadband light source. Light of appropriate bandwidth is typically generated by a superluminescent diode or laser with extremely short pulses. The spatial resolution of OCT in the axial direction is provided by the coherence gate, which selects signal light only from a cross-sectional volume of thickness defined by the coherence length of the illumination source. Superluminescent diodes typically provide 10- to 20-μm axial resolution. Higher resolution can be obtained with ultrashort pulsed lasers.

Interference of the light reflected by the sample and the reference mirror in the interferometer arms can occur only when the optical path lengths of the two arms match to within the coherence length of the optical source. Depth scanning can be performed in the time- or spectral domain. Time-domain OCT systems vary the reference arm path length, inducing changes in the depth from which the backscattered light of the sample is detected. In spectral-domain or Fourier-domain OCT, the axial signal intensity is calculated based on changes in the interference spectrum. The interference between probe and reference beam causes changes in the spectrum which is measured using a suitable spectrometer,[106] or by rapidly and repeatedly sweeping a narrow line width laser source in a mode called swept-source OCT.[106–108]

In addition to amplitude and phase, OCT can also be used to analyze changes in polarization of the probe beam, revealing the polarization properties (birefringence, dichroism) of selected regions inside a turbid medium.[109]

Optical coherence microscopy (OCM) combines the advantages of confocal microscopy with the principles of low-coherence interferometry.[104,110,111] High contrast and detection sensitivity are achieved via rejection of out-of-focus light, resulting in improved optical sectioning capabilities deep within highly scattering media. Both OCT and OCM usually employ single-mode optical fibers for illuminating and collecting light from the sample. However, OCT uses a low NA objective lens with an extended depth of field, providing sectioning through coherence only. OCM, on the other hand, utilizes a high NA lens, providing sectioning through a combination of coherence and confocal effects.

Polarizing

The polarizing microscope (Fig. 35) generally differs from a standard transilluminating microscope by the addition of a polarizer before the condenser; a compensator slot and analyzer behind the objective lens; strain-free optics; a graduated, revolving stage; centrable lens mounts; cross-hairs in the ocular aligned parallel or at 45° to the polarizer axes; and a focusable Bertrand lens that can be inserted for conoscopic observation of interference patterns in the back aperture of the objective lens. In addition, the front element of the condenser can be swung into place for higher-NA conoscopic observations or swung out for low-NA orthoscopic observations of larger field areas.

The same components can be made to fit on an epi-illumination stand for observing opaque or reflective-type samples, such as in metallurgy. As outlined earlier, in epi-illumination a beam-splitting mirror separates the illumination and imaging light paths before the objective lens. In polarizing microscopy one needs to pay special attention to the beam-splitting mirror, which typically introduces polarization aberrations. The aberrations can be significantly reduced by a so-called Smith reflector replacing the regular dichromatic or half-shaded mirror. While a regular beam splitter reflects the incoming beam with a 45° angle of incidence, the Smith reflector uses two 22.5° reflections, first off a full mirror, followed by a second reflection off a 50/50 beam splitter. While the number of reflections has doubled, the steeper angle of incidence of 22.5° for both reflections reduces the overall polarization distortions compared to a regular beam splitter.

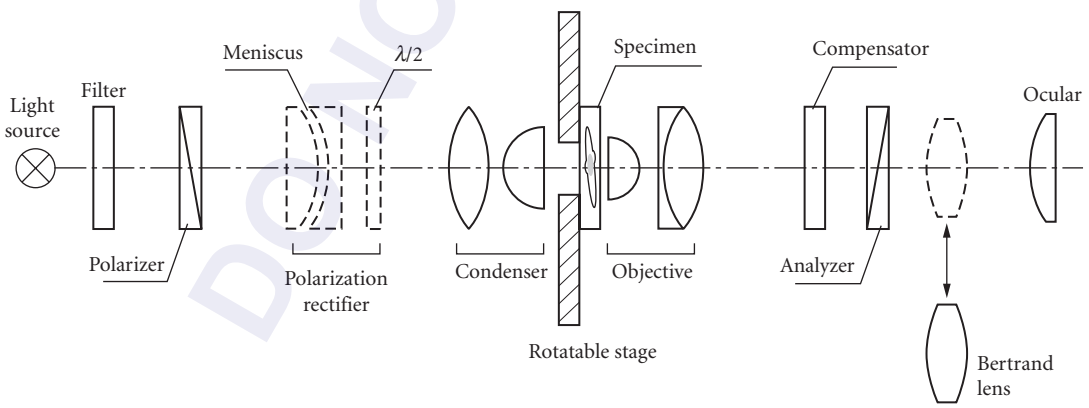

FIGURE 35 Optical train of a polarized light microscope with polarizer, analyzer, and compensator. An optional polarization rectifier can achieve improved sensitivity for low retardance measurements. With an optional Bertrand lens one examines the objective back focal plane for conoscopic interference figures.

Equipped with these standard components, the polarizing microscope represents a powerful analytical tool for the identification of crystals, fibers, and other optically anisotropic materials.[51,68] With standard polarizing microscopes, one can image and measure polarization optical parameters on objects which are larger than a few micrometers and which introduce retardance values greater than several tens of nanometers. However, as the dimension of the object or magnitude of retardance decrease below these ranges, one needs to use special techniques or devices for detecting and measuring birefringence or even for generating a reliable image with high-NA lenses.

The basic ingredients that are needed to detect low levels of birefringence (retardance ≤ 10 nm) are high-extinction optics, use of low-retardance compensator, light source with high irradiance, and high-sensitivity detector (e.g., dark adaptation for visual observation and measurements). The need for high extinction optics applies to all components of the polarization optical train, which starts and ends with the polarizer and analyzer, respectively, and all optical components placed between them. Most manufacturers carry objective and condenser lenses that are either made or specially selected for polarized light observations. Such objectives typically carry the designation P, PO, or POL on their lens barrel and are designed to induce minimal polarization distortions (see Table 2).

Dichroic polarizing filters have replaced calcite prisms (which introduce astigmatism to all but collimated rays) as polarizer and analyzer in all but the most demanding applications. Modern dichroic polarizers are available with extinction factors better than 1000 and transmission better than 90 percent of the light that is fully polarized parallel to the transmission axis. These specs are satisfactory for most applications, in part because even POL-designated microscope lenses that are placed between the polarizer and analyzer cause polarization distortions that typically reduce the extinction of the polarization optical train significantly below 1000. The polarization distortions are typically caused by stress birefringence in the lens glass and by the differential transmission and phase shift of polarized light that passes through the peripheral regions of highly curved lens surfaces.[112] The latter distortions result in four bright quadrants separated by a dark cross (the Maltese cross) that is seen conoscopically for crossed linear polarizers in the absence of a birefringent specimen. These distortions also give rise to anomalous diffraction, based on a four-leaved clover pattern replacing the Airy disk or each weakly birefringent image point.[113,114]

To counteract polarization distortions that occur at high NA lens surfaces, Inoué and colleagues have introduced polarization rectifiers[115,116] made of a zero power lens with meniscus and a half-wave plate (Fig. 35). Using rectified optics Inoué and Sato[117] were able to reveal the chromosome arrangement in living sperm based on high-contrast polarized light images (Fig. 36). Unfortunately, rectifiers are commercially not available for modern microscope objectives, which contain many lens elements and complex antireflection coatings, making the construction of a rectifier highly specific to each objective and condenser lens. However, some manufacturers have succeeded better than others in selecting antireflection coatings that minimize the polarization distortions. Therefore, it is advisable to carefully select microscope optics, testing the polarization performance of similar lenses from several manufacturers and even within the product range of the same manufacturer, before acquiring critical components.

The compensator is located between the polarizer and analyzer, either before or after the specimen. There are several types of compensators (often named after their inventors), which are typically made of birefringent plates or wedges that can be translated or rotated in fine increments while observing the specimen.[118] The effect of the compensator on the polarization of the transmitted or reflected light either adds to or subtracts from (compensates) the effect caused by the specimen. While not absolutely necessary for some basic observations, the compensator (a) can significantly improve the detection and visibility of weakly birefringent objects, (b) is required to determine the slow and fast axis of specimen birefringence, and (c) is an indispensable tool for the quantitative measurement of object birefringence (see, e.g., Ref. 119); for a discussion of the Poincaré sphere as an analogue device to compute the effect of compensators, or of birefringent objects in general, on polarized light see Ref. 120).

Over the years several schemes have been proposed to automate the measurement process and exploit more fully the analytical power of the polarizing microscope. These schemes invariably involve the traditional compensator, which is either moved under computer control[121] or replaced

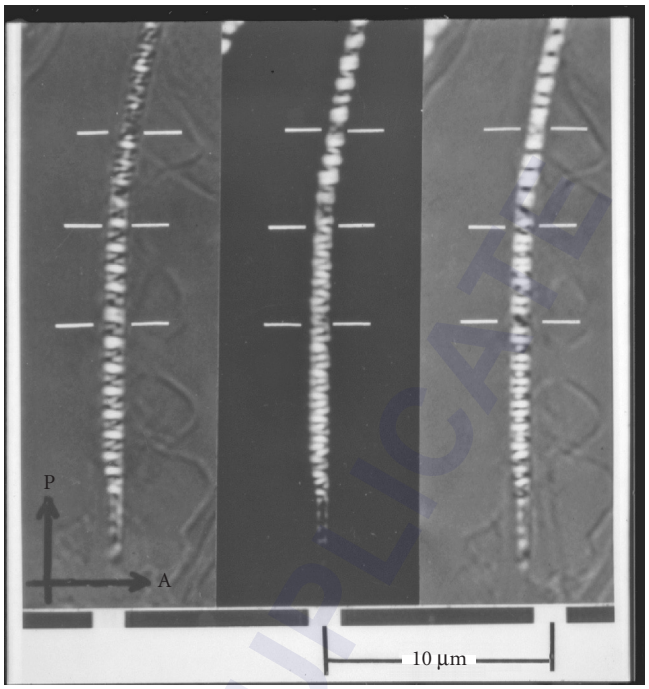

FIGURE 36 Sperm head observed with a rectified polarizing microscope at three different settings of mica compensator. Detailed distribution of birefringence in these chromosomes is shown with great clarity by immersion in dimethyl sulfoxide (refractive index 1.475). White bars: positions of chromosomal "breaks"; probably correspond to the end of each chromosome.[117]

by electro-optical modulators, such as Pockel-cells,[122] Faraday rotators,[123] and liquid crystal variable retarders.[124] These schemes also involve quantitative intensity measurements using electronic light detectors, such as photomultipliers or charge-coupled device (CCD) cameras. For strictly quantitative measurements, acquisition and processing algorithms relate measured image intensities and compensator settings to optical characteristics of the specimen (see, e.g., Ref. 125). As an example of a quantitative, high-resolution birefringence map, we show in Fig. 37 the retardance image of a Siemens star that was etched into a thin silica layer.[50] The image was recorded using the LC-PolScope equipped with a liquid-crystal universal compensator.[126]

Polarized light microscopy is usually practiced in two, mutually exclusive observation modes, called orthoscopy and conoscopy. In orthoscopy, the specimen is viewed directly, while in conoscopy the ocular is replaced by a telescope lens that lets one observe conoscopic interference figures formed in the back focal plane of the objective lens.[68] In conoscopy, the sample birefringence is measured as a function of the tilt angle of rays passing through the specimen. Hence, this observation mode reveals the inclination angle of the optic axis of a uniformly birefringent specimen region, in addition to the azimuth of the optic axis. In orthoscopy, the inclination angle, which is the angle between the optic axis and the plane of observation, is usually not evident. Recently, orthoscopic and conoscopic views were combined in a single, so-called polarized light field image recorded with a microlens array in the intermediate image plane of an LC-PolScope.[21]

Another approach to measuring the three-dimensional birefringence properties of small birefringent objects uses a so-called universal stage, invented by E.S. Fedorov more than 100 years ago, in

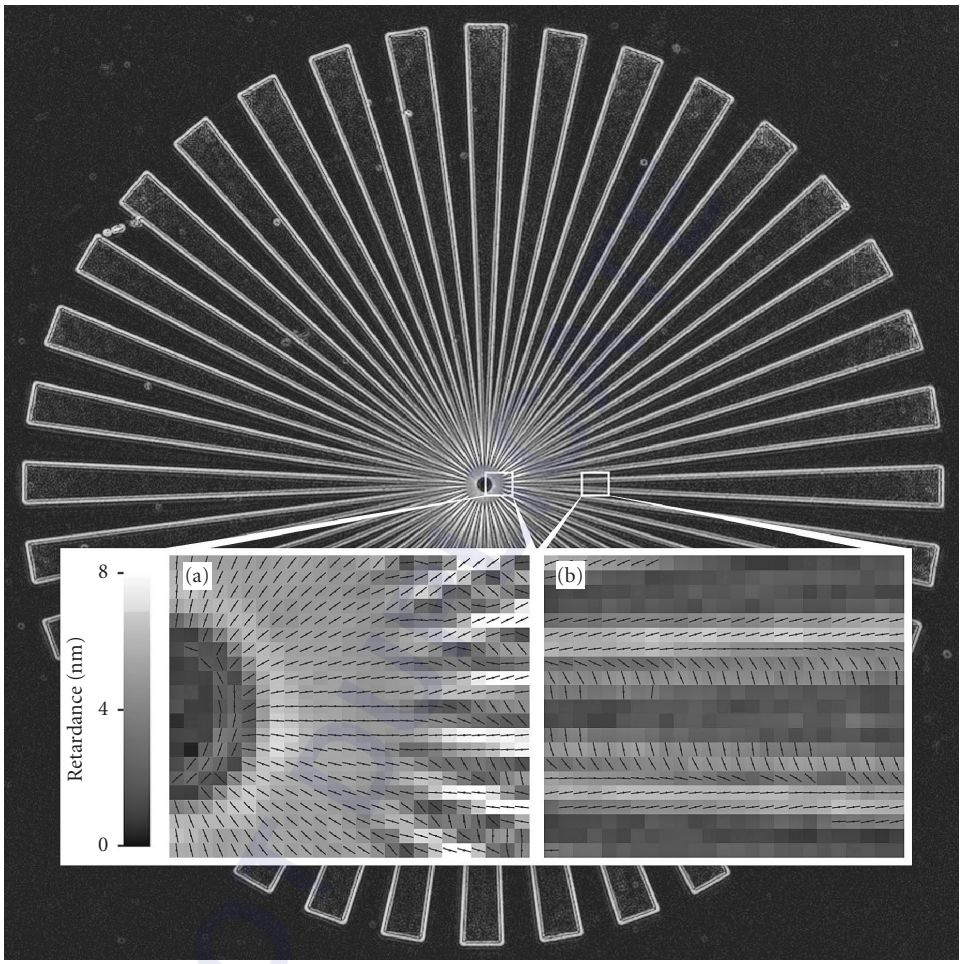

FIGURE 37 Siemens star etched into 90-nm-thick SiO_2 layer and imaged with the LC-PolScope. The dimensions of the star pattern are the same as the one described in Fig. 21. Image brightness is linearly proportional to the retardance measured at all pixel locations. Insets show magnified portions of the pattern with lines indicating the measured slow axis orientation. (a) In the central region birefringence is observed all the way to the inner black disk. Unresolved wedge tips generate form birefringence with the slow axes parallel to the wedge orientations. (b) Edges of a well-resolved wedge portion display edge birefringence, which is composed of two birefringent layers flanking each edge.[127] (60 × /1.4 NA PlanApo oil objective lens and oil condenser with aperture diaphragm reduced to 0.9 NA.)

which the specimen is mounted between two glass hemispheres.[22] Rotation of the specimen through measured angles around two or more axes allows one to explore the three-dimensional birefringence patterns of a small specimen region that is located in the common center of rotation. Alternatives to the universal stage include the spindle stage by Bloss[128] and motorized goniometric stages by Glazer and collaborators.[129,130]

Instead of rotating the specimen under a stationary optical system, Shribak and Oldenbourg implemented a scheme involving a high numerical aperture imaging system and oblique illumination with varying tilt angle of the illuminating beam.[131] For each angle a high-resolution retardance map

is generated representing the polarization properties of the sample as projected along the tilted axis of illumination. Four such maps, each generated with a different tilt angle, are combined to produce a three-dimensional birefringence map. The system is called *Scanned Aperture LC-PolScope* and is described here in more detail in the section "Aperture Scanning."

Fluorescence

Fluorescence microscopy is one of the few modes of microscopy in which the illuminating wavelength differs from that of the emitted. In early designs, the exciting waves were prevented from contaminating the fluorescence image by a combination of (1) special illumination (such as the use of a dark-field condenser) that prevented the direct rays from entering the objective lens, and (2) the use of a barrier filter. The barrier filter absorbs the exciting light while transmitting much of the longer fluorescence wavelengths.

Today most fluorescence microscopes (or attachments) use epi-illumination incorporating interchangeable filter cubes (after Ploem, see Fig. 6) that are matched to the fluorochrome. The filter cube is placed in the collimated beam between the objective and a tube lens, at the intersection of the microscope axis and that of the excitation illuminator located on a side arm. The objective lens serves both as the condenser and the objective. A field diaphragm, and sometimes an aperture iris, is placed in the illuminating side arm together with the source collector at appropriate conjugate planes. The illuminating beam, commonly emitted by a xenon or mercury arc lamp, is filtered through a narrow band path interference filter and reflected down into the objective by a dichromatic beam splitter. The fluorescence imaging beam originating from the specimen passes straight through the dichromatic beam splitter and associated barrier filter and reaches the ocular or camera. Each fluorescence cube contains the appropriate excitation interference filter, dichromatic beam splitter, and barrier filter so that they can be switched as a group, for example, to rapidly inspect specimens containing (or stained with) multiple fluorochromes.

For fluorochromes requiring shorter-wave UV excitation, objective lenses must be designed for greater short-wavelength transmission and low autofluorescence. While aberrations for the shorter-UV exciting wavelengths are generally not as well-corrected as for the imaging wavelengths, it should be noted that such aberrations, or lack of parfocality, directly affect the resolution and efficiency in the case of confocal fluorescence microscopes.

Also, it should be noted that, while little effort is commonly made to fill the objective aperture with the illuminating beam (presumably with the rationale that this should not affect image resolution because each fluorescent object is emitting incoherently relative to its close neighbor), one finds that in practice the fluorescent image is much improved by filling the aperture, for example, by use of an optical fiber light scrambler. While the reasons for this improvement are not fully understood, one explanation might lie in the more efficient excitation of randomly oriented fluorophores by a high-NA illumination beam, which excites even those fluorophores that have their linear transition moment aligned parallel to the microscope axis.

While most fluorescence microscopes today use epi-illumination (since epi-illumination provides advantages such as avoiding loss of excitation by self-absorption by underlying fluorochrome layers, generating an image that more closely approximates an intuitive one when reconstructed in three dimensions, etc.), improvements in interference filters open up new opportunities for fluorescence microscopy using transillumination. New interference filters are available with exceptionally high extinction ($>10^5$) and sharp cutoff of the excitation wavelengths, coupled with high transmission of the pass band. With transillumination, one can more reliably combine fluorescence with polarization-based microscopy or carry out polarized fluorescence measurements with greater accuracy, since one can avoid the use of dichromatic beam splitters, which tend to be optically anisotropic.

Fluorescence microscopy particularly benefits from electronic imaging, especially with the use of low-noise, chilled CCDs as imaging detectors, digital computers to enhance and rapidly process the signal (such as in ratio imaging), and the new fluorescence-conjugated chemical probes that provide incredible sensitivity and selectivity.[11,12,132–135]

For imaging specimens that are labeled with more than two or three types of spectrally distinct fluorophores, a technique known as spectral imaging is becoming available. Spectral imaging combines spectroscopy and imaging, measuring the spectral composition of the light recorded at each point of the image. When spectral imaging is applied to fluorescence microscopy, the filter cube is modified as to transmit a broad range of emission wavelengths. A spectrometer placed before the detector samples the emission spectrum at appropriate resolution and intervals (channels) for wavelengths longer than the excitation wavelength. Spectral imaging systems can either be integrated into the microscope (manufacturers include Leica, Nikon, Zeiss) or can be added to an existing stand (manufacturers include Cambridge Research and Instrumentation Inc., Lightform Inc.). Datasets are typically stored as stacks of images, in which each slice corresponds to a wavelength channel. Powerful algorithms reduce an experimental dataset to indicate for each image point the weighted contributions of pure fluorophores whose spectra are stored in a library.[136,137]

Confocal Microscopy

In confocal microscopy, the specimen is scanned point by point either by displacing the specimen (stage scanning) or by scanning a minute illuminating spot (beam scanning), generally in a TV-raster fashion. In either case, the scanning spot is an Airy disk formed by a high-NA objective lens. An exit pinhole is placed conjugate to the spot being scanned so that only the light originating from the scanned spot is transmitted through the exit pinhole. Thus, light originating from other regions of the specimen or optical system is prevented from reaching the photo detector (Fig. 38).[138,139]

This optical arrangement reduces blurring of the image from out-of-focus light scattering, fluorescence, and the like, and yields exceptionally clear, thin optical sections. The optical sections can then be processed and assembled electronically to yield three-dimensional displays or tilted plane projections. Alternatively, the specimen itself can be scanned through a tilted plane (e.g., by implementing a series of x scans with y, z incremented) to yield a section viewed from any desired orientation, including that normal to the microscope axis.

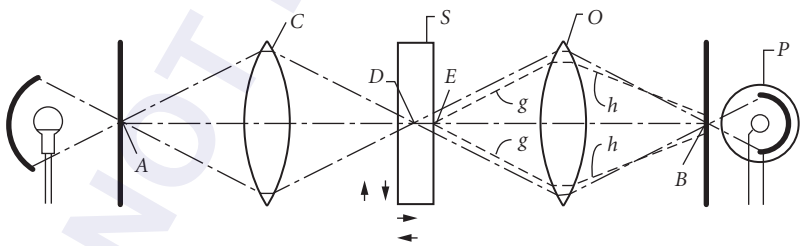

FIGURE 38 Optical path in simple confocal microscope. The condenser lens C forms an image of the first pinhole A onto a confocal spot D in the specimen S. The objective lens O forms an image of D into the second (exit) pinhole B which is confocal with D and A. Another point, such as E in the specimen, would not be focused at A or B, so that the illumination would be less and, in addition, most of the light g-h scattered from E would not pass the exit pinhole. The light reaching the phototube P from E is thus greatly attenuated compared to that from the confocal point D. In addition, the exit pinhole could be made small enough to exclude the diffraction rings in the image of D, so that the resolving power of the microscope is improved. The phototube provides a signal of the light passing through points D_1, D_2, D_3, etc. (*not shown*), as the specimen is scanned. D_1, D_2, D_3, etc. can lie in a plane normal to the optical axis of the microscope (as in conventional microscopy), or parallel to it, or at any angle defined by the scanning pattern, so that optical sections can be made at angles tilted from the conventional image plane. Since, in the stage-scanning system, D is a small spot that lies on the axis of the microscope, lenses C and O can be considerably simpler than conventional microscope lenses.[138,139]

The stage-scanning confocal microscope can yield vastly expanded fields of view. Here the image area is not limited by the field of view of the optics but only by the range of movement of the specimen and ability of the photo detector and processor to handle the vast information generated at high speed. Furthermore, the objective lens needs only to be corrected for a narrow field of view on axis.[6,138] Laser disk recorders are a form of application that takes advantage of these attributes.

The beam-scanning confocal microscope is typically implemented in the reflective or epi-illumination mode. This mode has the advantage that the illuminating beam and the returning light scattered back by the sample pass through the same objective lens and beam-steering devices needed for scanning the sample. The prototype of a modern beam-scanning confocal microscope uses two galvanometric mirrors (one for each dimension of a two-dimensional image) that scan a focused laser beam across a stationary sample field. The backscattered light is collected by the objective and bounces off the same mirrors which "descan" the returning light before it passes through a stationary beamsplitter (to separate the backscattered light from the incoming beam) and a stationary exit pinhole. The exit pinhole is located in a conjugate image plane, while the scanning mirrors are located in positions that are conjugate to the back focal plane of the objective lens. By (indirectly) placing the mirrors into the objective back focal plane, the angular scan of the mirrors is translated into a positional scan of the focused laser beam in the specimen. Beam-scanning microscopes typically require additional relay optics that project the objective back focal plane into the mirror locations.

The laser-scanning, epi-illuminating confocal microscope was developed into a practical instrument in the late 1980s and immediately adopted with great enthusiasm for fluorescence imaging in the life sciences. Because laser beams are typically highly collimated, a source or entrance pinhole is commonly omitted in this instrument. The beam splitter combining and separating the illumination and imaging paths is implemented as a dichroic (also called dichromatic) mirror providing high reflectivity at short wavelengths and high transmissivity at longer wavelengths (or vice versa, depending on the particular optical design). A whole industry has evolved around designing and manufacturing dichromatic mirrors that are appropriate for specific fluorescent dyes and combination of dyes.

For direct viewing of confocal images in reflective mode a Nipkow disk is used for scanning multiple beams across a stationary sample field. The multiple beams originate in many thousands of pinholes arranged helically on a modified Nipkow disk that is located in the image plane of the objective lens. Thus, a single spinning disk can be made to provide synchronously scanning entrance and exit pinholes.[140,141] To overcome the considerable light loss associated with the original designs by Petrán and Kino, Yokogawa Electric Corp. employed a second, coaxially aligned Nipkow disk containing microlenses in its CSU-10 disk confocal scanner (Fig. 39). Each pinhole on the first Nipkow disk has a corresponding microlens on the second Nipkow disk that focuses the laser light into the pinhole. Thus, the light efficiency is increased by a factor equal to the ratio of the microlens to pinhole area. Instead of the 1 percent or so found with conventional Nipkow disk systems, some 40 to 60 percent of the light impinging on the disk containing the microlenses becomes transmitted through the pinholes to illuminate the specimen. Accordingly, the CSU-10 provides a light efficient scan unit that permits direct visual viewing of the confocal image, a great advantage when studying moving objects such as living cells.[142,143]

In a confocal microscope, the exit pinhole can be made smaller than the diameter of the Airy diffraction image formed by the objective lens so that the Airy disk is trimmed down to regions near its central peak. With this optical arrangement, the unit diffraction pattern that makes up the image turns out to be the square of the Airy pattern given in Eq. (2). Thus, the radius at half maximum of the central bright area (Airy disk) is reduced by a factor of 1.36. (The radial position of the first minimum in both patterns is still equal to r_{Airy}.) The shape of the unit diffraction pattern is thus sharpened so that, compared to nonconfocal imaging, two points which radiate incoherently (as in fluorescence microscopy) can be expected to approach each other by up to a factor of $\sqrt{2}$ closer to each other before their diffraction patterns encounter the Rayleigh limit. In Fig. 20 the contrast transfer characteristics of a confocal microscope in the coherent imaging mode is compared with the nonconfocal, incoherent imaging mode using the same lenses. Note that the limiting resolution is the same for both imaging modes, while the contrast transfer of the confocal mode increase more steeply for increasing grating periods.

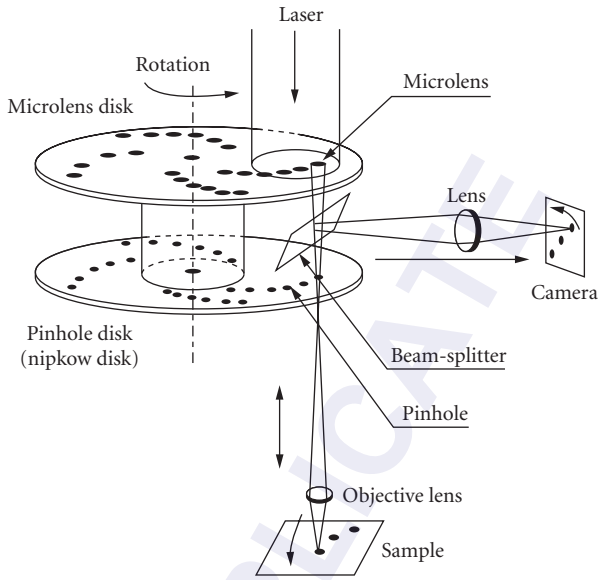

FIGURE 39 Schematic of the Yokogawa CSU-10 confocal disk scanner. The expanded and collimated laser beam illuminates the upper Nipkow disk containing some 20,000 microlenses. Each microlens focuses the laser beam onto its corresponding pinhole, thus significantly raising the fraction of the illuminating beam that is transmitted by the main Nipkow disk containing the pinhole array. The backscattered or fluorescent light is collected by the objective lens and focused back onto the Nipkow disk containing the array of pinholes, which now act as confocal exit pinholes. A beam splitter located between the first and second Nipkow disk reflects the light toward a camera. A lens projects an image of the pinhole array onto the camera, that acquires a confocal image while the Nipkow disk rotates with high speed. After carefully designing the array pattern and implementing a precise and vibration-free rotation of the Nipkow disks, the confocal disk scanner can produce clean, high-resolution images free of fixed pattern noise. In fluorescence imaging, the camera can be replaced by an ocular for direct viewing of the confocal image. (*Schematic provided by Yokogawa Electric Corporation.*)

Rather than using confocal optics to eliminate image blurring from out-of-focus planes, one can achieve the same end by computational deconvolution of a stack of serial optical sections obtained by wide field microscopy.[49,144,145] While computationally intensive and time consuming, this image restoration method allows one to isolate clean optical sections from a stack of images that can be acquired at higher speed and higher efficiency than with laser-scanning confocal microscopy and in modes of contrast generation typically not accessible to confocal imaging.

Alternatively, thin optical sections can be obtained directly with digital enhanced video microscopy using high-NA condenser and objective lenses. Requiring little processing, this approach is especially convenient when many stacks of optical sections have to be acquired at high rates in succession, for example in order to record rapid, three-dimensional changes in microscopic domains over time.

Structured Illumination

The quest for improved resolution beyond the diffraction limit has led to the development of several methods that modify the illumination pattern in wide-field microscopy. In standard wide field microscopy, the specimen is illuminated using condenser optics that ideally projects a uniform field of light into the specimen. In structured illumination setups, however, a finely patterned illuminating field is projected into the specimen, providing a means for generating optical sections similar to confocal microscopy and for improving resolution.

Wilson and colleagues[146] first described a simple method of obtaining optical sectioning in a conventional wide-field microscope by projecting a single-spatial-frequency grid pattern onto the object. Images taken at three spatial positions of the grid were processed in real time to produce optically sectioned images that are substantially similar to those obtained with confocal microscopes. The sectioning capability is achieved by superimposing an illumination pattern that is only in focus at a thin section through the specimen, while all other sections of the specimen are illuminated with a more or less blurred version of the pattern. The specimen with the superimposed grid pattern is then imaged with regular wide field optics focused on the grid pattern inside the specimen. Hence, all image features that have the grid pattern imposed on them are located in this specimen section, while image features from other sections of the specimen appear nearly uniformly illuminated. For removing those out-of-focus features and removing the intruding effect of the illumination pattern on the specimen image, three raw sample images are recorded, each with the illumination pattern slightly shifted in position. Subsequently, the raw images are computationally combined to generate an optical section of the sample without the grid pattern noticeable in the image. The company Carl Zeiss has adopted this strategy in its ApoTome slider module for generating optical sections using epi-illumination.

Instead with a regular grid pattern, the sample can also be illuminated with a random speckle pattern to provide depth discrimination in thick, fluorescently labeled tissues.[147,148] The technique consists of illuminating a sample with a sequence of speckle patterns and displaying the differential intensity variance of the resultant sequence of fluorescence images. The advantage of speckle illumination is that it provides diffraction-limited illumination granularity that is highly contrasted even in scattering media.

Structured illumination strategies that go beyond optical sections and provide lateral resolution that exceeds the classical diffraction limit by a factor of 2 or more have been devised by Gustafsson.[149] The sample is illuminated with a series of excitation light patterns, which cause normally inaccessible high-resolution information to be encoded into the observed image. The recorded images are linearly processed to extract the new information and produce a reconstruction with twice the normal resolution. Unlike confocal microscopy, the resolution improvement is achieved with no need to discard any of the light arriving from the specimen.

In addition to improving the lateral resolution this method can be applied in three dimensions to double the axial as well as the lateral resolution, with true optical sectioning.[150] A grating is used to generate three mutually coherent light beams, which interfere in the specimen to form an illumination pattern that varies both laterally and axially. The spatially structured excitation intensity causes normally unreachable high-resolution information to become encoded into the observed images through spatial frequency mixing. This new information is computationally extracted and used to generate a three-dimensional reconstruction with twice as high resolution, in all three dimensions, as is possible in a conventional wide-field microscope.

Structured illumination is primarily used in fluorescence microscopy, where in principle it is capable of unlimited resolution. To achieve unlimited resolution, structured illumination has to be combined with a nonlinear dependence of the fluorescence emission rate on the illumination intensity.[151,152] As an example of this concept, Gustafsson experimentally demonstrated saturated structured-illumination microscopy, in which the nonlinearity arises from saturation of the excited state. This method can be used in a simple, wide-field (nonscanning) microscope, which uses only a single, inexpensive laser, and requires no unusual photophysical properties of the fluorophore. The practical resolving power is determined by the signal-to-noise ratio, which in turn is limited by photobleaching. Experimental results show that a two-dimensional point resolution of < 50 nm is possible on sufficiently bright and photostable samples.

Light Field

Instead of increasing resolution in a single image plane, it is sometimes desirable to trade lateral resolution for axial resolution in a three-dimensional image stack. To this end, Marc Levoy and colleagues[20] have replaced the regular camera on a standard, wide-field microscope by a camera with microlens array, a so-called light field camera or plenoptic camera.[153] The array consists of a hundred thousand or more microlenses arranged in a square up to the size of the microscope's field number. The array is placed in the intermediate image plane of the objective lens. Behind the array the sensor chip is located in the backfocal plane of the microlenses. In other words, the light field camera samples the specimen image on a regular grid at intervals that corresponds to the pitch of the microlens array. At each grid point the camera captures a small subimage of the objective's back focal plane. Hence, the camera captures a hybrid image of the specimen that is sampled not only in space but also along different directions through the specimen.

The raw light field image, when presented to the eye, cannot be directly interpreted since it consists of a multitude of small disk-shaped images (of the objective's back focal plane) arranged on a regular grid. However, a single light field image is used to reconstruct a multitude of conventional images of a specimen that is viewed along different directions or focused to different object planes.[20] These differing views are all based on a single light field image that was captured by a single camera exposure. Hence light field microscopy can be especially useful when imaging three-dimensional structures that change rapidly in time, such as living cells and tissues. Based on a single snapshot one can reconstruct a stack of optical sections that were all recorded at the same point in time, thus avoiding registration problems between sections.

However, the versatility of generating different views and optical sections from a single light field image comes at a price. The sacrifice one makes is a reduction in image size. Specifically, if each microlens subimage contains $N \times N$ pixels, then the computed images will contain N^2 fewer pixels than if the microlenses were not present. In return, we can compute N^2 unique oblique views of the specimen, and we can generate a focal stack containing N slices with nonoverlapping depths of field.[20]

The recording of light field images is compatible with several contrast modes, including fluorescence and polarized light microscopy. One of the first areas to take advantage of simultaneous optical sections was fluorescence microscopy of functional neuronal tissues and the recording of three-dimensional excitation patterns. In polarized light field microscopy, the microlens array generates a hybrid image consisting of an array of small conoscopic images, each sampling a different object area.[21] Analysis of the array of conoscopic images reveals the birefringence of each object area as a function of the propagation direction of transmitted light rays. Compared to traditional conoscopy and related methods, the vastly improved throughput and quantitative analysis afforded by the light field LC-PolScope, for example, make it the instrument of choice for measuring three-dimensional birefringence parameters of complex structures. Since light field microscopy was implemented only a few years ago, additional application areas of this new method are likely to emerge in the future.

Aperture Scanning

In the aperture-scanning microscope devised by Ellis for phase-contrast microscopy, the tip of a flexible signal optical fiber, illuminated by an Hg arc, makes rapid circular sweeps at the periphery of the condenser aperture.[65] This circular, scanning illumination spot replaces the conventional phase annulus in the condenser aperture plane. A quarter-wave plate and absorber, both covering only a small area conjugate to the illuminating spot, spins in synchrony with the fiber at the objective back aperture (or its projected conjugate). Thus, the specimen is illuminated by a narrow, coherent beam that enters the specimen obliquely at high NA, with the azimuth orientation of the beam swinging around and around to generate a full cone of illumination within the integration time of the detector. With this aperture-scanning approach, the specimen is illuminated by a large-NA cone of light which is temporally incoherent, with the phase disk covering only a small fraction of the area normally occupied by the phase ring in conventional phase-contrast systems. The small size of the phase

disk, while appropriately reducing the amplitude and introducing the requisite $\lambda/4$ wave phase retardation to the rays not scattered by the specimen, allows the transmission of a much larger fraction of the scattered rays that carry the high spatial frequency information. The aperture-scanning phase-contrast microscope thus provides a very thin optical section. The image is also virtually free of the phase halo that obscures image detail adjacent to refractile boundaries in conventional phase-contrast microscopy.

For polarized light microscopy an aperture scanning scheme was designed and built by Shribak and Oldenbourg using a liquid crystal device in the front focal plane of the condenser lens.[131,154] The liquid crystal device was designed for two functions: (1) to create oblique illumination of the specimen, and (2) to measure the birefringence parameters of microscopic objects for each of four oblique tilt angles of illumination. By measuring the object retardance along each of the four tilted projections, the inclination angle of the optic axis of birefringent objects was revealed, in addition to the orientation or azimuth angle in the plane of focus. The inclination angle of the optic axis is usually not evident from traditional polarized light images (see section on polarized light).

Extending this concept, modulation of the transfer functions of the condenser and objective apertures with electro-optical devices should open up intriguing new opportunities. Such modulation eliminates the need for mechanical scanning devices, the spatial distribution of the modulation function can be altered at will, and the amplitude and phase of light passing each point in the aperture can be adjusted rapidly, even coupled dynamically to the image signal through a feedback loop to generate dynamic spatial filters that enhance or select desired features in the image.

28.5 MANIPULATION OF SPECIMEN

In addition to viewing microscopic specimens, the light microscope and microscope objectives are also used to project reduced high-intensity images of source patterns into the object plane in order to optically manipulate minute regions of the specimen. Photolithography and laser disk recorders are examples of important industrial applications, which have prompted the design of specially modified objective lenses for such purposes.

Microbeam Irradiation, Ablation

Many applications are also found in the biomedical field, initially using UV-transmitting, moderately high NA objectives that are parfocalized for visible light and UV down to approximately 250 nm (Zeiss Ultrafluar, also quartz monochromats from Leitz). In its extreme form, a concentrated image of a circular- or slit-shaped UV or laser source of selected wavelengths is imaged onto a biological specimen to locally ablate a small targeted organelle; for example, a part of a chromosome, the microtubules attached thereto, or tiny segments of cross-striated muscle, are irradiated with the microbeam in order to sever their mechanical connections and, for example, to analyze force transduction mechanisms.[155,156] In other cases, oriented chromophores can be selectively altered at the submolecular level, for example, by polarized UV microbeam irradiation. The stacking arrangement of the DNA nucleotide bases (which exhibit a strong UV dichroism, as well as birefringence in visible light) can be selectively altered and disclose the coiling arrangement of DNA molecules within each diffraction-limited spot in the nucleus of living sperm.[117] Brief microirradiation of slit- or grid-shaped patterns of UV are used to bleach fluorescent dyes incorporated into membranes of living cells. The time course of recovery of fluorescence into the bleached zone measures the rate of diffusion of the fluorescently tagged molecules in the membrane and reveals unexpected mobility patterns of cell membrane components.[157,158]

Lasers have become the dominant source for microbeam irradiation experiments in cell and developmental biology and in other application areas. Laser sources can have a wide range of tunable wavelengths (217 to 800 nm), energies, and exposure durations (down to 25×10^{-12}).[159] They are often used together with sensitizing dyes or fluorescent markers to target specific organelles.[160] They can be used in conjunction with versatile beam-shaping optics such as spatial light modulators.[161]

Photosensitive and Caged Compounds

Selected target molecules within minute regions in living cells can be modified, tagged, or activated by focused beams of light. The target molecules can be naturally photosensitive species such as chlorophyll (which produces oxygen where illuminated with the appropriate visible wavelengths), rhodopsin (which isomerizes and triggers the release of calcium ions and action potentials in retinal cells), or artificially introduced photosensitive reagents such as the drug colchicine (whose antimitotic activity is abolished locally with 366-nm irradiation).

Of the photosensitive compounds, the *caged compounds* have a far-reaching potential. These are compounds that are synthesized so as to "cage" and hide the active chemical group until a photosensitive part of the compound is altered (e.g., by long-wavelength UV irradiation) and unmasks the hidden active group. Thus, by preloading with the appropriate caged compound and irradiating the cell selectively in the region of interest, one can test the role of the uncaged compound. For example, the role of ATP can be tested using caged ATP and ATP analogs; response to subtle increase in calcium ions can be seen using caged calcium or caged calcium chelators.[162,163] Likewise, caged fluorescent dyes are irradiated to locally label and follow the transport of subunits within macromolecular filaments in a dividing cell.[164] Caged glutamate in brain slices was photolyzed using a holographically generated illumination pattern for simultaneous multispot activation of different dendrites.[161]

Optical Tweezers

Intense laser beams concentrated into a diffraction spot can generate a photon-driven force great enough to capture and suspend small particles whose refractive index differs from its surrounding.[165,166] Applied to microscopy, a single swimming bacterium or micrometer-sized organelles in live cells can be trapped and moved about at will at the focus of a near-infrared laser beam focused by an objective lens of high NA. While the energy density concentrated at the laser focus is very high, the temperature of the trapped object remains within a degree or so of its environment; biological targets typically exhibit low absorbance at near-infrared wavelengths and thermal diffusion through water from such minute bodies turns out to be highly effective. Thus, the bacterium continues to multiply while still trapped in the focused spot, and it swims away freely when the laser beam is interrupted.

The ability to use "optical tweezers," not only to capture and move about minute objects but to be able to instantly release the object, provides the microscopist with a unique form of noninvasive, quick-release micromanipulator.[167]

Optical tweezers are now being used in the investigation of an increasing number of biochemical and biophysical processes, from the basic mechanical properties of biological polymers to the multitude of molecular machines that drive the internal dynamics of the cell. Innovation continues in all areas of instrumentation and technique, with much of this work focusing on the refinement of established methods and on the integration of this tool with other forms of single-molecule manipulation or detection. These developments have important implications for the expanded use of optical tweezers in biochemical research.[168]

28.6 ACKNOWLEDGMENTS

Shinya Inoué was the principal author of the chapter on microscopes in the previous edition of the *Handbook of Optics*. The authors wish to thank Dr. Inoué for his many suggestions regarding the reorganization of the content, for a new contribution on the single-sideband edge enhancement (SSEE) technique, and for his consent to use much of the previous text and figures for the new edition. In acknowledging contributions to both editions, the authors also wish to thank Gordon W. Ellis of the University of Pennsylvania, late Katsuji Rikukawa, Yoshiyuki Shimizu, and Hiroohi Takenaka from Nikon K. K., Japan, Ernst Keller and Rudi Rottenfusser of Carl Zeiss, Inc., Jan Hinsch

of Leica, Inc., Mortimer Abramovitz of Olympus, Inc., and Lee Shuett and Mel Brenner of Nikon, Inc., who all provided helpful information and insights into microscope design.

The preparation of this chapter was supported in part by the National Institutes of Health grants R01 EB002583 awarded to R.O. and R01 EB005710 awarded to M.S.

REFLECTIVE AND CATADIOPTRIC OBJECTIVES

Lloyd Jones

College of Optical Sciences
University of Arizona
Tucson, Arizona

29.1 GLOSSARY

A	4th-order aspheric deformation coefficient
AN	4th-order nonsymmetric deformation coefficient
B	6th-order aspheric deformation coefficient
C	8th-order aspheric deformation coefficient
c	surface base curvature
CON	conic constant
D	10th-order aspheric deformation coefficient
FN	focal ratio
GLA	glass type
h	radial surface height
INF	infinite radius of curvature
k	conic constant
n	index of refraction
R	radius of curvature
RDX	radius of curvature in the *x* dimension
RDY	radius of curvature in the *y* dimension
STO	stop surface
SUR	surface number
t	element thickness
THI	thickness of element or distance to next surface or element
Z	surface sag

29.2 INTRODUCTION

During the initial stages of an optical design, many optical engineers take advantage of existing configurations that exhibit useful properties. This chapter is a compilation of reflective and *catadioptric* objective designs that should help inform the reader of available choices and provide reasonable starting solutions.

The chapter also includes a cursory introduction to some of the more important topics in system analysis, such as angular and linear blur size, *image irradiance*, scaling, and stray light control.

An extensive list of referenced reading material and brief definitions of terms italicized throughout the text are included.

29.3 GLASS VARIETIES

Glasses used in the designs are represented in terms of index of refraction and Abbe number or *V* number, below. The *V* number indicates glass dispersion. Most glasses can be obtained from a number of vendors.

Glass	Index of Refraction	*V* Number
BK7	1.516	64.2
F2	1.620	36.3
F9	1.620	38.1
FK51	1.487	84.5
FN11	1.621	36.2
Germanium	4.037	117.4
LLF1	1.548	45.8
LAK21	1.640	60.1
PSK2	1.569	63.2
Silica	1.445	27.7
Silicon	3.434	147.4
Sapphire	1.735	15.5
SK1	1.610	56.5
SK2	1.607	56.8
SK3	1.609	58.9
SK16	1.620	60.3
SF5	1.673	32.1
SF10	1.728	28.5
UBK7	1.517	64.3

29.4 INTRODUCTION TO CATADIOPTRIC AND REFLECTIVE OBJECTIVES

The variety of objectives presented in this chapter is large. Most of the intricate detail relating to each design is therefore presented with the design itself. In the following paragraphs, analysis of the general features of the catadioptric and reflective objectives is undertaken.

Conic Mirrors

It is apparent after a brief perusal of the designs that there are many surface types. Among these are the sphere, paraboloid, hyperboloid, prolate ellipsoid, and oblate ellipsoid. The oblate

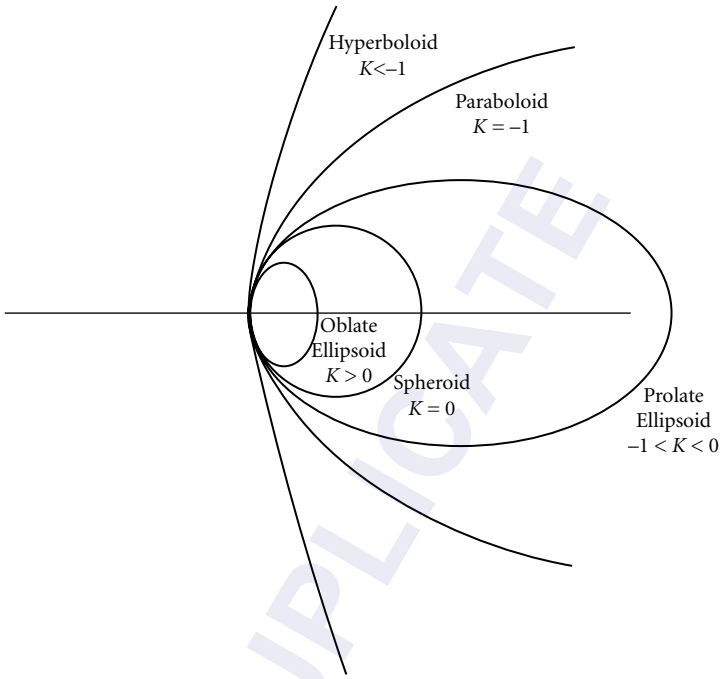

FIGURE 1 Relative shapes of conic surfaces in two dimensions.

ellipsoid is a prolate ellipsoid turned on its side. The equation of a conic is given by the expression

$$Z = \frac{ch^2}{1+\sqrt{1-(1+k)c^2h^2}} \tag{1}$$

where Z is the surface sag, k is the *conic constant*, c is the surface base curvature, and h is the radial height on the surface. The relative shapes of these surfaces are illustrated in Fig. 1.

Conic mirrors give perfect geometric imagery when an axial point object is located at one conic focus and the axial point image is located at the other conic focus. Figure 2 illustrates these ray paths.

General Aspheres

General aspheres are surfaces with fourth- and higher-order surface deformation on top of a flat or curved surface.[1] The surface deformation of a rotationally symmetric general asphere is given by the relation

$$Z = \frac{ch^2}{1+\sqrt{1-(1+k)c^2h^2}} + Ah^4 + Bh^6 + Ch^8 + Dh^{10} \tag{2}$$

where A, B, C, and D are 4th-, 6th-, 8th-, and 10th-order coefficients that determine the sign and magnitude of the deformation produced by that order. Although general aspheres allow correction of *third-* and *higher-order aberrations* and may reduce the number of elements in an optical system, general aspheres are more expensive than spheres or conics. If aspheric deformation is required, conic surfaces should be tried first, especially since a conic offers higher-order correction.[2]

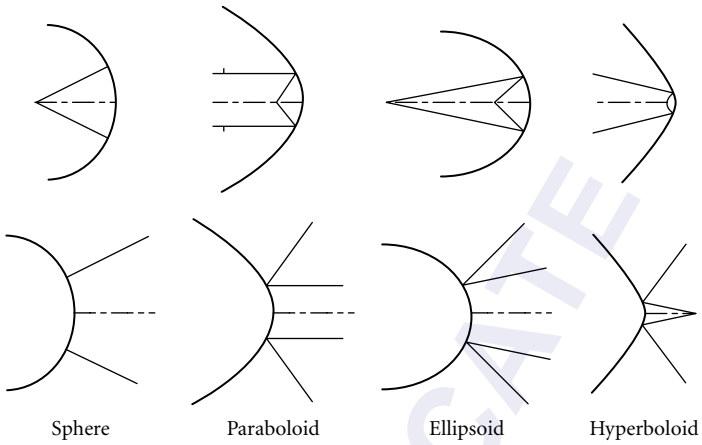

FIGURE 2 Ray paths for perfect axial imagery.

Obscurations

Obscurations that block portions of the entering beam reduce image irradiance and image contrast[3,4] in reflective and catadioptric systems. Several methods are used to reduce or eliminate completely the effects of an obscuration (see Fig. 3).

Figure 3*a* illustrates a commonly employed technique for reducing large-mirror obscuration: a small secondary mirror close to the intermediate image moves the larger tertiary mirror out of the beam path.

Figure 3*b* is an illustration of an eccentric pupil system. All elements are symmetric about the same axis and the aperture stop is decentered for a clear light path.

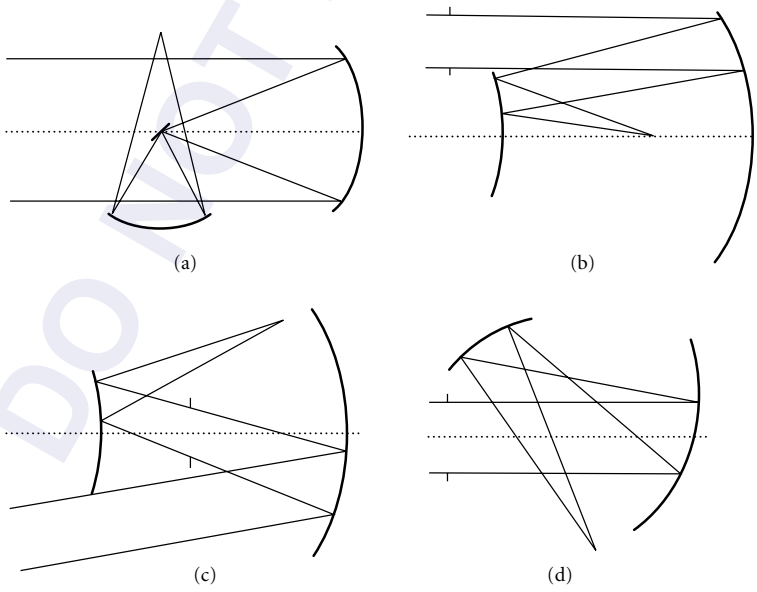

FIGURE 3 Reducing the size of or eliminating an obscuration.

Figure 3*c* is an example of an off-axis objective with the field of view biased to direct the center of view away from any intervening elements. All elements and apertures are symmetric about the *optical axis*.

Figure 3*d* is an illustration of a tilted and decentered-component objective. Each element is rotationally symmetric about its own unique optical axis which may be tilted and/or decentered. The imaging behavior of this system is more complicated to deal with than the imaging behavior of eccentric pupil and off-axis systems. Vector aberration theory[5,6] has been developed to properly model the imaging behavior of these systems.

Stray Light Suppression

Suppression of light diffracted from apertures and obscurations is facilitated with intermediate images and a real and accessible *Lyot stop*. Figure 4*a* illustrates a generic refractive configuration with an intermediate image and Lyot stop. Figure 4*b* illustrates where the diffracted light (shaded region) originates and terminates (at one edge of each aperture, for clarity).

A *field stop* is placed at the focus of the first lens to block diffracted light produced by the front light baffle. To block unwanted objects within the field of view, an occulting disc may be inserted at the focus of the first lens, as is done with a Lyot coronagraph in order to block the sun. By oversizing the field stop slightly, the light diffracted at the field stop falls just outside of the detector area.

Following the field stop is a second lens that reimages the intermediate image to the final image and the *entrance pupil* to the Lyot stop (the shaded region in Fig. 4*a* illustrates how the entrance pupil is imaged). Undersizing the Lyot stop blocks the light diffracted at the entrance pupil. In this way the Lyot stop becomes the *aperture stop* of the system.

Another application of the Lyot stop in the infrared (assuming the Lyot stop is located exterior to the objective optics) is as a cold stop.[7] The cold stop (Fig. 4*a*) is a baffle that prevents stray infrared light, radiated from the housing, from impinging upon the detector from outside its intended field.

Reflective and Catadioptric Objective Designs

The objectives to follow are listed according to *focal ratio* and design type. Objectives have a 20-cm diameter and catadioptric systems are optimized for a wavelength range from 480 to

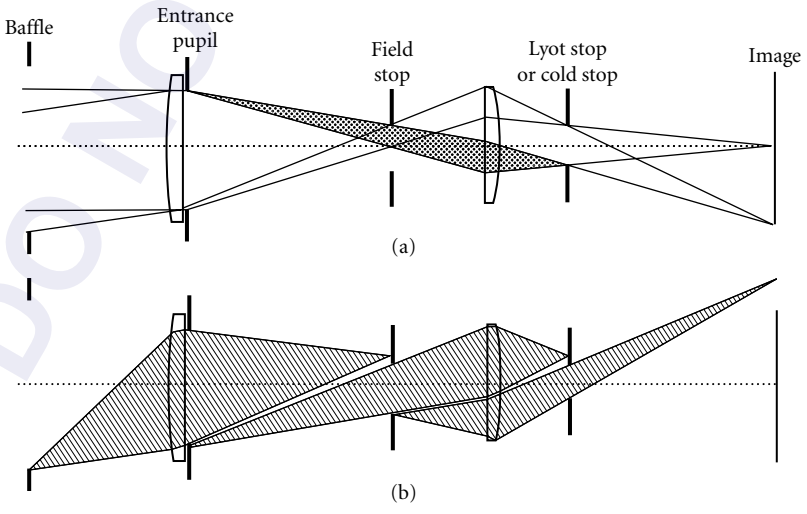

FIGURE 4 Generic objectives with apertures.

680 nm unless otherwise stated. The angles of surface and element tilts are with respect to the horizontal optical axis. Decenters are also with respect to the optical axis. Since many of the designs are *aplanatic, anastigmatic,* and free of chromatic aberrations, the position of the stop does not affect third-order aberration correction and may be chosen to minimize *vignetting, distortion,* element size, or stray light contamination. All aberrations mentioned in this section are third-order unless otherwise stated.

Definitions of the abbreviated terminology used in the lens data are as follows:

SUR Surface number.

RDY Surface radius of curvature. A positive value means the center of curvature lies to the right of the surface; negative to the left.

THI Thickness of element or distance to next element. The value is positive if the next surface lies to the right of the surface.

GLA Glass-type or mirror surface, the latter referred to by the abbreviation REFL.

CON Conic constant k.

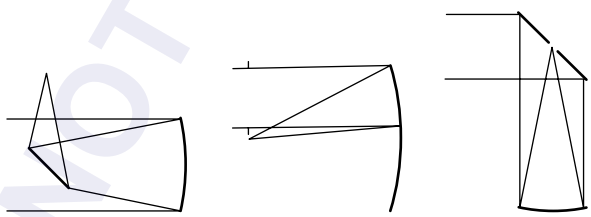
STO Stop surface.

INF A surface with an infinite radius of curvature; that is, a flat surface.

A, B, C, D The 4th-, 6th-, 8th-, and 10th-order aspheric deformation coefficients in Eq. (2).

A potential source of confusion is the terminology used to describe Mangin elements; that is, refractive elements with reflective back surfaces. This is illustrated in design 2 (F/4 Mangin): a ray enters the second refractive surface of the element (surface 2) and travels to the right where it intersects the mirror surface (surface 3). The thickness of surface 2 is therefore positive. The ray is reflected by the mirror surface (surface 3) and travels back through the glass element to surface 2; hence, the notation F9/REFL and the negative surface 3 thickness. Since surface 2 and 4 represent the same surface, the radii are the same.

F/4 Paraboloid Objective



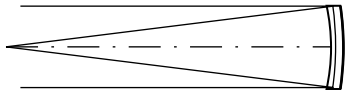
(a) Newtonian (b) Herschelian (c) Pfund

Comments A single parabolic mirror objective can be arranged in a variety of forms, the best known being the Newtonian. Here a mirror flat diverts the image away from the light path. A tipped-mirror configuration is the Herschelian; a modern version is untipped and employs an eccentric-pupil to give an accessible image. A "backwards" Newtonian, the Pfund has a large flat-mirror primary. The Pfund has a smaller obscuration than the Newtonian and requires no diffraction-inducing support structure for the folding flat.

As has been mentioned, the on-axis performance of a paraboloid objective is perfect. Off-axis, *coma* quickly degrades image quality. For objectives slower than F/11, the easy-to-fabricate spherical mirror gives the same performance as a paraboloid when diffraction is also considered.

The paraboloid objective has image quality as good as a Cassegrain (design 3) of equivalent FN and aperture diameter, and is easier to align. The Cassegrain has the advantage of being compact.

F/4 Mangin



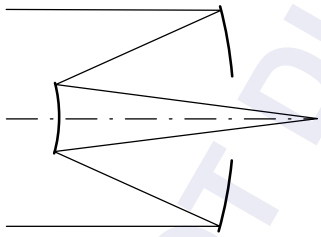
SUR	RDY	THI	GLA
1	−75.15	1.0	BK7
2	−307.1	1.4	F9
3	−123.63	−1.4	F9/REFL
4	−307.1	−1.0	BK7
5	−75.15	−80.48	

Comments The Mangin[8] was invented by a French engineer of the same name to replace difficult-to-fabricate paraboloids in light houses. The objective relies upon the overcorrected *spherical aberration* produced by the negative first surface to cancel the undercorrected spherical aberration produced by the focusing, reflective surface. The chromatic aberration of the Mangin is reduced by achromatizing with two glasses of different dispersions. *Secondary spectrum* limits on-axis performance, and coma, one-half that of a spherical mirror, is the primary field-limiting aberration. Kingslake[9] takes the reader through the design of a Mangin mirror.

Mangin mirrors are susceptible to ghost reflections from the refractive surfaces. Antireflection coatings are usually needed.

In some cases the overcorrected chromatic aberration of a Mangin is used to cancel undercorrected chromatic aberration produced by a refractive element. The Schupmann or medial objective[10,11] has a positive refractive element with undercorrected chromatic aberration which is annulled by a Mangin element.

F/4 Cassegrain

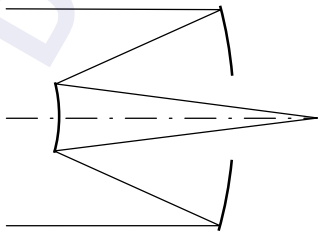


SUR	RDY	THI	GLA	CON
STO	−45.72	−16	REFL	−1
2	−19.2	24.035	REFL	−3.236

Comments The ubiquitous Cassegrain is predominant in situations where a small field of view, high resolution, compact size, long effective focal length, and accessible image are required. The classical Cassegrain is composed of a paraboloid primary and hyperboloid secondary, giving perfect imagery on-axis whenever the primary image coincides with the hyperboloidal focus. Coma and *field curvature* limit off-axis performance.

Many books discuss the first- and third-order properties of Cassegrain objectives. The Rutten,[12] Schroeder,[13] Korsch,[14] and Smith[3] texts are among these.

F/4 Ritchey-Chretien

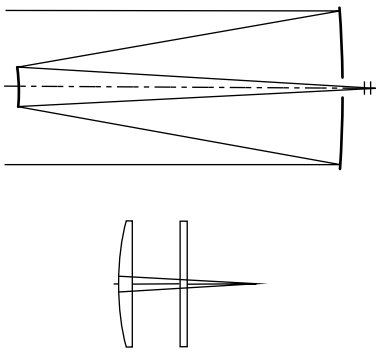


SUR	RDY	THI	GLA	CON
STO	−45.72	−16	REFL	−1.072
2	−19.2	24.034	REFL	−3.898

Comments The aplanatic Cassegrain or Ritchey-Chretien[15] is also corrected for coma, leaving astigmatism and field curvature uncorrected. Both mirrors of the Ritchey-Chretien are hyperboloids.

Numerous modern telescope objectives are of Ritchey-Chretien form; among these are the Hubble space telescope and the infrared astronomical satellite IRAS.

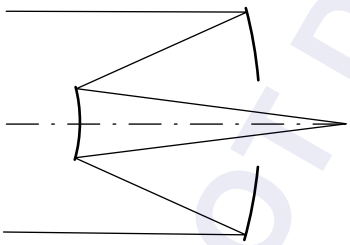
F/9 Ritchey-Chretien Telescope with Two-Lens Corrector



SUR	RDY	THI	GLA	CON
STO	−2139.7	−794.0	REFL	−1.0778
2	−802.83	853.96	REFL	−4.579
3	67.73	2.54	BK7	
4	90.39	9.9		
5	−1925.6	1.27	BK7	
6	129.1	14.39		

Comments This is a design by Wynne[16] for the correction of the Cassegrain focus of a large (350-cm) Ritchey-Chretien. The corrector removes the inherent astigmatism and field curvature of the Ritchey-Chretien. Other Cassegrain focus correctors are discussed by Schulte,[17] Rosin,[18] and Wilson.[19]

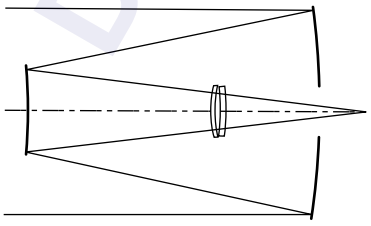
F/4 Dall-Kirkham



SUR	RDY	THI	GLA	CON
STO	−45.72	−16	REFL	−0.6456
	Sixth-order term:		0.593E-10	
2	−19.2	24.035	REFL	

Comments The Dall-Kirkham is another Cassegrain corrected for spherical aberration. The primary is an ellipsoid with sixth-order aspheric deformation and the secondary is spherical. An inverse Dall-Kirkham, or Carlisle, is just the reverse, with a spherical primary. There is *zonal spherical aberration* without the sixth-order deformation. Five times more coma is produced by the Dall-Kirkham than the classical Cassegrain, seriously limiting the field of view.

F/4 Cassegrain with Field Corrector and Spherical Secondary

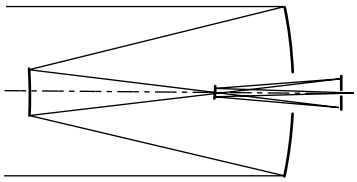


SUR	RDY	THI	GLA	CON
1	−94.21	−27.937	REFL	−1
STO	−94.29	17.72	REFL	
3	17.59	0.35	Silica	
4	8.76	0.491		
5	−64.15	0.6	Silica	
6	−13.41	13.67		

Comments By adding zero-power refractive correctors, the performance of a reflective objective is substantially enhanced. Zero power is maintained to prevent *axial color*. Such is the case with this objective similar to one designed by Rosin.[20] All third-order aberrations, with the exception of distortion, are corrected. The surfaces, with the exception of the primary, are spherical. One of the most attractive features of this design, in comparison to the Schmidt which will be discussed shortly, is the small size of the refractive elements. Add to this the capability of eliminating any remaining spherical aberration in an assembled objective by adjusting the axial positions of the lenses.

Zero *Petzval sum* and, hence, a flat image (in the absence of astigmatism) is ensured by giving the mirrors the same curvature and the lens elements equal and opposite power.

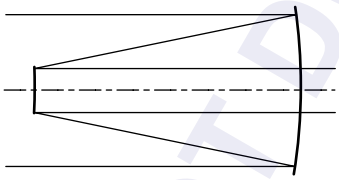
F*/15 *Spherical-Primary Cassegrain with Reflective Field Corrector



SUR	RDY	THI	GLA	CON
STO	−84.03	−30.69	REFL	
2	−46.56	36.83	REFL	20.97
3	−17.39	−14.77	REFL	−0.8745
4	−20.87	16.26	REFL	−96.62

Comments This well-corrected design from Korsch[14] has an easily manufactured spherical primary and is intended for use as a large-aperture telescope objective. Another all-reflective corrector of Gregorian form has been developed for a fast (F/0.6) spherical primary.[21]

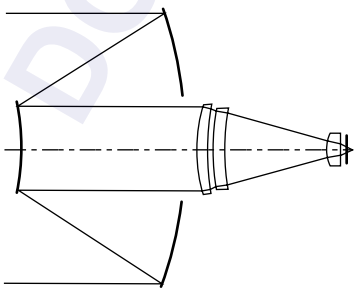
Afocal Cassegrain-Mersenne Telescope



SUR	RDY	THI	GLA	CON
STO	−100	−35	REFL	−1
2	−30	40	REFL	−1

Comments The Mersenne contains two confocal paraboloids working at infinite conjugates. It is aplanatic, anastigmatic, and can be made distortion-free by choosing an appropriate stop location. The utility of confocal mirrors has been emphasized by Baker[22] and Brueggeman,[23] and is illustrated in the following design.

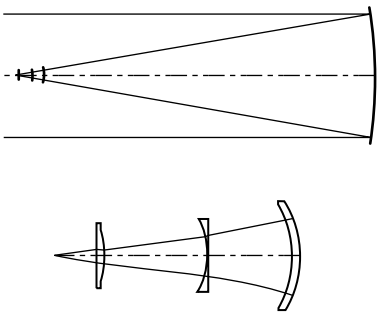
Dual-Magnification Cassegrain



SUR	RDY	THI	GLA	CON
STO	−33.99	−11.69	REFL	−1
2	−10.61	12.76	REFL	−1
3	10.486	0.877	Silicon	
4	25.673	0.462		
5	48.33	0.798	Germanium	
6	22.68	7.57		
7	3.52	1.0	Silicon	
8	4.22	0.377		
9	INF	0.16	Sapphire	
10	INF	0.396		

Comments This IR design is related to one introduced by Fjeidsted.[24] The system offers two magnifications and fields of view. The high-magnification configuration is with the afocal Mersenne in the optical path. Removing the secondary lets light pass directly to the refractive assembly and a larger field of view is observed. The spectral range is from 3.3 to 4.2 μm.

F/3.2 Three-Lens Prime Focus Corrector



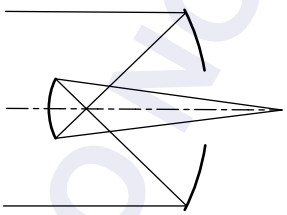
SUR	RDY	THI	GLA	CON
STO	−1494.57	−684.08	REFL	−1
2	−26.98	−2.6	UBK7	
3	−31.3	−22.43		
4	−53.96	−0.586	UBK7	
5	−19.0	−28.87		
6	−33.36	−2.042	UBK7	
7	236.7	−11.65		

Comments This is a three-lens corrector for a 250-cm parabolic mirror. The corrector was developed by Wynne[16,25] for the region of the spectrum extending from 365 to 1014 nm. It is used to extend the field of a parabolic mirror. Versions for a Ritchey-Chretien primary also exist. The corrector is able to correct spherical aberration, coma, astigmatism, and field curvature while keeping chromatic aberrations under control. The field of view can be extended considerably for smaller apertures.

The three-spherical lens corrector is one of the best large-optics prime-focus correctors to come along, both in terms of image quality and ease of fabrication. Other designs have either not performed as well or were heavily dependent on aspheric figuring.

This and other prime-focus correctors are surveyed in articles by Gascoigne,[26] Ross,[27] Meinel,[28] Schulte,[29] Baker,[30] and Wynne.[31]

F/4 Gregorian

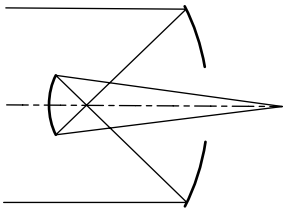


SUR	RDY	THI	GLA	CON
STO	−24.62	−16	REFL	−1
2	6.4	24.1	REFL	−0.5394

Comments The classical Gregorian is aberration-free on-axis when the paraboloidal mirror image coincides with one of the ellipsoidal-mirror foci; the other focus coincides with the final image. Like the Cassegrain, off-axis image quality is limited by coma and field curvature. The ellipsoidal secondary reimages the entrance pupil to a location between the secondary and final image. Thus, there exists the possibility of unwanted-light suppression at the primary-mirror image and *exit pupil*.

The Gregorian is longer than the Cassegrain and thus more expensive to support and house, but it produces an erect image and the concave secondary is easier to produce. In eccentric-pupil versions it has an accessible prime focus.

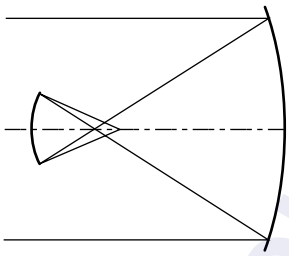
F/4 Aplanatic Gregorian



SUR	RDY	THI	GLA	CON
STO	−24.62	−16	REFL	−0.989
2	6.4	24.1	REFL	−0.5633

Comments The aplanatic Gregorian is corrected for spherical aberration and coma. Both mirrors are ellipsoids. Astigmatism and field curvature limit off-axis imagery.

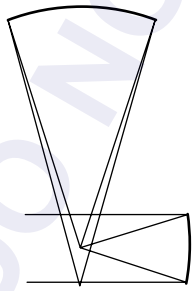
F/1.25 Flat-Medial-Field Aplanatic Gregorian



SUR	RDY	THI	GLA	CON
STO	−34.68	−22.806	REFL	−0.767
2	6.47	7.924	REFL	−0.1837

Comments The Gregorian's field performance is enhanced if image accessibility is sacrificed. This version of the Gregorian[14] is aplanatic. A flat *medial image* is achieved by balancing Petzval curvature with astigmatism, which remains uncorrected.

F/1.25 Flat-Medial-Field Aplanatic Gregorian with Spherical Primary

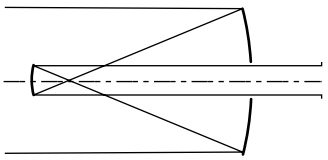


SUR	RDY	THI	GLA	CON
STO	−42.59	−21	REFL	
2	INF	46.51	REFL	
		Tilt: 45°		
3	−49.84	−54.08	REFL	−0.078

Comments The field of this objective[14] is larger than its cousins, the classical and aplanatic Gregorians, even with the spherical primary. Spherical aberration and coma are corrected, and the medial image is flat. The design has a real intermediate image and exit pupil. The obvious drawback is the size of the secondary in relation to the size of the entrance pupil, which is 15 cm in diameter.

Korsch[14] analyzes two other designs that are loosely referred to as Gregorians.

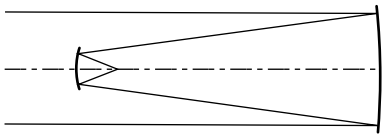
Afocal Gregorian-Mersenne Telescope



SUR	RDY	THI	GLA	CON
STO	−50	−30	REFL	−1
2	10	40	REFL	−1

Comments The Gregorian Mersenne, also composed of confocal paraboloids, is aplanatic, anastigmatic, and can be corrected for distortion. The Gregorian-Mersenne has an intermediate image and an accessible exit pupil.

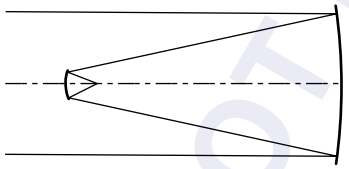
F/1.25 Couder



SUR	RDY	THI	GLA	CON
STO	−142.86	−52.9	REFL	−6.285
2	23.08	7.1142	REFL	−0.707

Comments The Couder,[32] composed of two conic mirrors, is corrected for third-order spherical aberration, coma, and astigmatism. Unfortunately, the Couder is long for its focal length and the image is not readily accessible.

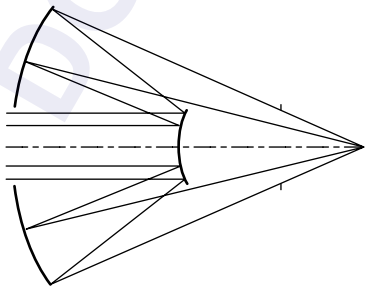
F/1.25 Aplanatic, Flat-Medial-Image Schwarzschild



SUR	RDY	THI	GLA	CON
STO	−91.57	−38.17	REFL	−2.156
2	23.67	4.637	REFL	5.256

Comments The aplanatic, flat-medial-image Schwarzschild[33] is similar in appearance to the Couder but the secondary mirror and image locations are different for identical *secondary magnifications.*

F/1.25 Aplanatic, Anastigmatic Schwarzschild



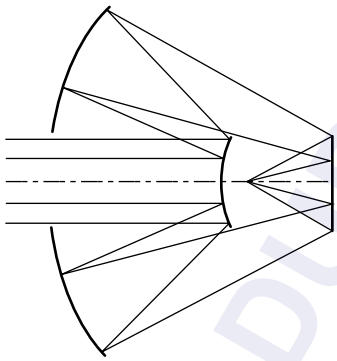
SUR	RDY	THI	GLA
1	30.62	−49.44	REFL
2	80.14	80.26	REFL
STO	INF	24.864	

Comments The spherical-mirror Schwarzschild[33] is aplanatic, *anastigmatic*, and distortion-free.[34] The Schwarzschild relies on the principle of symmetry for its high level of aberration correction and a large field of view. All surfaces have the same center of curvature at the aperture stop. Hence, there are no off-axis aberrations. Spherical aberration is produced but each mirror produces an equal and opposite amount, thus canceling the effect of the aberration. Some higher-order aberrations are also corrected.[34] Eccentric portions of this design—above and below the optical axis in the picture—form well-corrected, unobscured designs. Zonal spherical aberration from the mix of third- and higher-order terms limits on- and off-axis performance.

An aspheric plate positioned at the center-of-curvature of the mirrors removes this aberration as illustrated in the next design.

Wetherell and Rimmer,[35] Korsch,[14] Schroeder,[13] Linfoot,[36] and Gascoigne[26] offer a general third-order analysis of two-mirror systems. The closed-form solutions described provide insight into third-order aberration theory of reflective systems.

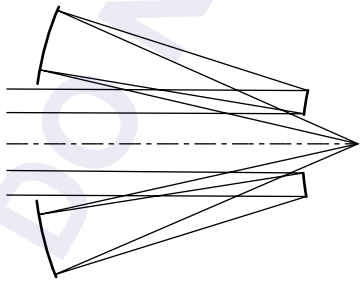
F*/1 *Aplanatic, Anastigmatic Schwarzschild with Aspheric Corrector Plate



SUR	RDY	THI	GLA
1	24.547	−39.456	REFL
2	63.92	64.528	REFL
STO	INF	−19.098	REFL
	A:	−0.9998E-7	
	B:	−0.1269E-9	

Comments With an aspheric plate at the aperture stop, spherical aberration is eliminated. The only aberrations still remaining are of higher order. To correct these, the mirrors must also be aspherized. Linfoot[36] and Abel[34] describe this design.

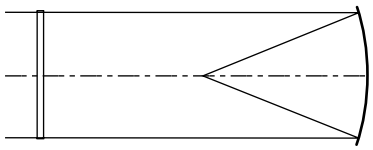
F*/1.25 *Anastigmatic, Flat-Image Schwarzschild



SUR	RDY	THI	GLA	CON
1	69.7	−50.56	REFL	5.47
STO	71.35	61.26	REFL	0.171

Comments With just two conics, this design type[33] achieves aplanatic and anastigmatic performance on a flat image surface. The flat field is attained by making the curvatures of the mirrors equal. Eccentric portions above or below the optical axis form unobscured versions; the design may alternatively be used off-axis. Sasian[6,37] and Shafer[38] have explored many of this design's features.

F/1.25 *Schmidt*



SUR	RDY	THI	GLA	CON
STO	1554	1	PSK2	
		A: −0.2825E-5		
		B: −0.1716E-8		
2	INF	52.33		
3	−52.95	−26.215	REFL	

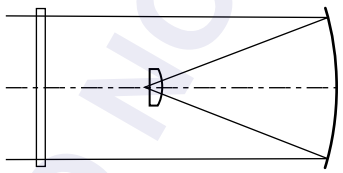
Comments The Schmidt[39] also relies on the principle of symmetry; that is, the aperture stop is located at the center of curvature of the spherical mirror and hence the mirror produces no off-axis aberrations.

The Schmidt corrector is flat with aspheric deformation figured in to correct the spherical aberration produced by the mirror. It is positioned at the aperture stop because off-axis aberrations are independent of aspheric deformation when an aspheric surface coincides with the stop. Hence the Schmidt plate has no effect on off-axis aberrations, and the benefits of concentricity are preserved.

The corrector introduces chromatic variation of spherical aberration (spherochromatism). A small amount of positive power in the corrector introduces undercorrected axial color to reduce the effects of this aberration. Further improvement is obtained by achromatizing the corrector with two glasses of different dispersions.

Higher-order aberrations degrade image quality at low focal ratios and large field angles. Kingslake,[9] Schroeder,[13] Maxwell,[40] and Linfoot[36] provide additional details of this and other catadioptric objectives.

F/1.25 *Field-Flattened Schmidt*



SUR	RDY	THI	GLA
STO	598.7	1.155	PSK2
	A:	−0.273E-5

2	INF	40.38	
3	−52.95	−24.06	REFL
4	−10.35	−1.49	PSK2
5	INF	−0.637	

Comments As is known from third-order aberration theory, a thin element will be nearly aberration-free, except for Petzval curvature, and distortion when it is placed in close proximity to an image. Therefore, by properly choosing the lens power and index to give a Petzval curvature of equal and opposite sign to the Petzval curvature introduced by the other optics, the image is flattened.

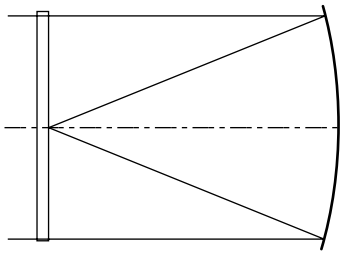
The image in the Schmidt above has been flattened with the lens near the image plane. The only aberrations introduced by the lens are spherochromatism and *lateral color*, lateral color being the most noticeable aberration; this can be removed by achromatizing the field-flattening lens. The close proximity of the lens to the image can cause problems with light scattered from areas

on the lens surfaces contaminated by dirt and dust particles. Clean optics are a must under these circumstances.

The field-flattening lens provides two more positive results. First, the lens introduces a small amount of coma which is compensated by moving the Schmidt corrector toward the mirror somewhat, thus reducing the overall length of the objective. Second, *oblique spherical aberration,* one of the primary field-limiting, higher-order aberrations of the Schmidt, is substantially reduced.

Besides its usual function as a telescope or photographic objective, the field-flattened Schmidt has also been used as a spectrograph camera.[41]

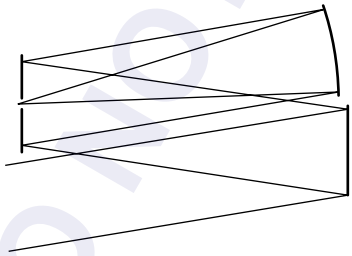
F*/1.25 *Wright



SUR	RDY	THI	GLA	CON
1	INF	1.0	BK7	
2	−699.8	26.1	BK7	
		A: 0.6168E-5		
		B: 0.5287E-8		
3	−53.24	−26.094	REFL	1.026

Comments The Wright[42] is one-half the length of the Schmidt. It also relies on aspheric deformation of the corrector plate for the elimination of spherical aberration. Coma, introduced as the corrector is removed from the center of curvature of the mirror, is cancelled with conic deformation of the mirror; the surface figure is that of an oblate ellipsoid. The remaining astigmatism and Petzval curvature are balanced for a flat medial image. The only on-axis aberration, spherochromatism, is corrected by achromatizing the corrector.

F*/4 *Reflective Schmidt



SUR	RDY	THI	GLA
STO	−66752	−67.37	REFL
	A: 0.5083E-7		
2	INF	66.6	REFL
3	−133.97	−66.85	REFL

Comments Another way of defeating chromatic aberration is to eliminate it altogether with a reflective corrector.[43] The elements are removed from the light path with a field bias (9°), and hence the objective is off-axis. Spherical aberration, coma, and astigmatism are all corrected. At large field angles, beyond about 12° half-field angle, oblique spherical aberration becomes evident, but otherwise this design provides excellent performance on a curved image over a 24° field of view. In order to avoid severe obstruction of the light path, the full 24° can be taken advantage of only in the plane that extends perpendicular to the picture of the design above. A considerably reduced field of view is allowed in the plane of the picture.

F/0.6 Solid Schmidt

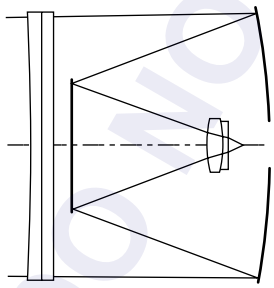
6	−45.86	−0.245		
7	−10.295	−1.136	BK7	
8	INF	−0.026		

Comments All monochromatic aberrations, with the exception of distortion, are corrected by the appropriately-named solid Schmidt, a system used mostly as a spectrograph camera.[44] All chromatic aberrations, with the exception of lateral color, are corrected. The imaging theory behind the solid Schmidt is expounded by Baker.[45] With a refractive index n, the solid Schmidt is n^2 times faster than the conventional Schmidt. Focal ratios of F/0.3 have been obtained. Schulte[44] offers a design similar to the one given here.

F/1.25 Schmidt-Cassegrain



SUR	RDY	THI	GLA	CON
STO	INF	0.8	489.574	
		A: −0.1928E-4		
		B: 0.298E-7		
2	2269.1	1.0	583.303	
3	INF	16.49		
		A: −0.1085E-4		
		B: 0.2806E-7		
4	−55.9	−15.0	REFL	1.077
5	INF	10.267	REFL	
6	9.1	1.2	489.574	
7	−8.577	0.018		
8	−8.59	0.3	583.303	
9	−87.44	1.317		

Comments The Schmidt-Cassegrain[46] represents a successful attempt to resolve the difficulties related to the curved image, considerable length, and awkwardly located image of the Schmidt objective, without destroying the positive attributes of the design.

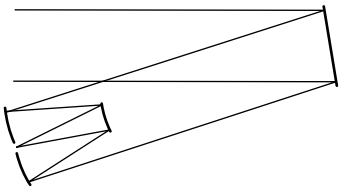
The Schmidt-Cassegrain comes in a wide variety of forms—too many to go into here. Linfoot[36] performs an extensive exploration of the design, with one and two aspheric plate correctors. Warmisham[47] has gone as far as three. Wayman[48] has analyzed a *monocentric* Schmidt-Cassegrain.

In this fast version of the Schmidt-Cassegrain, the corrector is close to the flat secondary. Usually one or both mirrors are aspherics. An achromatized image-flattening lens has been introduced.

An image-flattening lens is not usually required with a Schmidt-Cassegrain since enough degrees of freedom exist for aberration correction and a flat image. In this case, the secondary mirror is flat and one degree of freedom is lost. Additionally, the primary mirror power introduces a strong Petzval contribution which necessitates a field-flattening lens.

The first three digits of the six-digit code in the glass column identify the indices of the materials in the design, in this case plastics. These are 1.489 and 1.583; the *Abbe-numbers* are given by the last three digits and they are 57.4 and 30.3, respectively. The two plastics have nearly identical thermal coefficients and are very light. Buchroeder[49] analyzes designs of this variety with two aspheric correctors. Shafer[50] offers a Schmidt-Cassegrain with an aspheric meniscus corrector. Only two elements are used since the secondary mirror surface is on the corrector. Rutten[12] has examples of Schmidt-Cassegrains in a number of configurations.

F/3.4 Reflective Schmidt-Cassegrain



SUR	RDY	THI	GLA	CON
STO	INF	−92.16	REFL	
	A: 0.13344E-6	AN: −0.1255E-1		
2	84	26	REFL	
3	84	−25.848	REFL	−0.3318

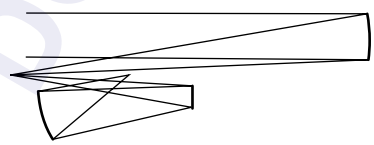
Comments The reflective Schmidt-Cassegrain exhibits all the nice properties of the Schmidt-Cassegrain and, in addition, is achromatic. Schroeder[51] points out that, because the corrector is tilted (9° here), adequate aberration correction requires a nonrotationally symmetric corrector plate. The nonaxially symmetric surface deformation in this design is given by

$$Z = A[(1-AN)X^2 + (1+AN)Y^2]^2 \tag{3}$$

where A is the fourth-order symmetric coefficient and AN is the fourth-order nonsymmetric coefficient. The y dimension is in the plane of the picture; the x dimension is perpendicular to it.

Since the corrector is tilted by 9°, the reflected rays are deviated by twice that amount. The element spacings (THI) are no longer measured along the horizontal optical axis after reflection off the corrector, but along the line of deviation. The secondary and tertiary are tilted by 18°.

F/2 Shafer Relayed Virtual Schmidt



SUR	RDY	THI	GLA
STO	−320	−159.82	REFL
2	106.7	80.0	REFL
3	INF	−68.51	REFL
	A: 0.1882E-5		
	B: 0.1273E-8		
	C: −0.1757E-12		
	D: 0.1766E-14		
4	63.967	40.774	REFL

Comments Shafer[52] has introduced an eccentric-pupil (18-cm stop decenter), virtual Schmidt objective similar to this but with a decentered quaternary mirror. The center of curvature of the spherical primary is imaged by the concave secondary onto the flat Schmidt tertiary mirror.

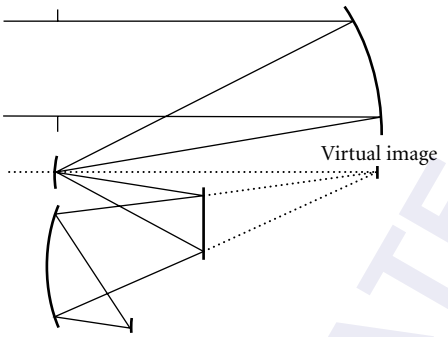


FIGURE 5 Picture of virtual Schmidt with decentered quaternary.

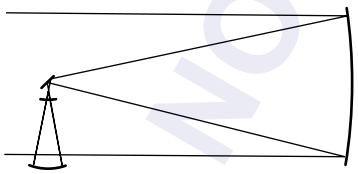
Now the Schmidt plate, which appears to be at the primary center of curvature, is aspherized to produce a well-corrected virtual image, hence the name (see Fig. 5). In this configuration, the Schmidt plate is one-half the size of the primary.

The Schmidt plate and the spherical quaternary mirror form a finite conjugate Schmidt system. Thus, the spherical aberration of this mirror is also corrected.

Figure 5 shows a pictorial representation of the Shafer design with the last mirror decentered to provide a more accessible image. Since the primary and quaternary mirrors no longer share the same axis of symmetry, a two-axis Schmidt corrector is required to remove the aberrations of both mirrors. The shape of this surface is described by Shafer, for an *F*/1, unobscured, wide-field design with an intermediate image and Lyot stop.

F*/2.2 *Spherical-Primary Objective that Employs the Schmidt Principle of Correction

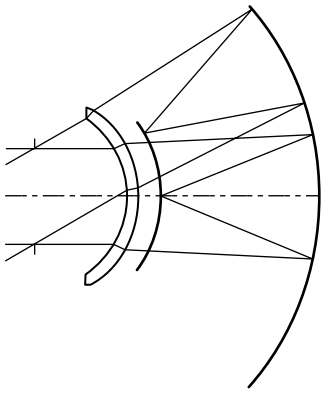


SUR	RDY	THI	GLA	CON
STO	−88.07	−42.517	REFL	
2	INF	2.2	REFL	
		Tilt: 45°		
3	−4.433	0.33	FK51	
4	−2.527	9.217		
5	−10.21	−9.217	REFL	−0.8631
6	−2.527	−0.33	FK51	
7	−4.433	−0.64		

Comments Baker[22] reports on a system where the center of curvature of a large, spherical primary is imaged by a positive lens onto a much smaller mirror where aspheric correction of spherical aberration occurs. A small field offset (0.25°) is required so that the one-to-one relay doesn't reimage the primary image back onto itself. To avoid overlap, this design is best used over a small or strip field of view.

Because of the geometry of the design, coma, astigmatism, image curvature, chromatic aberrations, and distortion are eliminated in addition to the spherical aberration correction from aspheric figuring of the tertiary mirror. Baker[22] offers several other interesting designs in his article, including an F/0.8, 10.6-μm, 180° field-of-view Roesch,[53] a design that incorporates a Schmidt with a strong negative lens or lens group before the aspheric corrector. The strong divergence produced by this lens reduces the amount of light blocked by the image plane but increases the size of the spherical mirror.

F/2 Maksutov



SUR	RDY	THI	GLA	CON
STO	INF	31.788		
2	−23.06	3.5	BK7	
3	−25.53	51.09		
4	−83.9	−43.8	REFL	

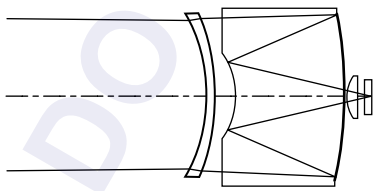
Comments The all-spherical Maksutov[54] was intended as an inexpensive alternative to the Schmidt at slower speeds. In small sizes it is indeed less expensive. The meniscus corrector is "self-achromatic" when the following relationship is satisfied:

$$t = \frac{n^2}{n^2 - 1}(R_2 - R_1) \tag{4}$$

where R_1 and R_2 are the radii, t is the thickness, and n is the refractive index of the corrector.

Bouwers[55] also developed a meniscus corrector. All elements of the Bouwers are concentric about the aperture stop. This ensures correction of third-order, off-axis aberrations over a nearly unlimited field of view. In exchange for the wide field, axial color is not well-corrected.

F/1.25 Solid Maksutov-Cassegrain



SUR	RDY	THI	GLA	CON
STO	INF	20.5

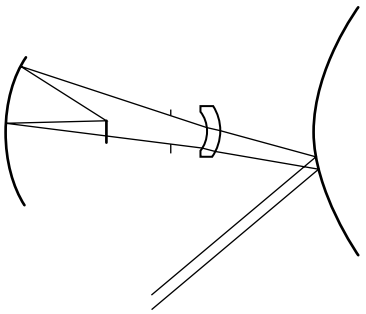
9	16.07	0.545		
10	INF	0.394	Silica	
11	INF	0.155		

Comments The solid Maksutov-Cassegrain shown here and the solid Schmidt-Cassegrains have been studied extensively by Wynne.[56,57] Lateral color is the most consequential aberration left uncorrected.

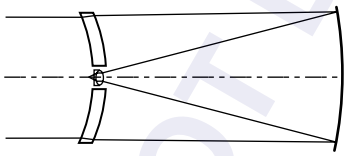
F/1.2 Wide-Field Objective with Maksutov Correction



SUR	RDY	THI	GLA	CON
1	12.467	−9.684	REFL	−3.243
2	−4.81	−1.267	FK51	
3	−3.762	−3.679		
STO	INF	−17.189		
5	15.98	10.64	REFL	

Comments This very wide field imaging system similar to one in Courtes[58] is essentially a Maksutov focused on the virtual image of the object produced by the hyperboloidal mirror. Both speed (F/1) and a very wide field of view (80° × 120°) can be achieved with this design form on a flat image but only for small apertures—1.25 cm in this case. Courtes et al.[59] describes similar systems with refractive and reflective Schmidt plates instead of a Maksutov corrector.

F/1 Gabor



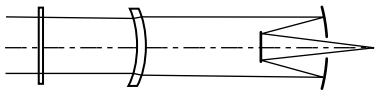
SUR	RDY	THI	GLA
STO	−23.3	2	SKI
2	−25.468	39.5	
3	−83.33	−40	REFL
4	−1.67	−1	BK7
5	9.85	−0.5	SF5
6	−7.71	−0.942	

Comments Another meniscus design was invented by Gabor.[60] The Gabor is more compact than the Maksutov or Bouwers, and has a smaller focal ratio and field of view.

The design shown here began without the field lens. The lens was introduced into the design with the surface closest to the image being concentric about the *chief ray* and the other surface being aplanatic.[61] A surface concentric about the chief ray is free of coma, astigmatism, distortion, and lateral color. The aplanatic surface is free of spherical aberration, coma, and astigmatism with the result that the lens is coma- and astigmatism-free. The spherical aberration produced by the lens is balanced against the spherical aberration produced by the two other elements. The chromatic aberrations were corrected by achromatizing the lens.

Shafer[62,63] offers interesting suggestions for design with aplanatic and concentric surfaces. Several varieties of field-flattening lens are described. Kingslake[9] runs through the design procedure for a Gabor.

F/4 Schmidt-Meniscus Cassegrain

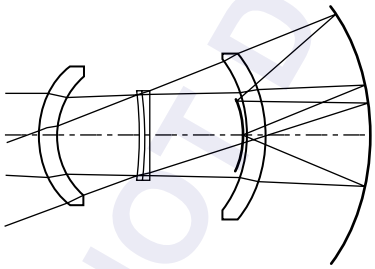


SUR	RDY	THI	GLA
STO	787.7	1.4	BK7
2	INF	32.69	
3	−32.69	2.62	BK7
4	−35.6	63.446	
5	−81.97	−21.78	REFL
6	−79.5	38.65	REFL

Comments This system, originally by Bouwers, uses a slightly positive plate to compensate the overcorrected chromatic aberration produced by the meniscus. The Bouwers produces very good quality on a flat image, over a large field of view.

Fourth- and sixth-order deformation added to the plate eliminates any residual spherical aberration. Lateral color and oblique spherical aberration affect field performance, although both are small.

F/1.2 Baker Super-Schmidt



SUR	RDY	THI	GLA
1	22.5	4.28	BK7
2	19.13	19.75	
STO	−11,783	1.4	F2

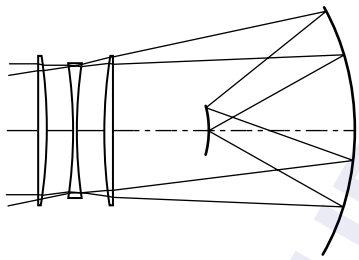
4	−135.5	1.3	SK2
5	INF	23.92	
6	−29.31	4.28	BK7
7	−32.42	25.1	
8	−55	−25.1	REFL
9	−32.42	−4.28	BK7
10	−29.31	−1.45	

Comments The Baker[64] super-Schmidt, a design that incorporates both meniscus and Schmidt correction, achieves excellent performance over a wide field of view. The field-limiting aberration of a fast Schmidt, *oblique spherical aberration*, is controlled by adding a concentric meniscus lens which also introduces overcorrected spherical aberration, thus reducing the amount of overcorrection needed from the Schmidt plate. Since oblique spherical is proportional to the amount of overcorrection in the Schmidt plate, the effect of this aberration is reduced.

The most apparent aberration produced by the meniscus is axial color. This is minimized by achromatizing the Schmidt corrector. Spherochromatism is reduced since the magnitudes produced by the Schmidt corrector and meniscus are nearly equal and have opposite signs. Another meniscus element is added to further reduce aberrations.

F/1 Baker-Nunn



SUR	RDY	THI	GLA
1	−491.9	1.06	LLF1
2	−115.6	4.23

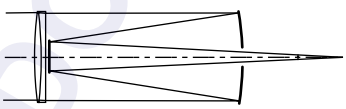
	B: −0.1348E-8		
6	491.87	36.77	
7	−42.03	−21.961	REFL

Comments The Baker-Nunn[65] was born of work by Houghton[66] during World War II. Houghton wished to find a less expensive alternative to the Schmidt. The result was a zero-power, three-lens combination with easy-to-make spherical surfaces. Spherical aberration and coma can be eliminated for any position of the corrector. The surfaces have equal radii so they can be tested interferometrically against one another using the Newton ring method. Residual spherical aberration that remains after assembly is removed by altering the spacing between the lenses.

F/10 Houghton-Cassegrain



SUR	RDY	THI	GLA
STO	145	1.2	BK7

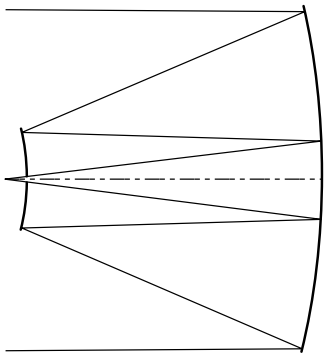
Comments Another short and fast catadioptric by Amon[76] is shown here. The second corrector is also the secondary mirror.

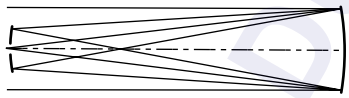
F/4 Eisenburg and Pearson Two-Mirror, Three-Reflection Objective



SUR	RDY	THI	GLA	CON
STO	−48.0	−17.289	REFL	−1.05
2	−14.472	17.289	REFL	−1.539
3	−48	−18.195	REFL	−1.05

Comments This aplanatic, two-mirror, three-reflection configuration was first introduced by Rumsey.[77] The design presented here comes from Eisenburg and Pearson.[78] The first and third surface represent the same surface.

F/4 Shafer Two-Mirror, Three-Reflection Objective



SUR	RDY	THI	GLA	CON
STO	−106.7	−80.01	REFL	−0.4066
2	80.01	80.01	REFL	−5.959
3	−106.7	−80.05	REFL	−0.4066

Comments Shafer[79] has documented numerous versions of multiple-reflection objectives. This is an aplanatic, anastigmatic design with field curvature. For optimum aberration correction, the primary is at the center of curvature of the secondary mirror. Shafer[80] suggests a ring field for a flat, accessible image on an annular surface, and a Lyot stop.

A simple ring field design is depicted in Fig. 6. Only one field angle θ is required, easing the difficulties associated with off-axis aberration correction. The single viewing direction is rotated about the optical axis, forming, in this case, a ring image. In reality, less than half the ring image is used to avoid interference of the image with the entering beam.

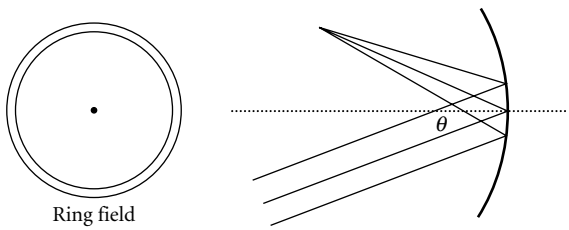


FIGURE 6 The ring field system.

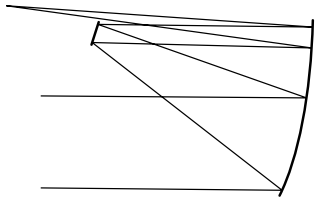
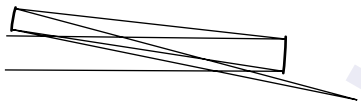
F/15 *Two-Mirror, Three-Reflection Objective*



SUR	RDY	THI	GLA	CON
STO	−116.33	−46.53	REFL	−1.024
2	−22.6	46.53	REFL	−1.0037
3	−116.33	−67.05	REFL	−1.024

Comments This is another aplanatic, anastigmatic, eccentric-pupil design which gives well-corrected imagery on a curved image. It has a 30-cm stop decenter.

F/15 *Yolo*



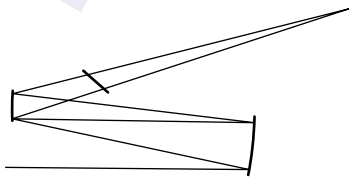
SUR	RDY	THI	GLA	CON
STO	−1015	−160.36	REFL	−4.278
		Tilt: −3.5°		
2	1045.72	208.19	REFL	
		RDX: 1035.0		
		Tilt: −9.82°		
		Image tilt: −11.7°		

Comments Leonard[81,82] invented the Yolo (named after a scenic county in California) so that he could have an achromatic system without obscurations. The result is a tilted and decentered component objective that gives the high contrast of an unobscured refractive objective without the chromatic effects.

Spherical aberration is corrected by the hyperboloidal figuring of the first surface. The anamorphism introduced into the secondary (by a warping harness) corrects astigmatism; RDX is the surface radius of curvature perpendicular to the picture. Coma is eliminated by adjusting the curvatures and tilting the secondary.

Relatives of the two-mirror Yolo are the Solano, an in-line three-mirror Yolo, or the three-dimensional, three-mirror Yolo.[83] As in design 28, thickness (THI) is measured along the deviated ray paths. With the angle of reflection known, element decenter may be easily determined.

F/15 *Schiefspiegler*



SUR	RDY	THI	GLA	CON
STO	−397.2	−101.4	REFL	−0.607
		Tilt angle: −4.5°		
2	−552.5	35.84	REFL	
		Tilt angle: 3.64°		
3	3411	0.52	BK7	
		Tilt angle: 50°		
4	INF	111.11		
		Tilt angle: 50.0529°		
		Image tilt angle: 22.80°		

Comments The Schiefspiegler ("oblique reflector" in German) was introduced about a century ago, and at the time was called a brachyt (or bent). The motivation behind the Schiefspiegler's design is essentially the same as the Yolo's. Like the Yolo, elements are tilted and decentered. Coma and astigmatism are corrected by tilting the secondary and corrector lens. The lens is thin and slightly wedged to minimize chromatic effects. Spherical aberration is corrected with the aspheric deformation of the primary.

A three-mirror Schiefspiegler, or Trischiefspiegler, has been developed by Kutter.[84] This design is all-reflective and completely achromatic. Like the Schiefspiegler, aspheric deformation of the primary corrects spherical aberration; coma and astigmatism are corrected with element tilts.

A four-mirror Schiefspiegler was recently introduced by Brunn.[85] For more on unusual telescope objectives, see Manly.[86]

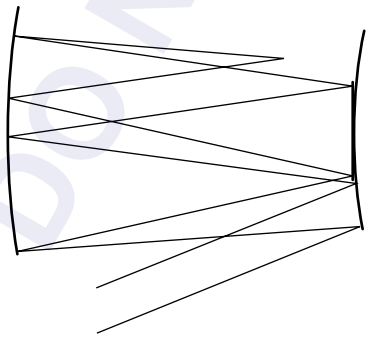
F/8 Catadioptric Herschelian Objective

SUR	RDY	THI	GLA
STO	269.61	1.487	BK7
2	INF	2.147	
	Element tilt:	0.35°	
3	−269.61	1.321	BK7
4	INF	151.97	
	Element tilt:	5.38°	
5	−317.26	−158.69	REFL
	Tilt angle:	3.0°	
	Image tilt angle:	0.174°	

Comments Several centuries ago, Herschel tilted his large parabolic mirror to give him access to the image. A spherical mirror in this design by D. Shafer[87] has been tilted for the same reason. Element tilts in the Houghton corrector control the astigmatism introduced by tilting the mirror. The Houghton corrector also eliminates the spherical aberration of the mirror with lens bending. Note the smaller focal ratio of this design compared to either the Yolo or the Schiefspiegler.

Other catadioptric Herschelians, as well as Schiefspieglers and Yolos, have been studied by Buchroeder[88] and Leonard.[82] Tilted, decentered, and unobscured Cassegrains are discussed by Gelles.[89]

F/4 SEAL

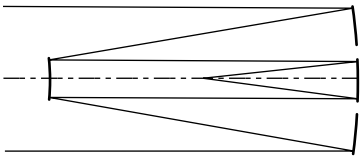


SUR	RDY	THI	GLA	CON
1	181.2	−147.8	REFL	
2	350.9	147.8	REFL	−0.404
STO	INF	−147.8	REFL	
4	350.9	119	REFL	−0.404

Comments For an all-reflective objective, this flat-image design provides an exceptionally wide, unobscured field of view—greater than 90° with a ring field. Referred to as the SEAL,[90] it is

derived from its cousin the WALRUS;[91] a related design has been described by Shafer.[92] The SEAL is another Mersenne-Schmidt hybrid: primary and secondary form an inverse-Mersenne; tertiary and quaternary (also the secondary) form a reflective Schmidt. Residual spherical aberration limits the performance, but by aspherizing the flat, this residual aberration is corrected as well. Clearing all obscurations requires at least a 22° field offset. The SEAL shown here is optimized for a 20° strip field although a square, rectangular, annular, or almost any shape field is possible.

F/4 Paul Three-Mirror Objective

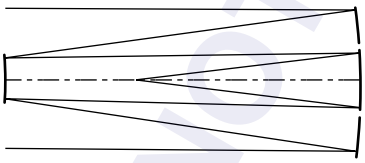


SUR	RDY	THI	GLA	CON
STO	−117.1	−42.87	REFL	−1
2	−31.38	42.87	REFL	−.6076
3	−42.87	−21.42	REFL	

Comments This design is based on work by Paul[93] and later by Baker,[94] who was looking for an achromatic field corrector for a parabolic primary. Their efforts culminated in a design similar to this one, which combines the properties of an afocal Cassegrain-Mersenne in the first two elements with the properties of an all-reflective Schmidt in the secondary and tertiary elements. Since both modules are corrected for spherical aberration, coma, and astigmatism to third order, the complete system is aplanatic and anastigmatic. Petzval curvatures are equal and opposite so a flat image is achieved. The conic deformation of the secondary is modified to give it an ellipsoidal shape. This gives the required Schmidt aspherization needed to correct the spherical aberration of the tertiary mirror.

Other all-reflective designs have been proposed by Meinel[21,95] and Baker.[22] The Meinel-Shack objective[96] exhibits similar performance and offers a more accessible image.

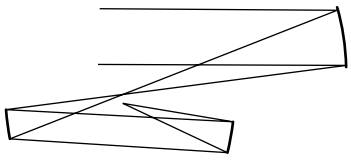
F/4 Alternative Paul Three-Mirror Objective



SUR	RDY	THI	GLA	CON
STO	−142.4	−49.28	REFL	−1
2	−39.51	49.28	REFL	
3	−54.69	−30.7	REFL	0.101

Comments This Paul objective has an aspheric tertiary mirror, instead of an aspheric secondary.

F/4 Off-Axis, Eccentric-Pupil Paul-Gregorian

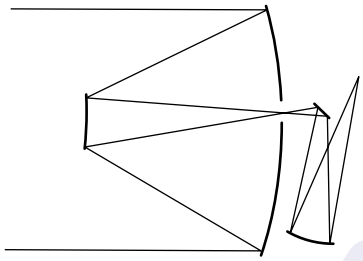


SUR	RDY	THI	GLA	CON
STO	INF	79.2		
2	−158.4	−118.8	REFL	−1
3	79.2	79.2	REFL	−1
		A: −0.2707E-6		
		B: −0.117E-9		
4	−77.53	−38.768	REFL	

Comments This eccentric-pupil (22-cm), off-axis (1°) design utilizes a Gregorian-Mersenne module in the primary and secondary mirrors. Spherical aberration produced by the spherical tertiary mirror is corrected by superimposing aspheric deformation on the paraboloid secondary, located at the tertiary mirror center of curvature. With all concave surfaces, field curvature is uncorrected. A real and accessible exit pupil and intermediate image offer possibilities for excellent stray-light suppression.

As is the case with the virtual Schmidt system, the tertiary mirror may be decentered to provide a more convenient image location. This requires two-axis aspheric deformation of the secondary mirror.[97]

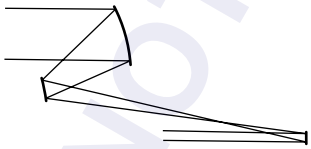
F/4 Three-Mirror Cassegrain



SUR	RDY	THI	GLA	CON
STO	−39.67	−15.814	REFL	−0.9315
2	−10.66	21	REFL	−2.04
3	INF	−9.05	REFL	
		Tilt: 45°		
4	13.66	13.651	REFL	−0.4479

Comments A design similar to the aplanatic, anastigmatic, flat-image design shown here was conceived by Korsch[98] and is described by Williams,[99] Korsch,[100] and Abel.[43] The exit pupil is accessible and an intermediate image exists. A 1° field offset is needed to displace the image from the folding flat. Residual coma limits field performance. Small element tilts and decenters will improve the performance of this design.

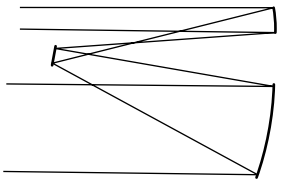
Three-Mirror Afocal Telescope



SUR	RDY	THI	GLA	CON
STO	−100.725	−33.514	REFL	−1
2	−46.109	100	REFL	−3.016
3	−74.819	−55.56	REFL	−1

Comments This 5× afocal design from Smith[2] is an eccentric-pupil Cassegrain and a parabolic tertiary combined. The design is aplanatic and anastigmatic. The entrance pupil is decentered by 32 cm.

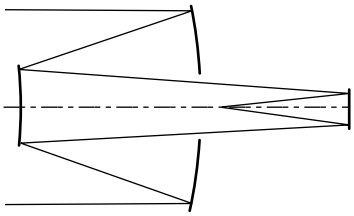
Three-Mirror Afocal Telescope



SUR	RDY	THI	GLA	CON
STO	−240	−200	REFL	−1
2	−160	200	REFL	−9
3	−480	−250	REFL	−1

Comments A similar design by Korsch[14] is also aplanatic and anastigmatic. The entrance pupil is decentered by 20 cm. Other afocal designs are described by Gelles[101] and King.[102]

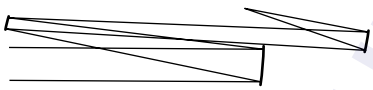
F/4 Three-Mirror Cassegrain



SUR	RDY	THI	GLA	CON
STO	−59.64	−18.29	REFL	−1.134
2	−28.63	33.74	REFL	−2.841
3	−55.05	−13.244	REFL	−5.938

Comments Robb[103] has introduced another aplanatic, anastigmatic, flat-image, three-mirror Cassegrain without an intermediate image.

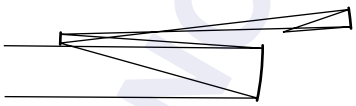
F/6.7 Spherical Primary Three-Mirror Objective



SUR	RDY	THI	GLA	CON
STO	−429.67	−149.87	REFL	
2	−104.16	211.14	REFL	3.617
3	−126.49	−73.0	REFL	−0.179

Comments Making the largest element in an objective a spherical mirror reduces cost and may enhance performance. This aplanatic, anastigmatic, flat-image, eccentric-pupil design (−35 cm stop decenter) with an unobscured light path is similar to one described by Korsch[14] and another developed for use as an astrometric camera by Richardson and Morbey.[104]

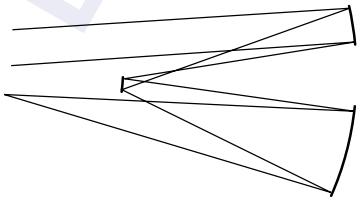
F/4 Spherical Primary Three-Mirror Objective



SUR	RDY	THI	GLA	CON
STO	−194.58	−79.13	REFL	
2	−64.42	113.68	REFL	12.952
3	−38.47	−26.24	REFL	−0.4826

Comments Here is another aplanatic, anastigmatic, flat-field, eccentric-pupil design with a 17-cm stop decenter and large spherical primary. There is an intermediate image and an accessible exit pupil.

F/4 Three-Mirror Korsch Objective

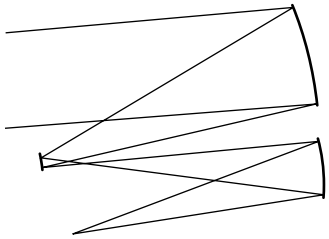


SUR	RDY	THI	GLA	CON
1	−201.67	−133.36	REFL	−0.689
STO	−96.5	131.8	REFL	−1.729
3	−172.54	−200.83	REFL	

Comments This off-axis (5°) design by Korsch[105] is aplanatic, anastigmatic, and has a flat image. The same configuration has been employed by Pollock[106] as a collimator. Characteristics include a large field of view, low pupil magnification, accessible pupils, and an intermediate image.

The tertiary in this design is spherical. With reoptimization, the secondary may also be spherical.

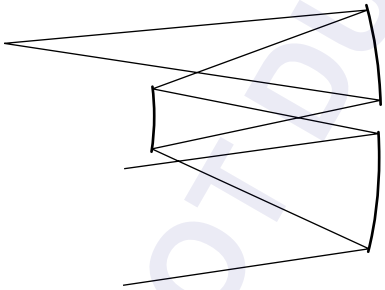
F/4 Three-Mirror Cook Objective



SUR	RDY	THI	GLA	CON
1	−123.2	−57.38	REFL	−0.7114
2	−37.46	57.45	REFL	−3.824
3	−51.89	−35.87	REFL	−0.1185
STO	INF	−15.92		

Comments This objective was introduced by Cook.[107–109] The aplanatic, anastigmatic, flat-image design shown here has a larger pupil magnification and a smaller field than the previous design. The eccentric-pupil, off-axis design has a −3.2-cm stop decenter and a 5° field bias. A space-based surveillance objective in this configuration has been developed and built by Wang et al.[110]

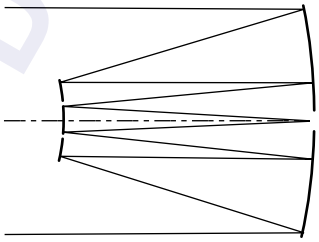
F/4 Three-Mirror Wetherell and Womble Objective



SUR	RDY	THI	GLA	CON
1	−166.19	−38.78	REFL	−2.542
STO	−55.19	38.78	REFL	−0.428
3	−82.46	−65.24	REFL	0.133

Comments Another aplanatic, anastigmatic, flat-image, off-axis (9°) design has been introduced by Wetherell and Womble.[111] Figosky[112] describes a variant of this form to be sent into orbit. The aperture stop is located at the secondary mirror; hence, this mirror is symmetric with respect to the optical axis.

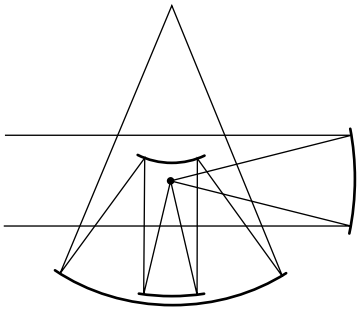
F/10 Korsch Three-Mirror, Four-Reflection Objective



SUR	RDY	THI	GLA	CON
STO	−66.44	−22.15	REFL	−1.092
2	−22.15	22.15	REFL	−1.295
3	−66.44	−22.15	REFL	−1.092
4	−44.29	21.96	REFL	0.8684

Comments The three-mirror, four-reflection design shown here from Korsch[113] is extremely compact for its 200-cm focal length, and the image is accessible.

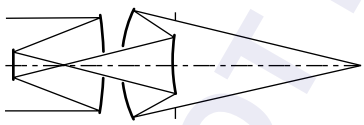
F/1.25 McCarthy



SUR	RDY	THI	GLA	CON
STO	−81.57	−40.21	REFL	−1
2	INF	25.09	REFL	
		Tilt: 45°		
3	−48.68	−29	REFL	−1
4	−19.15	30.64	REFL	
5	−49.85	−65.483	REFL	

Comments McCarthy[114] intended this design, which combines a Cassegrain-Mersenne primary and tertiary mirror with a quaternary and quintenary Schwarzschild arrangement, as a wide strip-field imager. Both the Mersenne and Schwarzschild groups are separately corrected for spherical aberration, coma, and astigmatism. The Petzval curvature of the Mersenne is equal and opposite in sign to the Petzval curvature of the Schwarzschild and hence there is no net Petzval curvature. The quaternary mirror may be moved out from the entering beam with only a slight reduction in performance.

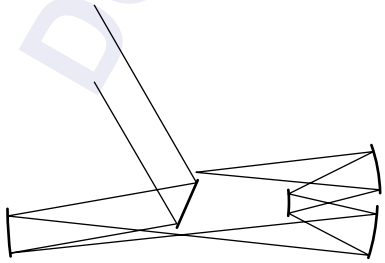
F/2.2 Cassegrain Objective with Schwarzschild Relay



SUR	RDY	THI	GLA	CON
1	−51.49	−19.01	REFL	−1.048
2	−37.37	34.19	REFL	−20.35
3	38.18	−10.493	REFL	−1.358
4	29.94	11.27	REFL	
STO	INF	40.484		

Comments Williams[115] describes a technique for optimizing a high-resolution system similar to this one while maintaining proper clearances, obscuration sizes, and packaging requirements. An all-reflective zoom system of the above configuration, developed by Johnson et al.,[116] gives a 4× zoom range and a field-of-view range of 1.5 to 6.0°. The Schwarzschild module and image position change with zoom position, while the front Cassegrain module remains fixed.

F/4 Altenhof Objective

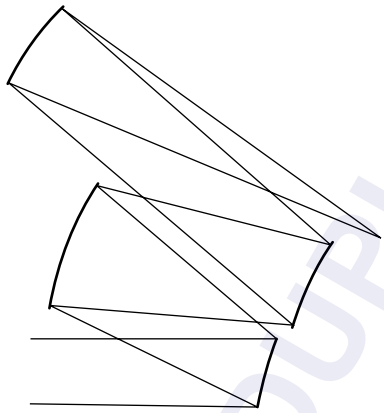


SUR	RDY	THI	GLA	CON
STO	INF	−80	REFL	
		Tilt: 25°		
2	155.64	165.53	REFL	
3	−77.26	−38.57	REFL	−0.0897
4	−34.146	40.367	REFL	
5	−80.65	−82.539	REFL	

Comments This objective is similar to one designed by Altenhof.[117] Intended as a ring field system, the flat primary couples the light incident from a large azimuthal angle (60°) into the system where the spherical primary mirror focuses the light to a poorly corrected image.

The three-mirror Offner relay,[9,118] a unit magnification relay which is corrected for spherical aberration, coma, and astigmatism, improves the degraded image in the process of reimaging it to a flat focal surface in the form of an annulus. A two-dimensional scene is imaged by rotating the flat mirror about an axis perpendicular to the picture so as to scan the other dimension. A two-dimensional mosaic image can also be produced by building up a series of one-dimensional annular strip images as the imaging system is moved along its trajectory.

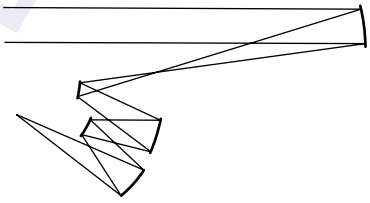
F*/4.5 *Shafer Four-Mirror, Unobscured Objective



SUR	RDY	THI	GLA
1	158.1	−71.21	REFL
	Tilt angle:	−16.44°	
STO	186.8	74.25	REFL
	Tilt angle:	−20.88°	
3	337.4	−111.4	REFL
	Tilt angle:	−24.82°	
4	239.1	121.4	REFL
	Tilt angle:	−34.76°	
	Image tilt angle:	−24.29°	

Comments This is a tilted and decentered-component infrared imaging system by David Shafer. Mirror tilts provide an unobscured path and help correct the aberrations. Thickness is measured along the deviated ray paths. With the reflection angle known, element decenter may be easily determined.

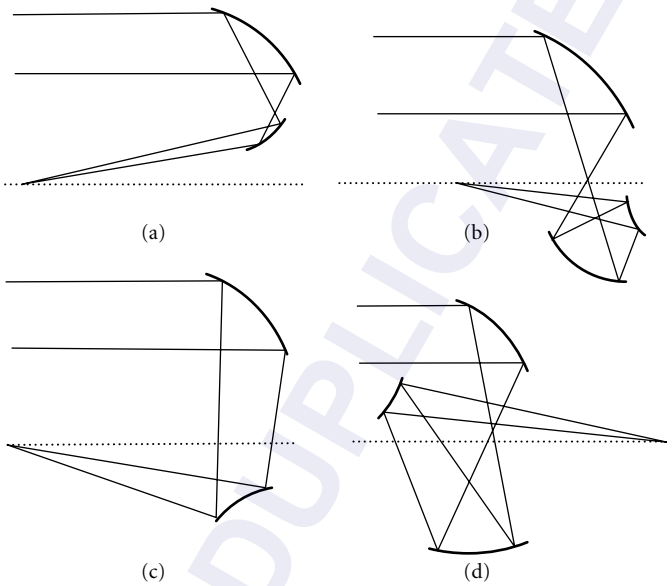
F*/4.5 *Shafer Five-mirror, Unobscured Objective



SUR	RDY	THI	GLA
1	−239.5	−160.2	REFL
	Tilt angle:	6.4°	
2	−228.9	48.69	REFL
	Tilt angle:	−9.2°	
3	−75.94	−37.24	REFL
	Tilt angle:	−19.01°	
STO	−39.81	39.24	REFL
	Tilt angle:	−28.82°	
5	−78.72	−74.5	REFL
	Tilt angle:	−40.55°	
	Image tilt angle:	−11.28°	

Comments Another all-spherical, tilted, and decentered-component infrared imager by Shafer is presented here. The entrance pupil is accessible and there is an intermediate image. A number of variations on this arrangement are described by Shafer.[80]

Korsch Two- and Three-Mirror Objectives



Comments A new class of eccentric-pupil objectives has been introduced by Korsch.[14] Unlike most systems, which are conceived using third-order aberration theory, these systems are based upon the fulfillment of *axial stigmatism,* the *Abbe sine condition,* and the *Herschel condition;* meeting these three conditions guarantees a perfect axial point image, axially perpendicular image area, and axial line element, respectively.

Design examples are not given for two reasons. First, rays strike some mirror surfaces at angles greater than 90°, which can cause ray-trace errors. Second, some of the surface shapes are particularly complex and must be entered in design software as a user-defined surface.

Design (*c*) gives perfect imagery on-axis and less than one milliradian resolution at all other points over a 6° field of view, for an aperture diameter equal to F/6.0 (F is focal length).

29.5 FIELD-OF-VIEW PLOTS

The plots that follow give rms spot size and angular resolution as a function of half-field of view. The curves have been generated by calculating the resolution for a number of field angles and connecting them with smooth curves. The dashed horizontal line is the Airy disc diameter for 0.55-μm radiation.

The numbers in the plots correspond to the designs presented in the previous section. The aperture of each design is 20 cm and the spectral range 480 to 680 nm, unless stated otherwise in the previous section.

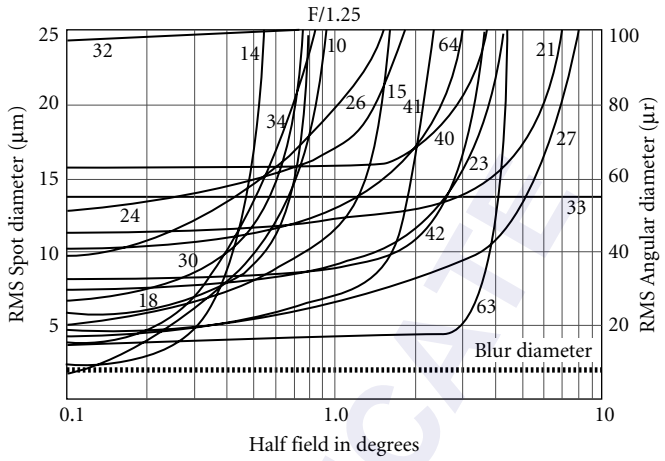


FIGURE 7 Field-of-view plots: F/1.25 on a flat image.

It should be kept in mind that these are representative designs: they have usually been optimized for a specific purpose; they are meant to be a starting place for the design of a new system that may have entirely different requirements.

Flat-field designs show consistent performance out to the field angle for which the objective is optimized. Beyond this point, the graph leaps upward. Reoptimization is needed if the field of view is to be extended further; a considerable increase in the average rms spot size may occur if this is attempted. The curved-image designs show a quadratic dependence with field angle.

Off-axis and eccentric-pupil designs have rectangular fields with most of the field of view in one dimension only. Data plotted for these designs are representative of the larger field.

In Figs. 8 and 10, plots for the curved image designs are provided. The curvature of the image is adjusted to give optimum performance. Figures 7 and 9 are for the flat image designs.

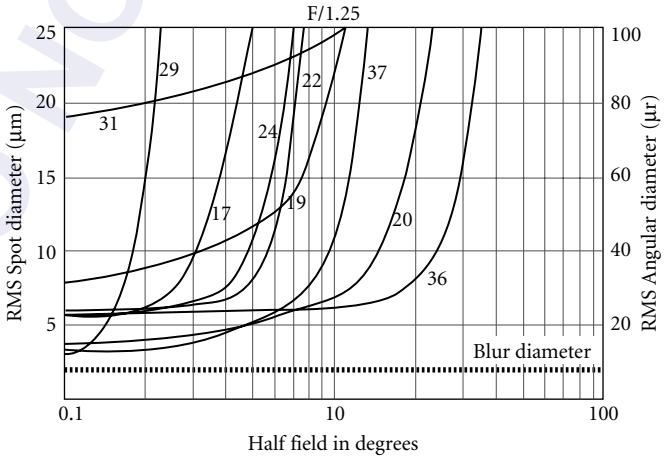

FIGURE 8 Field-of-view plots: F/1.25 on a curved image.

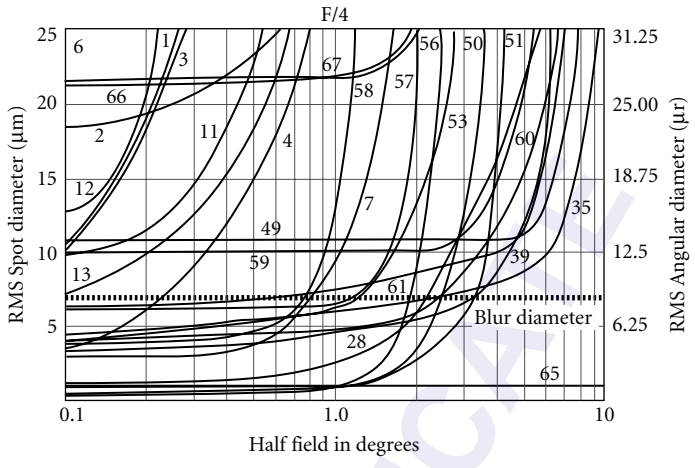

FIGURE 9 Field-of-view plots: F/4 on a flat image.

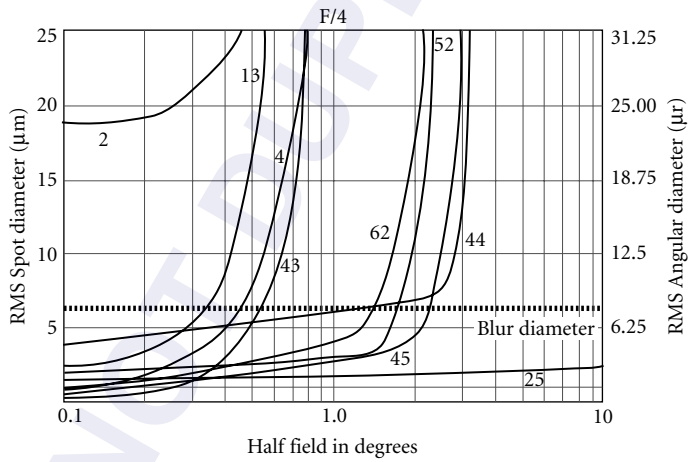

FIGURE 10 Field-of-view plots: F/4 on a curved image.

29.6 DEFINITIONS

Abbe number: A number that indicates the dispersion of a glass. Low dispersion glasses have a high Abbe number.

Abbe sine condition: A condition for zero coma, based on the requirement of equal marginal and paraxial magnifications. See Welford,[61] Kingslake,[9] or Korsch.[14]

anastigmatic: A surface or system free of astigmatism. Also stigmatic.

aperture stop: The aperture that limits the size of the axial beam passing through the system; the *chief ray* always passes through its center.

aplanatic: A surface or system that is corrected for spherical aberration and coma.

astigmatism: An aberration that generates two different focal positions for rays in two perpendicular planes centered on the optical axis. These are called the sagittal and tangential planes.

axial color: The variation in focal position with wavelength.

axial stigmatism: A characteristic of a surface which is able to produce a perfect image of a single point object on-axis.

catadioptric: An optical system composed of refractive and reflective elements: catoptric, reflective and dioptric, refractive.

chief ray: A ray that passes through the center of the aperture stop and the edge of the image or object.

coma: An aberration resulting from the change in magnification with ray height at the aperture, so that rays near the edge of the aperture are focused further from rays near the axis, for the same field point.

conic constant: A constant defined by

$$k = -\epsilon^2$$

where ϵ is the eccentricity of the conic.

distortion: The variation in magnification with field angle.

entrance pupil: The image of the aperture stop in object space. The chief ray passes or appears to pass through the center of the entrance pupil.

exit pupil: The image of the aperture stop in image space. The chief ray passes or appears to pass through the center of the exit pupil.

focal ratio: The effective focal length of an objective divided by its entrance-pupil diameter. Focal ratio is also referred to as the FN, F-number, and speed.

field curvature: Image curvature produced by the combined effects of astigmatism and Petzval curvature. When astigmatism is absent, the image surface coincides with the Petzval surface.

field stop: An aperture that limits the size of an intermediate or final image.

Herschel condition: A condition for invariance of aberrations with change in axial conjugates. See Welford[61] and Korsch.[14]

higher-order aberrations: Aberrations defined by the higher-order terms in the aberration power series expansion. See Welford[61] and Schulz.[1]

lateral color: An aberration that produces a dependence of image size on wavelength; also called chromatic difference of magnification.

Lyot stop: A real and accessible image of the aperture stop; used to block stray light.

marginal ray: A ray that passes through the center of the object or image and past the edge of the aperture stop.

medial image: The image halfway between the sagittal and tangential images. See Welford.[61]

monocentric system: An optical system in which all surfaces are concentric about the chief ray.

oblique spherical aberration: *A higher-order aberration* that is the variation of spherical aberration with field angle.

optical axis: The axis about which all optical elements are symmetric. In tilted and decentered systems, each element has a unique optical axis.

Petzval sum: The sum defined by

$$p = \Sigma \frac{\phi}{n}$$

where ϕ is element power and n is the index of refraction. The reciprocal of the Petzval sum is the image radius of curvature.

secondary magnification: System focal length divided by primary-mirror focal length.

secondary spectrum: The difference in focal position between two wavelengths corrected for axial color and one other wavelength which is not. For example, the blue and red focus coincide and the yellow focus is axially displaced.

spherical aberration: The only on-axis monochromatic aberration, spherical aberration results from rays at different heights coming to focus at different points along the optical axis. Smith,[3] Rutten,[12] Kingslake,[9] Mackintosh,[83] and Welford[61] discuss aberrations. Welford specifically addresses aberrations.

third-order aberrations: Any of the Seidel aberrations: spherical aberration, coma, astigmatism, Petzval curvature, and distortion. See Welford.[61]

vignetting: The off-axis clipping of light by apertures in an optical system.

virtual image: A real image is visible when a screen is placed at its location. The image is visible because rays from the object converge at the image. A virtual image is not visible when a screen is placed at its location since real rays do not converge.

zonal spherical aberration: The incomplete correction of spherical aberration at radial zones in the aperture. For example, spherical aberration could be corrected for rays close to the center and edge of the aperture, but not corrected at other ray heights in the aperture.

30.1 GLOSSARY

a	aperture shape factor; calibrates diffraction angle as function of aperture intensity distribution
A	area
C	capacitance, electrical
d	grating spacing, array element spacing
D	useful beam width in scan direction (see W); D_m = enlarged beam width due to a
f_e	data bandwidth
f	focal length
F	F-number (f/D)
FL	field lens
FOV	field of view
FWHM	full width (of δ) measured at half maximum intensity
H	vehicle height
I	resolution invariant; adaptation of Lagrange invariant, $I = \Theta D = \Theta' D'$, normalized intensity
k	scanning constant (see m)
m	scan magnification ($d\Theta/d\Phi$) (for m = constant, $m = k = \Theta/\Phi$)
m'	composite magnification
M	optical magnification (image/object)
n	number of facets, refractive index, diffractive order
N	number of resolution elements subtended by Θ or S
$\mathcal{N}$	total number of cells in a phased array
P	radiant power (watts)
PSF	point spread function (intensity distribution of focused spot)
q	number of cells in array period
Q	q-factor (electromechanical)

r	radius
R	reciprocity failure factor (≥ 1), scanner rpm
s	sensitivity (recording medium)
S	format width, no. of scans per revolution of scanner
t	time
T	time period, optical transfer factor (≤ 1)
V	vehicle velocity, electrical voltage
W	full aperture width, of which D is utilized (see ρ)
w	width at $1/e^2$ intensity
x	along-scan direction
y	cross-scan direction
α	angular departure from normal beam landing, spectral power transfer factor, radiation intensity parameter
γ	phosphor utilization factor (≤ 1)
δ	spot size; if Gaussian, measured across $1/e^2$ intensity width or at FWHM
Δ	shift distance
ε	chromatic error, ellipticity
η	duty cycle, conversion efficiency (≤ 1), efficiency
Θ, θ	optical scan angle, angular beamwidth
Φ	mechanical scan angle, along-track optical scan angle, optical field angle
λ	wavelength
Λ	wavelength (acoustic grating), array period
ρ	truncation ratio (W/D)
σ	Gaussian standard deviation
τ	transit time (acoustic), retrace time, dwell time

30.2 INTRODUCTION

This chapter provides an overview of optical scanning techniques in context with their operational requirements. System objectives determine the characteristics of the scanner which, in turn, influence adjacent system elements. For example, the desired resolution, format, and data rate determine the scanner aperture size, scan angle, and speed, which then influence the associated optics. The purpose of this chapter is to review the diverse options for optical scanning and to provide insight to associated topics, such as scanned resolution and the reduction of spatial errors. This broad perspective is, however, limited to those factors which bear directly on the scanner. Referencing is provided for related system relationships, such as image processing and data display. Topics are introduced with brief expressions of the fundamentals. And, where appropriate, historical and technical origins are referenced.

The subject of scanning is often viewed quite differently in two communities. One is classified as *remote sensing* and the other, *input/output scanning.* Associated component nomenclature and jargon are, in many cases, different. While their characteristics are expanded in subsequent sections, it is useful to introduce some of their distinctions here. Remote sensing detects objects from a distance, as by a space-borne observation platform. An example is infrared imaging of terrain. Sensing is usually *passive* and the radiation *incoherent* and often multispectral. Input/output scanning, on the other hand, is *local.* A familiar example is document reading (input) or writing (output). Intensive use of the laser makes the scanning *active* and the radiation *coherent.* The scanned point is focused via finite-conjugate optics from a local fixed source.

While the scanning components may appear interchangeable, special characteristics and operational modes often preclude this option. This is most apparent for diffractive devices such as

acousto-optic and holographic deflectors. It is not so apparent regarding the differently filled scanning apertures, imparting important distinctions in resolution and duty cycle. The unification of some of the historically separated parameters and nomenclature is considered an opportunity for this writing.

A recent concentration of R&D in the field of agile beam steering is presented in Sec. 30.8. Intensive work has yielded encouragement in the long quest for achieving, for example, the performance of articulated large mirrors while avoiding some of the systemic burdens of size, weight, and inertia. Recently, remarkable work has been done using microelectromechanical systems (MEMS) to make scanners on a small scale. Two particularly interesting devices are presented and are the digital micromirror device (DMD) incorporated into digital light processing (DLP) projectors and gimbal-less two-axis scanning-micromirror devices (GSMD). The DMD is essentially a two-dimensional array binary-state scanner or light switches, while the GSMD is a fully analog dual-axis scanner.

System Classifications

The following sections introduce the two principal disciplines of optical scanning, remote sensing, and input/output scanning, in preparation for discussion of their characteristics and techniques.

Remote Sensing The applications for passive (noninvasive) remote sensing scanners are varied and cover many important aspects of our lives. A signature representative of the target is obtained to form a signal for subsequent recording or display. This process is operationally distinct from active scanning, as expressed further in this chapter. Table 1 lists typical applications of these techniques. Clearly, remote scanning sensors can be hand held to satellite-borne.

A variety of scanning methods has been developed to accomplish the formation of image (or imagelike) data for remote sensing. These methods may be roughly divided into framing, pushbroom, and mechanical. Generally stated, frame scanning requires no physical scan motion and implies that the sensor has a two-dimensional array of detectors which are read out by use of electronic means (e.g., CCD), electron beam, or light beam. Such an array requires an optical system that has two-dimensional wide-angle capability. Pushbroom methods typically employ some external means to move the image of a linear array of detectors along the area to be imaged. Mechanical methods generally include one- and two-dimensional scanning techniques incorporating as few as one detector to multiple- detector arrays. As is the case for pushbroom methods, image formation by one-dimensional mechanical scanning requires that the platform containing the sensor (or in

TABLE 1 Representative Applications of Passive Scanning Sensors

Medical	Government
Cancer	Forest fires
Arthritis	Police
Whiplash	Smuggling
Industrial	Search and rescue
Energy management	Military
Thermal fault detection	Gun sights
Electronic circuit detection	Night vision
Nondestructive testing	Tactical
Scientific	Navigation
Earth resources	Missiles
Weather	Strategic
Astronomy	Aircraft
	ICBM
	Surveillance

some cases the object) be moved to create the second dimension of the image. The latter two methods are discussed further in later sections of this chapter.

Mechanical scanners can be configured to perform either one- or two-dimensional scan patterns. In the case of a one-dimensional scanner, the second dimension needed to form an image is most often generated by movement of the sensor platform.

A number of optical scanning systems have been invented to satisfy the wide variety of applications. In the early years of passive scanning systems, the entire optical system was often moved in order to produce either a one- or two-dimensional scan pattern. The advent of airborne mapping or reconnaissance electro-optical systems began during the 1950s. Typically, the scanner performed a one-dimensional scan in object-space, as defined under the section "Object-Space and Image-Space Scanners," orthogonal to the flight direction of the aircraft, while the motion of the aircraft generated the second dimension of the image. The resultant video information is stored on a recording medium such as photographic film, digital tape, and the like. The design and resultant performance of a scanning system are governed by a variety of parameters that are related by trade-off equations and considerations. The selection of the scanner type typically has a strong influence upon the ultimate system performance. In subsequent discussion, the more important parameters related to the scanner selection will be covered. The complexities of the total system design and optimization are not within the scope of this chapter.

Input/Output Scanning In contrast to remote sensing, which captures passive radiation, active input/output scanning illuminates an object or medium with a "flying spot," derived typically from a laser source. Some examples appear in Table 2, divided into two principal functions: *input* (detecting radiation scattered from the scanning spot) and *output* (recording or display). Input is modulated by the target to form a signal; output is modulated by a signal.

Some merit clarification. Under input is laser radar—a special case of active remote sensing, using the same coherent and flying-spot scanning disciplines as the balance of those exemplified. Earth resources imaging is the *recording* of remotely sensed image signals. Finally, data/image display denotes the general presentation of information, which could include "hard copy" and/or actively projected and displayed images.

Active scanning is synonymous with flying-spot scanning, the discipline most identified with the ubiquitous cathode-ray tube (CRT). While the utilized devices and their performance differ significantly, the distinctions between CRT and laser radiation are primarily their degrees of monochromaticity and coherence, as addressed later in this chapter.

Thus, most high-resolution and high-speed flying-spot scanning are now conducted using the laser as a light source. This work in input/output scanning concentrates on the control of laser radiation and the unique challenges encountered in deflecting photons, devoid as they are of the electric and magnetic fields accompanying the electron beam. Reference is provided[1–3] for pursuit of the CRT scanning discipline.

TABLE 2 Examples of Input/Output Scanning

Input	Output
Image scanning/digitizing	Image recording/printing
Bar-code reading	Color image reproduction
Optical inspection	Medical image outputs
Optical character recognition	Data marking and engraving
Optical data readout	Microimage recording
Graphic arts camera	Reconnaissance recording
Scanning confocal microscopy	Optical data storage
Color separation	Phototypesetting
Robot vision	Graphic arts platemaking
Laser radar	Earth resources imaging
Mensuration	Data/Image display

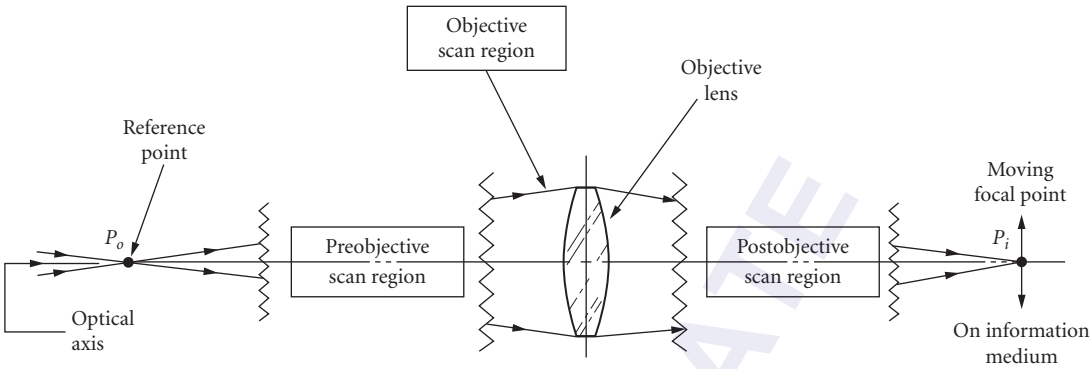

FIGURE 1 Conjugate imaging system, showing scan regions, as determined by position of scanning member relative to the objective lens. Translational (objective) scan and angular (pre/postobjective) scan can occur individually or simultaneously.[4]

Scanner classification Following the nomenclature introduced in the early 1970s,[4,5] laser scanners are designated as *preobjective, objective,* and *postobjective.* Figure 1 indicates the scan regions within a general conjugate optical transfer of a fixed reference (object) point P_o to a moving focal (image) point P_i. *The component which provides principal focusing of the wavefront identifies the objective lens.*

The scanner can perform two functions (see section "Objective, Preobjective, and Postobjective Scanning" later in this chapter): one is *translation* of the aperture with respect to the information medium. This includes translation of the lens element(s) or translation of the object, or both, and is identified as an *objective* scan. The other is *angular change* of the optical beam with respect to the information medium. Angular scanners are exemplified by plane mirrors on rotating substrates. Although lenses can be added to an angular scanner, it is seldom so configured. The scanner is either preobjective or postobjective. In holographic scanning, however, the hologram can serve as an objective lens and scanner simultaneously.

Radial symmetry and scan magnification A basic characteristic of some angular scanners is identified as *radial symmetry.* When an illuminating beam converges to or diverges from the nodal or rotating axis of an angular scanner, it is said to exhibit radial symmetry.[6] The collimated beam which is parallel to the rotating axis is a special case of radial symmetry, in which the illuminating beam propagates to or from a very distant point on the axis. Scanners exhibiting radial symmetry provide unity angular optical change for unity mechanical change. That is, $m = d\Theta/d\Phi = 1$, where Θ is the optical scan angle and is the mechanical change. The parameter m is called the *scan magnification,* discussed later under "Augmented Resolution, the Displaced Deflector" for Eq. (19). It ranges typically between 1 and approximately 2, depending on the scanner-illumination configuration, per Table 3. In remote sensing, $m = \Theta/\Phi = k$. (See "Compound Mirror Optics Configurations.")

The prismatic polygon (see "Monogon and Polygon Scanners") exhibits a variable m, depending on the degree of collimation or focusing of the output beam. When collimated, $m = 2$. When focusing, the value of m shifts from 2 according to the composite magnification

$$m' = 2 + r/f \tag{1}$$

where f and r are according to Fig. 4 and Eq. (19). This is similar to the ratio of angular velocities of the scanned focal point along the arc of a limaçon,[5]

$$\dot{\Theta}/\dot{\Phi} = 2\left(1 + \frac{\cos\Phi}{1 + f/r}\right) \tag{2}$$

TABLE 3 Typical Features of Pyramidal and Prismatic Polygon Scanners

Item	Description	Pyramidal	Prismatic
1	Input beam direction[a]	Radially symmetric[b] (typically parallel to axis)	Perpendicular to axis[c]
2	Output beam direction[a]	Arbitrary angle to axis (typically perpendicular)	Perpendicular to axis[c]
3	Scan magnification[b] (scanning constant)	1	2[b]
3a	Along-scan error magnification	1	2[b]
3b	Max. scan angle, Θ_{max} (n = no. of facets)	$2\pi/n$	$4\pi/n$[b]
4	Output beam rotation about its axis[d]	Yes	No
5	Aperture shape[e] (overilluminated)	Triangular/keystone	Rectangular
6	Enlargement of along-scan beam width	No	Yes[f] $D_m = D/\cos\alpha$
7	Error due to axial polygon shift[g]	Yes	No
8	Error due to radial polygon shift[g]	Yes	Yes
9	Fabrication cost	Greater	Lower

[a]With respect to rotating axis.
[b]See sections "Radial Symmetry and Scan Magnification" and "Augmenting and Scan Magnification." Output beam assumed collimated.
[c]All beams typically in same plane perpendicular to axis. See Figs. 26 and 28.
[d]Observable when beam is nonisotropic; e.g., elliptic, polarized, etc. Rotation of isotropic beam normally not perceived. See "Image Rotation and Derotation."
[e]See Table 4.
[f]α = angular departure from normal landing. See "Scanner-Lens Relationships."
[g]Shift of image focal point in noncollimated light. No error in collimated light.

Note that when $r \to 0$ or when $f \to \infty$, $\dot{\Theta}/\dot{\Phi} \to 2$. In holographic scanners which are not radially symmetric, m depends on the angles of incidence and diffraction of the input and first-order output beam,

$$m = \sin\theta_i + \sin\theta_o = \lambda/d \tag{3}$$

where θ_i and θ_o are the input and diffracted angles (with respect to the grating normal) and d is the grating spacing. For example, when $\theta_i = \theta_o = 30°$, $m = 1$; when $\theta_i = \theta_o = 45°$, $m = \sqrt{2}$.

30.3 SCANNED RESOLUTION

Remote Sensing Resolution and Data Rates

Figure 2 illustrates the scanning geometry for an airborne line-scanning system where the aircraft is flying along a "track" at a height H and velocity V. The total scanned field of view is θ_{max} and the cross-track and along-track instantaneous fields of view are $\Delta\theta$ and $\Delta\phi$, respectively.* The direction directly below the aircraft and normal to the scanned surface is called the *nadir*. The instantaneous field

*Cross-track and along-track in remote sensing correspond to along-scan and cross-scan, respectively, in input/output scanning.

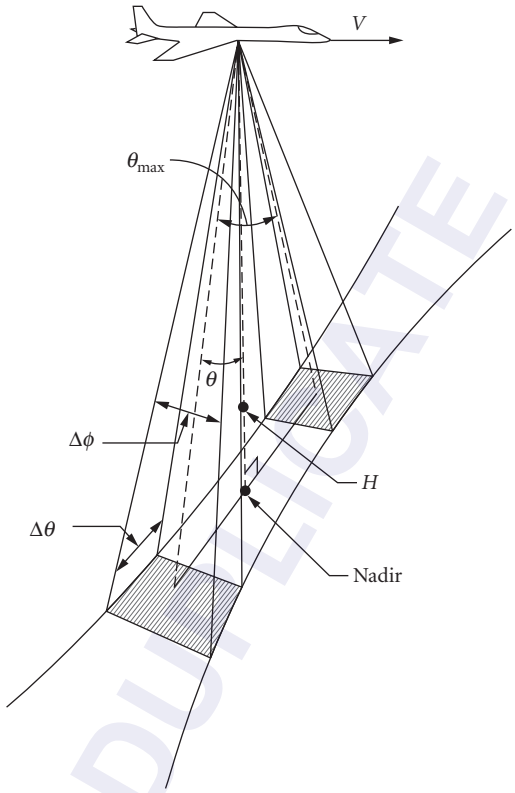

FIGURE 2 Scanning geometry for an airborne line-scanning system with a total scanned FOV of θ_{max}. The aircraft is flying at height H and velocity V. The cross-track and across-track instantaneous FOVs are $\Delta\theta$ and $\Delta\varphi$, respectively. (*After Wolfe, Proc. IRE, 1958.*)

of view is defined as the geometrical projection of the detector with spatial dimensions d_{ct} and d_{at} by the optics having a focal length of F. Therefore, $\Delta\theta = d_{ct}/F$ and $\Delta\theta = d_{at}/F$. Figure 2 shows the "bow-tie" distortion of the scanning geometry which will be discussed further under "Image Consequences."

The basic equation relating the aircraft velocity to the angular velocity of the scanning system to produce contiguous scan lines at the nadir is $V/H = \dot{s} \cdot \Delta\phi$, where $\dot{s}$ is the scanning system's scan rate in scans per second. For a system with n detector elements aligned in the flight direction, $V/H = n\dot{s} \cdot \Delta\phi$.

The number of resolution elements or pixels in a single scan line is

$$N = \frac{\theta_{max}}{\Delta\theta} \tag{4a}$$

$$= \frac{2\pi\theta_{max}}{360° \cdot \Delta\theta} \tag{4b}$$

where $\Delta\theta$ is in radians, θ_{max} is the total field of view measured in radians in Eq. (4*a*) and in degrees in Eq. (4*b*), for the scanning means employed, taking due regard for the duty cycle given

in Eq. (23). The scan rate, in scans per second, may be expressed as a function of the scan mirror speed by

$$\dot{s} = \frac{RS}{60} \tag{5}$$

where R is the scan mirror rpm and S is the number of scans produced by the scanning mechanism per revolution of the optics. It follows that the number of resolution elements or pixels per second per scan line is

$$\dot{N} = \frac{2\pi\theta_{\max} RS}{60 \cdot 360 \cdot \Delta\theta} \tag{6}$$

The angle $\theta_{\max}$ (in degrees) is determined by the configuration of the scan mirror and is $\theta_{\max} = 360 \cdot k/S$, where k is the scanning constant or scan magnification* and can have values ranging from 1 to 2. The specific value is dependent upon the optical arrangement of the scanner as exemplified in Table 3. The pixel rate may now be written as

$$\dot{N} = \frac{2\pi kR}{60\,\Delta\theta} \tag{7}$$

The information retrieval rate of a system is often expressed in terms of the dwell time τ or the data bandwidth f_e as

$$f_e = \frac{1}{2\tau} = \frac{\dot{N}}{2} \tag{8}$$

By combining the preceding equations, the data bandwidth for a multiple-detector system can be expressed as

$$f_e = \frac{\pi k(V/H)}{nS\Delta\theta\Delta\phi} \tag{9}$$

which illustrates clearly the relationship between important system parameters such as f_e being inversely proportional to instantaneous field-of-view solid angle ($\Delta\theta\Delta\phi$).

Input/Output Scanning

Resolution Criteria, Aperture Shape Factor The resolution of an optical scanner is expressed[5,7] by the number N of spots or elements that can be conveyed along a contiguous spatial path. The path is usually (nearly) linear and traversed with uniform velocity. Although the elements δ are analogous to the familiar descriptors *pixels* or *pels* (picture elements), such identification is avoided, for pixels often denote spatially digitized scan, where each pixel is uniform in intensity and/or color. Active optical scan, on the other hand, is typically contiguous, except as it may be subjected to modulation. Normally, therefore, the scanned spots align and convolve to form a continuous spatial function that can be divided into elements by modulation of their intensity. To avoid perturbation of the elemental point spread function (PSF) by the modulating (or sampling) process, we assume that the scan function is modulated in intensity with a series of (Dirac) pulses of infinitesimal width, separated by a time t such that the spatial separation between spot centers is $w = vt$, where v is the velocity of the

*See "Radial Symmetry and Scan Magnification" regarding scan magnification m which represents a more general form of the scanning constant k.

scanned beam. It is often assumed that the size δ of the thus-established elemental spot corresponds to w; that is, the width of the imaged spot is equal to the spacing from its neighbor.

To quantify the number N of such spots, those which exhibit a Gaussian intensity distribution are usually considered overlapping at one of two widths; at their $1/e^2$ intensity points, or at their 50 percent intensity points [the latter denoted as full width at half maximum (FWHM)]. Their relationship is

$$\delta_{\text{FWHM}} = 0.589\delta_{1/e^2} \tag{10}$$

The resolution N is identified with its measurement criterion, for the same system will convey different apparent N, per Eq. (10). That is, it will count approximately 1. 7 times as many spots at FWHM than at $1/e^2$ intensity.

These distinctions are accommodated[8] by their aperture shape factors a. For example, the above Gaussian aperture distribution is represented by shape factors

$$a_{1/e^2} = \frac{4}{\pi} = 1.27 \tag{11a}$$

$$a_{\text{FWHM}} = 0.589a_{1/e^2} = 0.75 \tag{11b}$$

When adapted to the applicable equation for spot size

$$\delta = aF\lambda \tag{12}$$

where $F = f/D$ is the F-number of the cone converging over the distance f from beam width D, and λ is the radiation wavelength, the resulting Gaussian spot size becomes

$$\delta_{1/e^2} = \frac{4}{\pi}\frac{f}{D}\lambda = 1.27F\lambda \tag{13a}$$

when measured across the $1/e^2$ intensity points, and

$$\delta_{\text{FWHM}} = 0.75F\lambda \tag{13b}$$

when measured across FWHM.

The factor a further accommodates the resolution changes due to changes in aperture shape, as for apodized and truncated Gaussians. Ultimate truncation is that manifest when the illuminating spatial distribution is much larger than the limiting aperture (overillumination or overfilling), forming the uniformly illuminated aperture.* Familiar analytic examples are the rectangular and round (or elliptic) apertures, which generate (for the variable x) the normalized intensity distributions $[\sin(x)/x]^2$ and $[2J_1(x)/x]^2$, respectively, where $J_1(x)$ is the first-order Bessel function of the first kind.

Figure 3 illustrates† the MTFs[9] of several uniformly illuminated apertures. Their intersections with the 0.5 MTF value identifies the spatial frequency at which their modulation is 50 percent. With the rectangular aperture as a reference (its straight line intersects 0.5 MTF at 50 percent of the limit frequency, forming $a = 1$), the intersections of the others with MTF = 0.5 yield corresponding spatial frequencies and relative a-values. Since the spatial frequency bandpass is proportional to $D/f = 1/F$, the apertures of the others must be widened by their a-values (effectively lowering their F-numbers) to render equivalent response midrange.

*Although the illumination and resulting PSFs are of a coherent wave, scanning forms a sequence of incoherently related intensity measurements of the space-shifting function, yielding an incoherent MTF.

†See Figs. 23 and 24 and related discussion for reduced power throughput due to approaching uniform illumination within the aperture.

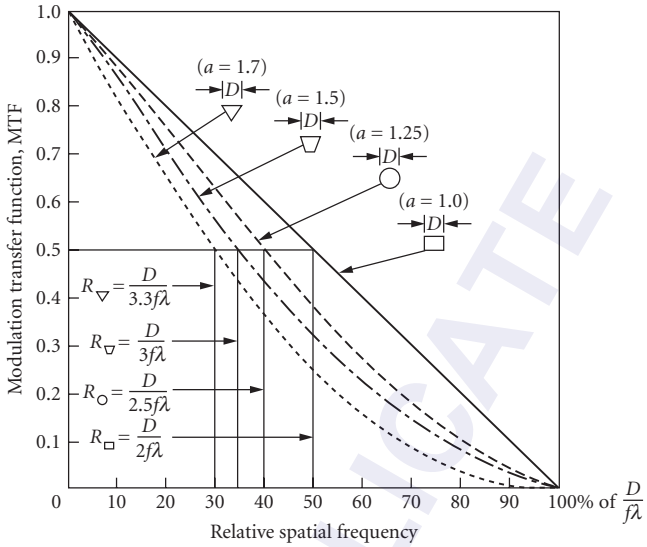

FIGURE 3 Modulation transfer function versus relative spatial frequencies for uniformly illuminated rectangular, round, keystone, and triangular apertures. Spatial frequency at 50 percent modulation (relative to that of rectangular aperture) determines the *a* value.[5]

Table 4 summarizes the aperture shape factors (a) for several useful distributions.[8] Truncated, when applied, is two dimensional. Noteworthy characteristics are

1. Scanning is in the direction of the width D or W.
2. The a-value of 1.25 for the uniformly illuminated round/elliptic aperture corresponds closely to the Rayleigh radius value of 1.22.
3. The Gaussian-illuminated data requires that the width D, measured at the $1/e^2$ intensity points be centered within the available aperture W. Two conditions are tabulated: untruncated[10] ($W \geq 1.7D$) and truncation at $W = D$.
4. The Gaussian-illuminated data also provides the a-values for 50 percent MTF, allowing direct comparison with performance of the uniformly illuminated apertures.

This data relates to apertures which, if apodized, are truncated two dimensionally. However, one-dimensional truncation of a Gaussian beam by parallel boundaries is not uncommon, typical of that for acousto-optic scanning. There, the limiting aperture width W is constant, as determined by the device, while the Gaussian width D is variable.[4,5,11,12] Table 5 tabulates the shape factor a for such conditions.

TABLE 4 Aperture Shape Factor *a*

Uniformly Illuminated			Gaussian Illuminated		
Shape		a	δ (Spot Overlap)	a (Untruncated) $W \geqq 1.7\,D$	a (Truncated) $W = D$
Rectangular		1.0	@ $1/e^2$ Intensity	1.27	1.83
Round/elliptic		1.25	@$\frac{1}{2}$–Intensity	0.75	1.13
Keystone		1.5	for 50% MTF	0.85	1.38
Triangular		1.7	Beam width D @ $1/e^2$, intensity centered within aperture width W		
Width D for 50% MTF		1.7			

TABLE 5 Aperture Shape Factor a for One-Dimensional Truncation of a Gaussian Intensity Distribution

Truncation Ratio $\rho = W/D$	Shape Factor a for 50% MTF
0	1.0
0.5	1.05
1.0	1.15
1.5	1.35
2.0	1.75

W = width of aperture.
D = width of Gaussian beam at $1/e^2$ intensity points.
W and D measured in scan direction.

To relate to data in Table 4, the case of $\rho = W/D = 0$ represents illumination through a narrow slit. This corresponds to the uniformly illuminated rectangular aperture, whence $a = 1$. When $\rho = 1$, then $W = D$ and the parallel barriers truncate the Gaussian beam at its $1/e^2$ intensity points. Compared to symmetric truncation, this allows more of the Gaussian skirts to contribute to the aperture width, providing $a = 1.15$ versus 1.38. When $\rho = 2$, the Gaussian beam of half the width of the boundaries is effectively untruncated, halving the resolution ($a = 1.75$ vs. 0.85), but maximizing radiometric throughput. (See Fig. 24, observing nomenclature, where $D = 2w_x$ and $W = 2r_o$.)

Fundamental Scanned Resolution The section on "Input/Output Scanning" introduced the two forms of optical scan: translation and angular deflection. Beam translation is conducted by objective scan, while angular deflection is either preobjective or postobjective. Examples of each are provided later in this chapter.

The resolution N_s of translational scan, by a beam focused to spot size δ executing a scanned path distance S, is simply,

$$N_s = \frac{S}{\delta} \tag{14}$$

Extremely high resolutions are practical, but are often limited to moderate speeds and bandwidths. Common implementations provide $N_s = 3000$ to 100,000.*

The resolution N of angular scan,† represented schematically in Fig. 4, capable of much higher speeds, is given by[4,5,7]

$$N_\theta = \frac{\Theta D_o}{a\lambda} \tag{15}$$

where Θ is the useful deflected optical angle and D_o is the effective aperture width at its nodal center, discussed in the next section. Common implementations provide $N_\theta = 2000$ to 30,000. Equation (15) is independent of spot size δ and dependent only on the aperture characteristics of D_o and a, and the wavelength λ. The beam could be converging, collimated, or diverging. When collimated, $D_o = D$, the actual width of the illuminated portion of the aperture. When converging or diverging, resolution augmentation occurs (see next section).

The numerator of Eq. (9) is a form of the Lagrange invariant,[13] expressed in this nomenclature as

$$n\Theta D = n'\Theta' D' \tag{16}$$

*A high-resolution laser printer provides $N = 3000$ to 10,000, and a high-resolution graphic arts imager $N = 10{,}000$ to 100,000.
†Derived from Eq. (4a) with $\sin \Delta\Theta \simeq \Delta\Theta = a\lambda/D_o$.

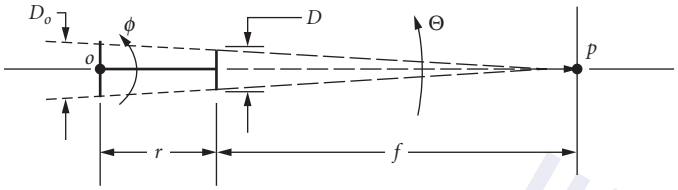

FIGURE 4 Deflecting element of width D (e.g., mirror of polygon) displaced by radius r from axis o, propagating a converging beam to p over focal distance f. Effective larger aperture D_o appears at rotating axis.[4]

where the primed terms are the refractive index, (small) angular deviation, and aperture width, respectively, in the final image space. For the common condition of $n = n'$ in air, the ΘD product and resolution N are conserved, invariant with centered optics following the deflector.

Augmented Resolution, the Displaced Deflector In general, a scanning system can accumulate resolution N by adding the two processes described previously, augmentation of angular scan with linear translation, forming

$$N = N_\theta + N_s \tag{17}$$

Augmentation occurs, for example, with conventional multielement scanners (such as polygons) having deflecting elements (facets) which are displaced from the rotating axis by a distance r, and whose output beam is noncollimated. One active element (of width D) and its focused output beam is illustrated in Fig. 4. For convenient analysis,[6] the deflecting element appears as overilluminated with an incident beam. The resulting resolution equations and focal spot positions are independent of over- or underillumination (see "Duty Cycle").

Augmentation for increased resolution is apparent in Fig. 4, in which the output beam is derived effectively from a larger aperture D_o which is located at o. By similar triangles, $D_o = D\ (1 + r/f)$, which yields from Eq. (15),

$$N = \frac{\Theta D}{a\lambda}\left(1 + \frac{r}{f}\right) \tag{18}$$

This corresponds to Eq. (17), for in the N_s term the aperture D executes a displacement component $S \simeq r\Theta$, which, with Eq. (12) forms Eq. (14).

Following are some noteworthy observations regarding the parenthetic augmentation term:

1. Augmentation goes to zero when $r = 0$ (deflector on nodal axis) or when $f = \infty$ (output beam collimated).
2. Augmentation adds when output beam is convergent (f positive) and subtracts when output beam is divergent (f negative).
3. Augmentation adds when r is positive and subtracts when r is negative (output derived from opposite side of axis o).

The fundamental or nonaugmented portion of Eq. (18), $N = \Theta D/a\lambda$, has been transformed to a nomograph, Fig. 5, in which the angle Θ is represented directly in degrees. $D/a\lambda$ is plotted as a radius, particularly useful when $a\lambda = 1$ μm, whereupon $D/a\lambda$ becomes the aperture size D, directly in mm. The set of almost straight bold lines is the resolution N. Multiples of either scale yield corresponding multiples of resolution.

Augmenting and scan magnification Equation (18) develops from Fig. 4, assuming that the optimal scan angle Θ is equal to the mechanical angle Θ. This occurs only when the scanner exhibits

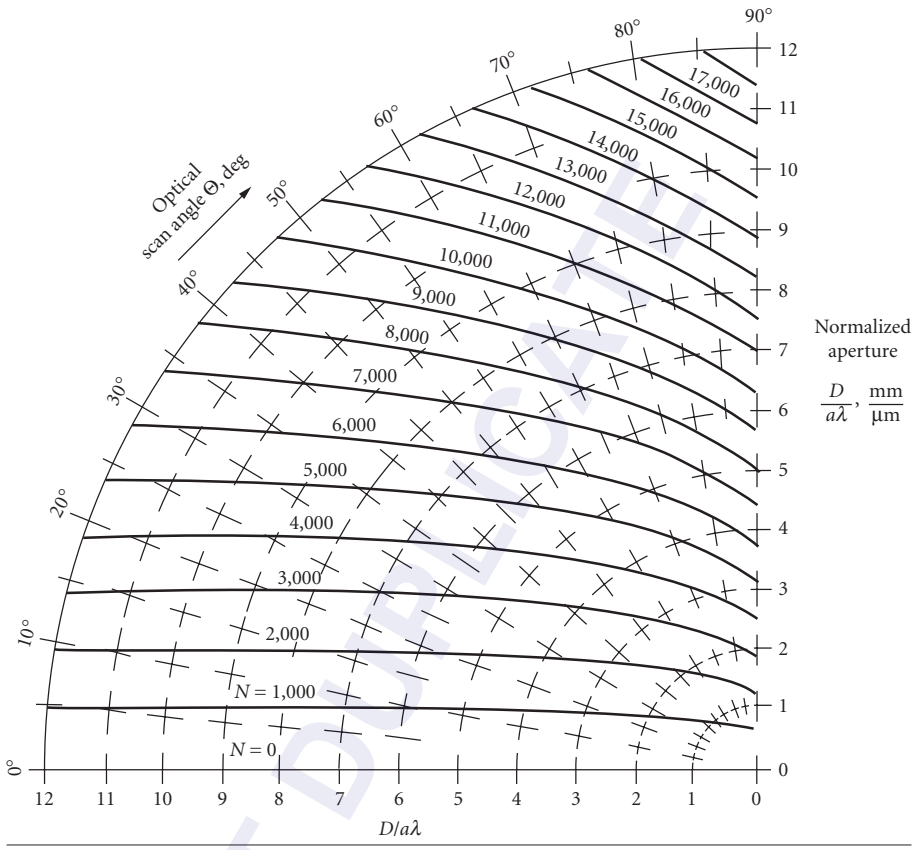

FIGURE 5 Nomograph of resolution equation $n=\frac{\theta D_4}{a\lambda}$.

radial symmetry (see "Radial Symmetry and Scan Magnification"). When, however, $m = d\Theta/d\phi \neq 1$, as for configurations represented in the section "Objective, Preobjective, and Postobjective Scanning," account must be taken of scan magnification m. Thus, the more complete resolution equation is represented by[6,14]

$$N=\frac{\Theta D}{a\lambda}\left(1+\frac{r}{mf}\right) \tag{19}$$

where per Fig. 4, Θ = optical scan angle (active)
D = scan aperture width
λ = wavelength (same units as D)
a = aperture shape factor
m = scan magnification (= $d\Theta/d\Phi$)
Φ = mechanical scan angle about o
r = distance from o to D
f = distance from D to p

[see variations for r and f under Eq. (18)].

Considering $m = \Theta/\Phi$ as a constant, another useful form is

$$N = \frac{\Phi D}{a\lambda}\left(m + \frac{r}{f}\right) \tag{20}$$

whose augmenting term shows a composite magnification

$$m' = m + r/f \tag{21a}$$

which, for the typical prismatic polygon becomes

$$m' = 2 + r/f \tag{21b}$$

Duty Cycle The foregoing resolution equations refer to the active portion of a scan cycle. The full scan period almost always includes a blanking or retrace interval. The ratio of the active portion to the full scan period is termed the duty cycle η. The blanking interval can include short overscan portions (straddling the active format), which are used typically for radiometric and timing calibration. The duty cycle is then expressed as

$$\eta = 1 - \tau/T \tag{22}$$

where τ is the blanking interval time and T is the full scan period. A reduced duty cycle increases instantaneous bandwidth for a given average data rate. In terms of the scan angle of polygons, for example, it limits the useful component to

$$\theta = \eta\theta_{\max} \tag{23}$$

where $\theta_{\max}$ is the full available scan angle (see Table 3).

Over- and Underillumination (Over- and Underfilling) In overillumination, the light flux encompasses the entire useful aperture. This is usually implemented by illuminating at least two adjacent apertures (e.g., polygon facets) such that the active one is always filled with light flux. This not only allows unity duty cycle, but provides for resolution to be maximized for two reasons: (1) blanking or retrace may be reduced to zero; and (2) the full available aperture width is operative as D throughout scan. The trade-off is the loss of illuminating flux beyond the aperture edges (truncation) and attendant reduction in optical power throughput (see "Coherent Source" under Sec. 30.5, p. 30.26). An alternative is to prescan[15] the light flux synchronously with the path of the scanning aperture such that it is filled with illumination during its entire transit.

In underillumination, the light flux is incident on a portion of the available aperture, such that this subtense delimits the useful portion D. A finite and often substantive blanking or retrace interval results, thereby depleting the duty cycle, but maximizing the transfer of incident flux to the scanned output.

30.4 SCANNERS FOR REMOTE SENSING

Early Single-Mirror Scanners

Early scanning systems comprised an object-space mirror followed by focusing optics and a detector element (or array). The first scanners were simple rotating mirrors oriented typically at 45° to the axis as illustrated in Fig. 6. The rotational axis of the scan mirror lies parallel to the flight direction. In Fig. 6*a*, the scan efficiency and duty cycle of the oblique or single ax-blade scanner (see monogon under "Monogon and Polygon Scanners") is quite low since only one scan per revolution ($S = 1$) is generated. The scan efficiency of the wedge or double ax-blade scanner shown in Fig. 6*b* is twice as great ($S = 2$), although the effective optical aperture is less than half that of the oblique scanner for the same mirror diameter. The scanning constant is $k = 1$ for both types (see "Remote Sensing Resolution and Data Rates" in Sec. 30.3).

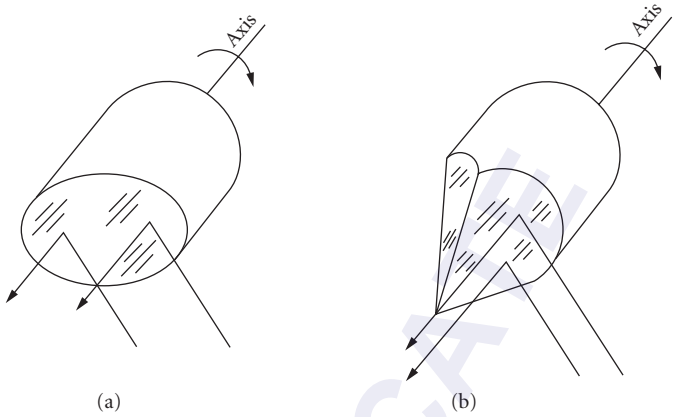

FIGURE 6 Early forms of scanners for remote sensing. The oblique or single ax-blade scanner is shown in (*a*) and the wedge or double ax-blade is shown in (*b*).

Compound Mirror Optics Configurations

The aforementioned scanners suffered from a varying optical aperture as a function of view angle. To overcome this difficulty that causes severe variation in the video resolution during a scan line, several new line scanner configurations were developed. Most notable among these was the rotating prism scanner invented by Howard Kennedy[16] in the early 1960s and which forms the basis for most of the produced wide-field-of-view line scanners. Figures 7 and 8 illustrate two

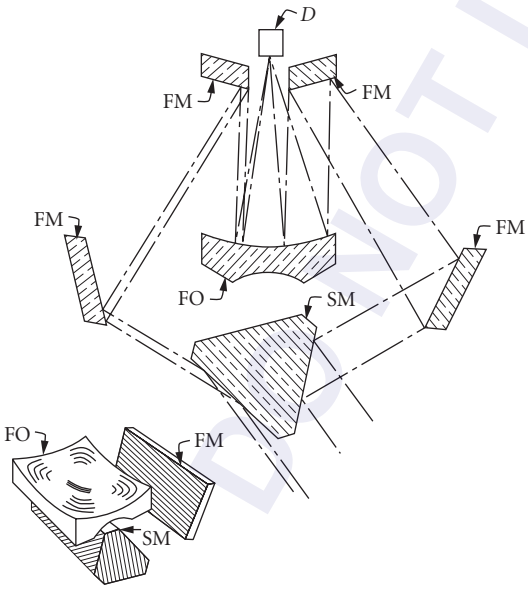

FIGURE 7 Basic split-aperture scanner with a three-sided scan mirror developed in the early 1960s. This scanner features wide FOV, constant optical aperture versus scan angle, and compact mechanical configuration.

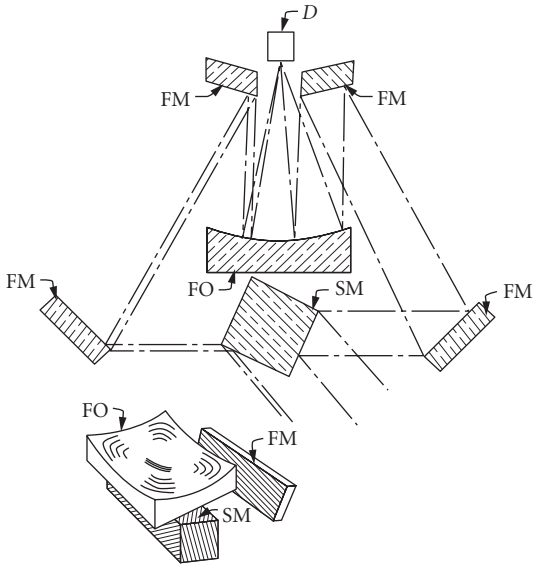

FIGURE 8 Basic split-aperture scanner with a four-sided scan mirror developed in the early 1960s. This scanner features wide FOV, constant optical aperture versus scan angle, and compact mechanical configuration.

configurations of this scanner. The three-sided scan mirror (SM) shown in Fig. 7 rotates about its longitudinal axis at a high rate and the concomitant folding mirrors (FMs) are arranged such that the scanned flux is directed onto suitable focusing optics (FO) which focuses the flux at the detector *D*. As may be seen in the drawing of a four-sided scanner shown in Fig. 8, the effective optical aperture is split into two portions such that their sum is a constant value as a function of view angle. The width of each portion varies as the view angle is changed, with the portions being of equal value at the nadir position. The isometric view in Fig. 8 shows a portion of the scanner comprising the scan mirror, one folding mirror, and the focusing mirror. For this design, the number of scans per rotation of the scan mirror is equal to the number of faces on the scan mirror, and the scanning constant is $k = 2$, which is also known as optical doubling (see item 3 of the prismatic polygon in Table 3). Also, two faces of the scan mirror are always used to form the total optical aperture. Another advantage of this scanner configuration is that it produces a compact design for the total scanner system, a major reason for its popularity for over a quarter of a century.

Image Consequences

In airborne sensing, it is reasonable to assume that the earth is flat beneath the aircraft. When viewing along the nadir, the detector spatial footprint on the ground is $H\,\Delta\theta$ and $H\,\Delta\phi$ in the across- and along-track directions, respectively. As the view angle (θ) moves away from the nadir, the geometric resolution on the ground changes as illustrated in Fig. 2, which creates the bow-tie pattern. In the cross-track direction, it is easily shown that the footprint dimension is $H\,\Delta\theta \cdot \sec^2\theta$, while in the along-track direction, the footprint dimension is $H\,\Delta\phi \cdot \sec\theta$. The change in footprint as a function of view angle can be significant. For example, if $\theta_{max} = 120°$, then the footprint area at the extremes of the scan line is about eight times greater than at the nadir.

Image Relation and Overlap

When a linear array of *n* detectors is used, it is easily seen that the image of the detector array rotates by exactly the same amount as the view angle if the scanner is pyramidal as shown in Fig. 6. No such rotation occurs for the prismatic polygon, as in the Kennedy scanner, for which each scan comprises *n* adjacent detector footprints on the ground that form a segmented bow tie. The next scan footprint has significant overlap with the preceding scan(s) for $\theta \neq 0$. A means to compensate for the radiometric difficulties caused by the overlap of scans has been developed.[17] In a single detector system, this artifact is easily compensated by electronic means.

Rotating Wedge Scanner

Figure 9 shows a simple rotating wedge scanner that allows the generation of a wide variety of scan patterns, including a line scan. By controlling the rotational rates and phasing of the wedges, such patterns as included in Fig. 10 can be realized.[18]

Circular Scan

In some cases, a circular scan pattern has found utility. Typically, the entire optical system is rotated about the nadir with the optical axis inclined at an angle ψ to the nadir. Figure 11 depicts an object-plane scanner showing how the aircraft or satellite motion creates contiguous scans. Although the duty cycle is limited, an advantage of such a scanner is that, at a given altitude, the footprint has the same spatial size over the scanned arc.

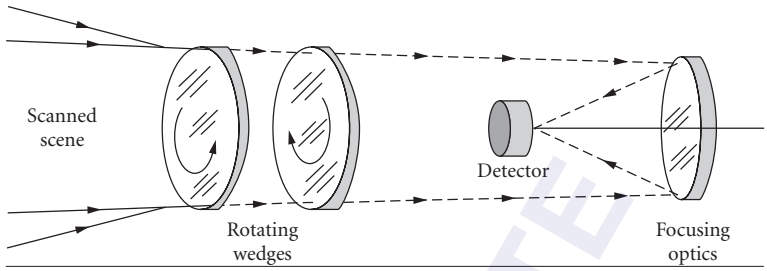

FIGURE 9 Basic geometry of a simple rotating wedge scanner. A wide variety of scan patterns can be produced by controlling the rotational rates and phasing of the wedges. In principal, the detector can view any point within the circular scanned FOV of the scanner. Figure 10 presents typical scan patterns for constant rotational rates. Two-dimensional raster scans can be generated if general positional control of each prism is allowed.

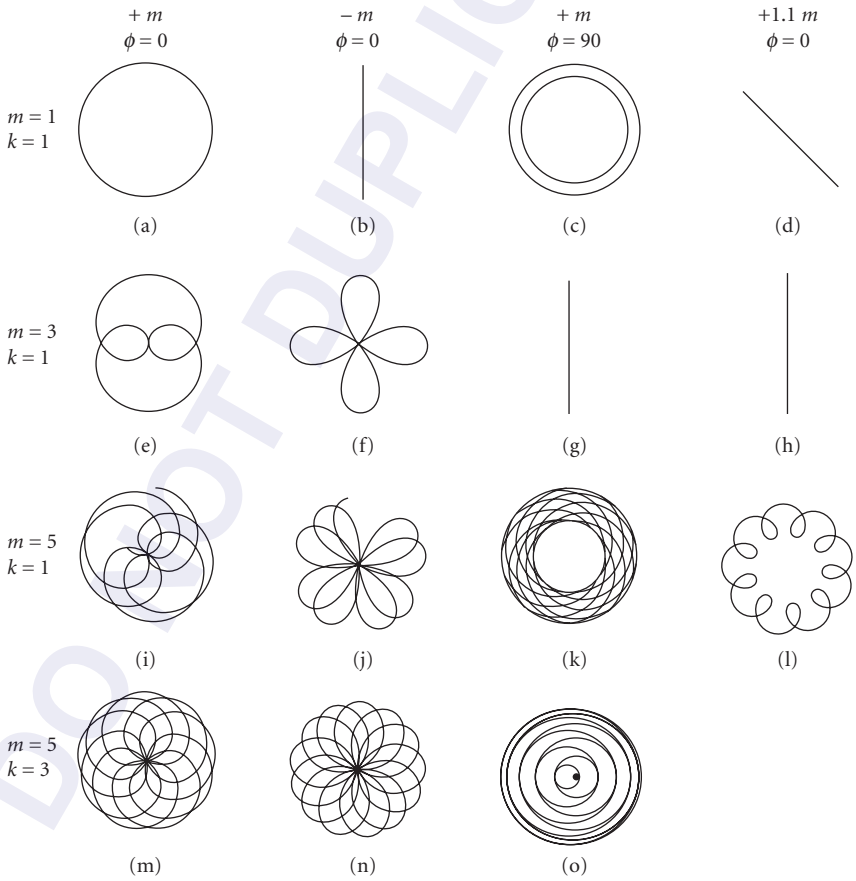

FIGURE 10 Typical scan patterns for a rotating wedge scanner. The ratio of the rotational frequencies of the two prisms is m, the ratio of the prism angles is k, and the phase relation at time zero is φ ($\varphi = 0$ implies the prism apexes are oriented in the same direction). A negative value of m indicates that the prisms are counter-rotating. (*After Ref. 18, Fig. 12, p. 12.*)

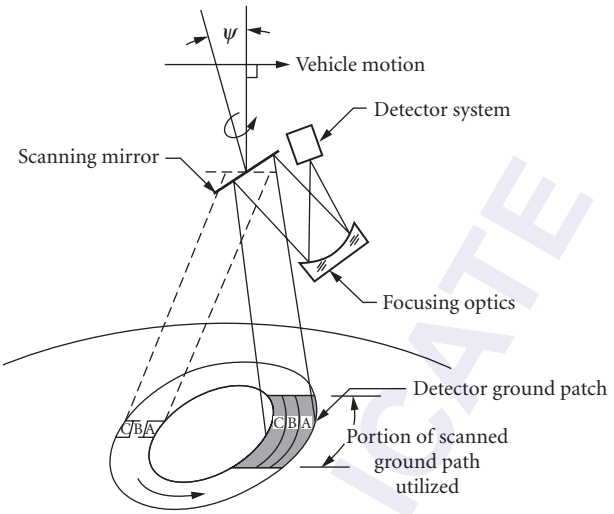

FIGURE 11 Basic configuration of a circular or conical scanner. The normal of the scanning mirror makes an angle ψ with the nadir. The scan pattern of the ground forms a series of arcs illustrated by scans A, B, and C. (*After Ref. 19, Fig. 8-3, p. 340.*)

Pushbroom Scan

A pushbroom scanner comprises typically an optical system that images onto the ground a linear array of detectors aligned in the cross-track direction or orthogonal to the flight direction. The entire array of detectors is read out every along-track dwell time which is $\tau_{at} = \Delta\phi/(V/H)$. Often, when a serial read-out array is employed, the array is rotated slightly such that the read-out time delay between detectors creates an image that is properly aligned to the direction of motion. Some state-of-the-art arrays can transfer the image data in parallel to a storage register for further processing. The principal advantage of the pushbroom scanner is that no moving parts are required other than the moving platform upon which it is located.

Two-Dimensional Scanners

Two-dimensional scanners have become the workhorses of the infrared community during the past two decades even though line scanners still find many applications, particularly in the area of earth resources. Scanners of this category can be classified into three basic groups, namely, object-space scanner, convergent-beam or image-space scanner, and parallel-beam or intermediate space scanner. Figure 12 depicts the generic form of each group.

Object-Space and Image-Space Scanners

The earliest two-dimensional scanners utilized an object-space scan mechanism. The simplest optical configuration is a single flat-mirror (see Fig. 12*a*) that is articulated in such a manner as to form a raster scan. The difficulty with this scan mechanism is that movement of a large mirror with the necessary accuracy is challenging. The size of the mirror aperture when in object space must be greater than that of the focusing optics. By using two mirrors rotating about orthogonal axes, the scan can be generated by using smaller mirrors, although

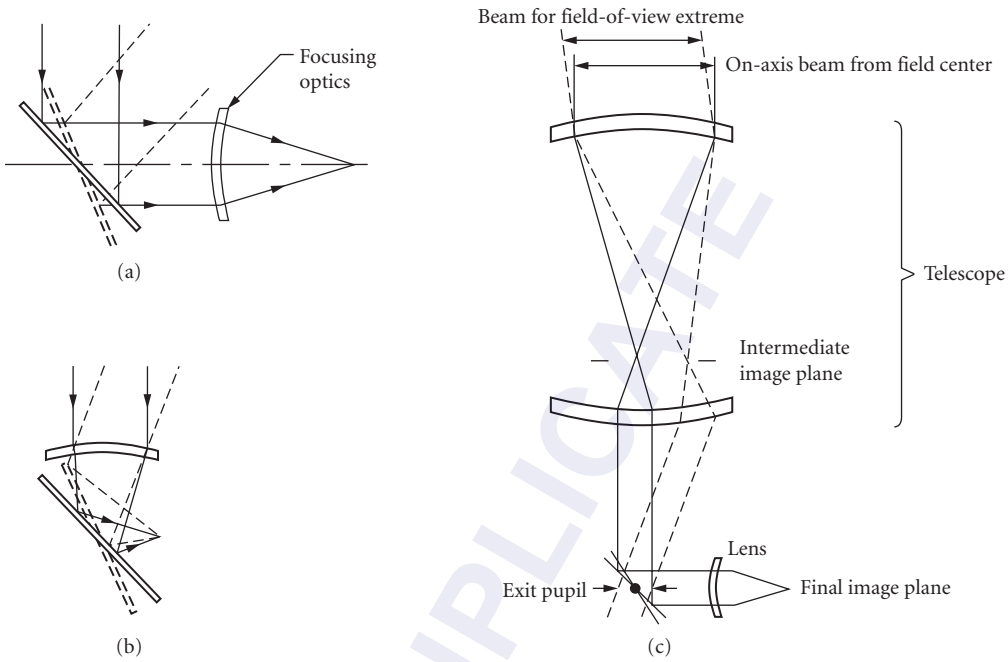

FIGURE 12 The three basic forms of two-dimensional scanners are shown in (*a*), (*b*), and (*c*). The object-space scanner in (*a*) comprises a scan mirror located in object space where the mirror may be moved in orthogonal angular directions. Image-space or convergent-beam scanner in (*b*) forms a spherical image surface due to motion of the scan mirror (unless special compensation motion of the scan mirror is provided). The parallel-beam or intermediate-space scanner is illustrated in (*c*). It is similar to the scanner in (*a*) except that the scan mirror is preceded by an afocal telescope. By proper selection of the afocal ratio and FOV, the scan mirror and focusing lens become of reasonable size. The scan mirror forms the effective exit pupil. (*After Ref. 20, Figs. 7.1 and 7.10.*)

the objective optics must have the capability to cover the entire field of view rather than the FOV of the detector. Figure 13 illustrates such a scanner[21] where mirror SM1 moves the beam in the vertical direction at a slow rate while mirror SM2 generates the high-speed horizontal scan. Although the focusing optics is shown preceding the image-space scan mirrors, the optics could be placed following the mirrors which would then be in object space. Although the high-F-number or low-numerical-aperture focusing lens before the mirrors must accommodate the FOV, it allows the use of smaller mirror facets. The left-hand side of Fig. 13 shows an integral recording mechanism that is automatically synchronized to the infrared receptor side. This feature is one of the more notable aspects of the configuration and sets the stage for other scanner designs incorporating the integrated scene and display scanner. A disadvantage of this scanner is the large size and weight of the vertical scan mirror, in part, to accommodate both scene and display scan.

A variation of the two-mirror object-space scanner is known as the discoid scanner, which produces a raster scan at TV rates.[22] Figure 14 depicts the scanner configuration which uses a high-speed, multiple-facet scan mirror SM1 to generate the horizontal scan and a small, oscillating flat mirror SM2 to produce the vertical scan. An advantage of this scanner is that only a single detector is needed to cover the FOV, although a linear array oriented in the scan direction is sometimes used, with time-delay integration, to improve sensitivity. A feature of the "paddle" mirror scanner is the maintenance of a relatively stable aperture on the second deflector without the use of relay optics (see Figs. 21 and 32 and the section on the "Parallel-Beam Scanner").

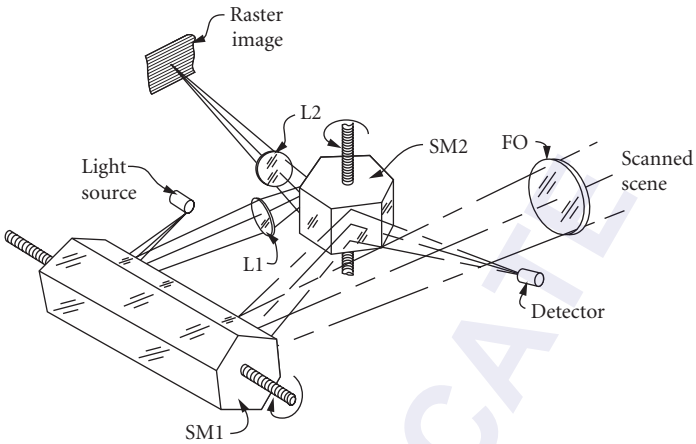

FIGURE 13 Early slow-scan-rate, image-space scanner where the flux from the scanned scene is imaged by the focusing objective lens FO onto the detector. The scene is scanned by mirrors SM1 (vertical) and SM2 (horizontal). A raster image of the scene is formed by imaging the light source using lenses L1 and L2. The display image and the scanned scene are synchronized by using the same pair of mirrors. The light source is modulated by the output of the detector.

Figure 15 depicts a reflective polygon scanner that generates the high-speed horizontal scan (per facet) by rotation of mirror SM about its rotational axis and the vertical movement of the scan pattern by tilting the spinning mirror about pivots P1 and P2 using cam C and its follower CF.[23] The path of the flux from the object reflects from the active facet A of the scan mirror to the folding mirror FM to the focusing mirror FO back through a hole in mirror FM to the detector located in dewar D. Almost

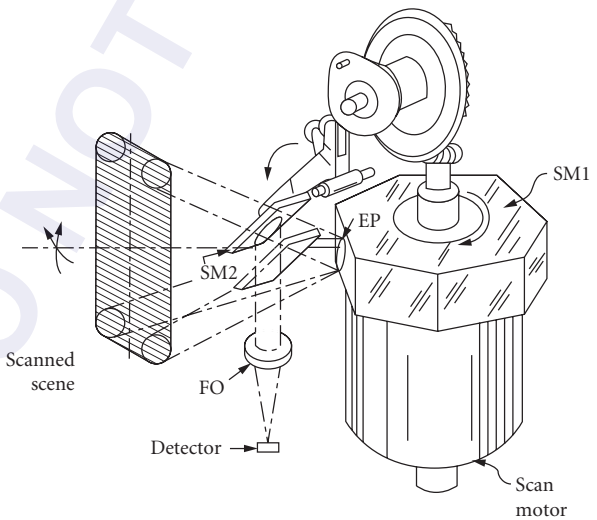

FIGURE 14 Real-time, object-space scanner that has a compact geometry. The exit pupil EP is located on the active facet of the horizontal scan mirror SM1.

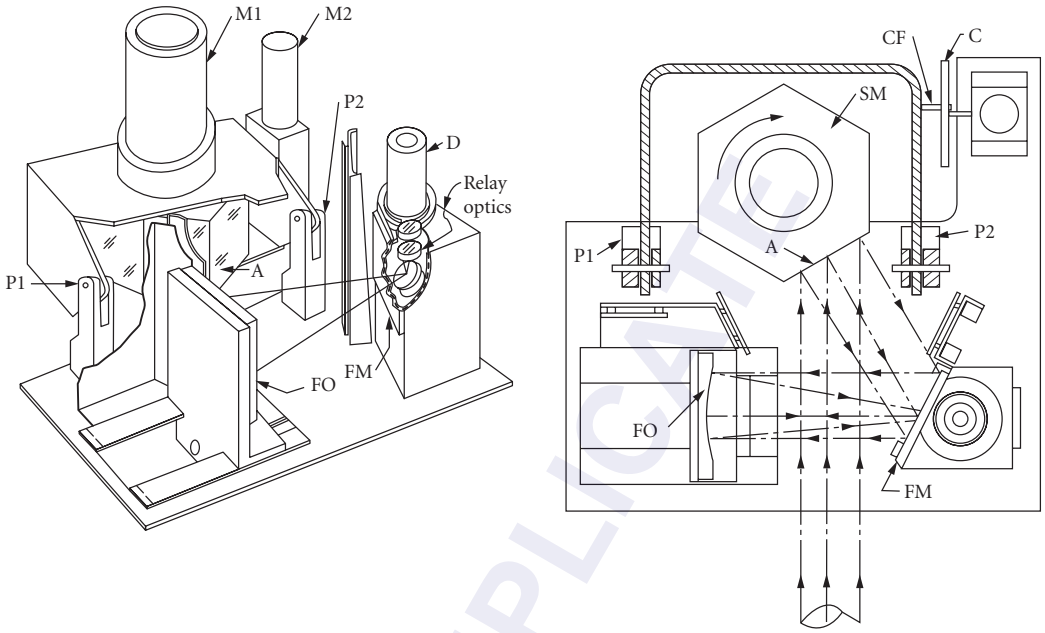

FIGURE 15 Object-space scanner that generates a raster scan using a single mirror SM which is driven by motor M1. The vertical motion of the mirror is accomplished by tilting the housing containing the scan mirror SM about pivots P1 and P2 using the drive mechanism comprising motor M2, cam C, and CF. The FOV of scanners of this type can exceed 30°.

all scanners of this type exhibit scanned-field distortion; that is the mapping of object to image space is nonrectilinear (e.g., see the target distortion discussion in the section "Image Consequences" on p. 30.16).

In general, convergent-beam, image-space scanners suffer from severe defocus over the scanned field of view due to the field curvature produced by the rotation of the scan mirror in a convergent beam. The use of this type scanner is therefore rather limited unless some form of focus correction or curved detector array is employed. A clever invention by Lindberg[24,25] uses a high-speed refractive prism and a low-speed refractive prism to create the scanned frame. Figure 16 shows the basic

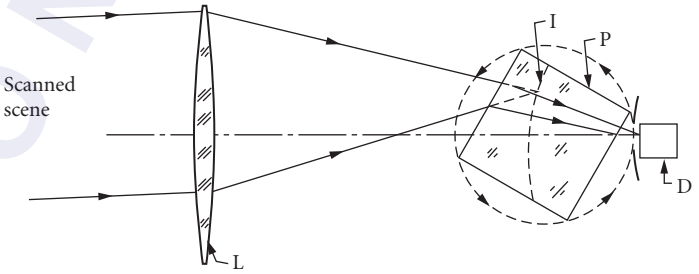

FIGURE 16 Basic configuration of a refractive prism scanner. The scan is generated by rotation of the prism. As shown, four scans are produced per complete rotation of the prism. By proper selection of the refractive index of the prism, reasonably wide FOV can be realized. Although only one prism is shown, a second prism can be included to produce the orthogonal scan direction.

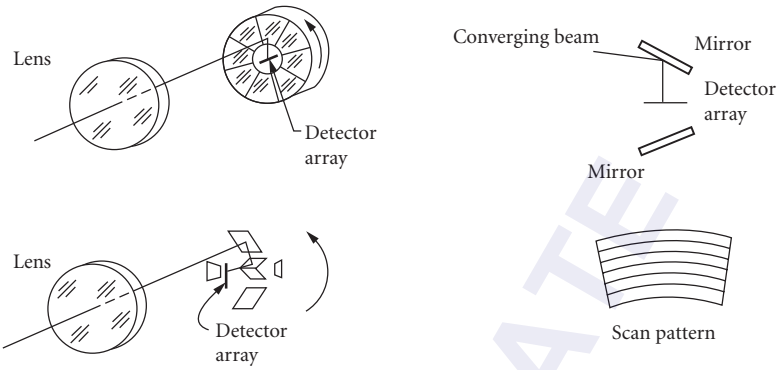

FIGURE 17 Rotating reflective or "soupbowl" scanner. (*After Ref. 20, Fig. 7.21, p. 309.*)

configuration for a one-dimensional scanner where the cube P is rotated about the axis orthogonal to the page. By proper selection of the refractive index and the geometry of the prism, focus is maintained over a significant and useful field of view. As can be seen from the figure, flux from the object at a given view angle is focused by lens L onto surface I which is then directed to the detector D by the refraction caused by the rotated prism. Numerous commercial and military thermographic systems have utilized this principle for passive scanning. Since the field of view, maximum numerical aperture, optical throughput, and scan and frame rates are tightly coupled together, such scanners have a reasonably constrained design region.

Other image-space scanners used in a convergent beam are the "soupbowl" and carousel scanners.[20] The soupbowl scanner shown in Fig. 17 uses a rotating array of mirrors to produce a circularly segmented raster scan. The mirror facets may be at the same angle to generate more frames per rotation, given a detector array that has adequate extent to cover the field of view. The facets could also be tilted appropriately with respect to one another to produce contiguous segments of the field of view if a small detector array is employed. Figure 18 illustrates the configuration of the carousel scanner which uses an array of mirrors arranged such that they create essentially a rectangular scan of the field of view. Another scanning means that has been used for certain forward-looking infrared systems (FLIRs) was to mechanically rotate a detector array of angular extent Φ about the

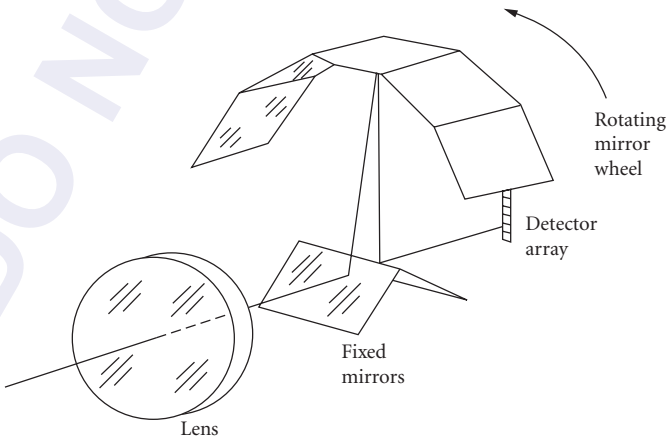

FIGURE 18 Rotating reflective carousel scanner. (*After Ref. 20, Fig. 7.22, p. 309.*)

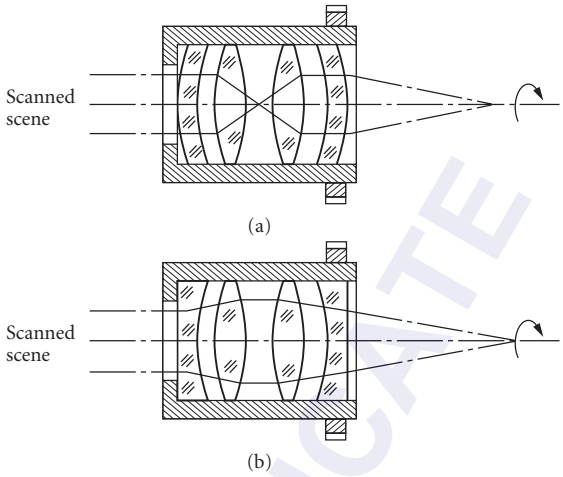

FIGURE 19 "Windshield wiper" scanner. The circular scan is generated by rotating the anamorphic optics about its optical axis. The detector array is located radially and offset from the optical axis. Two scans are produced for each complete rotation of the optics. The lens is shown in (*a*) at rotation angle θ and in (*b*) at rotation angle $\theta + 90°$. Although the lens shown is focal, the lens could be afocal and followed by a focusing lens.

optical axis of the focusing optics such that one end of the array was located an angular distance Φ_{os} from the optical axis. The rotating action generated a circular arc scan pattern similar to that of a windshield wiper. The inner radius of the scan pattern is Φ_{os} and the outer radius is $\Phi_{os} + \Phi$. Clearly, the scan efficiency is rather poor and the necessity to use slip rings or the equivalent to maintain electrical connections to the detector array complicated acceptance of this scanner. The windshield wiper scan can also be generated by rotating only the optics if the optics incorporates anamorphic elements. A pair of cylindrical lenses placed in an afocal arrangement, as illustrated in Fig. 19 at rotational angles θ and $\theta + 90°$, will rotate the beam passing through it at twice the rotational rate of the optics.[26] See "Image Rotation in Derotation" in Sec. 30.6.

Multiplexed Image Scanning

With the advent of detector arrays comprising significant numbers of elements, the use of a single scan mirror became attractive. Figure 20 presents the basic parallel-beam scanner configuration used for the common module FLIR and thermal night sights. The flat scan mirror SM is oscillated with either a sawtooth or a triangular waveform such that the detector array *D* (comprising 60, 120, or 180 elements) is scanned over the FOV in the azimuthal direction while the extent of the detector covers the elevation FOV. Since the detectors are spaced on centers two detector widths apart, the scan mirror is tilted slightly in elevation every other scan to produce a 2:1 interlaced scan of the FOV. As shown in Fig. 20, the back side of the scan mirror is used to produce a display of the scanned scene by coupling the outputs of the detectors to a corresponding array of LEDs which are projected to the user's eye by lenses L1, L2, L3, and L4.

Parallel-Beam Scanner

A more complex two-dimensional, parallel-beam scanner configuration of the type shown in Fig. 12*c* has been developed by Barr & Stroud and is illustrated in Fig. 21, which incorporates an oscillating mirror SM1, a high-speed polygon mirror SM2 driven by motor M2, and relay optics L1. (See discussion

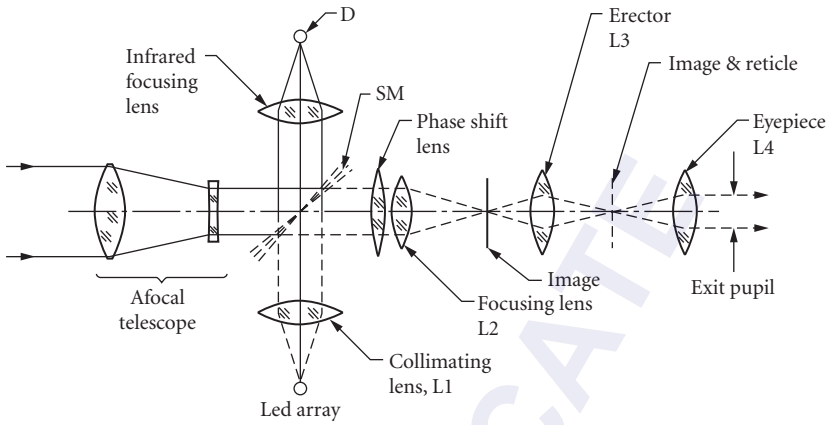

FIGURE 20 Basic configuration of the common module scanner. The front side of the flat scan mirror SM is used to direct the flux from the scanned scene to the detector *D* through the focusing lens. The outputs from the infrared detector array are used to modulate a corresponding LED array. The LED array is collimated by L1 and scanned over image space by the back side of SM. Lenses L2–L4 are used to project the image of the LED array to the observer's eye.

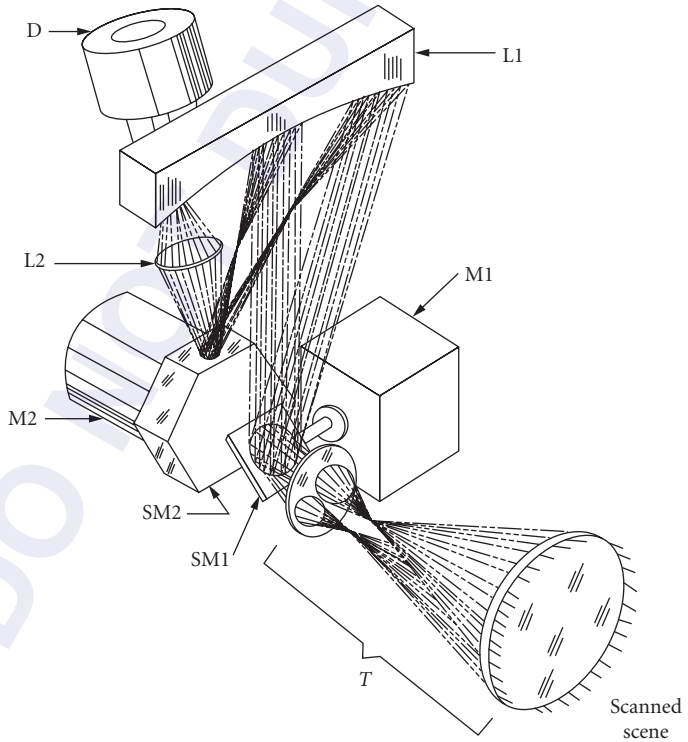

FIGURE 21 Compact real-time scanner. The horizontal scan mirror SM2 is shown in two positions to illustrate how the field of view is related to location on mirror L1. Mirror L1 serves as a relay mirror of the pupil on mirror SM1 to SM2.

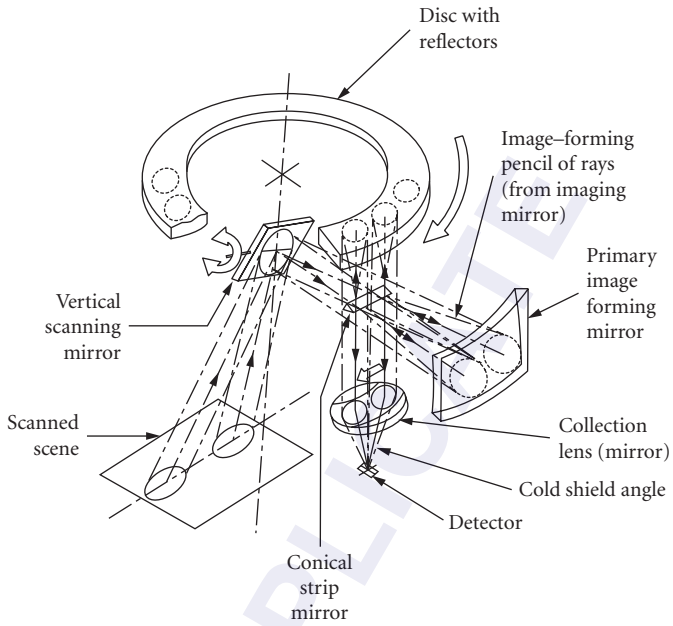

FIGURE 22 Extremely compact, real-time scanner. Diamond-turned optics are used throughout this configuration. (*After Ref. 28, Fig. 1.*)

at end of Sec. 30.5.)[27] An afocal telescope is located before the scanner to change the FOV, as is typical of parallel-beam scanners. Another innovative and compact two-dimensional scanner design by Kollmorgen is depicted in Fig. 22 and features diamond-turned fabrication technology for ease of manufacture and alignment of the mirrors and mounts.[28] Another parallel-beam scanner that uses a simple scan mirror has been developed.[29] The scan mirror is multifaceted with each facet tilted at an angle that positions the detector array in a contiguous manner in elevation. By having the nominal tilt angle of the facets be 45° to the rotation axis, minimal scanned-field distortion is realized.

30.5 SCANNING FOR INPUT/OUTPUT IMAGING

Power Density and Power Transfer

Incoherent Source This topic merits introduction as the predecessor to laser scanning—cathode-ray tube (CRT), flying-spot scanning and recording.[1,2,3] Adaptation to other forms of incoherent sources, such as light-emitting diodes (LEDs) will be apparent. Similarities and contrasts with the handling of coherent sources are expressed.

In a CRT, the electron beam power P (accelerating voltage beam current) excites a phosphor of conversion efficiency η and utilization factor γ. The resulting radiant power is transferred through an imaging system of optical transmission efficiency T and spectral power transfer α to a photosensitive medium of area a during a time t. The resulting actinic energy density is given by[3]

$$E = \frac{\eta \alpha T \gamma P t}{A} \text{ J/cm}^2 \tag{24}$$

[1 J (joule) = 1 W-s (watt-sec) = 10^7 ergs].

The first four terms are transfer factors (≤1) relating to the CRT, but adaptable to other radiant sources. They are determined[3] for a principal group of CRT recording phosphors having varying processes of deposition and aluminizing, and for two typical (silver halide) photosensitive spectral responses: noncolor sensitized and orthochromatic. The spectral transfer term α is determined from the relatively broad and nonanalytic spectral characteristics of the CRT phosphors and the photosensors,

$$\alpha \cong \frac{\sum_{i=1}^{n} \frac{P_i}{P_{\max}} \cdot \frac{S_i}{S_{\max}} \Delta\lambda_i}{\sum_{j=1}^{m} \frac{P_j}{P_{\max}} \Delta\lambda_j} (j \geq i) \tag{25}$$

where the Ps and the Ss are the radiant power and medium sensitivity, respectively, taken at significant equal wavelength increments $\Delta\lambda$.

The optical transfer term T is composed of three principal factors, $T = T_r T_f T_v$, where T_r is the fixed transmission which survives losses due to, for example, reflection and scatter, T_f is the fixed geometric transfer, and T_v is the spectrally variable transmission of, for example, different glass types. The fixed geometric transfer is given by[3]

$$T_f = \frac{\cos^4 \Phi V_\Phi}{1 + 4F^2(M+1)^2} \tag{26}$$

The numerator (≤1) is a transfer factor due to field angle Φ and vignetting[30] losses, F is the lens F-number, and M is the magnification, image/object. The variable component T_v requires evaluation in a manner similar to that conducted for the α. The resulting available energy density E is determined from Eq. (24) and compared to that required for satisfactory exposure of the selected storage material.

Coherent Source Determination of power transfer is much simplified by utilization of a monochromatic (single-line laser) source. Even if it radiates several useful lines (as a multispectral source), power transfer is established with a finite number of relatively simple determinations. Laser lines are sufficiently narrow, compared to the spectral characteristics of most transmission and detection media, so that single point evaluations at the wavelengths of interest are usually adequate. The complexity due to spectral and spatial distributions per Eqs. (25) and (26) are effectively eliminated.

In contrast to the incoherent imaging system described above, which suffers a significant geometric power loss represented by T_f of Eq. (26), essentially all the radiant power from the laser (under controlled conditions discussed subsequently) can be transferred to the focal spot. Further, in contrast to the typical increase in radiating spot size with increased electron beam power of a CRT, the radiating source size of the laser remains essentially constant with power variation. The focused spot size is determined (per the section "Resolution Criteria, Aperture Shape Factor") by the converging beam angle or corresponding numerical aperture or F-number, allowing for extremely high power densities. Thus, a more useful form of Eq. (24) expresses directly the laser power required to irradiate a photosensitive material as

$$P = \frac{sR}{T}\left(\frac{A}{t}\right) \text{watts} \tag{27}$$

where s = material sensitivity, J/cm^2
R = reciprocity failure factor, ≥1
T = optical throughput efficiency, ≤1
A = exposed area, cm^2
t = time over area, A

The reciprocity failure factor R appears in Eq. (27), since the exposure interval t (by laser) can be sufficiently short to elicit a loss in sensitivity of the photosensitive medium (usually registered by silver halide media). If the A/t value is taken as, for example, an entire frame of assumed uniform

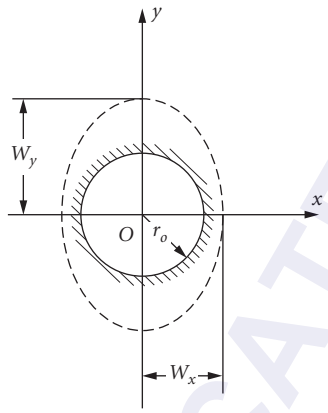

FIGURE 23 Irradiance of a single-mode laser beam, generalized to elliptical, centered within a circular aperture of radius r_o.[31] Glossary as published; D (as used here) = $2w_x$ and w (as used here) = $2r_o$.

exposure interval (including blanking), then the two-dimensional values of η must appear in the denominator, for they could represent a significant combined loss of exposure time.

The optical throughput efficiency T is a result of loss factors including those due to absorption, reflection, scatter, diffraction, polarization, diffraction inefficiency in acousto-optic and holographic elements, and beam truncation or vignetting. Each requires disciplined attention. While the radiation from (fundamental mode) laser sources is essentially conserved in traversing sufficiently large apertures, practical implementation can be burdensome in scanners. To evaluate the aperture size consistent with throughput power transfer, Figs. 23 and 24 are useful. The data is generalized to

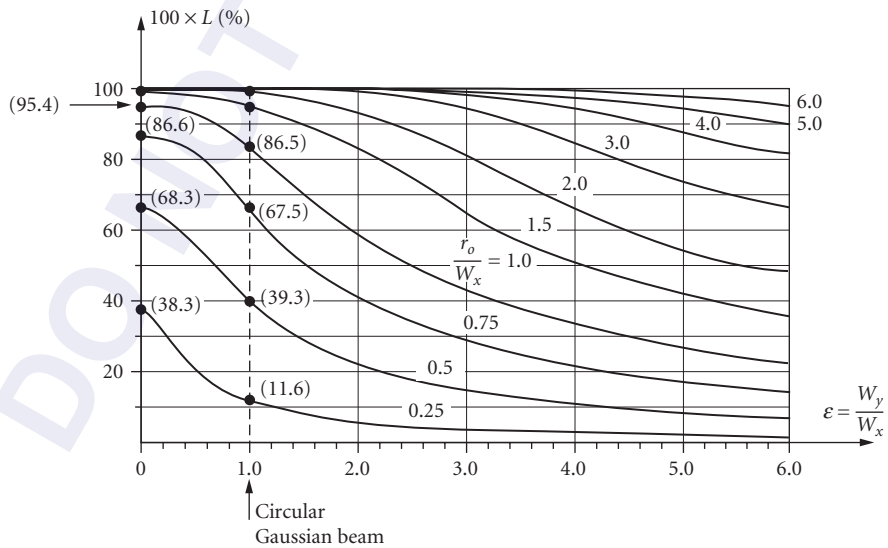

FIGURE 24 Variations of the encircled energy $100 \times L(\%)$ versus the ellipticity ε and the ratio r_o/w_x as a parameter.[31] Glossary as published; D (as used here) = $2w_o$ and w (as used here) = $2r_o$.

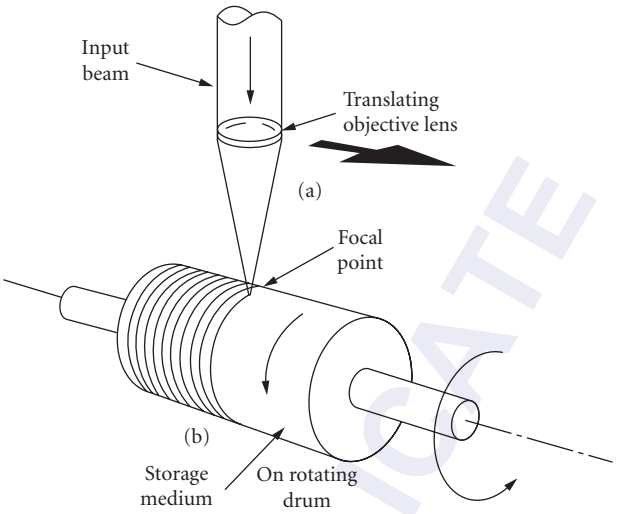

FIGURE 25 Drum configuration executing two forms of objective scan: (*a*) lens and its focal point translate with respect to storage medium and (*b*) storage medium translates with respect to lens during drum rotation.[4]

elliptic, accommodating the irradiance of typical laser diodes.[31,32] Figure 23 shows an irradiance distribution having ellipticity $\varepsilon = w_x/w_y$ (w @ $1/e^2$ intensity) apertured by a circle of radius r_o. Figure 24 plots the encircled power (percent) versus the ellipticity, with the ratio r_o/w_x as a parameter. When $\varepsilon = 1$, it represents the circular Gaussian beam. Another parameter closely related to this efficiency is the aperture shape factor (discussed previously) affecting scanned resolution. (Note: $D = 2w_x$ and $w = 2r_o$.)

Objective, Preobjective, and Postobjective Scanning

Classification Characteristics The scanner classifications designated as preobjective, objective, and postobjective were introduced previously and represented in Fig. 1 as a general conjugate optical transfer. This section expresses their characteristics.

Objective scan (transverse translational) Translation of an objective lens transverse to its axis translates the imaged focal point on the information surface. (Axial lens translation which optimizes focus is not normally considered scanning.) Translation of the information medium (or object) with respect to the objective lens forms the same effect, both termed objective scan.* The two forms of objective scan appear in Fig. 25, the configuration of a drum scanner.

Preobjective scan (angular) Preobjective scan can provide a flat image field.† This is exemplified by angularly scanning a laser beam into a flat-field or f-θ lens,[33] as illustrated in Fig. 26, an important technique discussed further under "Pyramidal and Prismatic Facets" and "Flat-Field Objective Optics."

*Objective scan is limited in speed because the translating lens elements or storage medium must execute the desired final scan velocity, limited by the articulation of relatively massive components.

†Applies beyond the small scan angle $\theta \simeq \arctan \theta$, which may be considered linear. Also, no separate dynamic focus to aid forming a flat field.

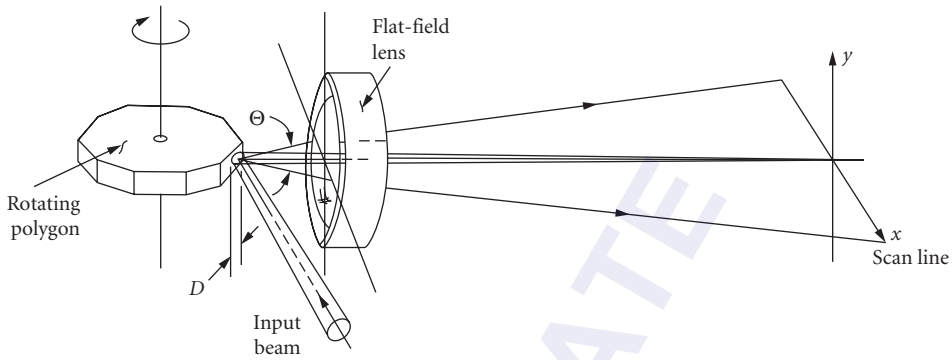

FIGURE 26 Polygon preobjective scan. The rotating polygon reflects and scans the input beam through the angle Θ. The flat-field lens transforms this Θ change to (nominally) linear x displacement along a straight scan line. The input beam and the scanned beam reside nominally in the same plane.[4]

Postobjective scan (angular) Postobjective scan which is radially symmetric per Fig. 27 generates a perfectly circular scan locus.* Departure from radial symmetry (e.g., focal point not on the axis of Fig. 27) generates noncircular (e.g., limaçon[5]) scan, except for when a postobjective mirror with its surface on its axis generates a perfectly circular scan locus, illustrated in Fig. 28. The input beam is focused beyond the axis at point o. Scan magnification $m = 2$.

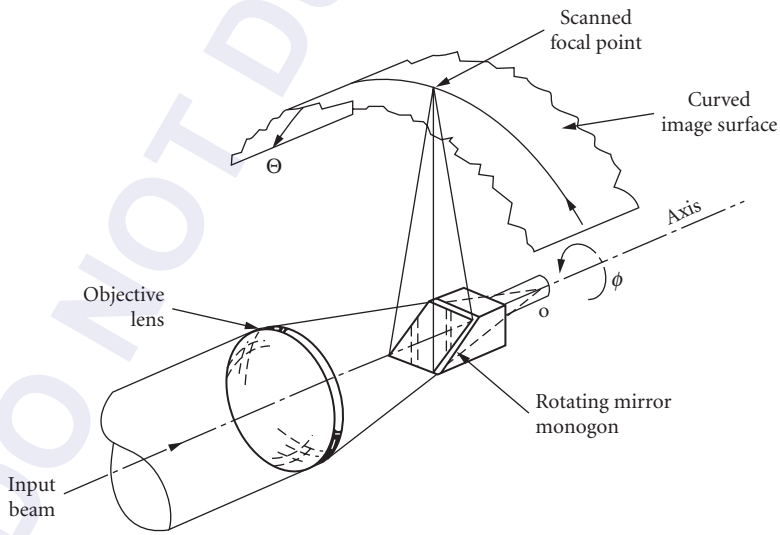

FIGURE 27 Monogon postobjective scan. Generates a curved image. When input beam is focused on the axis (at point o), then system becomes radially symmetric, and image locus forms section of a perfect circle.[4]

*Placing the objective lens in the output beam and coupling it rigidly to the scanner (e.g., of Fig. 27) maintains the same characteristic. This is identified as objective scan (angular). The scanner and lens may be combined, as in a hologram.

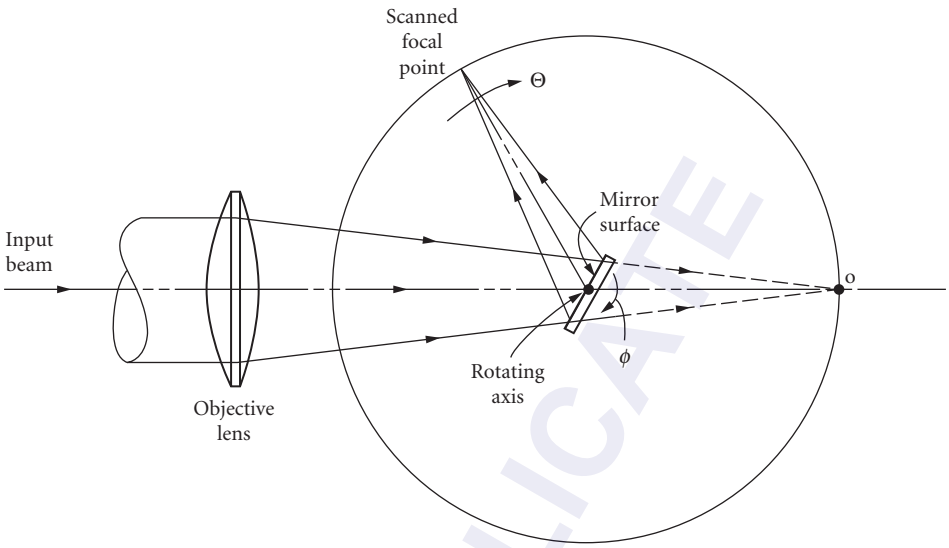

FIGURE 28 Postobjective scan with mirror surface on rotating axis. Input beam is focused by objective lens to point o, intercepted by mirror and reflected to scanning circular locus. Scan magnification $m = d\,\Theta/d\,\phi = 2^4$.

Objective Optics

The objective lens converges a scanned laser beam to a moving focal point. The deflector can appear before, at, or after the lens, forming preobjective, objective, and postobjective scanning, respectively (see previous discussion).

On-Axis Objective Optics The simplest objective lens arrangement is one which appears before the deflector, as in Fig. 27, where it is required only to focus a monochromatic beam on-axis. The (postobjective) deflector intercepts the converging beam to scan its focal point. Ideally, the process is conducted almost aberrationlessly, approaching diffraction-limited performance. Since the lens operates on-axis only (accommodates no field angle), if the F-number of the converging cone is sufficiently high (see "Resolution Criteria, Aperture Shape Factor"), it can be composed of a single lens element. This simple arrangement can scan a perfectly circular arc [see "Postobjective Scan (Angular)]", the basis for the elegance of the internal drum scanner and the requirement for adapting the information medium to a curved surface.

Flat-Field Objective Optics Almost all other lens configurations are required to form a flat field by transforming the angular scan to a straight line.[33] The deflector appears before the lens—preobjective. The most common configuration is similar to that of Fig. 26, as detailed further in "Design Considerations" under "Monogon and Polygon Scanners," in which the scanned beam is shown collimated. Application is not limited to polygon scanners. Similar lenses adapt to a variety of techniques, including galvanometer, acousto-optic, electro-optic, and holographic scanners. The lens must accept the scanned angle θ from the aperture D and converge the beam throughout the scanned field to a best-focus along a straight-line locus. Depending on the magnitudes of θ and D, the F-number of the converging cone and the desired perfection of straight-line focus and linearity, the lens assembly can be composed of from 2 to 7 (or more) elements, with an equal number of choices of index of refraction, 4 to 14 (or more) surfaces, and 3 to 8 (or more) lens spacings, all representing the degrees of freedom for the lens designer to accommodate performance. A typical arrangement of three elements is illustrated in Fig. 34.

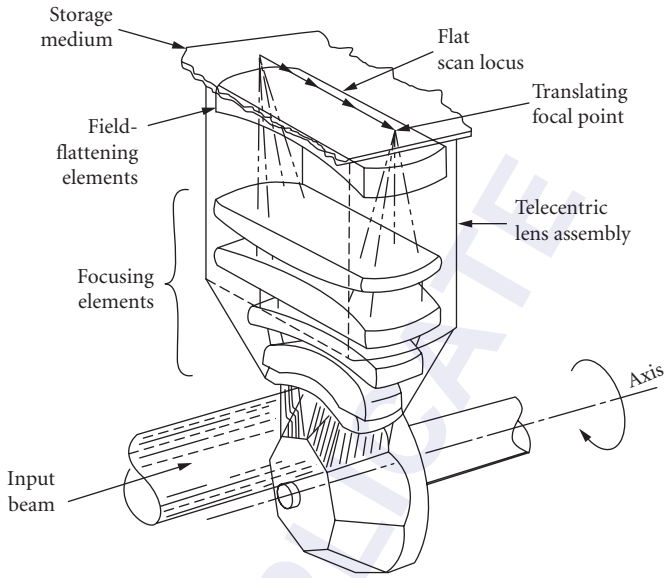

FIGURE 29 High-performance telecentric lens at output of pyramidal polygon scanner, see Fig. 34. (Lens elements shown cut for illustration only.)[4]

Telecentricity A more demanding arrangement is illustrated in Fig. 29, showing six elements forming a high-performance scan lens in a telecentric configuration.[30] Telecentricity is represented schematically in Fig. 30, in which an ideal thin-lens element depicts the actual arrangement of Fig. 29. Interposed one focal length f between the scanning aperture D (entrance pupil) and the flat image surface, the ideal lens transforms the angular change at the input to a translation of the output cone. The chief ray of the ideal output beam lands normal to the image surface. The degree of telecentricity is expressed by the angular departure from normal landing. Telecentricity is applied typically to restrict the spread of the landing beam and/or to retroreflect the probing beam efficiently

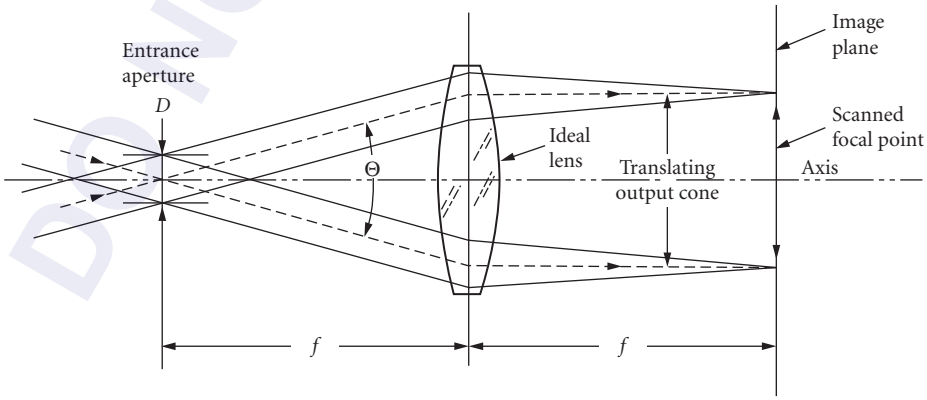

FIGURE 30 Telecentric optical system. Schematic illustration of ideal lens transforming angular scan Θ from aperture D to translational scan landing normal to the image plane.[4]

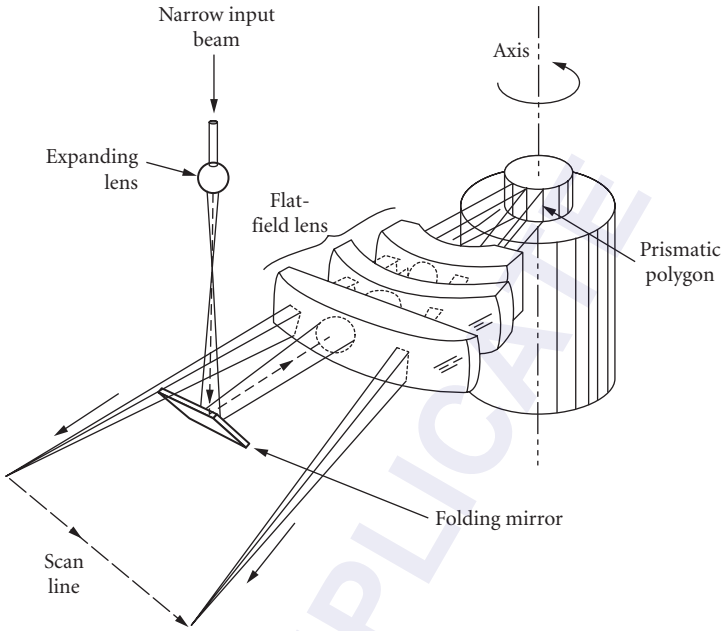

FIGURE 31 Prismatic polygon in double-pass configuration. Narrow input beam is focused by positive lens, expanded, and picked-off by folding mirror to be launched through flat-field lens (in reverse direction). Beam emerges collimated, illuminates facets and is reflected and scanned by rotating polygon to be reconverged to focus on scan line. Input and output beams are slightly skewed above and below lens axis to allow clear separation by folding mirror. (Flat-field lens elements shown cut for illustration.)[4]

for internal system calibration. This facility comes dearly, however, for the final lens elements must be at least as wide as the desired scan format. A further requirement is the need to correct the nonlinearity of the simple system of Fig. 30, in which the spot displacement is proportional to the tangent of the scan angle, rather than to the angle directly. As in all scan lenses, compensation to make displacement proportional to scan angle is termed the f-θ correction.

Double-pass and beam expansion Another variation of the objective lens is its adaptation to double-pass,[4,5,33] as depicted in Fig. 31. The lens assembly serves two functions: first, as the collimating portion of a lenticular beam expander*[33] and second, upon reflection by the scanner, as a conventional flat-field lens. This not only provides compaction, but since the illuminating beam is normal to the undeflected facet, the beam and facet undergo minimum enlargement, conserving the size of the deflector. A slight skew of the input and output planes, per Fig. 31, avoids obstruction of the input and scanned beams at the folding mirror. An alternate input method is to make the lens array wide enough to include injection of the input beam (via a small mirror) from the side; at an angle sufficiently off-axis to avoid obstruction of the reflected scanned beam.[33] This method imposes an off-axis angle and consequential facet enlargement and beam aberration, but allows all beams to remain in the same plane normal to the axis, avoiding the (typically) minor

*Beam expansion/compression can also be achieved nonlenticularly with prisms.[34] Introduction in 1964 of the phrase "beam expander" by Leo Beiser, and its dissemination to generic form, is summarized in App.1 of Ref. 6.

scanned bow which develops in the aforementioned center-skewed method. Other factors relating to increased surface scatter and reflection need be considered.

The requirement for beam expansion noted here is fundamental to the formation of the aperture width D which provides a desired scanned resolution. Since most gas lasers radiate a collimated beam which is narrower than that required, the beam is broadened by propagating it through an inverted telescope beam expander, that is, an afocal lens group having the shorter focal length followed by the longer focal length.* Operation may be reversed, forming *beam compression,* as required. In the previously described double-pass system (Fig. 31), the objective lens provides the collimating portion (long-focal-length group) of a beam expander.

Conservation of Resolution A most significant role of objective optics following the scanner is its determination of the integrity of scanned format, *not of scanned resolution,* as discussed under "Input/Output Scanning". Denoting N as the total number of scanned elements of resolution to be conveyed over a full format width, in first analysis, N is *invariant* with intervening ideal optics. In reasonably stigmatic systems, the lens determines the *size* of the spots, *not their total number.* The number of spots is determined *at the deflector,* whether it be galvanometer, acousto-optic, electro-optic, polygonal, holographic, phased array, or any other angular scanner. This invariance is expressed as

$$I = \theta D = \theta' D' \tag{28}$$

an adaptation of the Lagrange invariant [see "Fundamental Scanned Resolution," Eq.(16)], which is illustrated effectively with telescopic operation. If the scanned beam is directed through a telescope (beam compression), as in Fig. 32, the demagnification of f_2/f_1 reduces D to D', but also expands θ to θ' by the same paraxial factor, sustaining resolution invariance. If D were the deflecting aperture width and L_1 were its objective lens (telecentric in this case), then the image along surface S would exhibit the same number of N spots as would appear if the output beam from D' were focused by another objective lens to another image plane. This schematic represents, effectively, a pupil-transferring optical relay.[4,5] (See Chap. 17, "Lenses" and Chap. 18, "Afocal Systems" in this volume.)

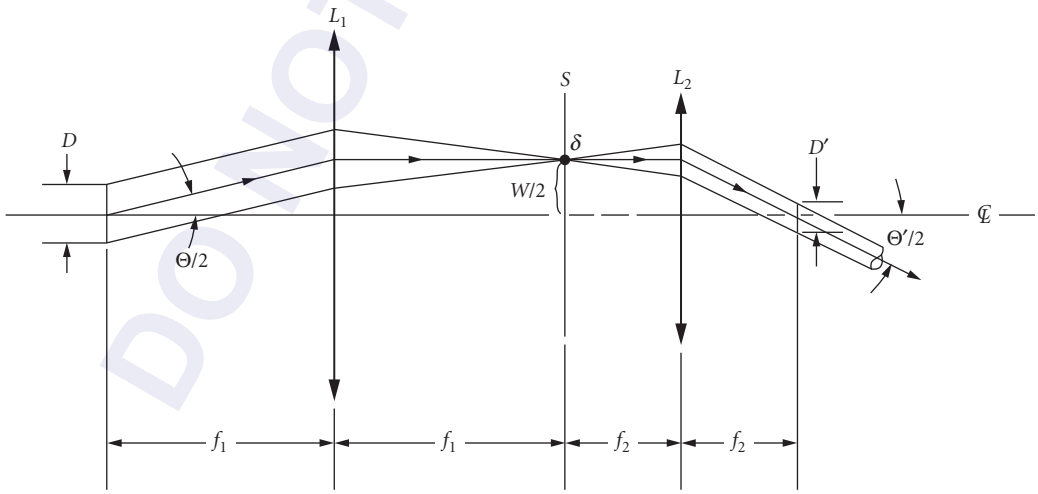

FIGURE 32 Illustration of invariance $I = \Theta D = \Theta' D'$ with telescopic transfer of scanned angle Θ from aperture D.[4]

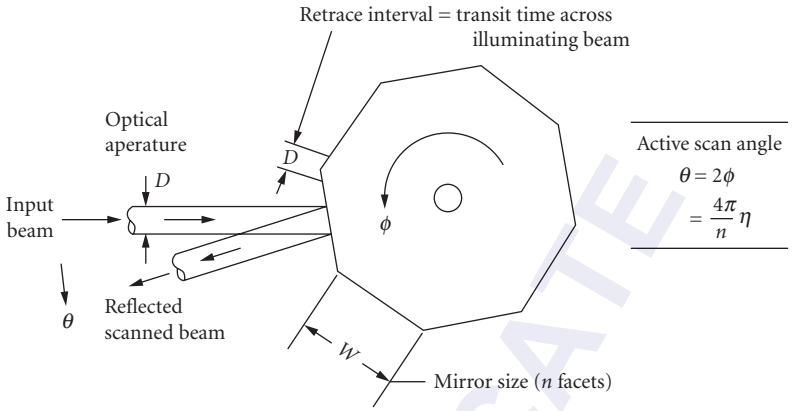

FIGURE 33 Prismatic polygon (underilluminated). Input beam perpendicular to axis. Its width D illuminates a portion of facet width W. Rotation through angle Φ yields scanned angle $\Theta = 2\Phi$, till facet corner encounters beam. Scan remains inactive for fraction D/W, yielding duty cycle $\eta = 1 - D_m/W$.[4]

30.6 SCANNER DEVICES AND TECHNIQUES

Many of the techniques addressed here for input/output imaging apply equally to remote sensing. Their reciprocal characteristic can be applied effectively by reversing the positions (and ray directions) of the light source(s) and detector(s). Preobjective and postobjective scanning have their counterparts in object-space and image-space scanning. A notable distinction, however, is in the option of underillumination or overillumination of the deflecting aperture in input/output imaging, while the aperture is most often fully subtended in collecting flux from a remote source. This leads to the required attention to aperture shape factor in input/output imaging, which is less of an issue in remote sensing. Another is the need to accommodate a relatively broad spectral range in remote sensing, while input/output operation can be monochromatic, or at least polychromatic. The frequent use of reflective optics in both disciplines tends to normalize this distinction.

Monogon and Polygon Scanners

The rotating mirrored polygon is noted for its capacity to render high data rate at high resolution. It is characterized by a multiplicity of facets which are usually plane and disposed in a regular array on a shaft which is rotatable about an axis. When the number of facets reduces to one, it is identified as a monogon scanner.

Pyramidal and Prismatic Facets Principal arrangements of facets are termed *prismatic* (Fig. 33) or *pyramidal* (see Fig. 34 and "Scanner-Lens Relationship"). Figure 27 is a single-facet pyramidal equivalent, while Fig. 28 is a single-facet prismatic equivalent (common galvanometer mount).

The prismatic polygon of Fig. 33 is oriented typically with respect to its objective optics in a manner shown in Fig. 26, while Fig. 34 shows the relationship of the pyramidal polygon to its flat-field lens. The pyramidal arrangement allows the lens to be oriented close to the polygon, while, as in Fig. 26, the prismatic configuration requires space for clear passage of the input beam.* Design consideration for this most popular arrangement is provided later in this chapter.

*In remote sensing, applying reciprocity, this is the *detected beam*.

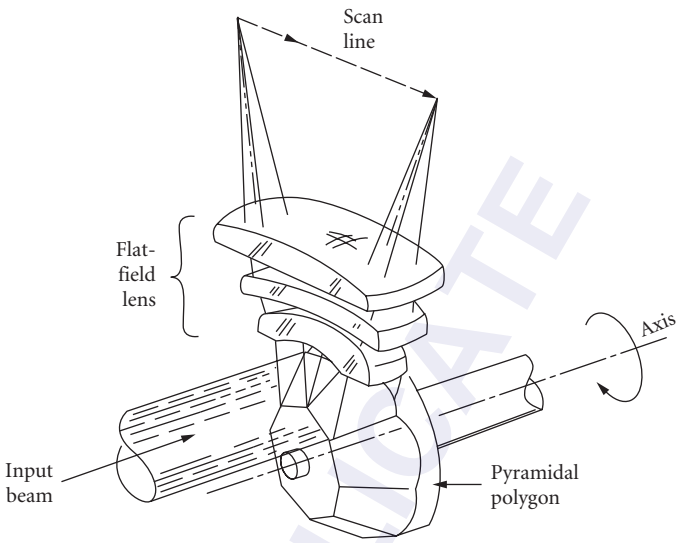

FIGURE 34 Pyramidal polygon (overilluminated). Input beam, parallel to axis, is scanned (by 45° pyramidal angle) in plane perpendicular to axis. When input beam illuminates two facets (as shown), one facet is active at all times, yielding (up to) 100 percent duty cycle. Facet width is full optical aperture *D,* minimizing polygon size for a given resolution, but wasting illumination around unused facet regions. Can operate underilluminated (per Fig. 33) to conserve throughput efficiency, but requires increased facet width (and polygon size) to attain high-duty cycle. (Flat-field lens elements shown cut for illustration.[4])

Table 3 lists significant features and distinctions of typical polygon scanners. Consequences of item 3, for example, are that the scan angle of the prismatic polygon is twice that of the pyramidal one for a given rotation. To obtain equal scan angles θ of equal beam width D (equal resolutions N) and to provide equal duty cycle (see "Augmenting and Scan Magnification") at equal scan rates, the prismatic polygon requires twice the number of facets, is almost twice the diameter, and rotates at half the speed of the pyramidal polygon. The actual diameter is determined with regard for the aperture shape factor (previously discussed) and the propagation of the beam cross section (pupil) across the facet during its rotation (see "Design Considerations").

Image Rotation and Derotation When a beam having a round cross section is focused to an isotropic point spread function (psf), the rotation of this distribution about its axis is typically undetectable. If, however, the psf is nonisotropic (asymmetric or polarized), or if an array of 2 or more points is scanned to provide beam multiplexing,[6] certain scanning techniques can cause an undesired rotation of the point and the array of points on the image surface.

Consider a monogon scanner, per Fig. 27. As shown, the input beam overilluminates the rotating mirror. Thus, the mirror delimits the beam, establishing a rectangular cross section which maintains its relative orientation with respect to the image surface. Thus, if uniformly illuminated, the focal point on the image surface (having in this case a $\text{sinc}^2 x \cdot \text{sinc}^2 y$ psf, x = along-scan and y = cross-scan) maintains the same orientation along its scanned line. If, however, the input beam is polarized, the axis of polarization of the imaged point will rotate directly with mirror rotation within the rectangular psf. Similarly will be rotation for any radial asymmetry (e.g., intensity or ellipticity) within the aperture, resulting in rotation of the psf.

Consider, therefore, the same scanner underilluminated with, for example, an elliptical Gaussian beam (with major axis horizontal). The axis of the imaged elliptic spot (intended major axis vertical)

will rotate directly with the mirror. Similarly, if the scanner is illuminated with multiple beams displaced slightly angularly in a plane (to generate an in-line array of spots), the axis of the imaged array will rotate directly with mirror rotation.

This effect is transferrable directly to the pyramidal polygon which is illuminated per Fig. 34. It may be considered as an array of mirrors, each exhibiting the same rotation characteristics as the monogon of Fig. 27. The mirrors of Fig. 34 are also overilluminated, maintaining a stationary geometric psf during scan (if uniformly illuminated), but subject to rotation of, for example, polarization within the psf. Similarly, it is subject to rotation of an elliptical beam within the aperture, or of a multiple-beam array.

Not so, however, for the mirror mounted per Fig. 28 (galvanometer mount), or for the prismatic polygon of Figs. 26 and 33, which may be considered a multifacet extension of Fig. 28. When the illuminating beam and the scanned beam form a plane which is normal to the axis of mirror rotation, execution of scan does not alter the characteristics of the psf, except for the possible vignetting of the optical aperture and possible alteration of reflection characteristics (e.g., polarization) with variation in incident angle. It is noteworthy that in the prior examples, the angles of incidence remained constant, while the image is subject to rotation; and here, the angles of incidence change, while the image develops no rotation.

The distinction is in the symmetry of the scanning system with respect to the illumination. The prior examples (maintaining constant incidence while exhibiting image rotation) are radially symmetric. The latter examples (which vary incidence but execute no image rotation) represent the limit of radial asymmetry. While mirrored optical scanners seldom operate in regions between these two extremes, holographic scanners can, creating possible complications with, for example, polarization rotation. This is manifest in the variation in diffraction efficiency of gratings for variation in *p* and *s* polarizations during rotation. (See "Operation in the Bragg Regime.")

Image Derotation Image derotation can be implemented by interposing another image-rotating component in the optical path to cancel that caused by the scanner. The characteristic of an image rotator is that it inverts an image.[13] Thus, with continuous rotation, it rotates the image, developing two complete rotations per rotation of the component. It must, therefore, be rotated at half the angular velocity of the scanner.

While the Dove prism[13] is one of the most familiar components used for image rotation, other coaxial image inverters include[13]

- Three-mirror arrangement, which simulates the optical path of the Dove prism
- Cylindrical/spherical lens optical relay
- Pechan prism, which allows operation in converging or diverging beams

Design Considerations A commonly encountered scanner configuration is the prismatic polygon feeding a flat-field lens in preobjective scan, illustrated schematically in Fig. 26. The size and cost of the flat-field lens (given resolution and accuracy constraints) is determined primarily by its proximity to the scanner and the demand on its field angle. A larger distance from the scanner (pupil relief distance) imposes a wider acceptance aperture for a given scan angle, and a wider scan angle imposes more complex correction for off-axis aberration and field flattening. The pupil relief distance is determined primarily by the need for the input beam (Fig. 26) to clear the edge of the flat-field lens. Also, a wider scan angle reduces the accuracy requirement for pixel placement. Since the scan angle θ subtends the desired number N of resolution elements, a wider angle provides a larger angular subtense per element and correspondingly larger allowed error in angle $\Delta\theta$ for a desired elemental placement accuracy ΔN. This applies in both along-scan and cross-scan directions, $\Delta\theta_x$ and $\Delta\theta_y$, respectively (see Sec. 30.7).

Subsequent consideration of the scanner-lens relationships requires a preliminary estimate of the polygon facet count, in light of its diameter and speed. Its speed is determined by the desired data rates and entails considerations which transcend the optogeometric ones developed here. Diffraction-limited relationships are used throughout, requiring adjustment for anticipated aberration in real systems. The wavelength λ is a convenient parameter for buffering the design to accommodate

aberration. For example, an anticipated fractional spot growth of 15 percent due to systematic aberration is accommodated by using $\lambda_+ = 1.15\lambda$.

Performance characteristics which are usually predisposed are the resolution N (elements per scan), the optical scan angle θ, and the duty cycle η. Their interrelationships are presented under "Input/Output Scanning," notably by Eqs. (15) and (23). The values of N and θ for a desired image format width must be deemed practical for the flat-field lens.

Following these preliminary judgments, the collimated input beam width D is determined from [see "Fundamental Scanned Resolution" Eq. (15)]

$$D = Na\lambda/\theta \tag{29}$$

where a is the aperture shape factor and λ is the wavelength. For noncollimated beams, see "Augmented Resolution, the Displaced Deflector," notably Eq. (19). The number of facets is determined from Table 3 and Eq. (23),

$$n = 4\pi\eta/\theta \tag{30}$$

whereupon it is adjusted to an integer.

Scanner-lens relationships The polygon size and related scan geometry into the flat-field lens may now be determined.[35] Figure 35 illustrates a typical prismatic polygon and its input and output beams, all in the same plane. One of n facets of width W is shown in three positions: undeflected and in its limit-rotated positions. The optical beams are shown in corresponding undeflected and limit positions, deflected by $\pm\theta/2$. A lens housing edge denotes the input surface of a flat-field lens. Angle γ provides clear separation between the input beam and the down-deflected beam or lens housing. The pupil relief distance P (distance ac) and its slant distance P_e (distance bc) are system parameters which establish angle α such that $\cos\alpha = P/P_e$. Angle α represents the off-axis illumination on the

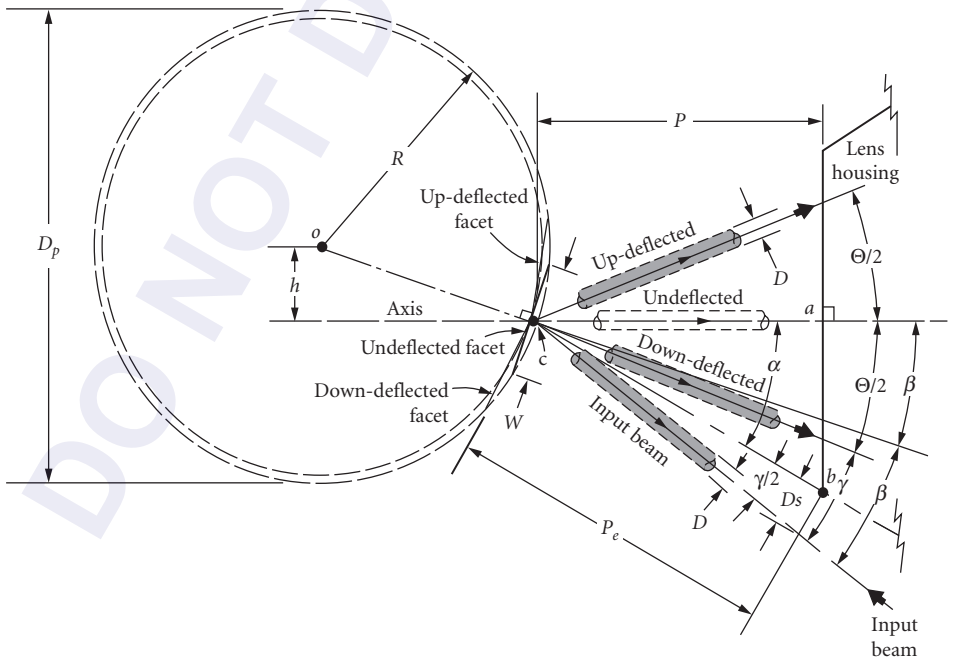

FIGURE 35 Polygon, beam, and lens relationships. Showing undeflected and limit facet and beam positions.[4]

polygon which broadens the input beam on the facet. The beam width D_m on the facet is widened due to α and due to an additional safety factor t ($1 \le t \le 1.4$) which limits one-sided truncation of the beam by the edge of the facet at the end of scan. Applying these factors, the beam width becomes

$$D_m = \frac{Dt}{\cos\alpha} \tag{31}$$

Following Eq. (15), the duty cycle is represented by $\eta = 1 - D_m/W$, yielding the facet width

$$W = D_m/(1-\eta) \tag{32}$$

from which the outer (circumscribed) polygon diameter is developed;[35] expressed by

$$D_p = \frac{Dt}{(1-\eta)\sin\pi/n\cos\alpha} \tag{33}$$

Solution of Eq. (33) or expressions of similar form[36] entails determination of α, the angle of off-axis illumination on the facet. This usually requires a detailed layout, similar to that of Fig. 35. Series approximation of cos α allows transformation of Eq. (33) to replace α with more direct dependence on the important lens parameter P (pupil relief distance), yielding,

$$D_p = \frac{Dt}{(1-\eta)\sin\pi/n} \cdot \frac{1+\theta Ds/2P}{1-\theta^2/8} \tag{34}$$

where, per Fig. 35, $s \approx 2$ is a safety multiplier on D for secure input/output beam separation and clearance.

Orientation of the scanner and lens also requires the height h, the normal distance from the lens axis to the polygon center. This is developed[35] as

$$h = R_c \sin(\gamma/2 + \theta/4) \tag{35}$$

where R_c is the radial distance oc, slightly shorter than the outer radius R, approximated to be

$$R_c = R\left[1 - \frac{1}{4}(\pi/n)^2\right] \tag{36}$$

Holographic Scanners

General Characteristics Almost all holographic scanners comprise a substrate which is rotated about an axis, and utilize many of the concepts representative of polygons. An array of holographic elements disposed about the substrate serves as facets, to transfer a fixed incident beam to one which scans. As with polygons, the number of facets is determined by the optical scan angle and duty cycle (see "Duty Cycle"), and the elemental resolution is determined by the incident beam width and the scan angle [see Eq. (15)]. In radially symmetric systems, scan functions can be identical to those of the pyramidal polygon. While there are many similarities to polygons, there are significant advantages and limitations.[6] The most attractive features of holographic scanners are

1. Reduced aerodynamic loading and windage with elimination of radial discontinuities of the substrate
2. Reduced inertial deformation with elimination of radial variations
3. Reduced optical-beam wobble when operated near the Bragg transmission angle

Additional favorable factors are

1. Operation in transmission, allowing efficient beam transfer and lens-size accommodation
2. Provision for disk-scanner configuration, with facets disposed on the periphery of a flat surface, designable for replication

3. No physical contact during exposure; precision shaft indexing between exposures allows for high accuracy in facet orientation
4. Filtering in retrocollection, allowing spatial and spectral selection by rediffraction
5. Adjustability of focus, size, and orientation of individual facets

Some limiting factors are

1. Need for stringent design and fabrication procedures, with special expertise and facilities in diffractive optics, instrumentation, metrology, and processing chemistry.
2. Accommodation of wavelength shift: exposure at one wavelength (of high photosensitivity) and reconstruction at another (for system operation). Per the grating equation[6] for first-order diffraction,

$$\sin\theta_i + \sin\theta_o = \lambda/d \tag{37}$$

where θ_i and θ_o are the input and diffracted output angles with respect to the grating normal and d is the grating spacing, a plane linear grating reconstructs a collimated beam of a shifted wavelength at a shifted angle. Since wavefront purity is maintained, it is commonly employed,[6] although it requires separate focusing optics (as does a polygon). When optical power is added to the hologram (to provide self-focusing), its wavelength shift requires compensation for aberration.[6] Further complications arise when intended for multicolor operation, even if plane linear gratings. Further, even small wavelength shifts, as from laser diodes, can cause unacceptable beam misplacements, requiring corrective action.[6,37]

3. Departure from radial symmetry develops complex interactions which require critical balancing to achieve good scan linearity, scan-angle range, wobble correction, radiometric uniformity, and insensitivity to input beam polarization.[6,36] This is especially demanding in systems having optical power in the holograms.
4. Systems which retain radial symmetry to maintain scan uniformity may be limited in Bragg angle wobble reduction, and can require auxiliary compensation, such as anamorphic error correction.

Holographic Scanner Configurations A scanner which embodies some of the characteristics expressed above is represented in Fig. 36.[38] A cylindrical glass substrate supports an array of equally spaced *hololenses* which image the input beam incident at *o* to the output point at *P*. Since point *o* intersects the axis, the scanner is radially symmetric, whereupon *P* executes a circular (arced) scan concentric with the axis, maintaining magnification $m = \theta/\Phi = 1$. A portion of the radiation incident on the image surface is backscattered and intercepted by the hololens, and reflected to a detector which is located at the mirror image *o′* of point *o.* The resolution of this configuration is shown to be analogous to that of the pyramidal polygon.[6]

An even closer analogy is provided by an earlier reflective form illustrated in Fig. 37, emulating the pyramidal polygon, Fig. 34. It scans a collimated beam which is transformed by a conventional flat-field lens to a scanned focused line. This is one of a family of holofacet scanners,[6] the most prominent of which tested to the highest performance yet achieved in combined resolution and speed—20,000 elements per scan at 200 Mpixels/s. This apparatus is now in the permanent collection of the Smithsonian Institution.

Operation in the Bragg Regime The aforementioned systems are radially symmetric and utilize substrates which allow derivation of the output beam normal to the rotating axis. While operation with radial asymmetry was anticipated in 1967,[39] it was not until operation in the Bragg regime was introduced[6,40] that major progress developed in disk configurations. Referring to Fig. 38, the input and output beams *I* and *O* appear as principal rays directed to and diffracted from the holographic sector HS, forming angles θ_i and θ_o with respect to the grating surface normal.

For the tilt-error reduction in the vicinity of Bragg operation, the differential in output angle $d\theta_o$ for a differential in hologram tilt angle $d\alpha$ during tilt error $\Delta\alpha$ is given by

$$d\theta_o = \left[1 - \frac{\cos(\theta_i + \Delta\alpha)}{\cos(\theta_o - \Delta\alpha)}\right] d\alpha \tag{38}$$

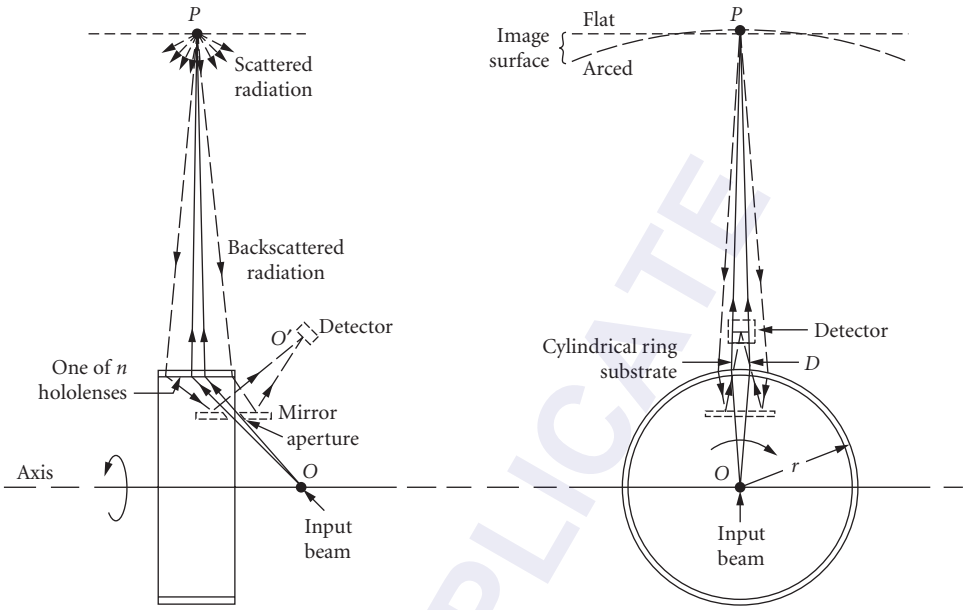

FIGURE 36 Transmissive cylindrical holographic scanner. Input beam underilluminates hololens which focuses diffracted beam to image surface. Dashed lines designate optional collection of backscattered radiation for document scanning.[6]

Hence, when $\theta_i = \theta_o$, a small $\Delta\alpha$ is effectively nulled. While the θ_i and θ_o depart from perfect Bragg symmetry during hologram rotation and scan, the reduction in error remains significant. An analogy of this important property is developed for the tilting of a refractive wedge operating at minimum deviation.[6] When $\theta_i = \theta_o \simeq 45°$, another property develops in the unbowing of the output

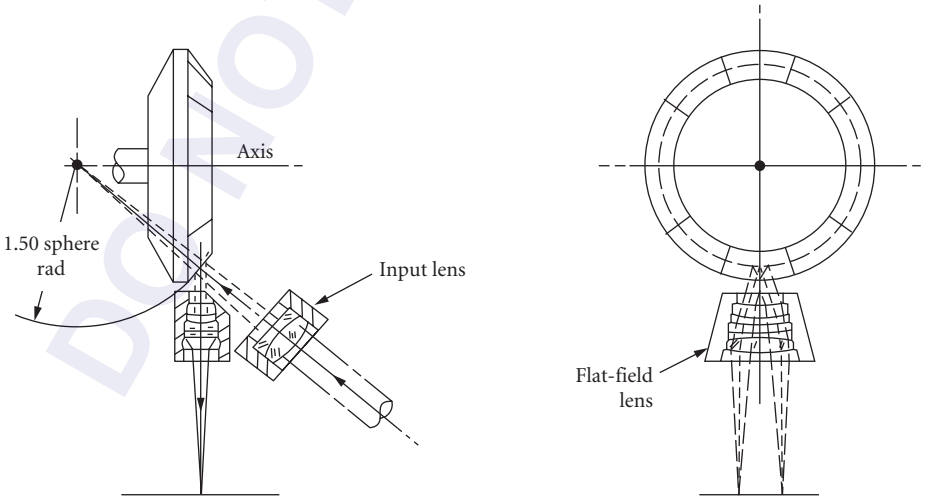

FIGURE 37 Reflective holofacet scanner, underilluminated. Flat-field microimage scanner (100 1p/mm over 11-mm format).

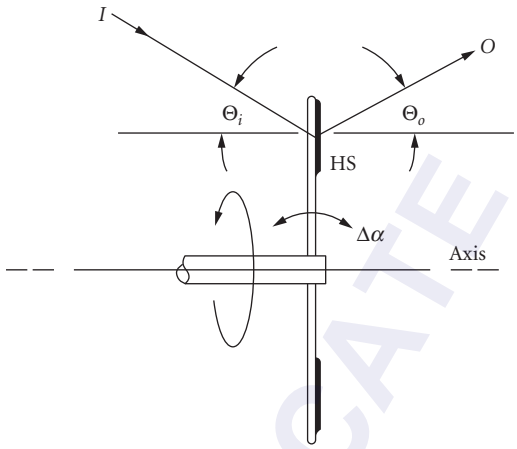

FIGURE 38 Holographic scanner in Bragg regime; $\Theta_i = \Theta_o$, in which output angle θ_o is stabilized against tilt error $\Delta\alpha$ of holographic segment HS.

scanned beam: the locus of the output beam resides (almost) in a plane normal to that of the paper over a limited but useful range.[6,37] Further, the incremental angular scan for incremental disk rotation becomes almost uniform: their ratio m at small scan angles is shown to be equal to the ratio λ/d of the grating equation [see the section on "Radial Symmetry and Scan Magnification" and Eq. (3)].[6] At $\theta_i = \theta_o = 45°$, $m = \lambda/d = \sqrt{2}$. This results in the output-scan angle to be $\sqrt{2}$ larger (in its plane) than the disk-rotation angle. While such operation provides the above attributes, it imposes two practical restrictions.

1. For high diffraction efficiency from relief gratings (e.g., photoresist), the depth-to-spacing ratio of the gratings must be extremely high, while the spacing $d = \lambda/\sqrt{2}$ must be extremely narrow. This is difficult to achieve and maintain, and difficult to replicate gratings which provide efficient diffraction.
2. Such gratings exhibit a high polarization selectivity, imposing a significant variation in diffraction efficiency with grating rotation (see "Image Rotation and Derotation").

Accommodation of these limitations is provided by reducing the Bragg angle and introducing a bow correction element to straighten the scan line. This is represented in Fig. 39; a high-performance scanner intended for application to the graphic arts. The Bragg angle is reduced to 30°. This reduces the magnification to $m = 1 = \lambda/d$ (as in radially symmetric systems), increases d to equal λ for more realizable deep-groove gratings, and reduces significantly the angular polarization sensitivity of the grating.

The elegance of the 45° Bragg configuration has been adapted[6] to achieve self-focusing in less demanding tasks (e.g., laser printing). This is exemplified in Fig. 40, which includes a holographic lens to balance the wavelength shift of the laser diode,[41,42,43] to shape the laser output for proper illumination of the scanner and to accommodate wavelength shift reconstruction. However, such multifunction systems are compounded by more critical centration requirements[6] and balancing of characteristics for achievement of a discrete set of objectives.

Galvanometer and Resonant Scanners

To avoid the scan nonuniformities which can arise from facet variations (see Sec. 30.7) of polygons or holographic deflectors, one might avoid multifacets. Reducing the number to one, the polygon becomes a monogon. This adapts well to the internal drum scanner (Fig. 27), which achieves a high

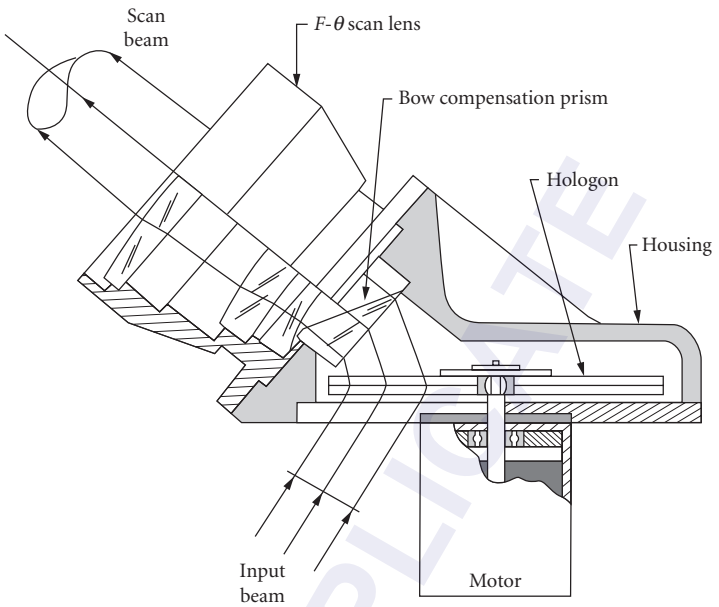

FIGURE 39 Plane linear grating (hologon) holographic disk scanner. Bragg angle of 30° provides fabricatable and polarization-insensitive grating structure, but requires bow compensation prism. Useful scan beam is in and out of plane of paper. (*After Holotek Ltd, Rochester, NY product data.*)

duty cycle, executing a very large angular scan within a cylindrical image surface. Flat-field scanning, however, as projected through a flat-field lens, allows limited optical scan angle, resulting in a limited duty cycle from a rotating monogon. If the mirror is vibrated rather than rotated completely, the wasted scan interval may be reduced. Such components must, however, satisfy system speed, resolution, and linearity. Vibrational scanners include the familiar galvanometer and resonant devices[4,5,44,45] and the less commonly encountered piezoelectrically driven mirror transducer.[5,45]

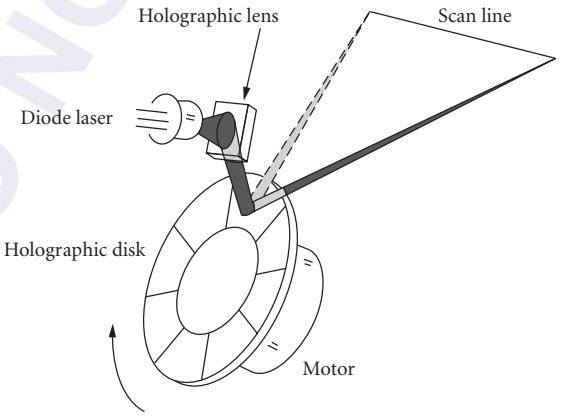

FIGURE 40 Holographic disk scanner with corrective holographic lens, both operating in approximately Bragg regime, providing complex error balancing.[42]

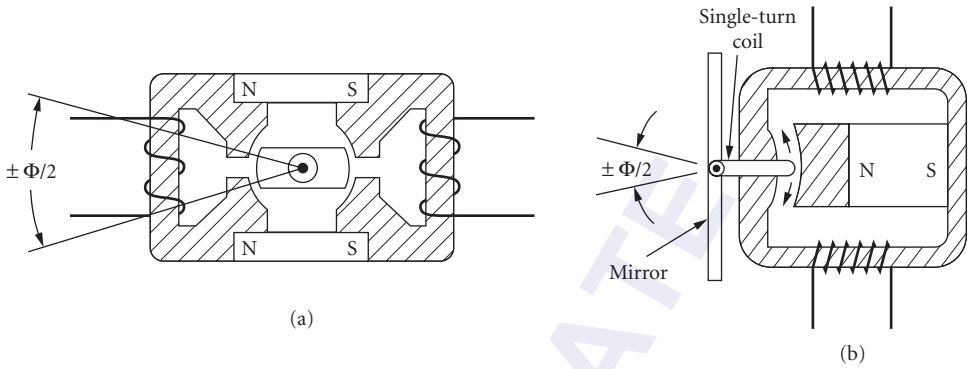

FIGURE 41 Examples of galvanometer and resonant scanner transducers. Fixed field of permanent magnet(s) is augmented by variable field from current through stator coils. (*a*) Galvanometer: torque rotates iron or magnetic core. Mirror surface (not shown) on extended shaft axis. (*b*) Resonant scanner: torque from field induced into single-turn armature coil (in plane perpendicular to paper) rotates mirror suspended between torsion bars. One stator coil may be nondriven and used for velocity pick-off.

The Galvanometer Referring to Fig. 41*a*, a typical galvanometer driver is similar to a torque motor. Permanent magnets provide a fixed field which is augmented (±) by the variable field developed from an adjustable current through the stator coils. Seeking a new balanced field, the rotor* executes a limited angular excursion ($\pm\Phi/2$). With the mirror and principal ray per Fig. 28, the reflected beam scans through $\pm\theta/2$, twice that of the rotor.

The galvanometer is a broadband device, damped sufficiently to scan within a wide range of frequencies, from zero to an upper value close to its mechanical resonance. Thus, it can provide the sawtooth waveform with a longer active linearized portion and shorter retrace time τ. This is represented in Fig. 42 (solid lines) showing rotation angle Φ versus time. As a broadband device, it can also serve for random access, positioning to an arbitrary location within its access-time limitations. For this feature of waveform shaping, the galvanometer was categorized as a *low inertia scanner.*[5]

The Resonant Scanner When damping is removed almost completely, large vibrations can be sustained only very near the resonant frequency of the oscillating system. The resonant scanner is thus characterized by larger angular excursions at a fixed and usually higher frequency, executing near-perfect sinusoidal oscillations. A typical driver configuration is illustrated in Fig. 41*b*. Figure 42 (dashed lines) shows a sinusoid with the same zero-crossings as those of the sawtooth waveform. Contrary to its popular designation as "low-inertia," the resonant scanner provides rigid time increments, as though it exhibits a high inertia. While the rotary inertia of the suspension system is low to allow high repetition rates, it permits no random access and no scan waveform shaping, as do the galvanometer, acousto-optic, electro-optic, and other wideband scanners designated as low-inertia devices.[5]

Suspension Systems In the vibrational scanners, the bearings and suspension systems are the principal determinants of scan uniformity. The galvanometer shaft must be sufficiently stiff and long to inhibit cross-scan wobble. However, to maximize the oscillating frequency, the armature is restricted in size and mass. Fortunately, its reciprocating motion tends to retrace its path (and its perturbations) faithfully over many cycles, making adjacent scans more uniform than if the same shaft rotated completely within the same bearings, as in a motor.

*Rotor types include moving iron, moving magnet, or moving coil. Figure 41*a* illustrates the first two and Fig. 41*b* exemplifies the moving coil type. Moving magnet types (having NdFeB high-energy magnetic material) can exhibit some advantage in lower inertia and higher torque.

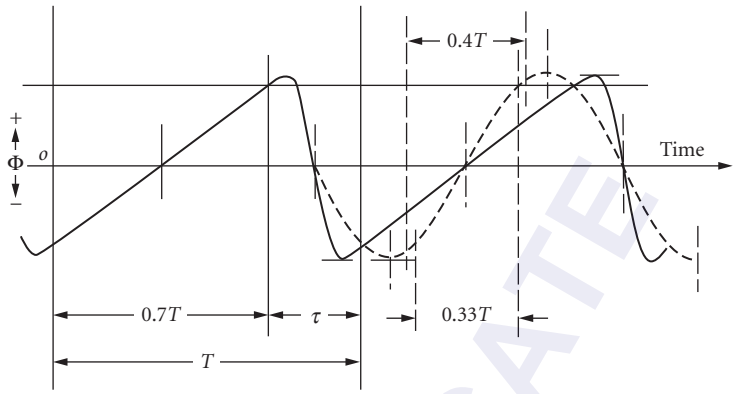

FIGURE 42 Waveforms (Φ vs. time) of vibrational scanners having same period and zero crossings. *Solid line*: galvanometer with linearized scan, providing 70 percent duty cycle. *Dashed line*: Resonant scanner providing 33.3 percent duty cycle (unidirectional) with 2:1 slope change, or 40 percent duty cycle with 3.24:1 slope change. Ratio of maximum slopes: resonant/galvanometer 2.6/1.[4]

Some bearings are flexure, torsion, or taut-band devices which insert almost no along-scan perturbations.[44] Because of their low damping, these suspensions are most often applied to the resonant scanner. When damped, they can serve for the galvanometer, suffering a small sacrifice in bandwidth and maximum excursion, but gaining more uniform scan with very low noise and almost unlimited life. Some considerations are their low radial stiffness and possible coupling perturbation from torsion, shift of the axis of rotation with scan angle, and possible appearance of spurious modes when lightly damped. Most of these factors can be well-controlled in commercial instrument designs.

Adaptations and Comparisons Because the resonant scanner oscillates sinusoidally, and we seek typically a linearized scan, some significant adaptations are often required. As illustrated in Fig. 42 (dashed lines), we must select from the sine function a central portion which is sufficiently linear to be linearized further by timing the pixels or extracting them out of memory at a corresponding rate.[46] To limit the variation in pixel rate to 2:1 (i.e., velocity at zero crossover will be twice that at the same limit), then the useful excursion must be restricted to 60°/90° or 66.7 percent of its peak angle. When scanning with only one slope of the sinusoid (as for generation of a uniformly spaced raster), this represents a duty cycle of only 33.3 percent. To raise the duty cycle, one must accommodate a greater variation in data rate. If, for example, the useful scan is 80 percent of its full excursion (40 percent when using one slope), then the velocity variation rises to 3.24×. That is, the data rate or bandwidth at crossover is 3.24 times that at the scan limit. Also, its bandwidth at crossover is approximately 2 1/2 times that of the galvanometer, as represented by their relative slopes in Fig. 42

There is a corresponding variation in the dwell time of the pixels, resulting in predictable but significant variation in image exposure or detectivity: 2:1 for 33.3 percent duty cycle and 3 1/4: 1 for 40 percent duty cycle. This may require compensation over the full scan interval, using position sensing and control.[45–48] In contrast, the broadband galvanometer with feedback can provide a highly linearized scan[44] at a duty cycle of approximately 70 percent.[5]

Acousto-Optic Scanners

Acousto-optic diffraction serves effectively for high-speed low-inertia optical deflection. It can provide random beam positioning within extremely short access times, or generate repetitive linear scans at very high rates, or divide a single beam into multiple beams for multiplexing applications. The tradeoff is, however, relatively low resolution, seldom providing more than $N = 1000$ elements per scan.

The principles of acousto-optics were formulated in 1932[49] and its attributes were applied only 5 years later to the Scophony TV projection system.[50] Its potential for laser scanning was explored in the mid-1960s.[51,52] While various acousto-optic interactions exist, laser scanning is dominated by operation in the Bragg regime.[5,53]

Fundamental Characteristics Diffraction from a structure having a periodic spacing Λ is expressed as $\sin \theta_i + \sin \theta_o = n\lambda/\Lambda$, where θ_i and θ_o are the input and output beam angles respectively, n is the diffractive order, and λ is the wavelength. Bragg operation requires that $\theta_i = \theta_o = \theta_B$. In a "thick" diffractor, length $L \geq \Lambda^2/\lambda$, wherein all the orders are transferred efficiently to the first, and the Bragg angle reduces to

$$\theta_B = \frac{1}{2}\frac{\lambda}{\Lambda} \tag{39}$$

Per Fig. 43, the grating spacing is synthesized by the wavefront spacing formed by an acoustic wave traveling through an elastic medium. An acoustic transducer at one end converts an electrical drive signal to a corresponding pressure wave which traverses the medium at the velocity v_s, whereupon it is absorbed at the far end to suppress standing waves. The varying pressure wave in the medium forms a corresponding variation in its refractive index. An incident light beam of width D is introduced at the Bragg angle (angle shown exaggerated). An electrical drive signal at the center frequency f_o develops a variable index grating of spacing Λ which diffracts the output beam at θ_B into position b. The drive signal magnitude is adjusted to maximize beam intensity at position b, minimizing intensity of the zero-order beam at position a. When f_o is increased to $f_s = f_o + \Delta f$, the grating spacing is decreased, diffracting the output beam through a larger angle, to position c. The small scan angle θ is effectively proportional to the change in frequency Δf.

The scan angle is $\theta = \lambda/\Delta\Lambda = (\lambda/v_s)\Delta f$. The beam width, traversed by the acoustic wave over the transit time τ is $D = v_s\tau$. Substituting into Eq. (15) and accounting for duty cycle per Eq. (22), the resolution of the acousto-optic scanner (total N elements for total Δf) is

$$N = \frac{\tau \Delta f}{a}(1 - \tau/T) \tag{40}$$

The $\tau\,\Delta f$ component represents the familiar time-bandwidth product, a measure of information-handling capacity.

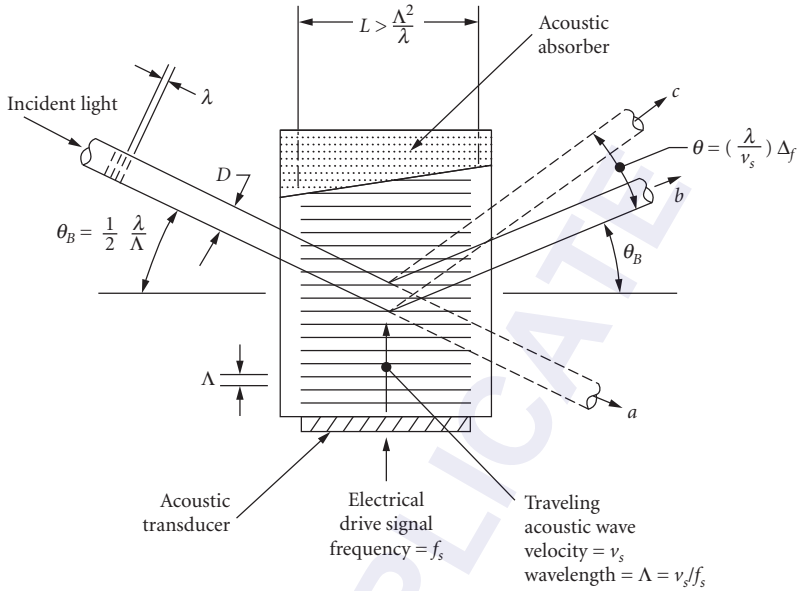
Deflection Techniques Because the clear aperture width W of the device is fixed, anamorphic optics is often used to illuminate W with an adjusted beam width D—encountering selective truncation by the parallel boundaries of W. The beam height (in quadrature to D) can be arbitrarily narrow to avoid apodization by the aperture. This one-dimensional truncation of the Gaussian beam requires assignment of an appropriate aperture shape factor a, summarized in Table 5.

Additional topics in acousto-optic deflection are cylindrical lensing due to linearly swept f_s,[53] correction for decollimation in random access operation,[5] Scophony operation,[54] traveling lens or chirp operation,[55] correction for color dispersion,[56] polarization effects,[57] and multibeam operation.[58]

Electro-Optic (Gradient) Scanners

The gradient deflector is a generalized form of beam scanner[4,5,59] in which the propagating wavefronts undergo increasing retardation transverse to the beam, thereby changing the wavefront spacing (wavelength) transverse to the beam. To maintain wavefront continuity, the rays (orthogonal trajectories of the wavefronts) bend in the direction of the shorter wavelength. Referring to Fig. 44*a*, this bend angle θ through such a deflection cell may be expressed as

$$\theta = k_o(dn/dy)l \tag{41}$$



Output beam position	Beam condition	Acoustic frequency
a	Undiffracted zero order	f_s = zero (or amplitude = 0)
b	Nominal Bragg angle Θ_B	$f_s = f_o$ (center frequency)
c	Added diffraction, scanned through angle Θ	$f_s = f_o + \Delta f$

FIGURE 43 Bragg acousto-optic deflector (angles exaggerated for illustration). Electrical drive signal generates traveling acoustic wave in medium which simulates a thick optical grating. Relationship between the output beam position and the electrical drive frequency is tabulated.[4]

where n is taken as the number of wavelengths per unit axial length l, y is the transverse distance, and k_o is a cell system constant. For the refractive material form in which the wavefront traverses a change Δn in index of refraction and the light rays traverse the change in index over the full beam aperture D in a cell of length L, then the relatively small deflection angle becomes[4,5]

$$\theta = (\Delta n/n_f)L/D \tag{42}$$

where n_f is the refractive index of the final medium (applying Snell's law and assuming sin $\theta = \theta$). Following Eq. (15), the corresponding resolution in elements per scan angle is expressed as

$$N = (\Delta n/n_f)L/a\lambda \tag{43}$$

The Δn is given by

$$\text{(for class I materials)} \quad \Delta n = n_o^3 r_{ij} E_z \tag{44a}$$

$$\text{(for class II materials)} \quad \Delta n = n_e^3 r_{ij} E_z \tag{44b}$$

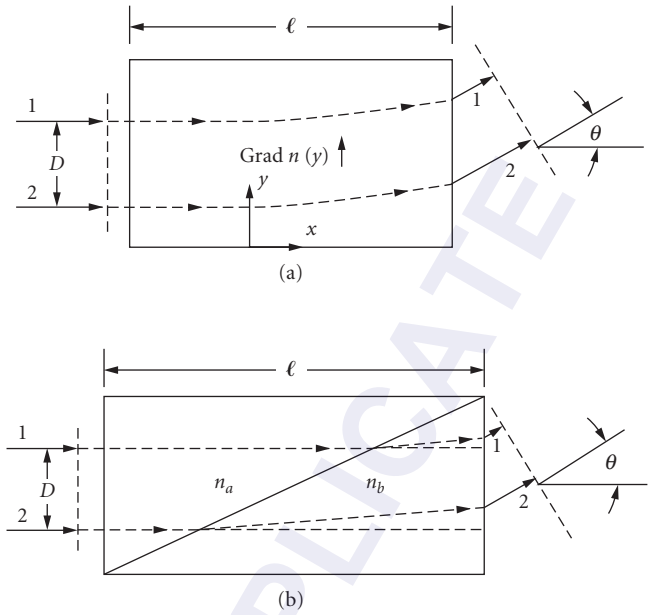


FIGURE 44 Equivalent gradient deflectors: (*a*) basic deflector cell composed of material having grad $n(y)$. Ray 1, propagating through a higher refractive index, is retarded more than Ray 2, tipping the wavefront through angle Θ (including boundary effect). (*b*) Analogous prismatic cell, in which $n_a > n_b$, such that Ray 1 is retarded more than Ray 2, tipping the wavefront through angle Θ.[4]

where $n_{o,e}$ is the (ordinary, extraordinary) index of refraction, r_{ij} is the electro-optic coefficient, and $E_z = V/Z$ is the electric field in the z direction (see Fig. 45).

Methods of Implementation An electroacoustic method of developing a time-dependent index gradient was proposed in 1963[60] utilizing the (harmonic) pressure variations in an acoustically driven cell (of a transparent elastic material). Although this appears similar to acousto-optic deflection (see "Acousto-Optic Scanners"), it differs fundamentally in that the cell is terminated reflectively rather than absorptively (to support a standing wave). Also, the acoustic wavelength is much longer than the beam width, rather than much shorter for Bragg operation. A method of approaching a linearly varying index gradient utilizes a quadrupolar array of electrodes bounding an electro-optic material,[61,62] and is available commercially.[63]

A continuous index gradient can be simulated by the use of alternating electro-optic prisms.[59,64] A single stage biprism is illustrated in Fig. 44*b* and an iterated array for practical implementation appears in Fig. 45. Each interface imparts a cumulative differential in retardation across the beam. The direction and speed of retardation is controlled by the index changes in the electro-optic material. While resolution is limited primarily by available materials, significant experiment and test is reported for this form of deflector.[5]

Drive Power Considerations The electrical power dissipated within the electro-optic material is given by[5]

$$P = \frac{1}{4}\pi V^2 C f / Q \tag{45}$$

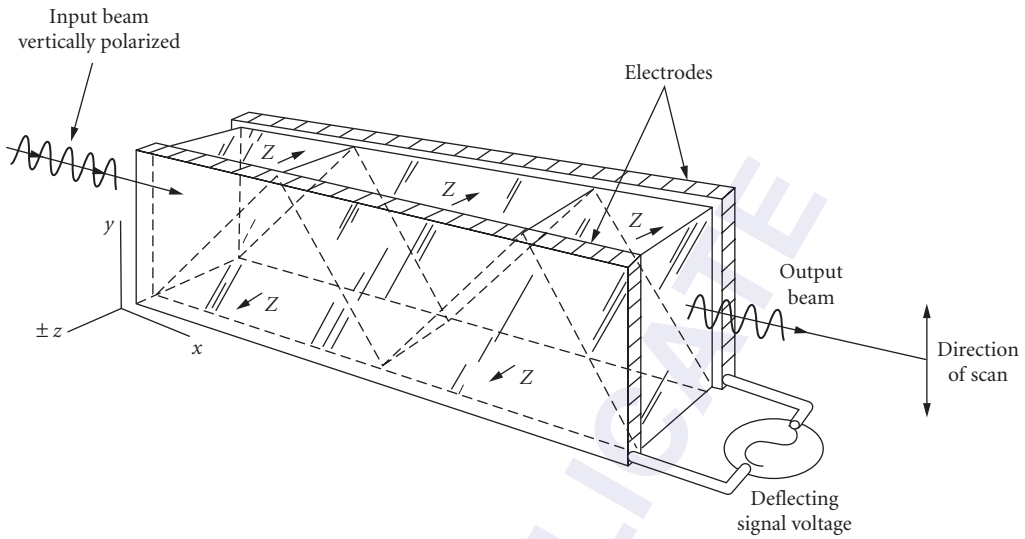

FIGURE 45 Iterated electro-optic prism deflector. Indicating alternating crystallographic (z) axes. Input beam polarization for class 1 electro-optic coefficient (r_{63}) materials.[4]

where V is the applied (p-p sinusoidal) voltage in volts, C is the deflector capacitance in farads, f is the drive frequency in hertz and Q is the material Q factor [Q = 1/loss tangent (tan δ) $\simeq$ 1/power factor, (Q > 5)].

The capacitance C for transverse electroded deflectors is approximately that for a parallel-plate capacitor of (rectangular) length L, width Y, and dielectric thickness Z (per Fig. 45)

$$C = 0.09\kappa LY/Z \text{ picofarads} \tag{46}$$

where k is the dielectric constant of the material (L, Y, Z in centimeters).

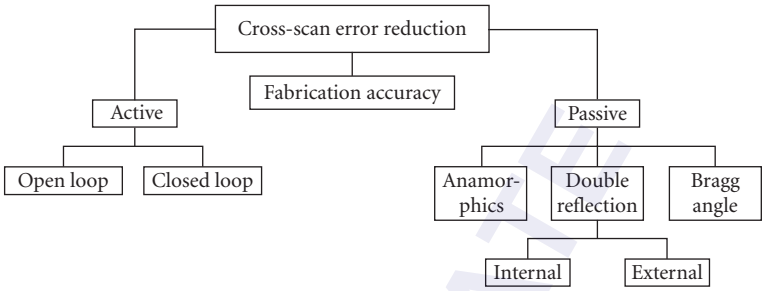
The loss characteristics of materials which determine their operating Q are often a strong function of frequency beyond 10^5 Hz. The dissipation characteristics of some electro-optic materials are provided,[5,65,66] and a resolution-speed-power figure of merit has been proposed.[67]

Unique Characteristics Most electro-optic coefficients are extremely low, requiring high drive voltages to achieve even moderate resolutions (to $N \simeq 100$). However, these devices can scan to very high speeds (to 10^5/s) and suffer effectively no time delay (as do acousto-optic devices), allowing use of broadband feedback for position control.

30.7 SCAN-ERROR REDUCTION

High-resolution scanners often depend on precise rotation of a shaft about its axis, said shaft supporting a multiplicity of deflecting elements (facets, mirrors, holograms). The control of angular uniformity of these multielements with respect to the axis, and of the axis with respect to its frame, can create an imposing demand on fabrication procedures and consequential cost. Since uniformity of beam position in the cross-scan direction may not be approached by phasing and timing of the data (as can be the along-scan errors), several noteworthy techniques have been developed to alleviate this burden.

TABLE 6 Techniques for Cross-Scan Error Reduction



Available Methods

The general field of cross-scan error reduction is represented in Table 6. *Fabrication accuracy* may be selected as the only discipline, or it may be augmented by any of the auxiliary methods. The *active* ones utilize high-speed low-inertia (A-O or E-O) or piezoelectric deflectors[5,68] or lower-speed (galvanometer) deflectors which are programmed to rectify the beam-position errors. While open-loop programming is straightforward (while accounting for angular magnification/demagnification as a function of the accessed beam size), elegant closed-loop methods may be required to rectify pseudorandom perturbations. This must, however, be cost-effective when compared to the alternatives of increased fabrication accuracy and of the *passive* techniques.

Passive Methods

Passive techniques require no programming. They incorporate optical principles in novel configurations to reduce beam misplacement due to angular error in reflection or diffraction. Bragg-angle error reduction of tilted holographic deflectors is discussed in the section, "Operation in the Bragg Regime."

Anamorphic Error Control Anamorphic control, the most prominent treatment, may be applied to any deflector. The basics and operational characteristics[6] are summarized here.

Separating the nonaugmented portion of the resolution equation [Eq. (19)] into quadrature components and denoting the cross-scan direction as y, then the error, expressed in the number of resolvable elements, is

$$N_y = \frac{\theta_y D_y}{a\lambda} \tag{47}$$

where $a\lambda$ is assumed constant, θ_y is the angular error of the output beam direction, and D_y is the height of the beam illuminating the deflector. The objective is to make $N_y \to 0$. Mechanical accuracies determine θ_y, while anamorphics are introduced to reduce D_y; usually accomplished with a cylindrical lens focusing the illuminating beam in the y direction upon the deflector. [The quadrature (along-scan) resolution is retained by the unmodified D_x and scan angle θ_x.] As D_y is reduced, the y displacement error is reduced. Following deflection, the y-direction scanned spot distribution is restored by additional anamorphics—restoring the nominal converging beam angle (via F_y, the F-number forming the scanning spot in the y direction).

The error reduction ratio is

$$R = D_y'/D_y \tag{48}$$

where D_y' is the compressed beam height and D_y is the original beam height on the deflector.

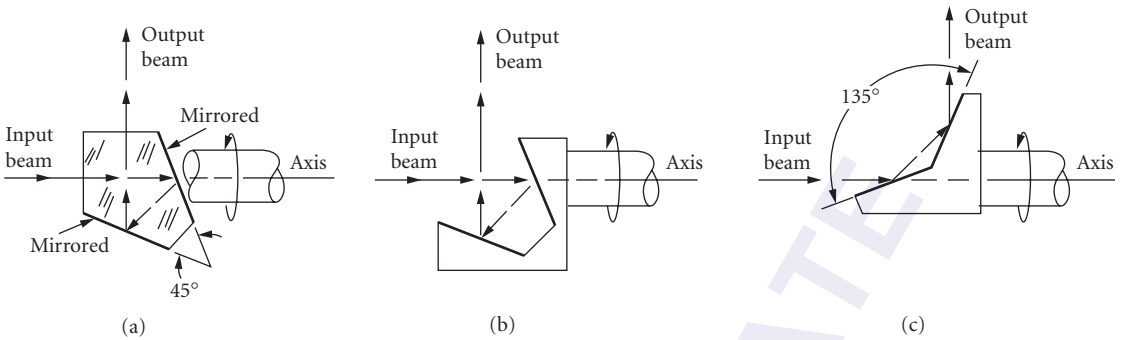


FIGURE 46 Monogon scanners employing double-reflection: (*a*) pentaprism; (*b*) pentamirror; and (*c*) open mirror.[4]

A variety of anamorphic configurations has been instituted, with principal variations in the output region, in consort with the objective lens, to reestablish the nominal F_y while maintaining focused spot quality and uniformity.

Double-Reflection Error Control In double-reflection (Table 6), the deflector which creates a cross-scan error is reilluminated by the scanned beam in such phase as to tend to null the error. This can be conducted in two forms: internal and external.

An internal double-reflection scanner is exemplified by the pentaprism monogon[69] in Fig. 46*a*; a (glass) substrate having two of its five surfaces mirrored. This is an optically stabilized alternate to the 45° monogon of Fig. 27, operating preobjective in collimated light. Tipping the pentaprism cross-scan (in the plane of the paper) leaves the 90° output beam unaffected. A minor translation of the beam is nulled when focused by the objective lens. The pentamirror[69] per Fig. 46*b,* requires, however, significant balancing and support of the mirrors, since any shift in the nominal 45° included angle causes twice the error in the output beam. A stable double-reflector is the open mirror monogon[70] of Fig. 46*c.* Its nominal 135° angle serves identically to maintain the output beam angle at 90° from the axis, independently of cross-scan wobble. With a rigid included angle and simple balancing, it can provide high-speed operation.

Two variations which double the duty cycle, as would a two-faceted pyramidal polygon or ax-blade scanner (see "Early Single-Mirror Scanners") appear in Fig. 47. Figure 47*a* is effectively two pentamirrors

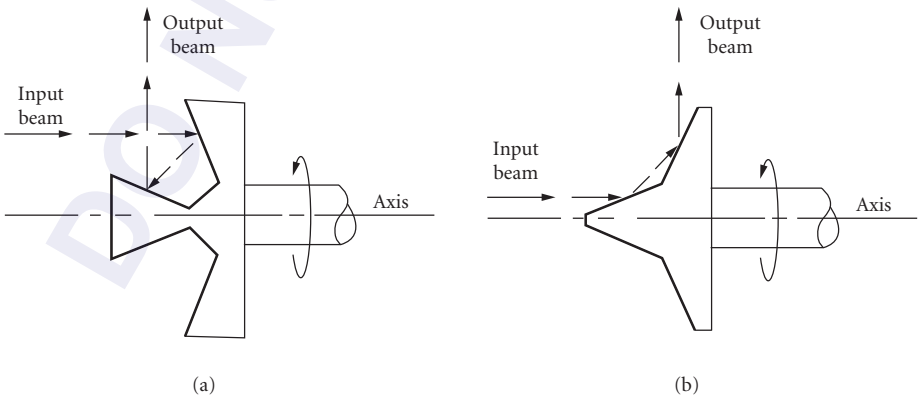

FIGURE 47 Paired scanners employing double-reflection: (a) paired pertamirror "butterfly" scanner and (*b*) paired open mirror scanner. [4]

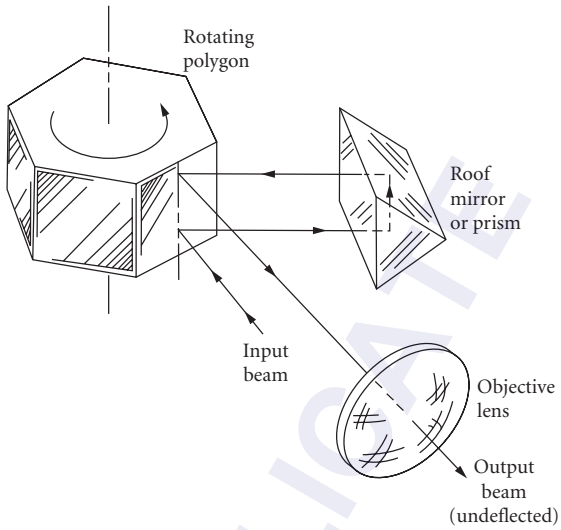

FIGURE 48 Method of external double-reflection—shown in undeflected position. Components and distances not to scale. Only principal rays shown.[4]

forming a *butterfly scanner*[71] and Fig. 47*b* is effectively a pair of open mirrors.[72] The absolute angles of each half-section must maintain equality to within half of the allowed error in the output beam. Also, the center section of Fig. 47*a* must be angularly stable to within one-quarter of the allowed error, because an increased included angle on one side forms a corresponding decrease on the other. Other dynamic considerations involve inertial deformation, and the beam displacements and mirror widths (not shown) to accommodate the distance of the input beam from the axis during rotation.

The need for near-perfect symmetry of the multiple double-reflectors can be avoided by transferring the accuracy requirement to an *external* element that redirects recurrent beam scans. One such form[73] is illustrated in Fig. 48. A prismatic polygon illuminated with a collimated beam of required width (only principal rays shown) deflects the beam first to a roof mirror, which returns the beam to the same facet for a second deflection toward the flat-field lens. The roof mirror phases the returned beam such as to null the cross-scan error upon the second reflection. Several characteristics are noteworthy:

1. The along-scan angle is doubled. That is, scan magnification $m = 4$ rather than 2.
2. This normally requires increasing the number of facets to provide the same angle with the same duty cycle.
3. However, during polygon rotation, the point of second reflection shifts significantly along the facet and sacrifices duty cycle.
4. The pupil distance from the flat-field lens is effectively extended by the extra reflections, requiring a larger lens to avoid vignetting.
5. The roof mirror and flat-field lens must be sized and positioned to minimize obstruction of the input and scanned beams. Allow for finite beam widths (see "Scanner-Lens Relationships").

30.8 AGILE BEAM STEERING

A class of low-inertia scanning, called *agile beam steering*[74–77] was developed initially for such challenging tasks as laser radar (LIDAR) and forward-looking infrared (FLIR) systems. Further advancement may allow its extension to more general application. The motivation for this

work is to achieve the performance of the scanned mirror while avoiding some of the concomitant burdens of size, weight, and inertia. This has been a long-envisioned goal of many earlier researchers in work having important similarities[5] to the more current activity in agile beam steering. Recent research has harvested new resources such as liquid crystal E-O phase shifters micromachined devices, and microlens techniques assembled in novel configurations. Two principal approaches have dominated investigation and development, viz., the phased array and the decentered microlens array; along with some of their principal variations. Although the basic operation of these two array types differ, they both develop the same form of the steered output wavefronts

Phased Array Beam Steering

The directing of radiation in the radio and microwave regions by driving antenna arrays with controlled relative phase was especially familiar to the early radar specialist.[78,79] Its adaptation to the optical spectrum, notably as radiated by lasers, was investigated[80] in 1964 following the invention of the laser and continued[81–83] through the early 1970s. The prospect of altering the direction of a laser beam with small adjustments on a group of radiators appeared *very* attractive. With the introduction of electrostatically actuated membrane mirror arrays[82] in 1971, and the programming of electro-optic crystal arrays[83] in 1972, operational utility was affirmed. Beam steering with arrays of mirrors was investigated[81] in 1967. Further work was conducted in mirror array beam steering in the infrared region, where mirror reflectance exceeds the transmittance of even the exotic infrared materials, and where the longer wavelength imposes lower requirements on mirror flatness. With the current use of faster acting electro-optic materials and novel design variations, substantive advances have been achieved.

The steering of an optical wavefront by phase variation is introduced with the effect of refractive prisms.[84,87] Figure 49*a* illustrates a plane wavefront in air incident parallel to the plane surface of one dielectric wedge. Within the material of refractive index >1, the wavelength is compressed proportionately, while the fronts remain parallel to the incident wavefront. A linearly increasing local phase delay results from the progressive retardation of the wavefronts across the enlarging wedge thickness. Traversing the tilted boundary, the wavelength in air is reexpanded and its angle of propagation is refracted as illustrated. This is exemplified in the iterated prismatic deflector of Fig. 45 given the dynamics of the electro-optic material.

To provide a wide aperture, the single prism of Fig. 49*a* can exhibit substantive bulk. To relieve this, the long wedge profile is divided into an array of smaller wedge increments where each causes a linear phase delay of from 0 to 2π. As illustrated in Fig. 49*b*, when implemented as described below, it provides the same deflection as the continuous single wedge. Along with the need to accommodate both the slope and refractive index of the material, one must dimension the periods of the wedges such that they form 2π phase differentials (or multiples thereof, i.e., modulo 2π) at the operating wavelength to assemble continuous nonstaircased wavefronts in the near field. This is functionally analogous to the reflective blazed grating, in which high efficiency is achieved when the angle of specular reflection (from the sawtooth slopes of the grating surfaces) coincides with the angle of diffraction *at the selected wavelength.* Thus, an array formed of such 2π phase differentials exhibits dispersion which limits efficient performance to narrow spectral-band (near-monochromatic) operation. Work conducted to alleviate this limitation is discussed in if "Development of Phased Arrays" subsection.

The above examples provide continuous phase retardation by virtue of their linear surface slopes; incremental or continuous. Incremental phase retardation can be controlled in transmission by an array of small electro-optic cells, and in reflection by precise actuation of individual mirrored pistons. An array of refractive phase retarders and the assembly of the radiated wavelets into contiguous wavefronts is represented in Fig. 49*c*. Operation is similar with pistons, except that the reflective piston requires displacement of only half of the 2π phase-retardation distance. A thin electro-optic retarder having a reflective ground plane requires not only half thickness, but attains a

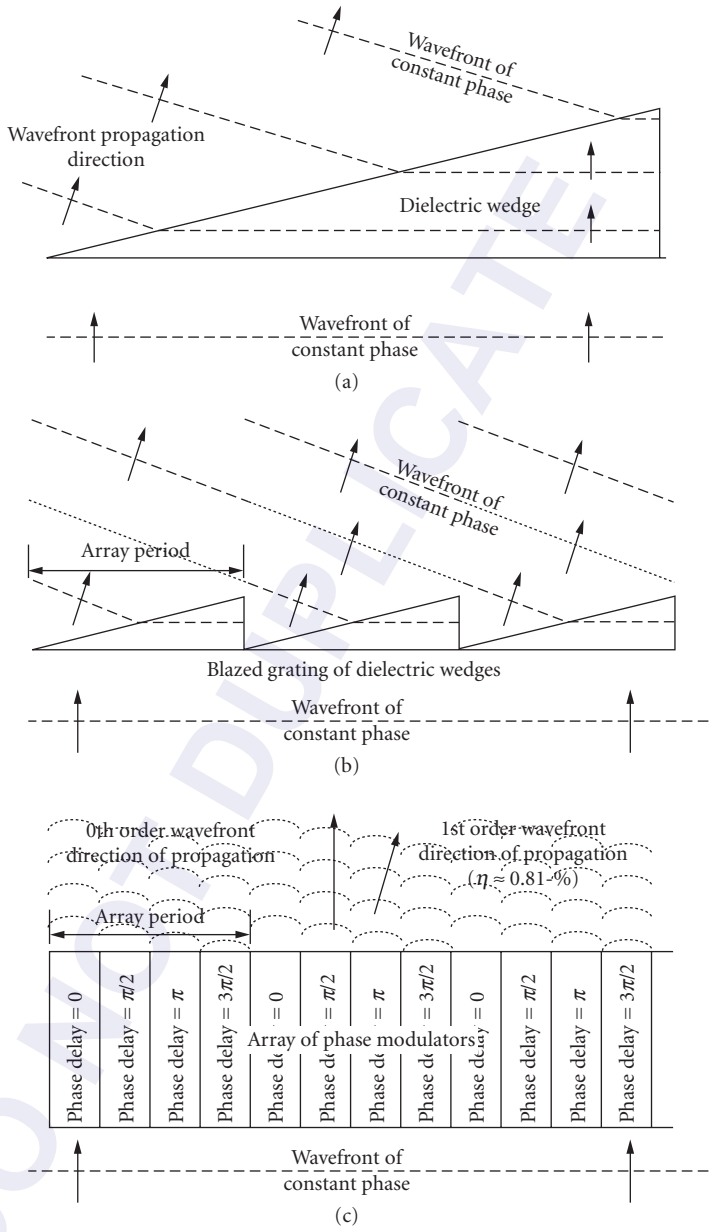

FIGURE 49 Illustrative steps (*a*, *b*, and *c*) toward optical-phased array beam steering. (Wavefront enters parallel to each bottom surface.) (*a*) Single dielectric wedge, illustrating familiar refraction of plane wavefront. (*b*) Synthesis of (*a*) with array of wedges. Each wedge imparts a 2π phase delay over each array period. (*c*) Synthesis of (*b*) with multiple delay elements (4 per 2π period). Output wavelets superpose into wavefronts having idealized efficiency of 81 percent. Greater multiplicity provides higher efficiency. (*After Refs. 84 and 87.*)

fourfold increase in switching speed which can be useful for a nominally slow liquid crystal retarder. An alternative option, shown in this figure, shows division of the full 2π phase change into four substeps per full cycle, which diffracts 81 percent of the energy into the first order. If more steps are available, then the diffraction efficiency is greater. For example, eight-step cycle attains an otherwise lossless efficiency of 95 percent. Figure 49 is a combination of three separated illustrations[84,87] to unify their progression.[74,85,86] The heuristic observations rendered above are affirmed by the considerations which follow.

The Analytic Base

The angular beam relationships of the phased array are expressed by the diffraction grating equation,[87]

$$\sin(\theta_i)+\sin(\theta_o)=n\lambda/\Lambda \tag{49a}$$

where θ_i and θ_o are the input and output beam angles with respect to the grating normal (boresight), n is the diffraction order, λ is the free space wavelength, and Λ is the grating (array) period, per Fig. 49*b* and *c*. As in Fig. 49*c* showing four delay elements per array period, for q delay elements, each separated by a fixed distance d, $\Lambda=qd$. Since the number of elements in each period is $q = 2\pi/\phi$, where ϕ is the phase shift between elements, then $\Lambda=(2\pi/\phi)d$ is the distance required to assemble a one-wave phase difference. When $\theta_i = 0$, the angle of first-order wave propagation (Fig. 49*c*) is given by

$$\sin\theta_o=\lambda/\Lambda \tag{49b}$$

$$=\lambda/qd=\lambda\phi/2\pi d \tag{49c}$$

The normalized intensity I of the radiation pattern follows the analogy of the one-dimensional microwave phased array[79] expressed as

$$I=(\sin N\alpha/N\sin\alpha)^2 \tag{50}$$

with

$$\alpha=\pi d/\lambda(\sin\theta-\sin\theta_o) \tag{51}$$

where θ is the angle with respect to the grating normal at which the field in free space is measured, and N is the number of phase shifters in the array. The elemental spacing d provides uniform phase difference ϕ between elements.

The efficiency η_q of a linear array having the nominal (blazed) 2π phase resets, illustrated in Fig. 49*b* and *c* is expressed by

$$\eta_q=\left(\frac{\sin\dfrac{\pi}{q}}{\pi/q}\right)^2=\operatorname{sinc}^2\frac{\pi}{q} \tag{52}$$

where q is number of elements per 2π array period. This may be recognized as similar to the Fourier transform[13] of a uniformly illuminated linear aperture.[87] Inserting values of q, i.e., 4 and 8, Eq. (52) yields $\eta_4 = 0.81$ and $\eta_8 = 0.95$, respectively, as indicated earlier. With a reduced q, lower efficiency results from depletion of the main lobe to the sidelobes due to wavefront staircasing.

Typical liquid crystal phase retarder elements exhibit a unique loss factor established by the minimum space required to relax its orientation from a 2π phase shift to zero. This "flyback" transition is analogous to the flyback time τ of many conventional scanners as expressed in Eq. (22) as $\eta = 1 - \tau/T$, where T is the full scan period. This represents a time loss burdening high-speed operation. The duty cycle for liquid crystal elements is given by

$$\eta_\Lambda = (1 - \lambda/\Lambda)^2 \tag{53}$$

where the time terms are replaced with λ representing the flyback width and Λ the full 2π width. The expression is squared to denote the radiated intensity rather than the time in Eq. (22), as illustrated by the solid line in Fig. 42. In addition, fill factor accounts for a cell having its operating portion occupy less than its full allotted area while the vignetting factor accounts for the loss of input illumination beyond the boundary of the array.

The far-field angular beamwidth θ_B is expressed as a minor variation to the familiar diffraction relation

$$\theta_B = a\lambda/D \tag{54a}$$

where a is the aperture shape factor[87] modifying the beamwidth, discussed in Sec. 30.3. With the full aperture width $D = Nd$,

$$\theta_B = a\lambda/Nd \tag{54b}$$

The Resolution of Phased Arrays

Equation (54) denotes the output beamwidth, that is the breadth of the principal lobe of radiation. For scanned resolution (Sec. 30.3), the number N of these adjacent lobes which fill the field-of-view along a linear track represents the number of phase-shifting calls in a linear phased array. Analogous to Eq. (4*a*),

$$\mathcal{N} = \theta/\theta_B \tag{55}$$

Half of the full deflected field angle θ is represented by the (positive) first diffracted order of grating [i.e., $n = +1$ in Eq. (49)]. When the array is addressed in complementary phase sequence, the same deflection magnitude results in the opposite ($n = -1$) direction. Thus, for typically small θ_o in Eq. (49) and with $D = \mathcal{N}d$, the numerator for Eq. (55) becomes

$$\theta = \frac{2\lambda}{qd} = \frac{2\lambda}{qD}\,\mathcal{N} \tag{56}$$

With $\theta_B = a\lambda/D$ providing the denominator of Eq. (55), and accounting for the central boresight position, the steered resolution reduces to

$$\mathcal{N} = 1 + \frac{2}{aq}\,\mathcal{N} \tag{57a}$$

which is independent of wavelength. Although Eq. (57) appears to differ from the fundamental Eq. (15) for scanned resolution, substituting Eq. (56) into the fundamental equation and adding one for the boresight beam yields Eq. (57).

With a as a relative constant, the ratio of the two variables $\mathcal{N}$ and q dominates the total number of elements divided by the number of elements per phase reset. Thus, the number of phase resets is the principal variable which determines the steered resolution and $\mathcal{N}/q = D/\Lambda$, where Λ is the array period. Since q is a parameter of the system, its adjustment also affects[88] the closeness of the adjacent steering states.

When a is unity, it denotes uniform illumination upon a rectangular aperture. This yields a far-field intensity distribution[89] of the $\text{sinc}^2(x)$ function having a main lobe within equispaced null

intervals. Rayleigh resolution requires this uniform illumination upon a rectangular aperture, and that the adjacent spots in the far field overlap such that the maximum of each main lobe coincides with the first null of each adjacent one. Further delimiting Eq. (57*a*) is that it is impractical to form a modulo 2π array in which q is less than three cells in view of the resulting disruption of the ramp wavefronts and the loss in efficiency. Letting $a = 1$ and setting $q_{\min} = 3$, the steered resolution is often expressed as an assumed Rayleigh resolution yielding

$$\mathcal{N}_{\max} = 1 + \frac{2}{3}\mathcal{N} \tag{57b}$$

A common illumination (laser) is the Gaussian function, with adjustment of the aperture overfill (and/or with complementary Gaussian filtering) to control the intensity distributed across the full aperture width W. The degree of overfill is, however, moderated by the reduction in light throughput due to aperture vignetting. As W is illuminated more uniformly, it may be limited by the appearance of fine structure beyond the main lobe when approaching the appearance of the sinc^2 function.

To quantify this value of a, different conditions can be considered[87] and tabulated, summarizing its value for the Gaussian beam of width D, either falling substantially within the aperture W (untruncated beam), or when the $1/e^2$ intensity of the input beam occurs at the aperture boundary (truncated beam). These are two typical illumination conditions of most conventional deflectors. For the rectangular aperture of width $W >$ height, illumination with a Gaussian beam primarily in the W or scan direction is further evaluated and tabulated (Table 5) providing data of current interest. A variable beam width D (at $1/e^2$ intensity) illuminates the full width W of a linear array. Assigning a parameter $\rho = \text{W/D}$, when $\rho = 1$, the $1/e^2$ beamwidth matches the full aperture width W. At $\rho = 1.5$, the array is 1.5 times wider than that of the $1/\text{e}^2$ beamwidth. This terminates the Gaussian function at $\pm 3\sigma$, where its intensity tapers to a small fraction of its maximum value, representing a practical limit on the narrowness of the input beam. At the other extreme, when $\rho \to 0$, the input beamwidth $D \gg W$, extracting near-uniform illumination from the center of the beam, and imposing extreme light loss beyond the aperture. This is the case of $a \to 1$. The aperture shape factors for the other two cases are determined; at $\rho = 1$, $a = 1.15$ and at $\rho = 1.5$, $a = 1.35$. Related to the topic of resolution is the *finesse* which is the smallest addressable increment of beam position. Consideration of this factor[87] involves (a potentially nonuniform) adjustment of the values of q (number of delay elements per array period).

Development of Phased Arrays

Work using nematic-phase liquid crystal electro-optic retarders is detailed comprehensively in a 1993 Air Force document.[86] The materials are known as types E7 and PTTP-33 liquid crystals, having birefringence $\Delta = (n_e - n_o) \approx 0.2$ in the infrared, requiring a cell be only 5 optical waves thick for a full-wave phase shift in transmission and only 2.5 waves thick in reflection. The thinner the cell, the shorter is its reorientation time. Switching speeds in the millisecond range with high-efficiency, diffraction-limited steering have been demonstrated at 10.6 pm with CO_2 lasers, and at 1.06 μm and 0.53 μm with Nd:YAG lasers. The cascading of tandem scanners by optical relaying[5] is a means for adding the contributions of two or more deflectors with each operating optimally. One-dimensional arrays may be compounded having one for azimuth and one for elevation. Also, individual deflectors requiring excessive spatial separation may be cascaded using relay optics to avoid walk-off of the beam from the second aperture by the action of the first deflector.[89]

Another approach to tandem arrays,[90] named discrete/offset cascade, reduces potential "noise" (beam artifacts) n in the instances of large quantization mismatches when cascading phase-delayed groups. Experiments have demonstrated improved overall diffraction efficiency, along with requiring a reduced number of control lines. (A similar approach was demonstrated with microlens arrays.[91]) Also significant is the use of an electro-optic phase retarder other than liquid crystal. The material selected was PLZT (lead lanthanum zirconate titanate) which exhibits a large electro-optic coefficient, broadband optical transmission, very fast switching, and good thermal stability,[92] and is a well-documented ceramic material, familiar in electro-optic modulation and deflection. Mirrored

piston-like phase adjustment is also reviewed,[76] and later work[93] describes both continuous phase change and binary phase shift.

Problems in broadband operation of phased arrays are reviewed[74] and early work was directed toward their solution.[94,95] A wavelength-independent phase shift is achieved by polarization modulation of chiral smectic liquid crystals (CSLC), providing action similar to the mechanical rotation of a waveplate. However, grating dispersion remains due to wavelength deviation from nominal 2π phase resets, rendering a variation in efficiency η_d similar to Eq. (52)

$$\eta_d = \text{sinc}^2 \varepsilon \tag{58}$$

where ε is the chromatic error due to mismatch of the nominal 2π phase reset. Not only is energy lost, but side-lobe amplitudes increase and nondiffracted components result in image blurring and interference from sources outside the desired acceptance angle. This dispersion is reduced with the application of achromatic Fourier transform optics,[96] as investigated in more recent comprehensive work,[97] yielding precautions regarding the ability to reduce dispersion completely and the difficulty in implementation of the technology. More conventional achromatic optics has been applied[98] to the decentered lens; the second of the two major techniques for agile beam steering which is discussed next.

The Decentered Lens and Microlens Arrays

The decentering of one lens with respect to a matching afocal lens is an alternative to the phased array described above. Although its basic action differs from the phased systems, when smaller lenses are formed into a mating periodic array, the assembly can exhibit some of the characteristics of phased arrays, including functioning as blazed gratings.[75] However, single lens-group operation can avoid some of the image faults of array steering as later discussed.

Consider Fig. 50*a* illustrating a pair of afocal lenses (denoted 1 and 2) oriented originally on a common axis, now with lens 2 shifted "downward" through a distance Δ (dotted axes). Beyond the focus of lens (left lens), the diverging beam continues into lens 2 shifted angularly off its axis, resulting in deflecting the recollimated output beam through an angle θ_o. Thus, a transverse shift of one lens with respect to the other affects beam steering. The vignetting of the output beam and the related diversion of its residual output flux outside the lens is discussed subsequently. Constraining this simple two-lens technique is its limitation on the width of the lens aperture, consistent with the energy required for rapid Δ shift within a reasonable burden on acceleration of its more massive components.

Consider combining many lens pairs like lenses 1 and 2 (maintaining the F) to form an array of microlenses, as illustrated in Fig. 50*b*, and illuminating the group from the left by a single broad beam. The steered waves sum into the total field in a manner similar to those of the prior phased arrays and similar to Fig. 49*b*. This results in a significant decrease in mass for a given full aperture size and a decrease in shift distance Δ for the same steered angle. The effect is a reduction in Δ and in the acceleration/deceleration forces required for rapid beam steering. Although the composite wavefront is discontinuous, the segments are tipped at the same slopes such that the output exhibits the characteristics of a blazed grating. When, at the operating wavelength their junctions exhibit 2π phase differentials, a sawtooth pattern is formed typified by a high-diffraction efficiency blazed grating. This technique is satisfactory for small steered angles, where high fill factors remain at the second lens array, and the spurious components are a small residue. At wider steering angles, however, when the vignetting and the disruptive effects of the spurious components become significant, remedies are required.

A classic method for the control of such vignetting is to include a field lens[99] into the microlens array.[75] Fig. 50*c* illustrates this as a variation of Fig. 50*a* with a field lens (FL) inserted at the common focal plane of the original two lenses. The bar over the output pair of lenses represents physical connection for simultaneous shift. With equal focal lengths for all lenses, the expanding light cone completely fills the lens pair during Δ shift. This technique for realizing output efficiency and spectral quality is directly transferrable to the microlens array of Fig. 50*b* with an added plane of field

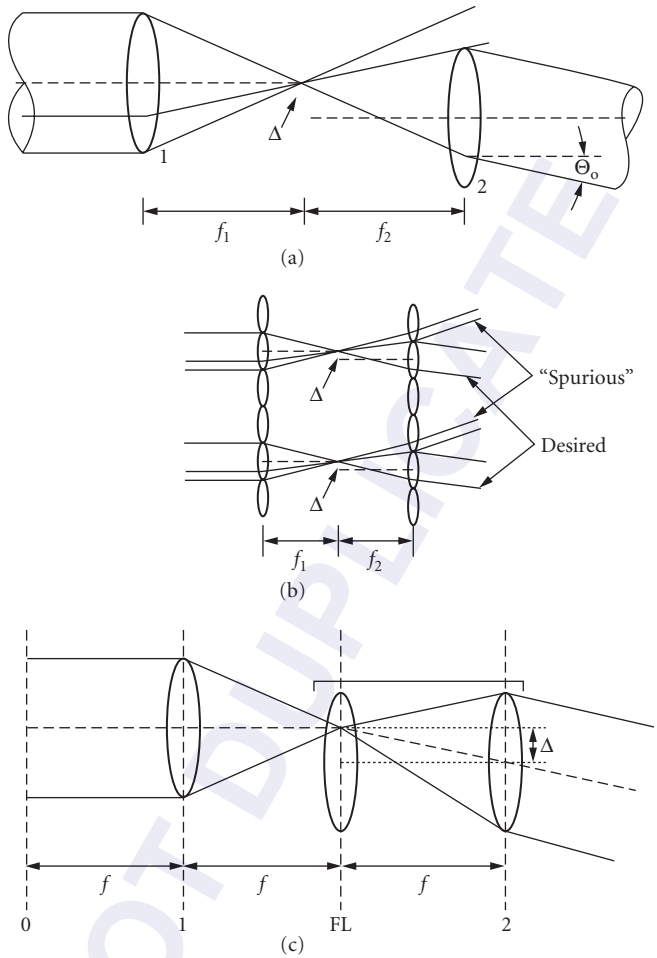

FIGURE 50 Beam steering with decentered lens of afocal pair shifted through distance Δ. (*a*) Single lens pair, showing Δ-shift deflecting major portion of output beam through angle Θ_o while upper portion of the beam by-passes lens 2. (*b*) Microlens arrays operating as in (*a*), but lighter and with smaller Δ-shift. The desired outputs accumulate, while the by-pass portions become spurious. (*c*) Field lens (FL) added to (*a*) provides constant filling of lens 2. When added to (*b*), the FLs maintain the wavefront synthesis of a blazed grating. (*After Refs.* 75 *and* 87.)

lenses affixed to the output array. The inertia can be accommodated by the force of piezoelectric or electrodynamic drive transducers. Alternatively, the single-element group may be shifted instead. A microlens-field lens design was fabricated and tested[100] over a ±1.6° field. Larger angles (±17°) have been demonstrated,[101] but with loss of beam quality.

Further consideration for reduction of the spurious beams during Δ shift is represented in Fig. 51. The method of Fig. 51*a* provides[75] some tolerance for beam displacement on lens 2 by changing the ratio of focal lengths. The initial condition of $f_1 = f_2$ is adjusted to $f_1/f_2 > 1$. This forms a beam compressor (see Fig. 32) with a compression ratio $\approx 2{:}1$. A similar approach is investigated[102] using

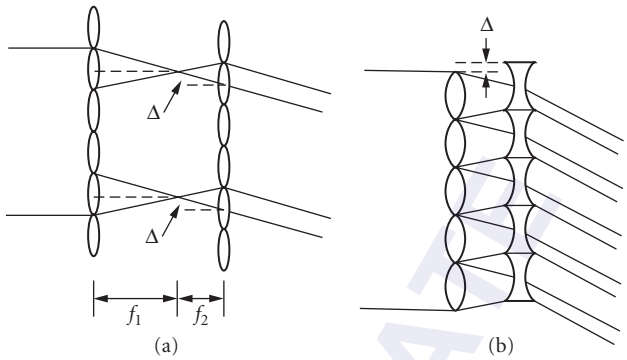

FIGURE 51 Elimination of spurious radiation over a range of operation with increased focal length ratio f_1/f_2. (*a*) Similar to Fig. 50 (*b*) with $f_1/f_2 \approx 2$. (*b*) Analogous galilean form with $f_1/f_2 \approx 2.5$ and the beam energy is conserved. However, the spaced output beams represent diffraction from a discontinuous blazed grating. (*After Refs. 75, 102 and 87*).

a positive-negative lens combination. Method in Fig. 51*a* employs the equivalent of a Keplerian telescope and method in Fig. 51*b* that of a Galilean telescope. While the spurious components of Fig. 50*b* may be abated over its initial range of operation, the fill factor at the second array is reduced. Although the energy is conserved in this reduced light cone, the ideal sawtooth pattern of the blazed grating is disrupted by the truncated sawtooth function. This, in turn, causes its own spurious noise[75,102] which limits operation to a small range of Δ shift. It is propsed[102] that the second array be maximally filled ideally by reducing the lens separation in Fig. 51*b* toward zero. Practically, this is approached with the development of thin binary optics microlens arrays. Binary forms of Fresnel zone patterns are fabricated utilizing high-resolution etching and transfer techniques formed on substrate materials. Hundred percent fill factors of lenslet arrays are attainable, approximating a continuous phase profile in a stepwise manner, to allow achievement of high diffraction efficiency. As presented earlier for a phased array composed of q elements per 2π phase reset [Eq. (52)], the efficiency η_b of a multilevel binary optic of m levels within one width of a Fresnel feature is given by[103] $\eta_b = \text{sinc}^2(1/m)$. An experimental system[102] utilized such arrays of F/5 microlenses; each having a 0.2 mm diameter. The second lenslet array was spaced from the first by 10 μm, allowing relative translation. This system steered a 6-mm HeNe beam over an 11.5° field using ±0.1-mm travel at a 35-Hz sweep rate. Practical mask alignment, etch errors, and transfer errors during fabrication reduced the 95 percent theoretical efficiency to 84 percent and 72 percent for the positive and negative lens arrays, respectively. Overall efficiency of the unsteered beam measured approximately 50 percent. The F/5 system exhibited low efficiency when steered. This is expected to improve with more precise fabrication and operation at lower F-numbers.

A variation to the above work was conducted using "phased-arraylike" binary optics.[77] A continuous quadratic phase function was sampled at equal intervals of Δx, forming a stepwise matching of the continuous phase profile. The Δ shifts are conducted in integral increments of Δx, where the formerly disruptive region is shown analytically to render a continuous linear phase profile across the full aperture. Experimental binary micro-optics were designed to compare phased-arraylike and microlens arrays, fabricated simultaneously and adjacent on the same quartz substrate. Tests confirmed that the phased-arraylike structure provided approximately. 50 percent increased intensity in the steered mode, and less than 1 percent leakage into the immediate (local) sidelobes. While stronger distant sidelobes developed, they were well separated from the steered mode.

As mentioned previously, achromatic optics applied to a single decentered lens system[98] reduces dispersion and allows operation in the 2 to 5 μm IR band. The prototype design of Fig. 50*c* was altered to avoid the high power intensity focus and its potential damage within the field lens FL.

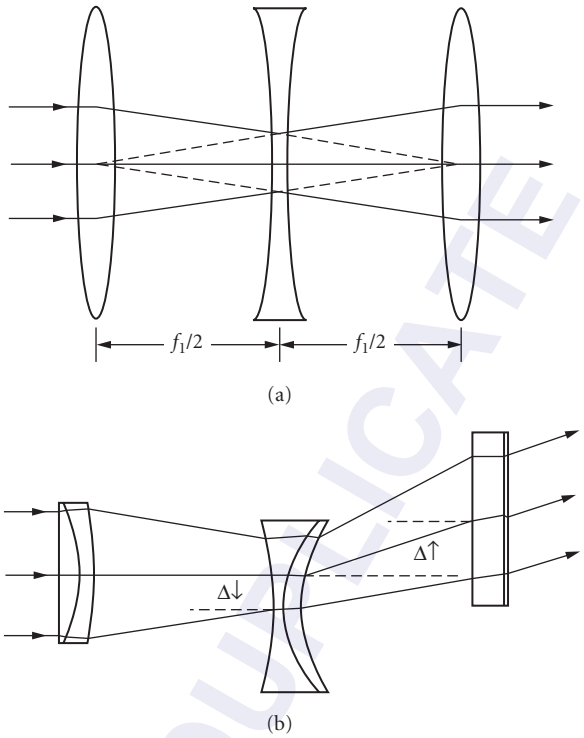

FIGURE 52 Adaptation for high power and achromatic operation. (*a*) Intense power at focus within the (positive) field lens FL of Fig. 50*c* is avoided by replacing it with a negative field lens (having 1/2 the focal length of the positive lenses). (*b*) System (to scale) achromatized and optimized for beam deflection of 22.5°. The field lens is shifted downward through distance $\Delta\downarrow$, while the output lens is shifted upward through the greater distance $\Delta\uparrow$. (*After Ref. 98.*)

Thus, per Fig. 52*a*, the positive field lens of Fig. 50*c* was replaced with a negative one, requiring a focal length one-fourth that of the positive lens. The system was achromatized and optimized for ±22.5° maximum deflection, as represented in Fig. 52*b*. The negative field lens and the output lens now require unequal and *opposite* shift directions to implement scan. The 60-mm diameter output lens requires ≈30 mm of Δ shift. This work demonstrated that for some systems, a single group of three cemented achromatic doublets enables eliminating several problems associated with microlens arrays, such as spurious diffraction, multiple beam orders, blind spots, and large dispersion while accommodating relatively wide scan angles.

Digital Micromirror Device

In 1987, the first digital micromirror device (DMD) was created at Texas Instruments.[104,105] Larry Hornbeck was granted the first patent for the DMD design in 1991.[106] This initial design was the basis for current digital micromirror device chips which were incorporated into digital light processing (DLP) projectors for both visible and infrared applications.[107–109,110] Although the DMD is an all-digital spatial light modulator (SLM) rather than the more traditional optical scanners of this

chapter, it is briefly discussed as it can be considered a binary-state scanner. Its impact on the display industry has been most significant.

A DMD is an array of "light switches" having a MEMS structure that is fabricated by using micromachining CMOS processes over a CMOS static random access memory (SRAM) integrated circuit.[110,111] Each light switch has an aluminum mirror that can reflect light in one of two directions depending on the state of the underlying memory cell. With the memory cell in the On state, the mirror rotates to +10°. With the memory cell in the Off state, the mirror rotates to −10°. By combining the DMD with a suitable light source and projection optics, the mirror reflects incident light either into or out of the pupil of the projection lens. Thus, the On state of the mirror appears bright and the Off state of the mirror appears dark. Gray scale is achieved by binary pulsewidth modulation of the incident light while color is achieved by using color filters, either stationary or rotating, in combination with one, two, or three DMD chips.

The DMD light switch is a MEMS structure consisting of a mirror that is rigidly connected to an underlying yoke. The yoke in turn is connected by two thin, mechanically compliant torsion hinges to support posts that are attached to the underlying substrate. Electrostatic fields developed between the underlying memory cell and the yoke and mirror cause rotation in the positive or negative rotation direction. The rotation is limited by mechanical stops to typically ±10°. The use of semiconductor and MEMS processing technologies allow production of very large arrays of these individually controllable micromirrors having minimal defects and high reliability.[112–114]

Gimbal-Less Two-Axis Scanning Micromirrors

Gimbal-less two-axis scanning-micromirror devices (GSMD) have been recently developed by Mirrorcle Technologies, Inc. and are based on multilevel beam silicon-on-insulator micro-electromechanical (SOI-MEMS) fabrication technology.[115] Due to their small scale and electrostatic actuation, these devices require ultralow power and can provide fast optical beam scanning in two axes when compared to the large-scale galvanometer-based optical scanners.[116] Laser beams can be deflected to optical scanning angles of up to 32° at very high speeds in both axes. Continuous full-speed operation of the electrostatic actuators that drive the GSMD dissipates less than 1 mW of power. These devices are made entirely of monolithic single-crystal silicon, resulting in excellent repeatability and reliability. The flat, smooth mirror surfaces can be coated with a thin film of metal with desired reflectivity. Larger mirrors can be bonded onto actuators for custom aperture sizes. In contrast to the two-state mirror movement of the DMD, the GSMD mirror movement is fully analog and can maintain a selected tilt angle or move dynamically upon command. At this time, huge arrays of micromirrors comprise typical DMD arrays, while GSMD arrays are presently limited to a few micromirrors; however, GSMD mirrors can be physically much larger than the DMD mirrors.

The GSMD are designed and optimized for point-to-point optical beam scanning mode of operation. A steady-state analog actuation voltage results in a steady-stage analog angle of rotation of the micromirror. Specifically, there is a one-to-one correspondence of actuation voltages and resulting angles that is highly repeatable. Positional precision in open-loop driving of the micromirrors is at least 14 bits, that is within 10 μrad. For a particular high-speed 3D tracking and position-measurement application, 16-bit precision has been demonstrated.[117] Devices can be operated over a very wide bandwidth from DC (they maintain position at constant voltage) to several kilohertz. Such fast and broadband capability allows nearly arbitrary waveforms such as vector graphics, constant velocity scanning, point-to-point step scanning, and the like.[118] The major advantage of the gimbal-less design is the capability to scan optical beams at equally high speeds in both axes. A typical GSMD with a 0.8-mm diameter micromirror achieves angular beam scanning of up to 600 rad/s and has first resonant frequency in both axes above 5 kHz. Devices with larger-diameter micromirrors are correspondingly slower due to the increased inertia.

The gimbal-less design combines one-axis electrostatic combdrive-based rotators,[115] and allows their operation to be nearly independent of the other axis' operation without the added inertia of a gimbal frame. A schematic diagram of the conceptual operation of the gimbal-less two-dimensional

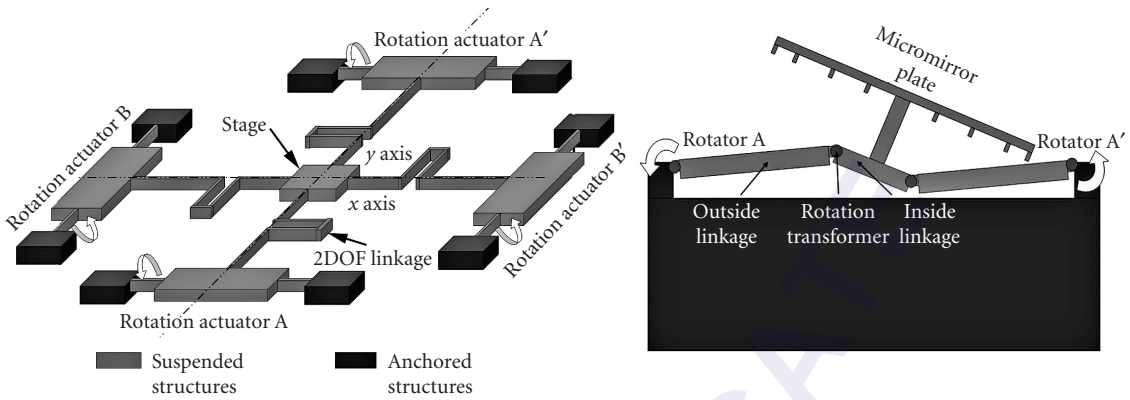

FIGURE 53 Schematic diagram of a gimbal-less two-axis scanning actuator based on four high aspect ratio rotators connected to the central pedestal by two degrees-of-freedom (2 DOF) linkages. Cross-sectional depiction of device operation.[116] (*Diagram courtesy of Mirrorcle Technologies, Inc.*).

designs is shown in Fig. 53. Two one-axis rotators are utilized for each axis of the overall two-dimensional scanner. For the *x* axis, actuators A and A′ are utilized, and for the *y* axis, actuators B and B′. The inside linkages are designed such that they allow torsion on the axis, specifically during the operation of the orthogonal axis. In other words, each linkage that connects a rotator to the central micromirror is actually designed to be a two degree-of-freedom component.

GSMD can also operate in the dynamic, resonant mode. When operated near the resonant frequency, devices give significantly more angle at lower operating voltages and sinusoidal motion. Resonant frequencies are in the range of several kilohertz, although in some cases one of the axes is made exceptionally stiff to achieve 16 kHz and faster actuation for video projection applications.[119]

The gimbal-less design lends itself inherently to a modular design approach, hence, several types of dual-axis actuator designs are available.[120] Each actuator can utilize rotators of arbitrary length, arbitrarily stiff linkages, and arbitrarily positioned mechanical rotation transformers. In addition, the GSMD can have an arbitrarily large mirror diameter. Because of modularity, these devices can be customized for the requirements of a particular application.

Silicon mirrors of up to 1.2 mm diameter can be fabricated as an integral (monolithic) part of some GSMDs. Due to the limitations of the fabrication steps of the actuator, the standard mirrors are relatively thick (24 μm.) The inherent properties of the single crystal silicon substrate yield a polished surface with nearly perfect flatness. Larger and customizable mirror sizes and shapes can be utilized by fabricating those separately and assembling them on top of gimbal-less actuators. A SEM image of a 2-mm diameter bonded mirror on an actuator is shown in Fig. 54. Sets of electrostatic actuators optimized for speed, angle, area footprint, or resonant driving are designed and realized in a self-aligned deep reactive ion etching (DRIE) fabrication process.[121] Metalized, ultralow inertia, single crystal mirrors stiffened by a backbone of thicker silicon beams (see Fig. 53) are created in a separate fabrication process. The diameter, as well as geometry, of the mirror is selected by customers, in order to optimize the trade-offs between speed, beam size, and scan angle for each individual application. The mirrors are subsequently bonded to the actuators. The modular approach allows either the absolute optimization of a device prior to fabrication, or the ability to economically adapt a small set of fabricated devices for a wide range of applications. Larger sizes up to 3.6 mm are regularly assembled in experiments and applications.

Summary of Agile Beam Steering

Two basic methods for low-inertia laser beam steering are presented: the phased array and the decentered lens. Although their operating principles differ, as arrays, they both form diffraction

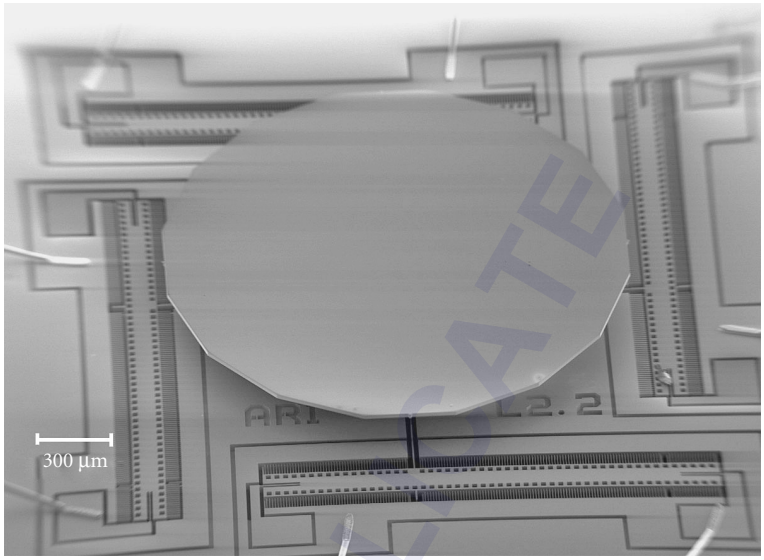

FIGURE 54 SEM image of a 2.0-mm diameter micromirror bonded to dual-axis actuators. (*Photograph courtesy of Mirrorcle Technologies, Inc.*)

gratings yielding output wavefronts having the properties of a blazed grating. While this results in high diffraction-efficiency at a selected wavelength, typical grating dispersion limits broadband operation. Complicating corrective measures have been applied to both array systems to approach broadband operation. The single decentered lens group avoids array dispersion. And, if its increased size and inertia can be tolerated, lenticular dispersion remains controllable with familiar achromatizing techniques. The dominant phased arrays are completely electro-optic, while the microlens array requires very small translations of reasonably low inertia assemblies. An alternative phased array utilizes individual micromirrors requiring minute ($\lambda/4$) *axial* displacements. However, difficulty may be encountered in fabrication of high optical-integrity and in providing the high optical-fill-factor of the electro-optic types. Another alternative microlens array is formed of Fresnel-lens-type binary optics. For low F-number lenticules, whose theoretical steering efficiency is high, their minimum feature sizes become miniscule and presently are difficult to fabricate.

Auxiliary control facilities can impose burdens of mass, volume, and cost. Phased arrays utilize complex multielement electrical programming, while the lens arrays require small but very precise positioning of their assemblies. Though such additional requirements are generally not detailed in the literature, a comparative analysis[121] provided some related observations. The authors preferred a microlens array over the liquid crystal phased array, thereby avoiding the "heavy burden" on electronic control of the many phase-delay elements. An *x-y* microlens array system was designed and built for test, and was compared to a two-galvanometer *x-y* system assembled of commercial components. Evaluations confirmed that the microlens system steered faster, consumed lower power, and packaged smaller and lighter. However, no comment appeared on design to minimize mirror inertia and to reduce the bulk of the components and their assembly. Nor was *x-y* relay optics[5] considered to allow minimum-sized mirrors serve to reduce inertia. Also, meriting evaluation is the *single mirror* suspended and actuated in *x-y* for precise two-dimensional scan.[122,123] Such diverse considerations are invaluable for rating design alternatives for their relative compliance to system requirements.

Glasgow, United Kingdom

31.1 GLOSSARY

A_{ba}	Einstein coefficient for spontaneous emission
a_o	Bohr radius
B_{if}	Einstein coefficient for transition between initial state $\|i\rangle$ and final state $\|f\rangle$
e	electron charge
ED	electric dipole term
E_{DC}	Dirac Coulomb term
E_{hf}	hyperfine energy
E_n	eigenvalues of quantum state n
EQ	electric quadrupole term
$\mathbf{E}(t)$	electric field at time t
$\mathbf{E}(\omega)$	electric field at frequency ω
g_a	degeneracy of ground level
g_b	degeneracy of excited level
g_N	gyromagnetic ratio of nucleus
h	Planck's constant
H_{so}	spin-orbit interaction Hamiltonian
I	nuclear spin
$I(t)$	emission intensity at time t
$\mathbf{j}$	total angular momentum vector given by $\mathbf{j} = \boldsymbol{l} \pm 1/2$
l_i	orbital state
m	electron mass
MD	magnetic dipole term
$n_\omega(T)$	equilibrium number of photons in a blackbody cavity radiator at angular frequency ω and temperature T

QED	quantum electrodynamics
$R_{nl}^{(r)}$	radial wave function
R_∞	Rydberg constant for an infinitely heavy nucleus
s	spin quantum number with the value 1/2
s_i	electronic spin
T	absolute temperature
W_{ab}	transition rate in absorption transition between states a and b
W_{ba}	transition rate in emission transition from state b to state a
Z	charge on the nucleus
$\alpha = e^2/4\pi\varepsilon_0\hbar c$	fine structure constant
$\Delta\omega$	natural linewidth of transition
$\Delta\omega_D$	Doppler width of transition
ε_o	permittivity of free space
$\zeta(r)$	spin-orbit parameter
μ_B	Bohr magneton
$\rho(\omega)$	energy-density at frequency ω
τ_R	radiative lifetime
ω	angular frequency
ω_k	mode k with angular frequency ω
$\langle f \vert V' \vert i \rangle$	matrix element of perturbation V

31.2 INTRODUCTION

This chapter outlines the physical basis of optical measurements in the wavelength/frequency and time domains. From the multiplicity of different apparatus, only simple examples are given of spectrometers designed for optical absorption, photoluminescence, and radiative decay measurements. Rather more detailed expositions are given of modern developments in laser spectrometers especially where high resolution is possible in both frequency and time domains. Included are specific developments for linewidth measurements down to tens of kilohertz using saturated absorption techniques as well as temporal decay characteristics in the sub-picosecond domain. A description is also given of a multiple resonance spectrometer including optically detected electron spin resonance and optically detected electron nuclear double resonance.

31.3 OPTICAL ABSORPTION SPECTROMETERS

General Principles

In optical absorption spectroscopy, electromagnetic radiation in the near-ultraviolet, visible, or near-infrared regions is used to excite transitions between the electronic states. Whereas atoms in low-pressure gas discharges exhibit very sharp lines, electronic centers in molecules and condensed matter display a variety of different bandshapes. In consequence, the absorbed intensity is a function of the photon wavelength (or energy). The most desirable experimental format plots the absorption coefficient α as a function of the radiation frequency ν, because ν is directly proportional to the energy separation between the states involved in the transition. Nevertheless, optical

spectroscopists quote peak positions and linewidths in energy units E (eV, meV), in wave numbers $\bar{\nu}$ (in cm^{-1}), in frequency units (ν or ω), or in wavelength λ [nanometers (nm) or micrometers (μm)]. The following approximate relationships exist: $1\ cm^{-1} = 1.24 \times 10^{-4}$ eV; 1 eV = 8066 cm^{-1}; and $E(\text{eV}) = 1.24/\lambda\ (\mu\text{m})$.

Very often the spectrometer output is given in terms of the specimen transmission, $T = I(\nu)/I_o(\nu)$ expressed as a percentage, or the optical density (or absorbance), $\text{OD} = \log_{10}(1/T)$, which are related to the absorption coefficient α by

$$\text{OD} = \log_{10}(1/T) = \alpha(\nu)l/2.303 \tag{1}$$

where l is the thickness of the sample. Typically one measures the absorption coefficient α over the wavelength range 185 to 3000 nm. Since α may be a function of both frequency ν and polarization $\hat{\varepsilon}$, we may use the designation $\alpha(\nu, \hat{\varepsilon})$. For a center containing N noninteracting absorbing centers per unit volume, each absorbing radiation at a frequency ν and polarization $\hat{\varepsilon}$, the attenuation of a beam of intensity $I_o(\nu, \hat{\varepsilon})$ by a solid of thickness l is given by

$$I(\nu, \hat{\varepsilon}) = I_o(\nu, \hat{\varepsilon}) \exp[-\alpha(\nu, \hat{\varepsilon})l] \tag{2}$$

Experimentally $I_o(\nu, \hat{\varepsilon})$ represents the transmission of the system in the absence of an absorbing specimen. In practice $I_o(\nu, \hat{\varepsilon})$ and $I(\nu, \hat{\varepsilon})$ are measured and the value of the absorption coefficient $\alpha(\nu, \hat{\varepsilon})$ at a particular frequency is obtained using the formula

$$\alpha(\nu, \hat{\varepsilon}) = \frac{1}{l} \ln \frac{I_o(\nu, \hat{\varepsilon})}{I(\nu, \hat{\varepsilon})} \tag{3}$$

$\alpha(\nu, \hat{\varepsilon})$ has units of cm^{-1} or m^{-1}. The variation of the absorption coefficient with frequency is difficult to predict. In general, the absorption transition has a finite width, and the absorption strength, $\int \alpha(\nu, \hat{\varepsilon}) d\nu$, is related to the density of absorbing centers and to the transition probability.

The value of the absorption coefficient in an isotropic material is related to the Einstein A coefficient for spontaneous emission by[1]

$$\alpha(\nu) = \left(N_a \frac{g_b}{g_a} - N_b \right) A_{ba} \frac{c^2}{8\pi\nu^2} \frac{1}{n^2} G(\nu) \tag{4}$$

where g_a and g_b are the statistical weights of the states, $G(\nu)$ is the lineshape function [defined such that $\int G(\nu) d\nu = 1$], c/n is the velocity of light in the medium, and n is the refractive index. In Eq. (4), the population densities in the ground and excited states, N_a and N_b, respectively, have been assumed to be invariant with time and unaffected by the absorption process. Under conditions of weak excitation we can ignore the small value of N_b, and replace N_a by N so that

$$\alpha(\nu) = N A_{ba} \frac{c^2}{8\pi\nu^2} \frac{1}{n^2} \frac{g_b}{g_a} G(\nu) = N\sigma G(\nu) \tag{5}$$

where σ is the *absorption cross section per center*. The absorption strength, i.e., the area under the absorption band, is related to σ by

$$\int \alpha(\nu) d\nu = N\sigma \tag{6}$$

If we ignore the refractive index and local field correction factors and assume a gaussian-shaped absorption band, then

$$Nf_{ab} = 0.87 \times 10^{17} \alpha(\nu_o) \Delta\nu \tag{7}$$

where $\alpha(\nu_o)$ is measured in cm^{-1}, $\Delta\nu$, the full-width at half maximum absorption, is measured in eV, and N is the number of centers cm^{-3}. Equation (7) is often referred to as *Smakula's formula*. To obtain the oscillator strength from the area under the absorption band, one needs an independent determination of the density of centers. For impurity ions in solids, N may be determined by chemical assay or by electron spin resonance.

The Double-Beam Spectrophotometer

The first essential of an absorption spectrophotometer is a broadband source: deuterium, hydrogen, xenon, and tungsten lamps are commonly used. Their outputs cover different wavelength ranges: a hydrogen lamp is suitable for wavelengths in the range 150 to 350 nm whereas high-pressure xenon lamps have usable light outputs in the range 270 to 1100 nm. For Xe arc lamps the output is relatively continuous in the wavelength range 270 to 800 nm apart from some sharp lines near 450 nm. In the infrared region 800 to 1100 nm, much of the most intense part of the output is in the form of sharp lines. In the arc lamp, radiation is due to the collision of Xe atoms with electrons which flow across the arc. Complete separation of the excited electrons from the atoms leads to ionization and the continuum output. The formation of Xe atoms in excited states leads to the sharp lines in the output from Xe arc lamps. Tungsten filament lamps may also be used in absorption spectrophotometers. The spectral output from such a heated filament is approximately that of a blackbody radiator at a temperature of 2000 K. In consequence, the emission intensity is a smooth function of wavelength with peak at 1500 nm, with the detailed curve following Planck's thermal radiancy law. Accordingly, the peak in the distribution of light varies with filament temperature (and therefore current through the filament), being determined by $\lambda_{max} T = 2.898 \times 10^{-3}$ mK. This relationship expresses Wien's wavelength displacement law. Although containing all wavelengths from the ultraviolet into the infrared region, the total output is fairly modest compared with a high-pressure mercury lamp.

Accurate measurements of the absorption coefficient at different wavelengths are best made using a double-beam spectrophotometer: a schematic is shown in Fig. 1. The exciting beam from the broadband source passes through a grating monochromator: the resulting narrow band radiation is divided by a beam-splitting chopper into separate monochromatic beams which traverse the sample and a reference channel. Thus the light incident on the sample and that which passes through the reference channel have the same wavelengths and is square-wave modulated (on/off) at some frequency in the range 1 to 5 kHz. The sample and reference beams are recombined at the phototube, and the magnitude and phase of sample and reference signals are amplified and compared by the lock-in detector. Chopping at a preselected frequency permits narrowband amplification of the detected signal. Thus any noise components in the signal are limited to a narrowband centered at the chopping frequency. The dc output from the lock-in detector is plotted as a function of wavelength using a pen recorder. Alternatively, the signal may be processed using a microcomputer, so that the absorbed intensity may be signaled as the transmission, the optical density [Eq. (1)], or the absorption coefficient [Eq. (3)] of the sample as a function of wavelength λ, wave number $\bar{\nu}$, or photon energy ($E = h\nu$).

Ensuring a high light throughput in both sample and reference channels usually limits the resolution of the monochromator used in the spectrophotometer (Fig. 1). In consequence, very narrow absorption lines, $\Delta\lambda < 0.1$ nm, are normally broadened instrumentally. Note that because in an absorption spectrophotometer one measures the light transmitted by the sample relative to that transmitted by the reference chamber [Eqs. (2) and (3)], the absorption coefficient is independent of the spectral dependencies of the lamp, the monochromator, and the detection system.

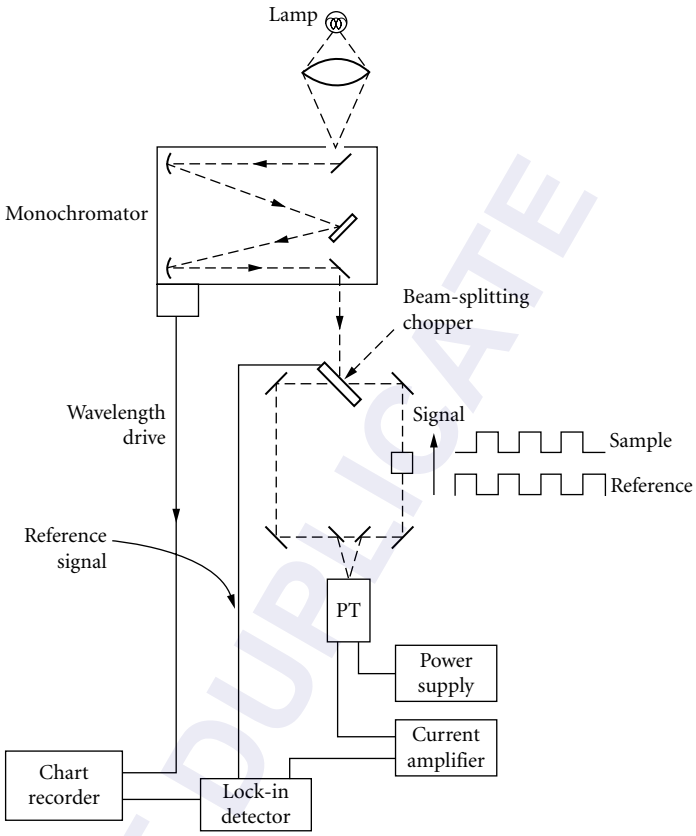

FIGURE 1 Block diagram of a dual-beam absorption spectrometer.

The measurement is also independent of the polarization properties of the monochromator system. By taking ratios, many nonideal behaviors of the components cancel.

31.4 LUMINESCENCE SPECTROMETERS

General Principles

To study luminescence it is necessary to optically pump into the absorption spectrum using high-intensity sources. Typical sources used in luminescence spectroscopy, which have broadbands in near ultraviolet and blue regions, include hydrogen and xenon arc lamps. The xenon arc lamp is particularly useful for exciting luminescence in the yellow-red region of the spectrum since xenon does not show interfering sharp line emission in this region. In general, high-pressure mercury (Hg) arc lamps have higher intensities than Xe arc lamps. However, the intensity is concentrated in sharp lines. Consequently, such lamps are utilized mainly with broadband absorbers or in situations that permit the individual lines to suit the absorption lines of the particular sample. In addition, a variety of lasers may be used, including Ar^+, Kr^+, He-Ne, and He-Cd lasers which have emissions at fixed wavelengths. Tunable dye lasers can be selected to closely match the absorption bands of particular

materials. Because of their low intensity, tungsten filament lamps are not normally used in luminescence spectrometers.

The light emitted is resolved into its component lines/bands using a monochromator. For medium resolution a 1-m Czerny-Turner monochromator will give a spectral resolution of about 0.02 nm. An order of magnitude lower resolution can be achieved using a grating spectrometer with focal length 0.25 m. The light emerging from the monochromator is detected using an electron multiplier phototube with associated high-voltage power supplies. Gallium arsenide phototubes operate with good quantum efficiency in the range 280 to 860 nm. For measurements in the near-infrared, a lead sulphide cell, cooled germanium photodetector, or special III-V compound photodiode may be used. Under steady-state optical pumping, a steady-state luminescence output is obtained and detected as a photocurrent which is amplified and converted to a voltage signal to be displayed on a pen recorder. Luminescence detection is inherently more sensitive than absorption measurements and sensitivities of 10^{11} centers cm^{-3} are routine.

Ideally, the excitation source should yield a constant light output at all wavelengths, the monochromator must pass all wavelengths with equal efficiency, and be independent of polarization. In addition, the detector should detect all wavelengths with equal efficiency. Unfortunately, such ideal light sources, monochromators, and phototubes are not available and it is necessary to compromise on the selection of components and to correct for the nonideal response of the luminescence spectrometer. Generally, luminescence spectra are recorded by selecting the excitation wavelength which results in the most intense emission and then scanning the wavelength of the emission monochromator. In consequence, techniques must be developed to allow for the wavelength-dependent efficiency of the emission monochromator and photomultiplier tube. This is not required in absorption spectrophotometers where the ratio of $I(\nu, \hat{\varepsilon})|I_o(\nu, \hat{\varepsilon})$ are used to compute the values of $\alpha(\nu, \hat{\varepsilon})$ from Eq. (3).

Modern spectrometers use diffraction gratings in monochromators rather than prisms. This results in less interference from stray light and in greater dispersion. Stray light may also be reduced using narrow entrance and exit slits as well as double monochromators (i.e., monochromators incorporating two gratings). Nevertheless, the transmission efficiency of the grating monochromator is a strong function of wavelength, which can be maximized at any given wavelength by choice of the blaze angle: the efficiency is less at other wavelengths as Fig. 2 shows. The stray light levels are to some extent controlled by exit and entrance slits. Smaller slit widths also yield higher resolution as do gratings with greater numbers of grooves per unit area. The efficiency of a grating monochromator also depends upon the polarization of the light. For this reason, the observed fluorescence intensities can be dependent upon the polarization of the emitted radiation. A typical plot of the

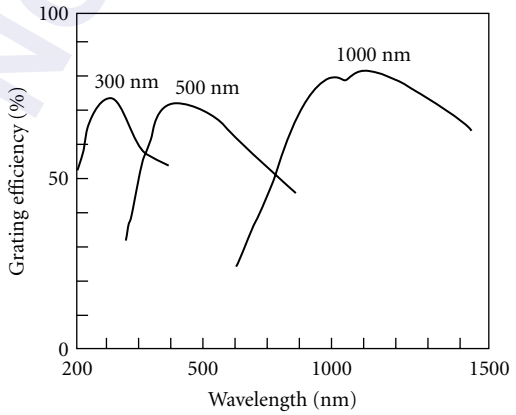

FIGURE 2 Showing how the grating efficiency varies with wavelength for gratings blazed at 300, 500, and 1000 nm.

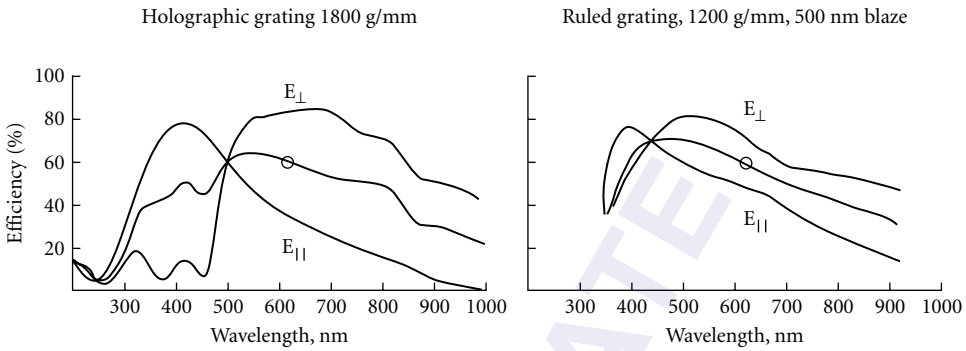

FIGURE 3 Showing the effect of polarization on the efficiency of a ruled grating with 1200 grooves/mm and blazed at 500 nm.

wavelength dependence of the efficiency of a ruled grating as a function of polarization is shown in Fig. 3. As a consequence, the emission spectrum of a sample can be shifted in wavelength and altered in shape by the polarization properties of the monochromator. In modern spectrometers the monochromators can be calibrated using standard lamps and polarizers, the information stored in the memory of the control computer, and the detected intensities corrected at the data processing stage of the experiment. Most manufacturers also provide data sheets describing monochromator performance, and use can be made of such data for approximate corrections to the measured spectra.

Care must be taken with polarization anisotropy measurements. Thin-film polarizers have absorption properties which are strongly wavelength-dependent. Precise corrections can be made using computer-controlled facilities with provision for computerized data processing. However, it is preferable to use a Glan-Thompson prism made from quartz or calcite which has good transparency from the ultraviolet into the infrared. Furthermore, the polarization properties are not wavelength-dependent.

In general terms, the light signal is detected using a photomultiplier tube in which the photon flux produces an electrical current that is proportional to the light intensity. The basis of the device is the photoelectric effect. Incident photons cause photoelectrons to be emitted from a photocathode with an efficiency dependent upon the incident wavelength. The photocathode is held at a high negative potential of 1000 to 2000 V. The photoelectrons are incident upon a series of dynodes which are also held at negative potentials in order to accelerate electrons toward the next dynode. Each photoelectron arriving at the first dynode chain causes the ejection of a further 10 to 20 electrons, depending on the voltage difference between photocathode and first dynode. This process of electron multiplication and consequent current amplification continues down the dynode chain until a current pulse arrives at the anode. Although the photomultiplier tube responds to individual photons, the individual current pulses are generally detected as an average signal.

The anode current must be directly proportional to the light intensity. However, at wavelengths longer than the work function of the photocathode, the photomultiplier tube is no longer sensitive to the incident photons. Thus, different photocathodes are used in different wavelength ranges. For phototubes used in the ultraviolet region, quartz windows are used. For the ultraviolet-visible region (200 to 550 nm) a K-Cs bialkali photocathode may be used; such devices have high quantum efficiency, up to 25 percent between 350 to 500 nm, high gain, and low dark current. Typically, the operating anode currents are of the order of a few microamps, whereas the dark current is in the nanoamp range. A somewhat more useful device, in that the quantum efficiency is almost constant from 300 to 860 nm, uses a GaAs photocathode. For longer wavelength operation, 800 to 1250 nm, a germanium photodiode may be used. In other words, spectroscopic studies over a wide wavelength range may require several different photodetectors to be used. Techniques for correcting for the nonideal wavelength-dependent properties of the monochromator, polarizers, and photomultiplier tubes have been described at length by Lackowicz.[2]

Luminescence Spectrometers Using Phase-Sensitive Detection

Where phase-sensitive detection techniques are used, the excitation intensity is switched on and off at a certain reference frequency so that the luminescence intensity is modulated at this same frequency. The detection system is then set to record signals at the reference frequency only. This effectively eliminates all noise signals except those closely centered on the modulation frequency. A typical luminescence spectrometer is shown in Fig. 4. The pumping light is modulated by a mechanical light chopper operating at frequencies up to 5 kHz. A reference signal is taken from the chopper to one channel of a lock-in detector. The magnitude and phase of the luminescence signal is then compared with the reference signal. Because of the finite radiative lifetime of the emission and phase changes within the electronics, the luminescence signal is not in phase with the reference signal. Hence, to maximize the output from the lock-in detector, the phase control of the reference signal is adjusted until input (luminescence) and reference signals to the lock-in detector are in phase. Of course, the phase of the reference signal may also be adjusted so that reference and luminescence signals are in quadrature giving zero output from the lock-in. This method of phase adjusting may enable one to separate the overlapping luminescence bands from different centers. In such experiments, the chopping frequency is adjusted so that there is an appreciable reduction in the luminescence intensity during the "off" half-cycle. This effectively puts an upper limit on the rate at which the lock-in system can operate.

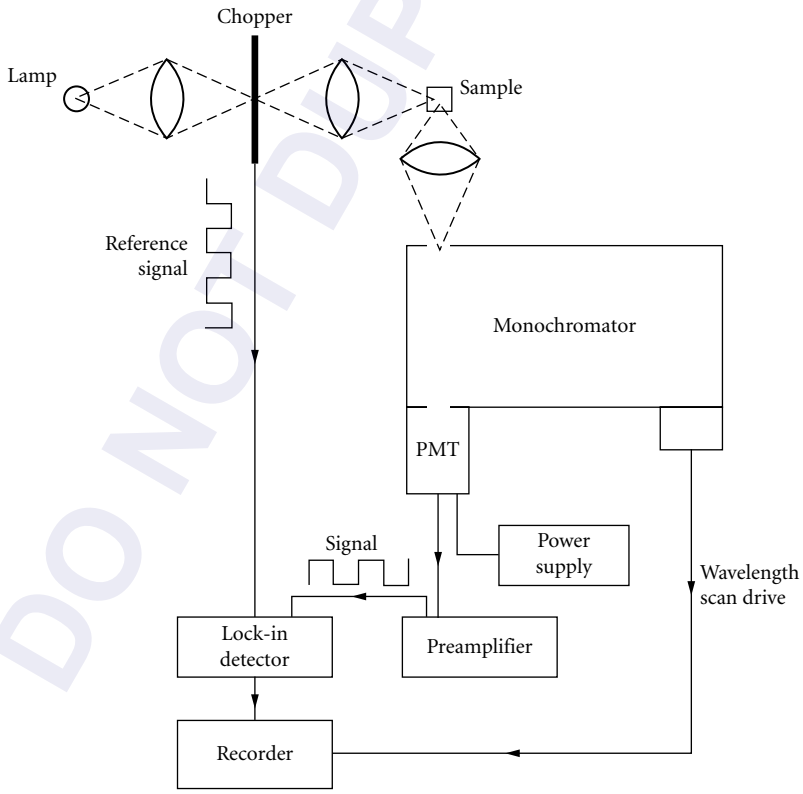

FIGURE 4 Schematic of a spectrometer for measuring luminescence spectra by phase-sensitive detection techniques.

The use of a mechanical chopper restricts the maximum modulation frequency to 5 kHz. Essentially, the mechanical chopper consists of a rotating blade of metal into which slots are cut at regular angular intervals. When the excitation beam is incident on the metal section, the excitation intensity at the sample is zero, and when on the slot, the sample receives the full intensity in the excitation beam. If the blade is rotated at a frequency of 1 Hz and there are n slots cut in the blade, then the excitation beam is essentially switched on/off at a rate of n Hz. Obviously, the modulation rate can be increased either by increasing the number of slots cut in the blade and/or by increasing the revolution rate. If the excitation is well-focused onto the chopper, then the modulation is in the form of a square wave with maximum modulation index $M = 1$.

Other modulators impose sinusoidal variations in the excitation intensity, at frequencies up to 50 MHz.[2] There are various means for providing sinusoidal intensity variations, including Kerr cells and Pockels cells. Both types require high electric fields to obtain the desired modulation and such high driver voltages may interfere with the detection of weak signals. Kerr cells do not transmit ultraviolet light and so may only be used in the visible/near-infrared region. The Pockels cells may be used in the ultraviolet region as well as at visible and infrared wavelengths. They may also be operated at variable frequencies. However, since they require highly collimated light sources for efficient operation, they require a laser for excitation. The ultrasonic Debye-Sears modulator overcomes the experimental difficulties associated with both Pockel cells and Kerr cells. A vibrating quartz crystal is used to set up standing waves in a tank containing an ethanol-water mixture. (The crystal restricts the device to operate at the fundamental and one or two harmonic frequencies only.) The standing waves act as a closely spaced refractive index diffraction grating normal to the incident exciting radiation. A slit permits only the undiffracted light to pass to the sample. The result is a sinusoidally varying light intensity with about 50 percent modulation index.

The emission signal is forced to respond to the modulated excitation at the same circular frequency ω as the excitation. However, the detected emission signal is delayed in phase by an angle ϕ relative to the excitation, and with reduced modulation depth. The radiative lifetime may be calculated from the measured phase angle ϕ and demodulation factor m. For a single exponential decay the appropriate relations are[3]

$$\tan\phi = \omega\tau_R \tag{8}$$

and

$$m = \left[1 + \omega^2\tau_R^2\right]^{-1/2} \tag{9}$$

Even with more complex processes, where several decaying species are present, phase angles and demodulation factors can be measured and used to calculate actual lifetimes.[3,4]

Phase-sensitive detection techniques may also be used to "time-resolve" overlapping absorption/luminescence spectra with different decay characteristics. The phase-sensitive detector (PSD) yields a direct-current signal proportional to the modulated amplitude and to the cosine of the phase difference between the detector phase ϕ_D and the signal phase ϕ, i.e.,

$$I(\lambda, \phi_D) = m_s I_o(\lambda)\cos(\phi_D - \phi) \tag{10}$$

where λ is the wavelength, $I_o(\lambda)$ is the steady-state excitation intensity, and m_s is the source modulation index. Now suppose that there are two components A and B with lifetimes $\tau_A < \tau_B$. The modulated emission measured with the PSD results in an unmodulated signal given by

$$I(\lambda, \phi_D) = m_s^A I_o^A(\lambda)\cos(\phi_D - \phi_A) + m_s^B I_o^B(\lambda)\cos(\phi_D - \phi_B) \tag{11}$$

If the phase-control of the PSD is adjusted so that $\phi_D = \phi_B + 90°$, then the second term in Eq. (11) is zero, and the output intensity is given by

$$I(\lambda, \phi_D) = m_s^A I_o^A(\lambda) \sin(\phi_B - \phi_A) \tag{12}$$

In other words, the emission output from species *B* has been suppressed. Species *A* can be suppressed at the detector phase angle $\phi_D = \phi_A + 90°$. If we now scan the wavelength, then the consequence of Eq. (12) is that the steady-state spectrum of species *A* is recorded, i.e., $I_o^A(\lambda)$, and conversely for species *B*.

In the example given in Fig. 5*a*, the steady-state fluorescence of a mixture of indole and dimethylindole dissolved in dodecane is shown.[5] With the detector phase angle set to 90°+9.7 and using a modulation frequency of 10 MHz in Fig. 5*b*, we resolve the indole emission with wavelength maximum at 306 nm. The phase angle of 9.7° corresponds to a radiative lifetime close to the isolated

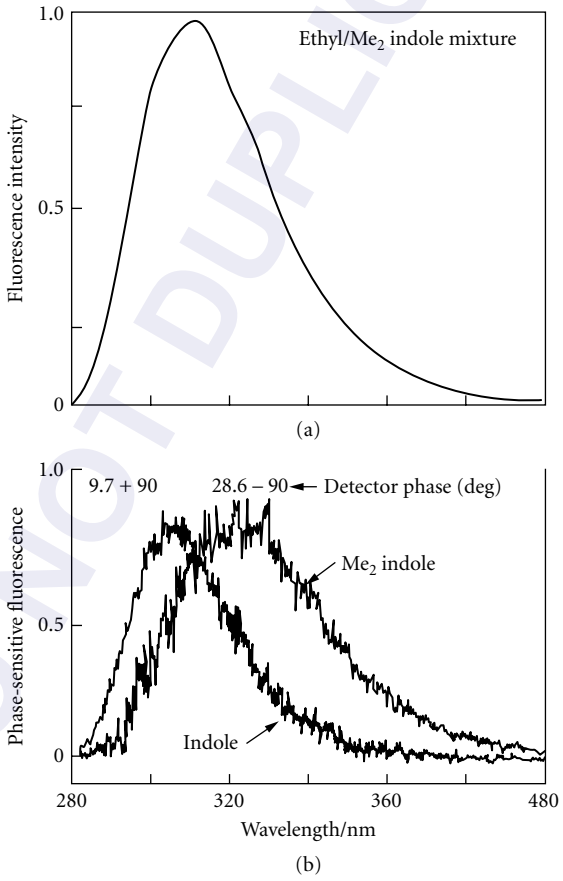

FIGURE 5 (*a*) Steady-state emission spectra of a mixture of indole and dimethylindole in dodecane and (*b*) shows the phase-resolved spectra of the indole and dimethylindole.[5]

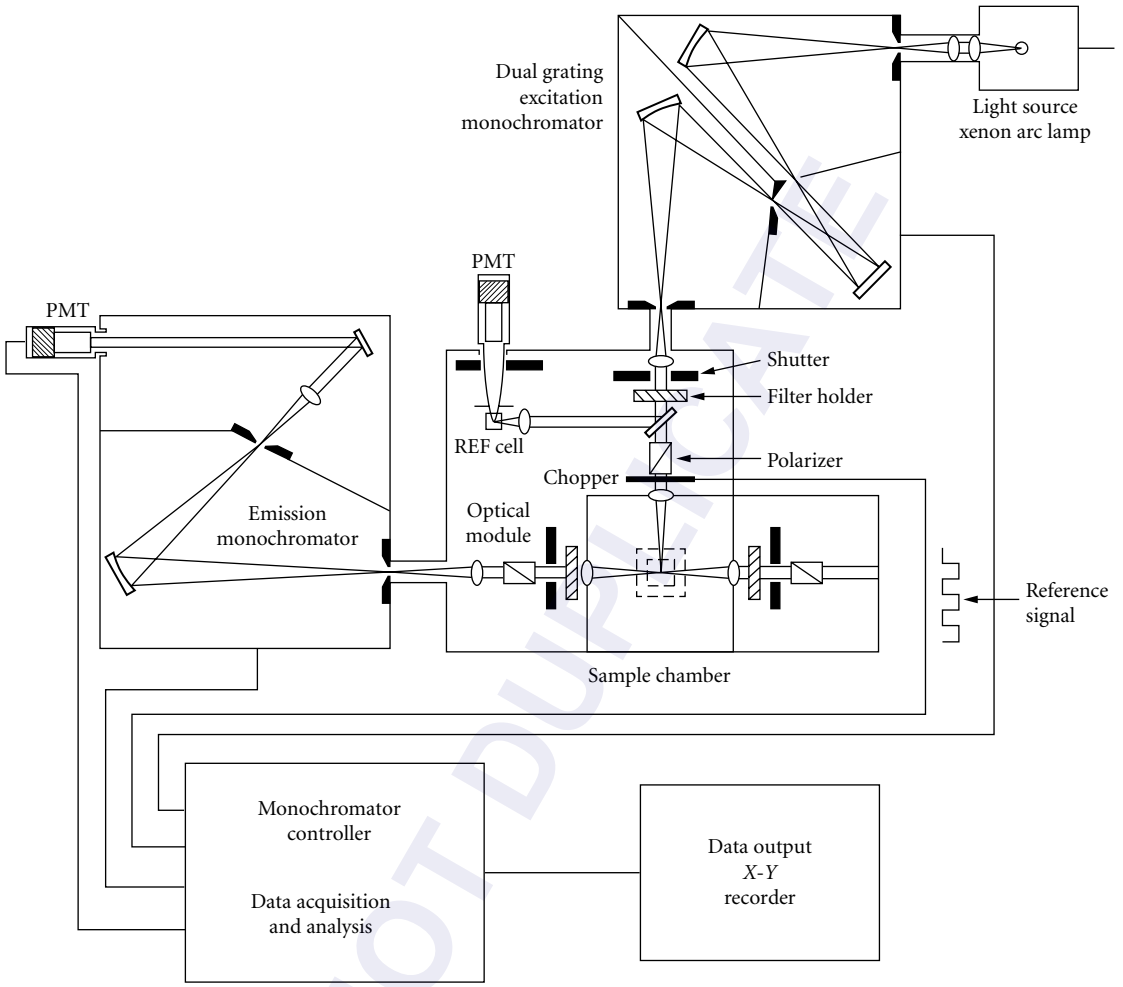

FIGURE 6 Schematic representation of a luminescence excitation spectrometer.

methylindole molecules in dodecane (τ_R = 5 ns). The suppression of the indole signal gives the dimethylindole spectrum with peak at 323 nm at a phase angle of 28.6 – 90°, giving the τ_R value of indole as 9.0 ns.

Luminescence Excitation Spectrometers

Some inorganic solids have strong overlapping absorption bands due to nonluminescent centers, which completely overwhelm the absorption spectrum related to a particular luminescence center. These difficulties are overcome by excitation spectroscopy, Fig. 6, in which the intensity of the luminescence output is recorded as a function of the wavelength of the excitation beam. Strong emission at a particular excitation wavelength signals that the emitting center absorbs strongly at that wavelength. In this way it is possible to determine the shape and position of the

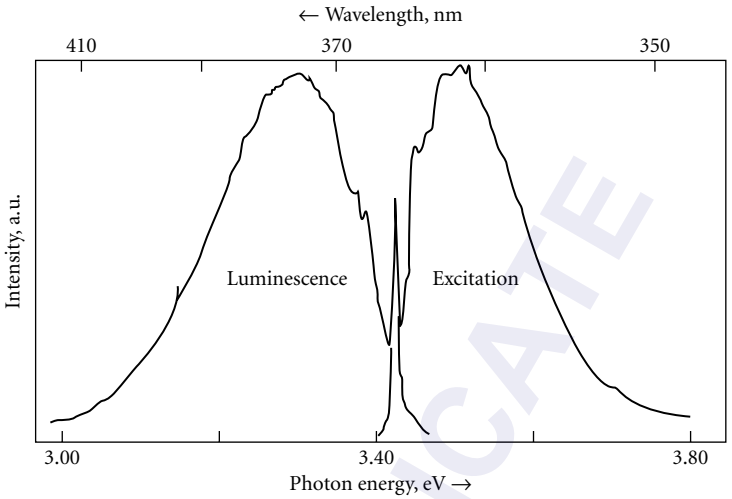

FIGURE 7 Luminescence and excitation luminescence spectrum of F_2 centers in MgO.

absorption bands which excite the emission process. A low-resolution scanning monochromator is placed immediately after the chopper, and light from its exit slit is then focused onto the sample. This monochromator may be of focal length only 250 mm and have a grating of area 5 cm × 5 cm, ruled with only 600 lines per mm. Alternatively, it may be a double monochromator chosen to reduce stray light levels. In either case, an optical band pass filter may be used in front of the monochromator. Generally, the grating blaze is chosen to give high efficiency in the ultraviolet/blue/green regions for the excitation monochromator (e.g., gratings blazed at 300 nm or 500 nm), whereas the emission monochromator is chosen to give high efficiency at visible and near-infrared wavelength (i.e., gratings blazed at 500 nm or 750 nm). With such an apparatus, it is possible to distinguish absorption transitions from several centers whose absorption bands partially or completely overlap. The example given in Fig. 7 shows the luminescence pattern emitted by F_2 centers in magnesium oxide and the excitation spectrum associated with this emission. Other strong absorption bands due to Fe^{3+} ions and F centers which overlap the F_2-absorption bands are strongly discriminated against by selective detection of the F_2-center luminescence.

31.5 PHOTOLUMINESCENCE DECAY TIME

Radiative Lifetime

In order to measure the radiative lifetime of a transition it is necessary to use a sharp intense pulse of excitation in the absorption band together with some means of recording the temporal evolution of the luminescence signal. Suitable excitation sources include pulsed lasers, flash lamps, or stroboscopes. Laser systems may produce pulses of duration 0.1 to 100 ps; flash lamps and stroboscopes will produce pulses of order 10^{-8} s and 10^{-5} s, respectively. A possible spectrometer system is shown in Fig. 8. Usually the luminescence yield following a single excitation pulse is too small for good signal-to-noise throughout the decay period. In consequence, repetitive pulsing techniques are used together with signal averaging to obtain good decay statistics. The pulse reproducibility of the stroboscope is advantageous in the signal averaging process in which the output from the detector is sampled at equally spaced time intervals after each excitation pulse. If the pulse is repeated N times

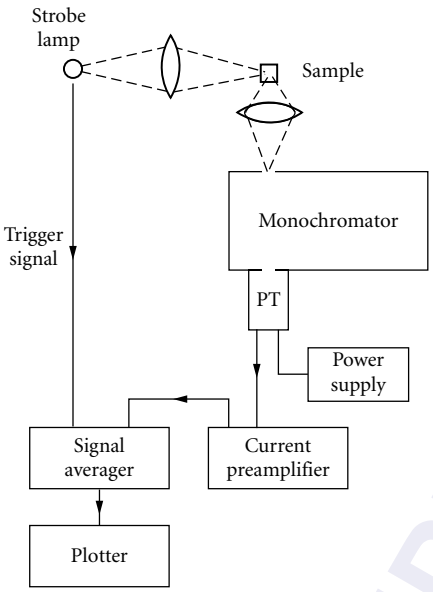

FIGURE 8 Spectrometer for measuring luminescence decay times.

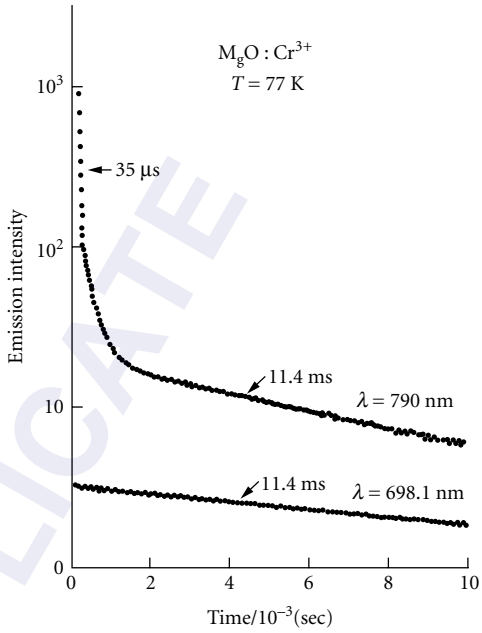

FIGURE 9 Decay in the intensity of Cr^{3+} luminescence in MgO. Detection of the broadband luminescence at 790 nm shows two components, one fast (τ_R = 35 μs) and one slow (τ_R = 11.4 ms). Detection of the R-line at 698.1 nm shows a single component with τ_R = 11.4 ms.

then there is an $N^{1/2}$ improvement in the signal-to-noise ratio. If a multichannel analyzer is used, the excitation pulse is used to trigger the analyzer, and hence the time between pulses need not be constant. Of course the phase sensitive detection spectrometer may also be used to measure lifetimes, but only down to about 100 μs.

An illustration of the data obtainable using the stroboscope technique is shown in Fig. 9. The luminescence signal detected is the broadband emission with peak at 780 nm from Cr^{3+} ions in orthorhombic symmetry sites in magnesium oxide measured at 77 K. At low Cr^{3+} ion concentration, the radiative lifetime of this luminescence center is 35 μs. These data show that the evolution of the intensity during the pulse-decay cycle is not necessarily in the form of a single exponential decay. On sampling the emission at times long relative to τ_R there is a component with characteristic decay time of 11.4 ms, which is the lifetime of Cr^{3+} ions occupying octahedral symmetry sites in magnesium oxide and which emit a characteristic R-line emission at 698.1 nm. This result implies that excitation is being transferred from excited Cr^{3+} ions in octahedral sites to Cr^{3+} in orthorhombic sites.

For rather faster decay processes (10^{-10}–10^{-8} s), fast flashlamps are used to excite the luminescence. The gated flashlamps have extremely reproducible pulses, down to 0.8-ns width with repetition rates of up to 50 kHz.[2] The usual gases for such lamps are hydrogen, deuterium, and air. Hydrogen has several advantages, not the least being the continuum output in the ultraviolet and visible ranges, with pulse profiles which are independent of wavelength. The combination of pulse-sampling techniques and computer deconvolution of the decaying luminescence enables decay times to be measured down to 20 ps. However, judicious choice of photomultiplier tube and careful design of the photomultiplier dynode chain is necessary to eliminate signal noise. It is usual to use coincidence single-photon counting techniques to obtain good decay data.[2]

Picosecond and Sub-Picosecond Relaxation

During the past two decades there have been quite remarkable developments in techniques for generating and measuring ultrashort pulses into the femtosecond domain. In semiconductors, a very wide range of ultrafast phenomena are being studied—electronhole plasma formation, exciton and biexciton formation dynamics, hot electron effects, phase-conjugate self-defocusing, and degenerate four-wave mixing. However, one very general optical phenomenon that may be addressed using ultrashort pulses involves nonradiative decay times in nonresonant fluorescence spectra. Such processes include ionic relaxations around a center in decaying from an excited state, sometimes including reorientations of anisotropic centers. Many picosecond phenomena, especially nonradiative decay processes, are studied by excite-and-probe techniques in which light pulses at wavelength λ_1 are used to excite a phenomenon of interest, and then a delayed optical pulse at wavelength λ_2 interrogates a change of some optical property of this phenomenon. Ideally, two sources of picosecond pulses at different, independently tunable wavelengths are required, which must be synchronized on the picosecond timescale.

A convenient experimental system for studying vibrational relaxation at color centers and transition metal ions in ionic crystals is shown in Fig. 10.[6] A mode-locked dye laser producing subpicosecond pulses at wavelength λ_1 is used both to pump in the absorption band and to provide the timing beam. Such pumping leads to optical gain in the luminescence band and prepares the centers in their relaxed state. The CW probe beam, collinear with the pump beam, operates at a longer wavelength, λ_2. The probe beam and gated pulses from the pump laser are mixed in a nonlinear optical crystal and a filter allows only the sum frequency of the pump and probe beams, which is detected by a phototube. The photomultiplier tube actually measures the rise in intensity of the probe beam which signals the appearance of gain when the F_A(Li)-centers have reached the relaxed excited state. The pump beam is chopped at low frequency to permit phase-sensitive detection. The temporal evolution gain signal is measured by varying the time delay between pump and gating pulses. Although specifically used by Mollenauer et al.[6] to probe the relaxation dynamics of color centers, the spectrometer system shown in Fig. 10 is readily adapted to other four-level systems, including transition metal ions.

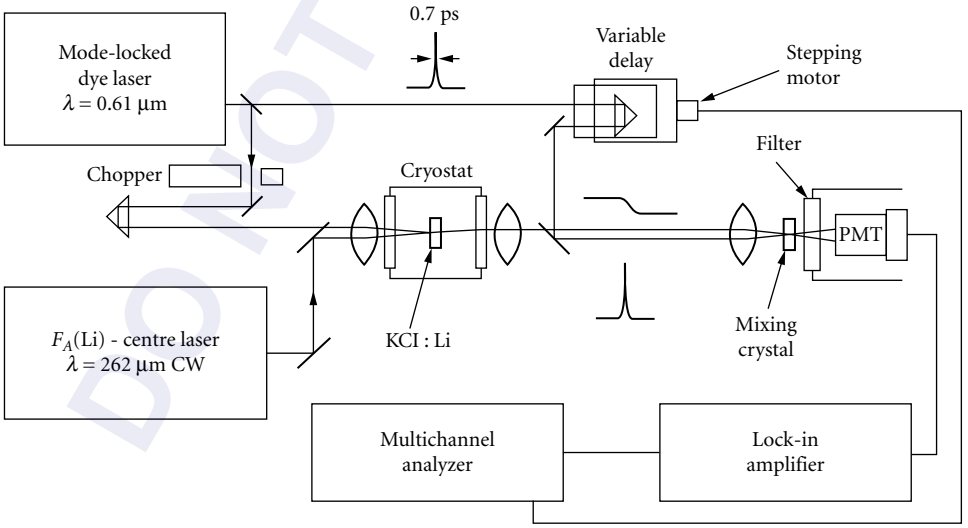

FIGURE 10 A sub-picosecond pump and probe spectrometer for measuring vibrational relaxation times in excited defects and transition metal ions.

31.6 POLARIZATION SPECTROMETERS

General Principles

The absorbed intensity is sometimes dependent on the optical anisotropy of the sample. Whether or not a transition is allowed in a particular polarization is determined by examining the value of the square of the matrix element $\langle b|\boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}_j|a\rangle$, see "Optical Spectroscopy and Spectroscopic Lineshapes" (Chap. 10 in this volume), Eqs. (12) and (13), where a and b are the states involved in the transition, $\boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}_j$ is the appropriate component of the dipole operator summed over all **j** electrons involved in the transition. Optical transitions may be linearly or circularly polarized. For an electronic dipole transition, the dipole operator is $\boldsymbol{\mu}_e\cdot\boldsymbol{\varepsilon}_E$ where $\boldsymbol{\mu}_e=\Sigma_j e\mathbf{r}_j$ is summed over the **j** electrons and $\boldsymbol{\varepsilon}_E$ is the unit electric polarization vector parallel to the E-field of the radiation. The matrix element is evaluated using group theory, which shows how the symmetry properties of the states affect the transition rate.[1] From this matrix element the selection rules of the transition are determined. The polarization of the radiation is defined in Fig. 11 by reference to the $\hat{z}$ direction of the system, which itself is assumed to be parallel to an external perturbation (static electric or magnetic fields) or to unique symmetry direction in a crystal. For the π-and σ-senses of linear polarization, the radiation travels in a direction perpendicular to $\hat{z}$ with its electric field $\hat{\boldsymbol{\varepsilon}}_E$ either parallel to $\hat{z}$ (π-polarization) or perpendicular to $\hat{z}$ (σ-polarization). The electric dipole operators are then given by $\Sigma_j e\mathbf{r}_j\cdot\hat{z}=\Sigma_j ez_j$ for π-polarization and $\Sigma_j ex_j$ or $\Sigma_j ey_j$ for σ-polarization. The $\hat{x}$ and $\hat{y}$ directions have been assumed equivalent. In α-polarization the radiation propagates along the unique symmetry axis, $\hat{z}$, with $\hat{\boldsymbol{\varepsilon}}_E$ anywhere in the x-y plane: in this case the electric dipole operator is also $\Sigma_j ex_j$ or $\Sigma_j ey_j$. We define right circularly polarized (RCP) radiation as having electric (and magnetic) polarization vectors which rotate clockwise when viewed from behind the direction of propagation. For electric dipole absorption transitions, the electric dipole operator for RCP light propagating in the z direction is $\Sigma_j e(x+jy)_j/\sqrt{2}$. Accordingly, in the case of LCP light, where the sense of rotation is anticlockwise, the electric dipole operator is $\Sigma_j e(x-iy)_j/\sqrt{2}$.

Polarized Absorption

Although the selection rules of dipole transitions provide for polarized spectra, the optical spectra of atoms in the absence of external fields and of electronic centers with octahedral symmetry in solids are isotropic. Since the unit polarization vector, $\hat{\boldsymbol{\varepsilon}}_E$, has direction cosines $\cos\alpha$, $\cos\beta$, and

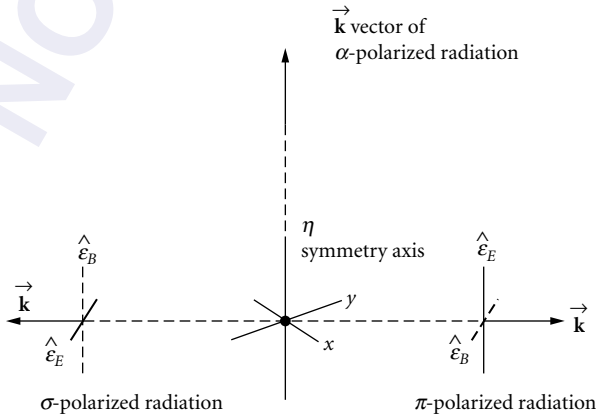

FIGURE 11 Definitions of the senses of α-, π- and σ-polarized light beams relative to a local symmetry axis.[1]

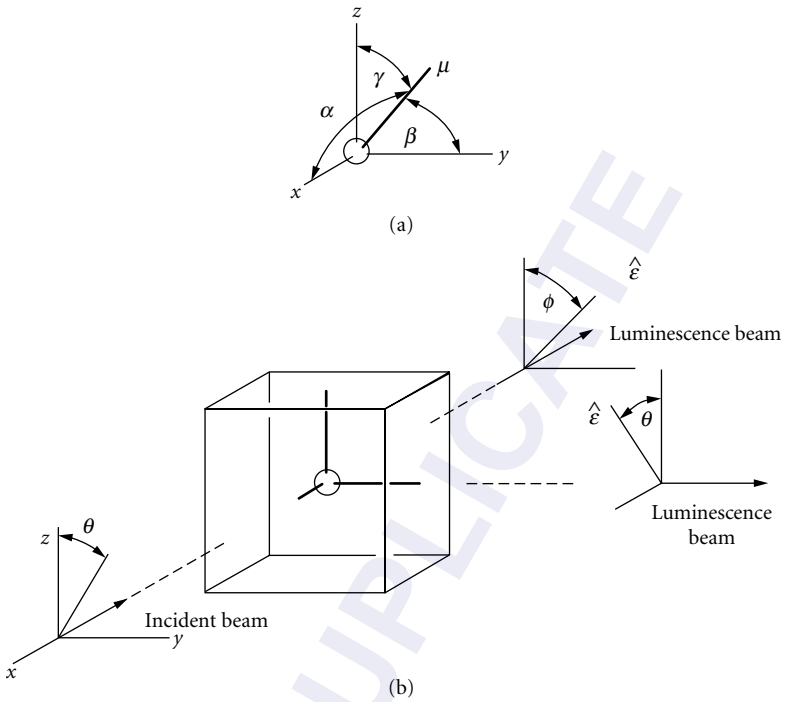

FIGURE 12 Showing (*a*) the orientation of the dipole moment μ relative to the *x*, *y*, and *z* axes and (*b*) two different geometrical arrangements used for polarized excitation luminescence spectroscopy.

$\cos\gamma$, where the angles α, β, and γ are defined in Fig. 12*a*, the square of the electric dipole matrix element is

$$|\langle b|\mu_x\cos\alpha+\mu_y\cos\beta+\mu_z\cos\gamma|a\rangle|^2 \tag{13}$$

When the center has octahedral symmetry the cross terms in Eq. (13) are zero so that the squared matrix element becomes

$$\langle\mu_x\rangle^2\cos^2\alpha+\langle\mu_y\rangle^2\cos^2\beta+\langle\mu_z\rangle^2\cos^2\gamma \tag{14}$$

using $\langle\mu_x\rangle=\langle b|\mu_x|a\rangle$ with similar expressions for $\langle\mu_y\rangle$ and $\langle\mu_z\rangle$. Since in octahedral symmetry

$$\langle\mu_x\rangle^2=\langle\mu_y\rangle^2=\langle\mu_z\rangle^2 \tag{15}$$

$|\langle\boldsymbol{\mu}\cdot\hat{\boldsymbol{\varepsilon}}\rangle|^2$ becomes $\langle\mu_x\rangle^2$ and the strength of the transition is independent of the direction of the polarization of the incident radiation and the direction of propagation.

In octahedral solids, the local symmetry of an electronic center may be reduced by the application of an external perturbation or internally through the presence of a nearby defect. In tetragonal symmetry with the *z* axis parallel to the symmetry axis, the transition probability is again given by

Eq. (14) but with $\langle\mu_x\rangle^2 = \langle\mu_y\rangle^2 \neq \langle\mu_z\rangle^2$. Since the transition probability for radiation at polarization $\hat{\boldsymbol{\varepsilon}}_E$ is then proportional to

$$\langle\mu_x\rangle^2(\cos^2\alpha + \cos^2\beta) + \langle\mu_z\rangle^2\cos^2\gamma = A + B\cos^2\gamma \tag{16}$$

where A and B are constants, the spectroscopic properties of the center are anisotropic. In terms of the experimental situation referred to in Fig. 12*b*, in α-polarization the angle γ is always $\pi/4$ radians, and the intensity is proportional to A. For π-polarization, the angles are $\alpha = \pi/4$, $\beta = \pi/4 - \alpha$, and $\gamma = 0$, and the intensity is proportional to B. Similarly, for σ-polarization, the intensity is proportional to A. This shows that in tetragonal symmetry a rotation of the polarizer from the $\gamma = 0$ to $\gamma = \pi/4$ in, for example, the *y*-*z* plane determines the magnitudes of A and B. The linear dichroism D is then given by $D = (B - A)/(A + B)$.

To illustrate these ideas, Fig. 13 shows the polarization of the ${}^2S_{1/2} \rightarrow {}^2P_{1/2}$, ${}^2P_{3/2}$ lines of atomic sodium, i.e., the D_1 and D_2 absorption lines, in the presence of an applied magnetic field. The Zeeman splittings of energy levels are much smaller than the spin-orbit splitting between the ${}^2P_{1/2}$ and ${}^2P_{3/2}$ levels. The wave functions are labeled in Fig. 11 by the M_J-values: the relevant Clebsch-Gordan coefficients and theoretical intensities of the transitions for linear and circular polarizations are shown in Fig. 13, as are the theoretical intensities of the ${}^2S_{1/2} \rightarrow {}^2P_{1/2}$, ${}^2P_{3/2}$ right circularly polarized (RCP) and left circularly polarized (LCP) absorption transitions. The experimental pattern of lines for π- and σ-polarizations are in excellent agreement with the predicted Zeeman pattern.

An analysis of the polarization properties of the sample absorption requires that a polarizer be inserted in the light path immediately prior to the sample chamber. For accurate measurements of the absorption anisotropy, the polarizers must be accurately positioned relative to the beam and rotatable. The angle of rotation about the beam must be accurately indexed so that the orientation-dependence of the anisotropy may be determined. The polarizer should also be removable since it is unnecessary for measurements with optically isotropic solids. A sample which has different absorption coefficients in different crystallographic directions is said to be *dichroic*. The dichroism is defined as

$$D = \frac{\alpha(\pi) - \alpha(\sigma)}{\alpha(\pi) + \alpha(\sigma)} = \frac{1}{l}\left(\frac{I(\pi) - I(\sigma)}{I(\pi) + I(\sigma)}\right) \tag{17a}$$

in the limit of small absorption coefficients.

Although discussion has focused on radiative absorption transitions via electric dipole transitions, a similar analysis can be made for magnetic dipole transitions. In this case, the phase relationships between the magnetic fields $\mathbf{B}_x$ and $\mathbf{B}_y$ are exactly the same as those between $\mathbf{E}_x$ and $\mathbf{E}_y$, and the magnetic dipole operator is $\boldsymbol{\mu}_m \cdot \boldsymbol{\varepsilon}_B$; where $\boldsymbol{\mu}_m = \Sigma_j (e/2m) \times (l + 2s)_j$ and $\boldsymbol{\varepsilon}_B$ is the unit vector along the direction of the magnetic field of the radiation. If the absorption transitions used to excite the luminescence are unpolarized, so too will be the resulting luminescence spectrum. However, as discussed above, the absorption spectrum of an atomic system may be made anisotropic by the application of an external field or by using polarized exciting radiation. The resulting emission spectrum will be correspondingly polarized. Absorption and luminescence spectra from optically isotropic solids can also be made anisotropic using similar techniques.

Polarized Absorption/Luminescence

Just as the absorption spectra of free atoms and isotropic solids are unpolarized, so too are the luminescence spectra, at least when exciting with unpolarized radiation. This is shown by simple extensions to the arguments leading to Eq. (15) in which the electric dipole operators for luminescence are the complex conjugates of those for the appropriate absorption transitions. In practice, both absorption and emission properties are anisotropic. Although the host crystal may possess a cubic unit cell in which the electronic centers are anisotropic, a regular distribution of equivalent sites will

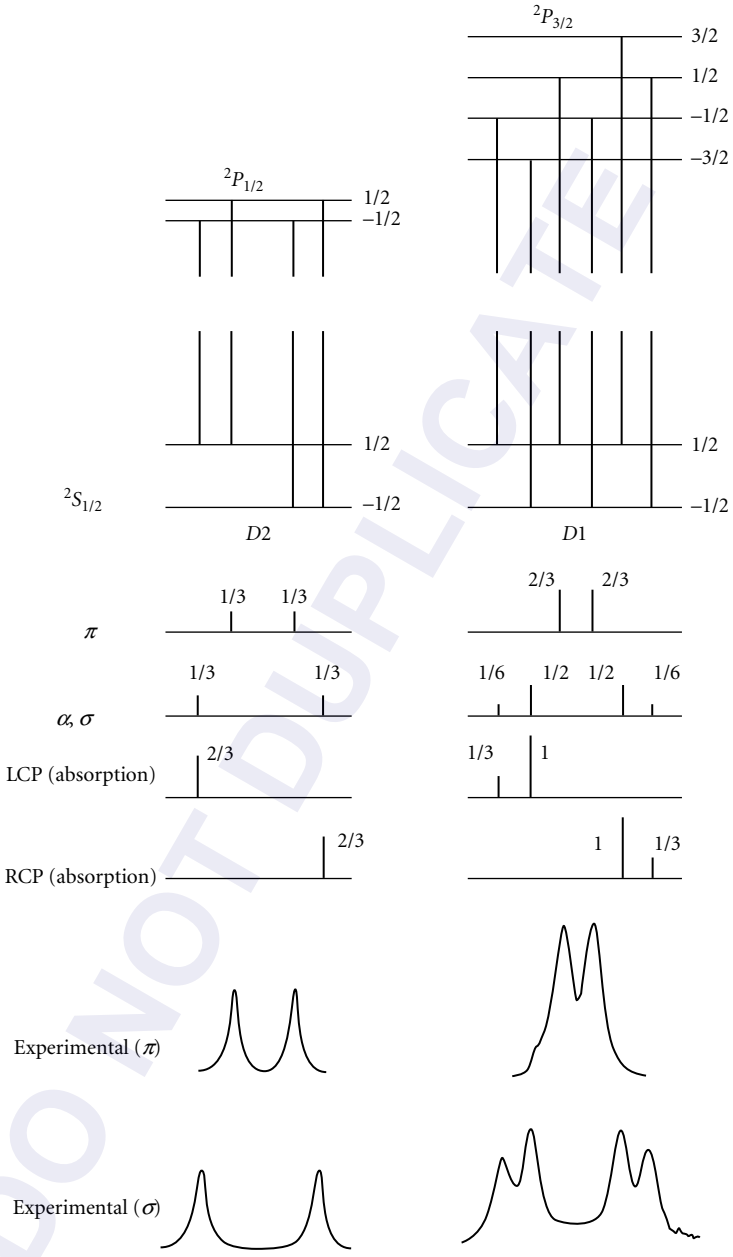

FIGURE 13 Zeeman splittings of $^2S_{1/2} \rightarrow {}^2P_{1/2}$, $^2P_{3/2}$ levels of sodium. The electric dipole matrix elements and relative intensities of linearly and circularly polarized absorption transitions are compared with some experimental spectra.[1]

still result in isotropic spectra. The use of polarized absorption/luminescence techniques can reveal details of the local site anisotropy. Such methods have been discussed by Henderson and Imbusch[1] and in more detail by Feofilev.[7]

To measure the effects of polarization on the absorption coefficient [i.e., $\alpha(\nu, \hat{\varepsilon})$] it is necessary to place a polarizer immediately before the beam splitter in the double-beam spectrophotometer, Fig. 1. In polarized luminescence measurements, linear polarizers are placed immediately before the sample in the absorption channel and just after the sample in the emission channel of a luminescence excitation spectrometer such as that shown in Fig. 6. The spectrometer may then operate in the "straight through" configuration or the emitted light may be collected in a direction at 90° to the direction of the excitation light, as illustrated in Fig. 13. Note that provision is made for rotatable polarizers in both excitation (θ) and detection channels (ϕ), and the measured emission signal will be a function of both θ and ϕ.

The circular dichroism may be defined in an analogous manner to the linear dichroism, i.e., Eq. (17*a*). Since circular dichroism has a specific relevance to the Zeeman effect, we use Fig. 14*a* and consider circularly polarized absorption transitions which are excited between two Kramers doublets. With light propagating along the direction of the magnetic field, the selection rule is that

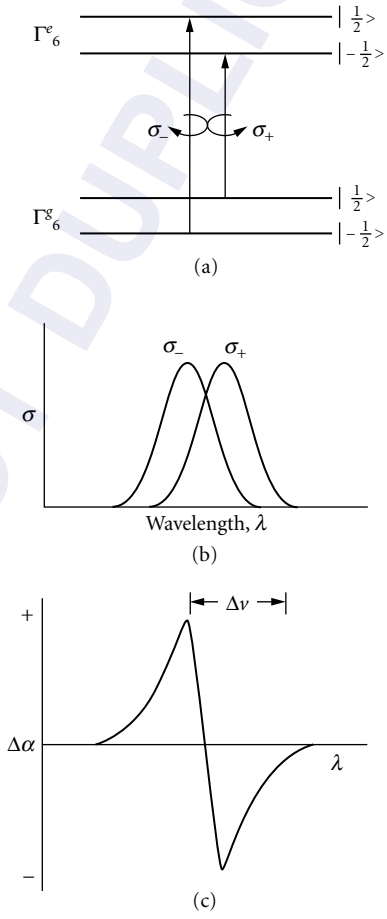

FIGURE 14 Circularly polarized dipole transitions excited between Kramers states.

σ-polarized light induces $\Delta M_s = +1$ absorption transitions and σ_+-polarized light induces absorption transitions in which $\Delta M_s = -1$. As a result of the Zeeman effect, the absorption peak splits into two overlapping bands (Fig. 14*b*) centered at different wavelengths with absorption coefficients $\alpha_\pm$ in σ_+- and σ_--polarizations that are different at particular frequencies. The peaks in the two oppositely polarized bands are separated in energy by $(g_e + g_g)\mu_B B$, where the *g*-values refer to the excited *e* and ground *g* states. The energy difference corresponds to a frequency splitting $\Delta\nu = (g_e + g_g)eB/4\pi m$, which for $g_e = g_g = 2.0$ and $B = 1\ T$ gives a separation between band peaks of $\simeq$0.04 nm for a band centered at 500 nm. In a magnetic field, the difference $[\Delta\alpha(\nu)]$ in the absorption coefficients for σ_+ and σ_- circularly polarized light is referred to as *magnetic circular dichroism* (MCD). In the limit of small absorption coefficient the circular dichroism is

$$\Delta\alpha(\nu) \simeq -\frac{2(I_+(\nu) - I_-(\nu))}{l(I_+(\nu) + I_-(\nu))} \tag{17b}$$

where l is the sample thickness and $I_+(\nu)$, $I_-(\nu)$ refer to the transmitted intensities of the σ_+ and σ_- circularly polarized light at frequency ν.

In most cases, a splitting of only 0.04 nm would be hard to resolve directly by Zeeman effect measurements on a broadband. However, this Zeeman structure may be resolved by measuring $\Delta\alpha(\nu)$ as a function of magnetic field, as can be seen from a simple estimate. We approximate the MCD signal, $\Delta\alpha(\nu)$ for a sample of thickness l, as the product of the magnetic splitting $\Delta\nu$ with the rate of change of the absorption coefficient with frequency which is given by $d\alpha(\nu)/d\nu \approx \alpha(\nu_o)/\Gamma$, for a symmetrical, structureless band. Hence

$$\Delta\nu = \frac{\Delta\alpha(\nu)}{l} \times \frac{\Gamma}{\alpha(\nu_o)} \tag{18}$$

In a typical experiment, $\Delta\alpha(\nu)l \simeq 10^{-5}$ and $\alpha(\nu_o)l \sim 1$, hence $\Delta\nu \simeq 10^{-5}\Gamma$. For a typical broadband, $\Gamma \simeq 0.25$ eV $\simeq 2000$ cm^{-1} and Eq. (18) yields $\Delta\nu \simeq 0.02$ cm^{-1} (i.e., $\Delta\lambda \sim 0.05$ nm) which is of the same order of magnitude as the Zeeman splitting calculated above. Although the intensity changes, which determine the magnitude of $\Delta\alpha(\nu)$, may be quite small, they may be assumed very precisely using lock-in techniques. This is done very efficiently by replacing the circular polarizer in the excitation system by a stress-modulated quarter-wave plate, a device which transmits circularly polarized light, the polarization of which is switched between σ_+ and σ_- at the vibration frequency of the plate, usually $\approx$50 kHz. Using this piezo-optic modulation, MCD signals as low as 10^{-6} can be measured.[8]

The MCD signal is strongly dependent on both frequency and temperature. Since at low temperatures the populations $N_\pm$ of the $M_s = \pm 1/2$ levels of the spin 1/2 ground state are different for a system in thermal equilibrium, the MCD signal [Eq. (17*b*)] is given by

$$\Delta\alpha(\nu)l = \alpha_o(\nu)G(\Delta\nu)\tan h\left[\frac{g\mu_B B}{2kT}\right] \tag{19}$$

In this expression $\alpha_o(\nu)$ and the sample thickness, l, are experimental constants and, in consequence, the MCD signal only varies through the Brillouin function for the $s = 1/2$ ground state [i.e., $\tan h(g\mu_B B/2kT)$]. This MCD signal is paramagnetic, being strongest at high field and low temperature, and measurement of its magnitude probes the ground-state magnetization. In order to test Eq. (19) experimentally, it is best to work at either the positive or negative peak in Fig. 14 and so maximize the MCD signal. Having thus obtained a suitable MCD signal, its variation with temperature and magnetic field can then be measured. Excitation of the Kramers' system in Fig. 14 with circularly polarized radiation of appropriate frequency results in the circularly polarized emission. The electric dipole operators for RCP and LCP emission are the complex conjugates of those

for absorption. The consequent change in emission intensity, Eq. (17), is referred to as the magnetic circular polarization (MCP).

Optically Detected Magnetic Resonance

In optical absorption spectroscopy, electronic transitions (usually) out of the ground state may result in one of a rich tapestry of possible bandshapes, depending upon the strength of the electron-phonon coupling. Photoluminescence measurements involve transitions which originate on an excited electronic state and frequently the terminal state is the electronic ground state. Overlapping absorption and luminescence bands can cause difficulty in assigning individual optical absorption and luminescence bands to particular optical centers. Since the lifetimes of excited states are in the range 10^{-3} to 10^{-8} s, it is no trivial matter to measure excited-state electron spin resonance using the microwave detection techniques pioneered in ground-state studies. Geschwind et al.[9] developed techniques in which the excited-state ESR was detected optically. In favorable cases this method enables one to correlate in a single experiment ESR spectra in the ground state and in the excited state with particular optical absorption and luminescence spectra. The technique of measuring the effect of resonant microwave absorption on the MCD and/or MCP signal may be termed optically detected magnetic resonance (ODMR). In ODMR measurements involving the MCD signal, microwave-induced transitions between the Zeeman levels of the ground state are detected by a change in intensity of the absorption (i.e., MCD) spectrum. Electron spin resonance transitions in the excited state are signaled by microwave-induced changes in the MCP signal.

Figure 15 is a schematic drawing of an ODMR spectrometer. There are three necessary channels: a microwave channel and channels for optical excitation and detection. The microwave system is relatively simple, comprising a klystron or Gunn diode operating at some frequency in the range 8.5 to 50 GHz, followed by an isolator to protect the microwave source from unwanted reflected signals in the waveguide path. The microwave power is then square-wave modulated at frequencies up to 10 kHz, using a PIN diode. A variable attenuator determines the power incident upon the resonant cavity, although for high-power operation a traveling-wave amplifier might be added to the waveguide system. The sample is contained in the microwave cavity, which is designed to allow optical access of the sample by linearly or circularly polarized light traveling either parallel or perpendicular to the magnetic field direction. The cavity is submerged in liquid helium to achieve as large a population difference as possible between the Zeeman levels. The magnetic field is provided either by an electromagnet ($B \simeq 0-2.0\,T$) or a superconducting solenoid ($B \simeq 0-6.5\,T$). Radiation from the sample is focused onto the detection system, which in its simplest form consists of suitable filters, a polarizer, and photomultiplier tube. A high-resolution monochromator may be used instead of the filters to resolve sharp features in the optical spectrum. The signal from the phototube is processed using a phase-sensitive detector, or alternatively using computer data collection with a multichannel analyzer or transient recorder. The recorded spectrum is plotted out using a pen recorder as a function of either magnetic field or photon energy (or wavelength). With such an experimental arrangement one may examine the spectral dependence of the ODMR signal on the wavelength of the optical excitation or on the wavelength of the detected luminescence by use of one of the two scanning monochromators.

In order to carry out ODMR, microwave radiation of fixed frequency ν is introduced while the optical wavelength is kept at the positive or negative peak in Fig. 14*c*. The magnetic field is then adjusted until the ESR condition, $h\nu = g\mu_B B$, is satisfied. Since ESR transitions tend to equalize the populations N_+ and N_-, resonance is observed as a decrease in $\Delta\alpha(\nu)$, and as the microwave power is increased, the MCD gradually tends to zero. In certain circumstances the ground-state spin polarization may be used to monitor *excited-state* ESR transitions because of the selectivity of the transitions induced by circularly polarized radiation. This measurement technique is an example of *trigger detection* where one microwave photon in absorption triggers the detection of one optical photon emitted. The resulting enhancement in sensitivity relative to the normal ESR technique is approximately in the ratio of optical to microwave frequency (i.e., $10^{15}/10^{10} = 10^5$). At *x*-band (≈10 GHz), the ESR sensitivity is about 10^{10} spins per gauss linewidth so that ODMR sensitivity is of order 10^5

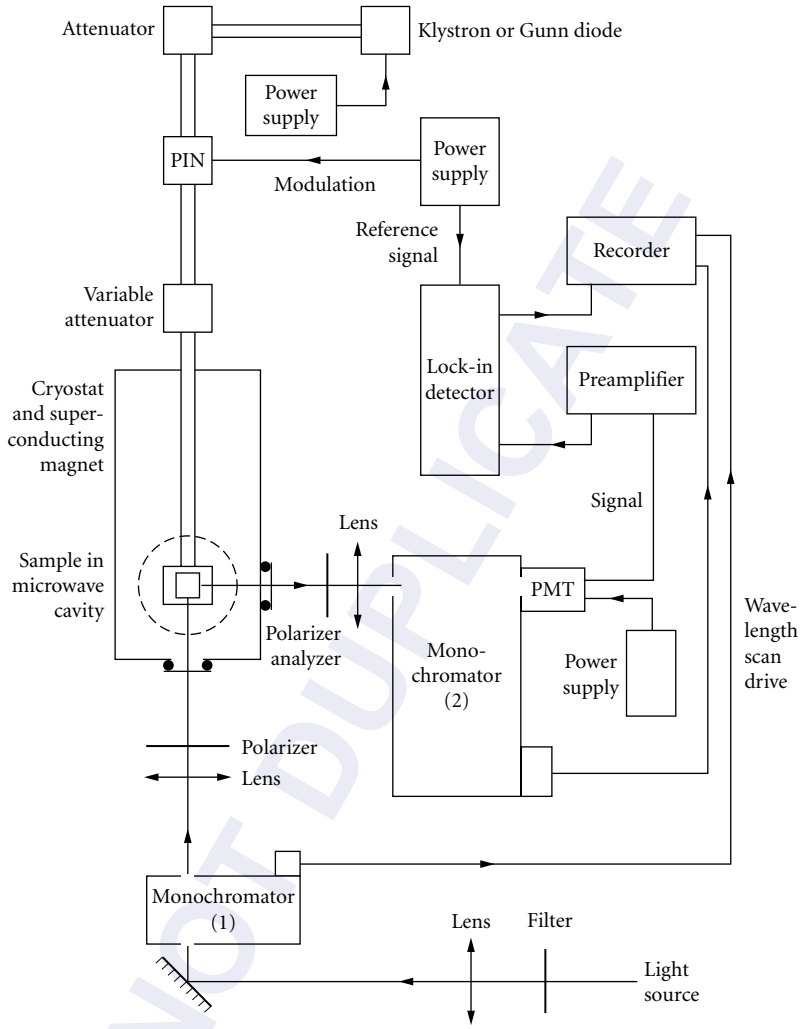

FIGURE 15 A schematic representation of a spectrometer for measuring optically detected magnetic resonance spectra via circularly polarized absorption or emission transitions.

atoms in the excited state. With the ODMR technique, one may gather information on a wide range of important solid-state processes including spin-lattice and cross relaxation, spin memory, energy transfer, electron-hole recombination, phonon bottlenecks, and spin coherence effects.

A major attribute of the ODMR technique is illustrated in Fig. 16, showing the optical characteristics of the ODMR spectrum of F centers in calcium oxide.[10] These spectra were measured at 18.7 GHz and 1.6 K with the magnetic field along a crystal ⟨100⟩ direction. A high-pressure xenon discharge lamp and monochromator (M_1 in Fig. 15) set at 400 nm was used to excite the fluorescence, which was detected through monochromator M_2. The spectrum consists of four equally spaced lines due to an $S = 1$ state of a center with tetragonal symmetry. Then with the magnetic field set at the strongest ODMR line, the excitation wavelength is scanned using monochromator M_1 (Fig. 15) over the visible and near-ultraviolet region. A single broad structureless excitation peak is observed

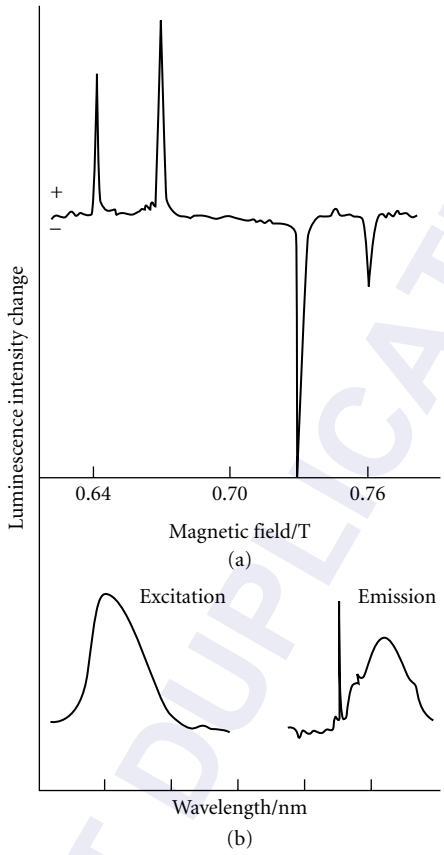

FIGURE 16 The ODMR spectrum of triplet state of *F*-centers in CaO.

at 400 nm corresponding to the $^1A_{1g} \rightarrow {}^1T_{1u}$ absorption band of the F center (Fig. 16). Subsequently, the excitation monochromator is set at the peak of this excitation band and the same magnetic field while the detecting monochromator (M_2 in Fig. 15) is scanned over the fluorescence spectrum. This spectral dependence (Fig. 16) shows a sharp zero-phonon line at a wavelength of 574 nm with an accompanying broad vibronic sideband with peak at 602 nm. In a single experiment, a unique and unambiguous relationship is established between the ESR spectrum, absorption, and fluorescence bands of an intrinsic lattice defect.

31.7 HIGH-RESOLUTION TECHNIQUES

Inhomogeneous broadening arises when individual atoms are distinguished by the frequency at which they absorb light. The absorption profile is then the sum of separate absorption lines. In atomic spectroscopy, the major source of the spectral linewidth is Doppler broadening; the frequency shift is $(\Delta\nu/\nu) = \pm(v_z/c)$ due to an atom moving with velocity component v_z towards (+) or away from (−) the observer. At thermal equilibrium, a gaussian lineshape is observed because of the

Maxwell-Boltzmann velocity distribution. In solids, the distribution of internal strains is a source of inhomogeneous broadening. Because crystals contain imperfections, electronic centers experience crystal fields which vary slightly from site to site in the crystal; in consequence, zero-phonon lines may have linewidths of order 0.1 to 50 cm^{-1}. The use of narrow-band laser excitation makes it possible to eliminate inhomogeneous broadening and to realize a resolution limited only by the homogeneous width of the transition, which in crystals can vary from kilohertz to gigahertz. This factor of 10^3 to 10^4 improvement in resolution enables the spectroscopist to carry out high-resolution studies of the physical properties and electronic structures of centers and of the mechanisms responsible for homogeneous broadening. Contributions to homogeneous width come from population dynamics and random modulation of the optical frequency by phonons and nuclear spins.

Saturated Absorption and Optical Holeburning

The experimental basis of recovering the homogeneous width of an inhomogeneously broadened optical spectrum, so-called saturated absorption or optical holeburning (OHB) spectroscopy, is illustrated in Fig. 17. An inhomogeneously broadened line of width Γ_{inh} is produced by many narrow components of homogeneous width $\Gamma_{hom} \ll \Gamma_{inh}$. Each component is centered at a different

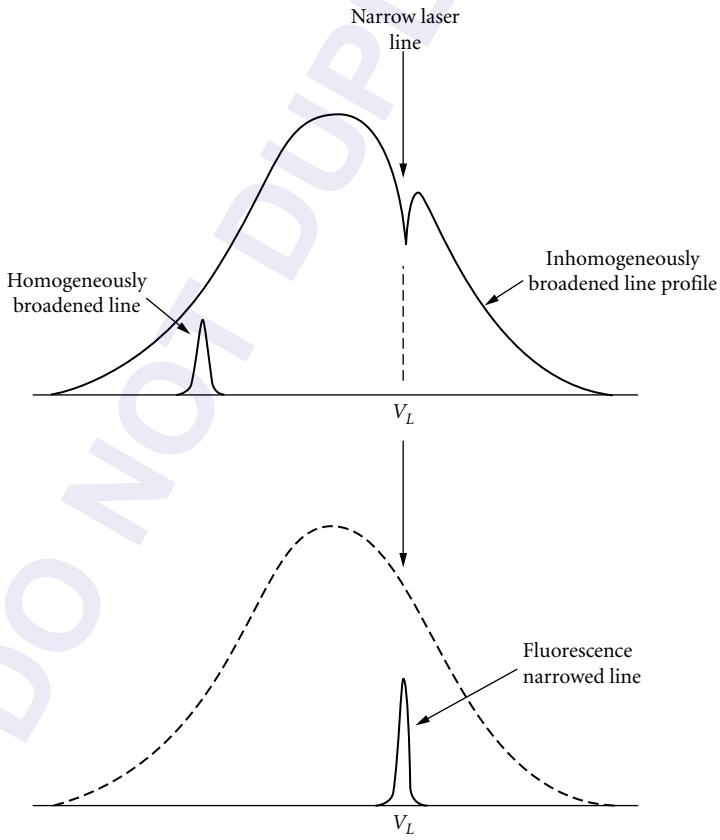

FIGURE 17 Optical holeburning (OHB) and fluorescence line narrowing (FLN) of an inhomogeneously broadened spectroscopic line.[1]

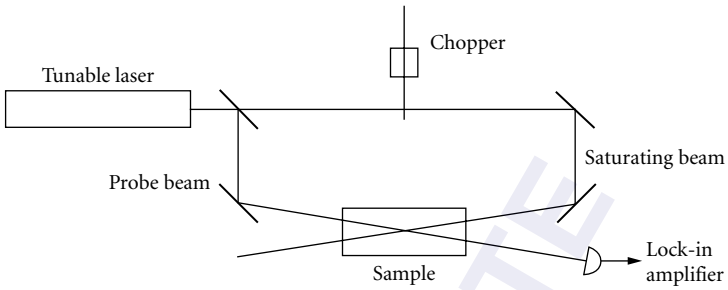

FIGURE 18 A spectrometer system for Doppler-free saturation spectroscopy.[12]

frequency within the inhomogeneous line profile. If a narrow laser line of frequency ν_L and bandwidth $\Gamma_L < \Gamma_{hom}$ is incident upon an atomic assembly having an inhomogeneously broadened linewidth Γ_{inh}, the resulting absorption of laser radiation depletes only that subassembly of excited centers whose energies are within Γ_{hom} of the laser line frequency ν_L. Consequently, a "hole" is burned in the lineshape in the neighborhood of ν_L. Resolution of the homogeneous width requires that $\Gamma_L < \Gamma_{hom} \ll \Gamma_{inh}$. In holeburning spectroscopy, the narrow laser linewidth and high power make it possible to maintain a significant fraction of those atoms with transition frequency ν_L in the excited state, where they no longer contribute to the absorption at this frequency. To observe holeburning experimentally requires that ~5 percent of those centers within the pump laser bandwidth be transferred to the excited state.

The first measurements of optical holeburning or saturated absorption spectroscopy in atoms were made by the Stanford group on the H_α-line ($n=2 \rightarrow n=3$) in hydrogen using a pulsed dye laser.[11] A schematic diagram of an appropriate absorption spectrometer is shown in Fig. 18. A strong laser beam interacts with those atoms that are moving with the right velocity to Doppler and shift them into resonance. If the laser beam is intense enough, it tends to equalize the population in the two levels, thereby reducing the intensity. The hole burned in the absorption profile, which extends over the natural width of the transition, is probed by a second beam at the same frequency but lower intensity and traveling in the opposite direction. This beam interacts with atoms having the same velocity but in the opposite direction to the saturating beam. When the laser is tuned to line center, both pump and probe beams interact with atoms moving with zero longitudinal velocity. The probe beam then measures the reduced absorption caused by the saturating beam. In experiments using pulsed lasers, very high intensity is required to achieve saturation and hence there must be very tight focusing and overlap of pump and probe beam. In consequence, CW lasers are preferred in both gas-phase and solid-state spectroscopy. Saturated absorption measurements on atomic hydrogen have been reviewed by Ferguson and Tolchard[12] and OHB in solids by Selzer[13] and by Yen.[14]

To burn a hole in a narrow absorption line in crystals requires that the laser be focused onto the sample for periods of order 10^2 to 10^3 s, depending upon the specific system. When the laser excitation is switched off, the holes recover on some timescale characteristic of the physical process responsible for holeburning. For short-lived holes the exciting beam is divided using a beam splitter into pump and probe beams. The weaker probe beam passes through an optoacoustic modulator which scans it backward and forward over the hole.[13] To observe long-lived holes, the sample is irradiated for a short time in the zero-phonon line with a few hundred milliwatts of single-mode dye laser light with a width of a few megahertz. The shape of the hole is then displayed by reducing the laser intensity to a few milliwatts and scanning the laser over the inhomogeneous line profile. Figure 19 shows an example of holeburning in the 601.28-nm line of $Pr^{3+}:LaCl_3$. The homogeneous width measured in this holeburning experiment is Γ_{hom} = 10 MHz, which corresponds to a lifetime of 10 ns. There have been many reports of holeburning spectroscopy on transition metal ions, rare-earth ions, and color centers in inorganic materials. For rare-earth ions, holeburning with lifetimes determined by the nuclear spin relaxation processes have been reported to vary from 10 to 10^3 s. Many measurements are aimed at the mechanisms leading to the homogeneous width of optical transitions.

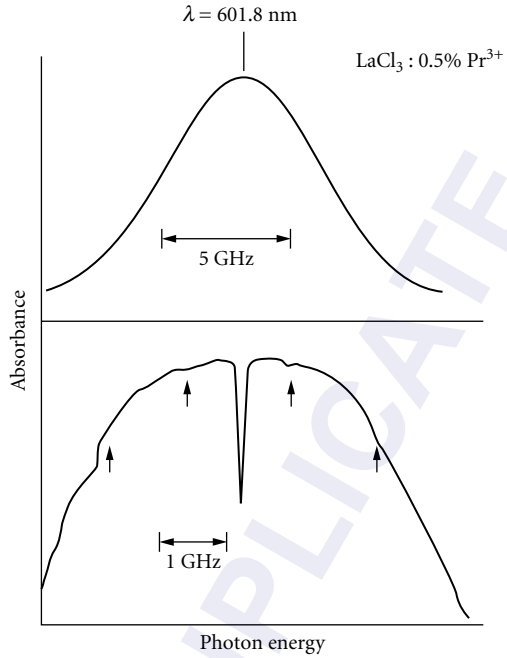

FIGURE 19 Optical holeburning in the 601.28-nm line of Pr^{3+} ions in $LaCl_3$. The hole was burned using some 200 W cm^{-2} of single-frequency laser light with a bandwidth of 2 MHz. The zero-phonon line has an inhomogeneous width of 7.5 GHz. (*After Harley and Macfarlane, 1986, unpublished.*)

In these cases, techniques have been developed for the detection of coherent transients (e.g., photon echo or free induction decay) because the measurements are made on the timescale of the dephasing and are not affected by spectral diffusion and other such processes.

Polarized Absorption Spectrometers

Polarized absorption spectroscopy is a technique related to sub-Doppler absorption spectroscopy. However, in this case use is made of the circularly polarized absorption properties of atomic transitions. In the Wieman-Hansch experiment,[11] the probe beam passes through crossed polarizers immediately before and after the sample. If the pump beam is unpolarized, the sample is optically isotropic and no light falls on the detector. However, if the $s \rightarrow p$ transitions are excited using RCP light, the pump beam induces optical anisotropy in the medium with which it interacts. In consequence, as pump and probe beams are tuned to line center so that both interact with the same class of atoms, the weak probe beam becomes slightly elliptically polarized and light is transmitted through the crossed polarizers. The advantage of the method is a factor of about 10^3 enhancement in sensitivity relative to saturation absorption spectroscopy. Sub-Doppler two-photon absorption spectroscopy is also much used in atomic physics.[15] The selection rule for two-photon absorption is that $\Delta l = 0$ or 2. In consequence, for $l = 1$ electron atoms $S \rightarrow S$ and $S \rightarrow D$ transitions are allowed.

Laser Stark Spectroscopy of Molecules

Sub-Doppler resolution enhancement is also used in studying the heterogeneously broadened rotational/vibrational spectra of molecules. Such spectra are generally observed in the mid-IR region and are studied using a wide variety of gas lasers (e.g., N_2O, CO, and CO_2). Such laser lines are not usually in exact resonance with the particular molecular transition: laser and molecular transition are brought into register using a variable electric field to tune the molecular system into resonance. In general, parallel-plate Stark cells are used in which free-space propagation of the short-wavelength infrared radiation occurs. This makes it easy to use both perpendicular and parallel polarization configurations in the electric resonance experiments so that both $\Delta M_J = 0$ and $\Delta M_J = \pm 1$ transitions are observed. The subject of laser Stark spectroscopy has been discussed at length by Duxbury.[16]

A schematic intracavity laser Stark spectrometer is shown in Fig. 20; the same basic principles are obtained as with optical holeburning spectroscopy. The effects of the saturating laser field are confined to a narrow frequency region centered on the velocity component of those molecules whose absorption is Doppler-shifted into resonance. In a standing wave field, two holes are burned, one on either side of the line center, corresponding to molecules moving toward or away from the detector. The applied electric field is used to tune the two holes to line center where they coalesce to give a sharp dip in the absorption coefficient at line center. Since the resonance method relies on the use of an electric field for tuning, it is necessary both to generate high uniform fields and to study molecules with appreciable Stark tuning coefficients. In order to generate high electric fields, which may approach 90 kV cm^{-1}, narrow electrode spacings from 1 to 4 mm are commonly used. With such narrow gaps, the plates must be flat to one or two fringes of visible light, and must be held accurately parallel. The gas pressure used must also be restricted to the low-pressure region below 100 mtorr. A potential difference of roughly 3000 V may be sustained without electrical breakdown across any gas at a pressure of 100 mtorr and below.

The electric field is then modulated at some convenient frequency to permit the use of phase-sensitive detection techniques. In order to get above the principal noise region of the electric discharge lasers used in the 5- and 10-μm regions and as pumps for the FIR lasers, it is necessary to use electric field modulation frequencies in the range from 5 to 100 kH. The amplitude of the electric field modulation used to detect the signals is usually small compared to the equivalent electric field linewidth of the transitions. The most common modulation waveform is sinusoidal.

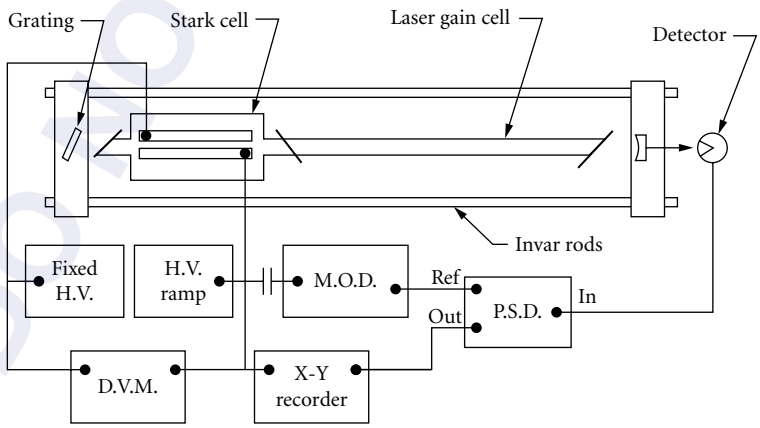

FIGURE 20 Schematic diagram of an intracavity laser Stark spectrometer. PSD stands for phase sensitive detector, DVM for digital voltmeter, HV for high voltage, and MOD for modulation source.[16]

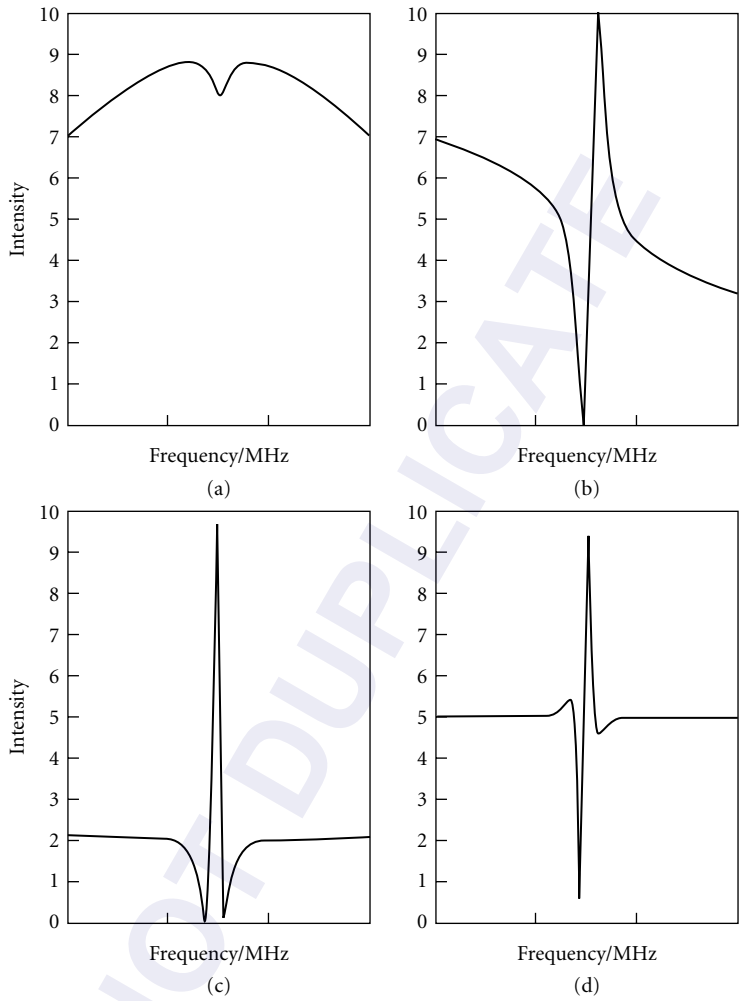

FIGURE 21 Lineshapes which occur when detecting at harmonics of the modulation frequency when small-amplitude field modulation is used. Doppler-broadened line showing the Lamb dip. (*a*) 30-MHz scan of a partially saturated Doppler-broadened line showing the Lamb dip; (*b*) 30-MHz scan with first-derivative detection; (*c*) 30-MHz scan with second-harmonic, second-derivative detection. The gain is increased by a factor of four from (*a*); and (*d*) 30-MHz scan with third-harmonic, third-derivative detection.

If the modulation amplitude is much smaller than the linewidth, detection at the fundamental modulation frequency results in a first derivative lineshape as in analogous electron spin resonance spectra. In order to remove the effects of sloping baselines produced by transitions with a slow Stark effect, it is common to use detection at either the second or third harmonic of the modulation frequency. Second-harmonic detection produces a second-derivative signal resembling a sharpened absorption line but with negative side lobes. Third-harmonic detection produces a third-derivative signal which resembles a sharpened first derivative, but which again possesses side lobes. Theoretical lineshapes are illustrated in Fig. 21. Second- and third-harmonic detection are particularly useful for

the observation of narrow saturation features free from background effects. The detectors used are quantum-limited liquid nitrogen cooled devices, PbSnTe or CdHgTe in the 10-μm region and InSb or Au doped Ge in the 5-μm region. In the far infrared, Golay cells have been used but in order to achieve a better signal-to-noise ratio it is necessary to use detectors cooled by liquid helium.

Just as in atomic spectroscopy one may use atomic beam spectroscopy as an alternative to absorption saturations, so too may one use molecular beam systems in high-resolution studies of the rotational-vibrational spectra of molecules.

Fluorescence Line Narrowing

Fluorescence line narrowing (FLN) is a technique complementary to that of OHB. It may also be understood by referring to Fig. 17. A narrow laser line is used to pump within the inhomogeneous linewidth Γ_{inh}. The laser interacts only with the subset of levels spanning the bandwidth of the laser Γ_L. These centers reradiate to some lower lying level, with a fluorescence linewidth much narrower than the inhomogeneous width. The fluorescence linewidth approaches the homogeneous width. In fact, for centers involved in a resonance fluorescence transition, the total FLN lineshape is a convolution of the laser lineshape and twice the homogeneous lineshape (once for the pump bandwidth and once for the fluorescence). The FLN linewidth Γ is then usually written as $\Gamma = \Gamma_L + 2\Gamma_h$. Experimentally, FLN requires a little more sophistication than does holeburning spectroscopy. Of course, one still requires a stable, high-resolution laser. Care must be used in extracting the true homogeneous linewidth, especially for nonresonant fluorescence. Many of the experimental problems relative to solid samples are discussed in the review by Selzer,[13] and numerous examples are given by Yen and Selzer.[17] The CW FLN spectrum shown in Fig. 22 is for the Cr^{3+} ion in aluminum oxide.[18] The fluorescence lifetime is 3.4 ms at 4.2 K. Hence the homogeneous width is of the order 0.3 kHz. A direct-phonon relaxation process between the two ^2E levels, $2\bar{A}$ and $\bar{E}$, separated in energy by 29 cm^{-1}, broadens the homogeneous width to ≈130 kHz. In CW measurements, a homogeneous width in excess of 100 MHz was reported.[18] The problem is relaxations due to super-hyperfine interactions with neighboring aluminum nuclei. The application of a dc magnetic field of only 40 mT has the effect of inhibiting relaxation due to local fields at the Cr^{3+} ions due to the ^{17}Al nuclear moments. A very considerable narrowing of the Cr^{3+} FLN spectrum is then achieved.

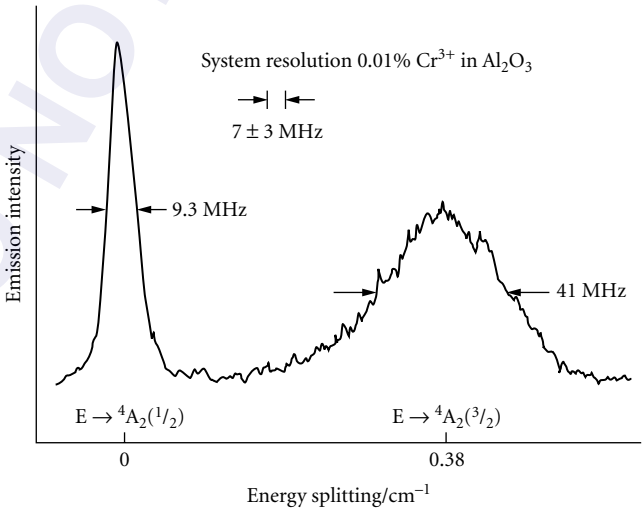

FIGURE 22 FLN in the R_1 transition of ruby.[18]

31.8 LIGHT SCATTERING

Light-scattering experiments are now a routine feature in many optical laboratories. The first observations of light scattering by small particles were reported by Tyndall.[19] Subsequently, theoretical work by Lord Rayleigh[20] showed both that the scattered intensity varied as the fourth power of the frequency and that the scattering was due to molecules rather than dust particles. Many of the early studies were concerned with the depolarization of the light after being scattered by the dust-free atmosphere. Of course, in the prelaser era, sufficient light intensity could only be achieved by use of strongly condensing lenses to focus light onto the gas cell. Very great care was then necessary to obtain reliable depolarization measurements. Even in the laser era it is still essential to avoid any effects due to parasitic light which often plague light-scattering experiments.

A significant early result from scattering of light by gases was that the scattered light intensity varied with the density of the gas being used as the sample. However, Lord Rayleigh discovered that the intensity scattered per molecule decreased by a factor of order 10 on condensation to the liquid phase. There is a somewhat smaller decrease in going from the liquid phase to the solid. Obviously, some scattering experiments become rather difficult in the solid state. The classical experimental geometry for studying Rayleigh scattering is in the 90° orientation for the scattered radiation. This is also the most useful orientation for Raman scattering in solids.[21]

One important feature of the structure of solids is the periodic disturbance of the crystal structure by the propagation of quantized elastic waves (i.e., phonons). Those elastic waves which travel at the velocity of sound (i.e., sonic waves) are essentially thermal density fluctuations in the elastic medium. Brillouin predicted that such fluctuations should give rise to fine structure in the Rayleigh scattered light when the Bragg coherence condition $\lambda_1 = 2\lambda_p \sin(\phi/2)$ is obeyed. Here λ_1 is the wavelength of light, λ_p is the wavelength of those phonons responsible for scattering the light, and ϕ is the scattering angle. Because the scattering centers are in motion, the scattered light is frequency shifted by the Doppler effect. It is an easy matter to show that the Doppler shift, $\Delta\nu$, is given by

$$\Delta\nu = \pm\nu_p = \pm 2\nu_1(\mathrm{v}/c)\sin(\phi/2) \tag{20}$$

where ν_p is the frequency of the density fluctuations in the medium and v is the velocity of sound in the medium. For light in the visible region then, that part of the phonon spectrum probed by the Brillouin scattering is in the gigahertz frequency region. In addition, the Brillouin components are completely polarized for 90° scattering. Before the advent of lasers, the study of Brillouin scattering effects in solids was exceedingly difficult. It remains a technique more used in gases than in condensed media.

Raman was one of numerous scientists engaged in research into light scattering during the decade 1920 to 1930. Much of his work was carried out using sunlight as a source. However, in experiments using monochromatic light, he observed in the spectrum of light scattered at 90° by liquid samples, new lines at wavelengths not present in the original light.[21] The frequency displacement of these new lines from source frequency was found to be independent of the wavelength of the incident light. This was contrary both to fluorescence excitation and Brillouin scattering [Eq. (20)]; hence was born a new scattering phenomenon for which Raman was awarded the Nobel prize and which now bears his name. The frequency shifts in the Raman spectrum of a particular substance are related to but not identical to infrared absorption frequencies. In general, infrared transitions occur when there is a change in the electric dipole moment of a center as a consequence of the local atomic vibrations. The Raman lines occur when a change in polarizability is involved during atomic vibrations. This usually means that infrared transitions occur only between states of opposite parity whereas Raman transitions occur between states of the same parity. Thus the infrared and Raman spectra give complementary information about the vibrational spectra of spectroscopic centers.

Raman scattering measurements have found wide application in condensed matter physics. The spectrometer systems have much in common with fluorescence spectrometers, although lasers provide the excitation source almost without exception. Single-frequency lasers (He-Ne, Ar^+, Ke^+) and tunable dye lasers and solid-state lasers have all been used. Most lasers provide a polarized output and it is necessary to modify this to allow the excitation polarization to be varied. The scattered

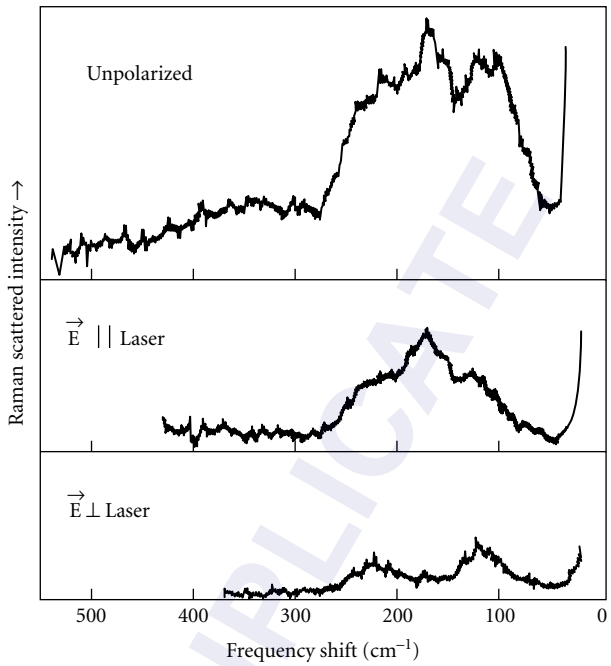

FIGURE 23 Raman spectra of *F*-centers in NaCl for different polarizations of the detected radiation. The shifts are measured relative to the 514.5 nm wavelength of the Ar^+ laser.[20]

light is observed via a monochromator in a direction normal to the laser beam. Again, provision is made for the polarization of the scattered radiation to be analyzed. To permit observation closer to the laser line, double or triple monochromators are used to eliminate all traces of stray light. Furthermore, one must take trouble to separate out the Raman-scattered light from any fluorescence signal. Since the Raman signal is instantaneous, it is comparatively straightforward to recover the desired signal from the decaying fluorescence signal using time-resolution techniques.

An example of the application of Raman spectroscopy in color center physics is shown in Fig. 23. The intensity of scattering versus wavelength shift from the Ar^+ laser excitation is shown for F-centers in NaCl[22] for which the longitudinal optic frequency is 270 cm^{-1}. The major Raman-shifted spectrum occurs below 200 cm^{-1}, showing that the vibrational interaction is due to ionic displacements close to the defect. These local modes have broad peak centers near $\hbar\omega = 175$ cm^{-1}. A comparison of the polarized and unpolarized excitation spectra shows that the local mode scattering is supplemented by a lattice vibrational contribution covering much of the 0 to 500 cm^{-1} frequency shift.

32.1 GLOSSARY

A	area
a	amplitude
C	ratio of peaks to valleys
d	distance
E	electric field
F	finesse
FSR	free spectral range
I	intensity
$J_i(\ )$	Bessel function
L	length
m	integer
N	number of fringes
n	refractive index
p	optical path difference
R	reflectance
r	radius
T	transmittance
v	velocity
λ	wavelength
θ	angle
ν	frequency
φ	phase
ψ	phase difference
ω	angular velocity

32.2 INTRODUCTION

Optical interferometers have made possible a variety of precision measurements using the interference phenomena produced by light waves.[1,2] This chapter presents a brief survey of the basic types of interferometers and discusses some of their applications.

32.3 BASIC TYPES OF INTERFEROMETERS

Interferometric measurements require an optical arrangement in which two or more beams, derived from the same source but traveling along separate paths, are made to interfere. Interferometers can be classified as *two-beam* interferometers or *multiple-beam* interferometers according to the number of interfering beams; they can also be grouped according to the methods used to obtain these beams.

The Fizeau Interferometer

In the Fizeau interferometer, as shown in Fig. 1, interference fringes of equal thickness are formed between two flat surfaces separated by an air gap and illuminated with a collimated beam. If one of the surfaces is a standard reference flat surface, the fringe pattern is a contour map of the errors of the test surface. Absolute measurements of deviations from flatness can be made by an intercomparison of three surfaces. Modified forms of the Fizeau interferometer are also used to test convex and concave surfaces by using a converging or diverging beam.[3]

The Michelson Interferometer

The Michelson interferometer, shown schematically in Fig. 2, uses a beam splitter to divide and recombine the beams. As can be seen, one of the beams traverses the beam splitter three times, while the other traverses it only once. Accordingly, a compensating plate of the same thickness as the beam splitter is introduced in the second beam to equalize the optical paths in glass. With an extended source, the interference pattern is similar to that produced in a layer of air bounded by the mirror M_1 and M_2', the image of the other mirror in the beam splitter. With collimated light, fringes of equal thickness are obtained. The Michelson interferometer modified to use collimated light (the Twyman-Green interferometer) is used extensively in optical testing.[4]

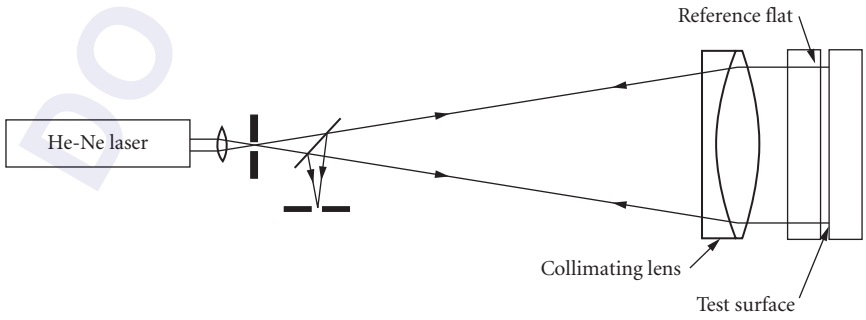

FIGURE 1 The Fizeau interferometer.

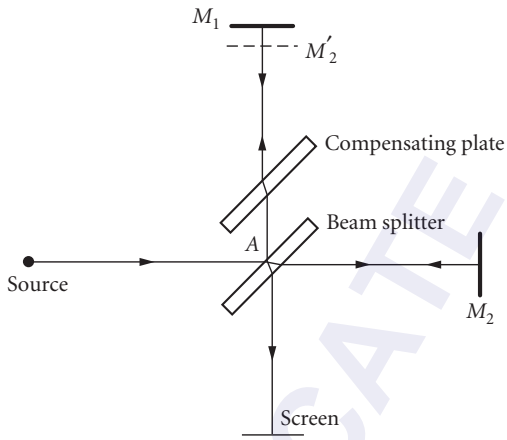

FIGURE 2 The Michelson interferometer.

The Mach-Zender Interferometer

The Mach-Zehnder interferometer uses two beam splitters and two mirrors to divide and recombine the beams. As shown in Fig. 3, the fringe spacing and the plane of localization of the fringes obtained with an extended source can be controlled by varying the angle between the beams and their lateral separation when they emerge from the interferometer. The Mach-Zehnder interferometer has been used for studies of gas flows and plasmas.

The Sagnac Interferometer

In the Sagnac interferometer, as shown in Fig. 4, the two beams traverse the same closed path in opposite directions. Because of this, the interferometer is extremely stable and easy to align, even with an extended broadband light source.

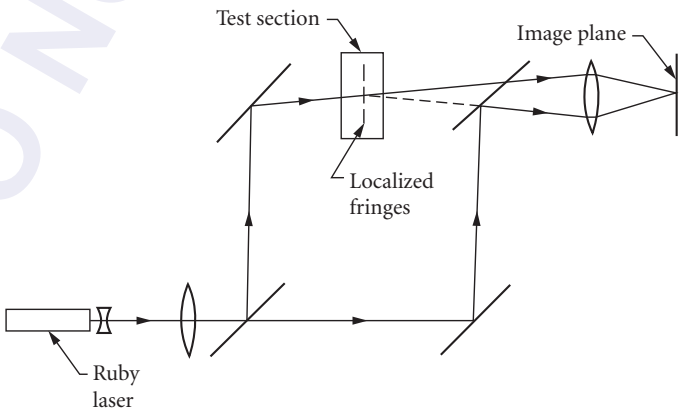

FIGURE 3 The Mach-Zehnder interferometer.

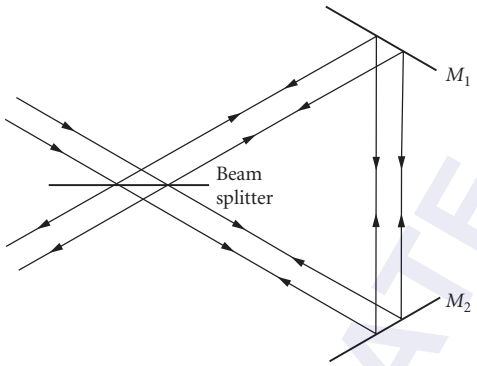

FIGURE 4 The Sagnac interferometer.

The Sagnac interferometer has been used for rotation sensing. When the interferometer is rotated with an angular velocity ω about an axis making an angle θ with the normal to the plane of the interferometer, a phase difference φ is introduced between the beams given by the relation

$$\varphi = (8\pi\omega A \cos\theta)/\lambda c \tag{1}$$

where A is the area enclosed by the light path, λ is the wavelength, and c is the speed of light.

Polarization Interferometers

Polarization interferometers are used in interference microscopy.[5] The Nomarski interferometer, shown schematically in Fig. 5, uses two Wollaston (polarizing) prisms to split and recombine the beams. If the separation of the beams in the object plane (the lateral shear) is small compared to the dimensions of the object, the optical path difference corresponds to the phase gradients in the test object.

Grating Interferometers

Gratings can be used as beam splitters in the Michelson and Mach-Zender interferometers. Such an arrangement is very stable, since the angle between the beams is affected only to a small extent by the orientation of the gratings. Figure 6 is a schematic of an interferometer that has been used to test fine-ground surfaces at grazing incidence utilizing two diffraction gratings to split and recombine the beams.[6]

Shearing Interferometers

Shearing interferometers are widely used for optical testing, since they eliminate the need for a reference surface. As shown in Fig. 7, in a lateral shearing interferometer two images of the test wavefront are superimposed with a mutual lateral displacement, while in a radial shearing interferometer one of the images is contracted or expanded with respect to the other.[7,8]

The Fabry-Perot Interferometer

The Fabry-Perot interferometer[9] is used widely in high-resolution spectroscopy. It consists of two flat, parallel surfaces with highly reflecting, semitransparent coatings. If the surfaces are separated by a distance d and the medium between them has a refractive index n, the normalized value of the transmitted intensity at a wavelength λ for rays traversing the interferometer at an angle θ is

$$I_T(\lambda) = T^2/(1 + R^2 - 2R\cos\varphi) \tag{2}$$

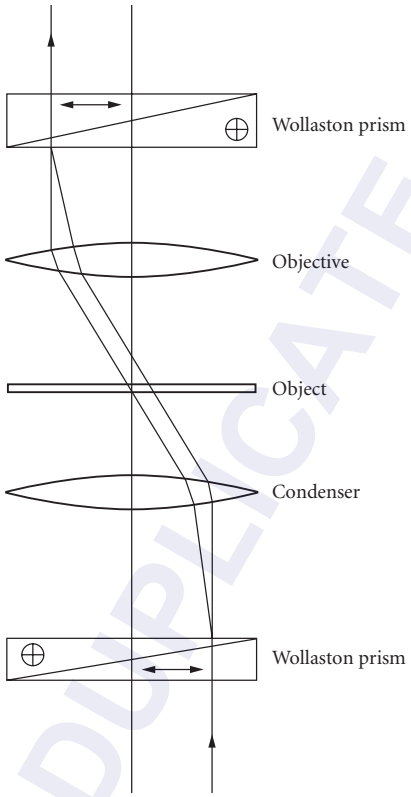

FIGURE 5 The Nomarski interferometer.

where T and R are, respectively, the transmittance and reflectance of the surfaces and $\varphi = (4\pi/\lambda)nd\cos\theta$. With an extended source of monochromatic light, the fringes seen by transmission are narrow, concentric rings. The free spectral range (FSR), which corresponds to the range of wavelengths that can be handled without successive orders overlapping, is given by the relation

$$\mathrm{FSR}_{\lambda} = \lambda^2/2nd \tag{3}$$

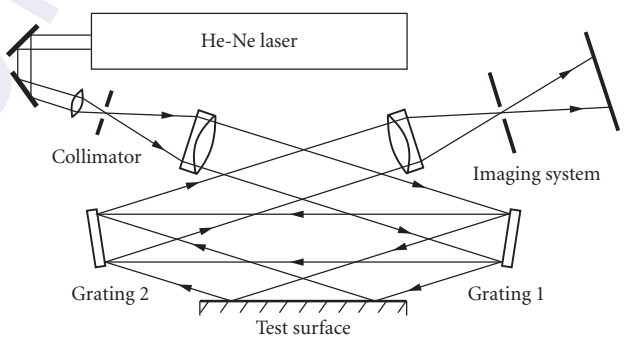

FIGURE 6 Grating interferometer used to test fine-ground surfaces at grazing incidence. (*From Ref. 6.*)

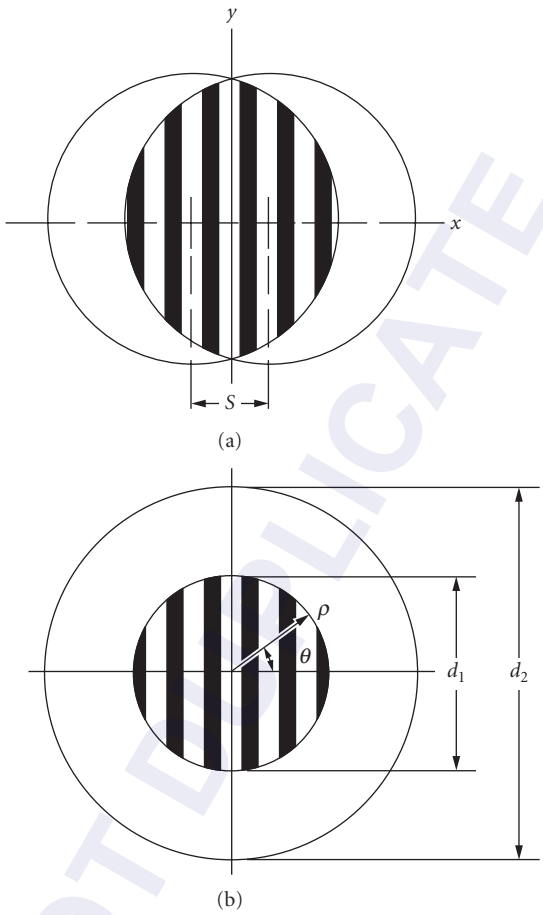

FIGURE 7 Fields of view in (*a*) lateral and (*b*) radial shearing interferometers.

while the width of the peaks at half the maximum intensity corresponds to a change in φ given by the relation

$$\Delta\varphi = 2(1-R)/R^{1/2} \tag{4}$$

The ratio of the free spectral range to the width of the fringes at half maximum intensity is known as the *finesse F,* and is given by the relation

$$F = \pi R^{1/2}/(1-R) \tag{5}$$

Two useful variants of the Fabry-Perot interferometer are the multiple-passed Fabry-Perot interferometer and the confocal Fabry-Perot interferometer. With the conventional Fabry-Perot interferometer, the ratio of the intensity at the maxima to that at the minima between them is

$$C = [(1+R)/(1-R)]^2 \tag{6}$$

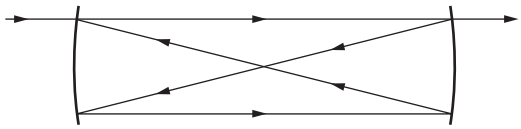

FIGURE 8 Ray paths in a confocal Fabry-Perot interferometer.

and for typical values of reflectance ($R \approx 0.95$), the background due to a strong spectral line may mask a neighboring weak satellite. A much higher contrast factor may be obtained by double- or multiple-passing the interferometer.[10,11]

The confocal Fabry-Perot interferometer uses two spherical mirrors whose spacing is chosen, as shown in Fig. 8, so that their foci coincide. Any ray, after traversing the interferometer four times, then emerges along its original path.[12] The confocal Fabry-Perot interferometer has a higher throughput than the plane Fabry-Perot interferometer and produces a uniform output field. It is, therefore, the preferred form for operation in a scanning mode by using piezoelectric spacers to vary the separation of the mirrors.

32.4 THREE-BEAM AND DOUBLE-PASSED TWO-BEAM INTERFEROMETERS

Because of the sinusoidal intensity distribution in two-beam interference fringes, it is difficult to estimate their position visually to better than 1/20 of their spacing. However, it is possible to detect much smaller optical path variations using the intensity changes in a system of interference fringes.

Three-Beam Interferometers

Zernike's three-beam interferometer, shown schematically in Fig. 9, uses three beams produced by division of a wavefront at a screen containing three parallel, equidistant slits.[13] In this arrangement, the optical paths of all three beams are equal at a point in the back focal plane of the lens L_2. The two outer slits provide the reference beams, while the beam from the middle slit, which is twice as broad, is used for measurements. The intensity at any point in the interference pattern is then given by the relation

$$I = I_0[3 + 2\cos 2\psi + 4\cos\psi\cos\varphi] \tag{7}$$

where ψ is the phase difference between the two outer beams, and φ is the phase difference between the middle beam and the two outer beams at the center of the field. The intensities at adjacent maxima are equal only when φ is an odd multiple of $\pi/2$. Two positions of the plane of observation can

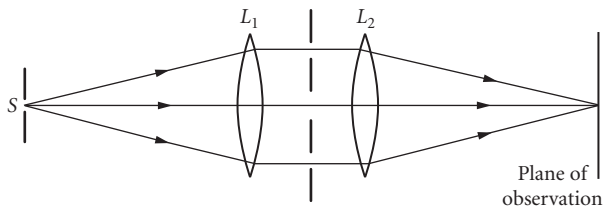

FIGURE 9 Zernike's three-beam interferometer.

be found that satisfy this condition, one inside and the other outside the focus, and any small change in the optical path of the middle beam can be measured from the shift in these positions.

Three-beam fringes can also be produced with an optical system similar to that in the Jamin interferometer.[14] Settings are made by means of a compensator in the middle beam and can be repeated to $\lambda/200$ by visual observation, and to better than $\lambda/1000$ with a photoelectric detector.[15]

Double-Passed Two-Beam Interferometers

Fringes whose intensity is modulated in the same manner as three-beam fringes can be produced by reflecting the beams emerging from a two-beam interferometer back through the interferometer.[16] In this case also, the intensity of the adjacent fringes is equal when the phase difference between the single-passed beams is

$$\varphi = (2m+1)\pi/2 \tag{8}$$

where m is an integer. Measurements can be made with a precision of $\lambda/1000$.

32.5 FRINGE-COUNTING INTERFEROMETERS

One of the main applications of interferometry has been in accurate measurements of length using the wavelengths of stabilized lasers. Electronic fringe counting has become a practical technique for such measurements.[17]

The very narrow spectral line widths of lasers make it possible to use a heterodyne system. In one implementation of this technique, a He-Ne laser is forced to oscillate simultaneously at two frequencies, ν_1 and ν_2, separated by a constant frequency difference of about 2 MHz, by applying an axial magnetic field.[18] These two waves, which are circularly polarized in opposite senses, are converted to orthogonal linear polarizations by a $\lambda/4$ plate.

As shown in Fig. 10, a polarizing beam splitter reflects one beam to a fixed reflector, while the other is transmitted to a movable reflector. A differential counter receives the beat frequencies from the photodetector D_s and a reference photodetector D_R. If the two reflectors are stationary, the two beat frequencies are the same, and the net count is zero. However, if one of the reflectors is moved, the change in the optical path is given by the net count.

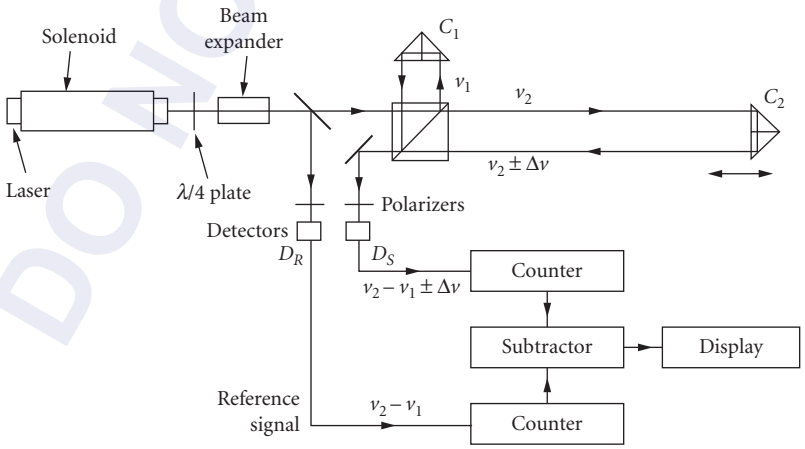

FIGURE 10 Heterodyne fringe-counting interferometer. (*After Ref. 18 © Copyright Hewlett-Packard Company. Reproduced with permission.*)

32.6 TWO-WAVELENGTH INTERFEROMETRY

If a length is known within certain limits, the use of a wavelength longer than the separation of these limits permits its exact value to be determined unambiguously by a single interferometric measurement. One way to synthesize such a long wavelength is by illuminating the interferometer simultaneously with two wavelengths λ_1 and λ_2. The envelope of the fringes then corresponds to the interference pattern that would be obtained with a synthetic wavelength

$$\lambda_s = \lambda_1 \lambda_2 / |\lambda_1 - \lambda_2| \tag{9}$$

This technique can be implemented very effectively with a carbon dioxide laser, since it can operate at a number of wavelengths that are known very accurately, yielding a wide range of synthetic wavelengths.[19]

Two-wavelength interferometry and fringe-counting can be combined to measure lengths up to 100 m by switching the laser rapidly between two wavelengths as one of the mirrors of a Twyman-Green interferometer is moved over the distance to be measured.[20]

32.7 FREQUENCY-MODULATION INTERFEROMETERS

New interferometric techniques are possible with laser diodes which can be tuned electrically over a range of wavelengths.[21] One of these is frequency-modulation interferometry.

Figure 11, shows a frequency-modulation interferometer that can be used to measure absolute distances, as well as relative displacements, with high accuracy.[22] In this arrangement, the signal beam reflected from the movable mirror returns as a circularly polarized beam, since it traverses the $\lambda/8$ plate twice. The reference beam reflected from the front surface of the $\lambda/8$ plate interferes with the two orthogonally polarized components of the signal beam at the two detectors to produce outputs that vary in quadrature and can be fed to a counter to determine the magnitude and sign of any displacement of the movable mirror.

To make direct measurements of the optical path difference, the frequency of the laser is ramped linearly with time by using a function generator to vary the injection current of the laser. An optical

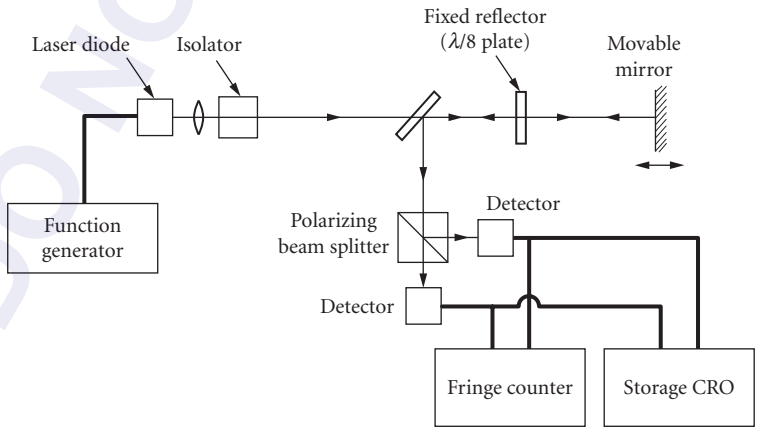

FIGURE 11 Frequency-modulation interferometer for measurements of distance. (*From Ref. 22.*)

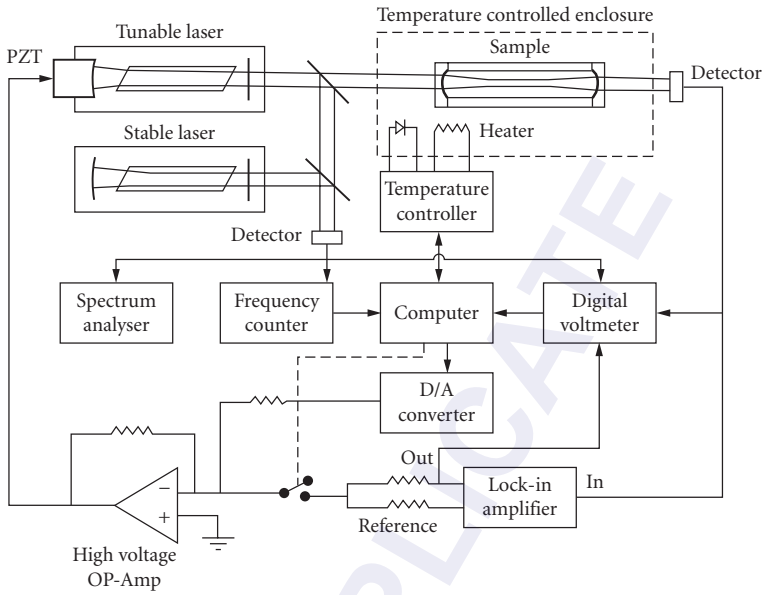

FIGURE 12 Heterodyne interferometer for measurements of thermal expansion. (*From Ref. 24.*)

path difference p introduces a time delay p/c between the two beams, so that they produce a beat signal with a frequency

$$f = (p/c)(dv/dt) \tag{10}$$

where dv/dt is the rate at which the laser frequency is varying with time.

32.8 HETERODYNE INTERFEROMETERS

In heterodyne interferometers, a frequency difference is introduced between the two beams by means of two acousto-optic modulators operated at slightly different frequencies. The output signal from a square-law detector then contains an ac component at the difference frequency whose phase corresponds to the phase difference between the interfering light waves.[23]

Heterodyne techniques can also be used for measurements of very small changes in length.[24,25] In the setup shown in Fig. 12, the frequency of a laser is locked to a transmission peak of a Fabry-Perot interferometer formed by attaching two mirrors to the ends of the sample. The beam from this slave laser is mixed at a photodetector with the beam from a stable reference laser. Changes in the separation of the mirrors can be evaluated from the changes in the beat frequency.

A simple arrangement for measuring small displacements uses two diode lasers with external cavities. A displacement of the reflecting mirror of one cavity results in a change in the beat frequency.[26]

32.9 PHASE-SHIFTING INTERFEROMETERS

In phase-shifting interferometers, the phase difference between the two beams in the interferometer is varied linearly with time and the values of intensity at any point in the interference pattern are integrated over a number of equal segments covering one period of the sinusoidal signal.

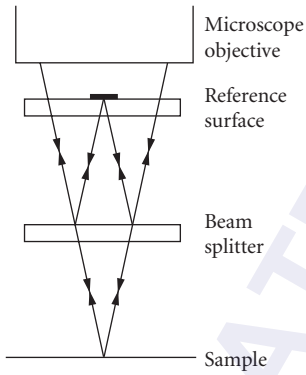

FIGURE 13 Schematic of a compact optical system (the Mirau interferometer) used for phase-stepping interference microscopy.

Alternatively the phase difference between the two beams can be changed in a number of equal steps, and the corresponding values of intensity at each data point are measured and stored. In both cases, the values obtained can be represented by a Fourier series, whose coefficients can be evaluated to obtain the original phase difference between the interfering beams at each point.[27,28] Typically, four measurements are made at each point, corresponding to phase intervals of 90°. If I_1, I_2, I_3, and I_4 are the values of intensity obtained, the phase difference between the interfering beams is given by the relation

$$\tan \varphi(x, y) = (I_1 - I_3)/(I_2 - I_4) \tag{11}$$

Phase-shifting interferometers are used widely in optical testing, since a detector array can be used in conjunction with a microcomputer to make measurements simultaneously at a large number of points covering the interference pattern.

Figure 13 is a schematic of a compact optical system (the Mirau interferometer) used for phase-shifting interference microscopy. In this setup, the phase-steps are introduced by mounting the sample on a piezoelectric transducer (PZT) to which an appropriately varying voltage is applied. In a Fizeau interferometer, it is possible to use a laser diode as the light source and vary its output frequency.[29] If the initial optical path difference between the beams in the interferometer is p, a frequency shift $\Delta\nu$ in the output of the laser diode introduces an additional phase difference between the beams

$$\Delta\varphi = (2\pi p/\nu)\,\Delta\nu \tag{12}$$

Another way of shifting the phase of a beam of light is by a cyclic change in its state of polarization. Since the resulting phase shift (the Pancharatnam phase) is very nearly achromatic, measurements can be made with white light, so that phase ambiguities at steps are eliminated.[30]

32.10 PHASE-LOCKED INTERFEROMETERS

The output intensity from an interferometer depends on the phase difference between the beams. In phase-locked interferometers, any variation in the output intensity is detected and fed back to a phase modulator in the measurement path so as to hold the output intensity constant. The changes in the optical path can then be estimated from the changes in the drive signal to the phase modulator.[31]

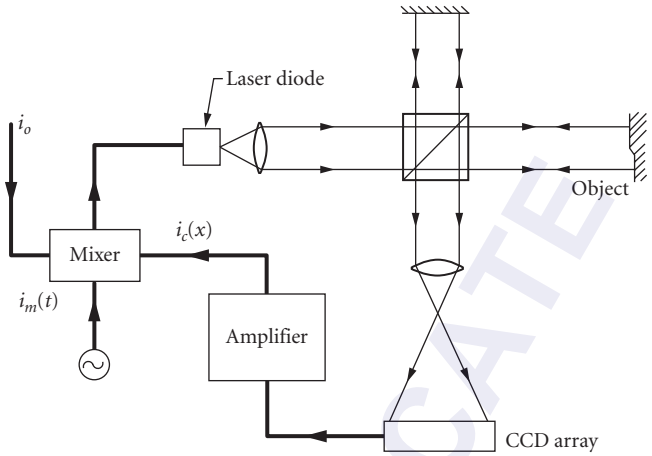

FIGURE 14 Schematic of a phase-locked interferometer using a laser diode source. (*From Ref. 32.*)

Drifts can be eliminated by using an ac amplifier. If the phase of one beam in the interferometer is subjected to a sinusoidal modulation

$$\Delta\varphi(t) = \Delta\varphi \sin \omega t \tag{13}$$

with an amplitude $\Delta\varphi \ll \pi$, the output signal at the modulation frequency has an amplitude

$$I_\omega(t) = 4(I_1 I_2)^{1/2} J_1(\Delta\varphi) \sin \varphi \tag{14}$$

and drops to zero when $\varphi = m\pi$, where m is an integer. Since, at this point, both the magnitude and the sign of this signal change, it can be used as the input to a servo system that locks the phase difference between the beams at this point.

With a laser diode, it is possible to compensate for changes in the optical path difference by a change in the illuminating wavelength. A typical setup is shown in Fig. 14. The injection current of the laser then consists of a dc bias current i_o, a control current i_c, and a sinusoidal modulation current $i_m(t) = i_m \cos \omega t$ whose amplitude is chosen to produce the required phase modulation.[32]

Direct measurements of changes in the optical path are possible by sinusoidal phase-modulating interferometry, which uses a similar setup, except that in this case the amplitude of the phase modulation is much larger (typically around π radians). The modulation amplitude is determined from the amplitudes of the components in the detector output corresponding to the modulation frequency and its third harmonic. The average phase difference between the beams can then be determined from the amplitudes of the components at the modulation frequency and its second harmonic.[33]

32.11 LASER-DOPPLER INTERFEROMETERS

Light scattered from a moving particle undergoes a frequency shift, due to the Doppler effect, that is proportional to the component of its velocity in a direction determined by the directions of illumination and viewing. With laser light, this frequency shift can be evaluated by measuring the frequency of the beats produced by the scattered light and a reference beam, or by the scattered light from two illuminating beams incident at different angles.[34,35]

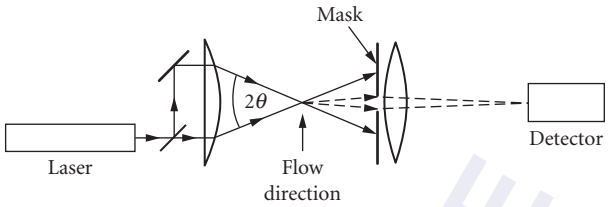

FIGURE 15 Optical arrangement used for laser-Doppler velocimetry.

Laser-Doppler interferometry can be used for measurements of the velocity of moving materials,[36] as well as for measurements, at a given point, of the instantaneous flow velocity of a moving fluid to which suitable tracer particles have been added.[37] A typical optical system for measurements on fluids is shown in Fig. 15. If the two illuminating beams in this arrangement make equal but opposite angles $\pm\theta$ with the viewing direction, the frequency of the beat signal is given by the relation

$$f = (2|v| \sin\theta)/\lambda \tag{15}$$

where v is the component of the velocity of the particle in the plane of the beams at right angles to the direction of observation. To distinguish between positive and negative flow directions, the frequency of one of the beams is offset by a known amount by means of an acousto-optical modulator. Simultaneous measurements of the velocity components along two orthogonal directions can be made by using two pairs of beams in orthogonal planes. Interactions between the two pairs of beams are avoided by using different laser wavelengths.

Laser diodes and optical fibers can be used to build very compact laser-Doppler interferometers.[38,39] A frequency offset can be introduced between the beams either by using a piezoelectric fiber-stretcher driven by a sawtooth waveform in one path, or by ramping the injection current of the laser diode linearly.

Laser-Doppler interferometry can also be used to measure vibration amplitudes. Typically, one of the beams in an interferometer is reflected from a point on the vibrating specimen, while the other, whose frequency is offset, is reflected from a fixed reference mirror. The output from a photodetector then consists of a component at the offset frequency (the carrier) and two sidebands. The amplitude of the vibration can be determined from a comparison of the amplitudes of the carrier and the sidebands.[40] This technique can measure vibration amplitudes down to a few thousandths of a nanometer.[41]

32.12 LASER-FEEDBACK INTERFEROMETERS

Laser-feedback interferometers use the fact that the output of a laser is strongly affected if, as shown in Fig. 16, a fraction of the output beam is reflected back into the laser cavity by an external mirror M_3. The output of the laser then varies cyclically with the position of M_3, one cycle of modulation corresponding to a displacement of M_3 by half a wavelength.[42]

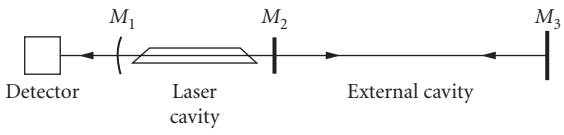

FIGURE 16 Schematic of a laser-feedback interferometer.

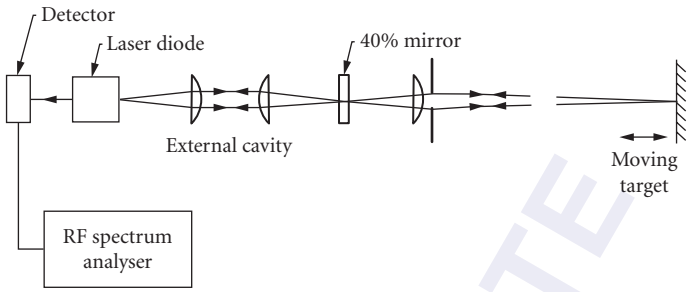

FIGURE 17 Feedback interferometer using a diode laser for velocimetry. (*From Ref. 47.*)

The operation of such an interferometer can be analyzed by considering the two mirrors M_3 and M_2 as a Fabry-Perot interferometer that replaces the output mirror of the laser. A variation in the spacing of M_3 and M_2 results in a variation in the reflectivity of this interferometer for the laser wavelength and, hence, in the gain of the laser.

A very compact laser-feedback interferometer can be set up with a single-mode laser diode.[43] Small displacements can be detected by measuring the changes in the laser output when the laser current is held constant. Measurements can be made over a larger range by mounting the laser on a piezoelectric transducer and using an active feedback loop to stabilize the length of the optical path from the laser to the mirror.[44]

Laser-feedback interferometers can also be used for velocimetry. If the light reflected from the moving object is mixed with the original oscillating wave inside the laser cavity, the beat signal can be observed in the beam leaving the rear end of the laser.[45,46] Very high sensitivity can be obtained with a laser diode operated near threshold.[47] If a separate external cavity is used, as shown in Fig. 17, to ensure single-mode operation, measurements can be made at distances up to 50 m.

32.13 FIBER INTERFEROMETERS

Analogs of conventional two-beam interferometers can be built with single-mode optical fibers. High sensitivity can be obtained with fiber interferometers because it is possible to have very long optical paths in a small space. In addition, because of the extremely low noise level, sophisticated detection techniques can be used.

Fiber-Interferometer Rotation Sensors

Fiber interferometers were first used for rotation sensing, by replacing the ring cavity in a conventional Sagnac interferometer with a closed, multiturn loop made of a single-mode fiber.[48] For a loop rotating with an angular velocity ω about an axis making an angle θ with the plane of the loop, the phase difference introduced between the two counterpropagating beams is

$$\Delta\varphi = (4\pi\omega L r \cos\theta)/\lambda c \tag{16}$$

where L is the length of the fiber, r is the radius of the loop, λ is the wavelength, and c is the speed of light. High sensitivity can be obtained by increasing the length of the fiber in the loop. In addition, very small phase shifts can be measured, and the sense of rotation determined, by introducing a nonreciprocal phase modulation in the beams and using a phase-sensitive detector.[49]

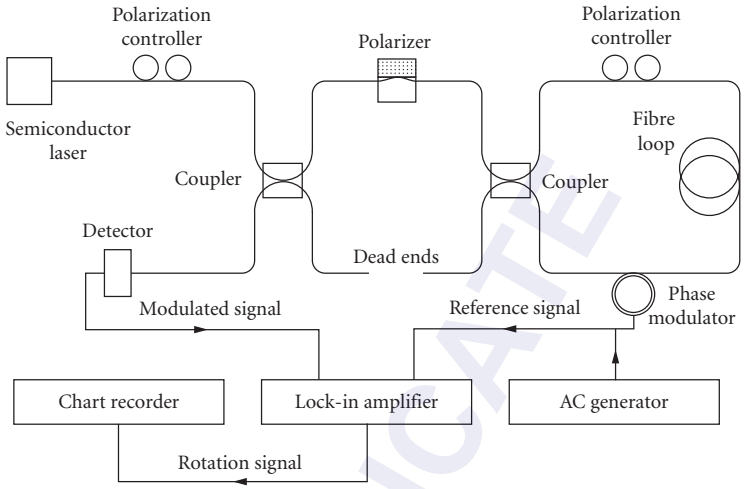

FIGURE 18 Fiber-interferometer for rotation sensing. (*From Ref. 50.*)

Figure 18 is a schematic of a typical all-fiber interferometric rotation sensor.[50] In this arrangement, the beam splitters are replaced by optical couplers, and a phase modulator consisting of a few turns of the fiber wound around a piezoelectric cylinder is located near one end of the optical fiber coil.

Fiber-interferometer rotation sensors have the advantages of small size and low cost. If care is taken to minimize noise due to back scattering and nonreciprocal effects due to fiber birefringence, performance close to the limit set by photon noise can be obtained.[51]

Generalized Fiber-Interferometer Sensors

The optical path length in a fiber is affected by its temperature and also changes when the fiber is stretched, or when the pressure changes. Accordingly, an optical fiber can be used in an interferometer to sense changes in these parameters.[52]

Figure 19 is a schematic of an all-fiber interferometer that can be used for such measurements.[53] A layout analogous to a Mach-Zehnder interferometer avoids optical feedback to the laser. Optical

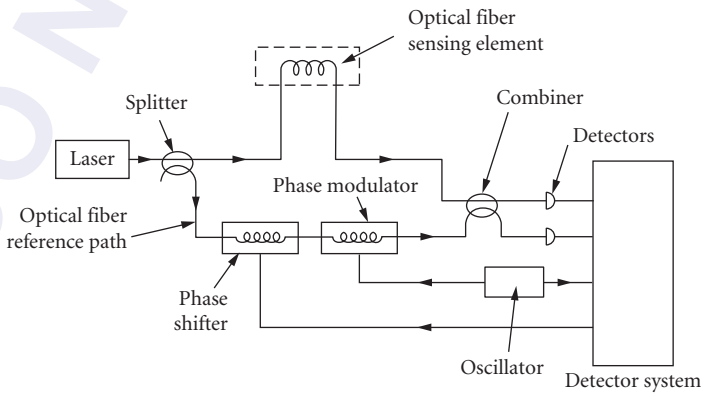

FIGURE 19 Schematic of a typical fiber-interferometer sensor. (*From Ref. 53.*)

fiber couplers are used to divide and recombine the beams, and measurements can be made with either a heterodyne system or a phase-tracking system. Detection schemes involving either laser-frequency switching or a modulated laser source can also be used. Optical phase shifts as small as 10^{-6} radian can be detected.

Fiber interferometers can also be used for measurements of magnetic or electric fields with a fiber sensor bonded to a magnetostrictive element[54] or jacketed with a piezoelectric polymer.[55] Phase ambiguities can be overcome by using a birefringent fiber[56] or by fiber-optic low-coherence interferometry, using a broad-band source.[57]

Multiplexed Fiber-Interferometer Sensors

Fiber-interferometer sensors can be multiplexed to measure different quantities at different locations with a single light source and detector and the same set of transmission lines. Techniques developed for this purpose include frequency-division multiplexing, time-division multiplexing, and coherence multiplexing.[58–62]

32.14 INTERFEROMETERIC WAVE METERS

Tunable lasers have created a need for instruments that can measure their output wavelengths with an accuracy commensurate with their narrow line width. Dynamic wave meters have greater accuracy but can be used only with continous wave (cw) sources; static wave meters can also be used with pulsed lasers.

Dynamic Wave Meters

A dynamic wave meter typically consists of a two-beam interferometer in which the number of fringes crossing the field is counted as the optical path is changed by a known amount. In one form, shown in Fig. 20, two beams, one from the laser whose wavelength is to be determined and another from a frequency stabilized He-Ne laser, traverse the same two paths in opposite directions.[63] The fringe systems formed by these two lasers are imaged on the two detectors D_1 and D_2, respectively. If, then, the end reflector is moved through a distance d, we have

$$\lambda_1/\lambda_2 = N_2/N_1 \tag{17}$$

where N_1 and N_2 are the numbers of fringes seen by D_1 and D_2, respectively, and λ_1 and λ_2 are the wavelengths in air. To obtain the highest precision, it is also necessary to measure the fractional order numbers. This can be done by phase-locking an oscillator to an exact multiple of the frequency

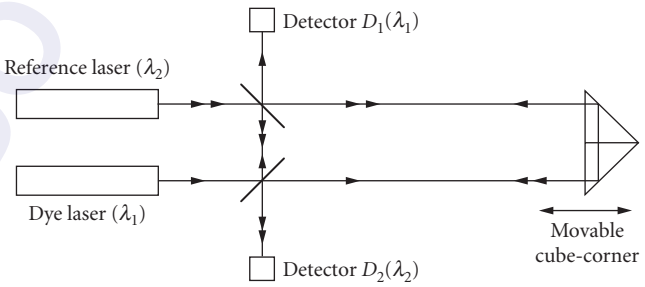

FIGURE 20 Optical system of a dynamic interferometric wave meter. (*From Ref. 63.*)

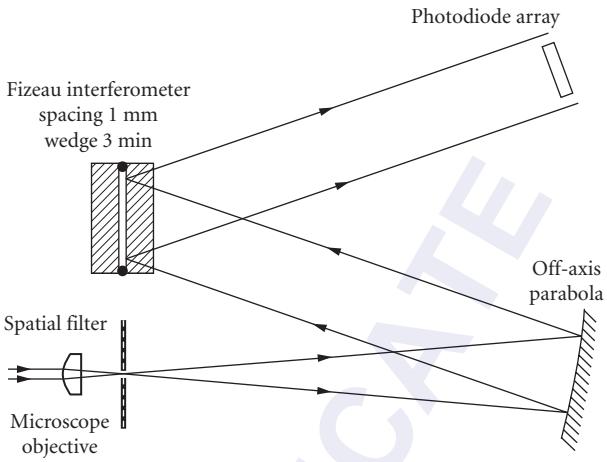

FIGURE 21 Schematic of a static interferometric wave meter. (*From Ref. 67.*)

of the ac signal from the reference channel, or by digitally averaging the two signal frequencies.[64] It is also possible to use a vernier method in which the counting cycle starts and stops when the phases of the two signals coincide.[65] With these techniques, a precision of 1 part in 10^9 can be obtained.

Another type of dynamic wave meter uses a scanning Fabry-Perot interferometer in which the separation of the mirrors is changed slowly. If this interferometer is illuminated with the two wavelengths to be compared, peak transmission will be obtained for both wavelengths at intervals given by the condition

$$m_1\lambda_1 = m_2\lambda_2 = p \tag{18}$$

where m_1 and m_2 are the changes in the integer order and p is the change in the optical path difference.[66] A precision of 1 part in 10^7 can be obtained with a range of movement of only 25 mm, because the Fabry-Perot fringes are much sharper than two-beam fringes.

Static Wave Meters

The simplest type of static wave meter is based on the Fizeau interferometer.[67] As shown in Fig. 21, a collimated beam from the laser is incident on two uncoated fused-silica flats separated by about 1 mm and making an angle of about 3 min of arc with each other. The intensity distribution in the fringe pattern formed in the region in which the shear between the two reflected beams is zero is recorded by a linear detector array.[68] In the first step, the integral interference order is calculated from the spatial period of the interference pattern: the exact value of the wavelength is then calculated from the positions of the maxima and minima.

32.15 SECOND-HARMONIC AND PHASE-CONJUGATE INTERFEROMETERS

Nonlinear optical elements are used in second-harmonic and phase-conjugate interferometers.[69]

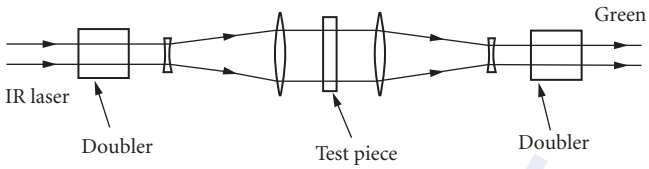

FIGURE 22 Second-harmonic interferometer: analog of the Mach-Zehnder interferometer. (*From Ref. 70.*)

Second-Harmonic Interferometers

One type of second-harmonic interferometer, shown in Fig. 22, is an analog of the Mach-Zehnder interferometer.[70] In this interferometer, the infrared beam from a Q-switched Nd: YAG laser ($\lambda_1 = 1.06\,\mu m$) is incident on a frequency-doubling crystal. The green ($\lambda_2 = 0.53\,\mu m$) and infrared beams emerging from this crystal traverse the test piece and are then incident on another frequency-doubling crystal.

The fringe number at any point in this interferometer is

$$N = (n_1 - n_2)d/\lambda_2 \tag{19}$$

where n_1 and n_2 are the refractive indices of the test specimen at 1.06 and 0.53 μm, respectively, and d is its thickness.

Phase-Conjugate Interferometers

In a phase-conjugate interferometer, the wavefront that is being studied is made to interfere with its conjugate.[71] Such an interferometer has the advantage that a reference wavefront is not required; in addition, the sensitivity of the interferometer is doubled.

Figure 23 is a schematic of a phase-conjugate interferometer that is an analog of the Fizeau interferometer.[72] In this interferometer, the signal beam is incident on a conventional, partially reflecting mirror placed in front of a single crystal of barium titanate which functions as an internally self-pumped phase-conjugate mirror.

An interferometer in which both mirrors have been replaced by phase-conjugating mirrors is unaffected by misalignment of the mirrors and the field of view is normally completely dark. However, because of the delay in the response of the phase conjugator, dynamic changes in the optical path difference are displayed.[73,74]

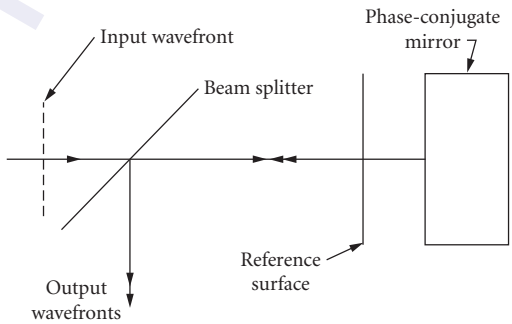

FIGURE 23 Schematic of a phase-conjugate Fizeau interferometer. (*From Ref. 72.*)

Interferometric Optical Switches

Nonlinear optical effects have also been exploited to develop high-speed interferometric optical switches.[75]

32.16 STELLAR INTERFEROMETERS

A star can be considered as an incoherent light source whose dimensions are small compared to its distance from the earth. Accordingly, the complex degree of coherence between the fields at two points on the earth's surface is given by the normalized Fourier transform of the intensity distribution over the stellar disc.

Michelson's Stellar Interferometer

Michelson used the interferometer shown schematically in Fig. 24 to make observations of the visibility of the fringes formed by light from a star, for different separations of the mirrors. The separation at which the fringes disappeared was used to determine the angular diameter of the star. The problems encountered by Michelson in making measurements at mirror separations greater than 6 m have been overcome in new versions of this interferometer.[76]

The Intensity Interferometer

The intensity interferometer[77] uses measurements of the correlation between the fluctuations in the intensity at two photodetectors separated by a suitable distance, which is proportional to the square of the modulus of the degree of coherence of the fields. Atmospheric turbulence only affects the phase of the incident waves and has no effect on the measured correlation. In addition, since the spectral bandwidth is limited by the electronics, it is only necessary to equalize the optical paths to within a few centimeters. It was therefore possible to use light collectors separated by distances up to 188 m.

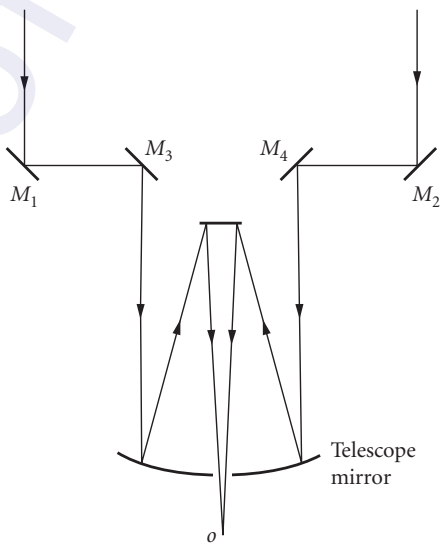

FIGURE 24 Michelson's stellar interferometer.

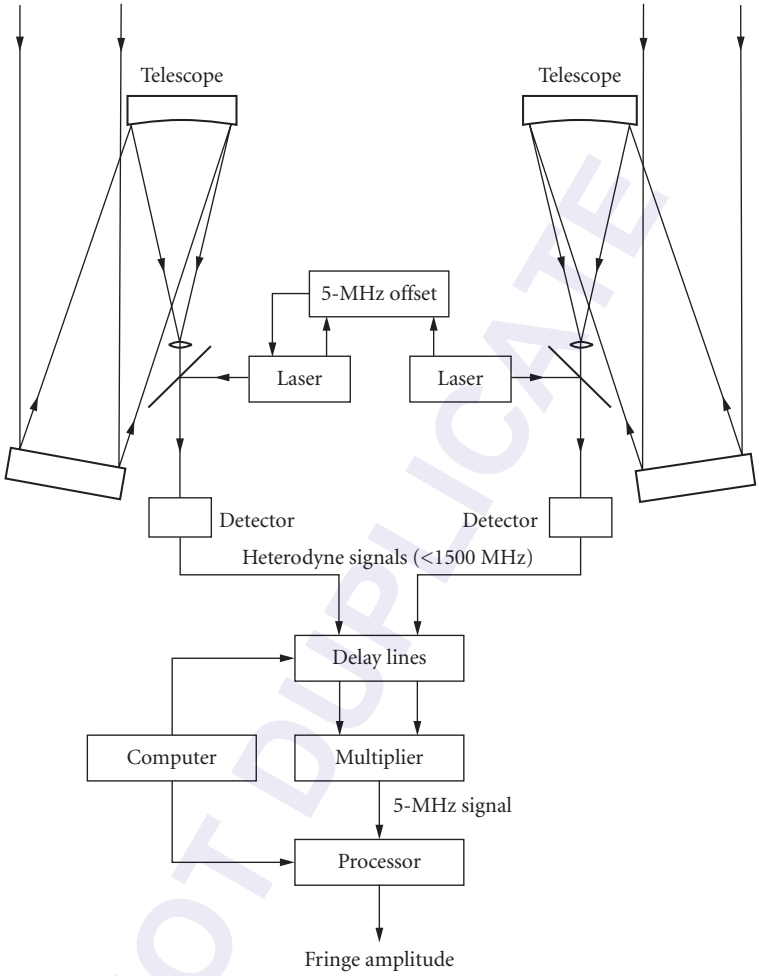

FIGURE 25 Schematic of an infrared heterodyne stellar interferometer. (*From Ref. 78.*)

Heterodyne Stellar Interferometers

In heterodyne stellar interferometers, as shown in Fig. 25, light from the star is mixed with light from two CO_2 lasers, whose frequencies are offset by 5 MHz with respect to each other, at two photodetectors, and the resulting heterodyne signals are multiplied in a correlator. The output signal from the correlator is a measure of the degree of coherence of the wave fields at the two photodetectors.[78–80]

As in the intensity interferometer, it is only necessary to equalize the two paths to within a few centimeters. However, higher sensitivity is obtained, because the output is proportional to the product of the intensities of the laser and the star.

Nulling Interferometers and Interferometric Arrays

Problems arise when trying to detect a planet near a star. Nulling interferometers reduce the flux from the star, relative to its surroundings, by making the light from the star interfere with itself.[81]

Another advance is the application of multielement interferometric arrays to obtain high-resolution images of stellar objects.[82,83]

32.17 GRAVITATIONAL-WAVE INTERFEROMETERS

Gravitational waves produced by cosmic sources, such as binary systems of neutron stars, collapsing supernovas and black holes, can be thought of as an alternating strain that propagates through space, affecting the dimensions and spacing of all material objects.

Since gravitational waves are transverse quadrupole waves, the effect of a gravitational wave on a Michelson interferometer would be a change in the difference of the lengths of the two arms.[84] However, to obtain the required sensitivity to strains, of the order of 1 part in 10^{21}, unrealistically long arms (>100 km) would be needed. In the LIGO project, higher sensitivity is obtained by using, as shown in Fig. 26, two identical Fabry-Perot interferometers (d = 4 km) at right angles to each other, with their mirrors mounted on freely suspended masses.[85] The separations of the mirrors are compared by locking the frequency of a laser to a transmission peak of one interferometer and using a servo system to adjust the length of the other interferometer continuously, so that its peak transmittance is also at the same frequency.

Even higher sensitivity is obtained by making use of the fact that, to avoid overloading the detector, the interferometer is normally adjusted so that observations are made on a dark fringe. Most of the light is then returned to the source. This light is recycled by using an extra mirror to reflect it back into the interferometer with the right phase.

33.1 GLOSSARY

A	wave amplitude
a	diameter of viewing lens in speckle imaging system
d	fringe spacing
d_{sp}	characteristic speckle diameter
$\mathbf{E}$	electric field vector
$\hat{\mathbf{e}}$	polarization unit vector
f	wave frequency
I	field irradiance
I_H	irradiance of the field in plane of hologram
K	proportionality constant
k	propagation constant
r	radial position coordinate
T	transmittance of the hologram
v	distance from lens to image plane in speckle imaging system
θ_1, θ_2	object and reference beam angles
λ	wavelength
ϕ	wave phase
Ψ	complex field amplitude
Ψ_H	complex field amplitude in plane of hologram
Ψ_O	complex amplitude of object wave field
Ψ_R	complex amplitude of reference wave field
Ψ_T	complex amplitude of field transmitted by hologram

33.2 INTRODUCTION

The three-dimensional imagery produced by holography accounts for much of the popular interest in this technique. Conceptual applications, such as the holodeck seen on the television series *Star Trek: The Next Generation,* and actual applications, like the widespread use of embossed holograms on book and magazine covers, gift wrapping, product packaging, and credit cards, have fascinated and captured the imagination of millions. Holography was discovered in 1947 by Gabor and revived in the early 1960s through the work of Leith and Upatnieks. Since that time, most practitioners in the field believe that technical applications, rather than imaging, have represented the utility of holography in a more significant way. This chapter is a brief overview of some of the more important technical applications, particularly as they relate to a variety of instrumentation problems. The discussion addresses several ways holography has been used to observe, detect, inspect, measure, or record numerous physical phenomena. The second section presents a brief review of the basic principles of wavefront reconstruction. The third section (Sec. 33.4) addresses one of the more important application of holography—holographic interferometry. Included in this section is a review of electronic or television holography which takes this powerful interferometric technique into the real-time domain. Section 33.5 addresses several instrumental applications of holographic optical elements (HOEs). Sections 33.6 and 33.7 discuss ways in which holography has been applied in the semiconductor industry. Section 33.8 briefly addresses the holographic storage of information.

33.3 BACKGROUND AND BASIC PRINCIPLES

Holography is a method of recording and reconstructing wavefronts residing anywhere in the electromagnetic spectrum or acoustic spectrum. This chapter addresses optical holography as practiced in or near the visible region of the electromagnetic spectrum. The principals of wavefront reconstruction were discovered by Gabor[1–3] in an attempt to improve the resolving power of the electron microscope. The original purpose was never accomplished, but this basic discovery evolved into one of the most significant new fields of study in the twentieth century. Gabor's early work received little attention because the lack of a light source with sufficient coherence severely limited the quality of the images produced. However, the invention of the laser in the early 1960s heralded a holographic renaissance. During this period, Leith and Upatnieks[4,5] recognized the parallels between their work in coherent radar and Gabor's wavefront reconstruction concepts. Their experiments in the optical region of the spectrum with the newly available HeNe laser produced the first high-quality, three-dimensional images. The publication of this work created an explosive interest in the field as well as many unrealistic predictions about what might be accomplished with holographic three-dimensional imagery. The work of numerous researchers established the medium's true capabilities and limitations; consequently, many successful applications ensued. Progress continues to be made in the development of new materials and techniques sustaining a high level of interest in holography and its technical, commercial, and artistic applications.

Holography is most often associated with its ability to produce striking three-dimensional images. Therefore, a logical place to start in understanding holography is to compare this imaging science with its two-dimensional predecessor—photography. A light wavefront is characterized by several parameters; the two most important of these are its intensity (or irradiance) and its local direction of propagation. Photography records only one of these parameters—intensity—in the plane of the recording medium or photographic film. The intensity distribution of a light wave emanating from an object may be recorded by simply exposing a film plate placed in proximity to the object; however, this will not produce a discernible image. Recording a photograph is accomplished by imaging the object onto the film with a lens, thereby establishing a correspondence between points on the object and points in the film plane.

Holography also records the intensity distribution of a wavefront; in addition, the local propagation direction (or phase) is recorded through the process of optical interference. The process in its simplest form is illustrated in Fig. 1. The light from a laser is split into two parts, expanded with a short-focal-length lens (usually a microscope objective), and spatially filtered with a pinhole to

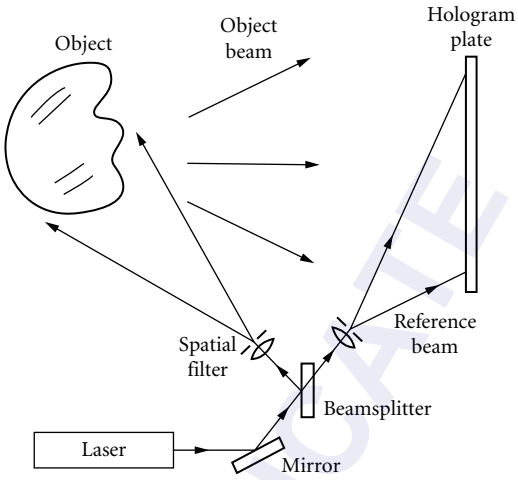

FIGURE 1 Typical optical arrangement for making a simple laser transmission hologram.

remove intensity variations caused primarily by nonuniformities in the lens. One of the split beams (object beam) is directed to the object; the other (reference beam) is incident directly on the recording medium (such as high-resolution silver halide film). The light reflected from and scattered by the object combines with the reference beam at the plate to form an interference fringe field. These fringes are recorded by the film. The spacing of these fringes d is given by the grating equation

$$d = \frac{\lambda}{(\sin\theta_1 + \sin\theta_2)} \tag{1}$$

where λ is the wavelength of the light, and θ_1 and θ_2 are the angles made by the object and reference beams relative to the normal. For visible light and common recording geometries, the fringe frequency $(1/d)$ can exceed 2000 fringes (or line-pairs) per millimeter. Therefore, the recording material must be of very high resolution relative to conventional photographic film which is usually in the range of 50 line-pairs per millimeter. The stability of the fringe is extremely sensitive to the mechanical motion of the object and optical components. To record holograms with good fringe stability, the optical system must be stable enough to prevent motions greater than a fraction of a wavelength. For this reason, the common practice is to use rigid optical components placed on a stable, vibration-isolated table.

Illumination of the developed hologram by the reference beam alone reveals a three-dimensional image which is essentially identical to the original object as viewed in laser light. Observing the holographic image of the object is exactly like looking at the object through the window formed by the plate with full parallax and look-around capability. The object wave is reconstructed when the illumination (reference) wave is diffracted by the grating formed in the recording medium. This grating is formed by variation of the optical transmittance or optical thickness of the material along the fringe lines. The amplitude hologram formed with silver halide film may be converted to a phase hologram by bleaching; this results in a significant increase in diffraction efficiency. Other materials (such as photopolymer film) produce phase holograms directly.

The holographic recording and reconstruction process may be described in general mathematical terms as follows. The object and reference fields satisfy the Helmholtz equation

$$\nabla^2\mathbf{E} + k^2\mathbf{E} = 0 \tag{2}$$

where $\mathbf{E}$ is the electric field vector and $k = 2\pi/\lambda$ is the propagation constant.

A spherical wave solution of this equation may be expressed in the form

$$\mathbf{E} = Ae^{ikr}\mathbf{e}^{i2\pi ft}\hat{\mathbf{e}} \tag{3}$$

where A is the amplitude of the wave, f is the frequency, and $\hat{\mathbf{e}}$ is the polarization unit vector.

The complex field amplitude Ψ is defined as

$$\Psi = Ae^{i\phi} \tag{4}$$

where $\phi = kr$ is the phase. The irradiance of the field is given by

$$\begin{aligned} I &= \mathbf{E}\cdot\mathbf{E}^* = \Psi\Psi^*\hat{\mathbf{e}}\cdot\hat{\mathbf{e}} = \Psi\Psi^* \\ &= A^2 = |\Psi|^2 \end{aligned} \tag{5}$$

where $*$ denotes the complex conjugate.

The field in the plane of the hologram Ψ_H is the sum of the object and reference fields:

$$\Psi_H = \Psi_O + \Psi_R \tag{6}$$

and the irradiance of the field at the hologram is given by (assuming parallel polarization of the waves):

$$\begin{aligned} I_H &= \Psi_H\Psi_H^* = (\Psi_O + \Psi_R)(\Psi_O + \Psi_R)^* \\ &= |\Psi_O|^2 + |\Psi_R|^2 + \Psi_O\Psi_R^* + \Psi_R\Psi_O^* \end{aligned} \tag{7}$$

After processing, and apart from a constant term, the transmittance T of the hologram is proportional to the irradiance of the field at the hologram;

$$T = K[|\Psi_O|^2 + |\Psi_R|^2 + \Psi_O\Psi_R^* + \Psi_R\Psi_O^*] \tag{8}$$

When illuminated by the reference wave, the field transmitted by the hologram Ψ_T is given by the hologram transmittance multiplied by the reference wave field:

$$\Psi_T = K[\Psi_R(|\Psi_O|^2 + |\Psi_R|^2) + |\Psi_R|^2\Psi_O + \Psi_R^2\Psi_O^*] \tag{9}$$

The first term in this equation for Ψ_T is simply the transmitted wave altered by an attenuation factor. The second term is the original object wave multiplied by an amplitude factor; this term represents the virtual holographic image of the object. The third term is the conjugate object wave. In off-axis holography, the real image formed by this wave is weak, lies out of the field of view, and does not make a significant contribution to the imaging process. However, for Gabor's original in-line holography, this term represented an objectionable twin image which overlapped and obstructed viewing of the desired image. An important contribution of the Leith and Upatnieks off-axis reference scheme was the elimination of this twin image.

Many different types of holograms can be made by varying the location of the object relative to the recording medium, the directions and relative angles of the object and reference beams, and the wavefront curvature of these beams. The properties of these hologram types vary greatly; much research has been performed to characterize and successfully apply the different formats. Vigorous work is still being pursued in both areas of imaging and technical applications. For a thorough explanation of holography and its many applications, the reader may consult any of several standard texts on the subject (e.g., Refs. 6–11).

33.4 HOLOGRAPHIC INTERFEROMETRY

Interferometry provides a means of measuring optical path differences through the analysis of fringe patterns formed by the interference of coherent light waves. Optical path differences of interest may be produced by mechanical displacements, variations in the contour of one surface relative

to another, and variations in the refractive index of a material volume. Classical interferometry involves the interference of two relatively simple optical wavefronts which are formed and directed by optical components. These components must be of sufficient quality that they do not introduce random phase variations across the field that compete with or totally mask the optical path length differences of interest. Typical examples of classical interferometry include the use of configurations such as the Michelson or Twyman Green and Mach-Zehnder interferometers to determine the surface figure of optical components, study the refractive index variation in optical materials, and visualize the properties of flowing gases. The need for high-quality optical surfaces in classical interferometry is a consequence of the difficulty, using classical optical methods, of generating two separate but identical optical wavefronts of arbitrary shape. Although it was not immediately recognized by early holography researchers, the ability to holographically record then replay an arbitrary wavefront in a predictable fashion obviated this basic limitation of classical interferometry. With holographic interferometry, polished optical surfaces are not required and diffusely reflecting objects of any shape may be studied.

In holographic interferometry, a wavefront is stored in the hologram and later compared interferometrically with another wavefront. Phase differences between these two wavefronts produce fringes that can be analyzed to yield a wide range of both qualitative and quantitative information about the system originating these two wavefronts. Several researchers working independently made experimental observations related to this fact.[12–17] Once the full implication of this discovery was realized, a period of intense research activity began to develop a solid theoretical understanding of this powerful new technique. Holographic interferometry quickly became the most important application of the relatively young science of holography. Although other branches of holography have successfully matured, most notably HOEs, holographic interferometry remains today the area in which holography has probably made the greatest impact.

As stated earlier, holographic interferometry involves the interferometric comparison of two wavefronts separated in time. This comparison can be made in a variety of ways which constitute the basic methods of holographic interferometry: real-time, double-exposure, and time-average. Real-time interferometry is realized by the interference of a holographically reconstructed object wave with the wave emanating from the actual object. This is accomplished as follows. The holographic plate is exposed, developed, then replaced in its holder in its original position. Reference- and object-beam intensities are adjusted so that the illuminated object and its holographic image are of approximately equal brightness. Since the reconstructed object wavefront is 180° out of phase with the object wavefront, the object should be dark when viewed through the holographic plate. In practice, one or two broad fringes usually appear across the object due to emulsion shrinkage effects and lack of complete mechanical precision in returning the holographic plate to its original position. Any disturbance of the object which results in a mechanical displacement of its surface will now produce a fringe system which can be viewed in real time. The structure and periodicity of the fringes are related to the surface displacement. The mechanical surface deformation can result from an applied force, change in pressure, change in temperature, or any combination of the three. The quantitative details of this surface deformation can be derived from an analysis of this fringe system.

In double-exposure holographic interferometry, the two wavefronts to be compared are stored in the same hologram. This is done by holographically recording the image of the object under study in two exposures separated in time in the same holographic plate. If nothing is done to alter the object wavefront between these two exposures, the resulting image will appear as for a single-exposure hologram. However, if the object is perturbed in some way between these two exposures, an interference fringe system will appear in the final image. Again, this fringe system is related to the mechanical deformations of the object surface caused by the disturbance. Real-time holographic interferometry allows one to study the effects of object perturbation of varying types and degrees over any desired length of time and in real time. In contrast, double-exposure holographic interferometry examines a particular change of the state of the object between two particular points in time. A double-exposure holographic interferogram then might be thought of as a single data point record. The interferogram might be a record of the change of the object from one stable state to another, which might be recorded with a continuous wave laser. Or the interest might be to compare two states of a rapidly varying system most effectively recorded using a pulsed laser.

In some respects, the double-exposure holographic interferogram involves less experimental complexity, because both exposures are made in a single hologram plate held in a fixed position. Mechanical registration of the plate to a baseline position is not required. Emulsion shrinkage due to wet process development of silver halide film affects the holographic fringe systems for both exposures in the same way; therefore, it is not a problem for double-exposure interferometry. Another feature which may or may not be of benefit, depending on the parameters of the experiment, is that the superimposed images for the two exposures are in phase, thereby producing a bright baseline image. Double-exposure interferometry has been used very effectively to record fast events such as the flight of a bullet passing through a chamber.[18] The first exposure is made of the chamber alone before passage of the bullet; the second exposure is made with the bullet in midflight. The interferogram is an interference recording of the refractive index variations in the chamber created by the disturbance of the bullet.

Vibrating surfaces may be studied using either real-time or time-average holographic interferometry.[16,19] A vibrating object presents a continuum of surface configurations or surface deformations to an interferometric system. A unique interferometric fringe system is associated with each state of the surface for any particular point in time during the vibrating cycle. In real-time interferometry, the interference fringes are formed by the addition of wavefronts from the surface of the object at rest and from the vibrating surface at some point during its vibrating cycle. The fringe pattern observed is a visual time average of this continuum set of interferogram fringe systems. A time-average holographic interferogram is made by exposing the holographic plate while the object is vibrating; the exposure time is usually multiple vibration periods. This hologram may be thought of as a continuum set of exposures, each recording the interference of the object wave with its temporal counterparts in the rest of the continuum over one cycle. The end result is a fringe pattern, directly related to the surface vibration pattern, in which the fringe lines represent contours of constant vibration amplitude. A more physical view of the process derives from observing that holographic fringe movement in the recording medium due to object movement nullifies the holographic recording. Thus, regions of a vibrating surface in motion (antinodes) will appear dark while regions at rest (nodes) will appear bright.

Stroboscopic illumination has long been used to study objects in motion. Coupling this technique with holographic interferometry produces interferograms of vibrating objects with enhanced fringe visibility and greater information content. The technique may be used to make real-time observations or to record double-exposure holograms of vibrating surfaces. In the real-time configuration, the hologram of the test object at rest is made in the usual fashion. The object is then vibrated and strobed with a laser set to flash at a particular point in the vibrating cycle. The fringe system formed is produced by interference of the wavefront from the object at rest and the wavefront from the object at this particular point in the cycle. The timing of the laser flash may be varied to observe the evolution of the surface vibration throughout its entire cycle. A double-exposure interferogram is formed by exposing the hologram plate to two flashes from the strobed laser. In this manner, any two states of the vibrating surface may be compared during its cycle by varying the timing of the laser flashes and their separation. The actual exposure may extend over several vibration cycles. This method results in fringes of much higher contrast than those yielded by time-average holography.

An interesting variant of hologram interferometry is contour generation.[20–22] This is accomplished by making two exposures of an object with a refractive index change in the medium surrounding the object or a change in the laser wavelength between exposures. Either method yields fringes on the surface of the object. The fringe positions are related to the height of points on the object relative to a fixed plane. The two-wavelength method may be implemented in real-time by first making a hologram of an object in the usual manner at one wavelength, then illuminating both the object and the processed hologram (carefully placed in its original position) at a different wavelength. Both methods have been successfully applied in a variety of situations.

In many cases, the interpretation of the fringe pattern produced by a holographic interferogram is a simple matter of qualitative assessment. For example, defects or flaws may be identified by anomalous local variations in a background fringe pattern. The presence or absence of these

anomalies may provide all the information required in a nondestructive evaluation experiment. However, a detailed quantitative assessment of the mechanical deformation of the surface may be desired—this can involve a complex mathematical analysis of the fringe system. Quantitative analysis of the fringe pattern is often complicated by the fact that the fringes are not necessarily localized on the surface of the object. The interpretation of holographic interferograms and analysis of the fringe data have been the subject of considerable study.[23–27] Numerous methods such as sandwich holographic interferometry,[28,29] fringe linearization interferometry,[30] difference holographic interferometry,[31] and fringe carrier techniques[32] have been developed to facilitate this interpretation. In addition, the development of automatic fringe reading systems and data reduction software have greatly aided this process. However, fringe data reduction remains a challenge for many situations despite the progress that has been made.

The basic methods of holographic interferometry (real-time, double-exposure, and time-average) are in widespread use and continue to be the mainstay of this technique. However, important refinements have been made which have greatly added to the power of holographic interferometry. These advances include the use of real-time recording media[33,34] and heterodyne holographic interferometry[35] Real-time holographic recording materials (such as photorefractive crystals) provide an adaptive feature that makes the interferometer less sensitive to vibration, air currents, and other instabilities. The reliability of the interferometric process in a hostile environment is thus improved. Heterodyne techniques using two separate reference waves and a frequency shift between these two waves upon reconstruction has greatly improved the accuracy of holographic interferometry. Measurements with accuracies as high as $\lambda/1000$ can be made using heterodyne methods. Holographic moiré,[36] infrared holographic interferometry,[37] and the use of optical fibers[38] have also significantly extended the capabilities of holographic interferometry.

In the laboratory, where conditions are well-controlled, silver halide film has been the recording material of choice for holographic interferometry due to its relatively high sensitivity, low cost, and reliability. However, in field applications such as the factory floor, the wet processing requirements of silver halide film make this material much less attractive and, for some time, inhibited the use of holographic interferometry in many situations. Other materials that do not require wet processing (such as photopolymer films) are available, but these materials have very low sensitivity. The development of the thermoplastic recording material,[39] which does not require wet processing but retains the high sensitivity of silver halide film, made possible the much more convenient application of holographic interferometry in industrial situations. Several companies have commercially marketed holocamera systems using this material. A holographic interferogram made using one of these holocamera systems is shown in Fig. 2.

Holographic interferometry has been applied to an enormous range of problems; this is a simple testimony to its utility and versatility. The classical interferometric testing of the figure of optical components during fabrication can be augmented with holographic interferometry to test for figure during the grinding process since the surface of the test object does not need to be polished.[21] The ability of holographic interferometry to make precise measurements of very small mechanical displacements has enabled it to be used in stress-strain measurements in materials, components, and systems. Mechanical displacements observed with holographic interferometry are often the result of thermal disturbances. Measurement of these thermally induced mechanical displacements with holographic interferometry can provide an accurate determination of the heat transfer properties of the material or system under study.[40] Similarly, diffusion coefficients in liquids can be determined using holographic interferometry.[41,42] Flow visualization and the accurate determination of fluid-flow properties using holographic interferometry has been an intense area of study.[43–45] As noted earlier, the technique can also be used to study high-speed events using short-pulse lasers in the double-pulse mode. Vibration analysis is one of the more powerful applications of holographic interferometry. In this area, the technique has been applied to a diverse array of problems including studies of the vibration properties of musical instruments,[46] vibration patterns in the human eardrum,[47] and vibration properties of mechanical parts such as turbine blades.[48] The application of holographic interferometry to turbine blade mechanics is illustrated in Fig. 3. One of the great virtues of holographic interferometry is that a tremendous wealth of

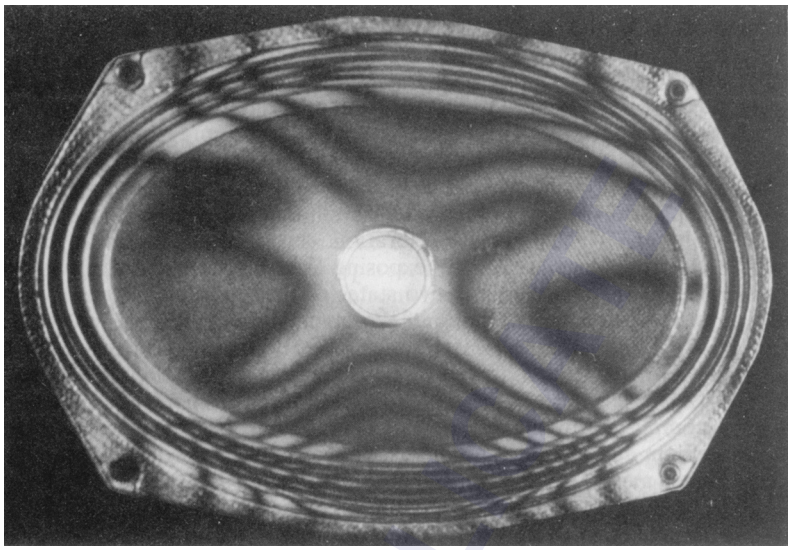

FIGURE 2 Time-average holographic interferogram of a loudspeaker vibrating at resonance. (*Photo courtesy of Newport Corporation.*)

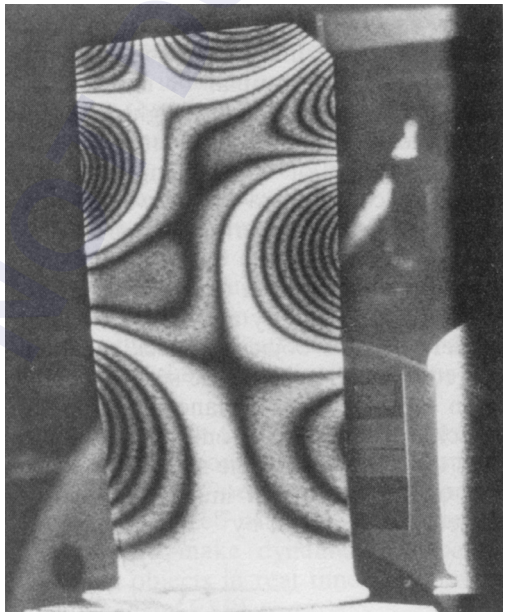

FIGURE 3 Time-average holographic interferogram displaying one of the vibration modes of a turbine blade. (*Photo courtesy of Karl Stetson, United Technologies Research Center.*)

information can be garnered from its application without destroying the test object or system. As a result, nondestructive evaluation or nondestructive testing has been one of the most important areas of application for this technique. As an example, holographic interferometry has been successfully used to observe subsurface defects in solid opaque objects. Even though the interference pattern is produced strictly by mechanical surface deformations, these surface variations are often indicative of subsurface changes (e.g., ply separations in automobile tires and interlayer delamination in composite materials).[49] Subsurface defects are usually manifest in local anomalies of the fringe pattern and a qualitative examination of the interferogram will often discern the effect. The literature is replete with articles describing these and many other applications of holographic interferometry. For the reader interested in an in-depth discussion of the theory and application of holographic interferometry, numerous textbooks and review articles are available (see, for example, Refs. 6–8 and 50–57).

Electronic Holography

Even with the use of thermoplastic recording media, holographic interferometry remains a challenge and, in many cases, unacceptable technique for industrial applications—particularly those that involve on-line quality testing in a production environment. Speckle-pattern interferometry,[58] another technique closely associated with holographic interferometry, alleviates many shortcomings of the traditional holographic approach when combined with electronic image recording and processing equipment.

Speckle is the coarse granular or mottled intensity pattern observed when a diffuse surface is illuminated with coherent light. Wavelets reflected from the randomly oriented facets of an optically rough surface interfere to produce this effect when the size of the facets is on the order of a wavelength or larger. Although this interference occurs throughout the space occupied by the wave scattered by the surface, the interference that produces the observable pattern takes place in the plane of the detector or recording medium (i.e., the retina of the eye or the film plane of a camera). The speckle-pattern recorded by an imaging system (eye or camera) is known as *subjective speckle,* while the intensity variation detected by a scanning detector above a coherently illuminated diffuse surface is referred to as *objective speckle*. Objective speckle is the resultant sum of the waves scattered from all parts of the surface to a point in space; in subjective speckle, wave summation in the observation plane is limited to the resolution cell of the system. The objective-speckle scale depends only on the plane in space where it is viewed, not on the image system used to view it. The size of the image plane or subjective speckle depends on the aperture of the viewing or imaging system. For subjective speckle, the characteristic speckle diameter, d_{sp} is given by[59]

$$d_{sp} \approx \frac{2.4\lambda v}{a} \tag{10}$$

where λ is the wavelength, v is the distance from the lens to the image plane, and a is the diameter of the viewing lens aperture.

A fringe pattern is formed when the speckle patterns of the diffuse surface in its original and displaced positions are properly combined. The formation of this fringe pattern is known as speckle-pattern interferometry, of which there are two basic types: speckle-pattern photography and speckle-pattern correlation interferometry. Both techniques, which form the basis for electronic speckle-pattern interferometry (ESPI), and other forms of electronic holography will be discussed in this section. The remarks made here are derived from Ref. 58, which contains a thorough discussion of the topic.

By varying the recording and viewing configurations, speckle-pattern interference fringes can be made sensitive to in-plane and out-of-plane displacements, displacement gradients, and the first derivative of displacement gradients. Speckle-pattern interferometry has two distinct advantages over holographic interferometry: (1) the direction of the magnitude sensitivity of the fringes can be varied over a larger range, and (2) the resolution of the recording medium

for speckle-pattern interferometry does not need to be nearly as high. Therefore, speckle-pattern interferometry is a much more flexible technique, although the fringe definition is not nearly as good as with holographic interferometry due to the degradation of the images by the speckle pattern.

In speckle-pattern photography, the object is illuminated by a single light beam; no reference beam is involved. Some of the light scattered by the object is collected by a lens and recorded on photographic film. The film plane may be an image plane (in-focus) or some other plane (out-of-focus). The location of the film plane determines whether the resulting interferometric fringes are sensitive to in-plane or out-of-plane motion. Two exposures of the film are made: one with the object in its original position, the second with the object deformed or displaced. Proper illumination of the film negative with coherent light produces a fringe pattern in the observation plane which is related to the object motion. With the use of appropriate recording and viewing geometries, the fringes may be made to superimpose an image of the object. If the object is illuminated by a plane wavefront and the film is in the focal plane of a lens, the fringes are related to out-of-plane displacement gradients. Illumination of the object by a diverging wavefront in the proper geometry yields fringes related to the tilt of the object. Speckle-pattern photography can be used to make time-average stroboscopic and double-pulse measurements just as in holographic interferometry. In speckle-pattern correlation interferometry, a reference beam (either specular or diffuse) is incident upon the observation or recording plane in addition to the light scattered by the object. Interferometric fringes are produced by the correlation of the speckle patterns in the observation plane for the displaced and undisplaced object. Real-time or live-correlation fringes may be produced as follows. The object and reference beams are recorded with the object in its original position using photographic film. The film is developed and the film negative is replaced in its original position. The negative is illuminated with object and reference light, and the object is displaced. Correlation fringes are produced by the process of intensity multiplication. Because of the contrast reversal of the film negative, minimum transmission is found in areas of maximum correlation between the pattern recorded and the pattern produced by the displaced object. Unfortunately, the correlation fringes produced using this technique are of low contrast.

The variation in the correlation of the two speckle patterns which produces the fringes may be made sensitive to different components of surface displacement by using different object and reference beam geometries. One of the most important configurations uses a specular in-line reference beam introduced with a beam splitter or mirror with a pin hole. This configuration may be used to make dynamic displacement measurements or to observe the behavior of vibrating objects in real time. This particular optical geometry is also the most popular arrangement for ESPI.

In ESPI, the photographic film processing methods used for speckle-pattern photography and speckle-pattern correlation interferometry are replaced by video recording and display technology. The concept of using video equipment for this purpose was originated by several researchers working independently during the same period.[60–63] For speckle-pattern interferometry, the minimum speckle size is usually in the range of 5 to 100 μm so that standard television (TV) cameras can be used to record the pattern. The main advantage of using TV equipment is the high data rate. Real-time correlation fringes may be produced and displayed on the TV monitor at 30 frames per second. In addition, the full array of modern video image processing technology is available to further manipulate the image once it is recorded and stored in the system. Another advantage is the relatively high light sensitivity of TV cameras which operate at low light levels, thus enabling satisfactory ESPI measurements with relatively low power lasers.

The ready availability of advanced video recording and processing equipment, its ease of use, and its flexible adaption to various applications make ESPI a near-ideal measurement system in many instances—particularly, industrial situations (such as an assembly line) where rapid data generation and retrieval, and high throughput are required. ESPI overcomes many of the objections of holographic interferometry and has been used extensively for industrial measurements.

Intensity correlation fringes in ESPI are produced by a process of video subtraction or addition. In the subtraction process, the image of a displaced object is subtracted from an electronically

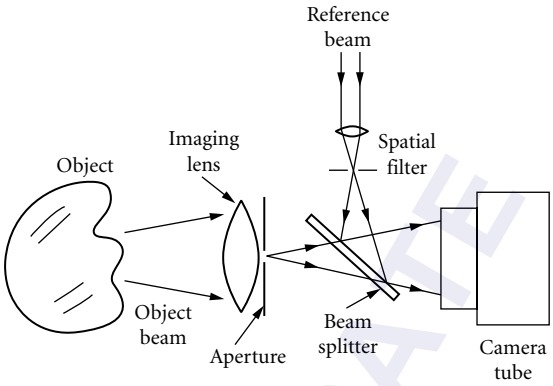

FIGURE 4 Typical ESPI optical arrangement with in-line reference beam.

stored image of the object in its original position to produce the correlation fringes. To observe these fringes, the subtracted video signal is rectified and high-pass filtered, then displayed on a video monitor. This video processing is analogous to the reconstruction step in holography.

For the addition method, both original and displaced images are added optically at the photo cathode of the TV camera. The TV camera detects the light intensity and, again, the signal is full-wave rectified, high-pass filtered, and displayed on the TV monitor. Because of the persistence of the TV tube, the two images need not be recorded simultaneously; however, they must be presented to the camera within its persistence time, usually on the order of 100 ms. The various optical configurations used in speckle-pattern correlation interferometry, employing both specular and diffuse reference beams, may be used in ESPI as well. The most popular of these configurations uses a specular in-line reference beam and may be used to make real-time vibration studies. ESPI has been used for this purpose more than any other application. This optical configuration is shown in Fig. 4. The object and reference beams in Fig. 4 are derived from the same laser with the use of a beam splitter, not shown for simplicity. In holographic interferometry, a high-resolution film is used and the reference beam angle may be any practical value desired. In ESPI, the recording medium (TV camera) has a resolution two orders of magnitude lower than holographic film (on the order of 30 line-pairs per millimeter). Therefore, in ESPI, an in-line reference beam must be used. Furthermore, the aperture of the system must be small enough to keep the interference angle below 1°. All the usual modes of holographic interferometry (real-time, time-average, stroboscopic, and double-exposure) may be performed with ESPI. A time-average ESPI interferogram of an object made with the system operating in the subtraction mode is shown in Fig. 5*a*. For comparison, a holographic interferogram of the same object is shown in Fig. 5*b*. ESPI has been applied to a wide range of measurement problems. These applications are discussed in numerous books, technical papers, and review articles.[64–71]

Despite the flexibility of ESPI and its ease of use, fringe definition is poor compared to holographic interferometry—this has somewhat limited its use. Speckle-averaging and video-processing techniques have provided some improvement in interferogram quality, but very fine interference fringes are still difficult to discern with ESPI. A significant improvement in interferogram quality has been achieved with a newer technique: electro-optic holography (EOH).[72–74] This technique uses the same speckle interferometer optical configuration as ESPI, but processes the video images in a different manner. In EOH, a phase-stepping mirror is added to the reference leg to advance the phase of the reference beam by 90° between successive video frames. Subsequent processing of these phase-stepped images combined with frame and speckle averaging provides interferograms in real-time with nearly the same

resolution and clarity of the traditional film-based holographic interferogram. An interferogram made with an EOH system is shown in Fig. 6.

33.5 HOLOGRAPHIC OPTICAL ELEMENTS

An optical element with the power to direct and/or focus a light wave can be made by recording the fringe pattern formed by two interfering light beams. HOEs or diffractive optical elements, thus produced, have several features that distiuguish them from conventional optics. A compilation of articles on diffractive optics may be found in Ref. 75. References 76 and 77 provide past reviews of the field.

Different types of elements may be produced by varying the curvature of the interfering wavefronts, interbeam angle, and configuration of the recording surface. Lenses with mild or very strong focusing power and plane or focusing mirrors are easily produced. The recording substrate may be plane or any arbitrarily curved shape. An element combining diffractive power with refractive power can be made by placing the recording medium on a curved surface. This method may be used to reduce the aberration of the combined optic since the achromatic dispersion of diffraction and refraction are of opposite sign. Although any of the many types of holographic recording materials may be used to make an HOE, dichromated gelatin and photoresist are preferred because of their high resolution and extremely low optical scatter. Dichromated gelatin has the additional advantage of forming HOEs of very high diffraction efficiency. Photoresist forms a surface relief hologram which makes possible the economical mass production of HOEs with straightforward mechanical replication means. Since the power of an HOE is derived from diffraction at the element's surface, the HOE may be very thin and lightweight. HOEs may be produced by the direct interference of physical light waves, or by calculating the desired interference pattern and printing this pattern onto a substrate by either photographic or electron beam lithographic means. Computer-generated HOEs are advantageous when the required optical wave-fronts are difficult to create physically.

The use of the term "holographic optics" is not technically correct because the definition of holography implies that at least one of the wavefronts being combined to produce an interference record is an information carrier. Consequently, the term "diffractive optics" has gained popularity

and, when applied to gratings, the term "interference gratings" is certainly more appropriate. In this brief discussion, however, we will continue to use the "holographic" terminology.

Certainly one of the most common and successful applications of holographic optics is as a grating in spectrographic instruments.[78–80] The main advantage of holographic gratings* are that they can be made free of the random and periodic groove variation found in even the finest-ruled gratings, and they have low light scatter. This latter property is especially important when even a small amount of stray light is objectionable (such as in the study of Raman spectra of solid samples). To produce high-quality holographic gratings, extreme care must be used in the fabrication process. Photoresist is the preferred recording material for reasons mentioned above; however, it is very insensitive and requires long exposure times, often many hours. Therefore, a highly stable optical system is essential. The recording room must be free of air currents, the air must be filtered and dust-free, and the photoresist coating must be defect-free. Stray light scatter from optical mounts and other objects in the recording setup must be eliminated by proper baffling and masking. The interfering beams must be appropriately conditioned by spatial filtering to ensure diffraction-limited performance. If beam-forming optics are used, for example, to produce collimated beams for making plane holographic gratings, these optics must be aberration-free and of diffraction-limited quality.

After exposure and chemical development, the surface relief pattern is metalized and the holographic grating is replicated as conventional master-ruled gratings are replicated. Both positive and negative photoresists are available for making holographic gratings, however, the negative resist is seldom used.

Grating-diffraction efficiency in the various orders is determined by the groove profile. In a ruled grating, the groove is profiled by appropriately shaping the diamond tool. Holographic gratings have a sinusoidal profile; blazing, in this case, is accomplished by ion etching. A wide range of groove spacing is possible with ruled gratings, however, holographic gratings offer more flexibility with respect to the groove pattern. For example, groove curvature may be used in holographic gratings to reduce aberrations in the spectrum, thereby improving the throughput and resolution of imaging spectrometers. The grooves in ruled gratings are produced by the traveling diamond tool, one after another. In holographic gratings, all grooves are produced in parallel; thus, the fabrication time for holographic gratings can be considerably shorter.

Another important instrumental HOE application is in optical beam scanning; the most common example of this is the supermarket scanner.[81] Laser beam scanning is usually accomplished by either mechanical means (e.g., rotating mirror) or with the use of some transparent medium whose optical properties are changed by some sort of stimulation (e.g., acousto-optic cell). Holographic scanners offer advantages over both of these more conventional methods.

The working principle of the holographic scanner may be illustrated by considering the translation of a focusing lens through an unexpanded laser beam. As the beam intercepts the lens from one side to the other, it is simultaneously deflected and focused at the lens focal point on the lens axis. Thus, moving the lens back and forth causes the laser beam to sweep back and forth in the focal plane of the lens. In its basic form, a holographic scanner is simply an HOE lens or mirror translating through the scan beam. The principal advantage of the holographic scanner over conventional scanning means is the ability to combine beam deflection and focusing into a single element. The form of both the deflection and focusing function can be tailored in a very flexible way by proper design of the HOE formation optical system. For example, the scan element may be easily made a line segment rather than a focal spot, and the locus of the scanned focal spot or line may be placed on either plane or curved surfaces. Multiple scan beams with multiple focal points may be generated by a scanner in the form of a segmented rotating disk. Each segment or facet of this disk has different deflection and focal properties. As the disk rotates through the beam, a multiplicity of scan beams is produced which can densely fill the desired scanned volume. This feature is especially important in a supermarket application because it allows products of varying sizes and shapes to be rapidly scanned. A further advantage of the HOE scanner is that the scanner disk can be small, thin, and lightweight, thereby greatly reducing the demands on the drive system. The disk format also produces little air movement due to windage and is very quiet in operation.

*The discussion here on holographic gratings is taken largely from Ref. 80. The author is indebted to Christopher Palmer of the Milton Roy Company for making an advance copy of this material available.

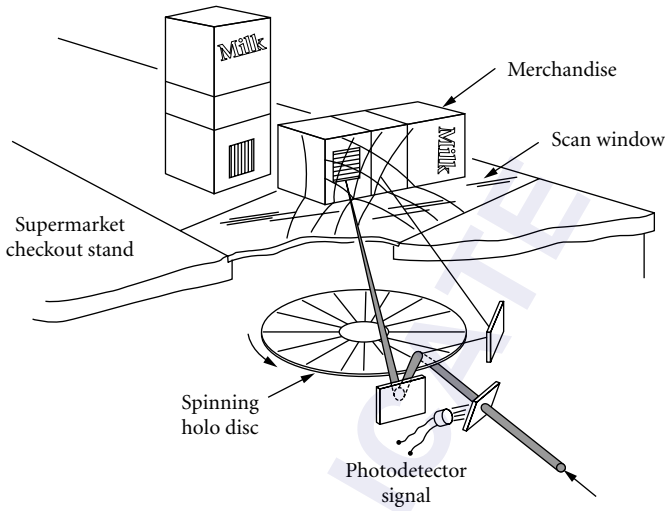

FIGURE 7 Schematic of a holographic supermarket scanner. (*Reprinted from Ref. 81, p. 9; courtesy of Marcel Dekker, Inc.*)

In addition to serving as the beam deflector, the holographic scanner also collects the light scattered from the laser spot on the product and directs it to the optical detector. This scattered light illuminates the holographic scanner along the conjugate object beam path and is diffracted into the fixed conjugate reference or primary scan beam path where it is accessed by a beam splitter. The light scattered from all points in the scan volume is thus directed to a single, fixed detector position. An optical schematic for a point-of-sales scanner is shown in Fig. 7.

The ability to combine several optical functions into a single HOE makes this device attractive in many situations. Significant savings in space, weight, and cost can often be realized by replacing several conventional elements with a single HOE device. This feature has been incorporated into an optical head for compact disk applications with the use of a multifunctional HOE.[82] An optical diagram of the device is shown in Fig. 8. The objective lens images the light-emitting point

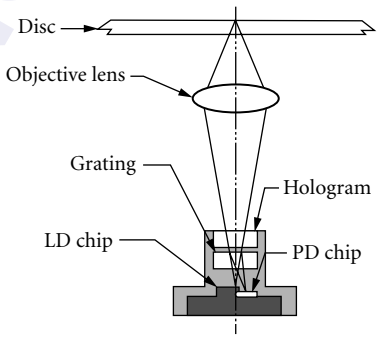

FIGURE 8 Diagram of compact disk optical head employing a holographic optical element. (*Diagram courtesy of Wai-Hon Lee, Hoetron, Inc.*)

of the laser diode (LD) to the compact disk. The light scattered from this focal point on the disk is reimaged by the objective lens through the HOE to the photodetector (PD). In this application, the HOE serves as a spherical lens, beam splitter, aberration-correcting lens, and cylindrical lens. In addition to simplifying the optical system, the HOE provides a better means of aligning the optical system.

Holography has even been applied to one of the oldest instrumental functions known—the keeping of time. This has been accomplished by using an HOE as a holographic sundial.[83]

33.6 HOLOGRAPHIC INSPECTION

Quality assurance inspection and testing, important functions in any industrial manufacturing process, have also benefited from advances in holography. Holographic methods have been applied to the quality control problem in several areas, such as identifying and locating subsurface mechanical defects and determining the presence or absence of certain surface features. Holographic interferometry has been successfully applied to some of these problems,[84–86] and optical processing methods have also yielded good results in many cases.[87] Matched and spatial filtering in the Fourier transform plane of an optical processing system have proved to be especially powerful means of identifying features and determining surface detail. In this section, we describe a unique combination of holography and classical optical processing methods that made possible a very successful means of rapidly detecting defects in devices with highly regular and repetitive patterns.

Defects in integrated circuit photomasks and wafers at various stages of processing can greatly diminish the final device yield. Since the economics of wafer production is strongly influenced by yield, there has been an ever-present incentive to increase this yield by minimizing the number of defects introduced at various points in the production process. One way to increase yield is to identify these defects early, and eliminate them before they cascade in a multiplicative manner through the various stages of the process.

For years, the inspection of integrated circuit photomasks and wafers was performed by either manual microscopic examination or automated serial scanning using an optical detector. The latter method involves comparison of the detector signal from a magnified portion of the test pattern to a similar portion of a reference pattern, adjacent pattern, or digital design database. In either case, the inspection process was long and tedious, often requiring many hours or days to inspect a single photomask or wafer. These methods are very slow because of the large number of pixels involved and the serial pixel-by-pixel nature of the inspection. Clearly, a great advantage would be afforded by the ability to examine all the pixels in parallel rather than serial format.

This observation prompted a number of researchers to consider optical processing methods for integrated circuit inspection and for addressing other types of problems involving highly repetitive patterns such as cathode-ray tube masks and TV camera tube array targets.[88–90] The concept in all cases was to eliminate perfect pattern information and highlight defect areas of the image by spatial filtering in the Fourier transform plane. These methods met with only limited success because of the difficulty in fashioning effective blocking filters and the need for extremely high quality, large-aperture, low F-number Fourier transform lenses. Despite considerable work in this area, none of these efforts resulted in the development, production, and in-process use of integrated circuit inspection systems using Fourier optical processing concepts.

This situation was reversed by the adaption of a holographic documentation system used to document the surface microstructure of high-energy laser optical component test samples.[91,92] A schematic diagram of the holographic documentation optical system is shown in Fig. 9. An F/3.42 lens was used to image the test target onto the hologram film and an argon laser operating at a wavelength of 514.5 nm was the illumination source. A polarizing beam-splitting cube and a half-wave plate were used to split the beam into object and reference beams, and to adjust the beam ratios. A second polarizing beam-splitting cube and quarter-wave plate were used to efficiently illuminate the test target and direct the reflected light to the holographic plate. The holographic image was reconstructed

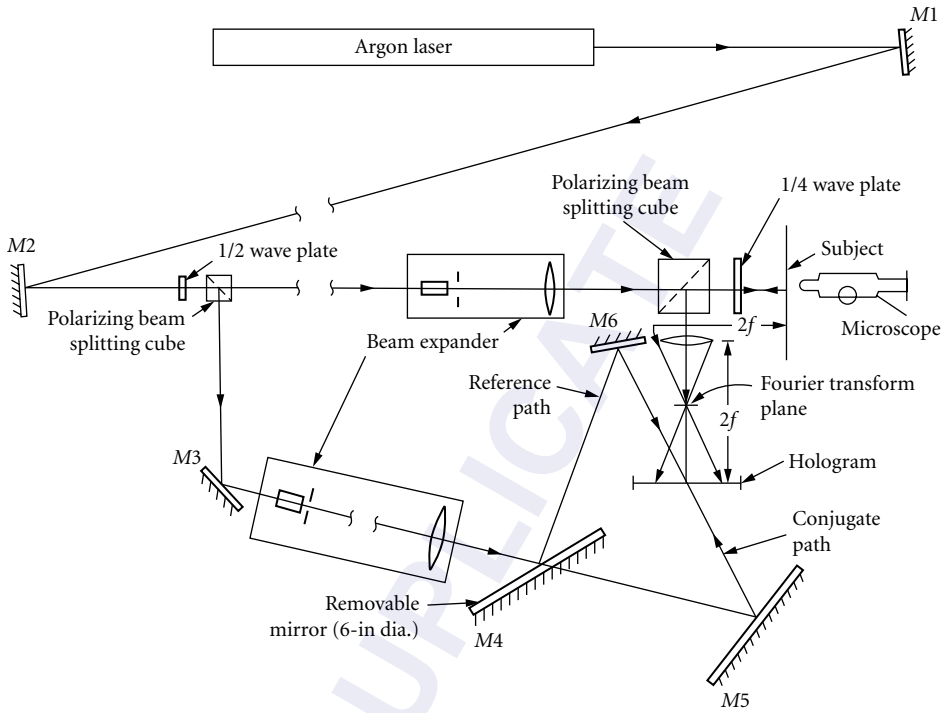

FIGURE 9 Holographic documentation optical system. (*Reprinted from Ref. 92, p. 87; courtesy of Oxford University Press.*)

with the conjugate reference beam by removing mirror *M*4. The test target was removed and the holographic image of the sample was examined with the aid of a microscope. The calculated resolution of this system (classic Rayleigh resolution limit) was 4.0 μm. A photograph of the holographic reconstruction of the standard Air Force resolution target made with this system is shown in Fig. 10. The smallest bars in this target are on 4.4-μm centers. Thus, the resolution observed with this system was comparable to the calculated value.

In considering how the documentation system might be adapted to other applications (including the integrated circuit inspection problem), Fusek et al. observed that because the real image of the test target was being examined by conjugate reconstruction, both functions of the classic Fourier optical system (i.e., transform and inverse transform) were performed in the documentation system.[93,94] Because of reverse ray tracing, a high-quality matched pair of specially designed Fourier transform lenses is no longer required to produce a diffraction-limited output image. As with previous work, the objective was to attenuate the image area where the pattern is defect-free and highlight the defects. This is done simply by placing the appropriate blocking filter in the Fourier transform plane. The method works effectively only if the filter efficiently blocks the light associated with defect-free areas of the image and efficiently transmits the defect light. Fortunately, this is the case for integrated circuit masks and wafers which consist of regular patterns of circuit elements repeated many times over the area of the wafer. For such patterns, the intensity distribution in the Fourier transform plane is a series of sharp spikes or bright points of light. Low spatial frequencies associated with slowly varying features (such as line-spacing) are represented by light points near the optical axis of the imaging lens. High spatial frequencies, representing such features as edge and corner detail, lie farther out in the Fourier transform plane. The Fourier transform plane intensity pattern for a production-integrated circuit photomask is shown in Fig. 11. Since defects are usually

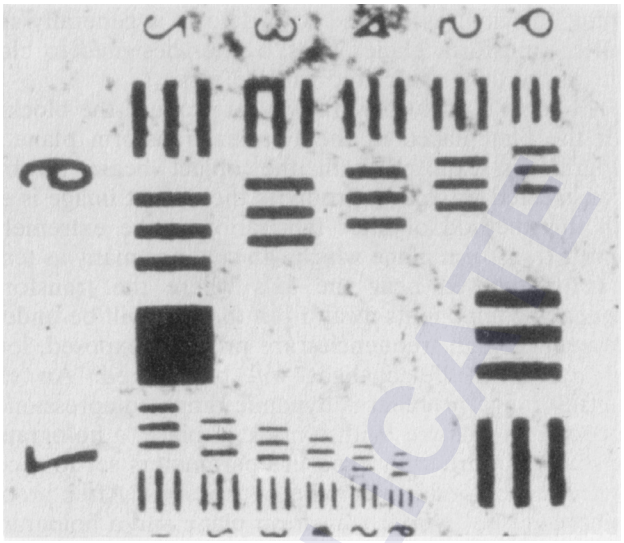

FIGURE 10 Magnified image of the holographic reconstruction of the Air Force resolution target. (*Reprinted from Ref. 92, p. 88; courtesy of Oxford University Press.*)

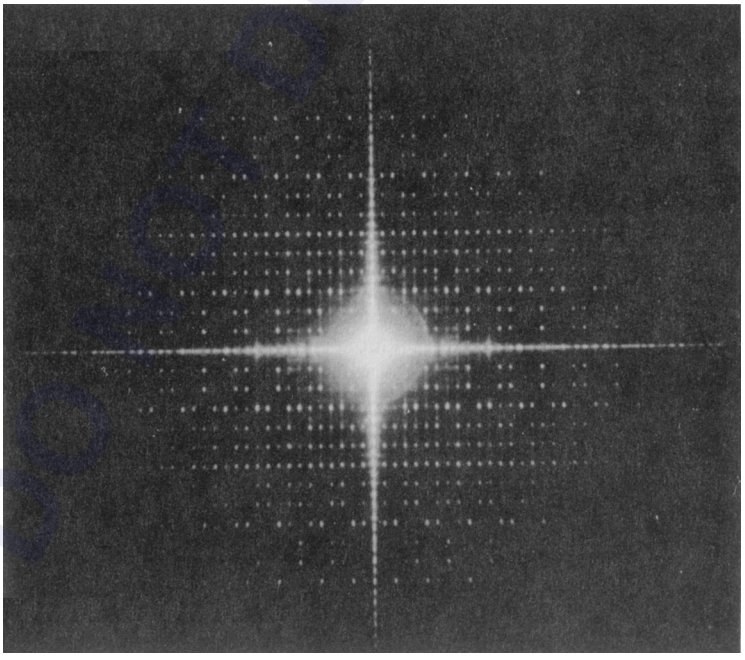

FIGURE 11 Optical Fourier transform of a production-integrated circuit photomask. (*Reprinted from Ref. 92, p. 98; courtesy of Oxford University Press.*)

of a nonregular nature, the light associated with defects is generally spread out fairly uniformly over the Fourier transform plane. Thus, a filter designed to block the regular-pattern light passes most of the light associated with defects.

The most straightforward way to produce the blocking filter is by photographic means, with the film placed in the Fourier transform plane. The filter is made first, then the hologram is exposed with the object beam passing through this filter. Thus, the reconstructed wave that produces the output image is effectively filtered twice. A problem with this method of filter fabrication is the extremely large range of intensities in the Fourier transform plane which can cover as many as ten orders of magnitude. If the filter is properly exposed near the axis where the transform light is brightest, high-spatial-frequency components away from the axis will be underexposed and inadequately filtered. However, if high frequencies are properly exposed, low frequencies will be overexposed, and too much defect light will be filtered. An effective means of alleviating this intensity-range problem is dynamic range compression by multistep filter generation. The process is as follows. With a mask in place, a holographic plate is exposed to the Fourier transform pattern with exposure parameters set to record the intensity distribution in the low-frequency region near the optical axis. After processing, this plate (Stage 1 filter) is replaced in the Fourier transform plane and a hologram of the mask is made through this filter. The hologram is illuminated by the conjugate reference beam and a second filter plate (Stage 2 filter) is exposed to the resulting Fourier transform intensity pattern. This pattern now has its low-frequency components attenuated because of the action of the Stage 1 filter. The Stage 2 filter can now be used to record a Stage 3 filter. The process may be repeated as many times as necessary to produce a filter with the desired attenuation properties. Because the defect light is of much lower intensity in the Fourier transform plane than the light corresponding to nondefect areas, defect light does not contribute significantly to the exposure of the filter, and the object under test (containing defects) may be used to generate the filter. Stage 1 and 2 filters for a defect calibration test mask (Master Images VeriMask™) are shown in Fig. 12.

Performance of the breadboard documentation system using the VeriMask is shown in Fig. 13. Figure 13*a* is a photo of a magnified region of the VeriMask containing a pinhole defect. Figure 13*b* shows the Stage 2 filter image of this same defect which is clearly enhanced. In addition, dimensional variations in the mask pattern from die to die are also highlighted.

The breadboard holographic inspection technology developed by Fusek and coworkers was further advanced and placed into production by Insystems of San Jose, California.[95–98] This company produced a series of mask and wafer inspection machines based on the holographic optical processing technique. The optical configuration of the Insystems Model 8800 Wafer Inspection System is shown in Fig. 14. The commercial instrument used an argon ion laser as the light source, and the system functioned in an optical manner identical to that of the original breadboard device. However, many refinements were incorporated into the commercial system which yielded substantially improved performance over the breadboard system. These refinements, which included a sophisticated Fourier transform lens design, made possible adequate performance without using the multistep filter generation technique. The wafer test piece and the hologram were placed on a rotating stage under a microscope and a video camera so that the filtered image of the defect and the microscopic image of the defect on the actual wafer could be viewed simultaneously. Figure 15 illustrates the advanced filtering capability of the commercial instrument. This instrument was sensitive to defects as small as 0.35 μm.

Disadvantages of the holographic defect detection system are the inconvenience and time delays associated with the wet processing of the silver halide holographic recording material. The use of photorefractive crystals, which operate in real time and do not require wet processing, has been studied as a means of eliminating these disadvantages.[97] The dual functions of image recording and spatial filtering are combined by placing the crystal in the Fourier transform plane and adjusting the reference beam intensity to the level of the defect light intensity. Since the light in the Fourier transform plane associated with defects is much lower in intensity than nondefect light, only the defects will be recorded with high diffraction efficiency. Practical use of photorefractive crystals in this application has not been realized, however, because these crystals have relatively low sensitivity and are not available in large sizes with good optical quality.

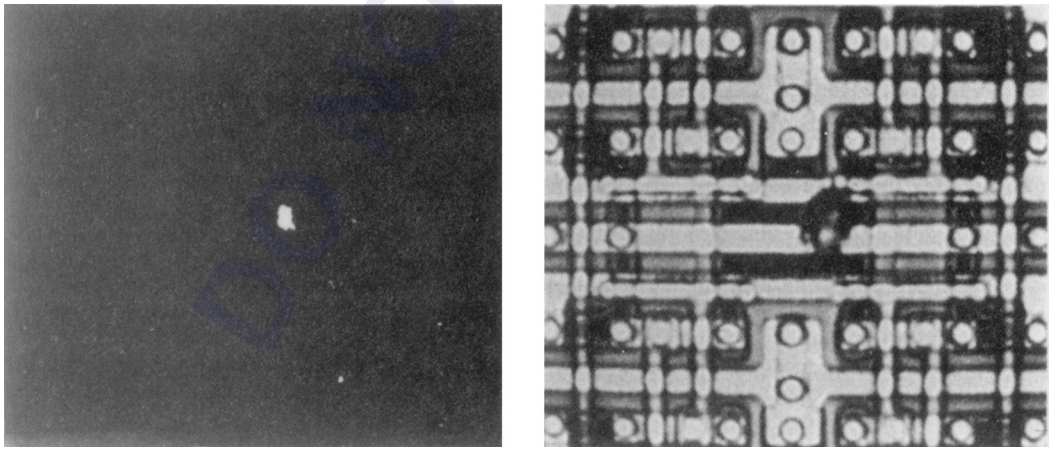
33.7 HOLOGRAPHIC LITHOGRAPHY

The lithographic transfer of an integrated circuit photomask pattern to a resist-coated integrated circuit wafer has been accomplished by several methods, including contact printing, proximity printing, and step-and-repeat imaging. Each method has advantages and disadvantages. Contact printing is a simple, straightforward method suitable for printing large wafer areas, but damage to



(a) (b)

the mask and contamination of the wafer are common problems. Proximity printing is resolution-limited because of near-field diffraction. The diffraction problem can be eliminated by imaging the mask onto the wafer, but full-field imaging systems do not provide the resolution required over the full area of the wafer. Stepper systems, which image only a small area of the mask at a time, provide the required resolution; however, they are complex and expensive because of the resolution demands placed on the optical imaging system and the mechanical difficulty in accurately stitching together the multiple image patterns over the full area of the wafer.

Clearly, a full-field method of printing the image onto the full area of the wafer with the required resolution is desirable. A holographic system capable of accomplishing this task was developed by Holtronic Technologies Limited.[98–100] Rather than using a lens system to image the mask on to the wafer, the Holtronic holographic system used real-image projection by conjugate illumination to overlay the mask image onto the wafer. Near-field holography was used to record the mask image by placing the mask in close proximity to the recording medium (100-μm separation) and illuminating the mask from the back with a collimated laser beam (364-nm line from an argon ion laser). To allow the introduction of an off-axis reference beam, an image of the mask could be relayed to the hologram plane with a lens. The approach taken was to eliminate the need for this lens with the use of the total internal reflection holography scheme of Stetson.[101] A diagram illustrating the optical principle is shown in Fig. 16.

Light transmitted and diffracted by the mask is incident directly on the holographic recording material which is deposited onto the opposing surface of a prism. Reference light is introduced through the diagonal surface of the prism and reflected at the holographic coating/air interface by total internal reflection. The recording medium was Dupont photopolymer. The holographic exposure was made with an expanded reference beam illuminating the entire hologram area.

Since three beams pass through the photosensitive material, three gratings are formed: (1) a reflection grating formed by the incident and reflected reference beams, (2) a reflection grating formed by the object beam and the incident reference beam, and (3) a transmission grating formed

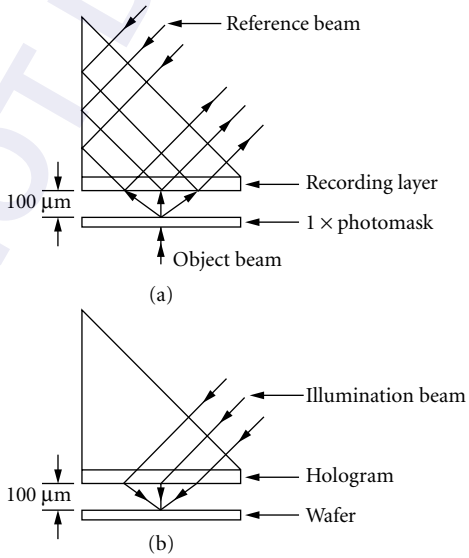

FIGURE 16 Basic optical arrangement for total internal reflection holographic lithography: (*a*) hologram exposure and (*b*) reconstruction onto a resist-coated substrate. (*Reprinted from Ref. 99; courtesy of PennWell Publications.*)

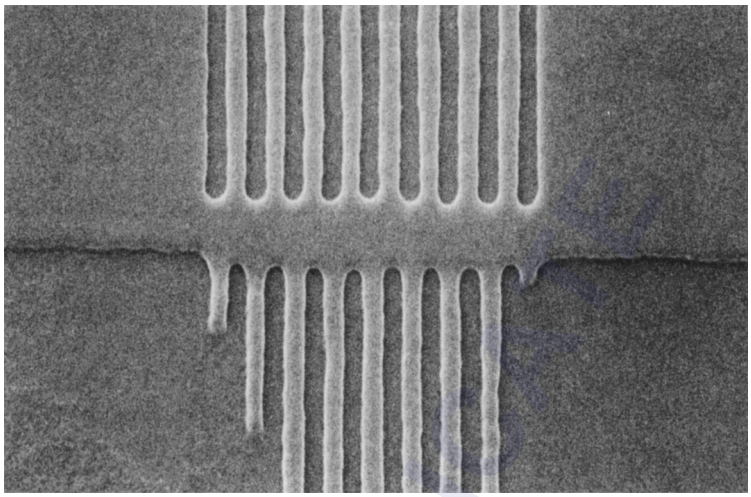

FIGURE 17 Scanning electron micrograph of 0.3-μm lines and spaces printed in photoresist by holographic lithography. (*Photo courtesy of Holtronic Technologies Ltd.*)

by the object beam and the reflected reference beam. To reconstruct the mask wavefront, an illumination beam conjugate to the reflected reference beam is introduced through the prism. This incident illumination beam interacts with the transmission object grating to form the conjugate real image of the mask. The totally internally reflected and the Lippmann-reflected illumination beams interact with the reflection object grating to reinforce the mask image.

During reconstruction and exposure of the photoresist-coated wafer, a small-area illumination beam is scanned over the hologram surface. Dynamic focusing of this scanned exposure beam eliminates the requirement that the mask and wafer substrates be ultraflat. Figure 17 illustrates the 0.3-μm resolving capability of the holographic lithography process in 0.3-mm thick resist. The lines shown were printed on a silicon wafer coated with Olin Hunt HPR 204 i-line photoresist and developed using the Hunt HPRD 429 developer. The effective numerical aperture of the system was greater than 0.7.

33.8 HOLOGRAPHIC MEMORY

The information storage capability of holograms has been the subject of considerable study over the years with several applications in mind. With the parallel information storage and processing capability of holograms, and the promise of shorter access times, computer memory has received particular attention. Two review articles provide good summaries of this field of research through 1990.[102,103] However, little mention is made of the work of Russian scientists who have also been very active in this field (see, for example, Refs. 104–116).

Of all the holographic material recording possibilities available, volume storage in photorefractive crystals has received the most attention. There are two main reasons for this emphasis: (1) the large information storage capacity of these crystals, and (2) their capability to meet the write-read-erase requirement in real time with no wet-chemical or other material-processing delays. However, no commercial memory systems using holographic storage have been developed. One reason for this is the relatively large volume of space occupied by the laser beam-steering equipment and other optical components required in such a system, even though the actual holographic storage element may occupy a volume of less than a few cubic centimeters. However, the primary reason

is the limitations of the recording material. Despite their distinct advantages over other recording material candidates, photorefractive crystals have some significant limitations. It is difficult to grow large crystals with good optical quality and to achieve stable, long-term storage without destructive readout.

Work by Redfield and Hesselink[117–119] was directed toward overcoming these previous limitations. Rather than concentrating on developing large, high-quality crystals, their approach was to form a large-volume memory element by using an array of small crystallites of strontium barium niobate in the form of small cubes or crystalline fibers. Techniques have also been developed for accessing the holographic information stored in these crystallites without destructive readout. Information is stored in the memory structure by recording Fourier holograms of checkerboard patterns (pages) of digital information. Access times were projected to be 100 to 1000 times faster than with conventional magnetic disk drives.

33.9 CONCLUSION

This chapter has briefly reviewed some of the more important instrumental applications of holography and demonstrated how holographic methods have been used to creatively solve a variety of measurement and recording problems. These successful applications should pave the way for additional advances in this field. Consequently, we anticipate that the list of technical applications of holography will expand significantly in the future.

Corporate Research and Technology
Rochester, New York

34.1 INTRODUCTION AND OVERVIEW

The xerographic process was invented in the 1930s by Chester Carlson, who was looking for a simple process to copy office documents. The process consists of the creation of an electrostatic image on an *image receptor*, development of the image with dyed or pigmented charged particles referred to as *toner*, transfer of the toner from the image receptor to the paper, fusing the toner to the paper, cleaning the residual toner from the image receptor, and finally, erasing whatever is left of the original electrostatic image. The process is then repeated on the cleaned, electrostatically uniform image receptor. In the most common embodiment of the process, the electrostatic image is created optically from either a digital or a light lens imaging system on a charged *photoreceptor,* a material that conducts electric charge in the light and is an insulator in the dark. These steps are shown schematically in Fig. 1, in which the photoreceptor drum is shown to be rotating clockwise. In this review we summarize the more common ways in which these steps are carried out.

The process just outlined is the heart of copying and digital printing systems whose speeds can range from a few to 180 copies per minute. Repeating the process several times (once for each color and black if needed) can produce full-color images. Often the system contains means for either input or output collation and stapling or binding. The cost of these systems can range from hundreds of dollars to several hundred thousand dollars.

This review will not attempt to give complete references to the technical literature. There are several excellent books that do this.[1–4] In addition, there are older books that give an interesting historical perspective on the development of the technology.[5,6]

34.2 CREATION OF THE LATENT IMAGE

This section covers the creation of the electrostatic field image. First the more common optical systems are considered. Here, exposing a charged photoconductor to the optical image creates the latent electrostatic image. Then, ion writing systems, in which an insulator is charged imagewise with an ion writing head or bar to create the latent electrostatic image, are briefly discussed.

*Retired.

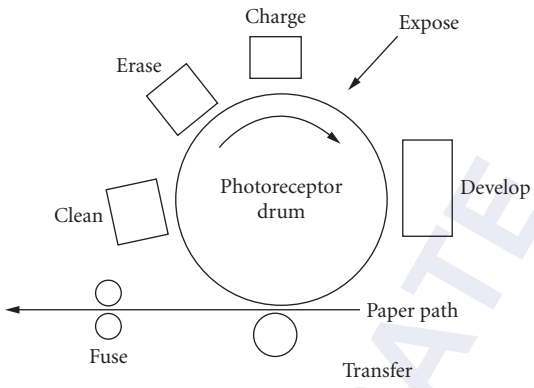

FIGURE 1 Schematic of xerographic process.

Optical Systems

We consider here ways in which the photoreceptor is charged, the required physical properties of the photoreceptor, and common exposure systems.

Charging Figure 2 schematically shows the charging and exposure of the photoreceptor. In this case the charging is shown to be positive. The two devices commonly used to charge the photoreceptor, the *corotron* and the *scorotron*, are shown schematically in Fig. 3. The corotron approximates a constant-current device, the scorotron a constant-voltage device.

The operational difference between the two devices is that the scorotron has a control screen. In both cases, a high potential, shown negative here, is applied to the corotron wires, creating a cloud of negative ions around the wires. In the case of the corotron, the negative ions drift under the influence of the electric field between the wires and the photoreceptor. Since the charging voltage of the photoreceptor is significantly less than that of the corona wires, the electric field and the resulting photoreceptor-charging current remain roughly constant. The charge voltage of the photoreceptor is then simply determined from the current per unit length of the corotron, the photoreceptor velocity under the corotron, and the capacitance per unit area of the photoreceptor.

In the case of the scorotron, the photoreceptor voltage and the voltage on the control grid determine the charging field. Thus, when the photoreceptor reaches the grid voltage, the field and the current go to zero. Hence the constant-voltage-like behavior.

Photoreceptor The discharge of the photoreceptor is accomplished by charge transport through the photoconductive medium. There are many materials that have been used as photoconductors.

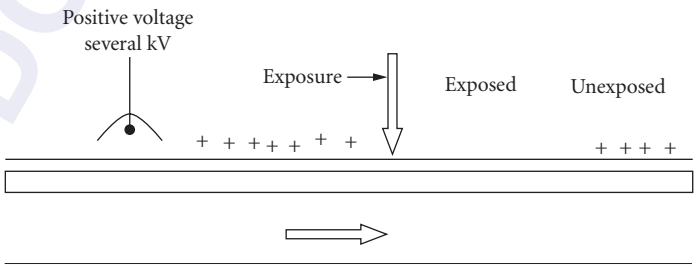

FIGURE 2 Charging and exposure of photoreceptor.

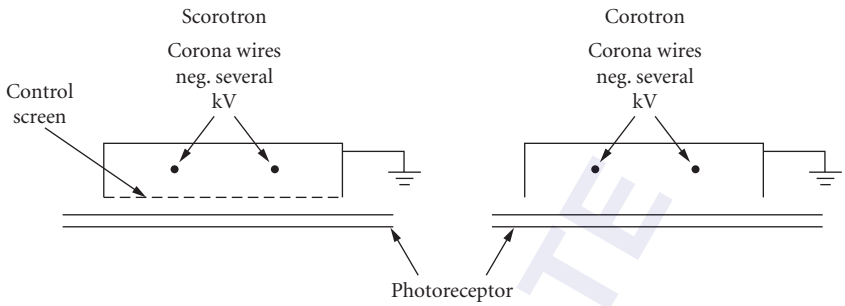

FIGURE 3 Scorotron and corotron.

The first photoreceptors were films 50 or 60 μm thick of amorphous selenium on a metallic substrate. These were followed by amorphous films of various selenium alloys, which were panchromatic and in some cases more robust. Other materials that have been used include amorphous silicon, which is quite robust as well as being panchromatic. Organic photoreceptors are used in most of the recent designs. Here the photoreceptor consists of a photogeneration layer on the order of 1 μm and a transport layer on the order of 20 μm thick.

The photoreceptor discharge process is shown in Fig. 4. The photoconductor is negatively charged, creating an electric field between the deposited charge and the ground plane. Light is shown to be incident on the generator layer. A hole is released that drifts upward under the influence of the electric field. Ideally the hole reaches the surface and neutralizes the applied surface charge. The electron that remains in the generator layer neutralizes the positive charge in the ground plane. Important characteristics of this process include the *dark decay* of the photoreceptor—how well the photoreceptor holds its charge in the dark—the quantum efficiency of the generation process, the transit time of the hole across the transport layer, whether or not it gets trapped in the process, and whether or not there are any residual fields remaining across the generator layer.

In order for the photoreceptor to hold its charge in the dark (Ref. 2, pp. 104–112), the charge on the surface must not be injected into the transport layer and drift to the substrate. There must be no bulk generation of charge in the transport layer. Finally, there must be no injection and transport of charge from the conductive ground plane into the transport layer. Modern photoreceptors dark-decay at rates of less than a few volts per second.

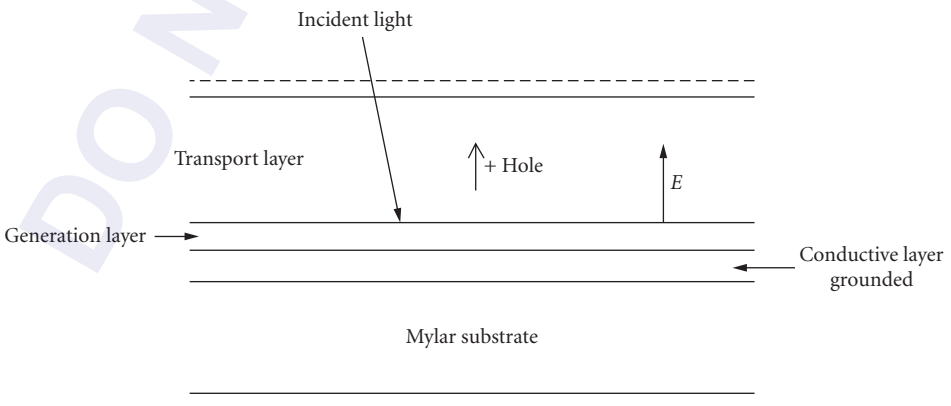

FIGURE 4 Photoreceptor discharge process.

The transport time of the photogenerated charge through the transport layer determines the rate at which the electrostatic latent image builds up. This limits the shortest time between exposure and development.

Charge trapped within the bulk of the photoreceptor can cause electrostatic ghosts of earlier images that may be developed. Proper erase procedures as well as careful photoreceptor processing are required to eliminate ghosts.

Exposure At present, both conventional light lens and digital exposure systems are in use. Conventional systems include both full-frame flash and slit scanning systems. Belt photoreceptors allow for a flat focal plane that permits a quite conventional exposure system; a full-frame flash exposure is used from a flat platen. More interesting is the system that is shown in Fig. 1. Here a slit is exposed at a fixed position on the rotating drum. To accommodate the movement of the drum, the image must move with it within the exposure slit. This is done with a moving platen for the document or a fixed platen with a moving exposure system and pivoting mirrors. Often a selfoc lens is used to conserve space.

The "original" in a digital imaging system is a document stored in computer memory. The idea includes both computer printers and digital copiers. The two most common means of optically writing the image on the photoreceptor are scanning lasers and image bars. In its simplest form an image bar exposes a line at a time across the photoreceptor. It consists of a full-width array of adjacent light-emitting diodes, one for each pixel. As the photoreceptor rotates under the image bar the diodes are turned on and off to write the image.

Laser scanning systems, also known as raster output scanning (ROS) systems, in their simplest embodiment use a laser diode that is focused and scanned across the photoreceptor by a rotating polygon. A so-called f-θ is used to achieve constant linear velocity of the spot across the photoreceptor. Often two or more diodes are focused several raster lines apart in order to write several lines at the same polygon speed. The laser diodes are modulated appropriately with the image information.

Prior to the development of laser diodes, HeNe lasers were used with acousto-optical modulators. In order to accommodate the slow response time of the acousto-optical crystal, the Scophony[7] system developed in the 1930s was used. The acousto-optic modulator consists of a piezoelectric transducer, which launches an acoustical wave in a transparent medium whose index of refraction is pressure sensitive. The acoustic wave, which is modulated with the image information, creates a phase-modulated diffraction pattern. The laser beam is expanded, passed through the crystal and by a stop that blocks the zeroth order of the diffraction pattern. The image of the acousto-optic modulator is then focused on the photoreceptor. Because of the phased imaging system, the resulting image is intensity modulated. However, the diffraction pattern is moving and thus the pixels are moving on the photoreceptor surface. To compensate for this motion, the image of the modulator is scanned in the opposite direction by the polygon at precisely the same speed at which the pixels are moving.

Ion Writing Systems

In an ion writing system the electrostatic image is created by depositing ions on a dielectric receiver in an imagewise fashion. It is typically used in high-speed applications. The requirements for the dielectric receiver are that it be mechanically robust and that it hold the charge through the development process. Transfer, fusing, and cleaning are essentially the same as in conventional xerography. Since (in principle at least) the photoreceptor can be replaced by a more durable dielectric receiver and since charging is eliminated, the process promises to be cheaper and more robust.

At least two techniques have been used commercially for writing the image: stylus writing and ion writing heads. In both cases the limitation appears to be resolution. A stylus writing head consists of an array of styli, one for each pixel. The dielectric receiver is moved under the array and a voltage greater than air breakdown is applied to each stylus as appropriate. The ion writing heads are an array of ion guns, which uses an electrode to control the ion flow to the receiver.

34.3 DEVELOPMENT

The role of the developer system is to apply toner to the appropriate areas of the photoreceptor. In the case of conventional exposure, these areas are the charged areas of the photoreceptor. This system is referred to as *charged area development* (CAD). For digital systems where lasers or image bars are employed, the designer has a choice; the regions to be developed can be left charged as in the conventional system. Alternatively, the photoreceptor can be discharged in the regions to be toned. This is referred to as *discharged area development* (DAD). Image quality and reliability drive the choice. For either CAD or DAD, charged toner is electrostatically attracted to the photoreceptor.

There are many different techniques for developing the electrostatic latent image. We consider first two-component magnetic brush development and, in that context, outline many of the more general considerations for all development systems. Other interesting systems will then be described.

Two-Component Magnetic Brush Development

The developer in two-component magnetic brush development consists of magnetized carrier beads and toner. Here the toner is typically 10 μm and the carrier 200 to 300 μm. The two components are mixed together and, by means of triboelectric charging, charge is exchanged between the toner and carrier. The much smaller toner particles remain attached to the carrier beads so that in a properly mixed developer there is little or no free toner. The role of the carrier is thus twofold: to charge the toner and, because of its magnetic properties, to enable the transport of the two-component developer. As will be seen, the conductivity of the carrier plays an important role in development. The carrier often consists of a ferrite core coated with a polymer chosen principally to control the charging characteristics of the developer.

The toner is a polymer containing pigment particles. For black systems the pigment is carbon black; for full color the subtractive primaries (cyan, magenta, and yellow) are used. In highlight color systems (black plus a highlight color) the pigment is the highlight color or perhaps a combination of pigments yielding the desired color. The choice of the polymer and, to some degree, the colorants is also constrained by the charging properties against the carrier and by the softening temperature, which is set by the fusing requirements. The covering power of the toner is determined by the concentration of the pigment. Typically a density of 1 is achieved on the order of 1 mg/cm^2 of toner.

A typical magnetic brush development system is shown schematically in Fig. 5.

The developer roll transports the developer (beads and carrier) from the sump to the nip between the developer roll and the photoreceptor where development takes place. The magnetic fields hold the developer on the roll and the material is moved along by friction. A carefully spaced doctor blade is used to control and limit the amount of developer on the roll.

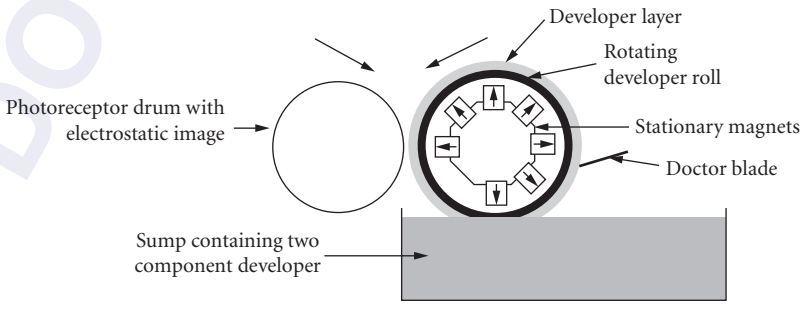

FIGURE 5 Magnetic brush development system.

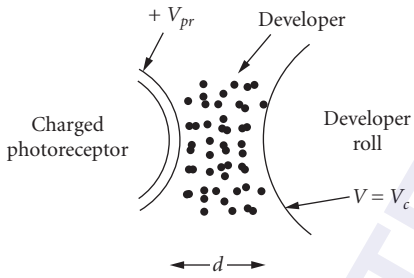

FIGURE 6 Details of nip between charged photoreceptor and developer roll.

Key to the development process is the triboelectric charge on the toner particle. The charge exchange between the toner and carrier can be thought of in terms of the alignment of the Fermi levels of the two materials in order to reach thermodynamic equilibrium. Thus a knowledge of the work functions (the energy required to lift an electron from the Fermi level to vacuum) gives a first-order estimate of the toner charge. Impurities and the pigments also play a large role in the triboelectric charging, as do the manufacturing processes. Often charge control agents are used to control the toner charging. The toner adheres to the carrier bead because of electrostatic attraction (they are of opposite polarity) and whatever other adhesion forces there are. Figure 6 schematically shows the details of the nip between the charged photoreceptor and the development roll.

The Development of Solid Areas The principal driving force for development is the electric field $E = (V_{pr} - V_c)/d$ where it is assumed that the developer is an insulator. (The conductive case will be considered presently.) V_{pr} is the voltage on the photoreceptor and V_c is a small voltage used to suppress development in background regions by reversing the field. The toner, however, is attached to the carrier beads and must be detached before it can be deposited on the photoreceptor. The electric field plays a role in this, as do the mechanical forces that result from impaction with the photoreceptor and the mixing of the developer within the nip. The density of the developer in the nip, the toner concentration, the magnetic field, and the electric field thus all affect the rate of toner deposition. Developed toner may also be scavenged from the photoreceptor by, say, an oppositely charged carrier bead impacting on the developed area. Development proceeds until the two rates are equal or until the photoreceptor emerges from the nip.

The voltage V_c is used to provide a reverse electric field to prevent toner deposition in what should be toner-free regions. This is required to prevent toner from adhering to the photoreceptor for nonelectrostatic reasons. Developers may contain a small amount of wrong-sign toner for which this field is a development field. This requires careful formulation of the developer and as well as judicious sizing of the cleaning field.

As development proceeds and toner is deposited on the photoreceptor, current flows from the developer roll to the photoreceptor, neutralizing the charge on the photoreceptor. This process may be viewed as the discharging of a capacitor—the photoreceptor—through a resistor—the developer. Thus, as a first-order approximation, the time constant for development is simply determined from the capacitance per unit area of the photoreceptor and the resistivity of the developer. The nip design must be such that the photoreceptor is in the nip on the order of a time constant or more. Typically development takes place to 50 percent or more of complete neutralization of the photoreceptor and is roughly a linear function of the development field until saturation is reached.

The resistivity of the developer plays a large role in the rate of development. Two cases may be considered: the insulating magnetic brush (IMB) and the conductive magnetic brush (CMB). In the case of conductive development (CMB) the effective spacing to the development electrode or roller is smaller than d (see Fig. 6), thereby increasing the apparent electric field and the rate of development. Ideally development proceeds to neutralization for CMB. If the resistivity of the developer is

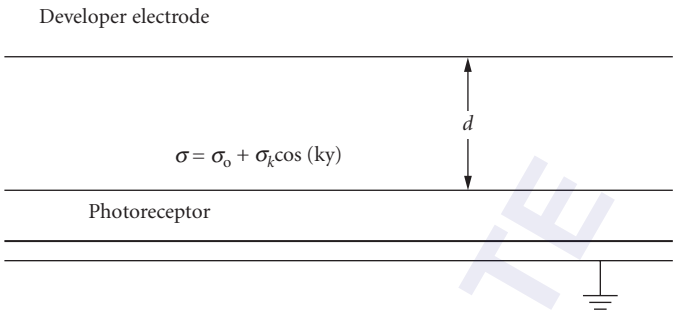

FIGURE 7 Calculating electric fields above a sinusoidal charge distribution.

large, the spacing is larger and the development is slower. In addition, space charge may develop in the nip, further slowing down development.

The Development of Lines For solid-area development with a highly resistive developer, the electric field that controls development is given by $E = (V_{pr} - V_c)/d$ (Fig. 6). For lines this is no longer true. It was recognized early on that lines develop much faster than solids due to the fact that the electric field at the edge of a large solid area is quite a bit stronger than at the center. This edge-enhancing effect was quite prominent in early xerographic development systems. A general approach to understanding line development is to calculate the modulation transfer function (MTF) or sine-wave response. It is relatively straightforward to calculate the electric fields above a sinusoidal charge distribution (Ref. 2, pp. 25–37), as shown in Fig. 7. The question is what field to use and whether or not a linear analysis is appropriate in what would appear to be a very nonlinear system.

As development proceeds, the fields decrease due to the neutralization of the charge on the photoreceptor. Furthermore, the fields fall off approximately exponentially in distance from the surface of the photoreceptor. Finally, space charge can accumulate in the developer nip; thus the assumption of a well-defined dielectric constant is questionable. Shown in Fig. 8 (taken from Ref. 2) is the normal component of the initial electric field 27 μm above the photoreceptor surface. The photoreceptor is 60 μm thick. The dielectric constant is 6.6, and the photoreceptor is charged to an average field of 15 V/μm. The dielectric constant of the nip is assumed to be 21 and the thickness of the nip is assumed to be 1700 μm. Here it is seen that, at least initially, lines with a spatial frequency of, say, 5 lines per mm develop at a rate 4 times faster than a solid area. If development is designed to go close to completion, this ratio can be much reduced.

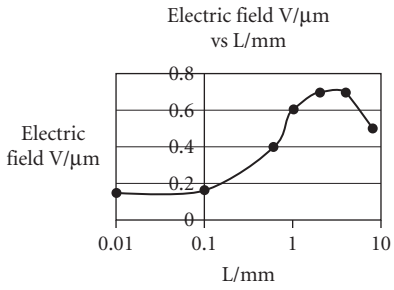

FIGURE 8 The normal electric field as a function of spatial frequency.

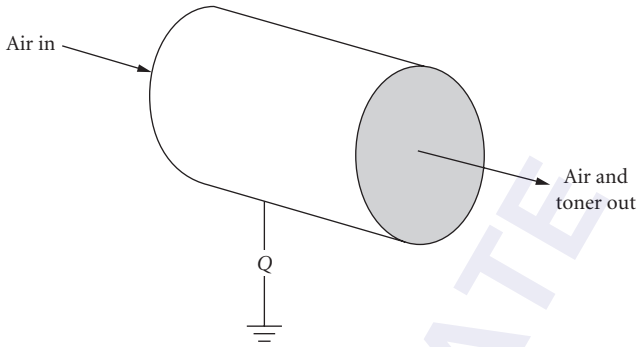

FIGURE 9 Faraday cage used to measure charge on toner.

Measuring Toner Charge

The measurement of the charge on the toner is fundamental to characterization of a developer, that is, a toner and carrier bead mix. A Faraday cage is used with screens on either end (Fig. 9). The screen mesh is such that toner can pass through and the carrier cannot.

The developer is loaded into the cage. A jet of air is blown through the cage, removing the toner. Both the charge and the weight of the removed toner are measured. The quotient is referred to as the *tribo* and is measured in units of microcoulombs per gram. The results depend on how the developer is mixed. Useful, properly mixed developers have tribos ranging between 10 and, say, 30 μC/g.

The distribution of the charge can be obtained from what is called a *charge spectrograph.*[8] (See Fig. 10.) The charged toner is blown off the developer mixture and inserted into the laminar air stream flowing in the tube. An electric field is applied normal to the toner flow. Within the tube the toner is entrained in the air and drifts transversely in the direction of the electric field. It is collected on the filter. The displacement of the toner d can be calculated from the charge on the toner Q_t, the

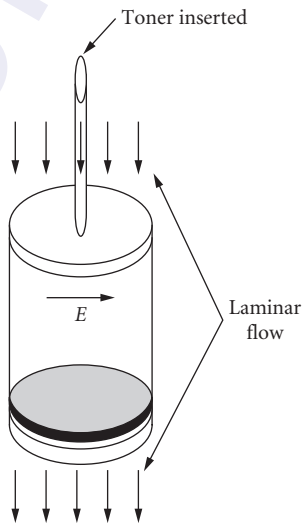

FIGURE 10 Charge spectrograph.

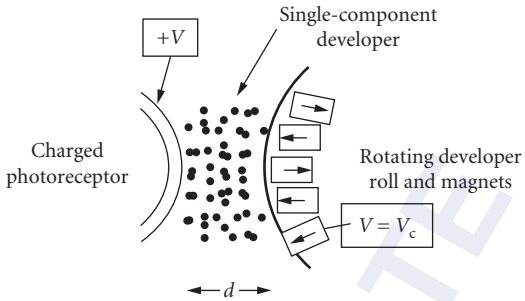

FIGURE 11 Single-component development.

electric field E, and the viscous drag, which is proportional to the radius r_t of the particle and the viscosity of the air η. Thus

$$d=(Q_t/r_t)(E/6\pi\eta)$$

Using a computerized microscope to measure the number of toner particles as well as the radius and displacement, it is possible to obtain the charge and size distribution of the toner. This technique is particularly important as it yields the amount of wrong-sign toner in the developer.

Other Development Systems

Among the other useful development systems are inductively charged single-component development, powder cloud development, and electrophoretic or liquid immersion development (LID).

Single-Component Development In inductively charged single-component development the toner is both conductive and magnetic. The system is shown schematically in Fig. 11. The toner is charged inductively in response to the electric field with charge injected from the developer roll. The charge is transferred to the toner closest to the developer roll. The toner then is attracted to the photoreceptor. The materials issues are to ensure charge injection from the developer roll while at the same time preventing charge transfer from the toner to the photoreceptor.

Powder Cloud Development A powder cloud development system is shown in Fig. 12. Here toner is injected above the grid, drifts through the grid, acquires a negative charge, and is transported to the photoreceptor by the electric field. As is seen, at the edge of a charged area, the fields are such as to prevent toner from entering into the region near the edge, thus diminishing edge development.

Liquid Immersion Development An electrophoretic developer consists of toner particles suspended in a nonconducting fluid. Charge exchange takes place between the fluid and the toner particles.

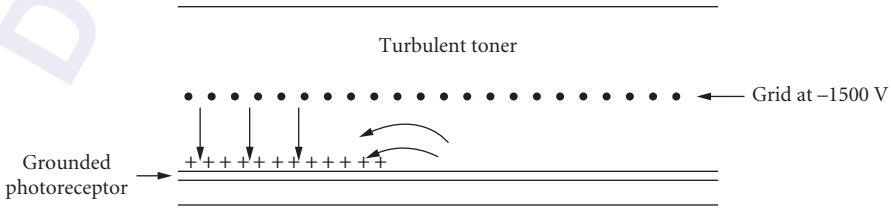

FIGURE 12 Powder cloud development system.

The charged toner then follows the field lines to the photoreceptor. The development rates can be determined from the toner charge and the image-driven electric field. In commercial systems, the developer fluid is pumped between the photoreceptor and a development roll. Controlling the toner charge is a major materials problem. The details of preparation play an important role. Surface-active agents also play an important role in the charging of the toner.

34.4 TRANSFER

After development, the toner is held on the photoreceptor by electrostatic forces. Electrostatic transfer is accomplished by applying an electric field either by means of a corotron or a bias transfer roll to attract the toner to the paper (Fig. 1). The paper is brought into contact with the image on the photoreceptor if nonelectrostatic forces are assumed negligible; it is possible to calculate[9] where the toner splits as a function of the applied field and the thickness of the photoreceptor, toner layer, and paper. The nonelectrostatic forces, say, Van der Waals forces, between toner particles and between the toner and the photoreceptor can play an important role. Transfer efficiencies can run over 90 percent.

The difficult engineering problem is to bring the possibly charged paper into and out of contact with the photoreceptor without causing toner disturbances due possibly to air breakdown or premature transfer resulting in a loss of resolution. Bias transfer rolls with a semiconductive coating having carefully controlled relaxation times are required.

34.5 FUSING

After transfer the toner must be permanently fixed to the paper. This can be accomplished with the application of heat and possibly pressure. The idea is to have the toner flow together as well as into the paper. Surface tension and pressure play important roles. Many different types of fusing systems exist, the simplest of which is to pass the paper under a radiant heater. Here the optical absorption of the toner must be matched to the output of the lamp. This usually requires black toner.

Roll fusing systems are quite common. Here the paper is passed between two rolls, with the heated roll on the toner side. The important parameters are the roll temperature and dwell time of the image in the nip of the rollers. Release agents are used to assist the release of the paper from the rollers.

The fusing system imposes material constraints on the toner. Low-melt toners are preferred for fusing, but they cause the developer to age faster.

34.6 CLEANING AND ERASING

There are many ways of removing the untransferred toner from the photoreceptor in preparation for the next imaging cycle. Vacuum-aided brushes are common. Here a fur brush is rotated against the photoreceptor; the toner is removed from the photoreceptor by the brush and from the brush by the vacuum. These systems tend to be noisy because of the vacuum assist. Electrostatic brushes have also been used. Here a biased conductive brush removes the toner from the photoreceptor and then "develops" it onto a conductive roller, which in turn is cleaned with a blade. A development system biased to remove toner from the photoreceptor has also been used. The simplest of the cleaning systems is a blade cleaner; it is compact, quiet, and inexpensive.

Along with the removal of untransferred toner, the photoreceptor must be returned to a uniform and preferably uncharged state. Ghosting from the previous image may result from trapped charge within the photoreceptor. Erasing is accomplished using strong uniform exposure.

34.7 CONTROL SYSTEMS

Proper operation of the xerographic system requires system feedback control to maintain excellent image quality. Among the things to be controlled are charging, exposure, and toner concentration and development. At a minimum, toner gets used and must be replaced. The simplest control system counts pages, assumes area coverage, and replenishes the toner appropriately. The photoreceptor potential after charging and after exposure can be measured with an electrostatic voltmeter. Changes to the charging and exposures can then be appropriately made. The toner optical density of a developed patch on the photoreceptor of known voltage contrast can be measured with a densitometer. In digital systems the actual area coverage can be determined by counting pixels. These two measurements allow the control of toner concentration.

34.8 COLOR

There are many full-color and highlight-color copiers and printers available commercially. All of the recent designs are digital in that the image is either created on a computer or read in from an original document and stored in a digital format. Thus in a full-color process the half-toned cyan, magenta, yellow, and black separations are written on the photoreceptor by the ROS or image bar. The process is then essentially repeated for each separation.

Full Color

The xerographic processor can be configured in several different ways for full color. In a cyclic process a system like the one shown in Fig. 13 is used. The paper is attached to the bias transfer roll and the cycle is repeated four times for full color. The significant new issues are the need for four developer housings, registration, and the fusing of the thicker toner layers. The cyan image must be developed with just cyan. It is also important not to disturb the cyan image on the photoreceptor as it passes through the other housings. The developer housings are therefore mechanically or electrically switched in or out depending on the image written.

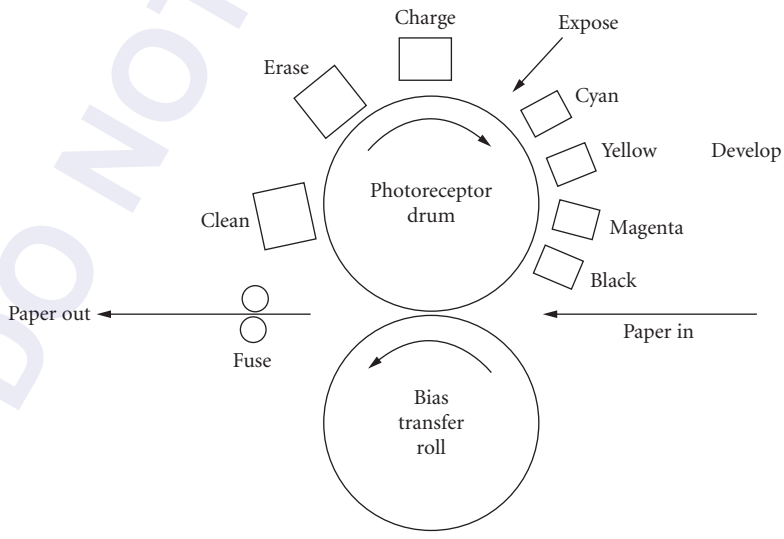

FIGURE 13 Cyclic full-color process.

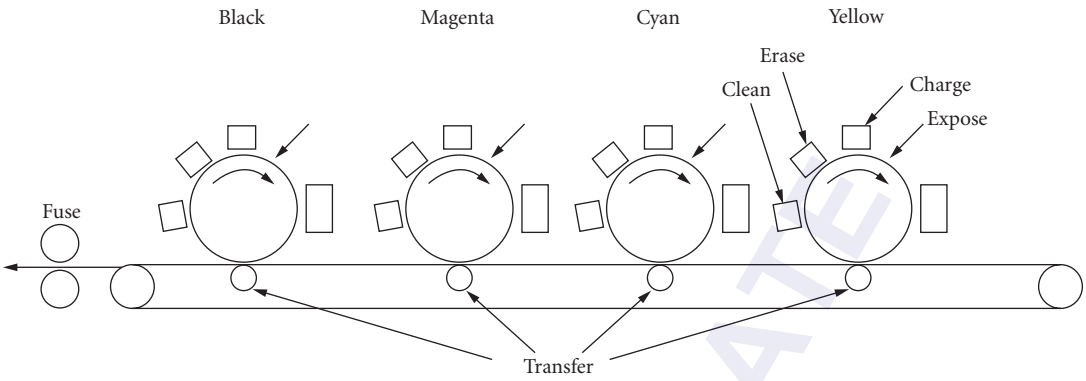

FIGURE 14 Tandem full-color process.

In Fig. 13 the transfer roll and the photoreceptor are the same diameter. Registration is accomplished by writing the image on the same place on the photoreceptor in each cycle. The temperature and dwell time in the fuser are controlled to achieve a good fuse.

Tandem configurations are also used. Here four separate processors are used as shown in Fig. 14. A belt transfer system is shown. The paper is attached to the belt and moved from station to station. The rollers shown behind the belt are used to apply the bias required for transfer. The order of development, shown here with yellow first, is chosen to minimize the effects of contamination. Other transfer systems are also possible. The image can be transferred directly to the belt and then, after the last station, to the paper.

Comparison of these two systems is interesting. The cyclic system has fewer parts and is therefore less expensive and likely more reliable. The tandem system has more parts but is a factor of 4 faster for full color than the cyclic system.

Highlight Color

Highlight color is black plus one color, say red, which is used to accentuate or highlight important parts of the image. It can be achieved with the full-color systems just discussed. Also, the full-color system can be modified to contain just the black plus the highlight color. A single-pass highlight color system was developed at Xerox that retains much of the simplicity and throughput of a single-color system. Referred to as *Tri-Level*,[10,11] it encodes the black and highlight color on the photoreceptor as different voltages. The electrostatic arrangement is shown in Fig. 15. The photoreceptor is discharged to three levels. In this case full charge is black, the highlight is discharged to a low level, and white is maintained at some intermediate level.

Two developer housings are used, one for each color. In this case the black toner is negative and the color toner is positive. The housings are biased as shown. The image is passed sequentially through the two housings. The black region appears as a development field for black. Both the background and highlight color regions are cleaning fields for black and no development takes place. The same considerations apply to the highlight color. On the photoreceptor the resulting image contains opposite-polarity toner. The images are passed under a pretransfer corotron to reverse the sign of one of the toners. Thus, at the cost of an additional housing and a pretransfer charging device and no cost in throughput, a black-plus-one-color system can be designed.

The difficulties of the system are under consideration. Since the maximum charging voltage is limited, the voltage contrast is reduced by more than a factor of 2. The first image must not be disturbed when passing through the second developer housing. Both of these constraints require sophisticated developer housing design.

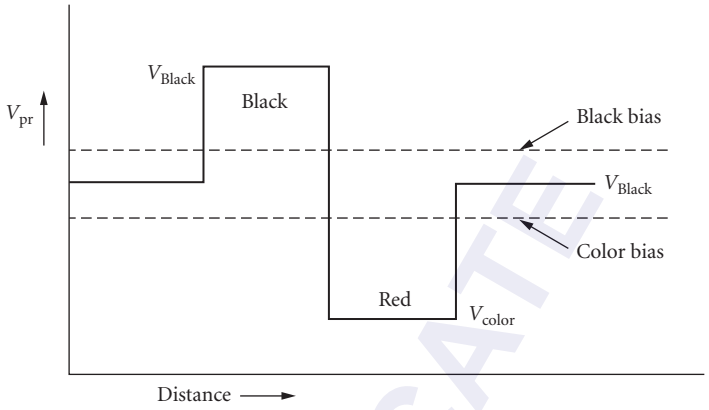

FIGURE 15 Tri-Level process.

PRINCIPLES OF OPTICAL DISK DATA STORAGE

Masud Mansuripur

College of Optical Sciences
University of Arizona
Tucson, Arizona

35.1 INTRODUCTION

Since the early 1940s magnetic recording has been the mainstay of electronic information storage worldwide. Audiotapes provided the first major application for the storage of information on magnetic media. Magnetic tape has been used extensively in consumer products such as audiotapes and videocassette recorders (VCR); it has also found application in backup/archival storage of computer files, satellite images, medical records, etc. Large volumetric capacity and low cost are the hallmarks of tape data storage, although sequential access to the recorded information is perhaps the main drawback of this technology. Magnetic hard disk drives have been used as mass-storage devices in the computer industry ever since their inception in 1957. With an areal density that has doubled roughly every 2 years, hard disks have been and remain the medium of choice for secondary storage in computers.* Another magnetic storage device, the floppy disk, has been successful in areas where compactness, removability, and rapid access to the recorded information have been of primary concern. In addition to providing backup and safe storage, inexpensive floppies with their moderate capacities (2 Mbytes on a 3.5-in-diameter platter is typical) and reasonable transfer rates have provided the crucial function of file/data transfer between isolated machines. All in all, it has been a great half-century of progress and market dominance for magnetic storage which is only now beginning to face a serious challenge from the technology of optical recording.

Like magnetic recording, a major application of optical data storage is the secondary storage of information for computers and computerized systems. Like the high-end magnetic media, optical disks can provide recording densities in the range of 10^7 bits/cm^2 and beyond. The added advantage of optical recording is that, like floppies, these disks can be removed from the drive and stored on the shelf. Thus the functions of the hard disk (i.e., high capacity, high data transfer rate, rapid access) may be combined with those of the floppy (i.e., backup storage, removable media) in a single optical disk drive. Applications of optical recording are not confined to computer data storage. The enormously successful compact audio disk (CD) which was introduced in 1983 and has since

*Achievable densities on hard disks are presently in the range of 10^7 bits/cm^2; random access to arbitrary blocks of data in these devices can take on the order of 10 ms, and individual read-write heads can transfer data at the rate of several megabits per second.

become the de facto standard of the music industry, is but one example of the tremendous potentials of the optical disk technology.

A strength of optical recording is that, unlike its magnetic counterpart, it can support read-only, write-once, and erasable/rewritable modes of data storage. Consider, for example, the technology of optical audio/video disks. Here the information is recorded on a master disk which is then used as a stamper to transfer the embossed patterns to a plastic substrate for rapid, accurate, and inexpensive reproduction. The same process is employed in the mass production of read-only files (CD-ROM, O-ROM) which are now being used to distribute software, catalogs, and other large databases. Or consider the write-once-read-many (WORM) technology, where one can permanently store massive amounts of information on a given medium and have rapid, random access to them afterward. The optical drive can be designed to handle read-only, WORM, and erasable media all in one unit, thus combining their useful features without sacrificing performance and ease of use. Moreover, the media can contain regions with prerecorded information as well as regions for read/write/erase operations on the same platter, thus offering opportunities for applications that have heretofore been unthinkable.

This chapter presents the conceptual basis for optical storage systems, with emphasis on disk technology in general and magneto-optical (MO) disk in particular. Section 35.2 is devoted to a discussion of some elementary aspects of disk data storage including the concept of track, definition of the access time, and the physical layout of data. Section 35.3 describes the function of the optical path; included are properties of the semiconductor laser diode, characteristics of the beam-shaping optics, and features of the focusing (objective) lens. The limited depth of focus of the objective lens and the eccentricity of tracks dictate that optical disk systems utilize closed-loop feedback mechanisms for maintaining the focused light spot on the right track at all times. Automatic focusing and automatic track-following schemes are described in Secs. 35.4 and 35.5. The physical process of thermomagnetic recording is the subject of Sec. 35.6, followed by a discussion of MO readout in Sec. 35.7. Certain important characteristics of MO media are summarized in Sec. 35.8. Concluding remarks and an examination of trends for future optical recording devices are the subject of Sec. 35.9.

Alternative methods of optical data storage such as reversible phase-change, photochemical spectral hole burning, three-dimensional volume holographic storage, photon echo, photon trapping, etc., will not be discussed in this chapter. The interested reader may consult the following references for information concerning these alternative storage schemes:

35.2 PRELIMINARIES AND BASIC DEFINITIONS

The format and physical layout of recorded data on the storage medium as well as certain operational aspects of disk drive mechanism will be described in the present section.

The Concept of Track

The information on magnetic and optical disks is recorded along tracks. Typically, a track is a narrow annulus at some distance r from the disk center, as shown in Fig. 1. The width of the annulus is denoted by W_t, while the width of the guard band, if any, between adjacent tracks is denoted by W_g.

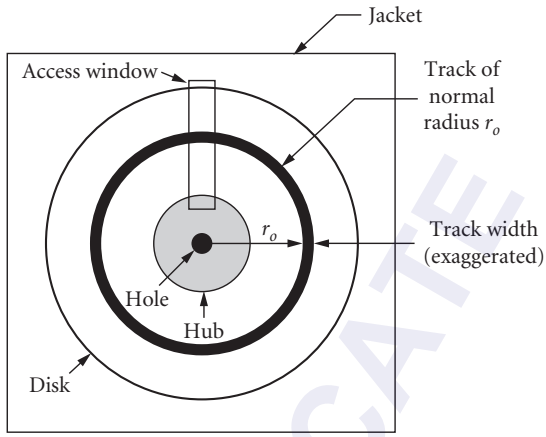

FIGURE 1 Physical appearance and general features of an optical disk. The read-write head gains access to the disk through a window in the jacket; the jacket itself is for protection purposes only. The hub is the mechanical interface with the drive for mounting and centering the disk on the spindle. The track shown here is of the concentric-ring type, with radius r_0 and width W_t.

The track-pitch is the center-to-center distance between neighboring tracks and is therefore equal to $W_t + W_g$. A major difference between the magnetic floppy disk, the magnetic hard disk, and the optical disk is that their respective track-pitches are presently of the order of 100, 10, and 1 μm. Tracks may be fictitious entities, in the sense that no independent existence outside the pattern of recorded marks may be ascribed to them. This is the case, for example, with the compact audio disk format where prerecorded marks simply define their own tracks and help guide the laser beam during readout. In the other extreme are tracks that are physically engraved on the disk surface before any data is ever recorded. Examples of this type of track are provided by pregrooved WORM and magneto-optical disks. Figure 2 shows micrographs from several recorded optical disk surfaces. The tracks along which data is written are clearly visible in these pictures.

It is generally desired to keep the read-write head stationery while the disk spins and a given track is being read from or written onto. Thus, in an ideal situation, not only should the track be perfectly circular, but also the disk must be precisely centered on the spindle axis. In practical systems, however, tracks are neither precisely circular, nor are they concentric with the spindle axis. These eccentricity problems are solved in low-performance floppy drives by making tracks wide enough to provide tolerance for misregistrations and misalignments. Thus the head moves blindly to a radius where the track center is nominally expected to be, and stays put until the reading or writing is over. By making the head narrower than the track-pitch, the track center is allowed to wobble around its nominal position without significantly degrading the performance during read-write operations. This kind of wobble, however, is unacceptable in optical disk systems which have a very narrow track, about the same size as the focused beam spot. In a typical situation arising in practice the eccentricity of a given track may be as much as 50 μm, while the track-pitch is only about 1 μm, thus requiring active track-following procedures.

A popular method of defining tracks on an optical disk is by means of pregrooves, which are either etched, stamped, or molded onto the substrate. The space between neighboring grooves is called *land* (see Fig. 3*a*). Data may be written in the groove with the land acting as a guard band. Alternatively, the land may be used for recording while the grooves separate adjacent tracks. The groove depth is optimized for generating an optical signal sensitive to the radial position of the

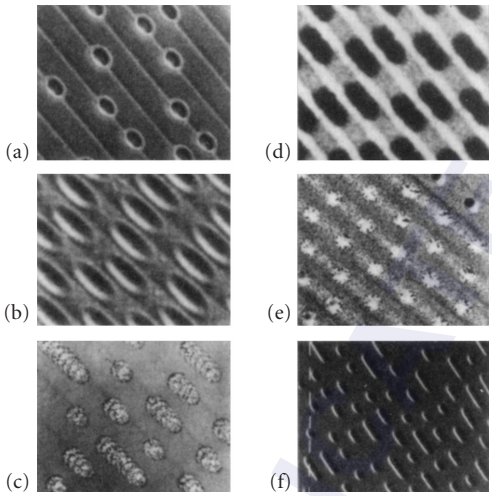

FIGURE 2 Micrographs of several types of optical storage media. The tracks are straight and narrow with a 1.6-μm pitch, and are diagonally oriented in each frame. (*a*) Ablative, write-once tellurium alloy. (*b*) Ablative, write-once organic dye. (*c*) Amorphous-to-crystalline, write-once phase-change alloy GaSb. (*d*) Erasable, amorphous magneto-optic alloy GdTbFe. (*e*) Erasable, crystalline-to-amorphous phase-change tellurium alloy. read-write laser beam. For the push-pull method of track-error detection (described in Sec. 35.5) the groove depth is in the neighborhood of $\lambda/8$, where λ is the wavelength of the light beam.

In digital data storage each track is divided into small segments called *sectors*. A sector is intended for the storage of a single block of data which is typically either 512 or 1024 bytes. The physical length of a sector is thus several millimeters. Each sector is preceded by header information such as the identity of the sector, identity of the corresponding track, synchronization marks, etc. The header information may be preformatted onto the substrate, or it may be written directly on the storage layer. Pregrooved tracks may be "carved" on the optical disk either as concentric rings or as a single continuous spiral. There are certain advantages to each format. A spiral track contains a succession of sectors without interruption, whereas concentric rings may each end up with some empty space that is too small to become a sector. Also, large files may be written onto (and read from) spiral tracks without jumping to the next track, which is something that occurs when concentric tracks are used. On the other hand, multiple-path operations such as write-and-verify or erase-and-write which require two paths each for a given sector, or still-frame video are more conveniently handled on concentric-ring tracks.

Another suggested track format is based on the idea of a sampling servo. Here the tracks are identified by occasional marks placed permanently on the substrate at regular intervals, as shown in Fig. 3*b*. Details of track-following by the sampled-servo scheme will follow shortly (see Sec. 35.5), suffice it to say at this point that servo marks help the system identify the position of the focused spot relative to the track center. Once the position is determined it is fairly simple to steer the beam and adjust its position on the track.

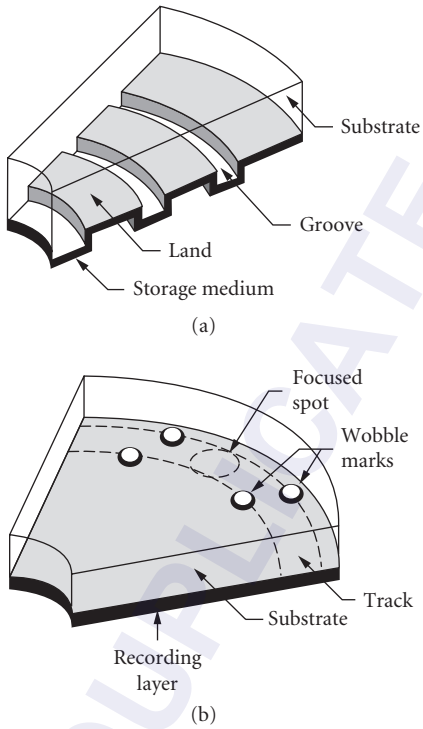

FIGURE 3 (*a*) Lands and grooves in an optical disk. The substrate is transparent, and the laser beam must pass through it before reaching the storage medium. (*b*) Sampled-servo marks in an optical disk. These marks which are offset from the track center provide information regarding the position of focused spot.

Disk Rotation Speed

When a disk rotates at a constant angular velocity ω, a track of radius r moves with the constant linear velocity $V = r\omega$. Ideally, one would like to have the same linear velocity for all the tracks, but this is impractical except in a limited number of situations. For instance, when the desired mode of access to the various tracks is sequential, such as in audio- and video-disk applications, it is possible to place the head in the beginning at the inner radius and move outward from the center thereafter while continuously decreasing the angular velocity. By keeping the product of r and ω constant, one can achieve constant linear velocity for all tracks.* Sequential access mode, however, is the exception rather than the norm in data storage systems. In most applications, the tracks are accessed randomly with such rapidity that it becomes impossible to adjust the rotation speed for constant linear velocity. Under these circumstances the angular velocity is kept constant during normal operation. Typical

*In compact audio disk players the linear velocity is kept constant at 1.2 m/s. The starting position of the head is at the inner radius r_{min} = 25 mm, where the disk spins at 460 rpm. The spiral track ends at the outer radius r_{max} = 58 mm, where the disk's angular velocity is 200 rpm.

rotation rates are 1200 and 1800 rpm for slower drives, and 3600 rpm for the high-end systems. Higher rotation rates (5000 rpm and beyond) are certainly feasible and will likely appear in future generations of optical storage devices.

Access Time

The direct access storage device used in computer systems for the mass storage of digital information is a disk drive capable of storing large quantities of data and accessing blocks of this data rapidly and in random order. In read-write operations it is often necessary to move the head to new locations in search of sectors containing specific data items. Such random relocations are usually time-consuming and can become the factor that limits performance in certain applications. The access time τ_a is defined as the average time spent in going from one randomly selected spot on the disk to another. The access time τ_a can be considered the sum of seek time τ_s, which is the average time needed to acquire the target track, and a latency τ_l, which is the average time spent on the target track waiting for the desired sector; thus $\tau_a = \tau_s + \tau_l$. The latency is half the revolution period of the disk, since a randomly selected sector is, on the average, halfway along the track from the point where the head initially lands. Thus, for a disk rotating at 1200 rpm $\tau_l = 25$ ms, while at 3600 rpm $\tau_l \simeq 8.3$ ms. The seek time, on the other hand, is independent of the rotation speed, but is determined by the travel distance of the head during an average seek, as well as by the mechanism of head actuation. (It can be shown that the average length of travel in a random seek is one-third of the full stroke.) In magnetic disk drives where the head/actuator assembly is relatively lightweight, (a typical Winchester head weighs about 5 g) the acceleration and deceleration periods are short, and seek times are typically around 10 ms. In optical disk systems, on the other hand, the head, being an assembly of discrete elements, is fairly large and heavy (typical weight ≃50 to 100 g), resulting in values of t_s that are several times greater than those obtained in magnetic recording. The seek times reported for commercially available optical drives presently range from 20 msec in high-performance 3.5-in drives to 100 ms in larger drives. One must emphasize, however, that the optical disk technology is still in its infancy; with the passage of time the integration and miniaturization of the elements within the optical head will surely produce lightweight devices capable of achieving seek times in the range of several milliseconds.

Organization of Data on Disk

For applications involving computer files and data, each track is divided into a number of sectors where each sector can store a fixed-length block of binary data. The size of the block varies among the various disk/drive manufacturers, but typically it is either 512 or 1024 bytes. As long as the disk is dedicated to a particular drive (such as in magnetic hard drives) the sector size is of little importance to the outside world. However, with removable media the sector size (among other things) must be standardized, since now various drives need to read from and write onto the same disk.

A block of user data cannot be directly recorded on a sector. First, it must be coded for protection against errors (error-correction coding) and for the satisfaction of channel requirements (modulation coding). Also, it may be necessary to add synchronization bits or other kinds of information to the data before recording. Thus a sector's capacity must be somewhat greater than the amount of raw data assigned to it. A sector also must have room for "header" information. The header is either recorded during the first use of the disk by the user, as in formatting a floppy disk, or is written by the manufacturer before shipping the disk. The header typically contains the address of the sector plus synchronization and servo bits. In magnetic disks the header is recorded magnetically, which makes it erasable and provides the option of reformatting at later times. On the negative side, formatting is time-consuming and the information is subject to accidental erasure. In contrast, the optical disk's sector headers may be mass-produced from a master at the time of manufacture, thus eliminating the slow process of soft formatting. The additional space used by the codes and by the header information constitutes the overhead. Depending on the quality of the disk, the degree of

sophistication of the drive, and the particular needs of a given application, the overhead may take as little as 10 percent and as much as 30 percent of a disk's raw capacity.

35.3 THE OPTICAL PATH

The optical path begins at the light source which, in all laser disk systems in use today, is a semiconductor GaAs diode laser. Several unique features of the laser diode have made it indispensable for optical recording applications: its small size ($\simeq 300 \times 50 \times 10$ μm) makes possible the construction of compact head assemblies, its coherence properties allow diffraction-limited focusing to extremely small spots, and its direct modulation capability eliminates the need for external intensity modulators. The operating wavelength of the laser diode can be selected within a limited range by proper choice of material composition; presently, the shortest wavelength available from the III-V class of semiconductor materials is 670 nm.

Figure 4*a* shows a typical plot of laser power output versus input current for a GaAs-based laser diode. The lasing starts at the threshold current, and the output power rapidly increases beyond that

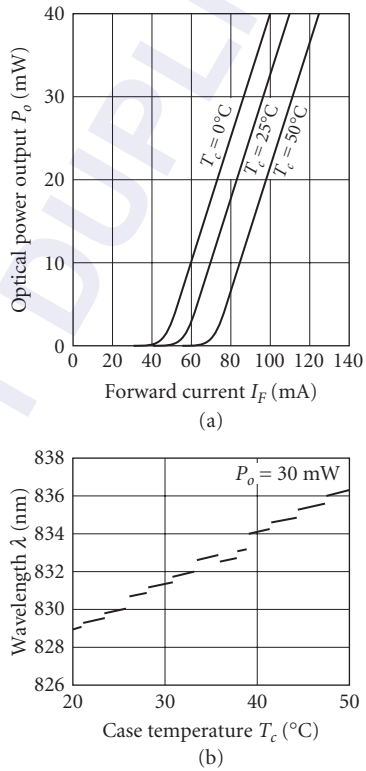

FIGURE 4 (*a*) Optical output power versus forward-bias current for a typical diode laser. Different curves were obtained at different ambient temperatures. (*b*) Variations of wavelength as function of case temperature for typical diode laser. The output power is fixed at $P_o = 30$ mW. (*From Sharp Laser Diode User's Manual.*)

point. Below threshold, the diode operates in the spontaneous emission mode and its output is incoherent. After threshold, stimulated emission takes place, yielding coherent radiation. Of course, the output power cannot increase indefinitely and beyond a certain point the laser fails catastrophically. Fortunately, the required optical power levels for the read/write/erase operations in present-day data storage systems are well below the failure levels of these lasers. Available lasers for data storage applications have threshold currents around 40 mA, maximum allowable currents of about 100 mA, and peak output powers [CW (continuous wave) mode] around 50 mW. The relationship between the injection current and the output light power is very sensitive to the operating temperature of the laser, as evidenced by the various plots in Fig. 4*a*. Also, because the semiconductor material's bandgap is a function of the ambient temperature, there is a small shift in the operating wavelength of the device when the temperature fluctuates (see Fig. 4*b*). For best performance it is usually necessary to mount the laser on a good heat-sink, or try to steady its temperature by closed-loop feedback.

The output optical power of the laser can be modulated by controlling the injection current. One can apply pulses of variable duration to turn the laser on and off during the recording process. The pulse duration can be as short as a few nanoseconds, with rise and fall times which are typically less than 1 ns. This direct-modulation capability of the laser diode is particularly welcome in optical disk systems, considering that most other sources of coherent light (such as gas lasers) require bulky and expensive devices for external modulation. Although readout of optical disks can be accomplished at constant power level in CW mode, it is customary (for noise reduction purposes) to modulate the laser at a high frequency in the range of several hundred MHz.

Collimation and Beam Shaping

Since the cross-sectional area of the active region in a laser diode is only about 1 μm^2, diffraction effects cause the emerging beam to diverge rapidly. This phenomenon is depicted schematically in Fig. 5*a*. In practical applications of the laser diode, the expansion of the emerging beam is arrested by a collimating lens, such as that shown in Fig. 5*b*. If the beam happens to have aberrations (astigmatism is particularly severe in diode lasers), then the collimating lens must be designed to correct this defect as well.

In optical recording it is most desirable to have a beam with circular cross section. The need for beam shaping arises from the special geometry of the laser cavity with its rectangular cross section. Since the emerging beam has different dimensions in the directions parallel and perpendicular to the junction, its cross section at the collimator becomes elliptical, with the initially narrow dimension expanding more rapidly to become the major axis of the ellipse. The collimating lens thus produces a beam with elliptical cross section. Circularization may be achieved by bending various rays of the beam at a prism, as shown in Fig. 5*c*. The bending changes the beam's diameter in the plane of incidence, but leaves its diameter in the perpendicular direction intact.

The output of the laser diode is linearly polarized in the plane of the junction. In some applications (such as readout of compact disks or read-write on WORM media) the polarization state is immaterial as far as interaction with the storage medium is concerned. In such applications one usually passes the beam through a polarizing beam splitter (PBS) and a quarter-wave plate, as in Fig. 6, and converts its polarization to circular. Upon reflection from the disk, the beam passes through the quarter-wave plate once again, but this time emerges as linearly polarized in a direction perpendicular to the original direction of polarization. The returning beam is thus directed away from the laser and toward the detection module, where its data content is extracted and its phase/amplitude pattern is used to generate error signals for automatic focusing and tracking. By thoroughly separating the returning beam from the incident beam, one not only achieves efficiency in the use of the optical power, but also succeeds in preventing the beam from going back to the laser where it causes instabilities in the laser cavity and, subsequently, increases the noise level. Unfortunately, there are situations where a specific polarization state is required for interaction with the disk; magneto-optical readout which requires linear polarization is a case in point. In such instances the simple combination of PBS and quarter-wave plate becomes inadequate and one must resort to other (less efficient) means of separating the beams.

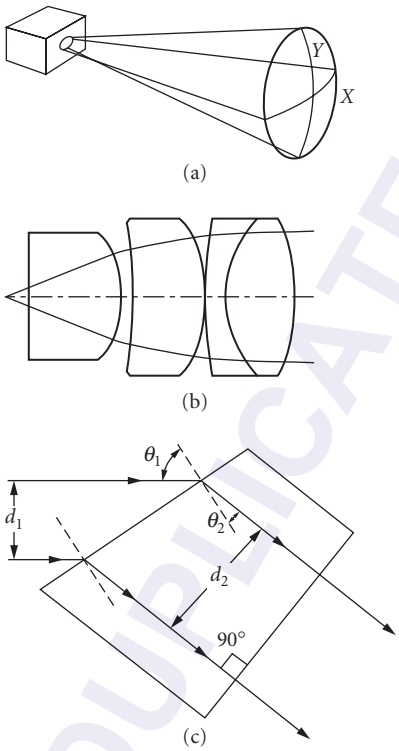

FIGURE 5 (*a*) Away from the facet, the output beam of a diode laser diverges rapidly. In general, the beam diameter along *X* is different from that along *Y*, which makes the cross section of the beam elliptical. Also, the radii of curvature R_x and R_y are not the same, thus creating a certain amount of astigmatism in the beam. (*b*) Multielement collimator lens for laser diode applications. Aside from collimating, this lens also corrects astigmatic aberrations of the beam. (*c*) Beam-shaping by deflection at a prism surface. Θ_1 and Θ_2 are related by the Snell's law, and the ratio d_2/d_1 is the same as $\cos\Theta_2/\cos\Theta_1$. Passage through the prism circularizes the elliptical cross section of the beam.

Focusing

The collimated and circularized beam of the laser is focused on the surface of the disk using an objective lens. The objective is designed to be aberration-free, so that its focused spot size is limited only by the effects of diffraction. Figure 7*a* shows the design of a typical objective made from spherical optics. According to the classical theory of diffraction, the diameter of the beam, *d*, at the objective's focal plane is

$$d \simeq \frac{\lambda}{\text{NA}} \tag{1}$$

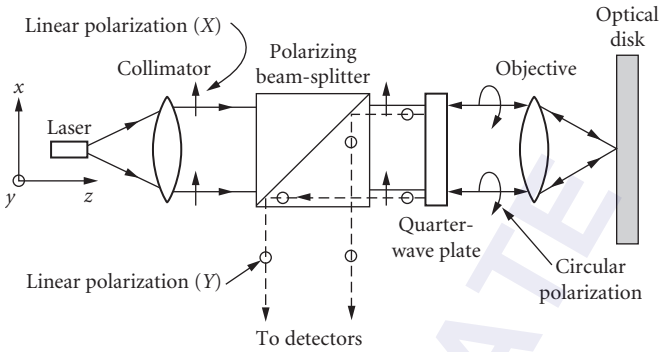

FIGURE 6 Separation of incident and reflected beams at the polarizing beam splitter (PBS). The quarter-wave plate converts the linearly polarized incident beam into one with circular polarization and converts the returning beam back to linear, but with its polarization vector orthogonal to that of the incident beam. This 90° rotation of polarization is responsible for the diversion of the reflected beam toward the detection channel.

where λ is the wavelength of light and NA is the numerical aperture of the objective. In optical recording it is desired to achieve the smallest possible spot, since the size of the spot is directly related to the size of marks recorded on the medium. Also, in readout, the spot size determines the resolution of the system. According to Eq. (1) there are two ways to achieve a small spot: reducing the wavelength and increasing the numerical aperture. The wavelengths currently available from GaAs lasers are in the range of 670 to 840 nm. It is possible to use a nonlinear optical device to double the frequency of these lasers, thus achieving blue light. Good efficiencies have been demonstrated by frequency doubling. Also recent developments in II-VI materials have improved the prospects for obtaining green and blue light directly from semiconductor lasers. Consequently, there is hope that in the near future optical storage systems will operate in the wavelength range of 400 to 500 nm. As for the numerical aperture, current practice is to use a lens with NA $\simeq$ 0.5–0.6. Although this value might increase slightly in the coming years, much higher numerical apertures are unlikely, since they put strict constraints on the other characteristics of the system and limit the tolerances. For instance, the working distance at high NA is relatively short, making access to the recording layer through the substrate more difficult. The smaller depth of focus of a high-NA lens will make attaining/maintaining proper focus more difficult, while the limited field of view might restrict automatic track-following procedures. A small field of view also places constraints on the possibility of read/write/erase operations involving multiple beams.

The depth of focus of a lens, δ, is the distance away from the focal plane over which tight focus can be maintained (see Fig. 7*b*). According to the classical theory of diffraction,

$$\delta \simeq \frac{\lambda}{\mathrm{NA}^2} \tag{2}$$

Thus for $\lambda = 700$ nm and NA = 0.6 the depth of focus is about ± 1 μm. As the disk spins under the optical head at the rate of several thousand rpm, the objective must stay within a distance of $f \pm \delta$ from the active layer if proper focus is to be maintained. Given the conditions under which drives usually operate, it is impossible to make rigid enough mechanical systems to yield the required positioning tolerances. On the other hand, it is fairly simple to mount the objective lens in an actuator capable of adjusting its position with the aid of closed-loop feedback control. We emphasize that by going to shorter wavelengths and/or larger numerical apertures (as is required for attaining higher data densities) one will have to face a much stricter regime as far as automatic focusing is concerned. Increasing the numerical aperture is particularly worrisome, since δ drops with the square of NA.

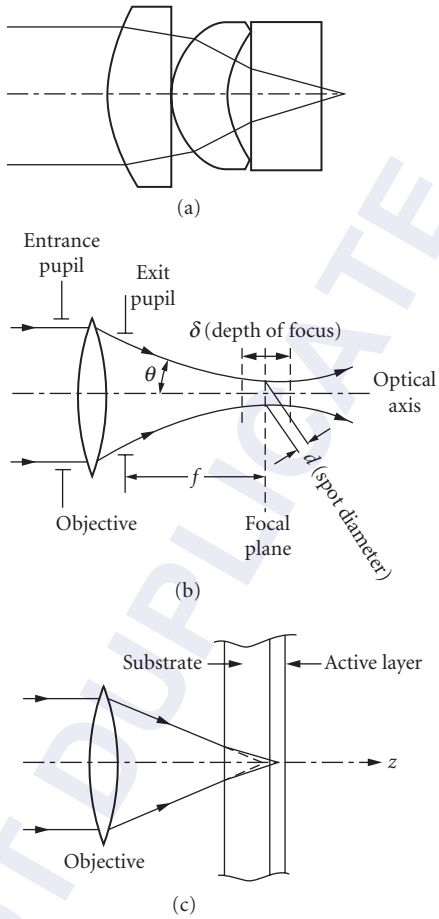

FIGURE 7 (*a*) Multielement lens design for a high-NA videodisc objective. (*After D. Kuntz, "Specifying Laser Diode Optics,"* Laser Focus, *March 1984.*) (*b*) Various parameters of the objective lens. The numerical aperture is NA = sin Θ. The spot diameter d and the depth of focus δ are given by Eqs. (1) and (2), respectively. (*c*) Focusing through the substrate can cause spherical aberration at the active layer. The problem is corrected by a proper design for the objective lens, which takes the substrate into account.

A source of spherical aberrations in optical disk systems is the substrate through which the light must pass in order to reach the active layer. Figure 7*c* shows the bending of the rays at the surface of the disk, which causes the aberration. This problem can be solved by taking into account the effects of the substrate in the design of the objective, so that the lens is corrected for all aberrations, including those arising at the substrate. Recent developments in molding of aspheric glass lenses have gone a long way in simplifying the lens design problem. Figure 8 shows a pair of molded glass aspherics

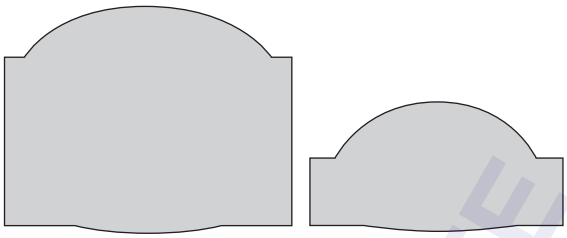

FIGURE 8 Molded glass aspheric lens pair for optical disk application. These singlets can replace the multielement spherical lenses shown in Figs. 5*b* and 7*a*.

designed for optical storage applications; both the collimator and the objective are single-element lenses and are corrected for axial aberrations.

Laser Noise

Compared to other sources of coherent light such as gas lasers, laser diodes are noisy and unstable. Typically, within a diode laser's cavity several modes compete for dominance. Under these circumstances, small variations in the environment can cause mode-hopping which results in unpredictable power-level fluctuations and wavelength shifts. Unwanted optical feedback is specially troublesome, as even a small fraction of light returning to the cavity can cause a significant rise in the noise level. Fortunately, it has been found that high-frequency modulation of the injection current can be used to instigate power sharing among the modes and thereby reduce fluctuations of the output optical power. In general, a combination of efforts such as temperature stabilization of the laser, antireflection coating of the various surfaces within the system, optical isolation of the laser, and high-frequency modulation of the injection current can yield acceptable levels of noise for practical operation of the device.

35.4 AUTOMATIC FOCUSING

Since the objective lens has a large numerical aperture (NA ≥ 0.5) its depth of focus δ is shallow ($\delta \simeq \pm 1$ μm at $\lambda = 780$ nm). During all read/write/erase operations, therefore, the disk must remain within a fraction of a micrometer from the focal plane of the objective. In practice, however, the disks are not flat and are not always mounted rigidly parallel to the focal plane, so that during any given revolution movements away from focus (by as much as ±50 μm) may occur. Without automatic adjustment of the objective along the optic axis, this runout (or disk flutter) will be detrimental to the operation of the system. In practice, the objective is mounted on a small actuator (usually a voice coil) and allowed to move back and forth to keep its distance from the disk within an acceptable range. Since the spindle turns at a few thousand rpm, if the disk moves in and out of focus a few times during each revolution, then the voice coil must be fast enough to follow these movements in real time; in other words, its frequency response must extend from DC to several kHz.

The signal that controls the voice coil is obtained from the light reflected from the disk. There are several techniques for deriving the focus error signal (FES), one of which is depicted in Fig. 9*a*. In this so-called obscuration method a secondary lens with one-half of its aperture covered is placed in the path of the reflected light, and a split-detector is placed at the focal plane of this secondary lens. When the disk is in focus, the returning beam is collimated and the secondary lens will focus the

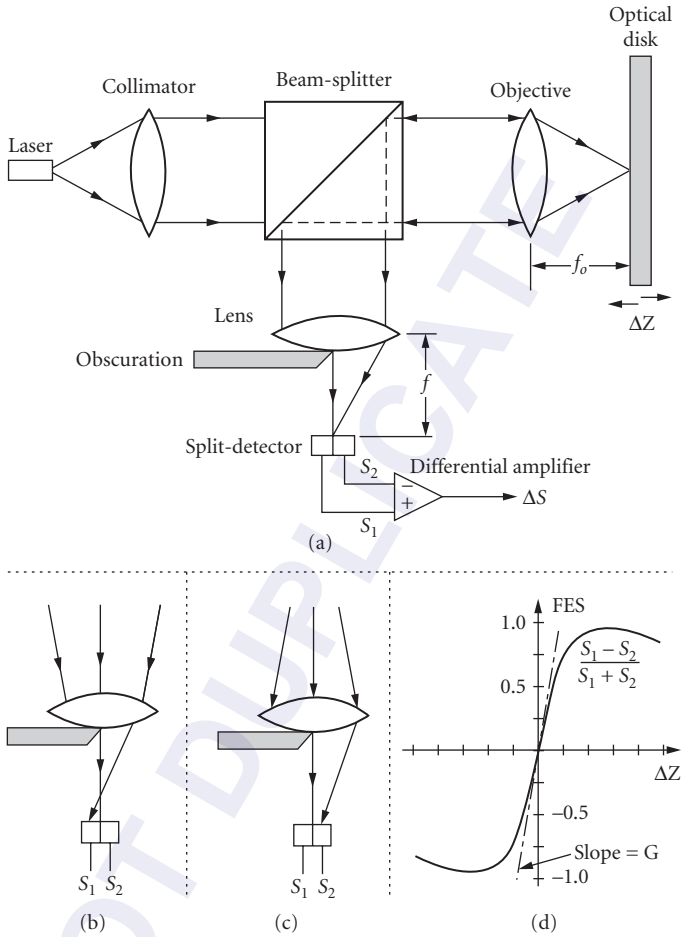

FIGURE 9 Focus error detection by the obscuration method. In (*a*) the disk is in focus, and the two halves of the split detector receive equal amounts of light. When the disk is too far from the objective (*b*) or too close to it (*c*), the balance of detector signals shifts to one side or the other. A plot of the focus error signal versus defocus is shown in (*d*), and its slope near the origin is identified as the FES gain, G.

beam at the center of the split-detector, giving a difference signal ΔS equal to zero. If the disk now moves away from the objective, the returning beam will become converging, as in Fig. 9*b*, sending all the light to detector 1. In this case ΔS will be positive and the voice coil will push the lens toward the disk. On the other hand, when the disk moves close to the objective, the returning beam becomes diverging and detector 2 receives the light (see Fig. 9*c*). This results in a negative ΔS which forces the voice coil to pull back and return ΔS to zero.

A given focus error detection scheme is generally characterized by the shape of its focus error signal ΔS versus the amount of defocus ΔZ. One such curve is shown in Fig. 9*d*. The slope of the FES curve near the origin is of particular importance, since it determines the overall performance and stability of the servo loop. In general, schemes with a large slope are preferred, although certain

other aspects of system performance should also be taken into consideration. For instance, variations of the FES during seek operations (where multiple track-crossings occur) should be kept at a minimum, or else the resulting "feedthrough" might destabilize the focus servo. Also, it is important for a focus-error-detection scheme to be insensitive to slight imperfections of the optical elements, as well as to the positioning and mechanical misalignments; otherwise, the manufacturing cost of the device may become prohibitive. Finally, the focusing scheme must have a reasonable acquisition range, so that at start-up (or in those occasions where focus is lost and needs to be acquired again) the system can move in the proper direction to establish focus.

35.5 AUTOMATIC TRACKING

Consider a circular track with a certain radius, say, r_0, and imagine viewing a portion of it through the access window (see Fig. 1). It is through this window that the read-write head gains access to the disk and, by moving in the radial direction, reaches the various tracks. To a viewer looking through the window, a perfectly circular track centered on the spindle axis will look stationary, irrespective of the rotational speed of the disk. However, any track eccentricity will cause an apparent motion toward or away from the center. The peak-to-peak radial distance traveled by a track (as seen through the window) might depend on a number of factors, including centering accuracy of the hub, deformability of the disk substrate, mechanical vibrations, manufacturing tolerances, etc. For a 3.5-in plastic disk, for example, this peak-to-peak motion can be as much as 100 μm. Assuming a rotation rate of 3600 rpm, the apparent radial velocity of the track will be a few millimeter per second. Now, if the focused spot (which is only about 1 μm) remains stationary while trying to read or write on this track (whose width is also about 1 μm), it is clear that the beam will miss the track for a good fraction of every revolution cycle.

Practical solutions to the above problem are provided by automatic track-following techniques. Here the objective lens is placed in a fine actuator, typically a voice coil, which is capable of moving the necessary radial distances and maintaining a lock on the desired track. The signal that controls the movement of this actuator is derived from the reflected light itself, which carries information about the position of the focused spot relative to the track. There exist several mechanisms for extracting the track-error signal (TES) from the reflected light. All these methods require some sort of structure on the disk surface to identify the position of the track. In the case of read-only disks (CD, CD-ROM, and video disk) the embossed pattern of data provides ample information for tracking purposes. In the case of write-once and erasable disks, tracking guides are impressed on the substrate during the manufacturing process. The two major formats for these tracking guides are pregrooves (for continuous tracking) and sampled-servo marks (for discrete tracking). A combination of the two schemes, known as continuous/composite format, is often used in practice. This format is depicted schematically in Fig. 10 which shows a small section containing five tracks, each consisting of the tail end of a groove, synchronization marks, a mirror area for adjusting offsets, a pair of wobble marks for sampled tracking, and header information for sector identification.

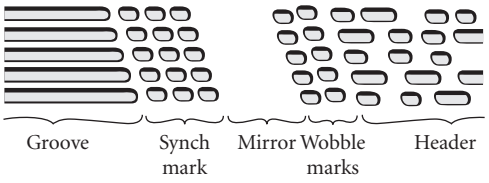

FIGURE 10 Servo offset fields in continuous/composite format contain a mirror area and offset marks for tracking. (*Marchant, 1990.*)

Tracking on Grooved Regions

As shown in Fig. 3*a*, grooves are continuous depressions that are embossed, etched, or molded onto the substrate prior to deposition of the storage medium. If the data is recorded on the grooves, then the lands are not used except for providing a guard band between neighboring grooves. Conversely, the land regions may be used to record the information, in which case grooves provide the guard band. Typical track widths are about one wavelength of the light. The guard bands are somewhat narrower, their exact shape and dimensions depending on the beam size, required track-servo accuracy, and the acceptable levels of crosstalk between adjacent tracks. The groove depth is typically around one-eighth of one wavelength ($\lambda/8$) which gives the largest TES in the push-pull method. The geometrical shape of the groove's cross section might be rectangular, trapezoidal, triangular, or some smooth version of these curves.

When the focused spot is centered on a given track, it is diffracted symmetrically from the two edges, resulting in a balanced far-field pattern. As soon as the spot moves away from the center, the symmetry breaks down and the far-field distribution tends to shift to one side or the other. A split photodetector placed in the path of the reflected light can therefore sense the relative position of the spot and provide the appropriate feedback signal (see Fig. 11). This is the essence of the push-pull

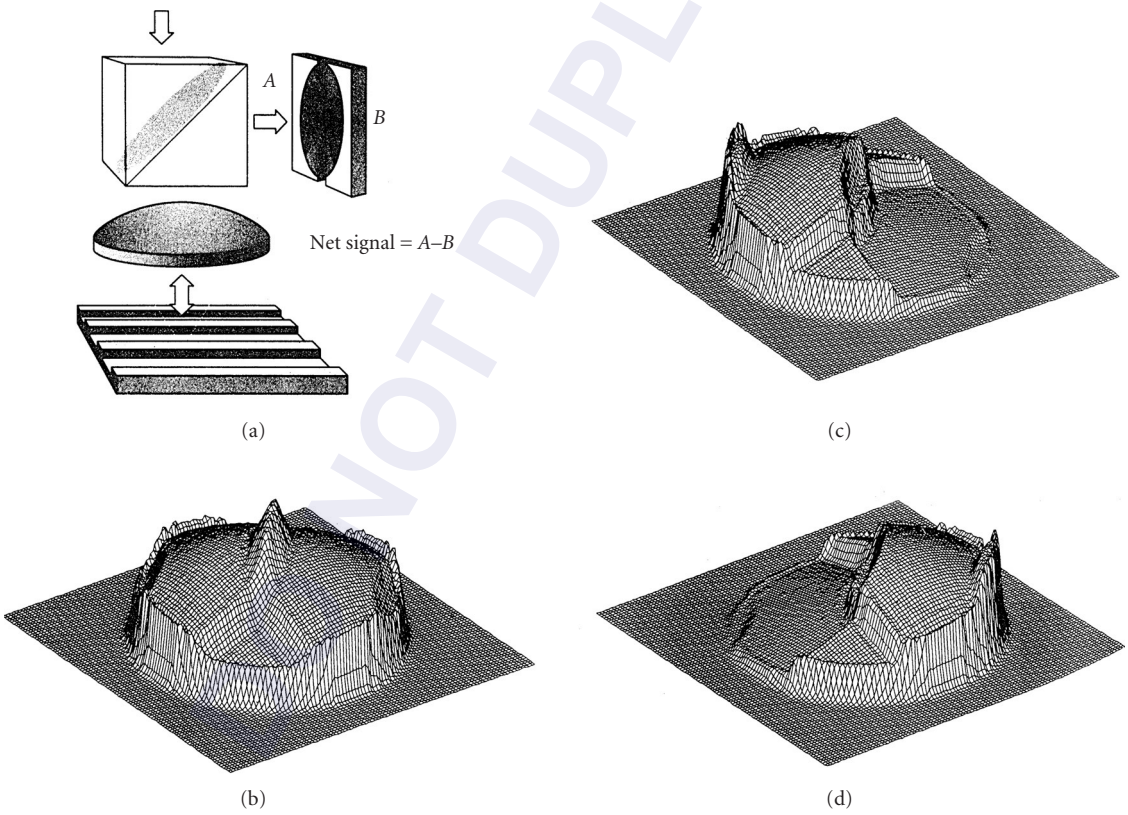

FIGURE 11 (*a*) Push-pull sensor for tracking on grooves. (*Marchant, 1990.*) (*b*) Light intensity distribution at the detector plane when the disk is in focus and the beam is centered on the track. (*c*) Light intensity distribution at the detector plane when the disk is in focus and the beam is centered on the groove edge. (*d*) Same as (*c*) except for the spot being on the opposite edge of the groove.

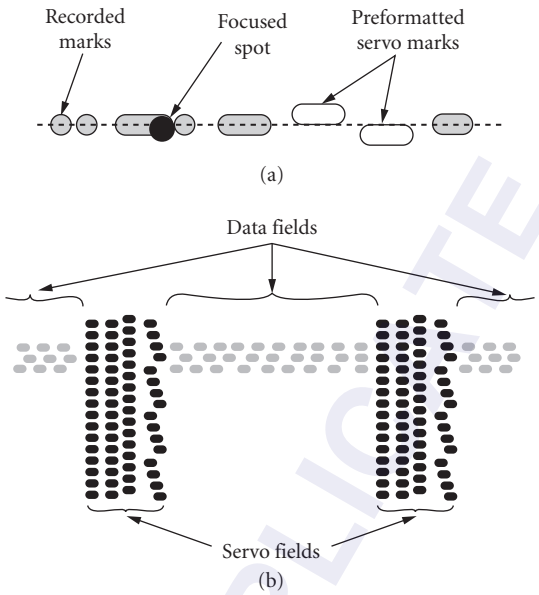

FIGURE 12 (*a*) In sampled tracking a pair of preformatted servo marks helps locate the position of the focused spot relative to the track center. (*b*) servo fields occur frequently and at regular intervals in sampled servo format. The data area shown here has data recorded on three tracks. (*Marchant, 1990.*)

method. Figure 11 also shows intensity plots at the detector plane after reflection from various locations on the grooved surface. Note how the intensity shifts to one side or the other depending on whether the spot moves to the right edge or to the left edge of the groove.

Sampled Tracking

Since dynamic track runout is usually a slow and gradual process, there is actually no need for continuous tracking as done on grooved media. A pair of embedded marks, offset from the track center as in Fig. 12*a*, can provide the necessary information for correcting the relative position of the focused spot. The reflected intensity will indicate the positions of the two servo marks as two successive short pulses. If the beam happens to be on track, the two pulses will have equal magnitudes and there shall be no need for correction. If, on the other hand, the beam is off-track, one of the pulses will be stronger than the other. Depending on which pulse is the stronger, the system will recognize the direction in which it has to move and will correct the error accordingly. Sampled-servo mark pairs must be provided frequently enough to ensure proper track-following. In a typical application, the track might be divided into groups of 18 bytes, 2 bytes dedicated as servo offset areas and 16 bytes filled with other format information or left blank for user data. Figure 12*b* shows a small section from a sampled-servo disk containing a number of tracks, three of which are recorded with user data. The track-servo marks in this case are preceded by synch marks (also prerecorded on the servo offset area). Note in Fig. 12*b* that the format marks repeat a certain pattern every four tracks. This pattern is known as a "gray code," and allows the system to recognize and correct minor track-counting errors during the seek operation.

Track Counting During the Seek Operation

In the seek operation the coarse actuator moves the head assembly across the disk to a new location where the desired track is located. In order to avoid landing on a nearby track and being forced to perform a second (fine) seek, most systems in use today count the tracks as they are being crossed. In this way the head can land on the correct track and thereby minimize the overall seek time. The sampled-servo format is not suitable for this purpose, since the servo marks do not occur frequently enough to allow uninterrupted counting. In contrast, grooved media provide the necessary information for track-counting.

During a seek operation the focus servo loop remains closed, maintaining focus as the head crosses the tracks. The tracking loop, on the other hand, must be opened. The zero crossings of the TES then provide the track count. Complications may arise in this process, however, due to eccentricities of tracks. As was mentioned earlier, to an observer looking through the access window, an eccentric track moves in and out radially with a small (but not insignificant) velocity. As the head approaches the desired track and slows down to capture it, its velocity might fall just short of the apparent track velocity. Under these circumstances, a track which has already been counted may catch up with the head and be counted once again. Intelligence must be built into the system to recognize and avoid such problems. Also, through the use of gray codes and similar schemes, the system can be made to correct its occasional miscounts before finally locking onto the destination track.

35.6 THERMOMAGNETIC RECORDING PROCESS

Recording and erasure of information on a magneto-optical disk are both achieved by the thermomagnetic process. The essence of thermomagnetic recording is shown in Fig. 13. At the ambient temperature the film has a high magnetic coercivity* and therefore does not respond to the externally applied field. When a focused laser beam raises the local temperature of the film, the hot spot becomes magnetically soft (i.e., its coercivity drops). As the temperature rises, coercivity drops continuously until such time as the field of the electromagnet finally overcomes the material's resistance to reversal and switches its magnetization. Turning the laser off brings the temperatures back to normal, but the reverse-magnetized domain remains frozen in the film. In a typical situation in practice, the film thickness may be around 300 Å, laser power at the disk $\simeq$10 mV, diameter of the focused spot $\simeq$1 μm, laser pulse duration ~50 ns, linear velocity of the track $\simeq$10 m/s, and the magnetic field strength $\simeq$200 gauss. The temperature may reach a peak of 500 K at the center of the spot, which is certainly sufficient for magnetization reversal, but is not nearly high enough to melt or crystalize or in any other way modify the structure of the material.

The materials of MO recording have strong perpendicular magnetic anisotropy. This type of anisotropy favors the "up" and "down" directions of magnetization over all other orientations. The disk is initialized in one of these two directions, say, up, and the recording takes place when small regions are selectively reverse-magnetized by the thermomagnetic process. The resulting magnetization distribution then represents the pattern of recorded information. For instance, binary sequences may be represented by a mapping of zeros to up-magnetized regions and ones to down-magnetized regions [non-return to zero (NRZ) scheme]. Alternatively, the non-return to zero inverted (NRZI) scheme might be used, whereby transitions (up-to-down and down-to-up) are used to represent the ones in the bit sequence.

Recording by Laser Power Modulation

In this traditional approach to thermomagnetic recording, the electromagnet produces a constant field, while the information signal is used to modulate the power of the laser beam. As the disk rotates under the focused spot, the pulsed laser beam creates a sequence of up/down domains along

*Coercivity of a magnetic medium is a measure of its resistance to magnetization reversal. For example, consider a thin film with perpendicular magnetic moment saturated in the $+Z$ direction, as in Fig. 13*a*. A magnetic field applied along $-Z$ will succeed in reversing the direction of magnetization only if the field is stronger than the coercivity of the film.

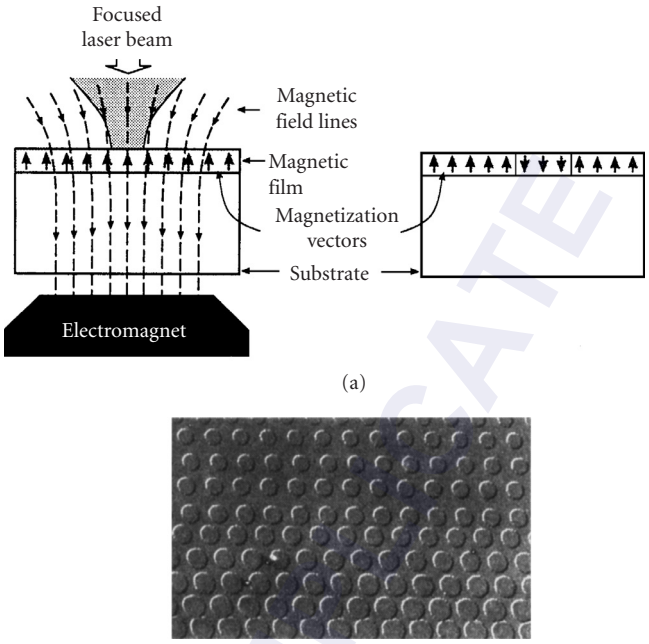

FIGURE 13 (*a*) Thermomagnetic recording process. The field of the electromagnet helps reverse the direction of magnetization in the area heated by the focused laser beam. (*b*) Lorentz micrograph of domains written thermomagnetically. The various tracks shown here were written at different laser powers, with power level decreasing from top to bottom.

the track. The Lorentz electron micrograph in Fig. 13*b* shows a number of domains recorded by laser power modulation (LPM). The domains are highly stable and may be read over and over again without significant degradation. If, however, the user decides to discard a recorded block and to use the space for new data, the LPM scheme does not allow direct overwrite; the system must erase the old data during one revolution and record the new data in a subsequent revolution cycle.

During erasure, the direction of the external field is reversed, so that up-magnetized domains in Fig. 13*a* now become the favored ones. Whereas writing is achieved with a modulated laser beam, in erasure the laser stays on for a relatively long period of time, erasing an entire sector. Selective erasure of individual domains is not practical, nor is it desired, since mass data storage systems generally deal with data at the level of blocks, which are recorded onto and read from individual sectors. Note that at least one revolution cycle elapses between the erasure of an old block and its replacement by a new block. The electromagnet therefore need not be capable of rapid switchings. (When the disk rotates at 3600 rpm, for example, there is a period of 16 ms or so between successive switchings.) This kind of slow reversal allows the magnet to be large enough to cover all the tracks simultaneously, thereby eliminating the need for a moving magnet and an actuator. It also affords a relatively large gap between the disk and the magnet tip, which enables the use of double-sided disks and relaxes the mechanical tolerances of the system without overburdening the magnet's power supply.

The obvious disadvantage of LPM is its lack of direct overwrite capability. A more subtle concern is that it is perhaps unsuitable for the pulse width modulation (PWM) scheme of representing binary waveforms. Due to fluctuations in the laser power, spatial variations of material properties,

lack of perfect focusing and track-following, etc., the length of a recorded domain along the track may fluctuate in small but unpredictable ways. If the information is to be encoded in the distance between adjacent domain walls (i.e., PWM), then the LPM scheme of thermomagnetic writing may suffer from excessive domain-wall jitter. Laser power modulation works well, however, when the information is encoded in the position of domain centers [i.e., pulse position modulation (PPM)]. In general, PWM is superior to PPM in terms of the recording density, and methods that allow PWM are therefore preferred.

Recording by Magnetic Field Modulation

Another method of thermomagnetic recording is based on magnetic field modulation (MFM), and is depicted schematically in Fig. 14*a*. Here the laser power may be kept constant while the information signal is used to modulate the direction of the magnetic field. Photomicrographs of typical domain patterns recorded in the MFM scheme are shown in Fig. 14*b*. Crescent-shaped domains are the hallmark of the field modulation technique. If one assumes (using a much simplified model) that the magnetization aligns itself with the applied field within a region whose temperature has passed a certain critical value, T_{crit}, then one can explain the crescent shape of these domains in the following way: with the laser operating in the CW mode and the disk moving at constant velocity, temperature distribution in the magnetic medium assumes a steady-state profile, such as that in Fig. 14*c*. Of course, relative to the laser beam, the temperature profile is stationary, but in the frame

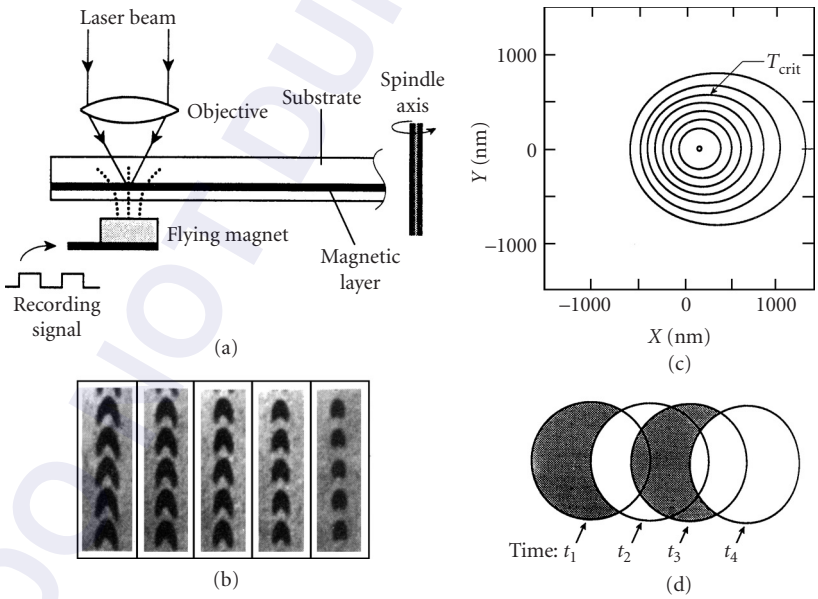

FIGURE 14 (*a*) Thermomagnetic recording by magnetic field modulation. The power of the beam is kept constant, while the magnetic field direction is switched by the data signal. (*b*) Polarized-light microphotograph of recorded domains. (*c*) Computed isotherms produced by a CW laser beam, focused on the magnetic layer of a disk. The disk moves with constant velocity under the beam. The region inside the isotherm marked as T_{crit} is above the critical temperature for writing, thus its magnetization aligns itself with the direction of the applied magnetic field. (*d*) Magnetization within the heated region (above T_{crit}) follows the direction of the applied magnetic field, whose switchings occur at times t_n. The resulting domains are crescent-shaped.

of reference of the disk the profile moves along the track with the linear track velocity. The isotherm corresponding to T_{crit} is identified as such in the figure; within this isotherm the magnetization always aligns itself with the applied field. A succession of critical isotherms along the track, each obtained at the particular instant of time when the magnetic field switches direction, is shown in Fig. 14*d*. From this picture it is not difficult to see how the crescent-shaped domains form, and also to understand the relation between the waveform that controls the magnet and the resulting domain pattern.

The advantages of magnetic field modulation recording are that (1) direct overwriting is possible, and (2) domain wall positions along the track, being rather insensitive to defocus and laser power fluctuations, are fairly accurately controlled by the timing of the magnetic field switchings. On the negative side, the magnet must now be small and fly close to the disk surface if it is to produce rapidly switched fields with a magnitude of a few hundred gauss. Systems that utilize magnetic field modulation often fly a small electromagnet on the opposite side of the disk from the optical stylus. Since mechanical tolerances are tight, this might compromise the removability of the disk in such systems. Moreover, the requirement of close proximity between the magnet and the storage medium dictates the use of single-sided disks in practice.

Thermal Optimization of the Media—Multilayer Structures

The thermal behavior of an optical disk can be modified and improved if the active layer is incorporated into a properly designed multilayer structure, such as that shown in Fig. 15. In addition to thermal engineering, multilayers allow protective mechanisms to be built around the active layer; they also enable the enhancement of the signal-to-noise ratio in readout. (This latter feature is further explored in Sec. 35.7.) Multilayers are generally designed to optimize the absorption of light by creating an antireflection structure, whereby a good fraction of the incident optical power is absorbed in the active layer. Whereas the reflectivity of bare metal films is typically over 50 percent, a quadrilayer structure can easily reduce that to 20 percent or even less, if so desired. Multilayers can also be designed to control the flow of heat generated by the absorbed light. The aluminum reflecting layer in the quadrilayer of Fig. 15, for instance, may be used as a heat sink for the magnetic layer, thus minimizing the undesirable effects of lateral heat diffusion within the magnetic medium.

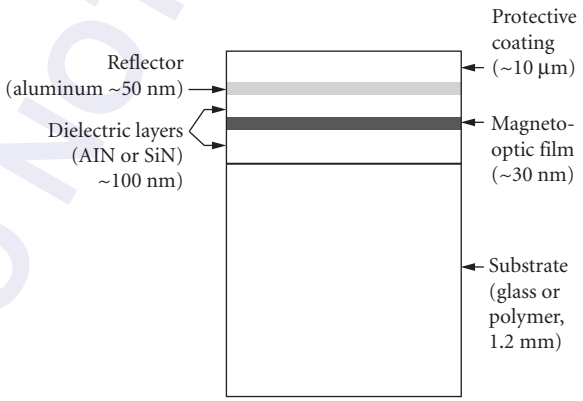

FIGURE 15 Quadrilayer magneto-optical disk structure. This particular design is for use in the substrateincident mode, where the light goes through the substrate before reaching the MO layer. The thicknesses of the various layers can be optimized for enhancing the read signal, increasing the absorbed laser power, and controlling the thermal profile. Note in particular that the aluminum layer can play the dual roles of light reflector and heat sink.

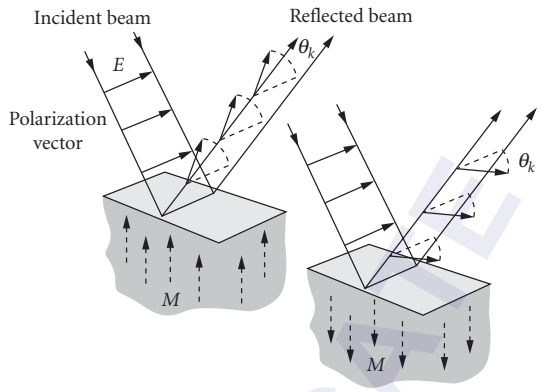

FIGURE 16 Schematic diagram describing the polar magneto-optical Kerr effect. Upon reflection from the surface of a perpendicularly magnetized medium, the polarization vector undergoes a rotation. The sense of rotation depends on the direction of magnetization **M**, and switches sign when **M** is reversed.

35.7 MAGNETO-OPTICAL READOUT

The information recorded on a perpendicularly magnetized medium may be read with the aid of the polar magneto-optical Kerr effect. When linearly polarized light is normally incident on a perpendicular magnetic medium, its plane of polarization undergoes a slight rotation upon reflection. This rotation of the plane of polarization, whose sense depends on the direction of magnetization in the medium, is known as the polar Kerr effect. The schematic representation of this phenomenon in Fig. 16 shows that if the polarization vector suffers a counterclockwise rotation upon reflection from an up-magnetized region, then the same vector will rotate clockwise when the magnetization is down. A magneto-optical medium is characterized in terms of its reflectivity R and its Kerr rotation angle θ_k.* In MO readout, it is the sign of the rotation angle that carries the information about the state of magnetization of the medium, i.e., the recorded bit pattern.

The laser used for readout is usually the same as that used for recording, but its output power level is substantially reduced in order to avoid erasing (or otherwise obliterating) the previously recorded information. For instance, if the power of the write/erase beam is 20 mW, then for the read operation the beam is attenuated to about 3 or 4 mW. The same objective lens that focuses the write beam is now used to focus the read beam, creating a diffraction-limited spot for resolving the recorded marks. Whereas in writing the laser was pulsed to selectively reverse-magnetize small regions along the track, in readout it operates with constant power, i.e., in CW mode. Both up- and down-magnetized regions are read as the track passes under the focused light spot. The reflected beam, which is now polarization-modulated, goes back through the objective and becomes collimated once again; its information content is subsequently decoded by polarization-sensitive optics, and the scanned pattern of magnetization is reproduced as an electronic signal.

*In reality, the reflected state of polarization is not linear, but has a certain degree of ellipticity. One may consider the reflected polarization as consisting of two linear components: $E_{\|}$ which is parallel to the direction of incident polarization, and $E_{\perp}$ which is perpendicular to it. Now, if $E_{\|}$ is in phase with $E_{\perp}$, the net magneto-optic effect will be a pure rotation of the polarization vector. On the other hand, if $E_{\|}$ and $E_{\perp}$ are 90° out of phase, then the reflected polarization will be elliptical, with no rotation whatsoever. In practice, the phase difference between $E_{\|}$ and $E_{\perp}$ is somewhere between 0° and 90°, resulting in a reflected beam which has some degree of ellipticity ϵ_k, with the major axis of the polarization ellipse rotated by an angle θ_k (relative to the incident **E** vector). By inserting a Soleil-Babinet compensator in the reflected beam's path, one can change the phase relationship between $E_{\|}$ and $E_{\perp}$ in such a way as to eliminate the beam's ellipticity; the emerging polarization then will become linear with an enhanced rotation angle. In this chapter, reference to Kerr angle implies the effective angle which includes the above correction for ellipticity.

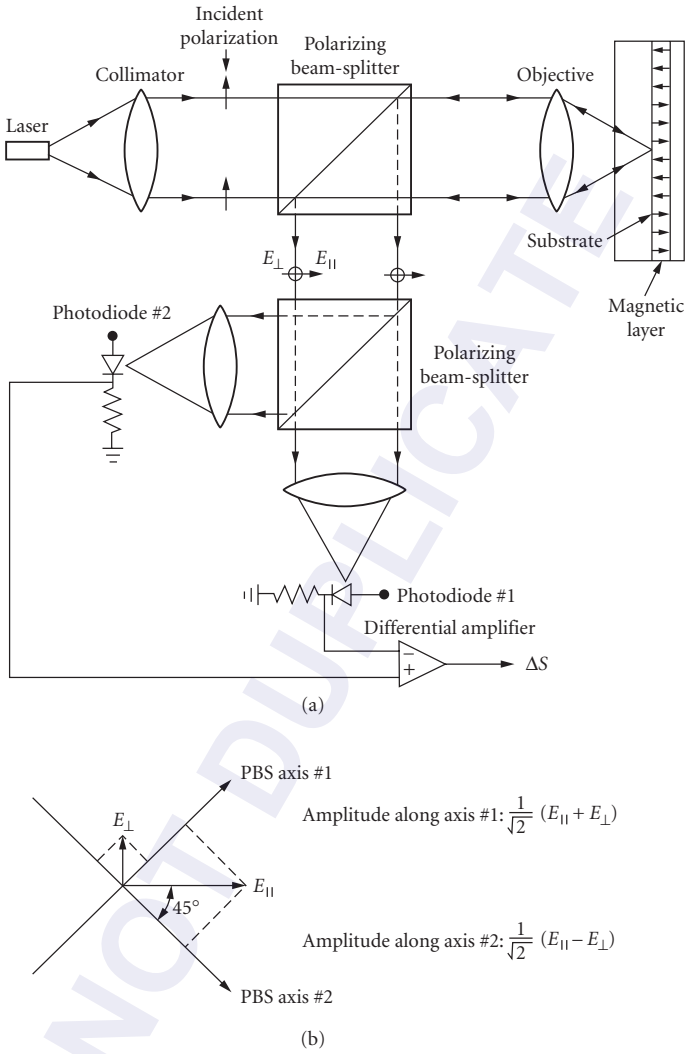

FIGURE 17 Differential detection scheme utilizes a polarizing beam splitter and two photodetectors in order to convert the rotation of polarization to an electronic signal. $E_{||}$ and $E_\perp$ are the reflected components of polarization; they are, respectively, parallel and perpendicular to the direction of incident polarization. The diagram in (*b*) shows the orientation of the PBS axes relative to the polarization vectors.

Differential Detection

Figure 17 shows the differential detection system that is the basis of magneto-optical readout in practically all erasable optical storage systems in use today. The beam splitter (BS) diverts half of the reflected beam away from the laser and into the detection module. The polarizing beam splitter (PBS) splits the beam into two parts, each carrying the projection of the incident polarization along

one axis of the PBS, as shown in Fig. 17*b*. The component of polarization along one of the axes goes straight through, while the component along the other axis splits off to the side. If, upon reflection from the disk, the polarization did not undergo any rotations whatsoever, then the beam entering the PBS would be polarized at 45° to the PBS axes, in which case it would split equally between the two branches. Under this condition, the two detectors generate identical signals and the differential signal ΔS will be zero. Now, if the beam returns from the disk with its polarization rotated clockwise (rotation angle = θ_k), then detector 1 will receive more light than detector 2, and the differential signal will be positive. Similarly, a counterclockwise rotated beam entering the PBS will generate a negative ΔS. The electronic signal ΔS thus reproduces the pattern of magnetization along the scanned track.

Enhancement of the Signal-to-Noise Ratio by Multilayering

The materials suitable for optical recording presently have very small Kerr angles (typically $\theta_k \simeq 0.5°$), with the result that the signal ΔS is correspondingly small. Multilayering schemes designed for the enhancement of the MO signal increase the interaction between the light and the magnetic medium by encapsulating a thin film of the MO material in an antireflection-type strucure. By providing a better index match between the MO film and its surroundings, and also by circulating the light through the MO film, multilayered structures manage to trap a large fraction of the incident light within the magnetized medium, and thus increase the Kerr rotation angle. These efforts inevitably result in a reduced reflectivity, but since the important parameter is the magneto-optically generated component of polarization, $E_\perp = \sqrt{R} \sin \theta_k$, it turns out that a net gain in the signal-to-noise ratio can be achieved by adopting the multilayering schemes. Reported enhancements of $E_\perp$ have been as large as a factor of 5. The popular quadrilayer structure depicted in Fig. 15 consists of a thin film of the MO material, sandwiched between two transparent dielectric layers, and capped off with a reflecting metallic layer. The entire structure, which is grown on a transparent substrate (through which light must travel to reach the MO film), is protected by a lacquer layer on the top. Numbers shown in Fig. 15 for the various layer thicknesses are representative of currently designed quadrilayers.

The advantage of sending the light through the substrate is that the front facet of the disk stays out of focus during operation. In this way, small dust particles, finger prints, and scratches will not block the passage of light, and their deteriorating effects on the quality of the focused spot (which affects the integrity of both writing and readout) will be minimized. Any optical storage medium designed for removability ought to have the kind of protection that illumination through the substrate provides. The note of caution with substrate-side illumination is that, if the objective is simply designed for focusing in the air, then the oblique rays will bend upon entering the substrate and deviate from nominal focus, causing severe aberrations (see Fig. 7*c*). Therefore, the substrate thickness and refractive index must be taken into account in the objective's design.

Sources of Noise in Readout

The read signal is always accompanied by random noise. The effective noise amplitude (relative to the strength of the signal) ultimately limits the performance of any readout system. Part of the noise is thermal in nature, arising from random fluctuations of charge carriers within the photodiodes, resistors, and amplifiers. In principle, this source of noise can be mitigated by reducing the operating temperature of the device. However, since operating below the normal room temperature is not very practical for data storage systems, one must accept some of the limitations brought about by the thermal noise.

Another source of readout noise is shot noise which, in classical language, is due to random arrival of photons at the photodetector(s). This noise is a permanent companion of the read signal and cannot be eliminated, but the system parameters may be adjusted to minimize its effect. One

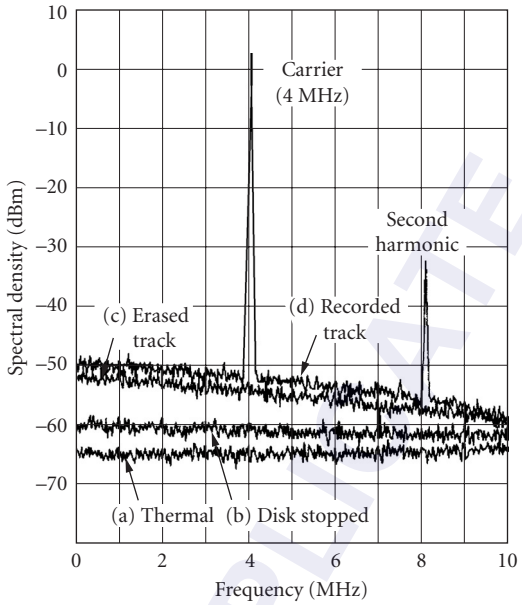

FIGURE 18 Spectra of the various noise components in magneto-optical readout.

property of the shot noise is that its rms amplitude is proportional to the square root of the available optical power P_o. Since the signal strength is directly proportional to P_o, it is clear that by increasing the read power of the laser one can enhance the ratio of signal-to-shot noise. There is, however, an upper limit on the laser read power, since the rise in the temperature of the medium will force the decline of its magneto-optical response.

Other sources of noise in magneto-optical readout include the laser noise, the media noise, and the data noise. Laser noise is caused by amplitude/phase fluctuations of the electromagnetic radiation that comprises the optical beam. Media noise arises from variations in the reflectivity/magneto-optic activity of the medium across its surface. The presence of grooves with rough and nonuniform edges can be a source of media noise as well. The term *data noise* refers to the unpredictable variations of the read signal arising from the imperfect shape/position of the recorded marks.

Figure 18 shows the various components of noise in a typical MO readout system, as detected by a spectrum analyzer. In (*a*) the light beam is blocked and the trace on the analyzer screen is solely due to the thermal noise. The trace in (*b*) where the beam reaches the detectors but the disk is stationary shows the combined effect of thermal, shot, and laser noise. Trace (*c*) corresponds to reading an erased track on a spinning disk; the noise here includes all of the above plus the media noise. When a single-frequency tone was recorded on the track and the read-back signal was fed to the spectrum analyzer, trace (*d*) was obtained. The narrow pulse at frequency f_0 is the first harmonic of the recorded signal; the corresponding second harmonic appears at $2f_0$. The noise level in this case is somewhat greater than that from the same track before the data was recorded. This difference is due to "data noise" and arises from jitter and nonuniformity of the recorded marks.

A commonly used measure of performance for optical recording media is the carrier-to-noise ratio (CNR). This is the ratio of the signal amplitude at the carrier frequency f_0 to the average level of noise. On a logarithmic scale the ratio is simply the difference between the two levels; in Fig. 18 the CNR is 53 decibels (dB).

35.8 MATERIALS OF MAGNETO-OPTICAL RECORDING

Amorphous rare earth transition metal alloys are presently the media of choice for erasable optical data storage applications. The general formula for the composition of the alloy may be written $(Tb_yGd_{1-y})_x(Fe_xCo_{1-z})_{1-x}$ where terbium and gadolinium are the rare earth (RE) elements, while iron and cobalt are the transition metals (TM). In practice, the transition metals constitute roughly 80 atomic percent of the alloy (i.e., $x \simeq 0.2$). In the transition metal subnetwork the fraction of cobalt is usually small, typically around 10 percent, and iron is the dominant element ($z \simeq 0.9$). Similarly, in the rare earth subnetwork Tb is the main element ($y \simeq 0.9$) while the Gd content is small or it may even be absent in some cases. Since the rare earth elements are highly reactive, RE-TM films tend to have poor corrosion resistance and, therefore, require protective coatings. In a disk structure such as that shown in Fig. 15, the dielectric layers that enable optimization of the medium for the best optical/thermal behavior also perform the crucial task of protecting the MO layer from the environment.

The amorphous nature of the material allows its composition to be continuously varied until a number of desirable properties are achieved. (In other words, the fractions x, y, z of the various elements are not constrained by the rules of stoichiometry.) Disks with large surface areas are coated uniformly with thin films of these media, and, in contrast to polycrystalline films whose grains and grain boundaries scatter the light beam and cause noise, these amorphous films are smooth and substantially noise-free. The films are deposited either by sputtering from an alloy target, or by cosputtering from multiple elemental targets. In the latter case, the substrate moves under the various targets and the fraction of a given element in the alloy film is determined by the time spent under the target as well as the power applied to that target. Substrates are usually kept at a low temperature (by water cooling, for instance) in order to reduce the mobility of deposited atoms and to inhibit crystal growth. Factors that affect the composition and short-range order of the deposited films include the type of the sputtering gas (argon, krypton, xenon, etc.) and its pressure during sputtering, the bias voltage applied to the substrate, deposition rate, nature of the substrate and its pretreatment, temperature of the substrate, etc.

Ferrimagnetism

The RE-TM alloys of interest in MO recording are ferrimagnetic, in the sense that the magnetization of the TM subnetwork is antiparallel to that of the RE subnetwork. The net magnetic moment exhibited by the material is the vector sum of the two subnetwork magnetizations. Figure 19 shows a typical temperature dependence of RE and TM magnetic moments, as well as the net saturation moment of the material. The exchange coupling between the two magnetic subnetworks is strong enough to give them the same critical temperature T_c. At $T = 0$ K the rare earth moment is stronger than that of the transition metal, giving the material a net moment along the direction of the RE magnetization. As the temperature rises, thermal disorder competes with interatomic exchange forces that tend to align the individual atomic dipole moments. The decrease of M_{RE} with the increasing temperature is faster than that of M_{TM}, and the net moment M_s begins to approach zero. At the compensation point temperature T_{comp}, the net moment vanishes. Between T_{comp} and T_c the net moment is dominated by the TM subnetwork and the material is said to exhibit TM-rich behavior (as opposed to when $T < T_{comp}$, where it exhibits RE-rich behavior). At the Curie temperature, thermal agitations finally break the hold of the exchange forces on magnetic dipoles, and the magnetic order disappears. Beyond T_c the material is in the paramagnetic state.

The composition of the materials of magneto-optical storage is chosen so that T_{comp} appears near the ambient temperature of $T_a \simeq 300$ K. Thus, under normal conditions, the net magnetization of the material is close to zero. Figure 20 shows a schematic drawing of the magnetization pattern in the cross section of a recorded track. Note that, although the net magnetization is nearly zero everywhere, the subnetwork moments have opposite orientations in adjacent domains. During readout the light from the GaAs laser interacts mainly with the transition metal subnetwork; thus, the MO Kerr signal is strong even though the net magnetization of the storage layer may be small. The magnetic

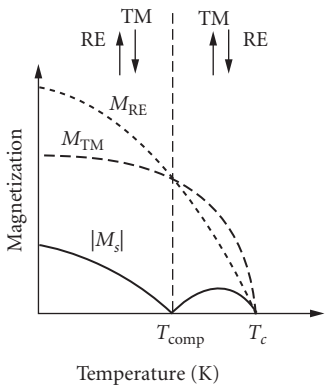

FIGURE 19 Temperature dependence of magnetization in amorphous RE-TM films. The moments of RE and TM subnetworks decrease monotonically, until they both vanish at the critical (Curie) temperature T_c. The net magnetization is the difference between the two subnetwork moments, and goes through zero at the compensation point $T_{comp.}$

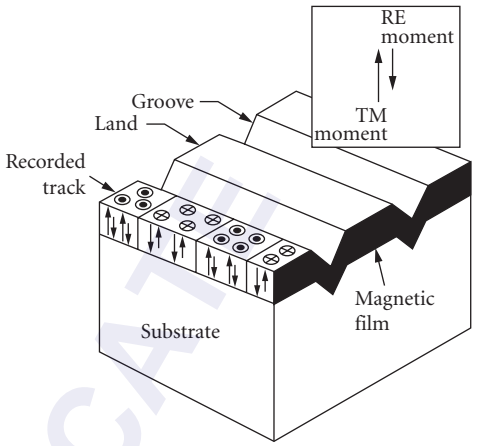

FIGURE 20 Schematic diagram showing the pattern of magnetization along a recorded track. The rare earth and the transition metal moments couple antiferromagnetically, so that the net magnetization everywhere is small. However, since the read beam interacts mainly with the TM subnetwork, the readout signal is not necessarily small.

electrons of iron and cobalt are in the 3*d* electronic shell, which forms the outer layer of the ion once the 4*s* electrons have escaped into the sea of conduction electrons. The magnetic electrons of Tb and Gd, in contrast, are within the 4*f* shell, concealed by the 5*s*, 5*p*, and 5*d* shells, even after the 6*s* electrons escape to the conduction band. A red or near-infrared photon is not energetic enough to penetrate the outer shell and interact with the magnetic 4*f* electrons, but it readily interacts with the exposed 3*d* electrons that constitute the magnetic moment of the TM subnetwork. It is for this reason that the MO Kerr signal in the visible and in the infrared is a probe of the state of magnetization of the TM subnetwork.

Perpendicular Magnetic Anisotropy

An important property of amorphous RE-TM alloy films is that they possess perpendicular magnetic anisotropy. The magnetization in these films favors perpendicular orientation even though there is no discernible crystallinity or microstructure that might obviously be responsible for this behavior. It is generally believed that atomic short-range order, established in the deposition process and aided by the symmetry-breaking at the surface of the film, gives preference to perpendicular orientation. Unequivocal proof of this assertion, however, is not presently available due to a lack of high-resolution observation instruments.

The perpendicular magnetization of MO media is in sharp contrast to the in-plane orientation of the magnetization vector in ordinary magnetic recording. In magnetic recording, the neighboring domains are magnetized in head-to-head fashion, which is an energetically unfavorable situation, since the domain walls are charged and highly unstable. The boundary between neighboring domains in fact breaks down into zigzags, vortices, and all manner of jagged, uneven structure in an attempt to reduce the magnetostatic energy. In contrast, adjacent domains in MO media are highly stable, since the pattern of magnetization causes flux closure, which reduces the magnetostatic energy.

Coercivity and the Hysteresis Loop

Typical hysteresis loops of an amorphous RE-TM thin film at various temperatures are shown in Fig. 21*a*. These loops, obtained with a vibrating sample magnetometer (VSM), show several characteristics of the MO media. (The VSM applies a slowly varying magnetic field to the sample and measures its net magnetic moment as a function of the field.) The horizontal axis in Fig. 21*a* is the applied field, which varies from −12 to +12 kOe, while the vertical axis is the measured magnetic moment per unit volume (in CGS units of emu/cm^3). The high degree of squareness of the loops signifies the following:

1. The remanent magnetization M_r is the same as the saturation magnetization M_s. Thus, once the sample is saturated with the help of an applied field, removing that field does not cause a reduction of the magnetic moment.
2. Transitions of the magnetization from up to down (or from down to up) are very sharp. The reverse field does not affect the magnetization until the critical value of H_c, the coercive field, is reached. At the coercive field the magnetization suddenly reverses direction, and saturation in the opposite direction is almost immediate.

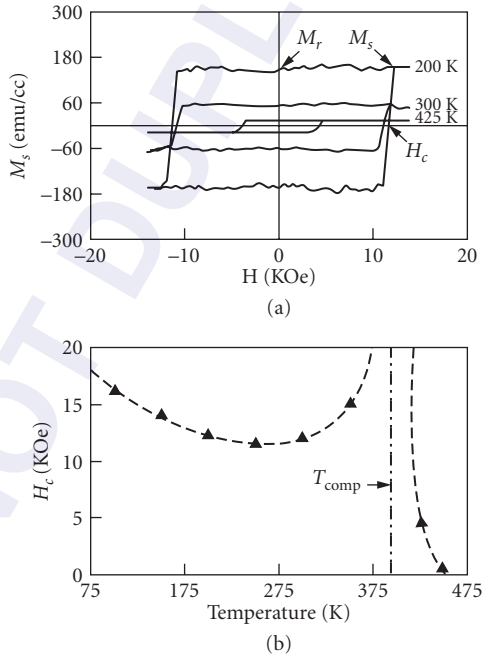

FIGURE 21 (*a*) Hysteresis loops of an amorphous $Tb_{27}(FeCo)_{73}$ film, measured by VSM at three different temperatures. The saturation moment M_s, the remanent moment M_r, and the coercive field H_c are identified for the loop measured at $T = 200$ K. (*b*) Coercivity as function of temperature for the above sample. At the compensation temperature, $T_{comp} = 400$ K, the coercivity is infinite; it drops to zero at the Curie point $T_c = 450$ K.

The fact that M_r is very nearly equal to M_s in MO media is significant, since it means that the recorded domains remain fully saturated and exhibit maximum signal during readout. The coercivity H_c, in addition to being responsible for the stability of recorded domains, plays an important role in the processes of thermomagnetic recording and erasure. The coercivity at room temperature, being of the order of several thousand oersteds, prevents fields weaker than H_c from destroying (or disturbing) any recorded data. With the increasing temperature, the coercivity decreases and drops to zero at the Curie point, T_c. Figure 21*b* is the plot of H_c versus T for the same sample as in (*a*). Note that at the compensation point the coercivity goes to infinity, simply because the magnetization vanishes, and the external field does not see any magnetic moments to interact with. Above T_{comp} the coercive field decreases monotonically, which explains the process of magnetization reversal during thermomagnetic recording: **M** switches sign once the coercivity drops below the level of the applied field.

35.9 CONCLUDING REMARKS

In this chapter we have reviewed the basic characteristics of optical disk data storage systems, with emphasis on magneto-optical recording. The goal has been to convey the important concepts without getting distracted by secondary issues and less significant details. As a result, we have glossed over several interesting developments that have played a role in the technological evolution of optical data storage. In this final section some of these developments are briefly described.

Multiple-Track Read-Write with Diode Laser Arrays

It is possible in an optical disk system to use an array of lasers instead of just one, focus all the lasers simultaneously through the same objective lens, and perform parallel read/write/erase operations on multiple tracks. Since the individual lasers of an array can be modulated independently, the parallel channels thus obtained are totally independent of each other. In going from a single-channel drive to a multiple-channel one, the optics of the system (i.e., lenses, beam splitters, polarization-sensitive elements, focus and track servos, etc.) remain essentially the same; only the lasers and detectors proliferate in number. Parallel track operations boost the sustainable data rates in proportion to the number of channels used.

Diffractive Optics

The use of holographic optical elements (HOEs) to replace individual refractive optics is a promising new development. Diffractive optical elements are relatively easy to manufacture, they are lightweight and inexpensive, and can combine the functions of several elements on a single plate. These devices are therefore expected to help reduce the cost, size, and weight of optical heads, making optical drives more competitive in terms of price and performance.

An example of the application of HOEs in MO systems is shown in Fig. 22, which shows a reflection-type element consisting of four separate holograms. The light incident on the HOE at an angle of 60° has a *p* component which is the original polarization of the laser beam, and an *s* component (parallel to the hologram's grooves) which is the magneto-optically generated polarization at the disk. Nearly 90 percent of the *s* and 70 percent of the *p* polarization in this case are reflected from the HOE without suffering any diffraction (i.e., in the zero-order beam); they are captured in the differential detection module and yield the MO read signal. The four holograms deflect 20 percent of the incident *p*-polarized light in the form of first-order diffracted beams and bring them to focus at four different spots on a multielement detector. The two small holograms in the middle, H_3 and H_4, focus their first-order beams on detectors P_3 and P_4, to generate the push-pull

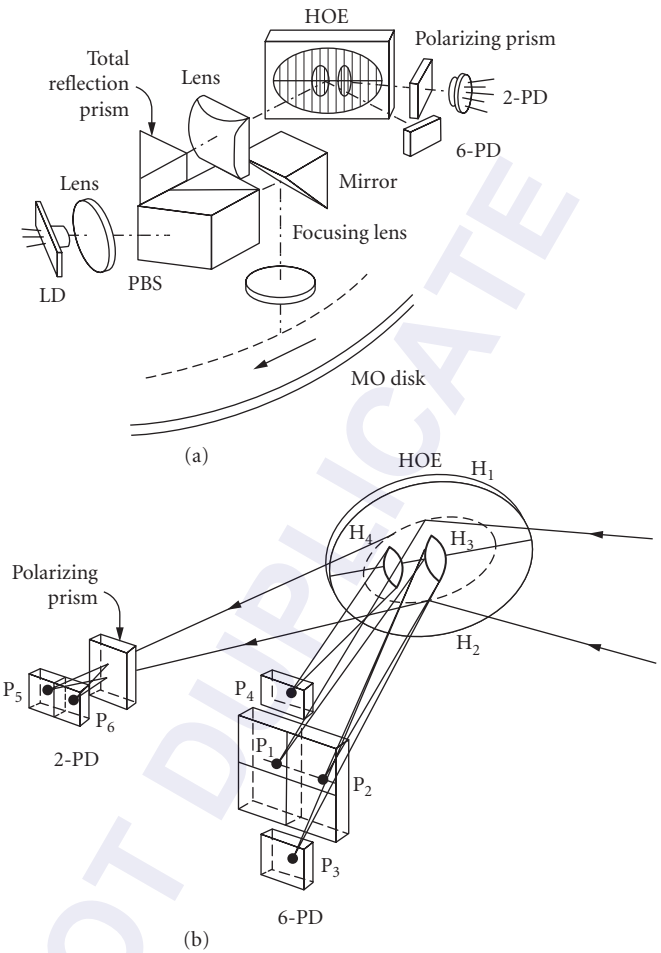

FIGURE 22 Application of holographic optical element (HOE) in optical recording. (*a*) Configuration of MO head using a polarization-sensitive reflection HOE. (*b*) Geometrical relation between holograms and detectors. (*After A. Ohba et al., SPIE Proceedings, Vol. 1078, 1989.*)

tracking-error signal. The other two holograms, H_1 and H_2, send the diffracted beams to a four-element detector in order to generate a focus-error signal based on the double knife-edge scheme. This HOE, therefore, combines the functions of beam splitting, masking, and focusing all in one compact unit.

Alternative Storage Media

The GaAlAs lasers of the present optical disk technology will likely be replaced in the future by light sources that emit in the blue end of the spectrum. Shorter wavelengths allow smaller marks to be recorded, and also enable the resolving of those marks in readout. Aside from the imposition of tighter tolerances on focusing and tracking servos, operation in the blue will require storage materials

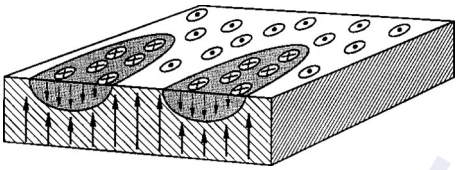

FIGURE 23 Direct overwrite in exchange-coupled magnetic multilayers involves the formation of domains that do not extend through the entire thickness of the magnetic medium.

that are sensitive to the short wavelengths. The current favorites for erasable optical recording media, the amorphous RE-TM alloys, may not be suitable for readout in the blue, since their magneto-optic Kerr signal drops at short wavelengths. A new class of magnetic materials which holds promise for future-generation device applications is the class of TM/TM superlattice-type media. The best-known material in this class is the Co/Pt-layered structure which consists of very thin layers of cobalt (typically one or two atomic layers), separated by several atomic layers of platinum. These polycrystalline films which have very small crystallites (grain diameter $\simeq$200 Å) are prepared either by electron beam evaporation or by sputtering. Co/Pt films have large perpendicular magnetic anisotropy, good signal-to-noise ratios in the blue, sufficient sensitivity for write/erase operations, and are environmentally more stable than the RE-TM media.

Direct Overwrite in Magneto-Optical Systems

The problem of direct overwrite (DOW) on MO media has been the subject of extensive research in recent years. Some of the most promising solutions have been based on exchange-coupled magnetic multilayered structures. The basic idea of recording on exchange-coupled bilayers (or trilayers) is simple and involves the writing of reverse domains that do not extend through the entire film thickness, such as those shown schematically in Fig. 23. Such domains are under pressure from their excessive wall energies to collapse and can readily be erased with a moderate-power laser pulse. DOW on exchange-coupled media is thus achieved by writing (i.e., creating reverse domains) with a high-power pulse, and erasing (i.e., eliminating domains) with a moderate-power pulse. An external magnetic field is usually required for writing on such media, but neither the direction nor the magnitude of this field needs to change during erasure.

Optical recording is an evolving technology, which will undoubtedly see many innovations and improvements in the coming years. Some of the ideas and concepts described here will hopefully remain useful for some time to come, while others may have a shorter lifetime and limited usefulness. It is the author's hope, however, that they all serve as a stepping-stone to profound new ideas.

35.10 FURTHER INFORMATION

Proceedings of the *Optical Data Storage Conference* are published annually by SPIE, the International Society for Optical Engineering. These proceedings document each year the latest developments in the field of optical recording.

Two other conferences in this field are the *International Symposium on Optical Memory* (ISOM) whose proceedings are published as a special issue of the *Japanese Journal of Applied Physics*, and the *Magneto-Optical Recording International Symposium* (MORIS) whose proceedings appear in a special issue of the *Journal of the Magnetics Society of Japan.*

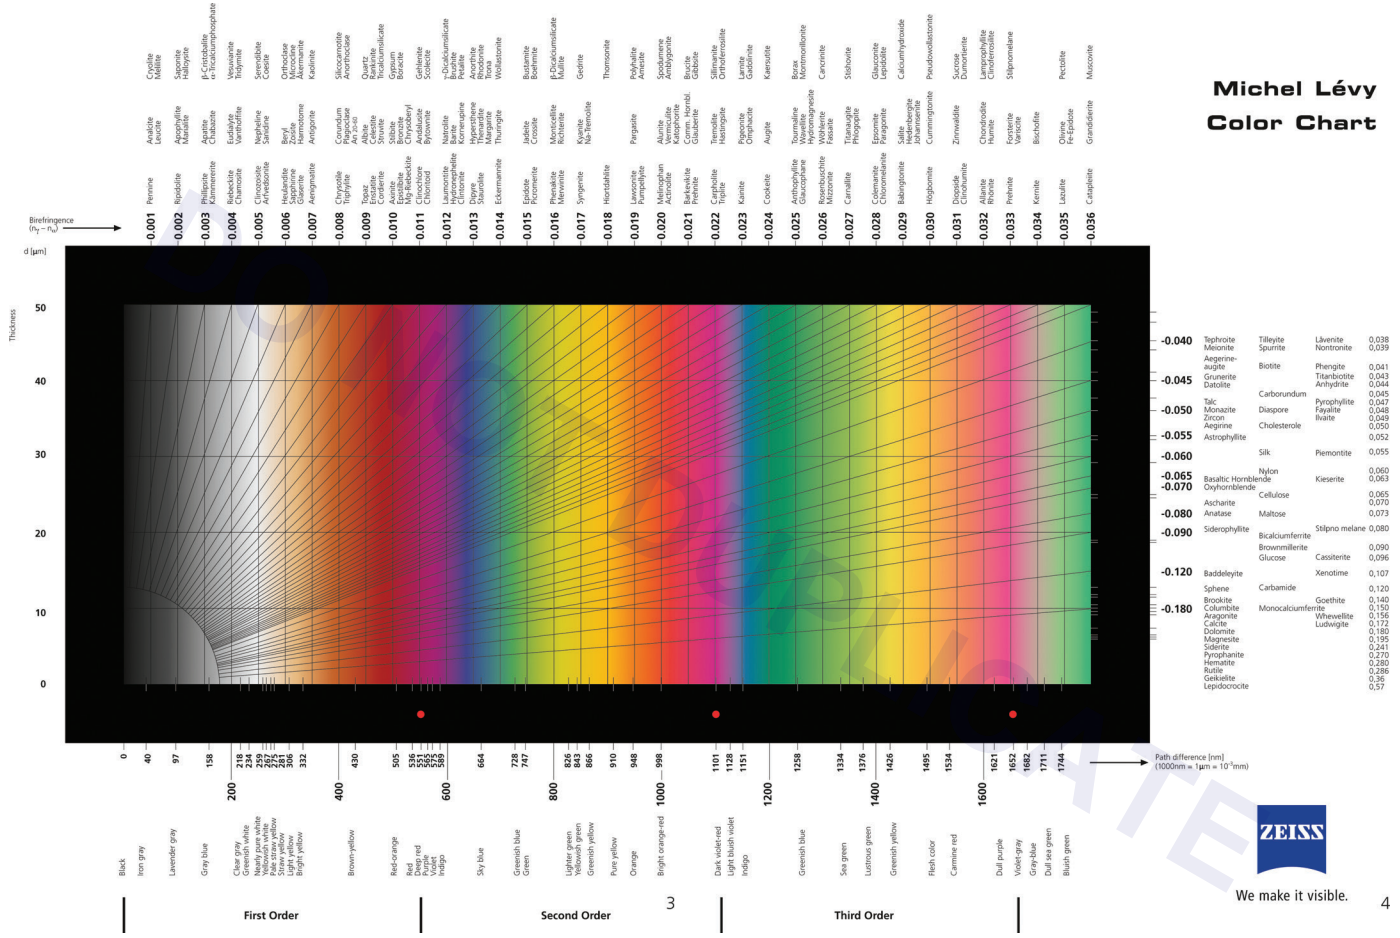

FIGURE 28.28 Michel Lévy Color Chart of interference colors. The horizontal sequence of colors is associated with the interference of two beams of white light whose mutual path difference increases from 0 (left, black for destructive interference) to more than 1700 nm (right, pale green). By comparing an experimentally observed color with the colors of this chart, one can estimate the path difference caused, for example, by the partial reflection off a thin dielectric film (e.g., soap bubble) or transmission through a thin birefringent sheet (e.g., mica) sandwiched between crossed polarizers. For birefringent materials, the path difference is the product of the birefringence (indicated along the upper and right edge) and the thickness (left edge) of the material. The diagonal lines assist in estimating one of the quantities (birefringence or thickness) from the observed color, if the other quantity is known. This brightness/color sequence is specific to interference phenomena that result in destructive interference for zero path difference (e.g., birefringent sheet between crossed polarizers.) A complementary color sequence applies to interference phenomena that result in constructive interference at zero path difference (e.g., birefringent sheet between parallel polarizers.)

BRIEF CONTENTS OF ALL VOLUMES

VOLUME I. GEOMETRICAL AND PHYSICAL OPTICS, POLARIZED LIGHT, COMPONENT AND INSTRUMENTS

VOLUME II. DESIGN, FABRICATION, AND TESTING; SOURCES AND DETECTORS; RADIOMETRY AND PHOTOMETRY

PART 1. DESIGN

PART 2. FABRICATION

PART 3. TESTING

PART 4. SOURCES

PART 5. DETECTORS

PART 6. IMAGING DETECTORS

PART 7. RADIOMETRY AND PHOTOMETRY

VOLUME III. VISION AND VISION OPTICS

VOLUME IV. OPTICAL PROPERTIES OF MATERIALS, NONLINEAR OPTICS, QUANTUM OPTICS

PART 1. PROPERTIES

PART 5. X-RAY AND NEUTRON OPTICS

Subpart 5.1. Introduction and Applications

Subpart 5.2. Refractive and Interference Optics

Subpart 5.3. Reflective Optics

Subpart 5.4. X-Ray Sources

EDITORS' PREFACE

The third edition of the *Handbook of Optics* is designed to pull together the dramatic developments in both the basic and applied aspects of the field while retaining the archival, reference book value of a handbook. This means that it is much more extensive than either the first edition, published in 1978, or the second edition, with Volumes I and II appearing in 1995 and Volumes III and IV in 2001. To cover the greatly expanded field of optics, the *Handbook* now appears in five volumes. Over 100 authors or author teams have contributed to this work.

Volume I is devoted to the fundamentals, components, and instruments that make optics possible. Volume II contains chapters on design, fabrication, testing, sources of light, detection, and a new section devoted to radiometry and photometry. Volume III concerns vision optics only and is printed entirely in color. In Volume IV there are chapters on the optical properties of materials, nonlinear, quantum and molecular optics. Volume V has extensive sections on fiber optics and x ray and neutron optics, along with shorter sections on measurements, modulators, and atmospheric optical properties and turbulence. Several pages of color inserts are provided where appropriate to aid the reader. A purchaser of the print version of any volume of the *Handbook* will be able to download a digital version containing all of the material in that volume in PDF format to one computer (see download instructions on bound-in card). The combined index for all five volumes can be downloaded from www.HandbookofOpticsOnline.com.

It is possible by careful selection of what and how to present that the third edition of the *Handbook* could serve as a text for a comprehensive course in optics. In addition, students who take such a course would have the *Handbook* as a career-long reference.

Topics were selected by the editors so that the *Handbook* could be a desktop (bookshelf) general reference for the parts of optics that had matured enough to warrant archival presentation. New chapters were included on topics that had reached this stage since the second edition, and existing chapters from the second edition were updated where necessary to provide this compendium. In selecting subjects to include, we also had to select which subjects to leave out. The criteria we applied were: (1) was it a specific application of optics rather than a core science or technology and (2) was it a subject in which the role of optics was peripheral to the central issue addressed. Thus, such topics as medical optics, laser surgery, and laser materials processing were not included. While applications of optics are mentioned in the chapters there is no space in the *Handbook* to include separate chapters devoted to all of the myriad uses of optics in today's world. If we had, the third edition would be much longer than it is and much of it would soon be outdated. We designed the third edition of the *Handbook of Optics* so that it concentrates on the principles of optics that make applications possible.

Authors were asked to try to achieve the dual purpose of preparing a chapter that was a worthwhile reference for someone working in the field and that could be used as a starting point to become acquainted with that aspect of optics. They did that and we thank them for the outstanding results seen throughout the *Handbook*. We also thank Mr. Taisuke Soda of McGraw-Hill for his help in putting this complex project together and Mr. Alan Tourtlotte and Ms. Susannah Lehman of the Optical Society of America for logistical help that made this effort possible.

We dedicate the third edition of the *Handbook of Optics* to all of the OSA volunteers who, since OSA's founding in 1916, give their time and energy to promoting the generation, application, archiving, and worldwide dissemination of knowledge in optics and photonics.

PREFACE TO VOLUME II

Volume II of the *Handbook of Optics* is a continuation of Volume I. It starts with optical system design and covers first-order layout, aberration curves, design software, specifications and tolerances, component mounting, stray light control, and thermal compensation techniques. Optical fabrication and testing are discussed next. A new chapter on the use of orthonormal polynomials in optical design and testing has been added. Such a polynomial representing balanced astigmatism is illustrated on the cover. The section on sources includes different types of lasers, laser stabilization, laser theory, and a discussion of ultrashort laser sources. Light-emitting diodes including the new "high-brightness" LEDs are presented. Artificial sources of light for both the laboratory and field are described along with a discussion of light standards calibration. The section on detectors includes high-speed and thermal detectors along with an analysis of signal detection. Imaging using film, detector arrays, and image tubes is discussed. This volume ends with a section on radiometry and photometry. Two new chapters have been added in this area. One is on spectroradiometry and the other is on lighting and applications.

Every effort was made to contact all the authors of chapters in the second edition that would appear in this edition so that they could update their chapters. However, the authors of several chapters could not be located or were not available. Their chapters are reproduced without update. Every effort has been made to ensure that such chapters have been correctly reproduced.

There are many other chapters in this edition of the *Handbook* that could have been included in Volumes I and II. However, page limitations prevented that. For example, in Volume V there is a section on Atmospheric Optics. It consists of three chapters, one on transmission through the atmosphere, another on imaging through atmospheric turbulence, and a third on adaptive optics to overcome some of the deleterious effects of turbulence.

The chapters are generally aimed at the graduate students, though practicing scientists and engineers will find them equally suitable as references on the topics discussed. Each chapter has sufficient references for additional and/or further study.

GLOSSARY AND FUNDAMENTAL CONSTANTS

Introduction

This glossary of the terms used in the *Handbook* represents to a large extent the language of optics. The symbols are representations of numbers, variables, and concepts. Although the basic list was compiled by the author of this section, all the editors have contributed and agreed to this set of symbols and definitions. Every attempt has been made to use the same symbols for the same concepts throughout the entire *Handbook*, although there are exceptions. Some symbols seem to be used for many concepts. The symbol α is a prime example, as it is used for absorptivity, absorption coefficient, coefficient of linear thermal expansion, and more. Although we have tried to limit this kind of redundancy, we have also bowed deeply to custom.

Units

The abbreviations for the most common units are given first. They are consistent with most of the established lists of symbols, such as given by the International Standards Organization ISO[1] and the International Union of Pure and Applied Physics, IUPAP.[2]

Prefixes

Similarly, a list of the numerical prefixes[1] that are most frequently used is given, along with both the common names (where they exist) and the multiples of ten that they represent.

Fundamental Constants

The values of the fundamental constants[3] are listed following the sections on SI units.

Symbols

The most commonly used symbols are then given. Most chapters of the *Handbook* also have a glossary of the terms and symbols specific to them for the convenience of the reader. In the following list, the symbol is given, its meaning is next, and the most customary unit of measure for the quantity is presented in brackets. A bracket with a dash in it indicates that the quantity is unitless. Note that there is a difference between units and dimensions. An angle has units of degrees or radians and a solid angle square degrees or steradians, but both are pure ratios and are dimensionless. The unit symbols as recommended in the SI system are used, but decimal multiples of some of the dimensions are sometimes given. The symbols chosen, with some cited exceptions, are also those of the first two references.

RATIONALE FOR SOME DISPUTED SYMBOLS

The choice of symbols is a personal decision, but commonality improves communication. This section explains why the editors have chosen the preferred symbols for the *Handbook*. We hope that this will encourage more agreement.

Fundamental Constants

It is encouraging that there is almost universal agreement for the symbols for the fundamental constants. We have taken one small exception by adding a subscript B to the k for Boltzmann's constant.

Mathematics

We have chosen i as the imaginary almost arbitrarily. IUPAP lists both i and j, while ISO does not report on these.

Spectral Variables

These include expressions for the wavelength λ, frequency ν, wave number σ, ω for circular or radian frequency, k for circular or radian wave number and dimensionless frequency x. Although some use f for frequency, it can be easily confused with electronic or spatial frequency. Some use $\tilde{\nu}$ for wave number, but, because of typography problems and agreement with ISO and IUPAP, we have chosen σ; it should not be confused with the Stefan-Boltzmann constant. For spatial frequencies we have chosen ξ and η, although f_x and f_y are sometimes used. ISO and IUPAP do not report on these.

Radiometry

Radiometric terms are contentious. The most recent set of recommendations by ISO and IUPAP are L for radiance [$Wcm^{-2}sr^{-1}$], M for radiant emittance or exitance [Wcm^{-2}], E for irradiance or incidance [Wcm^{-2}], and I for intensity [Wsr^{-2}]. The previous terms, W, H, N, and J, respectively, are still in many texts, notably Smith[4] and Lloyd[5] but we have used the revised set, although there are still shortcomings. We have tried to deal with the vexatious term *intensity* by using *specific intensity* when the units are $Wcm^{-2}sr^{-1}$, *field intensity* when they are Wcm^{-2}, and *radiometric intensity* when they are Wsr^{-1}.

There are two sets to terms for these radiometric quantities, which arise in part from the terms for different types of reflection, transmission, absorption, and emission. It has been proposed that the *ion* ending indicate a process, that the *ance* ending indicate a value associated with a particular sample, and that the *ivity* ending indicate a generic value for a "pure" substance. Then one also has reflectance, transmittance, absorptance, and emittance as well as reflectivity, transmissivity, absorptivity, and emissivity. There are now two different uses of the word emissivity. Thus the words *exitance, incidence,* and *sterance* were coined to be used in place of emittance, irradiance, and radiance. It is interesting that ISO uses radiance, exitance, and irradiance whereas IUPAP uses radiance excitance [*sic*], and irradiance. We have chosen to use them both, i.e., emittance, irradiance, and radiance will be followed in square brackets by exitance, incidence, and sterance (or vice versa). Individual authors will use the different endings for transmission, reflection, absorption, and emission as they see fit.

We are still troubled by the use of the symbol E for irradiance, as it is so close in meaning to electric field, but we have maintained that accepted use. The spectral concentrations of these quantities, indicated by a wavelength, wave number, or frequency subscript (e.g., L_λ) represent partial differentiations; a subscript q represents a photon quantity; and a subscript ν indicates a quantity normalized to the response of the eye. Thereby, L_ν is luminance, E_ν illuminance, and M_ν and I_ν luminous emittance and luminous intensity. The symbols we have chosen are consistent with ISO and IUPAP.

The refractive index may be considered a radiometric quantity. It is generally complex and is indicated by $\tilde{n} = n - ik$. The real part is the relative refractive index and k is the extinction coefficient. These are consistent with ISO and IUPAP, but they do not address the complex index or extinction coefficient.

Optical Design

For the most part ISO and IUPAP do not address the symbols that are important in this area.

There were at least 20 different ways to indicate focal ratio; we have chosen FN as symmetrical with NA; we chose f and efl to indicate the effective focal length. Object and image distance, although given many different symbols, were finally called s_o and s_i since s is an almost universal symbol for distance. Field angles are θ and ϕ; angles that measure the slope of a ray to the optical axis are u; u can also be sin u. Wave aberrations are indicated by W_{ijk}, while third-order ray aberrations are indicated by σ_i and more mnemonic symbols.

Electromagnetic Fields

There is no argument about **E** and **H** for the electric and magnetic field strengths, Q for quantity of charge, ρ for volume charge density, σ for surface charge density, etc. There is no guidance from Refs. 1 and 2 on polarization indication. We chose $\perp$ and $\|$ rather than p and s, partly because s is sometimes also used to indicate scattered light.

There are several sets of symbols used for reflection transmission, and (sometimes) absorption, each with good logic. The versions of these quantities dealing with field amplitudes are usually specified with lower case symbols: r, t, and a. The versions dealing with power are alternately given by the uppercase symbols or the corresponding Greek symbols: R and T versus ρ and τ. We have chosen to use the Greek, mainly because these quantities are also closely associated with Kirchhoff's law that is usually stated symbolically as $\alpha = \epsilon$. The law of conservation of energy for light on a surface is also usually written as $\alpha + \rho + \tau = 1$.

Base SI Quantities

length	m	meter
time	s	second
mass	kg	kilogram
electric current	A	ampere
temperature	K	kelvin
amount of substance	mol	mole
luminous intensity	cd	candela

Derived SI Quantities

energy	J	joule
electric charge	C	coulomb
electric potential	V	volt
electric capacitance	F	farad
electric resistance	Ω	ohm
electric conductance	S	siemens
magnetic flux	Wb	weber
inductance	H	henry
pressure	Pa	pascal
magnetic flux density	T	tesla
frequency	Hz	hertz
power	W	watt
force	N	newton
angle	rad	radian
angle	sr	steradian

Prefixes

Symbol	*Name*	*Common name*	*Exponent of ten*
F	exa		18
P	peta		15
T	tera	trillion	12
G	giga	billion	9
M	mega	million	6
k	kilo	thousand	3
h	hecto	hundred	2
da	deca	ten	1
d	deci	tenth	–1

f	femto		–15
a	atto		–18

Constants

c	speed of light vacuo [299792458 ms^{-1}]
c_1	first radiation constant = $2\pi c^2 h = 3.7417749 \times 10^{-16}$ [Wm^2]
c_2	second radiation constant = hc/k = 0.014838769 [mK]
e	elementary charge [$1.60217733 \times 10^{-19}$ C]
g_n	free fall constant [9.80665 ms^{-2}]
h	Planck's constant [$6.6260755 \times 10^{-34}$ Ws]
k_B	Boltzmann constant [1.380658×10^{-23} JK^{-1}]
m_e	mass of the electron [$9.1093897 \times 10^{-31}$ kg]
N_A	Avogadro constant [6.0221367×10^{23} mol^{-1}]
R_∞	Rydberg constant [10973731.534 m^{-1}]
ϵ_o	vacuum permittivity [$\mu_o^{-1} c^{-2}$]
σ	Stefan-Boltzmann constant [5.67051×10^{-8} Wm^{-1} K^{-4}]
μ_o	vacuum permeability [$4\pi \times 10^{-7}$ NA^{-2}]
μ_B	Bohr magneton [$9.2740154 \times 10^{-24}$ JT^{-1}]

General

B	magnetic induction [Wbm^{-2}, kgs^{-1} C^{-1}]
C	capacitance [f, C^2 s^2 m^{-2} kg^{-1}]
C	curvature [m^{-1}]
c	speed of light in vacuo [ms^{-1}]
c_1	first radiation constant [Wm^2]
c_2	second radiation constant [mK]
D	electric displacement [Cm^{-2}]
E	incidance [irradiance] [Wm^{-2}]
e	electronic charge [coulomb]
E_v	illuminance [lux, lmm^{-2}]
E	electrical field strength [Vm^{-1}]
E	transition energy [J]
E_g	band-gap energy [eV]
f	focal length [m]
f_c	Fermi occupation function, conduction band
f_v	Fermi occupation function, valence band

FN	focal ratio (f/number) [—]
g	gain per unit length [m^{-1}]
g_{th}	gain threshold per unit length [m^1]
H	magnetic field strength [Am^{-1}, Cs^{-1} m^{-1}]
h	height [m]
I	irradiance (see also E) [Wm^{-2}]
I	radiant intensity [Wsr^{-1}]
I	nuclear spin quantum number [—]
I	current [A]
i	$\sqrt{-1}$
Im()	imaginary part of
J	current density [Am^{-2}]
j	total angular momentum [kg m^2 s^{-1}]
$J_1()$	Bessel function of the first kind [—]
k	radian wave number $=2\pi/\lambda$ [rad cm^{-1}]
k	wave vector [rad cm^{-1}]
k	extinction coefficient [—]
L	sterance [radiance] [Wm^{-2} sr^{-1}]
L_v	luminance [cdm^{-2}]
L	inductance [h, m^2 kg C^2]
L	laser cavity length
L, M, N	direction cosines [—]
M	angular magnification [—]
M	radiant exitance [radiant emittance] [Wm^{-2}]
m	linear magnification [—]
m	effective mass [kg]
MTF	modulation transfer function [—]
N	photon flux [s^{-1}]
N	carrier (number)density [m^{-3}]
n	real part of the relative refractive index [—]
$\tilde{n}$	complex index of refraction [—]
NA	numerical aperture [—]
OPD	optical path difference [m]
P	macroscopic polarization [C m^{-2}]
Re()	real part of [—]
R	resistance [Ω]
r	position vector [m]
S	Seebeck coefficient [VK^{-1}]
s	spin quantum number [—]
s	path length [m]
S_o	object distance [m]
S_i	image distance [m]
T	temperature [K, C]
t	time [s]
t	thickness [m]
u	slope of ray with the optical axis [rad]
V	Abbe reciprocal dispersion [—]
V	voltage [V, m^2 kgs^{-2} C^{-1}]
x, y, z	rectangular coordinates [m]
Z	atomic number [—]

Greek Symbols

α	absorption coefficient [cm^{-1}]
α	(power) absorptance (absorptivity)

ϵ	diclectric coefficient (constant) [—]
ϵ	emittance (emissivity) [—]
ϵ	eccentricity [—]
ϵ_1	Re (ϵ)
ϵ_2	lm (ϵ)
τ	(power) transmittance (transmissivity) [—]
ν	radiation frequency [Hz]
ω	circular frequency = $2\pi\nu$ [rads^{-1}]
ω	plasma frequency [H_2]
λ	wavelength [μm, nm]
σ	wave number = $1/\lambda$ [cm^{-1}]
σ	Stefan Boltzmann constant [Wm^{-2}K^{-1}]
ρ	reflectance (reflectivity) [—]
θ, ϕ	angular coordinates [rad, °]
ξ, η	rectangular spatial frequencies [m^{-1}, r^{-1}]
ϕ	phase [rad, °]
ϕ	lens power [m^{-2}]
Φ	flux [W]
χ	electric susceptibility tensor [—]
Ω	solid angle [sr]

Other

$\Re$	responsivity
exp (x)	e^x
$\log_a(x)$	log to the base a of x
ln (x)	natural log of x
log (x)	standard log of x: $\log_{10}(x)$
Σ	summation
Π	product
Δ	finite difference
δx	variation in x
dx	total differential
∂x	partial derivative of x
$\delta(x)$	Dirac delta function of x
δ_{ij}	Kronecker delta

TECHNIQUES OF FIRST-ORDER LAYOUT

Warren J. Smith*

Kaiser Electro-Optics, Inc.
Carlsbad, California

1.1 GLOSSARY

A, B	scaling constants
d	distance between components
f	focal length
h	image height
I	invariant
j, k	indices
l	axial intercept distance
M	angular magnification
m	linear, lateral magnification
n	refractive index
P	partial dispersion, projection lens diameter
r	radius
S	source or detector linear dimension
SS	secondary spectrum
s	object distance
s'	image distance
t	temperature
u	ray slope
V	Abbe number
y	height above optical axis
α	radiometer field of view, projector field of view
ϕ	component power ($= 1/f$)

*Deceased.

1.2 FIRST-ORDER LAYOUT

First-order layout is the determination of the arrangement of the components of an optical system in order to satisfy the first-order requirements imposed on the system. The term "first-order" means the paraxial image properties: the size of the image, its orientations, its location, and the illumination or brightness of the image. This also implies apertures, *f*-numbers, fields of view, physical size limitations, and the like. It does not ordinarily include considerations of aberration correction; these are usually third- and higher-order matters, not first-order. However, ordinary chromatic aberration and secondary spectrum are first-order aberrations. Additionally, the first-order layout can have an effect on the Petzval curvature of field, the cost of the optics, the sensitivity to misalignment, and the defocusing effects of temperature changes.

The primary task of first-order layout is to determine the powers and spacings of the system components so that the image is located in the right place and has the right size and orientation. It is not necessary to deal with surface-by-surface ray-tracing here; the concern is with components. "Components" may mean single elements, cemented doublets, or even complex assemblies of many elements. The first-order properties of a component can be described by its Gauss points: the focal points and principal points. For layout purposes, however, the initial work can be done assuming that each component is of zero thickness; then only the component location and its power (or focal length) need be defined.

1.3 RAY-TRACING

The most general way to determine the characteristics of an image is by ray-tracing. As shown in Fig. 1, if an "axial (marginal)" ray is started at the foot (axial intercept) of the object, then an image is located at each place that this ray crosses the axis. The size of the image can be determined by tracing a second, "principal (chief)," ray from the top of the object and passing through the center of the limiting aperture of the system, the "aperture stop;" the intersection height of this ray at the image plane indicates the image size. This size can also be determined from the ratio of the ray slopes of the axial ray at the object and at the image; this yields the magnification $m = u_0/u'_k$; object height times magnification yields the image height.

The ray-tracing equations are

$$y_1 = -l_1 u_1 \tag{1}$$

$$u'_j = u_j - y_j \phi_j \tag{2}$$

$$y_{j+1} = y_j + d_j u'_j \tag{3}$$

$$l'_k = -y_k / u'_k \tag{4}$$

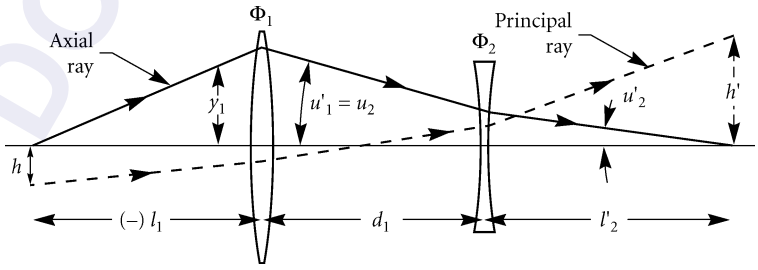

FIGURE 1

where l and l' are the axial intersection distances of the ray before and after refraction by the component, u and u' are the ray slopes before and after refraction, ϕ is the component power ($\phi = 1/f$), y_j is the height at which the ray strikes the jth component, and d_j is the distance from the jth to the $(j + 1)$th component. Equations (2) and (3) are applied sequentially to the components, from object to image.

These equations can be used in two different ways. When the components and spacings are known, the image characteristics can readily be calculated. In the inverse application, the (unknown) powers and spaces can be represented by symbols, and the ray can be traced symbolically through the postulated number of components. The results of this symbolic ray-tracing can be equated to the required characteristics of the system; these equations can then be solved for the unknowns, which are the component powers and spacings.

As an example, given the starting ray data, y_1 and u_1, we get

$$u_1' = u_1 - y_1\phi_1$$

$$y_2 = y_1 + d_1u_1' = y_1 + d_1(u_1 - y_1\phi_1)$$

$$u_2' = u_1' - y_2\phi_2$$

$$= u_1 - y_1\phi_1 - [y_1 + d_1(u_1 - y_1\phi_1)]\phi_2$$

$$y_3 = y_2 + d_2u_2' = \text{etc.}$$

Obviously the equations can become rather complex in very short order. However, because of the linear characteristics of the paraxial ray equations, they can be simplified by setting either y_1 or u_1 equal to one (1.0) without any loss of generality. But the algebra can still be daunting.

1.4 TWO-COMPONENT SYSTEMS

Many systems are either limited to two components or can be separated into two-component segments. There are relatively simple expressions for solving two-component systems.

Although the figures in this chapter show thick lenses with appropriate principal planes, "thin" lenses (whose thickness is zero and whose principal planes are coincident with the two coincident lens surfaces) may be used.

For systems with infinitely distant objects, as shown in Fig. 2, the following equations for the focal length and focus distance are useful:

$$f_{AB} = f_Af_B/(f_A + f_B - d) \tag{5}$$

$$\phi_{AB} = \phi_A + \phi_B - d\phi_A\phi_B \tag{6}$$

$$B = f_{AB}(f_A - d)/f_A \tag{7}$$

$$F = f_{AB}(f_B - d)/f_B \tag{8}$$

$$h' = f_{AB}\tan u_p \tag{9}$$

where f_{AB} is the focal length of the combination, ϕ_{AB} is its power, f_A and f_B are the focal lengths of the components, ϕ_A and ϕ_B are their powers, d is the spacing between the components, B is the "back

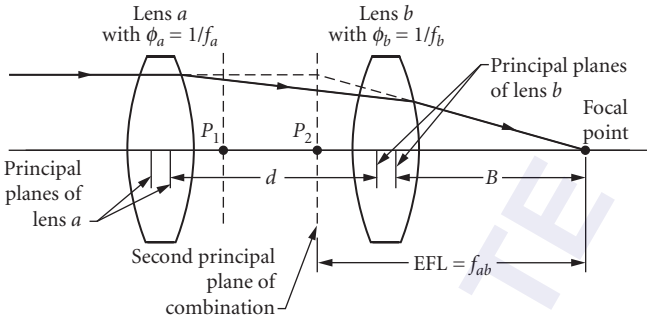

FIGURE 2

focus" distance from the B component, F is the "front focus" distance, u_p is the angle subtended by the object, and h' is the image height.

If f_{AB}, d, and B (or F) are known, the component focal lengths can be found from

$$f_A = df_{AB}/(f_{AB} - B) \tag{10}$$

$$f_B = -dB/(f_{AB} - B - d) \tag{11}$$

These simple expressions are probably the most widely used equations in optical layout work.

If a two-component system operates at *finite* conjugates, as shown in Fig. 3, the following equations can be used to determine the layout. When the required system magnification and the component locations are known, the powers of the components are given by

$$\phi_A = (ms - md - s')/msd \tag{12}$$

$$\phi_B = (d - ms + s')/ds' \tag{13}$$

where $m = h'/h$ is the magnification, s and s' are the object and image distances.

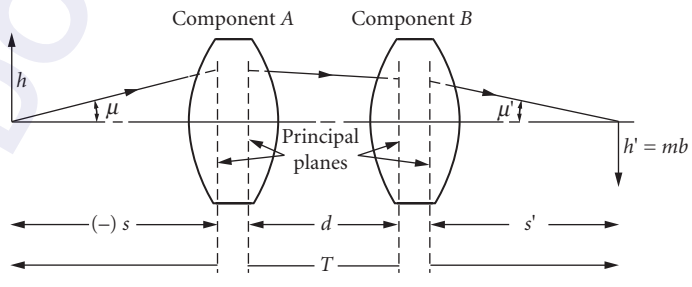

FIGURE 3

In different circumstances, the component powers, the object-to-image distance, and the magnification may be known and the component locations are to be determined. The following quadratic equation [Eq. (14)] in d (the spacing) is solved for d:

$$0 = d^2 - dT + T(f_A + f_B) + (m-1)^2 f_A f_B / m \tag{14}$$

and then

$$s = [(m-1)d + T]/[(m-1) - md\phi_A] \tag{15}$$

$$s' = T + s - d \tag{16}$$

1.5 AFOCAL SYSTEMS

If the system is afocal, then the following relations will apply:

$$\text{MP} = -(f_O/f_E) = (u_E/u_O) = (d_O/d_E) \tag{17}$$

and, if the components are "thin,"

$$L = f_O + f_E \tag{18}$$

$$f_O = -L \cdot \text{MP}/(1 - \text{MP}) \tag{19}$$

$$f_E = L/(1 - \text{MP}) \tag{20}$$

where MP is the angular magnification, f_O and f_E are the objective and eyepiece focal lengths, u_E and u_O are the apparent (image) and real (object) angular fields, d_O and d_E are the entrance and exit pupil diameters, and L is the length of the telescope as indicated in Fig. 4.

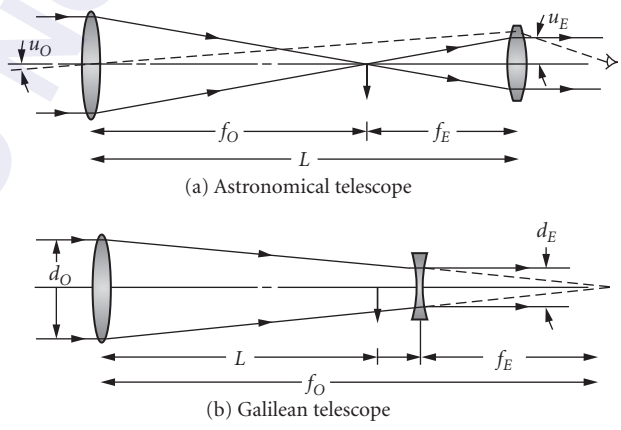

FIGURE 4

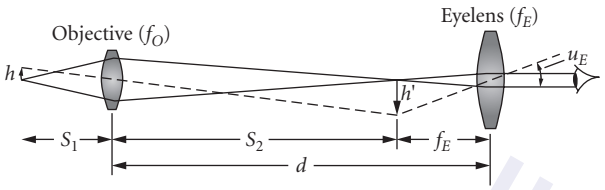

FIGURE 5

1.6 MAGNIFIERS AND MICROSCOPES

The conventional definition of magnifying power for either a magnifier or microscope compares the angular size of the image with the angular size of the object *when the object is viewed from a (conventional) distance of* 10 *inches.* Thus the magnification can be found from

$$\mathrm{MP} = 10''/f \tag{21}$$

for either a simple microscope (i.e., magnifier) or a compound microscope, where f is the focal length of the system. Using the symbols of Fig. 5, we can also write the following for the compound microscope

$$\mathrm{MP} = (f_E + f_O - d)10''/f_E f_O \tag{22}$$

$$\mathrm{MP} = m_O \times m_E$$

$$= (S_2/S_1)(10''/f_E) \tag{23}$$

1.7 AFOCAL ATTACHMENTS

In addition to functioning as a telescope, beam expander, etc., an afocal system can be used to modify the characteristics of another system. It can change the focal length, power, or field of the "prime" system. Figure 6 shows several examples of an afocal device placed (in these examples) before an imaging system. The combination has a focal length equal to the focal length of the prime system multiplied by the angular magnification of the afocal device. Note that in Fig. 6*a* and *b* the same afocal attachment has been reversed to provide two different focal lengths. If the size of the film or detector is kept constant, the angular field is changed by a factor equal to the inverse of the afocal magnification.

1.8 FIELD LENSES

Figure 7 illustrates the function of the field lens in a telescope. It is placed near (but rarely exactly at) an internal image; its power is chosen so that it converges the oblique ray bundle toward the axis sufficiently so that the rays pass through the subsequent component. A field lens is useful to keep the component diameters at reasonable sizes. It acts to relay the pupil image to a more acceptable location.

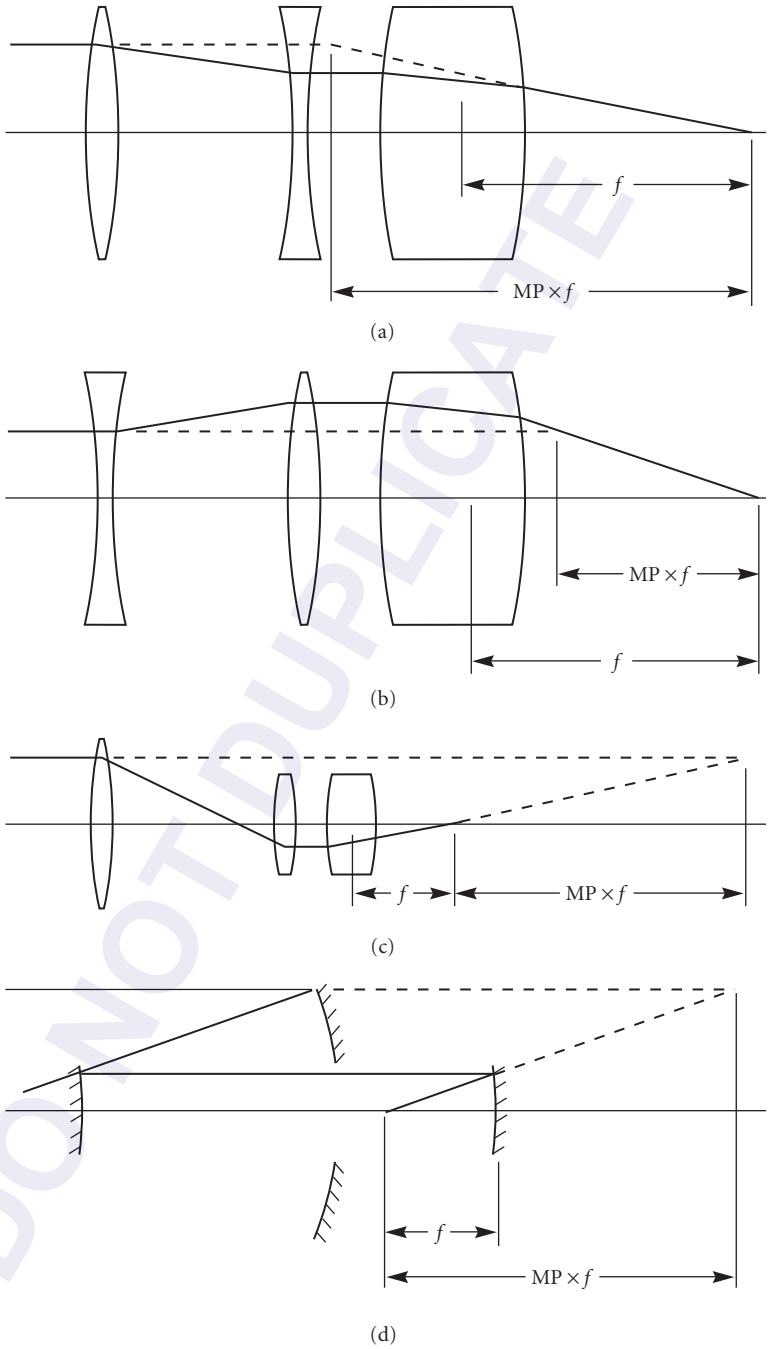

FIGURE 6

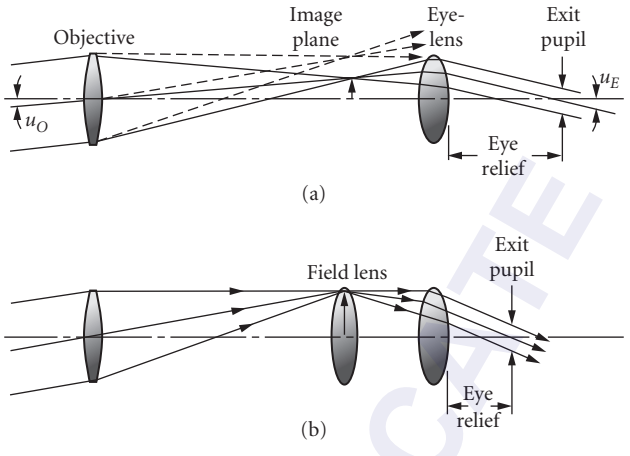

FIGURE 7

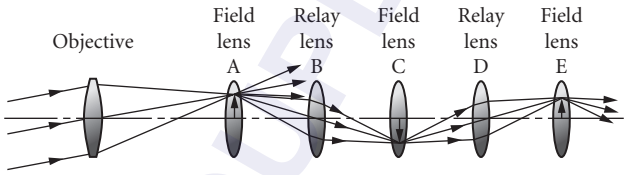

FIGURE 8

The required field lens power is easily determined. In Fig. 7 the most troublesome ray is that from the bottom of the objective aperture; its slope (u) is simply the height that it climbs divided by the distance that it travels. The required slope (u') for the ray after refraction by the field lens is defined by the image height (y), the "eyelens" semidiameter, and the spacing between them. Then Eq. (2) can be solved for the field lens power,

$$\phi = (u - u')/y \tag{24}$$

A periscope is used to carry an image through a long, small-diameter space. As shown in Fig. 8, the elements of a periscope are alternating field lenses and relay lenses. An optimum arrangement occurs when the images at the field lenses and the apertures of the relay lenses are as large as the available space allows. This arrangement has the fewest number of relay stages and the lowest power components. For a space of uniform diameter, both the field lenses and the relay lenses operate at unit magnification.

1.9 CONDENSERS

The projection/illumination condenser and the field lens of a radiation measuring system operate in exactly the same way. The condenser (Fig. 9) forms an image of the light source in the aperture of the projection lens, thereby producing even illumination from a nonuniform source. If the source

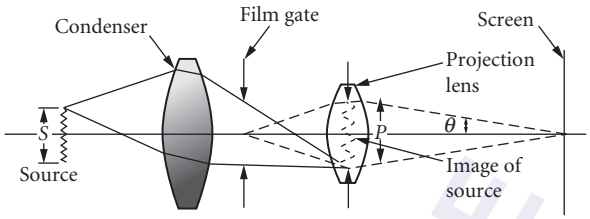

FIGURE 9

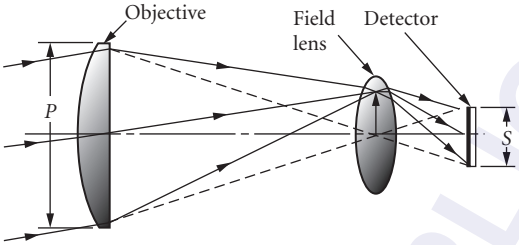

FIGURE 10

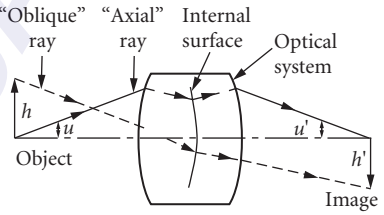

FIGURE 11

image fills the projection lens aperture, this will produce the maximum illumination that the source brightness and the projection lens aperture diameter will allow. This is often called Köhler illumination. In a radiometer type of application (Fig. 10), the field lens images the objective lens aperture on the detector, uniformly illuminating its surface and permitting the use of a smaller detector. Often, the smallest possible source or detector is desired in order to minimize power or maximize signal-to-noise. The smallest possible size is given by

$$S = P\alpha/2n \tag{25}$$

where S is the source or detector size, P is the projection lens or objective aperture diameter, α is the field angle of projection or the radiometer field of view, and n is the index in which the source or detector is immersed. This value for S corresponds to an (impractical) system speed of F/0.5. A source or detector size twice as large is a far more realistic limit, corresponding to a speed of F/1.0.

The *invariant*, $I = n(y_2u_1 - y_1u_2)$, where y_1, u_1, y_2, and u_2 are the ray heights and slopes of two different rays, is an expression which has the same value everywhere in an optical system. If the two rays used are an axial ray and a principal (or chief) ray as shown in Fig. 11, and if the invariant is evaluated at the object and image surfaces, the result is

$$hnu = h'n'u' \tag{26}$$

1.10 ZOOM OR VARIFOCAL SYSTEMS

If the spacing between two components is changed, the effective focal length and the back focus are changed in accord with Eqs. (5) through (9). If the motions of the two components are arranged so that the image location is constant, this is a mechanically compensated zoom lens, so called because

the component motions are usually effected with a mechanical cam. A zoom system may consist of just the two basic components or it may include one or more additional members. Usually the two basic components have opposite-signed powers.

If a component is working at unit magnification, it can be moved in one direction or the other to increase or decrease the magnification. There are pairs of positions where the magnifications are m and $1/m$ and for which the object-to-image distance is the same. This is the basis of what is called a "bang-bang" zoom; this is a simple way to provide two different focal lengths (or powers, or fields of view, or magnifications) for a system.

1.11 ADDITIONAL RAYS

When the system layout has been determined, an "axial" ray at full aperture and a "principal" ray at full field can be traced through the system. Because of the linearity of the paraxial equations, we can determine the ray-trace data (i.e., y and u) of *any* third ray from the data of these two traced rays by

$$y_3 = Ay_1 + By_2 \tag{27}$$

$$u_3 = Au_1 + Bu_2 \tag{28}$$

where A and B are scaling constants which can be determined from

$$A = (y_3u_1 - u_3y_1)/(u_1y_2 - y_1u_2) \tag{29}$$

$$B = (u_3y_2 - y_3u_2)/(u_1y_2 - y_1u_2) \tag{30}$$

where y_1, u_1, y_2, and u_2 are the ray heights and slopes of the axial and principal rays and y_3 and u_3 are the data of the third ray; these data are determined at any component of the system where the specifications for all three rays are known. These equations can, for example, be used to determine the necessary component diameters to pass a bundle of rays which are A times the diameter of the axial bundle at a field angle B times the full-field angle. In Fig. 12, for the dashed rays $A = +0.5$ and -0.5 and $B = 1.0$. Another application of Eqs. (27) through (30) is to locate either a pupil or an aperture stop when the other is known.

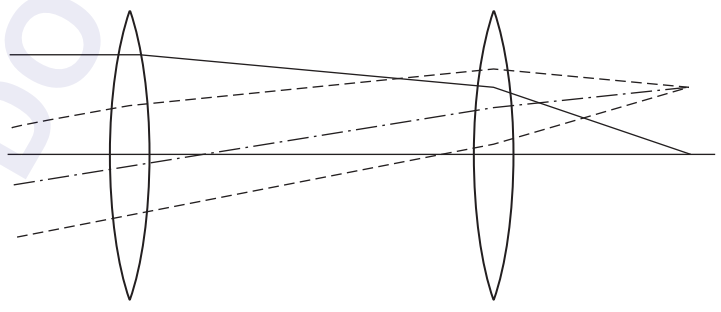

FIGURE 12

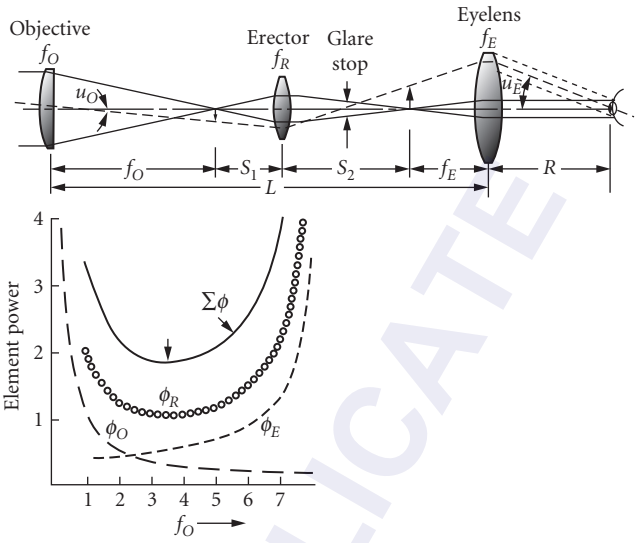

FIGURE 13

1.12 MINIMIZING COMPONENT POWER

The first-order layout may in fact determine the ultimate quality, cost, and manufacturability of the system. The residual aberrations in a system are a function of the component powers, relative apertures, and angular fields. The relationships are complex, but a good choice for a system layout is one which minimizes the sum of the (absolute) component powers, or possibly the sum of the (absolute) $y\phi$ product for all the components.

For example, in Fig. 13 the length, magnification, and the eye relief of the rifle scope are specified. There are five variables: three component powers and two spaces. This is one more variable than is necessary to achieve the specified characteristics. If we take the focal length of the objective component as the free variable, the component powers which satisfy the specifications can be plotted against the objective focal length, as in Fig. 13, and the minimum power arrangement is easily determined.

Minimizing the component powers will strongly tend to minimize the aberrations and also the sensitivity of the system to fabrication errors and misalignments. The *cost* of an optical element will vary with its diameter (or perhaps the square of the diameter) and also with the product of the diameter and the power. Thus, while first-order layout deals only with components, these relationships still apply reasonably well even when applied to components rather than elements. Minimizing the component powers does tend to reduce the cost on these grounds (and also because it tends to reduce the complexity of the components).

1.13 IS IT A REASONABLE LAYOUT?

A simple way to get a feel for the reasonableness of a layout is to make a rough scale drawing showing each component as single element. An element can be drawn as an equiconvex lens with radii which are approximately $r = 2(n-1)f$; for an element with an index of 1.5 the radii equal the focal length. The elements should be drawn to the diameter necessary to pass the (suitably vignetted) off-axis

bundle of rays as well as the axial bundle. The on-axis and off-axis ray bundles should be sketched in. This will very quickly indicate which elements or components are the difficult ones. If the design is being started from scratch (as opposed to simply combining existing components), each component can be drawn as an achromat. The following section describes achromat layout, but for visual-spectrum systems it is often sufficient to assume that the positive (crown) element has twice the power of the achromat and the (negative) flint element has a power equal to that of the achromat. Thus an achromat may be sketched to the simplified, approximate prescription: $r_1 = -r_2 = f/2$ and r_3 = plano.

Any elements which are too fat must then be divided or "split" until they look "reasonable." This yields a reasonable estimate of the required complexity of the system, even before the lens design process is begun.

If more or less standard design types are to be utilized for the components, it is useful to tabulate the focal lengths and diameters to get the (infinity) *f*-number of each component, and also its angular field coverage. The field coverage should be expressed both in terms of the angle that the object and image subtend from the component, and also the angle that the smaller of these two heights subtends as a function of the focal length (rather than as a function of that conjugate distance). This latter angle is useful because the coverage capability of a given design form is usually known in these terms, that is, *h/f,* rather than in finite conjugate terms. With this information at hand, a reasonable decision can be made as to the design type necessary to perform the function required of the component.

1.14 ACHROMATISM

The powers of the elements of an achromat can be determined from

$$\phi_A = \phi_{AB} V_A/(V_A - V_B) \tag{31}$$

$$\phi_B = \phi_{AB} V_B/(V_B - V_A) \tag{32}$$

$$= \phi_{AB} - \phi_A$$

where ϕ_{AB} is the power of the achromatic doublet and V_A is the Abbe *V*-value for the element whose power is ϕ_A, etc. For the visible spectral region $V = (n_d - 1)/(n_F - n_C)$; this can be extended to any spectral region by substituting the indices at middle, short, and long wavelengths for n_d, n_F, and n_C.

If the elements are to be spaced apart, and the back focus is *B,* then the powers and the spacing are given by

$$\phi_A = \phi_{AB} B V_A/(V_A B - V_B/\phi_{AB}) \tag{33}$$

$$\phi_B = -\phi_{AB} V_B/B(V_A B - V_B/\phi_{AB}) \tag{34}$$

$$D = (1 - B\phi_{AB})/\phi_A \tag{35}$$

For a complete system, the transverse *axial chromatic* aberration is the sum of $y^2\phi/Vu'_k$ for all the elements, where *y* is the height of the axial ray at the element and u'_k is the ray slope at the image. The *lateral color* is the sum of $yy_p\phi/Vu'_k$, where y_p is the principal ray height.

The *secondary spectrum* is the sum of $y^2\phi P/Vu'_k$, where *P* is the partial dispersion, $P = (n_d - n_c)/(n_F - n_c)$. Summed over two elements, this leads to an expression for the longitudinal secondary spectrum of an achromatic doublet

$$\text{SS} = f(P_B - P_A)/(V_A - V_B)$$

$$= -f(\Delta P/\Delta V) \tag{36}$$

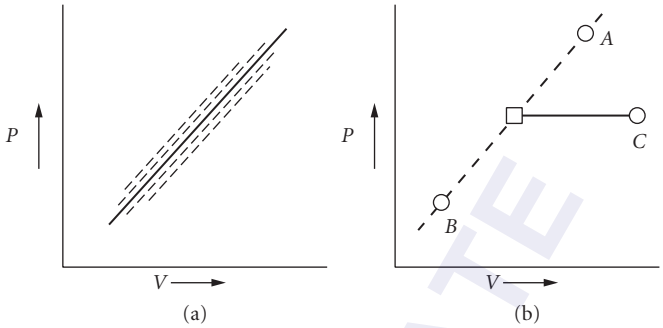

FIGURE 14

This indicates that in order to eliminate secondary spectrum for a doublet, two glasses with identical partial dispersions [so that $(P_A - P_B)$ is zero] are required. A large difference in V-value is desired so that $(V_A - V_B)$ in the denominator of Eqs. (31) and (32) will produce reasonably low element powers. As indicated in the schematic and simplified plot of P versus V in Fig. 14*a*, most glasses fall into a nearly linear array, and $(\Delta P/\Delta V)$ is nearly a constant for the vast majority of glasses. The few glasses which are away from the "normal" line can be used for apochromats, but the ΔV for glass pairs with a small ΔP tends to be quite small. In order to get an exact match for the partial dispersions so that ΔP is equal to zero, two glasses can be combined to simulate a third, as indicated in Fig. 14*b*. For a unit power ($\phi = 1$) apochromatic triplet, the element powers can be found from

$$X = [V_A(P_B - P_C) + V_B(P_C - P_A)]/(P_B - P_A) \tag{37}$$

$$\phi_C = V_C/(V_C - X) \tag{38}$$

$$\phi_B = (1-\phi_C)(P_C - P_A)V_B/[V_B(P_C - P_A) + V_A(P_B - P_C)] \tag{39}$$

$$\phi_A = 1 - \phi_B - \phi_C \tag{40}$$

1.15 ATHERMALIZATION

When the temperature of a lens element is changed, two factors affect its focus or focal length. As the temperature rises, all dimensions of the element are increased; this, by itself, would lengthen the focal length. However, the index of refraction of the lens material also changes with temperature. For many glasses the index rises with temperature; this effect tends to shorten the focal length.

The thermal change in the power of a thin element is given by

$$d\phi/dt = -\phi[a - (dn/dt)/(n-1)] \tag{41}$$

where dn/dt is the differential of index with temperature and a is the thermal expansion coefficient of the lens material. Then for a thin doublet

$$d\phi/dt = \phi_A T_A + \phi_B T_B \tag{42}$$

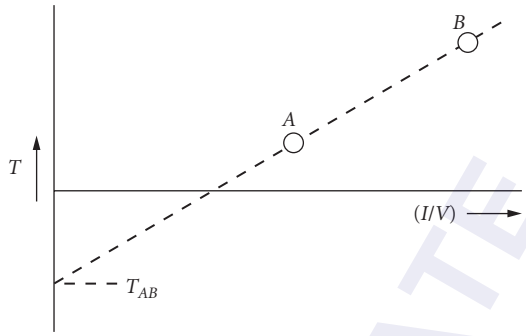

FIGURE 15

where

$$T = [-a + (dn/dt)/(n-1)] \tag{43}$$

and ϕ is the doublet power.

For an athermalized doublet (or one with some desired $d\phi/dt$) the element powers are given by

$$\phi_A = [(d\phi/dt) - \phi T_B]/(T_A - T_B) \tag{44}$$

$$\phi_B = \phi - \phi_A \tag{45}$$

To get an athermalized *achromatic* doublet, a plot of T against $(1/V)$ for all the glasses/materials under consideration is made. A line drawn between two glass points is extended to intersect the T axis as indicated in Fig. 15. Then the value of the $d\phi/dt$ for the achromatic doublet is equal to the doublet power times the value of T at which the line intersects the T axis. A pair of glasses with a large V-value difference and a small or zero T axis intersection is desirable.

An athermal achromatic triplet can be made with three glasses as follows:

$$\phi_A = \phi V_A (T_B V_B - T_C V_C)/D \tag{46}$$

$$\phi_B = \phi V_B (T_C V_C - T_A V_A)/D \tag{47}$$

$$\phi_C = \phi V_C (T_A V_A - T_B V_B)/D \tag{48}$$

$$D = V_A (T_B V_B - T_C V_C) + V_B (T_C V_C - T_A V_A) + V_C (T_A V_A - T_B V_B) \tag{49}$$

2.2 INTRODUCTION

Many optical designers use aberration curves to summarize the state of correction of an optical system, primarily because these curves give a designer important details about the relative contributions of individual aberrations to lens performance. Because a certain design technique may affect only one particular aberration type, these curves are more helpful to the lens designer than a single-value merit function. When a design is finished, the aberration curves serve as a summary of the lens performance and a record for future efforts. For applications such as photography, they are most useful because they provide a quick estimate of the effective blur circle diameter.

The aberration curves can be divided into two types: those that are expressed in terms of ray errors and those in terms of the optical path difference (OPD). OPD plots are usually plotted against the relative ray height in the entrance pupil. Ray errors can be displayed in a number of ways. Either the transverse or longitudinal error of a particular ray relative to the chief ray can be plotted as a function of the ray height in the entrance pupil. Depending upon the amount and type of aberration present, it is sometimes more appropriate to plot the longitudinal aberration as a function of field angle.

For example, astigmatism or field curvature is more easily estimated from field plots, described below. Frequently, the curves are also plotted for several wavelengths to characterize chromatic performance. Because ray error plots are the most commonly used format, this entry will concentrate on them.

2.3 TRANSVERSE RAY PLOTS

These curves can take several different forms, depending on the particular application of the optical system. The most common form is the transverse ray aberration curve. It is also called lateral aberration, or ray intercept curve (also referred to by the misleading term "rim ray plots"). These plots are generated by tracing fans of rays from a specific object point for finite object distances (or a specific field angle for an object at infinity) to a linear array of points across the entrance pupil of the lens. The curves are plots of the ray error at an evaluation plane measured from the chief ray as a function of the relative ray height in the entrance pupil (Fig. 1). For afocal systems, one generally plots angular aberrations, the differences between the tangents of exiting rays and their chief ray in image space.

If the evaluation plane is in the image of a perfect image, there would be no ray error and the curve would be a straight line coincident with the abscissa of the plot. If the curve were plotted for a different evaluation plane parallel to the image plane, the curve would remain a straight line but it would be rotated about the origin. Usually the aberration is plotted along the vertical axis, although some designers plot it along the horizontal axis.

The curves in Fig. 1 indicate a lens with substantial underconnected spherical aberration as evidenced by the characteristic S-shaped curve. Since a change of the evaluation plane serves only to rotate the curve about the origin, a quick estimate of the aberrations of a lens can be made by reading the scale of the ray error axis (y axis) and mentally rotating the plot. For example, the blur spot can be estimated from the extent of a band that would enclose the curve *a* in Fig. 1, but a similar estimate could be made from the curves *b* or *c,* also.

The simplest form of chromatic aberration is axial color. It is shown in Fig. 2 in the presence of spherical aberration. Axial color is the variation of paraxial focus with wavelength and is seen as a difference in slope of the aberration curves at the origin as a function of wavelength. If the slopes of the curves at the origin for the end wavelengths are different, primary axial color is present. If primary axial color is corrected, then the curves for the end wavelengths will have the same slope at the origin. But if that slope differs from the slope of the curve for the center wavelength, then secondary axial color is present.

A more complex chromatic aberration occurs when the aberrations themselves vary with wavelength. Spherochromatism, the change of spherical aberration with wavelength, manifests itself as a difference in the shapes of the curves for different colors. Another curve that provides a measure of lateral color, an off-axis chromatic aberration, is described below.

For a point on the axis of the optical system, all ray fans lie in the meridional plane and only one plot is needed to evaluate the system. For off-axis object points, a second plot is added to evaluate a fan of skew rays traced in a sagittal plane. Because a skew ray fan is symmetrical across the meridional

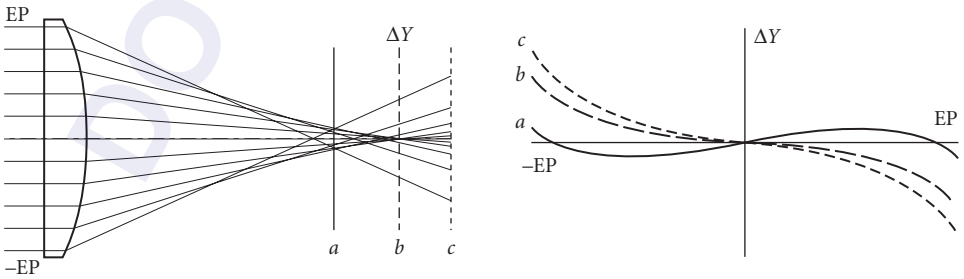

FIGURE 1 (*Left*) Rays exiting a lens are intercepted at three evaluation planes. (*Right*) Ray intercept curves plotted for the evaluation planes: (*a*) at the point of minimum ray error (circle of least confusion); (*b*) at the paraxial image plane; and (*c*) outside the paraxial image plane. (See also color insert.)

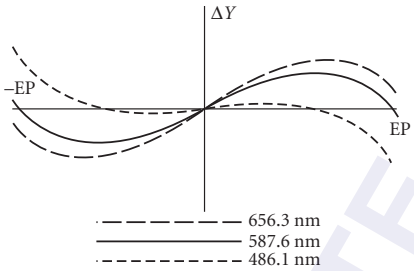

FIGURE 2 Meridional ray intercept curves of a lens with spherical aberration plotted for three colors. (See also color insert.)

plane, only one side of the curve is usually plotted. For all curves the plots are departures from the chief ray location in the evaluation plane (Fig. 3). (In the case of the on-axis point, the chief ray is coincident with the optical axis.) For systems of small-field coverage only two or three object points need to be analyzed, but for wide-angle systems, four or more field points may be necessary.

What can be determined most easily from a comparison between the meridional and sagittal fans is the amount of astigmatism in the image for that field point. When astigmatism is present, the image planes for the tangential and sagittal fans are located at different distances along the chief ray. This is manifested in the ray intercept curves by different slopes at the origin for the tangential and sagittal curves. In Fig. 3 the slopes at the origins of the two curves are different at both 70 percent and full field, indicating astigmatism at both field points. The fact that the difference in the slopes of these two curves has changed sign between the two field points indicates that at some field angle between 70 percent and full field, the slopes are equal and there is no astigmatism there. In addition, the variation of slopes for each curve as a function of field angle is evidence of field curvature.

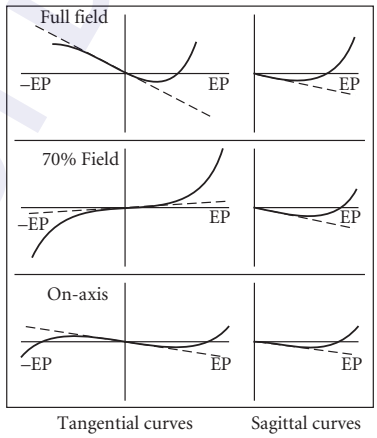

FIGURE 3 Evaluation of a lens on-axis and at two off-axis points. The reduction of the length of the curve with higher field indicates that the lens is vignetting these angles. The differences in slopes (dashed lines) at the origin between the meridional and skew curves indicate that the lens has astigmatism at these field angles. The variation in the slopes with field indicates the presence of field curvature. (See also color insert.)

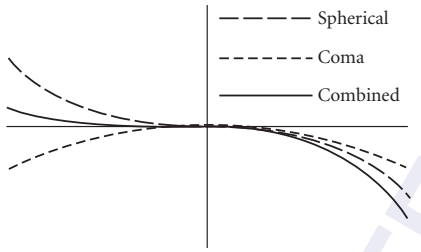

FIGURE 4 Ray intercept curve showing coma combined with spherical aberration. (See also color insert.)

The off-axis aberration of pure primary coma would be evident on these plots as a U-shaped curves for the meridional fan and sagittal fans, the tangential curve being three times larger than the sagittal curve. The "U" will be either upright or upside down depending on the sign of the coma. In almost all cases coma is combined with spherical to produce an S-shaped curve that elongates one of the arms of the "S" and shortens the other (Fig. 4).

The amount of vignetting can be determined from the ray intercept curves also. When it is present, the meridional curves get progressively shorter as the field angle is increased (Fig. 3), since rays at the edges of the entrance pupil are not transmitted. Taken from another perspective, ray intercept curves can also provide the designer with an estimate of how far a system must be stopped down to provide a required degree of correction.

2.4 FIELD PLOTS

The ray intercept curves provide evaluation for a limited number of object points—usually a point on the optical axis and several field points. The field plots present information on certain aberrations across the entire field. In these plots, the independent variable is usually the field angle and is plotted vertically and the aberration is plotted horizontally. The three field plots most often used are: distortion, field curvature, and lateral color. The first of these shows percentage distortion as a function of field angle (Fig. 5).

The second type of plot, field curvature, displays the tangential and sagittal foci as a function of object point or field angle (Fig. 6*a*). In some plots the Petzval surface, the surface to which the image would

FIGURE 5 Field curve: distortion plot. The percentage distortion is plotted as a function of field angle. Note that the axis of the dependent variable is the horizontal axis. (See also color insert.)

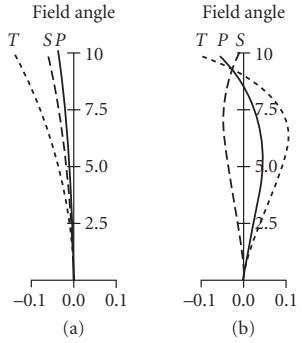

FIGURE 6 Field curve: field curvature plot. The locations of the tangential *T* and sagittal *S* foci are plotted for a full range of field angles. The Petzval surface *P* is also plotted. The tangential surface is always three times farther from the Petzval surface than from the sagittal surface: (*a*) an uncorrected system and (*b*) a corrected system. (See also color insert.)

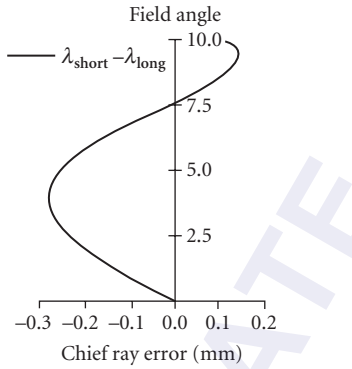

FIGURE 7 Field curve: lateral color plot. A plot of the transverse ray error between red and blue chief ray heights in the image plane for a full range of field angles. Here the distance along the horizontal axis is the color error in the image plane. (See also color insert.)

collapse if there were no astigmatism, is also plotted. This plot shows the amount of curvature in the image plane and amount of astigmatism over the entire field. In cases of corrected field curvature (Fig. 6*b*), this plot provides an estimate of the residual astigmatism between the axis and the corrected zone and an estimate of the maximum field angle at which the image possesses reasonable correction.

The last of the field curves provides information on color error as a function of field angle (Fig. 7). Lateral color, the variation of magnification with wavelength, is plotted as the difference between the chief ray heights at the red and blue wavelengths as a function of field angle. This provides the designer with an estimate of the amount of color separation in the image at various points in the field. In the transverse ray error curves, lateral color is seen as a vertical displacement of the end wavelength curves from the central wavelength curve at the origin.

Although there are other plots that can describe aberrations of optical systems (e.g., plot of longitudinal error as a function of entrance pupil height), the ones described here represent the ensemble that is used in most ray evaluation presentations.

2.5 ADDITIONAL CONSIDERATIONS

In many ray intercept curves the independent variable is the relative entrance pupil coordinate of the ray. However, for systems with high NA or large field of view, where the principal surface cannot be approximated by a plane, it is better to plot the difference between the tangent of the convergence angle of the chosen ray and the tangent of the convergence angle of the chief ray. This is because the curve for a corrected image will remain a straight line in any evaluation plane.[1] When plotted this way, the curves are called H-tan U curves.

Shifting the stop of an optical system has no effect on the on-axis curves. However, it causes the origin of the meridional curves of off-axis points to be shifted along the curve. In Fig. 8, the off-axis meridional curves are plotted for three stop positions of a double Gauss lens. The center curve (Fig. 8*b*) is plotted for a symmetrically located stop; the outer curves are plots when the stop is located at lens surfaces before and after the central stop.

It is usually sufficient to make a plot of the aberrations in the meridional and sagittal sections of the beam. The meridional section, defined for an optical system with rotational symmetry, is any plane containing the optical axis. It is sometimes called the tangential section. The sagittal section is a plane perpendicular to the meridional plane containing the chief ray. There are some forms of higher-order

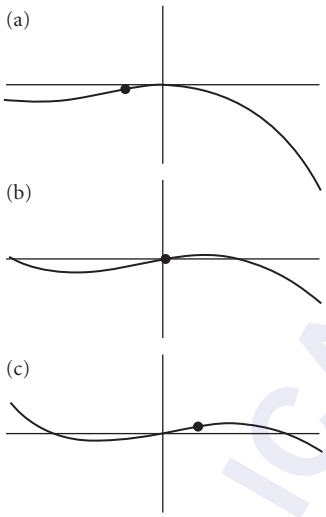

FIGURE 8 The effect of stop shifting on the meridional ray intercept curves of a double Gauss lens. (*a*) Stop located in front of the normal centrally located stop. (*b*) Stop at the normal stop position. (*c*) Stop behind the normal stop position. The dot locates the point on the curve where the origin is located for case (*b*). (See also color insert.)

coma that do not show in these sections.[2] In those cases where this aberration is suspected to be a problem, it may be helpful to look at a spot diagram generated from rays in all sections of the bundle.

For a rotationally symmetric system, only objects in a meridional plane need to be analyzed. Also for such systems, only meridional ray errors are possible for purely meridional rays. To observe certain coma types, it is a good idea to plot both the meridional and sagittal ray errors for sagittal rays. It is possible for the meridional section to show no coma and have it show only in the meridional error component of the sagittal fan,[2] but this aberration is normally small.

In addition to plots of the ray error in an evaluation plane, another aberration plot is one that expresses wavefront aberrations as an optical path difference from a spherical wavefront centered about the image point. These OPD plots are particularly useful for applications where the lens must be close to diffraction-limited.

2.6 SUMMARY

Aberration curves provide experienced designers with the information needed to enable them to correct different types of aberrations. Chromatic effects are much more easily classified from aberration curves also. In comparison to spot diagrams and modulation transfer function curves, the types of aberrations can be more easily seen and quantified. In the case of diffraction-limited systems, modulation transfer functions may provide better estimates of system performance.

3.1 GLOSSARY

a	axial ray
b	chief ray
c	curvature
d, e, f, g	aspheric coefficients
efl	effective focal length
FN	focal ratio
$f( )$	function
h	ray height
m	linear, lateral magnification
n	refractive index
PIV	paraxial (Lagrange) invariant
r	entrance pupil radius
t	thickness
u	ray slope
y	coordinate
z	coordinate
α	tilt about x (Euler angles)
β	tilt about y (Euler angles)
γ	tilt about z (Euler angles)
ϵ	displacement of a ray from the chief ray
μ	Buchdahl coefficients
κ	conic constant
ρ	radial coordinate
σ_1	spherical aberration

σ_2 coma
σ_3 astigmatism
σ_4 Petzval blur
σ_5 distortion

3.2 INTRODUCTION

The primary function of optical design software is to produce a mathematical description, or *prescription,* describing the shapes, locations, materials, etc., of an optical system that satisfies a given set of specifications. A typical optical design program contains three principal sections: *data entry, evaluation,* and *optimization*. The optical design programs considered here are to be distinguished from *ray-trace* programs, which are mainly concerned with evaluation, and *CAD* programs, which are mainly concerned with drawings. The essence of an optical design program is its optimization section, which takes a starting design and produces a new design that minimizes an *error function* that characterizes the system performance.

The first practical computer software for optical design was developed in the 1950s and 1960s.[1–4] Several commercially available programs were introduced during the 1970s, and development of these programs has continued through the 1980s to the present time. Although decades have passed since the introduction of optical design software, developments continue in optimization algorithms, evaluation methods, and user interfaces.

This chapter attempts to describe a typical optical design program. It is intended for readers that have a general background in optics, but who are not familiar with the capabilities of optical design software. We present a brief description of some of the most important mathematical concepts, but make no attempt to give a detailed development. We hope that this approach will give readers enough understanding to know whether an optical design program will be a useful tool for their own work.

Of course, many different programs are available, each with its own advantages and disadvantages. Our purpose is not to review or explain specific programs, but to concentrate on the basic capabilities. Some programs work better than others, but we make no quality judgment. In fact, we avoid reference, either explicit or implicit, to any particular program. The features and benefits of particular optical design programs are more than adequately described by software vendors, who are listed in optical industry buyer's guides.[5]

Figure 1 is a flowchart of a typical optical design project. Usually, the designer not only must enter the starting design and initial optimization data, but also must continually monitor the progress of the computer, modifying either the lens data or the optimization data as the design progresses to achieve the best solution. Even when the performance requirements are tightly specified, it is often necessary to change the error function during the design process. This occurs when the error function does not correlate with the desired performance sufficiently well, either because it is ill-conceived, or because the designer has purposefully chosen a simple error function to achieve improved speed.

The fact that there are alternate choices of action to be taken when the design is not good enough has led to two schools of thought concerning the design of an optical design program. The first school tries to make the interface between the designer and the program as smooth as possible, emphasizing the interactive side of the process. The second school tries to make the error function comprehensive, and the iteration procedure powerful, minimizing the need for the designer to intervene.

3.3 LENS ENTRY

In early lens design programs, lens entry was a "phase" in which the lens data for a starting design was read into the computer from a deck of cards. At that time, the numerical aspects of optical design on a computer were so amazing that scant attention was paid to the lens entry process. However, as the use of optical design software became more widespread, it was found that a great deal of a designer's time was spent punching cards and submitting new jobs, often to correct past mistakes. Many times, it turned out that the hardest part of a design job was preparing a "correct" lens deck!

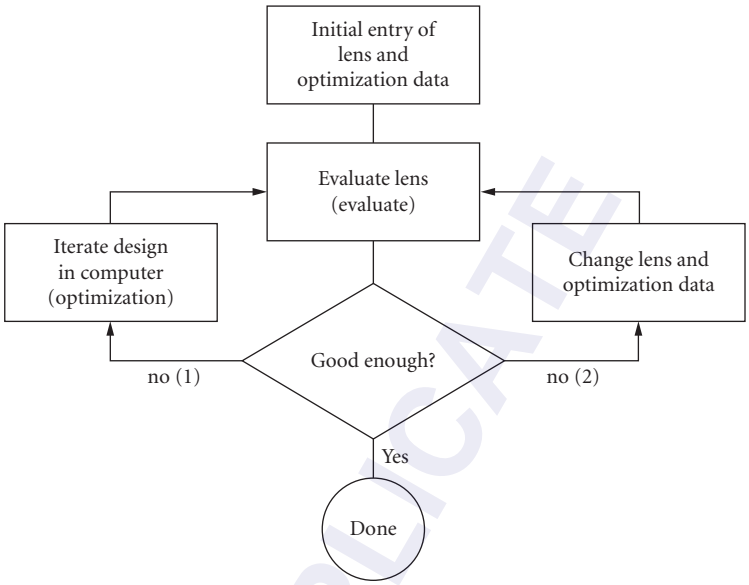

FIGURE 1 Flowchart for the lens design process. The action taken when a design is not satisfactory depends on how bad it is. The designer (or a design program) may change the lens data, or redefine the targets to ones that can be achieved.

Over the years, optical design programs have been expanded to improve the lens entry process, changing the function of this part of the program from simple lens entry to what might be called lens database management. A typical contemporary program provides on-line access to a library of hundreds of lenses, interactive editing, automatic lens drawings, and many features designed to simplify this aspect of optical design.

The lens database contains all items needed to describe the optical system under study, including not only the physical data needed to construct the system (curvatures, thicknesses, etc.), but also data that describe the conditions of use (object and image location, field of view, etc.). Some programs also incorporate optimization data in the lens database, while others provide separate routines for handling such data. In any case, the lens database is often the largest part of an optical design program.

The management of lens data in an optical design program is complicated by two factors. One is that there is a tremendous range of complexity in the types of systems that can be accommodated, so there are many different data items. The other is that the data are often described indirectly. A surface curvature may be specified, for example, by the required slope of a ray that emerges from the surface, rather than the actual curvature itself. Such a specification is called a *solve*, and is based on the fact that paraxial ray tracing is incorporated in the lens entry portion of most optical design programs.

It might seem curious that paraxial ray tracing is still used in contemporary optical design programs that can trace *exact* rays in microseconds. (The term *exact* ray is used in this chapter to mean a real skew ray. Meridional rays are treated as a special case of skew rays in contemporary software; there is not sufficient computational advantage to warrant a separate ray trace for them.) In fact, paraxial rays have some important properties that account for their incorporation in the lens database.

First, paraxial rays provide a linear system model that leads to analysis of optical systems in terms of simple bilinear transforms. Second, paraxial ray tracing does not fail. Exact rays can miss surfaces or undergo total internal reflection. Finally, paraxial rays determine the ideal performance of a lens. In a well-corrected lens, the aberrations are balanced so that the exact rays come to the image points defined by the paraxial rays, not the other way around.

Two basic types of data are used to describe optical systems. The first are the *general* data that are used to describe the system as a whole, and the other are the *surface* data that describe the individual surfaces and their locations. Usually, an optical system is described as an ordered set of surfaces,

beginning with an *object* surface and ending with an *image* surface (where there may or may not be an actual image). It is assumed that the designer knows the order in which rays strike the various surfaces. Systems for which this is not the case are said to contain *nonsequential* surfaces, which are discussed later.

General System Data

The general data used to describe a system include the aperture and field of view, the wavelengths at which the system is to be evaluated, and perhaps other data that specify evaluation modes, vignetting conditions, etc.

Aperture and Field of View The aperture and field of view of a system determine its conditions of use. The aperture is specified by the *axial ray*, which emerges from the vertex of the object surface and passes through the edge of the entrance pupil. The field of view is specified by the *chief ray*, which emerges from the edge of the object and passes through the center of the entrance pupil.

There are various common ways to provide data for the axial and chief rays. If the object is at an infinite distance, the entrance pupil radius and semifield angle form a convenient way to specify the axial and chief rays. For finite conjugates, the numerical aperture in object space and the object height are usually more convenient.

Some programs permit the specification of paraxial ray data by image-space quantities such as the *f*-number and the image height, but such a specification is less desirable from a computational point of view because it requires an iterative process to determine initial ray-aiming data.

Wavelengths It is necessary to specify the wavelengths to be used to evaluate polychromatic systems. Three wavelengths are needed to enable the calculation of primary and secondary chromatic aberrations. More than three wavelengths are required to provide an accurate evaluation of a typical system, and many programs provide additional wavelengths for this reason. There has been little standardization of wavelength specification. Some programs assume that the first wavelength is the central wavelength, while others assume that it is one of the extreme wavelengths; some require wavelengths in micrometers, while others in nanometers.

Other General Data Several other items of general data are needed to furnish a complete lens description, but there is little consistency between programs on how these items are treated, or even what they are. The only one that warrants mention here is the aperture stop. The *aperture stop* is usually defined to be the surface whose aperture limits the angle of the axial ray. Once the aperture stop surface is given, the positions of the paraxial pupils are determined by the imaging properties of the system. Since the aperture and field of view are determined formally by the paraxial pupils, the apertures are not associated with the exact ray behavior.

The "vignetting factor" is used to account for the differences between paraxial and exact off-axis ray heights at apertures. In particular, the vignetting factor provides, in terms of fractional (paraxial) coordinates, the data for an exact ray that grazes the apertures of a system. Typically, there is an upper, lower, and skew vignetting factor. The details of how such factors are defined and handled are program dependent.

Surface Data

Surface Location There are two basic ways to specify the location of surfaces that make up a lens. One is to specify the position of a surface relative to the immediately preceding surface. The other is to specify its position relative to some fixed surface (for example, the first surface). The two ways lead to what are called *local* and *global* coordinates, respectively. For ordinary lenses consisting of a series of rotationally symmetric surfaces centered on an optical axis, local coordinates are more convenient, but for systems that include reflectors, tilted, and/or decentered surfaces, etc., global

coordinates are simpler. Internally, optical design programs convert global surface data to local coordinates for speed in ray tracing.

Most optical design programs use a standard coordinate system and standard sign conventions, although there are exceptions.[6] Each surface defines a local right-handed coordinate system in which the z axis is the symmetry axis and the yz plane is the meridional plane. The local coordinate system is used to describe the surface under consideration and also the origin of the next coordinate system. Tilted elements are described by an Euler-angle system in which α is a tilt around the x axis, β is a tilt around the y axis, and γ is a tilt around the z axis. Since tilting and decentering operations are not commutative; some data item must be provided to indicate which comes first.

Surface Profile Of the various surfaces used in optical systems, the most common by far is the rotationally symmetric surface, which can be written as[7]

$$z = \frac{cr^2}{1+\sqrt{1-c^2(\kappa+1)r^2}} + dr^4 + er^6 + fr^8 + gr^{10}$$

$$r = \sqrt{x^2 + y^2}$$

c is the curvature of the surface; κ is the conic constant; and d, e, f, and g are aspheric constants. The use of the above equation is almost universal in optical design programs. The description of conic surfaces in terms of a conic constant κ instead of the eccentricity e used in the standard mathematical literature allows spherical surfaces to be specified as those with no conic constant. (The conic constant is minus the square of the eccentricity.)

Although aspheric surfaces include all surfaces that are not spherical, from a design standpoint there is a demarcation between "conic" aspheres and "polynomial" aspheres described using the coefficients d, e, f, and g. Rays can be traced analytically through the former, while the latter require numerical iterative methods.

Many optical design programs can handle surface profiles that are more complicated than the above, including cylinders, torics, splines, and even general aspheres of the form $z = f(x, y)$, where $f(x, y)$ is an arbitrary polynomial. The general operation of an optical design program, however, can be understood by considering only the rotationally symmetric surfaces described here.

As mentioned above, the importance of paraxial rays in optical system design has led to the indirect specification of lens data, using *solves*, as they are called, which permit a designer to incorporate the basic paraxial data describing a lens with the lens itself, rather than having to compute and optimize the paraxial performance of a lens as a separate task. Considering the jth surface of an optical system, let

y_j = ray height on surface
u_j = ray slope on image side
c_j = curvature of surface
n_j = refractive index on image side
t_j = thickness on image side

The paraxial ray trace equations can then be written as[8]

$$y_j = y_{j-1} + t_{j-1}u_{j-1}$$

$$n_j u_j = n_{j-1}u_{j-1} - y_j c_j (n_j - n_{j-1})$$

These equations can be inverted to give the curvatures and thicknesses in terms of the ray data. We have

$$c_j = \frac{n_{j-1}u_{j-1} - n_j u_j}{y_j(n_j - n_{j-1})}$$

$$t_j = \frac{y_{j+1} - y_j}{u_j}$$

The specification of curvatures and thicknesses by solves is considered to be on an equal basis with the direct specification of these items. The terminology used to specify solves is that the solves used to determine thickness are called *height solves,* and the solves used to determine curvature are called *angle solves.* Often, an axial ray height solve on the last surface is used to automatically locate the paraxial image plane, a chief ray height solve on the same surface to locate the exit pupil, and an axial ray angle solve is used to maintain a given focal length (if the entrance pupil radius is fixed). In some programs, additional types of solves are allowed, such as center of curvature solves, or aperture solves.

Of course, specifying lens data in terms of paraxial ray data means that whenever any lens data is changed, two paraxial rays must be traced through the system to resolve any following data that are determined by a solve. In an optical design program, this function is performed by a *lens setup* routine, which must be efficiently coded, since it is executed thousands of times in even a small design project.

Other functions of the lens setup routine are to precalculate values that are needed for repetitive calculations, such as refractive indices, rotation and translation matrices, etc. Many programs have the capability of specifying certain data items to be equal to (±) the value of the corresponding item on a previous surface. These are called *pickups,* and are needed for optimization of systems containing mirrors, as well as maintaining special geometrical relationships. Programs that lack pickups usually have an alternate means for maintaining the required linking between data items. Like solves, pickups are resolved by the lens setup routine, although they do not use paraxial data.

Other Surface Data *A* variety of other data is required to specify surfaces. Most important are apertures, discussed below, and refractive indices. Refractive indices are usually given by specifying the name of a catalog glass. In the lens setup routine, the actual refractive indices are calculated using an index interpolation formula and coefficient supplied by the glass manufacturer, together with the design wavelengths stored with the lens data. Other surface-related items include phase data for diffractive surfaces, gradient-index data, holographic construction data, and coatings.

Apertures have a somewhat obscure status in many optical design programs. Although apertures have a major role to play in determining the performance of a typical system, they do not usually appear directly in optimization functions. Instead, apertures are usually controlled in optimization by targets on the heights of rays that define their edges. If an aperture is specified directly, it will block rays that pass outside of it and cause typical optimization procedures to become unstable. Accordingly, some programs ignore apertures during optimization. Other programs allow the apertures to be determined by a set of exact "reference rays" that graze their extremities.

Nonsequential Surfaces In some optical systems, it is not possible to specify the order in which a ray will intersect the surfaces as it progresses through the system. The most common examples of such systems are prisms such as the corner-cube reflector, where the ordering of surfaces depends on the entering ray coordinates. Other examples of nonsequential surfaces include light pipes and a variety of nonimaging concentrators. Nonsequential surfaces can be accommodated by many optical design programs, but for the most part they are not "designed" using the program, but rather are included as a subsystem used in conjunction with another part of the system that is the actual

system being designed. Data specification of nonsequential surfaces is more complicated than ordinary systems, and ray tracing is much slower, since several surfaces must be investigated to see which surface is the one actually traversed by a given ray.

Lens Setup

Whenever the lens entry process is completed, the lens must be "set up." Pickup constraints must be resolved. If the system contains an internal aperture stop, the position of the entrance pupil must be determined. Then paraxial axial and chief rays must be traced through the system so that surface data specified by solves can be computed. Depending on the program, a variety of other data may be precomputed for later use, including aperture radii, refractive indices, and various paraxial constants.

The lens setup routine must be very efficient, since it is the most heavily used code in an optical design program. In addition to running whenever explicit data entry is complete, the code is also executed whenever the lens is modified internally by the program, such as when derivatives are computed during optimization, or when configurations are changed in a multiconfiguration system. Typically, lens setup takes milliseconds (at most), so it is not noticed by the user, other than through its effects.

Programming Considerations

In writing an optical design program, the programmer must make a number of compromises between speed, size, accuracy, and ease of use. These compromises affect the usefulness of a particular program for a particular application. For example, a simple, fast, small program may be well suited to a casual user with a simple problem to solve, but this same program may not be suited for an experienced designer who routinely tackles state-of-the-art problems.

The lens entry portion of an optical design program shows, more than any other part, the difference in programming models that occurred during the 1980s. Before the 1980s, most application programs were of a type called *procedural* programs. When such a program needs data, it requests it, perhaps from a file or by issuing a prompt for keyboard input. The type of data needed is known, and the program is only prepared to accept that kind of data at any given point. Although the program may branch through different paths in response to the data it receives, the program is responsible for its own execution.

With the popularization in the 1980s of computer systems that use a mouse for input the model for an application program changed from the procedural model described above to what is called an *event-driven* model. An event-driven program has a very simple top-level structure consisting of an initialization section followed by an infinite loop usually called something like the *main event loop.* The function of the main event loop is to react to user-initiated interrupts (such as pressing a key, or clicking a mouse button), dispatching such events to appropriate processing functions. In such a program, the user controls the execution, unlike a procedural program, where the execution controls the user.

An event-driven program usually provides a better user interface than a procedural program. Unfortunately, most optical design programs were originally written as procedural programs, and it is difficult to convert a procedural program into an event-driven program by "patching" it. Usually it is easier to start over. In addition, it is harder to write an event-driven program than a procedural program, because the event-driven program must be set up to handle a wide variety of unpredictable requests received at random times. Of course, it is this very fact that makes the user interface better. There is an aphorism sometimes called the "conservation of complexity," which states that the simpler a program is to use, the more complicated the program itself must be.

The data structures used to define lens data in an optical design program may have a major impact on its capabilities. For example, for various reasons it is usually desirable to represent a lens in a computer program as an array of surfaces. If the maximum size of the array is determined at compile time, then the maximum size lens that can be accommodated is built into the program.

As more data items are added to the surface data, the space required for storage can become unwieldy. For example, it takes about 10 items of real data to specify a holographic surface. If every surface were allowed to be a hologram, then 10 array elements would have to be reserved for each surface's holographic data. On the other hand, in most systems, the elements would never be used, so the data structure would be very inefficient. To avoid this, a more complicated data structure could be implemented in which only one element would be devoted to holograms, and this item would be used as an index into a separate array containing the actual holographic data. Such an array might have a sufficient number of elements to accommodate up to, say, five holograms, the maximum number expected in any one system.

The preceding is a simple example of how the data structure in an optical design program can grow in complexity. In fact, in a large optical design program the data structure may contain all sorts of indices, pointers, flags, etc., used to implement special data types and control their use. Managing this data while maintaining its integrity is a programming task of a magnitude often greater than the numerical processing that takes place during optical design.

Consider, for example, the task of deleting a surface from a lens. To do this, the surface data must of course be deleted, and all of the higher-numbered surfaces renumbered. But, in addition, the surface must be checked to see whether it is a hologram and, if so, the holographic data must also be deleted and that data structure "cleaned up." All other possible special data items must be tested and handled similarly. Then all the renumbered surfaces must be checked to see if any of the "pick up" data from a surface that has been renumbered, and the reference adjusted accordingly. Then other data structures such as the optimization files must be checked to see if they refer to any of the renumbered surfaces, and appropriate adjustments made. There may be several other checks and adjustments that must also be carried out.

Related to the lens entry process is the method used to store lens data on disc. Of course, lens data are originally provided to a program in the form of text (e.g., "TH 1.0"). The program *parses* this data to identify its type (a thickness) and value (1.0). The results of the parsing process (the binary values) are stored in appropriate memory locations (arrays). To store lens data on disc, early optical design programs used the binary data to avoid having to reparse it when it was recovered. However, the use of binary files has decreased markedly as computers have become fast enough that parsing lens input does not take long. The disadvantages of binary files are that they tend to be quite large, and usually have a structure that makes them obsolete when the internal data structure of the program is changed. The alternative is to store lens data as text files, similar in form to ordinary keyboard input files.

3.4 EVALUATION

Paraxial Analysis

Although the lens setup routine contains a paraxial ray trace, a separate paraxial ray trace routine is used to compute data for display to the user. At a minimum, the paraxial ray heights and slopes of the axial and chief ray are shown for each surface, in each color, and in each configuration.

The equations used for paraxial ray tracing were described in the previous section. Although such equations become exact only for "true" paraxial rays that are infinitesimally displaced from the optical axis, it is customary to consider paraxial ray data to describe "formal" paraxial rays that refract at the tangent planes to surfaces, as shown in Fig. 2. Here, the ray ABC is a paraxial ray that provides a first-order approximation to the exact ray ADE. Not only does the paraxial ray refract at the (imaginary) tangent plane BVP, but also it bends a different amount from the exact ray.

In addition to the computation of ray heights and slopes for the axial and chief ray, various paraxial constants that characterize the overall system are computed. The particular values computed depend on whether the system is *focal* (finite image distance) or *afocal* (image at infinity). For focal systems, the quantities of interest are (at a minimum) the focal length efl, the *f*-number FN, the paraxial (Lagrange) invariant PIV, and the transverse magnification *m*. It is desirable to compute such

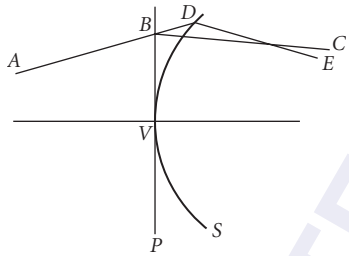

FIGURE 2 Showing the difference between a paraxial ray and a real ray. The paraxial ray propagates along *ABC*, while the real ray propagates along *ADE*.

quantities in a way that does not depend on the position of the final image surface. Let the object height be *h,* the entrance pupil radius be *r,* the axial ray data in object and image spaces be *y, u* and y', u', the chief ray data be $\bar{y}$, $\bar{u}$ and $\bar{y}'$, $\bar{u}'$, and the refractive indices be *n* and n'.

The above-mentioned paraxial constants are then given by

$$\text{efl} = \frac{-rh}{\bar{u}'r + u'h}$$

$$\text{FN} = -\frac{n}{2n'u'}$$

$$\text{PIV} = n(\bar{y}u - y\bar{u})$$

$$m = \frac{nu}{n'u'}$$

In addition to the paraxial constants, most programs display the locations of the entrance and exit pupils, which are easily determined using chief-ray data. Surprisingly, most optical design programs do not explicitly show the locations of the principal planes. In addition, although most programs have the capability to display "$y - \bar{y}$" plots, few have integrated this method into the main lens entry routine.

Aberrations

Although most optical designs are based on exact ray data, virtually all programs have the capability to compute and display first-order chromatic aberrations and third-order monochromatic (Seidel) aberrations. Many programs can compute fifth-order aberrations as well. The form in which aberrations are displayed depends on the program and the type of system under study, but as a general rule, for focal systems aberrations are displayed as equivalent ray displacements in the paraxial image plane.

In the case of the chromatic aberrations, the primary and secondary chromatic aberration of the axial and chief rays are computed. In a system for which three wavelengths are defined, the primary aberration is usually taken between the two outer wavelengths, and the secondary aberration between the central and short wavelengths.

The Seidel aberrations are computed according to the usual aberration polynomial. If we let ϵ be the displacement of a ray from the chief ray, then

$$\epsilon_y = \epsilon_{3y} + \epsilon_{5y} + \cdots$$

$$\epsilon_x = \epsilon_{3x} + \epsilon_{5x} + \cdots$$

For a relative field height h and normalized entrance pupil coordinates r and θ, the third-order terms are

$$\epsilon_{3y} = \sigma_1 \cos\theta r^3 + \sigma_2(2+\cos 2\theta) r^2 h + (3\sigma_3 + \sigma_4)\cos\theta r h^2 + \sigma_5 h^3$$

$$\epsilon_{3x} = \sigma_1 \sin\theta r^3 + \sigma_2 \sin 2\theta r^2 h + (\sigma_3 + \sigma_4)\sin\theta r h^3$$

The interpretation of the coefficients is generally as follows, but several optical design programs display tangential coma, rather than the sagittal coma indicated in the table.

σ_1	Spherical aberration
σ_2	Coma
σ_3	Astigmatism
σ_4	Petzval blur
σ_5	Distortion

The fifth-order terms are

$$\epsilon_{5y} = \mu_1 \cos\theta r^5 + (\mu_2 + \mu_3 \cos 2\theta) r^4 h + (\mu_4 + \mu_6 \cos^2\theta)\cos\theta r^2 h^2$$
$$+ (\mu_7 + \mu_8 \cos 2\theta) r^2 h^3 + \mu_{10} \cos\theta r h^4 + \mu_{12} h^5$$

$$\epsilon_{5x} = \mu_1 \sin\theta r^5 + \mu_3 \sin 2\theta r^4 h + (\mu_5 + \mu_6 \cos^2\theta)\sin\theta r^3 h^2$$
$$+ \mu_9 \sin 2\theta r^2 h^3 + \mu_{11} \sin\theta r h^4$$

These equations express the fifth-order aberration in terms of the Buchdahl μ coefficients. In systems for which the third-order aberrations are corrected, the following identities exist:

$$\mu_2 = \frac{3}{2}\mu_3$$

$$\mu_4 = \mu_5 + \mu_6$$

$$\mu_7 = \mu_8 + \mu_9$$

μ_1	Spherical aberration
μ_3	Coma
$(\mu_{10} - \mu_{11})/4$	Astigmatism
$(5\mu_{11} - \mu_{10})/4$	Petzval blur

$\mu_4 + \mu_6$	Tangential oblique spherical aberration
μ_5	Sagittal oblique spherical aberration
$\mu_7 + \mu_8$	Tangential elliptical coma
μ_9	Sagittal elliptical coma
μ_{12}	Distortion

Some programs display only the aberrations that have corresponding third-order coefficients, omitting oblique spherical aberration and elliptical coma.

The formulas needed to calculate the chromatic and third-order aberrations are given in the *U.S. Military Handbook of Optical Design.* The formulas for calculating the fifth-order aberrations are given in Buchdahl's book.[9]

Aberration coefficients are useful in optical design because they characterize the system in terms of its symmetries, allow the overall performance to be expressed as a sum of surface contributions, and are calculated quickly. On the negative side, aberration coefficients are not valid for systems that have tilted and decentered elements for systems that cover an appreciable field of view, and the accuracy of aberration coefficients in predicting performance is usually inadequate. Moreover, for systems that include unusual elements like diffractive surfaces and gradient index materials, the computation of aberration coefficients is cumbersome at best.

Ray Tracing

Exact ray tracing is the foundation of an optical design program, serving as a base for both evaluation and optimization. From the programmer's standpoint, the exact ray-trace routines must be accurate and efficient. From the user's viewpoint, the data produced by the ray-trace routines must be accurate and comprehensible. Misunderstanding the meaning of ray-trace results can be the source of costly errors in design.

To trace rays in an optical design program, it is necessary to understand how exact rays are specified. Although the details may vary from one program to the next, many programs define a ray by a two-step process. In the first step, an object point is specified. Once this has been done, all rays are assumed to originate from this point until a new object point is specified. The rays themselves are then specified by aperture coordinates and wavelength.

Exact ray starting data is usually normalized to the object and pupil coordinates specified by the axial and chief rays. That is, the aperture coordinates of a ray are specified as a fractional number, with 0.0 representing a point on the vertex of the entrance pupil, and 1.0 representing the edge of the pupil. Field angles or object heights are similarly described, with 0.0 being a point on the axis, and 1.0 being a point at the edge of the field of view.

Although the above normalization is useful when the object plane is at infinity, it is not so good when the object is at a finite distance and the numerical aperture in object space is appreciable. Then, fractional aperture coordinates should be chosen proportional to the direction cosines of rays leaving an object point. There are two reasons for this. One is that it allows an object point to be considered a point source, so that the amount of energy is proportional to the "area" on the entrance pupil. The other is that for systems without pupil aberrations, the fractional coordinates on the second principal surface should be the same as those on the first principal surface. Notwithstanding these requirements, many optical design programs do not define fractional coordinates proportional to direction cosines.

It is sometimes a point of confusion that the aperture and field of view of a system are specified by paraxial quantities, when the actual performance is determined by exact rays. In fact, the paraxial specifications merely establish a normalization for exact ray data. For example, in a real system the field of view is determined not by the angle of the paraxial chief ray, but by the angle at which exact rays blocked by actual apertures just fail to pass through the system. Using an iterative procedure, it is not too hard to find this angle, but because of the nonlinear behavior of Snell's law, it does not provide a convenient reference point.

There are two types of exact rays: *ordinary* or *lagrangian* rays, and *iterated* or *hamiltonian* rays. The designation of rays as lagrangian or hamiltonian comes from the analogy to the equations of motion of a particle in classical mechanics. Here we use the more common designation as ordinary or iterated rays. An ordinary ray is a ray that starts from a known object point in a known direction. An iterated ray also starts from a known object point, but its direction is not known at the start. Instead, it is known that the ray passes through some known (nonconjugate) point inside the system, and the initial ray direction is determined by an iterative procedure.

Iterated rays have several applications in optical design programs. For example, whenever a new object point is specified, it is common to trace an iterated ray through the center of the aperture stop (or some other point) to serve as a reference ray, or to trace several iterated rays through the edges of limiting apertures to serve as reference rays. In fact, many programs use the term *reference ray* to mean iterated ray (although in others, reference rays are ordinary rays). Iterated rays are traced using differentially displaced rays to compute corrections to the initial ray directions. Because of this, they are traced slower than ordinary rays. On the other hand, they carry more information in the form of the differentials, which is useful for computing ancillary data like field sags.

Reference rays are used as base rays in the interpretation of ordinary ray data. For example, the term *ray displacement* often refers to the difference in coordinates on the image surface of a ray from those of the reference ray. Similarly, the *optical path difference* of a ray may compare its phase length to that of the corresponding reference ray. The qualifications expressed in the preceding sentences indicate that the definitions are not universal. Indeed, although the terms *ray displacement* and *optical path difference* are very commonly used in optical design, they are not precisely defined, nor can they be. Let us consider, for example, the optical path difference.

Imagine a monochromatic wavefront from a specified object point that passes through an optical system. Figure 3 shows the wavefront *PE* emerging in image space, where it is labeled "actual wavefront." Because of aberrations, an ordinary ray perpendicular to the actual wavefront will not intersect the final image surface at the ideal image point *I*, but at some other point *Q*. The optical path difference (OPD) may be defined as the optical path measured along the actual ray between the actual wavefront and a reference sphere centered on the ideal image point.

Unfortunately, the ideal image point is not precisely defined. In the figure, it is shown as the intersection of the reference ray with the image surface, but the reference ray itself may not be precisely defined.

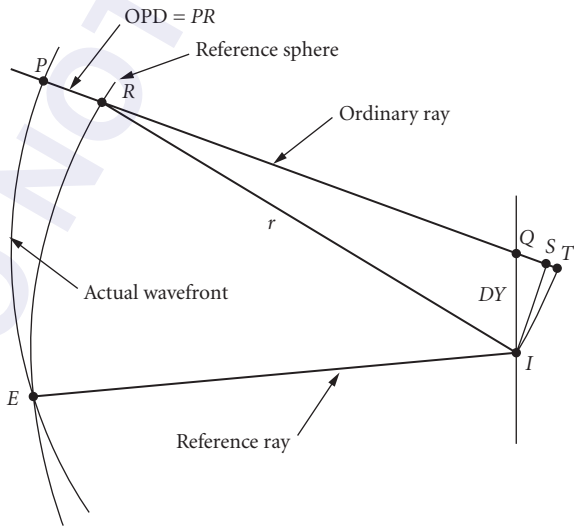

FIGURE 3 The relation between ray trajectories and optical path difference (OPD). See text.

Is it the ray through the center of the aperture stop, or perhaps the ray through the center of the actual vignetted aperture? These two definitions will result in different reference rays, and correspondingly different values for the optical path difference. In fact, in many practical applications neither definition is used, and the actual ideal image point is defined to be the one that minimizes the variance of the optical path difference (and hence maximizes the peak intensity of the diffraction image).

Moreover, the figure shows that even if the ideal image point is precisely defined, the value of the optical path difference depends on the point *E* where the actual wavefront interesects the reference sphere. For the particular point shown, the optical path difference is the optical length along the ordinary ray from the object point to the point *T,* less the optical length along the reference ray from the object point to the point *I*. As the radius of the reference sphere is increased, the point *T* merges with the point *S,* where a perpendicular from the ideal image point intersects the ordinary ray.

The above somewhat extended discussion is meant to demonstrate that even "well-known" optical terms are not always precisely defined. Not surprisingly, various optical design programs in common use produce different values for such quantities. There has been little effort to standardize the definitions of many terms, possibly because one cannot legislate physics. In any case, it is important for the user of an optical design program to understand precisely what the program is computing.

Virtually all optical design programs can trace single rays and display the ray heights and direction cosines on each surface. Other data, such as the path length, angles of incidence and refraction, and direction of the normal vector, are also commonly computed. Another type of ray-data display that is nearly universal is the ray-intercept curve, which shows ray displacement on the final image surface versus (fractional) pupil coordinates. A variation plots optical path difference versus pupil coordinates.

In addition to the uncertainty concerning the definition of ray displacement and optical path difference, there are different methods for handling the pupil coordinates. Some programs use entrance pupil coordinates, while others use exit pupil coordinates. In most cases, there is not a significant difference, but in the case of systems containing cylindrical lenses, for example, there are major differences.

Another consideration relating to ray-intercept curves is the way in which vignetting is handled. This is coupled to the way the program handles apertures. As mentioned before, apertures have a special status in many optical design programs. Rays can be blocked by apertures, but this must be handled as a special case by the program, because there is nothing inherent in the ray-trace equations that prevents a blocked ray from being traced, in contrast to a ray that misses a surface or undergoes total internal reflection.

Even though a surface may have a blocking aperture, it may be desirable to let the ray trace proceed anyway. As mentioned before, blocking rays in optimization can produce instabilities that prevent convergence to a solution even though all the rays in the final solution are contained within the allowed apertures. Another situation where blocking can be a problem concerns central obstructions. In such systems, the reference ray may be blocked by an obstruction, so its data are not available to compute the displacement or optical path difference of an ordinary ray (which is not blocked). The programmer must anticipate such situations and build in the proper code to handle them.

In the case of ray-intercept curves, it is not unusual for programs to display data for rays that are actually blocked by apertures. The user is expected to know which rays get through, and ignore the others, a somewhat unreasonable expectation. The justification for allowing it is that the designer can see what would happen to the rays if the apertures were increased.

In addition to ray-intercept curves, optical design programs usually display field sag plots showing the locations of the tangential and sagittal foci as a function of field angle and distortion curves. In the case of distortion, there is the question of what to choose as a reference height. It is generally easiest to refer distortion to the paraxial chief ray height in the final image surface, but in many cases it is more meaningful to refer it to the centroid height of a bundle of exact rays from the same object point. Again, it is important for the user to know what the program is computing.

Spot-Diagram Analysis

Spot diagrams provide the basis for realistic modeling of optical systems in an optical design program. In contrast to simple ray-trace evaluation, which shows data from one or a few rays, spot

diagrams average data from hundreds or thousands of rays to evaluate the image of a point source. Notwithstanding this, it should be understood that the principal purpose of an optical design program is to design a system, not to simulate its performance. It is generally up to the designer to understand whether or not the evaluation model of a system is adequate to characterize its real performance, and the prudent designer will view unexpected results with suspicion.

From a programmer's point of view, the most difficult task in spot-diagram analysis is to accurately locate the aperture of the system. For systems that have rotational symmetry, this is not difficult, but for off-axis systems with vignetted apertures it can be a challenging exercise. However, the results of image evaluation routines are often critically dependent on effects that occur near the edges of apertures, so particular care must be paid to this problem in writing optical design software. Like many other aspects of an optical design program, there is a trade-off between efficiency and accuracy.

A spot diagram is an assemblage of data describing the image-space coordinates of a large number of rays traced from a single object point. The data may be either monochromatic or polychromatic. Each ray is assigned a weight proportional to the fractional energy that it carries. Usually, the data saved for each ray include its *xyz* coordinates on the image surface, the direction cosines *klm,* and the optical path length or optical path difference from the reference ray. The ray coordinates are treated statistically to calculate root-mean-square spot sizes. The optical path lengths yield a measure of the wavefront quality, expressed through its variance and peak-to-valley error.

To obtain a spot diagram, the entrance pupil must be divided into cells, usually of equal area. Although for many purposes the arrangement of the cells does not matter, for some computations (e.g., transfer functions) it is advantageous to have the cells arranged on a rectangular grid. To make the computations have the proper symmetry, the grid should be symmetrical about the *x* and *y* axis. The size of the grid cells determines the total number of rays in the spot diagram.

In computing spot diagrams, the same considerations concerning the reference point appear as for ray fans. That is, it is possible to define ray displacements with respect to the chief-ray, the paraxial ray height, or the centroid of the spot diagram. However, for spot diagrams it is most common to use the centroid as the reference point, both because many image evaluation computations require this definition, and also because the value for the centroid is readily available from the computed ray data.

$a_i = \epsilon_{xi}$ = ray displacement in the *x* direction

$b_i = \epsilon_{yi}$ = ray displacement in the *y* direction

$c_i = k_i/m_i$ = ray slope in the *x* direction

$d_i = l_i/m_i$ = ray slope in the *y* direction

w_i = weight assigned to ray

The displacements of rays on a plane shifted in the *z* direction from the nominal image plane by an amount Δz are given by

$$\delta x_i = a_i + b_i \Delta z$$

$$\delta y_i = c_i + d_i \Delta z$$

If there are *n* rays, the coordinates of the centroid of the spot diagram are

$$\delta \bar{x} = \frac{1}{W} \sum_{i=1}^{n} w_i \delta x_i = A + B \Delta z$$

$$\delta \bar{y} = \frac{1}{W} \sum_{i=1}^{n} w_i \delta y_i = C + D \Delta z$$

where W is a normalizing constant that ensures that the total energy in the image adds up to 100 percent, and

$$A = \frac{1}{W}\sum_{i=1}^{n} w_i a_i$$

$$B = \frac{1}{W}\sum_{i=1}^{n} w_i b_i$$

$$C = \frac{1}{W}\sum_{i=1}^{n} w_i c_i$$

$$D = \frac{1}{W}\sum_{i=1}^{n} w_i d_i$$

The mean-square spot size can then be written as

$$\text{MSS} = \frac{1}{W}\sum_{i=1}^{n} w_i\{(\delta x_i - \delta\bar{x})^2 + (\delta y_i - \delta\bar{y})^2\}$$

Usually, the root-mean-square (rms) spot size, which is the square root of this quantity, is reported. Since the MSS has a quadratic form, it can be written explicitly as a function of the focus shift by

$$\text{MSS} = P + 2Q\,\Delta z + R(\Delta z)^2$$

where

$$P = \frac{1}{W}\sum_{i=1}^{n} w_i\{(a_i^2 + c_i^2) - (A^2 + C^2)\}$$

$$Q = \frac{1}{W}\sum_{i=1}^{n} w_i\{(a_i b_i + c_i d_i) - (AB + CD)\}$$

$$R = \frac{1}{W}\sum_{i=1}^{n} w_i\{(b_i^2 d_i^2) - (B^2 + D^2)\}$$

Differentiating this expression for the MSS with respect to focus shift, then setting the derivative to zero, determines the focus shift at which the rms spot size has its minimum value:

$$\Delta z_{\text{opt}} = -Q/R$$

Although the above equations determine the rms spot size in two dimensions, similar one-dimensional equations can be written for x and y separately, allowing the ready computation of the tangential and sagittal foci from spot-diagram data. In addition, it is straightforward to carry out the preceding type of analysis using optical path data, which leads to the determination of the center of the reference sphere that minimizes the variance of the wavefront.

Beyond the computation of the statistical rms spot size and the wavefront variance, most optical design programs include a variety of image evaluation routines that are based on spot diagram data. It is useful to characterize them as belonging to geometrical optics or physical optics, according to whether they are based on ray displacements or wavefronts, although, of course, all are based on the results of geometrical ray tracing.

Geometrical Optics Most optical design programs provide routines for computing radial diagrams and knife-edge scans. To compute a radial energy diagram, the spot-diagram data are sorted according to increasing ray displacement from the centroid of the spot. The fractional energy is then plotted as a function of spot radius. The knife-edge scan involves a similar computation, except that the spot-diagram data are sorted according to x or y coordinates, instead of total ray displacement.

Another type of geometrical image evaluation based on spot-diagram data is the so-called *geometrical optical transfer function* (GOTF). This function can be developed as the limiting case, as the wavelength approaches zero, of the actual diffraction MTF, or, alternately, in a more heuristic way as the Fourier transform of a line spread function found directly from spot-diagram ray displacements (see, for example, Smith's book[10]). From a programming standpoint, computation of the GOTF involves multiplying the ray displacements by 2π times the spatial frequency under consideration, forming cosine and sine terms, and summing over all the rays in the spot diagram. The computation is quick, flexible, and if there are more than a few waves of aberration, accurate. The results of the GOTF computation are typically shown as either plots of the magnitude of the GOTF as a function of frequency, or alternately in the form of what is called a "through-focus" MTF, in which the GOTF at a chosen frequency is plotted as a function of focus shift from the nominal image surface.

Physical Optics The principal physical optics calculations based on spot-diagram data are the modulation transfer function, sometimes called the "diffraction" MTF, and the point spread function (PSF). Both are based on the wavefront derived from the optical path length data in the spot diagram. There are various ways to compute the MTF and PSF, and not all programs use the same method. The PSF, for example, can be computed from the pupil function using the fast Fourier transform algorithm or, alternately, using direct evaluation of the Fraunhofer diffraction integral. The MTF can be computed either as the Fourier transfer of the PSF or, alternately, using the convolution of the pupil function.[11] The decision as to which method to use involves speed, accuracy, flexibility, and ease of coding.

In physical-optics-based image evaluation, accuracy can be a problem of substantial magnitude. In many optical design programs, diffraction-based computations are only accurate for systems in which diffraction plays an important role in limiting the performance. Systems that are limited primarily by geometrical aberrations are difficult to evaluate using physical optics, because the wavefront changes so much across the pupil that it may be difficult to sample it sufficiently using a reasonable number of rays. If the actual wavefront in the exit pupil is compared to a reference sphere, the resultant fringe spacing defines the size required for the spot diagram grid, since there must be several sample points per fringe to obtain accurate diffraction calculations. To obtain a small grid spacing, one can either trace many rays, or trace fewer rays but interpolate the resulting data to obtain intermediate data.

Diffraction calculations are necessarily restricted to one wavelength. To obtain polychromatic diffraction results it is necessary to repeat the calculations in each color, adding the results while keeping track of the phase shifts caused by the chromatic aberration.

3.5 OPTIMIZATION

The function of the optimization part of the program is to take a *starting design* and modify its construction so that it meets a given set of specifications. The starting design may be the result of a previous design task, a lens from the library, or a new design based on general optical principles and the designer's intuition.

The performance of the design must be measured by a single number, often known in optics as the *merit function,* although the term *error function* is more descriptive and will be used here. The error function is the sum of squares of quantities called *operands* that characterize the desired attributes. Examples of typical operands include paraxial constants, aberration coefficients, and exact ray displacements. Sometimes, the operands are broken into two groups: those that must be satisfied exactly, which may be called *constraints,* and others that must be minimized. Examples of constraints might include paraxial conditions such as the focal length or numerical aperture.

The constructional parameters to be adjusted are called *variables,* which include lens curvatures, thicknesses, refractive indices, etc. Often the allowed values of the variables are restricted, either by requirements of physical reality (e.g., positive thickness) or the given specifications (e.g., lens diameters less than a prescribed value). These restrictions are called *boundary conditions,* and represent another form of constraint.

Usually, both the operands and constraints are nonlinear functions of the variables, so optical design involves nonlinear optimization with nonlinear constraints, the most difficult type of problem from a mathematical point of view. A great deal of work has been carried out to develop efficient, general methods to solve such problems. Detailed consideration of these methods is beyond the scope of this chapter, and the reader is referred to a paper by Hayford.[12]

In a typical optical design task, there are more operands than variables. This means that there is, in general, no solution that makes all of the operands equal to their target values. However, there is a well-defined solution called the *least-squares* solution, which is the state of the system for which the operands are collectively as close to their targets as is possible. This is the solution for which the error function is a minimum.

The Damped Least-Squares Method

Most optical design programs utilize some form of the *damped least-squares* (DLS) method, sometimes in combination with other techniques. DLS was introduced to optics in about 1960, so it has a history of 50 years of (usually) successful application. It is an example of what is known as a *downhill* optimizer, meaning that in a system with multiple minima, it is supposed to find the nearest local minimum. In practice, it sometimes suffers from *stagnation,* yielding slow convergence. On the other hand, many designers over the years have learned to manipulate the damping factor to overcome this deficiency, and even in some cases to find solutions beyond the local minimum.

We consider first the case of unconstrained optimization. Let the system have M operands f_i and N variables x_i. The error function ϕ is given by

$$\phi = f_1^2 + f_2^2 + \cdots + f_M^2$$

Define the following:

$$\mathbf{A} = \text{derivative matrix, } A_{ij} \equiv \frac{\partial f_i}{\partial x_j}$$

$$\mathbf{G} = \text{gradient vector, } G_k \equiv \frac{1}{2}\frac{\partial \phi}{\partial x_k}$$

$$\mathbf{x} = \text{change vector}$$

$$\mathbf{f} = \text{error vector}$$

With these definitions, we have

$$\mathbf{G} = \mathbf{A}^T\mathbf{f}$$

If we assume that the changes in the operands are linearly proportional to the changes in the variables, we have

$$\mathbf{f} = \mathbf{A}\mathbf{x} + \mathbf{f}_0$$

$$\mathbf{G} = \mathbf{A}^T\mathbf{A}\mathbf{x} + \mathbf{G}_0$$

At the solution point, the gradient vector is zero, since the error function is at a minimum. The change vector is thus

$$\mathbf{x} = -(\mathbf{A}^T\mathbf{A})^{-1}\mathbf{G}_0$$

These are called the least-squares *normal equations,* and are the basis for linear least-squares analysis. When nonlinear effects are involved, repeated use of these equations to iterate to a minimum often leads to a diverging solution. To prevent such divergence, it is common to add another term to the error function, and this limits the magnitude of the change vector **x**. In the DLS method, this is accomplished by defining a new error function

$$\varphi = \phi + p\mathbf{x}^T\mathbf{x}$$

A key property of DLS is that the minimum of φ is the same as the minimum of ϕ since, at the minimum, the change vector **x** is zero. By differentiating and setting the derivative equal to zero at the minimum, we arrive at the damped least-squares equations

$$\mathbf{x} = -(\mathbf{A}^T\mathbf{A} + p\mathbf{I})^{-1}\mathbf{G}_0$$

which look like the normal equations with terms added along the diagonal. These terms provide the damping, and the factor p is called the *damping factor.* This particular choice of damping is called *additive damping* but, more generally, it is possible to add any terms to the diagonal and still maintain the same minimum. Some optical design programs multiply the diagonal elements of the $\mathbf{A}^T\mathbf{A}$ matrix by a damping factor, while others make them proportional to the second derivative terms. Although theoretical arguments are sometimes advanced to support the choice of a particular method of damping, in practice the choice of damping factor is an ad hoc way to accelerate convergence to a solution by limiting the magnitude (and changing the direction) of the change vector found from the normal equations.

In practical optical design work, it has been found that no single method for choosing the damping factor works best in all cases. In a particular problem, one method may be dramatically better than another, but in a different problem, the situation may be completely reversed. Every optical design program has its unique way of choosing the optimum damping, which makes each program different from the others, and gives it a raison d'être.

Although the principal use of the damping factor is to accelerate convergence by limiting the magnitude of the change vector, the damping factor has also been used routinely to increase the magnitude of the change vector to escape a local minimum. During the course of a minimization task, if the solution stagnates, or does not converge to what the designer believes to be an acceptable configuration, it may be possible to force the solution into another region by running one or more iterations with reduced damping in which the error function increases.

Constraints and Boundary Conditions There are two general methods used in optical design programs for handling constraints and boundary conditions. The first is to add a term (called a *penalty* function) to the error function that targets the constraint to its desired value. In the case of boundary violations, "one-sided" terms can be added, or special weighting functions can be constructed that increase in magnitude as a violation goes farther into a forbidden region. The other method augments

the number of equations by the number of constraints and solves the resulting equations using the Lagrange multiplier method. This produces a minimum that satisfies the constraints exactly and minimizes the remaining error function.

The penalty function method is more flexible and faster (since there are fewer equations) than the Lagrange multiplier method. On the other hand, the Lagrange multiplier method gives more precise control over the constraints. Both are commonly used in optical design software.

Other Methods

Although DLS is used in the vast majority of optical design applications, other methods are occasionally used,[12] and two warrant mention. These are *orthonormalization*, which has been used to overcome stagnation in some DLS problems, and *simulated annealing,* which has been used for global optimization.

Orthonormalization The technique of orthonormalization for the solution of optical design problems was introduced by Grey.[2] Although it solves the same problem as DLS does, it proceeds in a very different fashion. Instead of forming the least-squares normal equations, Grey works directly with the operand equations

$$\mathbf{A}\mathbf{x} = -\mathbf{f}$$

To understand Grey's method, it is best to forget about optics and consider the solution of these equations strictly from a mathematical point of view. The point of view that Grey uses is that **f** represents a vector in m-dimensional space. The columns of **A** can be regarded as basis vectors in this m-dimensional space. Since there are only n columns, the basis vectors do not span the space. The change vector **x** represents a projection of **f** on the basis vectors defined by **A**. At the solution point, the residual part of **f** will be orthogonal to its projection on the basis vectors.

In Grey's orthonormalization method, the solution of the equations is found by a technique similar to Gram-Schmidt orthogonalization, but during the solution process, the actual error function is evaluated several times in an effort to use the best variables to maximum advantage. Because of this, the method is computationally intensive compared to DLS. However, the extra computation is justified by a more accurate solution. The common wisdom is that orthogonalization is superior to DLS near a solution point, and inferior to DLS when the solution is far removed from the starting point.

Simulated Annealing Simulated annealing has been applied to optical design optimization, chiefly in problems where the task is to find a global minimum. The method varies drastically from other techniques. It makes no use of derivative information, and takes random steps to form trial solutions. If a trial solution has a lower error function than the current system, the new system replaces the old. If a trial solution has a higher error function than the current system, it may be accepted, depending on how much worse it is. The probability of acceptance is taken to be $\exp(-\Delta\phi/T)$, where T is an experimentally determined quantity. In general simulated annealing, T is provided by the user. In adaptive simulated annealing, T is reduced automatically according to algorithms that hold the system near statistical equilibrium.

Error Functions

Obviously, the choice of an error function has a major impact on the success of an optical design task. There are a number of requirements that an error function should meet. Most importantly, the error function should accurately characterize the desired properties of the system under design. There is little chance of success if the program is optimizing the wrong thing. Yet this is an area of great difficulty in computer-aided optical design, because it is at odds with efficiency. In order to obtain more accuracy, more extensive computations should be carried out, but this takes time.

There are two schools of thought concerning the implementation of error functions in optical design programs. The first holds that the designer should have complete control over the items included in the error function, while the second holds that the program itself should set up the basic error function, allowing the designer some degree of control through weighting functions. Neither school has demonstrated superiority, but the approach to error function construction taken by various optical design programs accounts for user allegiances that are sometimes remarkably strong.

The different ways that optical design programs handle error functions makes it difficult to discuss the topic here in anything other than broad detail. At one extreme are programs that provide practically no capability for the user to insert operands, displaying only the value of the overall error function, while at the other extreme are programs that make the user enter every operand individually. Regardless of the user interface, however, there are some general concepts that are universally relevant.

Error functions can be based on either aberration coefficients or exact-ray data (or both). In the early stages of design, aberration coefficients are sometimes favored because they provide insight into the nature of the design, and do not suffer ray failures. However, the accuracy of aberration coefficients for evaluating complex systems is not very good, and exact-ray data are used in virtually all final optimization work.

So far as exact-ray error functions are concerned, there is the question of whether to use ray displacements or optical path difference (or both). This is a matter of user (or programmer) preference. The use of ray displacements leads to minimizing geometrical spot sizes, while the use of optical path difference leads to minimizing the wavefront variance.

For exact-ray error functions, a suitable pattern of rays must be set up. This is often called a *ray set.* There are three common methods for setting up a ray set. The first is to allow the designer to specify the coordinates (object, pupil, wavelength, etc.) for a desired set of rays. This gives great flexibility, but demands considerable skill from the user to ensure that the resulting error function accurately characterizes performance.

The other two methods for setting up ray sets are more automatic. The first is to allow the user to specify object points, and have the program define a rectangular grid of rays in the aperture for each point. The second uses a Gaussian integration scheme proposed by Forbes to compute the rms spot size, averaged over field, aperture, and wavelength.[13] The Forbes method, which is restricted to systems having plane symmetry, leads to dividing the aperture into *rings* and *spokes.* For systems having circular pupils, the Forbes method has both superior accuracy and efficiency, but for vignetted pupils, there is little difference between the two.

Multiconfiguration Optimization

Multiconfiguration optimization refers to a process in which several systems having some common elements are optimized jointly, so that none of the individual systems but the *ensemble* of all of the systems is optimized. The archetype of multiconfiguration systems is the *zoom* system in which the focal length is changed by changing the separation between certain elements. The system is optimized simultaneously at high, medium, and low magnifications to produce the best overall performance.

Most of the larger optical design programs have the capability to carry out multiconfiguration optimization, and this capability is probably used more for non-zoom systems than for zoom systems. A common use of this feature is to optimize a focal system for through-focus performance in order to minimize sensitivity to image plane shifts. In fact, multiconfiguration optimization is used routinely to control tolerances.

Tolerancing

Beyond the task of desensitizing a given design, considerations of manufacturing tolerances become increasingly important as the complexity of optical designs increases. It is quite easy to

design optical systems that cannot be built because the fabrication tolerances are beyond the capability of optical manufacturing technology. In any case, specifying tolerances is an integral part of optical design, and a design project cannot be considered finished until appropriate tolerances are established.

Tolerancing is closely related to optimization. The basic tolerance computation is to calculate how much the error function changes for a small change in a construction parameter, which is the same type of computation carried out when computing a derivative matrix. Even more relevant, however, is the use of *compensators,* which requires reoptimization. A compensator is a construction parameter that can be adjusted to compensate for an error introduced by another construction parameter. For example, a typical compensator would be the image distance, which could be adjusted to compensate for power changes introduced by curvature errors.

There is considerable variation in how different optical design programs handle tolerancing. Some use the reoptimization method described here, while others use Monte Carlo techniques. Some stress interaction with the designer, while others use defaults for more automatic operation.

3.6 OTHER TOPICS

Of course, many other topics would be included in a full discussion of optical design software. Space limitations and our intended purpose prevents any detailed consideration, but a few of the areas where there is still considerable interest are the following.

Simulation

There is increased interest in using optical design programs to simulate the performance of actual systems. The goal is often to be able to calculate radiometric throughput of a system used in conjunction with a real extended source. It is difficult to provide software to do this with much generality, because brute force methods are very inefficient and hard to specify, while elegant methods tend to have restricted scope, and demand good judgment by the person modeling the physical situation. Nevertheless, with the increase in the speed of computers, there is bound to be an increasing use of optical design software for evaluating real systems.

Global Optimization

After several years during which there was little interest in optimization methodology, the tremendous increase in the speed of new computers has spawned a renewal of efforts to find global, rather than local, solutions to optical design problems. Global optimization is a much more difficult problem than local optimization. In the absence of an analytic solution, one never knows whether a global optimum has been achieved. All solution criteria must specify a region of interest and a time limit, and the method cannot depend on the starting point. The simulated annealing method described above is one area of continuing interest. Several methods for what might be called *pseudo-global* optimization have been used in commercial optical design programs, combining DLS with algorithms that allow the solution to move away from the current local minimum.

Computing Environment

Increasingly, optical design programs are used in conjunction with other software. Drawing programs, manufacturing inventory software, and intelligent databases are all relevant to optical design. While the conventional optical design program has been a *stand-alone* application, there is increasing demand for integrating optical design into more general design tasks.

3.7 BUYING OPTICAL DESIGN SOFTWARE

The complexity of the optical design process, together with the breadth of applications of optics, has created an ongoing market for commercial optical design software. For people new to optical design, however, the abundance of advertisements, feature lists, and even technical data sheets doesn't make purchasing decisions easy. The following commentary, adapted from an article, may be helpful in selecting an optical design program.[14] It considers five key factors: hardware, features, user interface, cost, and support.

Hardware

It used to be that the choice of an optical design program was governed by the computer hardware available to the designer. Of course, when the hardware cost was many times higher than the software cost, this made a great deal of sense. Today, however, the software often costs more than the hardware, and many programs can be run on several different computer platforms, so the choice of computer hardware is less important. The hardware currently used for optical design is principally IBM-PC compatible.

To run optical design software, the fastest computer that can be obtained easily is recommended. The iterative nature of optical design makes the process interminable. There is a rule, sometimes called the Hyde maxim, that states that an optical design is finished when the time or money runs out. Notwithstanding this, the speed of computers has ceased to be a significant impediment to ordinary optical design. Even low-cost computers now trace more than 1000 ray-surfaces/s, a speed considered the minimum for ordinary design work, and create the potential for solving new types of problems formerly beyond the range of optical design software.

Before desktop computers, optical design software was usually run on time-shared central computers accessed by terminals, and some programs are still in that mode. There seems to be general agreement, however, that the memory-mapped display found on PCs provide a superior working environment and dedicated desktop computer systems are currently most popular.

Features

If you need a particular feature to carry out your optical design task, then it is obviously important that your optical design program have that feature. But using the number of features as a way to select an optical design program is probably a mistake. There are more important factors, such as cost, ease of use, and scope. Moreover, you might assume that all the features listed for a program work simultaneously, which may not be true. For example, if a vendor states that its program handles holograms and toric surfaces, you might assume that you can work with holographic toroids, but this may not be true.

The continuing growth of optics and the power of desktop computers has put heavy demands on software vendors to keep up with the development of new technology. Moreover, since the customer base is small and most vendors now support the same computer hardware, the market has become highly competitive. These factors have led to a "feature" contest in which software suppliers vie to outdo each other. While this is generally good for the consumer, the introduction of a highly visible new feature can overshadow an equally important but less obvious improvement (for example, fewer bugs or better documentation). In addition, the presence of a number of extra features is no guarantee that the underlying program is structurally sound.

User Interface

There is very little in common between the user interfaces used by various optical design programs. Each seems to have its own personality. The older programs, originally designed to run in batch

mode on a large computer, are usually less interactive than ones that were written specifically for desktop computers. Batch programs tend to be built more around default actions than interactive programs, which require more user input. It would be hard to put any of today's major optical design programs in a box classified as either batch or interactive, but the look and feel of a program has a strong influence on its usefulness.

Many people don't realize that the most important benefit of using an optical design program is often the understanding that it provides the user about how a particular design works. It's often tempting to think that if the computer could just come up with a satisfactory solution, the design would be finished. In practice, it is important to know the trade-offs that are made during a design project. This is where the judgment of the optical engineer comes in, knowing whether to make changes in mechanical or electrical specifications to achieve the optimum balance in the overall system. Lens designers often say that the easiest lens to design is one that has to be diffraction-limited, because it is clear when to stop. If the question of how to fit the optics together with other system components is important, then the ability of the user to work interactively with the design program can be a big help.

Cost

In today's market, there is a wide range of prices for optical design software. This can be very confusing for the first-time buyer, who often can't see much difference in the specifications. The pricing of optical design software is influenced by (at least) three factors.

First, the range of tasks that can be carried out using an optical design program is enormous. The difference in complexity between the job of designing a singlet lens for a simple camera, and that of designing a contemporary objective for a microlithographic masking camera is somewhat akin to the difference between a firecracker and a hydrogen bomb.

Second, all software is governed by the factors originally studied in F. P. Brooks' famous essay *The Mythical Man-Month.*[15] Brooks was director of the group that developed the operating system for the IBM 360, a mainframe computer introduced in the 1960s. Despite its provocative title, Brooks' essay is a serious work that has become a standard reference for software developers. In it, he notes that if the task of developing a program to be used on a single computer by its author has a difficulty of 1, then the overall difficulty of producing integrated software written by a group of people and usable by anyone on a wide range of computers may be as high as 10. In recent years, the scope of the major optical design programs has grown too big for a single programmer to develop and maintain, which raises costs.

Third, there are structural differences in the way optical design software is sold. The original mainframe programs were rented, not sold. If the user did not want to continue monthly payments, the software had to be returned. PC programs, on the other hand, are usually sold with a one-time fee. In the optical design software business, several vendors offer a compromise policy, combining a permanent license with an optional ongoing support fee.

It would be nice if the buyer could feel comfortable that "you get what you pay for," but unfortunately this view is too simplistic. One program may lack essential capabilities, another may contain several unnecessary features when evaluated for a particular installation. Buying on the basis of cost, like features, is probably not a good idea.

Support

Support is an important aspect to consider in selecting an optical design program, and it is often difficult to know what is included in support. Minimal support consists of fixing outright bugs in the program. More commonly, support includes software updates and phone or email assistance in working around problems.

Optical design programs are typically not bug-free. Unlike simple programs like word processors, optimization programs cannot be fully tested, because they generate their own data. One result of this is that software vendors are generally reluctant to offer any warranty beyond a "best-effort"

attempt to fix reported problems. Unfortunately, there is no good way for buyers to know whether and when their particular problems may be fixed; the best approach is probably to assess the track record of the vendor by talking to other users.

Coupled with support is user training. Although it should be possible to use a program by studying the documentation, the major optical design software vendors offer regular seminars, often covering not only the mechanics of using their program, but also general instruction in optical design. For new users, this can be a valuable experience.

3.8 SUMMARY

As stated in the introduction, this chapter is intended as a survey for readers who are not regular users of optical design software. The form of an optical design program described here, consisting of lens entry, evaluation, and optimization sections, is used in many different programs. There has been little standardization in this field, so the "look and feel," performance features and extent of various programs are quite different. Nonetheless, it is hoped that with a knowledge of the basic features described here, the reader will be in a good position to judge whether an optical design program is of use, and to make an informed decision about whether one particular program is better than another.

4.1 GLOSSARY

ATF	approximate transfer factor
DTF	diffraction transfer function
MTF	modulation transfer function
W	wavefront error in units of wavelengths
W_{rms}	root-mean-square wavefront error
t-number	f-number adjusted for lens transmission
v	normalized spatial frequency

4.2 INTRODUCTION

Setting the specifications for an optical instrument or system is an essential part of engineering, designing, or purchasing an optical system. Since the optics usually serve as a portion of a larger system, the specifications are frequently set by project managers who do not have specific knowledge in the basics of optical systems. This can at times lead to unrealistic requirements being established; this can profoundly affect the probability of success for the system. Properly drafted specifications can make the entire project successful and cost effective. Poorly written specifications can lead to excess cost and ultimately project failure.

One of the difficulties with setting optical specifications is that the ultimate result of a beam of light passing through a complex assembly of components is affected by each of those components, which in turn need to be specified and tolerances placed upon the fabrication and assembly of those components. In the case of an imaging system, the problem is compounded by the need to describe an optical system which passes many bundles of light across a wide field of view. Even in the case of single beam, optical communications components, indirect issues such as scattered light and environmental stability may prove to be major issues.

*Retired.

In the worst case, the specifications may be set so high that the system is not capable of being manufactured. In most cases, the specifications interact with other devices, such as detector arrays, and matching the quality of the optic to the limits of the sensor is required. In this section some of the principles involved in setting the specifications will be discussed, and guidelines provided for carrying out the process of specification setting. The reader will have to extend these principles to the device or system that is being considered. In this chapter, the stress will be placed on imaging systems.

Specifications for optical systems cover a wide range of needs. Functional specifications of the image quality or other optical characteristics are required for the satisfactory operation of a system. These functional specifications serve as the goal for the design and construction of the optical system. In addition, these specifications are a basis for tolerances placed upon the components of the optical system and lead to detailed component specifications used for procurement of the optical elements of the system. Assembly specifications and detailed specifications of optical parts to be produced by a shop can be written based upon these component specifications. The detail and extent of information required is different at each step. Over- or underspecification can contribute significantly to the cost or feasibility of design of an optical system.

Functional specifications are also used to describe the characteristics that an instrument must demonstrate in order to meet the needs of the user. This may include top-level requirements such as size, weight, image scale, image format, power levels, spectral range, and so on. Component specifications are developed after design of the system and describe the optical components, surface, and materials used in the system to the detail necessary to permit fabrication of the components. Assembly specifications are another derivative of the design and system specifications. These include the statement of tolerances upon location of the components, as well as the procedure to be used in assembling and testing the system.

The development and writing of these specifications is important both for initiating and for tracking the course of development of an optical instrument. In a business or legal sense, specifications are used to establish responsibility for a contractor or subcontractor, as well as to define the basis for bidding on the job. Thus the technical specifications can have business importance as well as engineering significance. "Meeting the customer's specifications" is an essential part of any design and fabrication task. Identifying areas where the specifications could be altered with benefit to all parties is an important business and engineering responsibility.

Specifications are usually communicated as a written document following some logical format. Although there are some international standards that may cover the details of drawings of components, there is no established uniform set of standards for stating the specifications on a system or component. The detailed or component specifications are usually added as explanatory notes to drawings of the components to be fabricated. In modern production facilities, the specifications and tolerances are often part of a digital database that is accessed as part of the production of the components of the system.

The detail and the intent of each of these classes of specifications are different. Optical specifications differ from many mechanical or other sets of specifications in that numbers are applied to surfaces and dimensions that control the cumulative effect of errors imposed on a wavefront passing through the total system. Each of the specifications must be verifiable during fabrication, and the overall result must be testable after completion.

Mechanical versus Optical Specifications

There are two types of specifications that are applied to an optical system or assembly. One set of these includes mechanical tolerances on the shape or location of the components that indirectly affect the optical quality of the image produced by the system. Examples of this include the overall size or weight of the system. The other set consists of specialized descriptions that directly affect the image quality. Examples of this latter type of specification are modulation transfer function (MTF), illumination level, and location of the focal plane relative to the system.

System versus Components Specifications

Some specifications have meaning only with respect to the behavior of the entire optical system. Others apply to the individual components, but may affect the ability of the entire system to function.

An example of a system specification is a set of numbers limiting the range of acceptable values of the MTF that are required for the system. Another system specification is the desired total light transmission of the system.

Examples of component specifications are tolerances upon surface irregularity, sphericity, and scattering. The related component specification based upon the system light transmission specification might provide detailed statements about the nature and properties of the antireflective coatings to be applied to the surface of each element.

Image Specifications

The specifications that are applied to the image usually deal with image quality. Examples are modulation transfer function, fraction of scattered light, resolution, or distortion. In some cases, these specifications can be quite general, referring to the ability of the lens to deliver an image suitable for a given purpose, such as the identification of serial numbers on specific products that are to be read by an automated scanner. In other cases, the requirements will be given in a physically meaningful manner, such as "the MTF will be greater than 40 percent at 50 lines per millimeter throughout the field of view."

Other criteria may be used for the image specifications. One example is the energy concentration. This approach specifies the concentration of light from a point object on the image surface. For example, the specification might read "75 percent of the light shall fall within a 25-μm-diameter circle on the image." This quantity is obviously measurable by a photometer with appropriate-size apertures. The function may be computed from the design data by a method of numerical integration similar to that providing the point spread function or modulation transfer function.

Wavefront Specifications

Wavefront specifications describe the extent to which the wavefront leaving the lens or components conforms to the ideal or desired shape. Usually the true requirement for an optical system is the specification of image quality, such as MTF, but there is a relation between the image quality and the wavefront error introduced by the optical system. The wavefront error may be left to be derived from the functional image quality specification, or it may be defined by the intended user of the system.

For example, a wavefront leaving a lens would ideally conform to a sphere centered on the chosen focal location. The departure of the actual wavefront from this ideal, would be expressed either as a matrix or map of departure of the wavefront from the ideal sphere, as a set of functional forms representing the deviation, or as an average [usually root-mean-square (rms)] departure from the ideal surface. By convention, these departures are expressed in units of wavelength, although there is a growing tendency to use micrometers as the unit of measure.

The rms wavefront error is a specific average over the wavefront phase errors in the exit pupil. The basic definition is found by defining the nth power average of the wavefront $W(x, y)$ over the area A of the pupil and then specifically defining W_{rms} or, in words, the rms wavefront error is the square root of the mean square error minus the square of the mean wavefront error:

$$\bar{W}^n = \frac{1}{A}\int W(x,y)^n\,dx\,dy$$

$$W_{\text{rms}} = \sqrt{[\bar{W}^2] - [\bar{W}]^2}$$

The ability to conveniently obtain a complete specification of image quality by a single number describing the wavefront shape has proven to be questionable in many cases. Addition of a correlation

length, sometimes expressed as a phase difference between separated points, has become common. In other cases, the relative magnitude of the error when represented by various orders of Zernike polynomials is used.

There is, of course, a specific relationship between the wavefront error produced by a lens and the resulting image quality. In the lens, this is established by the process of diffraction image formation. In establishing specifications, the image quality can be determined by computation of the modulation transfer function from the known wavefront aberrations. This computation is quite detailed and, while rapidly done using present day computer techniques, is quite complex for general specification setting. An approximation which provides an average MTF or guide to acceptable values relating wavefront error and MTF is of great aid.

A perfect lens is one that produces a wavefront with no aberration, or zero rms wavefront error. By convention, any wavefront with less than 0.07 wave, rms, of aberration is considered to be essentially perfect. It is referred to as *diffraction-limited*, since the image produced by such a lens is deemed to be essentially indistinguishable from a perfect image.

The definition of image quality depends upon the intended application for the lens. In general, nearly perfect image quality is produced by lenses with wavefront errors of less than 0.15 wave, rms. Somewhat poorer image quality is found with lenses that have greater than about 0.15 wave of error. The vast majority of imaging systems operate with wavefront errors in the range of 0.1 to 0.25 wave, rms.

There are several different methods that can be used to establish this relationship. The most useful comparison is with the MTF for a lens with varying amounts of aberration. The larger the wavefront error, the lower will be the contrast at specific spatial frequencies. For rms error levels of less than 0.25 or so, the relation is generally monotonic. For larger aberrations, the MTF becomes rather complex, and the relation between rms wavefront error and MTF value can be multiple valued. Nevertheless, an approximate relation between MTF and rms wavefront error would be useful in setting reasonable specifications for a lens.

There are several possible approximate relations, but one useful one is the empirical formula relating root-mean-square wavefront error and MTF given by

$$\text{MTF}\ (\nu) = \text{DTF}\ (\nu) \times \text{ATF}\ (\nu)$$

The functional forms for these values are

$$\text{DTF}(\nu) = \frac{2}{\pi}[\arccos(\nu) - \nu\sqrt{1-\nu^2}\,]$$

$$\text{ATF}(\nu) = \left[1 - \left(\left(\frac{W_{\text{rms}}}{0.18}\right)^2\right)(1 - 4(\nu - 0.5)^2)\right]$$

$$\nu = \frac{\text{spatial frequency}}{\text{spatial frequency cutoff}} = \frac{N}{\left(\dfrac{1}{\lambda f\text{-number}}\right)}$$

These look quite complicated, but are relatively simple, as is shown in Fig. 1. This is an approximation, however, and it becomes progressively less accurate as the amount of the rms wavefront error W_{rms} exceeds about 0.18 wavelength. The approximation remains reasonably valid for lower spatial frequencies, less than about 25 percent of the diffraction limited cutoff frequency. The majority of imaging systems fall into this category.

Figure 1 shows a plot of several values for the MTF of an optical system using this approximate method of computation. The system designer can use this information to determine the appropriate level of residual rms wavefront error that will be acceptable for the system of interest. It is important to note that this is an empirical attempt to provide a link between the wavefront error and the

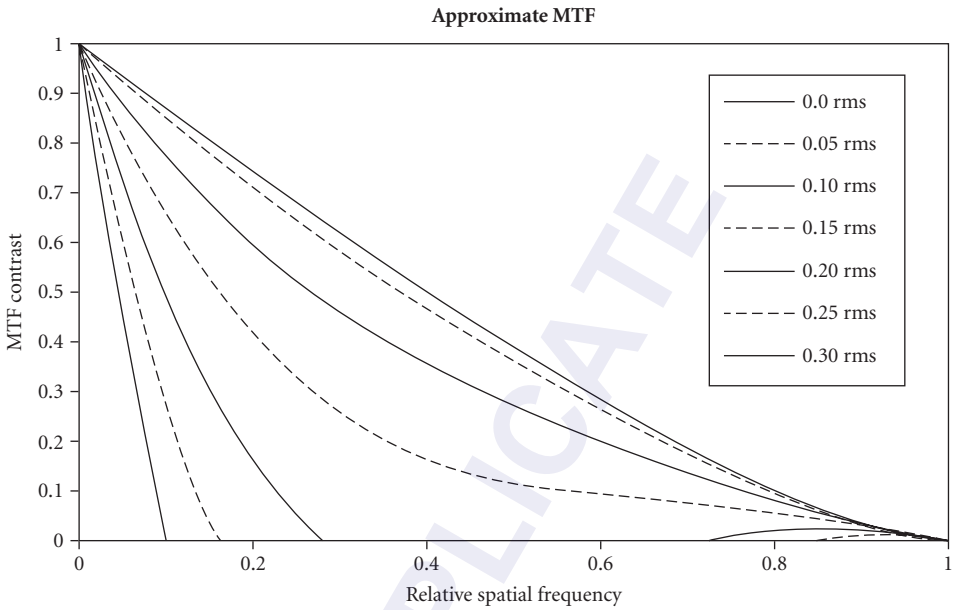

FIGURE 1 Approximate MTF curves from formula.

MTF as a single-value description of the state of correction of a system. Examination of the curves provides a method of communicating the specification to the system designer and fabricator. More detail on applying the rms wavefront error can be found in Chap.5, "Tolerancing Techniques."

In addition, it must be pointed out that most imaging systems operate over a finite wavelength range. Thus the specification of "wavefront error" can be a bit fuzzy, but is usually meant to mean either the wavefront error at a specified wavelength, or a weighted average over the wavelength band. This should be mentioned when writing the specifications. In either case, the stated wavefront error contains a measure that communicates the extent of perfection required of the optical system performance.

4.3 PREPARATION OF OPTICAL SPECIFICATIONS

Gaussian Parameters

The gaussian parameters determine the basic imaging properties of the lens. They are the starting point for setting the specifications for a lens system. In principle these numbers can be specified precisely as desired. In reality, overly tight specifications can greatly increase the cost of the lens. Some of the important parameters are shown in Table 1.

Table 1 is a sample of reasonable values that may be placed upon a lens. A specific case may vary from these nominal values. The image location, radiometry, and scale are fixed by these numbers. A specific application will require some adjustment of these nominal values. In general, specifications that are tighter than these values will likely result in increased cost and difficulty of manufacture.

There is an interaction between these numbers. For example, the tight specification of magnification and overall conjugate distance will require a very closely held specification upon the focal length. The interaction between these numbers should be considered by the user to avoid accidentally producing an undue difficulty for the fabricator. It may be appropriate to specify a looser tolerance on some of these quantities for the prototype lens, and later design a manufacturing process

TABLE 1 Gaussian Parameters

Parameter	Precision Target	Importance	How Verified
Focal length	1–2%	Determines focal position and image size	Lens bench
f-number	<±5%	Determines irradiance at image plane	Geometrical measurement
Field angle	<±2%	Determines extent of image	Lens bench
Magnification	<±2%	Determines overall conjugate distances	Trial setup of lens
Back focus	±5%	Image location	Lens bench
Wavelength range	As needed; set by detector and source	Describes spectral range covered by lens	Image measurement
Transmission	Usually specified as $>0.98^n$ for n surfaces	Total energy through lens	Imaging test, radiometric test of lens
Vignetting	Usually by requiring transmission to drop by less than 20% or so at the edge of the field	Uniformity of irradiance in the image	Imaging test, radiometric test of lens

to bring the production values within a smaller tolerance. However, it is appropriate that this be investigated fully at the design stage. The designer should be encouraged to consider the possibility of leaving adjustment possibilities in the lens design, so that a final assembly adjustment can bring the Gaussian parameters into the required tolerance range.

4.4 IMAGE SPECIFICATIONS

Image Quality

The rms wavefront error and the MTF for a lens have been discussed earlier as useful items to specify for a lens. Frequently, the user desires to apply a detection criterion to the image. This is always related to the application for the lens.

The most familiar functional specification that is widely used for system image quality is the resolution of the system. This is usually stated as the number of line pairs per millimeter that need to be visually distinguished or recognized by the user of the system. Since this involves both the physics of image formation as well as the psychophysics of vision, this is an interesting goal, but needs to be specified clearly to be of use to a designer. The reading of the resolution by a human observer is subjective, and the values obtained may differ between observers. Therefore, it is necessary to specify the conditions under which the test is to be carried out.

The type of target and its contrast need to be stated. The default standard in this case is the "standard" U.S. Air Force three-bar target, with high contrast, and a 6:1 ratio of bar length to width. This is usually selected as it will give the highest numerical values, certainly politically desirable. However, studies have shown that there is a better correlation between the resolution produced by a low-contrast target, say 2:1 contrast ratio, or 0.33 modulation contrast and the general acceptability of an image.

The resolution is, of course, related to the value of the MTF in the spatial frequency region of the resolution, as well as the threshold of detection or recognition for the observer viewing the target. If the thresholds are available, the above-described empirical relation between the rms wavefront error and the MTF can be used to estimate the allowable aberration that can be left in the system after design or fabrication.

In the case of a system not intended to produce an image to be viewed by a human, a specific definition of the required image contrast or energy concentration is usually possible. The signal-to-noise ratio of the data transmitted to some electronic device that is to make a decision can be calculated once a model for operation of the detector is assumed. The specification writer can then work backward through the required MTF to establish an acceptable level of image quality. The process is similar to that for the visual system above, except that the threshold is fully calculable.

In some cases, the fractional amount of energy collected by the aperture of the lens from a small angular source, such as a star, falling within the dimensions of a detector of a given size is desired. Such a requirement can be given directly to the designer.

Image Irradiance

The radiometry of the image is usually of importance. With an optical system containing the source, such as a viewer, projector, or printer, the usual specification is of the irradiance of the image in some appropriate units. Specifying the screen irradiance in watts per square centimeter or, more commonly, foot-lamberts, implies a number of optical properties. The radiance of the source, the transmission of the system, and the apertures of the lenses are derived from this requirement.

In the more usual imaging situation, the *f*-number and the transmission of the lens are specified. If the lens covers a reasonable field, the allowable reduction in image irradiance over the field of view must also be specified. This leads directly to the level of vignetting that can be allowed by the designer in carrying out the setup and design of the lens system.

There is an interaction between these irradiance specifications and the image quality that can be obtained. The requirement of a large numerical aperture leads to a more difficult design problem, as the high-order aberration content is increased in lenses of high numerical aperture.

An attempt to separate the geometrical aperture effects from the transmission of the components of the lens is accomplished through the *t*-number specification. Since the relative amount of irradiance falling on the focal plane is inversely proportional to the square of the *f*-number of a lens, the effect of tranmission of the lens can be included by dividing the *f*-number by the transmission of the lens.

$$t\text{-number} = \frac{f\text{-number}}{\sqrt{t}}$$

where t is the transmission factor for the lens. The transmission factor for the lens is the product of the bulk transmission of the glass and the transmission factor for each of the surfaces. When this is specified, the designer must provide a combination of lens transmission and relative aperture that meets or exceeds a stated value.

Depth of Focus

The definition of the depth of focus is usually the result of a tolerance investigation. The allowable focal depth is obtained by determining when an unacceptable level of image quality is obtained. There is an obvious relation between the geometry of the lens numerical aperture and the aberrations that establishes the change of MTF with focal position. This effect can be computed for specific cases, or estimated by recognizing that the relation between rms wavefront error and focus shift is

$$W_{\text{rms}_{\text{def}}} = \frac{\delta l}{8\lambda(f\text{-number})^2}$$

which can be used in the above approximate MTF to provide an estimate of the likely MTF over a focal range.

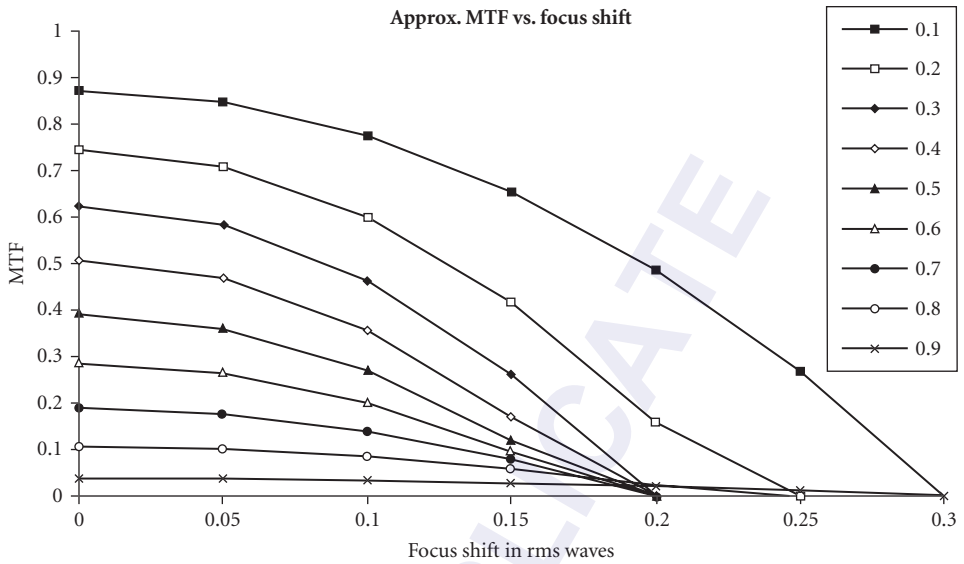

FIGURE 2 Approximate MTF as a function of focal position for various spatial frequencies.

If there is a basic amount of aberration present in the lens, then the approximation is that

$$W_{\text{rms}_{\text{total}}} = \sqrt{W^2_{\text{rms}_{\text{def}}} + W^2_{\text{rms}_{\text{lens}}}}$$

leading to a calculation of the estimated MTF value for the given spatial frequency and focal position. As an example, Fig. 2 provides a plot of the focal position change of the MTF. The interpretation of this curve is straightforward. Each of the curves provides the MTF versus focus for a spatial frequency that is the stated fraction of the cutoff spatial frequency. The defocus is given in units of rms wavelength error, which can be obtained from reference to the appropriate formula. Using this approximate data, a specification writer can determine whether the requirements for image quality, *f*-number, and focal depth are realistic.

An additional consideration regarding depth of focus is that the field of the lens must be considered. The approximate model presented here is used at an individual field point. An actual lens must show the expected depth of field across the entire image surface, which places some limits upon the allowable field curvature. In general, it is the responsibility of the specification writer to establish the goal. It is the responsibility of the optical designer to determine whether the goal is realizable, and to design a system to meet the needs. In a sensible project, there will be some discussion between the designer and the engineer writing the specifications in order to avoid an unrealizable set of goals being set.

4.5 ELEMENT DESCRIPTION

Each element of the lens to be fabricated must be described in detail, usually through a drawing. All of the dimensions will require tolerances, or plus and minus values that, if met, lead to a high probability that the specified image quality goals will be met.

Mechanical Dimensions

The mechanical dimensions are specified to ensure that the element will fit into the cell sufficiently closely that the lens elements are held in alignment. This will be a result of tolerance evaluation, and must include allowances for assembly, thermal changes, and so on.

An important item for any lens is the interface specification, which describes the method of mounting the lens to the optical device used with it. For some items, such as cameras and microscopes, there are standard sizes and screw threads that should be used. In other cases, the specification needs to describe a method for coupling or mounting the optics in which there is a strain-free transfer of load between the lens and the mounting.

Optical Parameters

The optical parameters of the lens element relate to the surfaces that are part of the image-forming process. The radius of curvature of the spherical refracting (or reflecting) surfaces needs to be specified, as well as a plus or minus value providing the allowable tolerances. When tested using a test glass or an interferometer, the important radius specification is usually expressed in terms of fringes of spherical departure from the nominal radius. In addition, the shape of the surface is usually specified in terms of the fringes of irregularity that may be permitted.

When specifying a surface that will be measured on an interferometer, adjustment of focus during the test can be made. In this case, the spherical component of the surface, that is, the fringes of radius error, can be specified independently of the irregularity fringes that are applicable to the surface. When test glasses are to be used, the spherical component must be fabricated to within a small level of error to permit accurate reading of the irregularity component of the surface.

The cosmetic characteristics of the surface also need to be stated. The specification for this is as yet a bit imperfect, with the use of a scratch-and-dig number. This is actually intended to be a comparison of surface scratches with a visual standard, but is generally accepted to be in terms of a ratio, such as 20:10, which means, more or less, scratches of less than 2-μm width and digs of less than 100-μm diameter. This specification is described in MIL-O-13830, and is referred to a set of standards that are used for visual comparison to the defects on the surface. There have been several attempts to quantify this specification in detail, but no generally accepted standard has yet been achieved. A broader description of these specifications is found in International Standards 10110 and 9211, discussed later in this chapter.

Material Specifications

The usual material for a lens is optical glass, although plastics are becoming more commonly used in optics. The specification of a material requires identification of the type, as, for example, BK7 glass from Schott. Additional data upon the homogeneity class and the birefringence needs to be stated in ordering the glass. The homogeneity is usually specified by class, currently P1 through P4 with the higher number representing the highest homogeneity, or lowest variation of index of refraction throughout the glass. The method of specifying glass varies with the manufacturer, and with the catalog date. It is necessary to refer to a current catalog to ensure that the correct specification is being used.

Similar data should be provided regarding plastics. Additional data about transmission is usually not necessary, as the type of material is selected from a catalog which provides the physical description of the material. Usually, the manufacturer of the plastic will be noted to ensure that the proper material is obtained.

Materials for reflective components similarly have catalog data describing the class and properties of the material. In specifying such materials, it is usually necessary to add a description of the form and the final shape required for the blank from which the components will be made.

Coating Specifications

The thin film coatings that are applied to the optical surfaces require some careful specification writing. In general, the spectral characteristics need to be spelled out, such as passband and maximum reflectivity for an antireflection coating. Requirements for the environmental stability also need to be described, with reference to tests for film adhesion and durability. Generally, the coating supplier will have a set of "in-house" specifications that will guarantee a specific result that can be used as the basis for the coating specification.

4.6 ENVIRONMENTAL SPECIFICATIONS

Temperature and Humidity

Specification setting should also include a description of the temperature range that will be experienced in use or storage. This greatly affects the choice of materials that can be used. The humidity and such militarily favorite specifications as salt spray tests are very important in material selection and design.

Shock and Vibration

The ruggedness of an instrument is determined by the extent to which it survives bad handling. A requirement that the lens shall survive some specified drop test can be used. In other cases, stating the audio frequency power spectrum that is likely to be encountered by the lens is a method of specifying ruggedness in environments such as spacecraft and aircraft. In most cases, the delivery and storage environment is far more stressing than the usage environment. Any specification written in this respect should be careful to state the limits under which the instrument is actually supposed to operate, and the range over which it is merely meant to survive storage.

4.7 PRESENTATION OF SPECIFICATIONS

Published Standards

There are published standards from various sources. The most frequently referred to are those from the U.S. Department of Defense, but a number of standards are being proposed by the International Standards Organization.

Format for Specifications

The format used in conveying specifications for an optical system is sometimes constrained by the governmental or industrial policy of the purchaser. Most often, there is no specific format for expressing the specifications.

The best approach is to precede the specifications with a brief statement as to the goals for the use of the instrument being specified. Following this, the most important optical parameters, such as focal length, *f*-number, and field size (object and image) should be stated. In some cases, magnification and overall object-to-image distance along with object dimension will be the defining quantities.

Following this, the wavelength range, detector specifications, and a statement regarding the required image quality should be given. The transmission of the lens is also important at this stage.

Following the optical specifications, the mechanical and environmental requirements should be stated. The temperature and humidity relations under which the optical system needs to operate as

well as a statement of storage environment are needed. Descriptions of the mechanical environment, such as shock and vibration, are also important, even if expressed generally.

Other important pieces of information, such as a desired cost target, can then be included. Any special conditions, such as the need to be exposed to rapid temperature changes or a radiation environment, should be clearly stated. Finally, some statement of the finish quality for the optical system should be given.

In many cases, a list of applicable governmental specifications will be listed. In each case it is appropriate to ensure that these referenced documents are actually available to the individual who has to respond to the specification.

Use of International Standards

An important tool in writing specifications is the ability to refer to an established set of standards that may be applicable to the system being designed. In some cases, the development of specifications is simplified by the specification writer being able to refer to a set of codified statements about the environment or other characteristics the system must meet. In other cases, the established standards can be used as a reference to interpret parts of the specifications being written. For example, there may be a set of standards regarding interpretation of items included in a drawing.

Standards are an aid, not an end to specification. If the instrument must be interchangeable with parts from other sources, then the standards must be adhered to carefully. In other cases, the standards can serve as an indicator of accepted good practice in design or fabrication. It is the responsibility of the specification writer to ensure that the standard is applicable and meaningful in any particular situation.

At the present time there is growing activity in the preparation of standards for drawings, interfaces and dimensions, MTF, and other properties of optical and electro-optical systems. The efforts in this direction are coordinated by the International Standards Organization, but there are a number of individual standards published by national standards organizations in Germany, England, Japan, and the United States. The first major publications are ISO 10110, detailing preparation of drawings for optical elements and systems and ISO 9211, on optical coatings. Other standards on optical testing and environmental requirements are in draft form.

The ISO standards are expected to provide significant detail on various standards issues, and should become the principal guiding documents. At present, the standards documents that are most used in the United States are the various military specifications, or MIL-SPEC documents, that cover many different aspects of optical systems.

Information on published standards is available from the American National Standards Institute (ANSI), 11 West 42d Street, New York, NY 11036, or may be downloaded at *www.webstore.ansi.org*. A recent (2008) review of this website showed over 350 individual documents dealing with these issues, the majority of which deal with issues regarding fiber optical systems. Information on U.S. Department of Defense standards can be searched for through the National Search Engine for Standards at *www.nssn.org*. Additional information about worldwide standards is available at *www.worldwidestandards.com*.

4.8 PROBLEMS WITH SPECIFICATION WRITING

Underspecification

Failure to specify all of the conditions leaves the user vulnerable to having an instrument that will not operate properly in the real world. In many cases, the designer may not be aware of situations that may arise in operation that may affect the proper choice of design methods. Therefore, the design may not meet the actual needs.

The engineer developing a specification should examine all aspects of the problem to be solved, and carefully set the boundaries for the requirements on an optical system to meet the needs. All of

the pertinent information about the image quality, environment, and relation to other systems that may interact with the lens being specified should be considered. The specifying engineer should also review the physical limits on the image quality and ensure that these are translated into realistic values.

Overspecification

Specifying image quality and focal position requirements too tightly can lead to problems. Overspecification would seem to ensure that the needs will be met, but difficulties in meeting these requirements can lead to designs that are difficult and expensive to build. Achieving the goals can be costly and may fail. In such cases, the penalty for not quite meeting very tight specifications can be serious, both economically and technically.

Boundary-Limit Specification

In most cases, the statement of goals or boundaries within which a lens must operate is better than stating specific values. This leaves the designer with some room to maneuver to find an economic solution to the design. Obviously, some fixed values are needed, such as focal length, *f*-number, and field angle. However, too-tight specifications upon such items as weight, space, and materials can force the design engineer into a corner where a less desirable solution is achieved.

Negotiation of Specifications

Finally it is important to note that unless there is an existing closely defined set of established specifications for an specific optical device (such as a fiber optics coupler, for example) each specification is the product of a single individual or group and reflects the experience and understanding of that individual. The procuring official should be prepared in some cases to act as a negotiator between the engineer and the supplier to ensure that a reasonable and successful set of verifiable specifications has been stated.

4.9 REFERENCES

There are many useful references on optical specifications that deal with specific topics not directly covered by the general discussion in this chapter. The most useful suggestion is that the users having the task of setting specifications on a specific product or system use the massive capabilities of Internet search engines to look for specific data applicable to that task. A general Google search on "Optical Specifications" provided 360,000 hits, of which probably less than 10 will be applicable to any specific problem.

TOLERANCING TECHNIQUES

Robert R. Shannon*

College of Optical Sciences
University of Arizona
Tucson, Arizona

5.1 GLOSSARY

a	relative tolerance error
BK7, SF2	types of optical glass
C to F	spectral region 0.486 to 0.656 μm
f-number	relative aperture as in $F/2.8$
n	refractive index
$r1$, $r2$, $r3$, $r4$	radii of curvature of surfaces
$t2$	airspace thickness in sample lens
V	Abbe number or reciprocal dispersion
W	wavefront or pupil function
x	change factor
Δ	finite change in a parameter
δ	small change in a parameter
λ	wavelength

5.2 INTRODUCTION

Determination of the tolerances on an optical system is one of the most important parts of carrying out an optical design. No component can be made perfectly; thus, stating a reasonable acceptable range for the dimensions or characteristics is important to ensure that an economical, functioning instrument results. The tolerances attached to the dimensions describing the parts of the lens system are an important communication by the designer to the fabrication shop of the precision required in making the components and assembling them into a final lens.

*Retired.

The tolerances are related to but are not the same as the specifications. Setting specifications is discussed in Chap. 4. The tolerances are responsive to the requested system specifications and are intended to ensure that the final, assembled instrument meets the requested performance. The specifications placed on the individual lens elements or components are derived from the tolerances. Thus there is an interactive relation between the tolerancing activity and the setting of specifications. The system specifications drive the tolerances that need to be determined, and the tolerances are used in setting the specifications for the components of the system. The reality is that neither of these processes can be done fully independently.

At this point it is important to note that most optical design programs include a tolerancing utility that can be used to generate and distribute tolerances automatically once a few questions about goals have been answered by the designer. This appears to be a seductively simple process that is usually quite useful, but can be very disastrous if used uncritically by anyone who does not understand the basics of the process being carried out.

There are three principal issues in optical tolerancing. The first is the setting of an appropriate goal for the image quality or transmitted wavefront to be expected from the system. The second is the translation of this goal into allowable changes introduced by errors occurring on each component of the system. The third is the distribution of these allowable errors against all of the components of the system, in which some components of the optical system may partially or completely compensate for errors introduced by other components.

In this chapter, some basic approaches to distributing tolerances within an optical assembly are discussed. The examples will deal with tolerancing to meet a specified wave-front error and level of image quality. Similar principles apply to nonimaging optical systems, once the procedures necessary for relating errors in components or alignment to the specified operating requirements are established. The user will obviously have to adapt these approaches to the specific system being toleranced.

Optical versus Mechanical Tolerances

The tolerances on mechanical parts, in which a dimension may be stated as a specific value, plus or minus some allowable error, are familiar to any engineer. For example, the diameter of a rotating shaft may be expressed as 20.00 mm + 0.01/−0.02 mm. This dimension ensures that the shaft will fit into another component, such as the inner part of a bearing, and that fabricating the shaft to within the specified range will ensure that proper operational fit occurs. These tolerances may include the effect of environmental effects, such as operating temperature or lubrication needs, on the mechanical assembly.

Optical tolerances are more complicated, as they are generally stated as a mechanical error in a dimension, but the allowable error is determined by the effect upon an entire set of wavefronts passing through the lens. For example, the radius of curvature of a surface may be specified as 27.00 mm ± 0.05 mm. The interpretation of this is that the shape of the optical surface should conform to a specific spherical form, but remain within a range of allowable curvatures. Meeting this criterion indicates that the surface will perform properly in producing a focused wavefront, along with other surfaces in the optical system. Verification that the specific component tolerance is met is usually carried out by an optical test, such as examining the fit to a test plate. Verification that the entire system operates properly is accomplished by an assembled system test in which a specified image quality criterion is measured.

Basis for Tolerances

The process involved in setting tolerances begins with setting of the minimum level of acceptable image quality. This is usually expressed as the desired level of contrast at a specific spatial frequency as expressed by the modulation transfer function. Each parameter of the system, such as a radius of curvature of a surface, is individually varied to determine how large an error in each component is allowed before the contrast is reduced to the specified level. This differential change is then used to set the allowable range of error in each component.

In most cases, direct computation of the change in the contrast is a lengthy procedure, so that a more direct function, such as the rms wavefront error, is used as the quality-defining criterion. In other cases, the quantity of importance will be the focal length, image position, or distortion.

In nonimaging systems, the beam divergence or the uniformity of illumination after passage through the system may be the criterion of interest.

Relating the computed individual errors in the system to the tolerances to be specified is not always a simple matter. If there are several components, some errors may compensate other errors. Thus, it would be easy to assign too tight a tolerance for each surface unless these compensating effects, as well as the probability of a specific distribution of errors, are used in assigning the final tolerances.

Tolerance Budgeting

The method of incorporating compensation of one error by another, as well as the likelihood of obtaining a certain level of error in a defined fabrication process, is called *tolerance budgeting.* As an example, in a lens system it may be found that maintaining the thickness of a component may be easier than keeping the surfaces of the component at the right spherical form. The designer may choose to allow a looser tolerance for the thickness and use some of the distributed error to tighten the tolerance on the radius of curvature. In other cases, the shop carrying out the fabrication may be known to be able to measure surfaces well, but has difficulty with the centering of the lenses. The designer may choose to trade a tight tolerance on the irregularity of the surfaces for a looser tolerance on the wedge in the lens components.

Finally, the effect of a plus error on one surface may be partially compensated by a minus error on another surface. If the probability of errors is considered, the designer may choose to budget a looser tolerance to both surfaces.

This budgeting of tolerances is one of the most difficult parts of a tolerancing process, since judgment, rather than hard numbers, is very much a part of the budget decisions. It is advisable for the engineer carrying out the tolerance budgeting to do some modeling of the system performance using trial sets of parameter variations based on the tolerances that have been obtained. This verification serves as a method if ensuring that the tolerances are indeed reasonable and justified.

Tolerance Verification

Simply stating a set of allowable errors does not complete the integrated process of design and fabrication. The errors must be measurable. Measurement of length can be gauged, but has to be within the capabilities of the shop fabricating the optics. Measurement of error in radius of curvature requires the use of an interferometer or test plates to determine the shape of the surface. Measurement of the nonspherical component of the surface, or the irregularity, requires either an estimate from the test plate, or a computation of the lack of fit to a spherical surface based on measured fringes.

Finally, the quality of a completed lens must be measurable. Use of a criterion that cannot be measured or controlled by the shop or by the user is not acceptable. The contrast mentioned is not always measurable by the optical shop. The surface errors as measured by an interferometer or by test plates are common.

As shown in the Chap. 4 on specifications, the average or rms wavefront error can be related to the level of contrast, or modulation transfer function (MTF), that can be expected in the image. In addition, measurement of the final wavefront from an assembled optical system is most frequently obtained by an optical shop in a summary method by using an interferometer. For this reason, wavefront tolerancing methods have become the most commonly used methods of defining and verifying tolerances.

5.3 WAVEFRONT TOLERANCES

The rms wavefront error tolerancing method will now be used as an example of the approach to evaluating the tolerances required to fabricate a lens. An example which discusses the axial image tolerances for a doublet will be used to provide insight into the tolerancing of a relatively simple system. Most optical tolerancing problems are far more complex, but this example provides an insight into the methods applied. The specific example selected for this chapter is an airspaced achromatic

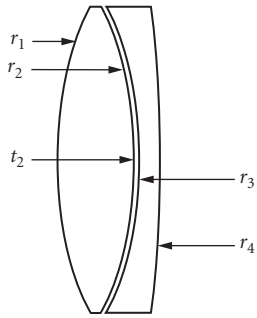

FIGURE 1 Drawing of the doublet lens used for tolerancing.

doublet using BK7 and SF2 glasses, *F*/2.8, 100-mm focal length. The lens design is nominally of moderately good quality, and is optimized over the usual *C* to *F* spectral range, with balanced spherical aberration, and is corrected for coma.

Figure 1 is a drawing of the sample doublet used in this chapter. The locations of the four radii of curvature and the airspace to be toleranced are indicated. The number of possible errors that actually can occur in such a simple lens is surprisingly large. There are four curvatures, two thicknesses, one airspace, and two materials that may have refractive index or dispersion errors. In addition to these seven quantities, there are two element wedge angles, four possible tilts, and four decenter possibilities, plus the irregularity on four surfaces and the homogeneity of two materials. So far, there are 21 possible tolerances that are required in order to completely define the lens. For interfacing to the lens mount, the element diameters, roundness after edging, and cone angle on the edges must be considered as well. More complex systems have far more possible sources of error. For the example here, only the four radii and the airspace separation will be considered.

Parameter Error Quality Definitions

The starting point for a tolerance calculation is the definition of a set of levels that may be used to define the initial allowable range of variation of the parameters in the lens. The magnitude of these classes of errors is determined by experience, and usually depends upon the type of fabrication facility being used. Table 1 presents some realistic values for different levels of shop capability.

These values are based on the type of work that can be expected from different shops, and serves as a guide for initiating the tolerancing process. It is obvious that the degree of difficulty in meeting the quality goals becomes more expensive as the required image quality increases.

Computation of Individual Tolerances

The individual tolerances to be applied to the parameters are obtained by computing the effect of some arbitrary but reasonable parameter changes upon the image-quality function. For the example doublet, if made perfectly with no errors in the individual components or assembly, the nominal amount of rms wavefront error at the central wavelength is 0.116 waves, rms. It is determined by the user from consideration of the needs for the application that the maximum amount of error that is acceptable is 0.15 waves, rms. Thus a distribution in allowable errors that results in no greater than about a 0.15 wavelength rms wavefront error would produce an acceptable system. The tolerancing task is to specify the tolerances on the radii of curvature and the separation between the component surfaces such that the goal is met.

TABLE 1 Reasonable Starting Points for Tolerancing a Lens System

Parameter	Commercial	Precision	High Precision
Wavefront residual	0.25 wave rms	0.1 wave rms	<0.07 wave rms
	2-wave peak	0.5 wave peak	<0.25 wave peak
Thickness	0.1 mm	0.01 mm	0.001 mm
Radius	1.0%	0.1%	0.01%
Index	0.001	0.0001	0.00001
V-number	1.0%	0.1%	0.01%
Homogeneity	0.0001	0.00001	0.000002
Decenter	0.1 mm	0.01 mm	0.001 mm
Tilt	1 arc min	10 arc sec	1 arc sec
Sphericity	2 rings	1 ring	0.25 ring
Irregularity	1 ring	0.25 ring	<0.1 ring

The reason for the choice of 0.15 wave rms is indicated by Fig. 2. The designer experimented with several choices of focus position to obtain a set of plots of the MTF for different amounts of error. This is not a completely general conclusion since the source of error produces an rms error which may not be the same for every source of error. But the samples permit the intelligent selection of an upper bound to the required error. In a lens with more sources of error, and with larger amounts of aberration in the basic design, setting up an example such as this is extremely important to avoid an error in the goal for the final image quality.

The first computation of the effect of nominal changes in the parameters on the rms wavefront error leads to the results in Table 2. (Only the radii and thickness are considered for this example.) The two columns for rms wavefront effect are first, for the aberration if no adjustment for best focus is made, and second, permitting the establishment of best focus after assembly of the lens.

Table 2 shows that the effect of a change in the parameter will have an effect proportional to the change, but that the factor relating the change to the resulting wavefront error is different for the various parameters. The amount of change permitted if the parameter is not compensated by allowing an adjustment for best focus is quite small. Any one of the parameters would have to be maintained within a range far less than the delta used in computation. The allowance of a compensating focal shift does greatly loosen the tolerance.

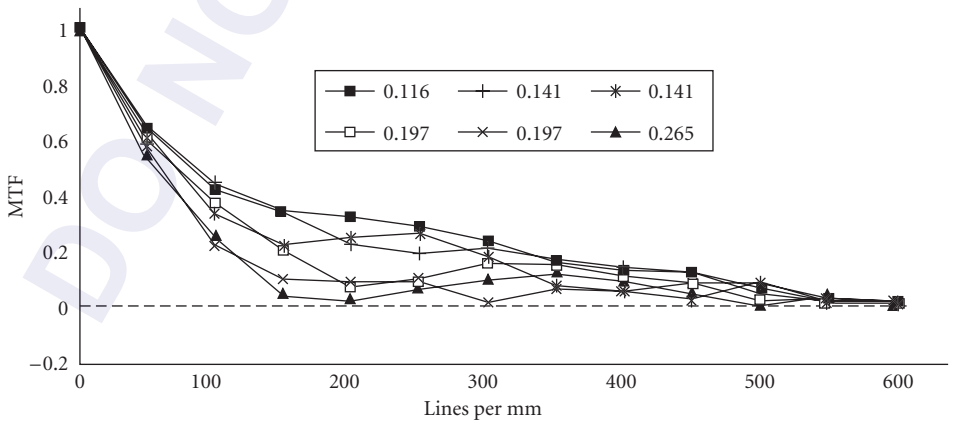

FIGURE 2 Some examples of the effect of various rms errors on the MTF of the sample doublet. (The rms error is stated in wavelengths.)

TABLE 2 Finite Differentials for Computing Tolerances

Parameter	Delta	Rms Uncompensated	Rms Compensated
*r*1	0.1%	0.740	0.117
*r*2	0.1%	1.187	0.171
*r*3	0.1%	1.456	0.157
*r*4	0.1%	0.346	0.110
*t*2	0.025 mm	1.155	0.152

Since the acceptable goal is 0.15 waves, rms, the amount of change of an individual parameter to attain the acceptable level is about 50 times that of *r*1 and *r*4, but the change of 0.1 percent would be excessive for *r*2 and *r*3. The allowable change for *t*2 alone would be just about the delta of 0.025 mm.

Combination of Tolerances

No parameter in a lens lives alone. The effect upon the image will be the result of combining the effect of all of the errors. If the errors are uncorrelated, then the usual statistical summing of errors can be used. This states that the total amount of aberration produced by the errors can be found by using

$$W_{\text{rms}} = \sqrt{\sum_i W_i^2} = \sqrt{\sum_i \left(a_i x_i \frac{\partial W_{\text{rms}}}{\partial x_i} \right)^2}$$

where the sum is taken over the *i* parameters of interest. The *x* factors are the amount of change used in computing the change of wavefront error and the *a* factors are the relative amount of tolerance error allotted to each parameter in units of the delta used in the computation.

There are implicit assumptions in the application of this method to distributing tolerances. The principal assumption is that the fabrication errors will follow normal gaussian statistics. For many fabrication processes, this is not true, and modification of the approach is required.

For the example of the doublet, Table 3 can be generated to evaluate the different possibilities in assigning tolerances. The allowable change in rms wavefront error is 0.033 waves; thus the root sum square of all of the contributors must not exceed that amount.

In Table 3 the first column identifies the parameter, the second states the delta used in the computation, the third states the amount of wavefront error caused by a delta amount. The final two columns show different budgeting of the allowable error. Distribution 1 loosens the outer radii and the thickness at the cost of maintaining the inner radii very tightly. Distribution 2 tightens the outer radii and spacing tolerances, but loosens the inner radii tolerances. Depending upon the capabilities of the shop selected to make the optics, one of these may be preferable.

The interpretation of these statistical summations is that they are the sum of a number of different random processes. Thus, if the interpretation of each of the values given is the width of a normal distribution, which implies that 67 percent of the samples lie within that value, then 67 percent of the resulting combinations will lie within that range. If the interpretation is a two- or three-sigma value, the interpretation of the result follows similarly.

TABLE 3 Two Possible Tolerance Distributions for the Doublet

Parameter	Delta	Coefficient	Distbn. 1	Distbn. 2
*r*1	0.1%	0.00071	10.0	0.1
*r*2	0.1%	0.05440	0.25	0.4
*r*3	0.1%	0.04069	0.25	0.4
*r*4	0.1%	0.00069	10.0	0.1
*t*2	0.025 mm	0.03589	0.75	0.5
		rms change	0.033	0.033

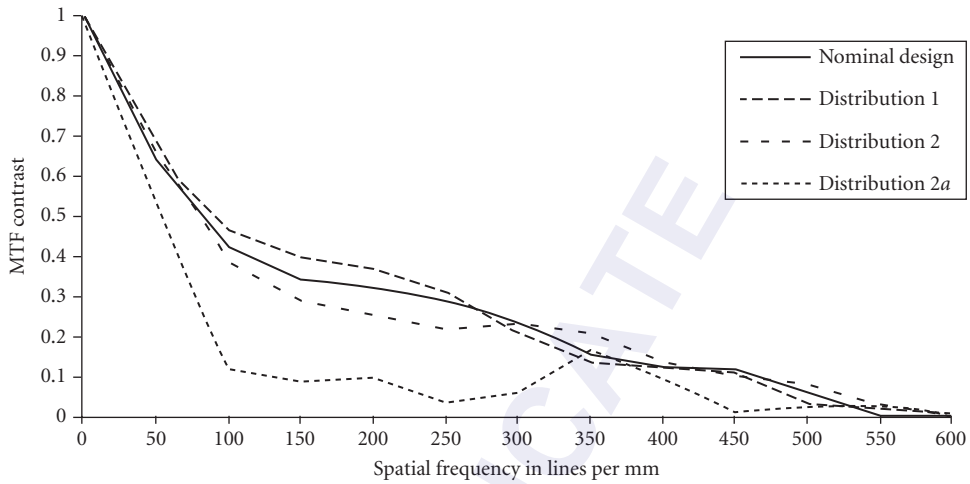

FIGURE 3 The resulting effect of different tolerance budgets for the sample doublet.

Figure 3 shows the effect of the various choices of allowable error distribution on the modulation transfer function of the lens. Either of the distributions stated in Table 3 provides an acceptable lens. For comparison, the allowable tolerances were doubled to provide distribution 2*a*, which is clearly not an acceptable lens. A spot check of some sample distributions is always relevant when doing tolerancing just to ensure that a reasonable relation between the toleranced system and acceptable image quality exists.

In any manufacturing process, the individual statistics will not necessarily follow a random rule. The interpretation is somewhat modified, but the principle still remains. In some cases, parameters may not be independent. For example, in the doublet there is a linking between the values of *r*2 and *r*3 that would loosen the tolerances if both are in error in the same direction. This could be used to advantage if the manufacturing process is carefully defined.

Use of Compensators

The use of compensators to loosen the tolerances was indicated above. An example of compensation for aberrations can be seen from a single lens element. If the first curvature is varied, both the element power and the spherical aberration from the element will change. However, a specific change of the second radius can restore the focal position and reduce the change of spherical aberration. Thus the tolerance allowed to the first curvature needs to take into account the possibility of a correlated or deliberate change in the second curvature. It is evident that the proper use of compensators can greatly loosen the tolerances applied to a surface.

A compensation that is frequently employed is the establishment of the correct focal position after assembly of the lens. If this procedure is followed, the individual tolerances on the surface of the elements can be loosened. It is obvious that the tolerancing and the development of a plan for fabrication and assembly must be coordinated.

5.4 OTHER TOLERANCES

Often, a particular optical parameter for the lens must be specified and maintained. Sometimes, for example, the focal length or back focus must be obtained within some tolerance. The computation of these paraxial constants for the lens can be made in the usual manner, and tolerances

obtained by using differentials relating each of the parameters to the quantity, such as the focal length, and then distributing the tolerances in a manner similar to that shown above for the doublet in Table 3.

Boresight

The pointing direction, or boresight, for a lens is sometimes of interest. Errors in boresight are usually due to asymmetric fabrication or mounting errors for the lens. In the simplest manner, one needs simply to trace an axial ray through the lens, and evaluate the direction of this ray as a result of introducing tilts and decenters of the surfaces, or of entire components. Tolerances on the lens parameters can be obtained by the procedure described for the doublet above, substituting the boresight error for the wavefront error.

Distortion

Distortion is the failure of the lens to provide a constant mapping from object space to image space. There are alternate interpretations for this error, which can have radial components due to symmetric errors in the lens, as well as tangential components from tilt and decenter of the lens components. This can be toleranced in the usual manner, but may be related to some general properties of the lens, such as the overall glass thickness of the components. In the simplest case, the tolerances upon distortion may be obtained from direct aberration computation. In complex cases, it may be necessary to compute the actual location of the centroid of the image as a function of image position and in the best image location.

Assembly

Assembly tolerances are related to the tolerances on image quality. The elements must be located and held in position so that the resulting image-quality goals are met. There are additional questions of allowing sufficient clearance between the elements and the lens barrel so that the elements can be inserted into the barrel without breaking or being strained by the mountings. These must be considered in stating the allowable dimensional range in the diameter, wedge, and concentricity of the edge of the lens.

5.5 STARTING POINTS

Shop Practice

Table 3, given as part of the sample tolerancing of the doublet, provides some estimates of the accuracies to which an optical shop may operate. These generic levels of error convey what is likely to be possible. The designer carrying out a tolerance evaluation should consult with probable fabrication shops for modification to this table. The tolerances that are ultimately assigned relate errors in the system to acceptable errors in the image. However, an understanding of shop practice is of great assistance in intelligent budgeting of tolerances.

Measurement Practice

Contemporary practice in optical fabrication and testing is to use interferometry to define wavefronts and surfaces. A convention that has become common in recent years is the use of polynomials

fitted to the wavefront as a method of describing the wavefront. There are several representations used, the most frequent of which is a limited set of Zernike polynomials. These ideally serve as an orthonormal set describing the wavefront or surface up to a specific order or symmetry. In tolerancing, the principal use for the coefficients of the Zernike set has been the easy computation of the rms wavefront error fitted to a given order. Thus the residual error in the system can be described after removal of low-order error such as focus or coma, which can sometimes be attributed to properties of the test setup.

5.6 MATERIAL PROPERTIES

The most important material is optical glass. Specification of the material usually includes some expected level of error in index of refraction or dispersion. In addition, glass is offered having several different levels of homogeneity of index of refraction. The usual range allows for grades of glass having index of refraction inhomogeneity ranging from ±0.00001 to less than ±0.0000001 within a single glass blank. It is usually assumed that this variation will be random, but the process of glass manufacturing does not guarantee this.

To place a tolerance upon the required glass homogeneity variation, the concept of wavefront tolerancing can be used. In general, the amount of wavefront error that can be expected along a glass path of length t through the glass is

$$\delta W = \frac{\delta N \times t}{\lambda}$$

For example, if a lens has a glass path of 5 cm but an error of 0.01 wavelengths is assigned to glass homogeneity, then the allowable glass homogeneity is about 0.00000013 within the glass. Thus precision-quality glass is needed for this application. For less glass path or looser tolerance assignment to glass homogeneity error, the required glass precision can be loosened. For a prism, the light path may be folded within the glass, so that an effective longer glass path occurs.

5.7 TOLERANCING PROCEDURES

The example of the doublet serves to illustrate the basic principles involved in determining the tolerances on a lens system. Most lens design programs contain routines that carry out tolerancing to various degrees of sophistication. Some programs are capable of presenting a set of tolerances automatically with only limited input from the designer. The output is a neat table of parameters and allowable ranges in the parameters that can be handed to the shop. This appears to be a quite painless method of carrying out a complex procedure, but it must be remembered that the process is based on application of a set of principles defined by the program writer, and the result is limited by the algorithms and specific logic used. In most cases, some trials of samples of the suggested tolerance distribution will suggest changes that can be made to simplify production of the lens system.

Direct Calculation

The preceding discussion describes methods used in calculating the tolerance distribution for a lens system. Frequently, tolerance determinations for special optical systems are required that either do not require the formal calculation described above, or may be sufficiently unusual that the use of a lens-design program is not possible. In that case, application of the principles is best accomplished directly.

The procedure is first to decide on a meaningful measure of the image quality required. In fact, the term "image quality" may require some broader interpretation. For example, the problem may be to optimize the amount of energy that is collected by a sensor in an optical communication system;

or the goal may be to scan a specific pattern with specific goals on the straightness of the projected spot or line during the scan.

The next step is to express the desired image quality in a numeric form. Usually, the rms wavefront error is the useful quantity. In some cases, other values such as the focus location of a beam waist or the size of the beam waist may be pertinent. In radiometric cases, the amount of flux within a specified area on the image surface (or within a specified angular diameter when projected to the object space) may be the pertinent value.

Once this is accomplished, the third step is to determine the relation between small changes in the parameters of the optical system and changes in the desired image quality function. This is usually accomplished by making small changes in each of the parameters, and computing the value of each differential as

$$\frac{dW}{dx_j} = \frac{\Delta W}{\Delta x_j}$$

where the right side is a finite differential. On occasion, the magnitude of this relation is nonlinear, and may require verification by using different magnitudes of change in the parameter.

This computation provides relations for independent, individual changes of the parameters. The possibility of compensation by joint changes in two or more parameters also has to be investigated. The best approach is to compute changes in the image-quality parameter in which specific coupling of parameters is included. For example, the differentials for variation of the curvatures of the two surfaces of a lens independently will be significantly different than the coupled changes of both surfaces simultaneously, either in the same or different directions.

Spreadsheet Calculation

The differentials must be combined in some manner to provide insight into the tolerance distribution. The best way to accomplish this is to develop a spreadsheet which allows simultaneous evaluation of the combination of errors using the equation for rms summation stated earlier. The use of spreadsheets for calculation is so common today that details need not be covered in this chapter.

Lens-Design Programs

The use of lens-design programs for tolerance calculation has become very widespread because of the proliferation of programs for use on the PC-level computer. The status of lens-design programs changes rapidly, so that any specific comments regarding the use of any program is sure to be out of date by the time this book appears in print. Suffice it to say that all of the principal programs have sections devoted to establishing tolerances. Usually the approach follows the procedures illustrated earlier in this chapter, with finite changes, or sometimes true computed analytical derivatives, used to establish a change table relating parameters to changes in the state of correction of the lens. In this case, the tolerances would be a listing of the allowed changes in the parameter to remain within some specified distance from the design values in aberration space. Some programs use a more complex approach where the allowable change in such quantities as the contrast value of the modulation transfer function at specified spatial frequencies is computed.

The distribution of tolerances is usually established according to the statistical addition rules given above. Some programs permit the user to specify the type of distribution of errors to be expected for various types of parameters.

As recommended above, it is strongly suggested that the user or designer not accept blindly the results of any tolerancing run but, rather, do some spot checking to verify the validity of the range of numbers computed. It is frequently found that alterations in the specified tolerances will occur as a result of such an investigation.

5.8 PROBLEMS IN TOLERANCING

Finally, it is useful to recite some of the problems remaining in establishing tolerances for a lens system. Even though the computational approach has reached a high level of sophistication for some lens-design programs, there are aspects of tolerancing that more closely approach an art than a science. The judgment of the designer or user of a tolerance program is of importance in obtaining a successful conclusion to a project.

Use of Computer Techniques

The use of a computer program mandates the application of rules that have been established by the writer of the program. These rules, of necessity, are general and designed to cover as many cases as possible. As such, they are not likely to be optimum for any specific problem. User modifications of the weighting, aberration goals, and tolerance image-quality requirements are almost always necessary.

Overtightening

The safe thing for a designer to do is to require very tight tolerances. This overtightening may ensure that the fabricated system comes close to the designed system, but the cost of production will likely be significantly higher. In some cases, the added cost generated by the overtight tolerances can raise the cost of the lens to the point where the entire project is abandoned.

The designer should consult with the fabricators of the optical system to develop an approach to assembly and testing that will allow the use of more compensating spacings or alignments to permit loosening of some of the tight tolerances.

Overloosening

A similar set of comments can be made about too-generous tolerances. In many schemes for production, these loose tolerances are justified by inclusion of an alignment step that corrects or compensates for cumulative system error. Too casual an approach to developing tolerances that require specific assembly processes, which are not fully communicated to the project, can result in a lens which is initially inexpensive to build, but becomes expensive after significant rework required to correct the errors.

Judgment factors

The preceding two sections really state that judgment is required. There is no completely "cookbook" approach to tolerancing any but the very simplest cases. The principles stated in this chapter need to be applied with a full knowledge of the relation between a change in a system parameter and the effect upon the image quality. In some cases, a completely novel relationship needs to be developed, which may include, for example, the connection between the alignment of a laser cavity and a nonlinear component included within the cavity. Finite difference calculations to obtain the output level can be developed using whatever computation techniques are appropriate. These values can be combined in a spreadsheet to examine the consequence of various distributions of the allowable errors.

5.9 REFERENCES

There are many useful references on optical tolerances that deal with specific topics not directly covered by the general discussion in this chapter. The most useful suggestion is that the users having the task of setting specifications on a specific product or system use the massive capabilities of internet search engines to look for specific data applicable to that task. A general Google search on "Optical Tolerances" provided 1,600,000 hits, of which probably less than 10 will be applicable to any specific problem.

MOUNTING OPTICAL COMPONENTS

Paul R. Yoder, Jr.

Consultant in Optical Engineering
Norwalk, Connecticut

6.1 GLOSSARY

a_G	acceleration factor
D_G	diameter of optic
E	Young's modulus
ID	internal diameter
K	constant factor
m	mass
OD	outer diameter
P	total preload
S_Y	yield stress
SPDT	single point diamond turning
t	thickness
Δ	deflection of spring or flange
ν	Poisson's ratio

6.2 INTRODUCTION AND SUMMARY

This chapter summarizes the techniques most commonly used to mount lenses, windows, small mirrors, and similar optical components as well as moderate-sized mirrors, and prisms within their mechanical surrounds to form optical instruments. Because of space limitations, mountings suitable for large (i.e., >85-cm diameter) optics are not discussed here. Two basic approaches for mounting optical components are considered: those in which the optic is held firmly against mechanical reference surfaces by applied forces (hard mounting) or those supported by benign means that do not inherently apply force (soft mounting). Descriptions of hard mountings include ones using threaded retaining rings, flanges, or springs while descriptions of soft

mountings include ones using flexures, elastomeric encapsulation, or bonding to mechanical pads. With either type of mounting, the required location and orientation of the optic relative to other portions of the instrument, that is, its alignment, is established during assembly in order to maximize performance. An important aspect of mounting design considered here is how the adverse influences of shock, vibration, temperature change, and moisture on alignment and system performance can be minimized. References cited here provide equations for designing and analyzing a large variety of mountings. Although we speak here of optics as if they are always made of glass and to mechanical parts (housings, cells, spacers, retainers, etc.) as if they are always made of metal, it should be understood that many of these mounting considerations also apply to other materials such as crystals, plastics, and composites.

6.3 MOUNTING INDIVIDUAL ROTATIONALLY SYMMETRIC OPTICS

Hard Mounting Techniques

In order to constrain an optic and preserve its alignment relative to other critical components of an optical instrument, hard mountings apply compressive forces to the glass at discrete locations or along line contacts. These forces, called preloads, are established during assembly and generally are of sufficient magnitude to hold the optic against appropriately located mechanical reference surfaces in the mount under all environmental conditions, including shock, vibration, and temperature changes. The magnitude of the preload P in N applied along any axis should be at least $9.81ma_G$, where m is the mass of the optic and any related components to be held by a single constraining means and a_G is the worst case acceleration expected to be encountered by the subassembly. This term a_G is understood to be a multiple of ambient gravity. If the optic is rotationally symmetric, glass-to-metal contact can be provided at the optic's cylindrical rim, at its ground bevels, or at its polished surfaces. Five degrees of freedom (three translations and two tilts) must be controlled. The sixth degree of freedom (rotation about the optic axis) is also adjusted and controlled in some cases to improve performance in the presence of residual optical wedge or if nonsymmetrical aspheric surfaces are involved. All six degrees of freedom must be constrained for noncircular optics, such as prisms.

The forces applied at the interfaces as well as those from gravity or imposed accelerations may distort the optical surfaces (thereby affecting performance) and introduce stress into the glass. Stress is known to cause birefringence, or, in extreme cases, damage to the optic—especially at low temperatures where shrinkage of the metal exerts maximum force on the glass. To minimize these adverse effects, forces must be kept within acceptable limits. Very few closed-form equations are available for predicting refracting or reflecting surface deformations due to applied forces. Finite element analyses are most frequently used for this purpose.[1,2] Explanation of how this is done is beyond the scope of this presentation.

Relatively simple analytical means for estimating compressive and tensile stresses introduced by mounting forces are detailed in the literature.[3,4] Most of these techniques are based on adaptations of standard formulations by Roark[5] and Timoshenko and Goodier.[6] The magnitude of the stress generated by a force depends not only upon the magnitude of that force, but also on the shapes of the surfaces in contact and Young's modulus and Poisson's ratio values for the glass and metal involved.

Statistical analyses backed by experimentation indicate that an optical component made by conventional high-quality grinding and polishing methods can usually withstand tensile stress as large as ~6.9 MPa without failure. This value is generally accepted as a "rule-of-thumb" tolerance for survival of the optic under stress.[7] Optics made by "controlled grinding" techniques,[8] polished and assembled with great care, and not scratched or otherwise damaged during use, might well survive long-term stress about 1.7 times greater.[9]

Under the more benign conditions of the operating environment (wherein the instrument must perform to specifications), survival is not a concern, but distortions of optical surfaces

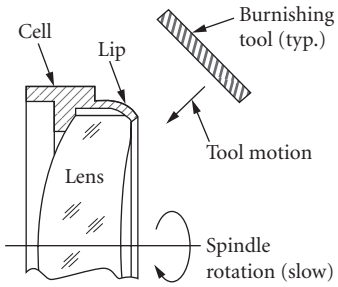

FIGURE 1 A small lens burnished into a cell made of malleable metal.

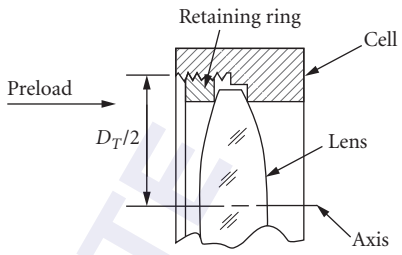

FIGURE 2 A lens preloaded in its cell with a threaded retaining ring.

due to mounting forces may degrade performance. High-performance optical systems and those using polarized light may also be especially sensitive to stress-induced birefringence. A commonly applied tolerance for stress in the glass in such cases is ~3.4 MPa. Analytical methods outlined in this chapter allow mounting stresses to be estimated to predict the potential success of a given design.

Burnished Mountings Figure 1 shows a very simple way to mount a lens element in a tubular cell. This cell has an internal shoulder against which the lens is to be held. The cell is mounted on a spindle, the lens is inserted and held in place gently, and the assembly is slowly rotated. The cell has a lip that extends beyond the rim of the lens. That lip is burnished with one or more hardened rod-shaped tool(s) over the edge of the lens as indicated in the right-hand view. The cell material must be malleable so it can be bent easily. Brass or annealed aluminum are common choices. The magnitude of the force, if any, introduced by the mounting cannot be quantified in this case because the bent metal tends to spring slightly away from the glass once tool pressure is removed. This type mounting is most suitable for use with small elements used in some endoscopes, simple microscope objectives, or low-cost cameras.

Mounts Using Threaded Retaining Rings This mounting, shown schematically in Fig. 2, is the type most frequently used to secure a lens element in its mount. Torque Q in N-mm applied to the ring with a wrench creates axial preload P to hold the lens against the shoulder very approximately as $5Q/D_T$, where D_T is the pitch diameter of the thread in millimeters.

The fit of the mating threads in the cell and retainer should be loose enough for the retainer to align itself to the centered lens surface; otherwise, lens alignment may be altered when the retainer is tightened. Such a fit may be specified as Class-1 or -2 per ANSI/ASME B1.1-2003.* During assembly, the lens should first be aligned in the cell and then held in place as the retainer is tightened to the required torque.

Mounts Using Annular Flanges Figure 3 shows a lens element preloaded against a shoulder by an annular flange that is deflected axially by a distance Δ from its nominal flat shape. Adapting an equation from Roark,[5] the deflection Δ required to produce a given preload P in N equals $(K_A - K_B)P/t^3$ where t is the flange thickness in millimeters and the constants K_A and K_B are determined by the material properties and the dimensions a and b indicated in the figure.

For a given design, the required deflection may be obtained by customizing the thickness of the spacer located under the flange and should be at least 10 times larger than the resolution capability of the device to be used to measure the flange deflection at the time of assembly. As the flange is bent, stress is developed within that component. To prevent damage to the flange, its thickness should equal $K_C P f_S / S_Y$ where the constant K_C depends upon the dimensions a and b and the flange material

*Unified Inch Screw Threads (UN and UNR Thread Form).

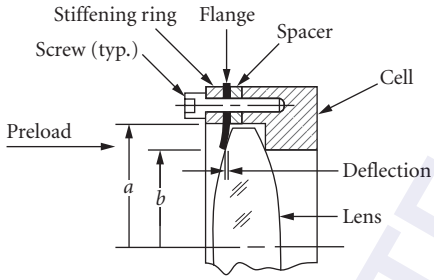

FIGURE 3 A lens preloaded in its cell with a deflected continuous ring flange.

properties. The quantity S_Y is the yield stress of the flange material and f_S is the desired safety factor. The stiffening ring shown next to the flange maintains uniform flange deflection between the attaching screws.

A significant advantage of the annular flange as compared to the threaded retaining ring is that the flange can be calibrated before installation by measuring the actual preload developed as a function of deflection. Then, one can be quite confident that the preload on the lens is as stated by the above relationship when that flange is deflected by the specific distance Δ. This level of confidence cannot be achieved with a threaded ring.

Soft Mounting Techniques

Elastomeric Mountings A convenient technique for mounting a lens in a cell is to inject a continuous annular ring of an elastomeric material such as room temperature vulcanizing (RTV) sealing compound between the lens rim and the inside surface of the cell (see Fig. 4). This is sometimes called an "elastomeric ring mounting." The thickness t_e equals $K_D D_G$, where D_G is the lens diameter and the constant K_D is determined from the material properties using a relationship attributed by Herbert[10] to R. Vanbezooijen. The lens is then virtually free of radial stress at all temperatures. This is because the elastomer expands or contracts with temperature changes just enough to always fill the radial gap between the glass and the metal.

Some designs using the elastomeric ring approach also benefit from the fact that a continuous ring of this material effectively seals the lens to its mount so, if this subassembly forms part of the exterior skin of an optical instrument, leakage of gases and moisture through that interface is prevented.

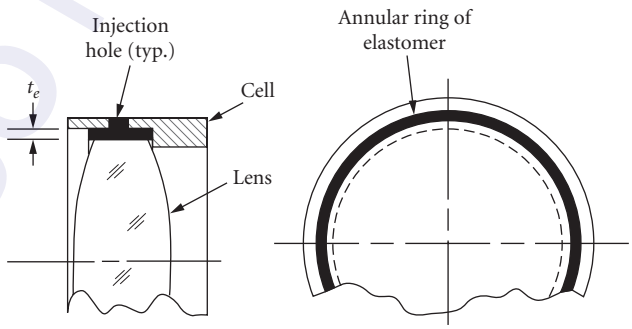

FIGURE 4 A lens supported in its cell by a continuous annular ring of elastomer.

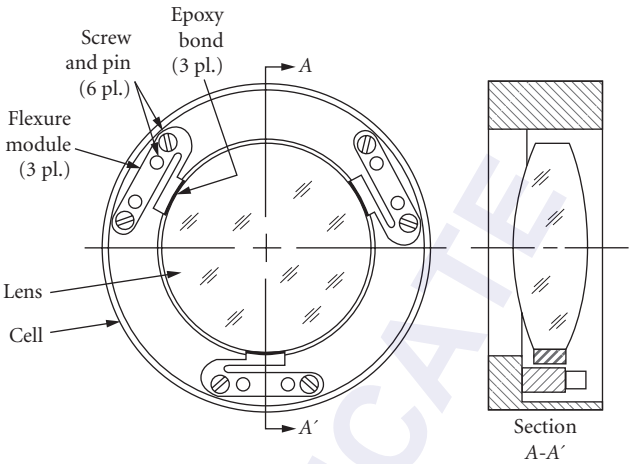

FIGURE 5 A lens bonded to three flexure modules attached to a cell.

Another type of elastomeric mounting for lenses uses discrete pads of elastomer located between the lens rim and the cell's inside surface. At least three such pads are needed to fully constrain the optic. They should be symmetrically distributed around the lens. The radial thicknesses of these pads can be sized as described above for the continuous ring.

Flexure Mountings High-performance optical systems require the optical axes of their lenses to be precisely centered mechanically with respect to some mechanical reference and to remain in that condition when the temperature changes. Because metal and glass components expand or contract with temperature at different rates, the optics may become decentered, tilted, or stressed when temperature changes occur in the above-described hard mountings. A properly designed support configuration using three or more symmetrically located identical flexures between the mount and lens rim will ensure that the lens stays as originally aligned and free of stress in spite of such changes.

Figure 5 shows a concept for a simple flexure mount design suggested by Ahmad and Huse.[11] Three identical flexure modules are made with narrow slots cut into them (by an electric discharge machining method) to form cantilevered flexure blades. Each blade has, at its free end, a curved pad shaped to interface with the lens rim. These modules are attached to the lens cell with screws passing through slightly oversized holes. In an alignment fixture, the optical axis of the lens is centered with respect to the axis of the cell. The modules are then adjusted to provide specific gaps between the pads and the lens rim and pinned in place. Epoxy is injected into those gaps and cured. Because the flexures are separate from the cell, they can be made from a material (such as titanium) with a higher yield stress than the cell. The cell is typically made of less expensive yet dimensionally stable material (such as stainless steel). More complex flexure designs and ones featuring a larger number of radial flexures have also been described.[12–16] Because of their inherent flexibility, flexure mountings should be analyzed to determine their responses to externally imposed shock and vibration.

6.4 MULTICOMPONENT LENS ASSEMBLIES

Groups of lenses used in optomechanical assemblies typically are individually mounted and constrained in seats machined into a housing or are separated axially by spacer rings within a common cylindrical bore in the housing. It is important for those lenses to have a common optical axis and the correct axial airspaces within allowable tolerances. We here consider several ways in which such assemblies can be designed.

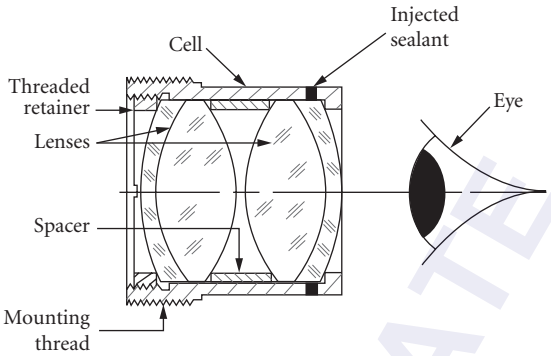

FIGURE 6 A telescope eyepiece with two lenses and a spacer assembled by the "drop-in" method.

Drop-In Assembly

If alignment requirements are not too demanding, lenses, housings, and spacers can be machined to reasonable tolerances and simply assembled without further machining or adjustment other than tightening a retainer to provide prescribed preload. Figure 6 shows an eyepiece for a low-power telescope assembled in this way. Radial clearances are typically ~0.075 mm, so individual lenses can easily be inserted into their seats. The eyepiece is configured to thread into a cylindrical opening in the telescope housing and to be focused by rotating the entire eyepiece. In some cases, the lenses are sealed to the cell and the threaded joint with the telescope also is sealed.

Many all-plastic lens assemblies used in consumer products are designed for swift drop-in assembly. The example shown in Fig. 7 is the objective for a rear-projection television system. Flexible tabs molded into the inside walls of both halves of the plastic housing project inward to form pockets for insertion of the three injection-molded plastic lens elements. Grooves (not shown) molded into the inside walls of the housings reduce stray light that otherwise could reduce contrast of the image. The housings are fastened together by self-tapping screws passing through flanges along each side, as indicated in the end view. Optical alignment relies on accuracy of the molding processes and is adequate for the application.

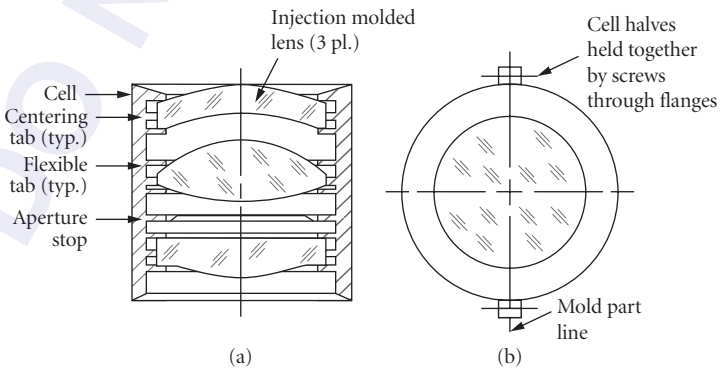

FIGURE 7 An all-plastic projection lens assembled by the "drop-in" method.

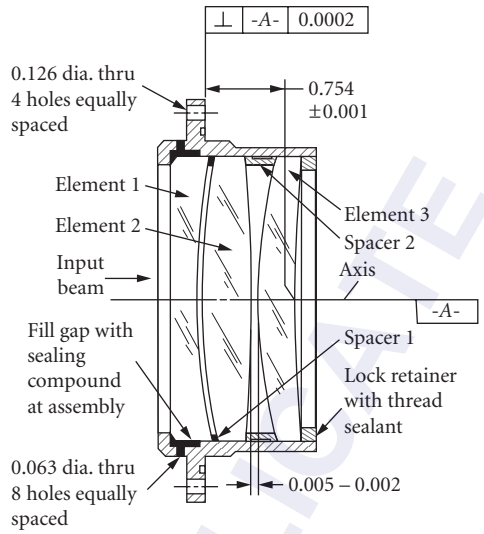

FIGURE 8 A telescope objective assembly with alignment resulting from tightly toleranced dimensions. Dimensions are in inches. (*From Yoder.*[17])

Tightly Toleranced Assemblies

When higher performance is required, the dimensional tolerances are tightened and better optical alignment is achieved. Figure 8 shows the objective lens assembly for a military telescope.[17] The three lenses are edged to fit the cell inside diameter with nominal radial clearances of 0.012 mm. All metal parts are made of stainless steel. The first spacer is made of sheet metal stock 0.025 ± 0.005 mm thick. It conforms to the spherical shapes of the adjacent lens surfaces under preload. The axial thicknesses of the lenses are toleranced to ± 0.005 mm. Residual optical wedge tolerances for the lenses are 12 arcsec. The beam deviation from these wedges is minimized at assembly by rotating (i.e., clocking) two lenses about their axes relative to the third lens to obtain maximum symmetry of the image of an on-axis artificial star. This image is observed with a microscope during alignment.

Lathe Assembly

A technique that is frequently used to obtain lens centration by minimizing radial clearances between lens ODs and cell IDs is called "lathe assembly" because it is done on a machinist's lathe. The diameters and thicknesses of a selected set of lenses are measured and recorded. The required central air spaces and their tolerances are obtained from the optical system design. Actual lens surface radii are obtained from interferometric measurements made during lens manufacture. This data accompanies the lenses to the machine shop where a partially machined cell or housing is customized to provide conical or toroidal interfaces with the polished surfaces of that particular set of lenses and to provide all other required dimensions for the optomechanical assembly within the required tolerances. Radial clearances of ~0.005 mm can be achieved by this method. This clearance is adequate for careful assembly of the lenses into the cell.

Figure 9[17] shows an air-spaced doublet lens subassembly created by this process. The individual lens seats are finish-machined at the time of assembly to fit those lenses. The length of the spacer (dimension *E*) and the location of the mounting flange (Datum B) relative to the front lens vertex

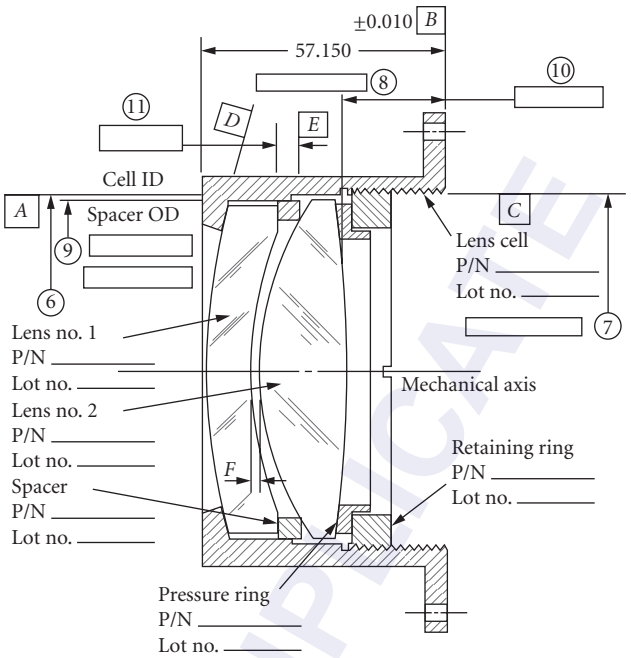

FIGURE 9 An air-spaced doublet assembled by the "lathe assembly" process. (*From Yoder.*[17])

are also machined to produce the proper air space and overall length. Both lenses are secured by the retainer. The actual values of the numbered dimensions are recorded in the boxes. If required, a complete pedigree of that particular assembly can be established for future reference from the measured data and inspection reports. This type of construction is especially suited for applications involving high accelerations. Bayar described an aerial camera lens assembled by this method.[18]

"Poker Chip" Assembly

Figure 10 is a partial section view through a lens assembly that features seven lenses: four doublets and three singlets. Each lens, except the largest, was centered interferometrically to the mechanical axis of its cell OD and held in place in that cell with annular rings of epoxy nominally 0.381 mm thick. After the adhesive was cured, the axial thicknesses of the cells were final machined so all axial air spaces would be within design tolerances. The cell subassemblies Numbers 6 through 2, which had been machined to the same ODs within tight tolerances, were then inserted into the stainless steel housing and secured by Cell No. 1 that was threaded into the housing to act as a retainer. The largest lens (No. 12) was held directly in the housing by its own retainer. Accuracy of internal alignment was built into the assembly by the fabrication process.[19] This type of construction is frequently referred to as "poker chip" assembly because the individual lens/cell subassemblies are stacked on top of each other inside the housing.

Lenses Adjusted at Assembly

Many complex lens assemblies to be used in very high-performance applications such as microlithographic projection systems need positional adjustment of a few carefully selected elements at the final stage of assembly. This is because application of the best possible optical and mechanical

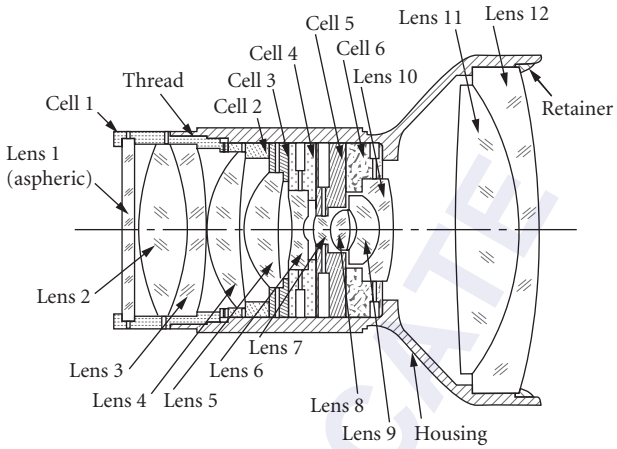

FIGURE 10 A projection lens comprising a stack of "poker chip" lens/cell subassemblies inserted into the bore of the mount. (*From Fischer.*[19])

manufacturing processes and extremely tight dimensional tolerances cannot make the lenses and mechanical parts accurately enough to obtain the full level of performance required by the application. An example is shown schematically in Fig. 11.[20]

This optomechanical system comprises twelve air-spaced "poker chip" subassemblies, stacked on top of each other with custom-made spacers placed between lapped coplanar pads on the cell faces

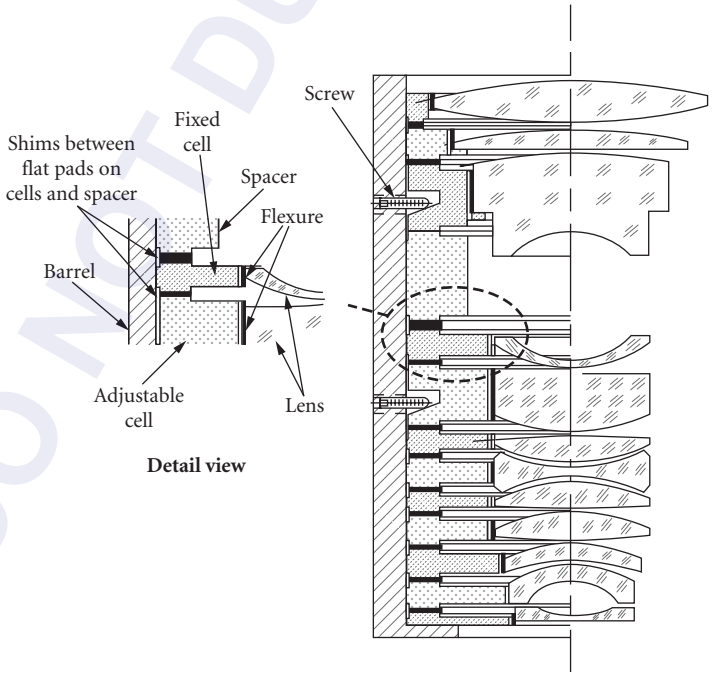

FIGURE 11 Partial section view of a "poker chip" lens assembly with two lenses adjusted after assembly to optimize performance. (*From Yoder.*[4])

to control axial air spaces. The lenses are mounted on flexures machined directly into the interior surfaces the cells. Ten of the subassemblies fit closely inside the stainless steel barrel. Two subassemblies are adjustable laterally in orthogonal directions from the outside. Optical performance of the system is measured interferometrically in near real time, while the adjustable lenses are moved very slightly until optimal performance is achieved. The adjustment mechanisms are then locked and the lens is installed into the microlithography system.

Determination of which lens elements to move in a given optical system to correct residual aberrations is a job for the lens designer working with mechanical engineers and metrology experts who help decide how to incorporate the needed mechanisms and to conduct the necessary tests. The sensitivities of spherical, coma, astigmatism, and distortion aberration contributions from each lens to lateral and axial displacements are determined by raytracing. The ideal candidates for correcting each aberration are lens shifts that modify that aberration significantly, but do not excessively affect the other aberrations. The results are reviewed to determine which lens movements are best to minimize each aberration. Williamson[20] outlined a procedure in which the aberration contributions of the optical system shown in Fig. 12*a* for specific axial and lateral displacements of each element are plotted as shown in Fig. 12*b* and *c*, respectively. Using phase-measuring ultraviolet interferometry

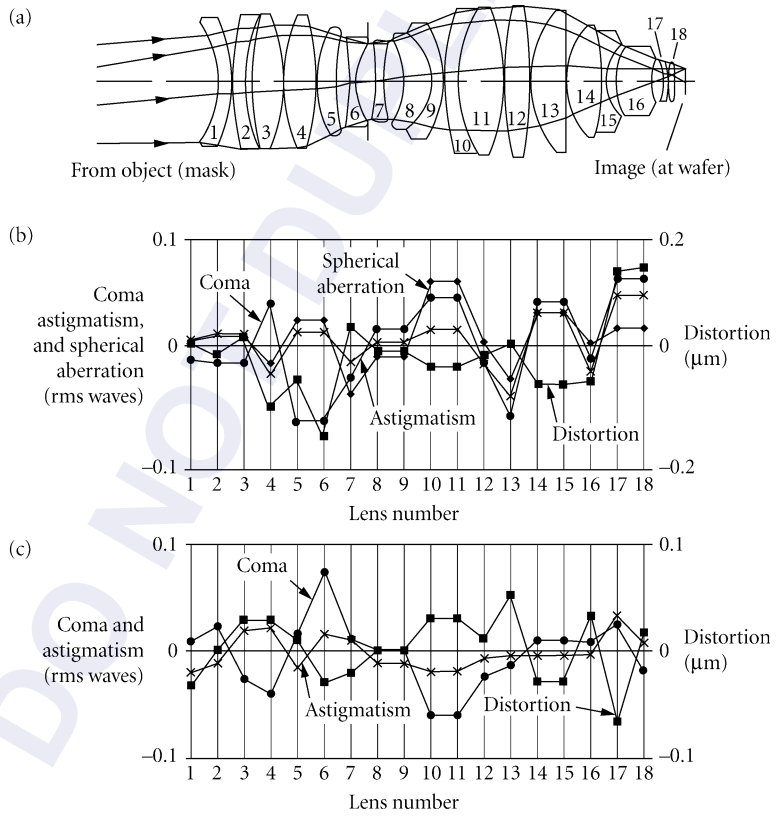

FIGURE 12 (a) Optical schematic of an 18-element lithographic projection lens. (b) The effects on aberrations of individually displacing each element axially by 25 μm. (c) Similar effects of displacing each element laterally by 5 μm. The best lenses to adjust for optimum system performance can be determined. (*From Williamson.*[20])

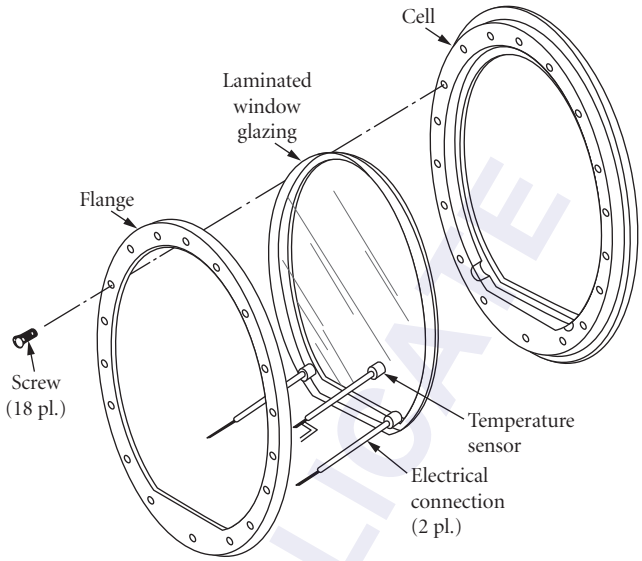

FIGURE 13 Exploded view of a heated window assembly used in a military application. (*Courtesy of Goodrich Corporation, Danbury, CT.*)

as the image quality monitor, all these aberrations can be significantly reduced by iteration of lens movements and the final system performance of production lens assemblies greatly enhanced.

6.5 MOUNTING WINDOWS AND DOMES

Small circular windows usually are secured in a mount with a threaded retainer or by an elastomeric ring. Noncircular ones are best held in place with elastomer. The continuous flange-mounting method can be used to advantage with larger windows. The one shown in Fig. 13 has an elliptical aperture of 20.32×30.5 cm.[4] The electrical connections shown provide current to a conductive coating on a buried surface, which keeps the window free of fog in high-humidity situations. The flange preloads the window into an aluminum cell. An elastomeric sealant is injected into a groove around the window's rim to seal it to the cell. The cell is sealed to the instrument housing with a gasket or an O-ring.

Figure 14 shows typical mountings for deeply curved spherical windows, called *shells* or *domes*. That in Fig. 14*a* is sealed and secured with a Neoprene gasket clamped in place by a flange[21] while that in Fig. 14*b* is secured and sealed with a continuous ring of elastomer.[4] In some more elaborate designs, an elliptically shaped sapphire dome is brazed with special metallic alloys to a titanium mount.[22]

6.6 MOUNTING SMALL MIRRORS AND PRISMS

General Considerations

The appropriateness of designs for mechanical mountings for small mirrors and prisms depends upon a variety of factors including: tolerable rigid body movement of the optic and distortion of its reflecting and/or refracting surface(s); the magnitudes, application locations, and directions

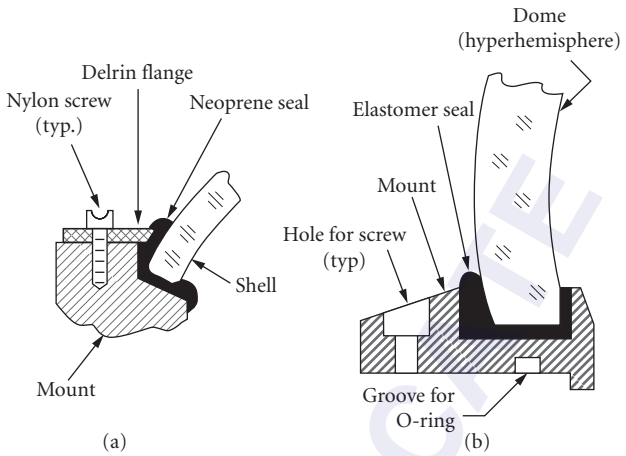

FIGURE 14 Typical mountings for (*a*) a thin shell and (*b*) a hyperhemispherical dome. [(*a*) *From Vukobratovich.*[21] (*b*) *from Yoder.*[4]]

of forces tending to move the optic with respect to its mount; steady-state and transient thermal effects (including gradients); the sizes and kinematic compatibility of interfacing optomechanical surfaces; and the rigidity and long-term stability of the structure supporting the optic. In addition, the designs must be compatible with assembly, maintenance, package size, weight, and configuration constraints, as well as being cost effective. The representative mounting designs described in the following sections illustrate proven mounting techniques.

Mechanically Clamped Mountings

Figure 15 shows a simple means for attaching a first surface flat mirror to a mechanical bracket.[23] Three cantilevered springs press the reflecting surface against three pads that have been lapped coplanar. The contacts between the springs and the mirror's back face are directly opposite the pads to minimize bending moments. This design constrains one translation and two tilts. Translations in the plane of the reflecting surface can most easily be constrained by dimensioning the spacers supporting the springs so as to just clear the rim of the mirror at minimum temperature. Rotation in that plane usually does not need to be constrained. Given the number of springs N, the spring material's Young's modulus E_M, its yield stress S_Y, and its Poisson's ratio ν_M, the spring lengths L and widths b, and an appropriate safety factor f_S, the spring thickness t that will provide a total preload P to the mirror is determined as $[K_{S1}PLf_S/(bS_YN)]^{1/2}$. The length of the spacer located under each spring is chosen to cause that spring to be deflected from its flat condition by Δ equal to $(K_{S2}L^3)(1-\nu_M^2)/(E_Mbt^3N)$. In these relationships, K_{S1} is 4 and K_{S2} is 0.75.

Elastomeric Mountings for Mirrors

Small mirrors can often be mounted in the manner illustrated by Fig. 4 for a lens. In applications where the optic does not need to be sealed in place with a continuous ring of elastomer, three or more discrete pads located between the lens rim and the cell ID can support it. Vanbezooijen's equation is again used to determine the pad thicknesses.[10] The lateral dimensions of the pads have, in some designs, been determined by finite element analysis that predicts the dynamic response of the subassembly to vibration inputs from the environment.[24]

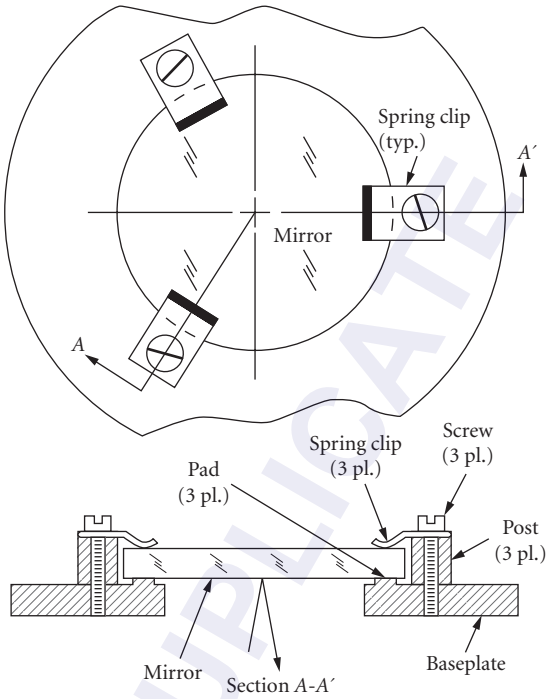

FIGURE 15 A simple mounting for a flat mirror preloaded with deflected cantilevered springs. (*From Yoder.*[23])

Spring-Loaded Mountings for Prisms

A spring-loaded mounting for a prism is illustrated in Fig. 16.[25] Here, a penta prism is preloaded against three coplanar pads on the baseplate by three cantilevered springs supported by posts with spacers machined to produce the necessary spring deflection and resultant preload, as described earlier for a mirror mounting. Constraint in the plane parallel to the pad surfaces is provided by a single spring (called a straddling spring) that is supported at each end and presses against the end of the prism. The dimensions and deflection of this spring are chosen to preload the prism against three locating pins that are pressed or threaded into strategically located holes in the baseplate. The relationships for t and Δ given in Sec. "Mechanically Clamped Mountings" apply also to the straddling spring, but K_{S1} equals 0.75, $N = 1$, and $K_{S2} = 0.0625$. How the direction of the force exerted by the straddling spring can be optimized to nearly equalize the stresses created in the prism at the interfaces with the pins has been explained in the literature.[26]

Bonded Mountings for Small Mirrors and Prisms

A widely used and successful technique for mounting small mirrors and prisms is to bond them directly to a plate or bracket with an adhesive such as epoxy. Any alignment adjustments that are needed should be built into the mount rather than into the glass-to-metal joint. Figure 17 shows a typical mirror mount of this type.[23] It has proven satisfactory for cases where the diameter-to-thickness ratio for the mirror substrate is at least 6:1. The mirror should then be stiff enough not to be excessively

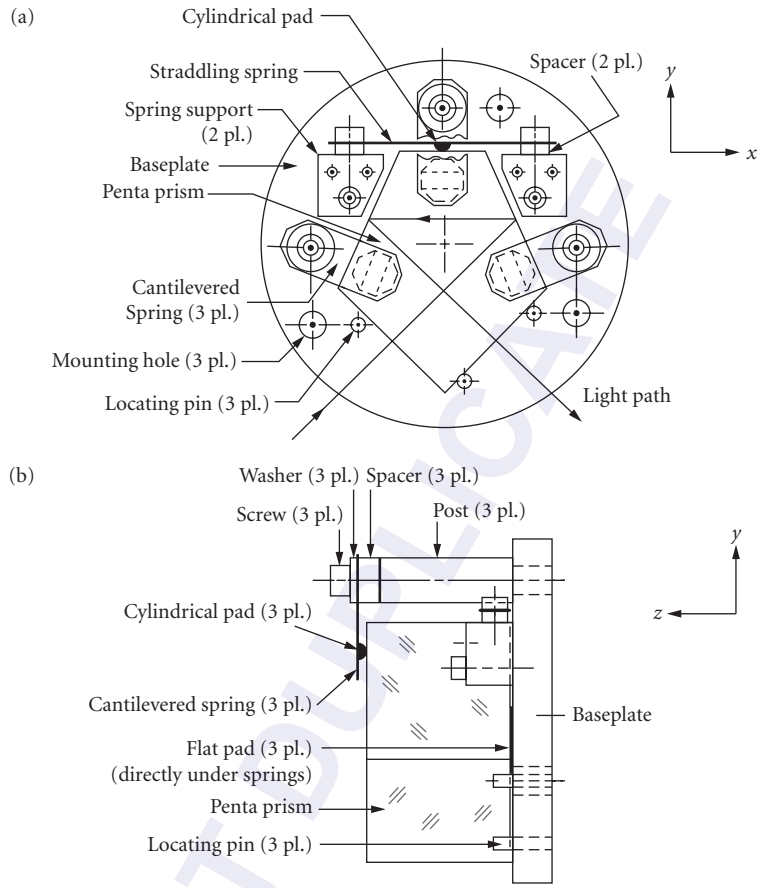

FIGURE 16 A penta prism preloaded against lapped pads on a baseplate with cantilevered and straddling springs. (*From Yoder.*[25])

distorted by shrinkage of the adhesive as it cures. Most prisms are thick enough that they are not distorted by this shrinkage.

All adhesive bonds need to have sufficient area for the joint to be strong enough to support the optic under all anticipated levels of acceleration. The minimum bond area Q_{MIN} is $9.81ma_G f_S/J$, where J is the strength of the cured adhesive joint and all other terms are as previously defined.[27] Bonding should be done on a fine ground surface of the optic for maximum joint strength. A typical value for J for a two-part epoxy such as 3M 2216B/A with bond thickness of 0.100 ± 0.025 mm is ~17.2 MPa. For conservative design, the factor f_S should be ~4. Successful bonding requires careful cleaning of the surfaces to be bonded and adequate curing time. The adhesive manufacturer's recommendations should be followed unless tests indicate otherwise for a specific application.

The 29-mm aperture roof penta prism in Fig. 18 is bonded in cantilevered fashion to a bracket nominally oriented vertically. The circular bond area is adequate to withstand a severe military shock and vibration environment. Some designs work better if the prism is supported from both sides. Figure 19 shows one way to do this. It was adapted from Beckmann.[28] The mount is designed with two arms, one of which has a hole bored through it. The prism is supported by a fixture in the proper location and orientation relative to the mount and epoxy bonded to the flat pad on the left arm. A plug made of the same

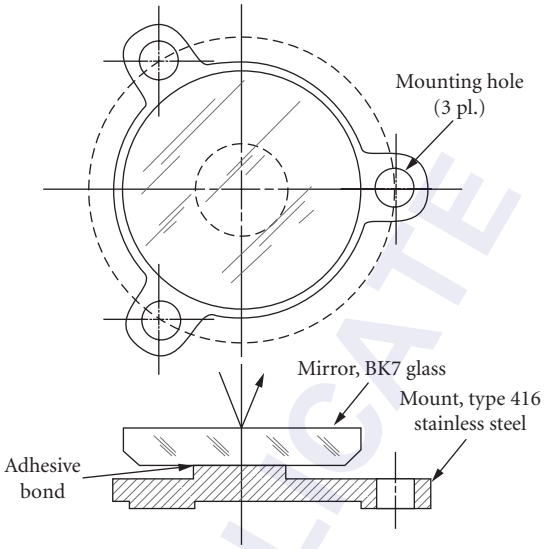

FIGURE 17 A flat mirror bonded on its back to a pad on its mount. (*From Yoder.*[23])

metal as the mount is then centered in the hole in the right arm and bonded to the right surface of the prism. When those bonds have cured, the plug is bonded into the right arm.

Flexure Mountings for Small Mirrors and Prisms

Circular mirrors as large as ~15-cm diameter have been successfully mounted on flexures in the general manner shown in Fig. 5 for a lens. Usually, these are image-forming mirrors, perhaps aspheric, that need to have constant centration relative to a system axis.

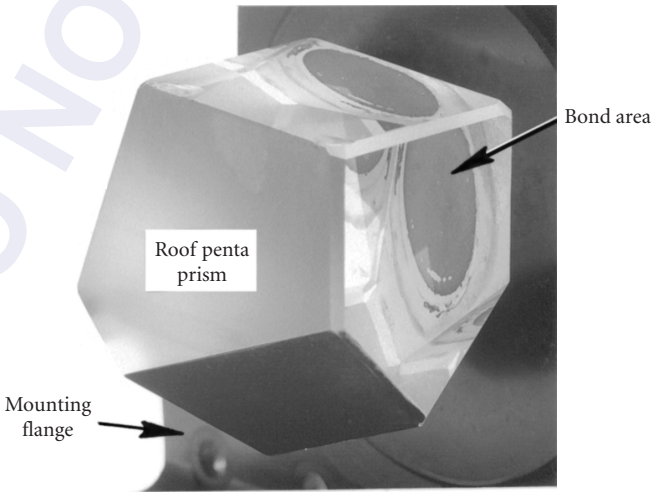

FIGURE 18 A roof penta prism bonded to a pad on a mounting flange.

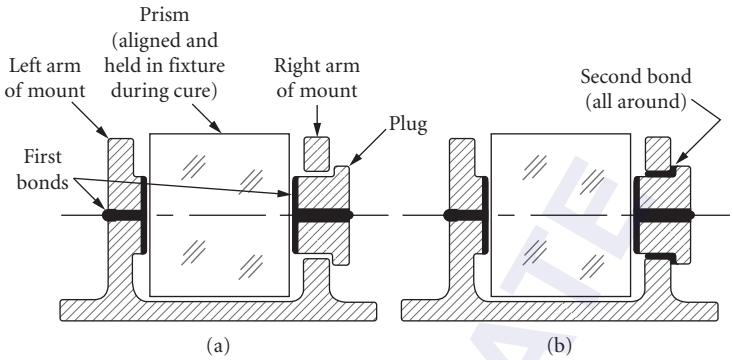

FIGURE 19 Concept for supporting a prism from both sides. (*a*) Prism bonded to left arm of mount and plug bonded to prism. (*b*) Plug bonded into right arm of mount. (*Adapted from Beckmann.*[28])

Prisms intended for use in relatively benign environments can be mounted on flexures. One way to do this is by attaching the prism to instrument structure through three posts with integral flexures at each end. Figure 20 shows a large multiple component Zerodur prism mounted in this manner. It has two wing prisms optically contacted to a third (base) prism, to which the flexures are bonded. The wing prism surfaces are perpendicular to each other and form a 15.2-cm-wide roof mirror that is inclined at 45° to the vertical. The reflected image is inverted horizontally as the optic turns the incident beam axis 90°. The orientations of three of the flexure joints are

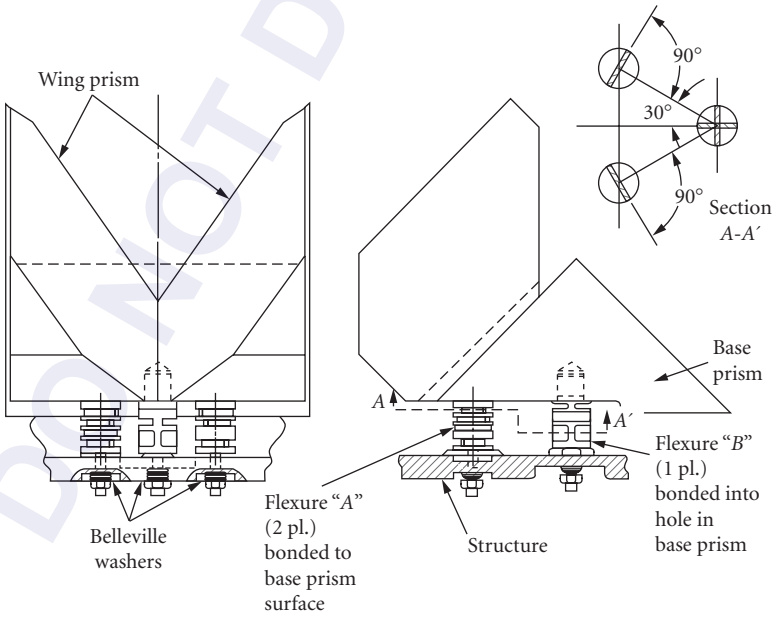

FIGURE 20 Optomechanical configuration of a large prism assembly with three flexure mounting posts to isolate the optic from dimensional changes under temperature changes. (*Courtesy of ASML Lithography, Wilton, CT.*)

as indicated in the section view A-A′. If attached to a structure that expands or contracts more than the prism as the temperature changes, the flexures simply bend very slightly and prevent the introduction of mounting forces that could distort the reflecting surfaces and interfere with performance of the optical system.

6.7 MOUNTING MODERATE-SIZED MIRRORS

General Considerations

The simple mirror mountings described earlier are not satisfactory for mirrors larger than about 15-cm diameter because they are too flexible to be treated as rigid bodies. The important criteria for selecting a suitable mounting are orientation with respect to gravity, performance level required, substrate material stiffness, and weight limitations. The mounting for a mirror to be used in a fixed horizontal- or vertical-axis orientation can be figured during polishing to compensate for gravity effects. Variable orientation applications require mounts that change their force distribution with inclination to keep surface deflections within tolerance. Both axial and radial supports are required. Mirrors to be used in space have the added requirement of release of gravitational force after being fabricated, tested, and installed into the instrument in a normal gravity environment. Choice of mounting depends strongly on the substrate configuration. Weight constraints generally lead to solid substrates with shaped back surfaces or ones built-up from multiple parts that are attached together. We here describe a few typical ways to support mirrors of various shapes as large as ~85 cm. Designs appropriate to both nonmetallic and metallic mirrors are considered.

Substrate Configurations

Figures 21*b* through *e* shows half-section views of four first-surface mirror solid substrates of the same diameter and material with concave surfaces of the same radius. Their back surface shapes differ and reduce the mirror weight as compared to a flat-back baseline design (Fig. 21*a*). All these mirrors, except one, can be supported within the telescope housing on a hub passing through the mirror's central perforation. For example, see Fig. 22. Here, the hub has a toroidal-shaped raised land that supports the 41-cm-diameter meniscus-shaped mirror radially and a shoulder that locates it axially. The radial support lies in the mirror's neutral plane where fore and aft bending moments are balanced. A threaded retaining ring provides axial preload. To focus, the locating ring is moved on the hub and secured with the clamping ring. The substrate configuration from Fig. 21 that cannot be hub mounted is the double arch configuration (Fig. 21*e*). It is best supported on flexures at three or more points spaced equally around the zone of greatest thickness.

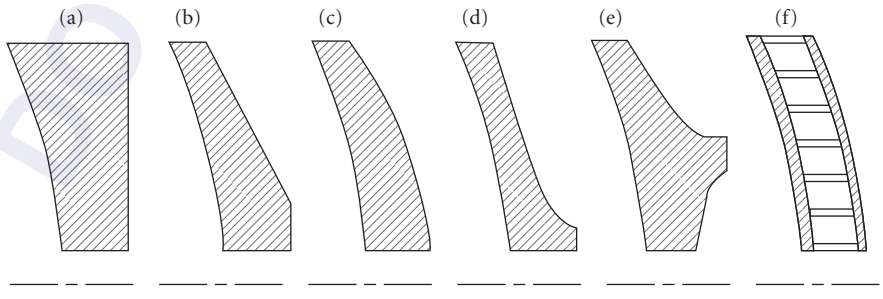

FIGURE 21 Sectional views of baseline concave-plane (*a*) and lightweighted mirror substrates (*b*) through (*e*) with contoured backs. Figure (*f*) shows a built-up substrate configuration.

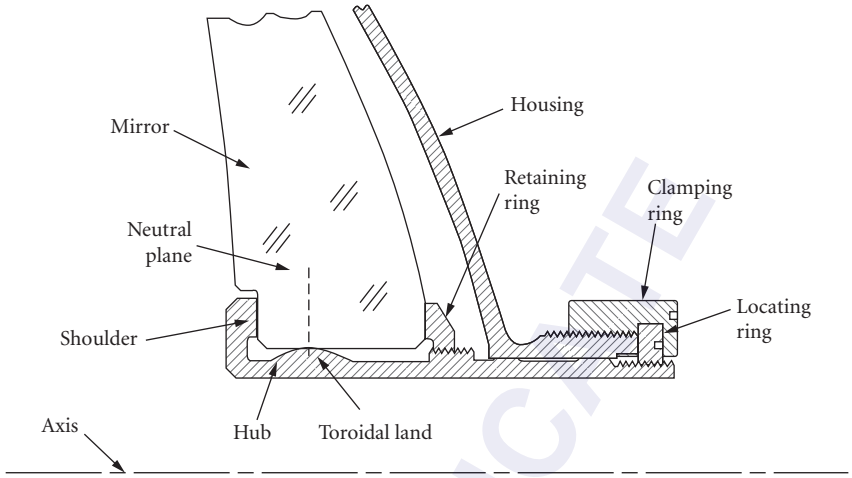

FIGURE 22 Hub mounting for a meniscus-shaped telescope mirror. Focus adjustment means is illustrated.

Lighter-weight mirror constructions typically employ built-up substrates such as that shown in Fig. 21*f*. A very successful type is the monolithic meniscus construction illustrated by Fig. 23. Such mirrors are usually made of Corning ULE. Strips of the material form the webs of a core to which front and back facesheets are fused. All joints in the core also are fused together. The spacing of the webs is large except at locations where axial and radial supports attach to the substrate. There, the spacing is considerably smaller to increase strength.

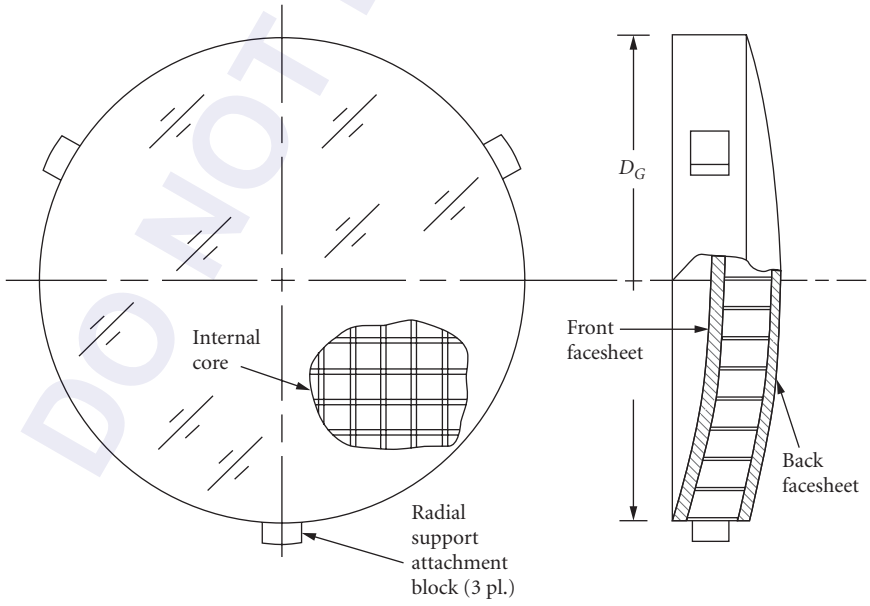

FIGURE 23 A completely fused (monolithic) built-up lightweight mirror substrate.

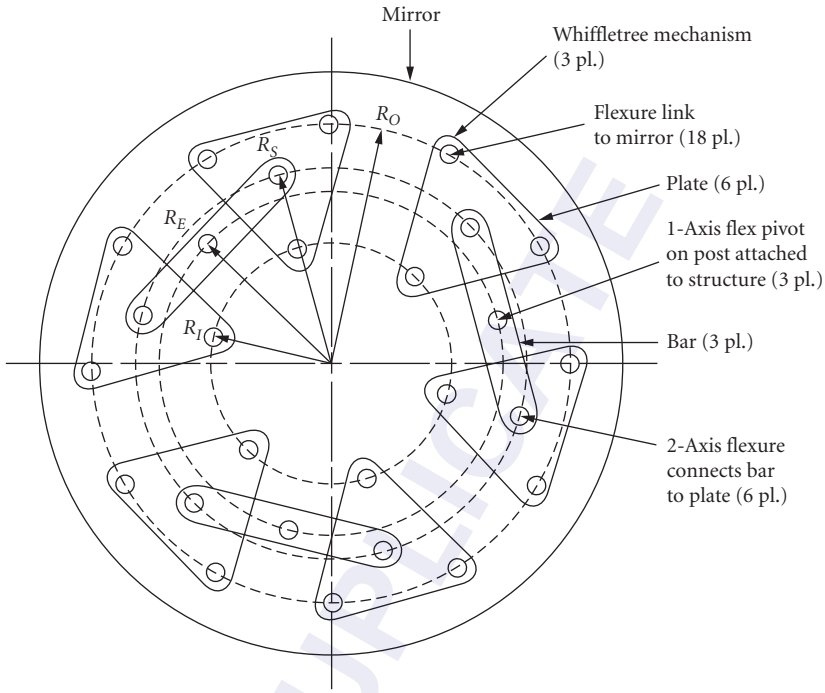

FIGURE 24 An 18-support Hindle-type mirror mount supporting the optic at multiple points on rings of radii R_O and R_I from three posts attached to structure at radius R_E. The whiffletree plates are centered on the ring of radius R_S.

Lever Mechanism Mountings

Because of the flexibility of lightweighted mirrors, axial support is frequently provided at many points on the back of the substrate. Hindle mounts[29] using multiple lever mechanisms (called "whiffletrees") are commonly used. Figure 24 shows such a mount with 18 supports for the mirror. The number of supports needed is the minimum number that keeps the gravitational sag of the reflecting surface between support points smaller than the deflection tolerance when the mirror axis is vertical.[4] To avoid friction effects, flexures (sometimes called "Flex-Pivots") are typically used as single-axis bearings in these mounts. Dual-axis bearings are usually necked-down posts that serve as flexures.

A mirror on a Hindle mount also needs radial support if it is to be used in any orientation other than axis vertical. This might be in the form of three or more mechanical links with universal-joint flexures at each end that are oriented tangent to the rim of the mirror and connect the mirror rim to the surrounding structure. Provision for such a support is shown in the mirror of Fig. 23. Multiple-point whiffletree radial supports have also been used for this purpose.[21]

Mountings for Metallic Mirrors

Metallic mirrors are generally easier to support than nonmetallic ones because attachments can be made directly to the substrate through, for example, threaded holes for screws. The metallic substrate may also be stiffer than the glass counterpart. An example is the aluminum mirror shown

by section and back views in Fig. 25*a*.[30] Here, a single-point diamond-turning (SPDT) method is employed to machine the optical surface and the axial and radial mounting interface surfaces on the mirror's back. In this method, many extremely fine cuts are made with a precision diamond tool as the substrate rotates about a common mechanical and optical axis. The tool moves on a prescribed path under interferometric control. This results in very accurate surface shapes and surface interrelationships, as well as smooth surfaces and very low residual stresses in the parts. The mating surfaces on the mount are also created by diamond turning. The mirror is shown installed in its mount in Fig. 25*b*. Optical surface distortions due to mounting forces are minimal because the contacting surfaces on the optic and its mount are parallel when drawn together.[31] When the mirror and its mount are made of the same material, the effects of temperature changes are minimized.

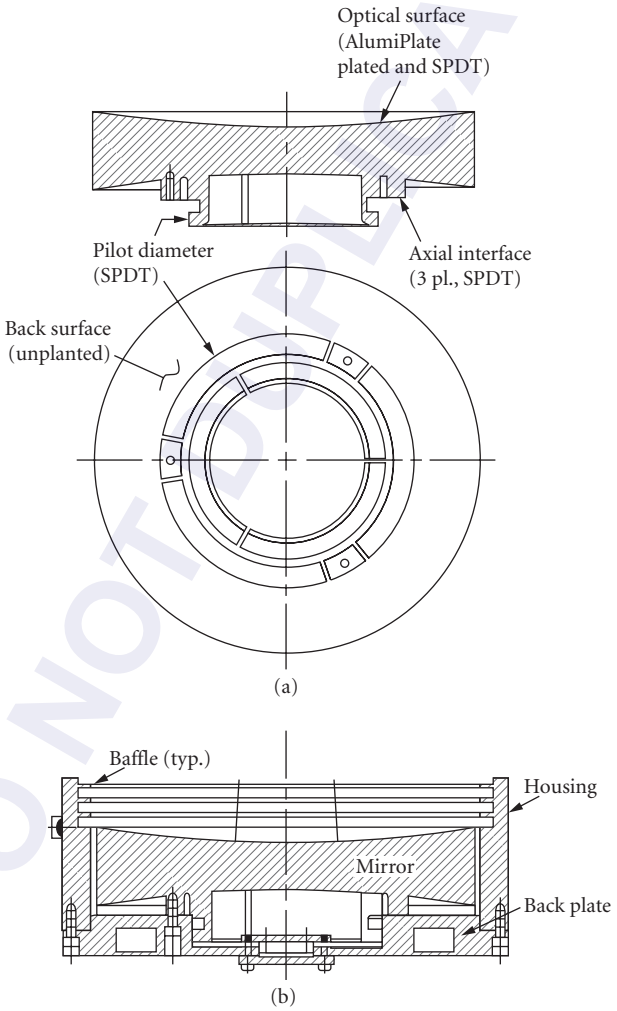

FIGURE 25 Optomechanical configuration (*b*) of an aluminum mirror (*a*) with optical and mounting surfaces machined by SPDT methods. The radial and axial interfaces are shown. (*From Vukobratovich et al.*[30])

6.8 CONTACT STRESSES IN OPTICS

The shape of the mechanical surface touching a lens, mirror, or prism surface is typically spherical, cylindrical, conical, or flat. Point contacts occur at spherical pads attached to the ends of springs while short line contacts occur if cylindrical pads are used on springs or if pins are used to locate the optic. Lenses, windows, and mirrors preloaded against mechanical constraints by a retaining ring or flange typically have circular line contacts with the metal around the edges of their apertures. The metal surface typically is conical for a convex glass surface and toroidal for a concave glass surface. The preloads applied through all of these interfaces cause elastic deformations of the glass and metal parts. Associated with these deformations are compressive and tensile stresses in those materials. Up-to-date analytical methods for estimation of these stresses have been presented in detail elsewhere.[4] Space constraints preclude discussion of those methods here. Once the tensile stress to be expected in a given optomechanical design has been quantified, it can be compared to the aforementioned rule-of-thumb tolerance to predict success or failure of the optomechanical design. Should the stress appear to be too large, certain design changes that can be made to reduce it are suggested in the referenced publication.

6.9 TEMPERATURE EFFECTS ON MOUNTED OPTICS

General Considerations

Because the temperature environment of any optical instrument is seldom constant, we should anticipate changes in dimensions of all parts, in refractive indices, and in material parameters [such as coefficient of thermal expansion (CTE) and Young's modulus] to occur throughout the lifetime of the device. These changes may defocus the system, change aberration balance, or degrade alignment. Athermalized designs are created in a manner to reduce the magnitudes of these effects to tolerable levels.

Prevention of Axial Gaps

Differential expansions and contractions of all types of materials with temperature changes may change the axial and/or radial relationships, that is, alignment between optics and their mechanical reference surfaces. Optomechanical assemblies that are adequately preloaded at assembly will tend to maintain optic-to-mount contact, but this preload will change as the temperature changes. It may disappear completely at elevated temperatures. Then the optics may be free to move if externally disturbed, as by vibration or shock. These component shifts may become permanent if the optic is decentered or tilted when the temperature drops and the mount reapplies forces to the optics.

To reduce this effect, each optical assembly might be designed to compensate for axial dimensional changes so axial preload changes are reduced to insignificance.[32] For example, the air-spaced triplet assembly of Fig. 26*a* is constructed of three optical glasses, an aluminum cell, and two aluminum spacers. The scale of the figure is as indicated. At maximum temperature, the physical separation of the interfacing points *A* and *B* in this particular assembly changes by 0.015 mm if computed for a path through the lenses and spacers, but changes by 0.030 mm if computed for a path through the cell. One or more axial air gaps totaling 0.015 mm would then exist somewhere within the assembly and the lenses might move or tilt within that space. If the design were to be modified by changing the metals in the cell and in one spacer, lengthening that spacer, and providing space for the larger spacer by adding a step bevel to the second lens—as indicated in Fig. 26*b*—the chosen materials and component dimensions would make the A-to-B separation remain equal for both paths for all temperature changes. Preload would then remain unchanged and misalignment would not occur.

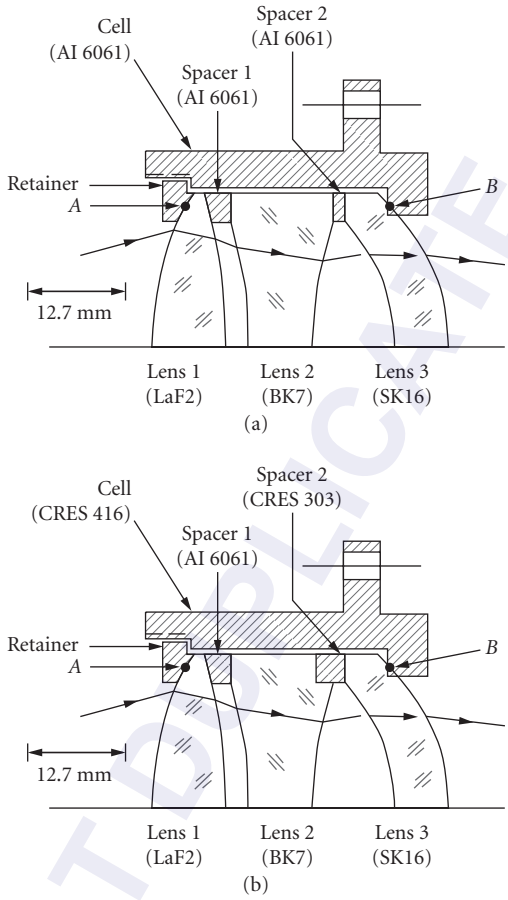

FIGURE 26 An air-spaced triplet lens assembly (*a*) in which an axial gap between glass and metal parts exists at high temperature, possibly allowing the lens to become misaligned. Modified design (*b*) is athermalized to maintain registry of the optics in the mount. (*Adapted from Yoder and Hatheway.*[32])

Focus Athermalization Techniques

Single Material Designs Figure 27 shows a reflecting telescope made of a single material, in this case, aluminum.[33] All dimensions change, but the assembly remains in alignment and the optical performance is unchanged (other than a small change in image scale) as the temperature changes. This telescope is an example of the use of single-point diamond-machining methods as all optical and mounting surfaces are precisely made in the proper geometric relationships so alignment accuracy is built-in.

Passive Athermalization Figure 28*a* illustrates the use of materials with dissimilar CTEs and carefully chosen axial dimensions so the axial distance between optical components (in this case, the two mirrors) remains constant when the temperature changes.[34] This keeps the optical performance within required limits. Control of the mirror separation of this telescope is modeled schematically in Fig. 28*b*. Positive signs associated with lengths of low and high CTE materials indicate how the

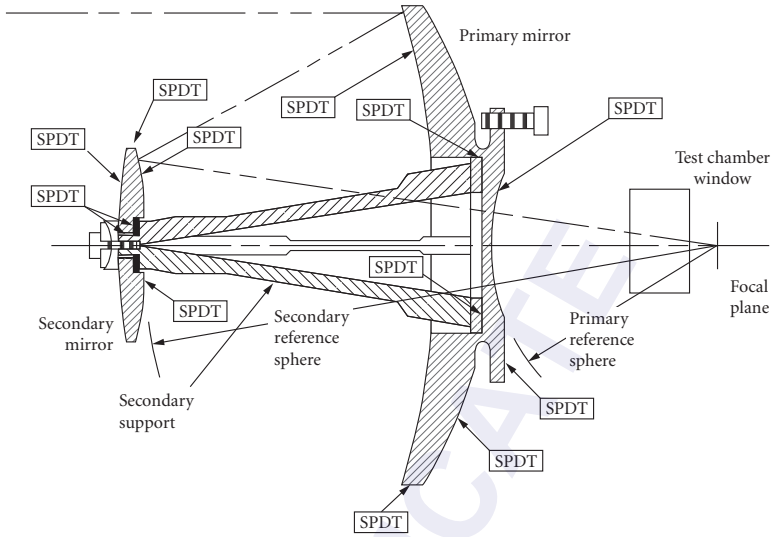

FIGURE 27 Schematic of an all-aluminum (athermalized) telescope objective with optical and mechanical interface surfaces finished by SPDT for ease of assembly without alignment. (*From Erickson et al.*[33])

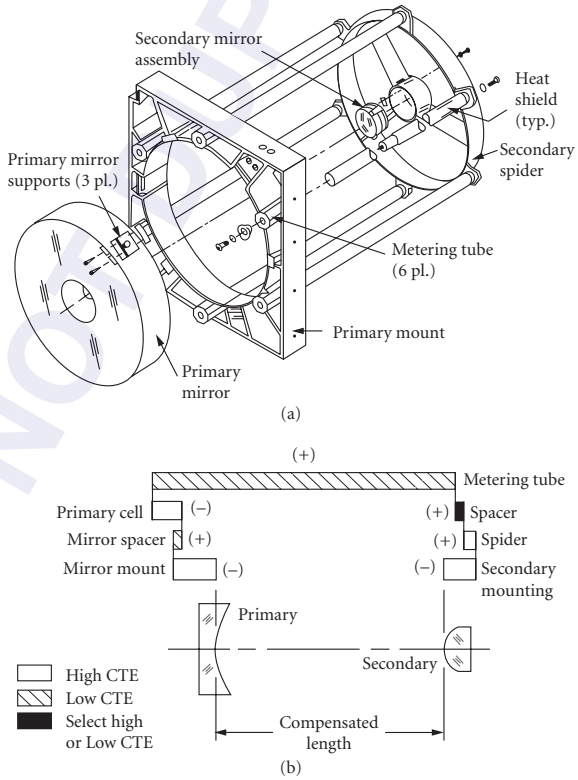

FIGURE 28 A passively athermalized telescope structure using Invar metering tubes to connect the primary and secondary mirror mounts. (*a*) Exploded view of the telescope. (*b*) Model of the compensation system. (*From Zurmehly and Hookman*[34])

mirror separation changes as the temperature rises. Proper choices of materials for their coefficients of thermal expansion and dimensions make the mirror separation remain constant as the temperature changes.

Active Athermalization When a source of power is available, components in an optical system can be physically moved to compensate for the effects of temperature changes. For example, Fig. 29*a* shows a concept for a zoom lens system in which locations of the moveable lenses are varied by motors as commanded by an internal microprocessor that monitors the temperature of the system.[35] As indicated in Fig. 29*b*, desired magnification inputs from the operator are automatically converted into the lens shifts required to focus properly on the object at the measured temperature.

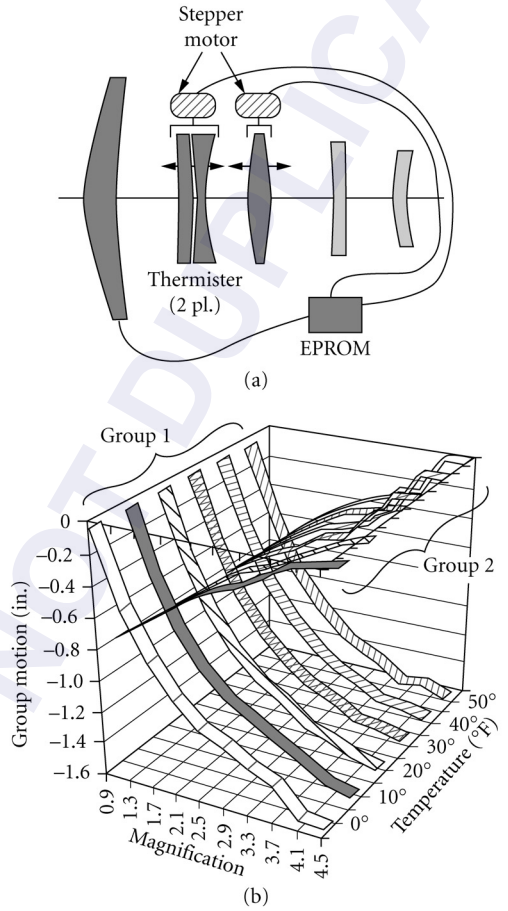

FIGURE 29 An actively athermalized zoom lens system that drives two lens groups to maintain focus at selectable magnification settings in spite of temperature changes. (*From Fischer and Kampe.*[35])

7.1 GLOSSARY

A	area
BRDF	bidirectional reflectance distribution function
GCF	geometric configuration factor
L	radiance
R	distance
θ, ϕ	angles
Φ	power
Ω	solid angle

7.2 INTRODUCTION

The analysis of stray light suppression is the study of all unwanted sources that reduce contrast or image quality. The control of stray light encompasses several very specialized fields of both experimental and theoretical research. Its basic input must consider (1) the optical design of the system; (2) the mechanical design, size, and shape of the objects in the system; (3) the thermal emittance characteristics for some systems; and (4) the scattering and reflectance characteristics of each surface for all input and output angles. It may also include spectral characteristics, spatial distribution, and polarization. Each of these areas may be concentrated on individually, but ultimately the analysis culminates in the merging of the various inputs.

Developments in detector technology, optical design software, diffraction-limited optical designs, fabrication techniques, and metrology testing have created a demand for sensors with lower levels of stray radiation. Ways to control stray light to meet these demands must be considered during the "preliminary" conceptual design. Decisions made at this time are, more often than not, irrevocable. This is because parallel studies based upon the initially accepted starting design are often very expensive. The task of minimizing the stray radiation that reaches the detector after the system has been

designed by "adding on" a suppression system is very difficult. Therefore, every effort should be made to start off with a sound stray light design. To ensure a sound design, some stray light analysis should be incorporated in the earliest stages of a preliminary design study.

This chapter presents some basic concepts, tools, and methods that you, the optical or mechanical designer, can consider when creating a sensor system. You do not need to be very experienced in stray light suppression to design basic features into the system, or to consider alternative designs that may significantly enhance the sensor's performance. The concepts are applicable to all sizes of optical instrumentation and to virtually all wavelengths. In some cases, you can use the concepts to rescue a design when experimental test results indicate a major design flaw.

7.3 CONCEPTS

This section outlines some concepts that you can use to reduce stray radiation in any optical system. The section also contains some experimental and computer-calculated data as examples that should give you some idea of the magnitude of the enhancement that is possible.

The power on a collector depends on the following:

1. The power from the stray light source.
2. The surface scatter characteristics of the source; these characteristics are defined by the bidirectional scatter distribution function (BSDF).
3. The geometrical relationship between the source and collector. This relationship is called the geometrical configuration factor (discussed later in this section).

To reduce the power on the detector, we can try to reduce the contributions from these elements:

$$\Phi_{\text{collector power}} = \Phi_{\text{source power}} \times \text{BRDF}_{\text{source}} \times \text{GCF}_{\text{source collector}} \times \pi \tag{1}$$

Ways to reduce each of these factors are discussed below. The creative use of aperture stops, Lyot stops, and field stops is an important part of any attempt to reduce the GCF term of the power transfer equation.

For the discussion that follows, examples from a two-mirror Cassegrain design, with the aperture stop at the primary, will be used to stimulate thoughts about stray light reduction possibilities for other sensors.[1] The system is shown in Fig. 1.

Critical Objects

The most fundamental concept is to start the stray light analysis from the detector plane of the proposed designs. The most critical surfaces in a system are those that can be seen from the detector position or focal surface. These structures are the only ones that contribute power to the detector. For this reason, direct your initial attention toward minimizing their power contributions by removing them from the field of view of the detector.

The basic idea is to visualize what would be seen if you were to look out of the system from the image plane. Unlike most users of optical instruments, the stray light designer's primary concern is seldom the object field, but rather all the interior surfaces that scatter light. It is necessary to look beyond the radii of the imaging apertures to find the sources of unwanted energy. Removing these sources from the field of the detector is a real possibility, and will result in a significant improvement in the system.

Real-Space Critical Objects

I will start out by identifying a particular critical real-space object that can be seen by the detector in our example; it is the inside of the secondary baffle. The direct view discussed here is different than the image of the same baffle reflected by the secondary which is discussed in the next section.

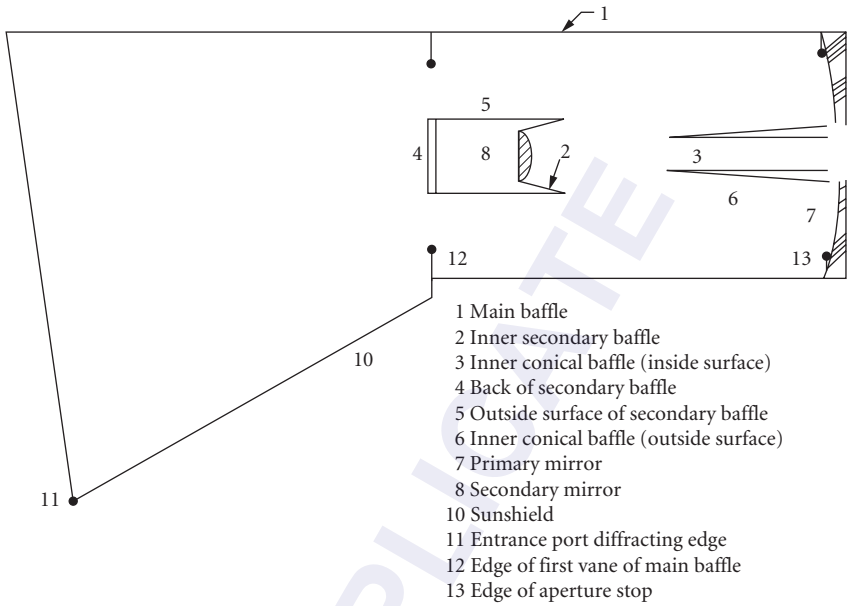

FIGURE 1 Typical Cassegrain design with the aperture stop at the primary. (*Ref. 2, p. 52.*)

Many Cassegrain secondary baffles have been designed to be cone-shaped (Fig. 2), usually approximating the converging cone of light from the primary. From the detector, portions of this secondary cone are seen directly as a critical surface. Since most of the unwanted energy is incident on this baffle from nearly the same direction as this surface is seen from the detector, the addition of vane structures would be of little help, assuming an optimum coating is used on the simple baffle. If the cone is made *more* cylindrical, the amount of critical cone area is reduced, and the angle at which the surface is seen gives a smaller projected area (Fig. 3).

Avoid making the baffle cylindrical because the outside of it would be seen. Since the detector is of a finite size there is a fan of rays off the primary representing the field of view of the telescope.

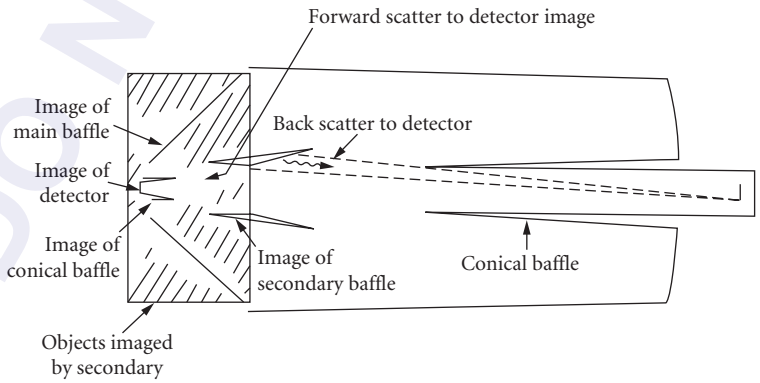

FIGURE 2 Direct and reflected scatter from the cone-shaped secondary baffle. (*Ref. 1, p. 4.*)

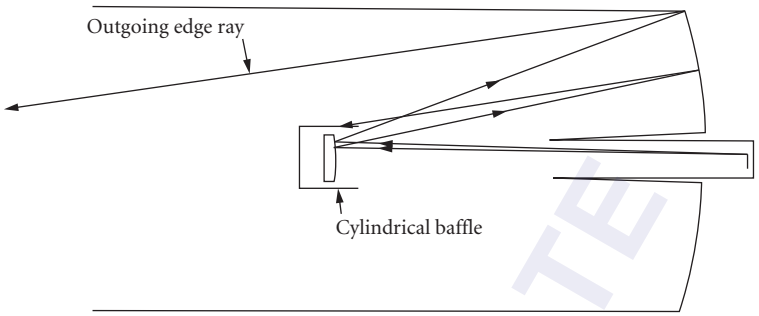

FIGURE 3 Reduced scatter from an almost cylindrical-shaped secondary baffle.

Although collimated for any point on the detector, any point not on axis would have its ray bundle at some angle to the optical axis, hence a cylindrical secondary baffle would be seen from off-axis positions on the detector.

Imaged Critical Objects

Imaged objects are often critical objects. They too can be seen from the detector. Determining which of the imaged objects are critical requires a bit of imagination and usually some calculations; stray light software can help you make the calculations. The Y-Y bar diagram can help you to conceptualize and determine the relative image distances and sizes with a minimum number of calculations.[3] The same could be done with other first-order imaging techniques (see Chap. 1 in this volume). Using the Cassegrain example again (Fig. 2), you can see that reflected off the secondary mirror are the images of the detector and the inside of the inner conical baffle (object 3 in Fig. 1). In some designs the outside of the conical baffle will be seen in reflection. These are *imaged critical objects*. If you wish, you can eliminate some of these images with a central obscuration on the secondary, or for the conical baffle, with a spherical mirror concentric about the image plane. The direct view to the inner conical baffle will remain, but the path from the image of it is removed.

The cone-shaped secondary baffle is also seen in reflection (Fig. 2). For the incident angles of radiation on this surface, the near specular (forward-scattering) characteristics will often be one of the most important stray light paths because the image of the detector is in that direction. This is an extension of *starting from the detector*. There is an image of the detector at the prime focus of the primary mirror. Often, as in this case, one location may be easier than another for you to determine what could be seen. By making the baffle more cylindrical, part of the *image* of the baffle is removed from the detector's view; as a result, the power that can scatter to the detector is reduced. Furthermore, it is sometimes possible to baffle most of this power from the field of view with one or two vanes (Fig. 4).

Continue the process of removing critical surfaces until all the critical surfaces have been considered for all points in the image plane. The power contributions from these surfaces will either go to zero, or at least be lessened after you reduce the area of the sections seen.

There is still more that can be done, since only the GCF term in the power transfer equation to the detector has been reduced. It is also possible to minimize the power onto the critical sections, which will become the source of power, Φ, at the next level of scatter. This approach can be very similar to the approach used for minimizing the power scattered to the image plane. The viewing is now forward from the critical surfaces instead of the image plane. By minimizing the BRDF and GCF factors of the surface scattering to the critical sections, the power incident on the critical surfaces will be reduced. Hence, the power to the detector is also reduced.

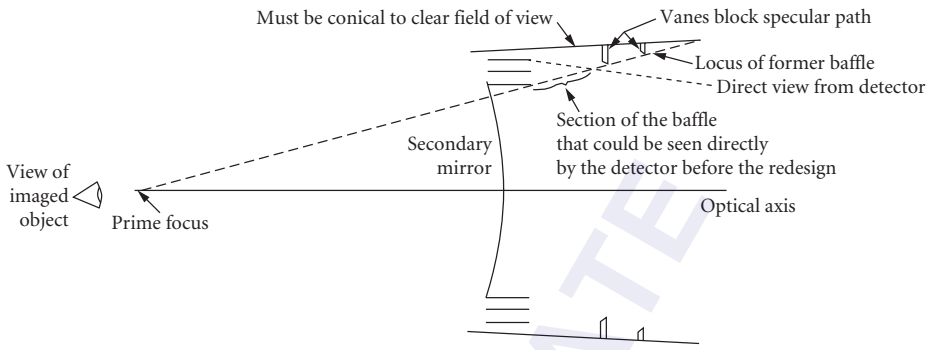

FIGURE 4 A cylindrical secondary baffle can be seen from off-axis positions on the detector.

Illuminated Objects

Minimizing the GCFs and BRDFs for the specific input and output angle is sometimes easier if you look into the system from the position of the stray light source in object space. By doing this, you can identify the surfaces that directly receive the unwanted energy. I will call these the *illuminated objects*. If any of these illuminated surfaces contain sections that the detector can see, then you should direct your initial efforts toward eliminating these paths. These paths will usually dominate all other stray light paths because there is only a single scatter before the stray light reaches the detector. An example of such a path that is often encountered is from the source onto the inner conical baffle of multimirror systems (Fig. 1). Some of the ways that the direct radiation can be eliminated is by extending the main baffle tube, increasing the obscuration ratio by increasing the diameter of the secondary baffle (Fig. 5), or by narrowing the field of view, which will allow you to extend the secondary baffle and the inner conical baffle toward each other.

The effect of eliminating this path is shown in a composite Point Source Transmittance (PST) plot in Fig. 6.[4] The PST plot is defined as the reference plane (detector plane in most cases) irradiance divided by the input irradiance along the line of sight. (See the section called "Point Source Transmittance Definitions" for a more detailed definition of PST.) For the case shown, the unwanted irradiance on the detector is reduced by over an order of magnitude.

Aperture Placement

I will now focus on the optical design aspects of a stray light suppression system, and give a qualitative discussion of some general aspects that you might consider. All optical systems will have at least

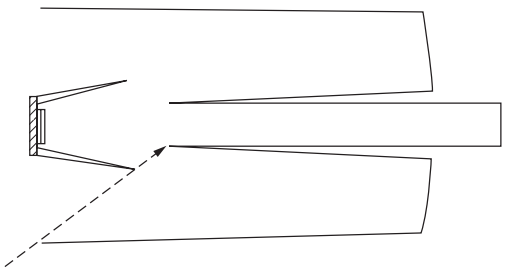

FIGURE 5 Increased obscuration ratio blocks direct path to inner conical baffle. (*Ref. 1, p. 6.*)

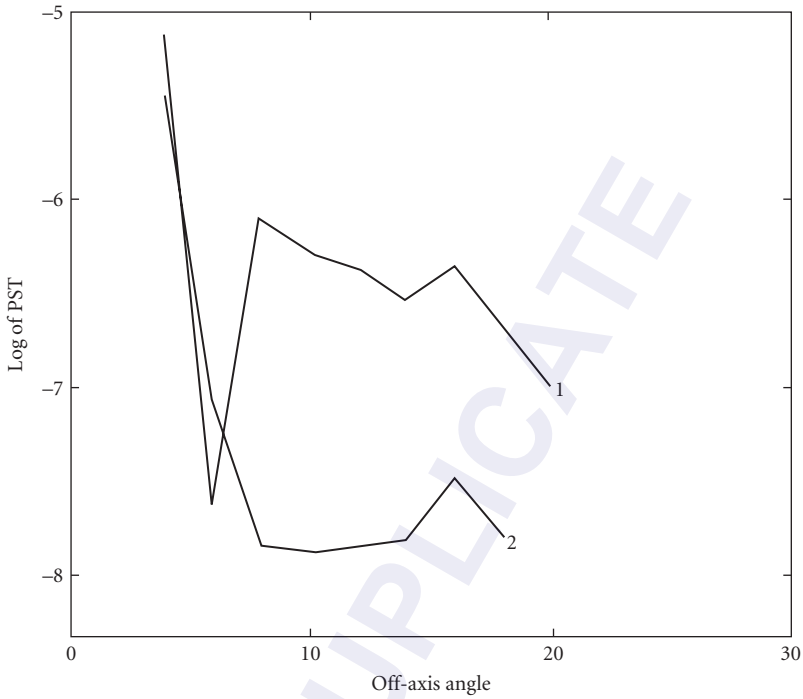

FIGURE 6 Point source transmittance with obscurations of (1) 0.333 and (2) 0.4. The 0.4 obscuration removed the direct path from the source to the inner conical baffle. (*Ref. 1, p. 6.*)

one aperture, called an *aperture stop*, that limits the size of the bundle of the incoming signal rays. Some systems will have field stops and/or Lyot stops. Each type of stop has a clearly defined role in stray radiation suppression, which is discussed in the following sections.

In many cases stop placement will have a much more noticeable effect on system performance than any vane structure, coating, or baffle redesign. Probably the only factor with more effect on the PST curve is the off-axis position of the source. Therefore, the benefits of any of the stops cannot be overemphasized.

Aperture Stops The aperture stop is the aperture that limits the size of the cone of radiation that will reach a point on the image plane. Sometimes shifting this stop allows the optical designer to better balance the aberrations. In a stray radiation suppression design, it plays a similar important role. All objects in the spaces preceding the stop in the optical path will not be seen unless they are imaging elements, central obscurations, or objects that vignette the field of view. Only a limited number of critical objects is possible before the aperture stop. In the intervening spaces from the stop to the image plane it is likely that many of the baffle surfaces will be seen. Figure 7 represents a two-mirror design, and Fig. 8 represents a three-element refracting system; both have the stop at the first element. In both cases the second element is oversized to accommodate the field of view from a point in the field stop; the amount depends on the full field of view of the design. Because the elements are oversized, the main baffle following the first element will be seen. This baffle will be a critical object, a direct path of unwanted energy. The "overviewing" is characteristic of all of the optical elements past the aperture stop.

If you move the stop along the optical path toward the detector plane, its performance as a stray radiation baffle will improve. If you shift the stop to the second element, the intermediate baffle will

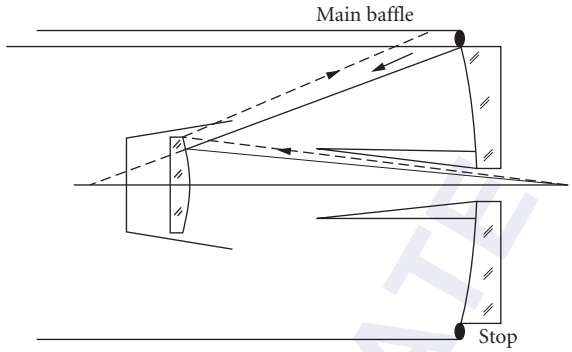

FIGURE 7 The oversized secondary allows the main baffle to be seen in reflection. (*Ref. 1, p. 8.*)

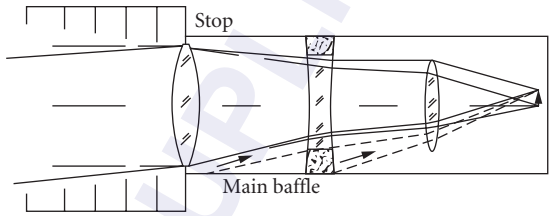

FIGURE 8 The main baffle is seen through the oversized secondary and tertiary. (*Ref. 1, p. 8.*)

not be seen. It is removed from the field of view of the detector, since the stop now eliminates direct paths from baffles in all spaces that precede it. Figure 9 shows the improvement in the PST curve for a two-mirror system. By moving the stop you have reduced the PST by a factor of 10. This is a desirable feature to consider for stray radiation reduction.

Direct paths from central obscurations can be blocked by a central disk located at some location deeper into the system; however, because of the parallax involved between the central obscuration disk and this central disk, the central disk obscuration will usually be a larger obstruction to imaging rays. In a reimaging design it is often possible to locate a central disk conjugate to the actual central obscuration.

Field Stops An aperture can be placed at intermediate *images* in a system to limit the field of view. Such an aperture will usually prevent any stray light from outside of the field of view from being directly imaged into the system beyond this field stop aperture. In a sense, its operation is just opposite that of an aperture stop. Baffle surfaces following a field stop cannot be seen from outside the field of view in the object plane, unless they are central obscurations. Note that with just a field stop, succeeding optical elements may allow out-of-field critical sections to be seen *through* the field stop, from within the field in the image plane (Fig. 11). Aperture stops are necessary to block such paths. Figures 10 and 11 show two such cases. Although for some designs the field stop is not 100 percent effective because of optical aberrations, its small size limits most of the unwanted stray light. Field stops therefore do not remove critical sections, but rather limit the propagation of power to illuminated objects. In reflecting systems, take care that the object side of the field stops does not become a critical area, which can be seen directly or in reflection from the image plane because unwanted energy is being focused onto them.[5]

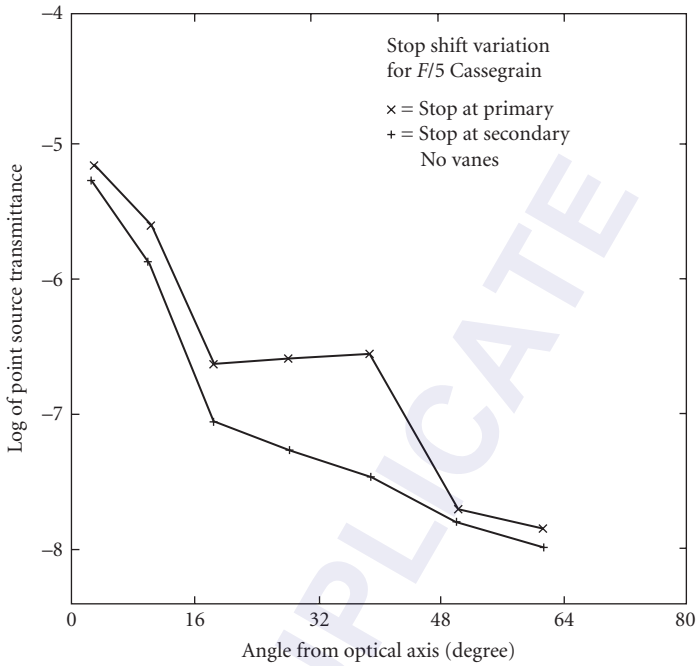

FIGURE 9 PST improvement with stop shift for the two-mirror system. (*Ref. 1, p. 8.*)

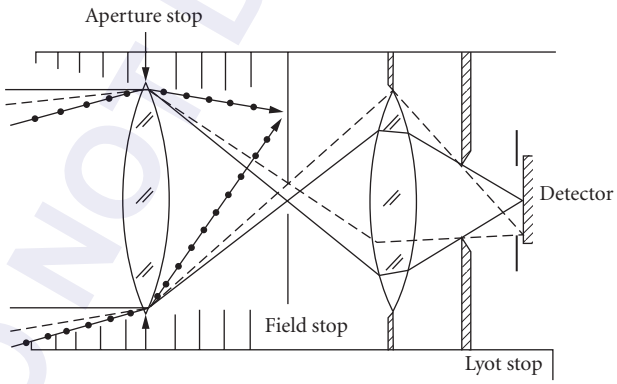

FIGURE 10 The addition of a Lyot stop prevents preceding baffles from being seen from the image.

Lyot Stops A limiting aperture placed at the location of the image of an aperture stop, sometimes called a glare stop or Lyot stop, has the same property as described for aperture stops. It should be slightly smaller than the image of the aperture stop. It limits the critical sections which are out of the field of view to those objects in succeeding spaces only. Since Lyot stops are by definition further along the optical path to the detector, the number of critical surfaces seen by the detector will be reduced. Usually, these stops are incorporated into the design to block the diffracted energy from an aperture stop and field stop pair, so that only secondary or tertiary diffracted energy reaches the image. Nevertheless, both diffracted and scattered energy are removed from the direct

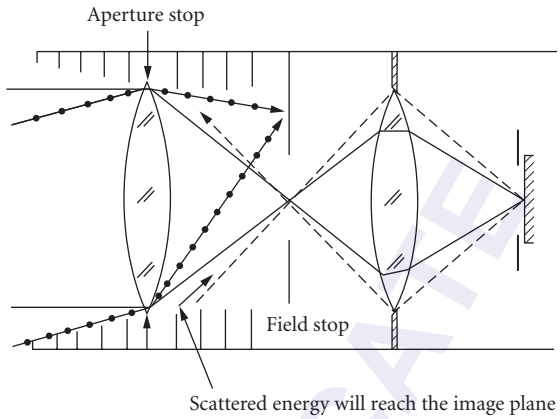

FIGURE 11 Out-of-field energy in object plane will not be imaged beyond field stop. Out-of-field energy elsewhere may be seen. (*Ref. 1, p. 9.*)

view of the image, re imaging the largest optical element as the stop takes full advantage of both the light-gathering power of the optics and the stray radiation suppression features provided by the stop. Figure 10 shows a system with a Lyot stop.

On space-based telescopes the image plane is often *shared* by one or more instruments. Each instrument reimages the telescope's image through some optical train, and eventually onto the detector. In that optical train there could be a logical place to use a Lyot stop to improve the stray light performance of the viewing instrument well beyond that of the telescope.

It is the combination of these different stops or apertures that helps minimize the propagation of unwanted energy by limiting the number of critical objects seen by the detector, and the objects illuminated by the stray light source.

When all direct paths have been eliminated, the next step is to determine the relationship between the sections that received power (illuminated objects) and the critical surfaces. This relationship takes the form of scattering *paths*; that is, stray light can scatter from the illuminated objects to the critical objects. To start reducing the stray light contributions from these paths, you can start at the critical surfaces as described above. But now you have more knowledge about where the direct incident power is being distributed throughout the system, since you can also look into the system from the source side to find the surfaces receiving direct power. With this information you can identify the possible paths between the illuminated and critical surfaces.

Design considerations for extended baffle shields (Figs. 12 and 13) provide a good example of starting from the source side to identify possible paths. In the examples, object 2 (an optical surface) is the largest contributor of scattered radiation and is the best superpolished mirror available

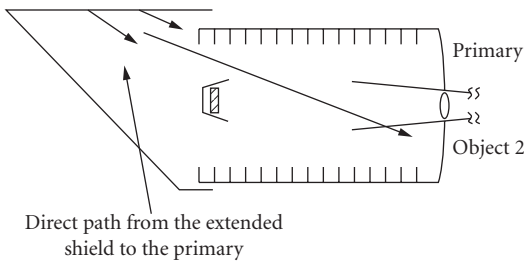

FIGURE 12 There is a direct path from the baffle to the primary mirror. (*Ref. 1, p. 7.*)

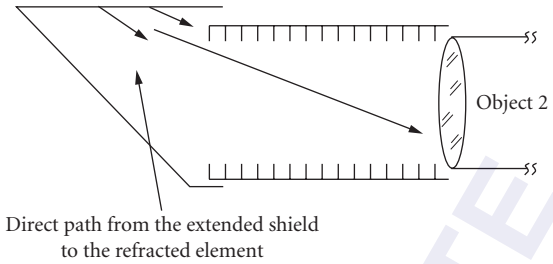

FIGURE 13 There is a direct path from the baffle to the refracting element. (*Ref. 1, p. 7.*)

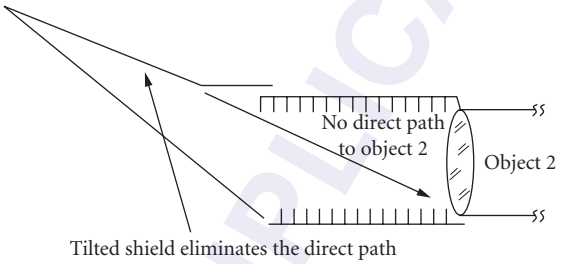

FIGURE 14 Direct paths are removed by properly tilting the shield. (*Ref. 1, p. 7.*)

(Fig. 12), or if it is a lens as in Fig. 13, it has the lowest possible scattering characteristics. It cannot be removed from the view of the image plane. If the initial power incident on object 2 is only from the extended shield, then by tilting the shield (Fig. 14), the power on the shield must first scatter to the main tube and then to the optical element. The combination is then referred to as a two-stage baffle. If vanes are added to the main baffle, the scattered radiation incident on the optical element will be reduced by many orders of magnitude when all the scattering solid angles and the number of absorbing surfaces are considered. Note that without the tilt to the shield, vanes on the main baffle are worthless because there is a direct path to the objective.

Figure 15 is an abstract representation of the process of reducing stray light in a sensor system. Start at the detector, then work from its conjugate image locations. Starting from the detector simplifies the analysis and directs your attention to the most productive solutions, because you can identify all the possible sources of stray light to the detector. You can then work at decreasing their number by slightly redesigning the baffles and stops. Next, identify which objects are illuminated. Discover how energy may propagate between them and you have identified the paths of stray light propagation. From then on the process of moving objects or blocking paths is quite simple, although the quantitative calculations might get difficult and may require some analysis software.

Baffles and Vanes

A few definitions are required to define baffles and vanes. Other authors have used their own different definitions. In this section the term *baffle* is used to describe conical structures (including cylindrical) that can also be described as tubelike structures. Their function is to shade, or occult, stray light from the source to one or more system components. The main baffle shields the primary

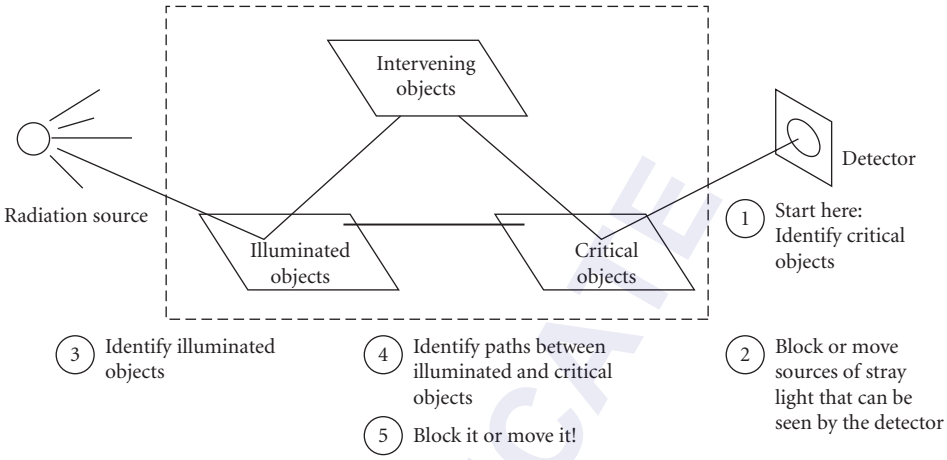

FIGURE 15 The first step in a stray light analysis begins from the detector plane, not from the source.

mirror from direct radiation at the larger off-axis angles. *Vanes* are structures put *on* baffles to affect the scatter characteristics of the surface. Other authors have used the term "baffles," or "glare stops," to describe these vanes.

Baffles In a well-designed system vanes play an important role only at large off-axis angles. For example, when one-tenth of the stray light falls on the primary of the Cassegrain design, then the main baffle receives the remaining 90 percent of the stray light. When the main baffle has properly designed vanes on it, light that falls on the baffles is attenuated by five orders of magnitude before it reaches the primary mirror. The resultant power on the primary mirror is then about 9.0×10^{-5} compared to the direct 10 percent that fell on the mirror. This results in less than 0.1 percent of the total on the primary. In addition, most of the subsequent scatter off the primary will be at much higher scatter angles. This will cause the scattered energy to have much lower BRDFs off the primary mirror when scattered in the direction of the detector, further reducing the scatter contribution from the baffle.

Only when no power illuminates the objective will the baffles play a significant role in the propagation paths of the stray light. Usually the system's performance merit function is then very good. Only if the stray light source has a tremendous amount of energy, like the sun, does the stray light become measurable.

Vanes The depth, separation, angle, and bevel of vanes are variables that need to be evaluated for every design. In the following paragraphs stray light analysis results are presented for both a centrally obscured system (Cassegrain) and an unobscured eccentric pupil design (Z-system).[6] Profiles of these systems are given in Figs. 2 and 16. Of the two designs, only the eccentric pupil design has a reimager that would allow for the placement of an intermediate field stop and an accessible Lyot stop, as discussed above.

The APART stray light analysis program was used to analyze the two designs. The APART program was a substantial software package that performed deterministic calculations of stray light propagation in optical systems.[2,7,8]

As an example of vane design considerations, the design of vanes on a main baffle tube will be explained. With minor differences, the design steps are the same for the Cassegrain and the eccentric pupil designs. In a reimaging system, vane structure deep in the system is usually not necessary, but there are exceptions. Figure 17 shows a collecting optical element that has some small field of view (FOV). The optical element could represent a primary mirror or a refractive element.

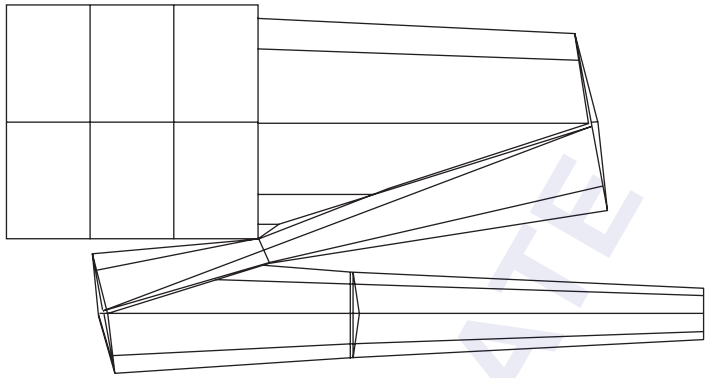

FIGURE 16 Confocal mirror system, eccentric pupil, no obscuration, low-scatter system. (*Ref. 6, p. 91.*)

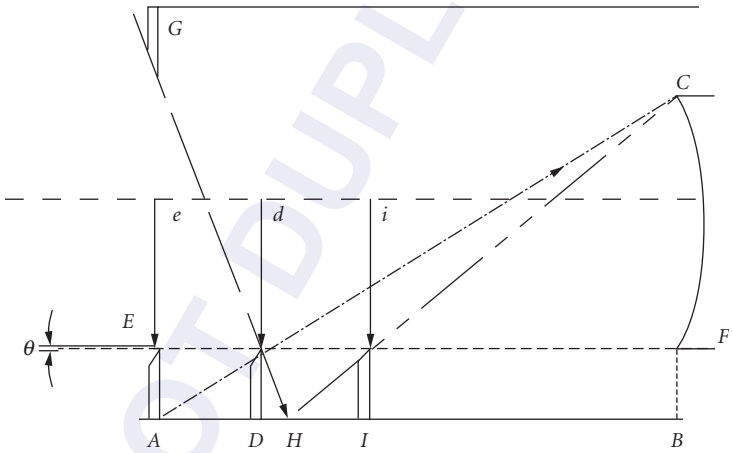

FIGURE 17 Vane placement design, lowercase letters are radii (measured from the optical axis), uppercase are *z* locations. (*Ref. 6, p. 94.*)

The placement of a straight, diffusely coated cylindrical tube would block the direct radiation from an external source, such as the sun, from reaching the optical element for a certain range of off-axis angles. If it were at a large off-axis angle, the forward scatter off the inside of the tube would be so high that it would normally not be acceptable. The solution is to add vanes to block this path.

Figures 18 and 19 depict the two cases that could represent the scatter from a baffle. In one case there are no vanes; in the other case there are vanes. This example shows how a propagation path is blocked by vanes. Vanes are useful, but a better approach is to make the solid angle (Ω_c) from the baffle (not the vanes) to the collectors of the scattered light go to zero, so that there is no path from the baffle and vane structure to the collecting object. By moving the baffle out of the field of view of the collector, the baffle's contribution goes to zero. There is no edge scatter, and no edge diffraction effects. That topic is in the realm of baffle design, which has already been touched on, and is well covered in the literature.[9,10]

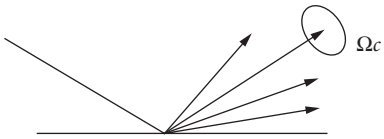

FIGURE 18 High forward scatter path. (*Ref. 6, p. 92.*)

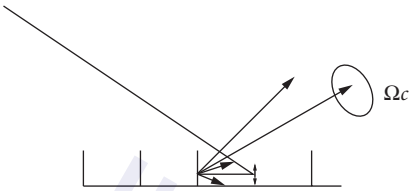

FIGURE 19 Forward scatter path highly attenuated by the vane structure. (*Ref. 6, p. 92.*)

Designing the Vane Spacing and Depth[11]

A first vane is most often placed at the entrance of the baffle and an external ray is brought in from object space at a maximum off-axis position. If there is no forebaffle the angle is 90° off axis. The depth of the vane cavity is normally dictated by space and weight requirements. Too little depth will dictate the requirement for many vanes. Then vane edge scatter eventually becomes the major source of scatter instead of multiple vane scatter.

The initial ray will strike the side wall at the base of the first vane (point *A* in Fig. 17). From this point, a design line is drawn/calculated (*AC*) from the wall to the edge of the optical element on the opposite side. This line (*AC*) intersects the edge ray (*EF*), at *z* position *D*. At this point a vane could be placed. Mathematically, this assures that any point below *C*, including those on the optical element, would not see any directly illuminated side wall. However, practicality dictates that some offset of point *D* to a point *D′* (not shown) is required to allow for tolerance errors in fabrication of the vane, thermal effects, assembly errors, and for stray light edge scatter and diffraction effects. The tolerance allowance is company-, material-, and design-dependent. Acceptable numbers are often about 0.125 mm for fabrication and assembly tolerances. For the rest of this analysis, assume that this is accounted for.

Continue the design process by constructing another line from the edge of the entrance aperture to the tip of the second vane to the wall (line *GH*). Draw a new *HC* line to the area near the objective and determine the placement of the third vane (at *I*); once tolerances are considered, iterate the process to reach a final design. In some cases you may have to consider more than just the scatter path to the objective. In the Cassegrain design you may also have to consider the inner conical baffle opening. It is beyond the present scope to go into further detail.[12]

Bevel Placement on Vanes In this short discussion on baffle-vane design and placement, I did not mention the placement of a slanted surface, or bevel, sometimes placed on a vane edge as shown in Fig. 20. Which side should the bevel go on? The answer is usually dictated by first-order scatter principles.[13,14] Near the front of the tube, direct radiation from a source at large off-axis angles will strike this bevel. If it is placed on the right side (Fig. 21), then the illuminated bevel will scatter its radiation all the way down into the tube to some optical surface. If placed on the left side, as depicted in Fig. 20, then it will go only 16° deeper into the system to the opposing vanes, a much better solution. For vanes deeper into the system, the bevel is placed on the right side. The point at which this is done is determined by the angle of the bevel and the diameter of the baffle tube. At some point, external radiation will not be able to directly strike the beveled edge if it is on the right-hand side of the vane. Only the nonbeveled, straight side will be illuminated. Therefore, the vane can rescatter only in the left side of the hemisphere, which is in the direction of going out of the system. If the bevel is placed on the left side, it can scatter 16° (in the example) deeper into the sensor; this is usually a needless design shortcoming that could be a significant error.

Vane Angle Considerations Another variation on the design feature of vanes that has sometimes been incorporated onto baffles in an optical system is angled vane structure. These vanes are nonplanar objects. This makes them quite tedious to cut out of sheet metal, fabricate, and install.

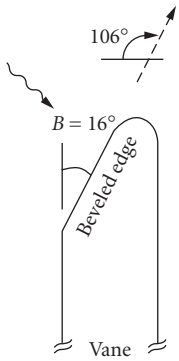

FIGURE 20 Placement of the bevel on the left side of the vane structure. (*Ref. 6, p. 96.*)

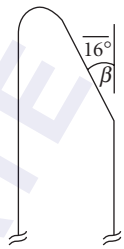

FIGURE 21 Placement of the bevel on the right side of the vane structure. (*Ref. 6, p. 96.*)

FIGURE 22 Vane structure angled at 90, 70, and 45°, respectively. (*Ref. 6, p. 97.*)

The next few paragraphs will present computer analysis results from two designs to show the effect of vanes on the propagated stray light. The vane angles used were 90, 70, and 45°, as depicted in Fig. 22.

The comparative stray light results for the Cassegrain system (Fig. 1) with a Martin Black coating on the vanes are shown in Fig. 23; in this system the vanes are on the main baffle, but not on the sunshade. There is no difference in the performance as the vane angle is varied from 45° to 90° (all three curves lie one on top of the other).

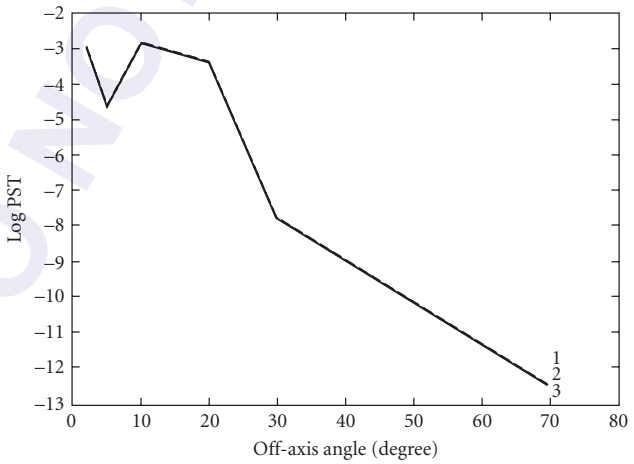

FIGURE 23 Cassegrain with Martin Black. Vane angles 1 = 90°, 2 = 70°, 3 = 45°. Log PST = detector irradiance divided by input irradiance. (*Ref. 6, p. 97.*)

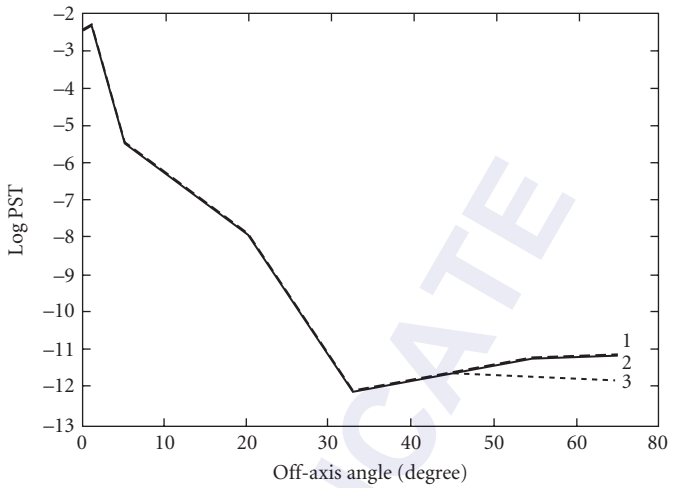

FIGURE 24 Z-system with Martin Black. Vane angles 1 = 45°, 2 = 70°, 3 = 90°. Vanes are on the sunshield. (*Ref. 6, p. 114.*)

The comparative results for the Z-system (Fig. 16) with vanes on the sunshield are shown in Fig. 24. The results differ from the Cassegrain results for source located at angles greater than 45° off-axis. This is because the primary side of the baffle is illuminated and scatters light directly to the primary mirror. The 70° baffles would fail for sources beyond 70° off-axis. The Cassegrain system has vanes on the main baffle (not the sunshade) and the sunshade occulted the direct illumination of the primary side of the 45° vanes. This accounts for the subtle but important difference in the results.

Usually the first-order scattering properties of the vane structures are more important than whether the vanes are angled or not. The results presented above confirm this statement. There are occasions where angled vanes would be beneficial, but to fully understand those cases a much longer explanation of diffuse vane baffle scatter is necessary. These results are detailed elsewhere.[15,16]

There are special situations where angled vanes will have a significant advantage over annular vanes. One example is a bright source at a fixed offset angle. I have seen such a feature on a space-borne telescope on a platform where there was nearby a brightly sunlit rocket-thruster casing at a fixed angle outside the field of view. Figure 25 shows the design where the vanes were aimed at the thruster at an angle where the primary mirror side (right side in Fig. 25) could not be directly illuminated by the sunlight scattered off the thruster. Under those circumstances most of the stray light

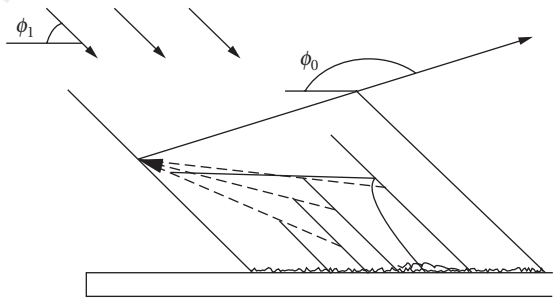

FIGURE 25 Angle-staggered vanes for fixed input angle. (*Ref. 6, p. 104.*)

had to make three scatters before exiting the vane cavity. In general, as soon as the position of the bright object is moved over a range of angles, the advantage of the angled vanes is lost. Nevertheless, there are many occasions within a sensor where the relative positions of a scattering source and a collecting object are fixed along a major stray light path. The front parts of the main-barrel baffle and the opening of the inner conical baffle in the Cassegrain design is an example. Many more examples could be cited. But the point is that you, as a designer, should first consider the first-order, single scatter paths off the baffle wall, each side of the vanes, and the bevel, for the full range of input values. Based on that information you can make the decision to user planar or angular vanes.

Vane Depth Considerations By varying the vane depth in the example analysis we can evaluate how the vane spacing-to-depth ratio affects system performance. Figure 26 gives the results of an analysis of the Cassegrain system with varying vane depths on the main baffle of 0.2, 0.4, and 0.8 inches. Figure 27 gives similar output from the Z-system analysis results. The performance of the system gets better as the vane depth increases from 0.2 to 0.4 inches, but there is little performance difference between the 0.4- and 0.8-inch baffle depths. The latter is the normal case. The 0.2-inch vane depth allows for a single path from the walls of the baffle tube, which increases the stray light propagation. Once that path is blocked by a greater vane depth, no further improvement should be expected due to further increases in vane depth.

The intent of presenting the two different optical designs was not to trade off one optical design against another. It needs to be made clear that the two optical sensors being used as examples are intentionally not equivalent from stray light design considerations. This is why the changes in performance are design-dependent. The nominal design of the eccentric pupil has a reimager, and the Cassegrain does not. The Cassegrain could have a reimager, in which case the stray light performance of both could be made essentially equal. It would depend on the optical design characteristics, F/#, field of view, obscuration ratio, etc. The Cassegrain design has a specular sunshield and the Z-system has a vaned diffuse baffle structure. Which would perform better could only be determined after all of these features are considered.

To summarize, the general points being made in this section are

1. Usually, angled vane structure has little, if any, additional benefit over straight, annular vanes, and the annular vanes are much easier to fabricate and assemble.
2. Once the depth of a diffuse black vane structure is deep enough to block the single scatter path, further increases will not improve performance.

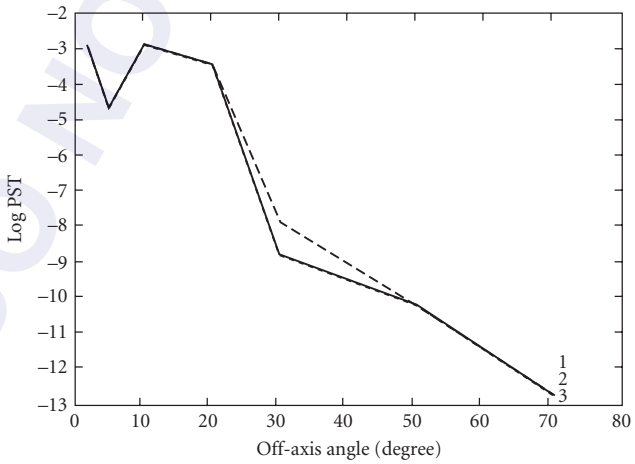

FIGURE 26 Cassegrain 90° baffles, coated with Martin Black, at varying depths; 1 = 0.2-inch, 2 = 0.4-inch, 3 = 0.8-inch depth. (Scatter is dominated by baffles.) (*Ref. 6, p. 98.*)

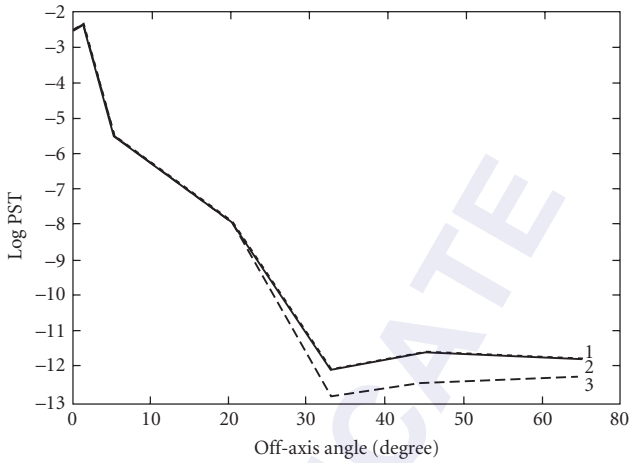

FIGURE 27 Z-system with varying vane depths. 1 = 0.2-inch, 2 = 0.4-inch, and 3 = 0.8-inch depth. (*Ref. 6, p. 114.*)

Specular Vanes Another aspect about vane structure that has been explored, but only in a limited way, is the specular vane cavity. Previous studies indicated that specular vanes have a problem with the aberrated rays and near specular angle scatter; this problem is severe enough to degrade the performance significantly.[17,18] In another study by Freniere this was not always true.[19] The ASAP[20] stray light software was used to evaluate the Z-system (Fig. 28) with (1) no vane structure, but with the main barrel baffle coated with Martin Black; (2) with Martin-Black-coated vanes; and (3) with a specular vane structure. The results show a dramatic degradation in the stray light performance without the coating on the main baffle tube. A subsequent specular baffle design developed by Nick Stavroudis has been shown to be a major improvement over previous concepts.[21]

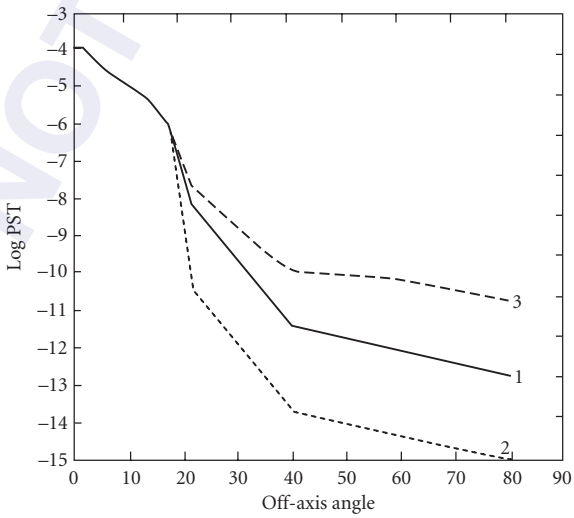

FIGURE 28 PST for unobscured pupil design without vane structure, with diffuse vane structure, and with specular vanes. 1 (solid) = no vanes, diffuse black coating; 2 (dotted) = diffuse vanes on main tube; 3 (dashed) = specular vanes on main tube. (*Ref. 6, p. 115.*)

Contamination Levels

Light scattered from a particulate-contaminated surface can have a pronounced effect on the stray light performance of a system.[22]

I will now relate the performance of both designs (the centrally obscured Cassegrain, and the unobscured eccentric pupil) as a function of the level of scatter, per MIL-STD 1246A.[23] This analysis evaluates the sensor for different amounts of contamination on the optics only. The levels of contamination as defined in IEST-STD-CC1246D are for a distribution of particles with a specified range in particle sizes.

Ray Young used Mie scattering theory to predict the BRDF of a mirror covered with such MIL-STD distributions.[24] Table 1 was generated from Young's work for the 10 μm radiation. This table shows the base BRDF value and the BRDF slope that would be used in a typical stray light analysis program for input. The base value is the BRDF value at $(\beta - \beta_0) = 0.01$ and the second term is the slope of the BRDF in a (log-log) plot of BRDF versus $(\beta - \beta_0)$. β_0 is the sine of the angle of incidence and β is the sine of the observation angle.[25] The terms work equally well for out-of-plane values, but the above definitions, for simplicity, assume in-plane scattering data. See also the works of Spyak.[22]

Spyak and Wolfe[26] did a series of experiments and calculations that relate BRDF to particulate contamination. They counted and sized particles on a mirror surface, and then measured the contribution of these particles to the mirror's BRDF at both visible (633 nm) and infrared (10.6 μm) wavelengths. They also performed Mie theory calculations and compared their calculations with the measured BRDFs. At both visible and infrared wavelengths, Mie theory calculations were a reasonable estimate for contribution of particulates to a mirror's BRDF. In most cases agreement between Mie calculations and their measurements were within a factor of two. Spyak and Wolfe also published Mie calculations of the BRDF expected from the MIL-STD-1246B (now IEST-STD-CC1246D) standard at 633 nm and 10.6 mm.*

Michael Dittman[27] has published a series of Mie calculations at five wavelengths. His calculations were done for the IEST 1246D distributions, but he considered an additional distribution in which the "particle slope" on the distribution was reduced from 0.926 to 0.383. The latter slope results in more large particles, and is commonly thought to be a more realistic distribution on surfaces that are exposed in a cleanroom environment.*

There is a problem with specifying the optics with this standard because it is difficult to reliably relate a level of contamination by particles to a BRDF performance. Two equal sizes and distributions of particulates may not give the same BRDF, because the index of refraction, the reflectivity, and the roughness of the particulates enter the calculations. In general, few people go to the trouble to determine these other factors. These factors will vary from one distribution to another. BRDF is the most usable value when performing a stray light analysis, so it should be the stray light specification. For manufacturing specifications, other parameters may be more appropriate, but they are not as good as BRDF for a stray light specification.

The level of scatter is also given in Table 1 along with the BRDF. The BRDF data from particulate scatter for the 5-, 10-, and 20-μm wavelengths for the 100, 300, and 500 contamination level have

TABLE 1 Mirror Scatter Relationships [Wavelength = 10 μm, BRDF Slope in Log $(\beta - \beta_o)$]

BRDF at $(\beta - \beta_o) = 0.01$	BRDF Slope	Cleanliness Level
0.02	–1.17	500
0.01	–1.17	454
0.001	–1.17	300
0.0001	–1.17	204
0.00001	–1.17	100

*Personal communication on partical contimination paragraphs, contributed by Dr. Gary Peterson, Breault Research Organization, Inc.

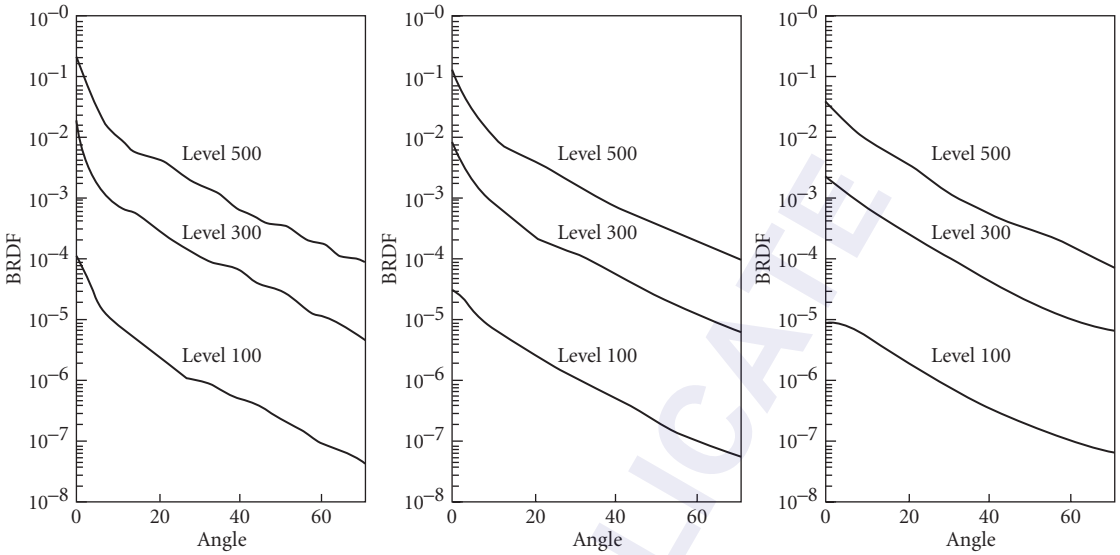

FIGURE 29 Predicted BRDFs on particles deposited on low–scatter mirror for cleanliness levels of 100, 300, and 500 at radiation wavelengths of 5.0, 10.0, and 20.0 μm.[24] (*Ref. 6, p. 105.*)

been plotted in Fig. 29. Consensus, not factually documented, indicates that the current state of the art of contamination control is at the cleanliness level of 300 to 500 for the 10-μm-wavelength region. Measured BRDFs below level 200 are achievable in the lab for short periods of time. A stray light analyst is strongly advised not to predict a system's performance with values below 1.0E-3 sr^{-1} in the 10-μm region. Based on historical performance, mirrors in the IR (10-μm region) consistently degrade to this value, usually because of particulate scatter. Research work performed under Rome Air Development Center contract for the detection, prevention, and removal of contamination from the ground and in space could greatly reduce the degradation currently experienced by IR sensors.[28]

Hal Bennett presents the significance of particulate scatter, as shown in Fig. 30.[29] This figure shows an agreement between measured data and theoretical data, and illustrates why IR sensors are usually more sensitive to particulate scatter than RMS scatter; the opposite is true in the visible. Figure 30 also indicates why the wavelength scaling law does not usually relate visible BRDF measurements to BRDF measurements in the IR. The physical process is different.

Figures 31 and 32 are the representative point source transmittances (defined as the irradiance on the detector divided by the incident irradiance) for the cleanliness levels of 100 through 500 for each design. The Cassegrain is much less affected by changes in contamination level, because the scatter from the black-coated surfaces dominates all other scatters. If the system had a reimager its performance would be better because these black surfaces would be blocked from the field of view of the detector, and the stray light performance would be due to the cleanliness level of the optics. The eccentric pupil design is sensitive to changes in the mirror coatings because it does have a reimager, and the major source of scatter is from the mirror surfaces.

In summary, the impact of particle contamination on the performance of a system will depend on how well the system is designed to suppress stray light. The goal is to be limited by a single optical element, such as the collecting lens or mirror, which is the objective of the system. The eccentric pupil design (Z-system) has this design feature. The better the optical design from a stray light point of view, the more the system's performance will be degraded by particle contamination. The more the system performance is determined by the black coatings, the more it will be sensitive to degradations in the coatings on the baffles.

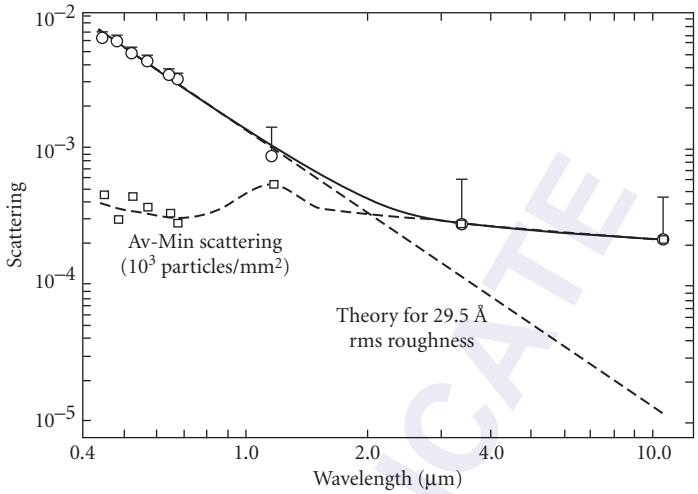

FIGURE 30 Scattering from polished dense flint glass. The diagonal line gives the contribution predicted for microirregularity scattering by a 29.5 Å rough surface. Circles indicate the minimum scattering observed, and the bars and squares the difference between the average and minimum scattering observed at several points on the surface. This difference may be related to particulate scattering. (*Ref. 29, p. 32.*)

Strut Design

In a centrally obscured system the central obscuration must be supported. In some designs (Schmidt-Cassegrains) the obscuration can be supported by a refractive element, but in most designs some form of struts are used. The most common error in strut design is to specify manufacture

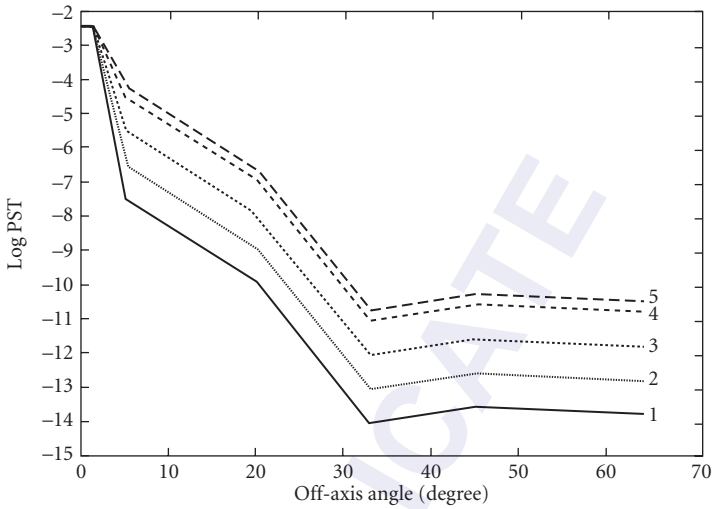

FIGURE 32 Z-system with mirrors at all five contamination levels. 1 = 100, 2 = 204, 3 = 300, 4 = 454, 5 = 500. (*Ref. 6, p. 113.*)

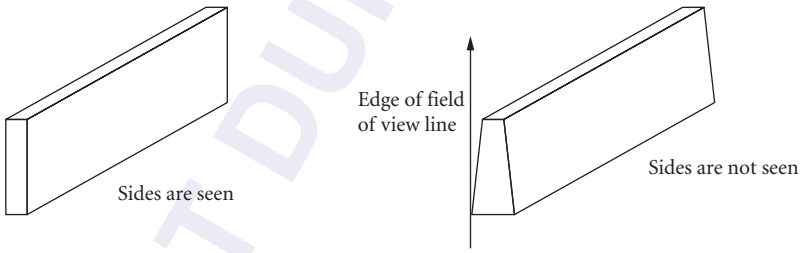

FIGURE 33 Angled strut design does not allow the detector to see the sides of the strut.

from a slab or plate of coated metal. Because all detectors have some finite field of view, the scatter from the sides of the struts can be seen from the image plane. Usually the struts are out "front" and exposed to more stray light sources than the objects deeper into the system. The near off-axis angles of incidence of scattered light off of the strut sides make for very high scattering toward the detector.

The proper strut design will preclude this path by making the object end of the strut narrower than the side nearest the objective (primary). This shape, shown in profile in Fig. 33, does not allow the detector to see the sides of the struts. The angle of the taper depends upon the object space field of view of the detector. It requires only a small change in design to remove this stray light path.

Basic Equation of Radiation Transfer

This section briefly discusses the most fundamental equation needed to perform the quantitative calculations of a stray light analysis. It reinforces the concept of first identifying what the detector can see and working on the geometry of the system to limit the stray light propagation, and not the BRDF term.

The fundamental equation relating to power transfer from one section to another is:

$$d\Phi_c = L_s(\theta_C, \phi_C)dA_s \frac{\cos(\phi_s)dA_c\cos(\phi_c)}{R_{sc}^2} \tag{2}$$

where $d\Phi_c$ is the differential power transferred, $L_s(\theta_C, \phi_C)$ is the radiance of the source section, dA_s and dA_c are the elemental areas of the source and collector, and ϕ_s and ϕ_c are the angles that the line of sight from the source to the collector makes with their respective normals. This equation can be rewritten as three factors that help clarify the reduction of scattered radiation.

$$d\Phi_c = \frac{L_s(\theta_C, \phi_C)}{E(\theta_i, \phi_i)} E(\theta_i, \phi_i)dA_s \frac{\cos(\phi_s)dA_c\cos(\phi_c)}{R_{sc}^2} \tag{3}$$

$$d\Phi_c = \text{BRDF}(\theta_i, \phi_i; \theta_C, \phi_C)d\Phi_s(\theta_i, \phi_i)d\Omega_{sc}\cos(\phi_s) \tag{4}$$

$$d\Phi_c = \text{BRDF}(\theta_i, \phi_i; \theta_c, \phi_c)d\Phi_s(\theta_i, \phi_i)\text{GCF}_{sc}\,\pi \tag{5}$$

$E(\theta_i, \phi_i)$ is the incident irradiance on the source section dA_s. GCF_{SC} is the projected solid angle from the source to the collector divided by π.

The GCF is independent of the first two terms and solely determined by the geometry of the system, including obscurations. The first term, BRDF (θ_i, ϕ_i; θ_c, ϕ_c), is the bidirectional reflectance distribution function. It is usually considered independent of the second term, the incident power, and is therefore a function of the surface characteristics only. When reducing stray radiation propagation, one or more of these terms must be reduced. If any one of these terms is reduced to zero, no power will be transferred between the source and collector.

Stray Radiation Paths

Since the third term (GCF) in Eq. (4) is the *only* term that can be reduced to *zero*, it should receive attention first. This is a crucial point in a stray light analysis. Therefore, the logical starting place for stray light reduction is with the critical objects, since it is the GCF terms for these transfers which can be reduced to zero. Most novice analysts make the mistake of working on the BRDF term first.

$$\text{GCF} = \frac{\cos(\phi_s)dA_c\cos(\phi_c)}{\pi R_{sc}^2}$$

The apparent possibilities for decreasing the GCF are to increase R_{sc}, ϕ_s, ϕ_c or to reduce the area dA_c. Not readily apparent is that the GCF is limited by apertures and obstructions. These features will, in some cases, block out the entire view of the source section from the collector so that there is no direct path. This is the mathematical basis for the logical approach, discussed at the beginning of the chapter. First block off as many direct paths of unwanted energy to the detector as possible, and then minimize the GCF for the remaining paths.

Point Source Transmittance Definitions

There are five common ways to define the merit function of the stray light in an optical sensor. The most common and preferred method is to define it as the output irradiance divided by the input irradiance, in terms of the *normalized detector irradiance* (NDI),[30] or in terms of the *point*

source normalized irradiance transmittance (PSNIT).[31] This merit function is appropriate because it describes an irradiance transmittance, and it is relatively independent of the detector size.

A term often used in the past was the *off-axis rejection* (OAR), defined as the detector power divided by the input power from the same source *on-axis*. The term *rejection* is a misnomer because by definition the term describes a power transmittance, which can have little correlation with the rejected stray light. The second objection is that as a merit function it varies significantly with the detector size. If you double the area of the detector, the OAR will increase by about the same factor even though the system hasn't performed significantly worse in any way.

Another term commonly used is the system's stray light *point source power transmittance* (PSPT), or its reciprocal, the *attenuation* of the system. The PSPT is the detector power divided by the input power into the sensor from the specified *off-axis angle*. Again, this term varies with the detector size. Sometimes there is no well-defined entrance port so the denominator is impossible to define. Note that the magnitude of attenuation would normally be expressed in terms of a positive exponential. Beware that attenuations are often incorrectly called out with negative exponents.

A final PST definition that is sometimes specified is the *point source irradiance transmittance* (PSIT), defined as the output irradiance divided by the entrance port input irradiance. This definition becomes inappropriate when there is no clearly defined entrance port.

Surface Scattering Characteristics

Of the three potentially important factors in scattered radiation analysis cited above (the radiance of the undesirable source or sources, the geometry of the scattered radiation paths (GCF), and the surface scattering characteristics, (BRDF)), usually the first possibility considered is to improve the surface coatings or the addition of vane structure. In concept it *appears* to be the right place to start and that it is straightforward. Neither is the case; the BRDF never goes to zero as does the GCF, and the BRDF varies with input and output angles. However, with accurate *bidirectional reflectance distribution function* (BRDF) data and knowledge about the variations with applications, time, wavelength, and other factors, BRDF problems can be dealt with. The scattering characteristics of surfaces are discussed by Church, and the scattering characteristics of black coatings by Pompea and Breault elsewhere in this *Handbook*. The addition of vane sections on baffles can usually be considered as a specialized "coating" with its own specialized BRDF.

BRDF Characteristics

Usually, BRDF data that are presented represent only one profile of the BRDF, and many such profiles for various angles of incidence are necessary for understanding the scattering characteristics. However, studies have shown that a single profile of a mirror's surface scattering characteristics can be used, with some approximations, to define the BRDF for all angles of incidence.[32] This is a significant achievement. It reduces the amount of data that must be taken, and it makes it easier to calculate, or estimate, the BRDF value for any set of input and output angles. The BRDF can also be reconstructed for cases where only a single profile of the function has been presented, which has been the usual practice.

The approximation has its limitations, as clearly detailed by Stover.[33] The approximation is quite good for nominal angles of incidence (see Fig. 34).[34] However, it breaks down for very high θ_i and high observation angles θ_0.

It is important to understand qualitatively the scattering characteristics of diffuse black coatings. Figure 35 shows the BRDF profile of Martin Black at 10.6 μm for several angles of incidence.[35] At near-normal angles of incidence the BRDF values are bowl-shaped; the values increase at large observation angles from the normal. At high angles of incidence the BRDF values in the near specular direction have increased by 2.5 orders of magnitude. There is a good discussion of the qualitative characteristics of diffuse black surfaces by Pompea and Breault elsewhere in this *Handbook*.

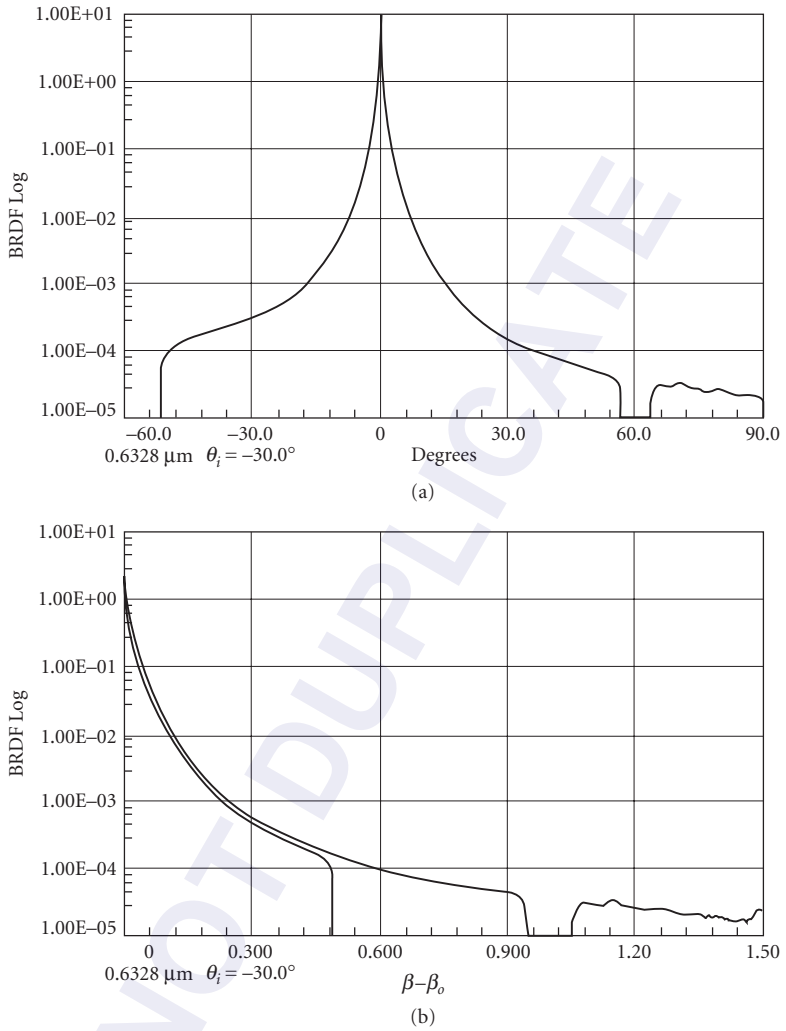

FIGURE 34 (*a*) The BRDF is asymmetrical when plotted against $\theta_s - \theta_i$, (*b*) The data in (*a*) exhibits near symmetry when plotted against $|\beta - \beta_o|$. The slight deviation from symmetry is due to the factor (cos $\theta_s Q$), where Q is a polarization factor. (*Ref. 34, p. 69, reprinted with permission.*)

7.4 OPTICAL SOFTWARE FOR STRAY LIGHT ANALYSIS

There is a small bevy of commercial optical software programs on the market that perform stray light analyses or some aspects of the stray light problems that are typically encountered. One must be knowledgeable of what each package can accomplish so the best thing to do is to ask for a demonstration of what each optical software manufacturer has to offer that is relevant to your design challenge. Here's a summary of a few commercially available optical software codes for stray light analysis. Note also that the programs' capabilities are always in a state of flux.

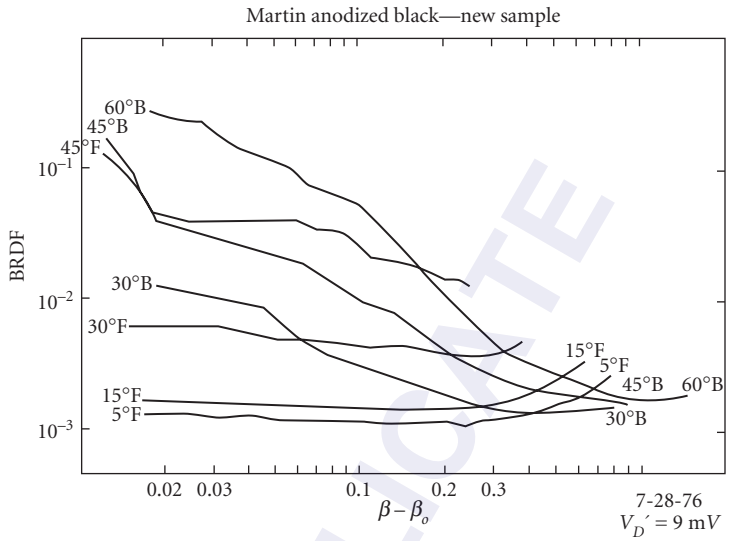

FIGURE 35 BRDF profile of Martin Black at 10 μm. (*F. O. Bartell et al., "A Study Leading to Improvements in Radiation Focusing and Control in Infrared Sensors," Final Report, Army Materials and Mechanics Research Center, December 1976.*)

ASAP, by Breault Research Organization, Inc.

ASAP Optical Software was developed to meet design and analysis criteria of imaging and illumination systems and the unique challenges of stray light analysis with CAD interoperability. ASAP is powered by the ASAP nonsequential ray-tracing engine—known throughout the optics industry for its accuracy and efficiency. Rays can encounter surfaces in any order and any number of times, with automatic ray splitting. Optimized for speed, ASAP will trace millions of rays in minutes. The standard edition of ASAP includes a license of the SolidWorks Parts Only 3D Modeling Engine—an intuitive 3D-design environment optimized for use with ASAP. The user can write ASAP geometry files from within SolidWorks, import XML files, or use BRO's proprietary smart-IGES system to import system models from any CAD package while maintaining fast, efficient ray trace speed.

Use ASAP to model complex imaging systems, illumination systems, and light-concentrating devices. Create highly accurate source models using source images, point sources, ray grids, and fans. Model incandescent bulbs, LEDs, CCFLs, and HID arc lamps, or import from the BRO Light Source Library. Perform the analyses necessary to validate your designs without experimental prototyping.

ASAP includes a distributed-processing capability allowing the user to complete big design and analysis jobs effectively in short-time span—spawn up to 5 additional ASAP sessions on other local area network (LAN), without leaving your desk. Web site: www.breault.com

FRED, by Photon Engineering

FRED is an optical engineering software package that uses a statistical ray sampling approach to analyzing incoherent stray light mechanisms in optical systems. The user can assign one or more of many different BSDF scatter functions to a surface. When a ray is incident on the surface, a specified number of scatter rays are generated in random directions into the hemisphere according to a uniformly random angular distribution, although a Monte-Carlo technique can be used

to generate scatter rays with directional ray density proportional to the BSDF function. The power assigned to any particular scatter ray is proportional to the incident ray power and value of the BSDF function evaluated in the direction of the scatter ray. Uniform sampling of angle space has the advantage that lower power scatter paths will be realized with higher probability. Ray-density direction sampling has the advantage that more rays are directed in the higher power directions which decreases the statistical noise in those directions.

When analyzing scatter from a surface, the user is often interested in only a subset of the entire hemispherical angular range. In these cases a technique called importance sampling can often be used to great advantage. The user can specify that the same number of scatter rays be generated into the importance sample direction as was originally directed into the hemisphere to decrease the statistical noise. An alternative is to decrease the number of rays but still achieve the same noise level. The desired angular range can be specified in a variety of ways and FRED will then direct scatter rays randomly into the specified range. The power assigned to each scatter ray is adjusted to account for the fact that it can be directed only into a subset of the entire hemisphere. Web site: www.photonengr.com

LightTools and CodeV, by Optical Research Associates

LightTools is a complete illumination design and analysis software product. It combines full optical accuracy, powerful optical and illumination analysis, and an intuitive graphical user interface in a 3D solid modeling environment where models interact with rays to produce virtual prototypes of manufacturable systems. A fully integrated illumination optimization capability automatically improves model performance. *LightTools*' Monte Carlo ray tracing facilitates accurate spectral modeling of the illuminance, luminance, intensity distributions, and CIE colorimetric data anywhere in the optomechanical model.

In addition to illumination system design, *LightTools* supports many other applications, from packaging studies to stray light analysis. For example, its ray path visualization collects and displays information about ray-surface interactions to identify system elements that are contributing to light loss, scatter, unintentional reflections, or ghost images. A unique point-and-shoot ray tracing capability allows rapid, interactive evaluation of optical behavior.

CODE V is used for the optimization, analysis, and tolerancing of image-forming optical systems and free-space photonic devices. Its many capabilities include powerful local and global optimization for optics, fast wavefront differential tolerancing that allows as-built considerations to be evaluated throughout the design process, and highly accurate diffraction beam propagation analysis. For stray light applications, CODE V can be used to analyze ghosts in imaging systems due to Fresnel reflections. Web site: www.opticalres.com

ZEMAX, by ZEMAX Development Corporation

The ZEMAX program, from ZEMAX Development Corporation, has two modes of use. Its primary use is as a sequential optical design (optimization) program. In this mode it has tools to help identify location of ghost pupils and images resulting from Fresnel reflections. A separate nonsequential mode has many capabilities necessary for stray light analysis, including scatter modeling with importance sampling.

ZEMAX's Nonsequential ray-tracing capabilities can further be extended to finding rays which have specific characteristics or properties. For example, imagine you are studying the stray light in a telescope:

How significant are rays which "ghost" reflected off of various surfaces (both mechanical and optical)?

Rays which are experience multiple reflections may be important, but how significant are those which experience more than four reflections?

How effective is a strategically placed baffle in terms of limiting the amount of stray light on the detector?

Website: www.zemax.com

TracePRO, by Lambda Research Corporation

TracePro, from Lambda Research Corporation, is a 3D Computer Aided Design (CAD) program for simulating the performance of illumination and optical systems. TracePro can model the propagation of light in imaging and nonimaging optomechanical systems. Models are created by combining imported lens designs, imported CAD geometry (IGES, STEP, SolidWorks, Pro/E, CATIA, or Inventor files), and geometrical objects created using TracePro's user interface. Optical properties are then assigned to each solid and surface using the TracePro interface or through the TracePro Bridge for SolidWorks. Source models are added by specifying grids, surface emitters, ray file data or by using the surface source utility. Rays are ray traced through the model, while keeping track of absorption, specular reflection and transmission, fluorescence and scatter at each intersected surface or volume scatter site.

From TracePro models, the user may ray trace and analyze:

- Light distributions in illumination and imaging systems
- Stray light, scattered light, and aperture diffraction
- Throughput, loss, or system transmittance
- Flux or power absorbed by surfaces and bulk media
- Light scattering in biological tissue
- Polarization effects
- Fluorescence effects
- Birefringence effects
- Lit Appearance

Website: www.lambdares.com

SPEOS, by Optis

OPTIS' simulation software family, SPEOS and OptisWorks. It manages and optimizes many of the optical aspects of a broad range of sensors: reflection, refraction, scatter from surfaces, diffraction, absorption, polarization, and Gaussian beam propagation. It calculates stray light, illumination, and realistic optical simulations. Any product that needs to manage interactions of light and surfaces is calculated. It deals with the various types of light sources also. The simulations limit the need for costly prototyping of systems.

OPTIS simulation software allows the designer to "see" and realistically render products to depict what the final performance of the illuminator will look like in its applied application with stunning similarity. Its software produces a unique and accurate physiological human vision model of the final lit product for comfort, safety, and performance.

7.5 METHODS

There are two distinct methods that have been used to evaluate a system for stray radiation. You can either build the system and test it, or you can model the system and try to predict its performance. Both methods have advantages and disadvantages. Taken *together* the two methods provide the means to ensure that the system will perform as desired.

Build-and-Test Approach

A common approach is to make the system and either use it or test it for stray radiation rejection. Certainly if the system consistently performs satisfactorily *in its operational environment*, it has passed the ultimate test. But what if it does not meet the desired or expected level of performance? Making more systems to test becomes expensive rapidly. In fact, for very large systems, usually only modifications ("fixes") can be contemplated because of the high cost. This is not the only argument against the build-and-test approach. The tests are rarely designed to determine *how* the scattered radiation is propagating through the system and which surfaces contribute most of the undesired radiation.

It is this information, and a thorough knowledge of the surface scattering characteristics, that is necessary to make measurable improvements to the system. Such a test, when determining the propagation paths, should yield information about how the system is reacting to its *test* environment, including the test equipment. Unless the tests are being conducted in the environment for which the system was designed, it is imperative to determine that the *test* environment is not giving erroneous results (either better or worse). Without analyzing the test configuration, you should expect that the environment *will* affect the system stray light measurements. It is also incorrect to assume that the test environment can only add to the stray light background. It is sometimes assumed that if the system passes the stray light tests in the lab it will only perform better in space or wherever its intended environment is. This is not necessarily true.

Now that several points have been made about the difficulty of making valid experimental tests, it must be stated that valid tests can and should be made. The measurement costs need not be prohibitive. Even relatively large optical systems have been fabricated and then modestly redesigned. Changes to the system can be made until the desired information and stray radiation rejection is attained. In some cases it will be less expensive to test an existing system and modify it if necessary than to analyze the system with computer software.

The system-level test need not be extensive; it is not necessary to have an all-encompassing measurement from on-axis to 90° off-axis. Indeed, few facilities are capable of making such tests when the attenuation gets even modestly high. An important point to recognize is that the most important paths to check are those at the nearer off-axis angles where the attenuation is not so high. These can usually be measured reliably.

At small off-axis angles the stray light noise is more often much higher than the detector background noise, while at the higher off-axis angles the stray light noise is well below the electronic/detector noise. From a performance point of view, at the higher off-axis angles there is usually only one additional scattering object (scatter from the main baffle) before these same near off-axis angle paths are encountered or are reinvolved. The validation of the analysis will only be susceptible to the scatter from this one object that can't be fully tested at the system level, but most of the scatter paths, and usually all the most important ones, will have been validated by the near off-axis measurements.

This one additional surface scatter most often (especially on space-based sensors) involves the vanes on the main baffle that shields the primary objective. It will normally reduce the optical noise incident upon it by four to five orders of magnitude. That's why the optical noise goes dramatically below the electronic noise. Its most important role is to occult the direct illumination of the objective which is usually part of the most significant direct scatter path. The performance of this baffle and its vane structure could be analyzed separately and then measured independently to confirm that it too will perform as predicted.

NOTE: Contrary to some published papers you cannot, in general, multiply the stray light transmittance of two parts of a sensor and determine the system's overall performance. Although the main baffle system can be analyzed (or measured) independently from the rest of the system, it is not correct to take its performance and multiply it times the stray light performance of the rest of the system. The stray light propagation paths are far more important than the magnitudes of the two parts. In the above analysis where it was proposed that the main baffle could be measured independently it was to confirm its performance alone. A full-system stray light analysis was assumed.

Computer Analysis

As with the experimental tests, computerized analyses are also subject to errors. The three most significant ones are software limitations, scatter data of samples (not the real system), and user error. No software is capable of putting in every detail of a complex design, yet the computer model must faithfully represent the actual performance of the system. On the other hand, the software can put in "parts" with far greater mathematical precision than these parts can actually be assembled. Unless special studies are made the analyst does not usually account for assembly errors that might affect the actual system. The scatter characteristics of the surfaces, usually defined in terms of the bi-directional reflectance distribution function (BRDF), are usually measured on sample substrates, and controls must be exercised to ensure that the samples tested represent the sensor's actual coatings, and that they do not change with time. The stray light analysis programs are also subject to errors in determining the significant paths. The experimental test is for the actual design, with real coatings, and will include any extraneous unintentional paths due to misalignment or other causes.

On the positive side, a software program can point out many flaws in the system that contribute stray radiation by considering the input BRDF characteristics of the coatings. A program can also do trade-off studies, parametric analysis, and in many other ways aid in the study of alternate designs. The analysis of the paths of scatter will suggest meaningful modifications and help to discard impossible designs. These analyses allow designers to test designs and make modifications before the design goes into production. This is very useful, since rejecting a sensor design is much easier when it is on paper than after it has already been built. It is usually much more cost-efficient than cutting new hardware, redesigning the system, or making fixes on the built system.

If you are in a field related to the optical design of a sensor, be it at the design level or the system level, you know that it would be preposterous to perform the optical design analysis and then put the system together without testing it for its image quality. Yet that is how far the pendulum has swung in favor of performing a stray light analysis over making a system-level stray light test. It reflects a major change in attitude since the early 1970s. It has been stated by stray light analysts that the reliability of a stray light analysis is now much higher than experimental test results, so some people avoid the latter. While there is a degree of truth in this statement, it is wrong to omit the stray light test at the system level.

The advantages and disadvantages of the two methods are summarized in Fig. 36. The disadvantages of the build-and-test approach are the strengths of the analysis method, whereas the strengths of the build-and-test approach cover the weaknesses of an analysis. Taken together these two methods give the greatest amount of reliable information which you can use to create the optimal system and have confidence in its performance. Jointly, they indicate the reliability of the analysis and test results.

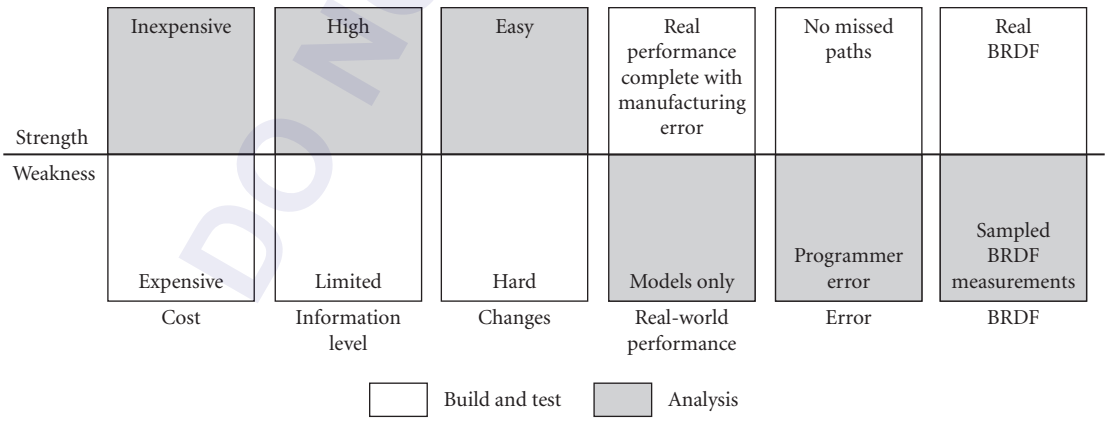

FIGURE 36 Build-and-test and analysis methods complement each other.

7.6 CONCLUSION

In summary, the issues involved in designing a system with stray light suppression in mind are

- **I.** System design concepts
  - **A.** Critical objects seen by the detector
  - **B.** Illuminated objects
  - **C.** Lyot stops
  - **D.** Field stops
  - **E.** Optical designs
- **II.** Baffle and vane design
  - **A.** Diffuse and specular vane cavities
  - **B.** Vane edge scatter
- **III.** Diffraction
- **IV.** Strut design
- **V.** Scattering theory
- **VI.** BRDF data
  - **A.** Log BRDF versus θ
  - **B.** Log BRDF versus log $(\beta - \beta_o)$
  - **C.** Polar plots
  - **D.** Isometric projections (3-D characteristics)
- **VII.** Coatings
  - **A.** Paints and anodized surfaces
  - **B.** AR coatings and other thin films
  - **C.** Mirror coatings
- **VIII.** Thermal emission
- **IX.** Ghost images
- **X.** Software
- **XI.** Detection, prevention, and removal of contamination

A step by step procedure that can help you to improve your system is:

- **I.** Start from the detector and identify what objects, called "critical objects," can be seen from various positions on the detector. Be sure to include a point near the edge of the detector.
- **II.** Work to remove the number of critical objects that the detector can see.
- **III.** Determine what objects the source of unwanted radiation can see, called the "illuminated objects."
- **IV.** If possible, reduce the number of illuminated objects seen.
- **V.** If there are illuminated objects that are also critical objects, work very hard on these paths. Orders of magnitude in improvement will be your reward.
- **VI.** If task V is not possible, then the computations are quite easy.
  - **A.** Calculate the power incident on the illuminated/critical objects.
  - **B.** Use Eq. (1) to calculate the transfer of power from the critical objects to the detector. Remember to properly account for the input and output angles when calculating the BRDF. *Do not* use a straight lambertian scatter distribution; there is no such distribution in reality.
- **VII.** Find all the paths connecting the illuminated objects to the critical objects.
- **VIII.** Evaluate the corresponding input and output angles at the illuminated and critical objects.

IX. Determine if vane structure will help, or if some other redesign will effectively block these paths.

X. For the calculated input and output angles, evaluate which coating would be lowest.

XI. Perform the stray light calculation using Eq. (1) in an iterative fashion. This should determine the most significant stray light path and quantify the amount of stray light on the detector

XII. Perform the above tasks for a series of off-axis positions of the point source.

THERMAL COMPENSATION TECHNIQUES

Philip J. Rogers and Michael Roberts

Pilkington Optronics
Wales, United Kingdom

8.1 GLOSSARY

c	surface curvature of an optical element
D	diameter
FN	F-number or focal ratio
f	paraxial focal length
G	thermo-optical constant (normalized thermal change of OPD)
h	(subscript) signifies "pertaining to the optic housing"
i	(subscript) number of a specific optical element
j	signifies a number of optical elements
K	Kelvin
k	thermal conductivity
n	refractive index
OPD	optical path difference
T	temperature
t	thickness
V	Abbe number of a refracting optical material
ν	spatial frequency
α	linear coefficient of thermal expansion
γ	thermal glass constant (normalized thermal change of optical power)
Δ	small, finite change
λ	wavelength
δ	infinitely small change of a parameter
ϕ	optical power (reciprocal of focal length)

8.2 INTRODUCTION

In the following, the thermal effects for which compensation is required are taken to be those that affect the focus and image scale of an optical system. Methods for quantifying and offsetting these effects were described some time ago,[1] similar information being provided by several other authorities.[2,3,4] The thermal compensation techniques described in this chapter, with the exception of intrinsic athermalization, involve either mechanical movement of one or more parts of the optical system, or compensation achieved solely by choice of optical materials. Except in Sec. 8.5 titled "Effect of Thermal Gradients," a homogeneous temperature change of all parts of the optical system is assumed.

Most optical materials undergo a change of refractive index n with temperature T, conveniently quoted as a rate of change $\delta n/\delta T$. The usual values of n and $\delta n/\delta T$ given for a material (and assumed in this chapter unless stated otherwise) are those relative to the surrounding air rather than the absolute values with respect to vacuum. Air has a $\delta n/\delta T$ of -1×10^{-6} at $T = 288$ K and 1 atmosphere air pressure for wavelengths between 0.25 and 20 μm:[5] allowance for this must be made when a lens operates in vacuum or in an enclosed space where the number of air molecules per unit volume does not change with temperature. The absolute $\delta n/\delta T$ of an optical material can be found from

$$\left(\frac{\delta n}{\delta T}\right)_{\text{abs}} = n_{\text{air}}\left(\frac{\delta n}{\delta T}\right) + n\left(\frac{\delta n}{\delta T}\right)_{\text{air}} \tag{1}$$

where the value of n_{air} is approximately 1.0.

8.3 HOMOGENEOUS THERMAL EFFECTS

Thermal Focus Shift of a Simple Lens

The rate of change of the power ϕ (reciprocal of the focal length f) of an optical element with temperature T can be obtained by differentiating the thin lens power equation $\phi = c(n - 1)$, where c is the total surface curvature of the element. For a linear thermal expansion coefficient α of the material from which the element is formed this gives

$$f = \frac{1}{\phi} \quad \frac{\delta f}{\delta T} = -\frac{1}{\phi^2}\frac{\delta \phi}{\delta T}$$

$$\frac{\delta \phi}{\delta T} = +\phi\left(\frac{\delta n/\delta T}{n-1}\alpha\right) \tag{2}$$

Therefore

$$\frac{\delta f}{\delta T} = -f\left(\frac{\delta n/\delta T}{n-1} - \alpha\right) \tag{3}$$

The material-dependent factor inside the parenthesis in Eqs. (2) and (3) is known as the thermal "glass" constant (γ) and represents the thermal power change due to an optical material normalized to unit ϕ and unit change of T. Tables 1 to 3 give γ values for a selected number of visual and

infrared materials along with the relevant V value (Abbe number) and other data. The much higher level of γ for infrared as opposed to glass optical materials indicates that thermal defocus (focus shift) is generally a much more serious problem in the infrared wavebands. The actual value of γ varies with both wavelength and temperature due to variations in the value of $\delta n/\delta T$ and α. In general, this is unlikely to cause major problems unless a wide wavelength or temperature range is

being considered.[6] Thermal defocus results not only from a change of optical power but also from the thermal expansion coefficient α_h of the housing. Equation (3) can be modified to allow for the effect of the latter:

Single thin lens:
$$\Delta f = -f(\gamma + \alpha_h)\Delta T \tag{4}$$

j thin lenses in contact:
$$\Delta f = -f\left[f\sum_{i-1}^{j}(\gamma_i \phi_i) + \alpha_h\right]\Delta T \tag{5}$$

Thermal Defocus of a Compound Optical Construction

Consider a homogeneous temperature change in an optical system that comprises two thin-lens groups separated from each other, the normalized thermal power change being the same in each lens group. Taking the thermal defocus calculated from Eq. (4) as unity, then that due to a compound optic comprising two separated components and of the same overall power can be estimated from Fig. 1.[7] The latter shows scaling of thermal defocus with respect to a simple thin lens, relative to front lens/image plane distance (overall length) for three different positions of the second lens group. The graph is divided into three basic lens constructions distinguished from each other by overall optical length and/or the sign of the power of the front lens group.

Figure 1 assumes germanium optics in an aluminum housing but change of either material, while altering values slightly, has no effect on the following two conclusions:

1. Telephoto/inverted telephoto constructions always give more (and Petzval lenses always give less) thermal defocus than an equivalent simple lens.
2. Thermal defocus reduces as the second lens group is moved toward the image plane, irrespective of lens construction: the efficacy of this procedure is limited, however, by the increased imbalance of optical powers between the groups.

The thermal defocus scaling technique could be extended to cover an optic comprising more than two lens groups. This extension has been carried out for the Cooke triplet construction[8] and for a series of separated thin lenses,[6] although only for the case of a zero-expansion housing.

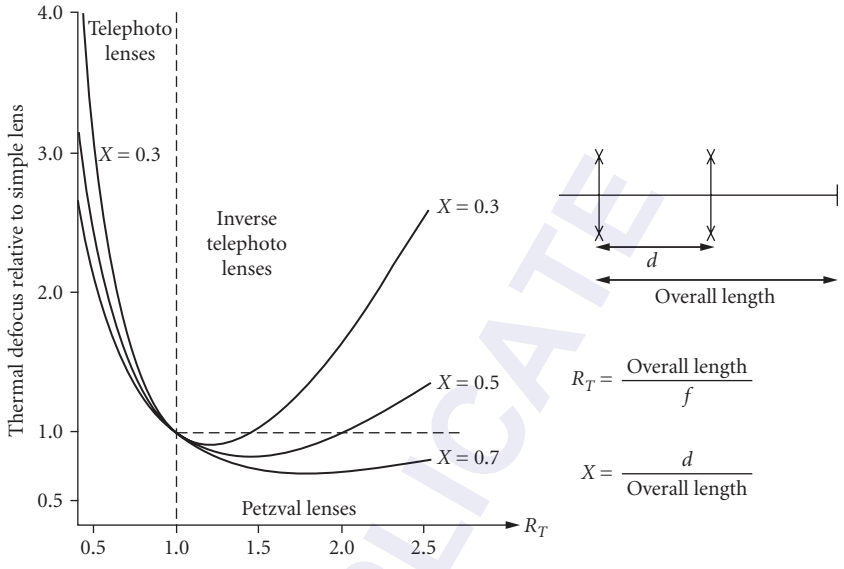

FIGURE 1 Effect of compound lens construction on thermal defocus. (*From Rogers.*[7])

8.4 TOLERABLE HOMOGENEOUS TEMPERATURE CHANGE (NO COMPENSATION)

Diffraction-Limited Optic

Equation (5) can be used to establish the temperature change ΔT that will result in a quarter-wave of longitudinal thermal defocus, a reasonable limit for a simple optic that is nominally diffraction-limited. Given an optic of diameter D and focal ratio FN imaging at a mean wavelength of λ:

Diffraction-based depth of focus: $$\Delta f = \pm 2\lambda(\text{FN})^2 \tag{6}$$

Combining Eqs. (5) and (6): $$\Delta T = \pm \frac{2\lambda(\text{FN})}{D\left[f\sum_{i=1}^{j}(\gamma_i\phi_i) + \alpha_h\right]} \tag{7}$$

Figure 2 gives ΔT against D results for a simple 8- to 12-μm bandwidth germanium optic in an aluminum housing:[9] the curves illustrate the small temperature change that can be tolerated in germanium optics before focus compensation is required. Partial avoidance of this particular problem may be achieved by the replacement of germanium by other infrared optical materials having lower values of γ: this may also be desirable to reduce high-temperature absorption but generally leads to much greater optical complexity.

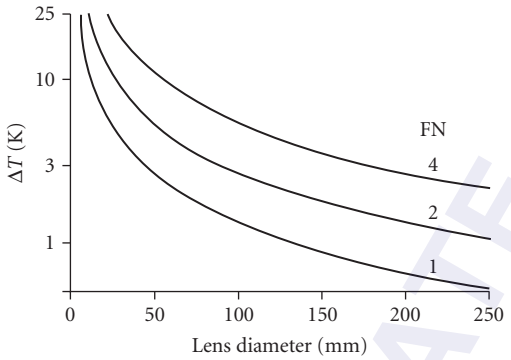

FIGURE 2 Tolerable temperature change for a simple germanium infrared lens. (*From Rogers.*[9])

Nondiffraction-Limited Optic

The depth of focus of an optic having a nominal performance far from the diffraction limit is a function of the residual aberration level and balance in the optic as well as its first-order parameters. An estimate related to a cutoff spatial frequency ν that gives a reasonable approximation in many cases can be obtained[10] from

Approximate depth of focus:
$$\Delta f = \pm \frac{(\mathrm{FN})}{\nu} \tag{8}$$

Combining Eqs. (5) and (8):
$$\Delta T = \pm \left\{ D\nu \left[f \sum_{i=1}^{j} (\gamma_i \phi_i) + \alpha_h \right] \right\}^{-1} \tag{9}$$

Notice that, given the approximation of this method, the value of ν can be determined by extending a straight line MTF from 1.0 response at zero spatial frequency, through the MTF point of interest, to the intersection of the line with the spatial frequency axis.

8.5 EFFECT OF THERMAL GRADIENTS

The previous sections assume a homogeneous temperature change in all parts of the optical system: in situations where steady-state or transient temperature gradients exist, further consideration is required.[1]

Allowance for the effect of steady-state longitudinal gradients can be made by applying a different value of T to each lens group and an average local temperature to each portion of the housing that separates two adjacent lens groups. Transient longitudinal gradients are a more difficult problem and, if severe, may require individual athermalization of each lens group in its own housing domain.

Steady-state or transient radial thermal gradients cause at least a shift of focus position, with the possible addition of a change of aberration correction. A localized radial temperature difference of

ΔT through the thickness t of a plane-parallel plate will cause a deviation of a ray of light[11] that can be quantified as an optical path difference (OPD):

$$\text{OPD} = t[\alpha(n-1) + \delta n/\delta T]\Delta T \tag{10}$$

The expression in the square bracket is often referred to as the thermo-optical constant G and is an approximate measure of the sensitivity of an optical material to radial gradients. More thorough analysis of the effects produced by radial thermal gradients includes computation of thermally induced stress and consequent anisotropic change of refractive index: in some cases, this may be a significant factor in image degradation.[12–14]

Tables 1 to 3 give values of G for the selected optical materials. Also tabulated is the thermal conductivity k, as in many cases G/k is a more appropriate measure of sensitivity given the greater ability of high-conductivity materials to achieve thermal equilibrium.

8.6 INTRINSIC ATHERMALIZATION

The need for athermalization can be avoided or minimized for some applications by employing optical power and mounting techniques that are inherently insensitive to temperature change. A concave spherical mirror fabricated from the same material that separates the mirror from its focal plane (e.g., an aluminum mirror in an aluminum housing) is in effect "self-athermalized" for a homogeneous distribution of temperature. The optical performance of a single spherical mirror is limited, but the above principle applies for more complex all-reflective optical constructions employing conic or other aspheric surface forms. A glass spherical mirror, although not thermally matched to an aluminum mounting, may be used as part of a self-athermalized catadioptric afocal in the infrared, a germanium Mangin being used in this case as a secondary mirror lens.[15] The high thermal power change of the negatively powered lens in the germanium Mangin, used in double-pass, compensates for the thermal defocus due to the glass primary, the housing, and the remaining germanium optics in the afocal—Fig. 3.[16]

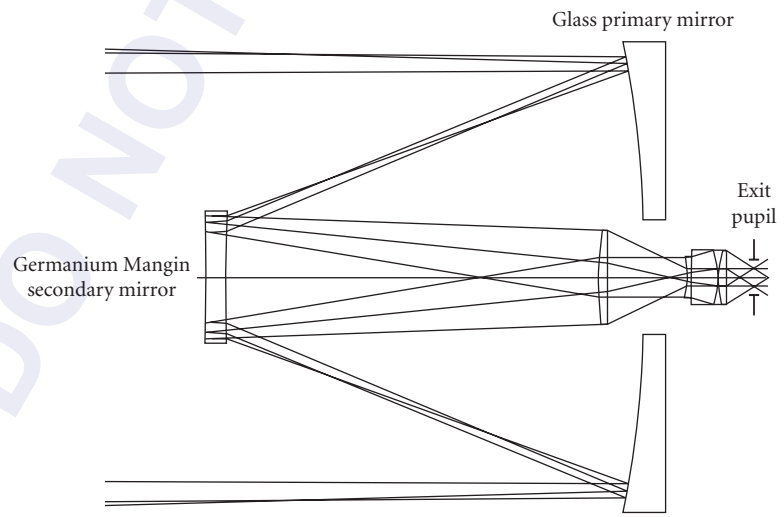

FIGURE 3 High magnification self-athermalized catadioptric afocal. (*From Norrie.*[16])

An alternative approach to the above is to use glass-ceramic mirrors within a nickel-iron alloy housing, since they can have thermal expansion coefficients approaching zero. A major advantage of this approach is its insensitivity to thermal gradients.

8.7 MECHANICAL ATHERMALIZATION

General

Mechanical athermalization essentially involves some agency moving one or more lens elements by an amount that compensates for thermal defocus—a simple manual option being to use an existing focus mechanism. Automatic methods are, however, preferable in many cases and can be divided into passive or active. Passive athermalization employs an agency, often involving materials (including liquids) with abnormal thermal expansion coefficients, to maintain focus without any powered drive mechanism being required. Automatic active athermalization involves the computation of focus compensation algorithms that are stored (usually electronically) and implemented by a powered device such as an electric motor. The following sections refer to a number of passive and active athermalization methods, although the list is by no means exhaustive.

Passive Mechanical Athermalization

The principal advantages of passive thermal compensation methods are their relative simplicity and potential reliability. Disadvantages are their inadequate response to transient temperature gradients and, generally, lack of adjustment to allow for errors or unforeseen circumstances. Passive methods are ideal in glass optics[17] where thermal effects are low, although here it is not too difficult to achieve optical athermalization (see later under "Optical Athermalization") except where very low secondary spectrum is required. In the infrared wavebands, where thermal effects are much greater due to the nature of the optical materials, it is difficult to achieve simple passive mechanical athermalization due to the large refocusing movement required, typically 1.5×10^{-4} per unit focal length per Kelvin for an aluminum-housed germanium optic. An exception to the above is the combination of silicon and germanium in 3- to 5-μm optics, where thermal defocus results largely from the expansion of the housing. In this case, use of more than one nonmetallic housing material can result in an athermalized optic, even one having two fields of view[18]—Fig. 4.

For infrared cases other than the above, the options are either to provide a mechanism that modifies mechanical expansion effects or to reduce the required refocusing movement by optical means.

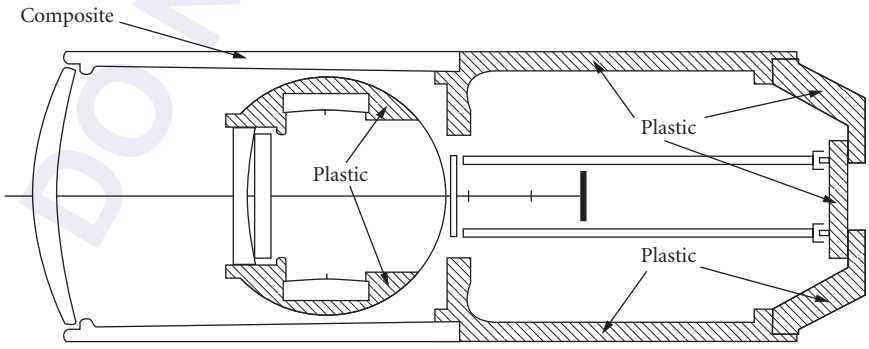

FIGURE 4 Part composite/part plastic mounting structure used for athermalization of a 3- to 5-μm IR optic. (*From Garcia-Nuñez and Michika.*[18])

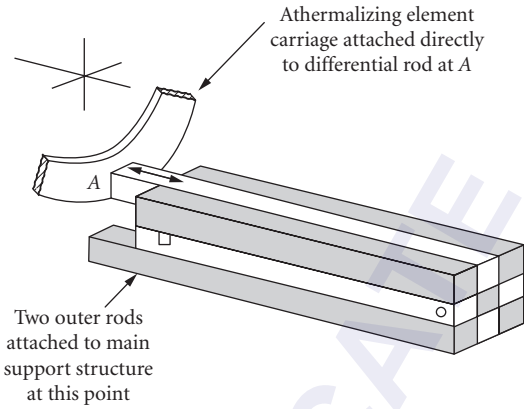

FIGURE 5 Passive mechanical thermal compensation using differential expansion rods. (*From Povey.*[19])

Examples of the former include[19] a series of linked rods of alternatively high and low expansion coefficient—Fig. 5—and a hydraulic method where the fluid contained in a large-volume reservoir expands into a small-bore cylinder—Fig. 6.

An interesting alternative employs shape-memory metal[20] to provide a large movement over a relatively small temperature range.[19] Another alternative is to employ a geodetic arrangement: in this method[19] an athermalizing adjustment of, for example, the separation between primary and secondary mirrors in a catadioptric, is produced by differing expansion coefficients of the primary mirror

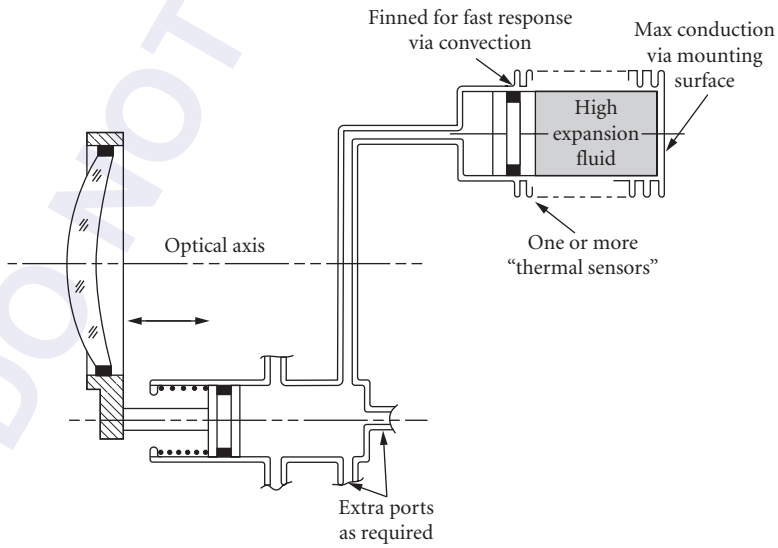

FIGURE 6 Passive mechanical thermal compensation using high-expansion-fluid thermal sensors. (*From Povey.*[19])

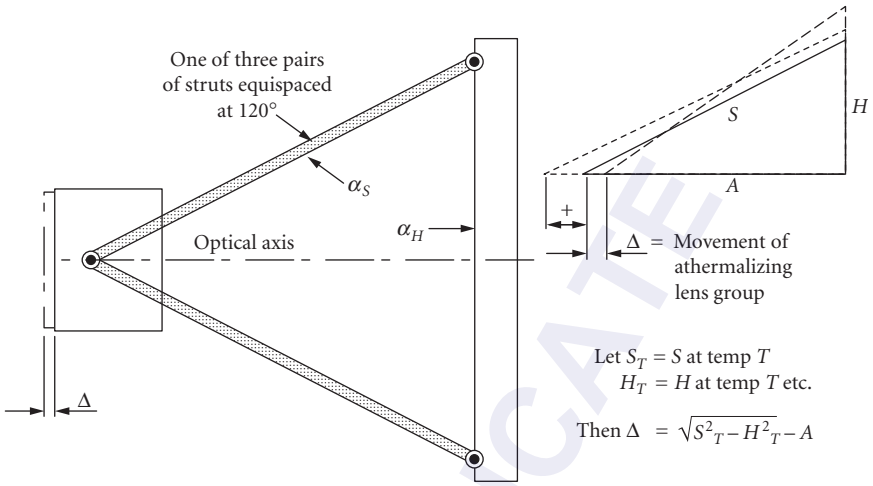

FIGURE 7 Geodetic support structure for positive or negative thermal compensation movement. (*From Povey.*[19])

mount and the secondary mirror struts—Fig. 7. Where none of the above methods are desirable, the option to reduce the necessary movement may be the only alternative. This may be achieved by an optical layout[9] configured such that the required athermalizing movement is reduced typically by a factor of four, but at the expense of somewhat greater optical complexity—Fig. 8.

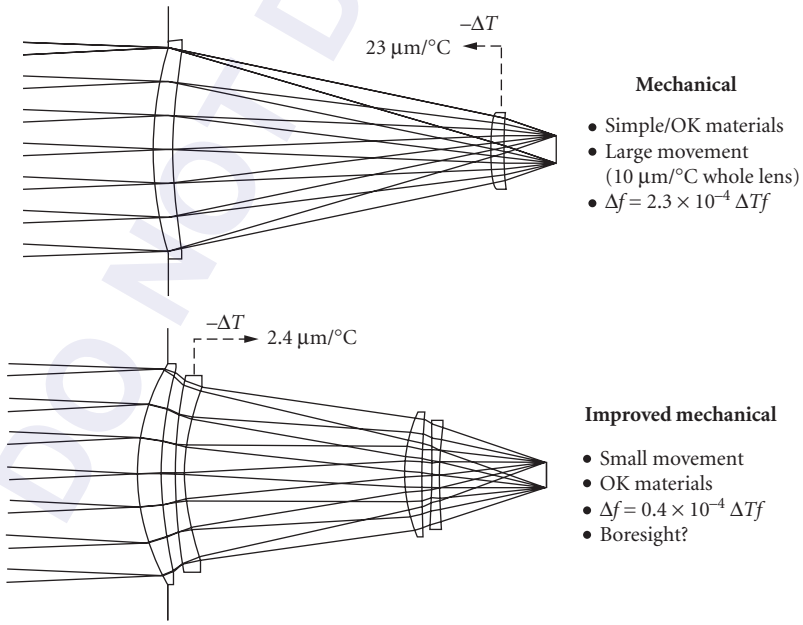

FIGURE 8 Alternative optical configurations for mechanically athermalized forward looking infrared (FLIR) systems. (*From Rogers.*[9])

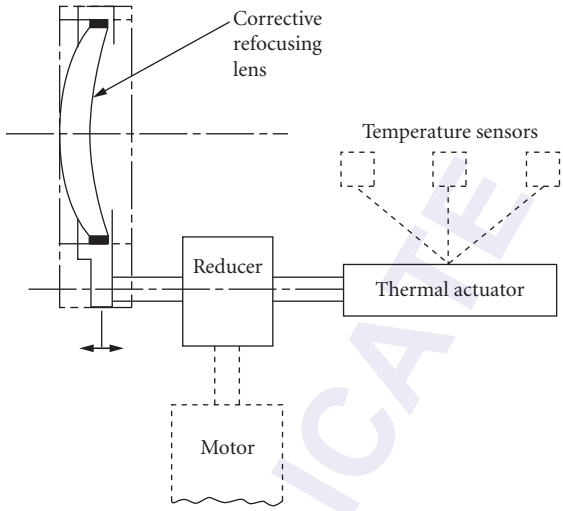

FIGURE 9 Active electromechanical athermalization—schematic.

Active Mechanical Athermalization

Active mechanical athermalization in its simplest form can be manual adjustment of a lens element or group for refocusing. For more complex optics, such as multi-field-of-view, a procedure can be specified for manual (or motorized) adjustment of several lens elements to maintain focus over a range of magnifications and temperatures.[21,22] Where automatic athermalization is required, a method can be employed that uses a combination of electronics and mechanics—Fig. 9. One or more temperature sensors located along the body of the optic feed their signals into an algorithm that calculates the required movement of a compensating lens and then initiates the motion. For simplicity, the compensating lens may be that which already provides close-distance focusing, thus requiring only an increase in the range of movement for athermalization. The location of sensors is especially important for infrared optics and should be dependent on the thermal sensitivity variations within the optical system.

Active electromechanical thermal compensation is particularly suitable where transient longitudinal temperature gradients are expected and for multi-field-of-view optics where thermal defocus is dependent on field-of-view setting. The algorithm required for elimination of the effects of a combination of both of the above is complex, but compensation may be accomplished by a single mechanical motion.[23]

A single motion does not, however, guarantee athermalization of image scale, in which case more than one compensatory movement may be required. Two motion athermalization in a zoom or dual-field-of-view infrared telescope can take advantage of the existing mechanisms required for field-of-view change. Also, by utilizing internal lens elements, problems associated with hermetically sealing an external focusing lens element can be avoided.[24–28] In order to maintain stability of aberration correction in infrared zoom telescopes, particularly those having a large zoom range, three-motion athermalization has been proposed.[29,30]

Active/Passive Athermalization

An improvement over simple manual active athermalization is to include partial passive athermalization. This is best suited to systems that already contain axially moving lens components, for example, a dual-field-of-view infrared telescope[31]—Fig. 10.[32] Here the majority of the athermalization is provided

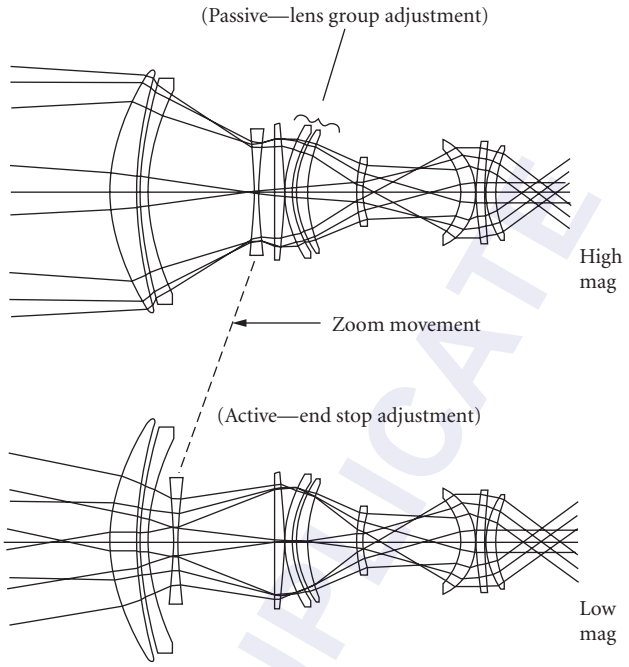

FIGURE 10 Part active, part passive mechanical athermalization. (*From Roberts.*[32])

by a mechanically passive device that adjusts the position of the rear lens group in the objective. The residual focus error is then corrected by small manual adjustments to the magnification change element. This technique can minimize the change of image scale and aberrations with temperature. A potential problem, however, is the subjective nature of best-focus determination.

Athermalization by Image Processing

Athermalization by image processing is suitable for some applications. A range of automatic focusing techniques exists but, while this approach has the advantage of not requiring temperature sensors, it does suffer the potential disadvantage of misinterpretation of image information.

8.8 OPTICAL ATHERMALIZATION

General

Athermalization of the focus position of an optical system by choice of refractive materials has been described extensively in the literature.[33–42] The requirements of overall optical power, achromatism, and athermalism demand that three conditions be satisfied for j thin lens elements in contact:

Power: $$\sum_{i=1}^{j} \phi_i = \phi \tag{11a}$$

TABLE 4 Unity Focal Length Athermal Two-Material Achromatic Combinations

Source: Rogers.[43]

Achromatism:
$$\sum_{i=1}^{j} \frac{\phi_i}{V_i} = 0 \tag{11b}$$

Athermalism:
$$\sum_{i=1}^{j} (\gamma_i \phi_i) + \phi \alpha_h = 0 \tag{11c}$$

The presence of three conditions implies the need for three different materials in order to obtain an exact solution. It is possible, however, to find achromatic combinations of two materials that are also athermal, provided that a simple condition is satisfied:[41]

$$V_1(\gamma_1 + \alpha_h) = V_2(\gamma_2 + \alpha_h) \tag{12}$$

Suitable combinations for thin-lens athermal achromats can be found by plotting a range of materials on a graph of γV against V, the slope of the line joining a chosen pair representing the required thermal expansion coefficient of the housing.[6]

A number of approximately athermal optical glass achromats exist of which those listed in Table 4[43]—with the exception of the last entry—represent examples with low to moderate secondary spectrum over the visible to near infrared waveband. The data given for these achromats are lens element total curvatures for unity focal length; secondary spectrum (second-order color); thin-lens Petzval sum; and an approximate indication of mass, normalized to the lowest value. The pairing of radiation-stabilized versions of SK5 and SF5, both of which have a low value of γ makes a good choice for athermalized space optics in a temperature-invariant mount.[6]

In the infrared wavebands the options are far more limited: at least one 3- to 5-μm waveband two-material athermal combination exists, namely, arsenic trisulfide and magnesium oxide, but there is currently no realistic pairing of materials in the 8- to 12-μm band.

Athermal Laser Beam Expanders

Many more two-material athermal combinations exist if the requirement for achromatism [Eq. (11*b*)] is removed. This is the situation that occurs with a (preferably) galilean laser beam expander, although here the two lens materials are separated.[44] From Eq. (4), making the thermal defocus Δf values equal

and opposite for the two lenses leads to a value for magnification at which two given materials in a specific housing material will provide an athermal beam expander (for a homogeneous temperature distribution):

$$\text{Magnification} = \frac{\gamma_1 + \alpha_h}{\gamma_2 + \alpha_h} \tag{13}$$

Three-Material Athermal Solutions

Graphical methods have been described that allow investigation of preferred three-material athermalized achromatic solutions.[41] An alternative method is the systematic evaluation of all possible combinations of three materials selected from a short list, each combination being allocated a risk factor dependent on material characteristics and solution sensitivity.[9] The optical powers of the three in-contact thin-lens elements are determined by solving Eq. (11*a* to *c*) which give for a unity focal length:

$$a = \frac{V_1V_2 - V_2V_3}{V_1V_3 - V_2V_3}, \phi_3 = \frac{(1-b)\gamma_1 + b\gamma_2 + \alpha_h}{(1-a)\gamma_1 + a\gamma_2 + \gamma_3} \tag{14a}$$

$$b = \frac{V_2}{V_2 - V_1}, \phi_2 = b - a\phi_3 \tag{14b}$$

$$\phi_1 = 1 - (\phi_2 + \phi_3) \tag{14c}$$

Tables 5 and 6 give a selection of lower-risk three-material solutions, in approximate order of increasing risk, for 3- to 5- and 8 to 12-μm infrared combinations, respectively. The data given are similar to those in Table 4, but the housing is assumed to be aluminum in all cases. Note that these tables are intended as a guide only and are based on currently available material data.

Athermalization of Separated Components

In many ways, thermal defocus and thermal change of focal length are analogous to longitudinal and lateral chromatic aberration, having the same first-order dependencies. For this reason it has been suggested that a thermal Abbe number, defined as $\gamma^{-1,3}$ be used to replace the chromatic

TABLE 5 Unity Focal Length Athermal Three-Material Achromatic Combinations for the 3- to 5-μm Waveband

{ } Very high transmission.
[ ] Low residual high-order chromatic aberration.

Abbe number (*V* value) in the usual chromatic aberration equations. Thermal expansion of the housing—obviously not present in chromatic calculations—does, however, complicate the situation a little.

In equations thus far, Δf has meant both thermal defocus and focal length change, as numerically these are the same for a thin lens. For separated components, rules similar to those for chromatic aberration apply, for example, two separated thin-lens groups—such as those described by Fig. 1—must be individually athermalized if both types of thermal "aberration" are to be corrected simultaneously. More complex optics (for example, multistage) may have transfer of thermal aberration between constituent lens groups but may still be corrected simultaneously for thermal focus shift and focal length change as a whole. This procedure can, however, lead to one lens group requiring excessive optical powers in order to achieve full overall correction—transient longitudinal thermal gradients may also cause problems.

Use of Diffractive Optics in Optical Athermalization

The term "hybrid optic" is generally used to signify a combination of refractive and diffractive means in an optical element. The diffractive part of the hybrid is usually a transmission hologram which for high efficiency would be of surface relief form, the surface structure being machined or etched onto the refractive surface.[45] The diffractive surface acts as a powered diffraction grating, producing large amounts of chromatic aberration which could be employed in an optic where a lightweight optically athermalized combination of two materials could be chosen without regard to achromatism: residual chromatic aberration could then be corrected by the hologram.[46]

Optimax Systems, Inc.
Ontario, New York

9.1 INTRODUCTION

The novel creations of optical designers have been limited by the fabricator's ability to manufacture and measure the elements of the optical prescription. A solution to a design criteria often existed only on paper as the required elements were not physically realizable. Optics manufacturing technology innovations continually expand the possibilities for optical components. Increasingly, manufacturing is tethered to metrology. Creation of optics metrology instruments with accuracy equal to that of optics manufacturing equipment and vice versa has driven process development. It is this developmental symbiosis that has brought determinism to the art of precision optics manufacturing. Metrology and machine innovations offer optics of higher quality and complexity in predictable timeframes. The requirement for skilled technicians is still vital in the manufacturing process; however, the skill set is increasingly one of craft in combination with science. Artisan opticians of yesteryear still provide value; however, the future of optics manufacturing is in the hands of the 21st century optics technicians.

The methods described below are the most common for typical optical components used in industrial, aerospace, and defense applications. For the spherical lens section, a brief overview of the traditional process is described first and then the latest methods. The remaining sections will provide general overviews. The focus will be exclusively on brittle materials. For our purposes, brittle materials are defined as those where the removal process is achieved by applying mechanical forces that fracture the surface, releasing fragmented particles in a controlled manner. Much has been documented on fine finishing of brittle materials such as optical glasses, ceramics, and crystals. Works by Preston[1], Silvernail[2], Izumitani[3], Buijs[4], Bach[5], Kaller[6], Lambropoulos[7], Golini[8], Cook[9], Jacobs[10] and DeGroote[11] have contributed greatly to the understanding of optics finishing processes.

9.2 MATERIAL FORMS OF SUPPLY

Optical glass is available in boule, slab, and gob forms. Boules are formed in special disposable pots that yield a batch or glass melt of a specific glass type, such as the borosilicate glass BK7, but whose detailed characteristics are unique to that batch. Slab is yielded from a continuous flow process.

Materials are homogeneously mixed and heated, and a continuous ribbon of glass is produced. These ribbons are cut into slabs that are generally 250 mm wide, 25 mm thick, and 350 mm long, although sizes vary significantly based on supplier and material. Gobs are also yielded from a continuous flow process; however, the molten glass flows through an orifice and is sliced like cookie dough at a predetermined frequency that ensures the desired volume for the application. Gobs are almost always made to customer specifications for glass type and volume. They are used as the preblank to produce near net shape molded blanks for high-volume lens systems. Many glass suppliers also provide polished preforms, usually balls. These are used for glass molding finished optics components.

Manufacturers will order the form that best suits their purpose. The closer to final form the material, the less waste and time consumed in bulk removal operations. When rough shaping material blanks from boule or slab forms, most manufactures use diamond impregnated saw blades and core drills to yield a part appropriate to yield the finished optic, generally called disks. Typically blanks or disks are several millimeters oversized from the final part's critical dimensions.

9.3 BASIC STEPS IN SPHERICAL OPTICS FABRICATION

Generating

This is a bulk material removal operation that starts with a near net shape molded blank or a disk.

Generating—Traditional The removal is accomplished through the application of diamonds embedded in a matrix on the cutting surface of a cup-shaped ring tool. The material is ground away as the diamonds create cracks in the surface, sweeping away glass particles where the fractures intersect.[12] The machine accuracy is generally akin to manually set, mechanically based control production equipment used in the machine tool industry. The operator continually monitors results and modifies machine settings as the cupped ring tools wear. Machine precision is adequate to control thicknesses to +/−0.025 mm and radius to +/−0.010-mm sagittal height, but the machine is only capable of coarse removal. Subsequent lapping operations are required in order to reduce subsurface damage[13] to a level where polishing is possible.

Generating—Modern The advent of deterministic microgrinding processes spearheaded by the work at the University of Rochester's Center for Optics Manufacturing[14] in the 1990s shifted the paradigm for finishing expectations from the generating operation. As a result, machines used in the generating operation have evolved to precision machine tool status. Generators manufactured by mainstream optics manufacturing equipment providers such as OptiPro,[15] Satisloh,[16] Schneider[17] and others, have created grinding solutions that enable the generating operation to predictably yield surfaces that are ready for polishing operations. This modern equipment makes use of CNC (computer numeric control) systems, robust motion and motion control systems such as precision linear ball slides, advanced machine base materials, structure design, and improved positioning feedback through optical encoders and other submicron feedback systems. Additionally, most of the machine builders provide in situ metrology options that enable operator assisted or completely automated parameter adjustment optimization. This is an important feature as the tool consumes itself during the process.

Complimenting the advent of advanced generating machine tools for optics generating has been the increased understanding of fixed abrasive grinding mechanisms. Deterministic microgrinding is typically preferred to loose abrasive lapping when fabricators have a choice. The residual damage from microgrinding can be estimated based on glass properties.[18] This aids in determining prepolish finish requirements so the overall process time for the optics can be optimized. Even with recent advancements in understanding the microgrinding process, the industry is far from offering a directory of ring tools optimized for the array of optical materials. Therefore the industry continues to rely heavily on empirical results to determine optimal setups.

Lapping

This process reduces subsurface damage left from generating to a manageable level in preparation for polishing.

Lapping—Traditional Lapping is the application of loose abrasive particles applied as slurry and pressed into the work surface by nominally constant applied pressure.[19] The process typically consists of applying the abrasive slurry between a cast-iron-rotating lapping tool and the optic. Both surfaces abrade away as they remain in random dynamic contact. The fabricator controls the material removal so the operation yields the desired surface radius and smoothness. The abrasive material, often aluminum oxide, is typically between 30- and 5-μm particle size. The operator steps through particle sizes, using progressively smaller abrasives. Removal amounts account for the subsurface damage from the prior generating or lapping operation, ideally completely removing it.

Lapping—Modern The use of diamond particles embedded in a resin or metal matrix have been popular for some time. Initially, these matrices were fabricated in pellets, fastened as desired on metal backing plates, and used as laps. Abrasive work is done by the diamonds and coolant serves as lubricant and carries the glass particulate away. Unlike loose abrasive lapping, the slurry is not the abrasive. Diamond tool manufactures also make diamond-sheet material for ready application to tools, and more recent products such as resin-bonded sheet materials from abrasive manufacturers such as 3M[20] can be used the same way.

Polishing

Polishing converts the finely fractured surface from the lapping or deterministic grinding operation [typical roughness of about 1-μm rms (root mean square)] into a specular surface of a surface roughness typically 1 to 3 nm rms. Polishing is a chemical-mechanical process. Water attacks the surface creating a chemically softened layer, and then the mechanical action of the abrasive in the polishing slurry, usually ceria based for optical glasses, removes the chemically softened outer layer of glass.[3]

Polishing—Traditional The polishing process is expected to remove the damage left from preceding operations, typically 5 to 20 μm of material. The intimate contact between the polishing tool and the optic, working with the slurry, slowly enhances the surface finish. The process is feedback based, and the fabricator works the part for a while and checks the outcome. Reacting to the results, the experienced fabricator controls various parameters to yield the desired form and finish of the polished surface.

The most basic polishing tool is a pitch polisher. Optical polishing pitch is a viscoelastic material. To form a pitch polisher, a metal tool of proper radius is coated with a 4 to 5-mm layer of polishing pitch. The pitch is warmed and formed to the optic. Once cool the brittle pitch will be cut to allow irrigation grooves for slurry access. When performed by artisans, pitch polishing can yield form errors equal to fractional wavelength of visible light routinely. Less capable fabricators may be limited to commercial quality, multiple wavelength form error outcomes.

By the 1980s, high-speed polishing had become very popular. One of the key innovations was the use of polyurethane polishing pads as a replacement for pitch. Polyurethane pads are a viscoelastic thermoplastic material with a higher viscosity than pitch. Polyurethane remains a polishing material staple and is the polishing material of choice for the fast removal seen in high-volume optics manufacturing.

Polishing—Modern Advances in deterministic polishing are dramatically changing the demands placed on optics manufacturers. Deterministic polishing is a feed-forward process, where the outcome is reasonably certain. Industry leaders in deterministic polishing development are QED/Schneider consisting of Magnetorheological Finishing (MRF)[21] and Zeeko/SATISLOH[22] who promote

a precessions polishing and air bladder solution. Each has created opportunities for manufacturers to produce optics at more predictable cost. Their application of CNC machining systems to the polishing process is revolutionizing the precision optics industry.[23]

All these new solutions rely on subaperture small "pad" polishing with a known removal rate, where the "pad" may be in the form of variable stiffness polishing fluid or compliant tool made from a variety of materials and consistencies. Originally used to finish large astronomical telescope optics, small pad methods have advanced in recent years to scale cost and size down so these technologies are available to the broader population of precision optics manufactures.

Deterministic subaperture polishing solutions combine a tool's known removal rate with an error map of the optic to produce a removal schedule. This feed-forward process relies completely on the accuracy of actual surface form information. In most cases this information is acquired from a variety of instruments such as coordinate measurement machines (CMM) or surface profilometers like the Taylor-Hobson Form TalySurf.[24] These instruments themselves or the software of the polishing tool convert points of data into an error map for a continuous surface. The removal profile dictates the dwell time for the small aperture polishing pad, and in general form error decreases by a factor of five per iteration. For example, if the form error is 1 wave, it is reasonable to expect that after a deterministic polishing iteration the form error will be ~1/5 wave, and after another iteration would be ~1/25 wave.

Newer technology that is also under development at a number of equipment manufacturers including QED and ZEEKO[25] incorporates fluid jet technology. Surfaces are corrected by directing a jet of abrasive/fluid mixture at a surface, the flow generates sufficient surface shear stress that chemical-mechanical polishing occurs.[26,27] The jet-polishing technology is especially promising for difficult to reach areas seen in asphere and conformal optical surfacing.

Edging

Most applications of lenses require mounting into a lens housing. Lens system performance is maximized when the centers of curvature reside on the cylindrical axis of the housing. The edging operation simultaneously creates a precise (+/− 0.025 mm or less) diameter for mounting and aligns the centers of curvature on the mechanical centerline of the lens.

Edging—Traditional[28] Earlier pitch-based methods consisted of using a precision spindle where a brass cup was trued using a cutting tool. This was basically a lathe-type operation and required a skilled combination of heat, pitch, spindle velocity, timing, and consistent axial force applied by a skilled artisan in order to set the lens in a "trued" position. Once the lens was blocked, a diamond wheel ground the diameter to final dimension. Lenses are typically brought to final polished state with the diameter of the lens 1- to 3-mm oversized.

This pitch method was almost entirely replaced with mechanical bell-clamping edging machines. Bell clamping employs two opposed coaxial synchronized precision spindles and is a pitch-free process. Each spindle is affixed with a precision cup of the appropriate size to capture the lens and allow auto alignment by virtue of the mechanical forces on the variably sloped surfaces. Once the lens is "clamped" into true position, an operator mechanically defines and initiates an automated grinding sequence.

Edging—Modern In recent years, the use of CNC edging equipment is enabling a single setup for multiple grinding operations. For example, it is fairly routine to process the diameter, sagitta with a step, bevel and a fiduciary flat, all in one operation. The CNC controller interface shows a series of cross-sections, and the operator fills in inputs for what is the starting point and what features are needed in the end. Simultaneous creation enssures the features will all run true relative to one another. In addition to facilitating grinding of more complex features, optional features such as micropositioning air blasts for automated alignment optimization and measurement enable precision placement of the optic. Lenses are still mechanically bell clamped.

9.4 PLANO OPTICS FABRICATION

A plano surface has a radius equal to infinity. Typically plano form specification does not differentiate between spherical power and irregularity, specifying lump sum reflected errors as flatness. Therefore, maintaining perfect flatness is critical during plano surface finishing. The process steps for plano surfaces are exactly the same as for spheres. Planos have the advantage of fixed radius, so often, companies, departments within companies, personnel and equipment will be plano specific. This specificity allows economies of scale and development of plano-specific solutions. An example of this are continuous polishers (CPs), in which a large (40–60 inches in diameter) annular lap is "conditioned" to maintain lap flatness independent of the workpiece size. The lap is forced by a large glass (or similar material) "conditioner" to stay flat. This persuasion by the conditioner imprints onto the work piece and maintains flatness as a result.

Double-sided CPs polish both sides of a window simultaneously. Much of the recent technology used in the precision plano window manufacturing has been taken from semiconductor industry's work-optimizing silicon wafer processes.

9.5 ASPHERE OPTICS FABRICATION

Aspheric lenses contain at least one optically active surface of nonconstant curvature. This is the primary differentiator from a spherical lens. Rotationally symmetric aspheric lenses are solids of revolution, where a general equation describes the cross section to be revolved (Fig. 1). Lenses of this style are capable of higher aberration order correction than spherical lenses. While the forms and their promise have been known to optical designers for centuries, for most of that time only the mildest forms have been physically realizable. The methods, machinery, and metrology are specific to asphere manufacturing.[14]

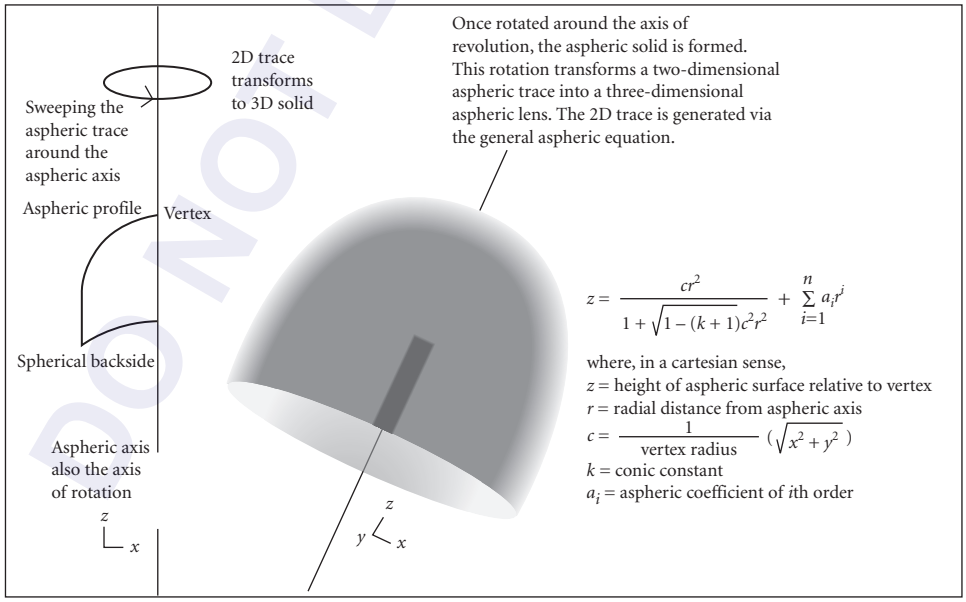

FIGURE 1 Sample general asphere form. (*Brandon Light, Optimax Systems, Inc.*)

Traditional full-aperture fabrication methods are not capable of manufacturing aspheric surfaces due to their nonconstant curvature. By changing the amount of contact from full to a region where change in local curvature approaches zero, some portions of traditional spherical lens-manufacturing techniques can be applied. Brittle removal by high-speed diamond grinding followed by ductile removal using a polishing slurry (ceria, alumina, etc.) can be used to prepare aspheric surfaces. Instead of full contact, curvature-insensitive local contact is used in grinding and polishing.

In aspheric grinding, a peripheral diamond wheel on a CNC platform traces the surface to generate the aspheric profile. In grinding, machine accuracy determines profile accuracy. A more accurate ground profile makes a more accurate polished profile more likely, since there's less correction needed. Particular attention must be paid to wheel wear, wheel balance, positional accuracy, and overall stiffness of the grinding platform. Imperfection in any of these grinding parameters will leave signatures in the ground surface.

The surface is then polished by working only a small area at a time. All of this must be done while maintaining location of the aspheric axis, the axis around which the solid of revolution was formed. Each iteration has an error inducement associated with it, so making as few correction runs as possible is a primary focus. Typically, asphere polishing is a feed-forward, deterministic process. While the local curvature may be constant, globally it is not. Polishing requires an adaptive tool and knowledge of what's ahead. The polishing tool needs to change to suit local curvature at a suitable rate of change. This requires knowledge of how the tool will evolve and how much removal is needed in which region. Deterministic processes provided by Zeeko/Satisloh and QED machinery, discussed earlier, are examples of such tools. These processes characterize the removal rate as a function of curvature for a given tool and combine that with an error map of the surface to be worked. The resulting removal schedule accommodates for volumes to be removed and tool performance at that local curvature.

Conventional interferometric techniques do not translate to aspheric manufacturing either. Since local curvature is nonconstant, interferometric techniques for aspheres are lock and key. The setup and equipment can be unique for a given aspheric form, so time and money demands are large. For example, form-specific computer-generated holograms (CGHs) may be required to provide feedback to the closed-loop deterministic polishing process. For a more cost-effective solution profilometry is the main two-dimensional compromise, and it is the current industry standard. Although more generalized interferometric solutions are beginning to be offered by QED, Zygo, and others.

Errors in centration are unrecoverable. In centering a spherical lens, errors can be removed. With sufficient diameter overage both centers of curvature could be positioned on the same axis and that axis could be made concurrent and coincidental with the mechanical axis. Since an aspheric surface is centered about an axis and not a point such realignment is not possible. Therefore, centration must be conserved throughout processing.

9.6 CRYSTALLINE OPTICS

As more optical work occurs outside the visible spectrum, use of optics made from nonglass brittle materials will grow. Single crystalline and polycrystalline materials are transparent far outside the usual spectral transmission range of glass. In many cases, the surfaces of these materials have differing hardness values depending on the orientation of the crystal boundaries. Soft laps tend to accentuate the grain boundaries of these materials, and that can lead to wavefront errors, mottled surfaces, and scattering. The traditional optical fabrication process can be adapted to crystal materials if some substitutions are made. The lapping process may substitute finely graded diamond for alumina and tin or zinc laps in place of the typical cast iron. Similarly, diamond suspensions are often used in polishing in place of ceria. Polishing laps may consist of synthetic materials like polyurethane or beeswax instead of optical pitches.[29,30]

9.7 PURCHASING OPTICS

There are a number of companies who offer lines of standard optical components. These suppliers can provide off-the-shelf optics in a variety of sizes, shapes, and quality levels. Most optics providers have areas of specialization, and the informed optics buyer will select vendors that match their specific optics requirements. When custom optics are required, it is best to understand the capabilities of prospective suppliers. Most optics companies promote a broad range of capabilities, but many tend to specialize in some manner. Professionals who are engaged in optics purchasing on a regular basis learn where to go for specific optics requirements. Often this education is paid for by awarding of numerous contracts across a broad array of parts and suppliers and experiencing the consequences of the decisions. Much is learned in the contract's postmortem review.

Optics purchasing is further complicated with the predominance of the internet as a research tool. Web sites and promotional materials often do not reflect a supplier's true capability and know-how.

Whether buying off-the-shelf or custom optics, it is always best to engage potential suppliers in dialog, preferably addressing tolerances and other manufacturing cost drivers. The buyer should be satisfied the supplier has the ability to meet and measure all critical criteria. For optics that approach a manufacturer's limits, it is especially important to understand the test and acceptance process, as there can be quite a divergence of metrology equipment and methods available for testing various parameters.[31] This is especially true for aspheres, where full format phase measuring interferometry or transmitted wavefront testing is not always within a supplier's capability.

9.8 CONCLUSION

Optics fabrication requires serial application of relatively simple steps. In the past, these steps were carefully carried out by artisans using traditional techniques. Modern approaches incorporate scientific research into the manufacturing process. Artisan skills integrate with the scientific know-how yielding a new breed of technology workers of the twenty-first century. Nevertheless, the basic process steps of grinding followed by polishing have remained. Introduction of new optical materials, more complex shapes and more narrow tolerance budgets will enable designers to develop improved solutions to old problems over an expanded spectrum, and modern manufacturing methods can make the optics physically realizable. Finally, the tendency for specialization among optics supplier requires open dialog between supplier and designer as a means to optimize successful relationships.

10.2 INTRODUCTION

The use of special machine tools with single-crystal diamond-cutting tools to produce optical surfaces on some metals and a limited range of other materials is called *diamond turning*. Over the last 50 years or so, diamond turning has matured to become the method of choice for producing some optical surfaces; in other applications, diamond turning provides a critical process step with radically different characteristics from most other optical fabrication methods.

In terms of geometry and motions required, the diamond-turning process is much like the step of "generating the optical surface" in traditional optical fabrication. However, the diamond-turning machine is a more sophisticated piece of equipment that produces the final surface, which frequently does not need the traditional polishing operation. The surface quality produced by the "best" diamond turning does not yet match the best produced by conventional polishing practice. The limits of diamond turning for both figure and surface-finish accuracy have not yet been reached—and diamond turning can be combined with postpolishing to improve surface finish and reduce scatter.[1] Also subaperture processing with small polishing tools or magnetorheological finishing (MRF) can be used to improve figure.

There are several important advantages of using diamond turning, including the ability to produce good optical surfaces to the edge of the element, to fabricate soft ductile materials that are difficult to polish, to eliminate alignment adjustments in some systems, and to fabricate shapes difficult to produce by other methods. The latest generation of diamond-turning machines incorporates up to five axes

†Certain commercial equipment, instruments, or materials are identified in this chapter. Such identification does not imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the products identified are necessarily the best available for the purpose.

of computer-controlled motion, allowing for production of anamorphic optics. Use of form tools on multiaxis machines enables production of "structured" optical surfaces[2] ranging from subwavelength structures through diffractive/refractive infrared (IR) elements to optical component molds.

If the advantages of diamond turning suggest this fabrication method, then it is important to determine early in the design phase of a project whether the material specified is appropriate for diamond turning and whether slideway travels and linear and rotary axis controls are available on the diamond-turning machine to support fabrication of complex structures.

Sections in this chapter highlight the following:

- The diamond-turning process
- The advantages of diamond turning
- Diamond-turnable materials
- Comparison of diamond turning and traditional optical fabrication
- Machine tools for diamond turning
- Basic steps in diamond turning
- Surface finish of diamond-turned optics
- Metrology of diamond-turned optics
- Conclusions

10.3 THE DIAMOND-TURNING PROCESS

The diamond-turning process produces finished surfaces by very accurately cutting away a thin chip or layer of the surface. Thus, it is generally applicable to ductile materials that machine well rather than to hard brittle materials traditionally used for optical elements. However, by using a grinding head on a diamond-turning machine in place of the tool, hard brittle materials can be finished. At very small effective depths of cut, brittle materials behave in an apparently ductile manner. This attribute allows fracture-free grinding of glasses and ceramics as well as diamond turning of optical surfaces on materials such as germanium, zinc selenide, and potassium dihydrogen phosphate (KDP).

In diamond turning, both the figure and surface finish are largely determined by the machine tool and the cutting process. Note, however, that material characteristics such as grain size and inclusion size limit the ultimate surface finish achievable. The tool has to be very accurately moved with respect to the optical element to generate a good optical surface, and the edge of the diamond tool has to be extremely sharp and free of defects.

10.4 THE ADVANTAGES OF DIAMOND TURNING

Diamond turning fits within a broad spectrum of optics fabrication processes. When compared with traditional optical fabrication methods of lapping and polishing (see, for example, Chap. 9, "Optical Fabrication," by Michael P. Mandina) diamond turning has several advantages.

- It can produce good optical surfaces clear to the edge of the optical element. This is important, for example, in making scanners, polygons, special shaped flats, and when producing parts with interrupted cuts.
- It can produce optical surfaces on soft ductile materials that are extremely difficult to polish.
- It can easily produce off-axis parabolas and other difficult-to-lap aspherical shapes.
- It can produce optical elements with a significant cost advantage over conventional lapping and polishing where the relationship of the mounting surface—or other feature—to the optical surface is very critical. Expressed differently, this feature of diamond turning offers the opportunity to eliminate alignment adjustments in some systems.

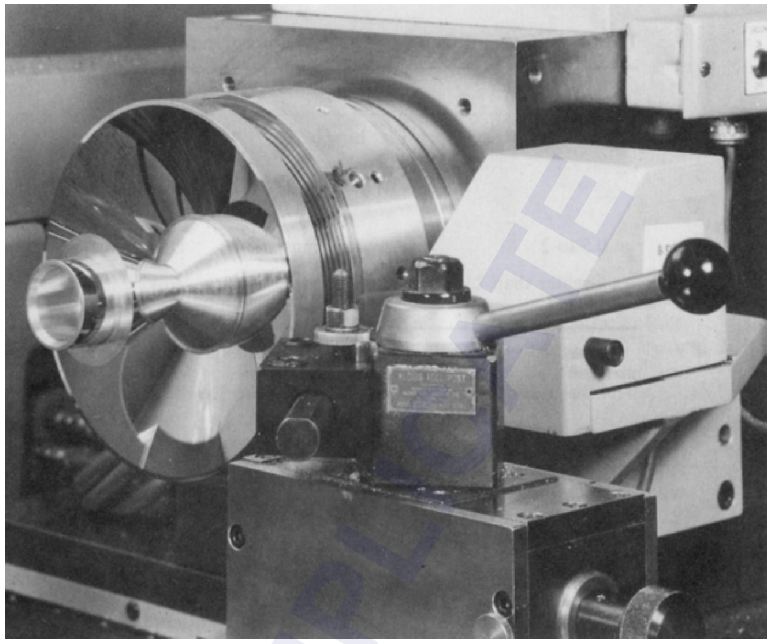

FIGURE 1 An axicon optical element being diamond turned. (*Courtesy of Rank Taylor Hobson, Keene, New Hampshire.*)

- It can fabricate optical shapes such as axicons, facetted optics, and grazing incidence X-ray optics that would be extremely difficult to fabricate by methods other than diamond turning (see Fig. 1).

Conflicts between optical requirements and diamond turnability on the one hand, and mechanical considerations on the other, often lead to the use of platings. Plating deficiencies, however, can cause as much trouble as poor bulk materials. For example, small changes in the composition of plated electroless nickel may cause dramatic changes in tool wear.[3]

Residual stress in the mirror blank, whether plated or not, can lead to changes in mirror shape with time. It is essential to pay careful attention to stress-relief prior to final diamond turning.

A decision to diamond turn an optical element, rather than fabricate it by the conventional polishing techniques, might be based on several different considerations such as type of element, size, and material. A general guide to different considerations in selecting diamond turning as a fabrication technique is presented in Table 1.

TABLE 1 General Guide to Optical Fabrication Methods

Size, m	Shape	Material	Preferred Method
Less than 0.5	Flat or sphere	Glass/ceramic	Polish
		Ductile metal	Diamond turn
	Asphere	Glass/ceramic	Grind/polish*
		Ductile metal	Diamond turn
0.5 to 2.0	Any axisymmetric	Ductile metal	Diamond turn†
Greater than 2.0	Any	Any	Large polishing machine

*Can generate shape or figure on a diamond-turning machine with a grinding head replacing the diamond tool. Subaperture polishing techniques, including techniques such as MRF, may be applied to advantage.

†Diamond-turning machines up to 2-m diameter have been built.

As indicated above, diamond turning has some unique characteristics. In some IR (and even visible) imaging systems, considerable improvements in optical performance have been obtained by combining a refractive aspheric surface and a diffractive surface in a single element. For IR applications, it is hard to produce such a component by any other fabrication process; for visible applications, such optics can be produced in volume from diamond-turned molds.

Another unique capability of diamond turning is to provide datums or alignment features machined in the same setup as the optical surface. "Snap-together" optical systems requiring no alignment adjustments after assembly are very attractive in some applications.

Over the last decade, there have been considerable advances in the ability to produce aspheric optics using computer-controlled generators and pad polishers. These technologies, combined with ion polishing, magnetorheological finishing, and computer-controlled polishing have enabled a new generation of aspheric optics. Ultimately the choice of manufacturing process requires a careful analysis of the options and the system requirements.

10.5 DIAMOND-TURNABLE MATERIALS

Selection of appropriate materials is, necessarily, a trade-off between application-specific requirements and optimization of the manufacturing process. This trade-off may drive the selection of a plated surface, for example, or the choice of fabrication steps.

Historically materials have been described as either "diamond turnable," or not, as if this were an inherent material property. This shorthand covers two different situations. One is that, in practice, some materials cause very rapid wear of the diamond; for example, it is widely known that ferrous materials cause rapid tool wear. The other is that, particularly for certain plastics, tool-workpiece interactions produce unacceptable optical surfaces.

A number of listings of diamond-turnable materials, such as the one included in Table 2, have been published. Such listings should be treated with caution. Typically, they are incomplete and do not provide sufficient information on the materials that are listed. For example, good optical surfaces are not generally produced on all aluminum alloys: Aluminum Alloy 6061 (Aluminum Association, Inc. designation) is the most commonly used alloy, although certain 5000 series and 7000 series alloys have their proponents, and 2024 aluminum has been used but, in general, does not produce the best surfaces.

TABLE 2 Diamond-Turnable Materials

Metals	Nonmetals	Plastics
Aluminum	Calcium fluoride	Polymethymethacrylate
Brass	Magnesium fluoride	Polycarbonates
Copper	Cadmium telluride	Polyimide
Beryllium copper	Zinc selenide	
Bronze	Zinc sulphide	
Gold	Gallium arsenide	
Silver	Sodium chloride	
Lead	Calcium chloride	
Platinum	Germanium	
Tin	Strontium fluoride	
Zinc	Sodium fluoride	
Electroless nickel	KDP	
	KTP	
	Silicon	

Similarly, gold is considered diamond-turnable, but problems have been reported machining large gold-plated optics. Conventional electroplated nickels (and bulk nickel) give rapid tool wear, but electroless nickel with phosphorous contents above about 10 percent, if appropriately heat treated, can be machined effectively.[4] Higher phosphorous contents (up to 15 percent) are obtainable in electroplated nickel[5,6] which also machines extremely well. Both materials are metastable and will transform—with exposure to the necessary time/temperature conditions—to a mixture of crystalline nickel with hard phosphides. This transformation is accompanied by a volume change, a degradation of optical characteristics of the surface, and a dramatic increase in tool wear.

Platings may also be optimized to give low ductility and hence minimum burr formation when machining Fresnels or the molds for micro-optics arrays such as arrays of retroreflectors. Platings over a diamond-turned sacrificial mandrel allow production of otherwise unobtainable forms. Plated surfaces, however, have characteristics which can adversely affect both fabrication and application; at some level the resulting structure is a temperature-sensitive bimetal strip. Pits and inclusions can cause significant fabrication issues.[7]

Silicon, although included in the listing given here, should be considered marginal as tool wear can be high. Reasonably large areas of amorphous silicon cladding are reported to have been successfully machined.

Over the last decade or so there have been significant advances in understanding of diamond tool wear. Mechanisms associated with abrasion and chipping typically provide one limit to diamond tool life. For example, when machining bulk aluminums the interactions between hard inclusions and the diamond tool clearly lead to wear. Such mechanisms, however, do not explain the very rapid wear observed when machining soft, high-purity iron.

Paul et al.[8] showed that machining metallic elements containing unpaired *d*-shell electrons results in catalyzed reactions between diamond and the work material. The same mechanism explains the role of phosphorous in electroless nickel and led to a recent breakthrough by Brinksmeier et al.[9] They showed that, like phosphorous, nitrogen in a nitride surface layer on steel combines with the unpaired *d*-shell electrons from the iron. The result is a dramatic reduction in tool wear, suggesting that diamond-turned steel molds (e.g., for plastic optics) may become practical in the near future. Previous approaches—such as diamond turning at cryogenic temperatures[10] or in methane or acetylene environments[11]—provided evidence of the mechanisms at work but were not widely adopted (and in the case of cryogenic machining was not intended by the original researchers to be practical).

For a number of years, Moriwaki[12] has been developing ultrasonic-assisted machining, including cutting when the tool is vibrated with an elliptical motion. Significant reductions in tool wear have been demonstrated, although the mechanism remains controversial. The amplitude and frequency of oscillation in the cutting direction are generally selected such that separation between the rake face of the tool and the chip is expected. In this case, one might postulate poisoning of the catalytic process by, for example, hydrocarbon-based cutting fluids. Elliptical motion would also move the clearance face out of contact. Other measurements show significant reductions in cutting forces,[13] suggesting a reduction of tool temperatures.

In case of some plastics, recent work by Gubbels et al.[14] shows that the chemical explanations of Paul et al.[8] do not apply, but that triboelectric effects dominate. In general, there are some suggestions that parameters, such as surface speed, are more important for successful diamond machining of plastics than for metal and crystalline substrates. Some plastics are diamond turned in volume production.

Other material characteristics, in addition to the material composition, are important. For example, large grain size results in a more pronounced "orange peel" as tools become dull and the variation in modulus of the different grain orientations leads to different deflections due to cutting forces. Residual stresses can relax over time and cause changes in figure. Because of these types of problems it is important to involve experienced personnel early in the design phase[15] to ensure that the material specified is appropriate. In some projects, the part is so valuable and/or so difficult to produce by other techniques, it is worth consuming tools more rapidly than would normally be acceptable. However, such a decision should be taken consciously, not by default late in a project.

10.6 COMPARISON OF DIAMOND TURNING AND TRADITIONAL OPTICAL FABRICATION

In diamond turning, the final shape and surface of the optic produced depend on the machine tool accuracy, whereas, in traditional optical fabrication, the final shape and surface of the optical element depend on the process variables involved with using an abrasive-loaded lap. The differences between diamond turning and traditional optical fabrication can be summarized by describing diamond turning as a displacement-controlled process versus a force-controlled process for traditional optical fabrication.[16] The goal in diamond turning is to have a machine tool that produces an extremely accurate path with the diamond tool, hence a displacement-controlled process. A traditional polishing machine used for optical fabrication depends on the force being constant over the area where the abrasive-loaded lap—or tool—touches the surface being worked. Selective removal of material can be produced by increasing the lap pressure in selected areas or by use of a zone lap. The stiffness of a diamond-turning machine is important because, to control the displacement, it is important that cutting forces and other influences do not cause unwanted displacements. Feeds, speeds, and depth of cut are typically much lower in diamond turning than conventional machining, thus giving lower forces. However, the displacements of concern are also much lower. Thus the stiffness required is as much, or more, of a concern than conventional machining even though the total force capability may be lower for diamond turning.

10.7 MACHINE TOOLS FOR DIAMOND TURNING

In general, the machine tools used for diamond turning are very expensive compared to the equipment needed for traditional optical fabrication. The positioning accuracy required for diamond turning is beyond the capability of conventional machine tools, thus some of the first widely adopted diamond-turning machines for fabricating optics were modified Moore measuring machines.[17]

Although there are some records of machine tools being used to generate optical surfaces as early as the seventeenth century, most of the effort is modern, accelerated in the 1960s and 1970s with the advent of computer-based machine tool controls and laser interferometer systems used as positional feedback devices. Evans[18] has documented much of the history of diamond turning and provides an extensive reference list. Ikawa[19] summarizes some of the research in metal cutting related to diamond turning and associated machine tools.

The early diamond-turning machines were two-axis lathes that could produce axisymmetric optical elements. With recent advances in computer-based control systems, and improved motion control and feedback sensors, multiaxis diamond-turning machines have become readily available. Two commercial diamond-turning machines are shown in Fig. 2. Both machines can be configured with five-axis motion control combining both linear and rotary axes. Measuring scales have replaced the laser interferometers in many diamond-turning machines and give a very reliable positioning feedback system at lower cost.

Programming of these multiaxis machines draws on the technology developed in precision machine shops for large five-axis machine tools used to make complicated parts. By adapting the multiaxis control to diamond-turning machines, a great variety of shapes can now be diamond turned which opens up the process to many new optical applications. Before judging an optical element shape to be unsuitable for diamond turning, a manufacturer of modern diamond-turning machines should be consulted.

Producing nonaxisymmetric parts—such as an off-axis parabola machined while centered on the rotating axis—has become possible with fast tool servos. These systems can rapidly move a cutting tool a short distance coordinated with the rotation of the spindle.[20] There are also cases where the machine's slideways or rotary motions can be used to produce nonaxisymmetric parts.

(b)

FIGURE 2 (*a*) Diamond-turning machine configurable for five-axis machining. (*Courtesy of Precitech, Inc., Keene, New Hampshire.*) (*b*) Diamond-turning machine configurable for five-axis machining. (*Courtesy of Moore Nanotechnology Systems, LLC., Keene, New Hampshire.*)

Many diamond-turning machines are used in the traditional turning lathe mode where the workpiece turns and the tool is held stationary in the tool post. Most diamond-turning machines can also be configured such that the tool rotates about the spindle axis—commonly called fly cutting—to produce components such as long flat mirror surfaces or other milled surfaces.

10.8 BASIC STEPS IN DIAMOND TURNING

Much like the traditional optical-fabrication process, the diamond-turning process can be described as a series of steps used to make an optical element. The steps used in diamond turning are

1. *Preparing the blank* with all the required features of the element with an extra thickness of material (generally 0.1-mm extra material or plating is adequate) on the surface to be diamond turned
2. *Mounting the blank* in an appropriate fixture or chuck on the diamond-turning machine
3. *Selecting the diamond tool* appropriate for the material and shape of the optical component
4. *Mounting and adjusting the diamond tool* on the machine
5. *Machining the optical surface* to final shape and surface quality
6. *Cleaning the optical surface* to remove cutting oils or solvents

Mounting the optical element blank on a diamond-turning machine is extremely important. If a blank is slightly distorted in the holding fixture, and then machined to a perfect shape on the machine, it will be a distorted mirror when released from the fixture. Therefore, fixtures and chucks to hold mirrors during diamond turning need to be carefully designed to prevent distortion. Often the best way to hold a mirror during machining is to use the same mounting method that will be used to hold the mirror in service.

It is advantageous in many applications to machine a substrate of aluminum or copper and then add a plating to be diamond turned. The design and application of platings is part science and part art. Many aspects of the platings as related to diamond turning were covered at the ASPE Spring 1991 Topical Meeting.[7]

Tool setting—the mounting and adjusting of the diamond-tipped cutting tool—is often accomplished by cutting a test surface, either on the actual mirror blank to be later machined over, or by placing a test piece on the machine just for tool setting. If the cutting tool is too high or too low, a defect at the center of a mirror is produced. It is possible, using reasonable care and patience, to set the tool height within about 0.1 μm of the exact center. Setting the tool in the feed direction after the height is correct is somewhat more difficult. For example, an error in setting will produce an ogive shape rather than a sphere which is not obvious until the figure is measured. Gerchman[21] describes these types of defects.

The selection of the tool for diamond turning is important. Large cutting tip radii (2 mm or greater) are often used when producing flats, convex, or concave mirrors with large radius of curvature. However, small-radii diamond tools are available (in the range of 0.1 mm) for making small deep mirrors or molds. Tools with special geometries, including so-called "dead sharp" tools, can be obtained for such applications as Fresnel lenses or retroreflector arrays. In general, approximately 0° rake tools, with about 5° or 6° front clearance, are used for diamond-turning ductile metals. Negative rake tools are often good for crystalline materials and positive rakes may be beneficial when machining some plastics. The cutting edge has to be chip free to produce a good diamond-turned surface. A normal specification for edge quality is "chip free when examined at 1000×." The edge sharpness is a concern for very small depths of cut—especially where the depth of cut is close to the cutting edge sharpness—because the cutting forces increase and more of a plowing than a cutting process occurs. The effect of cutting edge sharpness has been investigated by researchers, for example Lucca, et al,[22] however, there is currently no convenient way to specify and inspect tools for edge sharpness.

The orientation of the diamond itself on the shank is of concern because the single-crystal diamond is anisotropic. The orientation of diamond tools has been studied, for example, by Wilks,[23] Decker,[24] and Hurt.[25] It is necessary for the tool manufacturer to mount the diamond so that it can be shaped to the required radius and produce a good cutting edge. The usual orientation for diamond tools is with the cleavage plane parallel to the rake face.

The actual diamond turning, or machining to final size and surface finish, is often the fastest part of the process. The machine-tool controller has to be programmed to move the tool along the correct path, the chip-removal system has to be positioned, and the cutting-fluid applicator needs to be adjusted to provide consistent clean cutting.

For machining of flats and spherical surfaces, the part programs that define the machine motion are straightforward. But when cutting aspherical surfaces, caution has to be exercised so that the radius of the tool is properly handled in calculating the tool path. Modern computer-aided design (CAD) systems perform the necessary calculations, but tests should be performed prior to cutting a difficult or expensive component.

In general, the cutting speeds for diamond turning are similar to those used for conventional machining: less than 1 m/min to more than 100 m/min. However, the slower cutting speeds produced by facing to the center of a workpiece do not affect the surface finish in diamond turning as is often the case with nondiamond tools. Thus, varying the spindle speed to keep the cutting speed constant is not necessary in diamond turning. The upper speed for diamond turning is often limited by the distortion of the optical element due to inertial forces, especially for larger elements. The upper spindle speed can also be limited due to any unbalance of the workpiece and fixture. The feed rate in diamond turning is usually adjusted to give a good theoretical surface finish. (See the following section.)

Cleaning of diamond-turned optics has a lot in common with cleaning conventionally polished optics. But because many of the diamond-turned elements are of soft metals, caution has to be exercised to prevent scratching. In general, a degreaser is used (soap or solvent), followed by a rinse in pure ethyl alcohol. The drag-wiping technique traditionally used on some glass optics can be used on some diamond-turned elements. Care must be taken to ensure that the lens tissue is very clean and remains wet. Some work has been done to study the best solvents to use for cleaning diamond-turned optics from an environmental-impact standpoint.[26]

10.9 SURFACE FINISH OF DIAMOND-TURNED OPTICS

The surface structure is different for diamond-turned surfaces as compared with conventionally polished surfaces. A diamond-turned surface is produced by moving a cutting tool across the surface of the turning component, such as the facing operation illustrated in Fig. 3. Therefore, diamond-turned elements always have some periodic surface roughness, which can produce a diffraction-grating effect, whereas polished optical surfaces have a random roughness pattern. The traditional "scratch and dig" approach to describing surfaces is not meaningful for diamond-turned surfaces.

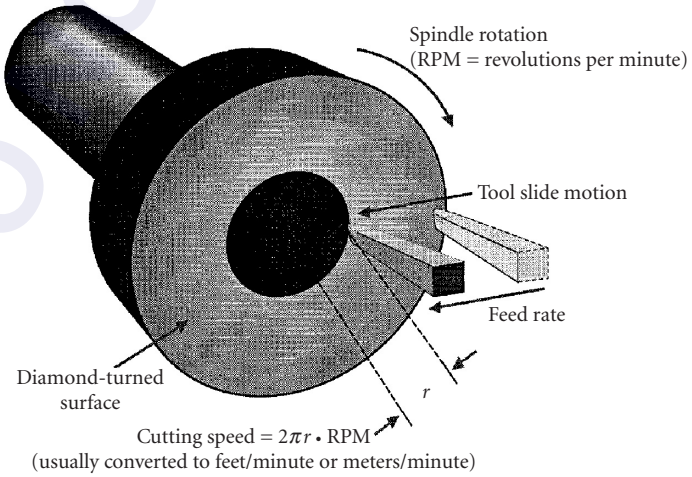

FIGURE 3 Diamond turning an optical element.

The machining process produces a periodic surface structure directly related to the tool tip radius and feed rate. The theoretical diamond-turned surface is illustrated in Fig. 4. The formula displayed in the figure for calculating the height of the cusps is

$$h = \frac{f^2}{8 \cdot R} \tag{1}$$

where h = peak-to-valley height of the periodic surface defect
f = feed per revolution
R = tool tip radius

For example, if a surface is diamond turned using a spindle speed of 31.4 rad/s (300 rpm), a feed of 7.5 mm/min, and a 5.0-mm tool tip radius:

$$h = \frac{(7.5/300)^2}{8 \times 5} = 1.56 \times 10^{-5}\ \text{mm}$$

$$h = 15.6\ \text{nm} \tag{2}$$

In addition to the "theoretical finish" based on cusp structure, the measured surface finish on diamond-turned parts is influenced by other factors.

- Waviness within the long-wavelength cut-off for surface measurement may be correlated, for example, with slide straightness errors.
- Asynchronous error motions of the spindle can cause surface defects. If, for a given angular spindle position, there is nonrepeatability in axial, radial, or tilt directions, these errors will transfer into surface structure. Details of spindle errors are important in diamond turning. Further information can be found in the "Axis of Rotation Standard."[27]
- External and self-induced vibration, not at the spindle frequency or at one of its harmonics, can have the same effect on finish—measured across the lay—as asynchronous spindle motions.
- Materials effects such as the differential elastic recovery of adjacent grains can cause steps in the machined surface that have an appearance commonly referred to as "orange peel." Impurities in the material can also degrade surface finish.
- Within each cusp, there can be a repeated surface structure related to chips in the edge of the tool.

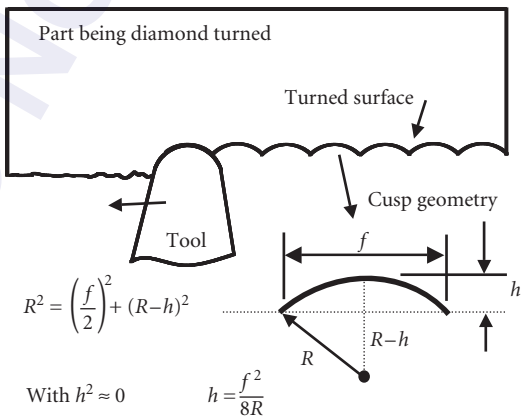

FIGURE 4 "Cusp" surface of diamond-turned optical element.

The Nomarski microscope is an excellent means of qualitatively evaluating diamond-turned surfaces. The Nomarski photo in Fig. 5*a* illustrates the periodic structure of a diamond-turned surface. The feed rate used in producing the surface causes the wavelength of the periodic structure to be about 8 μm. Figure 5*b* illustrates other defects in the diamond-turned surface when the Nomarski microscope is adjusted such that the periodic cusps are not seen.[28]

10.10 METROLOGY OF DIAMOND-TURNED OPTICS

In general, measurement of diamond-turned optics is similar to the measurement of any other optic; figure, midspatial frequency errors, transmitted wavefront, and surface roughness may all need characterization, depending on the specification. As with other optics, the choice of figure metrology is driven by the optical surface itself. Classical null tests—especially autocollimation tests for parabolae and the related tests for other conics—are widely used. Over the last decade or so, use of in-cavity holograms in Fizeau tests has increased. What remains elusive is a general test. Over a limited range of surfaces, subaperture stitching[29] may be viable or, for circularly symmetric aspheres, zonal stitching.[30] Kuechel[31] described a zonal technique that uses only the zone of null data and, hence, is free of retrace errors and applicable to a range of aspheres without the need for null optics. An instrument based on this technique is shown in Fig. 6.

One area in which diamond turning differs from conventional optics production is that the machine itself can be used as a measuring machine. The diamond tool can be replaced with an appropriate sensor (such as a capacitance sensor, air bearing linear variable differential transformer (LVDT), optical triangulation sensor, etc.) or the sensor can be built into an auxiliary mount. With sufficient care,[32] the geometric errors of the machine can be mapped so that the limits in the metrology are the uncertainties associated with probing and with the environment. This approach is particularly advantageous when making (and measuring) radical aspheres or discontinuous, structured surfaces[2] such as molds for facetted automotive lighting. On multiaxis machines, it is sometimes more useful to use a different combination of axes for metrology than for machining to better decouple machine geometry errors from measurement uncertainty. For example, on a diamond-turning machine with a *B* axis (rotary table), near hemispheres and some aspheres can conveniently be machined using only the *x* and *y* axes, with measurement of the departure from a best-fit sphere performed using a separate probe mounted on the rotary table.

FIGURE 6 Aspheric measuring system. (*Courtesy Zygo Corporation, Middlefield, CT.*)

FIGURE 7 Microinterferometer. (*Courtesy of Zygo Corporation*).

There is little practical difference between measuring optical surfaces produced using traditional methods and by diamond turning. It is worth bearing in mind, however, that during diamond turning there is usually a monotonic progression in cutting from outside diameter to inside diameter or vice versa; hence, diamond tool wear or small edge nicks will cause a degradation in finish that depends on position on the part. The surface finish measurement sampling strategy should be adjusted accordingly. Surfaces produced using traditional 2-axis or 3-axis diamond-turning have significantly different characteristics along and transverse to the lay; scattering is isotropic, a characteristic that should be considered in both the specification and metrology of diamond-turned optics. Four-axis and 5-axis machining using methods akin to milling produce cusp structures usually at different spatial wavelengths in both directions.

Microinterferometers (Fig. 7) have become the tool of choice for characterizing optical surfaces at spatial wavelengths down to the limits posed by the instrument transfer function.[33] Microinterferometers—particularly those using scanning coherence techniques frequently referred to as scanning white light interferometry (SWLI)—can be useful, provided the surface slopes and lateral extent are compatible with the available numerical aperture of the objective and the field of view. Replication—for example, using dental replica materials, silicone-based caulks, two-part epoxies, and the like—allows sampling of large surfaces, although there is inevitably some increase in "noise" due to the replication process.

Higher spatial frequency structured surfaces, such as retroreflectors or other micro-optic arrays,[34] often pose metrology challenges for which there is no general solution.

10.11 CONCLUSIONS

Diamond turning has been used for many years to commercially produce infrared optics. Some visible and ultraviolet applications are now possible. Moreover, the limits of diamond turning for both figure and surface finish accuracy have not yet been reached. Taniguchi[35] and others have shown that precision in both conventional machining and ultraprecision machining, such as diamond turning, has steadily improved for many decades, with roughly a factor of three improvements possible every 10 years. If this trend continues, we could expect diamond-turning machines with accuracies below 10 nm and even approaching 1 nm by the year 2020. Yet, it is important to remember that it becomes increasingly difficult to push the capabilities in this regime—nor is it clear that it is cost effective to do so. Other manufacturing techniques may be more appropriate for production of the highest quality optics.

The technology developed for diamond-turning optics in some industries is now beginning to impact the precision machining of nonoptical components. In the future, the improvement of all machine tools will likely be driven by both optical and nonoptical applications, with diamond-turning machines possibly reaching the accuracy level that will allow visible and ultraviolet optics to be fabricated by machining or grinding without postpolishing.

ORTHONORMAL POLYNOMIALS IN WAVEFRONT ANALYSIS

Virendra N. Mahajan*

The Aerospace Corporation
El Segundo, California

ABSTRACT

Zernike circle polynomials are in widespread use for wavefront analysis because they are orthogonal over a unit circle and represent balanced classical aberrations for imaging systems with circular pupils. However, they are not suitable for systems with noncircular pupils. Examples of such pupils are annular as in astronomical telescopes, elliptical as in the off-axis pupil of an otherwise rotationally symmetric system with a circular on-axis pupil, hexagonal as in the hexagonal segments of a large telescope, for example, Keck, and rectangular and square as in high-power laser beams. In this chapter, we list the orthonormal circle, annular, elliptical, hexagonal, rectangular, and square polynomials. The polynomials for a noncircular pupil can be obtained by orthogonalizing the circle polynomials over the pupil using the recursive Gram-Schmidt process or a nonrecursive matrix approach. These polynomials are unique in that they are not only orthogonal across such pupils, but also represent balanced classical aberrations for such pupils, just as the Zernike circle polynomials are unique in these respects for circular pupils. The polynomials are given in terms of the circle polynomials as well as in polar and Cartesian coordinates. The orthonormal polynomials for a one-dimensional slit pupil are given as a limiting case of a rectangular pupil. The polynomials corresponding to Seidel aberrations are illustrated isometrically, interferometrically, and with the corresponding point-spread functions (PSFs).

11.1 GLOSSARY

a	half width of a unit rectangular pupil
a_j	jth expansion coefficient
A	area of pupil
b	aspect ratio of a unit elliptical pupil

*The author is also an adjunct professor at the College of Optical Sciences, University of Arizona, Tucson, Arizona and Department of Optics and Photonics, National Central University, Chung Li, Taiwan. He gratefully acknowledges helpful discussions with Drs. Guang-ming Dai and Bill Swantner.

$E_j(x, y)$	orthonormal elliptical polynomial in Cartesian coordinates (x, y)
F	focal ratio of the image-forming light cone
$F_j(x, y)$	jth orthonormal polynomial
$H_j(x, y)$	orthonormal hexagonal polynomial
j	polynomial number
N_n	number of polynomials through an order n
$P_j(x)$	orthonormal slit polynomial along the x axis
$P_n(\cdot)$	Legendre polynomial of order n
$R_j(x, y)$	orthonormal rectangular polynomial
$R_n^m(\rho)$	Zernike circle radial polynomial
$R_n^m(\rho; \epsilon)$	Zernike annular radial polynomial
$S_j(x, y)$	orthonormal square polynomial
$W(x, y)$	wave aberration at a point (x, y)
$Z_j(\rho, \theta)$	orthonormal Zernike circle polynomial in polar coordinates (ρ, θ)
$Z_j(\rho, \theta; \epsilon)$	orthonormal Zernike annular polynomial
σ	standard deviation
σ^2	variance
ϵ	obscuration ratio of an annular pupil

11.2 INTRODUCTION

Optical systems generally have a circular pupil. The imaging elements of such systems have a circular boundary. Hence they also represent circular pupils in fabrication and testing. As a result, the Zernike circle polynomials have been in widespread use since Zernike introduced them in his phase contrast method for testing circular mirrors.[1] They are used in optical design and testing to understand the aberration content of a wavefront. They have also been used for analyzing the wavefront aberration introduced by atmospheric turbulence on a wave propagating through it.[2] Their utility stems from the fact that they are orthogonal over a unit circle and they represent balanced classical aberrations yielding minimum variance over a circular pupil.[3–6] They are unique in this respect since no other polynomials have these properties. Because of their orthogonality, when a wavefront is expanded in terms of them, the value of an expansion coefficient is independent of the number of polynomials used in the expansion. Hence, one or more polynomial terms can be added or subtracted without affecting the other coefficients. The piston coefficient represents the mean value of the aberration function and the variance of the function is given simply by the sum of the squares of the other expansion coefficients.[7]

For systems with noncircular pupils, the Zernike circle polynomials are neither orthogonal over such pupils nor do they represent balanced aberrations. Hence their special utility is lost. However, since they form a complete set, an aberration function over a noncircular wavefront can be expanded in terms of them. The expansion coefficients are no longer independent of each other and their values change as the number of polynomials used in the expansion changes. The piston coefficient does not represent the mean value of the aberration function, and the sum of the squares of the other coefficients does not yield the aberration variance.

The reflecting telescopes, such as the Hubble, have annular pupils and require polynomials that are orthogonal across an annulus to describe their aberrations.[8–11] The primary mirrors of large telescopes, such as the Keck, consist of hexagonal segments.[12] The wavefront analysis of such segments requires polynomials that are orthogonal over a hexagon. The pupil for off-axis imaging by a system with an axial circular pupil is vignetted, but can be approximated by an ellipse.[13] When a flat mirror is tested by shining a circular beam on it at some angle (other than normal incidence), the illuminated spot is elliptical. Similarly, the overlap region of two circular wavefronts that are

displaced from each other, as in lateral shearing interferometry[14] or in the calculation of the optical transfer function of a system,[15] can also be approximated by an ellipse. In such cases we need polynomials that are orthogonal over an ellipse. In Refs. 14 and 15, the polynomials that are orthogonal over an elliptical region were obtained simply by scaling the Cartesian coordinates by its aspect ratio. However, such orthogonal polynomials cannot represent classical aberrations. For example, defocus, which varies as ρ^2, has the same scale for both the x and y coordinates. Similarly, they cannot represent balanced classical aberrations, for example, coma balanced with tilt. High-power laser beams have rectangular or square cross sections[16] and require polynomials that are orthogonal over a rectangle or a square, respectively.

The polynomials orthonormal over a unit annulus, hexagon, ellipse, rectangle, and a square inscribed inside a unit circle may be obtained from the circle polynomials by the recursive Gram-Schmidt orthogonalization process[17,18] or a nonrecursive matrix approach.[19] The orthonormal polynomials representing balanced aberrations for a slit pupil can be obtained as a limiting case of the rectangular polynomials, where one dimension of the rectangle approaches zero. They are the Legendre polynomials.[20] We use the circle polynomials as the basis functions for the orthogonalization process, so that the relationship of a noncircle polynomial to the circle polynomials is evident, since the former is a linear combination of the latter. We give the orthonormal form of the polynomials so that when an aberration function is expanded in terms of them, each expansion coefficient (with the exception of piston) represents the standard deviation of the corresponding expansion term. The noncircle polynomials are given not only in terms of the circle polynomials, but in polar and Cartesian coordinates as well. The circle, annular, hexagonal, and square polynomials are given up to the eighth order, and the elliptical and rectangular polynomials are given up to the fourth order. Just as the Zernike circle polynomials uniquely represent the orthogonal and balanced aberrations across circular pupils, similarly, the orthonormal polynomials for the noncircular pupils given in this chapter also uniquely represent the orthogonal and balanced aberrations across such pupils.

Orthogonal square polynomials were obtained by Bray by orthogonalizing the circle polynomials, but he chose a circle inscribed inside a square instead of the other way around.[21] Thus his square with a full width of unity has regions that fall outside the unit circle. Defining a unit square in this manner has the disadvantage that the coefficient of a term in a certain polynomial does not represent its peak value. Products of x and y Legendre polynomials,[17] which are orthogonal over a square pupil, have been suggested for analysis of square wavefronts.[22] But they do not represent classical or balanced aberrations. For example, defocus is represented by a term in $x^2 + y^2$. While it can be expanded in terms of a complete set of Legendre polynomials, it cannot be represented by a single two-dimensional Legendre polynomial (i.e., as a product of x and y Legendre polynomial). The same difficulty holds for spherical aberration and coma, and the like.

Although in many imaging applications, the amplitude across the pupil is uniform, such is not always the case, for example, a system with an apodized pupil. An example of such a pupil is the Gaussian pupil, where the amplitude has the form of a Gaussian due either to an amplitude filter placed at the pupil or to the wave incident on the pupil being Gaussian, as in the case of a Gaussian laser beam. Again, the balanced aberrations for a Gaussian pupil have a form that is different from the corresponding balanced aberrations for a uniform pupil due to the amplitude weighting of the pupil.[23–25] The amount of defocus to optimally balance spherical aberration, or the amount of wavefront tilt to optimally balance coma, for example, is different for a Gaussian pupil than its corresponding value for a uniform pupil.

11.3 ORTHONORMAL POLYNOMIALS

In Cartesian coordinates (x, y), the aberration function $W(x, y)$ for a certain pupil may be expanded in terms of J polynomials $F_j(x, y)$ that are orthonormal over the pupil:[26]

$$W(x, y) = \sum_{j=1}^{J} a_j F_j(x, y) \tag{1}$$

where a_j is an expansion or the aberration coefficient of the polynomial $F_j(x, y)$. The orthonormality of the polynomials is represented by

$$\frac{1}{A}\int_{\text{pupil}} F_j(x,y)F_{j'}(x,y)\,dx\,dy=\delta_{jj'} \tag{2}$$

where A is the area of the pupil inscribed inside a unit circle, the integration is carried out over the area of the pupil, and $\delta_{jj'}$ is a Kronecker delta. If $F_1 = 1$, then the mean value of each polynomial, except for $j = 1$, is zero, that is,

$$\frac{1}{A}\int_{\text{pupil}} F_j(x,y)\,dx\,dy=0 \qquad \text{for } j\neq 1 \tag{3}$$

as may be seen by letting $j' = 1$ in Eq. (2). The aberration coefficients are given by

$$a_j=\frac{1}{A}\int_{\text{pupil}} W(x,y)F_j(x,y)\,dx\,dy \tag{4}$$

as may be seen by substituting Eq. (1) into Eq. (4) and using the orthonormality Eq. (2).

The mean and the mean square values of the aberration function are given by

$$\langle W(x,y)\rangle = a_1 \tag{5}$$

and

$$\langle W^2(x,y)\rangle=\sum_{j=1}^{J} a_j^2 \tag{6}$$

Accordingly, the variance σ^2 of the aberration function is given by

$$\sigma^2=\langle W^2(x,y)\rangle-\langle W(x,y)\rangle^2=\sum_{j=2}^{J} a_j^2 \tag{7}$$

where σ is the standard deviation of the aberration function. The number of polynomials J used in the expansion is a sufficiently large that the variance obtained from Eq. (6) equals the actual value obtained from the function $W(x, y)$ within some prescribed tolerance.

11.4 ZERNIKE CIRCLE POLYNOMIALS

An aberration function $W(\rho, \theta)$, across a *unit circle* can be expanded in terms of the orthonormal *Zernike circle polynomials* $Z_j(\rho, \theta)$ in the form[2,5]

$$W(\rho,\theta)=\sum_j a_j Z_j(\rho,\theta) \tag{8}$$

where (ρ, θ) are the polar coordinates of a point on the circle, $0 \le \rho \le 1$, $0 \le \theta < 2\pi$, and a_j are the expansion coefficients. The polynomials may be written in the form

$$Z_{\text{even}\,j}(\rho,\theta)=\sqrt{2(n+1)}\,R_n^m(\rho)\cos m\theta,\ m\neq 0 \tag{9a}$$

$$Z_{\text{odd}\,j}(\rho,\theta)=\sqrt{2(n+1)}\,R_n^m(\rho)\sin m\theta,\ m\neq 0 \tag{9b}$$

$$Z_j(\rho,\theta)=\sqrt{n+1}\,R_n^0(\rho),\ m=0 \tag{9c}$$

where n and m are positive integers (including zero) and $n - m \geq 0$ and even. It is evident from Eqs. (9) that the circle polynomials are separable in the polar coordinates ρ and θ. A radial polynomial $R_n^m(\rho)$ is given by

$$R_n^m(\rho) = \sum_{s=0}^{(n-m)/2} \frac{(-1)^s (n-s)!}{s!\left(\frac{n+m}{2}-s\right)!\left(\frac{n-m}{2}-s\right)!} \rho^{n-2s} \tag{10}$$

with a degree n in ρ containing terms in ρ^n, ρ^{n-2}, …, and ρ^m. It is even or odd in ρ depending on whether n (or m) is even or odd. Also, $R_n^n(\rho) = \rho^n$, $R_n^m(1) = 1$, and $R_n^m(0) = \delta_{m0}$ for even $n/2$ and $-\delta_{m0}$ for odd $n/2$. The polynomials $R_n^m(\rho)$ obey the orthogonality relation

$$\int_0^1 R_n^m(\rho) R_{n'}^m(\rho) \rho d\rho = \frac{1}{2(n+1)} \delta_{nn'} \tag{11}$$

The orthogonality of the angular functions yields

$$\int_0^{2\pi} d\theta \begin{cases} \cos m\theta \cos m'\theta \ , & j \text{ and } j' \text{ are both even} \\ \cos m\theta \sin m'\theta \ , & j \text{ is even and } j' \text{ is odd} \\ \sin m\theta \cos m'\theta \ , & j \text{ is odd and } j' \text{ is even} \\ \sin m\theta \sin m'\theta \ , & j \text{ and } j' \text{ are both odd} \end{cases}$$

$$= \begin{cases} \pi(1+\delta_{m0})\delta_{mm'} \ , & j \text{ and } j' \text{ are both even} \\ \pi\delta_{mm'} \ , & j \text{ and } j' \text{ are both odd} \\ 0 \ , & \text{otherwise} \end{cases} \tag{12}$$

Therefore, the Zernike polynomials are orthonormal according to

$$\int_0^1 \int_0^{2\pi} Z_j(\rho,\theta) Z_{j'}(\rho,\theta) \rho d\rho d\theta \Big/ \int_0^1 \int_0^{2\pi} \rho d\rho d\theta = \delta_{jj'} \tag{13}$$

The expansion coefficients are given by

$$a_j = \frac{1}{\pi} \int_0^1 \int_0^{2\pi} W(\rho,\theta) Z_j(\rho,\theta) \rho d\rho d\theta \tag{14}$$

as may be seen by substituting Eq. (8) into Eq. (14) and using the orthonormality Eq. (13).

While the index n represents the radial *degree* or the *order* of a polynomial, since it represents the highest power of ρ in the polynomial, m is referred to as its *azimuthal frequency.* The index j is a *polynomial-ordering number* and is a function of both n and m. The polynomials are ordered such that an even j corresponds to a symmetric polynomial varying as $\cos m\theta$, while an odd j corresponds to an antisymmetric polynomial varying as $\sin m\theta$. A polynomial with a lower value of n is ordered first, and for a given value of n, a polynomial with a lower value of m is ordered first.

The Zernike circle polynomials are unique in that they are the only polynomials in two variables ρ and θ, which (a) are orthogonal over a circle, (b) are invariant in form with respect to rotation of the coordinate axes about the origin, and (c) include a polynomial for each permissible pair of n and m values.[4,27]

The orthonormal Zernike circle polynomials and the names associated with some of them when identified with classical aberrations are listed in Table 1*a* for $n \leq 8$. The polynomials independent of θ are the spherical aberrations, those varying as $\cos\theta$ are the coma aberrations, and those varying as $\cos 2\theta$ are the astigmatism aberrations. The variation of several radial polynomials $R_n^m(\rho)$ with ρ is illustrated in Fig. 1.

TABLE 1*a* Orthonormal Zernike *Circle* Polynomials $Z_j(\rho, \theta)$ Ordered Such That an Even j Corresponds to a Symmetric Polynomial Varying as $\cos m\theta$, While an Odd j Corresponds to an Antisymmetric Polynomial Varying as $\sin m\theta$

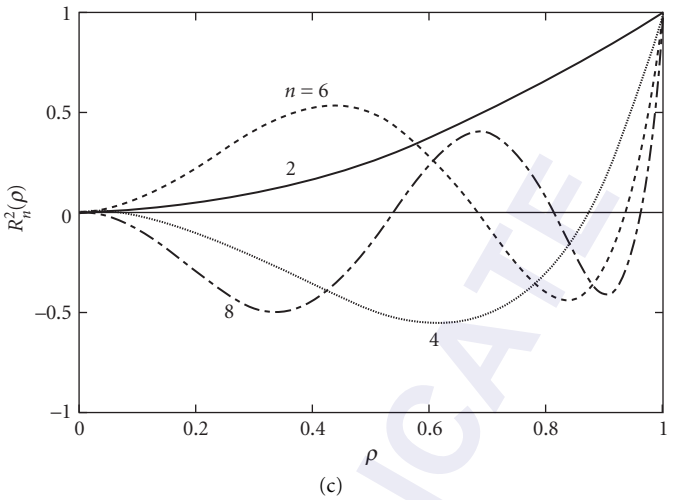

FIGURE 1 (*Continued*)

The number of polynomials of a given order n is $n + 1$. Their number through a certain order n is given by

$$N_n = (n+1)(n+2)/2 \tag{15}$$

For a rotationally symmetric imaging system, each of the $\sin m\theta$ terms is zero.[4,28–32] Accordingly the number of polynomials of an even order is $(n/2) + 1$ and $(n + 1)/2$ for an odd order. Their number through an order n is given by

$$N_n = \left(\frac{n}{2}+1\right)^2 \quad \text{for even } n \tag{16a}$$

$$= (n+1)(n+3)/4 \quad \text{for odd } n \tag{16b}$$

Relationships among the Indices *n, m,* and *j*

The number of polynomials N_n through a certain order n represents the largest value of j. Since the number of terms with the same value of n but different values of m is equal to $n + 1$, the smallest value of j for a given value of n is $N_n - n$. For a given value of n and m, there are two j values, $N_n - n + m - 1$ and $N_n - n + m$. The even value of j represents the $\cos m\theta$ term and the odd value of j represents the $\sin m\theta$ term. The value of j with $m = 0$ is $N_n - n$. For example, for $n = 5$, $N_n = 21$, and $j = 21$ represents the $\sin 5\theta$ term. The number of the corresponding $\cos 5\theta$ term is $j = 20$. The two terms with $m = 3$, for example, have j values of 18 and 19 representing the $\cos 3\theta$ and the $\sin 3\theta$ terms, respectively.

For a given value of j, n is given by

$$n = [(2j-1)^{1/2} + 0.5]_{\text{integer}} - 1 \tag{17}$$

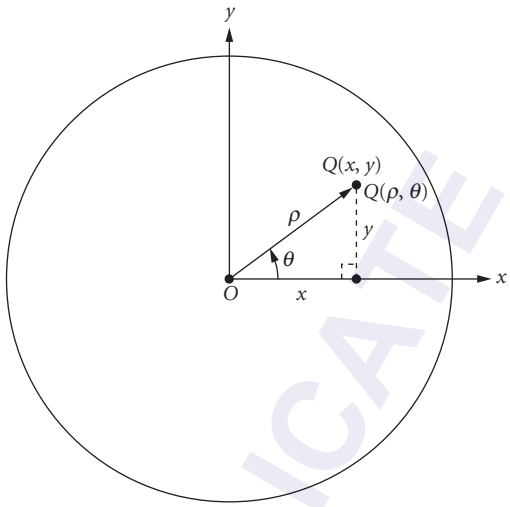

FIGURE 2 Cartesian and polar coordinates (x, y) and (ρ, θ), respectively, of a point Q in the plane of a unit circle representing the circular exit pupil of an imaging system.

where the subscript integer implies the integer value of the number in brackets. Once n is known, the value of m is given by

$$m = \begin{cases} 2\left\{[2j+1-n(n+1)]/4\right\}_{\text{integer}} & \text{when } n \text{ is even} \quad (18a) \\ 2\left\{[2(j+1)-n(n+1)]/4\right\}_{\text{integer}} - 1 & \text{when } n \text{ is odd} \quad (18b) \end{cases}$$

For example, suppose we want to know the values of n and m for the term $j = 10$. From Eq. (17), $n = 3$ and from Eq. (18b), $m = 3$. Hence, it is a $\cos 3\theta$ term.

The polar coordinates (ρ, θ) and the Cartesian coordinates (x, y) of a pupil point Q, as illustrated in Fig. 2, are related to each other according to

$$(x, y) = \rho(\cos\theta, \sin\theta) \quad (19)$$

The circle polynomials in the Cartesian coordinates (x, y) of a pupil point are listed in Table 1b. It is quite common in the optics literature to consider a point object lying along the y axis when imaged by a rotationally symmetric optical system, thus making the yz plane the tangential plane.[4,28–32] To maintain symmetry of the aberration function about this plane, the polar angle θ of a pupil point is accordingly defined as the angle made by its position vector $\overrightarrow{OQ}$ with the y axis, contrary to the standard convention as the angle with the x axis. We choose a point object along the x axis so that, for example, the coma aberration is expressed as $x(x^2 + y^2)$ and not as $y(x^2 + y^2)$. A positive value of our coma aberration yields a diffraction point spread function that is symmetric *about* the x axis (or symmetric *in* y) with its peak and centroid shifted to a positive value of x with respect to the Gaussian image point.

TABLE 1*b* Orthonormal Zernike *Circle* Polynomials $Z_j(x, y)$ in Cartesian Coordinates (x, y), Where $x = \rho\cos\theta$, $y = \rho\sin\theta$, and $0 \le \rho = \sqrt{x^2 + y^2} \le 1$

11.5 ZERNIKE ANNULAR POLYNOMIALS

The aberration function $W(\rho, \theta; \epsilon)$ across a *unit annulus* with an obscuration ratio ϵ, representing the ratio of its inner and outer radii, as illustrated in Fig. 3*a*, can be expanded in terms of a complete set of *Zernike annular polynomials* $Z_j(\rho, \theta; \epsilon)$ that are orthonormal over the unit annulus in the form[8–11]

$$W(\rho, \theta; \epsilon) = \sum_j a_j Z_j(\rho, \theta; \epsilon) \tag{20}$$

where a_j is an expansion coefficient of the polynomial, $\epsilon \le \rho \le 1$ and $0 \le \theta < 2\pi$. The annular polynomials are written in a manner similar to the circle polynomials. Thus

$$Z_{\text{even}\,j}(\rho, \theta; \epsilon) = \sqrt{2(n+1)}\, R_n^m(\rho; \epsilon) \cos m\theta, \quad m \neq 0 \tag{21a}$$

$$Z_{\text{odd}\,j}(\rho, \theta; \epsilon) = \sqrt{2(n+1)}\, R_n^m(\rho; \epsilon) \sin m\theta, \quad m \neq 0 \tag{21b}$$

$$Z_j(\rho, \theta; \epsilon) = \sqrt{n+1}\, R_n^0(\rho; \epsilon), \quad m = 0 \tag{21c}$$

where n and m are positive integers (including zero) and $n - m \ge 0$ and even. The radial annular polynomials $R_n^m(\rho; \epsilon)$ obey the orthogonality relation

$$\int_\epsilon^1 R_n^m(\rho; \epsilon) R_{n'}^m(\rho; \epsilon) \rho d\rho = \frac{1-\epsilon^2}{2(n+1)} \delta_{nn'} \tag{22}$$

Accordingly, the annular polynomials obey the orthonormality condition

$$\int_\epsilon^1 \int_0^{2\pi} Z_j(\rho, \theta; \epsilon) Z_{j'}(\rho, \theta; \epsilon) \rho d\rho d\theta \Big/ \int_\epsilon^1 \int_0^{2\pi} \rho d\rho d\theta = \delta_{jj'} \tag{23}$$

The Zernike expansion coefficients are given by

$$a_j = \frac{1}{\pi(1-\epsilon)^2} \int_\epsilon^1 \int_0^{2\pi} W(\rho, \theta; \epsilon) Z_j(\rho, \theta; \epsilon) \rho d\rho d\theta \tag{24}$$

as may be seen by substituting Eq. (20) into Eq. (24) and using Eq. (23) for the orthonormality of the polynomials.

The annular polynomials are similar to the circle polynomials, except that they are orthogonal over an annular pupil. They can be obtained from the circle polynomials by the Gram-Schmidt orthogonalization process.[17] The radial polynomials are accordingly given by

$$R_n^m(\rho; \epsilon) = N_n^m \left[R_n^m(\rho) - \sum_{i \ge 1}^{(n-m)/2} (n-2i+1) < R_n^m(\rho) R_{n-2i}^m(\rho; \epsilon) > R_{n-2i}^m(\rho; \epsilon) \right] \tag{25}$$

where

$$< R_n^m(\rho) R_{n'}^m(\rho; \epsilon) > = \frac{2}{1-\epsilon^2} \int_\epsilon^1 R_n^m(\rho) R_{n'}^m(\rho; \epsilon) \rho d\rho \tag{26}$$

and N_n^m is a normalization constant such that the radial polynomials satisfy the orthogonality Eq. (22). Thus, $R_n^m(\rho; \epsilon)$ is a radial polynomial of degree n in ρ containing terms in ρ^n, ρ^{n-2},…, and ρ^m with coefficients that depend on ϵ. The radial polynomials are even or odd in ρ depending on whether n

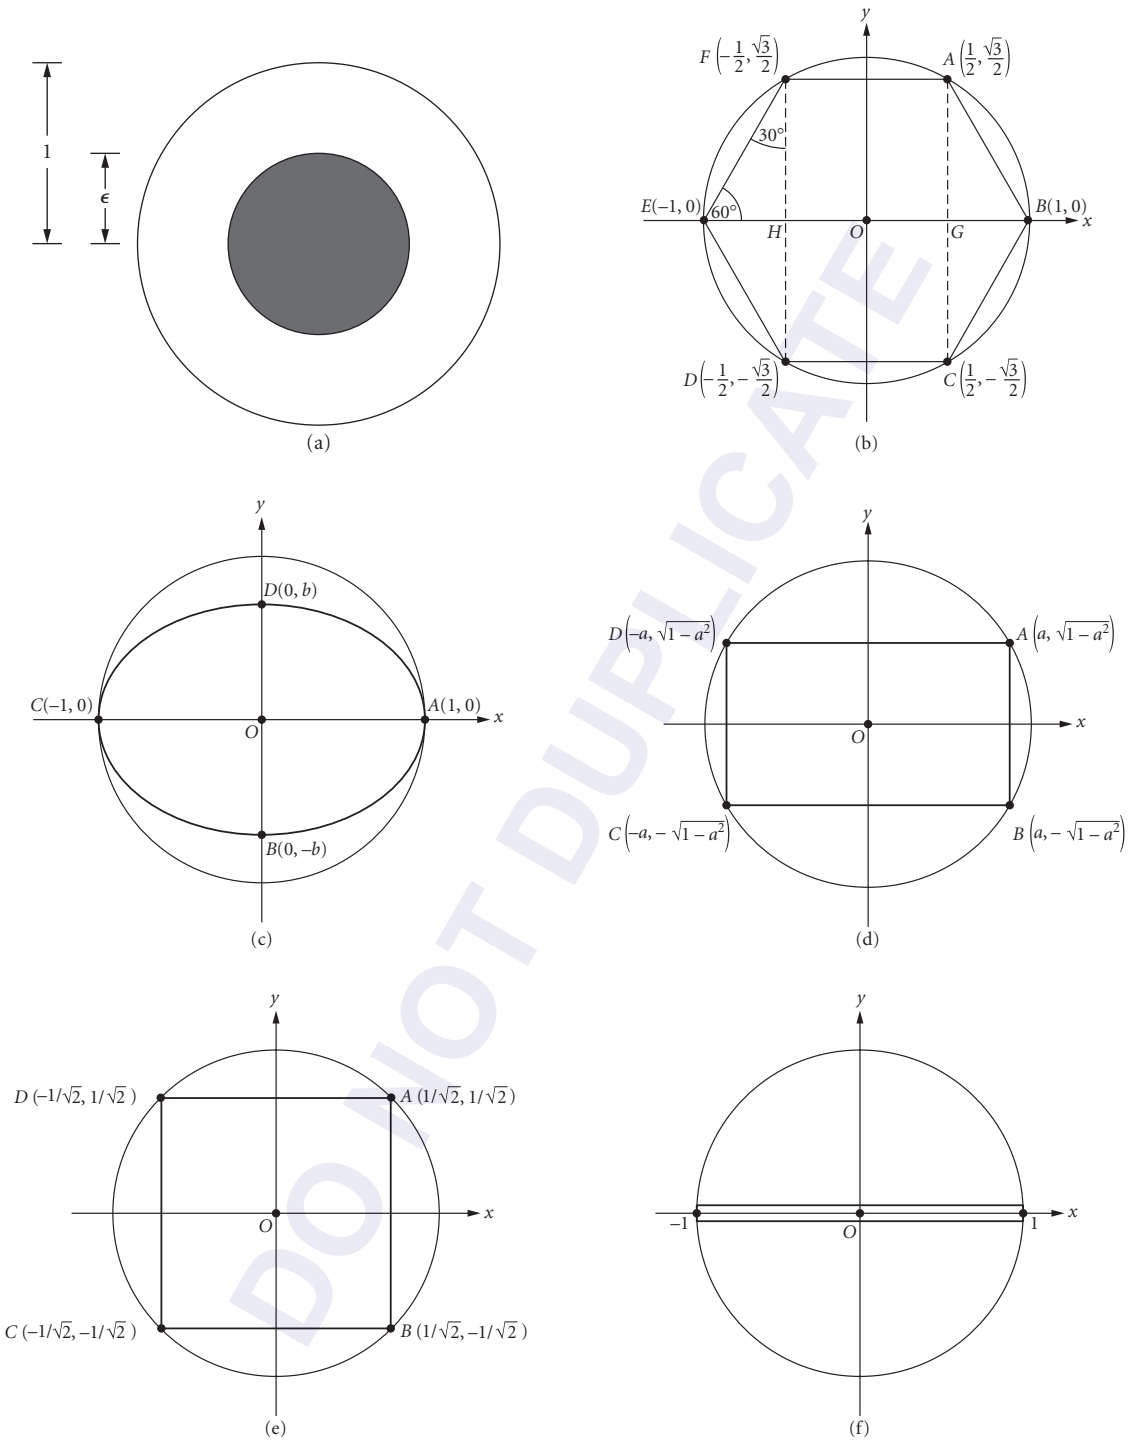

FIGURE 3 Unit pupils inscribed inside a unit circle: (*a*) annulus of obscuration ratio ϵ; (*b*) hexagon; (*c*) ellipse of aspect ratio b; (*d*) rectangle of half width a; (*e*) square of half width $1/\sqrt{2}$; and (*f*) slit.

(or m) is even or odd. For $m = 0$, the radial polynomials are equal to the Legendre polynomials $P_n(\cdot)$ according to

$$R_{2n}^0(\rho;\epsilon)=P_n\left[\frac{2(\rho^2-\epsilon^2)}{1-\epsilon^2}-1\right] \tag{27}$$

Thus, they can be obtained from the circle radial polynomials $R_{2n}^0(\rho)$ by replacing ρ by $[(\rho^2-\epsilon^2)/(1-\epsilon^2)]^{1/2}$, that is,

$$R_{2n}^0(\rho;\epsilon)=R_{2n}^0\left[\left(\frac{\rho^2-\epsilon^2}{1-\epsilon}\right)^{1/2}\right] \tag{28}$$

It can be seen from Eqs. (22) and (25) that

$$R_n^n(\rho;\epsilon)=\rho^n\Big/\left(\sum_{i=0}^{n}\epsilon^{2i}\right)^{1/2} \tag{29}$$

$$=\rho^n\{(1-\epsilon^2)/[1-\epsilon^{2(n+1)}]\}^{1/2} \tag{30}$$

Moreover,

$$R_2^{n-2}(\rho;\epsilon)=\frac{n\rho^n-(n-1)[(1-\epsilon^{2n})/(1-\epsilon^{2(n-1)})]\rho^{n-2}}{\{(1-\epsilon^2)^{-1}[n^2(1-\epsilon^{2(n+1)})-(n^2-1)(1-\epsilon^{2n})^2/(1-\epsilon^{2(n-1)})]\}^{1/2}} \tag{31}$$

It is evident that the radial polynomial $R_n^n(\rho;\epsilon)$ differs from the corresponding circle polynomial $R_n^n(\rho)$ only in its normalization. We also note that

$$\begin{aligned} R_n^m(1;\epsilon)&=1,\ m=0\\ &\neq 1,\ m\neq 0 \end{aligned} \tag{32}$$

The variation of several Zernike annular radial polynomials with ρ is shown in Fig. 4 for $\epsilon = 0.5$.

It is evident from Eqs. (21) that the annular polynomials, like the circle polynomials, are separable in the polar coordinates ρ and θ. This is a consequence of the radial symmetry of the annular pupil. As may be evident from the Gram-Schmidt orthogonalization process, each annular polynomial is a linear combination of the circle polynomials.[33] Accordingly, each radial polynomial $R_n^m(\rho;\epsilon)$ can be written as a linear combination of the polynomials $R_n^m(\rho)$, $R_{n-2}^m(\rho)$, . . ., and $R_m^m(\rho)$. For example,

$$R_3^1(\rho;\epsilon)=\frac{1}{(1-\epsilon^2)(1+5\epsilon^2+5\epsilon^4+\epsilon^6)^{1/2}}[(1+\epsilon^2)R_3^1(\rho)-2\epsilon^4R_1^1(\rho)] \tag{33a}$$

and

$$R_4^0(\rho;\epsilon)=\frac{1}{(1-\epsilon^2)^2}[R_4^0(\rho)-3\epsilon^2R_2^0(\rho)+\epsilon^2(1+\epsilon^2)R_0^0(\rho)] \tag{33b}$$

The Zernike annular radial polynomials for $n \leq 8$ are listed in Table 2*a*. The number polynomials of a certain order or through a certain order n is given by the same expressions as in the case of Zernike circle polynomials. Table 2*b* lists the full annular polynomials illustrating their ordering. In Table 2*c*, they are given in the Cartesian coordinates.

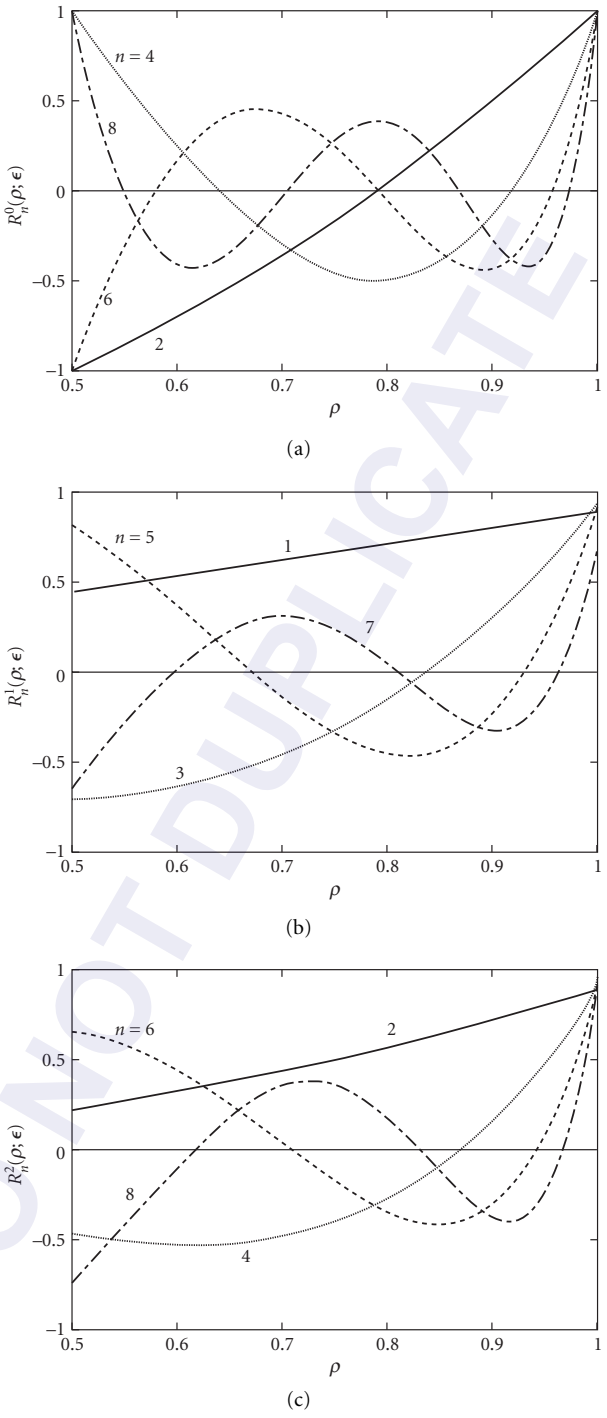

FIGURE 4 Variation of a Zernike *annular* radial polynomial $R_n^m(\rho;\epsilon)$ with ρ for $\epsilon = 0.5$: (*a*) defocus and spherical aberrations; (*b*) tilt and coma; and (*c*) astigmatism.

11.6 HEXAGONAL POLYNOMIALS

Figure 3*b* shows a *unit hexagon* inscribed inside a unit circle. Each side of the hexagon has a length of unity. The area of the hexagon is $A = 3\sqrt{3}/2$. The orthonormality of the hexagonal polynomials $H_j(x, y)$ implies that[26]

$$\frac{2}{3\sqrt{3}} \int_{\text{hexagon}} H_j(x, y) H_{j'}(x, y)\, dx\, dy = \delta_{jj'} \tag{34}$$

The orthonormal hexagonal polynomials are given in Tables 3 up to the eighth order in three different but equivalent forms. In Table 3*a*, each hexagonal polynomial is written in terms of the circle polynomials, thus illustrating the relationship between the two. In particular, it helps determine the potential error made when a hexagonal aberration function is expanded in terms of the circle polynomials.[34] The polynomials up to H_{19} are given in their analytical form, but those with $j > 19$ are written in a numerical form because of the increasing complexity of the coefficients of the circle polynomials. In Table 3*b*, the hexagonal polynomials are given in polar coordinates, showing one-to-one correspondence with the circle polynomials, but illustrating the difference from them. This form is convenient for analytical calculations because of the integration of trigonometric functions over symmetric limits. Finally, in Table 3*c*, they are given in Cartesian coordinates, as they would be used for any quantitative numerical analysis of, say, an interferogram.

From Table 3*a*, we note that each hexagonal polynomial consists of cosine or sine terms, but not both. Unlike the circle,[3–6] annular,[8–11] or Gauss[23,24] polynomials, the hexagonal polynomials are generally not separable in ρ and θ due to the lack of radial symmetry of the hexagonal pupil. The first 13 polynomials, that is, up to H_{13}, are separable, but H_{14} and H_{15} are not; H_{16} through H_{19} are separable, but H_{20} and H_{21} are not. Accordingly, the notion of two indices n and m with dependence on m in the form of $\cos m\theta$ or $\sin m\theta$, as in the case of circle polynomials, loses significance. For example, the Zernike polynomial Z_{14} for $n = 4$ and $m = 4$ varies as $\cos 4\theta$, but H_{14} has a term in $\cos 2\theta$ also. Hence, the hexagonal polynomials can be ordered by a single index only. While the polynomials H_{11} and H_{22} representing the balanced primary and secondary spherical aberrations are radially symmetric, the polynomial H_{37} representing the balanced tertiary spherical aberration is not, since it consists of an angle-dependent term in Z_{28} or $\cos 6\theta$ also. If this term is not included in the polynomial H_{37}, the standard deviation of the aberration increases from a value of unity to 1.3339.

11.7 ELLIPTICAL POLYNOMIALS

Figure 3*c* shows a *unit ellipse* of an aspect ratio b inscribed inside a unit circle. The semimajor and semiminor axes of the ellipse have lengths of unity and b, respectively. Of course, a unit ellipse is not unique, since b can have any value between 0 and 1. It is represented by an equation

$$x^2 + y^2/b^2 = 1 \tag{35a}$$

$$

pupil, each elliptical polynomial consists of either cosine or sine terms, but not both. For example, E_6 is a linear combination of Z_6, Z_4, and Z_1. It also shows that the balancing defocus for (zero-degree) Seidel astigmatism is different for an elliptical pupil compared to that for a circular,[3–6] annular,[8–11] or a Gaussian pupil.[23–25] Moreover, E_{11} is a linear combination of Z_{11}, Z_6, Z_4, and Z_1. Thus, spherical aberration ρ^4 is balanced with not only defocus ρ^2 but astigmatism $\rho^2\cos^2\theta$ as well. The elliptical polynomials are generally more complex in that they are made up of a larger number of circle polynomials. These results are a consequence of the fact that the x and y dimensions of the elliptical pupil are not equal. As expected, the elliptical polynomials reduce to the circle polynomials as $b \to 1$, that is, as the unit ellipse approaches a unit circle.

11.8 RECTANGULAR POLYNOMIALS

Figure 3*d* shows a *unit rectangle* inscribed inside a unit circle. While the distance of a corner point of the rectangle, such as A, from its center O is unity, the half widths of the rectangle along the x and y axes are a and $\sqrt{1-a^2}$, respectively. Accordingly, the aspect ratio of the rectangle is $\sqrt{1-a^2}/a$, and its area is $4a\sqrt{1-a^2}$. As in the case of a unit ellipse, a unit rectangle is also not unique, since a can have any value between 0 and 1. The orthonormality of the rectangular polynomials $R_j(x, y)$ is represented by[26]

$$\frac{1}{4a\sqrt{1-a^2}}\int_{-\sqrt{1-a^2}}^{\sqrt{1-a^2}} dy \int_{-a}^{a} R_j(x, y)R_{j'}(x, y)dx = \delta_{jj'} \tag{37}$$

The rectangular polynomials thus obtained up to the fourth order are given in Tables 5 in the same manner as the hexagonal and elliptical polynomials. As in the case of hexagonal and elliptical polynomials, each rectangular polynomial also consists of either cosine or sine terms, but not both. Like the elliptical polynomials, the rectangular polynomials also consist of a larger number of circle polynomials. The rectangular polynomial R_{11}, like the elliptical polynomials E_{11}, representing a balanced primary spherical aberration is not radially symmetric, since it consists of a term in astigmatism Z_6 or $\cos 2\theta$. As discussed below, the rectangular polynomials reduce to the square polynomials as $a \to 1/\sqrt{2}$, and the slit polynomials for a slit pupil parallel to the x axis as $a \to 1$.

11.9 SQUARE POLYNOMIALS

Figure 3*e* shows a *unit square* inscribed inside a unit circle, as in the case of a rectangle. The distance of a corner point of the square, such as *A*, from its center *O* is unity, but each of its sides has a length of $\sqrt{2}$ and its area is 2. The orthonormality of the square polynomials $S_j(x, y)$ is represented by[26]

$$\frac{1}{2}\int_{-1/\sqrt{2}}^{1/\sqrt{2}} dy \int_{-1/\sqrt{2}}^{1/\sqrt{2}} S_j(x, y)S_{j'}(x, y)dx = \delta_{jj'} \tag{38}$$

The square polynomials through the eighth order are given in terms of the Zernike polynomials in Table 6*a*. The first 15 polynomials are given in their analytical form, but those with $j > 15$ are written in a numerical form because of the increasing complexity of the coefficients of the circle polynomials. The corresponding polynomials in polar and Cartesian coordinates are given in Tables 6*b* and 6*c*, respectively. Of course, up to the fourth order, they can be obtained simply from the rectangular polynomials $R_j(x, y)$ given in Tables 5 by letting $a = 1/\sqrt{2}$. The square polynomial S_{11} representing the balanced primary spherical aberration is radially symmetric, but the polynomial S_{22} representing the balanced secondary spherical aberration is not, since it consists of a term in Z_{14} or $\cos 4\theta$ also. Similarly, the polynomial S_{37} representing the balanced tertiary spherical aberration is also not radially symmetric, since it consists of terms in Z_{14} and Z_{26} both varying as $\cos 4\theta$.

11.10 SLIT POLYNOMIALS

By letting $a \to 1$ in the rectangular pupil, we obtain a *unit slit* pupil that is parallel to the *x* axis, as illustrated in Figure 3*f*. The corresponding orthonormal polynomials representing balanced aberrations for such pupils can be obtained from the rectangular polynomials $R_j(x, y)$ given in Table 5*c* by letting $y \to 0$ and $a \to 1$. Half of the rectangular polynomials thus reduce to zero. Some of the other polynomials are redundant. For example, the one-dimensional defocus and astigmatism can not be distinguished from each other. The slit polynomials are orthonormal according to[26]

$$\frac{1}{2}\int_{-1}^{1} P_j(x)P_{j'}(x)dx = \delta_{ij} \tag{39}$$

The relevant orthonormal slit polynomials are listed in Table 7. They are the Legendre polynomials,[17] which represent balanced aberrations uniquely.[20,26] Since the pupil is one dimensional along the *x* axis, the aberrations vary with *x* only.

11.11 ABERRATION BALANCING AND TOLERANCING, AND DIFFRACTION FOCUS

For small aberrations, the Strehl ratio of the image of a point object is approximately given by $1 - \sigma^2$ or $\exp(-\sigma^2)$ when the standard deviation σ of the aberration is in units of radians.[4,5,35] The Zernike circle and annular polynomials are separable in ρ and θ. The balanced spherical aberrations for these radially symmetric pupils are radially symmetric, and the balanced primary astigmatism for them has the same form. This is also true of a Gaussian circular or annular pupil, again because of the radial symmetry of the pupil and the amplitude across it.[23–25] From the orthonormal form H_4 of defocus for a hexagonal pupil, the sigma of the defocus aberration ρ^2 is given by $(1/12)\sqrt{43/5}$. The hexagonal polynomials H_5 and H_6 show that the balanced astigmatism has the same form as the circle polynomials Z_5 and Z_6, respectively. Thus the relative amount of defocus ρ^2 that balances classical or Seidel astigmatism $\rho^2\cos^2\theta$ is the same for a hexagonal pupil as for a circular pupil. Hence, for

TABLE 7 Orthonormal Polynomials for a Unit *Slit* Pupil

j	Aberration	Orthonormal Polynomials
1	Piston	1
2	Tilt	$\sqrt{3}x$
3	Defocus	$(\sqrt{5}/2)(3x^2-1)$
4	Coma	$(\sqrt{7}/2)(5x^3-3x)$
5	Spherical aberration	$(3/8)(35x^4-30x^2+3)$
6	Secondary coma	$(\sqrt{11}/8)(63x^5-70x^3+15x)$
7	Secondary spherical aberration	$(\sqrt{13}/16)(231x^6-315x^4+105x^2-5)$

a small amount of astigmatism, the diffraction focus for an inscribed hexagonal pupil is the same as for a circular pupil.[4,5] For an image with a focal ratio of F, it lies along the z axis at a distance of $-8F^2$ times the amount of the balancing defocus from the Gaussian image point. However, the hexagonal polynomials H_7 and H_8 show that the relative amount of tilt $\rho\cos\theta$ that optimally balances classical or Seidel coma $\rho^3\cos\theta$ is $-14/25 \approx -0.56$ compared to $-2/3$ for a circular pupil. The diffraction focus in this case lies along the x axis at a distance of $-2F$ times the amount of tilt from the Gaussian image point. Similarly, the hexagonal polynomial H_{11} shows that the relative amount of defocus that optimally balances classical primary or Seidel spherical aberration ρ^4 is $-257/301 \approx -0.85$ compared to a value of -1 for a circular pupil. It has the consequence that the diffraction focus lies closer to the Gaussian image point in the case of coma, and closer to the Gaussian image plane in the case of spherical aberration, compared to their corresponding locations for a circular pupil. While the balanced primary and secondary spherical aberrations H_{11} and H_{22} are radially symmetric, the balanced tertiary spherical aberration H_{37} is not. The tertiary spherical aberration ρ^8 is balanced not only by defocus ρ^2 and primary and secondary spherical aberrations ρ^4 and ρ^6, but by a term in Z_{28} or $\rho^6\cos 6\theta$ as well.

In the case of an elliptical pupil, the sigma of Seidel astigmatism $\rho^2\cos\theta$ is given by $\sigma_a = 1/4$, independent of its aspect ratio b, and thus equal to that for a circular pupil. Since Seidel astigmatism x^2 varies only along the x axis for which the unit ellipse has the same length as a unit circle, the sigma is independent of b. The amount of balancing defocus ρ^2 for astigmatism is different in the case of an elliptical or a rectangular pupil from the value of $-1/2$ for a circular pupil. Moreover, for these pupils, spherical aberration ρ^4 is balanced not only by defocus ρ^2 but astigmatism $\rho^2\cos^2\theta$ as well. This is a consequence of the fact that the x and y dimensions of the these pupils are not equal.

A square pupil is a special case of a rectangular pupil for which $a = 1/\sqrt{2}$. It is evident from the square polynomials S_5 and S_6 that they have the same form as the corresponding circle polynomials. Thus there is no additional defocus for balancing astigmatism, as may be seen by the absence of a Z_4 term in the expression for S_6. Hence, the diffraction focus of a system does not change when its circular pupil is replaced by an inscribed square pupil. Unlike an elliptical or a rectangular pupil, the primary spherical aberration in a square pupil is balanced by defocus only, as is evident from the radially symmetric expression for S_{11}. However, the balanced secondary and tertiary spherical aberrations are not radially symmetric, since they contain angle-dependent terms varying as $\cos 4\theta$. From the polynomials S_7, S_8, and S_{11}, the diffraction foci in the case of coma and spherical aberration are closer to the Gaussian image point and the Gaussian image plane, respectively, compared to their corresponding locations for a circular pupil.

The sigma of Seidel aberrations with and without balancing are listed in Table 8 for elliptical and rectangular pupils. The corresponding values for a circular, hexagonal, square, and a slit pupil are listed in Table 9.[26] As expected, the results for an elliptical pupil reduce to those for a circular pupil as $b \to 1$, and the results for a rectangular pupil reduce to those for a square pupil as $a \to 1/\sqrt{2}$. As the area of a unit pupil decreases in going from a circular to a hexagonal to a square pupil (from π to $3\sqrt{3}/2 \approx 2.6$ to 2), the sigma of an aberration decreases and its tolerance for a certain Strehl ratio

TABLE 9 Standard Deviation or Sigma of a Primary and a Balanced Primary Aberration for Circular, Hexagonal, Square, and Slit Pupils

Sigma	Circle	Hexagon	Square	Slit
σ_d	$1/(2\sqrt{3})$	$(1/12)\sqrt{43/5}$	$(1/3)\sqrt{2/5}$	$2/(3\sqrt{5})$
	$= 1/3.464$	$= 1/4.092$	$= 1/4.743$	$= 1/3.354$
σ_a	$1/4$	$(1/24)\sqrt{127/5}$	$1/(3\sqrt{5})$	-
		$= 1/4.762$	$= 1/6.708$	-
σ_{ba}	$1/(2\sqrt{6})$	$(1/4)\sqrt{7/15}$	$1/(3\sqrt{10})$	-
	$= 1/4.899$	$= 1/5.855$	$= 1/9.487$	-
σ_c	$1/(2\sqrt{2})$	$(1/4)\sqrt{83/70}$	$\sqrt{3/70}$	$1\sqrt{7}$
	$= 1/2.828$	$= 1/3.673$	$= 1/4.831$	$= 1/2.646$
σ_{bc}	$1/(6\sqrt{2})$	$(1/20)\sqrt{737/210}$	$(1/15)\sqrt{31/21}$	$2/(5\sqrt{7})$
	$= 1/8.485$	$= 1/10.676$	$= 1/12.346$	$= 1/6.614$
σ_s	$2/(3\sqrt{5})$	$(1/6)\sqrt{59/35}$	$(2/45)\sqrt{101/7}$	$4/15$
	$= 1/3.354$	$= 1/4.621$	$= 1/5.923$	$= 1/3.750$
σ_{bs}	$1/(6\sqrt{5})$	$(1/84)\sqrt{4987/215}$	$(2/315)\sqrt{67}$	$8/105$
	$= 1/13.416$	$= 1/17.441$	$= 1/19.242$	$= 1/13.125$

increases. The slit pupil is more sensitive compared to a circular pupil, except for spherical aberration for which it is slightly less sensitive. To obtain the Seidel coefficients from the orthonormal coefficients of a noncircular wavefront, all significant coefficients that contain a Seidel term must be taken into account, just as in the case of Zernike coefficients.[36]

11.12 ISOMETRIC, INTERFEROMETRIC, AND PSF PLOTS FOR ORTHONORMAL ABERRATIONS

The aberration-free point-spread functions (PSFs) for unit pupils considered in this chapter are shown in Fig. 5, illustrating their symmetry, for example, 6-fold symmetry for a hexagonal pupil. Their linear scale is such that the first zero of the PSF, for example, for a square pupil occurs at unity in units of λF (corresponding to 1.22 for a circular pupil). Here λ is the wavelength of the object radiation and F is the focal ratio of the image-forming light cone. These PSFs are the ultimate goal of fabrication and testing. The obscuration ratio of the annular pupil in Fig. 5*b* is $\epsilon = 0.5$; the aspect ratio of the elliptical pupil in Fig. 5*d* is $b = 0.85$; and the half width of the rectangular pupil in Fig. 5*e*

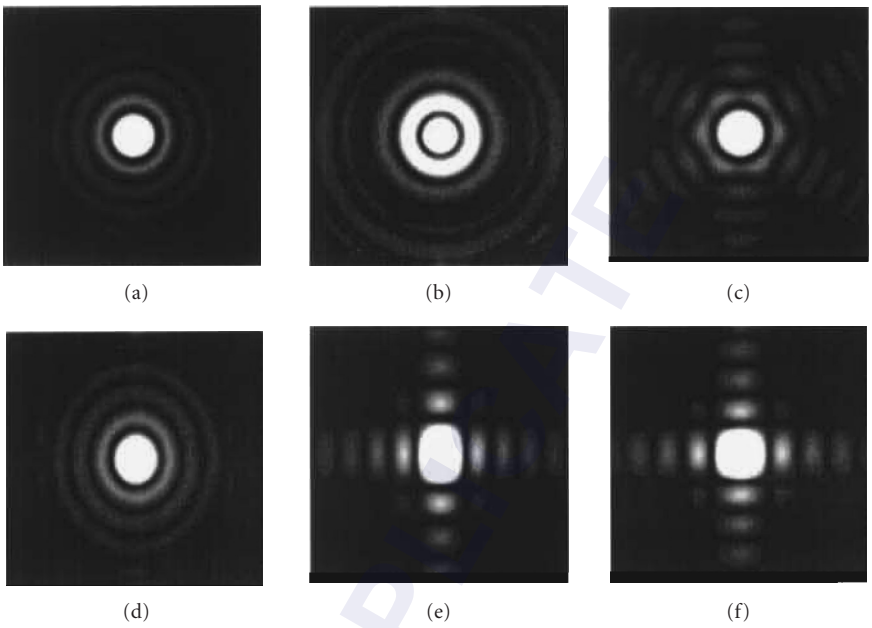

FIGURE 5 Aberration-free PSFs for different unit pupils: (*a*) Circular; (*b*) annular with obscuration ratio $\epsilon = 0.5$; (*c*) hexagonal; (*d*) elliptical with aspect ratio $b = 0.85$; (*e*) rectangular with half width $a = 0.8$; and (*f*) square.

is $a = 0.8$. The orthonormal polynomials corresponding to a Seidel aberration for a hexagonal, elliptical, rectangular, and square pupils are illustrated in three different but equivalent ways in Fig. 6.[7] In Fig. 6*d*, as in Fig. 5*a* the aspect ratio of the elliptical pupil is $b = 0.85$. In Fig. 6*e*, as in Fig. 5*e*, the half width of the rectangular pupil is $a = 0.8$. For each polynomial, the isometric plot at the top illustrates its shape as produced, for example, in a deformable mirror. The standard deviation of each polynomial aberration in the figure is one wave. An interferogram, as in optical testing, is shown on the left. The number of fringes, which is equal to the number of times the aberration changes by one wave as we move from the center to the edge of a pupil, is different for the different polynomials. Each fringe represents a contour of constant phase or aberration. The fringe is dark when the phase is an odd multiple of π or the aberration is an odd multiple of $\lambda/2$. On the right for each polynomial are shown the PSFs, which represent the images of a point object in the presence of a polynomial aberration.

11.13 USE OF CIRCLE POLYNOMIALS FOR NONCIRCULAR PUPILS

Since the Zernike circle polynomials form a complete set, any wavefront, regardless of the shape of the pupil (which defines the perimeter of the wavefront) can be expanded in terms of them.[34] However, unless the pupil is circular, advantages of orthogonality and aberration balancing are lost. For example, the mean value of a Zernike circle polynomial across a noncircular pupil is not zero, the Zernike piston coefficient does not represent the mean value of the aberration, the other Zernike coefficients do not represent the standard deviation of the corresponding aberration terms, and the variance of the aberration is not equal to the sum of the squares of these other coefficients. Moreover, the value of a Zernike coefficient changes as the number of polynomials used in the

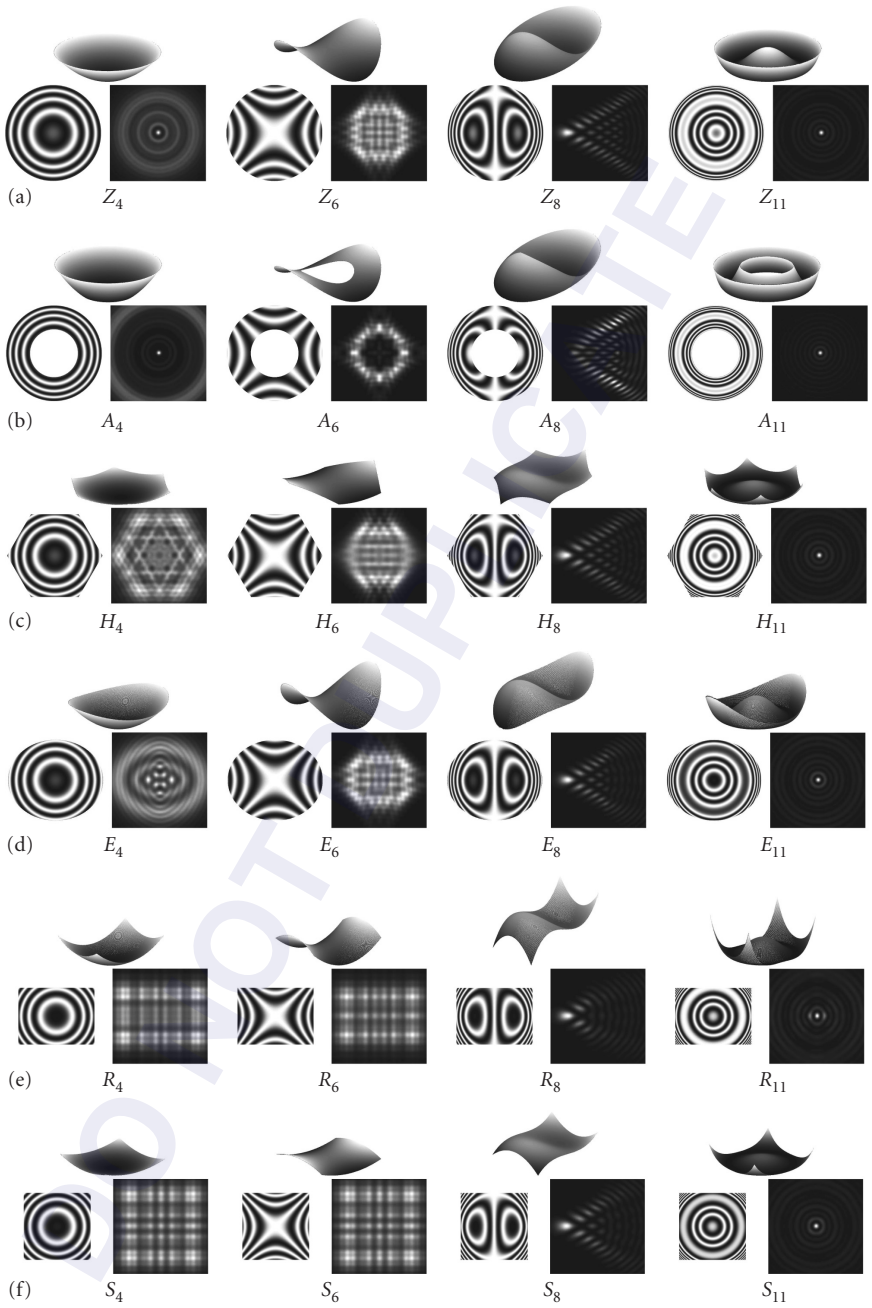

FIGURE 6 Isometric plots, interferograms, and PSFs for defocus ($j = 4$), astigmatism ($j = 6$), coma ($j = 8$), and spherical aberration ($j = 11$) in unit pupils. (*a*) Circular; (*b*) annular with $\epsilon = 0.5$; (*c*) hexagonal; (*d*) elliptical with aspect ratio $b = 0.85$; (*e*) rectangular with half width $a = 0.8$; and (*f*) square.

expansion of an aberration function changes. Hence, the circle polynomials are not appropriate for analysis of noncircular wavefronts. The polynomials given in this chapter for various pupils uniquely represent balanced classical aberrations that are also orthogonal across those pupils, just like the Zernike circle polynomials are for a circular pupil. Since each orthonormal polynomial is a linear combination of the Zernike circle polynomials, the wavefront fitting is as complete with the latter as it is with the former. However, since the circle polynomials do not represent the balanced classical aberrations for a noncircular pupil, the Zernike coefficients do not have the physical significance of their orthonormal counterparts. But the tip/tilt and defocus values in an interferometrically obtained aberration function, representing the lateral and longitudinal errors of an interferometer setting, obtained from the corresponding Zernike circle coefficients when the function is approximated with only the first four circle polynomials in a least square sense are identically the same as those obtained from the corresponding orthonormal coefficients. Accordingly, the aberration function obtained by subtracting the tip/tilt and defocus values from the measured aberration function is independent of the nature of the polynomials used in the expansion, regardless of the domain of the function or the shape of the pupil, so long as the nonorthogonal expansion is in terms of only the first four circle polynomials. The difference function is what is provided to the optician to zero out from the surface under fabrication by polishing.

11.14 DISCUSSION AND CONCLUSIONS

The Zernike circle polynomials are in widespread use for wavefront analysis in optical design and testing, because they are orthogonal over a unit circle and represent balanced aberrations of systems with circular pupils. When an aberration function of a circular wavefront is expanded in terms of them, the value of an expansion coefficient is independent of the number of polynomials used in the expansion. Accordingly, one or more terms can be added or subtracted without affecting the other coefficients. The piston coefficient represents the mean value of the aberration function and the other coefficients represent the standard deviation of the corresponding terms. The variance of the aberration is given simply by the sum of the squares of those other aberration coefficients.

We have also listed the orthonormal polynomials for analyzing the wavefronts across noncircular pupils, such as annular, hexagonal, elliptical, rectangular, and square. These polynomials are for unit pupils inscribed inside a unit circle. Such a choice keeps the maximum value of the distance of a point on the pupil from its center to be unity, thus easily identifying the peak of value of a classical aberration across it. Each orthonormal polynomial for the pupils considered consists of either the cosine or the sine terms, but not both due to the biaxial symmetry of the pupils. Whereas the circle and annular polynomials are separable in their dependence on the polar coordinates ρ and θ of a pupil point due to the radial symmetry of the pupils, only some of the polynomials for other pupils are separable. Hence polynomial numbering with two indices n and m, as for circular and annular polynomials, loses significance, and must be numbered with a single index j. The hexagonal polynomials H_{11} and H_{22} representing the balanced primary and secondary spherical aberrations are radially symmetric, but the polynomial H_{37} representing the balanced tertiary spherical aberration is not, since it contains an angle-dependent term in Z_{28} or $\cos 6\theta$ also. A hexagonal pupil has two distinct configurations where the hexagon in one is rotated by 30° with respect to that in the other. Only some of the polynomials are the same for the two configurations.[26] While the balancing defocus to optimally balance Seidel astigmatism for a hexagonal or a square pupil is the same as that for circular and annular pupils, it is different for the elliptical and rectangular pupils. For the elliptical and rectangular pupils, the Seidel or primary aberration ρ^4 is balanced not only by defocus but astigmatism as well. The square polynomial S_{11} representing the balanced primary spherical aberration is radially symmetric, but the square polynomial S_{22} representing the balanced secondary spherical aberration is not, since it contains a term in Z_{14} or $\cos 4\theta$ also. Similarly, the polynomial S_{37} representing the balanced tertiary spherical aberration is also not radially symmetric, since it consists of terms in Z_{14} and Z_{26} both varying as $\cos 4\theta$. We have illustrated orthonormal polynomials in three different but equivalent ways: isometrically, interferometrically, and by the corresponding aberrated PSFs.

The sigma of a Seidel aberration with and without balancing decreases as the area of a unit pupil decreases in going from a circular to a hexagonal to a square pupil. The sigma for Seidel astigmatism $\rho^2\cos\theta$ for an elliptical pupil is independent of its aspect ratio and, therefore, is the same as for a circular pupil. This is due to the fact that the aberration is one dimensional along the dimension for which the unit ellipse has the same length as the unit circle. Since a slit pupil is one dimensional, there is no distinction between defocus and astigmatism. It is more sensitive to a Seidel aberration with or without balancing compared to a circular pupil, except for spherical aberration for which it is slightly less sensitive.

When the aberration function is known only at a discrete set of points, as in a digitized interferogram, the integral for determining the aberration coefficients reduces to a sum and the orthonormal coefficients thus obtained may be in error, since the polynomials are not orthonormal over the discrete points of the aberration data set. The magnitude of the error decreases as the number of points increases. This is not a serious problem when the wavefront errors are determined by, say, phase-shifting interferometry,[37] since the number of points can be very large. However, when the number of data points is small, or the pupil is irregular in shape due to vignetting, then ray tracing or testing of the system yields wavefront error data at an array of points across a region for which closed-form orthonormal polynomials are not available. In such cases, we can determine the coefficients of an expansion in terms of numerical polynomials that are orthogonal over the data set, obtained by the Gram-Schmidt orthogonalization process.[7,38] However, if we just want to determine the values of tip/tilt and defocus terms, yielding the errors in interferometer settings, they can be obtained by least squares fitting the aberration function data with only these terms.

12.1 GLOSSARY

B	baseline length
f	focal length
f	signal frequency
f_b	back focal length
I	irradiance
N	average group refractive index
R	radius of curvature of an optical surface
r	radius of curvature of a spherometer ball
R	range
α	attenuation coefficient
λ	wavelength of light
Λ	synthetic wavelength
τ	delay time

In the optical shop, the measuring process has the purpose to obtain a comparison of physical variables using optical means. In this chapter we describe the most common procedures for the measurements of length, angle, curvature, and focal length of lenses and mirrors. The reader may obtain some more details about these procedures in the book *Optical Shop Testing* by D. Malacara,[1] or in Chap. 32, "Interferometers," in Vol. I.

*Note: Figures 27, 30 and 31 are from *Optical Shop Testing*, 3d ed., edited by D. Malacara. (Reprinted with permission John Wiley and Sons, Inc. New York, 2007.)

12.2 INTRODUCTION AND DEFINITIONS

Lens parameter measuring in the optical shop has been a permanent problem in respect to the unit's agreement. Usually, rather than using SI units for length specifications, wavelength units is still a common reference for precision length measurements. Although the meter is obtained practically from the wavelength of a krypton source, helium-neon lasers are a common reference wavelength. The generally accepted measurement system of units is the International System or Sistéme International (SI).

Time is the fundamental standard and is defined as follows: "The second is the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium 133 atom." Formerly, the meter was a fundamental standard defined as 1,650,763.73 wavelengths in vacuum of the orange-red spectral line from the $2p_{10}$ and $5d_5$ levels of the krypton 86 atom. Shortly after the invention of the laser, it was proposed to use a laser line as a length standard.[2] In 1986, the speed of light was defined as 299,792, 458 m/s, thus the meter is now a derived unit defined as "the distance traveled by light during 1/299,792,458 of a second." The advantages of this definition, compared with the former meter definition, lie in the fact that it uses a relativistic constant, not subjected to physical influences, and is accessible and invariant. To avoid a previous definition of a time standard, the meter could be defined as "The length equal to 9,192,631,770/299,792,458 wavelengths in vacuum of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium 133 atom."[3,4] Modern description of the time and distance standards are described by Cundiff et al.[5]

The measurement process is prone to errors. They may be systematic or stochastic. A systematic error occurs in a poorly calibrated instrument. An instrument low in systematic error is said to be accurate. Accuracy is a measure of the amount of systematic errors. The accuracy is improved by adequate tracing to a primary standard. Stochastic errors appear due to random noise and other time-dependent fluctuations that affect the instrument. Stochastic errors may be reduced by taking several measurements and averaging them. A measurement from an instrument is said to be reproducible when the magnitude of stochastic errors is low. Reproducibility is a term used to define the repeatability for the measurements of an instrument. In measurements, a method for data acquisition and analysis has to be developed. Techniques for experimentation, planning, and data reduction can be found in the references.[6,7]

12.3 LENGTH AND STRAIGHTNESS MEASUREMENTS

Length measurements may be performed by optical methods, since the definition of the meter is in terms of a light wavelength. Most of the length measurements are, in fact, comparisons to a secondary standard. Optical length measurements are made by comparisons to an external or internal scale a light time of flight, or by interferometric fringe counting.

Stadia and Range Finders

A *stadia* is an optical device used to determine distances. The principle of the measurement is a bar of known length W set at one end of the distance to be measured (Fig. 1). At the other end, a prism superimposes two images, one coming directly and the other after a reflection from a mirror, which are then observed through a telescope. At this point, the image of one end of the bar is brought in coincidence with that of the other end by rotating the mirror an angle θ. The mirror rotator is calibrated in such a way that for a given bar length W, a range R can be read directly in a dial, according to the equation:[8]

$$R = \frac{W}{\theta} \tag{1}$$

where θ is small and expressed in radians.

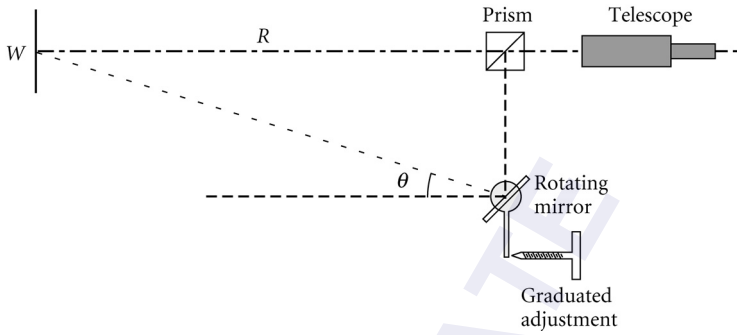

FIGURE 1 A stadia range meter. (*From Patrick.*[8])

Another stadia method uses a graduated bar and a calibrated reticle in the telescope. For a known bar length W imaged on a telescope with focal length f, the bar on the focal plane will have a size i, and the range can be calculated approximately by:[9]

$$R=\left(\frac{f}{i}\right)W \tag{2}$$

Most surveying instruments have stadia markings usually in a 1:100 ratio, to measure distances from the so-called anallatic point, typically the instrument's center. A theodolite may be used for range measurements using the subtense bar method. In this method, a bar of known length is placed at the distance to be measured from the theodolite. By measuring the angle from one end to another end of the bar, the range can be easily measured.

A range finder is different from the stadia, in that the reference line is self-contained within the instrument. A general layout for a range finder is shown in Fig. 2. Two pentaprisms are separated a known baseline B; two telescopes form an image, each through a coincidence prism. The images from the same reference point are superimposed in a split field formed by the coincidence prism. In one branch, a range compensator is adjusted to permit an effective coincidence from the reference images.

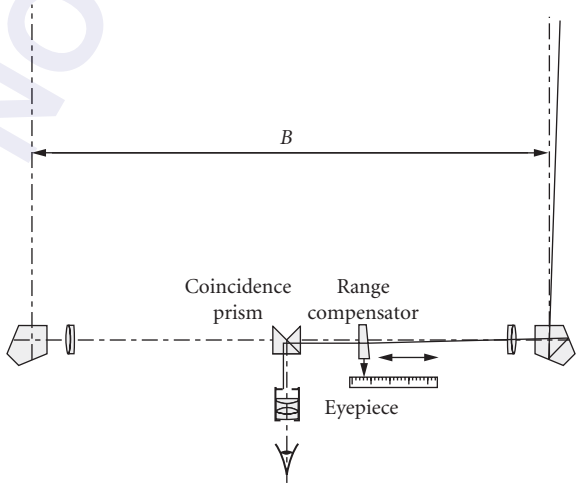

FIGURE 2 A range finder.

Assuming a baseline B and a range R, for small angles (large distances compared with the baseline), the range is

$$R = \frac{B}{\theta} \tag{3}$$

For an error $\Delta\theta$ in the angle measurement, the corresponding error ΔR in the range determination would be

$$\Delta R = -B\theta^{-2}\,\Delta\theta \tag{4}$$

and by substituting in Eq. (3),

$$\Delta R = -\frac{R^2}{B}\Delta\theta \tag{5}$$

From this last equation, it can be seen that the range error increases with the square of the range. Also, it is inversely proportional to the baseline. The angle error $\Delta\theta$ is a function of the eye's angular acuity, about 10 arcsec or 0.00005 rad.[10]

Pentaprisms permit a precise 90° deflection, independent of the alignment, and are like mirror systems with an angle of 45° between them. The focal length for the two telescopes in a range finder must be closely matched to avoid any difference in magnification. There are several versions of the range compensator. In one design, a sliding prism makes a variable deviation angle (Fig. 3*a*); in another system (Fig. 3*b*), a sliding prism displaces the image, without deviating it. A deviation can be also made with a rotating glass block (Fig. 3*c*). The Risley prisms (Fig. 3*d*) are a pair of counter rotating prisms located on the entrance pupil for one of the arms. Since the light beam is collimated, there is no astigmatism contribution from the prisms.[10] A unit magnification Galilean telescope (Fig. 3*e*) is made with two weak lenses. A sliding lens is used to form a variable wedge to deviate the image path.[8]

Time-Based and Optical Radar

Distance measurements can also be done by the time-of-flight method. An application of the laser, obvious at the time of its advent, is the measurement of range. Distance determination by precise timing is known as optical radar. Optical radar has been used to measure the distance to the moon.

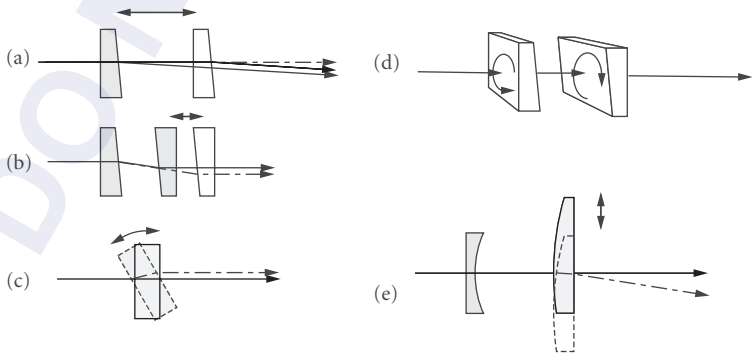

FIGURE 3 Range compensators for range finders (*a*) and (*b*) sliding prisms; (*c*) rotating glass block; (*d*) counterrotating prisms; and (*e*) sliding lens.

Since a small timing is involved, optical radar is applicable for distances from about 10 km. For distances from about a meter up to 50 km, modulated beams are used.

Laser radars measure the time of flight for a pulsed laser. Since accuracy depends on the temporal response of the electronic and detection system, optical radars are limited to distances larger than 1 km. Whenever possible, a cat's eye retro reflector is set at the range distance, making possible the use of a low power-pulsed laser. High-power lasers can be used over small distances without the need of a reflector. Accuracies of the order of 10^{-6} can be obtained.[11]

The beam modulation method requires a high-frequency signal, about 10 to 30 MHz (modulating wavelength between 30 and 10 m) to modulate a laser beam carrier. The amplitude modulation is usually applied, but polarization modulation may also be used. With beam modulation distance measurements, the phase for the returning beam is compared with that of the output beam. The following description is for an amplitude modulation distance meter, although the same applies for polarizing modulation. Assuming a sinusoidally modulated beam, the returning beam can be described by

$$I_R = \alpha I_0[1 + A\sin\omega(t - \tau)] \tag{6}$$

where α is the attenuation coefficient for the propagation media, I_o is the output intensity for the exit beam; ω is 2π times the modulated beam frequency, and τ is the delay time. By measuring the relative phase between the outgoing and the returning beam, the quantity ω is measured. In most electronic systems, the delay time τ is measured, so, the length in multiples of the modulating wavelength is

$$L = \frac{c}{2N_g}\tau \tag{7}$$

where N_g is the average group refractive index for the modulating frequency.[11]

Since the measured length is a multiple of the modulating wavelength, one is limited in range to one-half of the modulating wavelength. To measure with acceptable precision, and at the same time measure over large distances, several modulating frequencies are used, sometimes at multiples of ten to one another. The purpose is to obtain a synthetic wavelength Λ obtained from the mixing of two wavelengths λ_1, λ_2 as follows:[12,13]

$$\Lambda = \frac{\lambda_1\lambda_2}{\lambda_1 - \lambda_2} \tag{8}$$

To increment the range, several wavelengths are used to have several synthetic wavelengths. A frequency comb can increase the accuracy up to 8 nm in a range of 800 mm.[14] The use of a femtosecond mode locked laser produces the desired frequency comb.[15]

The traveling time is measured by comparing the phase of the modulating signal for the exiting and the returning beams. This phase comparison is sometimes made using a null method. In this method, a delay is introduced in the exiting signal, until it has the same phase as the returning beam, as shown in Fig. 4. Since the introduced delay is known, the light traveling time is thus determined.

Another method uses the down conversion of the frequency of both signals. These signals, with frequency f, are mixed with an electrical signal with frequency f_o, in order to obtain a signal with lower frequency f_L, in the range of a few kHz. The phase difference between the two low-frequency signals is the same as that between the two original signals. The lowering of the frequencies permits us to use conventional electronic methods to determine the phase difference between the two signals. A broad study on range finders has been done by Stitch.[16]

Interferometric Measurement of Small Distances

Interferometric methods may be used to measure small distances with a high degree of accuracy. This is usually done with a Michelson interferometer by comparing the thickness of the lens or glass

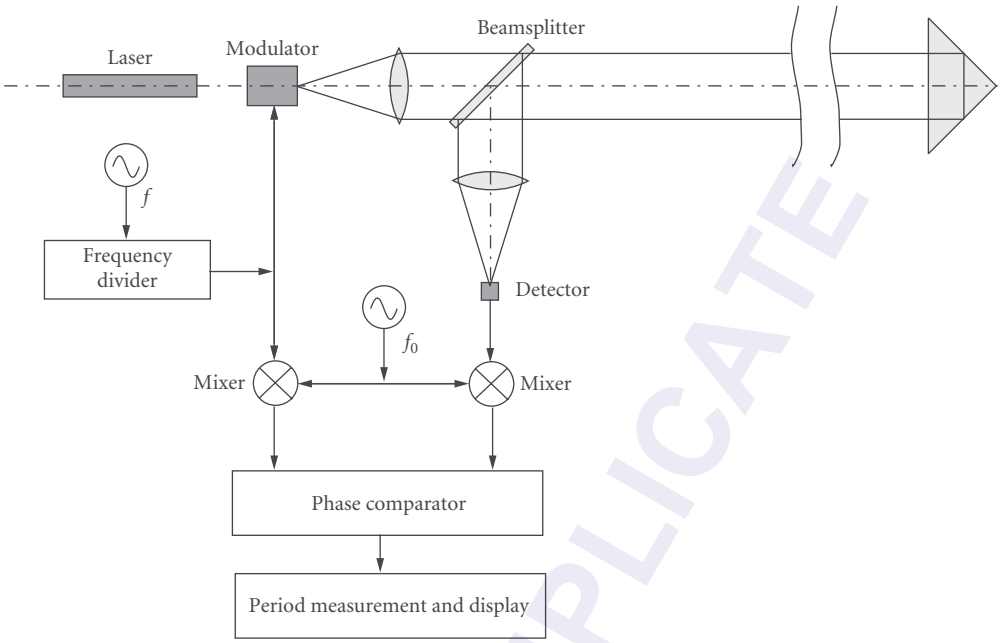

FIGURE 4 A wave modulation distance meter.

plate with that of a calibrated reference glass plate. Both plates must have approximately the same thickness and should be made with the same material.[17] The two mirrors of a dispersion-compensated Michelson interferometer are replaced by the glass plate to be measured and by a reference plane-parallel plate of the same material as the lens. (The next step is to adjust the interferometer, to produce white-light Newton rings with the front surfaces of the lens and the plate.) Then, the plate is translated along the arm of the interferometer until the rear surface produces white-light rings. The displacement is the optical thickness Nt of the measured plate.

Interferometric Measurement of Medium Distances

Long and medium distances may also be measured by interferometric methods.[18,19,20] Basically, the method counts the fringes in an interferometer while increasing or decreasing the optical path difference. The low temporal coherence or monochromaticity of most light sources limits this procedure to short distances. Lasers, however, have a much longer coherence length, due to their higher monochromaticity. Using lasers, it has been possible to make interferometric distance measurements over several meters.

In these interferometers, three things should be considered during their design. The first is that the laser light illuminating the interferometer should not be reflected back to the laser because that would cause instabilities in the laser, resulting in large irradiance fluctuations. As the optical path difference is changed by moving one of the mirrors, an irradiance detector in the pattern will detect a sinusoidally varying signal, but the direction of this change cannot be determined. Therefore, the second thing to be considered is that there should be a way to determine if the fringe count is going up or down; that is, if the distance is increasing or decreasing. There are two basic approaches to satisfy this last requirement. One is by producing two sinusoidal signals in phase quadrature (phase difference of 90° between them). The direction of motion of the moving prism may be sensed by determining the phase of which signal leads or lags the phase of the other signal. This information

is used to make the fringe counter increase or decrease. The alternative method uses a laser with two different frequencies. Finally, the third thing to consider in the interferometer design is that the number of fringes across its aperture should remain low and constant while moving the reflector in one of the two interferometer arms. This last condition is easily satisfied by using retroreflectors instead of mirrors. Then the two interfering wavefronts will always be almost flat and parallel. A typical retroreflector is a cube corner prism of reasonable quality to keep the number of fringes over the aperture low.

One method of producing two signals in quadrature is to have only a small number of fringes over the interferogram aperture. One possible method is by deliberately using an imperfect retroreflector. Then, the two desired signals are two small slits parallel to the fringes and separated by one-fourth of the distance between the fringes.[11] To avoid illuminating back the laser, the light from this laser should be linearly polarized. Then, a $\lambda/4$ phase plate is inserted in front of the beam, with its slow axis set at 45° to the interferometer plane to transform it into a circularly polarized beam.

Another method used to produce the two signals in quadrature phase is to take the signals from the two interference patterns that are produced in the interferometer. If the beam splitters are dielectric (no energy losses), the interference patterns will be complements of each other and, thus, the signals will be 90° apart. By introducing appropriate phase shifts in the beam splitter using metal coatings, the phase difference between the two patterns may be made 90°, as desired.[21] This method was used by Rowley,[22] as illustrated in Fig. 5. In order to separate the two patterns from the incident light beam, a large beam splitter and large retroreflectors are used. This configuration has the advantage that the laser beam is not reflected back. This is called a nonreacting interferometer configuration.

One more method, illustrated in Fig. 6, is the nonreacting interferometer designed at the Perkin-Elmer Corporation by Minkowitz and Vanir.[23] A circularly polarized light beam, produced by a linearly polarized laser and a $\lambda/4$ phase plate, illuminates the interferometer. This beam is divided by a beam splitter into two beams going to both arms of the interferometer. Upon reflection by the retro reflector, one of the beams changes its state of polarization from right to left circularly polarized. The two beams with opposite circular polarization are recombined at the beam splitter, thus producing linearly polarized light. The angle of the plane of polarization is determined by the phase difference between the two beams. The plane of polarization rotates 360° if the optical path difference

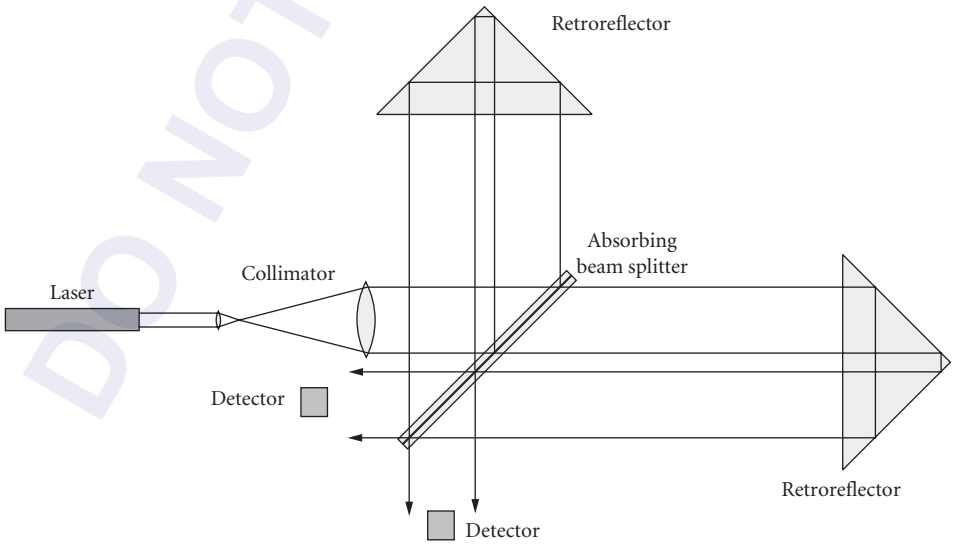

FIGURE 5 Two-interference pattern distance-measuring interferometer.

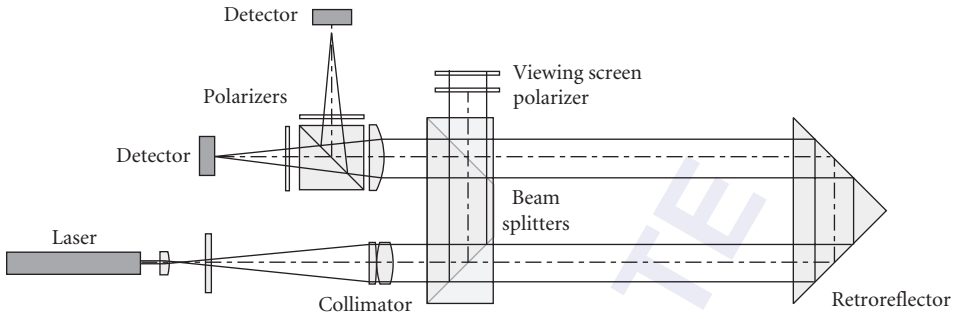

FIGURE 6 Minkowitz distance-measuring interferometer.

is changed by $\lambda/2$, the direction of rotation being given by the direction of the displacement. This linearly polarized beam is divided into two beams by a beam splitter. On each of the exiting beams, a linear polarizer is placed, one at an angle of +45° and the other at an angle of −45°. Then the two beams are in quadrature to each other.

In still another method, shown in Fig. 7, a beam of light, linearly polarized at 45° (or circularly polarized), is divided at a beam splitter, the *p* and *s* components. Then, both beams are converted to circular polarization with a $\lambda/4$ phase plate in front of each of them, with their axis at 45°. Upon reflection on the retro-reflectors, the handedness of the polarization is reversed. Thus, the linearly polarized beams exiting from the phase plates on the return to the beam splitter will have a plane of polarization orthogonal to that of the incoming beams. It is easily seen that no light returns to the laser. Here, the nonreacting configuration is not necessary but it may be used for additional protection. After recombination on the beam splitter, two orthogonal polarizations are present. Each plane of polarization contains information about the phase from one arm only so that no interference between the two beams has occurred. The two desired signals in quadrature are then generated by producing two identical beams with a nonpolarizing beam splitter with a polarizer on each exiting beam with their axes at +45° and −45° with respect to the vertical plane. The desired phase difference between the two beams is obtained by introducing a

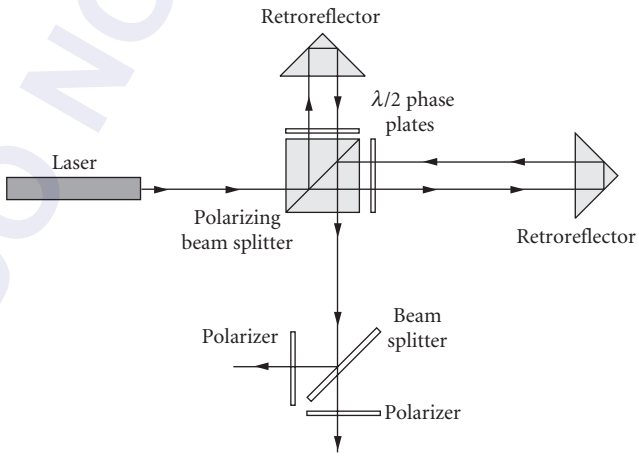

FIGURE 7 Brunning distance-measuring interferometer.

$\lambda/4$ phase plate after the beam splitter but before one of the polarizers with its slow axis vertical or horizontal. These two polarizers may be slightly rotated to make the two irradiances equal, at the same time preserving the 90° angle between their axes. If the prism is shifted a distance x, the fringe count is

$$\Delta_{\text{count}} = \pm\left[\frac{2x}{\lambda}\right] \tag{9}$$

where [ ] denotes the integer part of the argument.

These interferometers are problematic in that any change in the irradiance may be easily interpreted as a fringe monitoring the light source. A more serious problem is the requirement that the static interference pattern be free of, or with very few, fringes. Fringes may appear because of multiple reflections or turbulence.

A completely different method uses two frequencies. It was developed by the Hewlett Packard Co.[24,25] and is illustrated in Fig. 8. The light source is a frequency-stabilized He-Ne laser whose light beam is Zeeman split into two frequencies f_1 and f_2 by application of an axial magnetic field. The frequency difference is several megahertz and both beams have circular polarization, but with opposite sense. A $\lambda/4$ phase plate transforms the signals f_1 and f_2 into two orthogonal linearly polarized beams, one in the horizontal and the other in the vertical plane. A sample of this mixed signal is deviated by a beam splitter and detected at photo detector A, by using a polarizer at 45°. The amplitude modulation of this signal, with frequency $f_1 - f_2$, is detected and passed to a counter. Then, the two orthogonally polarized beams with frequencies f_1 and f_2 are separated at a polarizing beam splitter. Each is transformed into a circularly polarized beam by means of $\lambda/4$ phase plates. After reflection by the prisms, the handedness of these polarizations is changed. Then they go through the same phase plates where they are converted again to orthogonal linearly polarized beams. There is no light reflecting back to the laser. After recombination at the beam splitter, a polaroid at 45° will take the components of both beams in this plane. This signal is detected at the photo detector B. As with the other signal, the modulation with frequency $f_1 - f_2 + \Delta f$ is extracted from the carrier and sent to

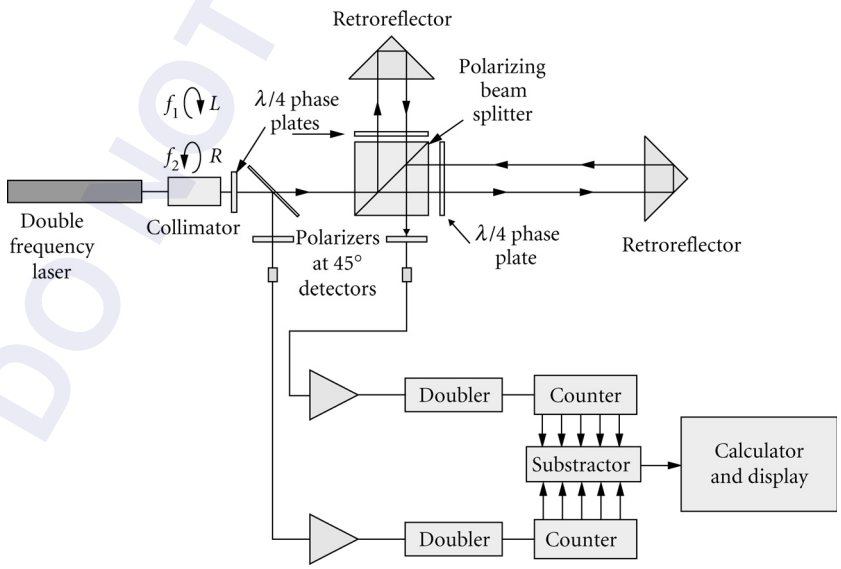

FIGURE 8 Hewlett Packard double-frequency distance-measuring interferometer.

another counter. The shift Δf in the frequency of this signal comes from a Doppler shift due to the movement of one of the retroreflectors,

$$\Delta f = \frac{2}{\lambda_2}\frac{dx}{dt} \tag{10}$$

where dx/dt is the cube corner prism velocity and λ_1 is the wavelength corresponding to the frequency f_1. The difference between the results of the two counters is produced by the displacement of the retroreflector. If the prism moves a distance x, the number of pulses detected is given by

$$\Delta_{\text{count}} = \pm\left[\frac{2x}{\lambda_2}\right] \tag{11}$$

The advantage of this method compared with the first is that fringe counting is not subject to drift. These signals may be processed to obtain a better signal-to-noise ratio and higher resolution.[25]

Straightness Measurements

Light propagation is assumed to be rectilinear in a homogeneous medium. This permits the use of a propagating light beam as a straightness reference. Besides the homogeneous medium, it is necessary to get a truly narrow pencil of light to improve accuracy. Laser light is an obvious application because of the high degree of spatial coherence. Beam divergence is usually less than 1 mrad for a He-Ne laser. One method uses a position-sensing detector to measure the centroid of the light spot despite its shape. In front of the laser, McLeod[26] used an axicon as an aligning device. When a collimated light beam is incident on an axicon, it produces a bright spot on a circular field. An axicon can give as much as 0. 01 arcsec.

Another method to measure the deviation from an ideal reference line uses an autocollimator. A light beam leaving an autocollimator is reflected by a mirror. The surface slope is measured at the mirror. By knowing the distance to the mirror, one can determine the surface's profile by integration, as in a curvature measurement (see "Optical Methods for Measuring Curvature," later in this chapter). A method can be designed for measuring flatness for tables on lathe beds.[27]

12.4 ANGLE MEASUREMENTS

Angle measurements, as well as distance measurements, require different levels of accuracy. For cutting glass, the required accuracy can be as high as several degrees, while for test plates, an error of less than a second of arc may be required. For each case, different measurement methods are developed.

Mechanical Methods

The easiest way to measure angles with medium accuracy is by means of mechanical nonoptical methods. These are

Sine Plate Essentially it is a table with one end higher than the other by a fixed amount, as shown in Fig. 9. Accuracy close to 30 arcmin may be obtained.

Goniometer This is a precision spectrometer. It has a fixed collimator and a moving telescope pointing to the center of a divided circle. Accuracies close to 20 arcsec may be obtained.

Bevel Gauge Another nonoptical method is by the use of a bevel gauge. This is made of two straight bars hinged at their edges by a pivot, as shown in Fig. 10. This device may be used to measure angle

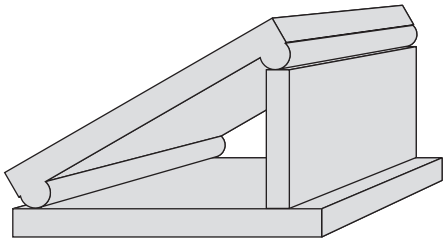

FIGURE 9 Sine plate.

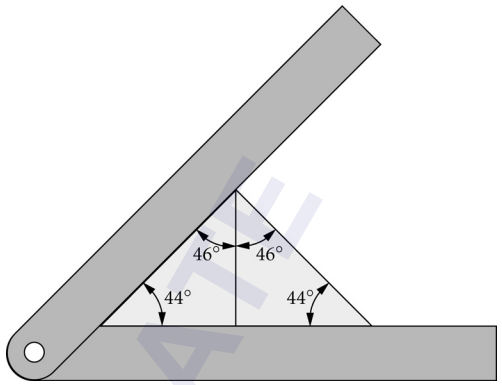

FIGURE 10 Bevel gauge.

prisms whose angle accuracies are from 45 to about 20 arcsec.[28] For example, if the measured prism has a 50-mm hypotenuse, a space of 5 μm at one end represents an angle of 0.0001 rad or 20 arcsec.

Numerically Controlled Machines (CNC) The advent of digitally controlled machines has brought to the optical shop machines to work prisms and angles with a high level of accuracy. Most machines can be adjusted within 0.5 arcmin of error.

Autocollimators

As shown in Fig. 11, an autocollimator is essentially a telescope focused at infinity with an illuminated reticle located at the focal plane. A complete description of autocollimators is found in Hume.[29] A flat reflecting surface, perpendicular to the exiting light beam, forms an image of the reticle on the same plane as the original reticle. Then, both the reticle and its image are observed through the eyepiece. When the reflecting surface is not exactly perpendicular to the exiting light beam, the reticle image is laterally displaced in the focal plane with respect to the object reticle. The magnitude of this of displacement d is

$$d = 2\alpha f \tag{12}$$

where α is the tilt angle for the mirror in radians and f is the focal length of the telescope.

Autocollimator objective lenses are usually corrected doublets. Sometimes a negative lens is included to form a telephoto lens to increase the effective focal length while maintaining compactness. The collimating lens adjustment is critical for the final accuracy. Talbot interferometry can be used for a precise focus adjustment.[30]

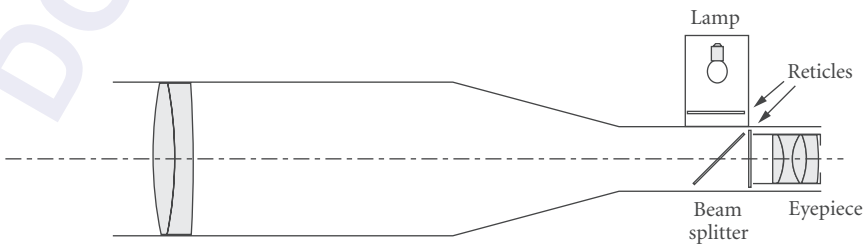

FIGURE 11 An autocollimator.

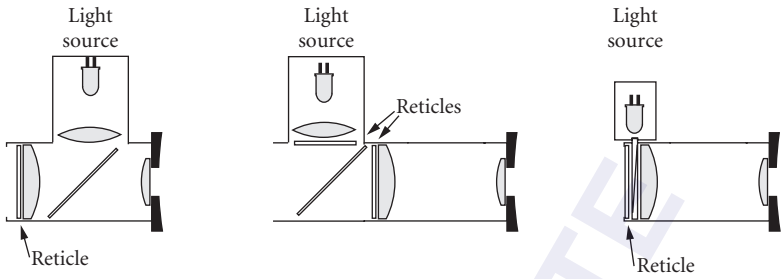

FIGURE 12 Illuminated eyepieces for autocollimators and microscopes. (*a*) Gauss; (*b*) bright line; and (*c*) Abbe.

The focal plane is observed through an eyepiece. Several types of illuminated reticles and eyepieces have been developed. Figure 12[31] illustrates some illuminated eyepieces, in all of which the reticle is calibrated to measure the displacement. Gauss and Abbe illuminators show a dark reticle on a bright field. A bright field[32] may be more appropriate for low reflectance surfaces. Rank[33] modified a Gauss eyepiece to produce a dark field. In other systems, a drum micrometer displaces a reticle to position it at the image plane of the first reticle. To increase sensitivity some systems, called microoptic autocollimators, use a microscope to observe the image.

Direct-reading autocollimators have a field of view of about 1°. Precision in an autocollimator is limited by the method for measuring the centroid of the image. In a diffraction-limited visual system, the diffraction image size sets the limit of precision. In a precision electronic measuring system, the accuracy of the centroid measurement is limited by the electronic detector, independent of the diffraction image itself, and can exceed the diffraction limit. In some photoelectric systems, the precision is improved by more than an order of magnitude.

Autocollimators are used for angle measurements in prisms and glass polygons. But they also have other applications; for example, to evaluate the parallelism between faces in optical flats or to manufacture divided circles.[34] By integrating measured slope values with an autocollimator, flatness deviations for a machine tool for an optical bed can also be evaluated.[27]

The reflecting surface in autocollimation measurements must be kept close to the objective in order to make the alignment easier and to be sure that all of the reflected beam enters the system. The reflecting surface must be of high quality. A curved surface is equivalent to introducing another lens in the system with a change in the effective focal length.[27]

Several accessories for autocollimators have been designed. For single-axis angle measurement, a pentaprism is used. An optical square permits angle measurements for surfaces at right angles. Perpendicularity is measured with a pentaprism and a mirror, as shown in Fig. 13. A handy horizontal reference can be produced with an oil pool, but great care must be taken with the surface stability.

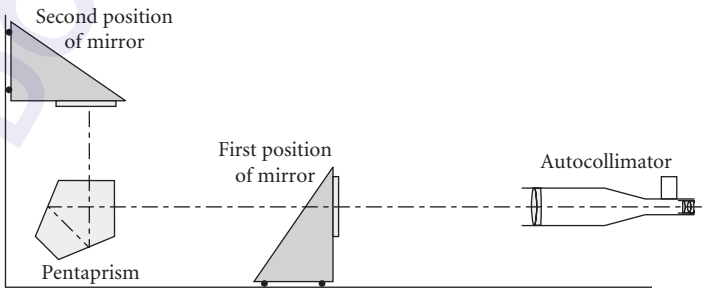

FIGURE 13 Perpendicularity measurement with an autocollimator.

Theodolites

Theodolites are surveying instruments to measure vertical and horizontal angles. A telescope with reticle is the reference to direct the instrument axis. In some theodolites, the telescope has an inverting optical system to produce an erect image. The reticle is composed of a crosswire and has a couple of parallel horizontal lines, called stadia lines, used for range measurements (see "Stadia and Range Finders" earlier in this chapter). The telescope has two focus adjustments: one to sharply focus the reticle according to the personal setting for each observer, and the other to focus the objective on the reticle. This later focus adjustment is performed by moving the whole eyepiece.

The theodolite telescope has a tree-screw base altitude-azimuth mounting on a base made horizontal with a spirit level. Divided circles attached to both telescope axes measure vertical and horizontal angles. In older instruments, an accuracy of 20 arcmin was standard. Modern instruments are accurate to within 20 arcsec, the most expensive of which can reach an accuracy of 1 arcsec. To remove errors derived from eccentric scales as well as orthogonality errors, both axes are rotated 180° and the measurement repeated. Older instruments had a provision for reading at opposite points of the scale. Scales for theodolites can be graduated in sexagesimal degrees or may use a centesimal system that divides a circle into 400 grades.

Some of the accessories available for theodolites include

1. An illuminated reticle that can be used as an autocollimator when directed to a remote retroreflector. The observer adjusts the angles until both the reflected and the instrument's reticle are superposed. This increases the pointing accuracy.
2. A solar filter, which can be attached to the eyepiece or objective side of the telescope. This is used mainly for geographic determination in surveying.
3. An electronic range meter, which is superposed to the theodolite to measure the distance. Additionally, some instruments have electronic position encoders that allow a computer to be used as an immediate data-gathering and reducing device.
4. A transverse micrometer for measuring angular separation in the image plane.

Accuracy in a theodolite depends on several factors in its construction. Several of these errors can be removed by a careful measuring routine. Some of the systematic or accuracy limiting errors are

1. Perpendicularity—deviation between vertical and horizontal scales. This error can be nulled by plunging and rotating the telescope, then averaging.
2. Concentricity deviation of scales. When scales are not concentric, they are read at opposite ends to reduce this error. Further accuracy can be obtained by rotating the instrument 90°, 180°, and 270° and averaging measurements.

Level

Levels are surveying instruments for measuring the deviation from a horizontal reference line. A level is a telescope with an attached spirit level. The angle between the telescope axis and the one defined by the spirit level must be minimized. It can be adjusted by a series of measurements to a pair of surveying staves (Fig. 14). Once the bubble is centered in the tube, two measurements are taken on

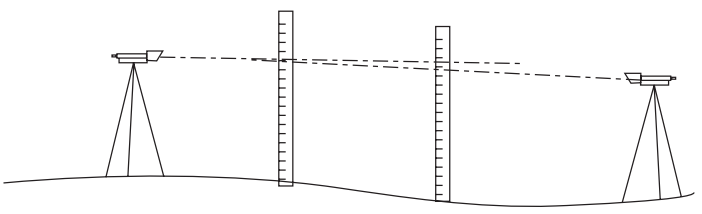

FIGURE 14 Level adjustment. (*After Kingslake.*[35])

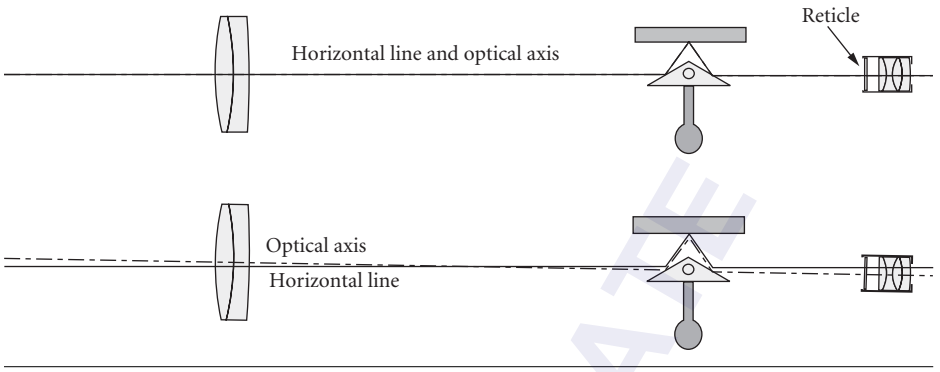

FIGURE 15 The autoset level.

each side of the staves.[35] The level differences between the two staves must be equal if the telescope axis is parallel with the level horizontal axis.

The autoset level (Fig. 15) uses a suspended prism and a fixed mirror on the telescope tube. The moving prism maintains the line aimed at the horizon and passing through the center of the reticle, despite the tube orientation, as long as it is within about 15 arcmin. Typical precision for this automatic level can go up to 1 arcsec.[27]

Interferometric Measurements

Interferometric methods find their main applications in measuring very small wedge angles in glass slabs[36,37] and in parallelism evaluation[38] by means of the Fizeau or Haidinger interferometers.[39]

Interferometric measurements of large angles may also be performed. In one method, a collimated laser beam is reflected from the surfaces by a rotating glass slab. The resulting fringes can be considered as coming from a Murty lateral shear interferometer.[40] This device can be used as a secondary standard to produce angles from 0° to 360° with accuracy within a second of arc. Further analysis of this method has been done by Tentori and Celaya.[41] In another system, a Michelson interferometer is used with an electronic counter to measure over a range of ±5° with a resolution of 10°.[42,43] An interferometric optical sine bar for angles in the milliseconds of arc was built by Chapman.[44]

Angle Measurements in Prisms

A problem frequently encountered in the manufacture of prisms is the precise measurement of angle. In most cases, prism angles are 90°, 45°, and 30°. These angles are easily measured by comparison with a standard but it is not always necessary.

An important aspect of measuring angles in a prism is to determine if the prism is free of pyramidal error. Consider a prism with angles A, B, and C (Fig. 16*a*). Let OA be perpendicular to plane ABC. If line AP is perpendicular to segment BC, then the angle AOP is a measurement of the pyramidal error. In a prism with pyramidal error, the angles between the faces, as measured in planes perpendicular to the edges between these faces, add up to over 180°. To simply detect pyramidal error in a prism, Johnson[45] and Martin[46] suggest that both the refracted and the reflected images from a straight line be examined (Fig. 16*b*). When pyramidal error is present, the line appears to be broken. A remote target could be graduated to measure directly in minutes of arc. A sensitivity of up to 3 arcmin may be obtained.

During the milling process in the production of a prism, a glass blank is mounted in a jig collinear with a master prism (Fig. 17). An autocollimator aimed at the master prism accurately sets the

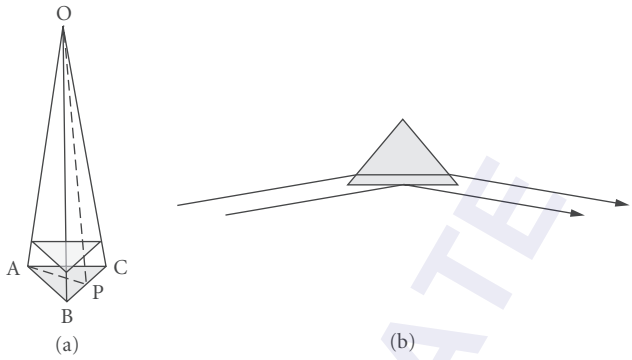

FIGURE 16 Pyramidal error in a prism (*a*) nature of the error and (*b*) test of the error.

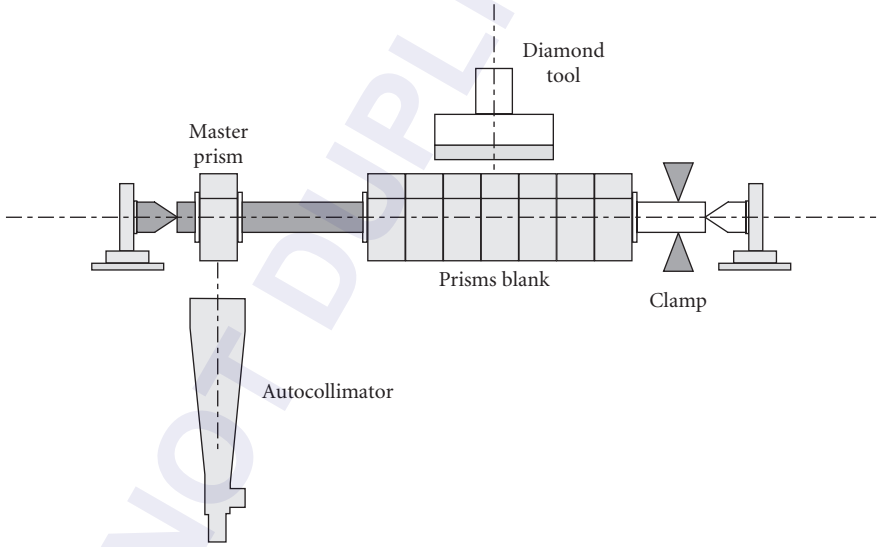

FIGURE 17 Milling prisms for replication.

position for each prism face.[47,48] With a carefully set diamond lap, pyramidal error is minimized. In a short run, angles can be checked with a bevel gauge. Visual tests for a prism in a bevel gauge can measure an error smaller than a minute of arc.[31]

A 90° angle in a prism can be measured by internal reflection, as shown in Fig. 18*a*. At the autocollimator image plane, two images are seen with an angular separation of $2N\alpha$, where α is the magnitude of the prism angle error, and its sign is unknown. Since the hypotenuse face has to be polished and the glass must be homogeneous, the measurement of the external angle with respect to a reference flat is preferred (Fig. 18*b*). In this case, the sign of the angle error is determined by a change in the angle by tilting the prism. If the external angle is decreased and the images separate further, then the external angle is less than 90°. Conversely, if the images separate by tilting in such way that the external angle increases, then the external angle is larger than 90°.

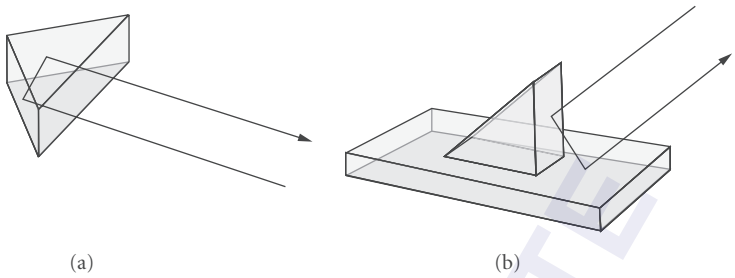

FIGURE 18 Right angle measurement in prisms: (*a*) internal measurement and (*b*) external measurement.

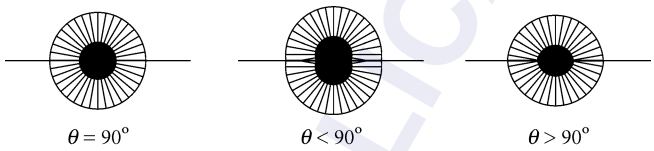

FIGURE 19 Retroreflected images of the observer's pupil in a 90° prism.

To determine the sign of the error, several other methods have been proposed. DeVany[49] suggested that when looking at the double image from the autocollimator, the image should be defocused inward. If the images tend to separate, then the angle in the prism is greater than 90°. Conversely, an outward defocusing will move the images closer to each other for an angle greater than 90°. Another way to eliminate the sign of the error in the angle is by introducing, between the autocollimator and the prism, a glass plate with a small wedge whose orientation is known. The wedge should cover only one-half of the prism aperture. Ratajczyk and Bodner[50] suggested a different method using polarized light.

Right-angle prisms can be measured using an autocollimator with acceptable precision.[51] With some practice, perfect cubes with angles more accurate than 2 arcsec can be obtained.[49] An extremely simple test for the 90° angle in prisms[45] is performed by looking to the retroreflected image of the observer's pupil without any instrument. The shape of the image of the pupil determines the error, as shown in Fig. 19. The sensitivity of this test is not very great and may be used only as a coarse qualitative test. As shown by Malacara and Flores,[52] a small improvement in the sensitivity of this test may be obtained if a screen with a small hole is placed in front of the eye, as in Fig. 20*a*. A cross centered on the small hole is painted on the front face of the screen. The observed images are as shown in the same Fig. 20*b*. As opposed to the collimator test, there is no uncertainty in the sign of the error in the tests just described, since the observed plane is located where the two prism surfaces intersect. An improvement described by Malacara and Flores,[52] combining these simple tests with an autocollimator, is obtained with the instrument in Fig. 21. In this system, the line defining the intersection between the two surfaces is out of focus and barely visible while the reticle is in perfect focus at the eyepiece.

Corner cube prisms are a real challenge to manufacture, since besides the large precision required in the angles, all surfaces should be exempt of any curvature. The dihedral angle in pentaprisms is tested usually with an interferometer. An error in the prism alignment results in an error in angle determination.[53] A simple geometric method for angle measurement in corner cube reflector has been described by Rao.[54] Also, the calculations for the electric field in a corner cube are performed by Scholl.[55] These calculations include the effect by nonhomogeneities, angle of incidence, and errors in the surface finish.

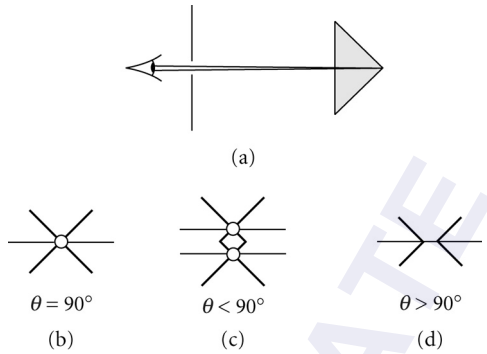

FIGURE 20 Testing a right-angle prism: (*a*) screen in front of the eye and (*b*) to (*d*) its observed images.

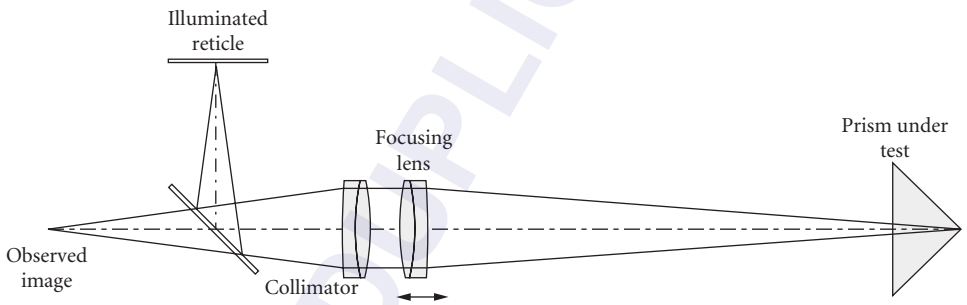

FIGURE 21 Modified autocollimator for testing the right angle in prisms without sign uncertainity in measured error.

12.5 CURVATURE AND FOCAL LENGTH MEASUREMENTS

The curvature of a spherical optical surface or the local curvature of an aspherical surface may be measured by means of mechanical or optical methods. Some methods measure the sagitta, some the surface slope, and some others directly locate the position of the center of curvature.

Mechanical Methods for Measuring Curvature

Templates The simplest and most common way to measure the radius of curvature is by comparing it with metal templates with known radii of curvature until a good fit is obtained. The template is held in contact with the optical surface with a bright light source behind the template and the optical surface. If the surface is polished, gaps between the template and the surface may be detected to an accuracy of one wavelength. If the opening is very narrow, the light passing through the gap becomes blue due to diffraction.

Test Plates This method uses a glass test plate with a curvature opposite to that of the glass surface to be measured. The accuracy is much higher than in the template method, but the surface must be polished.

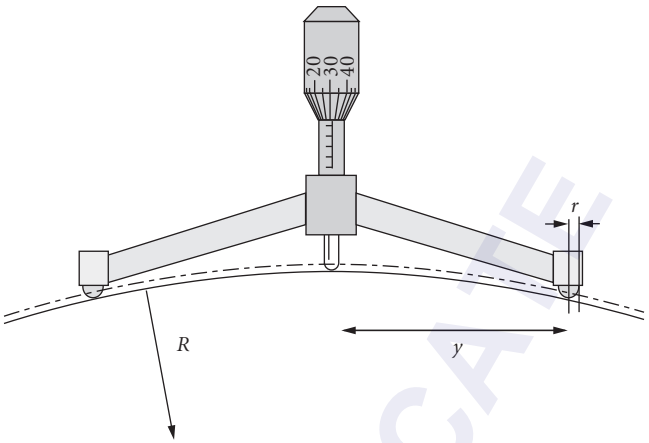

FIGURE 22 Three-leg spherometer.

Spherometers This is probably the most popular mechanical device used to measure radii of curvature. It consists of three equally spaced feet with a central moving plunger. The value of the radius of curvature is calculated after measuring the sagitta, as shown in Fig. 22. The spherometer must first be calibrated by placing it on top of a flat surface. Then it is placed on the surface to be measured. The difference in the position of the central plunger for these two measurements is the sagitta of the spherical surface being measured. Frequently, a steel ball is placed at the end of the legs as well as at the end of the plunger to avoid the possibility of scratching the surface with sharp points. In this case, if the measured sagitta is z, the radius of curvature R of the surface is given by

$$R = \frac{z}{2} + \frac{y^2}{2z} \pm r \tag{13}$$

where r is the radius of curvature of the balls. The plus sign is used for concave surfaces and the minus sign for convex surfaces. The precision of this instrument in the measurement of the radius of curvature for a given uncertainty in the measured sagitta may be obtained by differentiating Eq. (13)

$$\frac{dR}{dz} = \frac{1}{2} - \frac{y^2}{2z^2} \tag{14}$$

obtaining

$$\Delta R = \frac{\Delta z}{2}\left(1 - \frac{y^2}{z^2}\right) \tag{15}$$

This accuracy assumes that the spherometer is perfectly built and that its dimensional parameters y and r are well known. The uncertainty comes only from human or instrumental errors in the measurement of the sagitta. Noble[31] has evaluated the repeatability for a spherometer with $y = 50$ mm and an uncertainty in the sagitta reading equal to 5 μm, and has reported the results in Table 1 where it can be seen that the precision is better than 2 percent. An extensive analysis of the precision and accuracy of several types of spherometers is given by Jurek.[56]

A ring may be used instead of the three legs in a mechanical spherometer. A concave surface contacts the external edge of the cup, and a convex surface is contacted by the internal edge of the ring. Thus, Eq. (5) may be used if a different value of y is used for concave and convex surfaces, and r is taken as zero. Frequently in spherometers of this type, the cups are interchangeable in order to have different diameters for different surface diameters and radii of curvature. The main advantage of the

TABLE 1 Spherometer precision*

Radius of Sphere R (mm)	Sagitta Z (mm)	Fractional Precision ΔR (mm)	Precision $\Delta R/R$
10,000	0.125	−400	−0.040

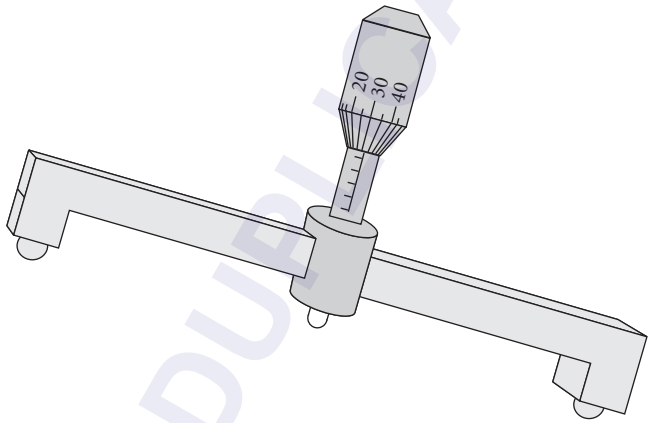

FIGURE 23 Bar spherometer.

use of a ring instead of three legs is that an astigmatic deformation of the surface is easily detected, although it cannot be measured.

A spherometer that permits the evaluation of astigmatism is the bar spherometer, shown in Fig. 23. It can measure the curvature along any diameter. A commercial version of a small bar spherometer for the specific application in optometric work is the Geneva gauge, where the scale is directly calibrated in diopters assuming that the refractive index of the glass is 1.53.

Automatic spherometers use a differential transformer as a transducer to measure the plunger displacement. This transformer is coupled to an electronic circuit and produces a voltage that is linear with respect to the plunger displacement. This voltage is fed to a microprocessor which calculates the radius of curvature or power in any desired units and displays it.

Optical Methods for Measuring Curvature

Foucault Test Probably the oldest and easiest method to measure the radius of curvature of a concave surface is the knife-edge test. In this method, the center of curvature is first located by means of the knife edge. Then, the distance from the center of curvature to the optical surface is measured.

Autocollimator The radius of curvature may also be determined through measurements of the slopes of the optical surface with an autocollimator as described by Horne.[57] A pentaprism producing a 90° deflection of a light beam independent of small errors in its orientation is used in this technique,

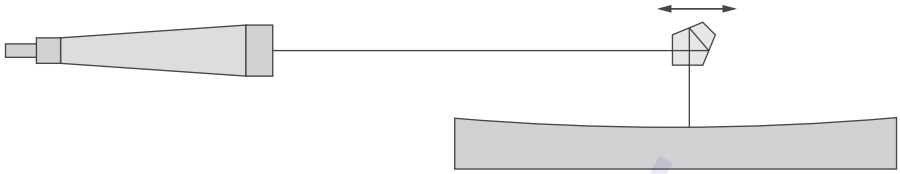

FIGURE 24 Autocollimator and pentaprism used to determine radius of curvature by measuring surface slopes.

as illustrated in Fig. 24, where the pentaprism travels over the optical surface to be measured along one diameter. First the light on the reticle of the autocollimator is centered on the vertex of the surface being examined. Then the pentaprism is moved toward the edge of the surface in order to measure any slope variations. From these slope measurements, the radius of curvature may be calculated. This method is useful only for large radii of curvature for either concave or convex surfaces.

Confocal Cavity Technique Gerchman and Hunter[58,59] have described the so-called optical cavity technique that permits the interferometric measurement of very long radii of curvature with an accuracy of 0.1 percent. The cavity of a Fizeau interferometer is formed, as illustrated in Fig. 25. This is a confocal cavity of *n*th order, where *n* is the number of times the path is folded. The radius of curvature is equal to approximately $2n$ times the cavity length Z.

Traveling Microscope This instrument is used to measure the radius of curvature of small concave optical surfaces with short radius of curvature. As illustrated in Fig. 26, a point light source is produced at the front focus of a microscope objective. This light source illuminates the concave optical surface to be measured near its center of curvature. Then this concave surface forms an image which is also close to its center of curvature. This image is observed with the same microscope used to illuminate the surface. During this procedure, the microscope is focused both at the center of curvature and at the surface to be measured. A sharp image of the light source is observed at both places. The radius of curvature is the distance between these two positions for the microscope.

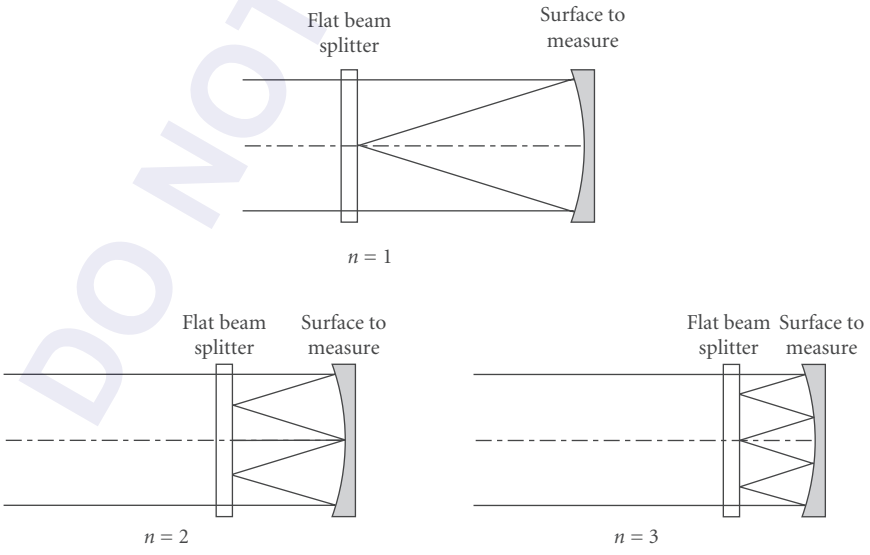

FIGURE 25 Confocal cavity arrangements used to measure radius of curvature.

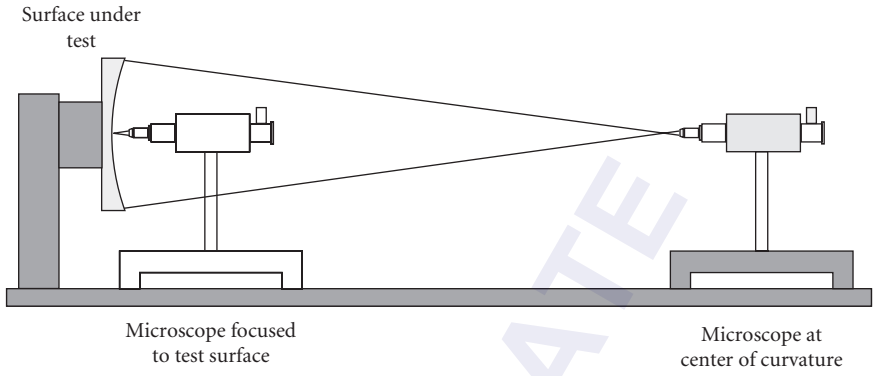

FIGURE 26 Traveling microscope to measure radii of curvature.

This distance traveled by the microscope may be measured on a vernier scale, obtaining a precision of about 0.1 mm. If a bar micrometer is used, the precision may be increased by an order of magnitude. In this case, two small convex buttons are required: one fixed to the microscope carriage and the other to the stationary part of the bench. They must face each other when the microscope carriage is close to the optical bench fixed component.

Carnell and Welford[32] describe a method that requires only one measurement. The microscope is focused only at the center of curvature. Then the radius of curvature is measured by inserting a bar micrometer with one end touching the vertex of the optical surface. The other end is adjusted until it is observed to be in focus on the microscope. Accuracies of a few microns are obtained with this method.

In order to focus the microscope properly, the image of an illuminated reticle must fall, after reflection, back on itself, as in the Gauss eyepiece shown in Fig. 12. The reticle and its image appear as dark lines in a bright field. The focusing accuracy may be increased with a dark field. Carnell and Welford obtained a dark field with two reticles, as in Fig. 12, one illuminated with bright lines and the other with dark lines.

A convex surface may also be measured with this method if a well-corrected lens with a conjugate longer than the radius of curvature of the surface under test is used. Another alternative for measuring convex surfaces is by inserting an optical device with prisms in front of the microscope, as described by Jurek.[56]

Some practical aspects of the traveling microscope are examined by Rank,[33] who obtained a dark field at focus with an Abbe eyepiece which introduces the illumination with a small prism. This method has been implemented using a laser light source by O'Shea and Tilstra.[60]

Additional optical methods to measure the radius of curvature of a spherical surface have been described. Evans[61,62,63] determines the radius by measuring the lateral displacements on a screen of a laser beam reflected on the optical surface when this optical surface is laterally displaced. Cornejo-Rodriguez and Cordero-Dávila,[64] Klingsporn,[65] and Diaz-Uribe et al.[66] rotate the surface about its center of curvature on a nodal bench.

Focal Length Measurements

There are two focal lengths in an optical system: the back focal length and the effective focal length. The back focal length is the distance from the last surface of the system to the focus. The effective focal length is the distance from the principal plane to the focus. The back focal length is easily measured, following the same procedure used for measuring the radius of curvature, using a microscope and the lens bench. On the other hand, the effective focal length requires the previous location of the principal plane.

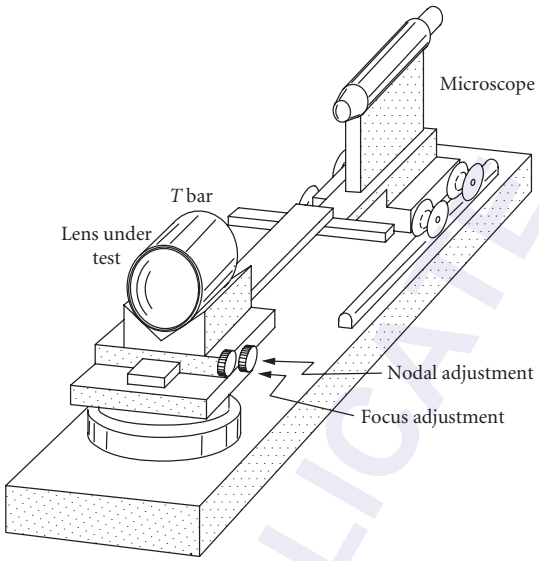

FIGURE 27 Nodal slide bench. (*From Malacara.*[1])

Nodal Slide Bench In an optical system in air, the principal points (intersection of the principal plane and the optical axis) coincide with the nodal points. Thus, to locate this point we may use the well-known property that small rotations of the lens about an axis perpendicular to the optical axis and passing through the nodal point do not produce any lateral shift of the image. The instrument used to perform this procedure, shown in Fig. 27, is called an optical nodal slide bench.[67] This bench has a provision for slowly moving the lens under test longitudinally in order to find the nodal point.

The bench is illuminated with a collimated light source and the image produced by the lens under test is examined with a microscope. The lens is then displaced slightly about a vertical axis as it is being displaced longitudinally. This procedure is stopped until a point is found in which the image does not move laterally while rotating the lens. This axis of rotation is the nodal point. Then, the distance from the nodal point to the image is the effective focal length.

Focimeters A focimeter is an instrument designed to measure the focal length of lenses in a simple manner. The optical scheme for the classical version of this instrument is shown in Fig. 28. A light source illuminates a reticle and a convergent lens, with focal length f, displaced at a distance x from the reticle. The lens to be measured is placed at a distance d from the convergent lens. The magnitude

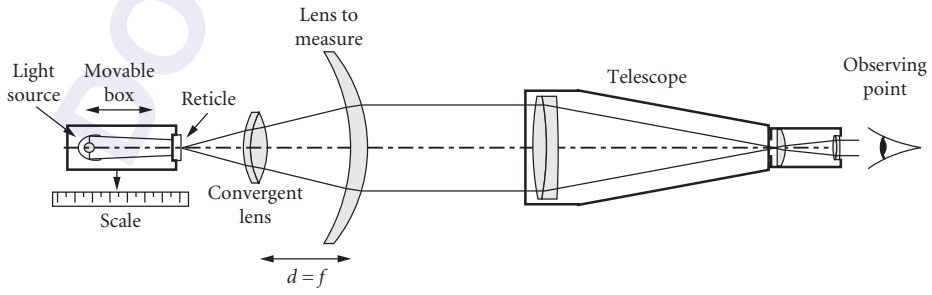

FIGURE 28 Focimeter schematics.

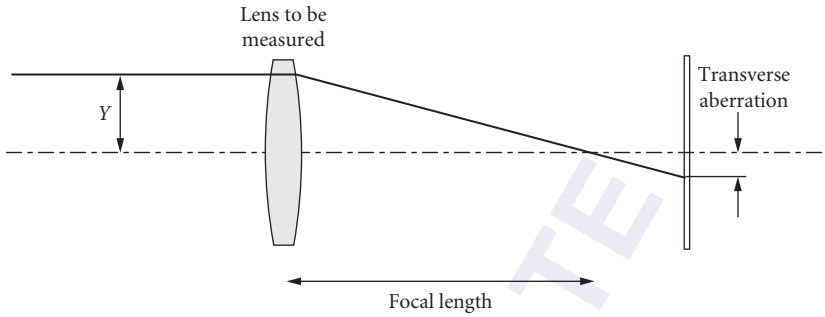

FIGURE 29 Focal length determination by transverse aberration measurements.

of x is variable and is adjusted until the light beam going out from the lens under test becomes collimated. This collimation is verified by means of a small telescope in front of this lens focused at infinity. The values of d and the focal length f are set to be equal. Then, the back focal length f_b of the lens under test is given by

$$\frac{1}{f_b} = \frac{1}{d} - \frac{x}{d^2} = P_v \tag{16}$$

where its inverse P_v is the vertex power. As can be seen, the power of the lens being measured is linear with respect to the distance x. There are many variations of this instrument. Some modern focimeters measure the lateral deviation of a light ray from the optical axis (transverse aberration), as in Fig. 29, when a defocus is introduced.[61,62,63] This method is mainly used in some modern automatic focimeters for optometric applications. To measure the transverse aberration, a position-sensing detector is frequently used. The power error of a focimeter can be obtained by derivation of Eq. (16)

$$\delta P_v = -\frac{\delta x}{f_c^z} \tag{17}$$

Thus, the power error is a linear function of the target position error and decreases with the square of the collimating lens focal distance.[70]

Other Focal Length Measurements

Moiré Deflectometry Moiré deflectometry method for focal length determination sends a collimated beam over a pair of Ronchi rulings (Fig. 30) depending on the convergence or divergence of the beam, the resulting moiré pattern rotates according to the convergence (Fig. 31). The rotation has an angle α that is related to the focal distance by[71,72]

$$f \approx \frac{d}{\theta \tan\alpha} \tag{18}$$

d being the ruling's pitch, θ is the angle between the ruling's lines, and α is the rotation angle of the moiré pattern.

Talbot Autoimages Talbot autoimages method for focal length determination is performed by sending a coherent beam of light into a Ronchi ruling. An image of the grating will be produced periodically and evenly spaced along the light beam. Every Talbot autoimage is an object for the lens

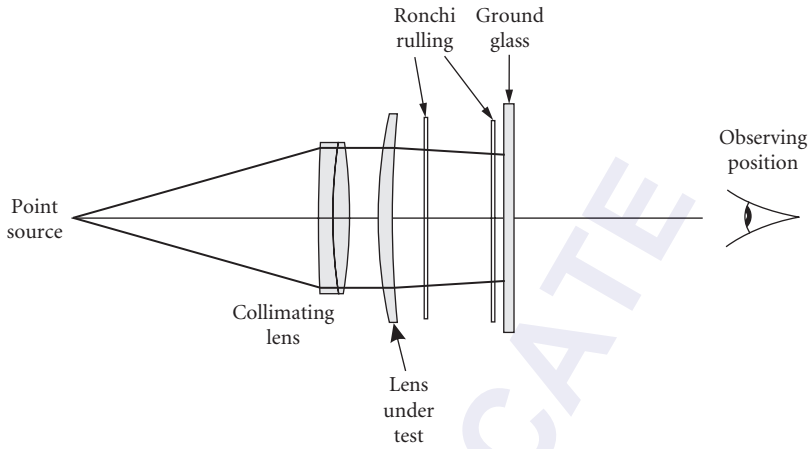

FIGURE 30 Moiré deflectometry lens power measurement. (*From Malacara.*[1])

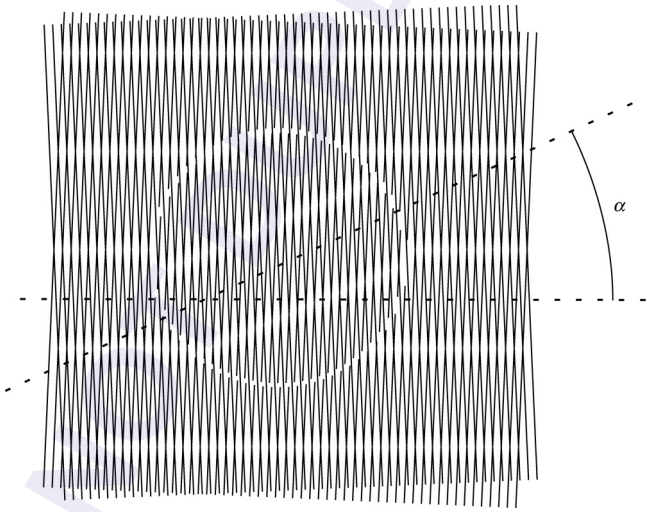

FIGURE 31 Moiré pattern as produced in a moiré deflectometer. (*From Malacara.*[1])

under test and produces a set of autoimages at the image side of the lens. To determine the lens focal length, another ruling coincident to the autoimages at the image plane is used.[73,74]

Fourier Transforms The Fourier-transforming property of a lens can be used in the focal-length determination. Horner[75] measured the diffraction pattern at the focal plane produced by a slit. For this method, the light beam does not have to be perfectly collimated.

Microlenses Micro-lenses applications require new methods for small focal length determination. The propagated Gaussian beam of a laser can be analyzed.[76,77] In this method, a lens is placed al the laser beam waist, then the propagating beam is measured to determine the focal length.

Fiber Optics A clever method used to automatically find the position of the focus has been described by Howland and Proll.[78] They used optical fibers to illuminate the lens in an autocollimating configuration, and the location of the image was also determined using optical fibers.

13.2 INTRODUCTION

The requirements for high-quality optical surfaces are more demanding every day. They should be tested in an easier, faster, and more accurate manner. Optical surfaces usually have a flat or a spherical *shape*, but they also may be toroidal or generally aspheric. Frequently, an aspherical surface is a conic of revolution, but an aspherical surface can only be made as good as it can be tested. Here, the field of optical testing will be reviewed. There are some references that the reader may consult for further details.[1]

13.3 CLASSICAL NONINTERFEROMETRIC TESTS

Some classical tests will never be obsolete, because they are cheap, simple, and provide qualitative results about the shape of the optical surface or wavefront almost instantly. These are the Foucault or knife-edge test, the Ronchi test, and the Hartmann test. They will be described next.

Foucault Test

The Foucault or knife-edge test was invented by Leon Foucault[2] in France, to evaluate the quality of spherical surfaces. This test described by Ojeda-Castañeda[3] detects the presence of transverse aberrations by intercepting the reflected rays deviated from their ideal trajectory, as Fig. 1 shows. The observer is behind the knife, looking at the illuminated optical surface, with the reflected rays entering the eye. The regions corresponding to the intercepted rays will appear dark, as in Fig. 2.

This test is extremely sensitive. If the wavefront is nearly spherical, irregularities as small as a fraction of the wavelength of the light may be easily detected. This is the simplest and most powerful qualitative test for observing small irregularities and evaluating the general smoothness of the spherical

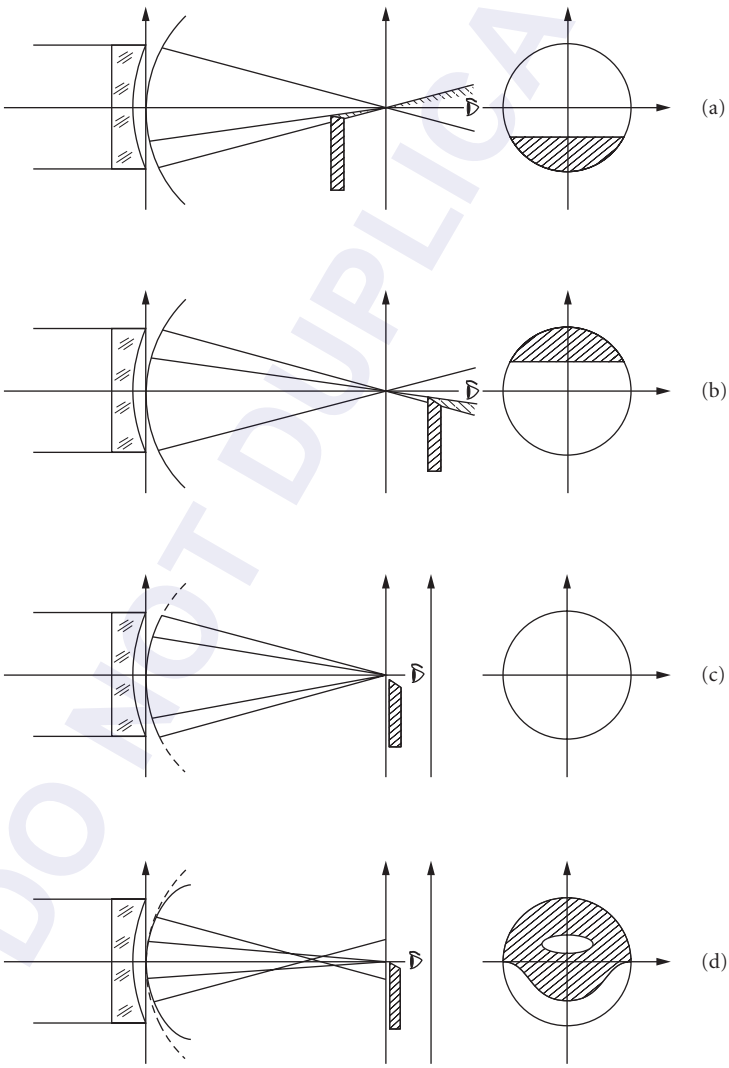

FIGURE 1 Optical schematics for the Foucault test of a spherical mirror at several positions of the knife edge.

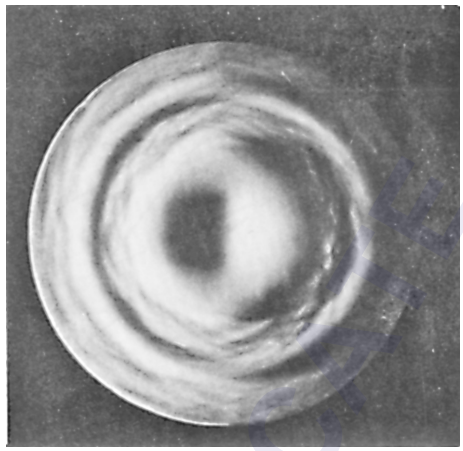

FIGURE 2 An optical surface being examined by the Foucault test. (*From Ojeda-Castañeda.*[3])

surface under test. Any other surface or lens may be tested, as long as it produces an almost spherical wavefront, otherwise, an aberration compensator must be used, as will be described later. Very often a razor blade makes a good, straight, sharp edge that is large enough to cover the focal region.

Ronchi Test

Vasco Ronchi[4] invented his famous test in Italy in 1923. A coarse ruling (50–100 lines per inch) is placed in the convergent light beam reflected from the surface under test, near its focus. The observer is behind the ruling, as Fig. 3 shows, with the light entering the eye. The dark bands in the ruling intercept light, forming shadows on the illuminated optical surface. These shadows will be straight and parallel only if the reflected wavefront is perfectly spherical. Otherwise, the fringes will be curves whose shape and separation depends on the wavefront deformations. The Ronchi test

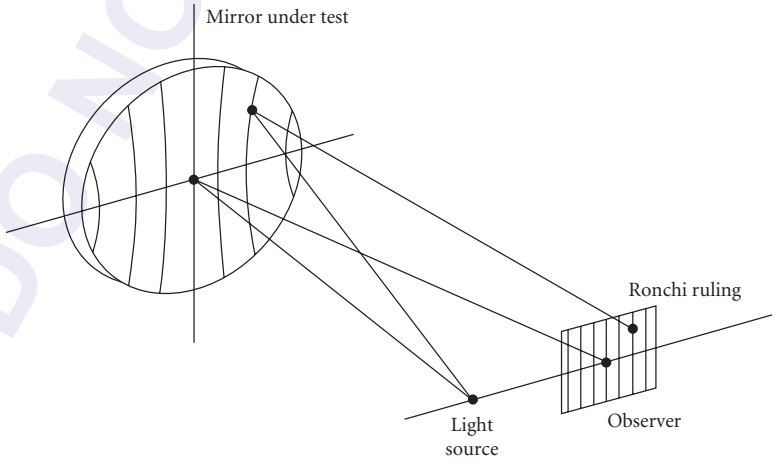

FIGURE 3 Testing a concave surface by means of the Ronchi test.

measures the transverse aberrations in the direction perpendicular to the slits on the grating. The wavefront deformations $W(x, y)$ are related to the transverse aberrations $TA_x(x, y)$ and $TA_y(x, y)$ by the following well-known relations:

$$TA_x(x, y) = -r\frac{\partial W(x, y)}{\partial x} \tag{1}$$

and

$$TA_y(x, y) = -r\frac{\partial W(x, y)}{\partial y} \tag{2}$$

where r is the radius of curvature of the wavefront $W(x, y)$. Thus, if we assume a ruling with period d, the expression describing the mth fringe on the optical surface is given by

$$\frac{\partial W(x, y)}{\partial x} = -\frac{md}{r} \tag{3}$$

Each type of aberration wavefront has a characteristic Ronchi pattern, as shown in Fig. 4; thus, the aberrations in the optical system may be easily identified, and their magnitude estimated. We may interpret the Ronchi fringes not only as geometrical shadows, but also as interferometric fringes, identical with those produced by a lateral shear interferometer.

Hartmann Test

J. Hartmann[5] invented his test in Germany. It is one of the most powerful methods to determine the figure of a concave spherical or aspherical mirror. Figure 5 shows the optical configuration used

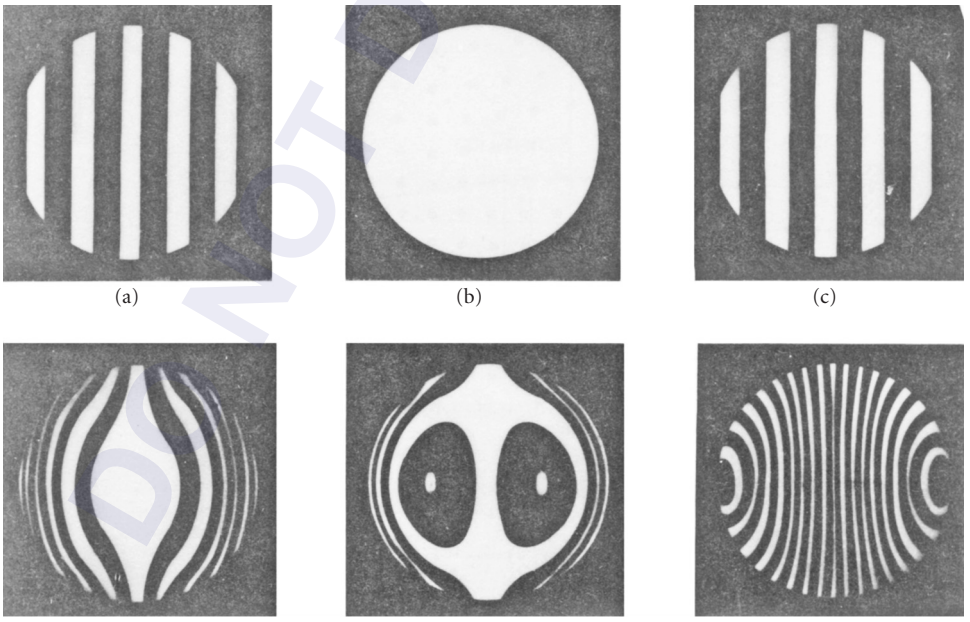

FIGURE 4 Typical Ronchi patterns for a spherical and a parabolic mirror for different positions of the Ronchi ruling.

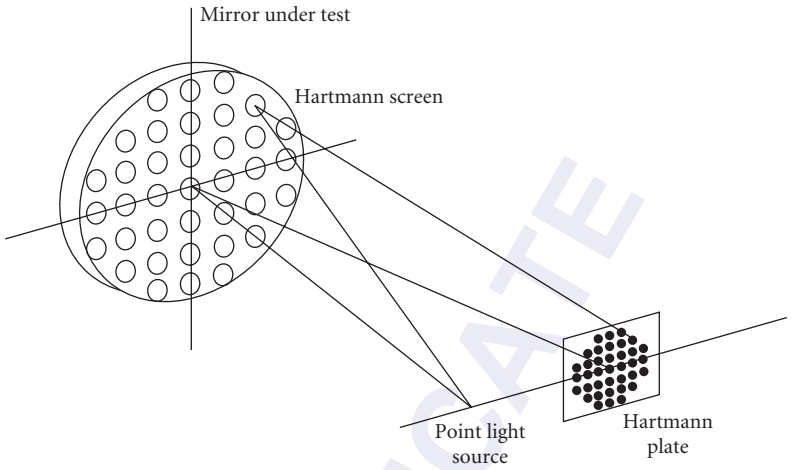

FIGURE 5 Optical arrangement to perform the Hartmann test.

in this test, where a point light source illuminates the optical surface, with its Hartmann screen in front of it. The light beams reflected through each hole on the screen are intercepted on a photographic plate near the focus. Then, the position of the recorded spots is measured to find the value of the transverse aberration on each point. If the screen has a rectangular array of holes, the typical Hartmann plate image for a parabolic mirror looks like that in Fig. 6. The wavefront $W(x, y)$ may be obtained from integration of Eqs. (1) and (2) as follows:

$$W(x, y) = -\frac{1}{r}\int_0^x TA_x(x, y)dx \tag{4}$$

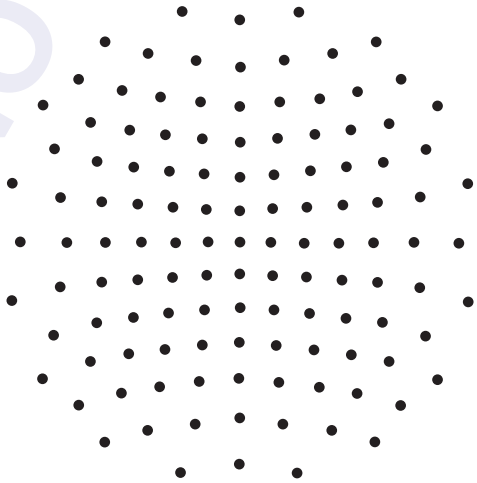

FIGURE 6 Array of spots in a Hartmann plate of a parabolic mirror.

and

$$W(x, y) = -\frac{1}{r}\int_0^y TA_y(x, y)dy \tag{5}$$

After numerical integration of the values of the transverse aberrations, this test provides the concave surface shape with very high accuracy. If the surface is not spherical, the transverse aberrations to be integrated are the difference between the measured values and the ideal values for a perfect surface. Extended, localized errors, as well as asymmetric errors like astigmatism, are detected with this test. The two main problems of this test are that small, localized defects are not detected if they are not covered by the holes on the screen. Not only is this information lost, but the integration results will be false if the localized errors are large. The second important problem of the Hartmann test is that it is very time consuming, due to the time used in measuring all the data points on the Hartmann plate. These problems are avoided by complementing this test with the Foucault test, using an Offner compensator, in order to be sure about the smoothness of the surface (discussed under "Measuring Aspherical Wavefronts"). Various stratagems are available to speed the process. These include modulating the light at different frequencies at each of the holes. Variations also include measuring in front of, behind, or at the focus to get slope information. This technique can be considered an experimental ray trace.

Hartmann-Shack Test

Platt and Shack,[6] proposed using a lenticular screen, instead of a screen with an array of holes, as illustrated in Fig. 7. This is a simple but important modification from the classic Hartmann. Some differences are
