HANDBOOK OF OPTICS

Volume I-V

Editor-in-Chief:
Michael Bass

Associate Editors:
Casimer M. DeCusatis
Jay M. Enoch
Vasudevan Lakshminarayanan
Guifang Li
Carolyn MacDonald
Virendra N. Mahajan
Eric Van Stryland

OSA

HANDBOOK OF OPTICS

ABOUT THE EDITORS

Editor-in-Chief: Dr. Michael Bass is professor emeritus at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

Associate Editors:
Dr. Casimer M. DeCusatis is a distinguished engineer and technical executive with IBM Corporation.

Dr. Jay M. Enoch is dean emeritus and professor at the School of Optometry at the University of California, Berkeley.

Dr. Vasudevan Lakshminarayanan is professor of Optometry, Physics, and Electrical Engineering at the University of Waterloo, Ontario, Canada.

Dr. Guifang Li is a professor at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

Dr. Carolyn MacDonald is a professor at the University at Albany, and director of the Center for X-Ray Optics.

Dr. Virendra N. Mahajan is a distinguished scientist at The Aerospace Corporation.

Dr. Eric Van Stryland is a professor at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

ISBN 978-0-07-175342-5, MHID 0-07-175342-7

The material in this eBook also appears in the print version of this title. ISBN: 978-0-07-170160-0, MHID: 0-07-170160-5.

COVER ILLUSTRATIONS

Left: Poincaré sphere describing light's polarization states is shown floating in front of a depolarized field of polarization ellipses, with linearly and circularly polarized fields propagating on its left and right, respectively. See Chaps. 12 and 15.

Middle: Triplet lens developed for photographic applications that can zero out the primary aberrations by splitting the positive lens of a doublet into two and placing one on each side of the negative lens. See Chap. 17.

Right: Micrographs of different optical storage media showing the straight and narrow tracks with 1.6-μm spacing between adjacent tracks. The recorded information bits appear as short marks along each track. See Chap. 35.

This page intentionally left blank.

CONTENTS OF VOLUME I

Chapter 15. Polarimetry *Russell A. Chipman* 15.1

Chapter 16. Ellipsometry *Rasheed M. A. Azzam* 16.1

Part 4. Components

Part 5. Instruments

CONTENTS OF VOLUME II

Part 1. Design

This page intentionally left blank.

CONTENTS OF VOLUME III

CONTENTS OF VOLUME IV

Part 1. Properties

CONTENTS OF VOLUME V

Part 1. Measurements

Part 2. Atmospheric Optics

Part 4. Fiber Optics

This page intentionally left blank.

CONTRIBUTORS TO HANDBOOK OF OPTICS

Jan P. Allebach *Electronic Imaging Systems Laboratory, School of Electrical and Computer Engineering, Purdue University, West Lafayette, Indiana* (VOL. III, CHAP. 24, "Human Vision and Electronic Imaging")

Joseph H. Altman *Institute of Optics, University of Rochester, Rochester, New York* (VOL. II, CHAP. 29, "Photographic Films")

Paul M. Amirtharaj *Sensors and Electron Devices Directorate, U.S. Army Research Laboratory, Adelphi, Maryland* (VOL. IV, CHAP. 5, "Optical Properties of Semiconductors")

Jeffrey Anshel *Corporate Vision Consulting, Encinitas, California* (VOL. III, CHAP. 23, "Vision Problems at Computers")

Ladan Arissian *Texas A&M University, College Station, Texas, and National Research Council of Canada, Ottawa, Ontario, Canada* (VOL. II, CHAP. 20, "Ultrashort Optical Sources and Applications")

Francisco Arregui *Public University Navarra, Pamplona, Spain* (VOL. V, CHAP. 24, "Optical Fiber Sensors")

Rasheed M. A. Azzam *Department of Electrical Engineering, University of New Orleans, New Orleans, Louisiana* (VOL. I, CHAP. 16, "Ellipsometry")

John D. Baloga *Imaging Materials and Media, Eastman Kodak Company, Rochester, New York* (VOL. II, CHAP. 30, "Photographic Materials")

Martin S. Banks *School of Optometry, University of California, Berkeley, California* (VOL. III, CHAP. 2, "Visual Performance")

Mark Bashkansky *Optical Sciences Division, Naval Research Laboratory, Washington, D.C.* (VOL. IV, CHAP. 15, "Stimulated Raman and Brillouin Scattering")

Michael Bass *CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida* (VOL. V, CHAP. 25, "High-Power Fiber Lasers and Amplifiers")

Marco W. Beijersbergen *Cosine Research B.V./Cosine Science & Computing B.V., Leiden University, Leiden, Netherlands* (VOL. V, CHAP. 49, "Pore Optics")

Leo Beiser *Consultant, Flushing, New York* (VOL. I, CHAP. 30, "Scanners")

Edward S. Bennett *College of Optometry, University of Missouri, St. Louis, Missouri* (VOL. III, CHAP. 20, "Optics of Contact Lenses")

Gisele Bennett *Electro-Optical Systems Laboratory and School of Electrical and Computer Engineering, Georgia Tech Research Institute, Georgia Institute of Technology, Atlanta, Georgia* (VOL. I, CHAP. 6, "Coherence Theory: Tools and Applications")

Jean M. Bennett* *Research Department, Michelson Laboratory, Naval Air Warfare Center, China Lake, California* (VOL. I, CHAPS. 12, 13, "Polarization", "Polarizers")

János A. Bergou *Institute for Quantum Studies and Department of Physics, Texas A&M University, College Station, Texas, and Department of Physics and Astronomy, Hunter College of the City University of New York, New York, New York* (VOL. II, CHAP. 23, "Quantum Theory of the Laser")

Paul R. Berman *Physics Department, University of Michigan, Ann Arbor, Michigan* (VOL. IV, CHAP. 11, "Coherent Optical Transients")

*Deceased.

Ellis Betensky *Opcon Associates, Inc., West Redding, Connecticut* (VOL. I, CHAP. 27, "Camera Lenses")

Donald H. Bilderback *Cornell High Energy Synchrotron Source, School of Applied and Engineering Physics, Cornell University, Ithaca, New York* (VOL. V, CHAP. 52, "Single Capillaries")

Craig F. Bohren *Pennsylvania State University, University Park, Pennsylvania* (VOL. I, CHAP. 7, "Scattering by Particles")

Glenn D. Boreman *CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida* (VOL. I, CHAP. 4, "Transfer Function Techniques")

John E. Bowers *Department of Electrical and Computer Engineering, University of California, Santa Barbara, California* (VOL. II, CHAP. 26, "High-Speed Photodetectors")

Arthur Bradley *School of Optometry, Indiana University, Bloomington, Indiana* (VOL. III, CHAP. 14, "Optics and Vision of the Aging Eye")

David H. Brainard *Department of Psychology, University of Pennsylvania, Philadelphia, Pennsylvania* (VOL. III, CHAPS. 10, 11, "Colorimetry", "Color Vision Mechanisms")

Robert P. Breault *Breault Research Organization, Tucson, Arizona* (VOL. II, CHAP. 7, "Control of Stray Light"; VOL. IV, CHAP. 6, "Characterization and Use of Black Surfaces for Optical Systems")

John A. Buck *Georgia Institute of Technology, School of Electrical and Computer Engineering, Atlanta, Georgia* (VOL. V, CHAPS. 10, 14, "Nonlinear Effects in Optical Fibers", "Optical Fiber Amplifiers")

Stephen A. Burns *School of Optometry, Indiana University, Bloomington, Indiana* (VOL. III, CHAP. 5, "Optical Generation of the Visual Stimulus")

Frank Carroll *MXISystems, Nashville, Tennessee* (VOL. V, CHAP. 59, "Inverse Compton X-Ray Sources")

William H. Carter* *Naval Research Laboratory, Washington, D.C.* (VOL. I, CHAP. 5, "Coherence Theory")

William Cassarly *Optical Research Associates, Pasadena, California* (VOL. II, CHAP. 39, "Nonimaging Optics: Concentration and Illumination")

Franco Cerrina *Department of Electrical and Computer Engineering, University of Wisconsin, Madison, Wisconsin* (VOL. V, CHAPS. 34, 35, 51, "Extreme Ultraviolet Lithography", "Ray Tracing of X-Ray Optical Systems", "The Schwarzschild Objective")

I-Cheng Chang *Accord Optics, Sunnyvale, California* (VOL. V, CHAP. 6, "Acousto-Optic Devices")

Zenghu Chang *Department of Physics, Kansas State University, Cardwell Hall, Manhattan, Kansas* (VOL. II, CHAP. 21, "Attosecond Optics")

Neil Charman *Department of Optometry and Vision Sciences, University of Manchester, Manchester, United Kingdom* (VOL. III, CHAP. 1, "Optics of the Eye")

Russell A. Chipman *College of Optical Sciences, University of Arizona, Tucson, Arizona* (VOL. I, CHAPS. 14, 15, "Mueller Matrices", "Polarimetry")

B. Ralph Chou *School of Optometry, University of Waterloo, Waterloo, Ontario, Canada* (VOL. III, CHAP. 12, "Assessment of Refraction and Refractive Errors and Their Influence on Optical Design")

Eugene L. Church *Instrumentation Division, Brookhaven National Laboratory, Upton, New York* (VOL. I, CHAP. 8, "Surface Scattering")

James H. Churnside *National Oceanic and Atmospheric Administration, Earth System Research Laboratory, Boulder, Colorado* (VOL. V, CHAP. 3, "Atmospheric Optics")

Richard O. Claus *Virginia Tech, Blacksburg, Virginia* (VOL. V, CHAP. 24, "Optical Fiber Sensors")

Ray Conley *X-Ray Science Division, Argonne National Laboratory, Argonne, Illinois, and National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, New York* (VOL. V, CHAP. 42, "Nanofocusing of Hard X-Rays with Multilayer Laue Lenses")

Sterling W. Cornaby *Cornell High Energy Synchrotron Source, School of Applied and Engineering Physics, Cornell University Ithaca, New York* (VOL. V, CHAP. 52, "Single Capillaries")

*Deceased.

Aaron Couture *GE Global Research Center, Niskayuna, New York* (VOL. V, CHAP. 61, "Advances in Imaging Detectors")

William Cowan *Department of Computer Science, University of Waterloo, Waterloo, Ontario, Canada* (VOL. III, CHAP. 22, "Displays for Vision Research")

M. George Craford *Hewlett-Packard Co., San Jose, California* (VOL. II, CHAP. 17, "Light-Emitting Diodes")

Katherine Creath *Optineering, Tucson, Arizona, and College of Optical Sciences, University of Arizona, Tucson, Arizona* (VOL. II, CHAP. 14, "Use of Computer-Generated Holograms in Optical Testing")

Mark Cronin-Golomb *Department of Biomedical Engineering, Tufts University, Medford, Massachusetts* (VOL. IV, CHAP. 12, "Photorefractive Materials and Devices")

Guang-ming Dai *Laser Vision Correction Group, Advanced Medical Optics, Milpitas, California* (VOL. V, CHAP. 4, "Imaging through Atmospheric Turbulence")

Johannes F. de Boer *Department of Physics,VU University, Amsterdam, and Rotterdam Ophthalmic Institute, Rotterdam, The Netherlands* (VOL. III, CHAP. 18, "Diagnostic Use of Optical Coherence Tomography in the Eye")

Casimer DeCusatis *IBM Corporation, Poughkeepsie, New York* (VOL. V, CHAPS. 15, 23, "Fiber Optic Communication Links (Telecom, Datacom, and Analog)", "Fiber-Optic Communication Standards")

Peter J. Delfyett *CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida* (VOL. V, CHAP. 20, "Optical Time-Division Multiplexed Communication Networks")

Pamela L. Derry *Boeing Defense & Space Group, Seattle, Washington* (VOL. II, CHAP. 19, "Semiconductor Lasers")

L. Diaz-Santana *Department of Optometry and Visual Science, City University, London, United Kingdom* (VOL. III, CHAP. 16, "Refractive Surgery, Correction of Vision, PRK, and Lasik")

Alain C. Diebold *College of Nanoscale Science and Engineering, University at Albany, Albany, New York* (VOL. IV, CHAP. 5, "Optical Properties of Semiconductors")

Jean-Claude Diels *Departments of Physics and Electrical Engineering, University of New Mexico, Albuquerque, New Mexico* (VOL. II, CHAP. 20, "Ultrashort Optical Sources and Applications")

Todd Ditmire *Texas Center for High Intensity Laser Science, Department of Physics, The University of Texas at Austin, Austin, Texas* (VOL. IV, CHAP. 21, "Strong Field Physics")

Jerzy A. Dobrowolski *Institute for Microstructural Sciences, National Research Council of Canada, Ottawa, Ontario, Canada* (VOL. IV, CHAP. 7, "Optical Properties of Films and Coatings")

Aristide Dogariu *CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida* (VOL. I, CHAP. 9, "Volume Scattering in Random Media")

Jonathan P. Dowling *Hearne Institute for Theoretical Physics, Department of Physics and Astronomy, Louisiana State University, Baton Rouge, Louisiana* (VOL. IV, CHAP. 23, "Quantum Entanglement in Optical Interferometry")

Majid Ebrahim-Zadeh *ICFO—Institut de Ciencies Fotoniques, Mediterranean Technology Park, Barcelona, Spain, and Institucio Catalana de Recerca i Estudis Avancats (ICREA), Passeig Lluis Companys, Barcelona, Spain* (VOL. IV, CHAP. 17, "Continuous-Wave Optical Parametric Oscillators")

Jeremy Ellis *CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida* (VOL. I, CHAP. 9, "Volume Scattering in Random Media")

Berthold-Georg Englert *Institute for Quantum Studies and Department of Physics, Texas A&M University, College Station, Texas, and Max-Planck-Institut für Quantenoptik, Garching bei München, Germany, and Abteilung Quantenphysik der Universität Ulm, Ulm, Germany* (VOL. II, CHAP. 23, "Quantum Theory of the Laser")

Jay M. Enoch *School of Optometry, University of California at Berkeley, Berkeley, California* (VOL. III, CHAPS. 8, 9, "Biological Waveguides", "The Problem of Correction for the Stiles-Crawford Effect of the First Kind in Radiometry and Photometry, a Solution")

Chris J. Evans *Zygo Corporation, Middlefield, Connecticut* (VOL. II, CHAP. 10, "Fabrication of Optics by Diamond Turning")

Bart Farell *Institute for Sensory Research, Syracuse University, Syracuse, New York* (VOL. III, CHAP. 3, "Psychophysical Methods")

Michael W. Farn *MIT/Lincoln Laboratory, Lexington, Massachusetts* (VOL. I, CHAP. 23, "Binary Optics")

Luis Figueroa *Boeing Defense & Space Group, Seattle, Washington* (VOL. II, CHAP. 19, "Semiconductor Lasers")

Ronald Frahm *Bergische Universität Wuppertal, Wuppertal, Germany* (VOL. V, CHAP. 30, "Requirements for X-Ray Spectroscopy")

Robert Q. Fugate *Starfire Optical Range, Directed Energy Directorate, Air Force Research Laboratory, Kirtland Air Force Base, New Mexico* (VOL. V, CHAP. 5, "Adaptive Optics")

Lars R. Furenlid *University of Arizona, Tucson, Arizona* (VOL. V, CHAP. 32, "Requirements for Nuclear Medicine")

Elsa Garmire *Dartmouth College, Hanover, New Hampshire* (VOL. V, CHAP. 13, "Sources, Modulators, and Detectors for Fiber Optic Communication Systems")

Sebastian Gauza *CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida* (VOL. V, CHAP. 8, "Liquid Crystals")

Wilson S. Geisler *Department of Psychology, University of Texas, Austin, Texas* (VOL. III, CHAP. 2, "Visual Performance")

Walter Gibson *X-Ray Optical Systems, Inc., East Greenbush, New York* (VOL. V, CHAPS. 29, 53, 60, "Requirements for X-Ray Fluorescence", "Polycapillary X-Ray Optics", "Introduction to X-Ray Detectors")

Harilaos Ginis *Institute of Vision and Optics, University of Crete, Greece* (VOL. III, CHAP. 16, "Refractive Surgery, Correction of Vision, PRK, and Lasik")

Norman Goldberg *Madison, Wisconsin* (VOL. I, CHAP. 25, "Cameras")

Douglas S. Goodman *Corning Tropel Corporation, Fairport, New York* (VOL. I, CHAP. 1, "General Principles of Geometrical Optics")

Joseph W. Goodman *Department of Electrical Engineering, Stanford University, Stanford, California* (VOL. I, CHAP. 11, "Analog Optical Signal and Image Processing")

John E. Greivenkamp *College of Optical Sciences, University of Arizona, Tucson, Arizona* (VOL. I, CHAP. 2, "Interference")

Mikhail Gubarev *NASA/Marshall Space Flight Center, Huntsville, Alabama* (VOL. V, CHAP. 64, "Grazing-Incidence Neutron Optics")

Eric M. Gullikson *Center for X-Ray Optics, Lawrence Berkeley National Laboratory, Berkeley, California* (VOL. V, CHAP. 36, "X-Ray Properties of Materials")

Anurag Gupta *Optical Research Associates, Tucson, Arizona* (VOL. II, CHAP. 40, "Lighting and Applications")

David J. Hagan *CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida* (VOL. IV, CHAP. 13, "Optical Limiting")

Roland H. Haitz *Hewlett-Packard Co., San Jose, California* (VOL. II, CHAP. 17, "Light-Emitting Diodes")

Thomas Halfmann *Institute of Applied Physics, Technical University of Darmstadt, Darmstadt, Germany* (VOL. IV, CHAP. 14, "Electromagnetically Induced Transparency")

John L. Hall *JILA, University of Colorado and National Institute of Standards and Technology, Boulder, Colorado* (VOL. II, CHAP. 22, "Laser Stabilization")

Parameswaran Hariharan *School of Physics, University of Sydney, Sydney, Australia* (VOL. I, CHAP. 32, "Interferometers")

Michael E. Harrigan *Harrigan Optical Design, Victor, New York* (VOL. II, CHAP. 2, "Aberration Curves in Lens Design")

James A. Harrington *Rutgers University, Piscataway, New Jersey* (VOL. V, CHAP. 12, "Infrared Fibers")

James E. Harvey *CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida* (VOL. V, CHAP. 44, "Reflective Optics")

Michael P. Hasselbeck *Department of Physics and Astronomy, University of New Mexico, Albuquerque, New Mexico* (VOL. IV, CHAP. 16, "Third-Order Optical Nonlinearities")

George Havrilla *Los Alamos National Laboratory, Los Alamos, New Mexico* (VOL. V, CHAP. 29, "Requirements for X-Ray Fluorescence")

Brian Henderson *Department of Physics and Applied Physics, University of Strathclyde, Glasgow, United Kingdom* (VOL. I, CHAPS. 10, 31, "Optical Spectroscopy and Spectroscopic Lineshapes", "Optical Spectrometers"; VOL. V, CHAP. 2, "Spectroscopic Measurements")

Kenneth O. Hill *Communications Research Centre, Ottawa, Ontario, Canada, and Nu-Wave Photonics, Ottawa, Ontario, Canada* (VOL. V, CHAP. 17, "Fiber Bragg Gratings")

Gerald C. Holst *JCD Publishing, Winter Park, Florida* (VOL. I, CHAP. 26, "Solid-State Cameras")

Chi-Shain Hong *Boeing Defense & Space Group, Seattle, Washington* (VOL. II, CHAP. 19, "Semiconductor Lasers")

Malcolm R. Howells *Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California* (VOL. V, CHAP. 38, "Gratings and Monochromators in the VUV and Soft X-Ray Spectral Region")

Lloyd Huff *Research Institute, University of Dayton, Dayton, Ohio* (VOL. I, CHAP. 33, "Holography and Holographic Instruments")

Steven L. Hulbert *National Synchrotron Light Source, Brookhaven National Laboratory, Upton, New York* (VOL. V, CHAP. 55, "Synchrotron Sources")

Sean D. Huver *Hearne Institute for Theoretical Physics, Department of Physics and Astronomy, Louisiana State University, Baton Rouge, Louisiana* (VOL. IV, CHAP. 23, "Quantum Entanglement in Optical Interferometry")

Ira Jacobs *The Bradley Department of Electrical and Computer Engineering, Virginia Polytechnic Institute and State University, Blacksburg, Virginia* (VOL. V, CHAP. 9, "Optical Fiber Communication Technology and System Overview")

J. Christopher James *Electro-Optical Systems Laboratory, Georgia Tech Research Institute, Georgia Institute of Technology, Atlanta, Georgia* (VOL. I, CHAP. 6, "Coherence Theory: Tools and Applications")

Fan Jiang *Electrical and Computer Engineering & Center for Nano Technology, University of Wisconsin, Madison* (VOL. V, CHAP. 34, "Extreme Ultraviolet Lithography")

C. Bruce Johnson *Johnson Scientific Group, Inc., Phoenix, Arizona* (VOL. II, CHAP. 31, "Image Tube Intensified Electronic Imaging")

R. Barry Johnson *Consultant, Huntsville, Alabama* (VOL. I, CHAPS. 17, 30, "Lenses", "Scanners")

Lloyd Jones *College of Optical Sciences, University of Arizona, Tucson, Arizona* (VOL. I, CHAP. 29, "Reflective and Catadioptric Objectives")

Abhay M. Joshi *Discovery Semiconductors, Inc., Cranbury, New Jersey* (VOL. II, CHAP. 25, "Photodetection")

Marshall K. Joy *National Aeronautics and Space Administration, Marshall Space Flight Center, Huntsville, Alabama* (VOL. V, CHAP. 47, "Astronomical X-Ray Optics")

Hyon Chol Kang *Materials Science Division, Argonne National Laboratory, Argonne, Illinois, and Advanced Materials Engineering Department, Chosun University, Gwangju, Republic of Korea* (VOL. V, CHAP. 42, "Nanofocusing of Hard X-Rays with Multilayer Laue Lenses")

Victor Kantsyrev *Physics Department, University of Nevada, Reno, Nevada* (VOL. V, CHAP. 57, "Pinch Plasma Sources")

Ursula Keller *Institute of Quantum Electronics, Physics Department, Swiss Federal Institute of Technology (ETH), Zurich, Switzerland* (VOL. IV, CHAP. 18, "Nonlinear Optical Processes for Ultrashort Pulse Generation")

Ali Khounsary *Argonne National Laboratory, Argonne, Illinois* (VOL. V, CHAP. 50, "Adaptive X-Ray Optics")

Jacob B. Khurgin *Department of Electrical and Computer Engineering, Johns Hopkins University, Baltimore, Maryland* (VOL. IV, CHAP. 22, "Slow Light Propagation in Atomic and Photonic Media")

Dennis K. Killinger *Center for Laser Atmospheric Sensing, Department of Physics, University of South Florida, Tampa, Florida* (VOL. V, CHAP. 3, "Atmospheric Optics")

Marvin Klein *Intelligent Optical Systems, Inc., Torrance, California* (VOL. IV, CHAP. 12, "Photorefractive Materials and Devices")

Thomas L. Koch *Lehigh University, Bethlehem, Pennsylvania* (VOL. I, CHAP. 21, "Integrated Optics")

R. John Koshel *Photon Engineering LLC, and College of Optical Sciences, University of Arizona, Tucson, Arizona* (VOL. II, CHAP. 40, "Lighting and Applications")

Walter F. Kosonocky* *New Jersey Institute of Technology, University Heights, Newark, New Jersey* (VOL. II, CHAP. 33, "Infrared Detector Arrays")

Lester J. Kozlowski *Altasens, Inc., Westlake Village, California* (VOL. II, CHAP. 33, "Infrared Detector Arrays")

Melvin H. Kreitzer *Opcon Associates, Inc., Cincinnati, Ohio* (VOL. I, CHAP. 27, "Camera Lenses")

Paul W. Kruse *Consultant, Edina, Minnesota* (VOL. II, CHAP. 28, "Thermal Detectors")

Vasudevan Lakshminarayanan *School of Optometry and Departments of Physics and Electrical Engineering, University of Waterloo, Waterloo, Ontario, Canada* (VOL. III, CHAPS. 8, 9, "Biological Waveguides", "The Problem of Correction for the Stiles-Crawford Effect of the First Kind in Radiometry and Photometry, a Solution")

Anthony LaRocca† *General Dynamics, Advanced Information Systems, Ypsilanti, Michigan* (VOL. II, CHAP. 15, "Artificial Sources")

Melvin Lax* *Department of Physics, City College of the City University of New York, New York, New York* (VOL. II, CHAP. 23, "Quantum Theory of the Laser")

Hwang Lee *Hearne Institute for Theoretical Physics, Department of Physics and Astronomy, Louisiana State University, Baton Rouge, Louisiana* (VOL. IV, CHAP. 23, "Quantum Entanglement in Optical Interferometry")

Susanne M. Lee *GE Global Research, Nikayuna, New York* (VOL. V, CHAP. 54, "X-Ray Tube Sources")

Bruno Lengeler *Physikalisches Institut, RWTH Aachen University, Aachen, Germany* (VOL. V, CHAP. 37, "Refractive X-Ray Lenses")

Frederick J. Leonberger *MIT Center for Integrated Photonic Systems, Cambridge, Massachusetts* (VOL. I, CHAP. 21, "Integrated Optics")

Guifang Li *CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida* (VOL. V, CHAP. 15, "Fiber Optic Communication Links (Telecom, Datacom, and Analog)")

Eric Lifshin *College of Nanoscale Science and Engineering,University at Albany, Albany, New York* (VOL. V, CHAP. 62, "X-Ray Spectral Detection and Imaging")

Chian Liu *X-Ray Science Division, Argonne National Laboratory, Argonne, Illinois* (VOL. V, CHAP. 42, "Nanofocusing of Hard X-Rays with Multilayer Laue Lenses")

Dirk Lützenkirchen-Hecht *Bergische Universität Wuppertal, Wuppertal, Germany* (VOL. V, CHAP. 30, "Requirements for X-Ray Spectroscopy")

John D. Lytle *Advanced Optical Concepts, Santa Cruz, California* (VOL. IV, CHAP. 3, "Polymeric Optics")

Carolyn MacDonald *University at Albany, Albany, New York* (VOL. V, CHAPS. 26, 53, 54, "An Introduction to X-Ray and Neutron Optics", "Polycapillary X-Ray Optics", "X-Ray Tube Sources")

Albert T. Macrander *X-Ray Science Division, Argonne National Laboratory, Argonne, Illinois* (VOL. V, CHAP. 42, "Nanofocusing of Hard X-Rays with Multilayer Laue Lenses")

Virendra N. Mahajan *The Aerospace Corporation, El Segundo, California* (VOL. II, CHAP. 11, "Orthonormal Polynomials in Wavefront Analysis"; VOL. V, CHAP. 4, "Imaging through Atmospheric Turbulence")

*Deceased.
†Retired.

Daniel Malacara-Hernández *Centro de Investigaciones en Óptica, A. C., León, Gto., México* (VOL. II, CHAPS. 12, 13, "Optical Metrology", "Optical Testing")

Zacarías Malacara *Centro de Investigaciones en Óptica, A. C., León, Gto., México* (VOL. II, CHAP. 12, "Optical Metrology")

Theresa A. Maldonado *Department of Electrical and Computer Engineering, Texas A&M University, College Station, Texas* (VOL. V, CHAP. 7, "Electro-Optic Modulators")

Pavel V. Mamyshev *Bell Laboratories—Lucent Technologies, Holmdel, New Jersey* (VOL. V, CHAP. 22, "Solitons in Optical Fiber Communication Systems")

Michael P. Mandina *Brandon Light, Optimax Systems, Inc., Ontario, New York* (VOL. II, CHAP. 9, "Optical Fabrication")

Masud Mansuripur *College of Optical Sciences, University of Arizona, Tucson, Arizona* (VOL. I, CHAP. 35, "Principles of Optical Disk Data Storage")

COVER ILLUSTRATIONS

Left: Poincaré sphere describing light's polarization states is shown floating in front of a depolarized field of polarization ellipses, with linearly and circularly polarized fields propagating on its left and right, respectively. See Chaps. 12 and 15.

Middle: Triplet lens developed for photographic applications that can zero out the primary aberrations by splitting the positive lens of a doublet into two and placing one on each side of the negative lens. See Chap. 17.

Right: Micrographs of different optical storage media showing the straight and narrow tracks with 1.6-μm spacing between adjacent tracks. The recorded information bits appear as short marks along each track. See Chap. 35.

EDITORS' PREFACE

The third edition of the *Handbook of Optics* is designed to pull together the dramatic developments in both the basic and applied aspects of the field while retaining the archival, reference book value of a handbook. This means that it is much more extensive than either the first edition, published in 1978, or the second edition, with Volumes I and II appearing in 1995 and Volumes III and IV in 2001. To cover the greatly expanded field of optics, the *Handbook* now appears in five volumes. Over 100 authors or author teams have contributed to this work.

Volume I is devoted to the fundamentals, components, and instruments that make optics possible. Volume II contains chapters on design, fabrication, testing, sources of light, detection, and a new section devoted to radiometry and photometry. Volume III concerns vision optics only and is printed entirely in color. In Volume IV there are chapters on the optical properties of materials, nonlinear, quantum and molecular optics. Volume V has extensive sections on fiber optics and x ray and neutron optics, along with shorter sections on measurements, modulators, and atmospheric optical properties and turbulence. Several pages of color inserts are provided where appropriate to aid the reader. A purchaser of the print version of any volume of the *Handbook* will be able to download a digital version containing all of the material in that volume in PDF format to one computer (see download instructions on bound-in card). The combined index for all five volumes can be downloaded from www.HandbookofOpticsOnline.com.

It is possible by careful selection of what and how to present that the third edition of the *Handbook* could serve as a text for a comprehensive course in optics. In addition, students who take such a course would have the *Handbook* as a career-long reference.

Topics were selected by the editors so that the *Handbook* could be a desktop (bookshelf) general reference for the parts of optics that had matured enough to warrant archival presentation. New chapters were included on topics that had reached this stage since the second edition, and existing chapters from the second edition were updated where necessary to provide this compendium. In selecting subjects to include, we also had to select which subjects to leave out. The criteria we applied were: (1) was it a specific application of optics rather than a core science or technology and (2) was it a subject in which the role of optics was peripheral to the central issue addressed. Thus, such topics as medical optics, laser surgery, and laser materials processing were not included. While applications of optics are mentioned in the chapters there is no space in the *Handbook* to include separate chapters devoted to all of the myriad uses of optics in today's world. If we had, the third edition would be much longer than it is and much of it would soon be outdated. We designed the third edition of the *Handbook of Optics* so that it concentrates on the principles of optics that make applications possible.

Authors were asked to try to achieve the dual purpose of preparing a chapter that was a worthwhile reference for someone working in the field and that could be used as a starting point to become acquainted with that aspect of optics. They did that and we thank them for the outstanding results seen throughout the *Handbook*. We also thank Mr. Taisuke Soda of McGraw-Hill for his help in putting this complex project together and Mr. Alan Tourtlotte and Ms. Susannah Lehman of the Optical Society of America for logistical help that made this effort possible.

We dedicate the third edition of the *Handbook of Optics* to all of the OSA volunteers who, since OSA's founding in 1916, give their time and energy to promoting the generation, application, archiving, and worldwide dissemination of knowledge in optics and photonics.

PREFACE TO VOLUME I

The third edition of the *Handbook of Optics* has been completely reorganized, expanded, and updated. The four volumes of the second edition grew to five in the current edition. Each volume is divided into parts, where each part, sometimes referred to as a section, consists of several chapters related to a certain topic. Volumes I and II are devoted primarily to the basic concepts of optics and optical phenomena, sometimes called classical optics. Volume I starts with geometrical optics and continues with physical optics. This includes interference, diffraction, coherence theory, and scattering. A new chapter on tools and applications of coherence theory has been added. A several-chapter section follows devoted to issues of polarized light. The chapter on polarimetry has been updated and its content on the Mueller matrices now appears in a separate chapter by that title. Next there are chapters on components such as lenses, afocal systems, nondispersive and dispersive prisms, and special optics that include integrated, miniature and micro-, binary, and gradient index optics. Finally, there are several chapters on instruments. They include cameras and camera lenses, microscopes, reflective and catadioptric objectives, scanners, spectrometers, interferometers, xerographic systems, and optical disc data storage.

There are many other chapters in this edition of the *Handbook* that could have been included in Volumes I and II. However, page limitations prevented that. For example, in Volume V there is a section on Atmospheric Optics. It consists of three chapters, one on transmission through the atmosphere, another on imaging through atmospheric turbulence, and a third on adaptive optics to overcome some of the deleterious effects of turbulence.

The chapters are generally aimed at the graduate students, though practicing scientists and engineers will find them equally suitable as references on the topics discussed. Each chapter has sufficient references for additional and/or further study.

The whole *Handbook* has been retyped and the figures redrawn. The reader will find that the figures in the new edition are crisp. Ms. Arushi Chawla and her team from Glyph International have done an outstanding job in accomplishing this monumental task. Many of the authors updated and proofread their chapters. However, some authors have passed away since the second edition and others couldn't be located. Every effort has been made to ensure that such chapters have been correctly reproduced.

GLOSSARY AND FUNDAMENTAL CONSTANTS

Introduction

This glossary of the terms used in the *Handbook* represents to a large extent the language of optics. The symbols are representations of numbers, variables, and concepts. Although the basic list was compiled by the author of this section, all the editors have contributed and agreed to this set of symbols and definitions. Every attempt has been made to use the same symbols for the same concepts throughout the entire *Handbook,* although there are exceptions. Some symbols seem to be used for many concepts. The symbol α is a prime example, as it is used for absorptivity, absorption coefficient, coefficient of linear thermal expansion, and more. Although we have tried to limit this kind of redundancy, we have also bowed deeply to custom.

Units

The abbreviations for the most common units are given first. They are consistent with most of the established lists of symbols, such as given by the International Standards Organization ISO[1] and the International Union of Pure and Applied Physics, IUPAP.[2]

Prefixes

Similarly, a list of the numerical prefixes[1] that are most frequently used is given, along with both the common names (where they exist) and the multiples of ten that they represent.

Fundamental Constants

The values of the fundamental constants[3] are listed following the sections on SI units.

Symbols

The most commonly used symbols are then given. Most chapters of the *Handbook* also have a glossary of the terms and symbols specific to them for the convenience of the reader. In the following list, the symbol is given, its meaning is next, and the most customary unit of measure for the quantity is presented in brackets. A bracket with a dash in it indicates that the quantity is unitless. Note that there is a difference between units and dimensions. An angle has units of degrees or radians and a solid angle square degrees or steradians, but both are pure ratios and are dimensionless. The unit symbols as recommended in the SI system are used, but decimal multiples of some of the dimensions are sometimes given. The symbols chosen, with some cited exceptions, are also those of the first two references.

RATIONALE FOR SOME DISPUTED SYMBOLS

The choice of symbols is a personal decision, but commonality improves communication. This section explains why the editors have chosen the preferred symbols for the *Handbook*. We hope that this will encourage more agreement.

Fundamental Constants

It is encouraging that there is almost universal agreement for the symbols for the fundamental constants. We have taken one small exception by adding a subscript B to the k for Boltzmann's constant.

Mathematics

We have chosen i as the imaginary almost arbitrarily. IUPAP lists both i and j, while ISO does not report on these.

Spectral Variables

These include expressions for the wavelength λ, frequency ν, wave number σ, ω for circular or radian frequency, k for circular or radian wave number and dimensionless frequency x. Although some use f for frequency, it can be easily confused with electronic or spatial frequency. Some use $\tilde{\nu}$ for wave number, but, because of typography problems and agreement with ISO and IUPAP, we have chosen σ; it should not be confused with the Stefan-Boltzmann constant. For spatial frequencies we have chosen ξ and η, although f_x and f_y are sometimes used. ISO and IUPAP do not report on these.

Radiometry

Radiometric terms are contentious. The most recent set of recommendations by ISO and IUPAP are L for radiance [$Wcm^{-2}sr^{-1}$], M for radiant emittance or exitance [Wcm^{-2}], E for irradiance or incidance [Wcm^{-2}], and I for intensity [Wsr^{-2}]. The previous terms, W, H, N, and J, respectively, are still in many texts, notably Smith[4] and Lloyd[5] but we have used the revised set, although there are still shortcomings. We have tried to deal with the vexatious term *intensity* by using *specific intensity* when the units are $Wcm^{-2}sr^{-1}$, *field intensity* when they are Wcm^{-2}, and *radiometric intensity* when they are Wsr^{-1}.

There are two sets to terms for these radiometric quantities, which arise in part from the terms for different types of reflection, transmission, absorption, and emission. It has been proposed that the *ion* ending indicate a process, that the *ance* ending indicate a value associated with a particular sample, and that the *ivity* ending indicate a generic value for a "pure" substance. Then one also has reflectance, transmittance, absorptance, and emittance as well as reflectivity, transmissivity, absorptivity, and emissivity. There are now two different uses of the word emissivity. Thus the words *exitance, incidence,* and *sterance* were coined to be used in place of emittance, irradiance, and radiance. It is interesting that ISO uses radiance, exitance, and irradiance whereas IUPAP uses radiance excitance [*sic*], and irradiance. We have chosen to use them both, i.e., emittance, irradiance, and radiance will be followed in square brackets by exitance, incidence, and sterance (or vice versa). Individual authors will use the different endings for transmission, reflection, absorption, and emission as they see fit.

We are still troubled by the use of the symbol E for irradiance, as it is so close in meaning to electric field, but we have maintained that accepted use. The spectral concentrations of these quantities, indicated by a wavelength, wave number, or frequency subscript (e.g., L_λ) represent partial differentiations; a subscript q represents a photon quantity; and a subscript ν indicates a quantity normalized to the response of the eye. Thereby, L_ν is luminance, E_ν illuminance, and M_ν and I_ν luminous emittance and luminous intensity. The symbols we have chosen are consistent with ISO and IUPAP.

The refractive index may be considered a radiometric quantity. It is generally complex and is indicated by $\tilde{n} = n - ik$. The real part is the relative refractive index and k is the extinction coefficient. These are consistent with ISO and IUPAP, but they do not address the complex index or extinction coefficient.

Optical Design

For the most part ISO and IUPAP do not address the symbols that are important in this area.

There were at least 20 different ways to indicate focal ratio; we have chosen FN as symmetrical with NA; we chose f and efl to indicate the effective focal length. Object and image distance, although given many different symbols, were finally called s_o and s_i since s is an almost universal symbol for distance. Field angles are θ and ϕ; angles that measure the slope of a ray to the optical axis are u; u can also be sin u. Wave aberrations are indicated by W_{ijk}, while third-order ray aberrations are indicated by σ_i and more mnemonic symbols.

Electromagnetic Fields

There is no argument about **E** and **H** for the electric and magnetic field strengths, Q for quantity of charge, ρ for volume charge density, σ for surface charge density, etc. There is no guidance from Refs. 1 and 2 on polarization indication. We chose $\perp$ and || rather than p and s, partly because s is sometimes also used to indicate scattered light.

There are several sets of symbols used for reflection transmission, and (sometimes) absorption, each with good logic. The versions of these quantities dealing with field amplitudes are usually specified with lower case symbols: r, t, and a. The versions dealing with power are alternately given by the uppercase symbols or the corresponding Greek symbols: R and T versus ρ and τ. We have chosen to use the Greek, mainly because these quantities are also closely associated with Kirchhoff's law that is usually stated symbolically as $\alpha = \epsilon$. The law of conservation of energy for light on a surface is also usually written as $\alpha + \rho + \tau = 1$.

Base SI Quantities

length	m	meter
time	s	second
mass	kg	kilogram
electric current	A	ampere
temperature	K	kelvin
amount of substance	mol	mole
luminous intensity	cd	candela

Derived SI Quantities

energy	J	joule
electric charge	C	coulomb
electric potential	V	volt
electric capacitance	F	farad
electric resistance	Ω	ohm
electric conductance	S	siemens
magnetic flux	Wb	weber
inductance	H	henry
pressure	Pa	pascal
magnetic flux density	T	tesla
frequency	Hz	hertz
power	W	watt
force	N	newton
angle	rad	radian
angle	sr	steradian

Prefixes

Symbol	*Name*	*Common name*	*Exponent of ten*
F	exa		18
P	peta		15
T	tera	trillion	12
G	giga	billion	9
M	mega	million	6
k	kilo	thousand	3
h	hecto	hundred	2
da	deca	ten	1
d	deci	tenth	–1
c	centi	hundredth	–2
m	milli	thousandth	–3
μ	micro	millionth	–6
n	nano	billionth	–9
p	pico	trillionth	–12
f	femto		–15
a	atto		–18

Constants

c	speed of light vacuo [299792458 ms^{-1}]
c_1	first radiation constant = $2\pi c^2 h = 3.7417749 \times 10^{-16}$ [Wm^2]
c_2	second radiation constant = hc/k = 0.014838769 [mK]
e	elementary charge [$1.60217733 \times 10^{-19}$ C]
g_n	free fall constant [9.80665 ms^{-2}]
h	Planck's constant [$6.6260755 \times 10^{-34}$ Ws]
k_B	Boltzmann constant [1.380658×10^{-23} JK^{-1}]
m_e	mass of the electron [$9.1093897 \times 10^{-31}$ kg]
N_A	Avogadro constant [6.0221367×10^{23} mol^{-1}]
R_∞	Rydberg constant [10973731.534 m^{-1}]
ϵ_o	vacuum permittivity [$\mu_o^{-1} c^{-2}$]
σ	Stefan-Boltzmann constant [5.67051×10^{-8} Wm^{-1} K^{-4}]
μ_o	vacuum permeability [$4\pi \times 10^{-7}$ NA^{-2}]
μ_B	Bohr magneton [$9.2740154 \times 10^{-24}$ JT^{-1}]

General

B	magnetic induction [Wbm^{-2}, kgs^{-1} C^{-1}]
C	capacitance [f, C^2 s^2 m^{-2} kg^{-1}]
C	curvature [m^{-1}]
c	speed of light in vacuo [ms^{-1}]
c_1	first radiation constant [Wm^2]
c_2	second radiation constant [mK]
D	electric displacement [Cm^{-2}]
E	incidance [irradiance] [Wm^{-2}]
e	electronic charge [coulomb]
E_v	illuminance [lux, lmm^{-2}]
E	electrical field strength [Vm^{-1}]
E	transition energy [J]
E_g	band-gap energy [eV]
f	focal length [m]
f_c	Fermi occupation function, conduction band
f_v	Fermi occupation function, valence band

FN	focal ratio (f/number) [—]
g	gain per unit length [m^{-1}]
g_{th}	gain threshold per unit length [m^1]
H	magnetic field strength [Am^{-1}, Cs^{-1} m^{-1}]
h	height [m]
I	irradiance (see also E) [Wm^{-2}]
I	radiant intensity [Wsr^{-1}]
I	nuclear spin quantum number [—]
I	current [A]
i	$\sqrt{-1}$
Im()	imaginary part of
J	current density [Am^{-2}]
j	total angular momentum [kg m^2 s^{-1}]
$J_1()$	Bessel function of the first kind [—]
k	radian wave number $=2\pi/\lambda$ [rad cm^{-1}]
k	wave vector [rad cm^{-1}]
k	extinction coefficient [—]
L	sterance [radiance] [Wm^{-2} sr^{-1}]
L_v	luminance [cdm^{-2}]
L	inductance [h, m^2 kg C^2]
L	laser cavity length
L, M, N	direction cosines [—]
M	angular magnification [—]
M	radiant exitance [radiant emittance] [Wm^{-2}]
m	linear magnification [—]
m	effective mass [kg]
MTF	modulation transfer function [—]
N	photon flux [s^{-1}]
N	carrier (number)density [m^{-3}]
n	real part of the relative refractive index [—]
$\tilde{n}$	complex index of refraction [—]
NA	numerical aperture [—]
OPD	optical path difference [m]
P	macroscopic polarization [C m^{-2}]
Re()	real part of [—]
R	resistance [Ω]
r	position vector [m]
S	Seebeck coefficient [VK^{-1}]
s	spin quantum number [—]
s	path length [m]
S_o	object distance [m]
S_i	image distance [m]
T	temperature [K, C]
t	time [s]
t	thickness [m]
u	slope of ray with the optical axis [rad]
V	Abbe reciprocal dispersion [—]
V	voltage [V, m^2 kgs^{-2} C^{-1}]
x, y, z	rectangular coordinates [m]
Z	atomic number [—]

Greek Symbols

α	absorption coefficient [cm^{-1}]
α	(power) absorptance (absorptivity)

ϵ	diclectric coefficient (constant) [—]
ϵ	emittance (emissivity) [—]
ϵ	eccentricity [—]
ϵ_1	Re (ϵ)
ϵ_2	lm (ϵ)
τ	(power) transmittance (transmissivity) [—]
ν	radiation frequency [Hz]
ω	circular frequency = $2\pi\nu$ [rads^{-1}]
ω	plasma frequency [H_2]
λ	wavelength [μm, nm]
σ	wave number = $1/\lambda$ [cm^{-1}]
σ	Stefan Boltzmann constant [Wm^{-2}K^{-1}]
ρ	reflectance (reflectivity) [—]
θ, ϕ	angular coordinates [rad, °]
ξ, η	rectangular spatial frequencies [m^{-1}, r^{-1}]
ϕ	phase [rad, °]
ϕ	lens power [m^{-2}]
Φ	flux [W]
χ	electric susceptibility tensor [—]
Ω	solid angle [sr]

Other

$\Re$	responsivity
exp (x)	e^x
$\log_a(x)$	log to the base a of x
ln (x)	natural log of x
log (x)	standard log of x: $\log_{10}(x)$
Σ	summation
Π	product
Δ	finite difference
δx	variation in x
dx	total differential
∂x	partial derivative of x
$\delta(x)$	Dirac delta function of x
δ_{ij}	Kronecker delta

1.1 GLOSSARY

(NS)	indicates nonstandard terminology
italics	definition or first usage
∇	gradient $(\partial/\partial x, \partial/\partial y, \partial/\partial z)$
prime, unprime	before and after, object and image space (not derivatives)
A	auxiliary function for ray tracing
A, A'	area, total field areas, object and image points
AB	directed distance from A to B
$\mathbf{a}$	unit axis vector, vectors
a_O, a_B, a_I	coefficients in characteristic function expansion
B	matrix element for symmetrical systems
B	auxiliary function for ray tracing
B, B'	arbitrary object and image points
$\mathbf{b}$	binormal unit vector of a ray path
$\mathscr{B}$	interspace (between) term in expansion
C	matrix element for conjugacy
$C(\mathscr{O}, \mathscr{B}, \mathscr{I})$	characteristic function
c	speed of light in vacuum
c	surface vertex curvature, spherical surface curvature
c_s	sagittal curvature
c_t	tangential curvature
D	auxiliary distance function for ray tracing
d	distance from origin to mirror
d	nominal focal distance
d, d'	arbitrary point to conjugate object, image points $d = AO$, $d' = A'O'$
d, d'	axial distances, distances along rays
d_H	hyperfocal distance
d_N	near focal distance
d_F	far focal distance

dA	differential area
ds	differential geometrical path length
E	image irradiance
E_0	axial image irradiance
E, E'	entrance and exit pupil locations
e	eccentricity
e_x, e_y, e_z	coefficients for collineation
F	matrix element for front side
F, F'	front and rear focal points
FN	F-number
FN_m	F-number for magnification m
$F( )$	general function
$F(x, y, z)$	general surface function
f, f'	front and rear focal lengths $f = PF$, $f' = P'F'$
G	diffraction order
g, g'	focal lengths in tilted planes
h, h'	ray heights at objects and images, field heights
$\mathscr{H}$	hamiltonian
I, I'	incidence angles
$\mathbf{I}$	unit matrix
i, i'	paraxial incidence angles
$\mathscr{I}$	image space term in characteristic function expansion
L	surface x-direction cosine
L	paraxial invariant
l, l'	principal points to object and image axial points $l = PO$, $l' = P'O'$
	axial distances from vertices of refracting surface $l = VO$, $l' = V'O'$
$\mathscr{L}$	lagrangian for heterogeneous media
M	lambertian emittance
M	surface z-direction cosine
m	transverse magnification
m_L	longitudinal magnification
m_α	angular magnification
m_E	paraxial pupil magnification
m_N	nodal point magnification $= n/n'$
m_P	pupil magnification in direction cosines
m_O	magnification at axial point
m_x, m_y, m_z	magnifications in the x, y, and z directions
N	surface z-direction cosine
N, N'	nodal points
NA, NA'	numerical aperture
n	refractive index
$\mathbf{n}$	normal unit vector of a ray path
NS	nonstandard
O, O'	axial object and image points
$\mathscr{O}$	object space term in expansion

P	power (radiometric)
P, P'	principal points
$P(\alpha, \beta; x, y)$ $P'(\alpha', \beta'; x', y')$	pupil shape functions
p	period of grating
$\mathbf{p}$	ray vector, optical direction cosine $\mathbf{p} = n\,\mathbf{r} = (p_x, p_y, p_z)$
p	pupil radius
p_x, p_y, p_z	optical direction cosines
$Q(\alpha, \beta; x, y)$ $Q'(\alpha', \beta'; x', y')$	pupil shape functions relative to principal direction cosines
q	resolution parameter
q_i	coordinate for Lagrange equations
$\dot{q}_i$	derivative with respect to a parameter
q, q'	auxiliary functions for collineation
$\mathbf{q}$	unit vector along grating lines
R	matrix element for rear side
r	radius of curvature, vertex radius of curvature
$\mathbf{r}$	ray unit direction vector $\mathbf{r} = (\alpha, \beta, \gamma)$
$\mathbf{S}$	surface normal $\mathbf{S} = (L, M, N)$
$S(x, y, x', y')$	point eikonal $V(x,\ y,\ z_0;\ x',\ y',\ z_{0'})$
s	geometrical length
s	axial length
s, s'	distances associated with sagittal foci
$\mathcal{S}$	skew invariant
$T(\alpha,\ \beta;\ \alpha',\ \beta')$	angle characteristic function
t	thickness, vertex-to-vertex distance
t, t'	distances associated with tangential foci
t	time
$\mathbf{t}$	tangent unit vector of a ray path
U, U'	meridional ray angles relative to axis
u, u'	paraxial ray angles relative to axis
u_M	paraxial marginal ray angle
u_C	paraxial chief ray angle
u_1, u_2, u_3, u_4	homogeneous coordinates for collineation
V	optical path length
$V(\mathbf{x}; \mathbf{x}')$	point characteristic function
V, V'	vertex points
v	speed of light in medium
W_{LMN}	wavefront aberration term
W_x, W_y, W_z	wavefront aberration terms for reference shift
$W(\xi, \eta; x, y, z)$	wavefront aberration function
$W'(\alpha, \beta; x', y')$	angle-point characteristic function
$W(x, y; \alpha', \beta')$	point-angle characteristic function
$\mathbf{x} = (x, y, z)$	position vector
$\mathbf{x}(\sigma)$	parametric description of ray path

$\dot{\mathbf{x}}(\sigma)$	derivative with respect to a parameter
$\ddot{\mathbf{x}}(\sigma)$	second derivative with respect to a parameter
y	meridional ray height, paraxial ray height
y_M	paraxial marginal ray height
y_C	paraxial chief ray height
y_P, y'_P	paraxial ray height at the principal planes
z	axis of revolution
$z(\rho)$	surface sag
z_{sphere}	sag of a sphere
z_{conic}	sag of a conic
z, z'	focal point to object and image distances $z = FO$, $z' = F'O'$
α, β, γ	ray direction cosines
α, β, γ	entrance pupil directions
α', β', γ'	exit pupil direction cosines
α_0, β_0	principal direction of entrance pupil
α'_0, β'_0	principal direction of exit pupil
$\alpha_{\text{max}}, \alpha_{\text{min}}$	extreme pupil directions
$\beta_{\text{max}}, \beta_{\text{min}}$	extreme pupil directions
Γ	$n' \cos I' - n \cos I$
$\delta x, \delta y, \delta z$	reference point shifts
$\Delta\alpha, \Delta\beta$	angular ray aberrations
$\Delta x, \Delta y, \Delta z$	shifts
ε	surface shape parameter
$\varepsilon_x, \varepsilon_y$	transverse ray aberrations
ξ, η	pupil coordinates—not specific
θ	ray angle to surface normal
	marginal ray angle
	plane tilt angle
κ	conic parameter
κ	curvature of a ray path
λ	wavelength
ψ	azimuth angle
	field angle
ϕ	power, surface power
	azimuth
ρ	radius of curvature of a ray path
	distance from axis
	radial pupil coordinate
σ	ray path parameter
	general parameter for a curve
τ	reduced axial distances
	torsion of a ray path
$\tau(\alpha', \beta'; x', y')$	pupil transmittance function
ω, ω'	reduced angle $\omega = nu$, $\omega' = n'u'$
$d\omega$	differential solid angle

1.2 INTRODUCTION

The Subject

Geometrical optics is both the object of abstract study and a body of knowledge necessary for design and engineering. The subject of geometrical optics is small, since so much can be derived from a single principle, that of Fermat, and large since the consequences are infinite and far from obvious. Geometrical optics is deceptive in that much that seems simple is loaded with content and implications, as might be suggested by the fact that some of the most basic results required the likes of Newton and Gauss to discover them. Most of what appears complicated seems so because of obscuration with mathematical terminology and excessive abstraction. Since it is so old, geometrical optics tends to be taken for granted and treated too casually by those who consider it to be "understood." One consequence is that what has been long known can be lost if it is not recirculated by successive generations of textbook authors, who are pressed to fit newer material in a fairly constant number of pages.

The Contents

The material in this chapter is intended to be that which is most fundamental, most general, and most useful to the greatest number of people. Some of this material is often thought to be more esoteric than practical, but this opinion is less related to its essence than to its typical presentation. There are no applications per se here, but everything is applicable, at least to understanding. An effort has been made to compensate here for what is lacking elsewhere and to correct some common errors. Many basic ideas and useful results have not found their way into textbooks, so are little known. Moreover, some basic principles are rarely stated explicitly. The contents are weighted toward the most common type of optical system, that with rotational symmetry consisting of mirrors and/or lens elements of homogeneous materials. There is a section "Rays in Heterogeneous Media," an application of which is gradient index optics discussed in Chap. 24. The treatment here is mostly monochromatic. The topics of caustics and anisotropic media are omitted, and there is little specifically about systems that are not figures of revolution. The section on aberrations is short and mostly descriptive, with no discussion of lens design, a vast field concerned with the practice of aberration control. Because of space limitations, there are too few diagrams.

Terminology

Because of the complicated history of geometrical optics, its terminology is far from standardized. Geometrical optics developed over centuries in many countries, and much of it has been rediscovered and renamed. Moreover, concepts have come into use without being named, and important terms are often used without formal definitions. This lack of standardization complicates communication between workers at different organizations, each of which tends to develop its own optical dialect. Accordingly, an attempt has been made here to provide precise definitions. Terms are italicized where defined or first used. Some needed nonstandard terms have been introduced, and these are likewise italicized, as well as indicated by "NS" for "nonstandard."

Notation

As with terminology, there is little standardization. And, as usual, the alphabet has too few letters to represent all the needed quantities. The choice here has been to use some of the same symbols more than once, rather than to encumber them with superscripts and subscripts. No symbol is used in a given section with more than one meaning. As a general practice nonprimed and primed quantities are used to indicate before and after, input and output, and object and image space.

References

No effort has been made to provide complete references, either technical or historical. (Such a list would fill the entire chapter.) The references were not chosen for priority, but for elucidation or interest, or because of their own references. Newer papers can be found by computer searches, so the older ones have been emphasized, especially since older work is receding from view beneath the current flood of papers. In geometrical optics, nothing goes out of date, and much of what is included here has been known for a century or so—even if it has been subsequently forgotten.

Communication

Because of the confusion in terminology and notation, it is recommended that communication involving geometrical optics be augmented with diagrams, graphs, equations, and numeric results, as appropriate. It also helps to provide diagrams showing both first-order properties of systems, with object and image positions, pupil positions, and principal planes, as well as direction cosine space diagrams, as required, to show angular subtenses of pupils.

1.3 FUNDAMENTALS

What Is a Ray?

Geometrical optics, which might better be called *ray optics,* is concerned with the light ray, an entity that does not exist. It is customary, therefore, to begin discussions of geometrical optics with a theoretical justification for the use of the ray. The real justification is that, like other successful models in physics, rays are indispensable to our thinking, notwithstanding their shortcomings. The ray is a model that works well in some cases and not at all in others, and light is necessarily thought about in terms of rays, scalar waves, electromagnetic waves, and with quantum physics—depending on the class of phenomena under consideration.

Rays have been defined with both corpuscular and wave theory. In corpuscular theory, some definitions are (1) the path of a corpuscle and (2) the path of a photon. A difficulty here is that energy densities can become infinite. Other efforts have been made to define rays as quantities related to the wave theory, both scalar and electromagnetic. Some are (1) wavefront normals, (2) the Poynting vector, (3) a discontinuity in the electromagnetic field,[1,2] (4) a descriptor of wave behavior in short wavelength or high frequency limit,[3] and (5) quantum mechanically.[4] One problem with these definitions is that there are many ordinary and simple cases where wavefronts and Poynting vectors become complicated and/or meaningless. For example, in the simple case of two coherent plane waves interfering, there is no well-defined wavefront in the overlap region. In addition, rays defined in what seems to be a reasonble way can have undesirable properties. For example, if rays are defined as normals to wavefronts, then, in the case of gaussian beams, rays bend in a vacuum.

An approach that avoids the difficulties of a physical definition is that of treating rays as mathematical entities. From definitions and postulates, a variety of results is found, which may be more or less useful and valid for light. Even with this approach, it is virtually impossible to think "purely geometrically"—unless rays are treated as objects of geometry, rather than optics. In fact, we often switch between ray thinking and wave thinking without noticing it, for instance in considering the dependence of refractive index on wavelength. Moreover, geometrical optics makes use of quantities that must be calculated from other models, for example, the index of refraction. As usual, Rayleigh[5] has put it well: "We shall, however, find it advisable not to exclude altogether the conceptions of the wave theory, for on certain most important and practical questions no conclusion can be drawn without the use of facts which are scarcely otherwise interpretable. Indeed it is not to be denied that the too rigid separation of optics into geometrical and physical has done a good deal of harm, much that is essential to a proper comprehension of the subject having fallen between the two schools."

The ray is inherently ill-defined, and attempts to refine a definition always break down. A definition that seems better in some ways is worse in others. Each definition provides some insight into the behavior of light, but does not give the full picture. There seems to be a problem associated with the uncertainty principle involved with attempts at definition, since what is really wanted from a ray is a specification of both position and direction, which is impossible by virtue of both classical wave properties and quantum behavior. So the approach taken here is to treat rays without precisely defining them, and there are few reminders hereafter that the predictions of ray optics are imperfect.

Refractive Index

For the purposes of this chapter, the optical characteristics of matter are completely specified by its refractive index. The *index of refraction* of a medium is defined in geometrical optics as

$$n = \frac{\text{speed of light in vacuum}}{\text{speed of light in medium}} = \frac{c}{v} \tag{1}$$

A *homogeneous medium* is one in which n is the same everywhere. In an *inhomogeneous* or *heterogeneous medium* the index varies with position. In an *isotropic medium* n is the same at each point for light traveling in all directions and with all polarizations, so the index is described by a scalar function of position. Anisotropic media are not treated here.

Care must be taken with equations using the symbol n, since it sometimes denotes the ratio of indices, sometimes with the implication that one of the two is unity. In many cases, the difference from unity of the index of air ($\simeq 1.0003$) is important. Index varies with wavelength, but this dependence is not made explicit in this chapter, most of which is implicitly limited to monochromatic light. The output of a system in polychromatic light is the sum of outputs at the constituent wavelengths.

Systems Considered

The optical systems considered here are those in which spatial variations of surface features or refractive indices are large compared to the wavelength. In such systems ray identity is preserved; there is no "splitting" of one ray into many as occurs at a grating or scattering surface.

The term *lens* is used here to include a variety of systems. *Dioptric* or *refractive* systems employ only refraction. *Catoptric* or *reflective* systems employ only reflection. *Catadioptric* systems employ both refraction and reflection. No distinction is made here insofar as refraction and reflection can be treated in a common way. And the term lens may refer here to anything from a single surface to a system of arbitrary complexity.

Summary of the Behavior and Attributes of Rays

Rays propagate in straight lines in homogeneous media and have curved paths in heterogeneous media. Rays have positions, directions, and speeds. Between any pair of points on a given ray there is a geometrical path length and an optical path length. At smooth interfaces between media with different indices rays refract and reflect. Ray paths are reversible. Rays carry energy, and power per area is approximated by ray density.

Reversibility

Rays are reversible; a path can be taken in either direction, and reflection and refraction angles are the same in either direction. However, it is usually easier to think of light as traveling along rays in a particular direction, and, of course, in cases of real instruments there usually is such a direction. The solutions to some equations may have directional ambiguity.

Groups of Rays

Certain types of groups of rays are of particular importance. Rays that originate at a single point are called a *normal congruence* or *orthotomic system,* since as they propagate in isotropic media they are associated with perpendicular wavefronts. Such groups are also of interest in image formation, where their reconvergence to a point is important, as is the path length of the rays to a reference surface used for diffraction calculations. Important in radiometric considerations are groups of rays emanating from regions of a source over a range of angles. The changes of such groups as they propagate are constrained by conservation of brightness. Another group is that of two meridional paraxial rays, related by the two-ray invariant.

Invariance Properties

Individual rays and groups of rays may have *invariance properties*—relationships between the positions, directions, and path lengths—that remain constant as a ray or a group of rays passes through an optical system.[6] Some of these properties are completely general, e.g., the conservation of étendue and the perpendicularity of rays to wavefronts in isotropic media. Others arise from symmetries of the system, e.g., the skew invariant for rotationally symmetric systems. Other invariances hold in the paraxial limit. There are also differential invariance properties.[7,8] Some ray properties not ordinarily thought of in this way can be thought of as invariances. For example, Snell's law can be thought of as a refraction invariant n sin I.

Description of Ray Paths

A *ray path* can be described parametrically as a locus of points $\mathbf{x}(\sigma)$, where σ is any monotonic parameter that labels points along the ray. The description of curved rays is elaborated in the section on heterogeneous media.

Real Rays and Virtual Rays

Since rays in homogeneous media are straight, they can be extrapolated infinitely from a given region. The term *real* refers to the portion of the ray that "really" exists, or the accessible part, and the term *virtual* refers to the extrapolated, or inaccessible, part.

Direction

At each position where the refractive index is continuous a ray has a unique direction. The direction is given by its unit *direction vector* $\mathbf{r}$, whose cartesian components are direction cosines (α, β, γ), i.e.,

$$\mathbf{r} = (\alpha, \beta, \gamma) \tag{2}$$

where $|\mathbf{r}|^2 = \alpha^2 + \beta^2 + \gamma^2 = 1$. The three direction cosines are not independent, and one is often taken to depend implicitly on the other two. In this chapter it is usually γ, which is

$$\gamma(\alpha, \beta) = \sqrt{1 - \alpha^2 - \beta^2} \tag{3}$$

Another vector with the same direction as $\mathbf{r}$ is

$$\mathbf{p} = n\mathbf{r} = n(\alpha, \beta, \gamma) = (p_x, p_y, p_z) \tag{4}$$

where $|\mathbf{p}|^2 = n^2$. Several names are used for this vector, including the *optical direction cosine* and the *ray vector*.

Geometrical Path Length

Geometrical path length is geometrical distance measured along a ray between any two points. The differential unit of length is

$$ds = \sqrt{dx^2 + dy^2 + dz^2} \tag{5}$$

The path length between points $\mathbf{x}_1$ and $\mathbf{x}_2$ on a ray described parametrically by $\mathbf{x}(\sigma)$, with derivative $\dot{\mathbf{x}}(\sigma) = d\mathbf{x}(\sigma)/d\sigma$ is

$$s(\mathbf{x}_1; \mathbf{x}_2) = \int_{\mathbf{x}_1}^{\mathbf{x}_2} ds = \int_{\mathbf{x}_1}^{\mathbf{x}_2} \frac{ds}{d\sigma} d\sigma = \int_{\mathbf{x}_1}^{\mathbf{x}_2} \sqrt{|\dot{\mathbf{x}}(\sigma)|^2}\, d\sigma \tag{6}$$

Optical Path Length

The *optical path length* between two points $\mathbf{x}_1$ and $\mathbf{x}_2$ through which a ray passes is

$$\text{Optical path length} = V(\mathbf{x}_1; \mathbf{x}_2) = \int_{\mathbf{x}_1}^{\mathbf{x}_2} n(\mathbf{x})\, ds = \mathrm{c} \int \frac{ds}{\mathrm{v}} = \mathrm{c} \int dt \tag{7}$$

The integral is taken along the ray path, which may traverse homogeneous and inhomogeneous media, and include any number of reflections and refractions. Path length can be defined for virtual rays. In some cases, path length should be considered positive definite, but in others it can be either positive or negative, depending on direction.[9] If $\mathbf{x}_0$, $\mathbf{x}_1$, and $\mathbf{x}_2$ are three points on the same ray, then

$$V(\mathbf{x}_0; \mathbf{x}_2) = V(\mathbf{x}_0; \mathbf{x}_1) + V(\mathbf{x}_1; \mathbf{x}_2) \tag{8}$$

Equivalently, the time required for light to travel between the two points is

$$\text{Time} = \frac{\text{optical path length}}{\mathrm{c}} = \frac{V}{\mathrm{c}} = \frac{1}{\mathrm{c}} \int_{\mathbf{x}_1}^{\mathbf{x}_2} n(\mathbf{x})\, ds = \int_{\mathbf{x}_1}^{\mathbf{x}_2} \frac{ds}{\mathrm{v}} \tag{9}$$

In homogeneous media, rays are straight lines, and the optical path length is $V = n \int ds =$ (index) × (distance between the points).

The optical path length integral has several interpretations, and much of geometrical optics involves the examination of its meanings. (1) With both points fixed, it is simply a scalar, the optical path length from one point to another. (2) With one point fixed, say $\mathbf{x}_0$, then treated as a function of $\mathbf{x}$, the surfaces $V(\mathbf{x}_0; \mathbf{x})$ = constant are geometrical wavefronts for light originating at $\mathbf{x}_0$. (3) Most generally, as a function of both arguments $V(\mathbf{x}_1; \mathbf{x}_2)$ is the *point characteristic function,* which contains all the information about the rays between the region containing $\mathbf{x}_1$ and that containing $\mathbf{x}_2$. There may not be a ray between all pairs of points.

Fermat's Principle

According to Fermat's principle[10–15] the optical path between two points through which a ray passes is an extremum. Light passing through these points along any other nearby path would take either more or less time. The principle applies to different *neighboring* paths. The optical path length of a ray may not be a global extremum. For example, the path lengths of rays through different facets of a Fresnel lens have no particular relationship. Fermat's principle applies to entire systems, as well as to any portion of a system, for example, to any section of a ray. In a homogeneous medium, the extremum is a straight line or, if there are reflections, a series of straight line segments.

The extremum principle can be described mathematically as follows.[16] With the end points fixed, if a nonphysical path differs from a physical one by an amount proportional to δ, the nonphysical optical path length differs from the actual one by a quantity proportional to δ^2 or to a higher order. If the order is three or higher, the first point is imaged at the second-to-first order. Roughly speaking,

the higher the order, the better the image. A point is imaged stigmatically when a continuum of neighboring paths have the same length, so the equality holds to all orders. If they are sufficiently close, but vary slightly, the deviation from equality is a measure of the aberration of the imaging. An extension of Fermat's principle is given by Hopkins.[17]

Ray and wave optics are related by the importance of path length in both.[18,19] In wave optics, optical path length is proportional to phase change, and the extremum principle is associated with constructive interference. The more alike the path lengths are from an object point to its image, the less the differences in phase of the wave contributions, and the greater the magnitude of the net field. In imaging this connection is manifested in the relationship of the wavefront aberration and the eikonal.

Fermat's principle is a unifying principle of geometrical optics that can be used to derive laws of reflection and refraction, and to find the equations that describe ray paths and geometrical wavefronts in heterogeneous and homogeneous media. It is one of a number of variational principles based historically on the idea that nature is economical, a unifying principle of physics. The idea that the path length is an extremum could be used mathematically without interpreting the refractive index in terms of the speed of light.

Geometrical Wavefronts

For rays originating at a single point, a *geometrical wavefront* is a surface that is a locus of constant optical path length from the source. If the source point is located at $\mathbf{x}_0$ and light leaves at time t_0, then the wavefront at time t is given by

$$V(\mathbf{x}_0; \mathbf{x}) = c(t - t_0) \tag{10}$$

The function $V(\mathbf{x}; \mathbf{x}_0)$, as a function of $\mathbf{x}$, satisfies the *eikonal equation*

$$\begin{aligned} n(\mathbf{x})^2 &= \left(\frac{\partial V}{\partial x}\right)^2 + \left(\frac{\partial V}{\partial y}\right)^2 + \left(\frac{\partial V}{\partial z}\right)^2 \\ &= |\Delta V(\mathbf{x}; \mathbf{x}_0)|^2 \end{aligned} \tag{11}$$

This equation can also be written in relativistic form, with a four-dimensional gradient as $0 = \Sigma(\partial V / \partial x_i)$.[20]

For constant refractive index, the eikonal equation has some simple solutions, one of which is $V = n[\alpha(x - x_0) + \beta(y - y_0) + \gamma(z - z_0)]$, corresponding to a parallel bundle of rays with directions (α, β, γ). Another is $V = n[(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2]^{1/2}$, describing rays traveling radially from a point (x_0, y_0, z_0).

In isotropic media, the rays and wavefronts are everywhere perpendicular to each other, a condition referred to as *orthotomic*. According to the *Malus-Dupin principle,* if a group of rays emanating front a single point is reflected and/or refracted any number of times, the perpendicularity of rays to wavefronts is maintained. The direction of a ray from $\mathbf{x}_0$ at $\mathbf{x}$ is that of the gradient of $V(\mathbf{x}_0; \mathbf{x})$

$$\mathbf{p} = n\mathbf{r} = \nabla V$$

or

$$n\alpha = \frac{\partial V}{\partial x} \quad n\beta = \frac{\partial V}{\partial y} \quad n\gamma = \frac{\partial V}{\partial z} \tag{12}$$

In a homogeneous medium, all wavefronts can be found from any one wavefront by a construction. Wavefront normals, i.e., rays, are projected from the known wavefront, and loci of points equidistant therefrom are other wavefronts. This gives wavefronts in both directions, that is, both subsequent and previous wavefronts. (A single wavefront contains no directional information.) The construction also gives virtual wavefronts, those which would occur or would have occurred if the medium extended infinitely. This construction is related to that of Huygens for wave optics. At each point on a wavefront there are two principal curvatures, so there are two foci along each ray and two caustic surfaces.[8,21]

The geometrical wavefront is analogous to the surface of constant phase in wave optics, and the eikonal equation can be obtained from the wave equation in the limit of small wavelength.[3,4] A way in which wave optics differs from ray optics is that the phase fronts can be modified by phase changes that occur on reflection, transmission, or in passing through foci.

Fields of Rays

In many cases the optical direction cosine vectors **p** form a field, where the optical path length is the potential, and the geometrical wavefronts are equipotential surfaces. The potential changes with position according to

$$dV = n\alpha\, dx + n\beta\, dy + n\gamma\, dz = n\mathbf{r}\cdot d\mathbf{x} = \mathbf{p}\cdot d\mathbf{x} \tag{13}$$

If $d\mathbf{x}$ is in the direction of a ray, then $dV/dx = n$, the maximum rate of change. If $d\mathbf{x}$ is perpendicular to a ray, then $dV/dx = 0$. The potential difference between any two wavefronts is

$$V_2 - V_1 = \int_{\mathbf{x}_1}^{\mathbf{x}_2} dV \tag{14}$$

where $\mathbf{x}_1$ and $\mathbf{x}_2$ are any two points on the respective wavefronts, and the integrand is independent of the path. Other relationships for rays originating at a single point are

$$0 = \nabla \times \mathbf{p} = \nabla \times (n\mathbf{r}) \qquad \text{and} \qquad 0 = \oint \mathbf{p}\cdot d\mathbf{x} \tag{15}$$

where the integral is about a closed path.[3] These follow since **p** is a gradient, Eq. (13). In regions where the rays are folded onto themselves by refraction or reflections, **p** and V are not single-valued, so there is not a field.

1.4 CHARACTERISTIC FUNCTIONS

Introduction

Characteristic functions contain all the information about the path lengths between pairs of points, which may either be in a contiguous region or physically separated, e.g., on the two sides of a lens. These functions were first considered by Hamilton,[22] so their study is referred to as *hamiltonian optics*. They were rediscovered in somewhat different form by Bruns[23,24] and referred to as eikonals, leading to a confusing set of names for the various functions. The subject is discussed in a number of books.[25–36]

Four parameters are required to specify a ray. For example, an input ray is defined in the $z = 0$ plane by coordinates (x, y) and direction (α, β). So four functions of four variables specify how an incident ray emerges from a system. In an output plane $z' = 0$, the ray has coordinates $x' = x'(x, y, \alpha, \beta)$, $y' = y'(x, y, \alpha, \beta)$, and directions $\alpha' = \alpha'(x, y, \alpha, \beta)$, $\beta' = \beta'(x, y, \alpha, \beta)$. Because of Fermat's principle, these four functions are not independent, and the geometrical optics properties of a system can be fully characterized by a single function.[32]

For any given system, there is a variety of characteristic functions related by Legendre transformations, with different combinations of spatial and angular variables.[34] The different functions are suited for different types of analysis. *Mixed* characteristic functions have both spatial and angular arguments. Those functions that are of most general use are discussed next. The others may be useful in special circumstances. If the regions have constant refractive indices, the volumes over which the characteristic functions are defined can be extended virtually from physically accessible to inaccessible regions.

From any of its characteristic functions, all the properties of a system involving ray paths can be found, for example, ray positions, directions, and geometrical wavefronts. An important use of

the characteristic functions is demonstrating general principles and fundamental limitations. Much of this can be done by using the general properties, e.g., symmetry under rotation. (Unfortunately, it is not always known how closely the impossible can be approached.)

Point Characteristic Function

The *point characteristic function* is the optical path integral $V(\mathbf{x};\mathbf{x}')=V(x, y, z; x', y', z')$ taken as a function of both points $\mathbf{x}$ and $\mathbf{x}'$. At point $\mathbf{x}$ where the index is n,

$$-n\alpha=\frac{\partial V}{\partial x} \quad -n\beta=\frac{\partial V}{\partial y} \quad -n\gamma=\frac{\partial V}{\partial z} \quad \text{or} \quad -\mathbf{p}=\nabla V \tag{16}$$

Similarly, at $\mathbf{x}'$, where the index is n',

$$n'\alpha'=\frac{\partial V}{\partial x'} \quad n'\beta'=\frac{\partial V}{\partial y'} \quad n'y'=\frac{\partial V}{\partial z'} \quad \text{or} \quad \mathbf{p}'=\nabla' V \tag{17}$$

It follows from the above equations and Eq. (4) that the point characteristic satisfies two conditions:

$$n^2=|\nabla V|^2 \qquad \text{and} \qquad n'^2=|\nabla' V|^2 \tag{18}$$

Therefore, the point characteristic is not an arbitrary function of six variables. The total differential of V is

$$dV(\mathbf{x};\mathbf{x}')=\mathbf{p}'\cdot d\mathbf{x}'-\mathbf{p}\cdot d\mathbf{x} \tag{19}$$

"This expression can be said to contain all the basic laws of optics".[36]

Point Eikonal

If reference planes in object and image spaces are fixed, for which we use z_0 and z_0', then the *point eikonal* is $S(x, y; x', y')=V(x, y, z_0; x', y', z_0')$. This is the optical path length between pairs of points on the two planes. The function is not useful if the planes are conjugate, since more than one ray through a pair of points can have the same path length. The function is arbitrary, except for the requirement[37] that

$$\frac{\partial^2 S}{\partial x\,\partial x'}\frac{\partial^2 S}{\partial y\,\partial y'}-\frac{\partial^2 S}{\partial x\,\partial y'}\frac{\partial^2 S}{\partial x'\,\partial y}\neq 0 \tag{20}$$

The partial derivatives of the point eikonal are

$$-n\alpha=\frac{\partial S}{\partial x} \quad -n\beta=\frac{\partial S}{\partial y} \quad \text{and} \quad n'\alpha'=\frac{\partial S}{\partial x'} \quad n'\beta'=\frac{\partial S}{\partial y'} \tag{21}$$

The relative merits of the point characteristic function and point eikonal have been debated.[37–39]

Angle Characteristic

The *angle characteristic function* $T(\alpha,\beta;\alpha',\beta')$, also called the *eikonal,* is related to the point characteristic by

$$\begin{aligned} T(\alpha, \beta; \alpha', \beta')=V(x, y, z; x', y', z')+n(\alpha x+\beta y+\gamma z) \\ -n'(\alpha' x'+\beta' y'+\gamma' z') \end{aligned} \tag{22}$$

Here the input plane z and output plane z' are fixed and are implicit parameters of T.

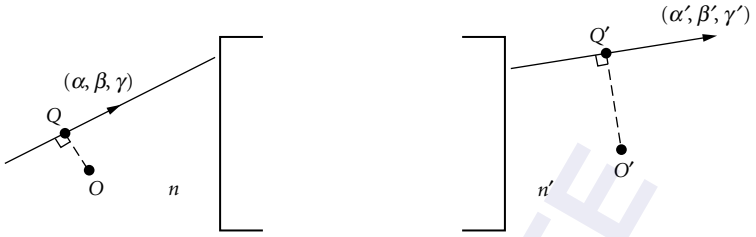

FIGURE 1 Geometrical interpretation of the angle characteristic function for constant object and image space indices. There is, in general, a single ray with directions (α, β, γ) in object space and $(\alpha', \beta', \gamma')$ in image space. Point O is the coordinate origin in object space, and O' is that in image space. From the origins, perpendiculars to the ray are constructed, which intersect the ray at Q and Q'. The angle characteristic function $T(\alpha, \beta; \alpha', \beta')$ is the path length from Q to Q'.

This equation is really shorthand for a Legendre transformation to coordinates $p_x = \partial V/\partial x$, etc. In principle, the expressions of Eq. (16) are used to solve for x and y in terms of α and β, and likewise Eq. (17) gives x' and y' in terms of α' and β', so

$$\begin{aligned} T(\alpha, \beta; \alpha', \beta') = V[x(\alpha, \beta), y(\alpha, \beta), z; x'(\alpha', \beta'), y'(\alpha', \beta'), z'] \\ + n[\alpha x(\alpha, \beta) + \beta y(\alpha, \beta) + \sqrt{1-\alpha^2-\beta^2}\, z] \\ - n'[\alpha' x'(\alpha', \beta') + \beta' y'(\alpha', \beta') + \sqrt{1-\alpha'^2-\beta'^2}\, z'] \end{aligned} \tag{23}$$

The angle characteristic is an arbitrary function of four variables that completely specify the directions of rays in two regions. This function is not useful if parallel incoming rays give rise to parallel outgoing rays, as is the case with afocal systems, since the relationship between incoming and outgoing directions is not unique. The partial derivatives of the angular characteristic function are

$$\frac{\partial T}{\partial \alpha} = n\left(x - \frac{\alpha}{\gamma} z\right), \quad \frac{\partial T}{\partial \beta} = n\left(y - \frac{\beta}{\gamma} z\right) \tag{24}$$

$$\frac{\partial T}{\partial \alpha'} = -n'\left(x' - \frac{\alpha'}{\gamma'} z'\right), \quad \frac{\partial T}{\partial \beta'} = -n'\left(y' - \frac{\beta'}{\gamma'} z'\right) \tag{25}$$

These expressions are simplified if the reference planes are taken to be $z = 0$ and $z' = 0$. The geometrical interpretation of T is that it is the path length between the intersection point of rays with perpendicular planes through the coordinate origins in the two spaces, as shown in Fig. 1 for the case of constant n and n'. If the indices are heterogeneous, the construction applies to the tangents to the rays. Of all the characteristic functions, T is most easily found for single surfaces and most easily concatenated for series of surfaces.

Point-Angle Characteristic

The *point-angle characteristic function* is a mixed function defined by

$$\begin{aligned} W(x, y, z; \alpha', \beta') &= V(x, y, z; x', y', z') - n'(\alpha' x' + \beta' y' + \gamma' z') \\ &= T(\alpha, \beta; \alpha', \beta') - n(\alpha x + \beta y + \gamma z) \end{aligned} \tag{26}$$

As with Eq. (22), this equation is to be understood as shorthand for a Legendre transformation. The partial derivatives with respect to the spatial variables are related by equations like those of Eq. (16), so $n^2 = |\nabla W|^2$, and the derivatives with respect to the angular variables are like those of Eq. (25). This function is useful for examining transverse ray aberrations for a given object point, since $\partial W/\partial \alpha'$, $\partial W/\partial \beta'$ give the intersection points (x', y') in plane z for rays originating at (x, y) in plane z.

Angle-Point Characteristic

The *angle-point characteristic function* is

$$\begin{aligned} W'(\alpha, \beta; x', y', z') &= V(x, y, z; x', y', z') + n(\alpha x + \beta y + \gamma z) \\ &= T(\alpha, \beta; \alpha', \beta') - n'(\alpha' x' + \beta' y' + \gamma' z) \end{aligned} \tag{27}$$

Again, this is shorthand for the Legendre transformation. This function satisfies relationships like those of Eq. (17) and satisfies $n'^2 = |\nabla' W'|^2$. Derivatives with respect to spatial variables are like those of Eq. (21). It is useful when input angles are given and output angles are to be found.

Expansions About an Arbitrary Ray

If two points on a ray that are not conjugate are taken as coordinate origins, and the z axes of the coordinate systems are taken to lie along the rays, then the expansion to second order of the point eikonal about these points is

$$\begin{aligned} S(x_1, y_1; x_2, y_2) = v &+ a_1 x_1^2 + b_1 x_1 y_1 + c_1 y_1^2 + a_2 x_2^2 + b_2 x_2 y_2 + c_2 y_2^2 \\ &+ d x_1 x_2 + e y_1 y_2 + f x_1 y_2 + g y_1 x_2 \end{aligned} \tag{28}$$

The other characteristic functions have similar expansions. These expansions have three types of terms, those associated with the input space, the output space, and "interspace" terms. From the coefficients, information about imaging along a known ray is obtained. This subject is treated in the references for the section "Images About Known Rays."

Expansions About the Axis

For rotationally symmetric systems, the building blocks for an expansion about the axis are

$$\text{Object space term:} \quad \mathcal{O} = x^2 + y^2 \quad \text{or} \quad \alpha^2 + \beta^2 \tag{29}$$

$$\text{Image space term:} \quad \mathcal{I} = x'^2 + y'^2 \quad \text{or} \quad \alpha'^2 + \beta'^2 \tag{30}$$

$$\text{Interspace term:} \quad \mathcal{B} = xx' + yy' \quad \text{or} \quad \alpha\alpha' + \beta\beta' \quad \text{or} \quad x\alpha' + y\beta' \quad \text{or} \quad \alpha x' + \beta y' \tag{31}$$

(Here $\mathcal{B} \equiv$ "between.") The interspace term combines the variables included in $\mathcal{O}$ and $\mathcal{I}$. The general form can be written as a series

$$C(\mathcal{O}, \mathcal{B}, \mathcal{I}) = \sum_{L,M,N} a_{LMN} \mathcal{O}^L \mathcal{B}^M \mathcal{I}^N \tag{32}$$

To second order, the expansion is

$$\begin{aligned} C(\mathcal{O}, \mathcal{B}, \mathcal{I}) = a_0 &+ a_{100}\mathcal{O} + a_{010}\mathcal{B} + a_{001}\mathcal{I} + a_{200}\mathcal{O}^2 + a_{020}\mathcal{B}^2 + a_{002}\mathcal{I}^2 \\ &+ a_{110}\mathcal{O}\mathcal{B} + a_{101}\mathcal{O}\mathcal{I} + a_{011}\mathcal{B}\mathcal{I} \end{aligned} \tag{33}$$

The constant term is the optical path length between coordinate origins in the two spaces. It is often unimportant, but it does matter if two systems are used in parallel, as in an interferometer. The three first-order terms give the paraxial approximation. For imaging systems, the second-order terms are associated with third-order ray aberrations, and so on.[30] It is also possible to expand the characteristic functions in terms of three linear combinations of $\mathcal{O}$, $\mathcal{B}$, and $\mathcal{I}$. These combinations can be chosen so that the characteristic function of an aberration-free system depends on only one of the three terms, and the other two describe the aberrations.[26,31,40]

Paraxial Forms for Rotationally Symmetric Systems

These functions contain one each of the object space, image space, and interspace terms, with coefficients a_O, a_I, and a_B. The coefficients of the object and image space terms depend on the input and output plane locations. That of the interspace term depends on the system power. Point eikonal:

$$S(x', y'; x, y) = a + a_O(x^2 + y^2) + a_B(xx' + yy') + a_I(x'^2 + y'^2) \tag{34}$$

Angle characteristic:

$$T(\alpha', \beta'; \alpha, \beta) = a + a_O(\alpha^2 + \beta^2) + a_B(\alpha\alpha' + \beta\beta') + a_I(\alpha'^2 + \beta'^2) \tag{35}$$

Point-angle characteristic:

$$W(x, y; \alpha', \beta') = a + a_O(x^2 + y^2) + a_B(x\alpha' + y\beta') + a_I(\alpha'^2 + \beta'^2) \tag{36}$$

Angle-point characteristic:

$$W'(\alpha, \beta, x', y') = a + a_O(\alpha^2 + \beta^2) + a_B(\alpha x' + \beta y') + a_I(x'^2 + y'^2) \tag{37}$$

The corresponding coefficients in these expressions are different from each other. The familiar properties of paraxial and gaussian optics can be found from these functions by taking the appropriate partial derivatives.

Some Ideal Characteristic Functions

For a system that satisfies certain conditions, the form of a characteristic function can sometimes be found. Thereafter, some of its properties can be determined. Some examples of characteristic functions follow, in each of which expression the function F is arbitrary.

For maxwellian perfect imaging (defined below) by a rotationally symmetric system between planes at $z = 0$ and $z' = 0$ related by transverse magnification m, the point characteristic function, defined for $z' \neq 0$, is

$$V(x', y', z'; x, y) = F(x^2 + y^2) + [(x' - mx)^2 + (y' - my)^2 + z'^2]^{1/2} \tag{38}$$

Expanding the expression above for small x, x', y, y' give the paraxial form, Eq. (34). The form of the point-angle characteristic is

$$W(x, y; \alpha', \beta') = F(x^2 + y^2) - m(n'\alpha' x + n'\beta' y) \tag{39}$$

The form of the angle-point characteristic is

$$W'(\alpha, \beta; x', y') = F(x'^2 + y'^2) + \frac{1}{m}(n\alpha x' + n\beta y') \tag{40}$$

The functions F are determined if the imaging is also stigmatic at one additional point, for example, at the center of the pupil.[26,34,40,41] The angular characteristic function has the form

$$T(\alpha, \beta; \alpha', \beta') = F[(n\alpha - mn'\alpha')^2 + (n\beta - mn'\beta')^2] \tag{41}$$

where F is any function.

For a lens of power ϕ that stigmatically images objects at infinity in a plane, and does so in either direction,

$$S(x, y; x', y') = -\phi(xx' + yy') \quad \text{and} \quad T(\alpha, \beta; \alpha', \beta') = \frac{nn'}{\phi}(\alpha\alpha' + \beta\beta') \tag{42}$$

Partially differentiating with respect to the appropriate variables shows that for such a system, the heights of point images in the rear focal plane are proportional to the sines of the incident angles, rather than the tangents.

1.5 RAYS IN HETEROGENEOUS MEDIA

Introduction

This section provides equations for describing and determining the curved ray paths in a heterogeneous or inhomogeneous medium, one whose refractive index varies with position. It is assumed here that $n(\mathbf{x})$ and the other relevant functions are continuous and have continuous derivatives to whatever order is needed. Various aspects of this subject are discussed in a number of books and papers.[42–49] This material is often discussed in the literature on gradient index lenses[50–54] and in discussions of microwave lenses.[55–58]

Differential Geometry of Space Curves

A curved ray path is a space curve, which can be described by a standard parametric description, $\mathbf{x}(\sigma) = [x(\sigma), y(\sigma), z(\sigma)]$, where σ is an arbitrary parameter.[46,59–62]

Different parameters may be used according to the situation. The path length s along the ray is sometimes used, as is the axial position z. Some equations change form according to the parameter, and those involving derivatives are simplest when the parameter is s. Derivatives with respect to the parameter are denoted by dots, so $\dot{\mathbf{x}}(\sigma) = d\mathbf{x}(\sigma)/d\sigma = [\dot{x}(\sigma), \dot{y}(\sigma), \dot{z}(\sigma)]$. A parameter other than s is a function of s, so $d\mathbf{x}(\sigma)/ds = (d\mathbf{x}/d\sigma)(d\sigma/ds)$.

Associated with space curves are three mutually perpendicular unit vectors, the tangent vector **t**, the principal normal **n**, and the binormal **b**, as well as two scalars, the curvature and the torsion. The direction of a ray is that of its unit *tangent vector*

$$\mathbf{t} = \frac{\dot{\mathbf{x}}(\sigma)}{|\dot{\mathbf{x}}(\sigma)|} = \dot{\mathbf{x}}(s) = (\alpha, \beta, \gamma) \tag{43}$$

The tangent vector **t** is the same as the direction vector **r** used elsewhere in this chapter. The rate of change of the tangent vector with respect to path length is

$$\kappa\mathbf{n} = \dot{\mathbf{t}}(s) = \ddot{\mathbf{x}}(s) = \left(\frac{d\alpha}{ds}, \frac{d\beta}{ds}, \frac{d\gamma}{ds}\right) \tag{44}$$

The *normal vector* is the unit vector in this direction

$$\mathbf{n} = \frac{\ddot{\mathbf{x}}(s)}{|\ddot{\mathbf{x}}(s)|} \tag{45}$$

The vectors **t** and **n** define the *osculating plane*. The *curvature* $\kappa = |\ddot{\mathbf{x}}(s)|$ is the rate of change of direction of **t** in the osculating plane.

$$\kappa^2 = \frac{|\dot{\mathbf{x}}(\sigma) \times \ddot{\mathbf{x}}(\sigma)|^2}{|\dot{\mathbf{x}}(\sigma)|^6} = |\ddot{\mathbf{x}}(s)|^2 = \left(\frac{d\alpha}{ds}\right)^2 + \left(\frac{d\beta}{ds}\right)^2 + \left(\frac{d\gamma}{ds}\right)^2 \tag{46}$$

The radius of curvature is $\rho = 1/\kappa$. Perpendicular to the osculating plane is the unit *binormal vector*

$$\mathbf{b} = \mathbf{t} \times \mathbf{n} = \frac{\dot{\mathbf{x}}(s) \times \ddot{\mathbf{x}}(s)}{|\ddot{\mathbf{x}}(s)|} \tag{47}$$

The *torsion* is the rate of change of the normal to the osculating plane

$$\tau = \mathbf{b}(s) \cdot \frac{d\mathbf{n}(s)}{ds} = \frac{[\dot{\mathbf{x}}(\sigma) \times \ddot{\mathbf{x}}(\sigma)] \cdot \dddot{\mathbf{x}}(\sigma)}{|\dot{\mathbf{x}}(\sigma) \times \ddot{\mathbf{x}}(\sigma)|^2} = \frac{[\dot{\mathbf{x}}(s) \times \ddot{\mathbf{x}}(s)] \cdot \dddot{\mathbf{x}}(s)}{|\ddot{\mathbf{x}}(s)|^2} \tag{48}$$

The quantity $1/\tau$ is the *radius of torsion*. For a plane curve, $\tau = 0$ and $\mathbf{b}$ is constant. The rates of change of $\mathbf{t}$, $\mathbf{n}$, and $\mathbf{b}$ are given by the Frenet equations:

$$\dot{\mathbf{t}}(s) = \kappa \mathbf{n}, \quad \dot{\mathbf{n}}(s) = -\kappa \mathbf{t} + \tau \mathbf{b}, \quad \dot{\mathbf{b}}(s) = -\tau \mathbf{n} \tag{49}$$

In some books, $1/\kappa$ and $1/\tau$ are used for what are denoted here by κ and τ.

Differential Geometry Equations Specific to Rays

From the general space curve equations above and the differential equations below specific to rays, the following equations for rays are obtained. Note that n here is the refractive index, unrelated to $\mathbf{n}$. The tangent and normal vectors are related by Eq. (59), which can be written

$$\nabla \log n = \kappa \mathbf{n} + (\nabla \log n \cdot \mathbf{t})\mathbf{t} \tag{50}$$

The osculating plane always contains the vector ∇n. Taking the dot product with $\mathbf{n}$ in the above equation gives

$$\kappa = \frac{\partial \log n}{\partial N} = \mathbf{n} \cdot \nabla \log n = \mathbf{b} \cdot (\dot{\mathbf{x}} \times \nabla \log n) \tag{51}$$

The partial derivative $\partial/\partial N$ is in the direction of the principal normal, so rays bend toward regions of higher refractive index. Other relations[46] are

$$\mathbf{n} = \rho \dot{\mathbf{x}}(s) \times [\nabla \log n \times \dot{\mathbf{x}}(s)] \tag{52}$$

$$\mathbf{b} = \rho \dot{\mathbf{x}}(s) \times \nabla \log n \quad \text{and} \quad 0 = \mathbf{b} \cdot \nabla n \tag{53}$$

$$\tau = \frac{(\dot{\mathbf{x}}(s) \times \nabla n) \cdot \nabla \dot{n}}{|\nabla n \times \dot{\mathbf{x}}(s)|^2} \tag{54}$$

Variational Integral

Written in terms of parameter σ, the optical path length integral, Eq. (7), is

$$V = \int n\, ds = \int \left(n \frac{ds}{d\sigma} \right) d\sigma = \int \mathscr{L}\, d\sigma \tag{55}$$

The solution for ray paths involves the calculus of variations in a way analogous to that used in classical mechanics, where the time integral of the lagrangian $\mathscr{L}$ is an extremum.[63] If $\mathscr{L}$ has no explicit dependence on σ, the mechanical analogue to the optics case is of no explicit time dependence.

Differential Equations for Rays

General Differential Equations Because the optical path length integral is an extremum, the integrand $\mathcal{L}$ satisfies the Euler equations.[46] For an arbitrary coordinate system, with coordinates q_1, q_2, q_3 and the derivatives with respect to the parameter $\dot{q}_i = dq_i/d\sigma$, the differential equations for the path are

$$0 = \frac{d}{d\sigma}\frac{\partial \mathcal{L}}{\partial \dot{q}_i} - \frac{\partial \mathcal{L}}{\partial q_i} = \frac{d}{d\sigma}\left(n\frac{\partial}{\partial \dot{q}_i}\frac{ds}{d\sigma}\right) - \frac{\partial}{\partial q_i}\left(n\frac{ds}{d\sigma}\right); \quad i = 1, 2, 3 \tag{56}$$

Cartesian Coordinates with Unspecified Parameter In cartesian coordinates $ds/d\sigma = (\dot{x}^2 + \dot{y}^2 + \dot{z}^2)^{1/2}$, so the x equation is

$$0 = \frac{d}{d\sigma}\left(n\frac{\partial}{\partial \dot{x}}\frac{ds}{d\sigma}\right) - \frac{ds}{d\sigma}\frac{\partial n}{\partial x} = \frac{d}{d\sigma}\left[\frac{n\dot{x}}{(\dot{x}^2 + \dot{y}^2 + \dot{z}^2)^{1/2}}\right] - (\dot{x}^2 + \dot{y}^2 + \dot{z}^2)^{1/2}\frac{\partial n}{\partial x} \tag{57}$$

Similar equations hold for y and z.

Cartesian Coordinates with Parameter $\sigma = s$ With $\sigma = s$, so $ds/d\sigma = 1$, an expression, sometimes called the *ray equation,* is obtained.[28]

$$\nabla n = \frac{d}{ds}\left(n\frac{d\mathbf{x}(s)}{ds}\right) = n\frac{d^2\mathbf{x}(s)}{ds^2} + \frac{dn[\mathbf{x}(s)]}{ds}\frac{d\mathbf{x}(s)}{ds} \tag{58}$$

Using $dn/ds = \nabla n \cdot \dot{\mathbf{x}}$, the ray equation can also be written

$$\nabla n = n\ddot{\mathbf{x}} + (\nabla n \cdot \dot{\mathbf{x}})\dot{\mathbf{x}} \quad \text{or} \quad \nabla \log n = \ddot{\mathbf{x}} + (\nabla \log n \cdot \dot{\mathbf{x}})\dot{\mathbf{x}} \tag{59}$$

Only two of the component equations are independent, since $|\dot{\mathbf{x}}| = 1$.

Cartesian Coordinates with Parameter $\sigma = \int ds/n$ The parameter $\sigma = \int ds/n$, for which $ds/d\sigma = n$ and $n^2 = \dot{x}^2 + \dot{y}^2 + \dot{z}^2$, gives[44]

$$\frac{d^2\mathbf{x}}{d\sigma^2} = \nabla(\tfrac{1}{2}n^2) \tag{60}$$

This equation is analogous to Newton's law of motion for a particle, $\mathbf{F} = m\, d^2\mathbf{x}/dt^2$, so the ray paths are like the paths of particles in a field with a potential proportional to $n^2(\mathbf{x})$. This analogy describes paths, but not speeds, since light travels slower where n is greater, whereas the particles would have greater speeds.[64,65]

Euler Equations for Parameter $\sigma = z$ If $\sigma = z$, then $ds/d\sigma = (\dot{x}^2 + \dot{y}^2 + 1)^{1/2}$ and $\mathcal{L} = \mathcal{L}(x, y; \dot{x}, \dot{y}; z)$. This gives[45,49]

$$0 = \frac{d}{dz}\left(n\frac{\partial}{\partial \dot{x}}\frac{ds}{dz}\right) - \frac{ds}{dz}\frac{\partial n}{\partial x} = \frac{d}{dz}\left[\frac{n\dot{x}}{(1 + \dot{x}^2 + \dot{y}^2)^{1/2}}\right] - (1 + \dot{x}^2 + \dot{y}^2)^{1/2}\frac{\partial n}{\partial x} \tag{61}$$

with a similar equation for y. The equations can also be written (Refs. 51, app. A, and 66) as

$$n\ddot{x} = (1 + \dot{x}^2 + \dot{y}^2)\left(\frac{\partial n}{\partial x} - \frac{\partial n}{\partial z}\dot{x}\right) \quad n\ddot{y} = (1 + \dot{x}^2 + \dot{y}^2)\left(\frac{\partial n}{\partial y} - \frac{\partial n}{\partial z}\dot{y}\right) \tag{62}$$

This parameter is particularly useful when n is rotationally symmetric about the z axis.

Hamilton's Equations with Cartesian Coordinates for Parameter $\sigma = z$ A set of Hamilton's equations can also be written in cartesian coordinates using z as the parameter.[45,49] The canonical momenta in cartesian coordinates are the optical direction cosines

$$p_x = \frac{\partial \mathscr{L}}{\partial \dot{x}} = n\alpha \qquad p_y = \frac{\partial \mathscr{L}}{\partial \dot{y}} = n\beta \tag{63}$$

The hamiltonian is

$$\mathscr{H}(x, y; p_x, p_y; z) = \dot{x}p_x + \dot{y}p_y - \mathscr{L} = -\sqrt{n^2(x, y, z) - (p_x^2 + p_y^2)} \tag{64}$$

Hamilton's equations are

$$\frac{dx}{dz} = \frac{\partial \mathscr{H}}{\partial p_x}, \qquad \frac{dy}{dz} = \frac{\partial \mathscr{H}}{\partial p_y}, \qquad \frac{dp_x}{dz} = -\frac{\partial \mathscr{H}}{\partial x}, \qquad \frac{dp_y}{dz} = -\frac{\partial \mathscr{H}}{\partial y} \tag{65}$$

It is not possible to write a set of Hamilton's equations using an arbitrary parameter and three canonical momenta, since they are not independent.[67] Another equation is

$$\frac{\partial \mathscr{H}}{\partial z} = \frac{d\mathscr{H}}{dz} = \frac{1}{\gamma}\frac{\partial n}{\partial z} \tag{66}$$

Paraxial Form of Hamilton's Equations for $\sigma = z$ In the paraxial limit, if n_0 is the average index, the above set of equations gives[49]

$$\frac{d^2x(z)}{dz^2} = \frac{1}{n_0}\frac{\partial n}{\partial x} \qquad \frac{d^2y(z)}{dz^2} = \frac{1}{n_0}\frac{\partial n}{\partial y} \tag{67}$$

Other Forms A variety of additional differential equations can be obtained with various parameters.[67] Time cannot be used as a parameter.[68] The equations can also be expressed in a variety of coordinate systems.[56,58,69–71]

Refractive Index Symmetries

When the refractive index has symmetry or does not vary with one or more of the spatial variables, the above equations may simplify and take special forms. If, in some coordinate system, n does not vary with a coordinate q_i, so $\partial n/\partial q_i = 0$, and if, in addition, $\partial/\partial q_i(ds/d\sigma) = 0$, then

$$\frac{\partial \mathscr{L}}{\partial q_i} = 0 \quad \text{and} \quad \frac{\partial \mathscr{L}}{\partial \dot{q}} = n\frac{\partial}{\partial \dot{q}}\left(\frac{ds}{d\sigma}\right) = \text{constant} \tag{68}$$

There is an associated invariance of the ray path.[44,49,56,58] (This is analogous to the case in mechanics where a potential does not vary with some coordinate.) A more esoteric approach to symmetries involves Noether's theorem.[72,73] There are a number of special cases.

If the index is rotationally symmetric about the z axis, $n = n(x^2 + y^2, z)$, then $\partial \mathscr{L}/\partial \phi = 0$, where ϕ is the azimuth angle, and the constant of motion is analogous to that of the z component of angular momentum in mechanics for a potential with rotational symmetry. The constant quantity is the *skew invariant,* discussed in the section "Skew Invariant."

If the refractive index is a function of radius, $n = n(r)$, there are two constants of motion. The ray paths lie in planes through the center ($r = 0$) and have constant angular motion about an axis through the center that is perpendicular to this plane, so $\mathbf{x} \times \mathbf{p}$ is constant. If the plane is in the x-y plane, then $n(\alpha y - \beta x)$ is constant. This is analogous to motion of a particle in a central force field. Two of the best-known examples are the Maxwell fisheye[48,74] for which $n(r) \propto (1 + r^2)^{-1}$, and the Luneburg lens,[45,75] for which $n(r) = \sqrt{2 - r^2}$ for $r \le 1$ and $n = 1$ for $r > 1$.

If n does not vary with z, then $\mathcal{H} = n\gamma$ is constant for a ray as a function of z, according to Eq. (66).

If the medium is layered, so the index varies in only the z direction, then $n\alpha$ and $n\beta$ are constant. If θ is the angle relative to the z axis, then $n(z)\sin\theta(z)$ is constant, giving Snell's law as a special case.

The homogeneous medium, where $\partial n/\partial x = \partial n/\partial y = \partial n/\partial z = 0$, is a special case in which there are three constants of motion, $n\alpha$, $n\beta$, and $n\gamma$, so rays travel in straight lines.

1.6 CONSERVATION OF ÉTENDUE

If a bundle of rays intersects a constant z plane in a small region of size $dx\,dy$ and has a small range of angles $d\alpha\,d\beta$, then as the light propagates through a lossless system, the following quantity remains constant:

$$n^2 dx\,dy\,d\alpha\,d\beta = n^2 dA\,d\alpha\,d\beta = n^2 dA\cos\theta\,d\omega = dx\,dy\,dp_x\,dp_y \tag{69}$$

Here $dA = dx\,dy$ is the differential area, $d\omega$ is the solid angle, and θ is measured relative to the normal to the plane. The integral of this quantity

$$\int n^2 dx\,dy\,d\alpha\,d\beta = \int n^2 dA\,d\alpha\,d\beta = \int n^2 dA\cos\theta\,d\omega = \int dx\,dy\,dp_x\,dp_y \tag{70}$$

is the *étendue,* and is also conserved. For lambertian radiation of radiance L_e, the total power transferred is $P = \int L_e n^2 d\alpha\,d\beta\,dx\,dy$. The étendue and related quantities are known by a variety of names,[76] including *generalized Lagrange invariant, luminosity, light-gathering power, light grasp, throughput, acceptance, optical extent,* and *area-solid-angle-product*. The angle term is not actually a solid angle, but is weighted. It does approach a solid angle in the limit of small extent. In addition, the integrations can be over area, giving $n^2 d\alpha\,d\beta \int dA$, or over angle, giving $n^2 dA \int d\alpha\,d\beta$. A related quantity is the geometrical vector flux,[77] with components $(\int dp_y dp_z, \int dp_x dp_z, \int dp_x dp_y)$. In some cases these quantities include a brightness factor, and in others they are purely geometrical. The étendue is related to the information capacity of a system.[78]

As special case, if the initial and final planes are conjugate with transverse magnification $m = dx'/dx = dy'/dy$, then

$$n^2 d\alpha\,d\beta = n'^2 m^2 d\alpha' d\beta' \tag{71}$$

Consequently, the angular extents of the entrance and exit pupil in direction cosine coordinates are related by

$$n^2 \int_{\text{entrance pupil}} d\alpha\,d\beta = n'^2 m^2 \int_{\text{exit pupil}} d\alpha'\,d\beta' \tag{72}$$

See also the discussion of image irradiance in the section on apertures and pupils.

This conservation law is general; it does not depend on index homogeneity or on axial symmetry. It can be proven in a variety of ways, one of which is with characteristic functions.[79–81] Phase space arguments involving Liouville's theorem can also be applied.[82–85] Another type of proof involves thermodynamics, using conservation of radiance (or brightness) or the principle of detailed balance.[86–89] Conversely, the thermodynamic principle can be proven from the geometrical optics one.[90–92] In the paraxial limit for systems of revolution the conservation of étendue between object and image planes is related to the two-ray paraxial invariant, Eq. (152). Some historical aspects are discussed by Rayleigh.[93,94]

1.7 SKEW INVARIANT

In a rotationally symmetric system, whose indices may be constant or varying, a *skew ray* is one that does not lie in a plane containing the axis. The *skewness* of such a ray is

$$\mathcal{S} = n(\alpha y - \beta x) = p_x y - p_y x \tag{73}$$

As a skew ray propagates through the system, this quantity, known as the *skew invariant,* does not change.[95–104] For a meridional ray, one lying in a plane containing the axis, $\mathcal{S} = 0$. The skewness can be written in vector form as

$$\mathcal{S} = \mathbf{a} \cdot (\mathbf{x} \times \mathbf{p}) \tag{74}$$

where **a** is a unit vector along the axis, **x** is the position on a ray, and **p** is the optical cosine vector at that position.

This invariance is analogous to the conservation of the axial component of angular momentum in a cylindrical force field, and it can be proven in several ways. One is by performing the rotation operations on α, β, x, and y (as discussed in the section on heterogeneous media). Another is by means of characteristic functions. It can also be demonstrated that $\mathcal{S}$ is not changed by refraction or reflection by surfaces with radial gradients. The invariance holds also for diffractive optics that are figures of rotation.

A special case of the invariant relates the intersection points of a skew ray with a given meridian. If a ray with directions (α, β) in a space of index n intersects the $x = 0$ meridian with height y, then at another intersection with this meridian in a space with index n', its height y', and direction cosine α' are related by

$$n\alpha y = n'\alpha' y' \tag{75}$$

The points where rays intersect the same meridian are known as *diapoints* and the ratio y'/y as the *diamagnification*.[99]

1.8 REFRACTION AND REFLECTION AT INTERFACES BETWEEN HOMOGENEOUS MEDIA

Introduction

The initial ray direction is specified by the unit vector $\mathbf{r} = (\alpha, \beta, \gamma)$. After refraction or reflection the direction is $\mathbf{r}' = (\alpha', \beta', \gamma')$. At the point where the ray intersects the surface, its normal has direction $\mathbf{S} = (L, M, N)$.

The *angle of incidence* I is the angle between a ray and the surface normal at the intersection point. This angle and the corresponding outgoing angle I' are given by

$$\begin{aligned} |\cos I| &= |\mathbf{r} \cdot \mathbf{S}| = |\alpha L + \beta M + \gamma N| \\ |\cos I'| &= |\mathbf{r}' \cdot \mathbf{S}| = |\alpha' L + \beta' M + \gamma' N| \end{aligned} \tag{76}$$

In addition

$$|\sin I| = |\mathbf{r} \times \mathbf{S}| \quad \text{and} \quad |\sin I'| = |\mathbf{r}' \times \mathbf{S}| \tag{77}$$

The signs of these expressions depend on which way the surface normal vector is directed. The surface normal and the ray direction define the *plane of incidence,* which is perpendicular to the vector cross product $\mathbf{S} \times \mathbf{r} = (M\gamma - N\beta, N\alpha - L\gamma, L\beta - M\alpha)$. After refraction or reflection, the outgoing ray is in the same plane. This symmetry is related to the fact that optical path length is an extremum.

The laws of reflection and refraction can be derived from Fermat's principle, as is done in many books. At a planar interface, the reflection and refraction directions are derived from Maxwell's equations using the boundary conditions. For scalar waves at a plane interface, the directions are related to the fact that the number of oscillation cycles is the same for incident and outgoing waves.

Refraction

At an interface between two homogeneous and isotropic media, described by indices n and n', the incidence angle I and the outgoing angle I' are related by *Snell's law*:[105]

$$n' \sin I' = n \sin I \tag{78}$$

If $\sin I' > 1$, there is total internal reflection. Another relationship is

$$n' \cos I' = \sqrt{n'^2 - n^2 \sin^2 I} = \sqrt{n'^2 - n^2 + n^2 \cos^2 I} \tag{79}$$

Snell's law can be expressed in a number of ways, one of which is

$$n[\mathbf{r} + (\mathbf{r} \cdot \mathbf{S})\mathbf{S}] = n'[\mathbf{r}' + (\mathbf{r}' \cdot \mathbf{S})\mathbf{S}] \tag{80}$$

Taking the cross product of both sides with $\mathbf{S}$ gives another form

$$n'(\mathbf{S} \times \mathbf{r}') = n(\mathbf{S} \times \mathbf{r}) \tag{81}$$

A quantity that appears frequently in geometrical optics (but which has no common name or symbol) is

$$\Gamma = n' \cos I' - n \cos I \tag{82}$$

It can be written in several ways

$$\Gamma = (n\mathbf{r} - n'\mathbf{r}') \cdot \mathbf{S} = -n \cos I + \sqrt{n'^2 - n^2 \sin^2 I} = -n \cos I + \sqrt{n'^2 - n^2 + n^2 \cos^2 I} \tag{83}$$

In terms of Γ, Snell's law is

$$n'\mathbf{r}' = n\mathbf{r} + \Gamma \mathbf{S} \tag{84}$$

or

$$n'\alpha' = n\alpha + L\Gamma, \quad n'\beta' = n\beta + M\Gamma, \quad n'\gamma' = n\gamma + N\Gamma \tag{85}$$

The outgoing direction is expressed explicitly as a function of incident direction by

$$n'\mathbf{r}' = n\mathbf{r} + \mathbf{S}[n\mathbf{r} \cdot \mathbf{S} - \sqrt{n'^2 - n^2 + (n\mathbf{r} \cdot \mathbf{S})^2}] \tag{86}$$

If the surface normal is in the z direction, the equations simplify to

$$n'\alpha' = n\alpha, \quad n'\beta' = n\beta, \quad n'\gamma' = \sqrt{n'^2 - n^2 + n^2\gamma^2} \tag{87}$$

If $\beta = 0$, this reduces to $n'\alpha' = n\alpha$, the familiar form of Snell's law, written with direction cosines, with $n'\gamma' = (n'^2 - n^2\alpha^2)^{1/2}$, corresponding to Eq. (79). Another relation from Eq. (85) is

$$\frac{n'\alpha' - n\alpha}{L} = \frac{n'\beta' - n\beta}{M} = \frac{n'\gamma' - n\gamma}{N} = \Gamma \tag{88}$$

All of the above expressions can be formally simplified by using $\mathbf{p} = n\mathbf{r}$ and $\mathbf{p}' = n'\mathbf{r}'$. For a succession of refractions by parallel surfaces,

$$n_1 \sin I_1 = n_2 \sin I_2 = n_3 \sin I_3 = \cdots \tag{89}$$

so the angles within any two media are related by their indices alone, regardless of the intervening layers. Refractive indices vary with wavelength, so the angles of refraction do likewise.

Reflection

The reflection equations can be derived from those for refraction by setting the index of the final medium equal to the negative of that of the incident medium, i.e., $n' = -n$, which gives $\Gamma = -2n \cos I$. The angles of incidence and reflection are equal

$$I' = I \tag{90}$$

The incident and reflected ray directions are related by

$$\mathbf{S} \times \mathbf{r}' = -\mathbf{S} \times \mathbf{r} \tag{91}$$

Another expression is

$$\mathbf{r}' = \mathbf{r} - (2\mathbf{S} \cdot \mathbf{r})\mathbf{S} = \mathbf{r} - (2 \cos I)\mathbf{S} \tag{92}$$

The components are

$$\alpha' = \alpha - 2L \cos I \qquad \beta' = \beta - 2M \cos I \qquad \gamma' = \gamma - 2N \cos I \tag{93}$$

This relationship can be written in terms of dyadics[106] as $\mathbf{r}' = (\mathbf{I} - \mathbf{SS}) \cdot \mathbf{r}$. This is equivalent to the matrix form[107–111]

$$\begin{pmatrix} \alpha' \\ \beta' \\ \gamma' \end{pmatrix} = \begin{pmatrix} 1-2L^2 & -2LM & -2LN \\ -2LM & 1-2M^2 & -2MN \\ -2LN & -2MN & 1-2N^2 \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \\ \gamma \end{pmatrix} \tag{94}$$

Each column of this matrix is a set of direction cosines and is orthogonal to the others, and likewise for the rows. The matrix associated with a sequence of reflections from plane surfaces is calculated by multiplying the matrices for each reflection. Another relationship is

$$\frac{\alpha' - \alpha}{L} = \frac{\beta' - \beta}{M} = \frac{\gamma' - \gamma}{N} \tag{95}$$

If the surface normal is in the z direction, so $(L, M, N) = (0, 0, 1)$, then

$$\alpha' = \alpha \qquad \beta' = \beta \qquad \gamma' = -\gamma \tag{96}$$

Reflection by a Plane Mirror: Positions of Image Points

If light from a point (x, y, z) is reflected by a plane mirror whose distance from the coordinate origin is d, and whose surface normal has direction (L, M, N), the image point coordinates (x', y', z') are given by

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} 1-2L^2 & -2LM & -2LN & 2dL \\ -2LM & 1-2M^2 & -2MN & 2dM \\ -2LN & -2MN & 1-2N^2 & 2dN \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{97}$$

This transformation involves both rotation and translation, with only the former effect applying if $d = 0$. It is an affine type of collinear transformation, discussed in the section on collineation. The effect of a series of reflections by plane mirrors is found by a product of such matrices. The transformation can also be formulated in terms of quaternions.[110,112]

Diffractive Elements

The changes in directions produced by gratings or diffractive elements can be handled in an ad hoc geometrical way[113,114]

$$n'\mathbf{r}'_G \times \mathbf{S} = n\mathbf{r} \times \mathbf{S} + G\frac{\lambda}{\mathrm{p}}\mathbf{q} \tag{98}$$

Here λ is the vacuum wavelength, p is the grating period, $\mathbf{q}$ is a unit vector tangent to the surface and parallel to the rulings, and G is the diffraction order. Equations (81) and (91) are special cases of this equation for the 0th order.

1.9 IMAGING

Introduction

Image formation is the principal use of lenses. Moreover, lenses form images even if this is not their intended purpose. This section provides definitions, and discusses basic concepts and limitations. The purposes of the geometrical analysis of imaging include the following: (1) discovering the nominal relationship between an object and its image, principally the size, shape, and location of the image, which is usually done with paraxial optics; (2) determining the deviations from the nominal image, i.e., the aberrations; (3) estimating image irradiance; (4) understanding fundamental limitations—what is inherently possible and impossible; and (5) supplying information for diffraction calculations, usually the optical path lengths.

Images and Types of Images

A definition of image (Webster 1934[115]) is: "The optical counterpart of an object produced by a lens, mirror, or other optical system. It is a geometrical system made up of foci corresponding to the parts of the object." The point-by-point correspondence is the key, since a given object can have a variety of different images.

Image irradiance can be found only approximately from geometrical optics, the degree of accuracy of the predictions varying from case to case. In many instances wave optics is required, and for objects that are not self-luminous, an analysis involving partial coherence is also needed.

The term *image* is used in a variety of ways, so clarification is useful. The light from an object produces a three-dimensional distribution in image space. The *aerial image* is the distribution on a mathematical surface, often that of best focus, the locus of points of the images of object points. An aerial image is never the final goal; ultimately, the light is to be captured. The *receiving surface* (NS) is that on which the light falls, the distribution of which there can be called the *received image* (NS). This distinction is important in considerations of defocus, which is a relationship, not an absolute. The record thereby produced is the *recorded image* (NS). The recorded image varies with the position of the receiving surface, which is usually intended to correspond with the aerial image surface. In this section, "image" means aerial image, unless otherwise stated.

Object Space and Image Space

The object is said to exist in *object space;* the image, in *image space*. Each space is infinite, with a physically accessible region called *real,* and an inaccessible region, referred to as *virtual*. The two spaces may overlap physically, as with reflective systems. Corresponding quantities and locations associated with the object and image spaces are typically denoted by the same symbol, with a prime indicating image space. Positions are specified by a coordinate system (x, y, z) in object space and (x', y', z') in image space. The refractive indices of the object and image spaces are n and n'.

Image of a Point

An *object point* is thought of as emitting rays in all directions, some of which are captured by the lens, whose internal action converges the rays, more or less, to an *image point,* the term "point" being used even if the ray convergence is imperfect. Object and image points are said to be *conjugate*. Since geometrical optics is reversible, if A' is the image of A, then A is the image of A'.

Mapping Object Space to Image Space

If every point were imaged stigmatically, then the entire object space would be mapped into the image space according to a transformation

$$x' = x'(x, y, z) \qquad y' = y'(x, y, z) \qquad z' = z'(x, y, z) \tag{99}$$

The mapping is reciprocal, so the equations can be inverted. If n and n' are constant, then the mapping is a collinear transformation, discussed below.

Images of Extended Objects

An *extended object* can be thought of as a collection of points, a subset of the entire space, and its stigmatic image is the set of conjugate image points. A surface described by $0 = F(x, y, z)$ has an image surface

$$0 = F'(x', y', z') = F[x(x', y', z'), y(x', y', z'), z(x', y', z')] \tag{100}$$

A curve described parametrically by $\mathbf{x}(\sigma) = [x(\sigma), y(\sigma), z(\sigma)]$ has an image curve

$$\mathbf{x}'(\sigma) = \{x'[x(\sigma), y(\sigma), z(\sigma)], y'[x(\sigma), y(\sigma), z(\sigma)], z'[x(\sigma), y(\sigma), z(\sigma)]\} \tag{101}$$

Rotationally Symmetric Lenses

Rotationally symmetric lenses have an *axis,* which is a ray path (unless there is an obstruction). All planes through the axis, the *meridians* or *meridional planes,* are planes with respect to which there is bilateral symmetry. An *axial object point* is conjugate to an *axial image point*. An axial image point is located with a single ray in addition to the axial one. Off-axis object and image points are in the same meridian, and may be on the same or opposite sides of the axis. The *object height* is the distance of a point from the axis, and the *image height* is that for its image. It is possible to have rotational symmetry without bilateral symmetry, as in a system made of crystalline quartz,[116] but such systems are not discussed here. For stigmatic imaging by a lens rotationally symmetric about the z axis, Eq. (99) gives

$$x' = x'(x, z) \qquad y' = y'(y, z) \qquad z' = z'(z) \tag{102}$$

Planes Perpendicular to the Axis

The arrangement most often of interest is that of planar object and receiving surfaces, both perpendicular to the lens axis. When the terms *object plane* and *image plane* are used here without further elaboration, this is the meaning. (This arrangement is more common for manufactured systems with flat detectors, than for natural systems, for instance, eyes, with their curved retinas.)

Magnifications

The term *magnification* is used in a general way to denote the ratio of conjugate object and image dimensions, for example, heights, distances, areas, volumes, and angles. A single number is inadequate when object and image shapes are not geometrically similar. The term magnification implies an increase, but this is not the case in general.

Transverse Magnification

With object and image planes perpendicular to the axis, the relative scale factor of length is the *transverse magnification* or *lateral magnification,* denoted by m, and usually referred to simply as "the magnification." The transverse magnification is the ratio of image height to object height, $m = h'/h$. It can also be written in differential form, e.g., $m = dx'/dx$ or $m = \Delta x'/\Delta x$. The transverse magnification has a sign, and it can have any value from $-\infty$ to $+\infty$. Areas in such planes are scaled by m^2. A lens may contain plane mirrors that affect the image parity or it may be accompanied by external plane mirrors that reorient images and change their parity, but these changes are independent of the magnification at which the lens works.

Longitudinal Magnification

Along the rotational axis, the *longitudinal magnification,* m_L, also called *axial magnification,* is the ratio of image length to object length in the limit of small lengths, i.e., $m_L = dz'/dz$.

Visual Magnification

With visual instruments, the perceived size of the image depends on its angular subtense. *Visual magnification* is the ratio of the angular subtense of an image relative to that of the object viewed directly. Other terms are used for this quantity, including "magnification," "power," and "magnifying power." For objects whose positions can be controlled, there is arbitrariness in the subtense without the instrument, which is greatest when the object is located at the near-point of the observer. This distance varies from person to person, but for purposes of standardization the distance is taken to be 250 mm. For instruments that view distant objects there is no arbitrariness of subtense with direct viewing.

Ideal Imaging and Disappointments in Imaging

Terms such as *perfect imaging* and *ideal imaging* are used in various ways. The ideal varies with the circumstances, and there are applications in which imaging is not the purpose, for instance, energy collection and Fourier transformation. The term *desired imaging* might be more appropriate in cases where that which is desired is fundamentally impossible. Some deviations from what is desired are called *aberrations,* whether their avoidance is possible or not. Any ideal that can be approximated must agree in its paraxial limit ideal with what a lens actually does in its paraxial limit.

Maxwellian Ideal for Single-Plane Imaging

The most common meaning of perfect imaging is that elucidated by Maxwell,[117] and referred to here as *maxwellian ideal* or *maxwellian perfection*. This ideal is fundamentally possible. The three conditions for such imaging of points in a plane perpendicular to the lens axis are: (1) Each point is imaged stigmatically. (2) The images of all the points in a plane lie on a plane that is likewise perpendicular to the axis, so the field is flat, or free from field curvature. (3) The ratio of image heights to object heights is the same for all points in the plane. That is, transverse magnification is constant, or there is no distortion.

The Volume Imaging Ideal

A more demanding ideal is that points everywhere in regions of constant index be imaged stigmatically and that the imaging of every plane be flat and free from distortion. For planes perpendicular to the lens axis, such imaging is described mathematically by the collinear transformation, discussed later. It is inherently impossible for a lens to function in this way, but the mathematical apparatus of collineation is useful in obtaining approximate results.

Paraxial, First-Order, and Gaussian Optics

The terms "paraxial," "first order," and "gaussian" are often used interchangeably, and their consideration is merged with that of collineation. The distinction is often not made, probably because these descriptions agree in result, although differing in approach. One of the few discussions is that of Southall.[118] A *paraxial* analysis has to do with the limiting case in which the distances of rays from the axis approach zero, as do the angles of the rays relative to the axis. The term *first order* refers to the associated mathematical approximation in which the positions and directions of such rays are computed with terms to the first order only in height and angle. *Gaussian* refers to certain results of the paraxial optics, where lenses are black boxes whose properties are summarized by the existence and locations of cardinal points. In the limit of small heights and angles, the equations of collineation are identical to those of paraxial optics. Each of these is discussed in greater detail below.

Fundamental Limitations

There are fundamental geometrical limitations on optical systems, relating to the fact that a given ray passes through many points and a given point lies on many rays. So the images of points on the same line or plane, or on different planes, are not independent. A set of rays intersecting at several points in object space cannot be made to satisfy arbitrary requirements in image space. Such limitations are best studied by the methods of hamiltonian optics.

Stigmatic Imaging

If all rays from an object point converge precisely to an image point, the imaging of this point is said to be *stigmatic*. The optical path lengths of all rays between two such points are identical. A stigmatic image point is located by the intersection of any two rays that pass through the points. An *absolute instrument* is one which images all points stigmatically.[119] For such imaging

$$n\delta x = n'\delta x', \quad n\delta y = n'\delta y', \quad n\delta z = n'\delta z' \tag{103}$$

where conjugate length elements are δx and $\delta x'$, δy and $\delta y'$, δz and $\delta z'$.

Path Lengths and Conjugate Points

All the rays from an object point to its stigmatic image point have the same optical path length. For focal lenses, the paths lengths for different pairs of conjugate points in a plane perpendicular to the axis are different, except for points on circles centered on the axis. For afocal lenses path lengths are nominally the same for all points in planes perpendicular to the axis. For afocal lenses with transverse magnification $\pm n/n'$, path lengths can be the same for all points. In general, the path lengths between different points on an object and image surface are equal only if the shape of the image surface is that of a wavefront that has propagated from a wavefront whose shape is that of the object surface.

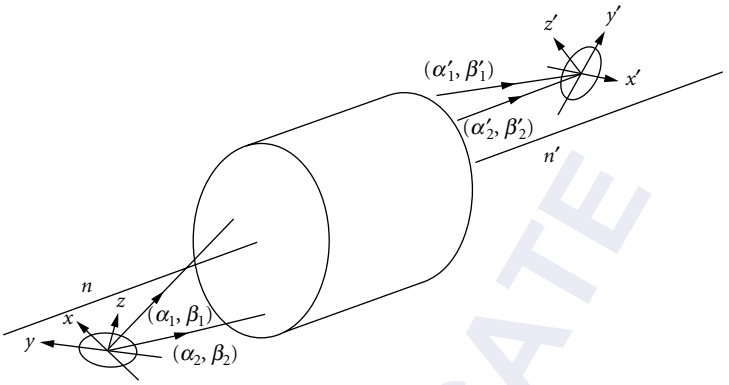

FIGURE 2 The cosine condition. A small area in object space about the origin in the *x*-*y* plane is imaged to the region around the origin of the *x′*-*y′* plane in image space. A pair of rays from the origin with direction cosines (α_1, β_1) and (α_2, β_2) arrive with (α'_1, β'_1) and (α'_2, β'_2). The direction cosines and the transverse magnification in the planes are related by Eq. (104).

The Cosine Condition

The *cosine condition* relates object space and image space ray angles, if the imaging is stigmatic over some area.[116,120,121] Let the *x*-*y* plane lie in the object surface and the *x′*-*y′* plane in the conjugate surface (Fig. 2). Two rays leaving a point in the object region have direction cosines (α_1, β_1) and (α_2, β_2), and the rays on the image side have (α'_1, β'_1) and (α'_2, β'_2). If the imaging is stigmatic, with local transverse magnification m on the surface, then

$$m = \frac{n(\alpha_1 - \alpha_2)}{n'(\alpha'_1 - \alpha'_2)} = \frac{n(\beta_1 - \beta_2)}{n'(\beta'_1 - \beta'_2)} \tag{104}$$

In the limit as $\alpha_1 \to \alpha_2$ and $\beta_1 \to \beta_2$, the cosine condition gives

$$m = \frac{n\,d\alpha}{n'\,d\alpha'} = \frac{n\,d\beta}{n'\,d\beta'} \tag{105}$$

This condition also holds in the more general case of *isoplanatic* imaging, where there is aberration that is locally constant across the region in question.[122,123]

The Abbe Sine Condition

The *sine condition* or *Abbe sine condition*[119,124] is a special case of the cosine condition for object and image planes perpendicular to the axis in regions about the axis. For a plane with transverse magnification m, let θ be the angle relative to the axis made by a ray from an axial object point, and θ' be that in image space. If the lens is free of coma

$$m = \frac{n\sin\theta}{n'\sin\theta'} = \frac{n\alpha}{n'\alpha'} = \frac{n\beta}{n'\beta'} \tag{106}$$

for all θ and θ'. There are signs associated with θ and θ', so that $m > 0$ if they have the same sign, and $m < 0$ if the signs are opposite. This equation is sometimes written with m replaced by the ratio of paraxial angles. There is sometimes the implication that θ and θ' refer only to the extreme angles passing through the lens, when in fact the sine condition dictates that the ratio of the sines is the constant for all angles. For an object at infinity, the sine condition is

$$\sin\theta' = -\frac{y}{f'} \qquad \text{or} \qquad n'\beta' = -y\phi \tag{107}$$

where y is the height of a ray parallel to the axis, ϕ is the power of the lens, and f' is the rear focal length. These relationships hold to a good approximation in most lenses, since small deviations are associated with large aberrations. A deviation from this relationship is called *offense against the sine condition,* and is associated with coma.[123,125–128] The sine condition does not apply where there are discontinuities in ray behavior, for example, in devices like Fresnel lenses, or to diffraction-based devices like zone plates.

The Herschel Condition

The *Herschel condition* is a relationship that holds if the imaging is stigmatic for nearby points along the axis.[119,129,130] The two equivalent relations are

$$m = \frac{n\sin\left(\frac{1}{2}\theta\right)}{n'\sin\left(\frac{1}{2}\theta'\right)} \qquad \text{and} \qquad m_L = \frac{n\sin^2(\frac{1}{2}\theta)}{n'\sin^2(\frac{1}{2}\theta')} = \frac{n(1-\gamma)}{n'(1-\gamma')} \tag{108}$$

The Herschel condition is inconsistent with the sine condition unless $m \pm n/n'$. So, in general, stigmatic imaging in one plane precludes that in others.

Sine and Herschel Conditions for Afocal Systems

For afocal systems the sine condition and Herschel condition are identical. For rays entering parallel to the axis at y and leaving at y', they are

$$m = \frac{y'}{y} \tag{109}$$

That is, the ratio of incoming and outgoing heights is independent of the incoming height. (Ref. 128, chap. 3, "The Sine Condition and Herschel's Condition").

Stigmatic Imaging Possibilities

For object and image spaces with constant refractive indices, stigmatic imaging is only possible for the entire spaces for afocal lenses with identical transverse and longitudinal magnifications $m = \pm n/n'$ and $|m_L| = |m|$. Such lenses re-create not only the intersection points, but the wavefronts, since the corresponding optical path lengths are the same in both spaces, Eq. (103). For other lenses with constant object and image space indices, the maxwellian ideal can be met for only a single surface. In addition, a single point elsewhere can be imaged stigmatically.[127,131] Nonplanar surfaces can be imaged stigmatically, a well-known example being the imaging of spherical surfaces by a spherical refracting surface, for a particular magnification.[119] For systems with spherical symmetry, it is possible that two nonplanar surfaces be stigmatically imaged.[132] In addition, various systems with heterogeneous indices can image stigmatically over a volume.

1.10 DESCRIPTION OF SYSTEMS OF REVOLUTION

Introduction

This section is concerned with the optical description of lens and mirror systems that are figures of revolution.[133–145] From a mechanical viewpoint, optical systems are comprised of lenses and mirrors. From the point of view of the light, the system is regions of media with different indices, separated by interfaces of various shapes. This section is limited to homogeneous isotropic media. It is further restricted to reflecting and refracting surfaces that are nominally smooth, and to surfaces that are figures of revolution arranged so their axes are collinear, so the entire system is a figure of revolution about the *lens axis*. (The often-used term "optical axis" is also used in crystallography. Moreover, the axis is often mechanical as well as "optical.") The lens axis is the z axis of an orthogonal coordinate system, with the x-y plane perpendicular. The distance from a point to the axis is $\rho = \sqrt{x^2 + y^2}$. Along the axis, the positive direction is from left to right.

Terminology

A *meridian* or *meridional plane* contains the axis, all such planes being equivalent. Meridional planes are planes of bilateral symmetry if the indices are homogeneous and isotropic. Some optical systems are comprised of pieces of surfaces of revolution, in which case it is still useful to discuss the behavior about the axis.

Reflection, Unfolded Diagrams

Light passes through refractive systems more or less in the same direction relative to the axis. In reflective and catadioptric systems, the light may change directions. (It may not, in the case of grazing incidence optics.) In order to consider all types of systems in a unified way, pictorially and algebraically, reflections can often be "unfolded," i.e., represented pictorially as transmission, with mirrors replaced by hypothetical lenses with the same properties, Figs. 3 and 18. Some structures must be taken into account several times in unfolding. For example, a hole may block light at one point along a ray and transmit it at another. (In some considerations, unfolding can be misleading—for instance, those involving stray light.)

Description of Surfaces

A *surface* is an interface between media with different refractive indices—either refracting or reflecting. The surface is the optical element, produced by a lens, which is a mechanical element. Surfaces can be described mathematically in many ways. (For example, conics can be described as loci of points with certain relationships.) In optical instruments, the entire surface is rarely used, and the axial region is usually special, so the description usually begins there and works out. The *vertex* of a figure of revolution intersects with the axis, and is a local extremum. The plane perpendicular to the axis and tangent to the vertex will be referred to as the *vertex plane* (NS). A surface can be described by its *sag*, the directed distance $z(\rho)$ from the vertex plane to the surface, Fig. 4. The vertex is usually taken to have $z(0) = 0$. The *vertex curvature* or *paraxial curvature* c and radius of curvature r are given by

$$c = \frac{1}{r} = \left.\frac{\partial^2 z(\rho)}{\partial \rho^2}\right|_{\rho = 0} \tag{110}$$

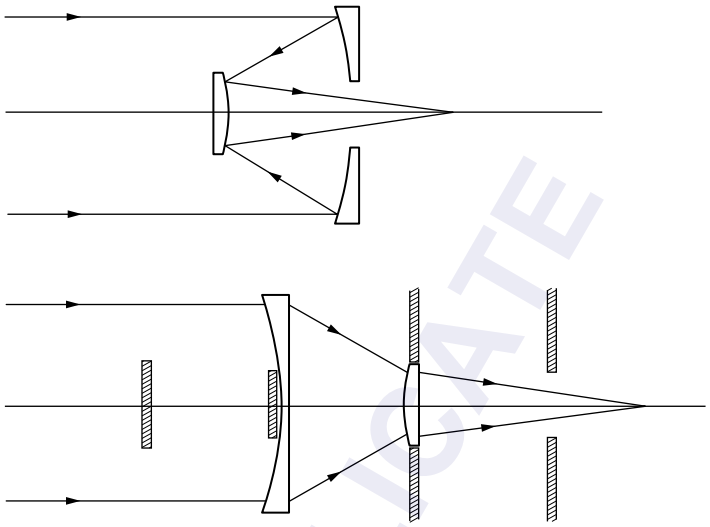

FIGURE 3 Example of an unfolded diagram. The two-mirror system above has an unfolded representation below. The reflective surfaces are replaced by thin lens equivalents. Their obstructions and the finite openings are accounted for by dummy elements.

For an arbitrary surface, this curvature is identical to that of the sphere which is a best fit on axis. The sign convention for curvature and radius is that c and r are positive if the center of curvature is to the right of the vertex, as in the case shown in Fig. 4. In general, the curvature is mathematically more foolproof than radius, since curvature can be zero, but it is never infinite, whereas radius is never zero, but may be infinite.

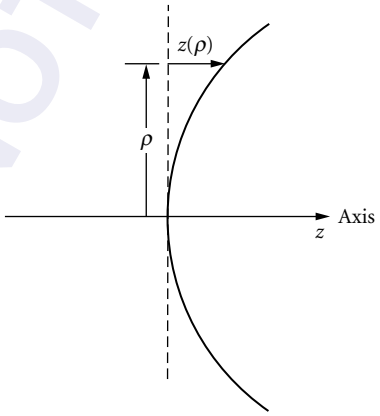

FIGURE 4 Description of a surface of revolution. The distance from the axis is ρ, and the sag $z(\rho)$ is the distance from the vertex tangent plane to the surface.

Spherical Surfaces

The spherical surface is the most common in optics, since it is most naturally produced. Spherical is the default, and is assumed when no other mention is made. Aspheres are thought of as deviating from spheres, rather than spheres as special cases of more general forms. The equation for a sphere with radius r, curvature c, and a vertex at $z = 0$ is

$$\rho^2 + (z-r)^2 = r^2 \tag{111}$$

The sag is given by

$$z(\rho) = r - \sqrt{r^2 - \rho^2} = r\left(1 - \sqrt{1 - c^2\rho^2}\right) = \frac{c\rho^2}{1 + \sqrt{1 - c^2\rho^2}} \tag{112}$$

The Taylor expansion is

$$z(\rho) = \tfrac{1}{2}c\rho^2 + \tfrac{1}{8}c^3\rho^4 + \tfrac{1}{16}c^5\rho^6 + \tfrac{5}{128}c^7\rho^8 + \tfrac{7}{256}c^9\rho^{10} + \cdots \tag{113}$$

At the point (x, y, z) on the surface of the sphere, the surface normal has direction cosines

$$(L, M, N) = \left(\frac{x}{r}, \frac{y}{r}, \frac{z-r}{r}\right) = (cx, cy, cz - 1) \tag{114}$$

Conics of Rotation

The general form of a conic of rotation about the z axis is

$$z(\rho) = \frac{r}{\varepsilon}\left(1 - \sqrt{1 - \varepsilon c^2\rho^2}\right) = \frac{c\rho^2}{1 + \sqrt{1 - \varepsilon c^2\rho^2}} \tag{115}$$

The value of ε determines the type of conic, as given in the table below. It is common in optics to use κ, the *conic parameter* or *conic constant,* related by

$$\kappa = \varepsilon - 1 \qquad \text{or} \qquad \varepsilon = 1 + \kappa \tag{116}$$

Another parameter used to describe conics is the *eccentricity e,* used in the polar coordinate form for conics about their focus: $r(\theta) = a/(1 + e\cos\theta)$ where $e^2 = -\kappa$. In the case of paraboloids, the first form of Eq. (115) breaks down. A cone can be approximated by a hyperbola with $\kappa = -\sec^2\theta$, where θ is the cone half angle.

Conic Type and Value of Parameter

Parameter	ε	κ	e
Oblate ellipsoid	$\varepsilon > 1$	$\kappa > 0$	—
Sphere	$\varepsilon = 1$	$\kappa = 0$	0
Prolate ellipsoid	$0 < \varepsilon < 1$	$-1 < \kappa < 0$	$0 < e < 1$
Paraboloid	$\varepsilon = 0$	$\kappa = -1$	$e = 1$
Hyperboloid	$\varepsilon < 0$	$\kappa < -1$	$e > 1$

The Taylor expansion for the sag is

$$z(\rho) = \tfrac{1}{2}c\rho^2 + \tfrac{1}{8}\varepsilon c^3\rho^4 + \tfrac{1}{16}\varepsilon^2 c^5\rho^6 + \tfrac{5}{128}\varepsilon^3 c^7\rho^8 + \tfrac{7}{256}\varepsilon^4 c^9\rho^{10} + \cdots \tag{117}$$

The surface normals are

$$(L, M, N) = [1 - 2c(\varepsilon - 1)z + c^2\varepsilon(\varepsilon - 1)z^2]^{-1/2}(cx, cy, cz - 1) \tag{118}$$

The sagittal and tangential curvatures are

$$c_s = \frac{c}{[1+(1-\varepsilon)c^2\rho^2]^{1/2}}, \quad c_t = \frac{c}{[1+(1-\varepsilon)c^2\rho^2]^{3/2}} \tag{119}$$

General Asphere of Revolution

For an arbitrary figure of revolution all of whose derivatives are continuous, the Taylor expansion is

$$z(\rho) = \tfrac{1}{2}c\rho^2 + q_4\rho^4 + q_6\rho^6 + \cdots \tag{120}$$

An asphere is often treated as a sphere that matches at the vertex and a deviation therefrom:

$$z(\rho) = z_{\text{sphere}}(\rho) + a_4\rho^4 + a_6\rho^6 + \cdots \tag{121}$$

Alternatively, nonconic aspheres can be treated as conics and a deviation therefrom:

$$z(\rho) = z_{\text{conic}}(\rho) + b_4\rho^4 + b_6\rho^6 + \cdots \tag{122}$$

The expansion coefficients are different in each case. Additional information on the coefficients is given by Malacara[144] and Brueggemann.[135] The sagittal and tangential curvatures are given in general by

$$c_s = \frac{\dot{z}(\rho)}{\rho[1+\dot{z}(\rho)^2]^{1/2}}, \quad c_t = \frac{\ddot{z}(\rho)}{[1+\dot{z}(\rho)^2]^{3/2}} \tag{123}$$

Here $\dot{z}(\rho) = dz(\rho)/d\rho$ and $\ddot{z}(\rho) = d^2z(\rho)/d\rho^2$.

1.11 TRACING RAYS IN CENTERED SYSTEMS OF SPHERICAL SURFACES

Introduction

Ray tracing is the process of calculating the paths of rays through optical systems. Two operations are involved, propagation from one surface to the next and refraction or reflection at the surfaces. Exact equations can be written for spherical surfaces and conics of revolution with homogeneous media.[146–153] Conics are discussed by Welford.[152] For general aspheres, the intersection position is found by iterating.[153,154] Nonsymmetric systems are discussed by Welford.[152]

Description and Classification of Rays in a Lens

For optical systems with rotational symmetry, rays are typically described in terms of the axial parameter z. A ray crosses each constant z plane at a point (x, y) with direction cosines (α, β, γ), where γ is not independent. Thus a ray is described by $[x(z), y(z)]$ and $[\alpha(z), \beta(z)]$.

For systems that are figures of revolution, *meridional rays* are those lying in a meridional plane, a plane that includes the axis, and other rays are *skew rays*. The *axial ray* corresponds to the axis of revolution. Rays are also classified according to their proximity to the axis. *Paraxial rays* are those in the limit of having small angles and small distances from the axis. Nonparaxial rays are sometimes referred to as *finite rays* or *real rays*. *Ray fans* are groups of rays lying in a plane. A *tangential fan* lies in a meridian, and intersects at a *tangential focus*. A *sagittal fan* lies in a plane perpendicular to a meridian, and intersects at a *sagittal focus.*

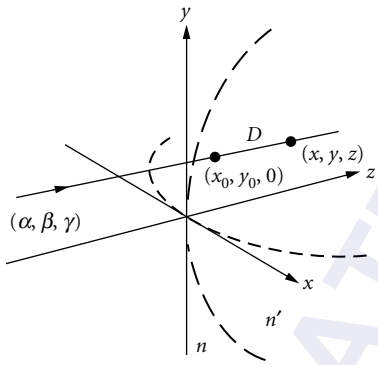

FIGURE 5 Intersection points. A ray with direction cosines (α, β, γ) intersects the vertex tangent plane at $(x_0, y_0, 0)$ and the optical surface at (x, y, z). The distance between these points is D, given by Eq. (126).

Transfer

In propagating through a homogeneous medium, a ray originating at (x_1, y_1, z_1) with directions (α, β, γ) intersects a z_2 plane at

$$x_2 = x_1 + \frac{\alpha}{\gamma}(z_2 - z_1) \qquad \text{and} \qquad y_2 = y_1 + \frac{\beta}{\gamma}(z_2 - z_1) \tag{124}$$

Intersection Points

Let the intersection points of the ray with the vertex plane at $z = 0$ be $(x_0, y_0, 0)$, Fig. 5. Define auxiliary functions

$$A(x_0, y_0; \alpha, \beta; c) = \gamma - c(\alpha x_0 + \beta y_0) \qquad \text{and} \qquad B(x_0, y_0, c) = c^2(x_0^2 + y_0^2) \tag{125}$$

The distance D along the ray from this point to the surface is given by

$$cD = A - \sqrt{A^2 - B} = \frac{B}{A + \sqrt{A^2 - B}} \tag{126}$$

The intersection point has the coordinates

$$x = x_0 + \alpha D, \qquad y = y_0 + \beta D, \qquad z = \gamma D \tag{127}$$

The incidence angle I at the intersection point is given by

$$\cos I = \sqrt{A^2 - B} \tag{128}$$

so

$$\Gamma = -n\sqrt{A^2 - B} + \sqrt{n'^2 - n^2 + n^2(A^2 - B)} \tag{129}$$

Mathematically, double intersection points are possible, so they must be checked for. If the ray misses the surface, then $A^2 < B$. If there is total internal reflection, the second square root in Eq. (129) is imaginary.

Refraction and Reflection by Spherical Surfaces

Rays refract or reflect at surfaces with reference to the local normal at the intersection point. The surface normal given by Eq. (114) is substituted in the general form for refraction, Eq. (85), to give

$$n'\alpha' = n\alpha - \Gamma cx, \quad n'\beta' = n\beta - \Gamma cy, \quad n'\gamma' = ny - \Gamma(1 - cz) \tag{130}$$

For reflection, the above equations are used, with $n' = -n$, so $\Gamma = 2n\cos I = 2n\sqrt{A^2 - B}$.

Meridianal Rays

The meridian is customarily taken to be that for which $x = 0$, so the direction cosines are $(0, \beta, \gamma)$. Let U be the angle between the axis and the ray, so $\beta = \sin U$ and $\gamma = \cos U$. The transfer equation, Eq. (124), becomes

$$y_2 = y_1 + \tan U(z_2 - z_1) \tag{131}$$

The second equation of Eq. (130) can be written

$$n'\sin U' - n\sin U = -cy(n'\cos I' - n\cos I) \tag{132}$$

If the directed distance from the vertex to the intersection point of the incident ray with the axis is l, the outgoing angle is

$$U' = U + \arcsin[(lc - 1)\sin U] - \arcsin\left[\frac{n}{n'}(lc - 1)\sin U\right] \tag{133}$$

The directed distance l' from the vertex to the axial intersection of the refracted ray is given by

$$cl' = 1 + (cl - 1)\frac{n}{n'}\frac{\sin U}{\sin U'} \tag{134}$$

For reflection, setting $n' = -n$ gives

$$U' = U + 2\arcsin[(lc - 1)\sin U] \tag{135}$$

1.12 PARAXIAL OPTICS OF SYSTEMS OF REVOLUTION

Introduction

The term *paraxial* is used in different ways. In one, paraxial rays are those whose distances from the axis and whose angles relative to the axis are small. This leaves questions of how small is small enough and how this varies from system to system. The other interpretation of the term, which is used here, is that paraxial rays represent a limiting case in which the distances from the axis and angles relative to the axis vanish. *Paraxial optics* then describes the behavior of systems in this limit. The ray-tracing equations in the paraxial limit are linear in angle and in distance from the axis, hence the term *first-order optics,* which is often considered equivalent to paraxial. (There are no 0th-order terms since the expansion is taken about the axis, so a ray with an initial height and angle of zero, i.e., a ray along the axis, has the same outgoing height and angle.) The linearity of the paraxial equations makes them simple and understandable, as well as expressible in matrix form. Paraxial ray tracing is discussed to some extent by almost every book that treats geometrical optics.

Paraxial ray tracing is done to determine the gaussian properties of lenses, to locate image positions and magnifications, and to locate pupils and determine their sizes. Another use of paraxial ray tracing, not discussed here, is the computation of third-order aberrations.[155]

Paraxial imaging is perfect in the sense that it agrees with the Maxwell ideal and with that of collineation. Point images everywhere are stigmatic, fields are flat, and there is no distortion. Aberration is often thought of as the difference between the behavior of finite rays and that of paraxial rays. If this approach is taken, then in the process of lens design, finite rays are made to agree, insofar as possible, with the paraxial ones, which cannot be similarly changed. In the paraxial limit, surfaces are described by their vertex curvatures, so conics, aspheres, and spheres are indistinguishable, the difference being in the fourth power and above. Consequently, aberrations can be altered by changing the surface asphericity without changing paraxial properties. A paraxial treatment can be done even if a system is missing the axial region, as in the case with central obstructions and off-axis sections of figures of revolution.

This section is concerned with systems of mirrors and lenses with rotational symmetry and homogeneous refractive indices. In this case, it suffices to work in a single meridian. Generalizations are found in the sections in this chapter on images about known rays and rays in heterogeneous media. Other generalizations involve expansions about given rays in systems that are not rotationally symmetric.

The Paraxial Limit

The lens axis is the z axis, and rays in the $x = 0$ meridian are considered. Ray heights are y, and angles relative to the axis are u. In the paraxial limit, the quantities u, $\tan u$, and $\sin u = \beta$ are indistinguishable. The z-direction cosine is $\gamma = \cos u \simeq 1$. Since the ray angles and heights are small, incidence angles are likewise, so $i \simeq \sin i$, $\cos I \simeq 1$, $\cos I' \simeq 1$, and $\Gamma = n' \cos I' - n \cos I \simeq n' - n$.

Transfer

In traversing a distance t between two planes, the height of a meridional ray changes from y to y' according to Eq. (124), $y' = y + t\beta/\gamma$. In the paraxial limit, this equation becomes

$$y' = y + tu \tag{136}$$

If a ray travels from one curved surface to the next, the distance t equals the vertex separation to first order, since the correction for the surface sag is of second order in height and angle. This term is given above in Eq. (127).

Refraction

The paraxial form of Snell's law, Eq. (78), is

$$n'i' = ni \tag{137}$$

Reflection

The law of reflection is the same for paraxial as for finite rays,

$$i' = -i \tag{138}$$

Angle of Incidence at a Surface

A ray with an angle u, which intersects a surface of curvature c at height y, makes an angle i with the local surface normal of the surface given by

$$i = u + yc \tag{139}$$

This equation is easily remembered from two special cases. When $y = 0$, the intersection is at the vertex, so $i = u$. When $u = -cy$, the ray is directed through the center of curvature, so $i = 0$.

Refraction at a Surface

The above equation combined with that for Snell's law gives

$$n'u' = nu - yc(n' - n) \tag{140}$$

This equation can also be obtained from the exact equation, $n'\beta' = n\beta - \Gamma cy$, Eq. (125). In the paraxial limit, $\Gamma = n' - n$, and the intersection height y is that in the vertex plane.

Reflection at a Surface

The relationship between incident and outgoing angles at a reflecting surface is found by combining Eqs. (138) and (139), to be

$$u' = -u - 2cy \tag{141}$$

Refraction and Reflection United: Surface Power

Reflection and refraction can be treated the same way mathematically by thinking of reflection as refraction with $n' = -n$, in which case Eq. (140) gives Eq. (141). A reflecting surface can be represented graphically as a thin convex-plano or concave-plano thin lens with index $-n$, where n is the index of the medium, Fig. 18. For both refraction and reflection,

$$n'u' = nu - y\phi \tag{142}$$

where the surface *power* ϕ is

$$\phi = c(n' - n) \tag{143}$$

If the surface is approached from the opposite direction, then n and n' are switched, as is the sign of c, so ϕ is the same in both directions. Thus ϕ is a scalar property of the interface, which can be positive, negative, or zero. The power is zero if $n' = n$ or $c = 0$. If $n' = n$, the surface is "invisible," and the rays are not bent. If $c = 0$, the rays are bent. For a planar refracting surface $n'u' = nu$, and a planar reflecting surface gives $u' = -u$.

Principal Focal Lengths of a Surface

A ray approaching a surface parallel to the axis ($u = 0$) with a height y has an outgoing angle given by

$$n'u' = -y\phi \tag{144}$$

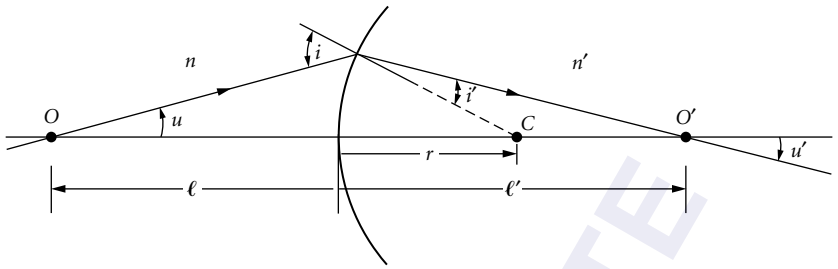

FIGURE 6 Refraction at a single spherical surface with center C and radius r. Axial object point O is imaged at O'.

This ray intercepts the axis at the *rear focal point,* whose directed distance from the vertex is $f' = y/u' = n'/\phi$. This directed distance is the *rear focal length*. Similarly, a ray entering from the right with $u' = 0$ intercepts the axis at the *front focal point,* a directed distance from the vertex of $f = y/u = -n/\phi$, the *front focal length*. Thus, a surface has a single power and two focal lengths, among which the following relationships hold:

$$f' = \frac{n}{\phi}, \quad f = -\frac{n}{\phi}, \quad \phi = -\frac{n}{f} = \frac{n'}{f'}, \quad \frac{f'}{f} = -\frac{n'}{n} \tag{145}$$

For a refracting surface, the signs of f' and f are opposite. For a reflecting surface $f' = f$.

Axial Object and Image Locations for a Single Surface

A ray from an axial point a directed distance l from the vertex of a surface that makes an angle u with the axis intersects the surface at height $y = -l/u$. After refraction or reflection, the ray angle is u', and the ray intersects the axis at a distance $l' = -y/u'$ from the vertex, Fig. 6. Substituting for u and u' in Eq. (142), the relationship between axial object and image distances is

$$\frac{n'}{l'} = \frac{n}{l} + \phi \tag{146}$$

This can also be written

$$n\left(\frac{1}{r} - \frac{1}{l}\right) = n'\left(\frac{1}{r} - \frac{1}{l'}\right) \tag{147}$$

This is a special case of the equations below for imaging about a given ray. The transverse magnification is $m = l'/l$.

Paraxial Ray Tracing

Paraxial rays are traced through an arbitrary lens by a sequence of transfers between surfaces and power operations at surfaces. Each transfer changes height but not angle, and each power operation changes angle but not height. An image can be found by applying Eq. (136) and Eq. (142) successively. Alternatively, matrix methods described later or in Sec. 1.17 can be used.

Linearity of Paraxial Optics

For both the transfer and power operations, the outgoing heights and angles depend linearly on the incoming heights and angles. So a system described by a sequence of such operations is also linear. Therefore, a ray that enters with height y and angle u leaves with $y'(y, u)$ and $u'(y, u)$ given by

$$y' = \left(\frac{\partial y'}{\partial y}\right) y + \left(\frac{\partial y'}{\partial u}\right) u \quad \text{and} \quad u' = \left(\frac{\partial u'}{\partial y}\right) y + \left(\frac{\partial u'}{\partial u}\right) u \tag{148}$$

These equations can also be thought of as the first terms of Taylor expansions of exact expressions for $y'(y, u)$ and $u'(y, u)$. These partial derivatives depend on the structure of the system, and they can be determined by tracing two rays through the system. The partial derivatives, other than $\partial u'/\partial y$, also depend on the axial locations of the input and output surfaces. The changes with respect to these locations are treated easily by matrix methods.

The Two-Ray Paraxial Invariant

The various rays that pass through a lens are not acted upon independently, so there are several invariants that involve groups of rays. Consider two meridional paraxial rays that pass through a lens. At a given plane, where the medium has an index n, one ray has height y_1 and angle u_1, and the other has y_2 and u_2. The quantity

$$L = n(y_1 u_2 - y_2 u_1) \tag{149}$$

which we refer to as the *paraxial invariant* (NS), is unchanged as the rays pass through the system. Applying Eq. (136) and Eq. (142) to the above expression shows that this quantity does not change upon transfer or upon refraction and reflection. The invariant is also related to the general skew invariant, Eq. (73), since a paraxial skew ray can be decomposed into two meridional rays.

Another version of the invariance relationship is as follows. Two objects with heights y_1 and y_2 are separated axially by d_{12}. If their image heights are y_1' and y_2', and the image separation is d_{12}', then

$$n \frac{y_1 y_2}{d_{12}} = n' \frac{y_1' y_2'}{d_{12}'} \tag{150}$$

An additional version of the invariance relationship is

$$\left(\frac{\partial y'}{\partial y}\right)\left(\frac{\partial u'}{\partial u}\right) - \left(\frac{\partial y'}{\partial u}\right)\left(\frac{\partial u'}{\partial y}\right) = \frac{n}{n'} \tag{151}$$

where the partial derivatives, Eq. (148), describe the action of any system.

The invariant applies *regardless* of the system. Thus, for example, if the lens changes, as with a zoom system, so that both of the outgoing rays change, their invariant remains. The invariant arises from basic physical principles that are manifested in a variety of ways, for example, as conservation of brightness and Liouville's theorem, discussed earlier in the section on conservation of étendue. This invariance shows that there are fundamental limits on what optical systems can do. Given the paraxial heights and angles of two input rays, only three of the four output heights and angles can be chosen arbitrarily. Likewise, only three of the four partial derivatives above can be freely chosen. The invariant is not useful if it vanishes identically. This occurs if the two rays are scaled versions of one another, which happens if both $u_1 = 0$ and $u_2 = 0$ for some z, or if both rays pass through the same axial object point, in which case $y_1 = 0$ and $y_2 = 0$. The invariant also vanishes if one of the rays lies along the axis, so that $y_1 = 0$ and $u_1 = 0$.

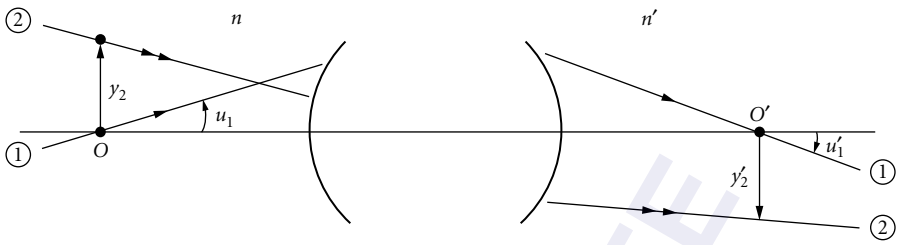

FIGURE 7 An object and image plane with ray 1 through the axial points and ray 2 through off-axis points. The location and magnification of an image plane can be found by tracing a ray from the axial object point O to axial image point O'. The magnification is given by Eq. (153). In the figure, u_1 and u'_1 have opposite signs, so the transverse magnification is negative.

Image Location and Magnification

To locate an image plane, any ray originating at the axial object point can be traced through the system to determine where it again intersects the axis, Fig. 7. The magnification for these conjugates can be found in two ways. One is to trace an arbitrary ray from any off-axis point in the object plane. The ratio of its height in the image plane to that in the object plane is the transverse magnification.

Alternately, the magnification can be found from the initial and final angles of the ray through the axial points. Let ray 1 leave the axial object point, so $y_1 = 0$. Let ray 2 originate in the object plane some distance from the axis. At the object plane $L = ny_2u_1$, and at the image plane $y'_2 = 0$, so $L = n'y'_2u'_1$. Therefore,

$$L = ny_2u_1 = n'y'_2u'_1 \tag{152}$$

So the magnification is

$$m = \frac{y'_2}{y_2} = \frac{nu_1}{n'u'_1} \tag{153}$$

The relative signs of u and u' determine that of the magnification. Equation (153) is a paraxial form of the sine condition Eq. (106). Squaring this equation gives $L^2 = n^2y_2^2u_1^2$, which is proportional to a paraxial form of the étendue. These matters are discussed further in the sections on conservation of étendue and on apertures. The quantity ny_2u_1 is sometimes referred to as *the* invariant, but it is not the most general form.

Three-Ray Rule

A further consequence of the paraxial invariant and of the linearity of paraxial optics is that once the paths of two paraxial meridional rays has been found, that of any third ray is determined. Its heights and angles are a linear combination of those of the other two rays. Given three rays, each pair has an invariant: $L_{12} = n(y_1u_2 - y_2u_1)$, $L_{23} = n(y_2u_3 - y_3u_2)$, and $L_{31} = n(y_3u_1 - y_1u_3)$. Therefore, in every plane

$$y_3 = -\frac{L_{23}}{L_{12}}y_1 + \frac{L_{31}}{L_{12}}y_2 \quad \text{and} \quad u_3 = -\frac{L_{23}}{L_{12}}u_1 + \frac{L_{31}}{L_{12}}u_2 \tag{154}$$

This assumes that no pair of the three rays are simply scaled versions of one another, i.e., that both $L_{23} \neq 0$ and $L_{31} \neq 0$.

Switching Axial Object and Viewing Positions

If an axial object and axial viewing position are switched, the apparent size of the image is unchanged. Put more precisely, let an object lie in a plane intersecting the axial point A and let its image be viewed from an axial point B' in image space that is not conjugate to A. If the object and viewing positions are switched, so the eye is at A and the object plane is at B', the subtense of the object as seen by the eye is unchanged.[156–159]

1.13 IMAGES ABOUT KNOWN RAYS

Given a ray, referred to here as the *central ray* (also "base ray"), other rays from a point on the central ray making a small angle with respect to it are focused at or near other points on the central ray. These foci can be determined if the path of a central ray is known, as well as the indices of the media through which it passes, and the principal curvatures at the surfaces where it intersects. Here indices are constant. At each intersection point with an optical surface, the wavefront has two principal curvatures, as does the surface. After refraction or reflection, the wavefront has two different principal curvatures. Accordingly, if a single point is imaged, there are two astigmatic focal lines at some orientation. These foci are perpendicular, but they do not necessarily lie in planes perpendicular to that of the central ray. The imaging of a small extended region is generally skewed, so, for example, a small square in a plane perpendicular to the central ray can be imaged as a rectangle, parallelogram, or trapezoid.

This is a generalization of paraxial optics, in which the central ray is the axis of a system of revolution. While not difficult conceptually, the general case of an arbitrary central ray and an arbitrary optical system is algebraically complicated. This case can also be analyzed with a hamiltonian optics approach, using an expansion of a characteristic function about the central ray, like that of Eq. (28). The subject is sometimes referred to as *parabasal optics*, and the central ray as the *base ray*. This subject has been discussed by numerous authors[160–186] under various names, e.g., "narrow beams," "narrow pencils," and "first order."

The following is limited to the case of meridional central rays and surfaces that are figures of revolution. The surface, at the point of intersection, has two principal curvatures c_s and c_t. [See Eqs. (119) and (123).] For spherical surfaces, $c_s = c_t = c$, and for planar surfaces $c = 0$. There is a focus for the sagittal fan and one for the tangential one, Fig. 8, the two foci coinciding if the imaging is stigmatic. After one or more surfaces are encountered, the separated foci are the sources for subsequent imaging. Let s and t be the directed distances from the intersection point of the central ray and the surface to the object point, and s' and t' be the distances from intersection point to the foci. The separation $|s' - t'|$ is known as the *astigmatic difference*.

For refraction

$$\frac{n'}{s'} = \frac{n}{s} + c_s\Gamma \qquad \text{and} \qquad \frac{n'\cos^2 I'}{t'} = \frac{n\cos^2 I}{t} + c_t\Gamma \tag{155}$$

where $\Gamma = n'\cos I' - n\cos I$, Eq. (82). The sagittal equation is simpler, providing a mnemonic for remembering which equation is which: "S" = sagittal = simpler. If the surface is spherical, and the ray fan makes an arbitrary angle of ψ with the meridian, then[175]

$$\frac{n'}{d'}(1-\cos^2\psi\sin^2 I') = \frac{n}{d}(1-\cos^2\psi\sin^2 I) + c\Gamma \tag{156}$$

where d and d' are the distances along the central ray from the surface to the object and image points. For normal incidence at a spherical surface $\Gamma = n' - n$, so both equations become

$$\frac{n'}{d'} = \frac{n}{d} + c(n' - n) \tag{157}$$

This also applies to surfaces of revolution if the central ray lies along the axis. This equation is identical to the paraxial equation, Eq. (146).

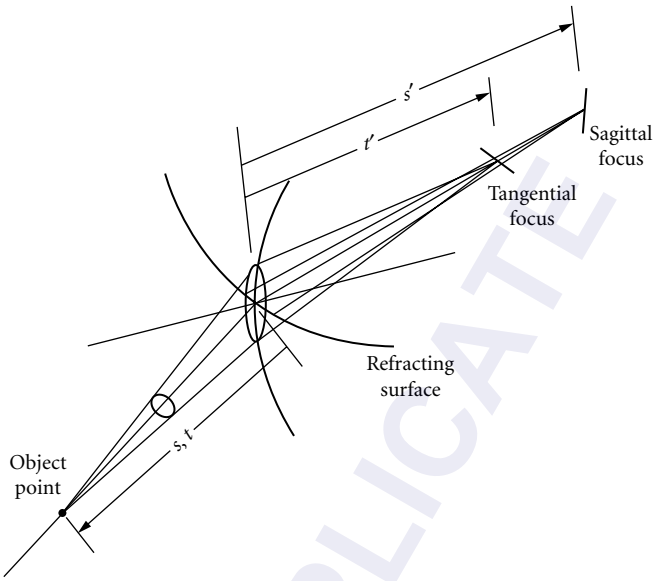

FIGURE 8 Astigmatic imaging of a point by a single refracting surface. The distance from the surface to the object point along the central ray of the bundle is $s = t$. The distances from the surface to the sagittal focus is s', and that to the tangential focus is t', as given by Eq. (155).

The corresponding relations for reflection are obtained by setting $n' = -n$ and $I' = I$ in the refraction equations, giving

$$\frac{1}{s'} = -\frac{1}{s} + 2c_s \cos I \qquad \text{and} \qquad \frac{1}{t'} = -\frac{1}{t} + \frac{2c_t}{\cos I} \tag{158}$$

For stigmatic imaging between the foci of reflective conics, $s = t$ is the distance from one focus to a point on the surface, and $s' = t'$ is that from the surface to the other focus. Therefore, $c_t = c_s \cos^2 I$. The reflection analogue to Eq. (156), for a spherical surface is

$$\frac{1}{d'} = -\frac{1}{d} + \frac{2c\cos I}{1 - \cos^2 \psi \sin^2 I} \tag{159}$$

These equations are known by several names, including *Coddington's equations*, *Young's astigmatic formulae*, and the *s-* and *t-trace formulae.*

1.14 GAUSSIAN LENS PROPERTIES

Introduction

The meaning of the term *gaussian optics* is not universally agreed upon, and it is often taken to be indistinguishable from paraxial optics or first-order optics, as well as collineation. Here the term is considered to apply to those aspects of paraxial optics discovered by Gauss,[187] who recognized that all rotationally symmetric systems of lens elements can be described paraxially by certain system properties. In particular, lenses can be treated as black boxes described by two axial length parameters and the locations of special points, called *cardinal points*, also called *Gauss points*. Once a lens is so

TABLE 1 Gaussian Notation and Definitions

By convention, in the diagrams the object space is to the left of the lens, image space is to the right, and rays go left to right. Object space quantities are unprimed, and image space quantities are primed, and quantities or positions that correspond in some way have same symbol, primed and unprimed. This correspondence can have several forms, e.g., the same type of thing or conjugate. The term *front* refers to object space, or left side, and *rear* to image space, or right side. A "front" entity may actually be behind a "rear" one. For example, a negative singlet has its object space focal point behind lens.

Scalars
n and n' object and image space refractive indices
ϕ power
m transverse magnification
m_N nodal plane magnification $= n/n'$
m_L longitudinal magnification
m_α angular magnification
u and u' paraxial ray angles (the positive direction is counterclockwise from the axis)
y and y' paraxial ray heights
y_P paraxial ray height at the principal planes $= y'_P$
Axial points
Cardinal points:
Focal points F and F', not conjugate
Principal points P and P', conjugate $m = +1$
Nodal points N and N', conjugate $m_N = n/n'$
Other points:
Axial object and image points O and O', conjugate
Arbitrary object and image points A and A', B and B'
Vertices V and V', not conjugate, in general
Directed axial distances
These distances here are between axial points and are directed.
Their signs are positive if from left to right and vice versa.
Types of distances: entirely in object or image space, between spaces
Principal focal lengths: $f = PF$ and $f' = P'F'$
Principal points to object and image axial points: $l = PO$ and $l' = P'O'$
Front and rear focal points to object and image axial points: $z = FO$ and $z' = F'O'$
Relations: $l = f + z$ and $l' = f' + z'$
Arbitrary point to conjugate object and image points: $d = AO$ and $d' = A'O'$
Distances between object space and image space points involve distances within both spaces, as well as a distance *between* the spaces, e.g., PP', FF', VV', and OO'. The distances between spaces depend on the particular structure of the lens. They can be found by paraxial ray tracing.

characterized, knowledge of its actual makeup is unnecessary for many purposes, and repeated ray traces need not be performed. For example, given the object location, the image location and magnification are determined from the gaussian parameters. From the gaussian description of two or more lenses, that of a coaxial combination can be found. Another consequence of Gauss's discovery is that there is an infinity of specific embodiments for any external prescription.

The lenses considered in this section are figures of revolution with uniform object space and image space indices n and n'. All quantities discussed in this section are paraxial, so the prefix "paraxial" is not repeated. For the purposes of this section, no distinction is made between real and virtual rays. Those in each space are considered to extend infinitely, and intersection points may be either accessible or inaccessible. The quantities used in this section are found in Table 1.

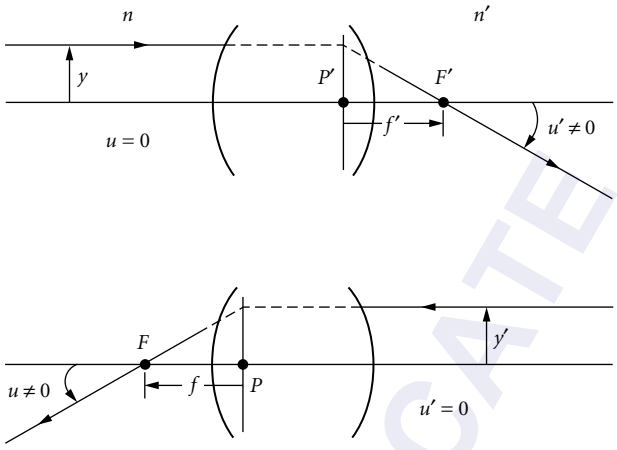

FIGURE 9 Diagrams for determining power, focal points, and focal lengths. Rays parallel to the axis in one space cross the axis in the other space at the focal points. The principal planes are at the intersections of entering and leaving rays. The power is given by Eq. (159). The lens in this diagram has positive power, a positive rear focal length, and a negative front focal length.

Power, Focal Lenses, and Afocal Lenses

A paraxial ray entering a lens parallel to the axis at a height y leaves with some angle u', Fig. 9. Likewise, a ray entering from the opposite side with height y' leaves with angle u. The *power* of the lens is defined by

$$\phi = -n'\frac{u'}{y} = n\frac{u}{y'} \tag{160}$$

The outgoing ray can have any angle, and the power can be positive, negative, or zero. If $u' = 0$, then $\phi = 0$ and the lens is *afocal* or *telescopic*. Lenses for which $\phi \neq 0$ are referred to here as *focal,* although the term "nonafocal" is more common. Afocal lenses are fundamentally different from focal ones, and are treated separately next. Power is the same in both directions, i.e., whether the ray enters from left to right or from right to left. The lens in Fig. 9 has $\phi > 0$, and that in Fig. 10

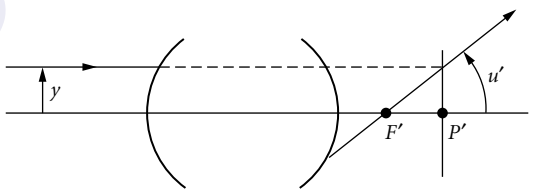

FIGURE 10 A lens with negative power and negative rear focal length. An incoming ray parallel to the axis with a positive height leaves the lens with a positive angle. The rear focal plane precedes the rear principal plane.

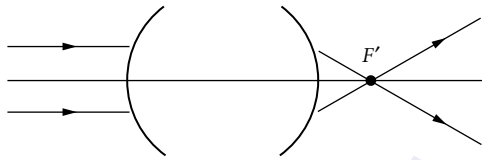

FIGURE 11 An ambiguous diagram. Two rays that enter a lens parallel to its axis converge at the rear focal point F'. Without specifying which ray is which, the sign of the power is not known.

has $\phi < 0$. Diagrams such as Fig. 11 show the location of the principal focal point, but not the sign of the power; two rays enter and two leave, but there is no indication of which is which. (Note that some negative lenses have accessible rear focal points.) Another expression for power involves two rays at arbitrary angles and heights. If two incident rays have (y_1, u_1) and (y_2, u_2), and a nonzero invariant $L = n(y_1u_2 - y_2u_1)$, and the outgoing ray angles are u_1' and u_2', then

$$\phi = -\frac{nn'}{L}(u_1'u_2 - u_2'u_1) \tag{161}$$

Focal Lenses

Focal lenses are those for which $\phi \neq 0$. Their cardinal points are the principal focal points, the principal points, and the nodal points. These points may be located anywhere on axis relative to the physical lens system. If they are inside a lens, then the intersection points referred to below are virtual. The cardinal points are pairs consisting of a member in object space and one in image space. The one in object space is often referred to as *front*, and the one in image space as *rear*, but this terminology may be misleading, since the points can be in any sequence along the axis.

Principal Focal Points Rays entering a lens parallel to its axis cross the axis at the *principal focal points* or *focal points*. Rays parallel to the axis in object space intersect the axis at the *rear focal point* F' in image space and those parallel in image space intersect at the *front focal point* F in object space, Fig. 9. The *principal focal planes* or *focal planes* are the planes perpendicular to the axis at the focal points. The terms *focal point* and *focal plane* are often used to refer to the images of any point or plane. In this chapter, *image point* is used for other points where rays are focused and *image plane* for other planes.

Principal Planes The *principal planes* are the conjugate planes for which the transverse magnification is unity, Fig. 12. The intersections of the principal planes and the axis are the *principal points,*

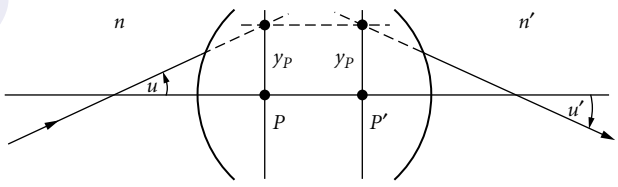

FIGURE 12 Principal planes as effective ray-bending surfaces. Incoming and outgoing paraxial rays intersect the object and image space principal planes at the same height y_P. The angles are related by Eq. (161).

denoted by P and P'. The *rear principal plane* is the locus of intersections between $u = 0$ rays incident from the left and their outgoing portions, Fig. 9. Likewise, the *front principal plane* is the intersection so formed with the rays for which $u' = 0$. A ray intersecting the first principal plane with height y_P and angle u leaves the second principal plane with height $y' = y_P$ and an angle given by

$$n'u' = nu - y_P\phi \tag{162}$$

The lens behaves as if the incoming ray intercepts the front principal plane, is transferred to the second with its height unchanged, and is bent at the second by an amount proportional to its height and to the power of lens. The power of the lens determines the amount of bending. For rays passing through the principal points, $y_P = 0$, so $u'/u = n/n'$.

Principal Focal Lengths The *focal lengths,* also called *effective focal lengths,* are the directed distances from the principal points to the focal points. The front and rear focal lengths are

$$PF = f = -\frac{n}{\phi} \qquad \text{and} \qquad P'F' = f' = \frac{n'}{\phi} \tag{163}$$

The two focal lengths are related by

$$\phi = -\frac{n}{f} = \frac{n'}{f'} \qquad \text{and} \qquad \frac{f}{f'} = -\frac{n}{n'} \tag{164}$$

This ratio is required by the paraxial invariant.[188] If $n = n'$, then $f' = -f$. If $n = n' = 1$, then

$$f' = -f = \frac{1}{\phi} \tag{165}$$

The focal lengths are the axial scaling factors for the lens, so axial distances in all equations can be scaled to them.

Nodal Points The *nodal points* are points of unit angular magnification. A paraxial ray entering the *object space nodal point N* leaves the *image space point N'* at the same angle, Fig. 13. The planes containing the nodal points are called *nodal planes*. A *nodal ray* is one that passes through the nodal points. Such a ray must cross the axis, and the point where it does so physically is sometimes called the *lens center*. In general, this point has no special properties. (Gauss suggested an alternate "lens center," the point midway between the principal points. Rotating a lens front to rear about this point would leave object and image positions and magnifications unchanged.)

If the refractive indices of the object space and image space are the same, the nodal points correspond to the principal points. If not, both nodal points are shifted according to

$$PN = P'N' = \frac{n' - n}{\phi} = f + f' \tag{166}$$

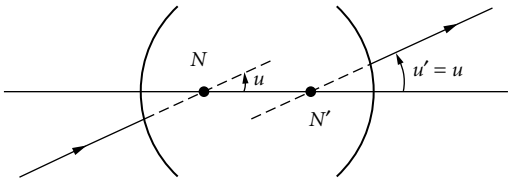

FIGURE 13 Nodal points. A paraxial ray through the object space nodal point N passes through image space nodal point N' with the same angle.

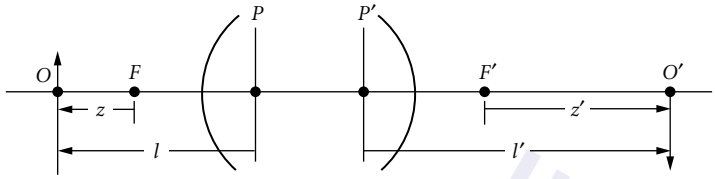

FIGURE 14 Directed distances used in common conjugate equations for focal lenses. Distances z and z' are from the focal points to axial conjugate points. Distances l and l' are from the principal points to axial conjugate points.

The distances from the nodal points to the focal points are

$$N'F' = -f \qquad \text{and} \qquad NF = -f' \tag{167}$$

The nodal points are conjugate, and the transverse magnification of the nodal planes is

$$m_N = \frac{n}{n'} \tag{168}$$

These equations can be recalled by the simple example of the single refracting surface, for which both nodal points correspond to the center of curvature.

Conjugate Equations For an object plane perpendicular to the axis at point O, there is an image plane perpendicular to the axis at O', in which the transverse magnification is m. Note that specifying magnification implies both object and image positions. There is a variety of *conjugate equations* (NS) that relate their positions and magnifications. The equations differ in which object space and image space reference points are used from which to measure the directed distances to the object and image. These equations can be written in several ways, as given below, and with reference to Fig. 14. Axial distances can be scaled to the focal lengths, or the distances can be scaled to the indices, with a common power term remaining.

The simplest conjugate equation is *Newton's equation,* for which the reference points are the focal points and the lengths therefrom are $z = FO$ and $z' = F'O'$. The equation can be written in several forms:

$$zz' = ff' \qquad \text{or} \qquad \frac{z'}{f'}\frac{z}{f} = 1 \qquad \text{or} \qquad \frac{z'}{n'}\frac{z}{n} = \frac{1}{\phi^2} \tag{169}$$

More generally, if A and A' are any pair of axial conjugate points, as are B and B', then

$$FA \times F'A' = FB \times F'B' \tag{170}$$

Another form is that for which the reference points are the principal points and the directed distances are $l = PO$ and $l' = P'O'$:

$$1 = \frac{f'}{l'} + \frac{f}{l} \qquad \text{or} \qquad \frac{n'}{l'} = \frac{n}{l} + \phi \tag{171}$$

If the reference points are arbitrary conjugates with magnification m_A and the axial distances are $d = AO$ and $d' = A'O'$, then

$$m_A \frac{n'}{d'} = \frac{1}{m_A}\frac{n}{d} + \phi \qquad \text{or} \qquad \frac{d'}{f'} = \frac{m_A^2 \dfrac{d}{f}}{1 - m_A \dfrac{d}{f}} \tag{172}$$

This equation also relates the curvatures of a wavefront at conjugate points. For a point source at A the radius of the wavefront at O is d, so at O' the radius is d'.

If the reference points are the nodal points, $m_A = m_N = n/n'$, and the axial distances are $d = NO$ and $d' = N'O'$, then

$$1 = \frac{f}{d'} + \frac{f'}{d} \quad \text{or} \quad \frac{n}{d'} = \frac{n'}{d} + \phi \tag{173}$$

The most general equation relating conjugate points is obtained when both reference points are arbitrary. Let the reference point in object space be a point A, at which the magnification is m_A, and that in image space be B', associated with magnification m'_B. If $d = AO$ and $d' = B'O'$, then

$$\frac{1}{\phi}\left(1 - \frac{m'_B}{m_A}\right) = \frac{1}{m_A} d - m'_B d' + \phi\, d\, d' \quad \text{or}$$
$$d' = \frac{\dfrac{1}{m_A} d + \left(\dfrac{m'_B}{m_A} - 1\right)\dfrac{1}{\phi}}{\phi d - m'_B} \tag{174}$$

All the other conjugate equations are special cases of this one with the appropriate choice of m_A and m'_B.

If the reference point in object space is the focal point, and that in image space is the principal plane, then $m_A = \infty$ and $m'_B = 1$, giving

$$\frac{n'}{z'\phi} = \frac{l\phi}{n} + 1 \quad \text{or} \quad \frac{f'}{z'} = \frac{l}{f} + 1 \tag{175}$$

Likewise, if the object space reference point is P and the image space reference is F', then

$$\frac{n'}{l'\phi} = \frac{z\phi}{n} + 1 \quad \text{or} \quad \frac{f'}{l'} = \frac{z}{f} + 1 \tag{176}$$

A relationship between distances to the object and image from the principal points and those from the focal points is

$$1 = \frac{z'}{l'} + \frac{z}{l} = \frac{F'O'}{P'O'} + \frac{FO}{PO} \tag{177}$$

Transverse Magnification In planes perpendicular to the axis, the *transverse magnification*, usually referred to simply as the *magnification*, is

$$m = \frac{x'}{x} = \frac{y'}{y} = \frac{dx'}{dx} = \frac{dy'}{dy} \tag{178}$$

There are several equations for magnification as a function of object position or image position, or as a relationship between the two. Newton's equations are

$$m = -\frac{f}{z} = -\frac{z'}{f'} = \frac{f}{f - l} = \frac{f' - l'}{f'} \tag{179}$$

Other relationships are

$$m = \frac{n}{n'}\frac{l'}{l} = -\frac{f}{f'}\frac{l'}{l} = \frac{z'}{l'}\frac{l}{z} \tag{180}$$

If $n = n'$, then $m = l'/l$. Another form, with respect to conjugate planes of magnification m_A is

$$mm_A = \frac{n}{d}\frac{d'}{n'} = \frac{f}{d}\frac{d'}{f'} \tag{181}$$

If d and d' are distances from the nodal points, $m = d'/d$. The change of magnification with respect to object or image positions with conjugacy maintained is

$$\frac{dm}{dz'} = -\frac{1}{f'} = \frac{m}{z'} \quad \text{and} \quad \frac{dm}{dz} = \frac{f}{z^2} = \frac{m^2}{f} = \frac{m}{z} \tag{182}$$

Images of Distant Objects If an object at a great distance from the lens subtends an angle ψ from the axis at the lens, then its paraxial linear extent is $y = z\psi$. The image height is

$$y' = my = \frac{-f}{z}y = -f\psi = \frac{n}{n'}f'\psi \quad \text{and} \quad \frac{dy'}{d\psi} = \frac{n}{n'}f' \tag{183}$$

If a distant object moves perpendicularly to the axis, then its image moves in the opposite direction if $f' > 0$ and in the same direction if $f' < 0$, so long as n and n' have the same sign.

Distance Between Object and Image The directed distance from an axial object point to its image contains three terms, one in object space, one in image space, and one relating the two spaces. The first two depend on the magnification and focal lengths. The interspace term depends on the particular structure of the lens, and is found by paraxial ray tracing. The most commonly used interspace distance is PP', since it equals zero for a thin lens, but the equations using FF' are simpler. Newton's equations give $z = -f/m$ and $z' = -mf'$, so the object-to-image distance is

$$OO' = FF' - z + z' = FF' - f'm + \frac{f}{m} = FF' - \frac{1}{\phi}\left(n'm + \frac{n}{m}\right) \tag{184}$$

This is the basic equation from which all others are derived. If the reference points are the principal points, then

$$OO' = PP' + f'(1-m) - f\left(1 - \frac{1}{m}\right) = PP' + \frac{1}{\phi}\left[n'(1-m) + n\left(1 - \frac{1}{m}\right)\right] \tag{185}$$

If the object-to-image distance is given, the magnification is

$$m = \frac{1}{2n'}(-q \pm \sqrt{q^2 - 4nn'})$$

where $q = \phi(OO' - PP') - n - n'$. (186)

There are two magnifications for which OO' is the same. The magnitude of their product is n/n'. The derivative of the object-to-image distance with respect to the magnification is

$$\frac{d}{dm}OO' = -f' - \frac{f}{m^2} = -f' - \frac{z^2}{f} = \frac{1}{\phi}\left(\frac{n}{m^2} - n'\right) \tag{187}$$

Extrema occur at $m \pm \sqrt{n/n'}$, giving $m = \pm 1$ if $n = n'$. The extrema are

$$OO' - FF' = \pm\frac{2}{\phi}\sqrt{nn'} = \pm 2\sqrt{-ff'} \tag{188}$$

or

$$OO' - PP' = \frac{1}{\phi}(n + n' \pm 2\sqrt{nn'}) = f' - f \pm 2\sqrt{-ff'} \tag{189}$$

For the common case of $n' = n$, the object-to-image distance is

$$OO' = PP' + f'\left(2 - m - \frac{1}{m}\right) \tag{190}$$

OO' is the same for magnifications m and $1/m$. For a lens with $f' > 0$, the extremum object-to-image distances are $OO' - PP' = 4f'$ with $m = -1$ and $OO' - PP' = 0$ for $m = +1$. If the object-to-image distance and the focal length are given, then the magnification is

$$m = -\frac{1}{2}s \pm \sqrt{\frac{1}{4}s^2 - 1}$$

$$\text{where } s = \frac{1}{f'}(OO' - PP') - 2. \tag{191}$$

The two values of m are reciprocal of each other.

Axial Separations and Longitudinal Magnification Two axial points A and B are imaged at A' and B' with magnifications m_A and m_B. Newton's equations give the object separation

$$\Delta z = z_A - z_B = \frac{m_A m_B}{m_B - m_A} f \tag{192}$$

The separation of their images is

$$\Delta z' = z'_A - z'_B = (m_B - m_A) f' \tag{193}$$

The ratio of the image and object separations is

$$\frac{\Delta z'}{\Delta z} = \frac{z'_A - z'_B}{z_A - z_B} = \frac{A'B'}{AB} = \frac{n'}{n} m_A m_B = -\frac{f'}{f} m_A m_B \tag{194}$$

If m_A and m_B have different signs, then the direction *of* $A'B'$ is opposite to that of AB. This occurs when A and B are on opposite sides of the front focal point. In the limit as the separation between A and B vanishes, m_A and m_B both approach the same magnification m. The *longitudinal magnification* m_L is the ratio of axial separations in the limit of small separations

$$m_L = \underset{A \to B}{\text{LIMIT}} \frac{A'B'}{AB} = \frac{dz'}{dz} = \frac{n'}{n} m^2 = -\frac{z'}{z} \tag{195}$$

This quantity is also called the *axial magnification*. Since m^2 is always positive, as an object moves axially in a given direction, its image moves in a constant direction. There is a discontinuity in image position when the object crosses the focal point, but the direction of motion stays the same. At the nodal points, the transverse and longitudinal magnifications are equal.

Angular Magnification The ratio of the outgoing to incoming ray angles, u'/u, is sometimes called the *angular magnification* m_α. If the ray passes through conjugate axial points with magnification m, then the angular magnification is

$$m_\alpha = \frac{u'}{u} = \frac{n}{n'} \frac{1}{m} \tag{196}$$

If the ray leaves an object point with height y in a plane for which the magnification is m, the outgoing ray angle is given by

$$n'u' = \frac{1}{m} nu - y\phi = \frac{1}{m}(nu - y'\phi) \tag{197}$$

The ratio u'/u is not constant unless $y = 0$ or $\phi = 0$.

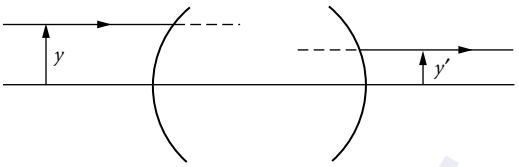

FIGURE 15 Afocal lens. Paraxial rays entering parallel to the axis leave parallel, in general at a different height. The ratio of the heights is the transverse magnification, which is constant.

Relationship Between Magnifications The transverse, angular, and longitudinal magnifications are related by

$$m_\alpha m_L = m \tag{198}$$

This relationship is connected to the paraxial invariant and also holds for afocal lenses.

Reduced Coordinates Many relationships are formally simplified by using reduced axial distances $\tau = z/n$ and $\tau' = z'/n'$ and reduced angles $\omega = nu$, $\omega' = n'u'$, which are paraxial optical direction cosines. For example, the angular magnification is $\omega'/\omega = 1/m$, and the longitudinal magnification is $d\tau'/d\tau = m^2$.

Mechanical Distances The cardinal points can be located anywhere on axis relative to the physical structure of the lens. The *vertex* of a lens is its extreme physical point on axis. The object space vertex is denoted by V and the image space vertex by V'. The two vertices are not, in general, conjugate. The *front focal distance FV* is that from the vertex to the front focal point, and the *rear focal distance V′F′* is that from the rear vertex to the rear focal point. Likewise, the *front working distance OV* is the distance from the object to the vertex, and the *rear working distance V′O′* is that from the vertex to the image. These lengths have no significance to the gaussian description of a lens. For example, a lens of a given focal length can have any focal distance and vice versa. For a *telephoto* lens the focal length is greater than the focal distance, and for a *retrofocus* lens the focal distance is greater than the focal length.

Afocal Lenses

An *afocal* or *telescopic* lens[189–191] is one for which $\phi = 0$. A ray entering with $u = 0$ leaves with $u' = 0$, Fig. 15. There are no principal focal points or focal lengths. In general, the $u = 0$ ray leaves at a different height than that at which it enters. The ratio y'/y is the same for all such rays, so the transverse magnification m is constant. Likewise, the longitudinal magnification is constant, equaling $m_L = (n'/n)m^2$, as is the angular magnification $u'/u = m_\alpha = n/(n'm)$. A parallel bundle of rays entering at angle u leaves as a parallel bundle at $u' = m_\alpha u$, Fig. 16. Summarizing:

$$m = \text{const}, \quad m_L = \frac{n'}{n}m^2 = \text{const}, \quad m_\alpha = \frac{n}{n'}\frac{1}{m} = \text{const}, \quad m = m_L m_\alpha \tag{199}$$

Any two of these magnifications provide the two scaling factors that describe the system. If $m = n/n'$, then $m_L = m$ and $m_\alpha = 1$, so image space is a scaled version of object space.

Afocal lenses differ fundamentally from focal lenses. Objects at infinity are imaged by afocal lenses at infinity, and objects at finite distances are imaged at finite distances. An afocal lens has no cardinal points and the focal length is undefined. Afocal lenses have no principal planes. If $m \neq 1$ there are no unit magnification conjugates, and if $m = 1$ there is only unit magnification. Likewise, there are no nodal points; the angular magnification is either always unity or always differs from unity.

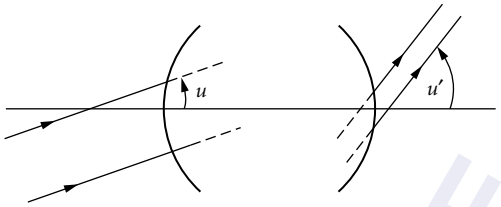

FIGURE 16 Afocal lens. Groups of paraxial rays entering parallel leave parallel, in general at a different angle. The ratio of the angles is the angular magnification, which is constant.

It is sometimes stated or implied that an afocal lens is a focal one with an infinite focal length, but this description is dubious. For example, the above equations relating magnification and conjugate positions to focal length are meaningless for afocal lenses, and they cannot be made useful by substituting $f = \infty$. The equations for the afocal lenses can be obtained from those for focal lenses with a limiting process, but for most purposes this approach is not helpful.

If the positions for a single axial conjugate pair A and A' are known, other pairs are located from the property of constant longitudinal magnification. If O and O' are another pair of conjugates, then

$$A'O' = m_L AO \tag{200}$$

As a function of distance AO, the object-to-image distance OO' is

$$OO' = AA' + (m_L - 1)AO \tag{201}$$

where AA' is the separation between the initially known conjugates. If $m_L = 1$, the object-to-image distance is constant. Otherwise, it can take any value. For all afocal lenses, except those for which $m_L = 1$, there is a position, sometimes called the *center*, at which $OO' = 0$, so the object and image planes coincide.

A principal use of afocal lenses is in viewing distant objects, as with binoculars. An object of height h at a great distance d from the lens subtends an angle $\psi \simeq h/d$. The image height is $h' = mh$, and the image distance is approximately $d' = m^2 d$. So the image subtends an angle $\psi' \simeq m\psi = \psi/m_\alpha$. Thus a telescope used visually produces an image which is actually smaller, but which is closer by a greater factor, so the subtense increases.

Determination of Gaussian Parameters

If a lens prescription is given, its gaussian properties can be obtained by paraxially tracing any two meridional rays whose invariant is not zero. A common choice for focal lenses is the rays with $u = 0$ and $u' = 0$, which give F, P, F', and P'. If a lens is known to be afocal, a single ray not parallel to the axis suffices, since such a ray gives a pair of conjugates and the angular magnification. If it is not known that the lens is afocal, two rays show that it is, as well as giving the required information about conjugates. Alternately, a matrix representation of the lens can be determined, from which the cardinal points are found, as described in the matrix section. The gaussian properties can also be determined experimentally in a number of ways.

Basic Systems

Single Refracting Surface Media of indices n and n' are separated by a surface of curvature c and radius r. The power is $\phi = (n' - n)c$. The principal points coincide at the vertex. The nodal points coincide at the center of curvature. The distance from principal points to nodal points is r.

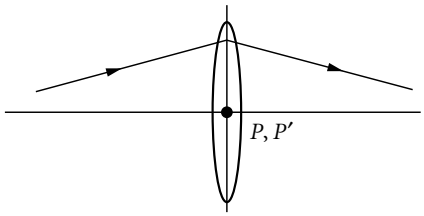

FIGURE 17 The thin lens approximation. The thickness of the lens is negligible, and the principal planes are coincident, so rays bend at the common plane.

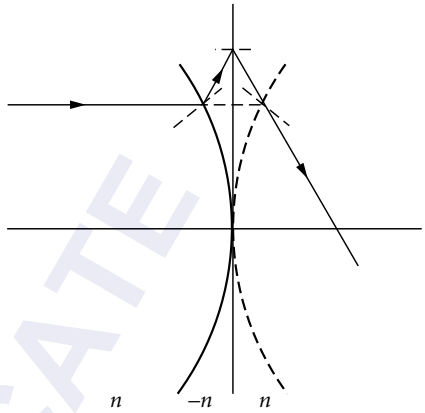

FIGURE 18 Reflecting surface represented unfolded. A convex mirror is represented as a convex plano thin lens with index $n' = -n$, where n is the index of the medium.

Thick Lens The term *thick lens* usually denotes a singlet whose vertex-to-vertex distant is not negligible, where negligibility depends on the application. For a singlet of index n in vacuum with curvatures c_1 and c_2 and thickness t, measured from vertex to vertex

$$\phi = \frac{1}{f'} = (n-1)\left[c_1 - c_2 - \frac{n-1}{n} t c_1 c_2\right] \tag{202}$$

A given power may be obtained with a variety of curvatures and indices. For a given power, higher refractive index gives lower curvatures. The principal planes are located relative to the vertices by

$$VP = \frac{n-1}{n}\frac{tc_2}{\phi} \quad \text{and} \quad V'P' = -\frac{n-1}{n}\frac{tc_1}{\phi} \tag{203}$$

These equations can be derived by treating the lens as the combination of two refracting surfaces. Two additional relationships are

$$PP' = VV' - \frac{n-1}{n}\frac{t(c_1 + c_2)}{\phi} \quad \text{and} \quad \frac{V'P'}{VP} = \frac{r_2}{r_1} = \frac{c_1}{c_2} \tag{204}$$

Thin Lens A *thin lens* is the limiting case of a refracting element whose thickness is negligible, so the principal planes coincide, and the ray bending occurs at a single surface, Fig. 17. In the limit as $t \to 0$, for a lens in vacuum the thick lens expressions give

$$\phi = \frac{1}{f'} = (n-1)(c_1 - c_2), \quad VP = V'P' = 0, \quad PP' = 0 \tag{205}$$

Single Reflecting Surface A reflecting surface has power $\phi = 2n/r = 2nc$. The principal points are located at the vertex. The nodal points are at the center of curvature.

Mirror as a Thin Lens In unfolding systems, a mirror can be thought of as a convex or concave plano thin lens, with an index $-n$, where n is the index of the medium in which it works, Fig. 18. All the thin lens equations apply, as well as those for third-order aberration equations, which are not discussed here.

1.15 COLLINEATION

Introduction

Collineation is a mathematical transformation that approximates the imaging action of a lens with homogeneous refractive indices in both spaces. This transformation takes points to points, lines to lines, and planes to planes. With an actual lens, incoming rays become outgoing rays, so lines go exactly to lines. In general, however, rays that intersect in object space do not intersect in image space, so points do not go to points, nor planes to planes. The collinear transformation is an approximate description of image geometry with the intervening optical system treated as a black box, not a theory that describes the process of image formation. Collineation is also referred to as *projective transformation*. The historical development of this approach, which was first applied to optics by Möbius,[192] is discussed by Southall.[193] Several authors give extensive discussions.[193–197] Projective transformation is used in computer graphics, and is discussed in this context in a number of recent books and papers.

The imaging described by collineation is, by definition, stigmatic everywhere, and planes are imaged without curvature. And for rotationally symmetric lenses, planes perpendicular to the axis are imaged without distortion. So the three conditions of maxwellian perfection are satisfied for all conjugates. Consequently, collineation is often taken as describing ideal imaging of the entire object space. However, it is physically impossible for a lens to image as described by collineation, except for the special case of an afocal lens with $m = m_L = n/n'$. The putative ray intersections of collineation violate the equality of optical path lengths for the rays involved in the imaging of each point. The intrinsic impossibility manifests itself in a variety of ways. As an example, for axial points in a plane with transverse magnification m and ray angles θ and θ' relative to the axis, collineation gives $m \propto \tan\theta/\tan\theta'$, but optical path length considerations require that $m \propto \sin\theta/\sin\theta'$. Another violation is that of the skew invariant $\mathcal{S} = n(\alpha y - \beta x)$. The ratio of this quantity before and after collineation is not unity, but $\mathcal{S}'/\mathcal{S} = \gamma'/\gamma$, where γ is the axial direction cosine in object space and γ' is that in image space.

The expressions for collineation do not contain refractive indices, another manifestation of their not accounting for optical path length. Rather than the refractive index ratio n'/n, which occurs in many imaging equations, the expressions of collineation involve ratios of focal lengths. For afocal lenses there are ratios of transverse and longitudinal magnifications or ratios of the focal lengths of the lenses making up the afocal system.

The expressions for actual ray behavior take the form of collineation in the paraxial, and, more generally, parabasal limits. So paraxial calculations provide the coefficients of the transformation for any particular system.

Collineation is most often treated by starting with the general form, and then reducing its complexity by applying the symmetries of a rotationally symmetric system, to give familiar simple equations such as Newton's.[198] Alternatively, it is possible to begin with the simple forms and to derive the general ones therefrom with a succession of images, along with translations and rotations. However, the more important use of these properties is in treating lenses lacking rotational symmetry. This includes those comprising elements that are arbitrarily oriented, that is, tilted or decentered—either intentionally or unintentionally. Other examples are nonplanar objects, tilted object planes, and arbitrary three-dimensional object surfaces.

Lenses, along with plane mirror systems, can form a succession of images and can produce translations and rotations. Correspondingly, a succession of collinear transformations is a collinear transformation, and these transformations form a group. It is associative, corresponding to the fact that a series of imaging operations can be associated pairwise in any way. There is a unit transformation, corresponding physically to nothing or to a unit magnification afocal lens. There is an inverse, so an image distorted as a result of object or lens tilt can be rectified by an appropriately designed system—to the extent that collineation validly describes the effects.

General Equations

The general form of the collinear transformation is

$$x' = \frac{a_1x + b_1y + c_1z + d_1}{ax + by + cz + d}, \quad y' = \frac{a_2x + b_2y + c_2z + d_2}{ax + by + cz + d}, \quad z' = \frac{a_3x + b_3y + c_3z + d_3}{ax + by + cz + d} \tag{206}$$

At least one of the denominator coefficients, a, b, c, d, is not zero. The equations can be inverted, so there is a one-to-one correspondence between a point (x, y, z) in object space and a point (x', y', z) in image space. The inverted equations are formally identical, and can be written by replacing unprimed quantities with primed ones and vice versa in the above equation. It is seen that a plane is transformed to a plane, since $a'x' + b'y' + c'z' + d' = 0$ has the same form as a function of (x, y, z). An intersection of two planes gives a line. It can also be shown that a line transforms to a line by writing the equation for a line in parametric form, with parameter σ, $x(\sigma) = x_0 + \alpha\sigma$, $y(\sigma) = y_0 + \beta\sigma$, $z(\sigma) = z_0 + \gamma\sigma$. Substituting in the transformation equations, it is found that $dx'/dy' = (dx'/d\sigma)/(dy'/d\sigma)$ is constant, as are other such ratios.

These equations contain 16 coefficients, but it is possible to divide all three equations through by one of the coefficients, so there are 15 independent coefficients in general. Since the location of an image point is described by three coordinates, five points that are not coplanar determine the transformation.

The ratios of the coefficient dimensions are determined by the fact that x, y, z and x', y', z' are lengths. A variety of schemes can be used and, in the expressions below, a given symbol may have different dimensions.

There are two major categories of the transformation, according to whether the denominator varies or is constant. That with a varying denominator corresponds to focal lenses. For afocal lenses, the demonimator is constant, and the general form of the transformation is

$$x' = a_1x + b_1y + c_1z + d_1, \quad y' = a_2x + b_2y + c_2z + d_2, \quad z' = a_3x + b_3y + c_3z + d_3 \tag{207}$$

Here coefficient d has been normalized to unity. Such a transformation is called *affine* or *telescopic.*

Coordinate Systems and Degrees of Freedom

The transformation involves two coordinate systems. The origin of each is located by three parameters, as is the orientation of each. This leaves three parameters that describe the other aspects of the transformation for the most general case of no symmetry. The number is reduced to two if there is rotational symmetry.

In addition to considering the transformation of the entire space, there are other cases, especially the imaging of planes. In each situation, there are specific coordinate systems in which the aspects of the relationship, other than position and orientation, are most simply expressed. Accordingly, different coordinate systems are used in the following sections. Thus, for example, the z axis in one expression may not be the same as that for another.

Simplest Form of the General Transformation

For focal lenses, the denominators are constant for a set of parallel planes

$$ax + by + cz + d = \text{constant} \tag{208}$$

Each such plane is conjugate to one of a set of parallel planes in the other space. Within each of these planes, the quantities $\partial x'/\partial x$, $\partial x'/\partial y$, $\partial x'/\partial z$ are constant, as are the other such derivatives.

Therefore, magnifications do not vary with position over these planes, although they do vary with direction. There is one line that is perpendicular to these planes in one space whose conjugate is perpendicular to the conjugate planes in the other space. It can be taken to be the z axis in one space and the z' axis in the other. The aximuths of the x-y and x'-y' axes are found by imaging a circle in each space, which gives an ellipse in the other. The directions of the major and minor axes determine the orientations of these coordinate axes. The *principal focal planes* are the members of this family of planes for which

$$0 = ax + by + cz + d \tag{209}$$

Lines that are parallel in one space have conjugates that intersect at the principal focal plane in the other. The *principal focal points* are the intersection of the axes with the focal planes.

Using these simplifying coordinate systems, the general transformation is

$$x' = \frac{a_1 x}{cz + d}, \quad y' = \frac{b_1 y}{cz + d}, \quad z' = \frac{c_3 z + d_3}{cz + d} \tag{210}$$

One of the six coefficients can be eliminated, and two of the others are determined by the choice of origins for the z axis and z' axis. If the origins are taken to be at the principal focal points, the transformation equations are

$$x' = \frac{e_x x}{z}, \quad y' = \frac{e_y y}{z}, \quad z' = \frac{e_z}{z} \tag{211}$$

where e_x, e_y, e_z are constants. Unless $e_x = e_y$ the images of shapes in constant z planes vary with their orientations. Squares in one orientation are imaged as rectangles, and in others as parallelograms. Squares in planes not perpendicular to the axes are imaged, in general, with four unequal sides.

For afocal lenses, the simplest form is

$$x' = m_x x, \quad y' = m_y y, \quad z' = m_z z \tag{212}$$

Spheres in one space are imaged as ellipsoids in the other. The principal axes of the ellipsoids give the directions of the axes for which the imaging equations are simplest.

Conjugate Planes

A pair of conjugate planes can be taken to have $x = 0$ and $x' = 0$, so the general transformation between such planes is

$$y' = \frac{b_2 y + c_2 z + d_2}{by + cz + d}, \quad z' = \frac{b_3 y + c_3 z + d_3}{by + cz + d} \tag{213}$$

There are eight independent coefficients, so four points that are not in a line define the transformation. In each space, two parameters specify the coordinate origins and one the orientation. Two parameters describe the other aspects of the transformation.

The simplest set of coordinates is found by a process like that described above. For focal lenses, constant denominators define a line set of parallel lines

$$by + cz + d = \text{constant} \tag{214}$$

with similar conjugate lines in the other space. There is a line that is perpendicular to this family in one space, whose conjugate is perpendicular in the other, which can be taken as the z axis on one side and the z' axis on the other. There is a *principal focal line* in the plane in each space, and a *principal focal point,* at its intersection with the axis. In this coordinate system the transformation is

$$y' = \frac{b_2 y}{cz + d}, \quad z' = \frac{c_3 z + d_3}{cz + d} \tag{215}$$

Of the six coefficients, four are independent and two are fixed by the choice of origins. If $z = 0$ and $z' = 0$ are at the principal focal points, then

$$y' = \frac{e_y y}{z}, \quad z' = \frac{e_z}{z} \tag{216}$$

where e_y and e_z are constants.

For afocal lenses, the general transformation between conjugate planes is

$$y' = b_2 y + c_2 z + d_2, \quad z' = b_3 y + c_3 z + d_3 \tag{217}$$

The simplest form of the transformation is

$$y' = m_y y, \quad z' = m_z z \tag{218}$$

where m_y and m_z are constants.

Conjugate Lines

A line can be taken to have $x = 0, y = 0, x' = 0, y' = 0$, so its transformation is

$$z' = \frac{c_3 z + d_3}{cz + d} \tag{219}$$

There are three independent coefficients, so three points determine them. The origins in the two spaces account for two of the parameters, leaving one to describe the relative scaling. The simplest forms are

$$\text{Focal: } z' = \frac{e_z}{z}; \quad \text{Afocal: } z' = m_z z \tag{220}$$

There is a relationship between distances along a line (or ray) that is unchanged in collineation.[193,199] If four points on a line *A, B, C, D* have images *A′, B′, C′, D′*, the *double ratio* or *cross ratio* is invariant under projective transformation, that is,

$$\frac{AC}{BC}\frac{BD}{AD} = \frac{A'C'}{B'C'}\frac{B'D}{A'D} \tag{221}$$

where *AC* is the distance from *A* to *C,* and likewise for other pairs.

Matrix Representation of the Transformation

The transformation can be expressed in linear form by using the variables (u_1, u_2, u_3, u_4) and (u'_1, u'_2, u'_3, u'_4), where $x = u_1/u_4$, $y = u_2/u_4$, $z = u_3/u_4$ and $x' = u'_1/u'_4$, $y' = u'_2/u'_4$, $z' = u'_3/u'_4$. These are referred to as *homogeneous coordinates*. The transformation can be written

$$\begin{pmatrix} u'_1 \\ u'_2 \\ u'_3 \\ u'_4 \end{pmatrix} = \begin{pmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ a & b & c & d \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{222}$$

In terms of the cartesian coordinates and an additional pair of terms q and q', the transformation can be expressed as

$$\begin{pmatrix} q'x' \\ q'y' \\ q'z' \\ q' \end{pmatrix} = \begin{pmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ a & b & c & d \end{pmatrix} \begin{pmatrix} qx \\ qy \\ qz \\ q \end{pmatrix} \tag{223}$$

The dimensions of q and q' depend on the choice of coefficient dimensions. Here $q'/q = ax + by + cz + d$, the equation for the special set of planes.

Certain sections of the matrix are associated with various aspects of the transformation.[200] The first three elements in the rightmost column have to do with translation. This is shown by setting $(x, y, z) = (0, 0, 0)$ to locate the conjugate in the other space. The first three elements in the bottom row are related to perspective transformation. The upper left-hand 3×3 array expresses rotation, skew, and local magnification variation.

For the simple form of the transformation expressed in Eq. (211), $a_1 = e_x$, $b_2 = e_y$, $d_3 = e_z$, $c = 1$, and the rest of the coefficients vanish. The general matrix representation for the afocal transformation is

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{224}$$

The quantities q and q' can also be included, in which case $q' = q$. In the simplest afocal form, Eq. (212), the matrix is diagonal with $a_1 = m_x$, $b_2 = m_y$, $d_3 = m_z$, and the rest of the nondiagonal coefficients vanishing. A succession of collineations can be treated by multiplying the matrices that describe them.[201] To combine lenses with arbitrary orientations and to change coordinate systems, compatible rotation and translation matrices are required. The transformation for a pure rotation with direction cosines (L, M, N) is

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} 1-2L^2 & -2LM & -2LN & 0 \\ -2LM & 1-2M^2 & -2MN & 0 \\ -2LN & -2MN & 1-2N^2 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{225}$$

The transformation for translation by $(\Delta x, \Delta y, \Delta z)$ is

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & \Delta x \\ 0 & 1 & 0 & \Delta y \\ 0 & 0 & 1 & \Delta z \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{226}$$

The quantities q and q' can be included if necessary. The transformations associated with conjugate planes can likewise be expressed with 3×3 matrices, and the transformations of lines with 2×2 matrices.

Rotationally Symmetric Lenses

For rotationally symmetric lenses, the simplest forms are obtained with the z and z' axes corresponding to the lens axis in the two spaces. There is one less degree of freedom than in the general case, and $a_1 = b_2$ in Eq. (210). The general transformation is thus

$$x' = \frac{a_1 x}{cz + d}, \quad y' = \frac{a_1 y}{cz + d}, \quad z' = \frac{c_3 z + d_3}{cz + d} \tag{227}$$

There are four degrees of freedom, two associated with the lens and two with the choice of coordinate origins. For focal lenses, the two axial length parameters are f and f'. If the coordinate origins are at the focal points,

$$x' = -\frac{fx}{z}, \quad y' = -\frac{fy}{z}, \quad z' = \frac{f'f}{z} \tag{228}$$

If the coordinate origins are conjugate and related by magnification m_0, then

$$x' = \frac{m_0 x}{1 + z/f}, \quad y' = \frac{m_0 y}{1 + z/f}, \quad z' = \frac{(f'/f) m_0^2 z}{1 + z/f} \tag{229}$$

The constant term in the numerator of the z' expression is the longitudinal magnification for $z = 0$, for which point $dz'/dz = (f'/f)m_0^2$. A special case of these equations is that for which the principal points are the origins, so $m_0 = 1$.

For rotationally symmetric afocal lenses, the two degrees of freedom are the transverse magnification $m_x = m_y = m$, and the longitudinal magnification $m_z = m_L$. The simplest set of transformation equations is

$$x' = mx, \quad y' = my, \quad z' = m_L z \tag{230}$$

where $z = 0$ and $z' = 0$ are conjugate. If $m = \pm 1$ and $m_L = \pm 1$ the image space replicates object space, except possibly for orientation. If $m_L = m$, the spaces are identical except for overall scaling and orientation. The m and m_L appear as functions of ratios of focal lengths of the lenses that make up the afocal system.

Rays for Rotationally Symmetric Lenses

A skew ray with direction cosines (α, β, γ) in object space is described in parametric form with parameter z as follows

$$x(z) = x_0 + \frac{\alpha}{\gamma} z, \quad y(z) = x_0 + \frac{\beta}{\gamma} z \tag{231}$$

For a focal lens, if $z = 0$ is taken to be the front focal plane, and $z' = 0$ is the rear focal plane, the parametric form of the ray in image space is

$$x'(z') = \left(-f\frac{\alpha}{\gamma}\right) + \left(-\frac{x_0}{f'}\right) z', \quad y'(z') = \left(-f\frac{\beta}{\gamma}\right) + \left(-\frac{y_0}{f'}\right) z' \tag{232}$$

So $x'_0 = -f\alpha/\gamma$, $y'_0 = -f\beta/\gamma$, $\alpha'/\gamma' = -x_0/f'$, $\beta'/\gamma' = -y_0/f'$. For meridional rays with $x = 0$, if θ and θ' are the ray angles in the two spaces, then $\tan\theta = \beta/\gamma$, $\tan\theta' = -y_0/f'$, and

$$\frac{\tan\theta}{\tan\theta'} = \frac{f'}{f} m \tag{233}$$

where m is the transverse magnification in a plane where the meridional ray crosses the axis.

For afocal lenses, if $z = 0$ and $z' = 0$ are conjugate planes, the ray in image space is given by

$$x'(z') = mx_0 + \left(\frac{m}{m_L}\frac{\alpha}{\gamma}\right) z', \quad y'(z') = my_0 + \left(\frac{m}{m_L}\frac{\beta}{\gamma}\right) z' \tag{234}$$

For meridianal rays with $x = 0$,

$$\frac{\tan\theta}{\tan\theta'} = \frac{m_L}{m} \tag{235}$$

Tilted Planes with Rotationally Symmetric Lenses

A plane making an angle θ with the lens axis in object space has an image plane that makes an angle θ', given by Eq. (233), the so-called *Scheimpflug condition*.[202,203] A tilted plane and its image are perpendicular to a meridian of the lens, Fig. 19. There is bilateral symmetry on these planes about the

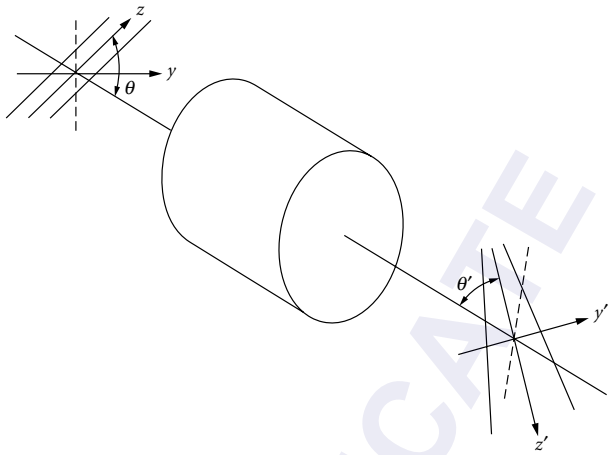

FIGURE 19 The image plane for a tilted object plane. The y-z plane is the object plane and the y'-z' plane is the image plane. The angles between the planes and the lens axis are θ and θ', which are related by Eq. (232). The conjugate points in these planes are related by Eq. (235).

intersection line with the meridian, which is taken to be the z axis in object space and the z' axis in image space. The perpendicular coordinates are y and y'. Letting m_0 be the transverse magnification for the axial point crossed by the planes, the transform equations are

$$y' = \frac{m_0 y}{1 + z/g}, \qquad z' = \frac{(g'/g) m_0^2 z}{1 + z/g} \tag{236}$$

Here g and g' are the focal lengths in the tilted planes, the distances from the principal planes to the focal planes of the lens, measured along the symmetry line, so

$$g = \frac{f}{\cos\theta}, \qquad g' = \frac{f'}{\cos\theta'}, \qquad \text{and} \qquad \frac{g'}{g} = \sqrt{\left(\frac{f'}{f}\right)^2 \cos^2\theta + \frac{1}{m_0^2}\sin^2\theta} \tag{237}$$

As $\theta \to 90°$, g and g' become infinite, and $(g'/g)m_0 \to 1$, giving $y' \to m_0 y$ and $z' \to m_0 z$. (Forms like Newton's equations may be less convenient here, since the distances from the axes to the focal points may be large.)

For an afocal lens with transverse magnification m and longitudinal magnification m_L, the object and image plane angles are related by Eq. (235). The conjugate equations for points in the planes are

$$y' = my, \qquad z' = (m_L^2 \cos^2\theta + m^2 \sin^2\theta)^{1/2} z \tag{238}$$

Here the origins may be the axial intersection point, or any other conjugate points.

Some General Properties

For all collinear transformations, points go to points, lines to lines, and planes to planes. In general, angles at intersections, areas, and volumes are changed. The degree of a curve is unchanged, so, for example, a conic is transformed into a conic. For focal systems, a "closed" conic, an ellipse or circle, may be imaged as either a closed or an "open" one, a parabola or hyperbola. For afocal systems, the

closedness and openness are preserved. With focal systems, the imaging of a shape varies with its location, but for afocal systems it does not. For afocal systems parallelness of lines is maintained, but for focal systems the images of parallel lines intersect. For afocal systems, equal distances along lines are imaged as equal distances, but are different unless the magnification is unity.

1.16 SYSTEM COMBINATIONS: GAUSSIAN PROPERTIES

Introduction

This section deals with combinations of systems, each of which is of arbitrary complexity. From a gaussian description of each lens and the geometry of the combination, the gaussian description of the net system can be found. If two rotationally symmetric lenses are put in series with a common axis, the resultant system is also rotationally symmetric. Its gaussian description is found from that of the two constituent lenses and their separations. The net magnification is the product of the two contributions, i.e., $m = m_1 \times m_2$. Matrix methods are particularly convenient for handling such combinations, and the results below can be demonstrated easily thereby. If two rotationally symmetric lenses are combined so their axes do not coincide, the combination can be handled with appropriate coordinate translations and rotations in the intermediate space, or by means of collineation. In the most general case, where subsystems without rotational symmetry are combined, the general machinery of collineation can be applied. There are three classes of combinations: focal-focal, focal-afocal, and afocal-afocal.

Focal-Focal Combination: Coaxial

The first lens has power ϕ_1 and principal points at P_1 and P_1', Fig. 20. The index preceding the lens is n and that following it is n_{12}. The second lens has power ϕ_2 and principal points at P_2 and P_2', with preceding index n_{12} and following index n'. The directed distance from the rear principal point of the first lens to the first principal point of the second lens is $d = P_1'P_2$, which may be positive or negative, since the lenses may have external principal planes. The power of the combination is

$$\phi = \phi_1 + \phi_2 - \frac{1}{n_{12}} d\phi_1\phi_2 \tag{239}$$

The two principal planes of the combination are located relative to those of the contributing lenses by directed distances

$$P_1P = +\frac{n}{n_{12}} d\frac{\phi_2}{\phi} \qquad P_2'P' = -\frac{n'}{n_{12}} d\frac{\phi_1}{\phi} \tag{240}$$

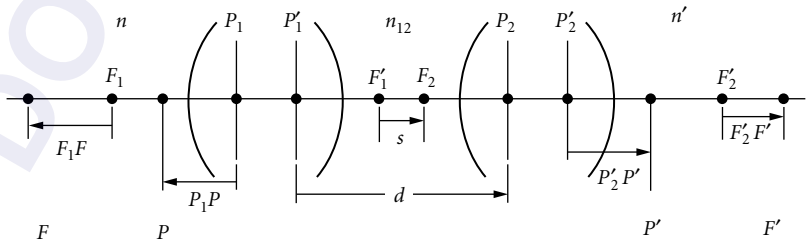

FIGURE 20 Coaxial combination of two focal lenses. The cardinal points of the two lenses are shown above the axis and those of the system below. The directions in this drawing are only one possible case.

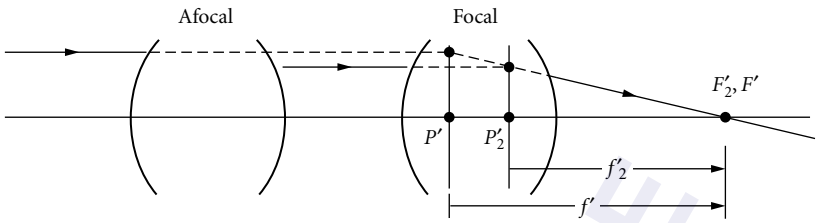

FIGURE 21 Coaxial combination of a focal lens and an afocal lens. In this drawing the afocal lens has a transverse magnification $0 < m_1 < 1$ and the focal lens has a positive power. The combination is a focal lens with focal length $f' = f'_2/m_1$. The focal point on the side of the focal lens is at the focal point of that lens alone.

If $\phi = 0$, the combination is afocal and there are no principal planes. In applying these equations, the inner-space index n_{12} must be the same as that for which the two lenses are characterized. For example, if two thick lenses are characterized in air and combined with water between them, these equations cannot be used by simply changing n_{12}. It would be necessary to characterize the first lens with water following it and the second lens with water preceding it.

Another set of equations involves the directed distance from the rear focal point of the first lens to the front focal point of the second, $s = F'_1F_2$. The power and focal lengths of the combination are

$$\phi = -\frac{1}{n_{12}} s\phi_1\phi_2, \quad f = +\frac{f_1 f_2}{s}, \quad f' = -\frac{f'_1 f'_2}{s} \tag{241}$$

The focal points are located with respect to those of the contributing lenses by

$$F_1F = +\frac{nn_{12}}{s\phi_1^2} = \frac{n_{12}}{n}\frac{f_1^2}{s}, \quad F'_2F' = -\frac{n'n_{12}}{s\phi_2^2} = -\frac{n'_{12}}{n'}\frac{f'^2_2}{s} \tag{242}$$

Another relationship is $(F_1F)(F'_2F') = ff'$. The system is afocal if $s = 0$. There are many special cases of such combinations. Another case is that when the first principal point of the second lens is at the rear focal point of the first, in which case the system focal length is that of the first. These relationships are proven by Welford.[204]

Focal-Afocal: Coaxial

A focal lens combined with an afocal lens is focal, Fig. 21. Here we take the afocal lens to be to the left, with magnification m_1. The focal lens to the right has power ϕ_2 and rear focal length f'_2. The power of the combination is $\phi_2 m_1$, and the rear focal length of the combination is $f' = f'_2/m_1$. On the side of the focal lens, the location of the principal focal point is unchanged. On the side of the afocal lens, the system focal point is located at the image of the focal point of the focal lens in the space between the two. Changing the separation between the lenses does not change the power or the position of the principal focal point relative to that of the focal lens. The principal focal point on the afocal lens side does move.

Afocal-Afocal: Coaxial

The combination of two afocal lenses is itself afocal, Fig. 22. If the two lenses have transverse magnifications m_1 and m_2, the combination has $m = m_1m_2$. A pair of conjugate reference positions is found from the conjugates in the outer regions to any axial point in the inner space. If the separation

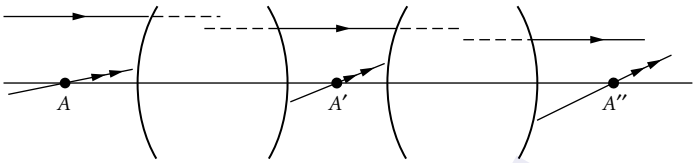

FIGURE 22 Coaxial combination of two afocal lenses. An internal point A' has an object space conjugate A and an image space conjugate A''. These two points can be used for position references in the overall object and image spaces.

between the two lenses changes, the combination remains afocal and the magnification is fixed, but the conjugate positions change. This result extends to a combination of any number of afocal lenses.

Noncoaxial Combinations: General

The most general combinations can be handled by the machinery of collineation. The net collineation can be found by multiplying the matrices that describe the constituents, with additional rotation and translation matrices to account for their relative positions. After obtaining the overall matrix, object and image space coordinate systems can be found in which the transformation is simplest. This approach can also be used to demonstrate general properties of system combinations. For example, by multiplying matrices for afocal systems, it is seen that a succession of afocal lenses with any orientation is afocal.

1.17 PARAXIAL MATRIX METHODS

Introduction

Matrix methods provide a simple way of representing and calculating the paraxial properties of lenses and their actions on rays. These methods contain no physics beyond that contained in the paraxial power and transfer equations, Eq. (136) and Eq. (142), but they permit many useful results to be derived mechanically, and are especially useful for lens combinations. The matrix description of systems is also useful in elucidating fundamental paraxial properties. With the symbolic manipulation programs now available, matrix methods also provide a means of obtaining useful expressions.

The optical system is treated as a black box represented by a matrix. The axial positions of the input and output planes are arbitrary. The matrix describes the relationship between what enters and what leaves, but contains no information about the specifics of the system within, and there is an infinity of systems with the same matrix representation.

The origin of matrix methods in optics is not clear. Matrices were used by Samson[205] who referred to them as "schemes." Matrices appear without comment in a 1908 book.[206] Matrix methods are treated in papers[207,208] and in many books.[209–218] Notation is not standardized, and many treatments are complicated by notation that conceals the basic structures.

This section is limited to rotationally symmetric lenses with homogeneous media. References are provided for systems with cylindrical elements. This treatment is monochromatic, with the wavelength dependence of index not made explicit.

The matrices are simplified by using *reduced axial distances* $\tau = t/n$ and *reduced angles* $\omega = nu$. The paraxial angles u are equivalent to direction cosines, and the reduced angles are optical direction cosines in the paraxial limit. For brevity, ω and τ are usually referred to in this section simply as "angle" and "distance."

Basic Idea: Linearity

Paraxial optics is concerned with the paraxial heights and paraxial angles of rays. A meridional ray entering a system has a given height y and angle ω and leaves with another height y' and angle ω'. Paraxial optics is linear, as discussed above, in the sense that both the outgoing height and angle depend linearly on the incoming height and angle. Writing Eq. (148) in terms of ω's gives

$$y' = \left(\frac{\partial y'}{\partial y}\right) y + \left(\frac{\partial y'}{\partial \omega}\right) \omega \quad \text{and} \quad \omega' = \left(\frac{\partial \omega'}{\partial y}\right) y + \left(\frac{\partial \omega'}{\partial \omega}\right) \omega \tag{243}$$

The partial derivatives are constant for a given system. This linearity is the basis of the matrix treatment, since these equations can be written in matrix form:

$$\begin{pmatrix} y' \\ \\ \omega' \end{pmatrix} = \begin{pmatrix} \dfrac{\partial y'}{\partial y} & \dfrac{\partial y'}{\partial \omega} \\ \dfrac{\partial \omega'}{\partial y} & \dfrac{\partial \omega'}{\partial \omega} \end{pmatrix} \begin{pmatrix} y \\ \\ \omega \end{pmatrix} \tag{244}$$

Basic Operations

The basic operations in paraxial ray tracing are transfer, Eq. (136), between surfaces and refraction or reflection at surfaces, Eq. (142).

Transfer Matrix

Transfer changes the height of a ray, in general, leaving the angle unchanged. In terms of reduced quantities, the relationships are

$$y' = y + tu = y + \frac{t}{n} un = y + \tau\omega \quad \text{and} \quad \omega' = \omega \tag{245}$$

The transfer matrix is

$$\begin{pmatrix} 1 & \tau \\ 0 & 1 \end{pmatrix} \tag{246}$$

For left-to-right transfer, $\tau > 0$. This gives a difference in signs between some of the terms in expressions here and those in the gaussian section, where directed distances are measured from a reference point related to the lens to the object.

Power Matrix

Refraction or reflection changes the angle of a ray, but not its height. The equations for reduced quantities are

$$n'u' = nu - y\phi = \omega' = \omega - y\phi \quad \text{and} \quad y' = y \tag{247}$$

Here $\phi = c(n' - n)$ for refraction and $\phi = -2nc$ for reflection, where c is the surface curvature, Eq. (143). The power matrix is

$$\begin{pmatrix} 1 & 0 \\ -\phi & 1 \end{pmatrix} \tag{248}$$

A planar reflecting or refracting surface has $\phi = 0$, so it is represented by the unit matrix.

Arbitrary System

A general system consists of a series of surfaces with powers $\phi_1, \phi_2, \ldots$ that are separated from one another by distances $\tau_1, \tau_2, \ldots$ Its matrix is the product

$$\begin{pmatrix} 1 & \tau_N \\ 0 & 1 \end{pmatrix} \cdots \begin{pmatrix} 1 & 0 \\ -\phi_2 & 1 \end{pmatrix} \begin{pmatrix} 1 & \tau_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\phi_1 & 1 \end{pmatrix} \begin{pmatrix} 1 & \tau_1 \\ 0 & 1 \end{pmatrix} \tag{249}$$

By convention, the successive matrices are concatenated from right to left, whereas ray tracing is done left to right.

A special case is a succession of transfers, itself a transfer.

$$\text{Succession of transfers: } \begin{pmatrix} 1 & \tau_1 + \tau_2 + \cdots \\ 0 & 1 \end{pmatrix} \tag{250}$$

Another is a series of refractions with no intervening transfer, itself a power operation.

$$\text{Succession of powers: } \begin{pmatrix} 1 & 0 \\ -(\phi_1 + \phi_2 + \cdots) & 1 \end{pmatrix} \tag{251}$$

Matrix Elements

Each matrix element has a physical significance, and the terms can be given mnemonic symbols associated with the conditions under which they are zero. (This practice is not standard.) If the initial ray angle is zero, the outgoing angles depend on the incident ray heights and the power of the system, according to $\omega' = -\phi y$, so $\partial\omega'/\partial y = -\phi$. If the initial surface is at the front focal plane, the outgoing ray angles depend only on the incident height, so $\partial\omega'/\partial\omega = 0$. This term is denoted by F for "front." Similarly, if the final surface is at the real focal plane, the outgoing ray heights depend only on the incoming angles, so $\partial y'/\partial y = R$ for "rear." If the initial and final planes are conjugate, then all incoming rays at a given height y have the outgoing height $y' = my$, regardless of their angle, so $\partial y'/\partial\omega = 0$ for conjugate planes. Since this term is related to the condition of conjugacy, $\partial y'/\partial\omega = C$ for "conjugate." With this notation, the general matrix is

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} \tag{252}$$

Dimensions

The terms R and F are dimensionless. C has the dimensions of length, and those of ϕ are inverse length. Dimensional analysis, as well as the consideration of Eq. (248), shows that the F and R terms will always contain products of equal numbers of ϕ_l's and τ_k's, such as $\phi_k\tau_l$. The ϕ expression contains terms like ϕ_k and $\tau_k\phi_l\phi_m$, with one more power term than distance terms. Similarly, C has terms like τ_k and $\tau_k\tau_l\phi_m$.

Determinant

Both the transfer and power matrices have unit determinants. Therefore, any product of such matrices has a unit determinant, a fact that is related to the two-ray paraxial invariant.

$$\begin{vmatrix} R & C \\ -\phi & F \end{vmatrix} = FR + C\phi = 1 \tag{253}$$

This provides an algebraic check. For afocal lenses and conjugate arrangements, $FR = 1$.

Possible Zeros

The possible arrangements of zeros in a system matrix is limited by the unit determinant restriction. There can be a single zero anywhere. In this case, either $C = 1/\phi$ or $F = 1/R$, and the remaining nonzero term can have any value. There can be two zeros on either diagonal. No row or column can contain two zeros, since a system represented by such a matrix would violate conservation of brightness. A matrix with double zeros in the bottom row would collimate all rays, regardless of their incoming position and direction. A matrix with all zeros in the top row represents a system that would bring all incoming light to a single point. A system whose matrix has double zeros in the first column would bring all incoming light to a focus on the axis. For double zeros in the second row, the system would concentrate all light diverging from an input point in a single output point with a single direction.

Operation on Two Rays

Instead of considering a single input and output ray, the matrix formalism can be used to treat a pair of rays, represented by a 2×2 matrix. In this case

$$\begin{pmatrix} y_1' & y_1' \\ \omega_1' & \omega_2' \end{pmatrix} = \begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} \begin{pmatrix} y_1 & y_2 \\ \omega_1 & \omega_2 \end{pmatrix} \tag{254}$$

Since the system matrix has a unit determinant, the determinants of the incoming and outgoing ray matrices are identical:

$$L_{12} = y_1'\omega_2' - y_2'\omega_1' = y_1\omega_2 - y_2\omega_1 \tag{255}$$

This is the paraxial invariant, Eq. (149). It is possible to operate on more than two rays, but never necessary, since any third ray is a linear combination of two, Eq. (154). Operations on two rays can also be handled with a complex notation in which two ray heights and two angles are each represented by a complex number.[219,220]

Conjugate Matrix

For conjugate planes, $y' = my$, so $C = 0$, $R = m$, and $F = 1/m$, giving

$$\begin{pmatrix} m & 0 \\ -\phi & 1/m \end{pmatrix} \tag{256}$$

The $1/m$ term gives the angular magnification, $u'/u = n/n'm$, Eq. (196). This matrix also holds for afocal lenses, in which case $\phi = 0$.

Translated Input and Output Planes

For a given system, the locations of the input and output planes are arbitrary. If the input plane is translated by τ and the output plane by τ', the resultant matrix is

$$\begin{pmatrix} R - \tau'\phi & C + \tau R + \tau' F - \tau\tau'\phi \\ -\phi & F - \tau\phi \end{pmatrix} \tag{257}$$

Note that the object-space translation term τ is grouped with F and the image-space term τ' with R. The equation $C = 0 = \tau R - \tau' F - \tau\tau'\phi$ gives all pairs of τ and τ' for which the input and output surfaces are conjugate.

Principal Plane-to-Principal Plane

If the input and output planes are the principal planes, then the matrix is a conjugate one, for which $m = +1$.

$$\begin{pmatrix} 1 & 0 \\ -\phi & 1 \end{pmatrix} \tag{258}$$

This is also the matrix representing a thin lens.

Nodal Plane-to-Nodal Plane

The nodal points are conjugate, with unit angular magnification, so $u' = u$ and $\omega' = n'\,\omega/n$. Thus

$$\begin{pmatrix} n/n' & 0 \\ -\phi & n'/n \end{pmatrix} \tag{259}$$

The transverse magnification $m_N = n/n'$ equals unity when $n = n'$. This matrix has no meaning for afocal lenses.

Focal Plane-to-Focal Plane

If the initial surface is at the front principal focal plane and the final surface is at the rear focal plane, the matrix is

$$\begin{pmatrix} 0 & 1/\phi \\ -\phi & 0 \end{pmatrix} \tag{260}$$

This is the "Fourier transform" arrangement, in which incident heights are mapped as angles and vice versa.

Translation from Conjugate Positions

If the input plane is translated τ from a plane associated with magnification m and the output plane is translated a distance τ' from the conjugate plane, the matrix is

$$\begin{pmatrix} m - \tau'\phi & m\tau + \tau'/m - \tau\tau'\phi \\ -\phi & 1/m - \tau\phi \end{pmatrix} \tag{261}$$

Setting $C = 0$ gives an equation that locates all other pairs of conjugate planes relative to the first one, Eq. (172).

Translation from Principal Planes

If the initial conjugate planes are the principal planes, then

$$\begin{pmatrix} 1 - \tau'\phi & \tau + \tau' - \tau\tau'\phi \\ -\phi & 1 - \tau\phi \end{pmatrix} \tag{262}$$

The equation for other conjugates is $C = 0 = \tau + \tau' - \tau\tau'\phi$, corresponding to Eq. (170). It follows that the distance from the input surface to the first principal plane is $\tau = (1 - F)/\phi$ and the distance from the output surface to the second principal plane is $\tau' = (1 - R)/\phi$.

Translation from Focal Planes

If the input plane is a distance τ from the front focal plane and the output plane a distance τ' from the rear focal plane, the matrix is

$$\begin{pmatrix} -\phi\tau' & \frac{1}{\phi}(1-\phi^2\tau\tau') \\ -\phi & -\phi\tau \end{pmatrix} \tag{263}$$

Thus F and R are proportional to the distances of the input and output surfaces from the object space and image space focal planes. Using Newton's formulas, this can also be written

$$\begin{pmatrix} m' & \frac{1}{\phi}\left(1-\frac{m'}{m}\right) \\ -\phi & \frac{1}{m} \end{pmatrix} \tag{264}$$

Here m' is the magnification that would obtain if the image point were as located by R, and m is that if the object point were located by F. The conjugate term vanishes when $m = m'$.

Conjugate Relative to Principal Focal Planes

If Eq. (263) is a conjugate matrix, it becomes

$$\begin{pmatrix} -\phi\tau' & 0 \\ -\phi & -\phi\tau \end{pmatrix} \tag{265}$$

The vanishing C term gives $0 = 1/\phi - \phi\tau\tau'$, which is the Newton equation usually written as $zz' = ff'$. The magnification terms are the other Newton's equations, $m = -\phi\tau'$ and $1/m = -\phi\tau$, which are usually written as $m = -z'/f' = -f/z$.

Afocal Lens

For afocal lenses $\phi = 0$. Since the determinant is unity, $F = 1/R$. And since the transverse magnification is constant, $R = m$, giving

$$\begin{pmatrix} m & C \\ 0 & 1/m \end{pmatrix} \tag{266}$$

A ray with $\omega = 0$ has $y' = my$, and $\omega' = \omega/m$ for all y. At conjugate positions, an afocal lens has the matrix

$$\begin{pmatrix} m & 0 \\ 0 & 1/m \end{pmatrix} \tag{267}$$

Performing a translation in both object and images spaces from the conjugate position gives

$$\begin{pmatrix} m & m\tau + \frac{\tau'}{m} \\ 0 & 1/m \end{pmatrix} \tag{268}$$

Setting $C = 0$ gives $\tau' = -m^2\tau$, which relates the location of a single conjugate pair to all others, Eq. (200).

Symmetrical Lenses

For lenses with symmetry about a central plane and symmetrically located input and output surfaces, $F = R$, so the matrix has the form

$$\begin{pmatrix} B & C \\ -\phi & B \end{pmatrix} \tag{269}$$

where $B^2 = 1 - \phi C$. The conjugate matrix has $m = \pm 1$.

Reversing Lenses

When a lens is flipped left to right along with their media, the matrix of the reversed system is obtained from that of the original one by switching the F and R terms.

$$\begin{pmatrix} F & C \\ -\phi & R \end{pmatrix} \tag{270}$$

This reversal maintains the exterior references planes, that is, the input surface for the initial system becomes the output surface for the flipped one and vice versa.

Inverse Systems

By the "inverse" of a lens is meant a second system that undoes the effect of a given one. That is, the rays at the output surface of the second system have the same height and angle as those at the input of the first system. The combination of a system and its inverse is afocal with unit magnification. The matrix representing the inverse system is the inverse of that representing the system.

$$\begin{pmatrix} F & -C \\ \phi & R \end{pmatrix} \tag{271}$$

The matrix provides no instruction as to how such a lens is made up. Alternatively, the inverse matrix can be interpreted as that whose input is y' and ω', with outputs y and ω.

Series of Arbitrary Lenses

The matrix for two successive lenses is

$$\begin{pmatrix} R_1R_2 - C_2\phi_1 & C_1R_2 + C_2F_1 \\ -\phi_1F_2 - \phi_2R_1 & F_1F_2 - C_1\phi_2 \end{pmatrix} = \begin{pmatrix} R_2 & C_2 \\ -\phi_2 & F_2 \end{pmatrix}\begin{pmatrix} R_1 & C_1 \\ -\phi_1 & F_1 \end{pmatrix} \tag{272}$$

For example, two given lenses separated by some distance have the matrix

$$\begin{pmatrix} R_2 & C_2 \\ -\phi_2 & F_2 \end{pmatrix}\begin{pmatrix} 1 & \tau \\ 0 & 1 \end{pmatrix}\begin{pmatrix} R_1 & C_1 \\ -\phi_1 & F_1 \end{pmatrix} \tag{273}$$

Multiplying from right to left gives a running product or "cumulative matrix," that shows the effect of the system up to a given plane.

Decomposition

Matrix multiplication is associative, so the system representation can be broken up in a number of ways. For example, the portion of a lens before and after the aperture stop can be used to find the

pupil locations and magnifications. An arbitrary lens matrix can be written as a product of three matrices:[221]

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ -\phi/R & 1 \end{pmatrix} \begin{pmatrix} R & 0 \\ 0 & 1/R \end{pmatrix} \begin{pmatrix} 1 & C/R \\ 0 & 1 \end{pmatrix} \tag{274}$$

or

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \begin{pmatrix} 1 & C/F \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1/F & 0 \\ 0 & F \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\phi/F & 1 \end{pmatrix} \tag{275}$$

Thus a general lens is equivalent to a succession of three systems. One has power and works at unit magnification. The second is a conjugate afocal matrix. The third is a translation. Each of these systems is defined by one of the three terms, either, R, ϕ/R, C/R or F, ϕ/F, C/F. This is another manifestation of the three degrees of freedom of paraxial systems.

Matrix Determination by Two-Ray Specification

If a two-ray input matrix is given along with the desired output, or the two input and output rays are measured to determine the matrix of an unknown lens, Eq. (254) gives

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \begin{pmatrix} y_1' & y_2' \\ \omega_1' & \omega_2' \end{pmatrix} \begin{pmatrix} y_1 & y_2 \\ \omega_1 & \omega_2 \end{pmatrix}^{-1} \tag{276}$$

so

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \frac{1}{y_1\omega_2 - y_2\omega_1} \begin{pmatrix} y_1'\omega_2 - y_2'\omega_1 & y_2'y_1 - y_1'y_2 \\ \omega_1'\omega_2 - \omega_2'\omega_1 & \omega_2'y_1 - y_2\omega_1' \end{pmatrix} \tag{277}$$

The denominator of the multiplicative factor is the paraxial invariant associated with the two rays, Eq. (149). As a special case, the two rays could be the marginal and chief rays. The input and output pairs must have the same invariant, or the matrix thus found will not have a unit determinant.

Experimental Determination of Matrix Elements

The matrix elements for an unknown lens can, in principle, be determined experimentally. One method, as mentioned in the preceding section, is to measure the heights and angles of an arbitrary pair of rays. Another method is as follows. The power term is found in the usual way by sending a ray into the lens parallel to the axis and measuring its outgoing angle. To find $C = \partial y'/\partial\omega$, the input ray angle is varied, while its height is unchanged. If the output height is graphed, its slope is C. Likewise, the other partial derivatives in Eq. (243) can be found by changing one of the input parameters while the other is fixed. The four measurements are redundant, the unit determinant providing a check of consistency.

Angle Instead of Reduced Angle

The matrices above can be modified to use the angles u and u', instead of the reduced angles. In terms of matrix theory, this amounts to a change in basis vectors, which is accomplished by multiplying by diagonal vectors with elements 1 and n or 1 and n', The result is

$$\begin{pmatrix} y \\ u' \end{pmatrix} = \begin{pmatrix} R & nC \\ -\dfrac{1}{n'}\phi & \dfrac{n}{n'}F \end{pmatrix} \begin{pmatrix} y \\ u \end{pmatrix} \tag{278}$$

This matrix has a constant determinant n/n'. The form of Eq. (252) is simpler.

Other Input-Output Combinations

Referring to Eq. (244), any pair of the four quantities y, ω, y', and ω' can be taken as inputs, with the other two as outputs, and the relationships can be expressed in matrix form. The four matrices in this section cannot be multiplied to account for the concatenation of lenses. If the angles are given, the heights are

$$\begin{pmatrix} y \\ y' \end{pmatrix} = \frac{1}{\phi}\begin{pmatrix} F & -1 \\ 1 & -R \end{pmatrix}\begin{pmatrix} \omega \\ \omega' \end{pmatrix} \tag{279}$$

The matrix is undefined for afocal lenses, for which the relationship of ω and ω' is independent of heights. Similarly, the angles can be expressed as functions of the heights by

$$\begin{pmatrix} \omega \\ \omega' \end{pmatrix} = \frac{1}{C}\begin{pmatrix} -R & 1 \\ -1 & F \end{pmatrix}\begin{pmatrix} y \\ y' \end{pmatrix} \tag{280}$$

For conjugates the expression breaks down, since there is no fixed relationship between heights and angles. If the input is a height on one side and an angle on the other, then

$$\begin{pmatrix} y' \\ \omega \end{pmatrix} = \frac{1}{F}\begin{pmatrix} 1 & C \\ \phi & 1 \end{pmatrix}\begin{pmatrix} y \\ \omega' \end{pmatrix} \tag{281}$$

For the inverse situation,

$$\begin{pmatrix} y \\ \omega' \end{pmatrix} = \frac{1}{R}\begin{pmatrix} 1 & -C \\ -\phi & 1 \end{pmatrix}\begin{pmatrix} y' \\ \omega \end{pmatrix} \tag{282}$$

The determinants of these matrices are, respectively, C, ϕ, R, and F.

Derivative Matrices

If the axial position of the input surface changes, the rate of change of the output quantities is

$$\begin{pmatrix} dy'/dz \\ d\omega'/dz \end{pmatrix} = \begin{pmatrix} 0 & R \\ 0 & -\phi \end{pmatrix}\begin{pmatrix} y \\ \omega \end{pmatrix} \tag{283}$$

If the axial position of the output surface can change, the rate of change of output quantities is

$$\begin{pmatrix} dy'/dz' \\ d\omega'/dz' \end{pmatrix} = \begin{pmatrix} -\phi & F \\ 0 & 0 \end{pmatrix}\begin{pmatrix} y \\ \omega \end{pmatrix} \tag{284}$$

Higher derivatives vanish.

Skew rays

The matrix formalism can be used to treat a paraxial skew ray, represented by a 2×2 matrix of x and y positions and directions α and β. In this case

$$\begin{pmatrix} x' & y' \\ n'\alpha' & n'\beta' \end{pmatrix} = \begin{pmatrix} R & C \\ -\phi & F \end{pmatrix}\begin{pmatrix} x & y \\ na & n\beta \end{pmatrix} \tag{285}$$

Since the lens matrix has a unit determinant, the determinants of the incoming and outgoing ray matrices are identical:

$$n'(y'\alpha' - x'\beta') = n(y\alpha - x\beta) \tag{286}$$

From Eq. (73), this is the skew invariant.

Relationship to Characteristic Functions

A lens matrix can be related to any one of the four paraxial characteristic functions, Eqs. (34) through (37), each of which has three first coefficients, associated with the three degrees of freedom of the matrix. Brouwer and Walther[222] derive the paraxial matrices from more general matrices based on the point angle characteristic function.

Nonrotationally Symmetric Systems

Systems comprising cylindrical lenses can also be treated paraxially by matrices.[223–228,221] The more general case of a treatment around an arbitrary ray is also represented by a 4×4 matrix.[229] This is treated by several of the references to the section "Images About Known Rays."

1.18 APERTURES, PUPILS, STOPS, FIELDS, AND RELATED MATTERS

Introduction

This section is concerned with the finite size of lenses and their fields, as expressed in various limitations of linear dimensions and angles, and with some of the consequences of these limits. (Other consequences, for example, resolution limitations, are in the domain of wave optics.) Terminology in this area is not well defined, and the terms typically used are insufficient for all the aspects of the subject, so this section deals considerably with definitions.

Field Size and Field Stop

The *field* or *field of view* of a lens is the region of object space from which light is captured or the region of image space that is used. The field size may be described in angular, linear, or area units, depending on the circumstances. (It can be described in still other ways, e.g., the number of pixels.) In and of itself, a lens does not have a definite field size, but beyond a certain size, image quality diminishes, both with respect to aberration correction and to light collection. A *field stop* is a physical delimiter of the field, which may be in either object or image space. A detector may be the delimiter.

Aperture Stop

Each object point can be thought of as emitting rays in all directions. Since lenses are finite in size, only some of the rays pass through them. The rays that do pass are referred to as *image-forming rays,* the ensemble of which is the *image-forming bundle*, also called the *image-forming cone,* although the bundle may not be conical. The bundle associated with each object point is delimited by one or more physical structures of the lens. For axial object points, the delimiting structure is called the *aperture*, the *stop*, or the *aperture stop*. The aperture may be either within the lens or outside of it on either side, Fig. 23. The aperture may be a structure whose sole purpose is delimiting the bundle, or it may be the edge of an optical element or a lens mount. The aperture stop may be fixed or adjustable, for instance, an iris. Which structure acts as the aperture can change with object position, Fig. 24. The size and position of the aperture do not effect the gaussian properties of the lens, i.e., the cardinal points and the conjugate locations and magnifications. They do affect the image irradiance, the aberrations, and the effects of defocus. The aperture is most commonly centered on axis, but this is not always so. With visual instruments, the aperture stop for the entire system may be either an aperture in the optics or the iris of the observer's eye.

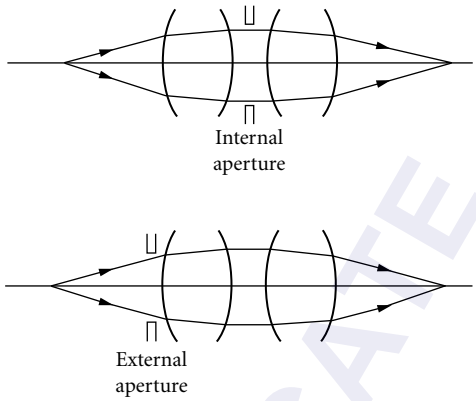

FIGURE 23 Axial ray cone and aperture stop. The upper lens has an internal aperture, and the lower one has an external aperture on the object side.

Marginal Rays and Chief Rays

Ray bundles are described to a considerable extent by specifying their central and extreme rays. For object planes perpendicular to the lens axis, there are two meridional rays of particular importance, defining the extremities of field and aperture, Fig. 25. These rays are reciprocal in that one is to the pupil what the other is to the field.

The *marginal ray* originates at the axial object point, intersects the conjugate image point, and passes through the edge of the aperture. This term is also used for rays from other field points that pass through the extremes of the aperture. The *paraxial marginal ray* is the marginal ray in the paraxial limit.

The *chief ray* or *principal ray* originates at the edge of the object field, intersects the edge of the image field, and passes approximately through the center of the aperture, and hence approximately through the center of the pupils. (Here we use "chief ray," since the prefix "principal" is so commonly used for other entities.) The term is also used for the central ray of other bundles. The *paraxial chief ray* passes exactly through the centers of the aperture and both paraxial pupils.

Field Angle

The *field angle* is that subtended by the field of view at the lens. This term is ambiguous, since several angles can be used, as well as angles in both object and image space. A nodal ray angle is the same in both spaces. If the nodal points are not at the pupils, the chief ray angle differs on the two sides. The ratio

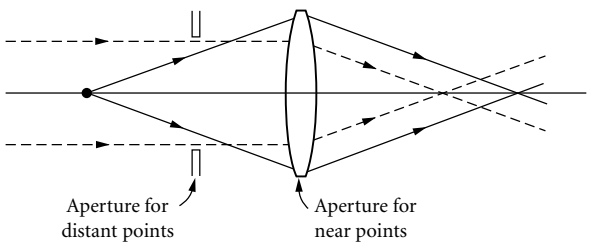

FIGURE 24 An example of change of aperture with axial object position. For distant points the aperture is the nominal stop. For near points the aperture is the rim of the lens.

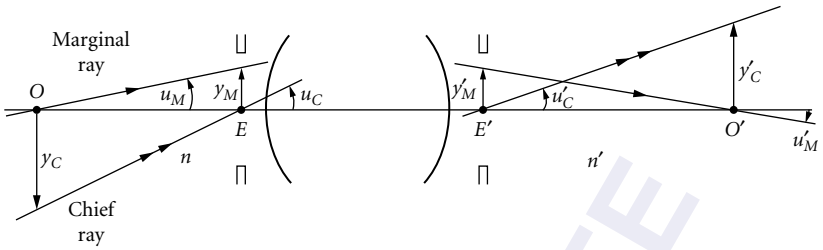

FIGURE 25 Schematic diagram of a lens with object and image planes, entrance and exit pupils, and marginal and chief rays. The entrance pupil is located at E and the exit pupil at E'. The chief ray passes through the edges of the fields and the centers of the pupils. The marginal ray passes through the axial object and image points and the edges of the pupils.

of paraxial chief ray angles is proportional to the paraxial pupil magnification, as discussed later, Eq. (289). If the lens is telecentric, the chief ray angle is zero. An afocal lens has no nodal points, and the paraxial ratio of output angles to input angles is constant. The concept of field angle is most useful with objects and/or images at large distances, in which case on the long conjugate side the various ray angles are nearly identical. On the short conjugate side, ambiguity is removed by giving the focal length, the linear size of the detector, and the principal plane and exit pupil positions. For finite conjugates, such information should be provided for both spaces.

Pupils

The term *pupil* is used in several ways, and care should be taken to distinguish between them. There are paraxial pupils, "real" pupils, pupils defined as ranges of angles, and pupil reference spheres used for aberration definition and diffraction calculations. The *entrance pupil* is the aperture as seen from object space—more precisely, as seen from a particular point in object space. If the aperture is physically located in object space, the entrance pupil is identical to the aperture. Otherwise, the entrance pupil is the image of the aperture in object space formed by the portion of the lens on the object side of the aperture. If the aperture is in image space, the entrance pupil is its image formed by the entire lens. Similarly, the *exit pupil* is the aperture as seen from image space. A *real pupil* is a physically accessible image of the aperture or the aperture itself, and a *virtual pupil* is an inaccessible image. Visual instruments often have external pupils, where the user's eye is located. The axial entrance pupil point is denoted here by E and the exit pupil by E'.

The pupils can be located anywhere on axis, except that they cannot coincide with the object or image. It is common to draw pupils as shown in Fig. 25, but they can also be on the side of the object or image away from the lens. The pupils are usually centered on axis, but not necessarily. Aberrations may shift pupils from nominal axial centration.

Both pupils are conjugate to the aperture, so they are conjugate to each other. The term *pupil imaging* refers to the relationship of the pupils with respect to each other and to the aperture. In pupil imaging, the chief ray of the lens is the marginal ray and vice versa. The *pupil magnification* m_p denotes the ratio of exit pupil size to entrance pupil size. The size may be specificed as linear or an angular extent, and the pupil magnification may be a transverse magnification, finite or paraxial, or a ratio of angular subtenses. In general, there is *pupil aberration,* so the image of the aperture in each space is aberrated, as is that of the imaging of one pupil to the other. Pupil imaging is subject to chromatic aberration, so positions, sizes, and shapes of pupils may vary with wavelength.

There is ambiguity about pupil centers and chief rays for several reasons. The center can be taken with respect to linear, angular, or direction cosine dimensions. Because of spherical pupil aberration, a ray through the center of the pupil may not also pass through the center of the aperture, and vice versa. The angular dimensions of pupils may change with field position. Pupil aberrations cause the actual pupil shape to be different from that of the paraxial pupil.

Pupils that are not apertures can have any linear size, since the aperture can be imaged at any magnification. If the aperture is within the lens, there is no particular relationship between the positions and linear sizes of the entrance and exit pupils, since the portions of the lens that precede and follow the aperture have no specific relationship. There is a relationship between the angular subtense of the pupils, as discussed below.

The angular size and shape of the pupils can vary with field position, and the pupils can change position if the aperture changes with object position. If the lens changes internally, as with a zoom, the sizes and positions of the pupils change.

Paraxial Description

The *paraxial pupils* are the paraxial images of the aperture. They are usually planar and perpendicular to the axis and are implicitly free from aberration. The paraxial chief ray passes through the center of both pupils and the aperture, and the paraxial marginal ray through the edges. The object and pupil magnifications and the distances from object to entrance pupil and from exit pupil to image are related by Eq. (194). If the object at O is imaged at O' with magnification m, and the pupil magnification from entrance pupil at E to exit pupil at E' is m_E, then from Eq. (194)

$$O'E' = \frac{n'}{n} m m_E OE \tag{287}$$

Paraxial Invariant for Full Field and Full Aperture

Let the height of the paraxial marginal ray be y_M at the entrance pupil and y'_M at the exit pupil, and that of the paraxial chief ray by y_C, at the object plane and y'_C at the image plane, Fig. 25. Let the angles of these rays be u_M, u_C, u'_M, u'_C. The two-ray paraxial invariant, Eq. (149), is

$$L = n y_C u_M = n y_M u_C = n' y'_M u'_C = n' y'_C u'_M \tag{288}$$

This relationship was rediscovered several times, so the conserved quantity is referred to by a variety of names, including the *Lagrange invariant*, the *Helmholtz invariant*, the *Smith invariant*, and with various hyphenated combinations of the proper names.[230,231] Further discussions are found in the sections on paraxial optics and on the étendue. The paraxial transverse magnification and paraxial pupil magnifications are related to the paraxial marginal and chief ray angles by

$$m = \frac{y'_C}{y_C} = \frac{n u_M}{n' u'_M} \quad \text{and} \quad m_P = \frac{y'_M}{y_M} = \frac{n u_C}{n' u'_C} \tag{289}$$

Pupil Directions

For some purposes, pupils are best described as ranges of directions, specified in direction cosines, rather than by linear extents of aperture images. Here the term *pupil directions* (NS) is used. This is particularly the case when dealing with a given region of the object. The construction for this description is shown in Fig. 26. The x and y axes of the object-space coordinate system lie in the object surface, and the x' and y' axes of the image-space coordinate system lie in the image surface. From a point on the object plane, the extreme set of rays that passes through the lens is found. Its intersection with a unit sphere about the object point is found, and perpendiculars are dropped to the unit circle on (or tangent to) the object plane, giving the extent in direction cosines.

The entrance pupil is delimited by a closed curve described by a relationship $0 = P(\alpha, \beta; x, y)$, and the exit pupil is likewise defined by $0 = P'(\alpha', \beta'; x', y')$. The spatial argument is included to indicate that the shape varies, in general, with the field position. There may be multiple regions, as in the case of central obstructions. It is usually preferable to define the pupils relative to *principal directions* (NS) (α_0, β_0) in object space and (α'_0, β'_0) in image space, where the two directions are

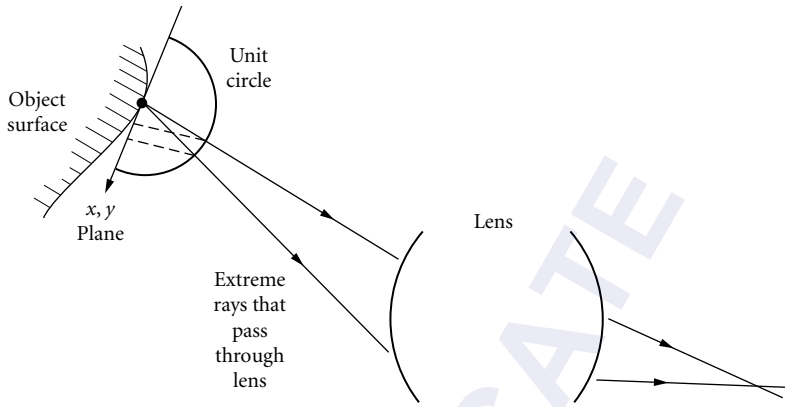

FIGURE 26 Construction for the description of the pupils with direction cosines. An *x-y* plane is tangent to the object surface at the object point, and a unit sphere is centered on the point. The intersections with the unit sphere of the rays are projected to the tangent plane to give the pupil direction cosines.

those of the same ray in the two spaces, usually a meridional ray. The principal directions are analogous to the chief rays. The entrance pupil is then given by $0 = Q(\alpha - \alpha_0, \beta - \beta_0; x, y)$ and the exit pupil by $0 = Q'(\alpha' - \alpha_0', \beta' - \beta_0'; x', y')$. For example, for a field point on the $x = 0$ meridian, the expression for the pupil might be well approximated by an ellipse, $0 = a\alpha^2 + b(\beta - \beta_0)^2$, where $(0, \beta_0)$ is the chief ray direction. If the imaging is stigmatic, the relationship between entrance and exit pupil angular shapes is provided by the cosine condition, Eq. (104).

$$Q'(\alpha', \beta'; x', y') = Q(m_P\alpha' - \alpha_0', m_P\beta' - \beta_0'; x, y) \tag{290}$$

The entrance and exit pupils have the same shapes when described in direction cosine space. They are scaled according to the *pupil angular magnification* (NS) $m_P = n/n'm$. The orientations may be the same or rotated 180°. There is no particular relationship between (α_0, β_0) and (α_0', β_0') which can, for example, be changed by field lenses. The principal directions are, however, usually in the same meridian as the object and image points, in which case $\alpha_0/\beta_0 = \alpha_0'/\beta_0'$. If the field point is in the x meridian, and the central ray is in this meridian, then $\alpha_0 = 0$ and $\alpha_0' = 0$. Even with aberrations, Eq. (290) usually holds to a good approximation. The aberration *pupil distortion* refers to a deviation from this shape constancy.

Pupil Directional Extent: Numerical Aperture and Its Generalizations

The angular extent of a pupil extent is limited by some extreme directions. In the example above of the elliptical shape, for instance, there are two half widths

$$\frac{1}{2}(\alpha_{\max} - \alpha_{\min}) \quad \text{and} \quad \frac{1}{2}(\beta_{\max} - \beta_{\min}) \tag{291}$$

For a rotationally symmetric lens with a circular aperture, the light from an axial object point in a medium of index n is accepted over a cone whose vertex angle is $\theta_{\max}$. The *object space numerical aperture* is defined as

$$NA = n \sin\theta_{\max} = n\sqrt{(\alpha^2 + \beta^2)_{\max}} = n\alpha_{\max} = n\beta_{\max} \tag{292}$$

Likewise, on the image side, where the index is n' and the maximum angle is $\theta'_{\max}$, the *image space numerical aperture* is

$$NA' = n' \sin \theta'_{\max} = n' \sqrt{(\alpha'^2 + \beta'^2)_{\max}} = n' \alpha'_{\max} = n' \beta'_{\max} \tag{293}$$

If the lens is free of coma, the sine condition, Eq. (106), gives for finite conjugates

$$m = \frac{n \sin \theta_{\max}}{n' \sin \theta'_{\max}} = \frac{NA}{NA'} \tag{294}$$

For infinite conjugates

$$\sin \theta'_{\max} = -\frac{y_{\max}}{f'} \quad \text{or} \quad n' \sin \theta'_{\max} = NA' = n \beta_{\max} = -y_{\max} \phi \tag{295}$$

If there is coma, these relationships are still good approximations. For a given lens and a given aperture size, the numerical aperture varies with the axial object position.

F-Number and Its Problems

The *F-number* is written in a variety of ways, including F/no. and F/#. It is denoted here by *FN*. The F-number is not a natural physical quantity, is not defined and used consistently in the literature, and is often used in ways that are both wrong and confusing.[232,233] Moreover, there is no need to use the F-number, since everything that it purports to describe or approximately describes is treated properly with direction cosines. The most common definition for F-number, applied to the case of an object at infinity, is

$$FN = \frac{\text{focal length}}{\text{entrance pupil diameter}} = \frac{1}{2 \tan \theta'} \tag{296}$$

where θ' is the outgoing angle of the axial imaging cone. In general, the F-number is associated with the tangents of collinear transformations, rather than the sines (or direction cosines) that are physically appropriate. It presumes that a nonparaxial ray entering parallel to the axis at height y leaves the rear principal plane at the same height and intersects the rear focal point, so that $\tan \theta' = y/f'$. However, this particular presumption contradicts Eq. (294), and in general, collineation does not accurately describe lens behavior, as discussed above.

Other problems with F-number, as it is used in the literature, include the following: (1) It is not defined consistently. For example, the literature also contains the definition F-number = (focal length)/(exit pupil diameter). (2) For lenses used at finite conjugates, the F-number is often stated for an object at infinity. In fact, given only the numerical aperture for an object at infinity, that for other conjugates cannot be determined. (3) There are confusing descriptions of variation of F-number with conjugates, for example, the equation $FN_m = (1 + m)FN_\infty$, where FN_m is the F-number for magnification m and FN_∞ is that for an object at infinity. In fact, numerical apertures for various magnifications are not so related. (4) The object and image space numerical apertures are related by Eq. (294), but there is no such relationship for tangents of angles, except that predicted by collineation, Eq. (232), which is approximate. (5) With off-axis field points and noncircular pupils, the interpretation of F-number is more ambiguous. (6) Afocal systems have finite numerical apertures when used at finite conjugates, but they have no analogue to Eq. (295). (7) Object and image space refractive indices are not accounted for by the F-number, whereas they are by the numerical aperture. (8) The F-number is often used as a descriptor of radiometric throughput, rather than of ray angles per se.

A related quantity is the *T-number*,[234] which accounts for both the convergence angle of the imaging cone and the fraction of power transmitted by the lens. This is useful as a single-number descriptor, but it is subject to all the confusion associated with the F-number.

Image Irradiance for Lambertian Objects

If the light from a region of an object is lambertian with a power/area M, then the emitted power per angle with angle according to $(M/\pi)\cos\theta\, d\omega = (M/\pi)\, d\alpha\, d\beta$. The power captured by the entrance pupil from a small object area dA is

$$dP = \frac{1}{\pi} M\, dA \int_{\text{entrance pupil}} d\alpha\, d\beta \tag{297}$$

(For a full hemisphere $\int d\alpha\, d\beta = \pi$, giving $dP = M\, dA$.) If there are no losses within the lens, the power reaching the conjugate image region dA' is the same. Using the conservation of étendue equation, Eq. (72), the image irradiance is

$$E = \frac{dP}{dA'} = \frac{1}{\pi} M \frac{n'^2}{n^2} \int_{\text{exit pupil}} d\alpha' d\beta' \tag{298}$$

The image irradiance does not depend explicitly on the magnification, but magnification is included implicitly, since, for a given lens, the subtense of the exit pupil varies with conjugates.

This equation applies everywhere in the field, and it applies to arbitrary object surface positions and orientations, so long as the direction cosines are defined with respect to the local object and image surface normals. These equations apply regardless of the chief ray angles, so they are applicable, for example, with telecentricity. In general, the pupil shape and principal direction vary with field position, so there is a gradation of irradiance in the image of a uniform lambertian object.

These equations do not account for all that influences image irradiance, for example, lens absorption and reflection. These effects can be included in the above expressions by adding an appropriate weighting function of angle and field in the above integrals, giving

$$E(x',\, y') = \frac{dP}{dA'} = \frac{1}{\pi} M(x,\, y) \frac{n'^2}{n^2} \int \tau(\alpha',\, \beta';\, x',\, y')\, d\alpha'\, d\beta' \tag{299}$$

where $\tau(\alpha',\, \beta';\, x',\, y')$ is the lens transmittance as a function of the direction cosines for the image point $(x',\, y')$. With externally illuminated objects that are not lambertian scatterers, these relationships do not hold. For example, in optical projectors the illumination is matched to the object and imaging lens to give nominally uniform image irradiance.

Axial Image Irradiance for Lambertian Objects

In the special case of circular pupils and axial object surfaces perpendicular to the axis, the collected power and image irradiance given above are

$$dP = M\, dA \sin^2\theta \quad \text{and} \quad E = M \frac{n'^2}{n^2} \sin^2\theta' \tag{300}$$

Power/Pixel

From wave optics, a lens working at the "resolution limit" has an image pixel size $q\lambda/n'\sin\theta'$, where λ is the vacuum wavelength and q is a dimensionless factor, typically of the order of unity. Applying Eq. (300) gives

$$\text{Power/pixel} = q^2 M \left(\frac{\lambda}{n}\right)^2 \tag{301}$$

$M(\lambda/n)^2$ is the energy emitted per square wavelength of object area. This is a fundamental radiometric quantity. Increasing q gives a greater numerical aperture than is nominally required for resolution, but in practice the aberration correction may be such that the actual resolution is not greater.

Cosine-to-the-Fourth Approximation

For distant, planar, uniform lambertian objects perpendicular to the lens axis, if the entrance pupil is well approximated by a circle, then the image irradiance varies approximately with the object space field angle ψ according to the *cosine-to-the-fourth* relationship

$$E(\psi) = E_0 \cos^4 \psi \tag{302}$$

where E_0 is the axial irradiance. There are three contributions to this dependence. (1) The angular distribution of a lambertian emitter varies as cos ψ. (2) The distance from the field point to the entrance pupil varies as $1/d^2 \propto \cos^2 \psi$. (3) Insofar as the pupil behaves as a rigid circle, its projected solid angle varies approximately as cos ψ. The cosine-to-the-fourth relationship should be used only as a guideline, since ray tracing permits more accurate calculations, and because of the ambiguities in the meaning of the field angle, as discussed above, and elsewhere.[235–239] For example, field angle is meaningless with telecentricity. Some lenses, especially wide-angle ones, are specifically designed so the pupil subtense increases with the field angle in order to compensate for effects (1) and (2) above, to produce a sufficiently uniform image.[240]

Total Lens Étendue

The total amount of power from a lambertian object that can be transferred through a lens is

$$\frac{1}{\pi} M \int_{\text{field}} dx\, dy \int_{\text{pupil}} d\alpha\, d\beta \tag{303}$$

The pupil integral may vary over the field. If the pupil is round and constant over the field, the étendue is proportional to $A(NA)^2$, where A is the area of the field. This quantity is also related to the total number of pixels in the field, and the ability of the lens to transfer information.[241] The term "area-solid angle product" is sometimes used, but this is an approximation. The total étendue is proportional paraxially to $\sim L^2$, where L is given by Eq. (288).

Vignetting

Vignetting occurs when an image-forming bundle is truncated by two or more physical structures in different planes, Fig. 27. Typically, one is the nominal aperture and another is the edge of a lens. Another case is that of central obstructions away from the aperture. When vignetting occurs, the image irradiance is changed, and its diminution with field height is faster than it otherwise would be. Aberration properties are also changed, so vignetting is sometimes used to eliminate light that would unacceptably blur the image.

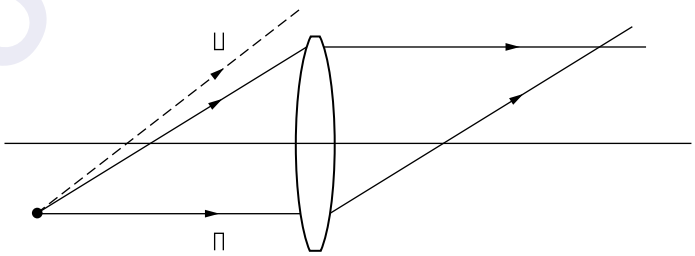

FIGURE 27 Example of vignetting. The dashed ray passes through the aperture, but misses the lens.

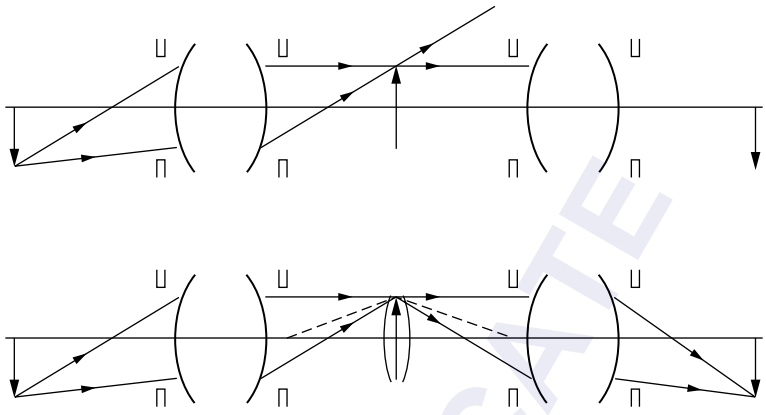

FIGURE 28 A pair of lenses relaying an image with and without a field lens. In the top figure, there is no field lens, and some of the light forming the intermediate image does not pass through the second lens. The amount lost depends on the two numerical apertures and increases with distance from the axis. In the lower figure, a field lens at the intermediate image forms an image of the exit pupil of the first lens into the entrance pupil of the next. No light is lost unless the numerical aperture of the second lens is less than that of the first.

Lens Combinations and Field Lenses

When lenses are used to relay images, the light is transferred without loss only if the exit pupil of one corresponds with the entrance pupil of the next. An example of the failure to meet this requirement is shown in Fig. 28. The axial point is reimaged satisfactorily, but off-axis bundles are vignetted. To transfer the light properly, a *field lens* in the vicinity of the intermediate image is used to image the exit pupil of the preceding lens into the entrance pupil of the next one. If the field lens is a thin lens in the image plane, then its magnification with respect to the image is unity. In practice, the field lens is usually shifted axially, so scratches or dust on its surface are out of focus. Its magnification then differs from unity. The focal length of a thin field lens in air is given by $1/f' = 1/a + 1/b$, where a is the distance from exit pupil of first lens to the field lens, and b is that from field lens to the entrance pupil of the second lens. The exit pupil is reimaged with a magnification b/a. If the sizes of the various pupils and their images are not matched, then the aperture of the combination is determined by the smallest. Field lenses affect aberrations.

Defocus

When the object and image-receiving surface are not conjugate there is *defocus*. If either the object or the receiving surface is considered to be correctly positioned, the defocus is associated with the other. Another situation is that in which the object and receiving surfaces are conjugate, but both are wrongly located, so that the image is sharp but the magnification is not what is desired.

Defocus has two basic geometrical effects, if there are no aberrations, Fig. 29. One is blurring, since the rays from an object point do not converge to a single point on the receiving surface. The blur size varies linearly with the axial defocus in image space and with the cone angle of the image-forming bundle. The shape of the blur is that of the exit pupil, projected on the receiving surface. The other effect of defocus is a lateral shift in position of the blur's centroid relative to that of the correctly focused point. The shift depends on the chief ray angle on the side of the lens where the defocus occurs. In the simplest case, the shift is approximately linear with field height, so acts as a

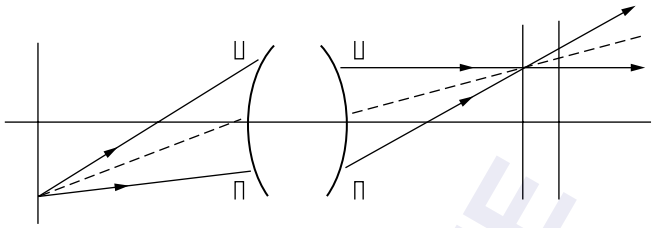

FIGURE 29 Defocus of the receiving surface. A receiving surface is shown in focus and shifted axially. The image of a point on the shifted surface is blurred, and its centroid is translated radially.

change of magnification. If the object is tilted or is not flat, the effects of defocus vary across the field in a more complicated way. Aberrations affect the nature of the blur. With some aberrations, the blur is different on the two sides of focus. With spherical aberration, the blur changes in quality, and with astigmatism the orientation of the blur changes.

In considering the geometrical imaging of a small region of a lambertian object, there is an implict assumption that the pupil is filled uniformly with light. In imaging an extended object that is externally illuminated, the light from a given region may not fill the pupil uniformly, so the character of the blurring is affected by the angular properties of the illumination and scattering properties of the object.

The amount of defocus can be described in either object or image space, and it can be measured in a variety of ways, for example, axial displacement, displacement along a chief ray, geometrical blur size, and wavefront aberration. The axial displacements in object and image space differ, in general, and are related by the longitudinal magnification. As expressed in wavefront aberration, i.e., optical path length, defocus is the same in both spaces. There are also various functional measurements of defocus, for example, the sizes of recorded images through focus.

Telecentricity

A lens is *telecentric* if the chief rays are parallel to one another. Most commonly, they are also parallel to the lens axis and perpendicular to the object and/or image planes that are perpendicular to the axis, Fig. 30. Telecentricity is often described by speaking of pupils at infinity, but the consideration of ray angles is more concrete and more directly relevant. A lens is *telecentric in object space* if the chief rays in object space are parallel to the axis, $\alpha_0 = 0$ and $\beta_0 = 0$. In this case the image of the aperture formed by the portion of the lens preceding it is at infinity and the aperture is at the rear focal plane of the portion preceding it. Similarly, a lens is *telecentric in image space* if the aperture is at the

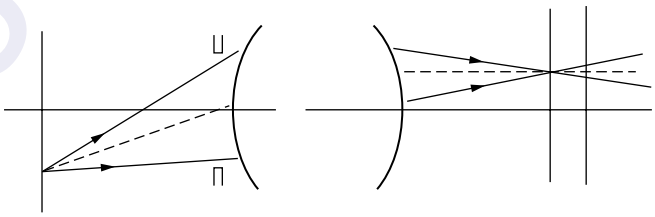

FIGURE 30 Example of telecentricity. The lens shown is telecentric in image space, in which chief rays are parallel to the axis. An axial shift in the receiving surface results in blurring, but does not translate the centroid, so there is no change in image scale.

front focal point of the subsequent optics, so $\alpha_0' = 0$ and $\beta_0' = 0$. More generally, but less commonly, the chief rays can be parallel to each other, but not necessarily to the axis, and not necessarily perpendicular to a (possibly tilted) object or image plane.

With tilted object and image surfaces and nonaxial pupils, the chief rays are not perpendicular to the object and/or image surfaces, but their angles are everywhere the same, so defocus can result in a rigid shift of the entire image.

A focal lens can be nontelecentric or telecentric on either side, but it cannot be doubly telecentric. An afocal lens can be nontelecentric, or doubly telecentric, but it cannot be telecentric on one side. A doubly telecentric lens must be afocal, and a singly telecentric lens cannot be afocal.

For a lens that is telecentric in image space, if the receiving surface is defocused, the image of a point is blurred, but its centroid stays fixed. However, if it is not telecentric in object space, then the scale changes if the object is defocused. The converse holds for object-space telecentricity without image-space telecentricity. For a doubly telecentric lens, an axial shift of either the object or the receiving plane produces blurring without a centroid shift. Although the magnification of an afocal lens does not change with conjugates, there can be an effective change with defocus if it is not telecentric. If the pupil is not on the axis or if the object and image planes are tilted, there can be telecentricity without the chief rays being perpendicular to the object and/or image planes. In these cases, defocus results in a rigid shift of the entire image.

Nominal telecentricity can be negated in several ways. Pupil aberrations may change the chief ray angles across the field. For an extended object that is externally illuminated the pupil may not be filled uniformly by light from a given region, so defocus can product a lateral image shift.

Depth of Focus and Depth of Field

The *depth of focus* and *depth of field* are the amounts of defocus that the receiving surface or object may undergo before the recorded image becomes unacceptable. The criterion depends on the application—the nature of the object, the method of image detection, and so on, and there are both ray and wave optics criteria for goodness of focus. For example, a field of separated point objects differs from that of extended objects. Depth of focus is usually discussed in terms of blurring, but there are cases where lateral shifts become unacceptable before blurring. For example, in nature photography blurring is more critical than geometrical deformation, while the opposite may be true in metrology.

Range of Focus and Hyperfocal Distance

In some cases, a geometrical description of defocus is applicable, and the allowable blur is specified as an angle.[242,243,234] The *hyperfocal distance* is

$$\text{Hyperfocal distance} = \frac{\text{diameter of the entrance pupil}}{\text{maximum acceptable angular blur}} = d_H \tag{304}$$

Let the object distance at which the lens is focused be d, the nearest distance at which the image is acceptable be d_N, and the furthest distance be d_F. All of these quantities are positive definite. The following relations are obtained:

$$d_F = \frac{d_H d}{d_H - d} \qquad \text{and} \qquad d_N = \frac{d_H d}{d_H + d} \tag{305}$$

The distances to either side of best focus are

$$d_F - d = \frac{d^2}{d_H - d} \qquad \text{and} \qquad d - d_N = \frac{d^2}{d_H + d} \tag{306}$$

The total range of focus is

$$d_F - d_N = \frac{2d^2 d_H}{d_H^2 - d^2} = \frac{2d}{(d_H/d)^2 - 1} \tag{307}$$

For $d > d_H$ the above quantities involving d_F are infinite (not negative). If the lens is focused at the hyperfocal distance or beyond, then everything more distant is adequately focused. If the lens is focused at the hyperfocal distance, i.e., $d = d_H$, the focus is adequate everywhere beyond half this distance, and this setting gives the greatest total range. If the lens is focused at infinity, then objects beyond hyperfocal distance are adequately focused. The hyperfocal distance decreases as the lens is stopped down.

1.19 GEOMETRICAL ABERRATIONS OF POINT IMAGES: DESCRIPTION

Introduction

In instrumental optics, the term *aberration* refers to a departure from what is desired, whether or not it is physically possible. Terms such as "perfect system" and "ideal system" indicate what the actual is compared to, and these terms themselves are not absolute, but depend on what is wished for. The ideal may be intrinsically impossible, in which case a deviation therefrom is not a defect. A further distinction is between aberrations inherent in a design and those that result from shortcomings in fabrication.

This section considers only the description of aberrations of point images, with the lens treated as a black box, whose action with respect to aberrations is accounted for by what leaves the exit pupil. A full consideration of aberrations involves, among other things, their causes, their correction, their various manifestations, and their evaluation. Aberrated images of extended objects are formed by overlapping blurs from the individual points. The analysis of such images is object- and application-dependent, and is beyond the scope of this section. Aberrations do vary with wavelength, but most of this discussion involves monochromatic aberrations, those at a single wavelength. In addition, aberrations vary with magnification. Aberrations are discussed to some extent in many books that treat geometrical optics.[244–253]

Descriptions

Aberration has many manifestations, and can be described in a variety of ways. For example, geometrical wavefronts, path lengths, ray angles, and ray intersection points can all differ from the nominal (and in wave optics there are additional manifestations). Terms such as "wavefront aberration" and "ray aberration" do not refer to fundamentally different things, but to different aspects of the same thing. Often, a single manifestation of the aberration is considered, according to what is measurable, what best describes the degradation in a particular application, or what a lens designer prefers to use for optimization during the design process.

Classification

Aberrations are classified and categorized in a variety of ways. These include pupil dependence, field dependence, order, evenness and oddness, pupil and field symmetry, and the nature of change through focus—symmetrical and unsymmetrical. In addition, there are natural groupings, e.g., astigmatism and field curvature. The classification systems overlap, and the decompositions are not unique. The complete aberration is often described as a series of terms, several schemes being used, as discussed below. The names of aberrations, such as "spherical," "coma," and "astigmatism," are not standardized, and a given name may have different meanings with respect to different expansions. Furthermore, the effects of aberrations are not simply separated. For example, "pure coma" can have effects usually associated with distortion. Defocus is sometimes taken to be a type of aberration, and

it is useful to think of it in this way, since it is represented by a term in the same expansion and since the effects of aberrations vary with focus. The number of terms in an expansion is infinite, and familiar names are sometimes associated with unfamiliar terms. To improve clarity, it is recommended that all the terms in an expansion be made explicit up to agreed-upon values too small to matter, and that, in addition, the net effect be shown graphically. Further, it is often helpful to show more than one of an aberration's manifestations.

Pupil and Field Coordinates

In this section, all the quantities in the equation are in image space, so primes are omitted. Field coordinates are x and y, with $h^2 = x^2 + y^2$, and (x, y) is the nominal image point in a plane $z = 0$. Direction cosines equally spaced on the exit pupil should be used for pupil coordinates but, in practice, different types of coordinates are used, including linear positions, spatial frequencies, and direction cosines. Here the pupil coordinates are ξ and η, which are dimensionless, with $\rho^2 = \xi^2 + \eta^2$. The overall direction of the pupil may vary with field. Here the $(\xi, \eta) = (0, 0)$ is always taken at the pupil center, the meaning of which may not be simple, as discussed in the section on pupils above. The angle of a meridian in the pupil is ψ. Entrance and exit pupil coordinates must be distinguished. For diffraction calculations, the exit pupil should be sampled at equal intervals in direction cosines, but a set of rays from an object point that is equally spaced in direction cosines may leave with uneven spacing, as a result of aberrations.

Wavefront Aberration

If an object point is imaged stigmatically, then the optical path lengths of all rays from the object point to its image are identical, and the geometrical wavefronts leaving the exit pupil are spherical. In the presence of aberrations, the wavefront is no longer spherical. Rather than describing the wavefront shape, it is usually preferable to consider the difference between the actual wavefront, and a nominal wavefront, often called the *reference sphere*, centered at a *reference point* that is usually the nominal image point. This reference sphere is usually taken to intersect the center of the pupil, since this gives the most accurate diffraction calculations. The *wavefront aberration* W is the optical path length from reference sphere to wavefront, or vice versa, according to the convention used, Fig. 31. Two sign conventions are in use; a positive wavefront aberration may correspond either to a wavefront which lags or leads the reference sphere. For each nominal image point (x, y, z), the wavefront aberration is a function of the pupil coordinates (ξ, η), so the functional form is $W(\xi, \eta; x, y, z)$,

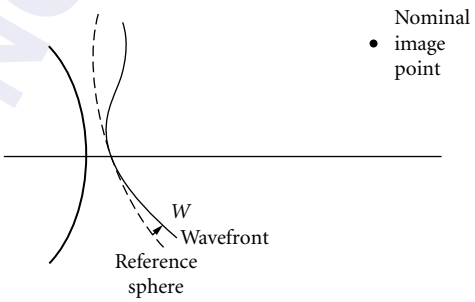

FIGURE 31 Wavefront aberration. The reference sphere is concentric with the nominal image point. The wavefront is taken that is tangent to the reference sphere in the center of the pupil. The wavefront aberration function is the distance from the reference sphere to the wavefront as a function of pupil coordiantes.

with the z usually suppressed, since the image plane is usually taken to be fixed. For a given lens prescription, W is found by tracing a set of rays from each object point to the reference sphere and calculating their path lengths. If the absolute path length is unimportant, the choice of the reference sphere's radius is not critical. Considered from the point of view of wave optics, the image of a point is degraded by phase differences across the reference sphere, so absolute phase is of no consequence, and the zero of the wavefront aberration can be chosen arbitrarily. By convention and convenience, the zero is usually taken at the center of the pupil, so $W(0, 0, x, y) = 0$. Absolute optical path lengths are significant for imaging systems with paths that separate between object and image in cases where there is coherence between the various image contributions. An error in absolute optical path length is called *piston error*. This results in no ray aberrations, so it is omitted from some discussions.

Ray Aberrations

In the presence of aberrations, the rays intersect any surface at different points than they would otherwise. The intersection of the rays with the receiving surface, usually a plane perpendicular to the axis, is most often of interest. The *transverse ray aberration* is the vectorial displacement $(\varepsilon_x, \varepsilon_y)$ between a nominal intersection point and the actual one. The displacement is a function of the position of the nominal image point (x, y) and the position in the pupil through which the ray passes (ξ, η). A complete description of transverse ray aberrations is given by

$$\varepsilon_x(\xi, \eta; x, y) \quad \text{and} \quad \varepsilon_y(\xi, \eta; x, y) \tag{308}$$

The *longitudinal aberration* is the axial displacement from nominal of an axial intersection point. This description is useful for points on the axis of rotationally symmetrical systems, in which case all rays intersect the axis. Such aberrations have both transverse and longitudinal aspects. The intersection with a meridian can also be used. The *diapoint* is the point where a ray intersects the same meridian as that containing the object point.[247] For an image nominally located at infinity, aberrations can be described by the slope of the wavefront relative to that of the nominal, that is, by ray angles rather than intersection points. A hypothetical ideal focusing lens can also be imagined to convert to transverse aberrations.

A *ray intercept diagram* shows the intersection points of a group of rays with the receiving surface.[254] The rays are usually taken to arise from a single object point and to uniformly sample the pupil, with square or hexagonal arrays commonly used. The ray intercept diagrams can suffer from artifacts of the sampling array, which can be checked for by using more than one type of array. Other pupil loci, for instance, principal meridians and annuli, can be employed to show particular aspects of the aberration. Intercept diagrams can also be produced for a series of surfaces through focus. Image quality may be better than ray diagrams suggest, since destructive interference can reduce the irradiance in a region relative to that predicted by the ray density.

Relationship of Wavefront and Ray Aberrations

Since rays are normal to geometrical wavefronts, Fig. 32, transverse ray aberrations are proportional to the slope of the wavefront aberration function. For systems of rotation with image space index n and marginal ray angle θ, the transverse aberrations are to a good approximation[251]

$$\varepsilon_x = \frac{1}{n \sin\theta} \frac{\partial W}{\partial \xi} \qquad \varepsilon_y = \frac{1}{n \sin\theta} \frac{\partial W}{\partial \eta} \tag{309}$$

The refractive index appears since W is an optical path length. If the rays are nominally parallel, then the partial derivatives give the angular ray errors

$$\Delta\alpha = \frac{1}{np} \frac{\partial W}{\partial \xi} \qquad \Delta\beta = \frac{1}{np} \frac{\partial W}{\partial \eta} \tag{310}$$

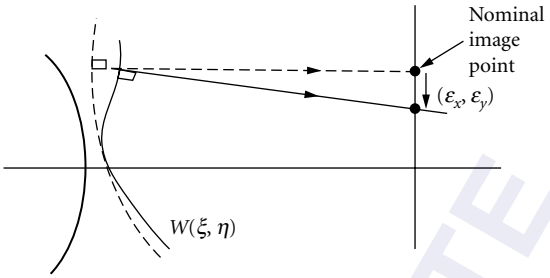

FIGURE 32 Ray aberration. Rays intersect the receiving plane at positions shifted from the nominal.

where p is the linear radius of the exit pupil, which cannot be infinite if the image is at infinity. These expressions may also have a multiplicative factor of −1, depending on the sign conventions. A sum of wavefront aberrations gives a transverse aberration that is the sum of the contributing ones.

Ray Densities

The density of rays near the nominal image point is[251]

$$\frac{1}{\text{Density}} \propto \left(\frac{\partial^2 W}{\partial \xi^2}\right)\left(\frac{\partial^2 W}{\partial \eta^2}\right) - \left(\frac{\partial^2 W}{\partial \xi \partial \eta}\right)^2 \tag{311}$$

Caustics are the surfaces where ray densities are infinite. Here, geometrical optics predicts infinite power/area, so the ray model is quantitatively inaccurate in this case.

Change of Reference Points

The center of the reference sphere may be displaced from the nominal image point. If the reference point is changed by linear displacement $(\delta x, \delta y, \delta z)$, then the wavefront aberration function changes from W to W' according to

$$W'(\xi,\ \eta;\ x,\ y;\ \delta x,\ \delta y,\ \delta z) = W(\xi,\ \eta;\ x,\ y) + W_x \xi + W_y \eta + W_z(\xi^2 + \eta^2) \tag{312}$$

where $W_x = n \sin\theta \delta x$

$$W_y = n \sin\theta \delta y \tag{313}$$

$$W_z = \tfrac{1}{2} n \sin^2\theta \delta z$$

The transverse ray aberration ε'_x and ε'_y with respect to the new reference points are

$$\varepsilon'_x = \varepsilon_x + \delta x + \sin\theta\, \delta z \qquad \varepsilon'_y = \varepsilon_y + \delta y + \sin\theta\, \delta z \tag{314}$$

The change through focus is accounted for by varying δz. Setting $\varepsilon'_x = \varepsilon'_y = 0$ gives the parametric equations $x(\delta z)$ and $y(\delta z)$ for a ray with pupil coordinates (ξ, η), relative to the nominal ray near the nominal image point.

Aberration Symmetries for Systems with Rotational Symmetry

If the lens, including the aperture, is a figure of rotation, only certain aberration forms are possible. For object points on axis, the wavefront aberration and the image blur are figures of revolution. For off-axis points, both wavefront aberration and blur are bilaterally symmetrical about the meridional plane containing the object point. For object points on a circle centered on the axis, the wavefront and ray aberrations are independent of azimuth, relative to the local meridian. In practice, there is always some imperfection, so the symmetries are imperfect and additional aberration forms arise.

Wavefront Aberration Forms for Systems with Rotational Symmetry

Here the pupil is taken to be circular, with the coordinate origin taken at the center. The field coordinates are normalized so $x^2 + y^2 = h^2 = 1$ at the edge of the field. The pupil coordinates are normalized, so that $\xi^2 + \eta^2 = \rho^2 = 1$ on the rim of the pupil. The algebra is simplified by using dimensionless coordinates. To add dimensions and actual sizes, replace the ξ by $\xi/\xi_{\max}$, and likewise for other variables. The simplest combinations of pupil and field coordinates with rotational symmetry are

$$x^2 + y^2 = h^2, \quad \xi^2 + \eta^2 = \rho^2, \quad \xi x + \eta y \tag{315}$$

The general wavefront aberration function can be expressed as a series of such terms raised to integral powers,

$$W(x, y; \xi, \eta) = \sum_{L, M, N=0} W_{LMN} (x^2 + y^2)^L (\xi^2 + \eta^2)^M (x\xi + y\eta)^N \tag{316}$$

where L, M, N are positive integers. The terms can be grouped in *orders* according to the sum $L + M + N$, where, by convention, the order equals $2(L + M + N) - 1$. The order number refers more directly to ray aberration forms than to wavefront forms, and it is always odd. The first-order terms are those for which $L + M + N = 1$, for the third-order terms the sum is two, and so on. The number of terms in the Qth order is $1 + (Q + 1)(Q + 7)/8$. For orders 1, 3, 5, 7, 9 the number of terms is 3, 6, 10, 15, 21. For each order, one contribution is a piston error, which is sometimes excluded from the count.

The expression of Eq. (316) is related to the characteristic function for a rotationally symmetrical system, Eq. (32). If the spatial coordinates are taken to be those of the object point, this is the point-angle characteristic function. In the hamiltonian optics viewpoint, the characteristic function is a sum of two parts. The first-order terms specify the nominal properties, and those of higher orders the deviation therefrom. This is discussed in the references given in that section. The term for which $L = M = N = 0$ has to do with absolute optical path length.

Since there is bilateral symmetry about all meridians, the expansion can be simplified by considering object points in a single meridian, customarily taken to be that for which $x = 0$. Doing so and letting the fractional field height be $y = h$ gives the wavefront aberration function

$$W(h; \rho, \eta) = \sum_{L, M, N=0} W_{LMN} h^{2L+N} \rho^{2M} \eta^N = \sum_{A, B, C} W'_{ABC} h^A \rho^B \eta^C \tag{317}$$

where $A = 2L + N$, $B = 2M$, $C = N$, and the order equals $(A + B + C) - 1$. Another form is obtained with the fractional pupil radius ρ and the pupil azimuth ψ, the angle from the $x = 0$ meridian, so $\eta = \rho \cos \psi$. With these pupil variables the wavefront aberration function is

$$W(h; \rho, \psi) = \sum_{L, M, N=0} W_{LMN} h^{2L+N} \rho^{2M+N} \cos^N \psi = \sum_{A, B, C} W''_{ABC} h^A \rho^B \cos^C \psi \tag{318}$$

where $A = 2L + N$, $B = 2M + N$, $C = N$, and the order is $A + B - 1$. For orders above the first, the W_{LMN}, W'_{ABC}, and W''_{ABC} are the *wavefront aberration coefficients.*

For a given field position, the wavefront aberration function for circular pupils can also be decomposed into the *Zernike polynomials*, also called *circle polynomials*, a set of functions complete and orthonormal on a circle.[249,255–257]

Third-Order Aberrations and Their Near Relatives

There are six third-order terms. The *Seidel aberrations* are spherical, coma, astigmatism, field curvature, distortion, and there is also a piston-error term. Expressions for these aberrations are given below, along with some higher-order ones that fall in the same classification. The terminology of higher-order aberrations is not standardized, and there are forms that do not have third-order analogues. This section uses the notation of the second expression of Eq. (318), without the primes on the coefficients.

It is useful to include *defocus* as a term in aberration expansions. Its wavefront aberration and transverse ray aberrations are

$$W = W_{020}\rho^2 \qquad \varepsilon_x \propto 2W_{020}\xi \qquad \varepsilon_y \propto 2W_{020}\eta \tag{319}$$

Coefficient W_{020} is similar to W_z, Eq. (313).

In *spherical aberration* the wavefront error is a figure of revolution in the pupil. The individual terms of the expansion have the form ρ^{2N}. The form that appears on axis, and which is independent of field position is

$$W = W_{020}\rho^2 + W_{040}\rho^4 + W_{060}\rho^6 + \cdots \tag{320}$$

where defocus has been included. The W_{040} term is the third-order term, the W_{060} is the fifth-order term, etc. The ray aberrations are

$$\begin{aligned} \varepsilon_x &\propto 2W_{020}\xi + 4W_{040}\rho^2\xi + 6W_{060}\rho^4\xi + \cdots \\ \varepsilon_y &\propto 2W_{020}\eta + 4W_{040}\rho^2\eta + 6W_{060}\rho^4\eta + \cdots \end{aligned} \tag{321}$$

There are also higher-order off-axis terms, called *oblique spherical aberration*, with forms $h^{2L}\rho^{2M}$. Spherical is an even aberration.

In *coma*, the wavefront aberration varies linearly with field height, so the general form is $h\rho^{2M}\eta = h\rho^{2M+1}\cos\psi$. Coma is an odd aberration. The wavefront expansion is

$$W = (W_{131}\rho^2 + W_{151}\rho^4 + \cdots)\eta h = (W_{131}\rho^3 + W_{151}\rho^5 + \cdots)\cos\psi h \tag{322}$$

The ray aberrations are

$$\begin{aligned} \varepsilon_x &\propto [W_{131}(2\xi\eta) + 4W_{151}(\xi^2 + \eta^2)\xi\eta + \cdots]h \\ \varepsilon_y &\propto [W_{131}(\xi^2 + 3\eta^2) + W_{151}(\xi^4 + 5\xi^2\eta^2 + 6\eta^4) + \cdots]h \end{aligned} \tag{323}$$

In *astigmatism* the wavefront aberration is cylindrical. The third-order term is

$$W = W_{222}h^2\eta^2 = W_{222}h^2\rho^2\cos^2\psi \tag{324}$$

with ray aberration

$$\varepsilon_x = 0 \qquad \varepsilon_y \propto 2W_{222}h^2\eta \tag{325}$$

Field curvature, also known as *Petzval curvature*, is a variation of focal position in the axial direction with field height. In its presence, the best image of a planar object lies on a nonplanar surface. Its absence is called *field flatness*. The wavefront aberration form is

$$W = (W_{220}h^2 + W_{420}h^4 + W_{620}h^6 + \cdots)\rho^2 \tag{326}$$

with symmetrical blurs given by

$$\begin{aligned} \varepsilon_x &\propto (W_{220}h^2 + W_{420}h^4 + W_{620}h^6 + \cdots)\xi \\ \varepsilon_y &\propto (W_{220}h^2 + W_{420}h^4 + W_{620}h^6 + \cdots)\eta \end{aligned} \tag{327}$$

The curvature of the best focus surface may have the same sign across the field, or there may be curvatures of both signs.

Astigmatism and field curvature are often grouped together. Combining defocus, third-order astigmatism, and third-order field curvature, the wavefront aberration can be written

$$W = W_{020}(\xi^2 + \eta^2) + [W_{220}\xi^2 + (W_{220} + W_{222})\eta^2]h^2 \tag{328}$$

The resultant ray aberration is

$$\varepsilon_x \propto [W_{020} + W_{220}h^2]\xi, \quad \varepsilon_y \propto [W_{020} + (W_{222} + W_{220})h^2]\eta \tag{329}$$

A tangential fan of rays, one that lies in the $x = 0$ meridian, has $\xi = 0$, so $\varepsilon_x = 0$. The *tangential focus* occurs where $\varepsilon_y = 0$, which occurs for a defocus of $W_{020} = -(W_{220} + W_{222})h^2$. Combining this result with Eq. (314) gives $\delta z \propto h^2$, the equation for the tangential focal surface. A sagittal fan of rays crosses the pupil in the $\eta = 0$ meridian, so $\varepsilon_y = 0$. The *sagittal focus* occurs where $\varepsilon_x = 0$, i.e., on the surface given by $W_{020} = -W_{220}h^2$.

In general, *distortion* is a deviation from geometrical similarity between object and image. For rotationally symmetrical lenses and object and image planes perpendicular to the axis, the error is purely radial, and can be thought of as a variation of magnification with field height. The aberration forms are

$$W = (W_{111}h + W_{311}h^3 + W_{511}h^5 + \cdots)\eta \tag{330}$$

with

$$\varepsilon_x = 0, \quad \varepsilon_y \propto W_{111}h + W_{311}h^3 + W_{511}h^5 + \cdots \tag{331}$$

In *pincushion* distortion the magnitude of magnification increases monotonically with field height, so the image is stretched radially. In *barrel distortion* the magnitude decreases, so the image is squeezed. In general, the aberration coefficients can be both positive and negative, so the direction of distortion can change as a function of field height and the distortion may vanish for one or more field heights.

For *piston error* the wavefront differs uniformly across the pupil from its nominal in a way that varies with field height.

$$W = W_{000} + W_{200}h^2 + W_{400}h^4 + W_{600}h^6 + \cdots, \quad \varepsilon_x = \varepsilon_y = 0 \tag{332}$$

There are no transverse ray aberrations.

Chromatic Aberrations

In general, the properties of optical systems vary with wavelength. The term *chromatic aberration* often refers to the variation in paraxial properties as a function of wavelength. Thus, *axial color* is related to differences of focal length and principal plane location with wavelength, and *lateral color*

is related to variations of magnification with wavelength. Also, the monochromatic aberrations vary in magnitude with wavelength. Reflective systems have identical ray properties at all wavelengths, but their wave properties vary with color, since a given variation in path length has an effect on phase that varies with wavelength.

Stop Size and Aberration Variation

For a given system, if the size of the aperture is changed, the marginal ray is changed, but not the chief ray. If the aperture is reduced, depth of focus and depth of field increase and image irradiance decreases. The rays from axial object points are more nearly paraxial, so the imaging tends to be better corrected. For off-axis points, some aberrations are changed and others are not. Distortion, as defined with respect to the chief ray, is not changed. Field curvature per se does not change, since the aperture size does not change the location of the best image surface (if there are no other aberrations), but the depth of focus does change, so a flat detector can cover a larger field.

Stop Position and Aberration Variation

For a given system, if the aperture is moved axially, the image-forming bundle passes through different portions of the lens elements. Accordingly, some aberrations vary with the position of the stop. Lens design involves an operation called the *stop shift,* in which the aperture is moved axially while its size is adjusted to keep the numerical apertures constant. In this operation, the marginal ray is fixed, while the chief ray is changed. This does not change the aberrations on axis. Most of those for off-axis points are changed, but third-order field curvature is unchanged.

2.1 GLOSSARY

A	amplitude
E	electric field vector
r	position vector
x, y, z	rectangular coordinates
ϕ	phase

2.2 INTRODUCTION

Interference results from the superposition of two or more electromagnetic waves. From a classical optics perspective, interference is the mechanism by which light interacts with light. Other phenomena, such as refraction, scattering, and diffraction, describe how light interacts with its physical environment. Historically, interference was instrumental in establishing the wave nature of light. The earliest observations were of colored fringe patterns in thin films. Using the wavelength of light as a scale, interference continues to be of great practical importance in areas such as spectroscopy and metrology.

2.3 WAVES AND WAVEFRONTS

The *electric field vector* due to an electromagnetic field at a point in space is composed of an amplitude and a phase

$$\mathbf{E}(x, y, z, t) = \mathbf{A}(x, y, z, t)e^{i\phi(x,y,z,t)} \tag{1}$$

or

$$\mathbf{E}(\mathbf{r}, t) = \mathbf{A}(\mathbf{r}, t)e^{i\phi(\mathbf{r},t)} \tag{2}$$

where **r** is the position vector and both the amplitude **A** and phase ϕ are functions of the spatial coordinate and time. As described in Chap. 12, "Polarization," the polarization state of the field is contained in the temporal variations in the amplitude vector.

This expression can be simplified if a linearly polarized monochromatic wave is assumed:

$$\mathbf{E}(x, y, z, t) = \mathbf{A}(x, y, z, t)e^{i[\omega t - \phi(x,y,z)]} \tag{3}$$

where ω is the angular frequency in radians per second and is related to the frequency ν by

$$\omega = 2\pi\nu \tag{4}$$

Some typical values for the optical frequency are 5×10^{14} Hz for the visible, 10^{13} Hz for the infrared, and 10^{16} Hz for the ultraviolet. Note that in the expression for the electric field vector, the time dependence has been eliminated from the amplitude term to indicate a constant linear polarization. The phase term has been split into spatial and temporal terms. At all locations in space, the field varies harmonically at the frequency ω.

Plane Wave

The simplest example of an electromagnetic wave is the *plane wave*. The plane wave is produced by a monochromatic point source at infinity and is approximated by a collimated light source. The complex amplitude of a linearly polarized plane wave is

$$\mathbf{E}(x, y, z, t) = \mathbf{E}(\mathbf{r}, t) = \mathbf{A}e^{i[\omega t - \mathbf{k}\cdot\mathbf{r}]} \tag{5}$$

where **k** is the wave vector. The wave vector points in the direction of propagation, and its magnitude is the wave number $k = 2\pi/\lambda$, where λ is the wavelength. The wavelength is related to the temporal frequency by the speed of light v in the medium:

$$\lambda = \frac{v}{\nu} = 2\pi\frac{v}{\omega} = \frac{c}{n\nu} = 2\pi\frac{c}{n\omega} \tag{6}$$

where n is the index of refraction, and c is the speed of light in a vacuum. The amplitude **A** of a plane wave is a constant over all space, and the plane wave is clearly an idealization.

If the direction of propagation is parallel to the z axis, the expression for the complex amplitude of the plane wave simplifies to

$$\mathbf{E}(x, y, z, t) = \mathbf{A}e^{i[\omega t - kz]} \tag{7}$$

We see that the plane wave is periodic in both space and time. The spatial period equals the wavelength in the medium, and the temporal period equals $1/\nu$. Note that the wavelength changes with index of refraction, and the frequency is independent of the medium.

Spherical Wave

The second special case of an electromagnetic wave is the spherical wave which radiates from an isotropic point source. If the source is located at the origin, the complex amplitude is

$$E(r, t) = (A/r)e^{i[\omega t - kr]} \tag{8}$$

where $r = (x^2 + y^2 + z^2)^{1/2}$. The field is spherically symmetric and varies harmonically with time and the radial distance. The radial period is the wavelength in the medium. The amplitude of the field decreases as $1/r$ for energy conservation. At a large distance from the source, the spherical wave can be approximated by a plane wave. Note that the vector characteristics of the field (its polarization) are not considered here as it is not possible to describe a linear polarization pattern

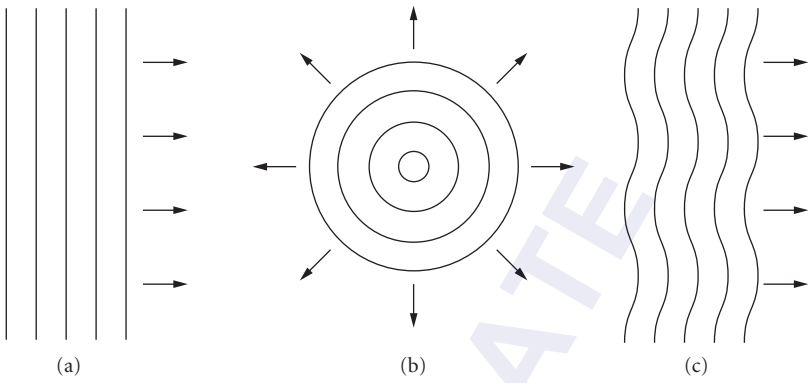

FIGURE 1 Examples of wavefronts: (*a*) plane wave; (*b*) spherical wave; and (*c*) aberrated plane wave.

of constant amplitude that is consistent over the entire surface of a sphere. In practice, we only need to consider an angular segment of a spherical wave, in which case this polarization concern disappears.

Wavefronts

Wavefronts represent surfaces of constant phase for the electromagnetic field. Since they are normally used to show the spatial variations of the field, they are drawn or computed at a fixed time. Wavefronts for plane and spherical waves are shown in Fig. 1*a* and *b*. The field is periodic, and a given value of phase will result in multiple surfaces. These surfaces are separated by the wavelength. A given wavefront also represents a surface of constant optical path length (OPL) from the source. The OPL is defined by the following path integral:

$$\mathrm{OPL} = \int_S^P n(s)\, ds \tag{9}$$

where the integral goes from the source S to the observation point P, and $n(s)$ is the index of refraction along the path. Variations in the index or path can result in irregularities or aberrations in the wavefront. An aberrated plane wavefront is shown in Fig. 1*c*. Note that the wavefronts are still separated by the wavelength.

The local normal to the wavefront defines the propagation direction of the field. This fact provides the connection between wave optics and ray or geometrical optics. For a given wavefront, a set of rays can be defined using the local surface normals. In a similar manner, a set of rays can be used to construct the equivalent wavefront.

2.4 INTERFERENCE

The net complex amplitude is the sum of all of the component fields,

$$\mathbf{E}(x, y, z, t) = \sum_i \mathbf{E}_i(x, y, z, t) \tag{10}$$

and the resulting field intensity is the time average of the modulus squared of the total complex amplitude

$$I(x, y, z, t) = \langle |\mathbf{E}(x, y, z, t)|^2 \rangle \tag{11}$$

where $\langle\,\rangle$ indicates a time average over a period much longer than $1/\nu$. If we restrict ourselves to two interfering waves $\mathbf{E}_1$ and $\mathbf{E}_2$, this result simplifies to

$$I(x, y, z, t) = \langle |\mathbf{E}_1|^2 \rangle + \langle |\mathbf{E}_2|^2 \rangle + \langle \mathbf{E}_1 \cdot \mathbf{E}_2^* \rangle + \langle \mathbf{E}_1^* \cdot \mathbf{E}_2 \rangle \tag{12}$$

or

$$I(x, y, z, t) = I_1 + I_2 + \langle \mathbf{E}_1 \cdot \mathbf{E}_2^* \rangle + \langle \mathbf{E}_1^* \cdot \mathbf{E}_2 \rangle \tag{13}$$

where I_1 and I_2 are the intensities due to the two beams individually, and the (x, y, z, t) dependence is now implied for the various terms.

This general result can be greatly simplified if we assume linearly polarized monochromatic waves of the form in Eq. (3):

$$\mathbf{E}_i(x, y, z, t) = \mathbf{A}_i(x, y, z, t) e^{i[\omega_i t - \phi_i(x, y, z)]} \tag{14}$$

The resulting field intensity is

$$I(x, y, z, t) = I_1 + I_2 + 2(\mathbf{A}_1 \cdot \mathbf{A}_2) \cos[(\omega_1 - \omega_2)t - (\phi_1(x, y, z) - \phi_2(x, y, z))] \tag{15}$$

The interference effects are contained in the third term, and we can draw two important conclusions from this result. First, if the two interfering waves are orthogonally polarized, there will be no visible interference effects, as the dot product will produce a zero coefficient. Second, if the frequencies of the two waves are different, the interference effects will be modulated at a temporal beat frequency equal to the difference frequency.

Interference Fringes

We will now add the additional restrictions that the two linear polarizations are parallel and that the two waves are at the same optical frequency. The expression for the intensity pattern now becomes

$$I(x, y, z) = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos[\Delta\phi(x, y, z)] \tag{16}$$

where $\Delta\phi = \phi_1 - \phi_2$ is the phase difference. This is the basic equation describing interference. The detected intensity varies cosinusoidally with the phase difference between the two waves as shown in Fig. 2. These alternating bright and dark bands in the intensity pattern

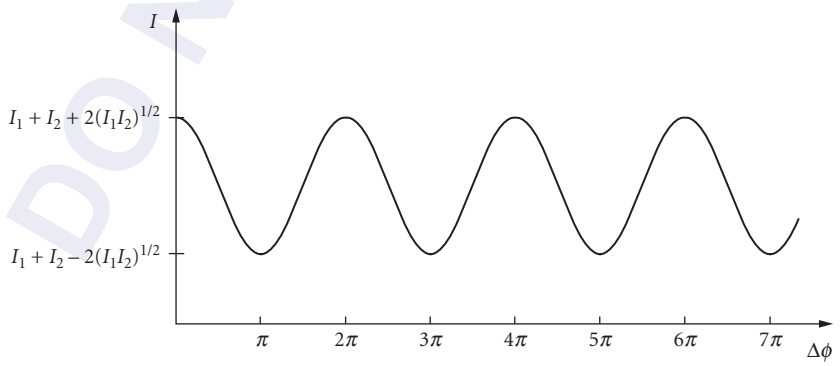

FIGURE 2 The variation in intensity as a function of the phase difference between two interfering waves.

TABLE 1 The Phase Difference and OPD for Bright and Dark Fringes (m an Integer)

	$\Delta\phi$	OPD
Bright fringe	$2m\pi$	$m\lambda$
Dark fringe	$2(m+1)\pi$	$(m+1/2)\lambda$

are referred to as *interference fringes*, and along a particular fringe, the phase difference is constant.

The phase difference is related to the difference in the optical path lengths between the source and the observation point for the two waves. This is the *optical path difference* (OPD):

$$\text{OPD} = \text{OPL}_1 - \text{OPL}_2 = \left(\frac{\lambda}{2\pi}\right)\Delta\phi \tag{17}$$

or

$$\Delta\phi = \left(\frac{2\pi}{\lambda}\right)\text{OPD} \tag{18}$$

The phase difference changes by 2π every time the OPD increases by a wavelength. The OPD is therefore constant along a fringe.

Constructive interference occurs when the two waves are in phase, and a bright fringe or maximum in the intensity pattern results. This corresponds to a phase difference of an integral number of 2π's or an OPD that is a multiple of the wavelength. A dark fringe or minimum in the intensity pattern results from *destructive interference* when the two waves are out of phase by π or the OPD is an odd number of half wavelengths. These results are summarized in Table 1. For conditions between these values, an intermediate value of the intensity results. Since both the OPD and the phase difference increase with the integer m, the absolute value of m is called the *order of interference*.

As we move from one bright fringe to an adjacent bright fringe, the phase difference changes by 2π. Each fringe period corresponds to a change in the OPD of a single wavelength. It is this inherent precision that makes interferometry such a valuable metrology tool. The wavelength of light is used as the unit of measurement. Interferometers can be configured to measure small variations in distance, index, or wavelength.

When two monochromatic waves are interfered, the interference fringes exist not only in the plane of observation, but throughout all space. This can easily be seen from Eq. (16) where the phase difference can be evaluated at any z position. In many cases, the observation of interference is confined to a plane, and this plane is usually assumed to be perpendicular to the z axis. The z dependence in Eq. (16) is therefore often not stated explicitly, but it is important to remember that interference effects will exist in other planes.

Fringe Visibility

It is often more convenient to rewrite Eq. (16) as

$$I(x,y) = I_0(x,y)\{1+\gamma(x,y)\cos[\Delta\phi(x,y,z)]\} \tag{19}$$

or

$$I(x,y) = I_0(x,y)\{1+\gamma(x,y)\cos[2\pi\text{OPD}(x,y)/\lambda]\} \tag{20}$$

where $I_0(x, y) = I_1(x, y) + I_2(x, y)$, and

$$\gamma(x, y) = \frac{2[I_1(x, y)I_2(x, y)]^{1/2}}{I_1(x, y) + I_2(x, y)} \tag{21}$$

Since the cosine averages to zero, $I_0(x, y)$ represents the average intensity, and $\gamma(x, y)$ is the local *fringe contrast* or *visibility*. The fringe visibility can also be equivalently calculated using the standard formula for modulation:

$$\gamma(x, y) = \frac{I_{\max}(x, y) - I_{\min}(x, y)}{I_{\max}(x, y) + I_{\min}(x, y)} \tag{22}$$

where $I_{\max}$ and $I_{\min}$ are the maximum and minimum intensities in the fringe pattern.

The fringe visibility will have a value between 0 and 1. The maximum visibility will occur when the two waves have equal intensity. Not surprisingly, the visibility will drop to zero when one of the waves has zero intensity. In general, the intensities of the two waves can vary with position, so that the average intensity and fringe visibility can also vary across the fringe pattern. The average intensity in the observation plane equals the sum of the individual intensities of the two interfering waves. The interference term redistributes this energy into bright and dark fringes.

Two Plane Waves

The first special case to consider is the interference of two plane waves of equal intensity, polarization and frequency. They are incident at angles θ_1 and θ_2 on the observation plane, as shown in Fig. 3. The plane of incidence is the x-z plane (the two k-vectors are contained in this plane). According to Eq. (5), the complex amplitude for each of these plane waves is

$$\mathbf{E}_i(x, y, z, t) = \mathbf{A}e^{i[\omega t - kz\cos(\theta_i) - kx\sin(\theta_i)]} \tag{23}$$

where the dot product has been evaluated. For simplicity we will place the observation plane at $z = 0$, and the phase difference between the two waves is

$$\Delta\phi(x, y) = kx(\sin\theta_1 - \sin\theta_2) = (2\pi x/\lambda)(\sin\theta_1 - \sin\theta_2) \tag{24}$$

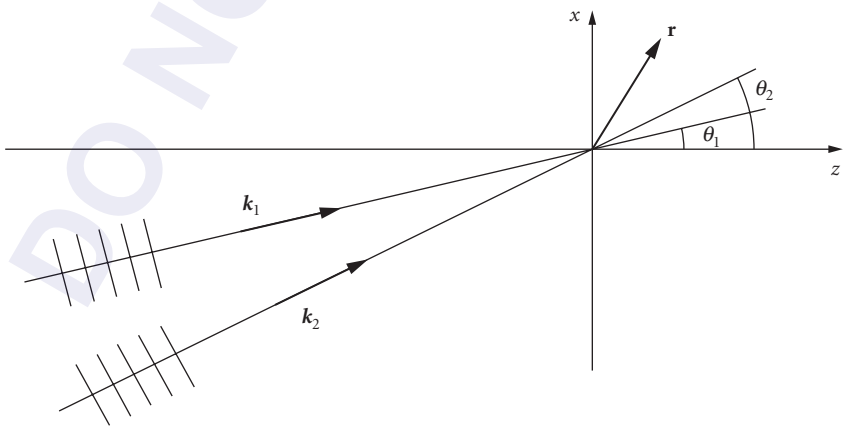

FIGURE 3 The geometry for the interference of two plane waves.

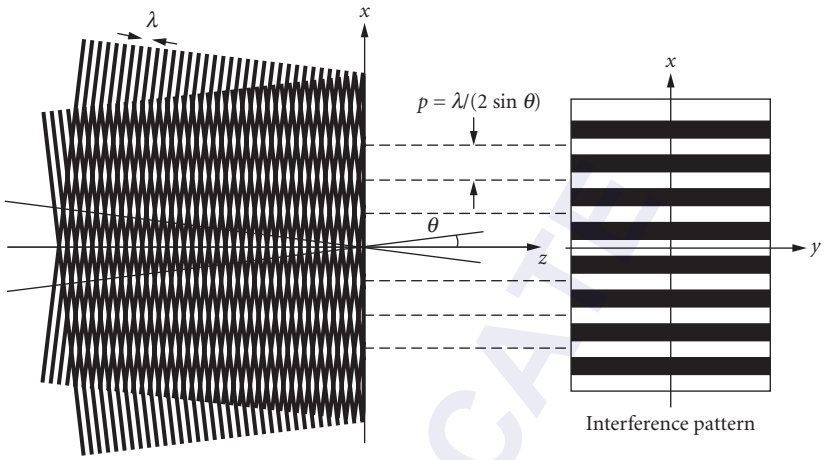

FIGURE 4 The interference of plane waves incident at $\pm\theta$ resulting in straight fringes.

The resulting intensity from Eq. (19) is

$$I(x,y)=I_0\{1+\cos[(2\pi x/\lambda)(\sin\theta_1-\sin\theta_2)]\} \tag{25}$$

where $I_0 = 2A^2$ is twice the intensity of each of the individual waves. Straight equispaced fringes are produced. The fringes are parallel to the y axis, and the fringe period depends on the angle between the two interfering beams.

The fringe period p is

$$p=\frac{\lambda}{\sin\theta_1-\sin\theta_2} \tag{26}$$

and this result can also be obtained by noting that a bright fringe will occur whenever the phase difference equals a multiple of 2π. A typical situation for interference is that the two angles of incidence are equal and opposite, $\theta_1 = -\theta_2 = \theta$. The angle between the two beams is 2θ. Under this condition, the period is

$$p=\frac{\lambda}{2\sin\theta}\approx\frac{\lambda}{2\theta} \tag{27}$$

and the small-angle approximation is given. As the angle between the beams gets larger, the period decreases. For example, the period is 3.8λ at 15° (full angle of 30°) and is λ at 30° (full angle of 60°). The interference of two plane waves can be visualized by looking at the overlap or moiré of two wavefront patterns (Fig. 4). Whenever the lines representing the wavefronts overlap, a fringe will result. This description also clearly shows that the fringes extend parallel to the z axis and exist everywhere the two beams overlap.

Plane Wave and Spherical Wave

A second useful example to consider is the interference of a plane wave and a spherical wave. Once again the two waves have the same frequency. The plane wave is at normal incidence, the spherical wave is due to a source at the origin, and the observation plane is located at $z = R$. The wavefront shape at the observation plane will be a spherical shell of radius R.

Starting with Eq. (8), the complex amplitude of the spherical wave in the observation plane is

$$E(\rho, t)=(A/R)e^{i[\omega t-k(R^2+\rho^2)^{1/2}]}\approx(A/R)e^{i[\omega t-\mathbf{k}(R+\rho^2/2R)]} \tag{28}$$

where $\rho=(x^2+y^2)^{1/2}$, and the square root has been expanded in the second expression. This expansion approximates the spherical wave by a parabolic wave with the same vertex radius. An additional assumption is that the amplitude of the field A/R is constant over the region of interest. The field for the plane wave is found by evaluating Eq. (23) at $z=R$ and $\theta=0$. The phase difference between the plane and the sphere is then

$$\Delta\phi(\rho)\approx\frac{\pi\rho^2}{\lambda R} \tag{29}$$

and the resulting intensity pattern is

$$I(\rho)=I_0\left[1+\cos\left(\frac{\pi\rho^2}{\lambda R}\right)\right] \tag{30}$$

The fringe pattern comprises concentric circles, and the radial fringe spacing decreases as the radius ρ increases. The intensities of the two waves have been assumed to be equal at the observation plane. This result is valid only when ρ is much smaller than R.

The radius of the mth bright fringe can be found by setting $\Delta\phi=2\pi m$:

$$\rho_m=\sqrt{2mR} \tag{31}$$

where m is an integer. The order of interference m increases with radius. Figure 5 shows a visualization of this situation using wavefronts. This fringe pattern is the Newton's ring pattern and is discussed in more detail later, under "Fizeau Interferometer." This picture also shows that the radii of the fringes increase as the square root of R.

The analysis of the spherical wave could also have been done by using the sag of a spherical wavefront to produce an OPD and then converting this value to a phase difference. The quadratic approximation for the sag of a spherical surface is $\rho^2/2R$. This corresponds to the OPD

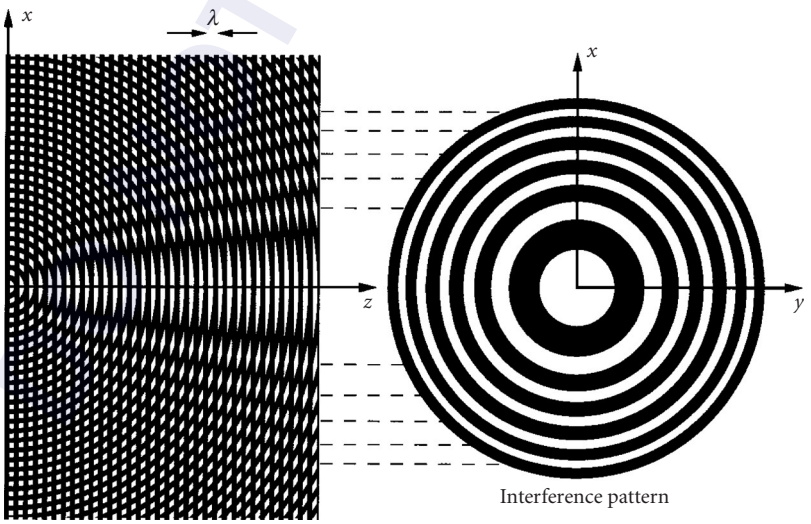

FIGURE 5 The interference of a plane wave and a spherical wave.

between the spherical and planar wavefronts. The equivalent phase difference [Eq. (18)] is then $\pi\rho^2/\lambda R$, as before.

Two Spherical Waves

When considering two spherical waves, there are two particular geometries that we want to examine. The first places the observation plane perpendicular to a line connecting the two sources, and the second has the observation plane parallel to this line. Once again, the sources are at the same frequency.

When the observations are made on a plane perpendicular to a line connecting the two sources, we can use Eq. (28) to determine the complex amplitude of the two waves:

$$E_i(\rho, t) \approx (A/R)e^{i[\omega t - k(R_i + \rho^2/2R_i)]} \tag{32}$$

Let $d = R_1 - R_2$ be the separation of the two sources. For simplicity, we have also assumed that the amplitudes of the two waves are equal (R is an average distance). The phase difference between the two waves is

$$\Delta\phi = \left(\frac{\pi\rho^2}{\lambda}\right)\left(\frac{1}{R_1} - \frac{1}{R_2}\right) + \frac{2\pi d}{\lambda} \approx \frac{2\pi d}{\lambda} - \left(\frac{\pi\rho^2}{\lambda}\right)\left(\frac{d}{R^2}\right) \tag{33}$$

where the approximation $R_1 R_2 \approx R^2$ has been made. There are two terms to this phase difference. The second is a quadratic phase term identical in form to the result obtained from spherical and plane waves. The pattern will be symmetric around the line connecting the two sources, and its appearance will be similar to Newton's rings. The equivalent radius of the spherical wave in Eq. (29) is R^2/d. The first term is a constant phase shift related to the separation of the two sources. If this term is not a multiple of 2π, the center of the fringe pattern will not be a bright fringe; if the term is π, the center of the pattern will be dark. Except for the additional phase shift, this intensity pattern is not distinguishable from the result in the previous section. It should be noted, however, that a relative phase shift can be introduced between a spherical wave and a plane wave to obtain this same result.

An important difference between this pattern and the Newton's ring pattern is that the order of interference ($|m|$ defined by $\Delta\phi = 2\pi m$) or phase difference is a maximum at the center of the pattern and decreases with radius. The Newton's ring pattern formed between a plane and a spherical wave has a minimum order of interference at the center of the pattern. This distinction is important when using polychromatic sources.

There are several ways to analyze the pattern that is produced on a plane that is parallel to a line connecting the two sources. We could evaluate the complex amplitudes by using Eq. (28) and moving the center of the spherical waves to $\pm d/2$ for the two sources. An equivalent method is to compare the wavefronts at the observation plane. This is shown in Fig. 6. The OPD between the two wavefronts is

$$\mathrm{OPD}(x, y) = \frac{[(x + d/2)^2 + y^2]}{2L} - \frac{[(x - d/2)^2 + y^2]}{2L} \tag{34}$$

where the quadratic approximation for the wavefront sag has been assumed, and L is the distance between the sources and the observation plane. After simplification, the OPD and phase differences are

$$\mathrm{OPD}(x, y) = \frac{xd}{L} \tag{35}$$

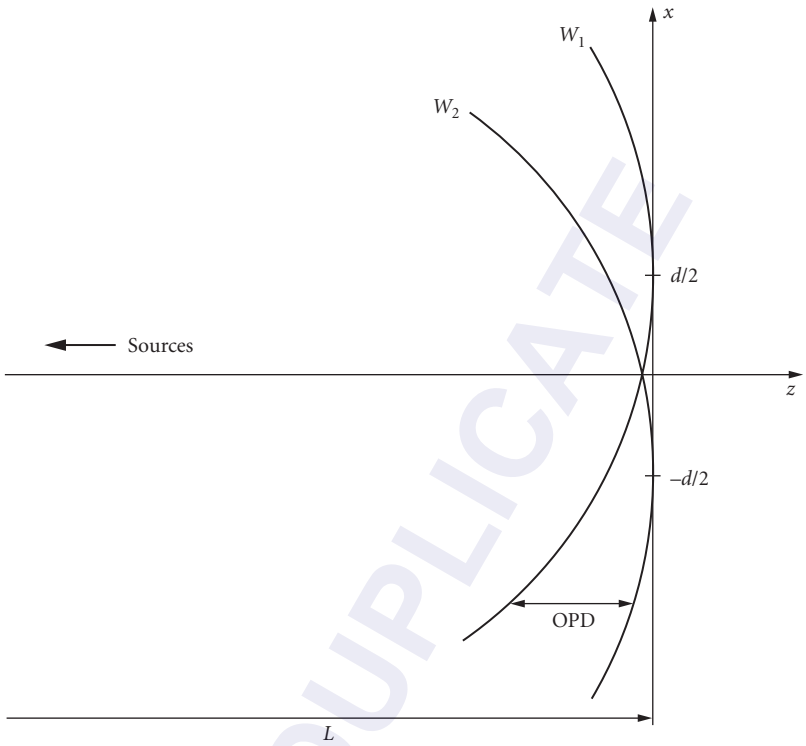

FIGURE 6 The interference of two spherical waves on a plane parallel to the sources.

and

$$\Delta\phi(x, y) = \frac{2\pi x d}{\lambda L} \tag{36}$$

Straight equispaced fringes parallel to the y axis are produced. The period of the fringes is $\lambda L/d$. This fringe pattern is the same as that produced by two plane waves. Note that these fringes increase in spacing as the distance from the sources increases. The approximations used require that L be much larger than ρ and d.

Figure 7 shows the creation of the fringe patterns for two point sources. The full three-dimensional pattern is a series of nested hyperboloids symmetric about the line connecting the sources. Above the two sources, circular fringes approximating Newton's rings are produced, and perpendicular to the sources, the fringes appear to be straight and equispaced. The actual appearance of these patterns is modified by the approximations used in the derivations, and as a result, these two specific patterns have limited lateral extent.

Aberrated Wavefronts

When an aberrated or irregularly shaped wavefront is interfered with a reference wavefront, an irregularly shaped fringe pattern is produced. However, the rules for analyzing this pattern are the same as with any two wavefronts. A given fringe represents a contour of constant OPD or phase difference between the two wavefronts. Adjacent fringes differ in OPD by one wavelength

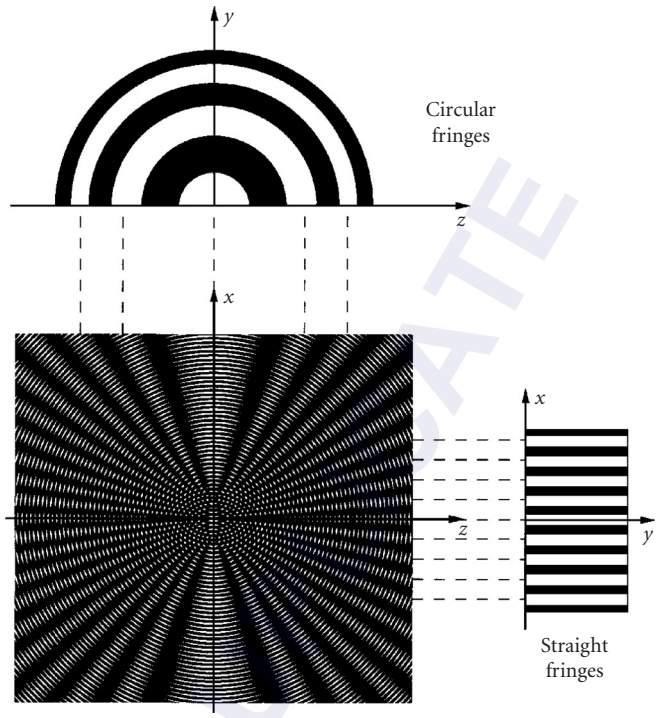

FIGURE 7 The interference of two spherical waves.

or equivalently correspond to a phase difference of 2π. If the reference is a plane wave, the absolute shape of the irregular wavefront is obtained. If the reference is a spherical wave, or another aberrated wave, the measured OPD or phase difference map represents the difference between the two wavefronts.

Temporal Beats

In Eq. (15) it was noted that if the waves are at different frequencies, the interference effects are modulated by a beat frequency. Rewriting this expression assuming equal-intensity parallel-polarized beams produces

$$I(x, y, t) = I_0\{1 + \cos[2\pi \Delta\nu t - \Delta\phi(x, y)]\} \tag{37}$$

where $\Delta\nu = \nu_1 - \nu_2$. The intensity at a given location will now vary sinusoidally with time at the beat frequency $\Delta\nu$. The phase difference $\Delta\phi$ appears as a spatially varying phase shift of the beat frequency. This is the basis of the heterodyne technique used in a number of interferometers. It is commonly used in distance-measuring interferometers.

In order for a heterodyne system to work, there must be a phase relationship between the two sources even though they are at different frequencies. One common method for obtaining this is accomplished by starting with a single source, splitting it into two beams, and frequency-shifting one beam with a known Doppler shift. The system will also work in reverse; measure the interferometric beat frequency to determine the velocity of the object producing the Doppler shift.

Coherence

Throughout this discussion of fringe patterns, we have assumed that the two sources producing the two waves have the same frequency. In practice, this requires that both sources be derived from a single source. Even when two different frequencies are used [Eq. (37)] there must be an absolute phase relation between the two sources. If the source has finite size, it is considered to be composed of a number of spatially separated, independently radiating point sources. If the source has a finite spectral bandwidth, it is considered to be composed of a number of spatially coincident point sources with different frequencies. These reductions in the spatial or temporal coherence of the source will decrease the visibility of the fringes at different locations in space. This is referred to as *fringe localization.* These effects will be discussed later in this chapter and also in Chap. 5, "Coherence Theory."

There are two general methods to produce mutually coherent waves for interference. The first is called *wavefront division*, where different points on a wavefront are sampled to produce two new wavefronts. The second is *amplitude division*, where some sort of beamsplitter is used to divide the wavefront at a given location into two separate wavefronts. These methods are discussed in the next sections.

2.5 INTERFERENCE BY WAVEFRONT DIVISION

Along a given wavefront produced by a monochromatic point source, the wavefront phase is constant. If two parts of this wavefront are selected and then redirected to a common volume in space, interference will result. This is the basis for *interference by wavefront division.*

Young's Double-Slit Experiment

In 1801, Thomas Young performed a fundamental experiment for demonstrating interference and the wave nature of light. Monochromatic light from a single pinhole illuminates an opaque screen with two additional pinholes or slits. The light diffracts from these pinholes and illuminates a viewing screen at a distance large compared to the pinhole separation. Since the light illuminating the two pinholes comes from a single source, the two diffracted wavefronts are coherent and interference fringes form where the beams overlap.

In the area where the two diffracted beams overlap, they can be modeled as two spherical waves from two point sources, and we already know the form of the solution for the interference from our earlier discussion. Equispaced straight fringes are produced, and the period of the fringes is $\lambda L/d$, where L is the distance to the screen and d is the separation of the pinholes. The fringes are oriented perpendicular to the line connecting the two pinholes.

Even though we already know the answer, there is a classic geometric construction we should consider that easily gives the OPD between the two wavefronts at the viewing screen. This is shown in Fig. 8. S_0 illuminates both S_1 and S_2 and is equidistant from both slits. The OPD for an observation point P at an angle θ or position x is

$$\text{OPD} = \overline{S_2P} - \overline{S_1P} \tag{38}$$

We now draw a line from S_1 to B that is perpendicular to the second ray. Since L is much larger than d, the distances from B to P and S_1 to P are approximately equal. The OPD is then

$$\text{OPD} \approx \overline{S_2B} = d\sin\theta \approx d\theta \approx \frac{dx}{L} \tag{39}$$

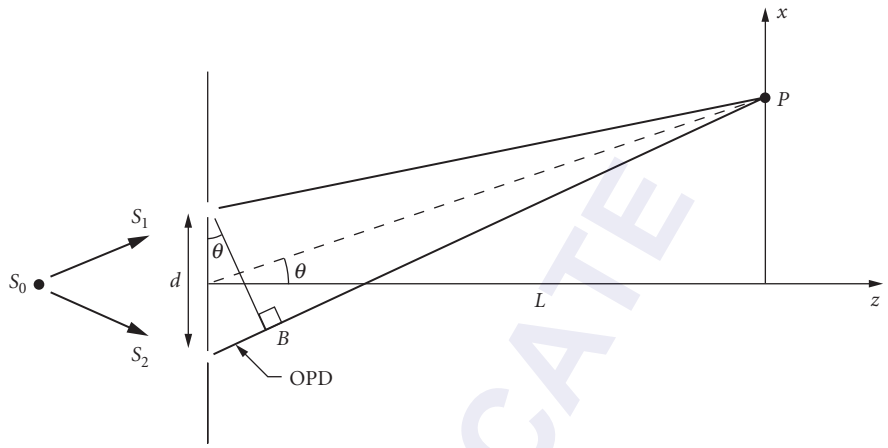

FIGURE 8 Young's double-slit experiment.

and constructive interference or a bright fringe occurs when the OPD is a multiple of the wavelength: OPD$\approx m\lambda$, where m is an integer. The condition for the mth order bright fringe is

$$\text{Bright fringe: } \sin(\theta)\approx\theta=\frac{m\lambda}{d} \quad \text{or} \quad x=\frac{m\lambda L}{d} \tag{40}$$

This construction is useful not only for interference situations, but also for diffraction analysis.

Effect of Slit Width

The light used to produce the interference pattern is diffracted by the pinholes or slits. Interference is possible only if light is directed in that direction. The overall interference intensity pattern is therefore modulated by the single-slit diffraction pattern (assuming slit apertures):

$$I(x)=I_0\,\text{sinc}^2\left(\frac{Dx}{\lambda L}\right)\left[1+\gamma(x)\cos\left(\frac{2\pi xd}{\lambda L}\right)\right] \tag{41}$$

where D is the slit width, and a one-dimensional expression is shown. The definition of a sinc function is

$$\text{sinc}(\alpha)=\frac{\sin(\pi\alpha)}{\pi\alpha} \tag{42}$$

where the zeros of the function occur when the argument α is an integer. The intensity variation in the y direction is due to diffraction only and is not shown. Since the two slits are assumed to be illuminated by a single source, there are no coherence effects introduced by using a pinhole or slit of finite size.

The term $\gamma(x)$ is included in Eq. (41) to account for variations in the fringe visibility. These could be due to unequal illumination of the two slits, a phase difference of the light reaching the slits, or a lack of temporal or spatial coherence of the source S_0.

Other Arrangements

Several other arrangements for producing interference by division of wavefront are shown in Fig. 9. They all use a single source and additional optical elements to produce two separate and mutually coherent sources. Fresnel's biprism and mirror produce the two virtual source images, Billet's split lens produces two real source images, and Lloyd's mirror produces a single virtual source image as a companion to the original source. Interference fringes form wherever the two resulting waves overlap (shaded regions). One significant difference between these arrangements and Young's two slits is that a large section of the initial wavefront is used instead of just two points. All of these systems are much more light efficient, and they do not rely on diffraction to produce the secondary wavefronts.

In the first three of these systems, a bright fringe is formed at the zero OPD point between the two sources as in the double-slit experiment. With Lloyd's mirror, however, the zero OPD point has a dark fringe. This is due to the π phase shift that is introduced into one of the beams on reflection from the mirror.

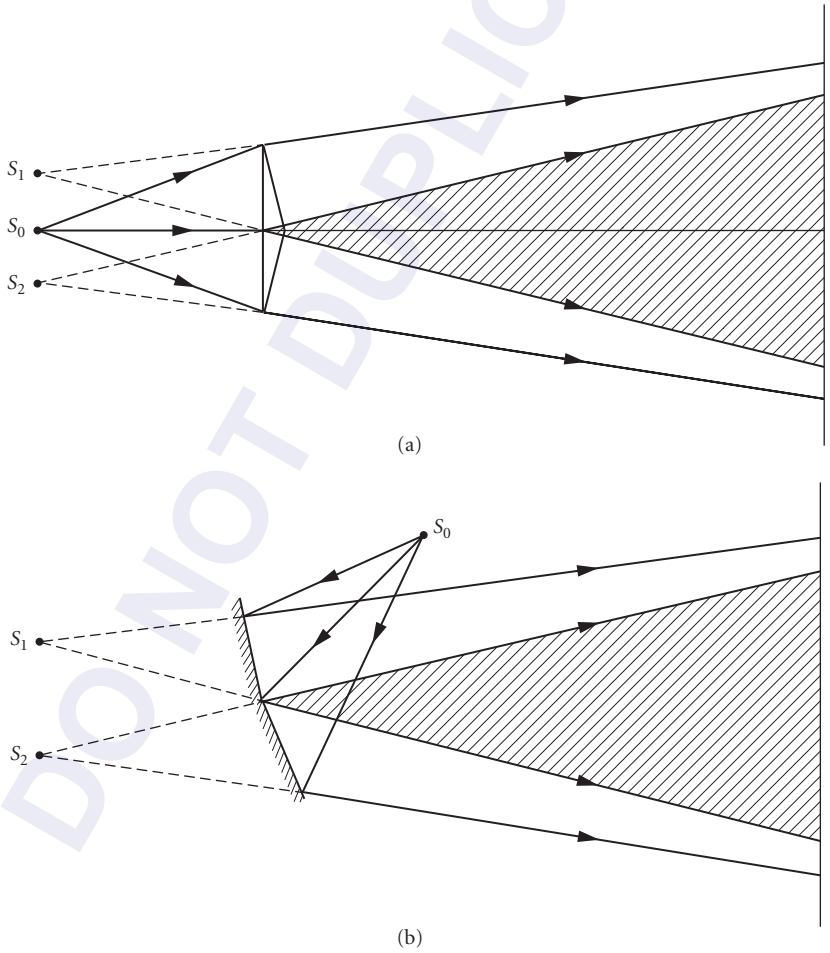

FIGURE 9 Arrangements for interference by division of wavefront: (*a*) Fresnel's biprism; (*b*) Fresnel's mirror; (*c*) Billet's split lens; and (*d*) Lloyd's mirror.

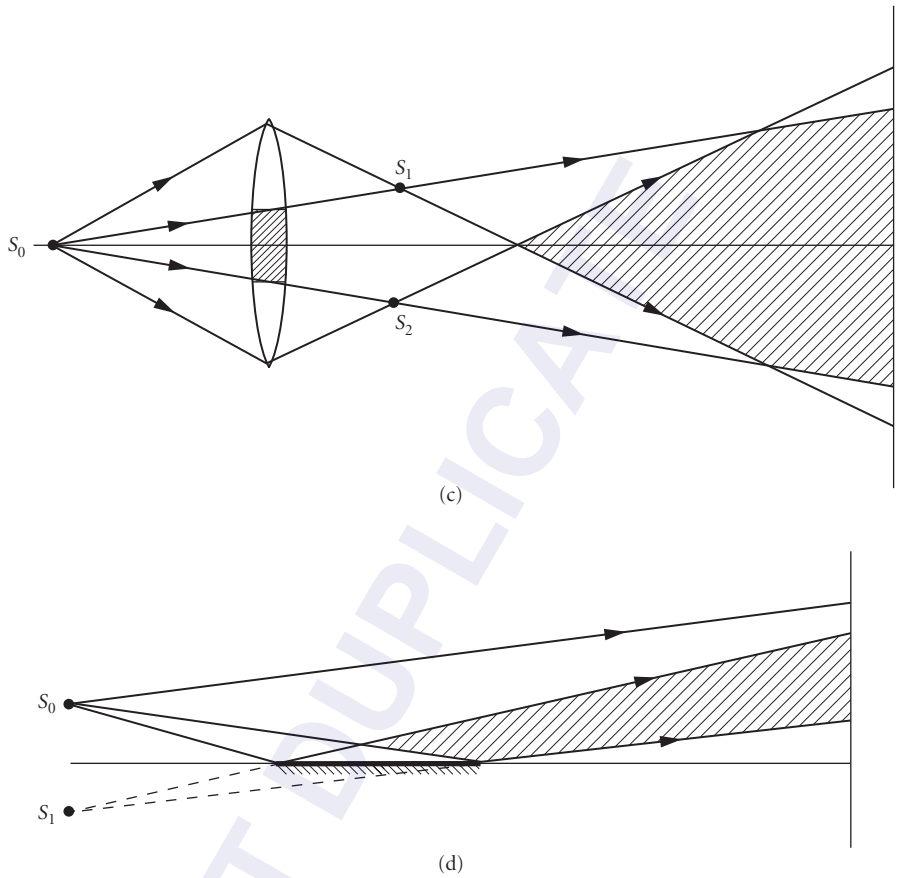

FIGURE 9 *(Continued)*

Source Spectrum

The simple fringe pattern produced by the two-slit experiment provides a good example to examine the effects of a source with a finite spectrum. In this model, the source can be considered to be a collection of sources, each radiating independently and at a different wavelength. All of these sources are colocated to produce a point source. (Note that this is an approximation, as a true point source must be monochromatic.) At each wavelength, an independent intensity pattern is produced:

$$I(x,\lambda)=I_0\left[1+\cos\left(\frac{2\pi xd}{\lambda L}\right)\right]=I_0\left[1+\cos\left(\frac{2\pi\,\mathrm{OPD}}{\lambda}\right)\right] \tag{43}$$

where the period of the fringes is $\lambda L/d$, and a fringe visibility of one is assumed. The total intensity pattern is the sum of the individual fringe patterns:

$$I(x)=\int_0^\infty S(\lambda)I(x,\lambda)d\lambda=\int_0^\infty S(\nu)I(x,\nu)d\nu \tag{44}$$

where $S(\lambda)$ or $S(\nu)$ is the source intensity spectrum which serves as a weighting function.

The effect of this integration can be seen by looking at a simple example where the source is composed of three different wavelengths of equal intensity. To further aid in visualization, let's use Blue (400 nm), Green (500 nm), and Red (600 nm). The result is shown in Fig. 10*a*. There are three cosine patterns, each with a period proportional to the wavelength. The total intensity is the sum of these curves. All three curves line up when the OPD is zero ($x = 0$), and the central bright fringe is now surrounded by two-colored dark fringes. These first dark fringes have a red to blue coloration with increasing OPD. As we get further away from the zero OPD condition, the three patterns get out of phase, the pattern washes out, and the color saturation decreases. This is especially true when the source is composed of more than three wavelengths.

It is common in white light interference situations for one of the two beams to undergo an additional π phase shift. This is the situation in Lloyd's mirror. In this case, there is a central dark fringe at zero OPD with colored bright fringes on both sides. This is shown in Fig. 10*b*, and the pattern is complementary to the previous pattern. In this case the first bright fringe shows a blue to red color smear. The dark central fringe is useful in determining the location of zero OPD between the two beams.

The overall intensity pattern and resulting fringe visibility can be computed for a source with a uniform frequency distribution over a frequency range of $\Delta\nu$:

$$I(x) = \frac{1}{\Delta\nu}\int_{\nu_0-\Delta\nu/2}^{\nu_0+\Delta\nu/2} I(x,\nu)\,d\nu = \frac{1}{\Delta\nu}\int_{\nu_0-\Delta\nu/2}^{\nu_0+\Delta\nu/2} I_0\left[1+\cos\left(\frac{2\pi\nu x d}{cL}\right)\right]d\nu \tag{45}$$

where ν_0 is the central frequency, and the $1/\Delta\nu$ term is a normalization factor to assure that the average intensity is I_0. After integration and simplification, the result is

$$I(x) = I_0\left[1+\operatorname{sinc}\left(\frac{xd\Delta\nu}{cL}\right)\cos\left(\frac{2\pi\nu_0 x d}{cL}\right)\right] \tag{46}$$

where the sinc function is defined in Eq. (42). A fringe pattern due to the average optical frequency results, but it is modulated by a sinc function that depends on $\Delta\nu$ and x. The absolute value of the

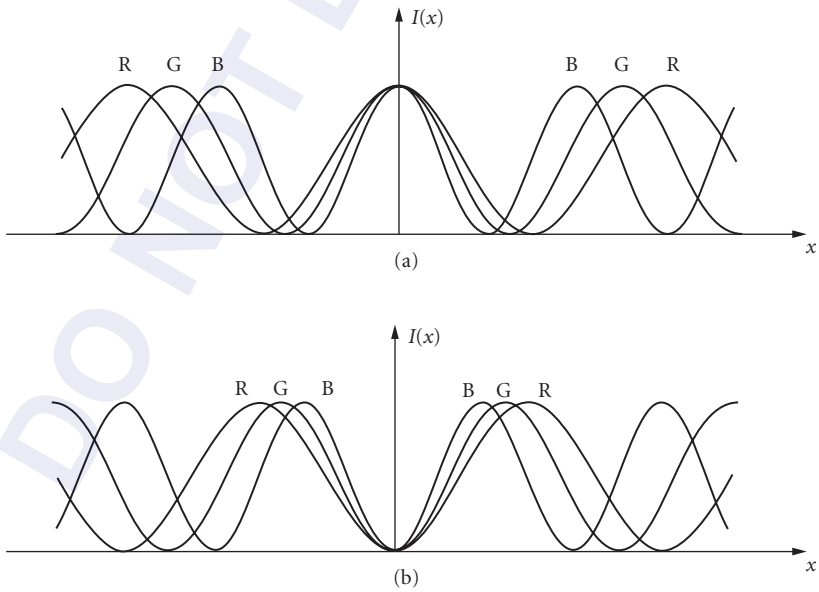

FIGURE 10 The interference pattern produced by a source with three separate wavelengths: (*a*) zero OPD produces a bright fringe and (*b*) zero OPD produces a dark fringe.

sinc function is the fringe visibility $\gamma(x)$, and it depends on both the spectral width and position of observation. The negative portions of the sinc function correspond to a π phase shift of the fringes.

It is informative to rewrite this expression in terms of the OPD:

$$I(x) = I_0\left[1 + \text{sinc}\left(\frac{\text{OPD}\,\Delta\nu}{c}\right)\cos\left(\frac{2\pi\,\text{OPD}}{\lambda_0}\right)\right] \tag{47}$$

where λ_0 is the wavelength corresponding to ν_0. Good fringe visibility is obtained only when either the spectral width is small (the source is quasi-monochromatic) or the OPD is small. The fringes are *localized* in certain areas of space. This result is consistent with the earlier graphical representations. In the area where the OPD is small, the fringes are in phase for all wavelengths. As the OPD increases, the fringes go out of phase since they all have different periods, and the intensity pattern washes out.

This result turns out to be very general: for an incoherent source, the fringes will be localized in the vicinity of zero OPD. There are two other things we should notice about this result. The first is that the first zero of the visibility function occurs when the OPD equals $c/\Delta\nu$. This distance is known as the *coherence length* as it is the path difference over which we can obtain interference. The second item is that the visibility function is a scaled version of the Fourier transform of the source frequency spectrum. It is evaluated for the OPD at the measurement location. The Fourier transform of a uniform distribution is a sinc function. We will discuss this under "Coherence and Interference" later in the chapter.

2.6 INTERFERENCE BY AMPLITUDE DIVISION

The second general method for producing interference is to use the same section of a wavefront from a single source for both resulting wavefronts. The original wavefront amplitude is split into two or more parts, and each fraction is directed along a different optical path. These waves are then recombined to produce interference. This method is called *interference by amplitude division.* There are a great many interferometer designs based on this method. A few will be examined here, and many more will be discussed in Chap. 32, "Interferometers."

Plane-Parallel Plate

A first example of interference by amplitude division is a plane-parallel plate illuminated by a monochromatic point source. Two virtual images of the point source are formed by the Fresnel reflections at the two surfaces, as shown in Fig. 11. Associated with each of the virtual images is a spherical wave, and interference fringes form wherever these two waves overlap. In this case, this is the volume of space on the source side of the plate. The pattern produced is the same as that found for the interference of two spherical waves (discussed earlier under "Two Spherical Waves"), and nonlocalized fringes are produced. The pattern is symmetric around the line perpendicular to the plate through the source. If a screen is placed along this axis, a pattern similar to circular Newton's ring fringes are produced as described by Eq. (33), where $d = 2t/n$ is now the separation of the virtual sources. The thickness of the plate is t, its index is n, and the distance R is approximately the screen-plate separation plus the source-plate separation. We have ignored multiple reflections in the plate. As with the interference of two spherical waves, the order of interference is a maximum at the center of the pattern.

The interference of two plane waves can be obtained by illuminating a wedged glass plate with a plane wavefront. If the angle of incidence on the first surface is θ and the wedge angle is α, two plane waves are produced at angles θ and $\theta + 2n\alpha$ due to reflections at the front and rear surfaces. Straight equispaced fringes will result in the volume of space where the two reflected waves overlap. The period of these fringes on a screen parallel to the plate is given by Eq. (26), where the two reflected angles are used.

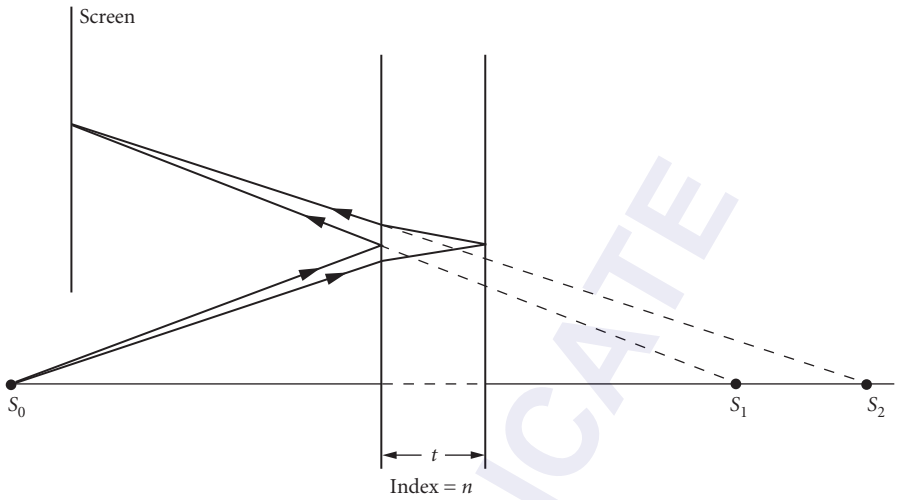

FIGURE 11 Interference from a plane-parallel plate and a point source.

Extended Source

An *extended source* is modeled as a collection of independent point sources. If the source is quasi-monochromatic, all of the point sources radiate at the same nominal frequency, but without a phase relationship. Each point source will produce its own interference pattern, and the net intensity pattern is the sum or integral of all the individual intensity patterns. This is the spatial analogy to the temporal average examined earlier under "Source Spectrum."

With an extended source, the fringes will be localized where the individual fringe position or spacing is not affected by the location of the point sources that comprise the extended source. We know from our previous examples that a bright fringe (or a dark fringe, depending on phase shifts) will occur when the OPD is zero. If there is a location where the OPD is zero independent of source location, all of the individual interference patterns will be in phase, and the net pattern will show good visibility. In fact, the three-dimensional fringe pattern due to a point source will tend to shift or pivot around this zero-OPD location as the point source location is changed. The individual patterns will therefore be out of phase in areas where the OPD is large, and the average intensity pattern will tend to wash out in these regions as the source size increases.

The general rule for fringe visibility with an extended quasi-monochromatic source is that the fringes will be localized in the region where the OPD between the two interfering wavefronts is small. For a wedged glass plate, the fringes are localized in or near the wedge, and the best visibility occurs as the wedge thickness approaches zero and is perhaps just a few wavelengths. The allowable OPD will depend on the source size and the method of viewing the fringes. This result explains why, under natural light, interference effects are seen in thin soap bubbles but not with other thicker glass objects. An important exception to this rule is the plane-parallel plate where the fringes are localized at infinity.

Fringes of Equal Inclination

There is no section of a plane-parallel plate that produces two reflected wavefronts with zero OPD. The OPD is constant, and we would expect, based on the previous section, that no high-visibility fringes would result with an extended source. If, however, a lens is used

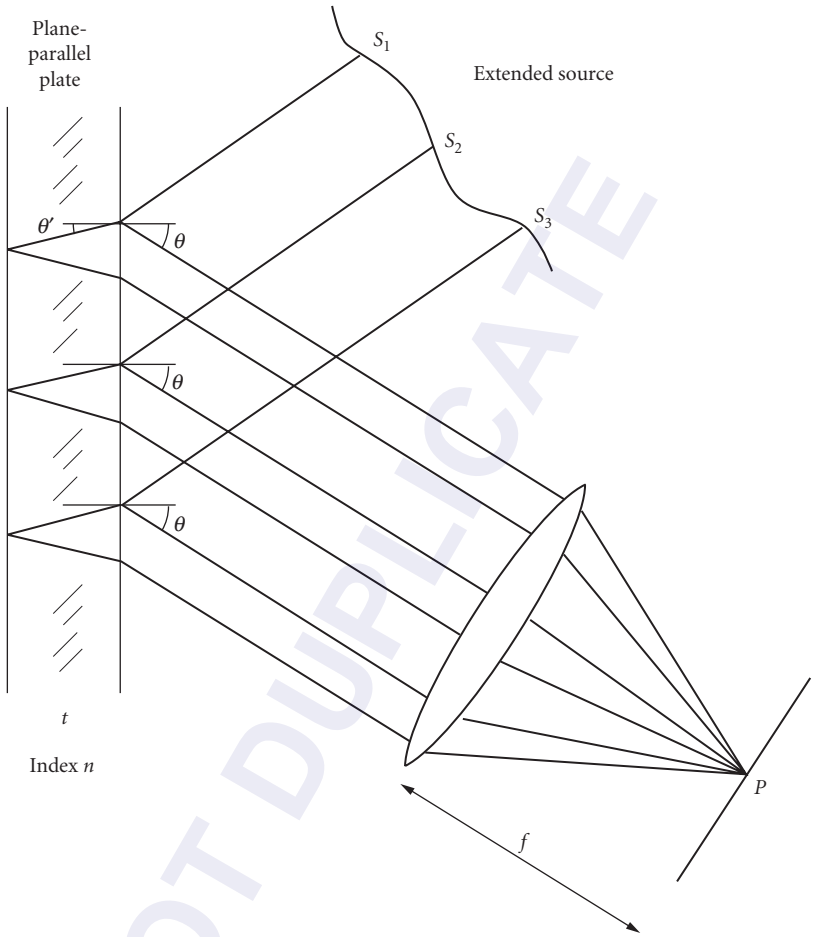

FIGURE 12 The formation of fringes of equal inclination.

to collect the light reflected from the plate, fringes are formed in the back focal plane of the lens. This situation is shown in Fig. 12, and any ray leaving the surface at a particular angle θ is focused to the same point P. For each incident ray at this angle, there are two parallel reflected rays: one from the front surface and one from the back surface. The reflections from different locations on the plate at this angle are due to light from different points in the extended source. The OPD for any pair of these reflected rays is the same regardless of the source location. These rays will interfere at P and will all have the same phase difference. High-visibility fringes result. Different points in the image plane correspond to different angles. The formation of these fringes localized at infinity depends on the two surfaces of the plate being parallel.

The OPD between the reflected rays is a function of the angle of incidence θ, the plate index n, and thickness t:

$$\text{OPD} = 2nt\cos\theta' \tag{48}$$

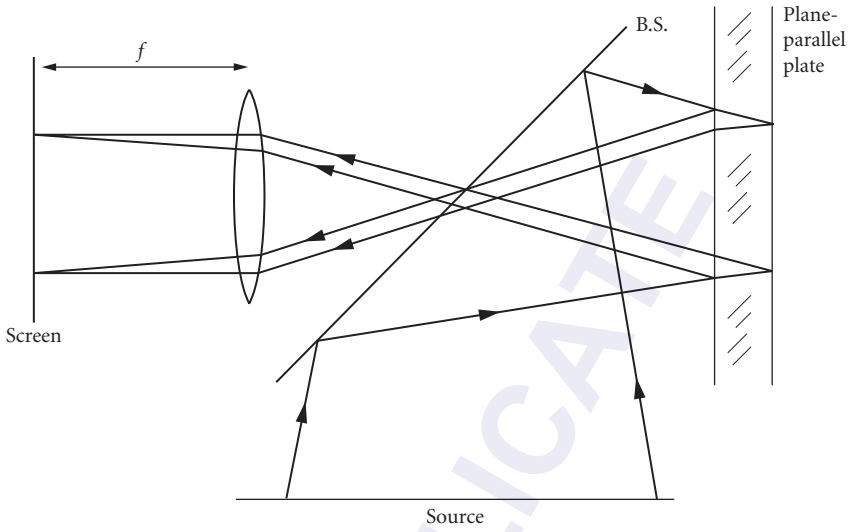

FIGURE 13 The formation of Haidinger fringes.

where θ' is the internal angle. Taking into account the half-wave shift due to the phase change difference of π between an internal and an external reflection, a dark fringe will result for angles satisfying

$$2nt\cos\theta' = m\lambda \quad \text{or} \quad \cos\theta' = \frac{m\lambda}{2nt} \tag{49}$$

where m is an integer. Since only the angle of incidence determines the properties of the interference (everything else is constant), these fringes are called *fringes of equal inclination*. They appear in the back focal plane of the lens and are therefore localized at infinity since infinity is conjugate to the focal plane. As the observation plane is moved away from the focal plane, the visibility of the fringes will quickly decrease.

When the axis of the lens is normal to the surfaces of the plate, a beamsplitter arrangement is required to allow light from the extended source to be reflected into the lens as shown in Fig. 13. Along the axis, $\theta = \theta' = 90°$, and symmetry requires that the fringes are concentric about the axis. In this special case, these fringes are called *Haidinger fringes*, and they are identical in appearance to Newton's rings [Eq. (30)]. If there is an intensity maximum at the center, the radii of the other bright fringes are proportional to the square roots of integers. As with other fringes formed by a plane-parallel plate (discussed earlier), the order of interference decreases with the observation radius on the screen. As θ' increases, the value of m decreases.

Fringes of Equal Thickness

The existence of fringes of equal inclination depends on the incident light being reflected by two parallel surfaces, and the angle of incidence is the mechanism which generates changes in the OPD. There are many arrangements with an extended source where the reflections are not parallel, and the resulting changes in OPD dominate the angle-of-incidence considerations. The fringes produced in this situation are called *fringes of equal thickness*, and we have stated earlier that they will be localized in regions where the OPD between the two reflections is small.

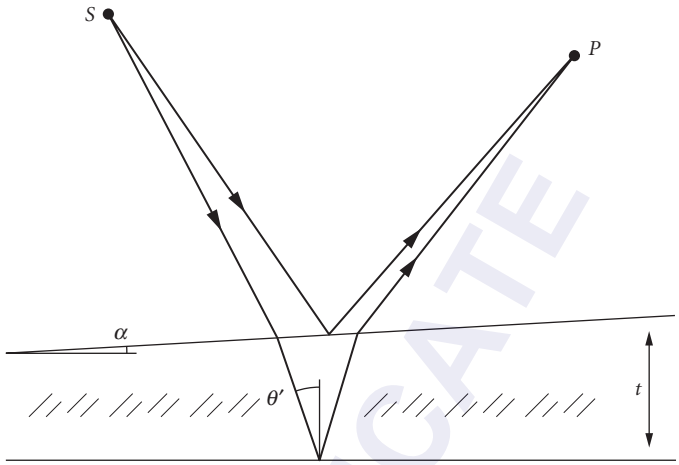

FIGURE 14 The ray path between a point source and an observation point for a wedged plate.

An example of fringes of equal thickness occurs with a wedged glass plate illuminated by a quasi-monochromatic extended source. We know that for each point in the source, a pattern comprising equispaced parallel fringes results, and the net pattern is the sum of all of these individual patterns. However, it is easier to examine this summation by looking at the OPD between the two reflected rays reaching an observation point P from a source point S. This is shown in Fig. 14. The wedge angle is α, the thickness of the plate at this location is t, its index is n, and the internal ray angle is θ'. The exact OPD is difficult to calculate, but under the assumption that α is small and the wedge is sufficiently thin, the following result for the OPD is obtained:

$$\text{OPD} \approx 2nt\cos\theta' \tag{50}$$

As other points on the source are examined, the reflection needed to get light to the observation point will move to a different location on the plate, and different values of both t and θ' will result. Different source points may have greatly different OPDs, and in general the fringe pattern will wash out in the vicinity of P.

This reduction in visibility can be avoided if the observation point is placed in or near the wedge. In this case, all of the paths between S and P must reflect from approximately the same location on the wedge, and the variations in the thickness t are essentially eliminated. The point P where the two reflected rays cross may be virtual. The remaining variations in the OPD are from the different θ's associated with different source points. This variation may be limited by observing the fringe pattern with an optical system having a small entrance pupil. This essentially limits the amount of the source that is used to examine any area on the surface. A microscope or the eye focused on the wedge can be used to limit the angles. If the range of values of θ' is small, high-visibility fringes will appear to be localized at the wedge. The visibility of the fringes will decrease as the wedge thickness increases.

It is common to arrange the system so that the fringes are observed in a direction approximately normal to the surface. Taking into account the additional phase shift introduced at the reflection from one of the surfaces, the conditions for bright and dark fringes are then

$$\text{Bright:}\quad 2nt - \frac{\lambda}{2} = m\lambda \tag{51}$$

and

$$\text{Dark:}\quad 2nt = m\lambda \tag{52}$$

where m is an integer greater than or equal to zero. Since t increases linearly across the wedge, the observed pattern will be straight equispaced fringes.

These same conditions hold for any plate where the two surfaces are not parallel. The surfaces may have any shape, and as long as the surface angles are small and the plate is relatively thin, high-visibility fringes localized in the plate are observed. Along a given fringe the value of m is constant, so that a fringe represents a contour of constant optical path length nt. If the index is constant, we have fringes of equal thickness. The fringes provide a contour map of the plate thickness, and adjacent fringes correspond to a change of thickness of $\lambda/2n$. An irregularly shaped pattern will result from the examination of a plate of irregular thickness.

Thin Films

With the preceding background, we can easily explain the interference characteristics of *thin films*. There are two distinct types of films to consider. The first is a thin film of nonuniform thickness, and examples are soap bubbles and oil films on water. The second type is a uniform film, such as would be obtained by vacuum deposition and perhaps used as an antireflection coating. Both of these films share the characteristic of being extremely thin—usually not more than a few wavelengths thick and often just a fraction of a wavelength thick.

With a nonuniform film, fringes of equal thickness localized in the film are produced. There will be a dark fringe in regions of the film where it is substantially thinner than a half wave. We are assuming that the film is surrounded by a lower-index medium such as air so that there is an extra π phase shift. If white light is used for illumination, colored bands will be produced similar to those diagramed in Fig. 10*b* (the curves would need to be modified to rescale the x axis to OPD or film thickness). Each color will produce its first maximum in intensity when the optical thickness of the film is a quarter of that wavelength. As the film thickness increases, the apparent fringe color will first be blue, then green, and finally red. These colored fringes are possible because the film is very thin, and the order of interference m is often zero or one [Eqs. (51) and (52)]. The interference patterns in the various colors are just starting to get out of phase, and interference colors are visible. As the film thickness increases, the various wavelength fringes become jumbled, and distinct fringe patterns are no longer visible.

When a uniform thin film is examined with an extended source, fringes of equal inclination localized at infinity are produced. These fringes will be very broad since the thickness of the film is very small, and large angles will be required to obtain the necessary OPD for a fringe [Eq. (49)]. A common use of this type of film is as an antireflection coating. In this application, a uniform coating that has an optical thickness of a quarter wavelength is applied to a substrate. The coating index is lower than the substrate index, so an extra phase shift is not introduced. A wave at normal incidence is reflected by both surfaces of the coating, and these reflected waves are interfered. If the incident wavelength matches the design of the film, the two reflected waves are out of phase and interfere destructively. The reflected intensity will depend on the Fresnel reflection coefficients at the two surfaces, but will be less than that of the uncoated surface. When a different wavelength is used or the angle of incidence is changed, the effectiveness of the antireflection coating is reduced. More complicated film structures comprising many layers can be produced to modify the reflection or transmission characteristics of the film.

Fizeau Interferometer

The *Fizeau interferometer* compares one optical surface to another by placing them in close proximity. A typical arrangement is shown in Fig. 15, where the extended source is filtered to be quasi-monochromatic. A small air gap is formed between the two optical surfaces, and fringes of equal thickness are observed between the two surfaces. Equations (51) and (52) describe the location of

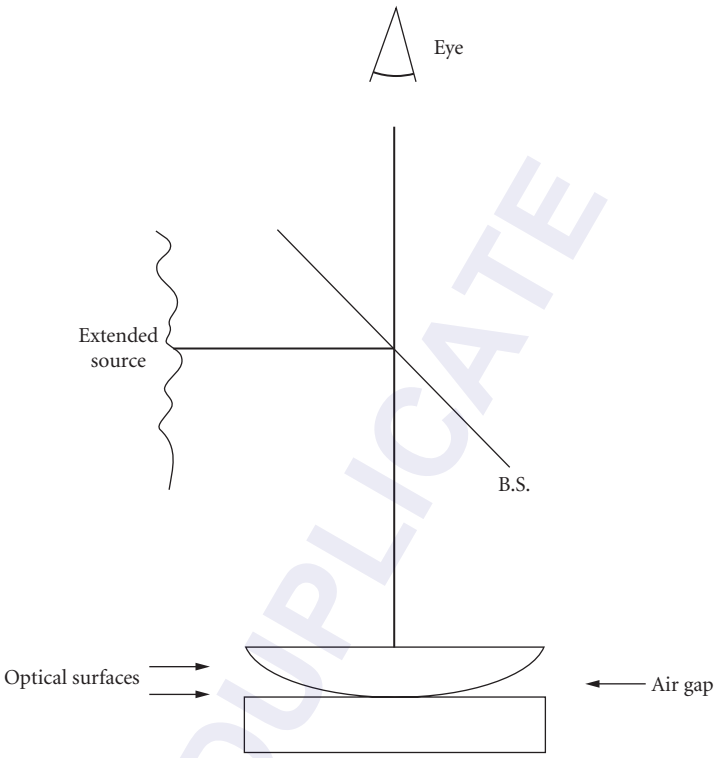

FIGURE 15 Fizeau interferometer.

the fringes, and the index of the thin wedge is now that of air. Along a fringe, the gap is of constant thickness, and adjacent fringes correspond to a change of thickness of a half wavelength. This interferometer is sometimes referred to as a *Newton interferometer*.

This type of interferometer is the standard test instrument in an optical fabrication shop. One of the two surfaces is a reference or known surface, and the interferometric comparison of this reference surface and the test surface shows imperfections in the test part. Differences in radii of the two surfaces are also apparent. The fringes are easy to interpret, and differences of as little as a twentieth of a wavelength can be visually measured. These patterns and this interferometer are further discussed in Chap. 13, "Optical Testing," in Vol. II. The interferometer is often used without the beamsplitter, and the fringes are observed in the direct reflection of the source from the parts.

The classic fringe pattern produced by a Fizeau interferometer is *Newton's rings*. These are obtained by comparing a convex sphere to a flat surface. The parabolic approximation for the sag of a sphere of radius R is

$$\text{sag}(\rho)=\frac{\rho^2}{2R} \tag{53}$$

and ρ is the radial distance from the vertex of the sphere. If we assume the two surfaces are in contact at $\rho = 0$, the OPD between the reflected waves is twice the gap, and the condition for a dark fringe is

$$\rho=\sqrt{m\lambda R} \tag{54}$$

Circular fringes that increase in radius as the square root of ρ are observed. Note that a dark fringe occurs at the center of the pattern. In reflection, this point must be dark, as there is no interface at the contact point to produce a reflection.

Michelson Interferometer

There are many two-beam interferometers which allow the surfaces producing the two wavefronts to be physically separated by a large distance. These instruments allow the two wavefronts to travel along different optical paths. One of these is the *Michelson interferometer* diagramed in Fig. 16*a*. The two interfering wavefronts are produced by the reflections from the two mirrors. A plate beamsplitter with one face partially silvered is used, and an identical block of glass is placed in one of the arms of the interferometer to provide the same amount of glass path in each arm. This cancels the effects of the dispersion of the glass beamsplitter and allows the system to be used with white light since the optical path difference is the same for all wavelengths.

Figure 16*b* provides a folded view of this interferometer and shows the relative optical position of the two mirrors as seen by the viewing screen. It should be obvious that the two

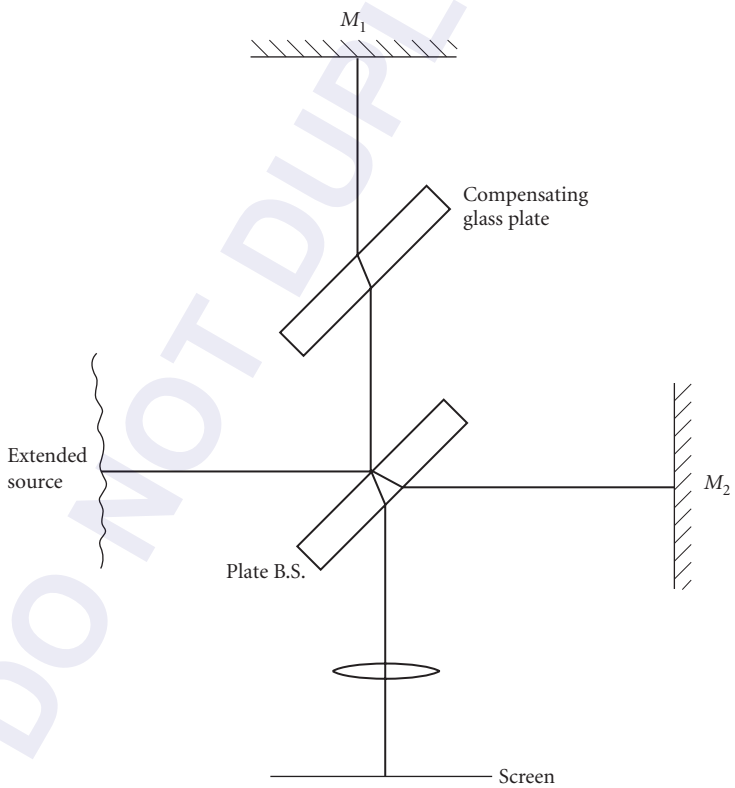

FIGURE 16 Michelson interferometer: (*a*) schematic view and (*b*) folded view showing the relative optical position of the two mirrors.

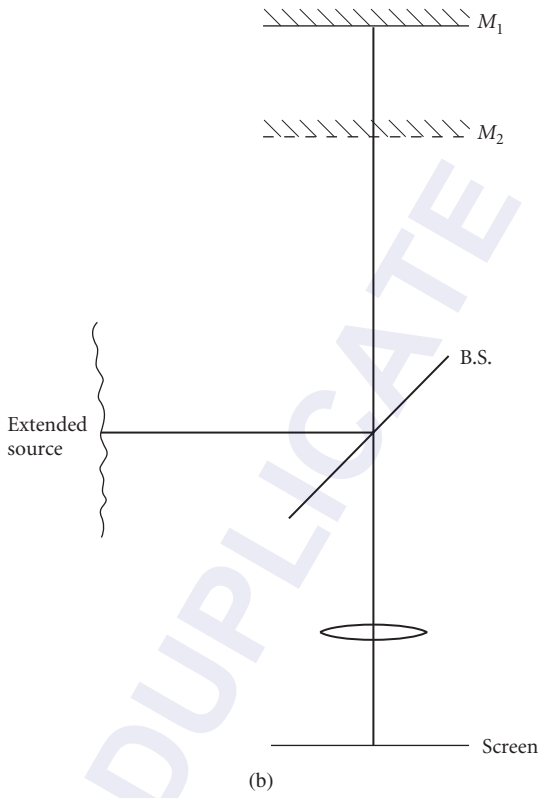

FIGURE 16 *(Continued)*

mirrors can be thought of as the two surfaces of a "glass" plate that is illuminated by the source. In this case, the index of the fictitious plate is one, and the reflectivity at the two surfaces is that of the mirrors. Depending on the mirror orientations and shapes, the interferometer either mimics a plane-parallel plate of adjustable thickness, a wedge of arbitrary angle and thickness, or the comparison of a reference surface with an irregular or curved surface. The type of fringes that are produced will depend on this configuration, as well as on the source used for illumination.

When a monochromatic point source is used, nonlocalized fringes are produced, and the imaging lens is not needed. Two virtual-source images are produced, and the resulting fringes can be described by the interference of two spherical waves (discussed earlier). If the mirrors are parallel, circular fringes centered on the line normal to the mirrors result as with a plane-parallel plate. The source separation is given by twice the apparent mirror separation. If the mirrors have a relative tilt, the two source images appear to be laterally displaced, and hyperbolic fringes result. Along a plane bisecting the source images, straight equispaced fringes are observed.

When an extended monochromatic source is used, the interference fringes are localized. If the mirrors are parallel, fringes of equal inclination or Haidinger fringes (as described earlier) are produced. The fringes are localized at infinity and are observed in the rear focal plane of the imaging lens. Fringes of equal thickness localized at the mirrors are generated when the mirrors are tilted.

The apparent mirror separation should be kept small, and the imaging lens should focus on the mirror surface.

If the extended source is polychromatic, colored fringes localized at the mirrors result. They are straight for tilted mirrors. The fringes will have high visibility only if the apparent mirror separation or OPD is smaller than the coherence length of the source. Another way of stating this is that the order of interference m must be small to view the colored fringes. As m increases, the fringes will wash out. The direct analogy here is a thin film. As the mirror separation is varied, the fringe visibility will vary. The fringe visibility as a function of mirror separation is related to the source frequency spectrum (see under "Source Spectrum" and "Coherence and Interference"), and this interferometer forms the basis of a number of spectrometers. When the source spectrum is broad, chromatic fringes cannot be viewed with the mirrors parallel. This is because the order of interference for fringes of equal inclination is a maximum at the center of the pattern.

An important variation of the Michelson interferometer occurs when monochromatic collimated light is used. This is the *Twyman-Green interferometer,* and is a special case of point-source illumination with the source at infinity. Plane waves fall on both mirrors, and if the mirrors are flat, nonlocalized equispaced fringes are produced. Fringes of equal thickness can be viewed by imaging the mirrors onto the observation screen. If one of the mirrors is not flat, the fringes represent changes in the surface height. The two surfaces are compared as in the Fizeau interferometer. This interferometer is an invaluable tool for optical testing.

2.7 MULTIPLE BEAM INTERFERENCE

Throughout the preceding discussions, we have assumed that only two waves were being interfered. There are many situations where multiple beams are involved. Two examples are the diffraction grating and a plane-parallel plate. We have been ignoring multiple reflections, and in some instances these extra beams are very important. The net electric field is the sum of all of the component fields. The two examples noted above present different physical situations: all of the interfering beams have a constant intensity with a diffraction grating, and the intensity of the beams from a plane-parallel plate decreases with multiple reflections.

Diffraction Grating

A *diffraction grating* can be modeled as a series of equispaced slits, and the analysis bears a strong similarity to the Young's double slit (discussed earlier). It operates by division of wavefront, and the geometry is shown in Fig. 17. The slit separation is d, the OPD between successive beams for a given observation angle θ is $d \sin(\theta)$, and the corresponding phase difference $\Delta\phi = 2\pi d \sin(\theta)/\lambda$. The field due to the nth slit at a distant observation point is

$$E_j(\theta) = Ae^{i(j-1)\Delta\phi} \qquad j = 1, 2, \ldots, N \tag{55}$$

where all of the beams have been referenced to the first slit, and there are N total slits. The net field is

$$E(\theta) = \sum_{j=1}^{N} E_j(\theta) = A\sum_{j=1}^{N} (e^{i\Delta\phi})^{j-1} \tag{56}$$

which simplifies to

$$E(\theta) = A\left(\frac{1-e^{iN\Delta\phi}}{1-e^{i\Delta\phi}}\right) \tag{57}$$

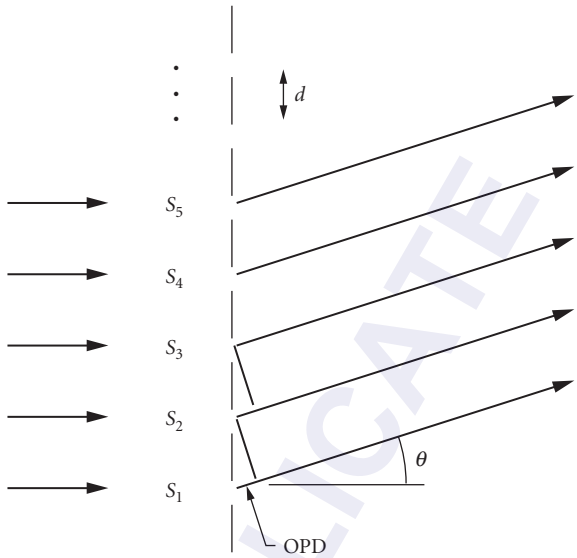

FIGURE 17 Diffraction grating: multiple-beam interference by division of wavefront.

The resulting intensity is

$$I(\theta)=I_0\left[\frac{\sin^2\left(\frac{N\Delta\phi}{2}\right)}{\sin^2\left(\frac{\Delta\phi}{2}\right)}\right]=I_0\left[\frac{\sin^2\left(\frac{N\pi d\sin(\theta)}{\lambda}\right)}{\sin^2\left(\frac{\pi d\sin(\theta)}{\lambda}\right)}\right] \tag{58}$$

where I_0 is the intensity due to an individual slit.

This intensity pattern is plotted in Fig. 18 for $N = 5$. The result for $N = 2$, which is the double-slit experiment, is also shown. The first thing to notice is that the locations of the maxima are the same, independent of the number of slits. A maximum of intensity is obtained whenever the phase difference between adjacent slits is a multiple of 2π. These maxima occur at the diffraction angles given by

$$\sin(\theta)=\frac{m\lambda}{d} \tag{59}$$

where m is an integer. The primary difference between the two patterns is that with multiple slits, the intensity at the maximum increases to N^2 times that due to a single slit, and this energy is concentrated into a much narrower range of angles. The full width of a diffraction peak between intensity zero corresponds to a phase difference $\Delta\phi$ of $4\pi/N$.

The number of intensity zeros between peaks is $N - 1$. As the number of slits increases, the angular resolution or resolving power of the grating greatly increases. The effects of a finite slit width can be added by replacing I_0 in Eq. (58) by the single-slit diffraction pattern. This intensity variation forms an envelope for the curve in Fig. 18.

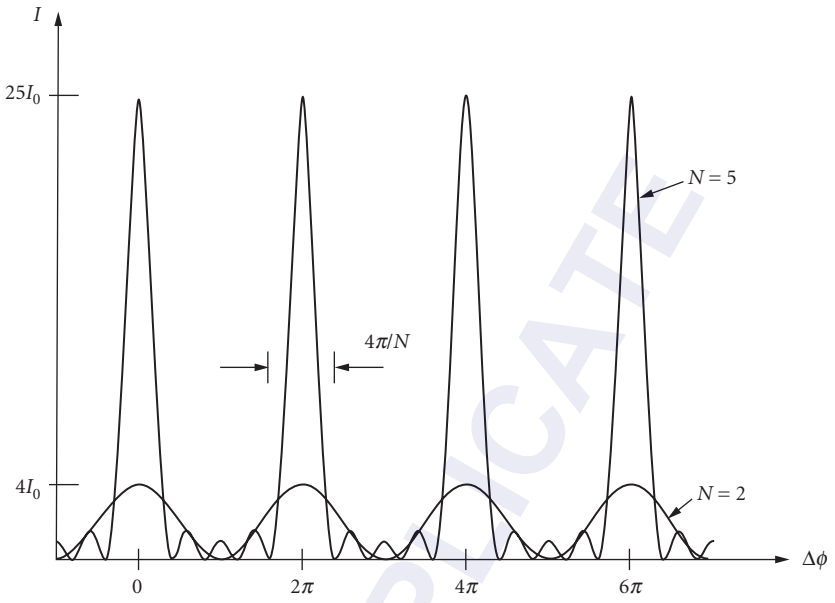

FIGURE 18 The interference patterns produced by gratings with 2 and 5 slits.

Plane-Parallel Plate

The plane-parallel plate serves as a model to study the interference of multiple waves obtained by division of amplitude. As we shall see, the incremental phase difference between the interfering beams is constant but, in this case, the beams have different intensities. A plate of thickness t and index n with all of the reflected and transmitted beams is shown in Fig. 19. The amplitude reflection and transmission coefficients are ρ and ρ', and τ and τ', where the primes indicate

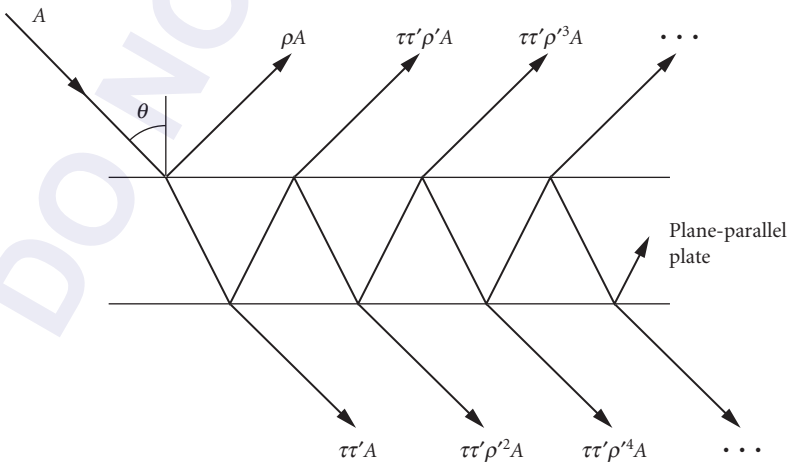

FIGURE 19 Plane-parallel plate: multiple-beam interference by division of amplitude.

reflection or transmission from within the plate. The first reflected beam is 180° out of phase with the other reflected beams since it is the only beam to undergo an external reflection, and $\rho = -\rho'$. Note that ρ' occurs only in odd powers for the reflected beams. Each successive reflected or transmitted beam is reduced in amplitude by ρ^2. The phase difference between successive reflected or transmitted beams is the same as we found when studying fringes of equal inclination from a plane-parallel plate:

$$\Delta\phi = \left[\frac{4\pi nt\cos(\theta')}{\lambda}\right] \tag{60}$$

where θ' is the angle inside the plate.

The transmitted intensity can be determined by first summing all of the transmitted amplitudes:

$$E(\Delta\phi) = \sum_{j=1}^{\infty} E_j = A\tau\tau' \sum_{j=1}^{\infty} (\rho^2 e^{i\Delta\phi})^{j-1} \tag{61}$$

where the phase is referenced to the first transmitted beam. The result of the summation is

$$E(\Delta\phi) = \left(\frac{A\tau\tau'}{1-\rho^2 e^{i\Delta\phi}}\right) \tag{62}$$

The transmitted intensity I_t is the squared modulus of the amplitude which, after simplification, becomes

$$\frac{I_t}{I_0} = \frac{1}{1+\left(\dfrac{2\rho}{1-\rho^2}\right)^2 \sin^2(\Delta\phi/2)} \tag{63}$$

where I_0 is the incident intensity. We have also assumed that there is no absorption in the plate, and therefore $\tau\tau' + \rho^2 = 1$. Under this condition of no absorption, the sum of the reflected and transmitted light must equal the incident light: $I_t + I_r = I_0$. The expressions for the transmitted and reflected intensities are then

$$\frac{I_t}{I_0} = \frac{1}{1+F\sin^2(\Delta\phi/2)} \tag{64}$$

and

$$\frac{I_r}{I_0} = \frac{F\sin^2(\Delta\phi/2)}{1+F\sin^2(\Delta\phi/2)} \tag{65}$$

and F is defined as

$$F \equiv \left(\frac{2\rho}{1-\rho^2}\right)^2 \tag{66}$$

F is the *coefficient of finesse* of the system and is a function of the surface reflectivity only. The value of F will have a large impact on the shape of the intensity pattern. Note that the reflected intensity could also have been computed by summing the reflected beams.

A maximum of transmitted intensity, or a minimum of reflected intensity, will occur when $\Delta\phi/2 = m\pi$, where m is an integer. Referring back to Eq. (60), we find that this corresponds to the angles

$$\cos\theta' = \frac{m\lambda}{2nt} \tag{67}$$

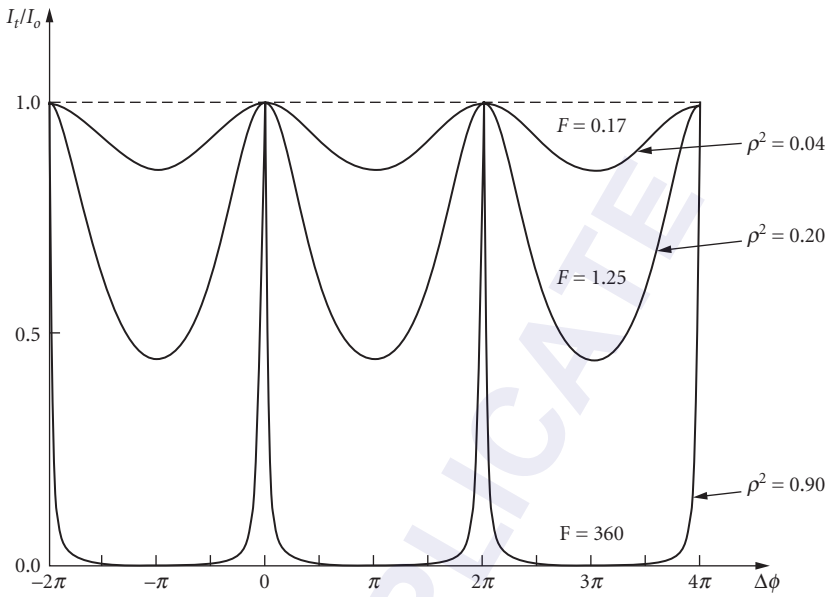

FIGURE 20 The transmitted intensity of a multiple-beam interference pattern produced by a plane-parallel plate.

This is exactly the same condition that was found for a plane-parallel plate with two beams [Eq. (49)]. With an extended source, fringes of equal inclination are formed, and they are localized at infinity. They must be at infinity since all of the reflected or transmitted beams are parallel for a given input angle. The fringes are observed in the rear focal plane of a viewing lens. If the optical axis of this lens is normal to the surface, circular fringes about the axis are produced. The locations of the maxima and minima of the fringes are the same as were obtained with two-beam interference

The shape of the intensity profile of these multiple beam fringes is not sinusoidal, as it was with two beams. A plot of the transmitted fringe intensity [Eq. (64)] as a function of $\Delta\phi$ is shown in Fig. 20 for several values of F. When the phase difference is a multiple of 2π, we obtain a bright fringe independent of F or ρ. When F is small, low-visibility fringes are produced. When F is large, however, the transmitted intensity is essentially zero unless the phase has the correct value. It drops off rapidly for even small changes in $\Delta\phi$. The transmitted fringes will be very narrow bright circles on an essentially black background. The reflected intensity pattern is one minus this result, and the fringe pattern will be very dark bands on a uniform bright background. The reflected intensity profile is plotted in Fig. 21 for several values of F.

The value of F is a strong function of the surface reflectivity $R = \rho^2$. We do not obtain appreciable values of F until the reflectivity is approximately one. For example, $R = 0.8$ produces $F = 80$, while $R = 0.04$ gives $F = 0.17$. This latter case is typical for uncoated glass, and dim broad fringes in reflection result, as in Fig. 21. The pattern is approximately sinusoidal, and it is clear that our earlier assumptions about ignoring multiple reflections when analyzing a plane-parallel plate are valid for many low-reflectivity situations.

The multiple beam interference causes an energy redistribution much like that obtained from a diffraction grating. A strong response is obtained only when all of the reflected beams at a given angle add up in phase. The difference between this pattern and that of a diffraction pattern is that there are no oscillations or zeros between the transmitted intensity maxima. This is a result of the

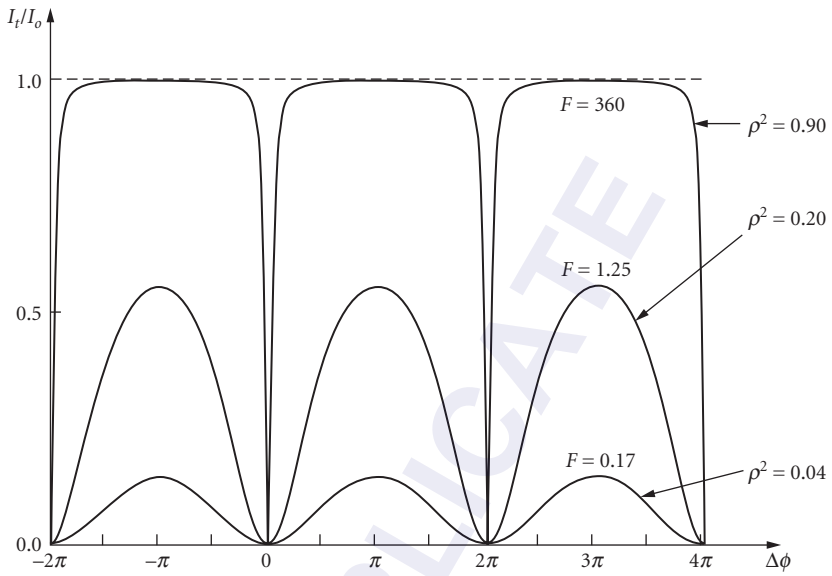

FIGURE 21 The reflected intensity of a multiple-beam interference pattern produced by a plane-parallel plate.

unequal amplitudes of the interfering beams. With a diffraction grating, all of the beams have equal amplitude, and the resultant intensity oscillates as more beams are added.

Multiple-beam fringes of equal thickness can be produced by two high-reflectivity surfaces in close proximity in a Fizeau interferometer configuration. The dark fringes will narrow to sharp lines, and each fringe will represent a contour of constant OPD between the surfaces. As before, a dark fringe corresponds to a gap of an integer number of half wavelengths. The area between the fringes will be bright. The best fringes will occur when the angle and the separation between the surfaces is kept small. This will prevent the multiple reflections from walking off or reflecting out of the gap.

Fabry-Perot Interferometer

The *Fabry-Perot interferometer* is an important example of a system which makes use of multiple-beam interference. This interferometer serves as a high-resolution spectrometer and also as an optical resonator. In this latter use, it is an essential component of a laser. The system is diagrammed in Fig. 22, and it consists of two highly reflective parallel surfaces separated by a distance t. These two separated reflective plates are referred to as a *Fabry-Perot etalon* or cavity, and an alternate arrangement has the reflected coatings applied to the two surfaces of a single glass plate. The two lenses serve to collimate the light from a point on the extended source in the region of the cavity and to then image this point onto the screen. The screen is located in the focal plane of the lens so that fringes of equal inclination localized at infinity are viewed. As we have seen, light of a fixed wavelength will traverse the etalon only at certain well-defined angles. Extremely sharp multiple-beam circular fringes in transmission are produced on the screen, and their profile is the same as that shown in Fig. 20.

If the source is not monochromatic, a separate independent circular pattern is formed for each wavelength. Equation (67) tells us that the location or scale of the fringes is dependent on the wavelength. If the source is composed of two closely spaced wavelengths, the ring structure is doubled,

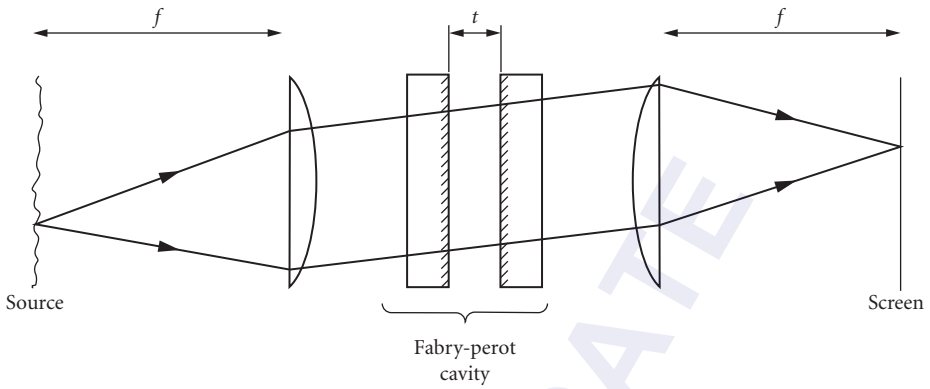

FIGURE 22 Fabry-Perot interferometer.

and the separation of the two sets of rings allows the hyperfine structure of the spectral lines to be evaluated directly. More complicated spectra, usually composed of discrete spectral lines, can also be measured. This analysis is possible even though the order of interference is highest in the center of the pattern. If the phase change $\Delta\phi$ due to the discrete wavelengths is less than the phase change between adjacent fringes, nonoverlapping sharp fringes are seen.

A quantity that is often used to describe the performance of a Fabry-Perot cavity is the *finesse* $\mathcal{F}$. It is a measure of the number of resolvable spectral lines, and is defined as the ratio of the phase difference between adjacent fringes to the full width-half maximum FWHM of a single fringe. Since the fringe width is a function of the coefficient of finesse, the finesse itself is also a strong function of reflectivity. The phase difference between adjacent fringes is 2π, and the half width-half maximum can be found by setting Eq. (64) equal to $\frac{1}{2}$ and solving for $\Delta\phi$. The FWHM is twice this value, and under the assumption that F is large,

$$\text{FWHM} = \frac{4}{\sqrt{F}} \tag{68}$$

and the finesse is

$$\mathcal{F} \equiv \frac{2\pi}{\text{FWHM}} = \frac{\pi\sqrt{F}}{2} = \frac{\pi\rho}{1-\rho^2} = \frac{\pi\sqrt{R}}{1-R} \tag{69}$$

where ρ is the amplitude reflectivity, and R is the intensity reflectivity. Typical values for the finesse of a cavity with flat mirrors is about 30 and is limited by the flatness and parallelism of the mirrors. There are variations in $\Delta\phi$ across the cavity. Etalons consisting of two curved mirrors can be constructed with a much higher finesse, and values in excess of 10,000 are available.

Another way of using the Fabry-Perot interferometer as a spectrometer is suggested by rewriting the transmission [Eq. (64)] in terms of the frequency ν:

$$T = \frac{I_t}{I_0} = \frac{1}{1 + F\sin^2(2\pi t\nu/c)} \tag{70}$$

where Eq. (60) relates the phase difference to the wavelength, t is the mirror separation, and an index of one and normal incidence ($\theta' = 0$) have been assumed. This function is plotted in Fig. 23, and a series of transmission spikes separated in frequency by $c/2t$ are seen. A maximum occurs whenever the value of the sine is zero. The separation of these maxima is known as the *free spectral range,* FSR. If the separation of the mirrors is changed slightly, these transmission peaks will scan the frequency axis. Since the order of interference m is usually very large, it takes

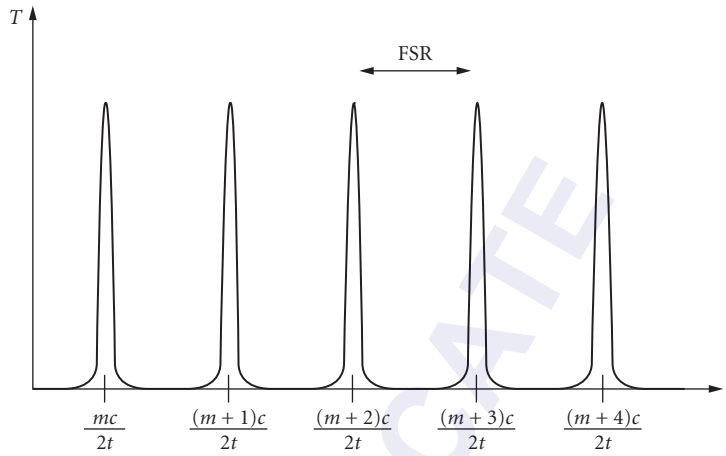

FIGURE 23 The transmission of a Fabry-Perot cavity as a function of frequency.

only a small change in the separation to move the peaks by one FSR. In fact, to scan one FSR, the required change in separation is approximately *t/m.* If the on-axis transmitted intensity is monitored while the mirror separation is varied, a high-resolution spectrum of the source is obtained. The source spectrum must be contained within one free spectral range so that the spectrum is probed by a single transmission peak at a time. If this were not the case, the temporal signal would contain simultaneous contributions from two or more frequencies resulting from different transmission peaks. Under this condition there are overlapping orders, and it is often prevented by using an auxiliary monochromator with the scanning Fabry-Perot cavity to preselect or limit the frequency range of the input spectrum. The resolution Δv of the trace is limited by the finesse of the cavity.

For a specific cavity, the value of m at a particular transmission peak, and some physical insight into the operation of this spectrometer, is obtained by converting the frequency of a particular transmission mode $mc/2t$ into wavelength:

$$\lambda = \frac{2t}{m} \quad \text{or} \quad t = m\frac{\lambda}{2} \tag{71}$$

For the mth transmission maximum, exactly m half waves fit across the cavity. This also implies that the round-trip path within the cavity is an integer number of wavelengths. Under this condition, all of the multiply-reflected beams are in phase everywhere in the cavity, and therefore all constructively interfere. A maximum in the transmission occurs. Other maxima occur at different wavelengths, but these specific wavelengths must also satisfy the condition that the cavity spacing is an integer number of half wavelengths.

These results also allow us to determine the value of m. If a 1-cm cavity is used and the nominal wavelength is 500 nm, $m = 40{,}000$ and FSR $= 1.5 \times 10^{10}$ Hz. The wavelength interval corresponding to this FSR is 0.0125 nm. If a 1-mm cavity is used instead, the results are $m = 4000$ and FSR $= 1.5 \times 10^{11}$ Hz $= 0.125$ nm. We see now that to avoid overlapping orders, the spectrum must be limited to a very narrow range, and this range is a function of the spacing. Cavities with spacings of a few tens of μm's are available to increase the FSR. Increasing the FSR does have a penalty. The finesse of a cavity depends only on the reflectivities, so as the FSR is increased by decreasing t, the FWHM of the transmission modes increases to maintain a constant ratio. The number of resolvable spectrum lines remains constant, and the absolute spectral resolution decreases.

A mirror translation of a half wavelength is sufficient to cover the FSR of the cavity. The usual scanning method is to separate the two mirrors with a piezoelectric spacer. As the applied voltage is changed, the cavity length will also change. An alternate method is to change the index of the air in the cavity by changing the pressure.

2.8 COHERENCE AND INTERFERENCE

The observed fringe visibility is a function of the spatial and temporal coherence of the source. The classical assumption for the analysis is that every point on an extended source radiates independently and therefore produces its own interference pattern. The net intensity is the sum of all of the individual intensity patterns. In a similar manner, each wavelength or frequency of a nonmonochromatic source radiates independently, and the temporal average is the sum of the individual temporal averages. *Coherence theory* allows the interference between the light from two point sources to be analyzed, and a good visual model is an extended source illuminating the two pinholes in Young's double slit. We need to determine the relationship between the light transmitted through the two pinholes. Coherence theory also accounts for the effects of the spectral bandwidth of the source.

With interference by division of amplitude using an extended source, the light from many point sources is combined at the observation point, and the geometry of the interferometer determines where the fringes are localized. Coherence theory will, however, predict the spectral bandwidth effects for division of amplitude interference. Each point on the source is interfered with an image of that same point. The temporal coherence function relates the interference of these two points independently of other points on the source. The visibility function for the individual interference pattern due to these two points is computed, and the net pattern is the sum of these patterns for the entire source. The temporal coherence effects in division of amplitude interference are handled on a point-by-point basis across the source.

In this section, the fundamentals of coherence theory as it relates to interference are introduced. Much more detail on this subject can be found in Chap. 5, "Coherence Theory."

Mutual Coherence Function

We will consider the interference of light from two point sources or pinholes. This light is derived from a common origin so that there may be some relationship between the complex fields at the two sources. We will represent these amplitudes at the pinholes as $E_1(t)$ and $E_2(t)$, as shown in Fig. 24. The propagation times between the two sources and the observation point are t_1 and t_2,

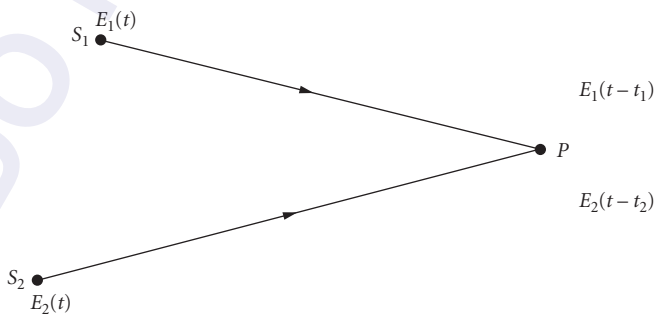

FIGURE 24 Geometry for examining the mutual coherence of two sources.

where the times are related to the optical path lengths by $t_i = \mathrm{OPL}_i/c$. The two complex amplitudes at the observation point are then $E_1(t - t_1)$ and $E_2(t - t_2)$, where the amplitudes have been scaled to the observation plane. The time-average intensity at the observation point can be found by returning to Eq. (13), which is repeated here with the time dependence:

$$I = I_1 + I_2 + \langle E_1(t-t_1)E_2^*(t-t_2)\rangle + \langle E_1^*(t-t_1)E_2(t-t_2)\rangle \tag{72}$$

where I_1 and I_2 are the intensities due to the individual sources. If we now shift our time origin by t_2, we obtain

$$I = I_1 + I_2 + \langle E_1(t+\tau)E_2^*(t)\rangle + \langle E_1^*(t+\tau)E_2(t)\rangle \tag{73}$$

where

$$\tau = t_2 - t_1 = \frac{\mathrm{OPL}_2 - \mathrm{OPL}_1}{c} = \frac{\mathrm{OPD}}{c} \tag{74}$$

The difference in transit times for the two paths is τ. The last two terms in the expression for the intensity are complex conjugates, and they contain the interference terms.

We will now define the *mutual coherence function* $\Gamma_{12}(\tau)$:

$$\Gamma_{12}(\tau) = \langle E_1(t+\tau)E_2^*(t)\rangle \tag{75}$$

which is the cross correlation of the two complex amplitudes. With this identification, the intensity of the interference pattern is

$$I = I_1 + I_2 + \Gamma_{12}(\tau) + \Gamma_{12}^*(\tau) \tag{76}$$

or, recognizing that a quantity plus its complex conjugate is twice the real part,

$$I = I_1 + I_2 + 2\,\mathrm{Re}\{\Gamma_{12}(\tau)\} \tag{77}$$

It is convenient to normalize the mutual coherence function by dividing by the square root of the product of the two self-coherence functions. The result is the *complex degree of coherence:*

$$\gamma_{12}(\tau) = \frac{\Gamma_{12}(\tau)}{\sqrt{\Gamma_{11}(0)\Gamma_{22}(0)}} = \frac{\Gamma_{12}(\tau)}{\sqrt{\langle |E_1(t)|^2\rangle\langle |E_1(t)|^2\rangle}} = \frac{\Gamma_{12}(\tau)}{\sqrt{I_2 I_2}} \tag{78}$$

and the intensity can be rewritten:

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\,\mathrm{Re}\{\gamma_{12}(\tau)\} \tag{79}$$

We can further simplify the result by writing $\gamma_{12}(\tau)$ as a magnitude and a phase:

$$\gamma_{12}(\tau) = |\gamma_{12}(\tau)|e^{i\phi_{12}(\tau)} = |\gamma_{12}(\tau)|e^{i[\alpha_{12}(\tau) - \Delta\phi(\tau)]} \tag{80}$$

where $\alpha_{12}(\tau)$ is associated with the source, and $\Delta\phi(\tau)$ is the phase difference due to the OPD between the two sources and the observation point [Eq. (18)]. The quantity $|\gamma_{12}(\tau)|$ is known as the *degree of coherence.* The observed intensity is therefore

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\,|\gamma_{12}(\tau)|\cos[\alpha_{12}(\tau) - \Delta\phi(\tau)] \tag{81}$$

The effect of $\alpha_{12}(\tau)$ is to add a phase shift to the intensity pattern. The fringes will be shifted. A simple example of this situation is Young's double-slit experiment illuminated by a tilted plane wave or a decentered source. With quasi-monochromatic light, the variations of both $|\gamma_{12}(\tau)|$ and $\alpha_{12}(\tau)$ with τ are slow with respect to changes of $\Delta\phi(\tau)$, so that the variations in the interference pattern in the observation plane are due primarily to changes in $\Delta\phi$ with position.

A final rewrite of Eq. (81) leads us to the intensity pattern at the observation point:

$$I = I_0\left\{1+\frac{2\sqrt{I_1 I_2}}{I_1+I_2}|\gamma_{12}(\tau)|\cos[\alpha_{12}(\tau)-\Delta\phi(\tau)]\right\} \tag{82}$$

where $I_0 = I_1 + I_2$. The fringe visibility is therefore

$$\gamma(\tau) = \frac{2\sqrt{I_1 I_2}}{I_1+I_2}|\gamma_{12}(\tau)| \tag{83}$$

and is a function of the degree of coherence and τ. Remember that τ is just the temporal measure of the OPD between the two sources and the observation point. If the two intensities are equal, the fringe visibility is simply the degree of coherence: $\gamma(\tau) = |\gamma_{12}(\tau)|$. The degree of coherence will take on values between 0 and 1. The source is *coherent* when $|\gamma_{12}(\tau)| = 1$, and completely incoherent when $|\gamma_{12}(\tau)| = 0$. The source is said to be *partially coherent* for other values. No fringes are observed with an incoherent source, and the visibility is reduced with a partially coherent source.

Spatial Coherence

The spatial extent of the source and its distance from the pinholes will determine the visibility of the fringes produced by the two pinhole sources (see Fig. 25). Each point on the source will produce a set of Young's fringes, and the position of this pattern in the observation plane will shift with source position. The value of $\alpha_{12}(\tau)$ changes with source position. The existence of multiple shifted patterns will reduce the overall visibility. As an example, consider a quasi-monochromatic source that consists of a several point sources arranged in a line. Each produces a high modulation fringe pattern in the observation plane (Fig. 26*a*), but there is a lateral shift between each pattern. The net pattern shows a fringe with the same period as the individual patterns, but it has a reduced modulation due to the shifts (Fig. 26*b*). This reduction in visibility can be predicted by calculating the degree of coherence $|\gamma_{12}(\tau)|$ at the two pinholes.

Over the range of time delays between the interfering beams that are usually of interest, the degree of coherence is a slowly varying function and is approximately equal to the value at $\tau = 0 : |\gamma_{12}(\tau)| = |\gamma_{12}(0)| = |\gamma_{12}|$. The *van Cittert–Zernike theorem* allows the degree of coherence in the geometry of Fig. 25 to be calculated. Let θ be the angular separation of the two pinholes as seen

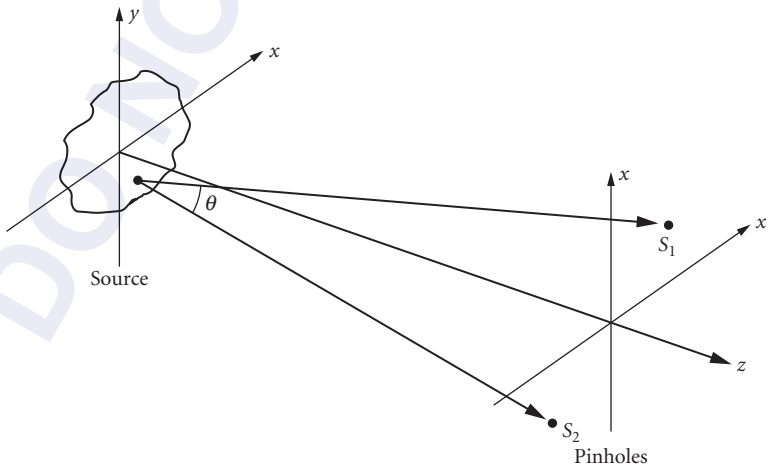

FIGURE 25 An extended source illuminating two pinholes.

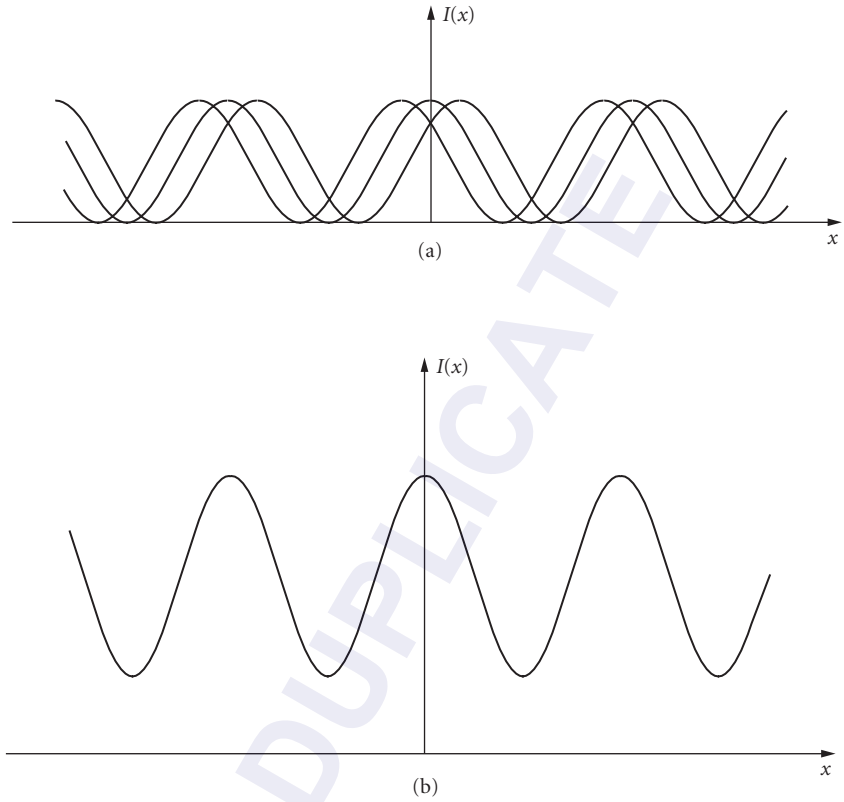

FIGURE 26 The interference pattern produced by a linear source: (*a*) the individual fringe patterns and (*b*) the net fringe pattern with reduced visibility.

from the source. This theorem states that degree of coherence between two points is the modulus of the scaled and normalized Fourier transform of the source intensity distribution:

$$|\gamma_{12}| = \left| \frac{\iint_S I(\xi,\eta) e^{i(2\pi/\lambda)(\xi\theta_x + \eta\theta_y)} d\xi\, d\eta}{\iint_S I(\xi,\eta) d\xi\, d\eta} \right| \tag{84}$$

where θ_x and θ_y are the x and y components of the pinhole separation θ, and the integral is over the source.

Two cases that are of particular interest are a slit source and a circular source. The application of the van Cittert–Zernike theorem yields the two coherence functions:

$$\text{Slit source of width } w: \quad |\gamma_{12}| = \left| \operatorname{sinc}\left(\frac{w\theta_x}{\lambda}\right) \right| = \left| \operatorname{sinc}\left(\frac{wa}{\lambda z}\right) \right| \tag{85}$$

$$\text{Circular source of diameter } d: \quad |\gamma_{12}| = \left| \frac{2J_1\left(\dfrac{\pi d\theta_x}{\lambda}\right)}{\dfrac{\pi d\theta_x}{\lambda}} \right| = \left| \frac{2J_1\left(\dfrac{\pi da}{\lambda z}\right)}{\dfrac{\pi da}{\lambda z}} \right| \tag{86}$$

where a is the separation of the pinholes, z is the distance from the source to the pinholes, the sinc function is defined by Eq. (42), and J_1 is a first-order Bessel function. The pinholes are assumed to be located on the x axis. These two functions share the common characteristic of a central core surrounded by low-amplitude side lobes. We can imagine these functions of pinhole spacing mapped onto the aperture plane. The coherence function is centered on one of the pinholes. If the other pinhole is then within the central core, high-visibility fringes are produced. If the pinhole spacing places the second pinhole outside the central core, low-visibility fringes result.

Michelson Stellar Interferometer

The *Michelson stellar interferometer* measures the diameter of stars by plotting out the degree of coherence due to the light from the star. The system is shown in Fig. 27. Two small mirrors separated by the distance a sample the light and serve as the pinholes. The spacing between these mirrors can be varied. This light is then directed along equal path lengths into a telescope, and the two beams interfere in the image plane. To minimize chromatic effects, the input light should be filtered to a small range of wavelengths. The modulation of the fringes is measured as a function of the mirror spacing to measure the degree of coherence in the plane of the mirrors. This result will follow

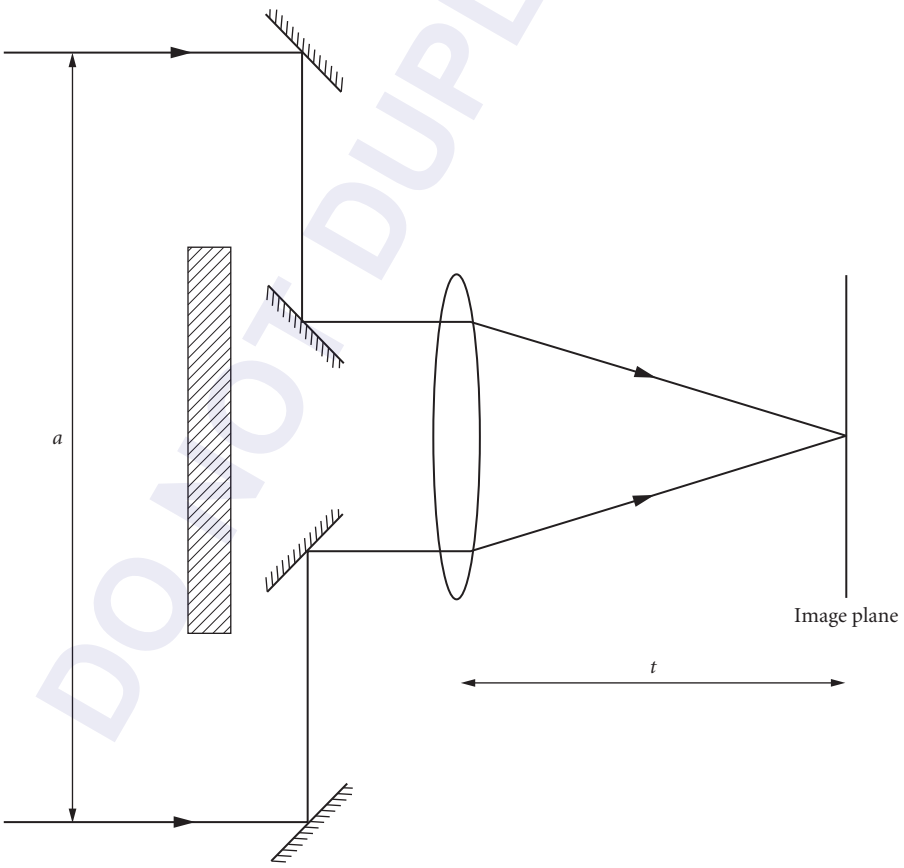

FIGURE 27 Michelson stellar interferometer.

Eq. (86) for a circular star, and the fringe visibility will go to zero when $a = 1.22\lambda\alpha$, where $\alpha = d/z$ is the angular diameter of the star. We measure the mirror separation that produces zero visibility to determine α. In a similar manner, this interferometer can be used to measure the spacing of two closely spaced stars.

Temporal Coherence

When examining temporal coherence effects, we use a source of small dimensions (a point source) that radiates over a range of wavelengths. The light from this source is split into two beams and allowed to interfere. One method to do this is to use an amplitude-splitting interferometer. Since the two sources are identical, the mutual coherence function becomes the *self-coherence function* $\Gamma_{11}(\tau)$. Equal-intensity beams are assumed. The complex degree of temporal coherence becomes

$$\gamma_{11}(\tau) = \frac{\Gamma_{11}(\tau)}{\Gamma_{11}(0)} = \frac{\langle E_1(t+\tau)E_1^*(t)\rangle}{\langle |E_1(t)|^2\rangle} \tag{87}$$

After manipulation, it follows from this result that $\gamma_{11}(\tau)$ is the normalized Fourier transform of the source intensity spectrum $S(\nu)$:

$$\gamma_{11}(\tau) = \frac{FT\{S(\nu)\}}{\int_0^\infty S(\nu)d\nu} = \frac{\int_0^\infty S(\nu)e^{i2\pi\nu t}dx}{\int_0^\infty S(\nu)d\nu} \tag{88}$$

The fringe visibility is the modulus of this result. Since $\gamma_{11}(\tau)$ has a maximum at $\tau = 0$, the maximum fringe visibility will occur when the time delay between the two beams is zero. This is consistent with our earlier observation under "Source Spectrum" that the fringes will be localized in the vicinity of zero OPD.

As an example, we will repeat the earlier problem of a uniform source spectrum:

$$S(\nu) = \text{rect}\left(\frac{\nu - \nu_0}{\Delta\nu}\right) \tag{89}$$

where ν_0 is the average frequency and $\Delta\nu$ is the bandwidth. The resulting intensity pattern is

$$I = I_0\{1 + \text{Re}\{\gamma_{12}(\tau)\}\} = I_0[1 + \text{sinc}(\tau\Delta\nu)\cos(2\pi\tau\nu_0)] \tag{90}$$

where the sinc function is the Fourier transform of the rect function. Using $\tau = \text{OPD}/c$ from Eq. (74), we can rewrite this equation in terms of the OPD to obtain the same result expressed in Eq. (47).

Laser Sources

The laser is an important source for interferometry, as it is a bright source of coherent radiation. Lasers are not necessarily monochromatic, as they may have more than one longitudinal mode, and it is important to understand the unique temporal coherence properties of a laser in order to get good fringes. The laser is a Fabry-Perot cavity that contains a gain medium. Its output spectrum is therefore a series of discrete frequencies separated by $c/2nL$, where L is the cavity length. For gas lasers, the index is approximately equal to one, and we will use this value for the analysis. If $G(\nu)$ is the gain bandwidth, the frequency spectrum is

$$S(\nu) = G(\nu)\,\text{comb}\left(\frac{2L\nu}{c}\right) \tag{91}$$

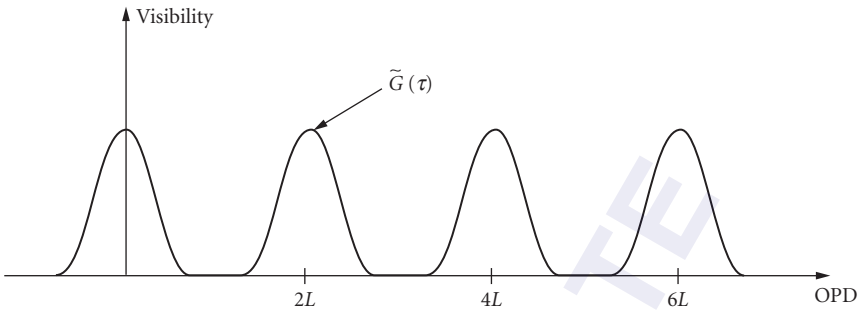

FIGURE 28 The fringe visibility versus OPD for a laser source.

where a comb function is a series of equally spaced delta functions. The number of modes contained under the gain bandwidth can vary from 1 or 2 up to several dozen. The resulting visibility function can be found by using Eq. (88):

$$\gamma(\tau)=|\gamma_{11}(\tau)|=\left|\tilde{G}(\tau)*\mathrm{comb}\left(\frac{c\tau}{2L}\right)\right|=\left|\tilde{G}(\tau)*\mathrm{comb}\left(\frac{\mathrm{OPD}}{2L}\right)\right| \tag{92}$$

where $\tilde{G}(\tau)$ is the normalized Fourier transform of the gain bandwidth, and $*$ indicates convolution. This result is plotted in Fig. 28, where $\tilde{G}(\tau)$ is replicated at multples of $2L$. The width of these replicas is inversely proportional to the gain bandwidth. We see that as long as the OPD between the two optical paths is a multiple of twice the cavity length, high-visibility fringes will result. This condition is independent of the number of longitudinal modes of the laser. If the laser emits a single frequency, it is a coherent source and good visibility results for any OPD.

2.9 APPLICATIONS OF INTERFERENCE

The fundamental measurement unit associated with interference is the wavelength of light. Every time the OPD in the system changes by one wave, an additional fringe is produced. Because of this sensitivity, interferometers find widespread use in many metrology and optical testing applications. Many of these applications are detailed in subsequent chapters of this *Handbook,* including Chap. 32, "Interferometers," in this volume, and Chap. 12, "Optical Metrology," and Chap. 13, "Optical Testing," in Vol. II. The applications of interferometry include distance and angle measurement, surface figure and finish metrology, profilometry, and spectroscopy. Techniques such as phase-shifting interferometry, heterodyne interferometry, and stitching interferometry have enabled the analysis of the interference patterns associated with the many interferometric measurement techniques in use.

The use of lasers in interferometers has greatly increased their utility. Because of their long coherence length, interference fringes can be produced even when there is a large OPD between the two interfering beams. Instruments such as the Tywman-Green interferometer and the laser-Fizeau interferometer can be used in a compact form to test very large optical surfaces.

3.2 INTRODUCTION

Starting with waves as solutions to the wave equation obtained from Maxwell's equations, the basics of diffraction of light are covered in this chapter. The discussion includes those applications where the geometry permits analytical solutions. At appropriate locations references are given to the literature and/or textbooks for further reading. The discussion is limited to an explanation of diffraction, and how it may be found in some simple cases with plots of fringe structure.

3.3 LIGHT WAVES

Light waves propagate through free space or a vacuum. They exhibit the phenomenon of diffraction with every obstacle they encounter. Maxwell's equations form a theoretical basis for describing light in propagation, diffraction, scattering and, in general, its interaction with material media. Experience has shown that the electric field **E** plays a central role in detection of light and interaction of light with matter. We begin with some mathematical preliminaries.

The electric field **E** obeys the wave equation in free space or vacuum:

$$\nabla^2\mathbf{E}-\frac{1}{c^2}\frac{\partial^2\mathbf{E}}{\partial t^2}=0 \tag{1}$$

where c is the velocity of light in vacuum. Each Cartesian component $\mathbf{E}_j$ ($j = x, y, z$) obeys the equation and, as such, we use a scalar function $\psi(\mathbf{r}, t)$ to denote its solutions, where the radius vector $\mathbf{r}$ has components, $\mathbf{r}=\hat{i}x+\hat{j}y+\hat{k}z$. The wave equation is a linear second-order partial differential equation. Linear superposition of its linearly independent solutions offers the most general solution. It has traveling plane waves, spherical waves, and cylindrical waves as examples of its solutions. These solutions represent optical wave forms. A frequently used special case of these solutions is the time harmonic version of these waves. We start with the Fourier transform on time,

$$\psi(\mathbf{r}, t) = \int\hat{\psi}(\mathbf{r}, \nu)\exp(-i2\pi\nu t)d\nu \tag{2}$$

where ν is a temporal (linear) frequency in hertz. The spectrum $\hat{\psi}(\vec{r}, \nu)$ obeys the Helmholtz equation,

$$\nabla^2\hat{\psi}+k^2\hat{\psi}=0 \tag{3}$$

with the propagation constant $k = 2\pi/\lambda = 2\pi\nu/c = \omega/c$, where λ is the wavelength and ω is the circular frequency. A Fourier component traveling in a medium of refractive index $n=\sqrt{\varepsilon}$, where ε is the dielectric constant, is described by the Helmholtz equation with k^2 replaced by n^2k^2. As a further special case, a plane wave may be harmonic in time as well as in space.

$$\psi(\mathbf{r}, t)=A\cos(\mathbf{k}\cdot\mathbf{r}-\omega t) \tag{4}$$

where $\mathbf{k}\equiv k\hat{s}$, $\hat{s}$ is a unit vector in the direction of propagation, and A is a constant. An expanding spherical wave may be written in the form

$$\psi(r, t)=\frac{A}{r}\cos(kr-\omega t) \tag{5}$$

For convenience of operations, a complex function is frequently used. For example, we write

$$\psi(\mathbf{r}, t)=A\exp[i(\mathbf{k}\cdot\mathbf{r}-\omega t)] \tag{6}$$

in place of Eq. (4) bearing in mind that only its real part corresponds to the optical wave form. The function $\psi(\mathbf{r}, t)$ is called the optical "disturbance" while the coefficient A is the amplitude.

In the general discussion of diffraction phenomenon throughout this chapter several classic source books have been used.[1–10] This discussion is a blend of ideas contained in these sources.

The mathematical solutions described heretofore, although ideal, are nevertheless often approximated in practice. A suitable experimental arrangement with a self-luminous source and a condensing lens to feed light to a small enough pinhole fitted with a narrowband spectral filter serves as a quasi-monochromatic, or almost monochromatic, point source. In Fig. 1, light behind the pinhole S is in the form of ever-expanding spherical waves. These waves are of limited spatial extent; all are

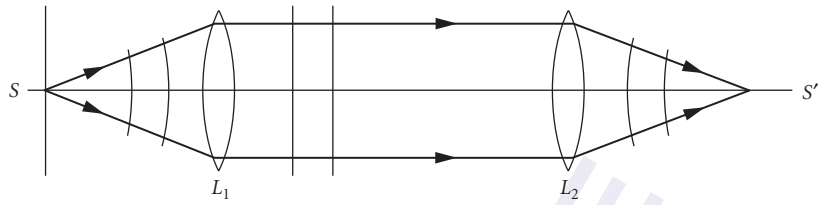

FIGURE 1 Experimental layout to describe the notation used for spherical and plane waves. *S*: pinhole source. L_1, L_2: lenses. *S′*: image.

approximately contained in a cone with its apex at the pinhole. When intercepted by a converging lens L_1, with the pinhole on its axis and at the front focal point, these spherical waves are converted to plane waves behind L_1. These plane waves also are limited spatially to the extent dictated by the aperture of the converging lens. A second converging lens, L_2, is behind the first converging lens and is oriented so that both lenses have a common optical axis and can form an image of the pinhole. The image S' is on the axis at the focal point behind the second lens and is formed by converging spherical waves. These waves, which converge toward the image, are limited spatially to the extent dictated by the aperture of the second lens and are approximately contained in a cone with its apex at the image of the pinhole.

It is necessary to clarify that "a small enough pinhole" means that the optics behind the pinhole are not able to resolve its structure.[1] A "narrowband filter" means that its pass band $\Delta\nu$ is much smaller than the mean frequency $\bar{\nu}$, that is, $\Delta\nu \ll \bar{\nu}$. In this situation, the experimental arrangement may be described by a quasi-monochromatic theory, provided that the path differences Δl of concern in the optics that follow the pinhole are small enough, as given by, $\Delta l \leq c/\Delta\nu$. If the path differences Δl involved are unable to obey this condition, then a full polychromatic treatment of the separate Fourier components contained within $\Delta\nu$ is necessary, even if $\Delta\nu \ll \bar{\nu}$. See, for example, Beran and Parrent[11] and Marathay.[12]

Limiting the extent of plane waves and spherical waves, as discussed before, causes diffraction, a topic of primary concern in this chapter. The simplifying conditions stated above are assumed to hold throughout the chapter, unless stated otherwise.

As remarked earlier, the electric field $\mathbf{E}$ $[V/m]$ plays a central role in optical detection. There are detectors that attain a steady state for constant incident beam power $[W]$, and there are those like the *photographic plate* that integrate the incident power over a certain time. For a constant beam power, the darkening of the photographic plate depends on the product of the power and exposure time. Since detectors inherently take the time average, the quantity of importance is the average radiant power $[W]$. Furthermore, light beams have a finite cross-sectional area, so it is meaningful to talk about the average power in the beam per unit area of its cross-section measured in square meters or square centimeters. In the standard radiometric nomenclature, this sort of measurement is called *irradiance, E* $[Wcm^{-2}]$. For a plane wave propagating in free space, the irradiance may be expressed in terms of the Poynting vector $\mathbf{S}$ by

$$E = \langle \mathbf{S} \rangle = \left(\frac{1}{2}\right)\left(\frac{\epsilon_0}{\mu_0}\right)^{1/2} \langle \mathbf{E} \cdot \mathbf{E} \rangle \tag{7}$$

The constants given in Eq. (7) may not be displayed with every theoretical result. The Poynting vector and irradiance are discussed further in Ref. 12 (pp. 280–285).

Light is properly described by a transverse vector field. Nevertheless, a scalar field is a convenient artifice to use in understanding the wave nature of light without the added complication of the vector components. The transverse nature of the field will be accounted for when the situation calls for it.

3.4 HUYGENS-FRESNEL CONSTRUCTION

Without the benefit of a fundamental theory based on Maxwell's equations and the subsequent mathematical development, Huygens sought to describe wave propagation in the days before Maxwell. Waves are characterized by constant-phase surfaces called *wavefronts.* If the initial shape at time t of such a wavefront is known in a vacuum or in any medium, Huygens proposed a geometrical construction to obtain its shape at a later time, $t + \Delta t$. He regarded each point of the initial wavefront as the origin of a new disturbance that propagates in the form of secondary wavelets in all directions with the same speed as the speed of propagation of the initial wave in the medium. These secondary wavelets of radii $c\Delta t$ are constructed at each point of the initial wavefront. A surface tangential to all these secondary wavelets, called the *envelope* of all these wavelets, is then the shape and position of the wavefront at time $t + \Delta t$. With this construct, Huygens explained the phenomena of reflection and refraction of the wavefront. To explain the phenomenon of diffraction, Fresnel modified Huygens' construction by attributing the property of mutual interference to the secondary wavelets. The modified Huygens' construction is called the Huygens-Fresnel construction. With further minor modifications it helps explain the phenomenon of diffraction and its various aspects, including those that are not so intuitively obvious.

Fresnel Zones

Let P_0 be a point source of light that produces monochromatic spherical waves. A typical spherical wave, $A/r_0 \exp[-i(\omega t - kr_0)]$, of radius r_0 at time t is shown in Fig. 2. The coefficient A stands for the amplitude of the wave at unit distance from the source P_0. At a later time this wave will have progressed to assume a position passing through a point of observation P with radius, $r_0 + b$. Fresnel zone construction on the initial wave offers a way to obtain the wave in the future by applying the Huygens-Fresnel construction. The zone construction forms a simple basis for studying and understanding diffraction of light.

From the point of observation P, we draw spheres of radii b, $b + \lambda/2$, $b + 2\lambda/2$, $b + 3\lambda/2, \ldots$, $b + j\lambda/2, \ldots$, to mark zones on the wave in its initial position, as shown in Fig. 2. The zones are

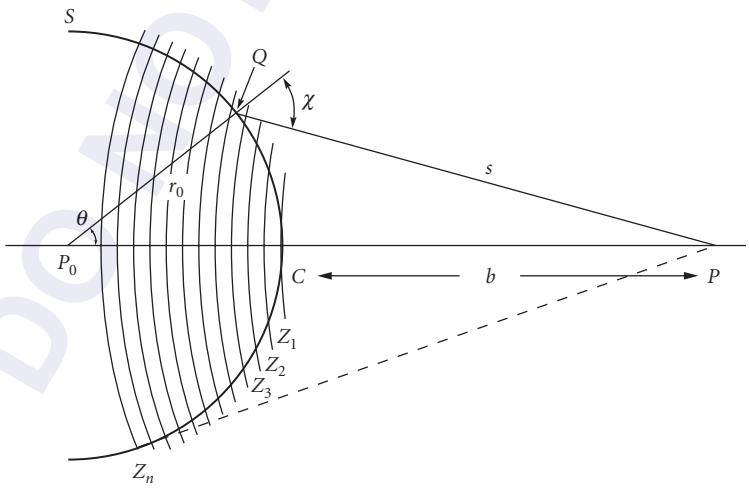

FIGURE 2 Fresnel zone construction. P_0: point source. S: wavefront. r_0: radius of the wavefront. b: distance CP. s: distance QP. (*After Born and Wolf.*[1])

labeled z_1, z_2,… z_j. The zone boundaries are successively half a wavelength away from the point of observation *P*. By the Huygens-Fresnel construction, each point of the wave forms a source of a secondary disturbance. Each secondary source produces wavelets that are propagated to the point *P*. A linear superposition of the contribution of all such wavelets yields the resulting amplitude at the point *P*. It is reasonable to expect that the contribution of the secondary wavelets is not uniform in all directions. For example, a wavelet at *C* is in line with the source P_0 and the point of observation *P*, while a wavelet at *Q* sees the point *P* at an angle χ with respect to the radius vector from the source P_0.

To account for this variation, an obliquity or inclination factor $K(\chi)$ is introduced. In the phenomenological approach developed by Fresnel, no special form of $K(\chi)$ is used. It is assumed to have the value unity at *C* where $\chi = 0$, and it is assumed to decrease at first slowly and then rapidly as χ increases. The obliquity factors for any two adjacent zones are nearly equal and it is assumed that it becomes negligible for zones with high enough index *j*.

The total contribution to the disturbance at *P* is expressed as an area integral over the primary wavefront,

$$\psi(P) = A\frac{\exp[-i(\omega t - kr_0)]}{r_0}\iint_s \frac{\exp(iks)}{s}K(\chi)dS \tag{8}$$

where *dS* is the area element at *Q*. The subscript *S* on the integrals denotes the region of integration on the wave surface. The integrand describes the contribution of the secondary wavelets. Fresnel-zone construction provides a convenient means of expressing the area integral as a sum over the contribution of the zones.

For optical problems, the distances involved, such as r_0 and *b*, are much larger than the wavelength λ. This fact is used very effectively in approximating the integral. The phases of the wavelets within a zone will not differ by more than π. The zone boundaries are successively $\lambda/2$ further away from the point of observation *P*. The average distance of successive zones from *P* differs by $\lambda/2$; the zones, therefore, are called half-period zones. Thus, the contributions of the zones to the disturbance at *P* alternate in sign,

$$\psi(P) = \psi_1 - \psi_2 + \psi_3 - \psi_4 + \psi_5 - \psi_6 + \cdots \tag{9}$$

where *j* stands for the contribution of the *j*th zone, $j = 1, 2, 3, \ldots$. The contribution of each annular zone is directly proportional to the zone area and is inversely proportional to the average distance of the zone to the point of observation *P*. The ratio of the zone area to its average distance from *P* is independent of the zone index *j*. Thus, in summing the contributions of the zones we are left with only the variation of the obliquity factor $K(\chi)$. To a good approximation, the obliquity factors for any two adjacent zones are nearly equal and for a large enough zone index *j* the obliquity factor becomes negligible. The total disturbance at the point of observation *P* may be approximated by

$$\psi(P) = 1/2(\psi_1 \pm \psi_n) \tag{10}$$

where the index *n* stands for the last zone contributing to *P*. The ± sign is taken according to whether *n* is odd or even. For an unobstructed wave, the integration is carried out over the whole spherical wave. In this case, the last term ψ_n is taken to be zero. Thus, the resulting disturbance at the point of observation *P* equals one-half of the contribution of the first Fresnel zone,

$$\psi(P) = 1/2\psi_1 \tag{11}$$

The contribution ψ_1 is found by performing the area integral of Eq. (8) over the area of the first zone. The procedure results in

$$\psi(P) = \frac{A}{r_0 + b}\lambda \ \exp\{-i[\omega t - k(r_0 + b) - \pi/2]\} \tag{12}$$

whereas a freely propagating spherical wave from the source P_0 that arrives at point P is known to have the form

$$\psi(P)=\frac{A}{r_0+b}\exp\{-i[\omega t-k(r_0+b)]\} \tag{12′}$$

The synthesized wave of Eq. (12) can be made to agree with this fact, if one assumes that the complex amplitude of the secondary waves, $\exp(iks)/s$ of Eq. (8) is $[1/\lambda \exp(-i\pi/2)]$ times the primary wave of unit amplitude and zero phase. With the time dependence $\exp(-i\omega t)$, the secondary wavelets are required to oscillate a quarter of a period ahead of the primary.

The synthesis of propagation of light presented above has far-reaching consequences. The phenomenon of light diffraction may be viewed as follows. Opaque objects that interrupt the free propagation of the wave block some or parts of zones. The zones, or their portions that are unobstructed, contribute to the diffraction amplitude (disturbance) at the point of observation *P.* The obstructed zones do not contribute.

Diffraction of Light from Circular Apertures and Disks

Some examples of unobstructed zones are shown in Fig. 3. Suppose a planar opaque screen with a circular aperture blocks the free propagation of the wave. The center *C* of the aperture is on the axis joining the source point *S* and the observation point *P,* as shown in Fig. 4. The distance and the size of the aperture are such that, with respect to point *P,* only the first two zones are uncovered as in Fig. 3*a.* To obtain the diffraction amplitude for an off-axis point such as *P,* one has to redraw the zone structure as in Fig. 4. Figure 3*b* shows the zones and parts of zones uncovered by the circular aperture in this case. Figure 3*c* shows the uncovered zones for an irregularly shaped aperture.

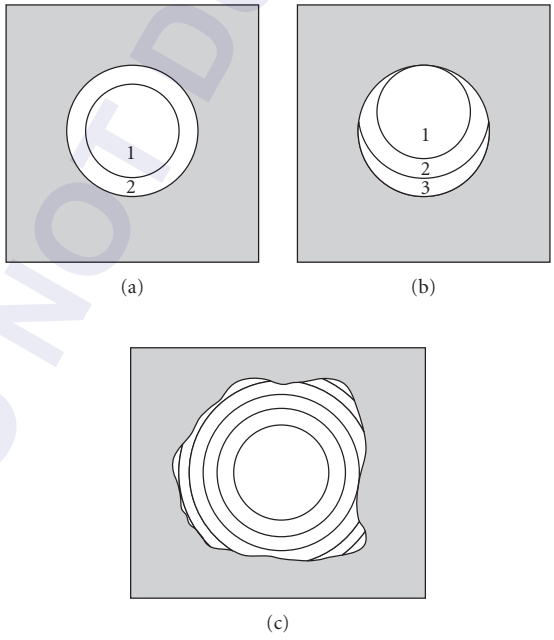

FIGURE 3 Some examples of unobstructed Fresnel zones that contribute to the amplitude at the observation point *P.* (*After Andrews.*[9])

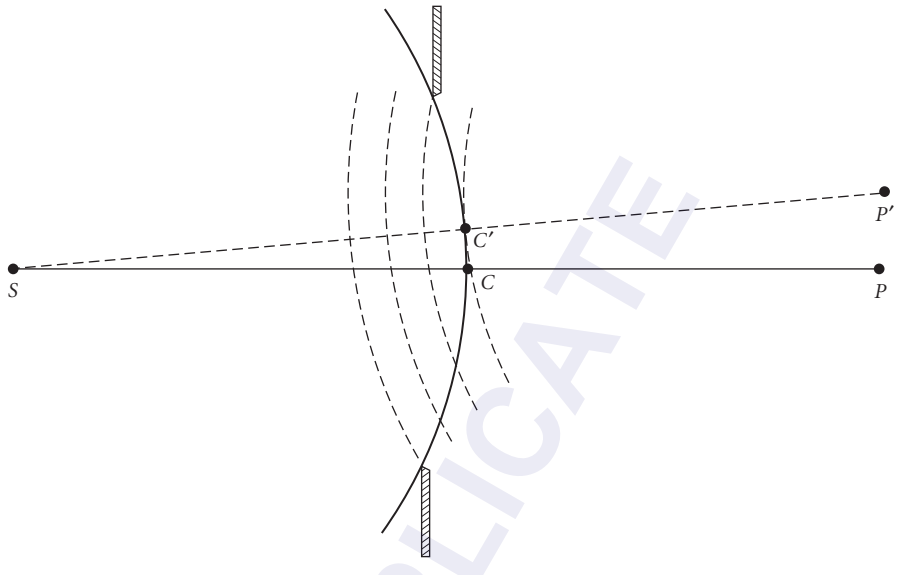

FIGURE 4 The redrawn zone structure for use with an off-axis point P'. (*After Andrews.*[9])

In Fig. 3*a* the first two zones are uncovered. Following Eq. (9), the resulting diffraction amplitude at P for this case is

$$\psi(P) = \psi_1 - \psi_2 \tag{13}$$

but, since these two contributions are nearly equal, the resulting amplitude is $\psi(P) = 0$!

Relocating point P necessitates redrawing the zone structure. The first zone may just fill the aperture if point P is placed farther away from it. In this case the resulting amplitude is

$$\psi(P) = \psi_1 \tag{14}$$

which is twice what it was for the unobstructed wave! Therefore the irradiance is four times as large!

On the other hand, if the entire aperture screen is replaced by a small opaque disk, the irradiance at the center of the geometrical shadow is the same as that of the unobstructed wave! To verify this, suppose that the disk diameter and the distance allows only one Fresnel zone to be covered by the disk. The rest of the zones are free to contribute and *do* contribute. Per Eq. (9) we have

$$\psi(P) = -\psi_2 + \psi_3 - \psi_4 + \psi_5 - \psi_6 + \cdots$$

The discussion after Eq. (9) also applies here and the resulting amplitude on the axis behind the center of the disk is

$$\psi(P) = -\frac{1}{2}\psi_2 \tag{15}$$

which is the same as the amplitude of the unobstructed wave. Thus, the irradiance is the same at point P as though the wave were unobstructed. As the point P moves farther away from the disk, the radius of the first zone increases and becomes larger than the disk.

Alternatively one may redraw the zone structure starting from the edge of the disk. The analysis shows that the point P continues to be a bright spot of light. As the point P moves closer to the disk, more and more Fresnel zones get covered by the disk, but the analysis continues to predict a bright spot at P. There comes a point where the unblocked zone at the edge of the disk is significantly weak; the point P continues to be bright but has reduced irradiance. Still closer to the disk, the analysis ceases to apply because P enters the near-field region, where the distances are comparable to

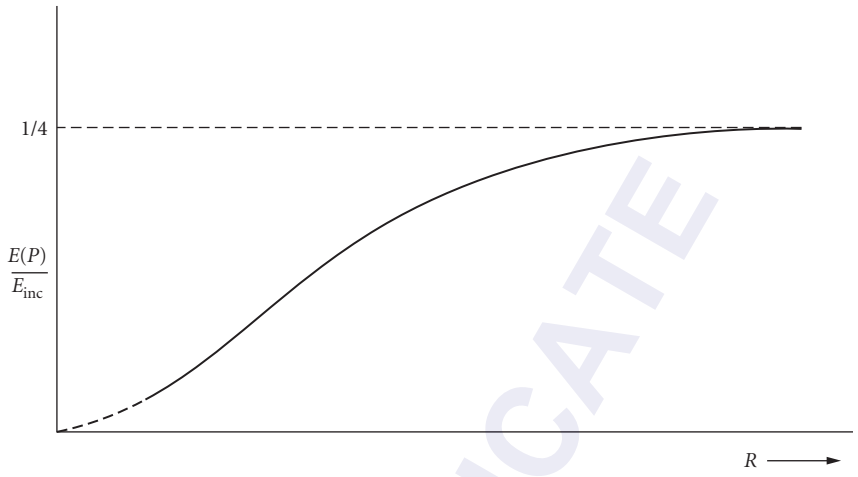

FIGURE 5 Variation of on-axis irradiance behind an opaque disk. *R*: distance along the axis behind the disk. (*From Marion and Heald.*[5])

the size of the wavelength. In Fig. 5, the variation of irradiance on the axial region behind the disk is shown. It is remarkable that the axial region is nowhere dark! For an interesting historical note, see Refs. 1 and 5.

For comparison, we show the variation of on-axis irradiance behind a circular opening in Fig. 6. It shows several on-axis locations where the irradiance goes to zero. These correspond to the situation where an even number of zones are exposed through the circular aperture. Only the first few zeros are shown, since the number of zeros per unit length (linear density) increases as the point *P* is moved closer to the aperture. The linear density increases as the square of the index *j* when *P* moves

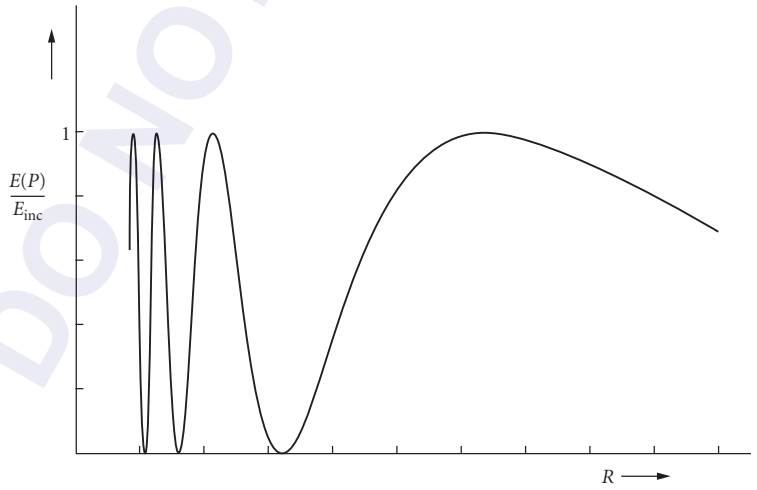

FIGURE 6 Variation of on-axis irradiance behind a circular opening. *R*: distance along the axis behind the opening. (*From Marion and Heald.*[5])

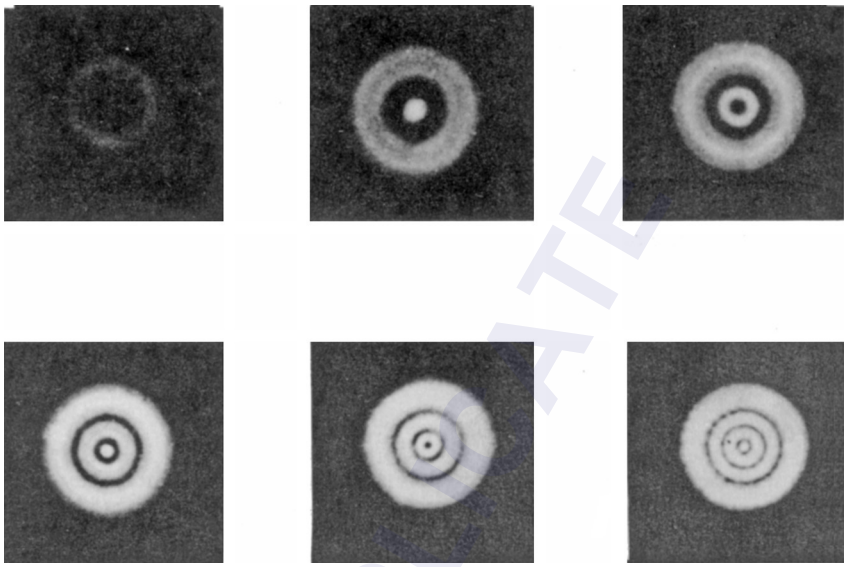

FIGURE 7 A series of pictures of diffraction patterns from circular apertures. (*After Andrews.*[9])

closer to the aperture. While far enough away, there comes a point where the first zone fills the aperture and, thereafter, there are no more zeros as the distance increases.

Figure 7 shows a series of diffraction patterns from a circular aperture. The pictures are taken at different distances from the aperture to expose one, two, three, etc., zones. Each time an odd number of zones is uncovered the center spot becomes bright. As we approach the pictures at the bottom right, more zones are exposed.

Babinet Principle

Irradiances for the on-axis points are quite different for the circular disk than for the screen with a circular opening. The disk and the screen with a hole form of a pair of complementary screens, that is, the open areas of one are the opaque areas of the other and vice versa. Examples of pairs of such complementary screens are shown in Fig. 8. Observe that the open areas of screen S_a taken with the open areas of the complementary screen S_b add up to no screen at all.

The Babinet principle states that the wave disturbance $\psi_S(P)$ at any point of observation P due to a diffracting screen S_a added to the disturbance $\psi_{\text{CS}}(P)$ due to the complementary screen S_b at the same point P equals the disturbance at P due to the unobstructed wave, that is,

$$\psi_S(P)+\psi_{\text{CS}}(P)=\psi_{\text{UN}}(P) \tag{16}$$

Recall that the wave disturbance at any point of observation P behind the screen is a linear superposition of the contributions of the unobstructed zones or portions thereof. This fact, with the observation that the open areas of screen S_a taken with the open areas of the complementary screen S_b add up to no screen at all, implies the equality indicated by the Babinet principle.

The application of Babinet's principle to diffraction problems can reduce the complexity of the analysis considerably. For an example of this, we once again return to diffraction of light due to a circular aperture and an opaque disk. For on-axis amplitude, the Rayleigh-Sommerfeld diffraction integral [see Eq. (43) later] can be evaluated in closed form.[6]

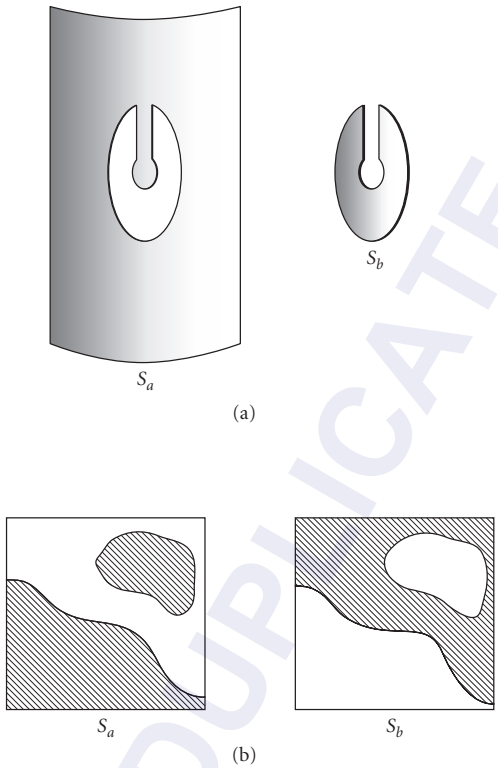

FIGURE 8 Examples of complementary screens, labeled S_a and S_b. (*After Jackson*[13] *and Andrews*.[9])

A circular aperture of radius a in a dark screen is illuminated by a normally incident plane wave, $A\exp(ikz)$, where z is the axis perpendicular to the plane of the aperture. The on-axis diffracted field ψ_{cir} is

$$\psi_{\text{cir}}(z) = A\exp(ikz) - \frac{Az}{\sqrt{a^2+z^2}}\exp\left(ik\sqrt{a^2+z^2}\right) \tag{17}$$

The corresponding irradiance at z is

$$E_{\text{cir}}(z) = |\psi_{\text{cir}}|^2 = A^2\left[1 + \frac{z^2}{a^2+z^2} - \frac{2z}{\sqrt{a^2+z^2}}\cos\left(k\left(\sqrt{a^2+z^2}-z\right)\right)\right] \tag{18}$$

See Fig. 9 for the on-axis irradiance plotted against the distance z from the circular aperture.

Next consider the dark screen and circular aperture is replaced by an opaque disk of the same radius a. Applying Babinet's principle, the on-axis diffracted field for the opaque disk illuminated by a normally incident plane wave is

$$\psi_{\text{disk}} = A\exp(ikz) - \psi_{\text{cir}} \tag{19}$$

$$\psi_{\text{disk}}(z) = \frac{Az}{\sqrt{a^2+z^2}}\exp\left(ik\sqrt{a^2+z^2}\right) \tag{20}$$

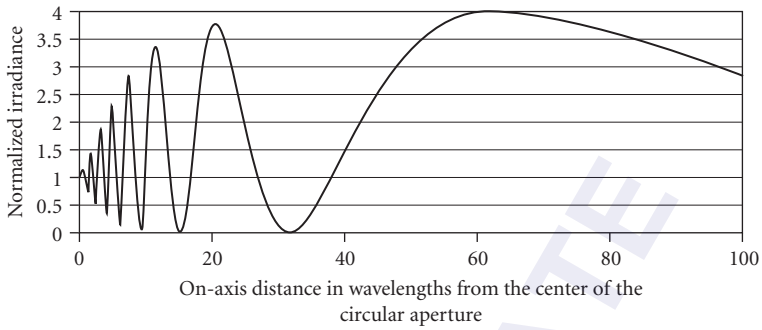

FIGURE 9 Normalized on-axis irradiance behind a circular aperture of radius 8λ, plotted as a function of z, the distance from the aperture in terms of wavelengths. At $z = 0$, the assumed boundary condition of unity is obtained. The maxima of the oscillations increases monotonically to a maximum value of 4 at $z = d^2/4\lambda$ when one Fresnel zone fills the aperture. For $z > d^2/4\lambda$ the irradiance decreases monotonically to zero.

The corresponding irradiance at z is

$$E_{\text{disk}}(z) = |\psi_{\text{disk}}|^2 = A^2 \frac{z^2}{a^2 + z^2} \tag{21}$$

See Fig. 10 for the variation of the on-axis irradiance with distance z from the opaque disk of radius a.

The behavior of the on-axis irradiance for the case of the opaque disk is quite different from that of the complementary circular aperture. There is no simple relationship between the irradiances of the two cases because they involve a squaring operation that brings in cross-terms.

It is important to note that the closed form expressions of Eq. (17) through Eq. (21) are valid only within the approximations of the Rayleigh-Sommerfield theory. The value of unity obtained by Eq. (18) reproduces the assumed boundary conditions of the theory.

Zone Plate

If alternate zones are blocked the contribution of the unblocked zones will add in phase to yield a large irradiance at the point of observation. An optical device that blocks alternate zones is called a *zone plate.* Figure 11 shows two zone plates made up of concentric circles with opaque alternate

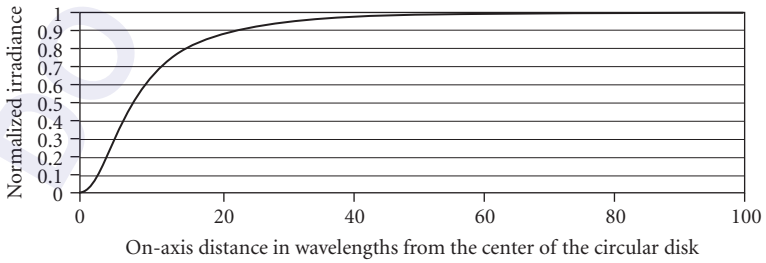

FIGURE 10 Normalized on-axis irradiance behind a disk of radius 8λ, plotted as a function of z, the distance from the aperture in terms of wavelengths. The irradiance is zero at $z = 0$ and increases monotonically to unity for large z.

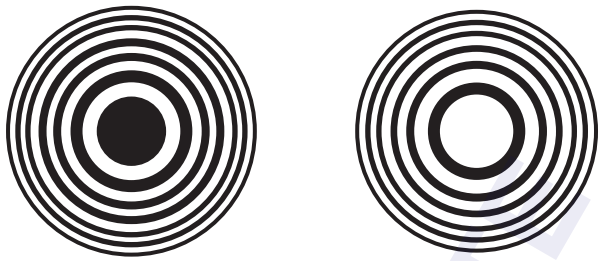

FIGURE 11 Two zone plates made up of concentric circles with alternate zones made opaque. They block odd-indexed or even-indexed zones, respectively. The radii of the zone boundaries are proportional to the square root of natural numbers. (*From Hecht and Zajac.*[10])

zones. They block odd-indexed or even-indexed zones, respectively. The radii of the zone boundaries are proportional to the square root of natural numbers.

We place a point source at a distance r_0 in front of the zone plate. If R_m is the radius of the mth zone, a bright image of this source is observed at a distance b behind the plate, so that

$$\frac{1}{r_0}+\frac{1}{b}=\frac{m\lambda}{R_m^2} \tag{22}$$

where λ is the wavelength of light from the source. This equation for the condition on the distance b is like the paraxial lens formula from which the focal length of the zone plate may be identified or may be obtained by setting the source distance $r_0 \to \infty$.

The focal length f_1 so obtained is

$$f_1=\frac{R_m^2}{m\lambda} \tag{23}$$

and is called the *primary focal length*. For unlike, the case of the lens, the zone plate has several secondary focal lengths. These are given by

$$f_{2n-1}=\frac{R_m^2}{(2n-1)m\lambda} \tag{24}$$

where $n = 1, 2, 3, \ldots$. In the case of the primary focal length, each opaque zone of the zone plate covers exactly one Fresnel zone. The secondary focal length f_3 is obtained when each opaque zone covers three Fresnel zones. It is a matter of regrouping the right-hand side of Eq. (9) in the form

$$\begin{aligned}\psi(P)=(\psi_1-\psi_2+\psi_3)-\langle\psi_4-\psi_5+\psi_6\rangle+(\psi_7-\psi_8+\psi_9)\\ -\langle\psi_{10}-\psi_{11}+\psi_{12}\rangle+(\psi_{13}-\psi_{14}+\psi_{15})-\cdots\end{aligned} \tag{25}$$

The zone plate in Fig. 11*b,* for example, blocks all even-indexed zones. It corresponds to omitting the terms enclosed in the angular brackets, $\langle\ldots\rangle$ in Eq. (25). The remaining terms grouped in parentheses add in phase to form a secondary image of weaker irradiance. The higher-order images are formed successively closer to the zone plate and are successively weaker in irradiance.

Further discussion may be found in several books listed in the references, for example, Ref. 10 (p. 375). The radii of the concentric circles in a zone plate are proportional to the square root of natural numbers. For equidistant source and image locations, say 10 cm at a wavelength of 500 nm,

$R_m = \sqrt{m} \times 0.16$ mm. Due to the smallness of the radii, a photographic reduction of a large-scale drawing is used.

Incidentally, the pair of zone plates of Fig. 11 form a pair of complementary screens. Per the Babinet principle, the groupings are

$$\begin{aligned}\psi_{\text{UN}}(P) &= \psi_S(P) + \psi_{\text{CS}}(P) \\ &= (\psi_1 + \psi_3 + \psi_5 + \psi_7 + \psi_9 + \psi_{11} + \cdots) \\ &\quad -(\psi_2 + \psi_4 + \psi_6 + \psi_8 + \psi_{10} + \psi_{12} + \cdots)\end{aligned} \tag{26}$$

The first group of terms corresponds to the zone plate of Fig. 11*b* and the second group of items corresponds to Fig. 11*a*.

3.5 CYLINDRICAL WAVEFRONT

A line source generates cylindrical wavefronts. It is frequently approximated in practice by a slit source, which, in turn, can illuminate straight edges and rectangular or slit apertures (see Fig. 12*a*). In this case, as we shall see, the phenomena of diffraction can be essentially reduced to a one-dimensional analysis for this source and aperture geometry.

Fresnel zones for cylindrical wavefronts take the form of rectangular strips, as shown in Fig. 12*a*. The edges of these strip zones are $\lambda/2$ farther away from the point of observation *P*. The treatment for the cylindrical wave parallels the treatment used for the spherical wave in Sec. 3.4. The line M_0 on the wavefront intersects at right angles to the line joining the source *S* and the point of observation *P*. Refer to M_0 as the axis line of the wavefront with respect to the point *P*. Let *a* be the radius of the wavefront with respect to the source slit and let *b* be the distance of *P* from M_0. Fresnel zones are now in the form of strips above and below M_0 and are parallel to it. The line pairs M_1M_1', M_2M_2', etc., are marked $\lambda/2$ farther away from the point of observation *P*. Fresnel zones are now half-period strips. Thus $PM_m = b + m\lambda/2$ and, to a good approximation, the arc length $(M_mM_{m+1}) = \sqrt{mab\lambda/(a+b)}(\sqrt{m+1} - \sqrt{m})$. For small values of *m* such as 1, 2, etc., the arc widths decrease rapidly while, for large values of *m* the neighboring strips have nearly equal widths. The lower-order strips have much larger areas compared to the ones further up from M_0. This effect is much more dominant than the variation of the obliquity factor $K(\chi)$ which has been neglected in this analysis.

Consider one single strip as marked in Fig. 12*b*. Imagine that this strip is divided into half-period sections as shown. The wavefront is almost planar over the width of this strip. All the sections on either side of the arc M_1M_2 contribute to the disturbance at *P*. The boundaries of these are marked N_1, N_2, etc. The area of these sections are proportional to $\sqrt{c\lambda}(\sqrt{n+1} - \sqrt{n})$. The areas of those half-period sections decrease rapidly at first and then slowly. The contribution to the disturbance at *P* from the higher-order sections is alternately positive and negative with respect to the first section near M_1M_2. Consequently, their contribution to the total disturbance at *P* is nearly zero.

The disturbance at *P* due to a single strip consists of the dominant contribution of the two sections from N_1 to N_1'. This conclusion holds for all the strips of the cylindrical wave. Following the procedure of Eq. (9) employed for the spherical wave,

$$\psi(P) = \psi_1 - \psi_2 + \psi_3 - \psi_4 + \psi_5 - \psi_6 + \cdots \tag{9'}$$

where $\psi(P)$ is the disturbance at *P* and *m* denotes the secondary wavelet contributions from strip zones of either side of the axis line M_0 of Fig. 12*a*. As in Eq. (11) the series can be summed, but here we need to account for the strip zone contribution from both sides of the axis line M_0: therefore, we have

$$\psi(P) = \psi_1 \tag{11'}$$

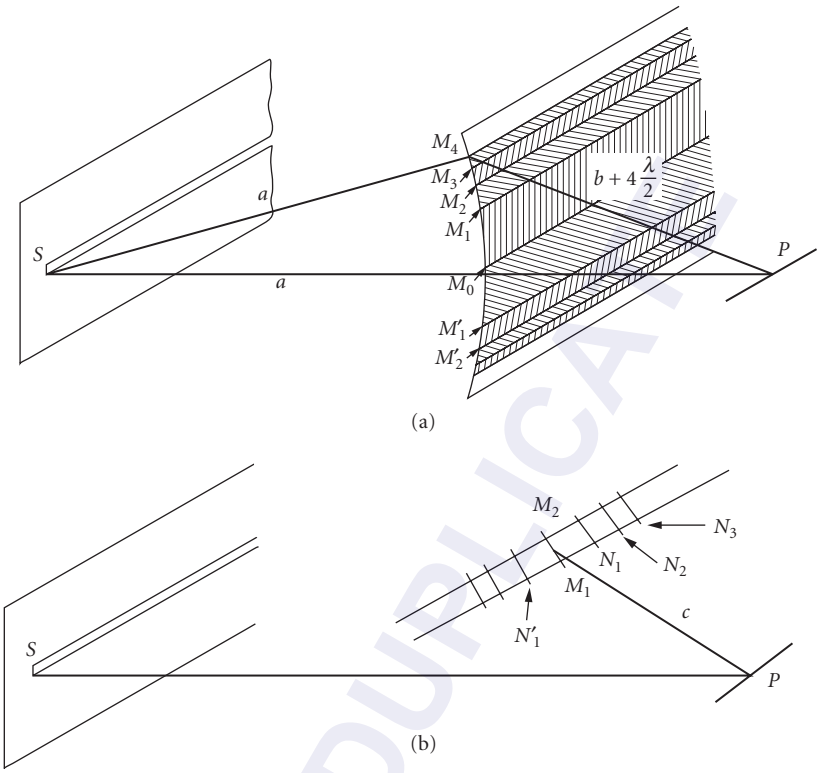

FIGURE 12 Fresnel zones for cylindrical wavefront. *S*: slit source. *a*: radius of the cylindrical wavefront. *b*: distance M_0 *P*. M_1, M'_1, etc.: zone boundaries. (*Adapted from Jenkins and White.*[2])

The first zone contributions can be computed and compared with the freely propagating cylindrical wave.

Fresnel Diffraction from Apertures with Rectangular Symmetry

Straight Edge A cylindrical wave from a slit source *S* illuminates an opaque screen with a straight edge *AB* oriented parallel to the slit, as shown in Fig. 13. It shows three special positions of the point of observation *P*. In Fig. 13*a, P* is such that all the strip zones above the axis line M_0 are exposed, while those below are blocked. The point *P* in Fig. 13*b* is such that the strip zones above M_0 and one zone below, marked by the edge M_1, are exposed. In Fig. 13*c, P* has moved into the geometrical shadow region. The strip M_1M_0 and all those below M_0 are blocked.

Following the discussion in Sec. 3.4, we discuss the disturbance at *P* for the three cases of Fig. 13. At the edge of the geometrical shadow

$$\psi_a(P) = 1/2\psi_1 \tag{27}$$

For Fig. 13*b* we have

$$\psi_b(P) = 1/2\psi_1 + \psi_1 = 3/2\psi_1 \tag{28}$$

As *P* is moved further up, there comes a point for which two strip zones below M_0 are exposed, resulting in $\psi(P) = 3/2\psi_1 - \psi_2$. As *P* explores the upper half of the observation plane, the amplitude

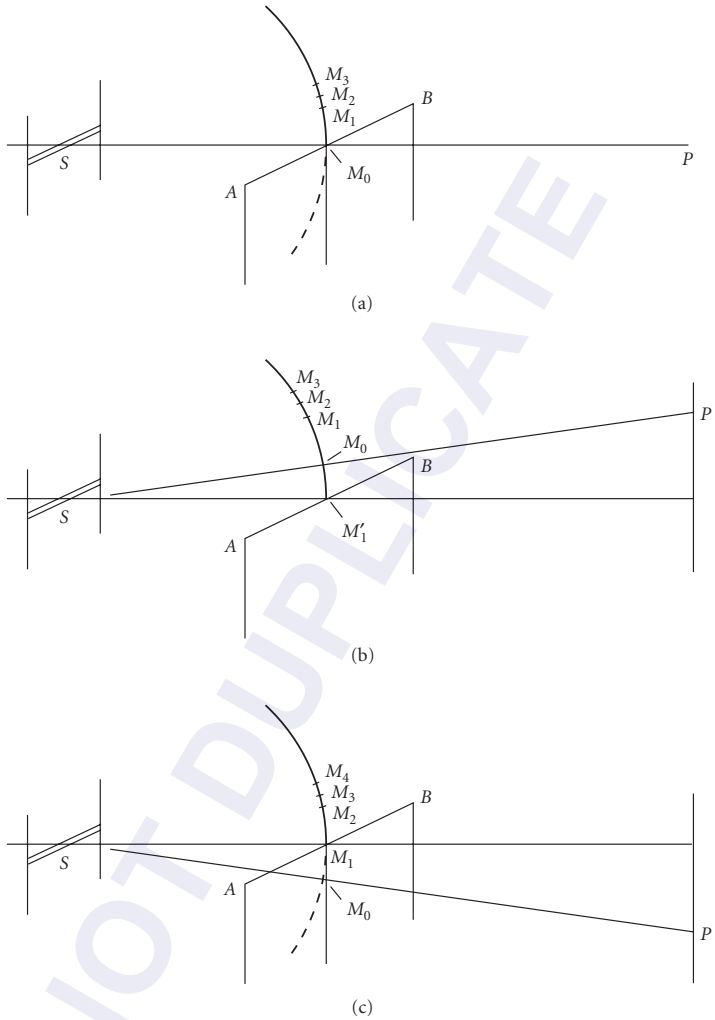

FIGURE 13 Fresnel zones for a cylindrical wavefront. The edges of these strip zones are $\lambda/2$ farther away from the point of observation *P*. *S*: slit source. *P*: point of observation. M_0: axis line of the cylindrical wave. *AB*: straight-edge opaque obstruction. (*After Jenkins and White.*[2])

and, hence, the irradiance go through maxima and minima according to whether an odd or even number of (lower) strip zones is exposed. Furthermore, the maxima decrease gradually while the minima increase gradually until the fringes merge into a uniform illumination that corresponds to the unobstructed wave.

In the geometrical shadow (see Fig. 13*c*)

$$\psi_c(P) = -1/2\psi_2 \tag{29}$$

As *P* goes further down, we get $\psi(P) = 1/2\psi_3$; in general, the number of exposed zones decreases and the irradiance falls off monotonically.

A mathematical analysis of Fresnel diffraction from apertures with rectangular symmetry is possible with the use of Fresnel integrals and the Cornu's spiral (vibration curve). Irradiance of the

diffraction pattern from a straight edge illuminated by a cylindrical wave is found by relating the spiral to the cylindrical wavefront and to the plane of observation. Figure 13 shows the diffraction geometry. The line or slit source is aligned parallel to the straight edge. The on-axis point of observation P is as shown in Fig. 13 and is defined as $P(0)$. An off-axis point of observation (see Fig. 13*b* and *c*) is defined as $P(x)$ at x. The plane passing through $P(0)$ and $P(x)$ is perpendicular to the edge. As shown in Fig. 12*a*, the radius of the cylindrical wave is a and the distance between M_0 and $P(0)$ is b. The distance of a point on the wavefront above M_0 labeled M_m to the point $P(0)$ is $b' = b + m\lambda/2$. The path difference $b' - b = \Delta$. To a good approximation,

$$\Delta \cong s^2 \frac{a+b}{2ab} \tag{30}$$

where s is the arc length between M_0 and M_m but is approximated by the corresponding chord length. For computational purposes the arc length s is converted to a dimensionless parameter v by defining the phase difference as

$$\delta = \frac{2\pi}{\lambda}\Delta = \frac{2\pi}{\lambda} s^2 \frac{a+b}{2ab} \equiv \frac{\pi}{2} v^2 \quad \Rightarrow \quad v = s\sqrt{\frac{2(a+b)}{\lambda ab}} \tag{31}$$

With Fig. 12 we can relate the arc length s with the coordinate x in the plane of observation,

$$x = s\left(\frac{a+b}{a}\right) \tag{32}$$

and therefore,

$$v = s\sqrt{\frac{2(a+b)}{\lambda ab}} = x\sqrt{\frac{2a}{\lambda b(a+b)}} \tag{33}$$

Cornu's Spiral The diffraction amplitude [see Eq. (8)] is given by

$$\psi(P) = A\frac{\exp[-i(\omega t - kr_0)]}{r_0}\iint_s \frac{\exp(iks)}{s} K(\chi)\, dS \tag{34}$$

For a cylindrical wave illumination of the straight edge, the double integral reduces to a single integral. The single integral describes integration along a line on the cylindrical wavefront parallel to the line source. For $r_0 = a$ and $s = b$ much larger than the width of the strip of Fresnel zone on the cylindrical wavefront, we use the approximation,

$$\psi(P) = C\frac{\exp(ik(a+b))}{ab} K(\chi) \int_{s_1}^{s_2} \exp(ik\Delta)\, ds \tag{35}$$

In this expression, $C = A\exp(-i\omega t)$. The formal limits of integration s_1 and s_2 designate the limit of integration appropriate for a slit aperture oriented parallel to the line source. For the straight edge problem, the upper limit is ∞ and the lower limit s_1 describes the location of the straight-edge with respect to the position of the point of observation P along the x axis. Thus, the amplitude is proportional to

$$\psi(P) = C'\left[\int_{-\infty}^{s_1} \exp(ik\Delta)\, dS\right] = C'\left[\int_{-\infty}^{0} \exp(ik\Delta)\, dS + \int_0^{s_1} \exp(ik\Delta)\, dS\right] \tag{36}$$

$$\psi(P) = C'\left\{\left[\frac{1}{2} + C(v_1)\right] + i\left[\frac{1}{2} + S(v_1)\right]\right\} \tag{37}$$

$$E(P)=|\psi(P)|^2=|C'|^2\left\{\left[\frac{1}{2}+C(v_1)\right]^2+\left[\frac{1}{2}+S(v_1)\right]^2\right\} \tag{38}$$

We have defined

$$C'=C\frac{\exp(ik(a+b))}{ab}K(\chi) \qquad \text{and} \qquad |C'|^2=\frac{|C|^2\,K(\chi)^2}{a^2b^2}$$

For the case of a cylindrical wave incident, Cornu's spiral helps in the calculation of the diffraction amplitude (Plane wave incidence is a special case in the limit where radius a of the cylindrical wave becomes very large compared to the distance b of the observation screen.) Cornu's spiral is defined in terms of the dimensionless parameter v. The description of this spiral begins with the definitions

$$C(v)=\int_0^v \cos\left(\frac{\pi}{2}v^2\right)dv \qquad S(v)=\int_0^v \sin\left(\frac{\pi}{2}v^2\right)dv \tag{39}$$

1. Cornu's spiral is a plot of $S(v)$ along the vertical axis and $C(v)$ along the horizontal axis with v as a parameter, $-\infty \le v \le \infty$.
2. The arc length measured along the spiral from the origin is v; $\delta v=\sqrt{[\delta C(v)]^2+[\delta S(v)]^2}$; $\delta C(v)$ and $\delta S(v)$ are the projections of the arc length on the horizontal and vertical axes, respectively.
3. The vector length from the origin to any point v on the spiral is proportional to diffracted amplitude.
4. The angle ϕ made by the vector measured from the horizontal equals the phase of the diffracted light;
   $\tan\phi=\dfrac{\delta S}{\delta C}=\tan\dfrac{\pi}{2}v^2 \Rightarrow \phi=\dfrac{\pi}{2}v^2.$
5. The radius of curvature = $\dfrac{dv}{d\phi}=\dfrac{1}{\pi v}.$
6. For large v, the spiral winds about two limit points
   $$v\to+\infty \quad C(+\infty)=+\frac{1}{2} \quad S(+\infty)=+\frac{1}{2}$$
   $$v\to-\infty \quad C(-\infty)=-\frac{1}{2} \quad S(-\infty)=-\frac{1}{2}$$
7. The magnitude of the diffraction integral has its maximum value when
   $\phi=\dfrac{3\pi}{4} \Rightarrow v=\sqrt{\dfrac{3}{2}}.$
8. Subsidiary maxima at $\phi=\dfrac{3\pi}{4}+2\pi n \Rightarrow v=\sqrt{\dfrac{3}{2}+4n}$, where $n=1, 2, 3, \ldots$.
9. Minimum values at $\phi=\dfrac{7\pi}{4}+2\pi m \Rightarrow v=\sqrt{\dfrac{7}{2}+4m}$, where $m=0, 1, 2, 3, \ldots$.

Cornu's spiral is plotted in Fig. 14 and tabulated in Table 1.

Figure 15 shows a plot of the irradiance in the diffraction pattern of light from a straight edge. The maxima and minima follow the description given in 8 and 9 in the above list. It is interesting to observe that the edge is neither at the maximum of the first fringe nor at the halfway point. It appears at one-fourth of the irradiance of the unobstructed wave. For a complete vectorial solution of diffraction of light by a straight edge, see Sommerfeld.[14]

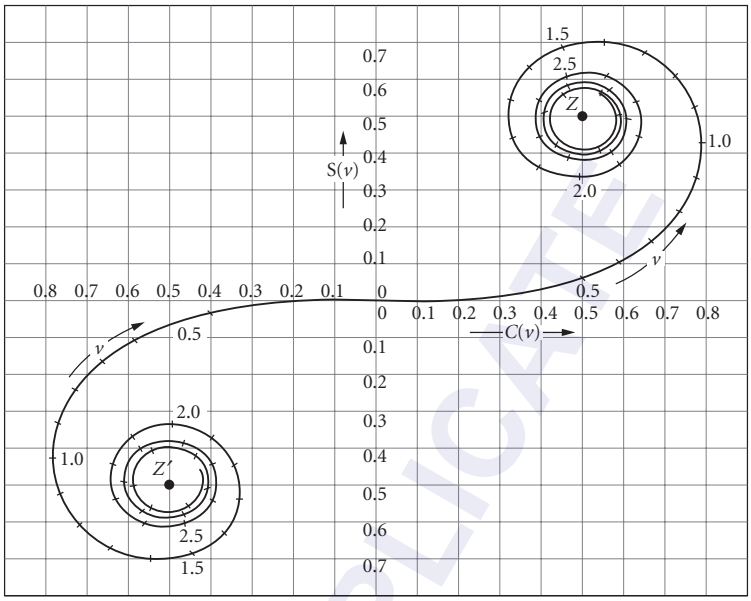

FIGURE 14 Cornu's spiral (vibration curve) for use with cylindrical waves and apertures with rectangular symmetry. (*Adapted from Jenkins and White*.[2])

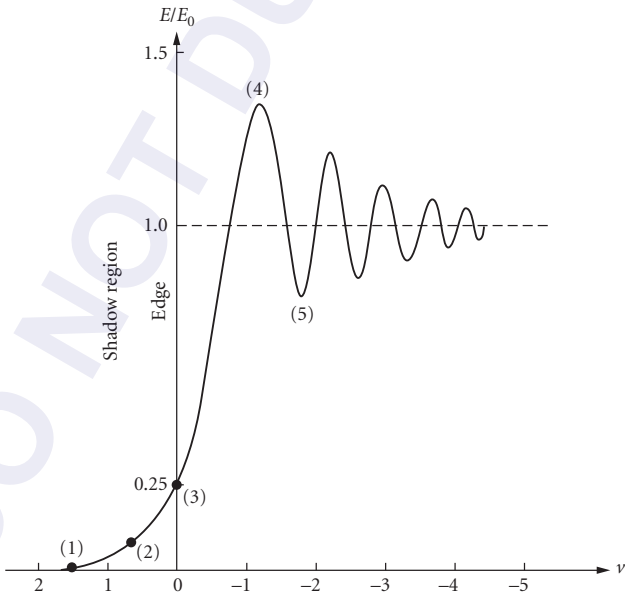

FIGURE 15 The plot of irradiance in the diffraction pattern of a straight edge *AB*. The plot is normalized to unity for the irradiance of the unobstructed wave. Labels 1 and 2 show points *P* in the geometrical shadow. Label 3 is at the edge of the geometrical shadow, while labels 4 and 5 are in the illuminated region. υ is a unitless variable to label distances along the plane of observation. Note: This table is adapted from Jenkins and White.[2]

Rectangular Aperture Figure 16 is a series of diagrams of irradiance distributions for light diffracted by single-slit apertures. A pair of marks on the horizontal axis indicate the edges of the geometrical shadow of the slit relative to the diffraction pattern. In all cases, relatively little light falls in the geometrical shadow region. The last diagram corresponds to a rather wide slit. It appears as two opposing straightedge diffraction patterns corresponding to the two edges of the slit.

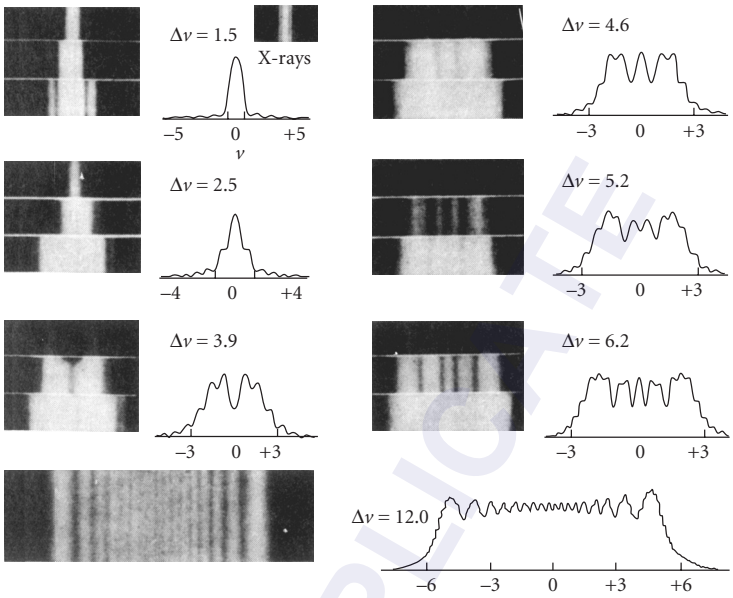

FIGURE 16 A series of diagrams of irradiance distributions for light diffracted by single-slit apertures of different widths. (*From Jenkins and White.*[2])

These patterns may be interpreted as obtained with the plane of observation fixed for different-size slits. Alternately, the slit size may be held fixed but move the plane of observation. For the first diagram the plane is far away. For the successive diagrams the plane is moved closer to the slit. The plane of observation is the closest for the last diagram of Fig. 16. The important parameter is the angular subtense of the slit to the observation plane. A similar comment applies to the case of the circular aperture[2,9] as shown in Fig. 7.

Opaque Strip Obstruction A slit aperture and an opaque strip or a straight wire form a pair of complementary screens. In Fig. 17 photographs of Fresnel diffraction patterns produced by narrow wires are shown with the corresponding theoretical curves. These theoretical curves show some more detail. Generally, the figures show the characteristic unequally spaced diffraction fringes of a straight edge on either side of the geometrical shadow. These fringes get closer and closer together, independent of the width of the opaque obstruction, and finally merge into a uniform illumination. Figure 17 also shows the maximum in the center and equally spaced narrow fringes within the shadow. The width of these fringes is inversely proportional to the width of the obstruction. We shall now discuss this detail.

Figure 18 shows the arrangement of the source *S,* opaque strip *AB,* and the plane of observation. A point x in the geometrical shadow receives light from Fresnel zones of both sides of the opaque strip. At each edge of the opaque strip the exposed zones add up effectively to one-half of the contribution of a single zone adjacent to that edge. Owing to the symmetry, the resulting disturbance from each edge starts out in phase. Light from the two edges adds constructively or destructively according to whether the path difference to the point x in the shadow region is an even or an odd multiple of $\lambda/2$. The situation is similar to two coherent sources separated by the width of the opaque strip. Young examined these fringes inside the geometrical shadow. In particular, he showed that if an opaque screen is introduced on one side of the opaque strip to block that part of the wave, then the straightedge diffraction fringes due to that edge, as well as the interference fringes in the shadow region, vanished.

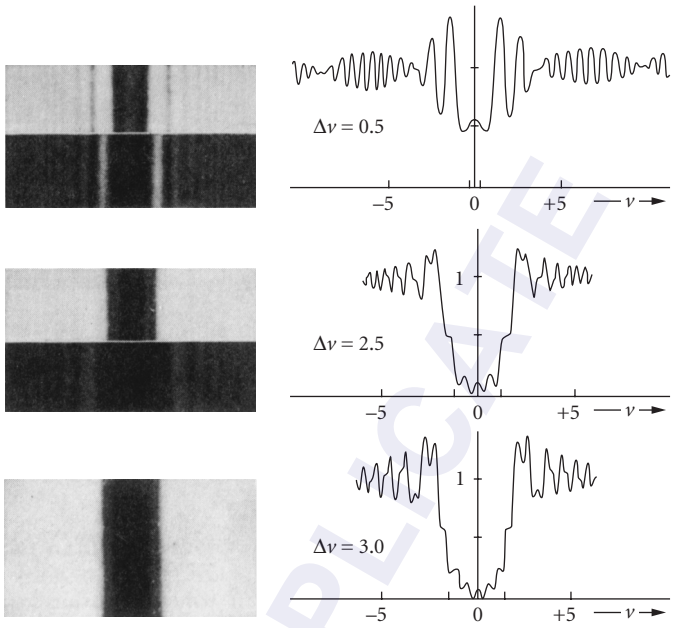

FIGURE 17 Fresnel diffraction patterns produced by narrow wires are shown with the corresponding theoretical curves. (*From Jenkins and White.*[2])

3.6 MATHEMATICAL THEORY OF DIFFRACTION

Kirchhoff showed that the Huygens-Fresnel construction follows from an integral theorem starting from the wave equation. The resulting mathematical expression is called the Fresnel-Kirchhoff diffraction formula.[1] This theory was further refined by Rayleigh and Sommerfeld.[7,12]

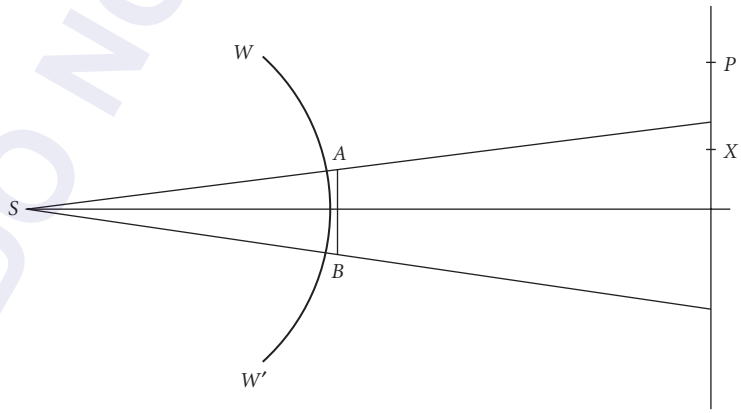

FIGURE 18 Arrangement of the source *S*, opaque strip *AB*, and the plane of observation. Point *x* is in the geometrical shadow region.

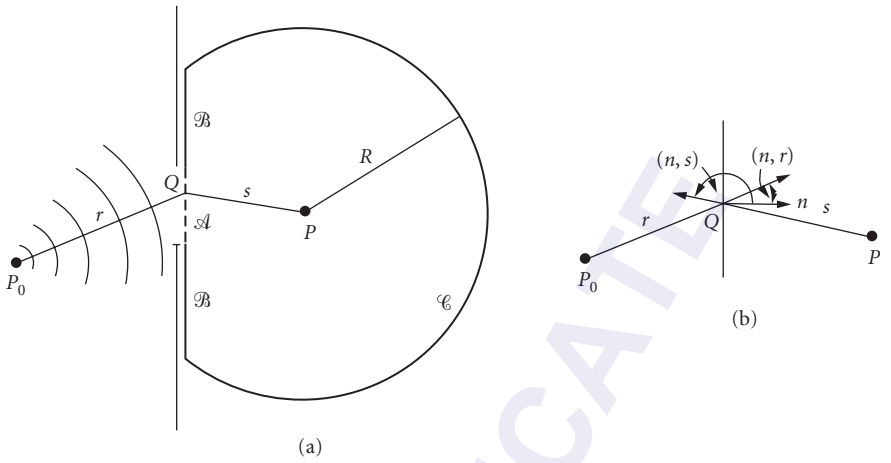

FIGURE 19 The closed surface for the diffraction problem. It is made up of the aperture plane and a large partial sphere centered at the point of observation *P*. (*From Born and Wolf.*[1])

It is well known in wave theory that the field values inside a volume enclosed by a bounding surface are determined by the values of the field and/or its normal derivative on this bounding surface. The solution is expressed in terms of the Green function of the problem, as in

$$\psi(P)=\left(\frac{1}{4\pi}\right)\iint_S\left\{\psi\left(\frac{\partial G}{\partial n}\right)-G\left(\frac{\partial \psi}{\partial n}\right)\right\}dS \tag{40}$$

where G is the Green function of the problem. The integral is over the arbitrary closed surface S. The symbol $\partial/\partial n$ stands for the normal derivative with the normal pointing into the volume enclosed by the surface.[1] A convenient Green function is the expanding spherical wave, $\exp(iks)/s$ from the point of observation P. The closed surface for the diffraction problem is made up of the aperture plane and a large partial sphere centered at the point of observation P, as shown in Fig. 19.

This is the starting point of Kirchhoff theory. It requires specifying the field values and its normal derivative on the bounding surface to obtain the field $\psi(P)$ at P in the volume enclosed by the surface. It is possible to show that the contribution of the surface integral on the partial sphere is zero. Kirchhoff assumed that the field and its normal derivative are zero on the opaque portion of the aperture plane. On the open areas of the aperture plane he assumed the values to be the same as incident (unperturbed) values. If the incident field is an expanding spherical wave $(a/r)\exp(ikr)$, then the field $\psi(P)$ is given by

$$\psi(P)=-\frac{ia}{2\lambda}\iint_A\left[\frac{\exp(ikr)}{r}\right]\left[\frac{\exp(iks)}{s}\right][\cos(n,\,r)-\cos(n,\,s)]dS \tag{41}$$

The area integral is over the open areas A of the aperture. As shown in Fig. 19, (n, s) and (n, r) are the angles made by s and r, respectively, with the normal to the aperture plane. The above equation is referred to as the Fresnel-Kirchhoff diffraction formula. From a strictly mathematical point of view the specification of field and its normal derivative over-specifies the boundary conditions. It is possible to modify the Green function so that only the field or its normal derivative $\partial\psi/\partial n$ needs to be specified. With this modification one obtains

$$\psi(P)=-\left(\frac{ia}{\lambda}\right)\iint_A\left[\frac{\exp(ikr)}{r}\right]\left[\frac{\exp(iks)}{s}\right]\cos(n,\,s)dS \tag{42}$$

This is referred to as the Rayleigh-Sommerfeld diffraction formula. Other than mathematical consistency, both formulas yield essentially similar results when applied to practical optical situations. They both use the approximate boundary conditions, namely, that the field is undisturbed in the open areas of the aperture and zero on the opaque regions of the aperture plane. The cosine factors in the above formulas play the role of the obliquity factor of the Huygens wave used in Eq. (8), more generally, the field (for a single temporal frequency) at the point of observation $P(x, y, z)$ may be expressed by[12]

$$\psi(x, y, z) = \iint_A \psi(x_s, y_s, 0)\left[\frac{1}{2\pi}\frac{z}{\rho}(1 - ik\rho)\frac{\exp(ik\rho)}{\rho^2}\right]dx_s\,dy_s \tag{43}$$

where $\psi(x_s, y_s, 0)$ are the values of the field in the aperture A, at $z = 0$. The expression in the square brackets is the normal derivative of the modified Green function. In this expression $\rho = [(x - x_s)^2 + (y - y_s)^2 + z^2]^{1/2}$ is the distance between a point in the aperture and the point of observation P, and the ratio z/ρ is the direction cosine of the difference vector. In the far zone where $k\rho \gg 1$, Eq. (43) reduces to Eq. (42) for the case of spherical wave illumination. Since the expression in the square brackets depends on the coordinate difference, $(x - x_s)$ and $(y - y_s)$, Eq. (43) has the form of a convolution integral. It is well known that the convolution integral has a corresponding product relationship in the Fourier-spatial-frequency domain. The two-dimensional Fourier decomposition of the field is

$$\psi(x, y, z) = \iint \hat{\psi}(p/\lambda, q/\lambda, z)\exp[+i2\pi(px + qy)/\lambda]d(p/\lambda)d(q/\lambda) \tag{44}$$

where p and q are the two-direction cosines. The third-direction cosine m is defined by

and
$$\begin{aligned} m &= +(1 - p^2 - q^2)^{1/2} \quad \text{for} \quad p^2 + q^2 \le 1 \\ m &= +i(p^2 + q^2 - 1)^{1/2} \quad \text{for} \quad p^2 + q^2 > 1 \end{aligned} \tag{45}$$

A similar decomposition as in Eq. (44) is used for the field in the aperture at $z = 0$, wherein the finite area of the aperture is included in the description of the incident field. With the help of Weyl's plane-wave decomposition of a spherical wave,

$$\frac{\exp(ikr)}{r} = \frac{i}{\lambda}\iint \frac{1}{m}\exp(ikmz)\exp\left[\frac{i2\pi}{\lambda}(px + qy)\right]dp\,dq \tag{46}$$

the Fourier transform of the expression in square brackets in Eq. (43) can be found. The relationship in the Fourier domain has the form

$$\hat{\psi}(p/\lambda, q/\lambda, z) = \hat{\psi}(p/\lambda, q/\lambda, 0)\exp(ikmz) \tag{47}$$

The inverse Fourier transform yields the disturbance in x, y, z space at point P. At $z = 0$ it reproduces the assumed boundary conditions, a property not shared by the Fresnel-Kirchhoff formula.

A plane-wave decomposition describes a function in (x, y, z) space in terms of the weighted sum of plane waves, each propagating in a direction given by the direction cosines (p, q, m). Equation (47) may be referred to as the angular spectrum formulation of diffraction. For application of this formulation see Ref. 15.

Fresnel and Fraunhofer Approximations

In practical optical situations, diffraction is mainly studied in the forward direction, that is, for small angles from the direction of propagation of the incident field. Furthermore, the distances involved

are much larger than the wavelength λ, $r \gg \lambda$. In this situation the distance ρ of Eq. (43) may be approximated by the low-order terms in the binomial expansion of the square root

$$\rho = \left[(x-x_s)^2 + (y-y_s)^2 + z^2\right]^{1/2} \cong \left(r - \frac{xx_s + yy_s}{r} + \frac{x_s^2 + y_s^2}{2r}\right) \tag{48}$$

where r is the radial distance of the observation point P, $r = \sqrt{x^2 + y^2 + z^2}$. When the terms quadratic in the aperture variables are retained, namely $(x_s^2 + y_s^2)$, we have a description of Fresnel diffraction. Let d be the maximum dimension of the aperture. If the plane of observation is moved to distance $z \gg d^2/\lambda$, the quadratic terms are negligible and Eq. (43) is approximated by

$$\psi(x, y, z) = \left(-\frac{i}{\lambda r}\right) \exp(ikr) \iint_A \psi(x_s, y_s, 0) \exp\left[-\frac{ik(xx_s + yy_s)}{r}\right] dx_s\, dy_s \tag{49}$$

This is the formula for Fraunhofer diffraction.

Fraunhofer Diffraction

Far enough away from the aperture, $z \gg d^2/\lambda$, Fraunhofer-type diffraction is found. Equation (49) shows that it has the form of a Fourier transform of the light distribution in the aperture. For more general conditions on the distance and angles to obtain Fraunhofer diffraction, see Born and Wolf.[1] Thus, instead of moving the observation plane to the far field, parallel light incident on the aperture can be brought to a focus by a converging lens as in Fig. 20, thus producing a Fraunhofer pattern of the aperture in the focal plane.

In an imaging situation (see Fig. 21), a diverging spherical wave is brought to a focus in the image plane. This is also an example of Fraunhofer diffraction pattern of the light distribution in the aperture A by a converging spherical wave. To realize Fraunhofer diffraction, a similar situation is obtained when a narrow diffracting aperture is held next to the eye focused on a distant point source. The diffraction pattern is observed in the plane of the source.

An optical processing setup is shown in Fig. 22 where collimated or parallel light is incident normally on plane 1. In this arrangement an inverted image of plane 1 is formed in plane 3. The imaging process may be thought of as a Fourier transform (Fraunhofer diffraction) of the light distribution in plane 1 onto plane 2, followed by another Fourier transform of the light distribution in plane 2 onto plane 3.

Recall our earlier discussion in relation to Eqs. (48) and (49). When the quadratic phase factor, $\exp[i\pi(x_s^2 + y_s^2)/\lambda r]$, may be approximated by unity, we are in the domain of Fraunhofer diffraction.

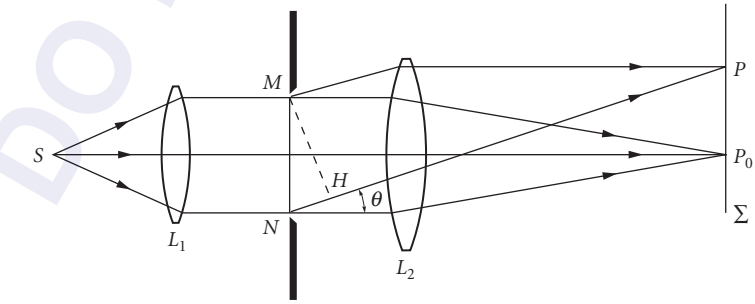

FIGURE 20 Arrangement to observe a Fraunhofer diffraction by a slit aperture. (*After Rossi.*[8])

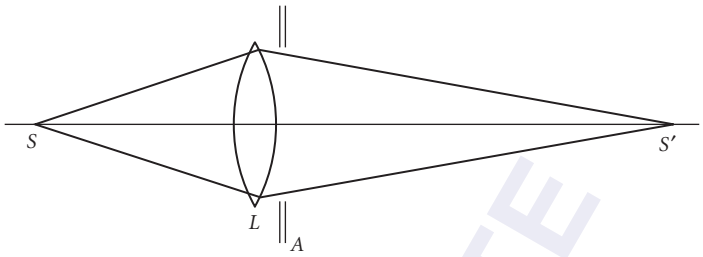

FIGURE 21 Fraunhofer diffraction of an aperture A, with a converging spherical wave. S: point source. L: converging lens. S': image.

From the point of view of Fresnel zone construction, the far-field condition, $z \gg d^2/\lambda$, means that for these distances z the first Fresnel zone overfills the aperture. The entire aperture contributes to the disturbance at any point in the Fraunhofer pattern. In Fresnel diffraction only relatively small portions of the aperture contribute to any one point in the pattern.

In this context, the term Fresnel number is frequently used. It is defined in terms of the product of two ratios. The radius r of the aperture to the wavelength λ times the radius of the aperture to the distance b measured from the aperture to the plane of observation:

$$\text{Fresnel number} \equiv N = \frac{r}{\lambda} \cdot \frac{r}{b} = \frac{1}{4b} \frac{d^2}{\lambda} \tag{50}$$

Thus, the Fresnel number can also be expressed as the ratio of the far-field distance, d^2/λ, to the distance b from the aperture. With the definition of the Fresnel zones in Sec. 3.4, these ratios indicate that the Fresnel number equals the number of Fresnel zones that may be drawn within the aperture from a point P at a distance b from the aperture.

Thus, well within the Fresnel region, $b \ll d^2/\lambda$, the Fresnel number is large. There are many zones in the aperture. As seen in Figs. 7 and 16, very little light falls within the geometrical shadow region; most of the light is in the confines of the aperture boundary dictated by geometrical optics. In the study of cavity resonators[16,17] and modes it is found that diffraction losses are small for large Fresnel numbers, $N \gg 1$. In the Fraunhofer region $b > d^2/\lambda$, $N < 1$ where the first Fresnel zone overfills the aperture as pointed out before.

In Figs. 23 and 24 the theoretical plots of Fraunhofer patterns of a rectangular aperture and a circular aperture, respectively, are shown. In the rectangular case the central maximum has equally spaced zeros on either side, while in the circular case the central maximum is surrounded by unequally spaced concentric dark rings. In both cases the central maximum occurs at the geometrical image of the point source that produced parallel light illumination on the aperture.

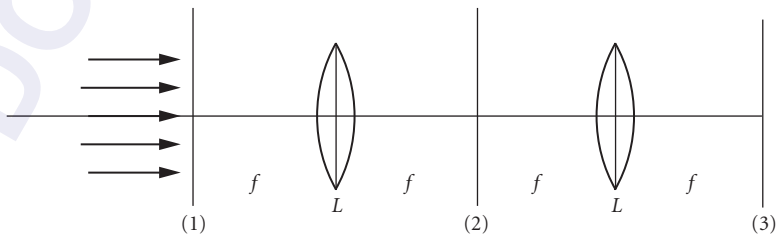

FIGURE 22 Optical processing arrangement. Collimated or parallel light is incident normally on plane 1. The system images plane 1 onto plane 3 with a Fourier transform in plane 2.

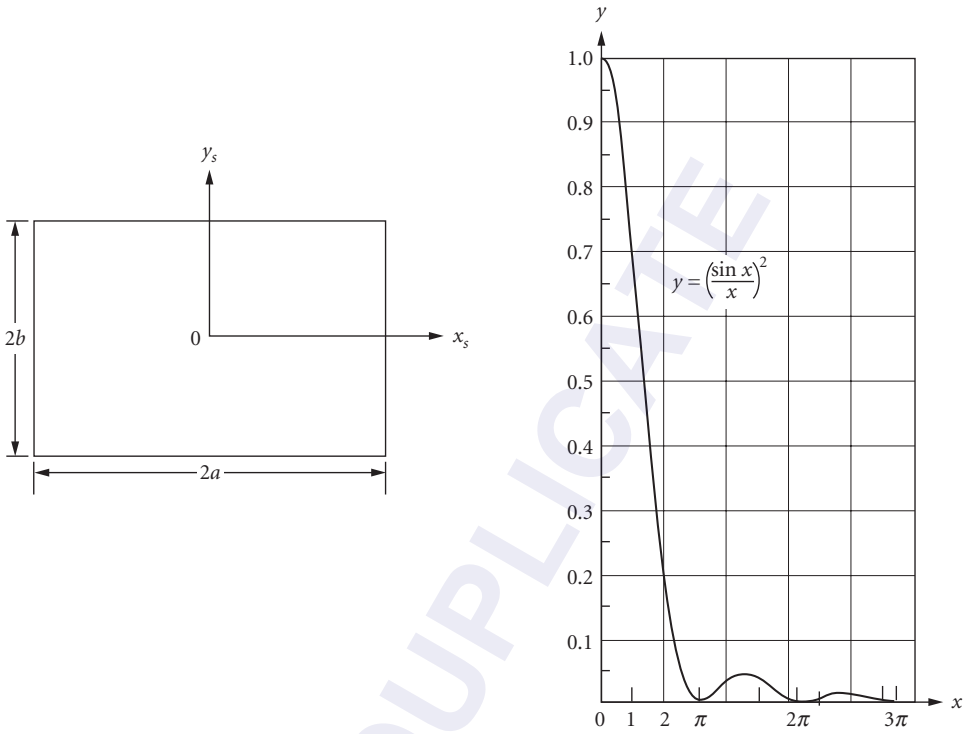

FIGURE 23 Rectangular aperture (in coordinates x_s and y_s) and one section of the diffraction pattern. Normalized irradiance y plotted against a unitless variable x as discussed in the text. (*From Born and Wolf.*[1])

The unitless variable x shown in the plots is defined as follows. (1) In the case of rectangular aperture, $x = 2\pi ap/\lambda$, where $2a$ is the width of the aperture in the x_s direction. In the other dimension $y = 2\pi bq/\lambda$, and $2b$ is the dimension in the y_s direction. As before, p and q are the direction cosines of the vector joining the center of the aperture to the point of observation. (2) In the case of circular aperture, the unitless radial variable $x = 2\pi aw/\lambda$, where $2a$ is the diameter of the aperture in the x_s, y_s plane and $w = \sqrt{p^2+q^2}$.

In the far field the size of the diffraction pattern is very large compared to the aperture that produced it. In the focal plane of the lens, $z = f$ and the size of the diffraction pattern is much smaller than the aperture. In both cases the patterns are in a reciprocal width relationship, that is, if the aperture is narrow in the x_s direction compared to y_s, the pattern is broader in the x direction compared to the y. A converging spherical lens illuminated by a plane wave produces in the focal plane a Fraunhofer diffraction pattern of the amplitude and phase of the aperture of a circular lens. When the lens has negligible phase errors, the diffraction pattern has a bright disk in the center surrounded by concentric dark rings. This is called an *Airy disk* and it plays an important role in the Rayleigh criterion of resolving power.

Fraunhofer Diffraction Pattern of a Double Slit

The diffraction pattern of two slits may be observed by using the optical arrangement of Fig. 25. The center-to-center separation of the two slits is h. The off-axis point P is in the direction θ from the axis as shown in the figure. The maxima and minima are determined according to whether the path

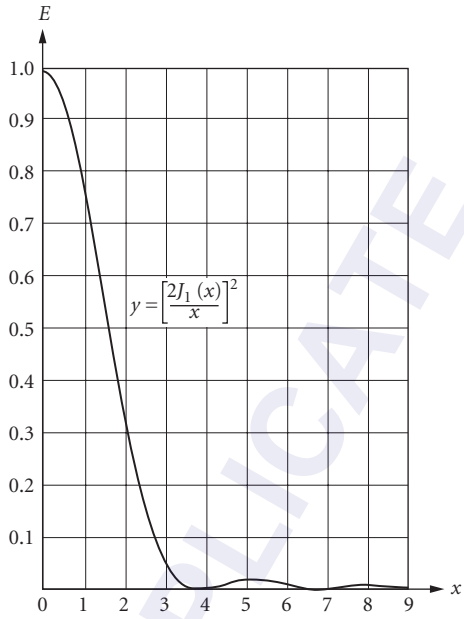

FIGURE 24 A section of the diffraction pattern of a circular aperture. The normalized irradiance E is plotted against a unitless variable x in the plane of observation as discussed in the text. (*From Born and Wolf.*[1])

difference O_1H is an even or odd multiple of a half-wave. Let E_0 be the irradiance at the center of the single-slit diffraction pattern. The irradiance distribution in the plane of observation is given by

$$E = 4E_0\left(\frac{\sin\alpha}{\alpha}\right)^2(\cos\delta)^2 \tag{51}$$

where $\delta = \pi h(\sin\theta)/\lambda$. The irradiance at the center of the double-slit pattern is $4E_0$. The second term, $(\sin\alpha/\alpha)^2$, describes the diffraction pattern of a single slit of width $2a$. Here $\alpha = 2\pi a(\sin\theta)/\lambda$.

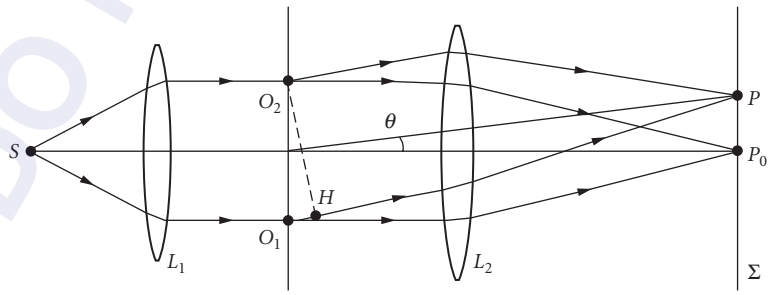

FIGURE 25 Arrangement to observe the Fraunhofer diffraction of an aperture consisting of two slits. *S*: point source. *P*: point of observation. O_1, O_2: two slit apertures with center-to-center separation *h*. (*From Rossi.*[8])

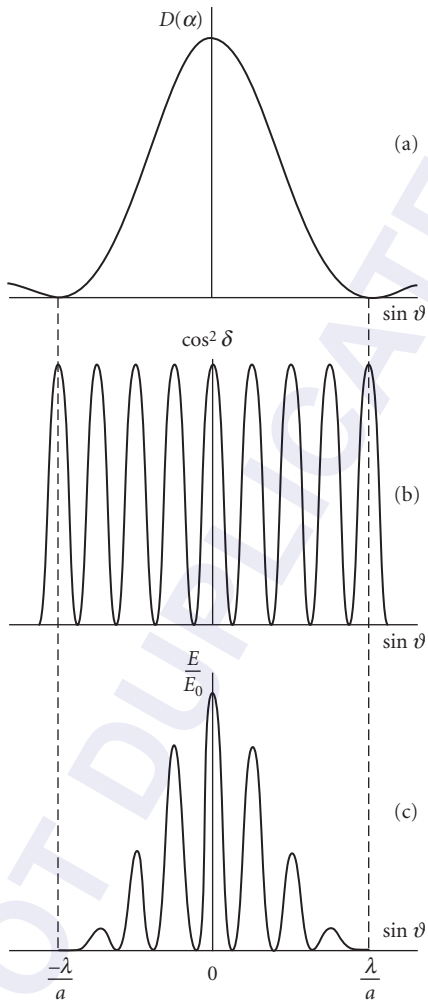

FIGURE 26 (*a*) Plot of a single-slit diffraction pattern $D(\alpha)$; (*b*) plot of a two-slit interference pattern; and (*c*) their product E/E_0. (*From Rossi.*[8])

The term $(\cos \delta)^2$ is the interference pattern of two slits. These two patterns as well as their product are sketched in Fig. 26.

Diffraction Grating

In Fig. 27, an arrangement similar to Fig. 25 permits observation of the Fraunhofer diffraction pattern of a grating, of N parallel and equidistant slits. The center-to-center separation between neighboring slits is h. As in the two-slit case, the Fraunhofer pattern consists of the diffraction due to one slit times the interference pattern of N slits. The irradiance distribution in the plane of observation is given by

$$E = N^2 E_0 \left(\frac{\sin \alpha}{\alpha} \right)^2 \left(\frac{\sin N\gamma}{N \sin \gamma} \right)^2 \tag{52}$$

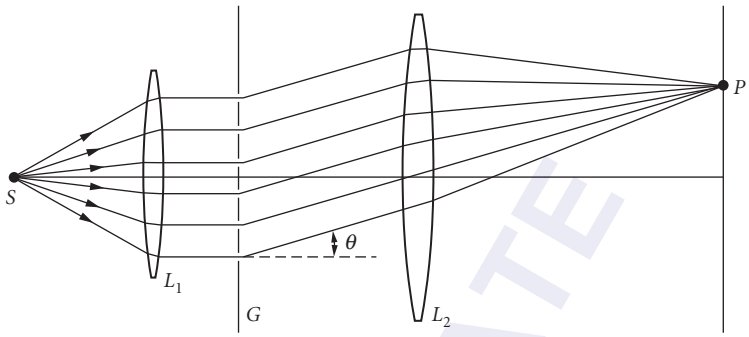

FIGURE 27 Arrangement to observe the Fraunhofer diffraction of an aperture consisting of N slits. S: slit source. P: point of observation. G: grating. (*From Rossi.*[8])

where $\gamma = \pi h(\sin\theta)/\lambda$ and N^2E_0 is proportional to the irradiance at the center of the N-slit pattern. The term $(\sin\alpha/\alpha)^2$ is the single-slit pattern as used with Eq. (51). In the case of multiple slits each slit is very narrow; hence, this pattern is very broad, a characteristic of Fraunhofer diffraction. The interference term $(\sin N\gamma/N\sin\gamma)^2$ shows prominent maxima when both the numerator and denominator are simultaneously zero; this happens when $\gamma = \pi h(\sin\theta)/\lambda = m\pi$, where m is an integer. It leads to the grating equation, namely,

$$h\sin\theta = m\lambda \tag{53}$$

There are several, $(N-1)$, subsidiary minima in between the principal maxima. This happens when the numerator is zero but the denominator is not, $\gamma = m\pi/N$. For the case of $N = 10$, these effects are sketched in Fig. 28, which shows the effect of the product of the diffraction and interference terms.

In general, as N increases the subsidiary maxima become more nearly negligible, while the principal maxima become narrower, being proportional to $(1/N)$. The location of the principal maxima other than the zeroth order $(m = 0)$ are proportional to the wavelength λ. The diffraction grating thus forms an important spectroscopic tool. Further discussion of gratings is given by Petit[18] and Gaylord and Moharam.[19]

3.7 STATIONARY PHASE APPROXIMATION

The diffracted field in the Rayleigh-Sommerfeld diffraction theory is given by

$$\psi(x, y, z) = \iint_A \psi(x_s, y_s, 0)\left[\frac{1}{2\pi}\frac{z}{\rho}(1-ik\rho)\frac{\exp(ik\rho)}{\rho^2}\right]dx_s dy_s \tag{54}$$

where $\psi(x_s, y_s, 0)$ is the field in aperture A. The diffracted field can also be represented by

$$\psi(x, y, z) = \iint_A \tilde{\psi}(L/\lambda, M/\lambda, 0)\exp\left[i2\pi(Lx+My+Nz)/\lambda\right]d(L/\lambda)d(M/\lambda) \tag{55}$$

The phase term in this integral is

$$\phi(L, M) \equiv 2\pi(Lx+My+Nz)/\lambda = \frac{2\pi}{\lambda}\left\{Lx+My+\sqrt{[1-(L^2+M^2)]}\,z\right\} \tag{56}$$

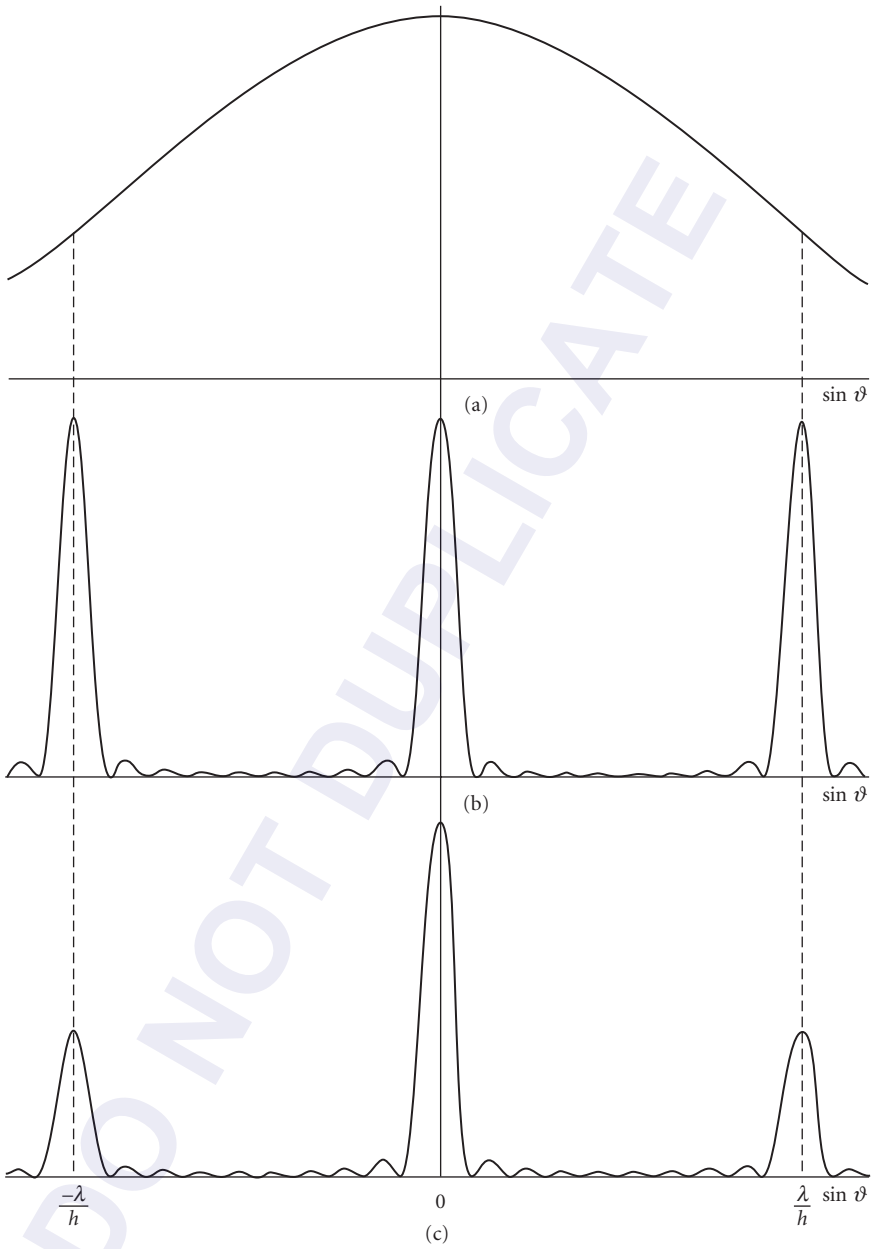

FIGURE 28 (*a*) Irradiance plot of a single-slit diffraction pattern; (*b*) partial plot of an $N = 10$ slit interference pattern; and (*c*) their product. (*From Rossi.*[8])

The special values of L and M that make the first derivatives of the phase zero,

$$\frac{\partial \phi}{\partial L} = 0 = \frac{\partial \phi}{\partial M} \tag{57}$$

are

$$L_0 = \pm \frac{x}{r} \quad \text{and} \quad M_0 = \pm \frac{y}{r} \tag{58}$$

where $r = \sqrt{x^2 + y^2 + z^2}$. The negative sign is omitted for forward propagation, $z > 0$. The phase is approximated by

$$\phi(L, M) \approx \phi(L_0, M_0) + \frac{1}{2}[\alpha(L - L_0)^2 + \beta(M - M_0)^2 + 2\gamma(L - L_0)(M - M_0)]$$

where the higher-order terms are neglected and α, β, and γ are the second derivatives evaluated at $L = L_0$ and $M = M_0$. These constant coefficients are given by

$$\phi(L_0, M_0) = kr \tag{59}$$

$$\alpha \equiv \frac{\partial^2 \phi}{\partial L^2} = -kr \frac{x^2 + z^2}{z^2} \tag{60a}$$

$$\beta \equiv \frac{\partial^2 \phi}{\partial M^2} = -kr \frac{y^2 + z^2}{z^2} \tag{60b}$$

and

$$\gamma \equiv \frac{\partial^2 \phi}{\partial L \partial M} = \frac{\partial^2 \phi}{\partial M \partial L} = -kr \frac{xy}{z^2} \tag{60c}$$

The resulting phase function is used in the double integral to obtain the diffracted field, $\psi(x, y, z)$. The reader may also refer to Ref. 1, app. III, Eq. (20). The above procedure yields the stationary phase approximation for the diffracted field given by

$$\psi(x, y, z) \approx -\frac{i}{\lambda} \frac{z}{r} \frac{\exp(ikr)}{r} \psi_{SP}\left(\frac{x}{r}, \frac{y}{r}\right) \tag{61}$$

where

$$\psi_{SP}\left(\frac{x}{r}, \frac{y}{r}\right) \equiv \iint_A \psi(x_s, y_s, 0) \exp\left[\frac{-i2\pi}{\lambda}\left(\frac{xx_s + yy_s}{r}\right)\right] dx_s\, dy_s$$

The diffracted field on a hemisphere is simply the spatial Fourier transform of the field distribution in the aperture as long as the distance r to the observation point satisfies the far-field condition

$$r \gg \frac{N^2 a^2}{\lambda} \tag{62}$$

where $N = z/r = \cos(\theta)$, the third direction cosine, a is the radius of the aperture, and λ is the wavelength of the light incident on the aperture. (θ is measured from the z axis, and as θ increases the far-field condition is weakened.) For observation points not satisfying the far-field condition, the higher-order terms of the stationary phase approximation cannot be neglected. Harvey[20] and

Harvey and Shack[21] have shown that these terms can be considered as aberrations of the spatial Fourier transform of the aperture field on the hemisphere of observation. In the stationary phase approximation, there is no restriction on the direction cosines, *L*, *M*, and *N*. Hence the diffracted field amplitude in Eq. (61) is valid over the entire hemisphere.

3.8 VECTOR DIFFRACTION

The popularity of the Fresnel-Kirchhoff diffraction formula in the scalar case stems from the fact that it is widely applicable and relatively easy to use. In the study of electromagnetic diffraction,[13,22] a similar formula can be obtained [see Ref. 13, Eq. (9.156)] but it has limited applicability because of the boundary conditions that must be satisfied.

These conditions are the ones related to perfectly conducting screens. They are not adequately approximated at optical frequencies. The study with finite conductivity makes for complicated mathematical procedures. From the point of view of instrumental optics the applicability of the theory then is severely limited.

In the optical literature, periodic structures such as gratings (both shallow and deep compared to the wavelength) have been studied. Boundary conditions are applied to perfectly conducting grating profiles.[18,19] The equation of the grating dictating the angular positions of the diffraction orders such as Eq. (53) continues to apply; the amount of power found in the different orders is significantly different in the vector theory compared to the scalar theory.

A special case of interest is discussed in detail by Jackson.[13] Consider a plane wave incident at an angle α on a thin, perfectly conducting screen with a circular hole of radius a in the x-y plane. The polarization vector (**E** field) of the incident wave lies in the x-z plane, which is taken to be the plane of incidence. The arrangement is shown in Fig. 29 where $\mathbf{k}_0$ stands for the wave vector of the incident wave and **k** is used for the diffracted field.

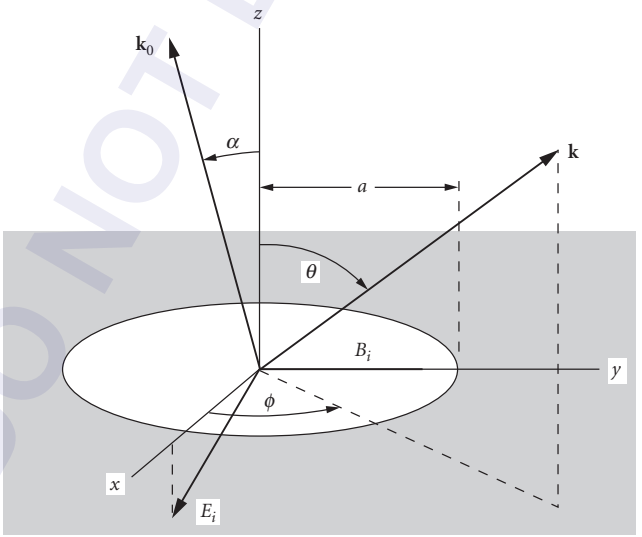

FIGURE 29 Coordinate system and aperture geometry for vector diffraction. α: angle of incidence. The E field is in the xz plane. $\mathbf{k}_0$: the wave vector of the incident wave. **k**: the diffracted field. (*From Jackson.*[13])

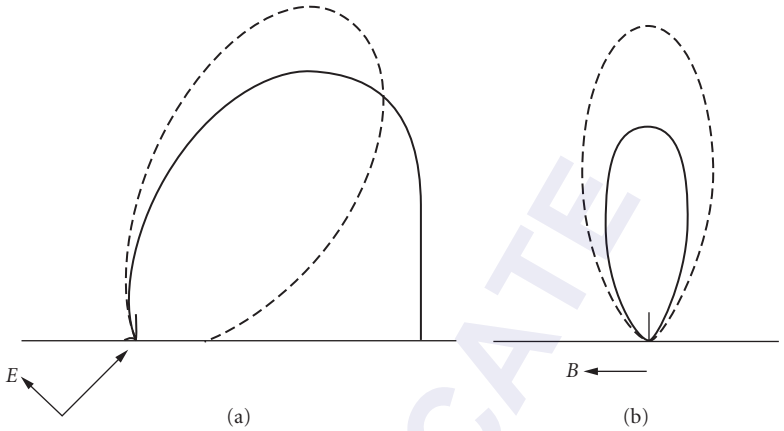

FIGURE 30 Fraunhofer diffraction pattern for a circular opening one wavelength in diameter in a thin-plane conducting screen. The angle of incidence is 45°. (*a*) Power-per-unit solid angle (radiant intensity) in the plane of incidence and (*b*) perpendicular to it. The solid (dotted) curve gives the vector (scalar) approximation in each case. (*From Jackson*.[13])

The vector and scalar approximations are compared in Fig. 30. The angle of incidence is equal to 45°and the aperture is one wavelength in diameter, $ka = \pi$. The angular distribution is shown in Fig. 30 for two cases. Figure 30*a* shows the distribution of the power per unit solid angle in the plane of incidence which contains the **E** field and Fig. 30*b* the distribution for the plane perpendicular to it. Both vector and scalar theories contain the Airy-disk-type distribution; the differences show in the angular distribution.

For normal incidence $\alpha = 0$ and $ka \gg 1$ the polarization dependence is unimportant and the diffraction is confined to very small angles in the forward direction (Airy-disk-type distribution) as we found before in Fig. 24 under Fraunhofer diffraction.

The Vector Huygens-Fresnel Secondary Source

Ideally, the fundamental model of any diffraction theory of light would retain the simplicity of Huygens' scalar secondary source and wavefront construction theory but also account for its vector nature. It has been shown that an electromagnetic wavefront can be modeled as a set of fictitious oscillating electric and magnetic surface charge and current densities existing at all points on the wavefront. The vector Huygens secondary source is a unit composed of two fictitious coincident dipoles; one electric and the other magnetic their magnitudes and orientation dictated by the wavefront boundary conditions. The fields of the vector Huygens secondary source are composed of the linear, vector superposition of the fields of these electric and magnetic dipoles. The electric dipole's axis lies in the plane of the page, is oriented in the vertical direction, and is located at the origin. The magnetic dipole's axis is perpendicular to the plane of the page and is also located at the origin. The vector of (a) the radiated electric field (Fig. 31*a*) is tangent to the spherical wavefront (represented by the outer circle) and lies in the plane of the page and (b) the radiated magnetic field (Fig. 31*b*) is tangent to the spherical wavefront (represented by the outer circle) and is perpendicular to the plane of the page. The Poynting vector (Fig. 31*c*) points radially outward. The magnitude of the irradiance is proportional to the length of the chord from the origin to the irradiance plot along the radius to the point of tangency. The strength of these vectors is proportional to the length of the chord from the origin to the field plot along the radius to the point of tangency.

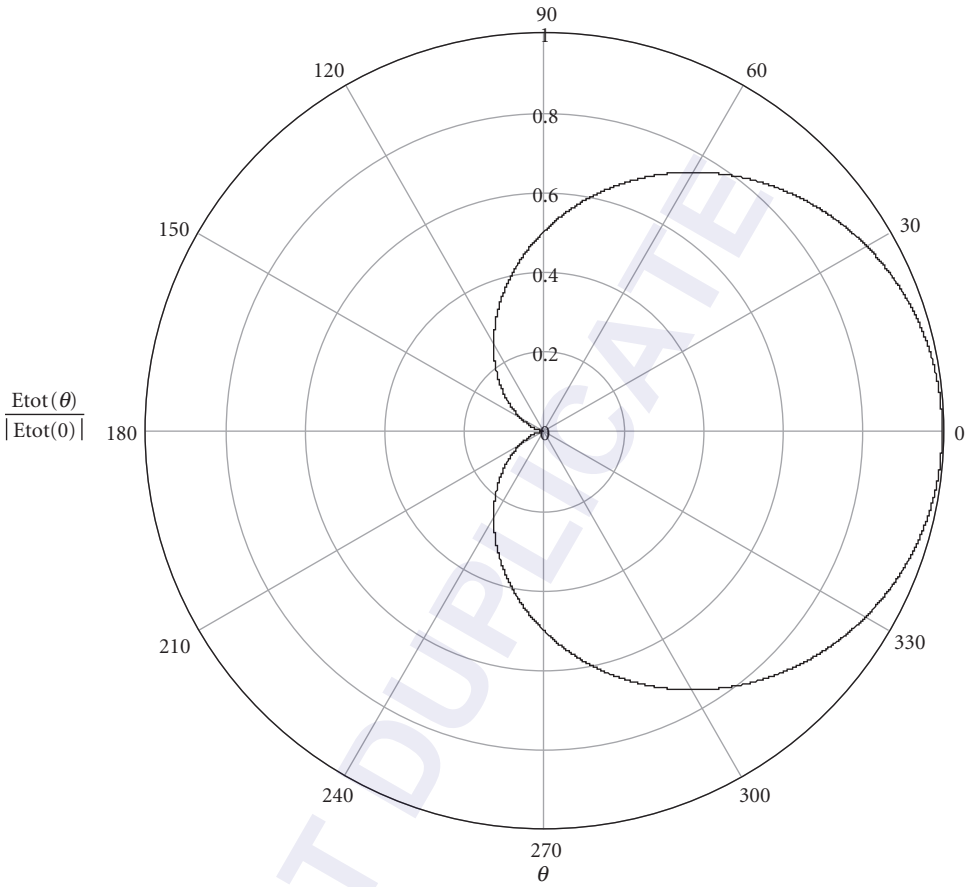

FIGURE 31*a* This figure is the mapping of the EM dipole's normalized electric field strength on the radiated spherical wavefront in the far zone of the EM dipole as a function of the angle between the direction of observation and $\hat{k}_{\mathrm{EM}}$ which lies in the plane of the page and is in the direction of the vector from the origin to 0 degrees.

The plot is rotationally symmetric about $\hat{k}_{\mathrm{EM}}$ which lies in the plane of the page and is in the direction of the vector from the origin to 0 degrees.

The diffracted field at any observation point is the summation of the fields radiated from the electriomagnetic dipoles in the aperture visible to the observation point as given by

$$\vec{E}(\vec{r}) = \frac{-i}{2\lambda^2} \iiint_{EPW} \left\{ \left[\hat{R}_s \times \vec{E}(\vec{r}_s) \right] \times \hat{R}_s - \sqrt{\frac{\mu_o}{\varepsilon_o}} \left[\hat{R}_s \times \vec{H}(\vec{r}_s) \right] \right\} \frac{\exp(ikR_s)}{R_s} d^3\vec{r}_s \tag{63}$$

$$\vec{H}(\vec{r}) = \frac{-i}{2\lambda^2} \iiint_{EPW} \left\{ \left[\hat{R}_s \times \vec{H}(\vec{r}_s) \right] \times \hat{R}_s + \sqrt{\frac{\varepsilon_o}{\mu_o}} \left[\hat{R}_s \times \vec{E}(\vec{r}_s) \right] \right\} \frac{\exp(ikR_s)}{R_s} d^3\vec{r}_s \tag{64}$$

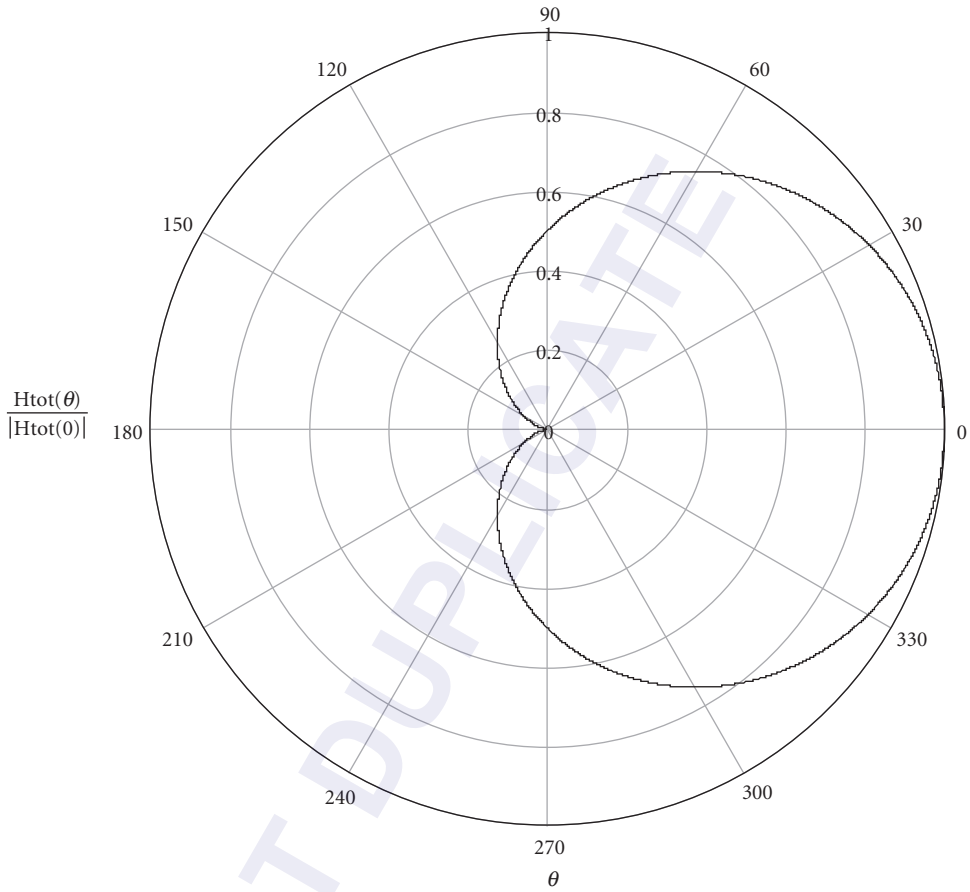

FIGURE 31*b* This figure is the mapping of the EM dipole's normalized magnetic field strength on the radiated spherical wavefront in the far zone of the EM dipole as a function of the angle between the direction of observation and $\hat{k}_{EM}$ which lies in the plane of the page and is in the direction of the vector from the origin to 0 degrees.

In these expressions, $\vec{E}(\vec{r})$ and $\vec{H}(\vec{r})$ are, respectively, the diffracted electric and magnetic fields at the point of observation $\vec{r}$. In the integrands, $\vec{E}(\vec{r}_s)$ and $\vec{H}(\vec{r}_s)$ are the fields of the wavefront incident on the aperture at point $\vec{r}_s$ and are related by

$$\vec{H}(\vec{r}_s) = \sqrt{\frac{\varepsilon_o}{\mu_o}}\hat{n}(\vec{r}_s) \times \vec{E}(\vec{r}_s) \tag{65}$$

Here $\hat{n}(\vec{r}_s)$ is the normal to the wavefront. We have defined $\vec{R}_s = \vec{r} - \vec{r}_s$ and use R_s for the magnitude and $\hat{R}_s$ for the unit vector in the direction of $\vec{R}_s$. The letters *EPW* under the volume integral stand for "exposed parts of the primary wavefront." The integration is restricted to the open areas of the aperture.

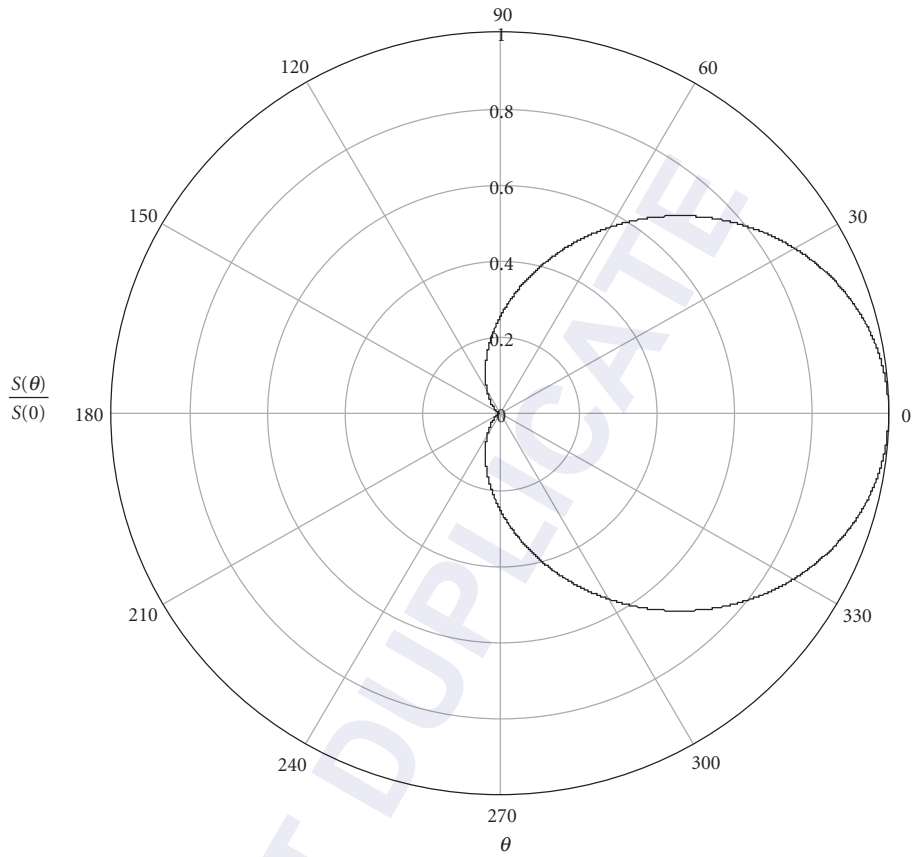

FIGURE 31*c* This figure is the mapping of the EM dipole's normalized irradiance on the radiated spherical wavefront in the far zone of the EM dipole as a function of the angle between the direction of observation and $\hat{k}_{\mathrm{EM}}$ which lies in the plane of the page and is in the direction of the vector from the origin to 0 degrees.

By use of vector identities, the curly bracket in Eq. (63) may be rewritten in the form

$$\left\{\left[\hat{R}_s \times \vec{E}(\vec{r}_s)\right] \times \hat{R}_s - \sqrt{\frac{\mu_o}{\varepsilon_o}}\left[\hat{R}_s \times \vec{H}(\vec{r}_s)\right]\right\} = \vec{E}_{\perp}(\vec{r}_s) + \vec{E}(\vec{r}_s)(\cos\chi) - \hat{n}(\vec{r}_s)(E_{\ell}(\vec{r}_s)) \tag{66}$$

In this expression $\vec{E}_{\perp}(\vec{r}_s)$ is the transverse component of $\vec{E}(\vec{r}_s)$ perpendicular to the direction $\hat{R}_s$ and $E_{\ell}(\vec{r}_s)$ is the longitudinal component of $\vec{E}(\vec{r}_s)$ parallel to the direction $\hat{R}_s$. The symbol χ stands for the angle between the unit vectors $\hat{R}_s$ and $\hat{n}(\vec{r}_s)$. In the special case where the angle χ is zero, the curly bracket reduces to $2\vec{E}_{\perp}(\vec{r}_s)$.

For further details and additional references, we refer to McCalmont[23] and Marathay and McCalmont.[24] Figure 32 is a sequence of irradiance profiles due to the diffraction of light by a narrow slit based on Eqs. (63) and (64). The sequence describes diffraction from deep within the Fresnel region into the Fraunhofer zone.

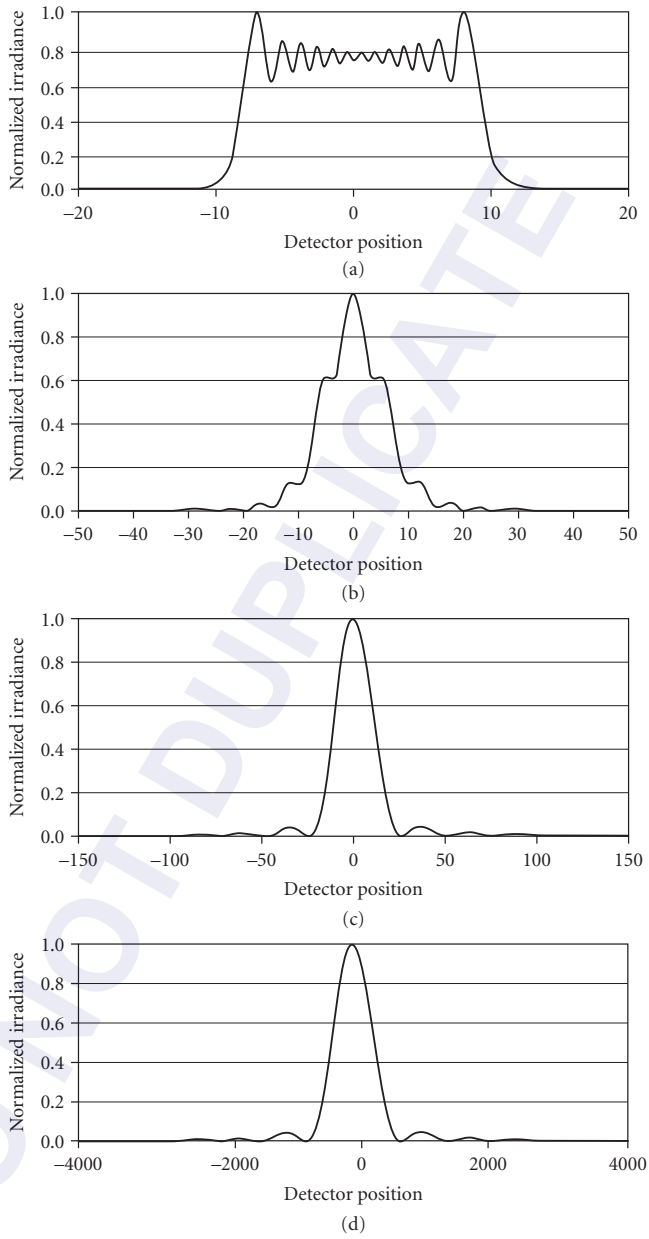

FIGURE 32 Flux density profiles along the horizontal x axis on an observation screen at the following distances: (*a*) 5λ, (*b*) 100λ, (*c*) 500λ, and (*d*) $15{,}000\lambda$. These profiles are due to diffraction by a rectangular slit and are based on Eqs. (63) and (64). The slit is of width 20λ. The first zero of the Fraunhofer pattern is at 2.81° from the optical axis. The incident field is a plane wave of unit amplitude, at normal incidence on the plane of the aperture and polarized in the vertical y-direction. The position on the x axis is in terms of wavelengths from the origin of the observation plan.

3.9 ACKNOWLEDGMENTS

The chapter is dedicated by Arvind Marathay to his wife Sunita and family and by John McCalmont to his wife Ingrid and family.

TRANSFER FUNCTION TECHNIQUES

Glenn D. Boreman

CREOL, The College of Optics and Photonics
University of Central Florida
Orlando, Florida

4.1 GLOSSARY

B	spot full width
CTF	contrast transfer function (square wave response)
$e(x)$	edge response
FN	focal ratio
$F(\xi, \eta)$	Fourier transform of $f(x, y)$
$f(x, y)$	object function
$G(\xi, \eta)$	Fourier transform of $g(x, y)$
$g(x, y)$	image function
$H(\xi, \eta)$	Fourier transform of $h(x, y)$
$h(x, y)$	impulse response
$\ell(x)$	line response
$S(\xi, \eta)$	power spectrum
W	detector dimension
$\delta(x)$	delta function
$\theta(\xi, \eta)$	phase transfer function
**	two-dimensional convolution

4.2 INTRODUCTION

Transfer functions are a powerful tool for analyzing optical and electro-optical systems. The interpretation of objects and images in the frequency domain makes available the whole range of linear-systems analysis techniques. This approach can facilitate insight, particularly in the treatment of complex optical problems. For example, when several optical subsystems are combined, the overall transfer function is the multiplication of the individual transfer functions. The corresponding analysis, without the use of transfer functions, requires convolution of the corresponding impulse responses.

4.3 DEFINITIONS

The image quality of an optical or electro-optical system can be characterized by either the system's impulse response or its Fourier transform, the transfer function. The impulse response $h(x, y)$ is the two-dimensional image formed in response to a delta-function object. Because of the limitations imposed by diffraction and aberrations, the image quality produced depends on the following: the wavelength distribution of the source; the F-number (FN) at which the system operates; the field angle at which the point source is located; and the choice of focus position.

A continuous object $f(x, y)$ can be decomposed, using the sifting property of delta functions, into a set of point sources, each with a strength proportional to the brightness of the object at that location. The final image $g(x, y)$ obtained is the superposition of the individually weighted impulse responses. This result is equivalent to the convolution of the object with the impulse response:

$$f(x, y)^{**} h(x, y) = g(x, y) \tag{1}$$

where the double asterisk denotes a two-dimensional convolution.

The validity of Eq. (1) requires shift invariance and linearity. Shift invariance is necessary for the definition of a single impulse response and linearity is necessary for the superposition of impulse responses. These assumptions are often violated in practice, but the convenience of a transfer-function analysis dictates that we preserve this approach if possible. While most optical systems are linear, electro-optical systems that include a receiver (such as photographic film, detector arrays, and xerographic media) are often nonlinear. A different impulse response (and hence transfer function) is obtained for inputs of different strengths. In optical systems with aberrations that depend on field angle, separate impulse responses are defined for different regions of the image plane.

Although $h(x, y)$ is a complete specification of image quality (given a set of optical parameters), additional insight is gained by use of the transfer function. A transfer-function analysis considers the imaging of sinusoidal objects, rather than point objects. It is more convenient than an impulse-response analysis because the combined effect of two or more subsystems can be calculated by a point-by-point multiplication of the transfer functions, rather than by convolving the individual impulse responses. Using the convolution theorem of Fourier transforms, we can rewrite the convolution of Eq. (1) as a multiplication of the corresponding spectra:

$$F(\xi, \eta) \times H(\xi, \eta) = G(\xi, \eta) \tag{2}$$

where the uppercase variables denote the Fourier transforms of the corresponding lowercase variables: $F(\xi, \eta)$ is the object spectrum; $G(\xi, \eta)$ is the image spectrum; $H(\xi, \eta)$ is the spectrum of the impulse response. As a transfer function, $H(\xi, \eta)$ multiplies the object spectrum to yield the image spectrum. The variables ξ and η are spatial frequencies in the x and y directions. Spatial frequency is the reciprocal of the crest-to-crest distance of a sinusoidal waveform used as a basis function in the Fourier analysis of an object or image. In two dimensions, a sinusoid of arbitrary orientation has a spatial period along both the x and y axes. The reciprocals of these spatial periods are the spatial frequencies ξ and η. Typical units of spatial frequency are cycles/millimeter when describing an image, and cycles/milliradian when describing an object at a large distance. For an object located at infinity, these two representations are related through the focal length of the image-forming optical system:

$$\xi_{\text{angular}}[\text{cycles/mrad}] = 0.001 \times \xi\,[\text{cycles/mm}] \times f[\text{mm}] \tag{3}$$

The function $H(\xi, \eta)$ in Eq. (2) is usually normalized to have unit value at zero frequency. This yields a transfer function relative to the response at low frequency, and ignores frequency-independent attenuations, such as losses caused by Fresnel reflection or by obscurations. This normalization is appropriate for most optical systems, because[1] the transfer function of an incoherent optical system is proportional to the two-dimensional autocorrelation of the exit pupil, which is maximum at zero frequency. For more general imaging systems (for example, the human eye, photographic film, and electronic imaging systems), the transfer function is not necessarily maximum at the origin, and may be more useful in an unnormalized form.

With the above normalization, $H(\xi, \eta)$ is called the optical transfer function (OTF). In general, OTF is a complex function, having both a magnitude and a phase portion:

$$\text{OTF}(\xi, \eta) = H(\xi, \eta) = |H(\xi, \eta)| \exp\{-j\theta(\xi, \eta)\} \tag{4}$$

The magnitude of the OTF, $|H(\xi, \eta)|$, is referred to as the modulation transfer function (MTF), while the phase portion of the OTF, $\theta(\xi, \eta)$, is referred to as the phase transfer function (PTF).

MTF is the magnitude response of the imaging system to sinusoids of different spatial frequencies. This response is described in terms of the modulation depth, a measure of visibility or contrast:

$$M = \frac{A_{\max} - A_{\min}}{A_{\max} + A_{\min}} \tag{5}$$

where A refers to a value of the waveform (typically W/cm^2 vs position) that describes the object or image. These quantities are nonnegative, so the sinusoids always have a dc bias. Modulation depth is thus a number between 0 and 1. The effect of the finite-size impulse response is that the modulation depth in the image is less than that in the object. This attenuation is usually more severe at high frequencies. MTF is the ratio of image modulation to object modulation, as a function of spatial frequency:

$$\text{MTF}(\xi, \eta) = \frac{M_{\text{image}}(\xi, \eta)}{M_{\text{object}}(\xi, \eta)} \tag{6}$$

PTF describes the relative phases with which the various sinusoidal components recombine in the image. A linear phase such as PTF = $x_0\xi$ corresponds to a shift of the image by an amount x_0, each frequency component being shifted the amount required to reproduce the original waveform at the displaced location. For impulse responses that are symmetric about the ideal image point, the PTF exhibits phase reversals, with a value of either 0 or π radians as a function of spatial frequency. A general impulse response that is real but not even yields a PTF that is a nonlinear function of frequency, resulting in image degradation. Linearity of PTF is a sensitive test for aberrations (such as coma) which produces asymmetric impulse responses, and is often a design criterion.

4.4 MTF CALCULATIONS

OTF can be calculated from wave-optics considerations. For an incoherent optical system, the OTF is proportional to the two-dimensional autocorrelation of the exit pupil. This calculation can account for any phase factors across the pupil, such as those arising from aberrations or defocus. A change of variables is required for the identification of an autocorrelation (a function of position in the pupil) as a transfer function (a function of image-plane spatial frequency). The change of variables is

$$\xi = \frac{x}{\lambda d_i} \tag{7}$$

where x is the autocorrelation shift distance in the pupil, λ is the wavelength, and d_i is the distance from the exit pupil to the image. A system with an exit pupil of full width D has an image-space cutoff frequency consistent with Eq. (7):

$$\xi_{\text{cutoff}} = \frac{1}{(\lambda\ \text{FN})} \tag{8}$$

where FN equals (focal length)/D for a system with the object at infinity, and d_i/D for a system operating at finite conjugates.

A diffraction-limited system has a purely real OTF. Diffraction-limited MTFs represent the best performance that a system can achieve, for a given FN and λ, and accurately describe systems with

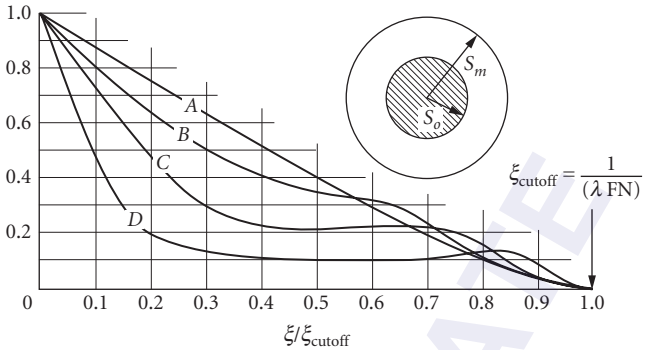

FIGURE 1 (*A*) Diffraction-limited MTF for system with circular pupil (no obscuration: $S_o/S_m = 0$). (*B*) through (*D*) are diffraction-limited MTF for a system with an annular pupil: (*B*) $S_o/S_m = 0.25$; (*C*) $S_o/S_m = 0.5$; (*D*) $S_o/S_m = 0.75$. (*Adapted from Ref. 4, p. 322.*)

negligible aberrations, whose impulse-response size is dominated by diffraction effects. A diffraction-limited system with a square exit pupil of dimensions $D \times D$ has a linear MTF along ξ or η:

$$\text{MTF}\left(\frac{\xi}{\xi_{\text{cutoff}}}\right) = 1 - \frac{\xi}{\xi_{\text{cutoff}}} \tag{9}$$

For a system with a circular exit pupil of diameter D, the MTF is circularly symmetric, with ξ profile:[2]

$$\text{MTF}\left(\frac{\xi}{\xi_{\text{cutoff}}}\right) = \frac{2}{\pi}\left\{\cos^{-1}\left(\frac{\xi}{\xi_{\text{cutoff}}}\right) - \frac{\xi}{\xi_{\text{cutoff}}}\left[1 - \left(\frac{\xi}{\xi_{\text{cutoff}}}\right)^2\right]^{1/2}\right\} \quad \text{if} \quad \xi \le \xi_{\text{cutoff}}$$
$$= 0 \quad \text{if} \quad \xi > \xi_{\text{cutoff}} \tag{10}$$

Equation (10) is plotted in Fig. 1, along with MTF curves obtained for annular pupils, which arise in obscured systems such as Cassegrain telescopes. The plots are functions of the obsuration ratio, and the emphasis at high frequencies has been obtained by an overall decrease in flux reaching the image, proportional to the obscured area. If the curves in Fig. 1 were plotted without normalization to 1 at $\xi = 0$, they would all be contained under the envelope of the unobscured diffraction-limited curve.

A system exhibiting effects of both diffraction and aberrations has an MTF curve bounded by the diffraction-limited MTF curve as the upper envelope. Aberrations broaden the impulse response, resulting in a narrower and lower MTF, with less integrated area.

The effect of defocus on the MTF is shown in Fig. 2. The MTF curves resulting from third-order spherical aberration are shown in Fig 3. MTF results for specific cases of other aberrations are contained in Ref. 3.

A geometrical-aberration OTF can be calculated from ray-trace data, without regard for diffraction effects. Optical-design computer programs typically yield a diagram of ray-intersection density in the image plane, a geometrical-optics spot diagram. A geometrical-aberration OTF is calculated by Fourier transforming the spot-density distribution. The OTF thus obtained is accurate if the impulse-response size is dominated by aberration effects. A one-dimensional uniform blur spot of full width B has the following OTF in the ξ direction:

$$\text{OTF}(\xi) = \frac{\sin(\pi \xi B)}{\pi \xi B} \tag{11}$$

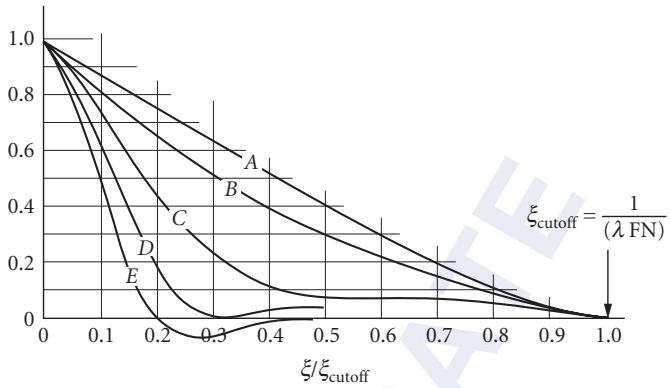

FIGURE 2 Diffraction MTF for a defocused system: (*A*) in focus, OPD = 0.0; (*B*) defocus = $\lambda/2N \sin^2 u$, OPD = $\lambda/4$; (*C*) defocus = $\lambda/N \sin^2 u$, OPD = $\lambda/2$; (*D*) defocus = $3\lambda/2N \sin^2 u$, OPD = $3\lambda/4$; and (*E*) defocus = $2\lambda/N \sin^2 u$, OPD = λ. (*Adapted from Ref. 4, p. 320.*)

which has a zero at $\xi = 1/B$, and also exhibits the phase reversals mentioned above. When an MTF has been calculated from ray trace data, an approximation to the total system MTF may be made[4] by multiplying the diffraction-limited MTF of the proper FN and λ with the ray-trace data MTF. This is equivalent to a convolution of the spot profiles from diffraction and geometrical aberrations.

In electronic imaging systems, an electronics subsystem performs signal-handling and signal-processing functions. The performance characterization of electronic networks by transfer-function techniques is well established. The usual independent variable for these time-domain transfer functions is the temporal frequency f (Hz). To interpret the electronics transfer function in the same units as the image-plane spatial frequency (cycles/mm), the temporal frequencies are divided by the scan velocity (mm/s). For a scanning system, this is the velocity of the instantaneous field of view, referred to as image coordinates. For a staring system, an effective scan velocity is the

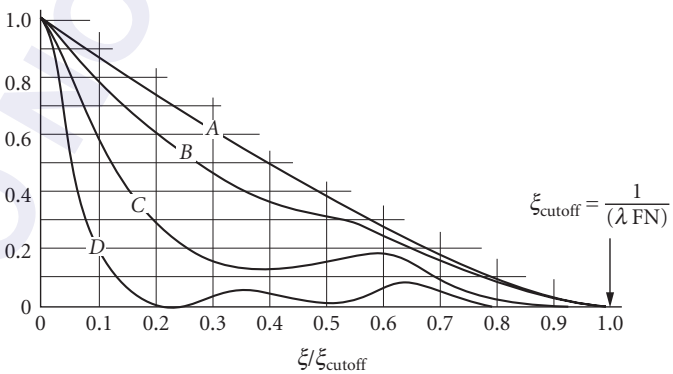

FIGURE 3 Diffraction MTF for system with third-order spherical aberration (image plane midway between marginal and paraxial foci): (*A*) $LA_m = 0.0$, OPD = 0; (*B*) $LA_m = 4\lambda/N \sin^2 u$, OPD = $\lambda/4$; (*C*) $LA_m = 8\lambda/N \sin^2 u$, OPD = $\lambda/2$; and (*D*) $LA_m = 16\lambda/N \sin^2 u$, OPD = λ. (*Adapted from Ref. 4, p. 322.*)

horizontal dimension of the image plane divided by the video line time. With this change of variables from temporal frequencies to spatial frequencies, the electronics can be analyzed as simply an additional subsystem, with its own transfer function that will multiply the transfer functions of the other subsystems. It should be noted that an electronics transfer function is not bounded by a pupil autocorrelation the way an optical transfer function is. Thus, it need not be maximum at the origin, and can amplify certain frequencies and have sharp cutoffs at others. Thus, the usual normalization of MTF may not be appropriate for analysis of the electronics subsystems, or for the entire imaging system including the electronics.

An unavoidable impact of the electronics subsystem is the contribution of noise to the image. This limits the amount of electronic amplification that is useful in recovering modulation depth lost in other subsystems. A useful figure of merit, which has been validated to correlate with image visibility,[5] is the area between two curves: the MTF and the noise power spectrum. To facilitate comparison on the same graph, the noise power spectrum is expressed in modulation depth units, and is interpreted as a noise-equivalent modulation depth (the modulation needed for unit signal-to-noise ratio) as a function of spatial frequency.

The detector photosensitive area has finite size, rather than being a true point. It thus performs some spatial averaging[6] on any irradiance distribution that falls on it. Large detectors exhibit more attenuation of high spatial frequencies than do small detectors. For a detector of dimension W in the x direction, the MTF is

$$\mathrm{MTF}(\xi)=\left|\frac{\sin(\pi\xi W)}{\pi\xi W}\right| \tag{12}$$

which has a zero at $\xi = 1/W$. This MTF component applies to any system with detectors, and will multiply the MTFs of other subsystems.

In electronic imaging systems, the image is typically sampled in both directions. The distance between samples will determine the image-plane spatial frequency at which aliasing artifacts will occur. Care must be taken in the calculation of MTF, because different impulse responses are possible depending on the location of the impulse response with respect to the sampling positions. This violates the assumption of shift-invariance needed for a transfer-function analysis.[7] One approach for defining a generalized MTF is to average over all possible positions of the impulse response with respect to the sampling lattice [Eq. (4) in Ref. 8]. Research is still underway on the specification of MTF for sampled-image systems.

4.5 MTF MEASUREMENTS

In any situation where the measurement of MTF involves the detection of the image-plane flux, one component of the measurement-system MTF is caused by the finite aperture of the detector, which can be accounted for in the calibration of the instrument by dividing out the detector MTF seen in Eq. (12).

When OTF is measured with a point-source object, the image formed by the system under test is the impulse response. The two-dimensional impulse response can be Fourier transformed in two dimensions to yield OTF (ξ, η). If an illuminated pinhole is used, it should be as small as possible. However, flux-detection considerations dictate a finite size for any source. The object is small enough not to affect the measurement if its angular subtense is much smaller than the angular subtense of the impulse response, when both are viewed from the aperture stop of the system. For sources of larger extent, a Fourier analysis can be made of the object, and an OTF can be calculated using Eq. (2), over the range of spatial frequencies provided by the source.

If higher flux levels are needed to maintain signal-to-noise ratio, a line response can be measured. The system under test is presented with an illuminated line source, which acts as a delta function in one direction and a constant in the other: $\delta(x)1(y)$. The system forms an image, the

line response $\ell(x)$, which is a summation of vertically displaced impulse responses. In general $\ell(x) \neq h(x,0)$[2]. The line response only yields information about one profile of OTF (ξ, η). The one-dimensional Fourier transform of the line response produces the corresponding profile of the two-dimensional OTF: $\mathcal{F}\{\ell(x)\} = \text{OTF}(\xi, 0)$. To obtain other profiles of the OTF, the line source is reoriented. Line response data are also available from the response of the system to a point source, using a receiver that integrates the impulse response along one direction: a detector that is long in one dimension and is scanned perpendicularly, or a long slit that is scanned in front of a large-area detector.

Another measurement of OTF uses the edge response $e(x)$, which is the response of the system to an illuminated knife edge. Each line in the open part of the aperture produces a displaced line response, so $e(x)$ is a cumulative distribution, related to the line response as follows: $d/dx\{e(x)\} = \ell(x)$, which Fourier transforms to the ξ profile of the OTF. The derivative operation increases the effect of noise. Any digital filter used for data smoothing has its own impulse response, and hence its own OTF contribution. The edge response can also be measured by using a scanning knife edge in front of a detector in the image plane, with a point-source or a line-source object.

An MTF calculated from a measured profile is the product of a diffraction MTF and a geometrical-aberration MTF. When combining the separately-measured MTFs of several optical subsystems, care should be taken to ensure that the diffraction MTF (determined by the aperture stop of the combined system) contributes only once to the calculation. The geometrical-aberration MTFs for each subsystem will cascade if each subsystem operates independently on an irradiance basis, with no partial coherence effects.[9] The major exception to this condition occurs when two subsystems are designed to correct for each other's aberrations, and the MTF of the combined system is better than the individual MTFs would indicate.

MTF can also be obtained by the system's response to a sine-wave target, where the image modulation depth is measured as a function of spatial frequency. PTF can also be measured from the position of the waveform maxima as a function of frequency. Sine-wave targets are available as photographic prints or transparencies, which are suitable for testing visible-wavelength systems. Careful control in their manufacture is exercised[10] to avoid harmonic distortions, including a limitation to relatively small modulation depths. Sine-wave targets are difficult to fabricate for testing infrared systems, and require the use of half-tone techniques.[11]

A more convenient target to manufacture is the three- or four-bar target of equal line and space width, with a binary transmission or reflection characteristic. These are widely used for testing both visible-wavelength and infrared systems. The square-wave response is called the contrast transfer function (CTF) and is not equivalent to the sine-wave response for which MTF is defined. CTF is a function of the fundamental spatial frequency ξ_f inverse of the bar-to-bar spacing) and is measured on the peak-to-valley variation of image irradiance. For any particular fundamental frequency, the measured response to bar targets will be higher than that measured for sinewaves of the same frequency, because additional harmonic components contribute to the modulation. For a square-wave pattern of infinite extent, an analytical relationship exists[12] between CTF(ξ_f) and MTF(ξ). Each Fourier component of the square wave has a known transfer factor given by MTF(ξ), and the modulation depth as a function of ξ_f of the resultant waveform can be calculated by Eq. (5). This process yields the following series:

$$\text{CTF}(\xi_f) = \frac{4}{\pi}\left\{\text{MTF}(\xi_f) - \frac{1}{3}\text{MTF}(3\xi_f) + \frac{1}{5}\text{MTF}(5\xi_f) - \frac{1}{7}\text{MTF}(7\xi_f) + \frac{1}{9}\text{MTF}(9\xi_f) - \cdots\right\} \quad (13)$$

CTFs for the practical cases of three- and four-bar targets are slightly higher than the CTF curve for an infinite square wave. Figure 4[13] compares the MTF for a diffraction-limited circular-aperture system with CTFs obtained for infinite, three- and four-bar targets. Because of the broad spectral features associated with bar patterns of limited extent, a finite level of modulation is present in the image, even when the fundamental frequency of the bar pattern equals the cutoff frequency of the system MTF.[14] The inverse process of expressing the MTF in terms of CTFs is more difficult analytically,

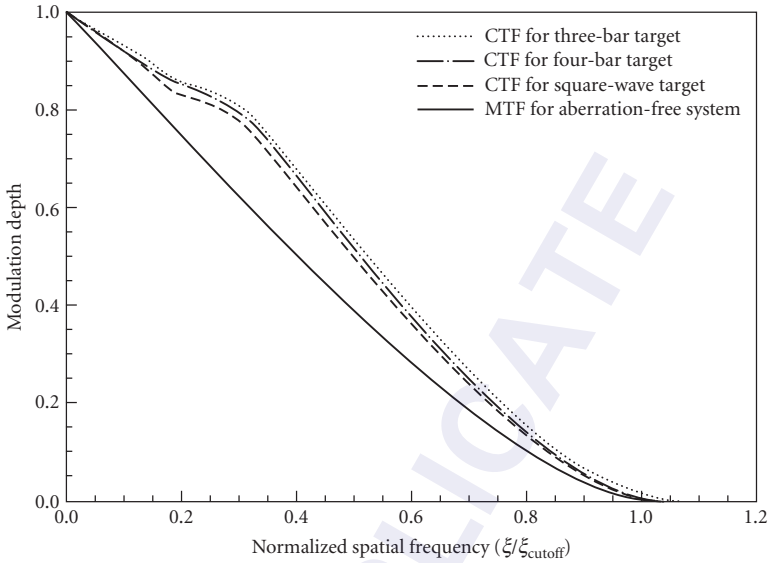

FIGURE 4 Comparison of MTF to CTFs obtained with infinite square wave, four-bar, and three-bar targets for a diffraction-limited system with circular pupil.

since square waves are not an orthogonal basis set for the expansion of sinusoids. A term-by-term series subtraction[12] yields the following:

$$\mathrm{MTF}(\xi_f)=\frac{\pi}{4}\left\{\mathrm{CTF}(\xi_f)+\frac{1}{3}\mathrm{CTF}(3\xi_f)-\frac{1}{5}\mathrm{CTF}(5\xi_f)+\frac{1}{7}\mathrm{CTF}(7\xi_f)+\frac{1}{11}\mathrm{CTF}(11\xi_f)-\cdots\right\} \quad (14)$$

Narrowband electronic filtering can be used to isolate the fundamental spatial-frequency component for systems where the image data are available as a time-domain waveform. These systems do not require the correction of Eq. (14), because the filter converts bar-target data to sinewave data.

The MTF can also be measured by the response of the system to a random object. Laser speckle provides a convenient means to generate a random object distribution of known spatial-frequency content. The MTF relates the input and output spatial-frequency power spectra of the irradiance waveforms:

$$S_{\mathrm{output}}(\xi,\eta)=|\mathrm{MTF}(\xi,\eta)|^2\times S_{\mathrm{input}}(\xi,\eta) \quad (15)$$

This method is useful in the measurement of an average MTF for sampled-image systems,[15] since the speckle pattern has a random position with respect to the sampling sites.

A number of interferometric methods have been developed for measuring MTF.[16] An interferogram of the wavefront exiting the system is reduced to find the phase map. The distribution of amplitude and phase across the exit pupil contains the information necessary for calculation of OTF by pupil autocorrelation.

5.1 GLOSSARY

I	intensity (use irradiance or field intensity)
k	radian wave number
$\mathbf{p}$	unit propagation vector
t	time
U	field amplitude
u	Fourier transform of U
W_ω	cross-spectral density function
$\mathbf{x}$	spatial vector
$\Gamma_{12}(\tau)$	mutual coherence function
$\Delta\ell$	coherence length
$\Delta\tau$	coherence time
μ_ω	complex degree of spatial coherence
ϕ	phase
ω	radian frequency
Real ( )	real part of ( )

5.2 INTRODUCTION

Classical Coherence Theory

All light sources produce fields that vary in time with highly complicated and irregular waveforms. Because of diffraction, these waveforms are greatly modified as the fields propagate. All light detectors measure the intensity time averaged over the waveform. This measurement depends on the integration

*Deceased. The author was a visiting scientist at the Johns Hopkins University Applied Physics Laboratory when this chapter was written.

time of the detector and the waveform of the light at the detector. Generally this waveform is not precisely known. Classical coherence theory[1–8] is a mathematical model which is very successful in describing the effects of this unknown waveform on the observed measurement of time-averaged intensity. It is based on the electromagnetic wave theory of light as formulated from Maxwell's equations, and uses statistical techniques to analyze the effects due to fluctuations in the waveform of the field in both time and space.

Quantum Coherence Theory

Classical coherence theory can deal very well with almost all presently known optical coherence phenomena; however, a few laboratory experiments require a much more complicated mathematical model, quantum coherence theory[9–11] to explain them. This theory is not based on classical statistical theory, but is based on quantum electrodynamics.[12–14] While the mathematical model underlying classical coherence theory uses simple calculus, quantum coherence theory uses the Hilbert space formulation of abstract linear algebra, which is very awkward to apply to most engineering problems. Fortunately, quantum coherence theory appears to be essential as a model only for certain unusual (even though scientifically very interesting) phenomena such as squeezed light states and photon antibunching. All observed naturally occuring phenomena outside of the laboratory appear to be modeled properly by classical coherence theory or by an approximate semiclassical quantum theory. This chapter will deal only with the simple classical model.

5.3 SOME ELEMENTARY CLASSICAL CONCEPTS

Analytical Signal Representation

Solutions of the time-dependent, macroscopic Maxwell's equations yield six scalar components of the electric and the magnetic fields which are functions of both time and position in space. As in conventional diffraction theory, it is much more convenient to treat monochromatic fields than it is to deal with fields that have complicated time dependencies. Therefore, each of these scalar components is usually represented at some typical point in space (given with respect to some arbitrary origin by the radius vector $\mathbf{x} = (x, y, z)$ by a superposition of monochromatic real scalar components. Thus the field amplitude for a typical monochromatic component of the field with radial frequency ω is given by

$$U_r(\mathbf{x}, \omega) = U_0(\mathbf{x}) \cos[\phi(\mathbf{x}) - \omega t] \tag{1}$$

where $U_0(\mathbf{x})$ is the field magnitude and $\phi(\mathbf{x})$ is the phase. Trigonometric functions like that in Eq. (1) are awkward to manipulate. This is very well known in electrical circuit theory. Thus, just as in circuit theory, it is conventional to represent this field amplitude by a "phasor" defined by

$$U(\mathbf{x}, \omega) = U_0(\mathbf{x}) e^{i\phi(\mathbf{x})} \tag{2}$$

The purpose for using this complex field amplitude, just as in circuit theory, is to eliminate the need for trigonometric identities when adding or multiplying field amplitudes. A time-dependent complex analytic signal (viz., Ref. 15, sec. 10.2) is usually defined as the Fourier transform of this phasor, i.e.,

$$u(\mathbf{x}, t) = \int_0^\infty U(\mathbf{x}, \omega) e^{-i\omega t} d\omega \tag{3}$$

The integration in Eq. (3) is only required from zero to infinity because the phasor is defined with hermitian symmetry about the origin, i.e., $U(-\mathbf{x}, \omega) = U^*(\mathbf{x}, \omega)$. Therefore, all of the information is contained within the domain from zero to infinity. To obtain the actual field component from the analytical signal just take the real part of it. The Fourier transform in Eq. (3) is well defined if the analytical signal represents a deterministic field. However, if the light is partially coherent, then the analytic signal is usually taken to be a stationary random process. In this case the Fourier inverse of

Eq. (3) does not exist. It is then possible to understand the spectral decomposition given by Eq. (3) only within the theory of generalized functions (viz., see Refs. 16, the appendix on generalized functions, and 17, pp. 25–30).

Scalar Field Amplitude

Each monochromatic component of an arbitrary deterministic light field propagating through a homogeneous, isotropic medium can always be represented using an angular spectrum of plane waves for each of the six scalar components of the vector field. The six angular spectra are coupled together by Maxwell's equations so that only two are independent.[18–20] Any two of the six angular spectra can be used to define two scalar fields from which the complete vector field can be determined. A polarized light field can be represented in this way by only one scalar field.[20,21] Thus it is often possible to represent one polarized component of a vector electromagnetic field by a single scalar field. It has also been found useful to represent completely unpolarized light by a single scalar field. In more complicated cases, where the polarization properties of the light are important, a vector theory is sometimes needed as discussed later under "Explicit Vector Representations."

Temporal Coherence and Coherence Time

Within a short enough period of time, the time dependence of any light field at a point in space can be very closely approximated by a sine wave (Ref. 15, sec. 7.5.8). The length of time for which this is a good approximation is usually called the *coherence time* $\Delta\tau$. The coherence time is simply related to the spectral bandwidth for any light wave by the uncertainty principle, i.e.,

$$\Delta\tau\,\Delta\omega \geq 1 \tag{4}$$

For a light wave which is also highly directional within some region of space (like a beam) so that it propagates generally in some fixed direction (given by the unit vector $\mathbf{p}$), the field amplitude is given by

$$u(\mathbf{x},\, t) = f(\mathbf{p}\cdot\mathbf{x} - ct) \tag{5}$$

Such a traveling wave will be approximately sinusoidal (and hence coherent) over some coherence length $\Delta\ell$ in the direction of $\mathbf{p}$ where from Eq. (4) we see that

$$\Delta\ell = c\,\Delta\tau \approx c/\Delta\omega \tag{6}$$

so that the coherence length varies inversely with bandwidth.

Spatial Coherence and Coherence Area

The time-dependent waveform for any light field is approximately the same at any point within a sufficiently small volume of space called the *coherence volume*. The projection of this volume onto a surface is termed a *coherence area*. If we have a field that, within some region, is roughly directional so that its field amplitude is given by Eq. (5), then the coherence length gives the dimension of the coherence volume in the direction of propagation $\mathbf{p}$, and the coherence area gives the dimensions of the coherence volume normal to this direction.

Measurements of Coherence

Coherence is usually measured by some form of interferometer that takes light from two test points in a light field, $\mathbf{x}_1$ and $\mathbf{x}_2$, and then allows them to interfere after introducing a time advance τ in the light from $\mathbf{x}_1$ relative to that from $\mathbf{x}_2$. If the field intensity of the interference pattern is measured as a function of τ, then in general it has the form (see Ref. 15, sec. 10.3.1)

$$I(\tau) = I(\mathbf{x}_1) + I(\mathbf{x}_2) + 2\,\mathrm{Real}(\Gamma_{12}(\tau)) \tag{7}$$

where $I(\mathbf{x}_1)$ is the intensity at the ith test point, and $\Gamma_{12}(\tau)$ is the mutual coherence function which measures the τ advanced correlation between the waveforms at the two test points (as subsequently defined under "Mutual Coherence Function"). There are many interferometers which have been developed to measure $\Gamma_{12}(\tau)$ in this way. One of the earliest techniques was developed by Thompson and Wolf.[22] They used a diffractometer to measure the coherence over a surface normal to the direction of propagation for a collimated beam from a partially coherent source. More recently, Carter[23] used an interferometer made from a grating and a microscope to similarly measure the coherence of a beam transverse to the direction of propagation.

5.4 DEFINITIONS OF COHERENCE FUNCTIONS

Mutual Coherence Function

In an older form of coherence theory[1] the principal coherence function was the mutual coherence function defined by[24]

$$\Gamma_{12}(\tau) \underset{T\to\infty}{\approx} \frac{1}{2T}\int_{-T}^{T} u(\mathbf{x}_1, t+\tau)u^*(\mathbf{x}_2, t)\,dt \tag{8}$$

where $u(\mathbf{x}, t)$ represents the complex analytic time-dependent signal at some point $\mathbf{x}$ and some time t as defined in Eq. (3). This definition was originally motivated by the fact that the intensity, as actually measured, is precisely this time averaged function with $\mathbf{x}_1 = \mathbf{x}_2$ and $\tau = 0$, and that this function is the most readily measured since it appears directly in Eq. (7). Thus it was clearly possible to measure $\Gamma_{12}(\tau)$ over some input plane, propagate it to an output plane,[25] and then find the intensity over the output plane from $\Gamma_{12}(\tau)$. It was assumed in this definition in Eq. (8) that $u(\mathbf{x}, t)$ is stationary in time so that $\Gamma_{12}(\tau)$ is only a function of τ and not of t. In most of the older literature, sharp brackets were usually used to represent this time average rather than an ensemble average (see Ref. 15, sec. 10.3.1). In the early 1960s it was found to be much more convenient to treat $u(\mathbf{x}, t)$ as an ergodic, stationary random process so that Eq. (8) could be replaced by

$$\Gamma_{12}(\tau) = \langle u(\mathbf{x}_1, t+\tau)u^*(\mathbf{x}_2, t)\rangle \tag{9}$$

where (everywhere in this chapter) the sharp brackets denote an ensemble average. After the change to ensemble averages the cross-spectral density function (to be defined shortly) became the most used correlation function in the coherence literature, because of the simpler and more general rules for its propagation (as discussed later under "Representations" on p. 5.16).

Complex Degree of Coherence

To obtain a function that depends only on the coherence properties of a light field it is often useful to normalize the mutual coherence function in the manner of

$$\gamma_{12}(\tau) = \frac{\langle u(\mathbf{x}_1, t+\tau)u^*(\mathbf{x}_2, t)\rangle}{\sqrt{\langle u(\mathbf{x}_1, t)u^*(\mathbf{x}_1, t)\rangle\langle u(\mathbf{x}_2, t)u^*(\mathbf{x}_2, t)\rangle}} \tag{10}$$

This is called the *complex degree of coherence*. It is a properly normalized correlation coefficient, so that $\gamma_{11}(0) = \gamma_{22}(0) = 1$. This indicates that the field at a point in space must always be perfectly coherent with itself. All other values of $\gamma_{12}(\tau)$ are generally complex with an amplitude less than one. This indicates that the fields at two different points, or at the same point after a time delay τ, are generally less than perfectly coherent with each other. The magnitude of the complete degree of spatial coherence (from zero to one) is a measure of the mutual coherence between the fields at the two test points and after a time delay τ.

Cross-Spectral Density Function

Just as in classical diffraction theory, it is much easier to propagate monochromatic light than light with a complicated time waveform. Thus the most frequently used coherence function is the cross-spectral density function, $W_\omega(\mathbf{x}_1, \mathbf{x}_2)$, which is the ensemble-averaged correlation function between a typical monochromatic component of the field at some point $\mathbf{x}_1$ with the complex conjugate of the same component of the field at some other point $\mathbf{x}_2$. It may be defined by

$$\delta(\omega-\omega')W_\omega(\mathbf{x}_1, \mathbf{x}_2)=\langle U(\mathbf{x}_1, \omega)U^*(\mathbf{x}_2, \omega')\rangle \tag{11}$$

The amplitude $U(\mathbf{x}, \omega)$ for a field of arbitrary coherence is taken to be a random variable. Thus $U(\mathbf{x}, \omega)$ represents an ensemble of all of the possible fields, each of which is represented by a complex phasor amplitude like that defined in Eq. (2). The sharp brackets denote an ensemble average over all of these possible fields weighted by the probability for each of them to occur. The correlation functions defined by Eqs. (11) and (9) are related by the Fourier transform pairs

$$\Gamma_{12}(\tau)=\int_0^\infty W_\omega(\mathbf{x}_1, \mathbf{x}_2)e^{-i\omega\tau}\,d\omega \tag{12}$$

and

$$W_\omega(\mathbf{x}_1, \mathbf{x}_2)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\Gamma_{12}(\tau)e^{i\omega\tau}\,d\tau \tag{13}$$

which is easily shown, formally, by substitution from Eq. (3) into (9) and then using (11). These relations represent a form of the generalized Wiener-Khintchine theorem (see Ref. 26, pp. 107–108).

Complex Degree of Spectral Coherence

Because the cross-spectral density function contains information about both the intensity (see "Intensity," which follows shortly) and the coherence of the field, it is useful to define another coherence function which describes the coherence properties only. This is the complex degree of spectral coherence (not to be confused with the complex degree of *spatial* coherence, which is a totally different function), which is usually defined by[27]

$$\mu_\omega(\mathbf{x}_1, \mathbf{x}_2)=\frac{W_\omega(\mathbf{x}_1, \mathbf{x}_2)}{\sqrt{W_\omega(\mathbf{x}_1, \mathbf{x}_1)W_\omega(\mathbf{x}_2, \mathbf{x}_2)}} \tag{14}$$

It is easy to show that this function is a properly normalized correlation coefficient which is always equal to unity if the field points are brought together, and is always less than or equal to unity as they are separated. If the magnitude of $\mu_\omega(\mathbf{x}_1, \mathbf{x}_2)$ is unity, it indicates that the monochromatic field component with radial frequency ω is perfectly coherent between the two points $\mathbf{x}_1$ and $\mathbf{x}_2$. If the magnitude of this function is less than unity it indicates less-than-perfect coherence. If the magnitude is zero it indicates complete incoherence between the field amplitudes at the two test points. For most partially coherent fields the cross-spectral density function has significantly large values only for point separations which keep the two field points within the same coherence volume. This function depends only on the positions of the points and the single radial frequency that the field components at the two points share. Field components of different frequency are always uncorrelated (and therefore incoherent), even at the same point.

Spectrum and Normalized Spectrum

Recently, the changes in the spectrum of light due to propagation have been studied using coherence theory. It is therefore useful to define the spectrum of light as just the monochromatic intensity

(which is just the trace of the cross-spectral density function) as a function of omega, and the spectrum of a primary source as a very similar function, i.e.,

$$S_U(\mathbf{x}, \omega) = \langle U_\omega(\mathbf{x}) U_\omega^*(\mathbf{x}) \rangle = W_U(\mathbf{x}, \mathbf{x})$$
$$S_Q(\mathbf{x}, \omega) = \langle \rho_\omega(\mathbf{x}) \rho_\omega^*(\mathbf{x}) \rangle = W_Q(\mathbf{x}, \mathbf{x}) \tag{15}$$

where the subscript Q indicates that this is a primary source spectrum, and the subscript U indicates that this is a field spectrum. The spectrum for the primary source is a function of the phasor $\rho_\omega(\mathbf{x})$ which represents the currents and charges in this source as discussed under "Primary Sources" in the next section. It is also useful to normalize these spectra in the manner

$$s_A(\mathbf{x}, \omega) = \frac{S_A(\mathbf{x}, \omega)}{\int_0^\infty S_A(\mathbf{x}, \omega)\, d\omega} \tag{16}$$

where the subscript A can indicate either U or Q, and the normalized spectrum has the property

$$\int_0^\infty s_A(\mathbf{x}, \omega)\, d\omega = 1 \tag{17}$$

so that it is independent of the total intensity.

Angular Correlation Function

A new coherence function, introduced for use with the angular spectrum expansion of a monochromatic component of the field,[28] is the angular correlation function defined by

$$\mathcal{A}_\omega(\mathbf{p}_1, \mathbf{p}_2) = \langle A_\omega(\mathbf{p}_1)\, A_\omega^*(\mathbf{p}_2) \rangle \tag{18}$$

where $A_\omega(\mathbf{p}_i)$ is the angular spectrum which gives the complex amplitude of the plane wave component of the field which propagates in the direction given by the unit vector $\mathbf{p}_i$. This is related to the cross-spectral density function over the $z = 0$ plane by the equation

$$\mathcal{A}(\mathbf{p}_1, \mathbf{p}_2) = \frac{1}{\lambda^4} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} W_\omega^{(0)}(\mathbf{x}_1', \mathbf{x}_2') e^{-ik(\mathbf{p}_1 \cdot \mathbf{x}_1' - \mathbf{p}_2 \cdot \mathbf{x}_2')} d^2\mathbf{x}_1'\, d^2\mathbf{x}_2' \tag{19}$$

This is the four-dimensional Fourier transform of the cross-spectral density function over the $z = 0$ plane. It represents a correlation function between the complex amplitudes of two plane wave components of the field propagating in the directions given by the unit vectors $\mathbf{p}_1$ and $\mathbf{p}_2$, respectively. It can be used to calculate the cross-spectral density function (as described later under "Angular Spectrum Representation") between any pair of points away from the $z = 0$ plane, assuming that the field propagates in a source-free homogeneous medium. In this chapter we will use single-primed vectors, as in Eq. (19), to represent radius vectors from the origin to points within the $z = 0$ plane, i.e., $\mathbf{x}' = (x', y', 0)$, as shown in Fig. 1.

All other vectors, such as $\mathbf{x}$ or $\mathbf{x}''$, are to be taken as three-dimensional vectors. Generally $\mathbf{s}$ and $\mathbf{p}$ are three-dimensional unit vectors indicating directions from the origin, a superscript (0) on a function indicates that it is the boundary condition for that function over the $z = 0$ plane, and a superscript (∞) on a function indicates that it is the asymptotic value for that function on a sphere of constant radius R from the origin as $R \to \infty$.

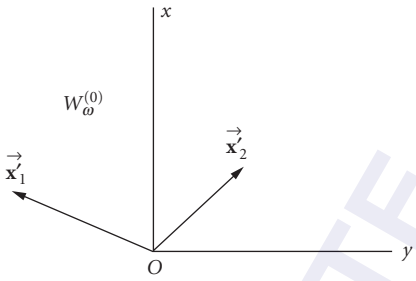

FIGURE 1 Illustrating the coordinate system and notation used for planar sources in the $z = 0$ plane.

Intensity

The intensity is usually considered to be the observable quantity in coherence theory. Originally it was defined to be the trace of the mutual coherence function as defined by Eq. (8), i.e.,

$$I(\mathbf{x}_1) \triangleq \Gamma_{11}(0) \underset{T\to\infty}{\approx} \frac{1}{2T}\int_{-T}^{T} u(\mathbf{x}_1, t)u^*(\mathbf{x}_1, t)dt \tag{20}$$

which is always real. Thus it is the time-averaged square magnitude of the analytic signal. This represents the measurement obtained by the electromagnetic power detectors always used to detect light fields. Since the change to ensemble averages in coherence theory, it is almost always assumed that the analytic signal is an ergodic random process so that the intensity can be obtained from the equation

$$I(\mathbf{x}_1) \triangleq \Gamma_{11}(0) = \langle u(\mathbf{x}_1, t)u^*(\mathbf{x}_1, t)\rangle \tag{21}$$

where the sharp brackets indicate an ensemble average. Usually, in most recent coherence-theory papers, the intensity calculated is actually the spectrum, which is equivalent to the intensity of a single monochromatic component of the field which is defined as the trace of the cross-spectral density function as given by

$$I_\omega(\mathbf{x}_1) \triangleq W_\omega(\mathbf{x}_1, \mathbf{x}_1) = \langle U(\mathbf{x}_1, \omega)\, U^*(\mathbf{x}_1, \omega)\rangle \tag{22}$$

Since different monochromatic components of the field are mutually incoherent and cannot interfere, we can always calculate the intensity of the total field as the sum over the intensities of its monochromatic components in the manner

$$I(\mathbf{x}_1) \triangleq \int_0^\infty I_\omega(\mathbf{x}_1)\, d\omega \tag{23}$$

Since in most papers on coherence theory the subscript omega is usually dropped, the reader should be careful to observe whether or not the intensity calculated is for a monochromatic component of the field only. If it is, the total measurable intensity can be obtained simply by summing over all omega, as indicated in Eq. (23).

Radiant Emittance

In classical radiometry the *radiant emittance* is defined to be the power radiated into the far field by a planar source per unit area. A wave function with some of the properties of radiant emittance has been defined by Marchand and Wolf using coherence theory [see Refs. 29, eq. (32), and 30].

However, because of interference effects, the far-field energy cannot be subdivided into components that can be traced back to the area of the source that produced them. The result is that the radiant emittance defined by Marchand and Wolf is not nonnegative definite (as it is in classical radiometry) except for the special case of a completely incoherent source. Since, as discussed in the next section under "Perfectly Incoherent Source," perfectly incoherent sources exist only as a limiting case, radiant emittance has not been found to be a very useful concept in coherence theory.

Radiant Intensity

In classical radiometry the *radiant intensity* is defined to be the power radiated from a planar source into a unit solid angle with respect to an origin at the center of the surface. This can be interpreted in coherence theory as the field intensity over a portion of a surface in the far field of the source, in some direction given by the unit vector **s**, which subtends a unit solid angle from the source. Thus the radiant intensity for a monochromatic component of the field can be defined in coherence theory as

$$J_\omega(\mathbf{s}) \underset{R\to\infty}{\approx} W_\omega^{(\infty)}(R\mathbf{s}, R\mathbf{s})R^2 \tag{24}$$

To obtain the total radiant intensity we need only sum this function over all omega.

Radiance

In classical coherence theory the radiance function is the power radiated from a unit area on a planar source into a unit solid angle with respect to an origin at the center of the source. In the geometrical optics model, from which this concept originally came, it is consistent to talk about particles of light leaving an area at a specified point on a surface to travel in some specified direction. However, in a wave theory, wave position and wave direction are Fourier conjugate variables. We can have a configuration space wave function (position) or a momentum space wave function (direction), but not a wave function that depends independently on both position and direction. Thus the behavior of a wave does not necessarily conform to a model which utilizes a radiance function.[31] Most naturally occurring sources are quasi-homogeneous (discussed later). For such sources, a radiance function for a typical monochromatic component of the field can be defined as the Wigner distribution function[32–35] of the cross-spectral density function over the $z = 0$ plane, which is given by

$$B_\omega(\mathbf{x}'_+, \mathbf{s}) = \frac{\cos\theta}{\lambda^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_\omega^{(0)}(\mathbf{x}'_+ + \mathbf{x}'_-/2, \mathbf{x}'_+ - \mathbf{x}'_-/2)e^{-ik\mathbf{s}\cdot\mathbf{x}'_-}d^2\mathbf{x}'_- \tag{25}$$

where θ is the angle that the unit vector **s** makes with the $+z$ axis. For quasi-homogeneous fields this can be associated with the energy radiated from some point $\mathbf{x}'_+$ into the far field in the direction **s**. Such a definition for radiance also works approximately for some other light fields, but for light which does not come from a quasi-homogeneous source, no such definition is either completely equivalent to a classical radiance function[31] or unique as an approximation to it. Much progress has been made toward representing a more general class of fields using a radiance function.[36] In general, waves do not have radiance functions.

Higher-Order Coherence Functions

In general, the statistical properties of a random variable are uniquely defined by the probability density function which can be expanded into a series which contains correlation functions of all orders. Thus, in general, all orders of correlation functions are necessary to completely define the statistical properties of the field. In classical coherence theory we usually assume that the partially coherent fields arise from many independent sources so that, by the central limit theorem of statistics,

the probability distribution function for the real and imaginary components of the phasor field amplitude are zero-mean gaussian random variables (See Ref. 8, sec. 2.72*e*). Thus, from the gaussian moment theorem, the field correlation functions of any order can be calculated from the second-order correlation functions, for example,

$$\langle U(\mathbf{x}_1, \omega)\, U^*(\mathbf{x}_1, \omega)\, U(\mathbf{x}_2, \omega)\, U^*(\mathbf{x}_2, \omega)\rangle = I_\omega(\mathbf{x}_1)\, I_\omega(\mathbf{x}_2) + |W_\omega(\mathbf{x}_1, \mathbf{x}_2)|^2 \tag{26}$$

Thus, for gaussian fields, the second-order correlation functions used in coherence theory completely define the statistical properties of the field. Some experiments, such as those involving intensity interferometry, actually measure fourth- or higher-order correlation functions.[37]

5.5 MODEL SOURCES

Primary Sources

In coherence theory it is useful to talk about primary and secondary sources. A primary source distribution is the usual source represented by the actual charge and current distribution which give rise to the field. For propagation from a primary source through a source-free media, the field amplitude is defined by the inhomogeneous Helmholtz equation [see Ref. 38, eq. (6.57)], i.e.,

$$\left(\nabla^2 + \frac{\omega^2}{c^2}\right) U_\omega(\mathbf{x}) = -4\pi\rho_\omega(\mathbf{x}) \tag{27}$$

where $\rho_\omega(\mathbf{x})$ represents the charge-current distribution in the usual manner. A solution to this wave equation gives

$$W_U(\mathbf{x}_1, \mathbf{x}_2) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_Q(\mathbf{x}_1'', \mathbf{x}_2'') K(\mathbf{x}_1, \mathbf{x}_1'') K^*(\mathbf{x}_2, \mathbf{x}_2'') d^3\mathbf{x}_1''\, d^3\mathbf{x}_2'' \tag{28}$$

for the cross-spectral density function, where $k = \omega/c = 2\pi/\lambda$

$$K(\mathbf{x}, \mathbf{x}'') = \frac{e^{ik|\mathbf{x}-\mathbf{x}''|}}{|\mathbf{x}-\mathbf{x}''|} \tag{29}$$

is the free-space propagator for a primary source, $W_U(\mathbf{x}_1, \mathbf{x}_2)$ is the cross-spectral density function for the fields (with suppressed ω-dependence), as defined by Eq. (11), and

$$W_Q(\mathbf{x}_1'', \mathbf{x}_2'') = \langle \rho_\omega(\mathbf{x}_1'') \rho_\omega^*(\mathbf{x}_2'')\rangle \tag{30}$$

is the cross-spectral density function for the source. This three-dimensional primary source can be easily reduced to a two-dimensional source over the $z = 0$ plane by simply defining the charge current distribution to be

$$\rho_\omega(\mathbf{x}) = \rho_\omega'(x, y)\delta(z) \tag{31}$$

where $\delta(z)$ is the Dirac delta function.

Secondary Sources

Often, however, it is more convenient to consider a field which arises from sources outside of the region in space in which the fields are of interest. Then it is sometime useful to work with boundary conditions for the field amplitude over some surface bounding the region of interest. In many coherence problems these boundary conditions are called a *planar secondary source* even though they are actually treated as boundary conditions. For example, most conventional diffraction equations

assume the boundary condition over the $z = 0$ plane is known and use it to calculate the fields in the $z > 0$ half-space. Then the field obeys the homogeneous Helmholtz equation [See Ref. 38, eq. (7.8)], i.e.,

$$\left(\nabla^2 + \frac{\omega^2}{c^2}\right) U_\omega(\mathbf{x}) = 0 \tag{32}$$

which has the solution

$$W_\omega(\mathbf{x}_1, \mathbf{x}_2) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_\omega^{(0)}(\mathbf{x}_1', \mathbf{x}_2') h(\mathbf{x}_1, \mathbf{x}_1') h^*(\mathbf{x}_2, \mathbf{x}_2') d^2\mathbf{x}_1' \, d^2\mathbf{x}_2' \tag{33}$$

where $W_\omega^{(0)}(\mathbf{x}_1', \mathbf{x}_2')$ is the boundary condition for the cross-spectral density function of the fields over the $z = 0$ plane (as shown in Fig. 1), $W_\omega(\mathbf{x}_1, \mathbf{x}_2)$ is the cross-spectral density function anywhere in the $z > 0$ half-space, and

$$h(\mathbf{x}, \mathbf{x}') = \frac{-1}{2\pi} \frac{d}{dz} \frac{e^{ik|\mathbf{x}-\mathbf{x}'|}}{|\mathbf{x}-\mathbf{x}'|} \tag{34}$$

is the free-space propagator for the field amplitude. This is a common example of a secondary source over the $z = 0$ plane.

Perfectly Coherent Source

The definition of a perfectly coherent source, within the theory of partial coherence, is somewhat complicated. The light from an ideal monochromatic source is, of course, always perfectly coherent. Such a field produces high-contrast interference patterns when its intensity is detected by any suitable instrument. However, it is possible that light fields exist that are not monochromatic but can also produce similar interference patterns and therefore must be considered coherent. The ability of light fields to produce interference patterns at a detector is measured most directly by the complex degree of coherence $\gamma_{12}(\tau)$, defined by Eq. (10). If a field has a complex degree of coherence that has unit magnitude for every value of τ and for every point pair throughout some domain D, then light from all points in D will combine to produce high-contrast interference fringes.[39] Such a field is defined to be perfectly coherent within D. Mandel and Wolf[27] have shown that the mutual coherence function for such a field factors within D in the manner

$$\Gamma_{12}(\tau) = \psi(\mathbf{x}_1)\psi^*(\mathbf{x}_2) e^{-i\omega\tau} \tag{35}$$

We will take Eq. (35) to be the definition of a perfectly coherent field. Coherence is not as easily defined in the space-frequency domain because it depends on the spectrum of the light as well as on the complex degree of spectral coherence. For example, consider a field for which every monochromatic component is characterized by a complex degree of spectral coherence which has unit magnitude between all point pairs within some domain D. Mandel and Wolf[40] have shown that for such a field the cross-spectral density function within D factors is

$$W_\omega(\mathbf{x}_1'' \mathbf{x}_2'') = \bar{U}(\mathbf{x}_1'', \omega)\bar{U}^*(\mathbf{x}_2'', \omega) \tag{36}$$

However, even if Eq. (36) holds for this field within D, the field may not be perfectly coherent [as perfect coherence is defined by Eq. (35)] between all points within the domain. In fact it can be completely incoherent between some points within D.[41] A secondary source covering the $z = 0$ plane with a cross-spectral density function over that plane which factors as given by Eq. (36) will produce a field in the $z > 0$ half-space (filled with free space or a homogeneous, isotopic dielectric) which has a cross-spectral density function that factors in the same manner everywhere in the half-space. This can be easily shown by substitution from Eq. (36) into Eq. (28), using Eq. (29). But, even if this is true for every monochromatic component of the field, Eq. (35) may not hold within the half-space for every point pair, so we cannot say that the field is perfectly coherent there. Perfectly coherent light

sources never actually occur, but sometimes the light from a laser can behave approximately in this way over some coherence volume which is usefully large. Radio waves often behave in this manner over very large coherence volumes.

Quasi-Monochromatic Source

In many problems it is more useful not to assume that a field is strictly monochromatic but instead to assume that it is only quasi-monochromatic so that the time-dependent field amplitude can be approximated by

$$u(\mathbf{x}, t) = u_0(\mathbf{x}, t)e^{-i\omega t} \tag{37}$$

where $u_0(\mathbf{x}, t)$ is a random process which varies much more slowly in time than $e^{-i\omega t}$. Then the mutual coherence function and the complex degree of spatial coherence can be usefully approximated by (see Ref. 15, sec. 10.4.1)

$$\begin{aligned} \Gamma_{12}(\tau) &= \Gamma_{12}(0)e^{-i\omega\tau} \\ \gamma_{12}(\tau) &= \gamma_{12}(0)e^{-i\omega\tau} \end{aligned} \tag{38}$$

within coherence times much less than the reciprocal bandwidth of the field, i.e., $\Delta\tau \ll 1/\Delta\omega$. In the pre-1960 coherence literature, $\Gamma_{12}(0)$ was called the *mutual intensity*. Monochromatic diffraction theory was then used to define the propagation properties of this monochromatic function. It was used instead of the cross-spectral density function to formulate the theory for the propagation of a partially coherent quasi-monochromatic field. While this earlier form of the theory was limited by the quasi-monochromatic approximation and was therefore not appropriate for very wideband light, the newer formulation (in terms of the cross-spectral density function) makes no assumptions about the spectrum of the light and can be applied generally. The quasi-monochromatic approximation is still very useful when dealing with radiation of very high coherence.[42]

Schell Model Source

Other, more general, source models have been developed. The most general of these is the Schell model source (see Refs. 43, sec. 7.5, and 44), for which we only assume that the complex degree of spectral coherence for either a primary or secondary source is stationary in space, so that from Eq. (14) we have

$$W_A(\mathbf{x}_1, \mathbf{x}_2) = \mu_A(\mathbf{x}_1 - \mathbf{x}_2)\sqrt{W_A(\mathbf{x}_1, \mathbf{x}_1)W_A(\mathbf{x}_2, \mathbf{x}_2)} \tag{39}$$

where the subscript A stands for U in the case of a Schell model secondary source and Q in the case of a Schell model primary source. The Schell model does not assume low coherence and, therefore, can be applied to spatially stationary light fields of any state of coherence. The Schell model of the form shown in Eq. (39) has been used to represent both three-dimensional primary sources[45,46] and two-dimensional secondary sources.[43,47,48]

Quasi-Homogeneous Source

If the intensity of a Schell model source is essentially constant over any coherence area, then Eq. (39) may be approximated by

$$W_A(\mathbf{x}_1, \mathbf{x}_2) = \mu_A(\mathbf{x}_1 - \mathbf{x}_2)I_A[(\mathbf{x}_1 + \mathbf{x}_1)/2] \tag{40}$$

where the subscript A can be either U, for the case of a quasi-homogeneous secondary source or Q, for the case of a quasi-homogeneous primary source. This equation is very useful in coherence theory because of the important exact mathematical identity.[49]

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\mu_{\omega}^{(0)}(\mathbf{x}_1'-\mathbf{x}_2')I_{\omega}^{(0)}[(\mathbf{x}_1'+\mathbf{x}_2')/2]e^{-ik(\mathbf{x}_1'\cdot\mathbf{p}_1-\mathbf{x}_2'\cdot\mathbf{p}_2)}dx_1'\,dy_1'\,dx_2'\,dy_2'$$
$$=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\mu_{\omega}^{(0)}(\mathbf{x}_-')e^{-ik(\mathbf{x}_-'\cdot\mathbf{p}_+)}dx_-'dy_-'\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}I_{\omega}^{(0)}(\mathbf{x}_+')e^{-ik(\mathbf{x}_+'\cdot\mathbf{p}_-)}dx_+'\,dy_+' \tag{41}$$

where

$$\mathbf{x}_+'=(\mathbf{x}_1'+\mathbf{x}_2')/2 \qquad \mathbf{x}_-'=\mathbf{x}_1'-\mathbf{x}_2'$$

and

$$\mathbf{p}_+=(\mathbf{p}_1+\mathbf{p}_2)/2 \qquad \mathbf{p}_-=\mathbf{p}_1-\mathbf{p}_2$$

which allows the four-dimensional Fourier transforms that occur in propagating the correlation functions for secondary sources [for example, Eqs. (49) or (54)] to be factored into a product of two-dimensional Fourier transforms. An equivalent identity also holds for the six-dimensional Fourier transform of the cross-spectral density function for a primary source, reducing it to the product of two three-dimensional Fourier transforms. This is equally useful in dealing with propagation from primary sources [for example, Eq. (53)]. This model is very good for representing two-dimensional secondary sources with sufficiently low coherence that the intensity does not vary over the coherence area on the input plane.[49,50] It has also been applied to primary three-dimensional sources.[45,46] to primary and secondary two-dimensional sources,[51,52] and to three-dimensional scattering potentials.[53,54]

Perfectly Incoherent Source

If the coherence volume of a field becomes much smaller than any other dimensions of interest in the problem, then the field is said to be *incoherent*. It is believed that no field can be incoherent over dimensions smaller than the order of a light wavelength. An incoherent field can be taken as a special case of a quasi-homogeneous field for which the complex degree of spectral coherence is approximated by a Dirac delta function, i.e.,

$$W_A(\mathbf{x}_1,\mathbf{x}_2)=I(\mathbf{x}_1)\delta^2(\mathbf{x}_1-\mathbf{x}_2)$$
$$W_Q(\mathbf{x}_1,\mathbf{x}_2)=I(\mathbf{x}_1)\delta^3(\mathbf{x}_1-\mathbf{x}_2) \tag{42}$$

where the two-dimensional Dirac delta function is used for any two-dimensional source and a three-dimensional Dirac delta function is used only for a three-dimensional primary source. Even though this approximation is widely used, it is not a good representation for the thermal sources that predominate in nature. For example, the radiant intensity from a planar, incoherent source is not in agreement with Lambert's law. For thermal sources the following model is much better.

Thermal (Lambertian) Source

For a planar, quasi-homogeneous source to have a radiant intensity in agreement with Lambert's law it is necessary for the complex degree of spectral coherence to have the form

$$\mu_A(\mathbf{x}_1-\mathbf{x}_2)=\frac{\sin(k|\mathbf{x}_1-\mathbf{x}_2|)}{k|\mathbf{x}_1-\mathbf{x}_2|} \tag{43}$$

to which arbitrary spatial frequency components with periods less than a wavelength can be added since they do not affect the far field.[55] It can also be shown that, under frequently obtained conditions, blackbody radiation has such a complex degree of spectral coherence.[56] It is believed that most naturally occurring light can be modeled as quasi-homogeneous with this correlation function.

5.6 PROPAGATION

Perfectly Coherent Light

Perfectly coherent light propagates according to conventional diffraction theory. By substitution from Eq. (36) into Eq. (33) using Eq. (34) we obtain

$$U_\omega(\mathbf{x}) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} U_\omega^{(0)}(\mathbf{x}')\frac{1}{2\pi}\frac{d}{dz'}\frac{e^{ik|\mathbf{x}-\mathbf{x}'|}}{|\mathbf{x}-\mathbf{x}'|}d^2\mathbf{x}' \tag{44}$$

which is just Rayleigh's diffraction integral of the first kind. Perfectly coherent light does not lose coherence as it propagates through any medium which is time-independent. For perfectly coherent light propagating in time-independent media, coherence theory is not needed.

Hopkin's Formula

In 1951 Hopkins[57] published a formula for the complex degree of spatial coherence for the field from a planar, secondary, incoherent, quasi-monochromatic source after propagating through a linear optical system with spread function $h(\mathbf{x}, \mathbf{x}')$, i.e.,

$$\gamma_{12}(0) = \frac{1}{\sqrt{I(\mathbf{x}_1)I(\mathbf{x}_2)}}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_\omega^{(0)}(\mathbf{x}_1')h(\mathbf{x}_1-\mathbf{x}_1')h^*(\mathbf{x}_2-\mathbf{x}_1')d^2\mathbf{x}_1' \tag{45}$$

where $I_\omega^{(0)}(\mathbf{x}')$ is the intensity over the source plane. This formula can be greatly generalized to give the complex degree of spectral coherence for the field from any planar, quasi-homogeneous, secondary source[58] after transmission through this linear optical system, i.e.,

$$\mu_{12}(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{I(\mathbf{x}_1)I(\mathbf{x}_2)}}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_\omega^{(0)}(\mathbf{x}')h(\mathbf{x}_1, \mathbf{x}')h^*(\mathbf{x}_2, \mathbf{x}')d^2\mathbf{x}' \tag{46}$$

provided that the spread function $h(\mathbf{x}, \mathbf{x}')$ can be assumed to be constant in its $\mathbf{x}'$ dependence over any coherence area in the source plane.

van Cittert–Zernike Theorem

Hopkins' formula can be specialized for free-space propagation to calculate the far-field coherence properties of planar, secondary, quasi-homogeneous sources of low coherence. In 1934 van Cittert[59] and, later, Zernike[60] derived a formula equivalent to

$$\mu_\omega(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{I(\mathbf{x}_1)I(\mathbf{x}_2)}}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_\omega^{(0)}(\mathbf{x}')\frac{e^{ik[|\mathbf{x}_1-\mathbf{x}'|-|\mathbf{x}_2-\mathbf{x}'|]}}{|\mathbf{x}_1-\mathbf{x}'||\mathbf{x}_2-\mathbf{x}'|}d^2\mathbf{x}' \tag{47}$$

for the complex degree of spectral coherence between any pair of points in the field radiated from an incoherent planar source, assuming that the points are not within a few wavelengths of the source. We can obtain Eq. (47) by substitution from Eq. (34) into Eq. (46) and then approximating

the propagator in a standard manner [see Ref. 61, eq. (7)]. Assume next, that the source area is contained within a circle of radius a about the origin in the source plane as shown in Fig. 4. Then, if the field points are both located on a sphere of radius R, which is outside of the Rayleigh range of the origin (i.e., $|\mathbf{x}_1| = |\mathbf{x}_2| = R \gg ka^2$), we can apply the Fraunhofer approximation to Eq. (47) to obtain

$$\mu_{12}(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{I(\mathbf{x}_1) I(\mathbf{x}_2)}} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} I_{\omega}^{(0)}(\mathbf{x}') e^{ik\mathbf{x}' \cdot (\mathbf{x}_1 - \mathbf{x}_2)/R} d^2\mathbf{x}' \tag{48}$$

This formula is very important in coherence theory. It shows that the complex degree of spectral coherence from any planar, incoherent source with an intensity distribution $I_{\omega}^{(0)}(\mathbf{x}')$ has the same dependence on $(\mathbf{x}_1 - \mathbf{x}_2)$, over a sphere of radius R in the far field, as the diffraction pattern from a closely related perfectly coherent planar source with a real amplitude distribution proportional to $I_{\omega}^{(0)}(\mathbf{x}')$ (see Ref. 15, sec. 10.4.2*a*). Equation (48) can also be applied to a planar, quasi-homogeneous source[49] that is not necessarily incoherent, as will be shown later under "Reciprocity Theorem."

Angular Spectrum Representation

Much more general equations for propagation of the cross-spectral density function can be obtained. Equation (33) is one such expression. Another can be found if we expand the fields in a source-free region of space into an angular spectrum of plane waves. Then we find that the cross-spectral density function over any plane can be calculated from the same function over a parallel plane using a linear systems approach. For an example, consider the two planes illustrated in Fig. 2.

We assume that the cross-spectral density function is known over the $z = 0$ plane in the figure, and we wish to calculate this function over the $z = d$ plane. To do this we first take the Fourier transform of the cross-spectral density function over the $z = 0$ plane according to Eq. (19)

$$\mathcal{A}_{\text{in}}(\mathbf{p}_1, \mathbf{p}_2) = \frac{1}{\lambda^4} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} W_{\omega}^{(0)}(\mathbf{x}_1', \mathbf{x}_2') e^{-ik(\mathbf{p}_1 \cdot \mathbf{x}_1' - \mathbf{p}_2 \cdot \mathbf{x}_2')} d^2\mathbf{x}_1' \, d^2\mathbf{x}_2' \tag{49}$$

to obtain the angular correlation function in which all of the phase differences between the plane wave amplitudes are given relative to the point at the origin. Second, we shift the phase reference

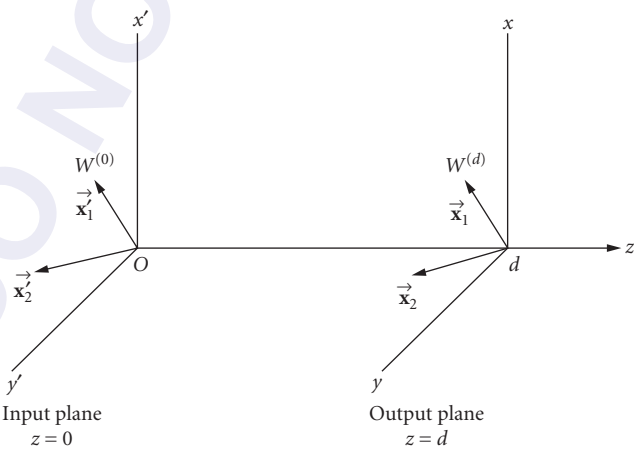

FIGURE 2 Illustrating the coordinate system for propagation of the cross-spectral density function using the angular spectrum of plane waves.

from the origin to the point on the z axis in the output plane by multiplying the angular correlation function by a transfer function, i.e.,

$$\mathscr{A}_{\text{out}}(\mathbf{p}_1, \mathbf{p}_2) = \mathscr{A}_{\text{in}}(\mathbf{p}_1, \mathbf{p}_2) \exp\,[ik(m_1 - m_2)d] \tag{50}$$

where d is the distance from the input to the output plane along the z axis (for back propagation d will be negative) and m_i is the third component of the unit vector $\mathbf{p}_i = (p_i, q_i, m_i)$, $i = 1$ or 2, which is defined by

$$\begin{aligned} m_i &= \sqrt{1 - p_i^2 - q_i^2} \quad \text{if } p_i^2 + q_i^2 \le 1 \\ &= i\sqrt{p_i^2 + q_i^2 - 1} \quad \text{if } p_i^2 + q_i^2 > 1 \end{aligned} \tag{51}$$

and is the cosine of the angle that $\mathbf{p}_i$ makes with the $+z$ axis for real m_i. Finally, to obtain the cross-spectral density function over the output plane, we simply take the Fourier inverse of $\mathscr{A}_{\text{out}}(\mathbf{p}_1, \mathbf{p}_2)$, i.e.,

$$W_{\omega}^{(d)}(\mathbf{x}_1, \mathbf{x}_2) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathscr{A}_{\text{out}}(\mathbf{p}_1, \mathbf{p}_2)\, e^{ik(\mathbf{p}_1\cdot\mathbf{x}_1 - \mathbf{p}_2\cdot\mathbf{x}_2)} d^2\mathbf{p}_1\, d^2\mathbf{p}_2 \tag{52}$$

where, in this equation only, we use $\mathbf{x}_i$ to represent a two-dimensional radius vector from the point $(0, 0, d)$ to a field point in the $z = d$ plane, as shown in Fig. 2. This propagation procedure is similar to the method usually used to propagate the field amplitude in Fourier optics. In coherence theory, it is the cross-spectral density function for a field of any state of coherence that is propagated between arbitrary parallel planes using the linear systems procedure. The only condition for the validity of this procedure is that the volume between the planes must either be empty space or a uniform dielectric medium.

Radiation Field

The cross-spectral density function far away from any source, which has finite size, can be calculated using a particularly simple equation. Consider a primary, three-dimensional source located within a sphere of radius a, as shown in Fig. 3. For field points, $\mathbf{x}_1$ and $\mathbf{x}_2$ which are much farther from

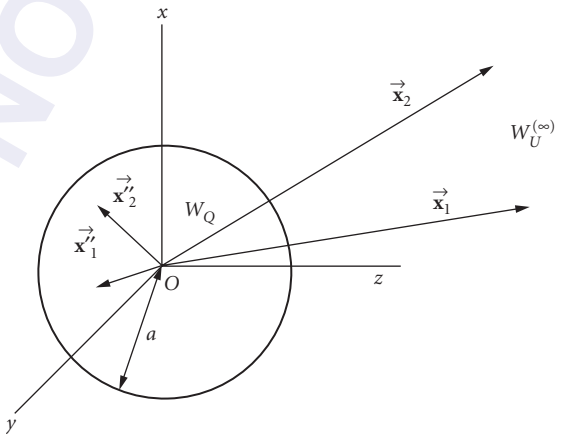

FIGURE 3 Illustrating the coordinate system used to calculate the cross-spectral density function in the far field of a primary, three-dimensional source.

the origin than the Rayleigh range ($|\mathbf{x}_i| \gg ka^2$), in any direction, a form of the familiar Fraunhofer approximation can be applied to Eq. (28) to obtain [see Ref. 62, eq. (2.5)]

$$W_U^{(\infty)}(\mathbf{x}_1, \mathbf{x}_2) = \frac{e^{ik(|\mathbf{x}_1| - |\mathbf{x}_2|)}}{|\mathbf{x}_1||\mathbf{x}_2|} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_Q(\mathbf{x}_1'', \mathbf{x}_2'') \times e^{-ik[\mathbf{x}_1 \cdot \mathbf{x}_1''/|\mathbf{x}_1| - \mathbf{x}_2 \cdot \mathbf{x}_2''/|\mathbf{x}_2|]}\, d^3\mathbf{x}_1''\, d^3\mathbf{x}_2'' \tag{53}$$

Thus the cross-spectral density function of the far field is proportional to the six-dimensional Fourier transform of the cross-spectral density function of its sources. A very similar expression can also be found for a two-dimensional, secondary source distribution over the $z = 0$ plane, as illustrated in Fig. 4.

If the sources are all restricted to the area within a circle about the origin of radius a, then the cross-spectral density function for all points which are outside of the Rayleigh range ($|\mathbf{x}_i| \gg ka^2$) from the origin and also in the $z > 0$ half-space can be found by using a different form of the Fraunhofer approximation in Eq. (33) [see Ref. 62, eq. (3.3)] to get

$$W_U^{(\infty)}(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\lambda^2}\frac{z_1}{|\mathbf{x}_1|}\frac{z_2}{|\mathbf{x}_2|}\frac{e^{ik(|\mathbf{x}_1| - |\mathbf{x}_2|)}}{|\mathbf{x}_1||\mathbf{x}_2|} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_U^{(0)}(\mathbf{x}_1', \mathbf{x}_2') \times e^{-ik[\mathbf{x}_1 \cdot \mathbf{x}_1'/|\mathbf{x}_1| - \mathbf{x}_2 \cdot \mathbf{x}_2'/|\mathbf{x}_2|]}\, d^2\mathbf{x}_1'\, d^2\mathbf{x}_2' \tag{54}$$

Because of both their relative simplicity (as Fourier transforms) and great utility, Eqs. (53) and (54) are very important in coherence theory for calculating both the radiant intensity and the far-field coherence properties of the radiation field from any source.

Representations

Several equations have been described here for propagating the cross-spectral density function. The two most general are Eq. (33), which uses an expansion of the field into spherical Huygens wavelets,

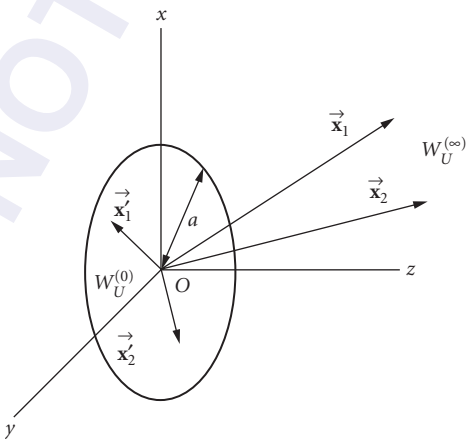

FIGURE 4 Illustrating the coordinate system for calculating the far field cross-spectral density function for a planar, secondary source distribution in the $z = 0$ plane. Single-primed coordinates indicate radius vectors from the origin to points within the $z = 0$ plane.

and Eqs. (49), (50), and (52), which use an expansion of the field into an angular spectrum of plane waves. These two formulations are completely equivalent. Neither uses any approximation not also used by the other method. The choice of which to use for a particular calculation can be made completely on a basis of convenience. The far-field approximations given by Eqs. (53) and (54), for example, can be derived from either representation. There are two bridges between the spherical and plane wave representations, one given by Weyl's integral, i.e.,

$$\frac{e^{ik|\mathbf{x}-\mathbf{x}''|}}{|\mathbf{x}-\mathbf{x}''|}=\frac{i}{\lambda}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{1}{m}e^{ik[p(x-x'')+q(y-y'')+m|z-z''|]}\,dp\,dq \tag{55}$$

where

$$\begin{aligned} m&=\sqrt{1-p^2-q^2} \quad \text{if} \quad p^2+q^2\le 1,\\ &=i\sqrt{p^2+q^2-1} \quad \text{if} \quad p^2+q^2>1 \end{aligned} \tag{56}$$

and the other by a related integral

$$\frac{-1}{2\pi}\frac{d}{dz}\frac{e^{ik|\mathbf{x}-\mathbf{x}''|}}{|\mathbf{x}-\mathbf{x}''|}=\frac{\pm 1}{\lambda^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}e^{ik[p(x-x'')+q(y-y'')+m|z-z''|]}\,dp\,dq \tag{57}$$

which can be easily derived from Eq. (55). In Eq. (57) the ± sign holds according to whether $(z-z'')\gtrless 0$. With these two equations it is possible to transform back and forth between these two representations.

Reciprocity Theorem

The radiation pattern and the complex degree of spectral coherence obey a very useful reciprocity theorem for a quasi-homogeneous source. By substituting from Eq. (40) into Eq. (53), and using Eq. (24) and the six-dimensional form of Eq. (41), it has been shown that the radiant intensity in the direction of the unit vector **s** from any bounded, three-dimensional, quasi-homogeneous primary source distribution is given by [see Ref. 45, eq. (3.11)]

$$J_\omega(\mathbf{s})=J_0\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\mu_Q(\mathbf{x}_-'')e^{-ik\mathbf{x}_-''\cdot\mathbf{s}}\,d^3\mathbf{x}_-'' \tag{58}$$

where $\mu_Q(\mathbf{x}_-'')$ is the (spatially stationary) complex degree of spectral coherence for the source distribution as defined in Eq. (40), and

$$J_0=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}I_Q(\mathbf{x}_+'')\,d^3\mathbf{x}_+'' \tag{59}$$

where $I_Q(\mathbf{x}_+'')$ is the intensity defined in Eq. (40). Note that the far-field radiation pattern depends, not on the source intensity distribution, but only on the source coherence. We also find from this calculation that the complete degree of spectral coherence between any two points in the far field of this source is given by [see Ref. 45, eq. (3.15)]

$$\mu^{(\infty)}u(R_1\mathbf{s}_1,R_2\mathbf{s}_2)=\frac{e^{ik(R_1-R_2)}}{J_0}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}I_Q(\mathbf{x}_+'')e^{ik\mathbf{x}_+''\cdot(\mathbf{s}_1-\mathbf{s}_2)}d^3\mathbf{x}_+'' \tag{60}$$

Note that the coherence of the far field depends, not on the source coherence, but rather on the source intensity distribution, $I_Q(\mathbf{x}_+'')$. Equation (60) is a generalization of the van Cittert–Zernike theorem to three-dimensional, primary quasi-homogeneous sources, which are not necessarily incoherent. Equation (59) is a new theorem, reciprocal to the van Cittert–Zernike theorem, which was discovered by Carter and Wolf.[45,49] Equations (58) and (60), taken together, give a reciprocity

relation. For quasi-homogeneous sources, far-field coherence is determined by source intensity alone and the far-field intensity pattern is determined by source coherence alone. Therefore, coherence and intensity are reciprocal when going from the source into the far field. Since most sources which occur naturally are believed to be quasi-homogeneous, this is a very useful theorem. This reciprocity theorem has been found to hold much more generally than just for three-dimensional primary sources. For a planar, secondary source, by substitution from Eq. (40) into Eq. (54) and then using Eq. (41), we obtain[49]

$$J_\omega(\mathbf{s}) = J_0' \cos^2\theta \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mu_U^{(0)}(\mathbf{x}_-')e^{-ik\mathbf{x}_-'\cdot\mathbf{s}}\, d^2\mathbf{x}_-' \tag{61}$$

where θ is the angle that $\mathbf{s}$ makes with the $+z$ axis, and where

$$J_0' = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_U^{(0)}(\mathbf{x}_+')\, d^2\mathbf{x}_+' \tag{62}$$

and we also obtain

$$\mu_U^{(\infty)})(R_1\mathbf{s}_1, R_2\mathbf{s}_2) = \frac{1}{J_0'}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_U^{(0)}(\mathbf{x}_+')e^{-ik\mathbf{x}_+'\cdot(\mathbf{s}_1-\mathbf{s}_2)}\, d^2\mathbf{x}_+' \tag{63}$$

Very similar reciprocity relations also hold for scattering of initially coherent light from quasi-homogeneous scattering potentials,[53,54] and for the scattering of laser beams from quasi-homogeneous sea waves.[63] Reciprocity relations which apply to fields that are not necessarily quasi-homogeneous have also been obtained.[64]

Nonradiating Sources

One additional important comment must be made about Eq. (58). The integrals appearing in this equation form a three-dimensional Fourier transform of $\mu_Q(\mathbf{x}_-'')$. However, $J_\omega(\mathbf{s})$, the radiant intensity that this source radiates into the far field at radial frequency ω, is a function of only the direction of $\mathbf{s}$, which is a unit vector with a constant amplitude equal to one. It then follows that only the values of this transform over a spherical surface of unit radius from the origin affect the far field. Therefore, sources which have a complex degree of spectral coherence, $\mu_Q(\mathbf{x}_-'')$, which do not have spatial frequencies falling on this sphere, do not radiate at frequency ω. It appears possible from this fact to have sources in such a state of coherence that they do not radiate at all. Similar comments can also be made in regard to Eq. (53) which apply to all sources, even those that are not quasi-homogeneous. From Eq. (53) it is clear that only sources which have a cross-spectral density function with spatial frequencies (with respect to both $\mathbf{x}_1''$ and $\mathbf{x}_2''$) on a unit sphere can radiate. It is believed that this is closely related to the phase-matching condition in nonlinear optics.

Perfectly Incoherent Sources

For a completely incoherent primary source the far-field radiant intensity, by substitution from Eq. (42) into Eq. (58), is seen to be the same in all directions, independent of the shape of the source. By substitution from Eq. (40) into Eq. (28), and then using Eqs. (14), (29), and (42), we find that the complex degree of spectral coherence for this incoherent source is given by

$$\mu_U(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{I(\mathbf{x}_1)/(\mathbf{x}_2)}}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_Q(\mathbf{x}'')\frac{e^{ik[|\mathbf{x}_1-\mathbf{x}''|-|\mathbf{x}_2-\mathbf{x}''|]}}{|\mathbf{x}_1-\mathbf{x}''||\mathbf{x}_2-\mathbf{x}''|}d^3\mathbf{x}'' \tag{64}$$

Thus it is only the source intensity distribution that affects the field coherence. Comparison of this equation with Eq. (47) shows that this is a generalization of the van Cittert–Zernike theorem to primary

sources. It is clear from this equation that the complex degree of spectral coherence depends only on the shape of the source and not the fact that the source is completely incoherent. For a completely incoherent, planar, secondary source the radiant intensity is given by

$$J_\omega(\mathbf{s}) = J_0' \cos^2\theta \tag{65}$$

independent of the shape of the illuminated area on the source plane, where θ is the angle that $\mathbf{s}$ makes with the normal to the source plane. This can be proven by substitution from Eq. (42) into Eq. (61). Note that such sources do not obey Lambert's law. The far-field coherence, again, depends on the source intensity as given by the van Cittert–Zernike theorem [see Eq. (47)] and not on the source coherence.

Spectrum

For a quasi-homogeneous, three-dimensional primary source the spectrum of the radiation $S_U^{(\infty)}(R\mathbf{s}, \omega)$ at a point $R\mathbf{s}$ in the direction $\mathbf{s}$ (unit vector) and at a distance R from the origin, in the far field of the source, can be found, as a function of the source spectrum $S_Q^{(0)}(\omega)$, by substitution from Eqs. (24) and (15) into Eq. (58) to get

$$S_U^{(\infty)}(R\mathbf{s}, \omega) = \frac{c^3 S_Q(\omega)}{\omega^3 R^2} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mu_Q(\underline{\mathbf{x}}'', \omega) e^{-ik\underline{\mathbf{x}}''\cdot\mathbf{s}}\, d^3(k\underline{\mathbf{x}}'') \tag{66}$$

where we explicitly indicate the dependence of the complex degree of spectral coherence on frequency. Notice that the spectrum of the field is not necessarily the same as the spectrum of the source and, furthermore, that it can vary from point to point in space. The field spectrum depends on the source coherence as well as on the source spectrum. A very similar propagation relation can be found for the far-field spectrum from a planar, secondary source in the $z = 0$ plane. By substitution from Eqs. (24) and (15) into Eq. (61) we get

$$S_U^{(\infty)}(R\mathbf{s}, \omega) = \frac{S_U^{(0)}(\omega)}{R^2} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mu_U^{(0)}(\underline{\mathbf{x}}', \omega) e^{-ik\underline{\mathbf{x}}'\cdot\mathbf{s}}\, d^2(k\underline{\mathbf{x}}') \tag{67}$$

This shows that the spectrum for the field itself is changed upon propagation from the $z = 0$ plane into the far field and is different in different directions $\mathbf{s}$ from the source.[65]

5.7 SPECTRUM OF LIGHT

Limitations

The complex analytic signal for a field that is not perfectly coherent, as defined in Eq. (3), is usually assumed to be a time-stationary random process. Therefore, the integral

$$\int_{-\infty}^{\infty} u(\mathbf{x}, t) e^{i\omega t} dt \tag{68}$$

does not converge, so that the analytic signal does not have a Fourier transform. Therefore, it is only possible to move freely from the space-time domain to the space-frequency domain along the path shown in Fig. 5. Equation (3) does not apply to time-stationary fields within the framework of ordinary function theory.

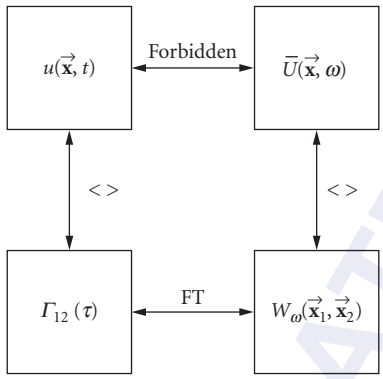

FIGURE 5 Illustrating the transformations which are possible between four functions that are used in coherence theory.

Coherent Mode Representation

Coherent mode representation (see Wolf[66,67]) has shown that any partially coherent field can be represented as the sum over component fields that are each perfectly self-coherent, but mutually incoherent with each other. Thus the cross-spectral density function for any field can be represented in the form

$$W_A(\mathbf{x}_1, \mathbf{x}_2) = \sum_n \lambda_n \phi_{A,n}(\mathbf{x}_1) \phi^*_{A,n}(\mathbf{x}_2) \tag{69}$$

where $\phi_{A,n}(\mathbf{x}_i)$ is a phasor amplitude for its nth coherent component. This representation can be used either with primary ($A = Q$), or secondary ($A = U$) sources. The phasor amplitudes $\phi_{A,n}(\mathbf{x}_i)$ and the complex expansion coefficients λ_n in Eq. (69) are eigenfunctions and eigenvalues of $W_A(\mathbf{x}_1, \mathbf{x}_2)$, as given by the equation

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_A(\mathbf{x}_1, \mathbf{x}_2)\phi_{A,n}(\mathbf{x}_2) d^3\mathbf{x}_2 = \lambda_n(\omega)\phi_{A,n}(\mathbf{x}_1) \tag{70}$$

Since $W_A(\mathbf{x}_1, \mathbf{x}_2)$ is hermitian, the eigenfunctions are complete and orthogonal, i.e.,

$$\sum_n \phi_{A,n}(\mathbf{x}_1)\phi^*_{A,n}(\mathbf{x}_2) = \delta^3(\mathbf{x}_1 - \mathbf{x}_2) \tag{71}$$

and

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \phi_{A,n}(\mathbf{x}_1)\phi^*_{A,m}(\mathbf{x}_1)\, d^3\mathbf{x}_1 = \delta_{nm} \tag{72}$$

where δ_{nm} is the Kronecker delta function, and the eigenvalues are real and nonnegative definite, i.e.,

$$\begin{aligned} &\text{Real}\,\{\lambda_n(\omega)\} \geq 0 \\ &\text{Imag}\,\{\lambda_n(\omega)\} = 0 \end{aligned} \tag{73}$$

This is a very important concept in coherence theory. Wolf has used this representation to show that the frequency decomposition of the field can be defined in a different manner than was done in Eq. (3). A new phasor,

$$\bar{U}_A(\mathbf{x}, \omega) = \sum_n a_n(\omega)\phi_{A,n}(\mathbf{x}, \omega) \tag{74}$$

where $a_n(\omega)$ are random coefficients such that

$$\langle a_n(\omega)a_m^*(\omega)\rangle = \lambda_n(\omega)\delta_{nm} \tag{75}$$

can be introduced to represent the spectral components of the field. It then follows[66] that, if the $\phi_{A,n}(\mathbf{x}_i)$ are eigenfunctions of the cross-spectral density function, $W_A(\mathbf{x}_1, \mathbf{x}_2)$ then the cross-spectral density function can be represented as the correlation function between these phasors at the two spatial points $\mathbf{x}_1$ and $\mathbf{x}_2$, i.e.,

$$W_A(\mathbf{x}_1, \mathbf{x}_2) = \langle \bar{U}_A(\mathbf{x}_1, \omega)\bar{U}_A^*(\mathbf{x}_2, \omega)\rangle \tag{76}$$

in a manner very similar to the representation given in Eq. (11) in respect to the older phasors. Notice, by comparison of Eqs. (11) and (76), that the phasors $\bar{U}_A(\mathbf{x}_i, \omega)$ and $U_A(\mathbf{x}_i, \omega)$ are not the same. One may formulate coherence theory either by defining $u(\mathbf{x}, t)$ in Fig. 5 and then moving in a counterclockwise direction in this figure to derive the correlation functions using the Wiener-Khintchene theory or, alternatively, defining $\bar{U}_A(\mathbf{x}_i, \omega)$ and moving in a clockwise direction to define the correlation functions using the coherent mode expansion.

Wolf Shift and Scaling law

From Eqs. (66) and (67) it is clear that the spectrum of a radiation field may change as the field propagates. It is not necessarily equal to the source spectrum as it is usually assumed. This brings up an important question. Why do the spectra for light fields appear so constant, experimentally, that a change with propagation was never suspected? Wolf[65] has provided at least part of the answer to this question. He discovered a scaling law that is obeyed by most natural fields and under which the normalized spectrums for most fields do remain invariant as they propagate. We can derive this scaling law by substitution from Eqs. (66) and (67) into Eq. (16). We then find that, if the complex degree of spectral coherence for the source is a function of $k\mathbf{x}_-$ only, i.e.,

$$\mu_A(\mathbf{x}_-, \omega) = f(k\mathbf{x}_-) \tag{77}$$

(so that this function is the same for each frequency component of the field, provided that the spatial separations of the two test points are always scaled by the wavelength), then the normalized spectrum in the far field is given by

$$s_U^{(\infty)}(R\mathbf{s}, \omega) = \frac{S_Q(\omega)/\omega^3}{\int_0^\infty S_Q(\omega)/\omega^3\, d\omega} \neq f(R\mathbf{s}) \tag{78}$$

if $S_Q(\omega)$ is the complex degree of spectral coherence for a primary, quasi-homogeneous source [see Additional Reading, Ref. 3, eq. (65)], and

$$s_U^{(\infty)}(R\mathbf{s}, \omega) = \frac{S_U^{(0)}(\omega)}{\int_0^\infty S_U^{(0)}(\omega)\, d\omega} = s_U^{(0)}(\omega) \neq f(R\mathbf{s}) \tag{79}$$

if $s_U^{(0)}(\omega)$ is the normalized spectrum for a secondary, quasi-homogeneous source [see Additional Reading, Ref. 3, eq. (51)]. In each case the field spectrum does not change as the field propagates. Since the cross-spectral density function for a thermal source [see Eq. (43)] obeys this scaling law, it is not surprising that these changes in the spectrum of a propagating light field were never discovered experimentally. The fact that the spectrum can change was verified experimentally only after coherence theory pointed out the possibility.[68–72]

5.8 POLARIZATION EFFECTS

Explicit Vector Representations

As discussed earlier under "Scalar Field Amplitude," the scalar amplitude is frequently all that is required to treat the vector electromagnetic field. If polarization effects are important, it might be necessary to use two scalar field amplitudes to represent the two independent polarization components. However, in some complicated problems it is necessary to consider all six components of the vector field explicitly. For such a theory, the correlation functions between vector components of the field become tensors,[73,74] which propagate in a manner very similar to the scalar correlation functions.

5.9 APPLICATIONS

Speckle

If coherent light is scattered from a stationary, rough surface, the phase of the light field is randomized in space. The diffraction patterns observed with such light displays a complicated granular pattern usually called *speckle* (see Ref. 8, sec. 7.5). Even though the light phase can be treated as a random variable, the light is still perfectly coherent. Coherence theory deals with the effects of time fluctuations, not spatial variations in the field amplitude or phase. Despite this, the same statistical tools used in coherence theory have been usefully applied to studying speckle phenomena.[75,76] To treat speckle, the ensemble is usually redefined, not to represent the time fluctuations of the field but, rather, to represent all of the possible speckle patterns that might be observed under the conditions of a particular experiment. An observed speckle pattern is usually due to a single member of this ensemble (unless time fluctuations are also present), whereas the intensity observed in coherence theory is always the result of a weighted average over all of the ensemble. To obtain the intensity distribution over some plane, as defined in coherence theory, it would be necessary to average over all of the possible speckle patterns explicitly. If this is done, for example, by moving the scatterer while the intensity of a diffraction pattern is time-averaged, then time fluctuations are introduced into the field during the measurement; the light becomes partially coherent; and coherence theory can be properly used to model the measured intensity. One must be very careful in applying the coherence theory model to treat speckle phenomena, because coherence theory was not originally formulated to deal with speckle.

Statistical Radiometry

Classical radiometry was originally based on a mechanical treatment of light as a flux of particles. It is not totally compatible with wave theories. Coherence theory has been used to incorporate classical radiometry into electromagnetic theory as much as has been found possible. It has been found that the usual definitions for the radiance function and the radiant emittance cause problems when applied to a wave theory. Other radiometric functions, such as the radiant intensity, have clear meaning in a wave theory.

Spectral Representation

It was discovered, using coherence theory, that the spectrum of a light field is not the same as that of its source and that it can change as the light field propagates away from its source into the radiation field. Some of this work was discussed earlier under "Perfectly Incoherent Sources" and "Coherent Mode Representation." This work has been found very useful for explaining troublesome experimental discrepancies in precise spectroradiometry.[71]

Laser Modes

Coherence theory has been usefully applied to describing the coherence properties of laser modes.[77] This theory is based on the coherent mode representation discussed under "Spectrum of Light."

Radio Astronomy

Intensity interferometry was used to apply techniques from radio astronomy to observation with light.[37] A lively debate ensued as to whether optical interference effects (which indicate partial coherence) could be observed from intensity correlations.[78] From relations like Eq. (26) and similar calculations using quantum coherence theory, it quickly became clear that they could.[79,80] More recently, coherence theory has been used to model a radio telescope[42] and to study how to focus an instrument to observe emitters that are not in the far field of the antenna array.[81] It has been shown[82] that a radio telescope and a conventional optical telescope are very similar, within a coherence theory model, even though their operation is completely different. This model makes the similarities between the two types of instruments very clear.

Noncosmological Red Shift

Cosmological theories for the structure and origin of the universe make great use of the observed red shift in the spectral lines of the light received from distant radiating objects, such as stars.[83] It is usually assumed that the spectrum of the light is constant upon propagation and that the observed red shift is the result of simple Doppler shift due to the motion of the distant objects away from the earth in all directions. If this is true, then clearly the observed universe is expanding and must have begun with some sort of explosion, called "the big bang." The size of the observable universe is estimated based on the amount of this red shift. A new theory by Wolf[84–87] shows that red shifts can occur naturally without Doppler shifts as the light propagates from the source to an observer if the source is not in thermal equilibrium, i.e., a thermal source as discussed earlier under "Thermal (Lambertian) Source." The basis of Wolf's theory was discussed in this papers.[84,85]

6.1 GLOSSARY

$\mathcal{F}$	Fourier transform operator
I	Intensity
k	wave number
u	complex field amplitude
Γ_{12}	mutual coherence function
J_{12}	mutual intensity function
μ_{12}	complex degree of coherence
$\mathbf{x}$	spatial vector

6.2 INTRODUCTION

The formalisms of coherence theory have been extensively developed over the past century, with roots extending back much further. An understanding of key concepts of the coherence properties of light waves and of their accompanying mathematical models can be exploited in specific applications to extract information about objects (e.g., stellar interferometry, microscopy[1,2]), to encrypt signals transmitted by optical fiber (coherence modulation), to explain puzzling phenomena observed in nature (sunlight-produced speckle, enhanced backscatter), and to prevent significant errors in the measurement of optical quantities (measurement of the reflectivity of diffuse surfaces), among other examples. There are cases where using a coherence-theory–based analysis provides not only insight into understanding system behavior but simplifies the analysis through reduced computational steps.

In Chap. 5, Carter provides a compendium of basic definitions from coherence theory, introduces mathematical models for light sources of fundamental importance, discusses how the coherence properties of optical wave fields evolve under propagation, and shows how the spectral properties of light waves relate to their coherence properties.[3] He also notes briefly several areas in which coherence theory has been exploited to advance significantly the understanding of optical phenomena. References 1-8 in Chap. 5 provide a suitable introduction to most aspects of classical (i.e., nonquantum) coherence theory. Since the publication of Vol. I of this *Handbook* series, Mandel and Wolf have written a comprehensive review of coherence theory and a brief discussion of specific applications.[4] Other informative sources include a compilation of early papers on coherence edited by Mandel and Wolf.[5]

The formal structures of coherence theory can be intimidating to the nonexpert trying to ascertain, for example, the effect of a particular light source on a given optical system. One has only to review the myriad of defined quantities or look at a six- or seven-dimensional integral expression describing an image-forming system to understand why. Nevertheless, the basic concepts of coherence theory, and certain of their key formulas, can be helpful even to the nonexpert when they are applied to the understanding of a variety of optical systems and phenomena. That said, it should be noted that sometimes the application of coherence theory formalisms only serves to obfuscate the operation of a given system. One objective of this chapter is to provide guidance as to when coherence theory can help and when it might serve largely to confuse. We note that coherence theory is not generally needed if the optical wave fields of concern can be modeled as being monochromatic or quasi-monochromatic. The subject of interferometry is easily treated without the inclusion of coherence theory if the source of light is a laser operating in a single mode, and optical coherence tomography is easily understood without appeal to much more than an understanding of temporal coherence theory.[6–10] It is with this latter point in mind that we emphasize on analyses involving the spatial coherence properties of the light.

6.3 KEY DEFINITIONS AND RELATIONSHIPS

We begin with the presentation of a set of tools that are critical to the analysis of certain applications. Although the cross-spectral density function[3,4] is often preferred in the modeling of the spatiotemporal coherence properties of light, in a discussion of the applications of coherence theory where physical understanding is important we find it preferable to work instead with the mutual coherence function, defined by[11]

$$\Gamma_{12}(\tau)=\langle u(\mathbf{x}_1, (t+\tau))u^*(\mathbf{x}_2, t)\rangle \tag{1}$$

where $u(\mathbf{x}, t)$ denotes the complex analytic signal associated with the scalar wave amplitude at position $\mathbf{x} = (x, y, z)$ and where the angular brackets <•> denote a suitable time average.*

*The nature of the time average is discussed later in this chapter. Note that in Chap. 5 Carter uses angular brackets to denote ensemble averages rather than time averages.

This function has the advantage of relating directly to quantities that can be measured by an easily visualized Young's two-pinhole interferometer. In theoretical developments $u(\mathbf{x}, t)$ is usually treated as an ergodic random process, and the time average is replaced with an ensemble average. However, because such conditions are not satisfied in all applications of interest, we maintain specific reference to time averages. The mutual intensity function, unlike the complex amplitude itself, is a measurable quantity. The temporal frequency bandwidth of optical signals typically far exceeds the bandwidth of any optical detector, thus preventing the direct measurement of $u(\mathbf{x}, t)$. As discussed by Greivencamp, a Young's two-pinhole interferometer can be used, at least conceptually, in the measurement process.[12]

In many cases we can assume the light to be quasi-monochromatic.[13] The narrowband condition $\Delta\lambda \ll \bar{\lambda}$ is satisfied, where $\Delta\lambda$ denotes the spectral bandwidth of the light and where $\bar{\lambda}$ is the mean wavelength, and the coherence length of the light,[3] $\Delta l \sim \bar{\lambda}^{-2}/\Delta\lambda$, is much greater than the maximum path length difference encountered in the passage of light from a source of interest to the measurement plane of concern. Under such conditions[11] the mutual coherence function is given by

$$\Gamma_{12}(\tau) = J_{12} e^{-i\omega t} \tag{2}$$

where ω is the mean angular frequency of the radiation and where J_{12}, the mutual intensity function, is given by

$$J_{12} = \Gamma_{12}(0) \tag{3}$$

Note that J_{12} depends on the spatial coordinates $\mathbf{x}_1$ and $\mathbf{x}_2$ but not on τ.

Effect of Transmissive Planar Object

In most of the applications considered in this chapter we are concerned with the behavior of J_{12} in a two-dimensional systems framework. Assume, therefore, that $\mathbf{x}_1$ and $\mathbf{x}_2$ represent the coordinates of a pair of points in a plane of constant z. The complex amplitude $u(\mathbf{x}, t)$ can then be written as $u(x, y, t)$, and J_{12} can be written in the form $J(x_1, y_1; x_2, y_2)$. If the wave field $u_{\text{inc}}(x, y, t)$ is incident upon a thin transmissive object of complex transmittance $t(x, y)$, the transmitted wave $u_{\text{trans}}(x, y, t)$ has amplitude $u_{\text{inc}}(x, y, t)t(x, y)$, and it is easily shown that the corresponding mutual intensity is given by

$$J_{\text{trans}}(x_1, y_1; x_2, y_2) = J_{\text{inc}}(x_1, y_1; x_2, y_2)\, t(x_1, y_1) t^*(x_2, y_2) \tag{4}$$

Of particular interest later is the case when the object is a thin spherical lens. The transmittance function of such a lens is given, in the paraxial approximation and ignoring an accompanying pupil function, by

$$t_{\text{lens}}(x, y) = \exp\left[-i\frac{k}{2f}(x^2 + y^2)\right] \tag{5}$$

where f denotes the focal length of the lens and where $k = 2\pi/\lambda$. Assuming a lens that is not the limiting aperture in a system and substitution in Eq. (4) yields

$$J_{\text{trans}}(x_1, y_1; x_2, y_2) = J_{\text{inc}}(x_1, y_1; x_2, y_2) \exp\left\{-i\frac{k}{2f}\left[\left(x_1^2 - x_2^2\right) + \left(y_1^2 - y_2^2\right)\right]\right\} \tag{6}$$

Effect of a General Linear System

If the wave amplitude $u(x, y, t)$ is input to a space-invariant two-dimensional linear optical system with spatial impulse response $h(x, y)$, the output wave amplitude has the form

$u_{out}(x, y; t) = u_{in}(x, y; t) \otimes\otimes h(x, y)$, where $\otimes\otimes$ denotes a two-dimensional convolution operation. The relationship for the corresponding mutual intensity functions is given by*

$$J_{out}(x_1, y_1; x_2, y_2) = J_{in}(x_1, y_1; x_2, y_2) \otimes\otimes h(x_1, y_1) ** h^*(x_2, y_2) \tag{7}$$

The cascade of two-dimensional convolutions in this equation can, if desired, be rewritten in the form of a four-dimensional convolution of $J_{in}(x_1, y_1; x_2, y_2)$ with a separable four-dimensional kernel:

$$J_{out}(x_1, y_1; x_2, y_2) = J_{in}(x_1, y_1; x_2, y_2) \otimes\otimes\otimes\otimes [h(x_1, y_1) h^*(x_2, y_2)] \tag{8}$$

Propagation of the Mutual Intensity

It is a straightforward matter to show how the mutual intensity of a wave field propagates.[14–16] In most applications, concern is with propagation in the Fresnel (paraxial) regime, in which case $h(x, y)$ in Eq. (7), denoted now by $h_z(x, y)$, is given by

$$h_z(x, y) = \frac{\exp(ikz)}{i\lambda z} \exp\left[\frac{ikz(x^2 + y^2)}{2z}\right] \tag{9}$$

where z is the plane-to-plane propagation distance. The factor $(-i)^{-1}\exp(ikz)$ can often be ignored.

If we assume the source distribution to be planar, quasi-monochromatic, and spatially incoherent [the latter condition implying that $J_{12} = \gamma_o I(\mathbf{x}_1)\delta(\mathbf{x}_1 - \mathbf{x}_2)$, where I denotes the optical intensity of the wave field and where γ_o is a constant that depends on characteristics of the source at the scale of a wavelength] with optical intensity $I_O(x, y)$, it can be shown by combining Eqs. (8) and (9) that the mutual intensity a distance z away from the source is given by

$$\begin{aligned} J_z(x_1, y_1; x_2, y_2) &= \frac{\exp(-i\phi)}{(\lambda z)^2} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_o(\xi, \eta) \exp\left[\frac{i2\pi}{\lambda z}(\Delta x\xi + \Delta y\eta)\right] d\xi d\eta \\ &= \frac{\exp(-i\phi)}{(\lambda z)^2} \hat{I}_o\left(\frac{\Delta x}{\lambda z}, \frac{\Delta y}{\lambda z}\right) \end{aligned} \tag{10}$$

where $\hat{I}_o(x, y)$ denotes the two-dimensional Fourier transform of the source-plane intensity, $\Delta x = x_1 - x_2$, $\Delta y = y_1 - y_2$, and where

$$\phi = \frac{\pi}{\lambda z}\left[\left(x_2^2 + y_2^2\right) - \left(x_1^2 + y_1^2\right)\right] \tag{11}$$

Equation (10) is a compact statement of the van Cittert-Zernike theorem. If the wave field corresponding to J_z in Eq. (10) is incident on a thin spherical lens of focal length $f = z$, then, through Eqs. (10) and (4), the quadratic phase factors of Eq. (11) are removed and the resulting mutual intensity has the simple form $(1/\lambda z)^2 \hat{I}_o(\Delta x/\lambda z, \Delta y/\lambda z)$. This distribution, it is noted, is a function of Δx and Δy alone, that is, it is a function only of the vector separation between the two sample points $\mathbf{x}_1$ and $\mathbf{x}_2$.

The Issue of Time Averages

The nature of the time average implied by the angular brackets in Eq. (1) will depend on the particular situation of concern. If, for example, $u(x, t)$ corresponds to the wave field produced by a white light source, adequate averaging is obtained over a time interval of roughly a picosecond (10^{-12} s). If, on the other hand, the light source is a stabilized laser with a temporal frequency bandwidth of several tens of kilohertz, the period over which the average is evaluated might be milliseconds in duration. Often the bandwidth of a detector determines the appropriate duration of the averaging process. If we are viewing white-light interference fringes by eye, the integration interval can be anywhere

*Although this expression does not appear in the standard textbooks on coherence theory, it is easily derived.

from a picosecond to perhaps a thirtieth of a second. If the same fringes are being observed with a megahertz-bandwidth measurement system, on the other hand, integration for times greater than a microsecond is inappropriate.

6.4 PROPAGATION, DIFFRACTION, AND SCATTERING: ENHANCED BACKSCATTER AND THE LAU EFFECT

Coherence theory can provide a useful tool for describing certain phenomena encountered in connection with wave field propagation, scattering, and diffraction by gratings. Two examples of cases where a coherence theory approach is especially enlightening are the phenomenon of enhanced backscatter (EBS) and the Lau effect, as discussed in the following subsections.

Enhanced Backscatter

Enhanced backscatter is observed when a laser beam, after passing through a fine-grained moving diffuser, is reflected back through the same moving diffuser. As illustrated in Fig. 1*a*, the far field contains, in addition to a broad background irradiance distribution, a tightly focused spot of light, corresponding to the diffraction-limited focusing of the partially recollimated incident beam. This result contrasts with that obtained with two *different* moving diffusers, as shown in Fig. 1*b*, in which case there is no focused light spot. Although a ray-optics model can provide some insight

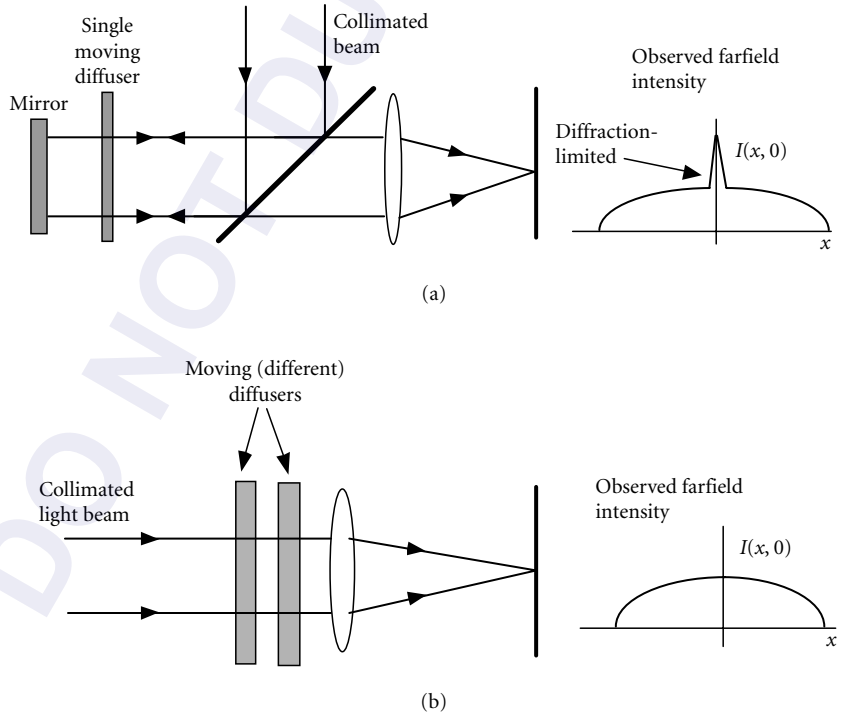

FIGURE 1 Scattering by moving diffusers: (*a*) enhanced backscatter (partial phase conjugation scattering) produced by double passage of light through the same diffuser and (*b*) conventional scattering produced by two different diffusers.

into this counter-intuitive phenomenon, coherence theory allows us to develop much greater understanding.

Consider the case where the incident wave field is quasi-monochromatic and of arbitrary spatial coherence properties. To simplify the math we work with a one-dimensional model. The moving diffuser is represented by a thin dynamic random phase screen with complex amplitude transmittance $\phi(x, t)$. Transmission of the incident wave $u(x, t)$ through the diffuser results in wave field $u(x, t)\phi(x, t)$, which propagates a distance z to be scattered a second time by an identical random phase screen. The doubly-scattered wave amplitude $u'(x, t)$ is given by[17]

$$u'(x, t) = \phi(x, t)\int_{-\infty}^{\infty} u(\xi, t)\phi(\xi, t)h_z(x-\xi)d\xi \tag{12}$$

where $h_z(x)$ represents the wave propagation kernel of Eq. (9). The mutual intensity of the doubly-scattered wave field is calculated as

$$\begin{aligned} J'(x_1, x_2) &= \langle u'(x_1, t)u'^*(x_2, t)\rangle \\ &= \left\langle \left[\phi(x_1, t)\int_{-\infty}^{\infty} u(\xi, t)\phi(\xi, t)h_z(x_1-\xi)d\xi\right]\left[\phi^*(x_2, t)\int_{-\infty}^{\infty} u^*(\eta, t)\phi^*(\eta, t)h_z^*(x_2-\eta)d\eta\right]\right\rangle \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\langle u(\xi, t)u^*(\eta, t)\rangle\langle\phi(x_1, t)\phi^*(x_2, t)\phi(\xi, t)\phi^*(\eta, t)\rangle h_z(x_1-\xi)h_z^*(x_2-\eta)d\xi\, d\eta \end{aligned} \tag{13}$$

where in expressing the effect of the time average it has been assumed that u and ϕ vary independently. To simplify this expression we note that $\langle u(\xi, t)u^*(\eta, t)\rangle$ is the mutual intensity $J(\xi, \eta)$ of the input wave field. Additionally, if $\phi(x, t)$ represents a spatially stationary, delta-correlated scatterer with suitably large excursions in phase, the second term in brackets in the integral of Eq. (13) can be modeled by

$$\langle\phi(x_1, t)\ \phi^*(x_2, t)\ \phi(\xi, t)\ \phi^*(\eta, t)\rangle = \gamma^2[\delta(x_1-x_2)\ \delta(\xi-\eta)+\delta(x_1-\eta)\ \delta(\xi-x_2)] \tag{14}$$

where

$$\gamma = \int_{-\infty}^{\infty}\langle\phi(\xi, t)\phi^*(0, t)\rangle d\xi \tag{15}$$

Making the appropriate substitutions in Eq. (13) yields

$$J'(x_1, x_2) = a(x_1)\delta(x_1-x_2)+b(x_1, x_2)J^*(x_1, x_2) \tag{16}$$

where

$$a(x_1) = \gamma^2 I(x_1)\otimes|h_z(x_1)|^2 \tag{17}$$

$$b(x_1, x_2) = \gamma^2 h_z(x_1-x_2)h_z^*(x_1-x_2) \tag{18}$$

and where the function $I(x)$ in Eq. (17) is the optical intensity of the incident wave. If the one-dimensional form of the Fresnel propagation kernel is substituted for $h_z(x)$,

$$h_z(x) = \frac{1}{\sqrt{i\lambda z}}\exp\left[\frac{i\pi}{\lambda z}x^2\right] \tag{19}$$

calculation of $a(x_1)$ and $b(x_1, x_2)$ yields

$$J'(x_1, x_2) = \delta(x_1-x_2)\gamma^2\int_{-\infty}^{\infty} I_{\text{inc}}(\xi)d\xi+\gamma^2 J_{\text{inc}}^*(x_1, x_2) \tag{20}$$

The doubly-scattered wave, $u'(x, t)$, can thus be thought of as consisting of two components. One component has the characteristics of a spatially incoherent wave and produces a general background glow in the far field. The second component, on the other hand, effectively replicates coherence properties of the incident wave, having mutual intensity $J^*_{\text{inc}}(x_1, x_2)$, the complex conjugate of that of the incident wave. A wave field with mutual intensity $J^*_{\text{inc}}(x_1, x_2)$ behaves like a time-reversed (or "backward-propagating") version of a wave field with mutual intensity $J_{\text{inc}}(x_1, x_2)$. Thus, if the incident wave is diverging, the doubly-scattered wave will contain, in addition to an incoherent component, a coherence-replicated component that is converging at the same rate. For the case illustrated in Fig. 1*a*, since the incident beam is collimated, the coherence-replicated component of the doubly-scattered wave also behaves like a collimated light beam.

It should be noted that evaluation of the time average for the term $\langle u(\xi, t)u^*(\eta, t)\rangle$ in Eq. (13) may be satisfactorily complete in a fraction of a microsecond—that is, after an interval large compared to the reciprocal bandwidth of the light incident on the diffuser—whereas calculation of the second brackets term, $\langle \phi(x_1, t)\phi^*(x_2, t)\phi(\xi, t)\phi^*(\eta, t)\rangle$, may require milliseconds or even seconds, depending on how rapidly the random phase screen evolves with time. What is essential is that $\phi(x, t)$ evolves satisfactorily over the duration of the time average. In the terminology of random processes, we require that $\phi(x, t)$ goes through a sufficient number of realizations as to provide a good statistical average of the bracketed quantity.

The enhanced backscatter phenomenon can be exploited, at least in theory, in the imaging of diffuser-obscured objects. Let the mirror in the system of Fig. 1*a* be replaced by a planar object with amplitude reflectance $\mathbf{r}(x)$, assuming that the incident wave is monochromatic and planar. Through an analysis quite similar to that above, one can show that the mutual intensity of the doubly-scattered wave field $J_{\text{ds}}(x_1, x_2)$ again contains two components, a coherent one and a spatially incoherent one. The coherent component, which can be measured by interferometric means, is proportional to the modulus of the Fresnel transform of the object reflectance function[18]

$$\mathbf{J}_{\text{dscoh}}(x_1, x_2) \propto \kappa^2 \left| \tilde{\mathbf{r}}_{z/2}\left(\frac{x_1+x_2}{2}\right)\right|^2 \tag{21}$$

where $\tilde{\mathbf{r}}_{z/2}(x)$, defined by

$$\tilde{\mathbf{r}}_{z/2}(x) = \int_{-\infty}^{\infty} \mathbf{r}(\eta) \exp\left[\frac{-ik(x-\eta)^2}{z}\right] d\eta \tag{22}$$

is proportional to the wave field that would result from illuminating the object with a normally incident plane wave and propagating the reflected wave a distance $z/2$. The resulting distribution is the object function blurred by Fresnel diffraction. This Fresnel-blurred image is less distinct than a normal image of the object; however, it is significantly less blurred than would be a conventional image obtained through the diffuser.

Lau Effect

In the Lau effect, an incoherently illuminated amplitude grating with grating constant d is followed by a second identical grating at a distance z_0.[19] If the second grating is followed by a converging spherical lens, fringes appear in the back focal plane of the lens whenever the distance z_0 is an integral multiple of $d^2/2\lambda$. The experimental geometry for observing this effect is illustrated in Fig. 2. If white light illumination is used, colored fringes are observed. Although the effect can be explained in terms of geometrical optics and scalar diffraction theory,[20] a much more elegant explanation results from a straightforward application of coherence theory.[21–25]

The essence of a coherence-based analysis using the mutual intensity function (expressed in one-dimensional coordinates for simplicity) is as follows: The incoherently illuminated

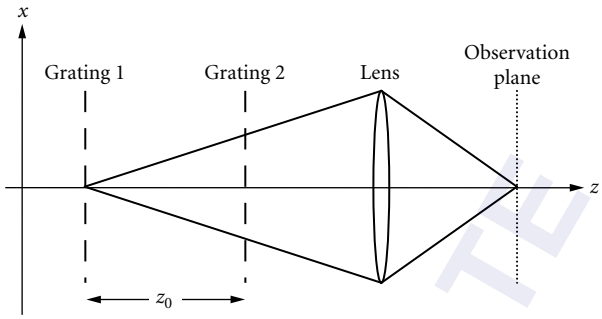

FIGURE 2 Geometry for examination of the Lau effect.

grating constitutes a periodic spatially incoherent source with period d with an intensity function described by

$$I_0(x) = \text{rect}\left(\frac{2x}{d}\right) \otimes \sum_{m=-\infty}^{\infty} \delta(x - md) \tag{23}$$

From the van Cittert-Zernike theorem [Eq. (10)] we know that the mutual intensity function of the propagated wave field arriving at the second grating can be expressed as

$$\begin{aligned} J_1(x_1, x_2) &= \frac{\exp(-i\varphi)}{(\lambda z_0)^2} \mathcal{F}\left\{\text{rect}\left(\frac{2x}{d}\right) \otimes \sum_{m=-\infty}^{\infty} \delta(x - md)\right\}\Bigg|_{u=\frac{\Delta x}{\lambda z_0}} \\ &= \frac{\exp(-i\varphi)}{(\lambda z_0)^2}\left[\frac{d}{2}\text{sinc}\left(\frac{d\Delta x}{2\lambda z_0}\right) \sum_{m=-\infty}^{\infty} \delta\left(\Delta x - \frac{m\lambda z_0}{d}\right)\right] \end{aligned} \tag{24}$$

where $\mathcal{F}$ denotes the fourier transform operation. The presence of the Dirac delta functions in the above expression indicates that the propagated wave reaching the second grating is spatially coherent only for transverse separations that are integer multiples of the distance $\lambda z_0/d$. If the second grating is treated as a transmissive planar object with a transmission function analytically equivalent to the previously defined intensity function $I_0(x)$, Eq. (4) can be used to describe the mutual intensity of the light leaving the grating, obtaining

$$\begin{aligned} J_2(x_1, x_2) &= \left[\text{rect}\left(\frac{2x_1}{d}, \frac{2x_2}{d}\right) \otimes\otimes \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} \delta(x_1 - kd, x_2 - ld)\right] \\ &\times \frac{\exp(-i\varphi)}{(\lambda z_0)^2}\left[\frac{d}{2}\text{sinc}\left(\frac{d\Delta x}{2\lambda z_0}\right) \sum_{m=-\infty}^{\infty} \delta\left(\Delta x - \frac{m\lambda z_0}{d}\right)\right] \end{aligned} \tag{25}$$

The first half of the above equation describes a two-dimensionally periodic spatial filter in the coherence domain with a period equal to d in both directions acting upon the mutual intensity of the light incident upon the grating. Maximum coherence (and hence maximum interference fringe-forming capability) is preserved when the period of the one-dimensional Dirac delta function in the second half of the equation (i.e., the nonzero coherence components of the incident light) is equal to the period of the two-dimensional Dirac delta function describing the coherence filter or $d = \lambda z_0/d$. A grating separation of $z_0 = d^2/\lambda$ meets this condition which is a special case of Lau's more general condition.

6.5 IMAGE FORMATION: LUKOSZ-TYPE SUPER-RESOLVING SYSTEM

It was in the analysis of imaging systems that coherence theory saw its first major application. Frits Zernike, in his classic 1938 paper on "The concept of degree of coherence and its application to optical problems," showed how the mutual coherence function could be employed in the wave-optics analysis of systems of lenses and apertures in such a way that modification of the system through extension, for example, through the addition of a field lens, did not necessarily require a return to the starting point in the analysis, that is, to the source of illumination.[16] In this section we illustrate the utility of Zernike's approach through application to a particular super-resolving imaging system.

In the 1960s Lukosz published a pair of papers on super-resolution imaging systems that continue to interest and intrigue people.[26,27] Lukosz-type systems can be used to increase the space-bandwidth product—in contemporary terms, the number of pixels—that can be transmitted from the object plane to the image plane with a system of a given numerical aperture. The intriguing nature and popularity of Lukosz-type imaging systems notwithstanding, they are surprisingly difficult to analyze in detail, and Lukosz's original papers present challenging reading for one who wants to understand quickly just how to model the systems mathematically. We show in this section how coherence theory tools can be used to good effect in the analysis of a super-resolution imaging system of our invention that is closely related to those described by Lukosz.[28] Closely related systems are described in Refs. 29 and 30.

The system of interest, illustrated in Fig. 3, consists of a quasi-monochromatic object, a pair of identical time-varying diffusers, a pair of lenses, and a pinhole aperture. The complex wave amplitude following Mask 2 (one-dimensional notation is used for simplicity) for an arbitrary pupil (aperture) function is given by

$$\mathbf{u}_3'(x,\,t)=\mathbf{M}(x,\,t)\int_{-\infty}^{\infty}\mathbf{M}(-\xi,\,t)\mathbf{u}_{\text{inc}}(-\xi,\,t)h_{\text{sys}}(x-\xi)d\xi \tag{26}$$

where $h_{\text{sys}}(x)$ is the complex-amplitude point spread function for the imaging system and $\mathbf{M}(x, t)$ is the complex amplitude transmittance of the masks. The wave field incident on Mask 1 is related to the object complex amplitude by $\mathbf{u}_{\text{inc}}(x) = \mathbf{u}_{\text{obj}}(x)\otimes h_d(x)$, where $h_d(x)$ is the Fresnel kernel appropriate for propagation through a distance d. Because of the dynamic (moving) diffusers and the effect of the small aperture, calculation of the corresponding optical intensity tells us virtually nothing about the object distribution. The mutual intensity in the output plane, on the other hand, can tell us a great deal about the object.

The mutual intensity of the wave incident on Mask 1 contains information about the mutual intensity of the object distribution through the relationship:

$$J_{\text{inc}}(x_1,\,x_2)=J_{\text{obj}}(x_1,\,x_2)\otimes h_d(x_1)\otimes h_d^*(x_2) \tag{27}$$

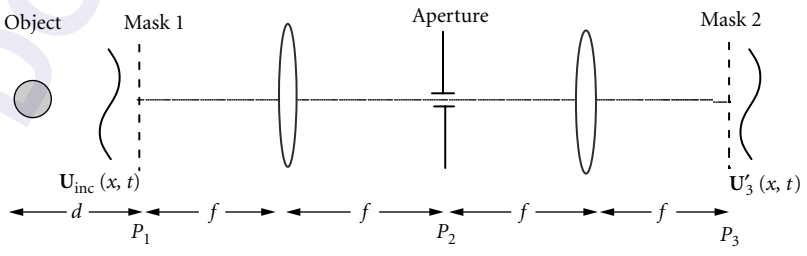

FIGURE 3 Geometry for Lukosz-type super-resolution optical system.

Because of the reversibility of the wave propagation phenomenon (manifested by the absence of nulls in the wave propagation transfer function), the mutual intensity of the object may be inferred from the mutual intensity of this incident wave field through

$$J_{\text{obj}}(x_1, x_2) = J_{\text{inc}}(x_1, x_2) \otimes h_d^*(x_1) \otimes h_d(x_2) \tag{28}$$

It is the nature of the system of Fig. 3 that this information can be transmitted to the output plane. As was done in the enhanced backscatter analysis, let the temporal behavior of the incident complex wave amplitude and the masks be statistically independent so that $\langle \mathbf{u}_{\text{inc}}(x, t)\mathbf{M}(x, t)\rangle = \langle \mathbf{u}_{\text{inc}}(x, t)\rangle\langle \mathbf{M}(x, t)\rangle$. In addition, assume that the masks are statistically homogenous random phase screens that satisfy the fourth-moment theorem, as reflected by Eq. (14), so that the time average with respect to the diffusers within the integral simplifies to a product of second-order moments and the autocorrelation function of the mask is sufficiently narrow that it can be modeled by a delta function within an integral.[31] Exploiting these conditions and exploiting the sifting property of the delta function, we can calculate the mutual intensity of the wave immediately following the second mask, that is, in plane 3:

$$\begin{aligned} J_3(x_1, x_2) = \kappa^2 J_{\text{inc}}^*(x_1, x_2) \left| \hat{\mathbf{P}}\left(\frac{x_1 + x_2}{\lambda f} \right) \right|^2 \\ + \kappa \gamma(x_1 - x_2) \int_{-\infty}^{\infty} I_{\text{inc}}(-\xi) \hat{\mathbf{P}}\left(\frac{x_1 - \xi}{\lambda f} \right) \hat{\mathbf{P}}^*\left(\frac{x_2 - \xi}{\lambda f} \right) d\xi \end{aligned} \tag{29}$$

where $\gamma(x)$ is the autocorrelation of the mask function and where I_{inc} is the optical intensity of the incident wave field.

The first term on the right in this equation is proportional to $|\hat{\mathbf{P}}()|^2$, the modulus of the imaging system impulse response ($\hat{\mathbf{P}}$ denotes the Fourier transform of the pupil function associated with the aperture), times the mutual intensity of the wave field incident on Mask 1. The second term corresponds to a spatially incoherent wave field. Through interferometric measurements, it is possible to infer the mutual intensity of the incident wave field, that is, to determine J_{inc} and thus J_{obj}.

6.6 EFFICIENT SAMPLING OF COHERENCE FUNCTIONS

Several schemes for optical imaging rely on the measurement or transmission of the spatiotemporal coherence function produced at an aperture by the waves from a distant object.[32,33] If the object is planar and spatially incoherent, this coherence function, described by the van Cittert-Zernike theorem,[34] is, to within a known quadratic phase factor, a function of the vector separation $(\Delta x, \Delta y)$ between pairs of points in the measurement plane, as illustrated in Eq. (10). As a consequence, the number of measurements required to characterize the function in a Nyquist sense is comparatively small. It is not necessary to sample the optical wave field at all possible pairs of points on a grid but, rather, only at a single pair of points for a given spacing $(\Delta x, \Delta y)$. For nonplanar objects, on the other hand, the coherence function has a more general form,[35] and the number of samples required of the coherence function necessarily increases. In order to keep the measurement time as small as possible, an efficient sampling strategy is desirable.

Nonuniform sampling grids have been shown to reduce the total number of samples required to unambiguously characterize the complex amplitude associated with a quasi-monochromatic optical wave field in certain cases.[36,37] In the following analysis it is shown that a nonuniform sampling scheme can also be effectively applied to the problem of sampling the mutual intensity produced in an aperture by a quasi-monochromatic, spatially incoherent three-dimensional object distribution. The analysis presented is of brief out of necessity, missing details being presented elsewhere.[38]

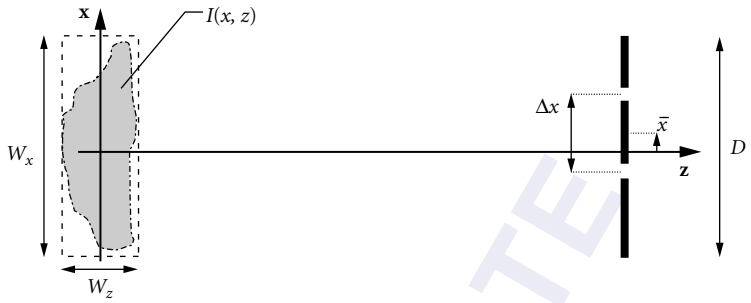

FIGURE 4 The optical coherence of the wave field generated by the source intensity distribution $I(x, z)$ is sampled in a plane some distance away from the center of the rectangular area bounding $I(x, z)$.

The source object, described by optical intensity $I(x, z)$, is assumed to be contained within a rectangular area of transverse width W_x and longitudinal depth W_z centered about the origin of the coordinate system, as shown in Fig. 4 (only one transverse dimension is considered for simplicity, extension to two being straightforward). If Fresnel-regime conditions are satisfied, the mutual intensity in the measurement plane can be shown to be given by the equation

$$J(x_1, x_2) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \frac{1}{\lambda(z-\zeta)} I(\xi, \zeta) \exp\left\{ j\frac{\pi}{\lambda(z-\zeta)}\left[(x_1-\xi)^2 - (x_2-\xi)^2\right]\right\} d\xi\, d\zeta \tag{30}$$

This function is conveniently expressed in terms of parameters $\bar{x} = (x_1 + x_2)/2$ and $\Delta x = (x_1 - x_2)$, with the result

$$J(\bar{x}, \Delta x) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \frac{1}{\lambda(z-\zeta)} I(\xi, \zeta) \exp\left[j\frac{2\pi\Delta x}{\lambda(z-\zeta)}(\bar{x}-\xi)\right] d\xi\, d\zeta \tag{31}$$

Criteria for both uniform and nonuniform sampling of this function are most easily determined if it is Fourier transformed, once with respect to the sample separation Δx and once with respect to sample-pair center coordinate $\bar{x}$:

$$\hat{J}_{\Delta x}(\bar{x}, \nu) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \frac{1}{\lambda(z-\zeta)} I(\xi, \zeta)\, \delta\left[\nu - \frac{(\bar{x}-\xi)}{\lambda(z-\zeta)}\right] d\xi\, d\zeta \tag{32}$$

$$\hat{J}_{\bar{x}}(\Delta\nu, \Delta x) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \frac{1}{\lambda(z-\zeta)} I(\xi, \zeta) \exp\left[-j\frac{2\pi\Delta x\xi}{\lambda(z-\zeta)}\right] \delta\left[\Delta\nu + \frac{\Delta x}{\lambda(z-\zeta)}\right] d\xi\, d\zeta \tag{33}$$

If the finite support of the object in x and z is taken into account, these functions can be shown to have regions of support bounded by lines given by the equations

$$\nu = \frac{1}{\lambda}\left(z \pm \frac{W_z}{2}\right)^{-1}\left(\bar{x} \pm \frac{W_x}{2}\right) \qquad \Delta\nu = \frac{\Delta x}{\lambda}\left(z \pm \frac{W_z}{2}\right)^{-1} \tag{34}$$

For distances z satisfying the condition $z \gg W_x$, the corresponding information bandwidths are well approximated by the expressions

$$B_\nu = \frac{W_x}{\lambda z} \qquad B_{\Delta\nu} = \frac{W_z \Delta x}{\lambda z^2} \tag{35}$$

A straightforward analysis based on the standard Nyquist criterion shows that uniform sample locations should be located according to the equations (letting D denote the size of the aperture in the measurement plane)

$$\bar{x}_m = \frac{m\lambda z}{2D} \qquad \Delta x_n = \frac{n\lambda z}{D + W_x} \tag{36}$$

whereas a generalized Nyquist analysis, appropriate for nonuniform sampling, yields the results

$$\bar{x}_{m,n} = \frac{mW_x z}{nW_z} \qquad \Delta x_n = \frac{n\lambda z}{W_x} \tag{37}$$

where the double subscripts m, n denote the sample order. The number of samples required is found by counting all valid indices (m,n), given the extent D of the measurement area. A comparison of the two sampling regimes shows that nonuniform sampling reduces the number of samples required by a factor $[(1+D/W_x)(1+D^2/\lambda z)]^{-1}$ and that the minimum separation between measurement points is increased by a factor $(1+D/W_x)$. This latter difference is beneficial because a constraint on the measurement apparatus is relaxed. Numerical demonstration based on system specifications given in Ref. 35 yields excellent results.

6.7 AN EXAMPLE OF WHEN NOT TO USE COHERENCE THEORY

Coherence theory can provide an extremely valuable and sometimes indispensible tool in the analysis of certain phenomena. On the other hand, it can be applied unnecessarily to certain optical systems where it tends to obfuscate rather than clarify system operation. An example is given by the Koehler-illumination imaging system modeled in Fig. 5. In this system, a uniform, spatially incoherent source is imaged by condenser lens 1 into the pupil plane of the imaging optics, the latter formed by lenses 2 and 3. Beginning with the source distribution, one can calculate, through a succession of operations based on relationships presented in Sec. 6.3, the coherence functions appropriate for the object plane, the pupil plane, and the image plane. The effect on the irradiance distributions in these planes can through this means be investigated. But is this the best way to proceed? In fact, if only the image-plane irradiance is of ultimate interest, it is not, the method being unnecessarily complicated.

Frits Zernike made an important but sometimes forgotten observation in his 1938 paper on the concept of the degree of coherence.[16] A coherence-function–based analysis of a system consisting of a cascade of subsystems, such as that just considered, can be advantageous if an objective is to calculate the irradiance of the wave field in more than a single plane. Thus, with regard to the system of Fig. 5, if calculations of the object illumination, the pupil-plane irradiance, and the image distribution are all

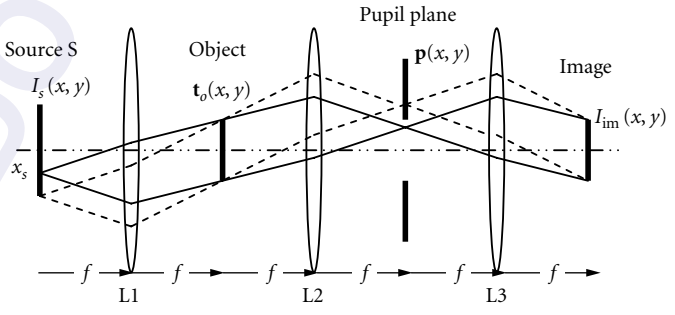

FIGURE 5 Koehler-illumination imaging model.

desired, then, assuming a quasi-monochromatic source, an analysis based on the plane-to-plane propagation of the mutual intensity of the light is the proper choice. In each plane of interest, the irradiance can be calculated from the mutual intensity without loss of the ability to propagate that mutual intensity function further in the system. If, on the other hand, the objective is simply the calculation of the image-plane irradiance distribution, given the source, object, and pupil functions, then, so long as the source is spatially incoherent, the precoherence theory approach to analysis is preferable. The image plane irradiance produced by light from a single source point is calculated, with an integration over the source distribution following. In many cases, this form of analysis provides greater insight into the operation of the system under investigation. For example, in the case of Koehler illumination, it shows that the source distribution should be uniform and that its image should overfill the aperture stop (pupil) by an amount proportional to the spatial-frequency bandwidth of the object wave amplitude transmittance function. Such insight is not readily available through a coherence-theory–based analysis.

6.8 CONCLUDING REMARKS

Some important points are summarized here:

1. Although it often appears in the analysis of optical systems, the complex amplitude associated with an optical wave field cannot be measured directly because of the very high frequencies of the wave field oscillations.
2. The optical intensity of the wave, which involves a time average, *can* be measured.
3. The mutual intensity of the wave can also be determined from measurements made using an interferometer.
4. Knowledge of the optical intensity of the wave in a given plane of an optical system does not, in general allow calculation of the mutual intensity and/or optical intensity of the wave in subsequent planes. (An exception is when the wave in that plane is spatially incoherent.)
5. By way of contrast, knowledge of the mutual intensity of the wave in a given plane *does* allow calculation of the mutual intensity and/or the optical intensity of the wave in subsequent planes.
6. If circular complex gaussian statistics for the wave field can be assumed, third- and higher-order moments of the wave field can be inferred from the second-order statistics—that is, from the mutual intensity—of the wave.[11,31]

Taken together, these statements imply that the mutual intensity of the quasi-monochromatic wave field in an optical system conveys all of the information that is measurable—and, in a valid sense, meaningful—through the system. Restating point (5) from this perspective, if the mutual intensity of a wave in one plane of an optical system is known, the mutual intensity—and, hence, the information content of the wave—can be determined in subsequent planes of that system.

7.1 GLOSSARY

a	radius
a_n, b_n	scattering coefficients
C	cross section
D_n	logarithmic derivative, $d/d\rho[\ln\psi_n(\rho)]$
E	Electric field strength
$\mathbf{e}_x$	unit vector in the x direction
f	$N\upsilon$
G	projected particle area
h	thickness
I	irradiance
I, Q, U, V	Stokes parameters
j	running index
k	imaginary part of the refractive index, $2\pi/\lambda$
m	relative complex refractive index
N	number
n	running index
P_n	associated Legendre functions of the first kind
p	phase function, normalized differential scattering cross section
Q	efficiencies or efficiency factors
r	distance
S	element of the amplitude-scattering matrix
υ	volume
W	power
X	scattering amplitude

x	size parameter, ka
α	absorption coefficient
θ	angle
λ	wavelength
π_n	$P_n^1/\sin\theta$
τ_n	$dP_n^1/d\theta$
ψ, ξ	Riccati-Bessel functions
Ω	solid angle
ω	radian frequency
$\|\|$	Parallel
$\perp$	perpendicular
Re	real part of

Subscripts

abs	absorbed
ext	extinction
sca	scattered

7.2 INTRODUCTION

Light scattering by particles plays starring and supporting roles on a variety of stages: astronomy, cell biology, colloid chemistry, combustion engineering, heat transfer, meteorology, paint technology, solid-state physics—the list is almost endless. The best evidence of the catholicity of scattering by particles is the many journals that publish papers about it.

Scattering by single particles is the subject of monographs by van de Hulst,[1] Deirmendjian,[2] Kerker,[3] Bayvel and Jones,[4] Bohren and Huffman,[5] Barber and Hill,[6] and of a collection edited by Kerker.[7] Two similar collections contain papers on scattering by atmospheric particles[8] and by chiral particles[9] (ones not superposable on their mirror images); scattering by chiral particles is also treated by Lakhtakia et al.[10] Papers on scattering by particles are included in collections edited by Gouesbet and Gréhan[11] and by Barber and Chang.[12] Within this *Handbook* scattering by particles is touched upon in Chap. 9, "Volume Scattering in Random Media," in this volume and Chap. 3, "Atmospheric Optics," in Vol. V. A grand feast is available for those with the juices to digest it. What follows is a mere snack.

A particle is an aggregation of sufficiently many molecules that it can be described adequately in macroscopic terms (i.e., by constitutive parameters such as permittivity and permeability). It is a more or less well-defined entity unlike, say, a density fluctuation in a gas or a liquid. Single molecules are not particles, even though scattering by them is in some ways similar (for a clear but dated discussion of molecular scattering, see Martin[13]).

Scattering by single particles is discussed mostly in the wave language of light, although multiple scattering by incoherent arrays of many particles can be discussed intelligibly in the photon language. The distinction between single and multiple scattering is observed more readily on paper than in laboratories and in nature. Strict single scattering can exist only in a boundless void containing a lone scatterer illuminated by a remote source, although single scattering often is attained to a high degree of approximation. A distinction made less frequently is that between scattering by coherent and incoherent arrays. In treating scattering by coherent arrays, the wave nature of light cannot be ignored: phases *must* be taken into account. But in treating scattering by incoherent arrays, phases *may* be ignored.

Pure water is a coherent array of water molecules; a cloud is an incoherent array of water droplets. In neither of these arrays is multiple scattering negligible, although the theories used to describe them may not explicitly invoke it.

The distinction between incoherent and coherent arrays is not absolute. Although a cloud of water droplets is usually considered to be an incoherent array, it is not such an array for scattering in the forward direction. And although most of the light scattered by pure water is accounted for by the laws of specular reflection and refraction, it also scatters light—weakly yet measurably—in directions not accounted for by these laws.[13]

A single particle is itself a coherent array of many molecules, but can be part of an incoherent array of many particles, scattering collectively in such a way that the phases of the waves scattered by each one individually are washed out. Although this section is devoted to single scattering, it must be kept in mind that multiple scattering is not always negligible and is not just scaled-up single scattering. Multiple scattering gives rise to phenomena inexplicable by single-scattering arguments.[14]

7.3 SCATTERING: AN OVERVIEW

Why is light scattered? No single answer will be satisfactory to everyone, yet because scattering by particles has been amenable to treatment mostly by classical electromagnetic theory, our answer lies within this theory.

Although palpable matter may appear to be continuous and is often electrically neutral, it is composed of discrete electric charges. Light is an oscillating electromagnetic field, which can excite the charges in matter to oscillate. Oscillating charges radiate electromagnetic waves, a fundamental property of such charges with its origins in the finite speed of light. These radiated electromagnetic waves are scattered waves, waves excited or driven by a source external to the scatterer: an incident wave from the source excites secondary waves from the scatterer; the superposition of all these waves is what is observed. If the frequency of the secondary waves is (approximately) that of the source, these waves are said to be *elastically* scattered (the term *coherently* scattered is also used).

Scientific knowledge grows like the accumulation of bric-a-brac in a vast and disorderly closet in a house kept by a sloven. Few are the attempts at ridding the closet of rusty or obsolete gear, at throwing out redundant equipment, at putting things in order. For example, spurious distinctions are still made between reflection, refraction, scattering, interference, and diffraction despite centuries of accumulated knowledge about the nature of light and matter.

Countless students have been told that specular reflection is localized at smooth surfaces, and that photons somehow rebound from them. Yet this interpretation is shaky given that even the smoothest surface attainable is, on the scale of a photon, as wrinkled as the back of a cowboy's neck. Photons conceived of as tiny balls would be scattered in all directions by such a surface, for which it is difficult even to define what is meant by an angle of incidence.

Why do we think of reflection occurring at surfaces rather than because of them whereas we usually do not think of scattering by particles in this way? One reason is that we can see the surfaces of mirrors and ponds. Another is the dead hand of traditional approaches to the laws of specular reflection and refraction.

The empirical approach arrives at these laws as purely geometrical summaries of what is observed—and a discreet silence is maintained about underlying causes. The second approach is by way of continuum electromagnetic theory: reflected and refracted fields satisfy the Maxwell equations. Perhaps because this approach, which also yields the Fresnel formulas, entails the solution of a boundary-value problem, reflected and refracted fields are mistakenly thought to originate from boundaries rather than from all the illuminated matter they enclose. This second approach comes to grips with the nature of light but not of matter, which is treated as continuous. The third approach is to explicitly recognize that reflection and refraction are consequences of scattering by discrete matter. Although this scattering interpretation was developed by Paul Ewald and Carl Wilhelm Oseen early in this century, it has diffused with glacial slowness. According to this interpretation, when the optically smooth interface between optically homogeneous dissimilar media is illuminated, the reflected and refracted waves are superpositions of vast numbers of secondary waves excited by the incident wave.

Thus reflected and refracted light is, at heart, an interference pattern of scattered light. Doyle[15] showed that although the Fresnel equations are obtained from macroscopic electromagnetic theory, they can be dissected to reveal their microscopic underpinnings.

No optics textbook would be complete without sections on interference and diffraction, a distinction without a difference: there is no diffraction without interference. Moreover, diffraction is encumbered with many meanings. Van de Hulst[1] lists several: small deviations from rectilinear propagation; wave motion in the presence of an obstacle; scattering by a flat particle such as a disk; an integral relation for a function satisfying the wave equation. To these may be added scattering near the forward direction and by a periodic array.

Van de Hulst stops short of pointing out that a term with so many meanings has no meaning. Even the etymology of diffraction is of little help: it comes from a Latin root meaning to break.

There is no fundamental distinction between diffraction and scattering. Born and Wolf[16] refer to scattering by a sphere as diffraction by a sphere. I leave it as a penance for the reader to devise an experiment to determine whether a sphere scatters light or diffracts it.

The only meaningful distinction is that between approximate theories. Diffraction theories obtain answers at the expense of obscuring the physics of the interaction of light with matter. For example, an illuminated slit in an opaque screen may be the mathematical source but it is not the physical source of a diffraction pattern. Only the screen can give rise to secondary waves that yield the observed pattern. Yet generations of students have been taught that empty space is the source of the radiation diffracted by a slit. To befuddle them even more, they also have been taught that two slits give an interference pattern whereas one slit gives a diffraction pattern.

If we can construct a mathematical theory (diffraction theory) that enables us to avoid having to explicitly consider the nature of matter, all to the good. But this mathematical theory and its quantitative successes should not blind us to the fact that we are pretending. Sometimes this pretense cannot be maintained, and when this happens a finger is mistakenly pointed at "anomalies," whereas what is truly anomalous is that a theory so devoid of physical content could ever give adequate results.

A distinction must be made between a physical process and the superficially different theories used to describe it. There is no fundamental difference between specular reflection and refraction by films, diffraction by slits, and scattering by particles. All are consequences of light interacting with matter. They differ only in their geometries and the approximate theories that are sufficient for their quantitative description. The different terms used to describe them are encrustations deposited during the slow evolution of our understanding of light and matter.

7.4 SCATTERING BY PARTICLES: BASIC CONCEPTS AND TERMINOLOGY

A single particle can be considered a collection of tiny dipolar antennas driven to radiate (scatter) by an incident oscillating electric field. Scattering by such a coherent array of antennas depends on its size and shape, the observation angle (scattering angle), the response of the individual antennas (composition), and the polarization state and frequency of the incident wave. Geometry, composition, and the properties of the illumination are the determinants of scattering by particles.

Perhaps the only real difference between optics and electrical engineering is that electrical engineers can measure amplitudes and phases of fields whereas the primary observable quantity in optics is the time-averaged Poynting vector (irradiance), an amplitude squared. Several secondary observables are inferred from measurements of this primary observable. Consider, for example, a single particle illuminated by a beam with irradiance I_i. The total power scattered by this particle is W_{sca}. Within the realm of linear optics, the scattered power is proportional to the incident irradiance. This proportionality can be transformed into an equality by means of a factor C_{sca}:

$$W_{sca} = C_{sca} I_i \tag{1}$$

For Eq. (1) to be dimensionally homogeneous C_{sca} must have the dimensions of area, hence C_{sca} has acquired the name *scattering cross section*.

Particles absorb as well as scatter electromagnetic radiation. The rate of absorption W_{abs} by an illuminated particle, like scattered power, is proportional to the incident irradiance:

$$W_{abs} = C_{abs} I_i \tag{2}$$

where C_{abs} is the *absorption cross section*. The sum of these cross sections is the *extinction cross section*:

$$C_{ext} = C_{sca} + C_{abs} \tag{3}$$

Implicit in these definitions of cross sections is the assumption that the irradiance of the incident light is constant over lateral dimensions large compared with the size of the illuminated particle. This condition is necessarily satisfied by a plane wave infinite in lateral extent, which, much more often than not, is the source of illumination in light-scattering theories.

The extinction cross section can be determined (in principle) by measuring transmission by a slab populated by N identical particles per unit volume. Provided that multiple scattering is negligible, the incident and transmitted irradiances I_i and I_t are related by

$$I_t = I_i e^{-NC_{ext}h} \tag{4}$$

where h is the thickness of the slab. Only the sum of scattering and absorption can be obtained from transmission measurements. To separate extinction into its components requires additional measurements.

Equation (4) requires that all particles in the slab be identical. They are different if they differ in size, shape, composition, or orientation (incident beams are different if they differ in wavelength or polarization state). Equation (4) is generalized to a distribution of particles by replacing NC_{ext} with

$$\sum_j N_j C_{ext,j} \tag{5}$$

where j denotes all parameters distinguishing one particle from another.

Instead of cross sections, normalized cross sections called *efficiencies* or *efficiency factors*, Q_{sca}, Q_{abs}, and Q_{ext}, often are presented. The normalizing factor is the particle's area G projected onto a plane perpendicular to the incident beam. No significance should be attached to efficiency used as shorthand for normalized cross section. The normalization factor is arbitrary. It could just as well be the total area of the particle or, to honor Lord Rayleigh, the area of his thumbnail.

Proper efficiencies ought to be less than unity, whereas efficiencies for scattering, absorption, and extinction are not so constrained. Moreover, some particles—soot aggregates, for example—do not have well-defined cross-sectional areas. Such particles have cross sections for scattering and absorption but the corresponding efficiencies are nebulous.

If any quantity deserves the designation efficiency it is the cross section per particle volume v. Equation (4) can be rewritten to display this:

$$I_t = I_i e^{-fh(C_{ext}/v)} \tag{6}$$

where $f = Nv$ is the total volume of particles per unit slab volume. For a given particle loading, specified by fh (volume of particles per unit slab area), transmission is a minimum when C_{ext}/v is a maximum.

Each way of displaying extinction (or scattering) versus particle size or wavelength of the incident beam tells a different story. This is illustrated in Fig. 1, which shows the scattering cross section, scattering efficiency, and scattering cross section per unit volume of a silicate sphere in air illuminated by visible light. These curves were obtained with van de Hulst's simple *anomalous diffraction* approximation[1] (all that is anomalous about it is that it gives such good results). Each curve yields a different answer to the question, what size particle is most efficient at scattering light? And comparison of Figs. 1*c* and 2 shows that scattering by a particle and specular reflection are similar.

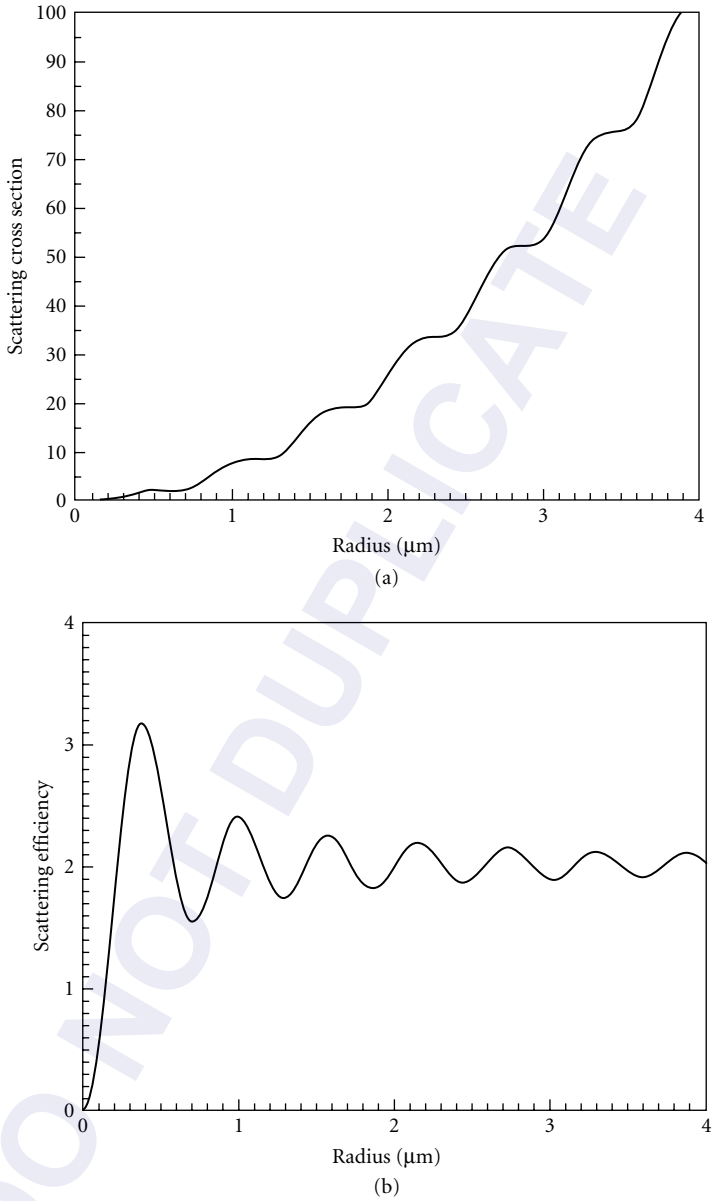

FIGURE 1 Scattering of visible light by a silicate sphere calculated using the anomalous diffraction approximation: (*a*) scattering cross section; (*b*) scattering efficiency (cross section normalized by projected area); and (*c*) volumetric scattering cross section (cross section per unit particle volume).

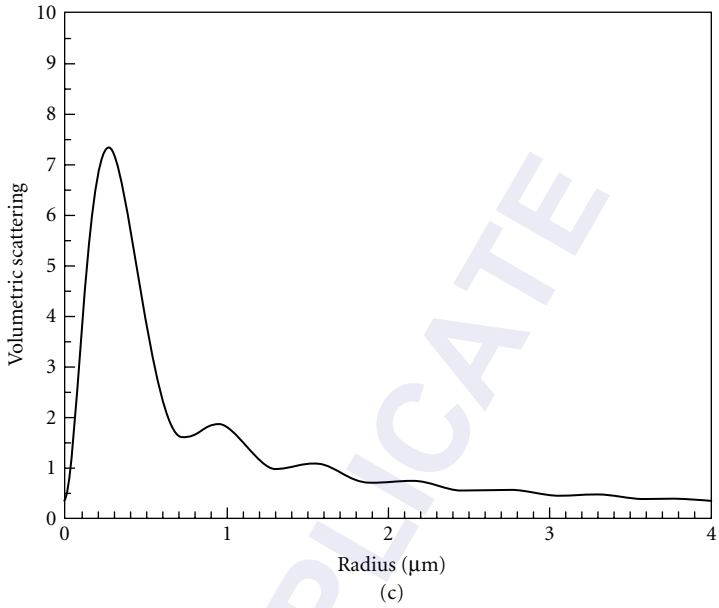

FIGURE 1 (*Continued*)

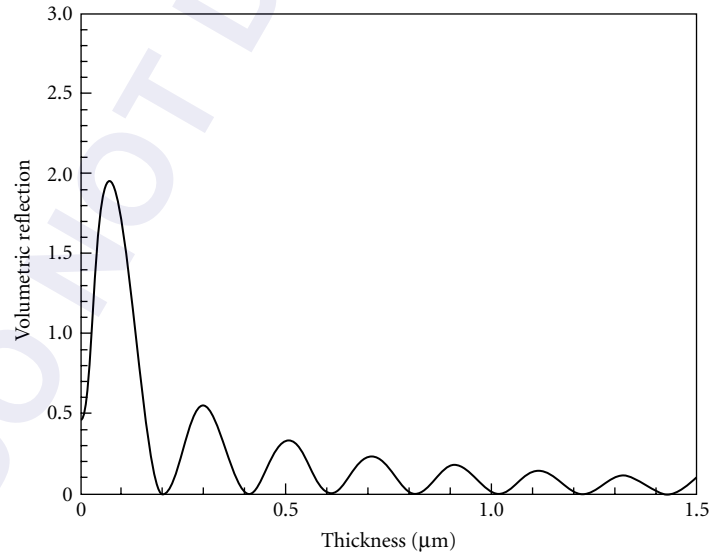

FIGURE 2 Reflected power per unit incident irradiance and unit volume of a silicate slab normally illuminated by visible light (reflectance divided by slab thickness).

At sufficiently large distances r from a scatterer of bounded extent, the scattered field $\mathbf{E}_s$ decreases inversely with distance and is transverse:

$$\mathbf{E}_s \sim \frac{e^{ik(r-z)}}{-ikr}\mathbf{X}E \qquad (kr \gg 1) \tag{7}$$

where $k = 2\pi/\lambda$ is the wave number of the incident plane harmonic wave $\mathbf{E}_i = \mathbf{e}_x E$, $E = E_0 \exp(ikz)$ propagating along the z axis. The *vector-scattering amplitude* is written as $\mathbf{X}$ as a reminder that the incident wave is linearly polarized along the x axis. Here and elsewhere the time-dependent factor $\exp(-i\omega t)$ is omitted.

The extinction cross section is related in a simple way to the scattering amplitude;

$$C_{\text{ext}} = \frac{4\pi}{k^2}\text{Re}\{(\mathbf{X}\cdot\mathbf{e}_x)_{\theta=0}\} \tag{8}$$

This remarkable result, often called the *optical theorem*, implies that plane-wave extinction depends only on scattering in the forward direction $\theta = 0$, which seems to contradict the interpretation of extinction as the sum of scattering in *all* directions and absorption. Yet extinction has two interpretations, the second manifest in the optical theorem: extinction is interference between incident and forward-scattered waves.

The scattering cross section is also obtained from the vector-scattering amplitude by an integration over all directions:

$$C_{\text{sca}} = \int_{4\pi} \frac{|\mathbf{X}|^2}{k^2} d\Omega \tag{9}$$

At wavelengths far from strong absorption bands, the scattering cross section of a particle small compared with the wavelength satisfies (approximately)

$$C_{\text{sca}} \propto \frac{v^2}{\lambda^4} \qquad (ka \to 0) \tag{10}$$

where a is a characteristic linear dimension of the particle. This result was first obtained by Lord Rayleigh in 1871 by dimensional analysis (his paper is included in Ref. 8).

The extinction cross section of a particle large compared with the wavelength approaches the limit

$$C_{\text{ext}} \to 2G \qquad (ka \to \infty) \tag{11}$$

The fact that C_{ext} approaches *twice* G instead of G is sometimes called the *extinction paradox*. This alleged paradox arises from the expectation that geometrical optics should become a better approximation as a particle becomes larger. But all particles have edges because of which extinction by them always has a component unaccounted for by geometrical optics. This additional component, however, may not be observed because it is associated with light scattered very near the forward direction and because all detectors have finite acceptance angles. Measured extinction is theoretical extinction reduced by the scattered light collected by the detector.

No particle scatters light equally in all directions; isotropic scatterers exist only in the dreams of inept theorists. The angular dependence of scattering can be specified by the *differential scattering cross section*, written symbolically as $dC_{\text{sca}}/d\Omega$ as a reminder that the *total* scattering cross section is obtained from it by integrating over all directions:

$$C_{\text{sca}} = \int_{4\pi} \frac{dC_{\text{sca}}}{d\Omega} d\Omega \tag{12}$$

The normalized differential scattering cross section p

$$p = \frac{1}{C_{\text{sca}}}\frac{dC_{\text{sca}}}{d\Omega} \tag{13}$$

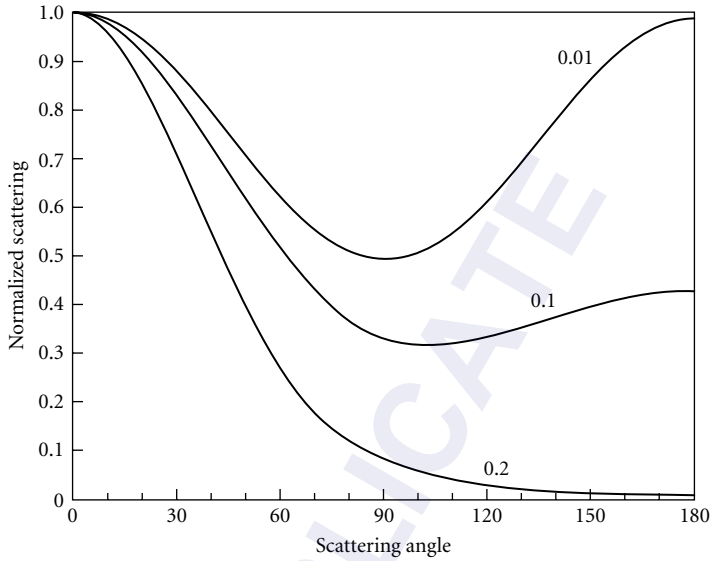

FIGURE 3 Scattering of unpolarized visible light by spheres of radii 0.01, 0.1, and 0.2 μm calculated according to the Rayleigh-Gans approximation.

is sometimes called the *phase function*. This coinage of astronomers (after the phases of astronomical bodies) confuses those who are perplexed by phase attached to a quantity from which phase in the usual optical sense is absent. To add to the confusion, the phase function is sometimes normalized to 4π instead of to unity.

A salient characteristic of scattering by particles is strong forward-backward asymmetry. Small metallic particles at far infrared wavelengths provide one of the few examples in which backscattering is larger than forward scattering. Except for very small particles, scattering is peaked in the forward direction; the larger the particle, the sharper the peak. Examples are given in Fig. 3, which shows differential scattering cross sections for unpolarized visible light illuminating spheres of various radii. These curves were obtained using the Rayleigh-Gans approximation,[1,3,5] valid for particles optically similar to the surrounding medium. Forward scattering is much greater than backscattering even for a sphere as small as 0.2 μm.

A simple explanation of forward-backward asymmetry follows from the model of a scatterer as an array of N antennas. If we ignore mutual excitation (the antennas are excited solely by the external source), the total scattered field is the sum of N fields, the phases of which, in general, are different except in the forward direction. Scattering by noninteracting scatterers in this direction—and only in this direction—is in-phase regardless of their separation and the wavelength of the source. Thus as N increases, the scattered irradiance increases more rapidly in the forward direction than in any other direction.

Particles are miniature polarizers and retarders: they scatter differently the orthogonal components into which incident fields can be resolved. Similarly, an optically smooth surface can be both a polarizer and retarder. Just as polarization changes upon reflection are described by decomposing electric fields into components parallel and perpendicular to the plane of incidence, it is convenient to introduce a *scattering plane,* defined by the directions of the incident and scattered waves, for describing scattering by particles.

The incident plane wave is transverse, as is the scattered field at large distances. Thus these fields can be decomposed into two orthogonal components, one parallel, the other perpendicular to the scattering plane. The orthonormal basis vectors are denoted by $\mathbf{e}_{\parallel}$ and $\mathbf{e}_{\perp}$ and form a right-handed

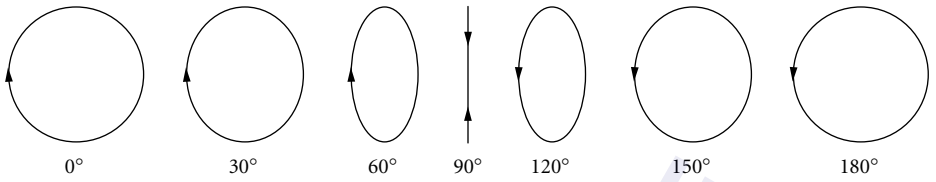

FIGURE 4 Vibration ellipses at various scattering angles for light scattered by a sphere much smaller than the wavelength of the incident right-circularly polarized light.

triad with the direction of propagation $\mathbf{e}_p$ (of either the incident or scattered waves): $\mathbf{e}_\perp \mathbf{x} \mathbf{e}_\parallel = \mathbf{e}_p$. Incident and scattered fields are specified relative to different basis vectors. With this decomposition the relation between fields can be written[1,5]

$$\begin{pmatrix} E_{\parallel s} \\ E_{\perp s} \end{pmatrix} = \frac{\mathbf{e}^{ik(r-z)}}{-ikr} \begin{pmatrix} S_2 & S_3 \\ S_4 & S_1 \end{pmatrix} \begin{pmatrix} E_{\parallel i} \\ E_{\perp i} \end{pmatrix} \tag{14}$$

where i and s denote incident and scattered, respectively. The elements of this *amplitude scattering matrix* (or Jones matrix) are complex-valued functions of the scattering direction.

If a single particle is illuminated by completely polarized light, the scattered light is also completely polarized but possibly differently from the incident light, and differently in different directions. An example is given in Fig. 4, which shows vibration ellipses of light scattered by a small sphere. The polarization state of the scattered light varies from right-circular (the polarization state of the incident light) in the forward direction, to linear (perpendicular to the scattering plane) at 90°, to left-circular in the backward direction.

Just as unpolarized light can become partially polarized upon specular reflection, scattering of unpolarized light by particles can yield partially polarized light varying in degree and state of polarization in different directions. Unlike specular reflection, however, an ensemble of particles can transform completely polarized incident light into partially polarized scattered light if all the particles are not identical.

Transformations of polarized light upon scattering by particles are described most conveniently by the *scattering matrix* (or Mueller matrix) relating scattered to incident Stokes parameters:[1,5]

$$\begin{pmatrix} I_s \\ Q_s \\ U_s \\ V_s \end{pmatrix} = \frac{1}{k^2 r^2} \begin{pmatrix} S_{11} & S_{12} & S_{13} & S_{14} \\ S_{21} & S_{22} & S_{23} & S_{24} \\ S_{31} & S_{32} & S_{33} & S_{34} \\ S_{41} & S_{42} & S_{43} & S_{44} \end{pmatrix} \begin{pmatrix} I_i \\ Q_i \\ U_i \\ V_i \end{pmatrix} \tag{15}$$

The scattering matrix elements S_{ij} for a single particle are functions of the amplitude-scattering matrix elements. Only seven of these elements are independent, corresponding to the four amplitudes and three phase differences of the S_j.

The scattering matrix for an ensemble of particles is the sum of matrices for each of them provided they are separated by sufficiently large random distances. Although all 16 matrix elements for an ensemble can be nonzero and different, symmetry reduces the number of matrix elements. For example, the scattering matrix for a rotationally and mirror symmetric ensemble has the form

$$\begin{pmatrix} S_{11} & S_{12} & 0 & 0 \\ S_{12} & S_{22} & 0 & 0 \\ 0 & 0 & S_{33} & S_{34} \\ 0 & 0 & -S_{34} & S_{44} \end{pmatrix} \tag{16}$$

7.5 SCATTERING BY AN ISOTROPIC, HOMOGENEOUS SPHERE: THE ARCHETYPE

An isotropic, homogeneous sphere is the simplest finite particle, the theory of scattering to which is attached the name of Gustav Mie.[17] So firm is this attachment that in defiance of logic and history every particle under the sun has been dubbed a "Mie scatterer," and Mie scattering has been promoted from a particular theory of limited applicability to the unearned rank of general scattering process.

Mie was not the first to solve the problem of scattering by an arbitrary sphere.[18] It would be more correct to say that he was the last. He gave his solution in recognizably modern notation and also addressed a real problem: the colors of colloidal gold. For these reasons, his name is attached to the sphere-scattering problem even though he had illustrious predecessors, most notably Lorenz.[19] This is an example in which eponymous recognition has gone to the last discoverer rather than to the first.

Mie scattering is not a physical process; Mie theory is one theory among many. It isn't even exact because it is based on continuum electromagnetic theory and on illumination by a plane wave infinite in lateral extent.

Scattering by a sphere can be determined using various approximations and methods bearing little resemblance to Mie theory: Fraunhofer theory, geometrical optics, anomalous diffraction, coupled-dipole method, *T*-matrix method, etc. Thus, is a sphere a Mie scatterer or an anomalous diffraction scatterer or a coupled-dipole scatterer? The possibilities are endless. When a physical process can be described by several different theories, it is inadvisable to attach the name of one of them to it.

There is no distinct boundary between so-called Mie and Rayleigh scatterers. Mie theory includes Rayleigh theory, which is a limiting theory strictly applicable only as the size of the particle shrinks to zero. Even for spheres uncritically labeled "Rayleigh spheres," there are always deviations between the Rayleigh and Mie theories. By hobbling one's thinking with a supposed sharp boundary between Rayleigh and Mie scattering, one risks throwing some interesting physics out the window. Whether a particle is a Mie or Rayleigh scatterer is not absolute. A particle may be graduated from Rayleigh to Mie status merely by a change of wavelength of the illumination.

One often encounters statements about Mie scattering by cylinders, spheroids, and other nonspherical particles. Judged historically, these statements are nonsense: Mie never considered any particles other than homogeneous spheres.

Logic would seem to demand that if a particle is a Mie scatterer, then Mie theory can be applied to scattering by it. This fallacious notion has caused and will continue to cause mischief, and is probably the best reason for ceasing to refer to Mie particles or Mie scatterers. Using Mie theory for particles other than spheres is risky, especially for computing scattering toward the backward direction.

More often than not, a better term than Mie or Rayleigh scattering is available. If the scatterers are molecules, molecular scattering is better than Rayleigh scattering (itself an imprecise term):[20] the former term refers to an agent, the latter to a theory. Mie scatterer is just a needlessly aristocratic name for a humble sphere. Wherever Mie scatterer is replaced with sphere, the result is clearer. If qualifications are needed, one can add small or large compared with the wavelength or comparable to the wavelength.

Briefly, the solution to the problem of scattering by an arbitrary homogeneous sphere illuminated by a plane wave can be obtained by expanding the incident, scattered, and internal fields in a series of vector-spherical harmonics. The coefficients of these expansion functions are chosen so that the tangential components of the electric and magnetic fields are continuous across the surface of the sphere. Thus this scattering problem is formally identical to reflection and refraction because of interfaces, although the sphere problem is more complicated because the scattered and internal fields are not plane waves.

Observable quantities are expressed in terms of the coefficients a_n and b_n in the expansions of the scattered fields. For example, the cross sections are infinite series:

$$C_{\text{ext}} = \frac{2\pi}{k^2}\sum_{n=1}^{\infty}(2n+1)\,\text{Re}\{a_n + b_n\} \tag{17}$$

$$C_{\text{sca}} = \frac{2\pi}{k^2}\sum_{n=1}^{\infty}(2n+1)(|a_n|^2 + |b_n|^2) \tag{18}$$

If the permeability of the sphere and its surroundings are the same, the scattering coefficients can be written

$$a_n = \frac{[D_n(mx)/m + n/x]\psi_n(x) - \psi_{n-1}(x)}{[D_n(mx)/m + n/x]\xi_n(x) - \xi_{n-1}(x)} \tag{19}$$

$$b_n = \frac{[mD_n(mx) + n/x]\psi_n(x) - \psi_{n-1}(x)}{[mD_n(mx) + n/x]\xi_n(x) - \xi_{n-1}(x)} \tag{20}$$

ψ_n and ξ_n are Riccati-Bessel functions and the logarithmic derivative

$$D_n(\rho) = \frac{d}{d\rho} \ln \psi_n(\rho) \tag{21}$$

The *size parameter x* is *ka,* where *a* is the radius of the sphere and *k* is the wavenumber of the incident light in the surrounding medium, and *m* is the complex refractive index of the sphere relative to that of this (nonabsorbing) medium. Equations (19) and (20) are one of the many ways of writing the scattering coefficients, some of which are more suited to computations than others.

During the Great Depression mathematicians were put to work computing tables of trigonometric and other functions. The results of their labors now gather dust in libraries. Today, these tables could be generated more accurately in minutes on a pocket calculator. A similar fate has befallen Mie calculations. Before fast computers were inexpensive, tables of scattering functions for limited ranges of size parameter and refractive index were published. Today, these tables could be generated in minutes on a personal computer. The moral is to give algorithms rather than only tables of results, which are mostly useless except as checks for someone developing and testing algorithms.

These days it is not necessary to reinvent the sphere: documented Mie programs are readily available. The first widely circulated program was published as an IBM report by Dave in 1968, although it no longer seems to be available. A Mie program is given in Ref. 5. Reference 6 includes a diskette containing scattering programs for spheres (and other particles). Wiscombe[21,22] suggested techniques for increasing the speed of computations, as did Lentz,[23] whose method makes use of continued fractions. Wang and van de Hulst[24] recently compared various scattering programs.

The primary tasks in Mie calculations are computing the functions in Eqs. (19) and (20) and summing series like Eqs. (17) and (18). Bessel functions are computed by recurrence. The logarithmic derivative, the argument of which can be complex, is usually computed by downward recurrence. $\psi_n(x)$ and $\xi_n(x)$ can be computed by upward recurrence if one does not generate more orders than are needed for convergence, approximately the size parameter *x*. When a program with no logical errors falls ill, it often can be cured by promoting variables from single to double precision.

Cross sections versus radius or wavelength convey physical information; efficiencies versus size parameter convey mathematical information. The size parameter is a variable with less physical content than its components, the whole being less than the sum of its parts. Moreover, cross section versus size parameter (or its inverse) is not equivalent to cross section versus wavelength. Except in the fantasy world of naive modelers, refractive indices vary with wavelength, and the Mie coefficients depend on *x* and *m*, wavelength being explicit in the first and implicit in the second.

The complex refractive index is written dozens of different ways, one of which is $n + ik$ (despite the risk of confusing the imaginary part with the wavenumber). The quantities *n* and *k* are called *optical constants*. But just as the Lord Privy Seal is neither a lord nor a privy nor a seal, optical constants are neither optical nor constant.

Few quantities in optics are more shrouded in myth and misconception than the complex refractive index. The real part for any medium is often defined as the ratio of the velocity of light *c* in free space to the phase velocity in the medium. This definition, together with notions that nothing can go faster than *c*, has engendered the widespread misconception that *n* must be greater than unity. But *n* can take on any value, even zero. The phase velocity is not the velocity of any palpable object or of any signal, hence is not subject to speed limits enforced by the special relativity police. The least physically relevant property of a refractive index is that it is a ratio of phase velocities. A refractive

index is a response function (or better, is simply related to response functions such as permittivity and permeability): it is a macroscopic manifestation of the microscopic response of matter to a periodic driving force.

When we turn to the imaginary part of the refractive index, we enter a ballroom in which common sense is checked at the door. It has been asserted countless times that an imaginary index of, say, 0.01 corresponds to a weakly absorbing medium (at visible and near-visible wavelengths). Such assertions are best exploded by expressing k in a more physically transparent way. The absorption coefficient α is

$$\alpha = \frac{4\pi k}{\lambda} \tag{22}$$

The inverse of α is the *e-folding distance* (or skin depth), the distance over which the irradiance of light propagating in an unbounded medium decreases by a factor of e. At visible wavelengths, the e-folding distance corresponding to $k = 0.01$ is about 5 μm. A thin sliver of such an allegedly weakly absorbing material would be opaque.

When can a particle (or any object) be said to be strongly absorbing? A necessary condition is that $\alpha d \gg 1$, where d is a characteristic linear dimension of the object. But this condition is not sufficient. As k increases, absorption increases—up to a point. As k approaches infinity, the absorption cross section of a particle or the absorptance of a film approaches zero.

One of the most vexing problems in scattering calculations is finding optical constants dispersed throughout dozens of journals. Palik[25] edited a compilation of optical constants for several solids. The optical constants of liquid water over a broad range were compiled by Hale and Querry;[26] Warren[27] published a similar compilation for ice. For other materials, you are on your own. Good hunting!

For small x and $|m|x$, the extinction and scattering efficiencies of a sphere are approximately

$$Q_{\text{ext}} = 4x \operatorname{Im}\left\{\frac{m^2-1}{m^2+2}\right\} \tag{23}$$

$$Q_{\text{sca}} = \frac{8}{3}x^4\left|\frac{m^2-1}{m^2+2}\right|^2 \tag{24}$$

These equations are the source of a nameless paradox, which is disinterred from time to time, a corpse never allowed eternal peace. If the sphere is nonabsorbing (m real), Eq. (23) yields a vanishing extinction cross section, whereas Eq. (24) yields a nonvanishing scattering cross section. Yet extinction never can be less than scattering. But note that Eq. (23) is only the first term in the expansion of Q_{ext} in powers of x. The first nonvanishing term in the expansion of Q_{sca} is of order x^4. To be consistent, Q_{ext} and Q_{sca} must be expanded to the same order in x. When this is done, the paradox vanishes.

The amplitude-scattering matrix elements for a sphere are

$$S_1 = \sum_n \frac{2n+1}{n(n+1)}(a_n\pi_n + b_n\tau_n) \tag{25}$$

$$S_2 = \sum_n \frac{2n+1}{n(n+1)}(a_n\tau_n + b_n\pi_n) \tag{26}$$

where the angle-dependent functions are

$$\pi_n = \frac{P_n^1}{\sin\theta} \qquad \tau_n = \frac{dP_n^1}{d\theta} \tag{27}$$

and P_n^1 are the associated Legendre functions of the first kind. The off-diagonal elements of the amplitude-scattering matrix vanish, because of which the scattering matrix is block-diagonal

and $S_{12} = S_{21}$, $S_{43} = -S_{34}$, $S_{44} = S_{33}$. Thus, when the incident light is polarized parallel (perpendicular) to the scattering plane, so is the scattered light, a consequence of the sphere's symmetry.

7.6 SCATTERING BY REGULAR PARTICLES

The field scattered by any spherically symmetric particle has the same form as that scattered by a homogeneous, isotropic sphere; only the scattering coefficients are different. One such particle is a uniformly coated sphere. Scattering by a sphere with a single layer was first treated by Aden and Kerker.[28] Extending their analysis to multilayered spheres is straightforward.[29]

New computational problems arise in going from uncoated to coated spheres. The scattering coefficients for both contain spherical Bessel functions, which are bounded only if their arguments are real (no absorption). Thus, for strongly absorbing particles, the arguments of Bessel functions can be so large that their values exceed computational bounds. This does not occur for uncoated spheres because the only quantity in the scattering coefficients with complex argument is the logarithmic derivative, a ratio of Bessel functions computed as an entity instead of by combining numerator and denominator, each of which separately can exceed computational bounds. It is not obvious how to write the scattering coefficients for a coated sphere so that only ratios of possibly large quantities are computed explicitly. For this reason the applicability of the coated-sphere program in Ref. 5 is limited. Toon and Ackerman,[30] however, cast the coated-sphere coefficients in such a way that this limitation seems to have been surmounted.

Bessel functions of large complex argument are not the only trap for the unwary. A coated sphere is two spheres. The size parameter for the outer sphere determines the number of terms required for convergence of series. If the inner sphere is much smaller than the outer, the various Bessel functions appropriate to the inner sphere are computed for indices much greater than needed. More indices are not always better. Beyond a certain number, round-off error can accumulate to yield terms that should make ever smaller contributions to sums but may not.

Scattering by spheres and by infinitely long circular cylinders illuminated normally to their axes are in some ways similar. Spherical Bessel functions in the sphere-scattering coefficients correspond to cylindrical Bessel functions in the cylinder-scattering coefficients. Unlike a sphere, however, an infinitely long cylinder cannot be enclosed in a finite volume. As a consequence, the field scattered by such a cylinder decreases inversely as the square root of distance r instead of inversely as r (for sufficiently large r).

Infinite particles may be mathematically tractable but they are physically unrealizable. In particular, cross sections for infinite cylinders are infinite. But cross sections per unit length of infinite cylinders are finite. Such cross sections may be applied to a finite cylindrical particle by multiplying its length by the cross section per unit length of the corresponding infinite particle. If the aspect ratio (length/diameter) of the finite particle is sufficiently large, what are vaguely called "end effects" may be negligible. Because no exact theory for a finite cylinder exists, the aspect ratio at which differences between finite and infinite cylinders become negligible is not known with certainty, although the value 10 is bruited about. Nevertheless, there always will be differences between scattering by finite and infinite particles, which may or may not be of concern depending on the application.

A physical difference between scattering by spheres and by cylinders is that cross sections for cylinders depend on the polarization state of the incident plane wave. But normally incident light illuminating an infinite cylinder and polarized perpendicular (parallel) to the plane defined by the incident wave and the cylinder axis excites only scattered light polarized perpendicular (parallel) to the plane defined by the scattered wave and the cylinder axis. Obliquely incident linearly polarized light can, however, excite scattered light having both copolarized and cross-polarized components.

Obliquely illuminated uncoated cylinders pose no special computational problems. Coated cylinders, however, pose the same kinds of problems as coated spheres and are even more difficult to solve. Toon and Ackerman's[30] algorithm for coated spheres is based on the fact that spherical Bessel functions can be expressed in a finite number of terms. Because cylindrical Bessel functions cannot

be so expressed, this algorithm cannot be extended to coated cylinders, for which Bessel functions must be computed separately rather than as ratios and can have values beyond computational bounds. Even if such bounds are not exceeded, problems still can arise.

Although Barabás[31] discussed in detail scattering by coated cylinders, Salzman and Bohren[32] found that his computational scheme is unsuitable when absorption is large. They attempted, with only partial success, to write programs for *arbitrary*-coated cylinders. Care must be taken in computing Bessel functions. The often-used Miller algorithm can be inadequate for large, complex arguments.

The simplest nonspherical, finite particle is the spheroid, prolate, or oblate. Because the scalar wave equation is separable in spheroidal coordinates, scattering by spheroids can be solved in the same way as for spheres and cylinders. The expansion functions are based on spheroidal rather than spherical or cylindrical wave functions. Asano and Yamamoto[33] were the first to solve in this way the problem of scattering by an arbitrary spheroid. Although Asano[34] subsequently published an extensive set of computations based on this solution, it has not seen widespread use, possibly because of the intractability and exoticness of spheroidal functions.

Computational experience with spheroids and even simpler particles such as spheres and cylinders leads to the inescapable conclusion that hidden barriers lie between a mathematical solution to a scattering problem and an algorithm for reliably and quickly extracting numbers from it.

7.7 COMPUTATIONAL METHODS FOR NONSPHERICAL PARTICLES

The widespread notion that randomly oriented nonspherical particles are somehow equivalent to spheres is symptomatic of a failure to distinguish between the symmetry of an ensemble and that of its members. Considerable effort has been expended in seeking prescriptions for equivalent spheres. This search resembles that for the Holy Grail—and has been as fruitless.

From extensive studies of scattering by nonspherical particles, Mugnai and Wiscombe[35] concluded that "after examining hundreds of nonspherical results and observing that they all cluster relatively close together, relatively far from the equivolume spheres (except at forward angles), we have come to regard nonspherical particles as normal, and spheres as the most unrepresentative shape possible—almost a singularity." This serves as a warning against using Mie theory for particles of all shapes and as a spur to finding methods more faithful to reality. We now turn to some of these methods. Keep in mind that no matter how different they may appear on the surface, they are all linked by the underlying Maxwell equations.

The *T-matrix method* is based on an integral formulation of scattering by an arbitrary particle. It was developed by Waterman, first for a perfect conductor,[36] then for a particle with less restricted properties.[37] It subsequently was applied to scattering problems under the name *extended boundary condition method* (EBCM).[38] Criticism of the *T*-matrix method was rebutted by Varadan et al.,[39] who cite dozens of papers on this method applied to electromagnetic scattering. Another source of papers and references is the collection edited by Varadan and Varadan.[40] Reference 6 is accompanied by a diskette containing *T*-matrix programs.

Linearity of the field equations and boundary conditions implies that the coefficients in the spherical harmonic expansion of the field scattered by any particle are linearly related to those of the incident field. The linear transformation connecting these two sets of coefficients is called the *T* (for transition) matrix.

The *T*-matrix elements are obtained by numerical integration. Computational difficulties arise for particles with high absorption or large aspect ratios. These limitations of the original *T*-matrix method have been surmounted somewhat by Iskander et al.,[41] whose extension is dubbed the iterative extended boundary condition method.

Although the *T*-matrix method is not restricted to axisymmetric particles, it almost exclusively has been applied to spheroids and particles defined by Chebyshev polynomials.[35,42,43]

Despite its virtues, the *T*-matrix method is not readily grasped in one sitting. Another method, variously called the Purcell-Pennypacker,[44] coupled-dipole,[45] digitized Green's function[46] method and

discrete dipole approximation,[47] is mathematically much simpler—the most complicated function entering into it is the exponential—and physically transparent. Although originally derived by heuristic arguments, the coupled-dipole method was put on firmer analytical foundations by Lakhtakia.[48]

In this method, a particle is approximated by a lattice of N dipoles small compared with the wavelength but still large enough to contain many molecules. The dipoles often are, but need not be, identical and isotropic. Each dipole is excited by the incident field and by the fields of all the other dipoles. Thus the field components at each site satisfy a set of $3N$ linear equations. These components can be calculated by iteration[44,49] or by inverting the $3N \times 3N$ coefficient matrix.[45] The coefficient matrix for only one particle orientation need be inverted. This inverse matrix then can be used to calculate scattering for other orientations.[50] A disadvantage of matrix inversion is that the number of dipoles is limited by computer storage.

Arrays of coupled dipoles were considered long before Purcell and Pennypacker entered the scene. More than half a century ago Kirkwood[51] treated a dielectric as an array of molecules, the dipole moment of each of which is determined by the external field and by the fields of all the other molecules. What Purcell and Pennypacker did was to apply the coupled-dipole method to absorption and scattering by optically homogeneous particles. They bridged the gap between discrete arrays and continuous media with the Clausius-Mosotti theory. Because this theory, like every effective-medium theory, is not exact, critics of their method have pronounced it guilty by association. But the Clausius-Mosotti theory is merely the effective-medium theory that Purcell and Pennypacker happened to use. Whatever flaws their method may have, one of them is not that it is forever chained to the ghosts of Clausius and Mosotti. Alleged violations of the optical theorem are easily remedied by using the exact expression for the polarizability of a finite sphere,[52] which in no way changes the structure of the method.

Draine[47] applied this method (under the label *discrete dipole approximation*) to extinction by interstellar grains, obtaining the field components with the conjugate gradient method. An outgrowth of his paper is that by Flatau et al.,[53] who considered scattering by rectangular particles. Goedecke and O'Brien[46] baptized their version of the digitized Green's function method and applied it to scattering of microwave radiation by snowflakes.[54] Varadan et al.[55] applied the method to scattering by particles with anisotropic optical constants. It also has been applied to scattering by helices,[56] by a cylinder on a reflecting surface,[57] and extended to intrinsically optically active particles.[58]

Although Yung's analysis[59] of a large (15,600) array of dipoles representing a sphere suggests that there are no intrinsic limitations to the coupled-dipole method, it is plagued with practical limitations, most notably its inability to treat particles (especially compact ones or ones with large complex refractive indices) much larger than the wavelength of the illumination. Chiapetta,[60] then Singham and Bohren,[61] reformulated the coupled-dipole method, expressing the total field at each dipole as the sum of the incident field and the fields scattered once, twice, and so on by all the other dipoles. Although this formulation is appealing because each term in the scattering-order series has a simple physical interpretation, the series can diverge. The greater the refractive index, the smaller the particle for which the series diverges. For a particle of given volume, fewer terms are needed for convergence the more the particle departs from sphericity. The greater the average separation between dipoles, the weaker the average interaction.

Except for improvements and refinements[52,62,63] that increase accuracy and speed but do not remove barriers imposed by particle size and composition, the coupled-dipole method has not changed much since it first was used by Purcell and Pennypacker. It is not, of course, limited to optically homogeneous particles. It can be applied readily to aggregates of small particles. Indeed, it is best suited to aggregates with low fractal dimension. Berry and Percival[64] considered scattering by fractal aggregates using what they call the *mean-field approximation*, which is essentially the Rayleigh-Gans approximation, in turn a form of the scattering-order formulation of the coupled-dipole method in which the dipoles are excited only by the incident field.

The arbitrary border separating electrical engineering from optics is never more obvious than when it comes to methods for computing scattering. The engineers have theirs, the optical scientists have theirs, and rarely do the twain meet. In the hope of promoting smuggling, even illegal immigration, I must at least mention two methods that fall almost exclusively in the domain of electrical engineering: the method of moments and the finite-difference time-domain technique (FDTD).

Anyone interested in the method of moments must begin with Harrington's book,[65] a focal point from which paths fan out in all directions.

As its name implies, the FDTD technique is applied to what electrical engineers call the *time domain* (as opposed to the *frequency domain*, which most optical scientists inhabit even though they may not know it) and is explicitly labeled a finite-difference method (all methods for particles other than those of simple shape entail discretization in one form or another). Papers by Yee,[66] Holland et al.,[67] Mur,[68] Luebbers et al.,[69] and references cited in them will get you started on the FDTD technique.

When pondering the welter of species and subspecies of methods keep in mind that the differences among them and their ranges of validity are probably smaller than their adherents think or are willing to admit. There is no method that will happily compute scattering of arbitrary waves by particles of arbitrary size and composition in a finite amount of time. Moreover, each method, whatever its merits and demerits, often requires a tedious climb up a learning curve.

SURFACE SCATTERING

Eugene L. Church and Peter Z. Takacs

Instrumentation Division
Brookhaven National Laboratory
Upton, New York

8.1 GLOSSARY OF PRINCIPAL SYMBOLS

A_o	illuminated area
A, B, C	model parameters
BRDF	bidirectional reflectance distribution function
$C(\tau)$	autocovariance function or ACF
$D(\tau)$	structure function
f_{xy}, f_x	spatial frequencies
g, g'	Strehl parameter or Rayleigh index
J_n	ordinary Bessel function
K_n	modified Bessel function
L_o	illuminated length
L_x, L_y	lengths of illuminated area
N	fractal index
P	incident or scattered power
R_α, r_α	Fresnel reflection coefficients
RCS	radar cross-section
S	two-sided power spectral density (PSD)
S^*	one-sided profile PSD
T	topothesy
$Z(x, y)$	topographic surface roughness
$Z(x)$	surface profile
1D, 2D	dimensionalities
$\langle \ldots \rangle$	ensemble average
α, β	linear-polarization parameters
ρ	correlation length
σ	root-mean-square roughness
τ	lag variable

8.2 INTRODUCTION

Imperfect surface finish degrades optical performance. The connection between the two is electromagnetic scattering theory, which is the subject of this chapter. Because of space limitations we limit our attention to the elemental case of simple highly reflective surfaces such as those used in x-ray imaging and other high-performance applications.

This chapter is divided into two parts. The first part discusses elementary physical optics and first-order perturbation theory of the scattering of electromagnetic waves by a randomly rough surface, ending with Eq. (35).

The second part discusses the interpretation of scattering measurements in terms of surface finish models, and the related question of surface-finish specification. Because many manufactured surfaces show an inverse-power-law behavior, we have concentrated on models that show this behavior. Two types of surfaces are considered throughout—1D or grating-like surfaces, and isotropic 2D surfaces.

The field of topographic surface scattering has been highly developed in radio physics, optics, and instrumentation over the past 50 years. There is a staggering volume of literature in each area, expressed in a bewildering variety of notations, which are summarized in Sec. 8.3. Important in-depth texts in these fields are the early reviews of Beckmann and Spizzichino[1] and the *Radar Cross-Section Handbook*[2], the more recent work of Ishimaru[3], Fung[4], the textbooks of Nieto-Vesperinas[5] and Voronovich[6], and most recently, the publications of Maradudin et al.[7].

Scattering measurements are discussed in the works of Stover[8] and Germer[9], and profile measurements using various optical techniques, including the Long Trace Profiler (LTP) are considered by Takacs et al.[10]

A number of important subjects have been omitted in the present review. These include instrumentation, statistical estimation, the effects of detrending, figure error, standards, and multilayer surfaces. Discussions of some of these and related subjects can be found in Chap. 11, "Analog Optical and Image Processing," in this volume and Chap. 4, "Imaging through Atmospheric Turbulence," Chap. 44, "Reflective Optics," and Chap. 46, "X-Ray Mirror Metrology," in Vol. V.

8.3 NOTATION

The scattering geometry is sketched in Fig. 1. Note that the angles of incidence, θ_i and θ_f, are always positive, and that the azimuthal angle φ_f is understood to be $\varphi_f - \varphi_i$ with $\varphi_i = 0$. Specular reflection occurs at $\theta_f = \theta_i$ and $\varphi_f = 0$, and backscatter at $\theta_f = \theta_i$ and $\varphi_f = \pi$.

The initial and final wavenumbers are

$$\mathbf{k}_i = \frac{2\pi}{\lambda}\begin{pmatrix} +\sin(\theta_i) \\ 0 \\ -\cos(\theta_i) \end{pmatrix} \quad \mathbf{k}_f = \frac{2\pi}{\lambda}\begin{pmatrix} +\sin(\theta_f)\cos(\varphi_f) \\ +\sin(\theta_f)\sin(\varphi_f) \\ +\cos(\theta_i) \end{pmatrix} \tag{1}$$

and the spatial frequency vectors are

$$\mathbf{f} = \frac{\mathbf{k}_f - \mathbf{k}_i}{2\pi} = \begin{pmatrix} f_x \\ f_y \\ f_z \end{pmatrix} = \frac{1}{\lambda}\begin{pmatrix} \sin(\theta_f)\cos(\varphi_f) - \sin(\theta_i) \\ \sin(\theta_f)\sin(\varphi_f) \\ \cos(\theta_f) + \cos(\theta_i) \end{pmatrix} \quad \mathbf{f}_{xy} = \begin{pmatrix} f_x \\ f_y \end{pmatrix} \tag{2}$$

These can be viewed as a generalization of the grating equation for first-order diffraction from a grating with the spatial wavelength $d = 1/f$.

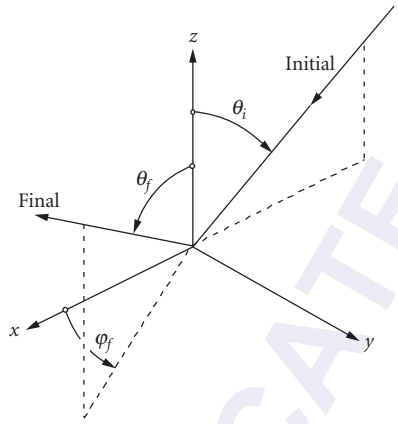

FIGURE 1 Coordinate system for 1D and 2D scattering. The *x*-*y* plane is the surface plane, with air/vacuum above and reflective material below. The planes of incidence and scattering are defined by the *z* axis and the initial and final directions of propagation.

The Jacobian relating configuration, wavenumber, and frequency space is

$$\cos(\theta_f)d\omega_f = \frac{1}{k^2}dk_x dk_y = \lambda^2 df_x df_y \qquad d\omega_f = \sin(\theta_f)d\theta_f d\varphi_f \tag{3}$$

The two orthogonal states of linear polarization have a variety of notations in the literature:

$$\begin{gathered} s\,(\text{senkrecht}) = h\,(\text{horizontal}) = \text{TE} = E = \perp\,(\text{perpendicular}) \\ \rightarrow \text{Dirichlet (soft) boundary condition} \\ p\,(\text{parallel}) = v\,(\text{vertical}) = \text{TM} = H = ||\,(\text{parallel}) \\ \rightarrow \text{Neumann (hard) boundary condition} \end{gathered} \tag{4}$$

Designation of initial (α) to final (β) states of polarization:

$$A_{\beta\alpha} = A_{\alpha\rightarrow\beta}$$

We use the optical or "p, s" notation hereafter. Circular and elliptically polarized results are obtained by taking appropriate linear combinations of these linear forms. Unpolarized results are obtained by summing over the final states of polarization and averaging over the initial states.

The polarization vector is a unit vector in the direction of the electric vector. A natural sign convention is

$$\hat{\mathbf{s}} = \hat{\mathbf{z}} \times \hat{\mathbf{k}} \qquad \hat{\mathbf{p}} = \hat{\mathbf{k}} \times \hat{\mathbf{s}} \qquad \hat{\mathbf{k}} = \hat{\mathbf{s}} \times \hat{\mathbf{p}} \tag{5}$$

but this is not universal.

One can make a distinction between scattering from a surface that is rough in both the *x* and *y* directions, and a grating like surface that is rough only along the *x* axis. The first generates a 2D or bistatic scattering pattern in the upper hemisphere, while the second scatters only into an infinitesimal region about the plane of incidence. Randomly-rough 1D surfaces are of special interest for research purposes since they are easier to fabricate with prescribed statistical properties than are 2D surfaces.[11–13] In the following discussions include 1D and 2D results side by side, wherever practical.

The distribution of the reflected and scattered power has a wide variety of notations in the optics and radar literature. For a 2D scatterer

$$\begin{aligned}\frac{1}{P_i}\left(\frac{dP}{d\omega_f}\right)^{(2D)}_{\alpha\to\beta} &= \frac{1}{A_o\cos(\theta_i)}\cdot\lim_{r\to\infty}\left[r^2\left|\frac{E_f}{E_i}\right|^2\right] = \frac{\left|f^{(2D)}_{\beta\alpha}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i)\right|^2}{A_o\cos(\theta_i)} \\ &= \frac{\sigma^{(2D)}_{\beta\alpha}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i)}{A_o\cos(\theta_i)} = \frac{\mathrm{RCS}^{(2D)}_{\beta\alpha}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i)}{4\pi A_o\cos(\theta_i)} = \frac{\gamma^{(2D)}_{\beta\alpha}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i)}{4\pi\cos(\theta_i)} \\ &= \mathrm{DSC}^{(2D)}_{\alpha\to\beta}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i) = \cos(\theta_f)\cdot\mathrm{BRDF}^{(2D)}_{\alpha\to\beta}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i) \\ &= \cos(\theta_i)\frac{A_o}{\lambda^2}D\{\rho\}^{(2D)} = I_{\alpha\beta}(Q)^{(2D)}\end{aligned} \tag{6}$$

and for a 1D scatterer

$$\begin{aligned}\frac{1}{P_i}\left(\frac{dP}{d\theta_f}\right)^{(1D)}_{\alpha\to\beta} &= \frac{1}{L_o\cos(\theta_i)}\cdot\lim_{r\to\infty}\left[r\left|\frac{E_f}{E_i}\right|^2\right] = \frac{2}{\pi k}\cdot\frac{\left|f^{(1D)}_{\beta\alpha}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i)\right|^2}{L_o\cos(\theta_i)} \\ &= \frac{\sigma^{(1D)}_{\beta\alpha}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i)}{L_o\cos(\theta_i)} = \frac{\mathrm{RCS}^{(1D)}_{\beta\alpha}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i)}{2\pi L_o\cos(\theta_i)} = \frac{\gamma^{(1D)}_{\beta\alpha}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i)}{2\pi\cos(\theta_i)} \\ &= \mathrm{DSC}^{(1D)}_{\alpha\to\beta}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i) = \cos(\theta_f)\cdot\mathrm{BRDF}^{(1D)}_{\alpha\to\beta}(\hat{\mathbf{k}}_f,\hat{\mathbf{k}}_i) \\ &= \cos(\theta_i)\frac{L_o}{\lambda}D\{\rho\}^{(1D)} = I_{\alpha\beta}(Q)^{(1D)}\end{aligned} \tag{7}$$

In Eqs. (6) and (7), P_i is the power incident on the surface; that is, $A_o \cos(\theta_i)\,|E_i|^2/(2\,\eta_o)$, where A_o is the total illuminated area of the surface for a 2D scatterer, and $A_o = 1 \times L_o$ for a 1D or grating-like scatterer. The f's here are the scattering amplitudes for spherical waves in 2D and cylindrical waves in 1D. σ is the bistatic cross-section, RCS is the bistatic radar cross-section, γ is the bistatic scattering coefficient, DSC is the differential scattering cross-section, and BRDF is the all-important radiometric quantity, the bidirectional reflectance distribution function. This is the quantity we will focus on in the detailed calculations described later in the chapter.

The cross-sections σ and RCS have the dimensions of area and length or "width." In practice, these are frequently converted to dimensionless forms by normalizing them to the appropriate power of the radiation wavelength or some characteristic physical dimension of the scattering object. On the other hand, γ and BRDF are dimensionless. The former is more appropriate for isolated objects, and the latter for distributed surface roughness. The γ's used here are the radar cross-section normalized to the illuminated surface area or length, although alternative definitions appear in the literature.

In Eq. (7), $D\{\rho\}$ and $I(Q)$ are quantities used in the books of Beckmann and Spizzichino[1] and Nieto-Vesperinas.[5]

At this point we do not distinguish deterministic and ensemble-average quantities, or coherent and incoherent scattering. These distinctions are discussed with respect to specific model calculations later in the chapter.

These full bistatic-scattering expressions may contain more information than is needed in practice. For example, scatterometry measurements[8,9] are usually performed in the plane of incidence ($\varphi_f = 0$ or π), and surface isotropy is checked by rotating the sample to intermediate values of φ between measurements. Similarly, the radar literature is frequently concerned only with measurements in the backscatter (retroscatter) direction, ($\theta_f = \theta_i$, $\varphi_f = \pi$).

In principle, relating the BRDF to topographic surface features is a straightforward application of Maxwell's equations, but approximations are frequently necessary to get practically useful results. The best known of these approximations are the physical-optics (Fresnel-Kirchhoff) and the small-perturbation (Rayleigh-Rice) methods. These are discussed in Secs. 8.4 and 8.5.

8.4 THE FRESNEL-KIRCHHOFF APPROXIMATION

Introduction

The Fresnel-Kirchhoff or physical-optics approximation is also known as the tangent-plane or Huygens wave approximation. It is valid when the surface roughness has a large radius of curvature, that is, it is locally flat, but places no direct restrictions on the surface height or slope. It is an inherently paraxial approximation, and in its simplest form discussed below [Eq. (8)] omits multiple scattering and shadowing effects. As a result, it does not generally satisfy the conservation of energy.

In this approximation the ensemble-average value of the BRDF is in 2D:

$$\langle \mathrm{BRDF}^{(2\mathrm{D})}_{\alpha\to\beta}\rangle^{\mathrm{FK}} = \frac{1}{\lambda^2}\cdot\frac{1}{\cos(\theta_i)\cos(\theta_f)}\cdot Q^{\mathrm{FK}}_{\alpha\to\beta}\cdot\langle \Im(\mathbf{f}_{xy})^{(2\mathrm{D})}\rangle$$

$$\langle \Im(\mathbf{f}_{xy})^{(2\mathrm{D})}\rangle = \int_{-\infty}^{+\infty} d\tau_{xy}\exp[i2\pi\mathbf{f}_{xy}\cdot\tau_{xy}]\cdot\exp\left[-\frac{1}{2}(2\pi f_z)^2\langle D(\tau_{xy})\rangle\right] \tag{8a}$$

and in 1D:

$$\langle \mathrm{BRDF}^{(1\mathrm{D})}_{\alpha\to\beta}\rangle^{\mathrm{FK}} = \frac{1}{\lambda}\cdot\frac{1}{\cos(\theta_i)\cos(\theta_f)}\cdot Q^{\mathrm{FK}}_{\alpha\to\beta}\cdot\langle \Im(f_x)^{(1\mathrm{D})}\rangle$$

$$\langle \Im(f_x)^{(1\mathrm{D})}\rangle = \int_{-\infty}^{+\infty} d\tau_x\exp[i2\pi f_x\tau_x]\cdot\exp\left[-\frac{1}{2}(2\pi f_z)^2\langle D(\tau_x)\rangle\right] \tag{8b}$$

In these expressions the Q carries the information on the polarization of the radiation and the properties of the surface material, and the real quantity $\langle\Im\rangle$ carries the information about the statistical properties of the surface roughness. This occurs through the dependence on the ensemble- average surface structure function, $\langle D(\tau)\rangle$

$$\langle D(\tau_{xy})\rangle = \langle D(|\tau_{xy}|)\rangle = \langle [Z(\mathbf{r}_{xy}+\tau_{xy}) - Z(\mathbf{r}_{xy})]^2\rangle \tag{9}$$

where r_{xy} is the position vector in the surface plane. The existence of $\langle D(\tau)\rangle$ requires that the surface roughness have statistically stationary first differences. In the limit of a perfectly smooth surface, $D(\tau)$ vanishes and the $\Im$'s become a delta function in the specular direction.

The exponential dependence on the roughness structure function in Eq. (8) is a consequence of the usual assumption that the height fluctuations, $Z(x, y)$, have a gaussian bivariate distribution. Nongaussian effects, which become manifest only for rough surfaces, are discussed in the literature.[11,13]

The polarization-materials factor can be written approximately as

$$Q^{\mathrm{FK}}_{\alpha\to\beta} = \left|A^{\mathrm{FK}}_{\alpha\to\beta}\right|^2\cdot R_{\alpha\to\beta}(\theta)$$

$$A^{\mathrm{FK}}_{s\to s} = -A^{\mathrm{FK}}_{p\to p} = \frac{(1+\cos(\theta_i)\cos(\theta_f))\cos(\varphi_f) - \sin(\theta_i)\sin(\theta_f)}{\cos(\theta_i)+\cos(\theta_f)} \tag{10}$$

$$A^{\mathrm{FK}}_{s\to p} = -A^{\mathrm{FK}}_{p\to s} = \sin(\varphi_f)$$

Although these results are correct for a perfect reflector, $R = 1$, the dependence on the surface reflectivity for an imperfect reflector is quite complicated.[2,4] Here we follow custom by arbitrarily factoring out a reflection coefficient R in the first line, where the R values are the Fresnel intensity reflectivities,

$$R_{\alpha\to\alpha}(\theta)=|r_\alpha(\theta)|^2 \qquad R_{\alpha\to\beta}(\theta)=\left|\frac{1}{2}(r_\alpha(\theta)-r_\beta(\theta))\right|^2 \tag{11}$$

and the r's are the amplitude reflection coefficients

$$r_s(\theta)=\frac{\mu\cos(\theta)-\sqrt{\mu\varepsilon-\sin^2(\theta)}}{\mu\cos(\theta)+\sqrt{\mu\varepsilon-\sin^2(\theta)}} \qquad r_p(\theta)=\frac{\varepsilon\cos(\theta)-\sqrt{\mu\varepsilon-\sin^2(\theta)}}{\varepsilon\cos(\theta)+\sqrt{\mu\varepsilon-\sin^2(\theta)}} \tag{12}$$

For simplicity in presentation we cavalierly evaluate these reflectivity factors at the local angle of incidence. That is, $R(\theta) = R(\theta_{\text{loc}})$, where $\theta_{\text{loc}} = |\ \theta_f\cos(\varphi_f) + \theta_i\ |/2$ in the plane of incidence.[2]

The material parameters ε and μ are the electric permeability and magnetic permittivity of the surface relative to vacuum. In the case of a perfect electrical conductor (PEC), $\varepsilon\to\infty$ and the R's are unity.

In the forward-scattering direction, $\varphi_f^2 \ll 1$, the Q's simplify to

$$Q^{\text{FK}}_{s\to s}=Q^{\text{FK}}_{p\to p}=\left[\frac{\cos((\theta_f+\theta_i)/2)}{\cos((\theta_f-\theta_i)/2)}\right]^2\cdot R_{\alpha\to\alpha}(\theta_{\text{loc}}) \qquad Q^{\text{FK}}_{s\to p}=Q^{\text{FK}}_{p\to s}=0 \tag{13}$$

and a related but different expression for $Q_{\alpha\alpha}$ in the retro-scattering direction, $\varphi_f = \pi$.

Statistically Stationary Surfaces

A random variable is statistically stationary if it has a finite mean-square value or variance, $\sigma^2 = \langle Z^2\rangle$.[14] In that case the structure function can be written as

$$\begin{aligned}\langle D(\tau_{xy})\rangle &= 2[\sigma^2-\langle C(\tau_{xy})\rangle] \qquad \sigma^2=\langle C(0)\rangle\\ \langle C(\tau_{xy})\rangle &= \langle C(|\tau_{xy}|)\rangle=\langle Z(\mathbf{r}_{xy}+\tau_{xy})Z(\mathbf{r}_{xy})\rangle\end{aligned} \tag{14}$$

where $\langle C(\tau)\rangle$ is the autocovariance function. The scattering integrals in Eq. (8) can then be written as

$$\begin{aligned}\langle\Im(\mathbf{f}_{xy})^{(2D)}\rangle &= e^{-g'}\int_{-\infty}^{+\infty}d\tau_{xy}\exp[i2\pi\mathbf{f}_{xy}\cdot\tau_{xy}]\cdot\exp[(2\pi f_z)^2\langle C(\tau_{xy})\rangle]\\ \langle\Im(f_x)^{(1D)}\rangle &= e^{-g'}\int_{-\infty}^{+\infty}d\tau_x\exp\left[i2\pi f_x\tau_x\right]\cdot\exp[(2\pi f_z)^2\langle C(\tau_x)\rangle]\\ g' &= (2\pi f_z\sigma)^2=\left[4\pi\left(\frac{\cos(\theta_i)+\cos(\theta_f)}{2}\right)\frac{\sigma}{\lambda}\right]^2 \qquad g=\left[4\pi\cos(\theta_i)\frac{\sigma}{\lambda}\right]^2\end{aligned} \tag{15}$$

The quantity g, the Strehl or Rayleigh index, is an important dimensionless measure of the degree of surface roughness [1,15] which will appear throughout the following discussions.

We now examine forms of the <BRDF> that follow from Eqs. (8) and (15) in four roughness regimes.

Perfectly Smooth Surfaces In perfectly smooth surfaces, where $g = 0$, Eq. (8) reduces to

$$\begin{aligned}\langle\text{BRDF}^{(2D)}_{\alpha\to\beta}\rangle^{\text{FK}} &= \frac{1}{\lambda^2}\cdot R_\alpha(\theta_i)\cdot\delta(\mathbf{f}_{xy})\cdot\delta_{\alpha,\beta}\\ \langle\text{BRDF}^{(1D)}_{\alpha\to\beta}\rangle^{\text{FK}} &= \frac{1}{\lambda}\cdot R_\alpha(\theta_i)\cdot\delta(f_x)\cdot\delta_{\alpha,\beta}\end{aligned} \tag{16}$$

that is, a sharp spike in the specular direction.

This spike is a delta function in spatial-frequency space and follows from the assumption of an infinite illumination area in Eq. (8). Later, in Sec. 8.6, we extend this idealized result to include the important effects of a finite-sized illumination area.

Slightly Rough Surfaces In slightly rough surfaces, $0 < g \ll 1$. In this case, expand the second exponent in Eq. (15) in a power series and keep the first two terms. These two terms separate the <BRDF> into "coherent" and "incoherent" parts:

$$\begin{aligned}\left\langle \mathrm{BRDF}^{(2\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{FK}}_{\mathrm{coherent}} &= (1-g)\cdot\frac{1}{\lambda^2}\cdot R_\alpha(\theta_i)\cdot\delta(\mathbf{f}_{xy})\cdot\delta_{\alpha,\beta}\\ \left\langle \mathrm{BRDF}^{(2\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{FK}}_{\mathrm{incoherent}} &= \frac{16\pi^2}{\lambda^4}\frac{[\cos(\theta_i)+\cos(\theta_f)]^2}{4\cos(\theta_i)\cos(\theta_f)}\cdot\left|A^{\mathrm{FK}}_{\alpha\to\beta}\right|^2\cdot R_{\alpha,\beta}(\theta_{\mathrm{loc}})\cdot\langle S(\mathbf{f}_{xy})^{(2\mathrm{D})}\rangle\end{aligned} \tag{17a}$$

and

$$\begin{aligned}\left\langle \mathrm{BRDF}^{(1\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{FK}}_{\mathrm{coherent}} &= (1-g)\cdot\frac{1}{\lambda}\cdot R_\alpha(\theta_i)\cdot\delta(f_x,0)_{f_x,0}\cdot\delta_{\alpha,\beta}\\ \left\langle \mathrm{BRDF}^{(1D)}_{\alpha\to\beta}\right\rangle^{\mathrm{FK}}_{\mathrm{incoherent}} &= \frac{16\pi^2}{\lambda^3}\frac{[\cos(\theta_i)+\cos(\theta_f)]^2}{4\cos(\theta_i)\cos(\theta_f)}\cdot\left|A^{FK}_{\alpha\to\beta}\right|^2\cdot R_\alpha(\theta_{loc})\cdot\delta_{\alpha,\beta}\cdot\langle S(f_x)^{(1\mathrm{D})}\rangle\end{aligned} \tag{17b}$$

The statistical properties of the surface appear here in the all-important quantities $\langle S^{(1\mathrm{D})}\rangle$ and $\langle S^{(2\mathrm{D})}\rangle$—the ensemble-averages of the 1D and 2D power spectral densities of the surface roughness. These are the Fourier transforms of the corresponding covariance functions:

$$\begin{aligned}\langle S(f_x)^{(1\mathrm{D})}\rangle &= \int_{-\infty}^{+\infty} d\tau_x \exp[i2\pi f_x\tau_x]\cdot\langle C(\tau_x)\rangle\\ \langle S(\mathbf{f}_{xy})^{(2\mathrm{D})}\rangle &= \int_{-\infty}^{+\infty} d\tau_{xy}\exp[i2\pi\mathbf{f}_{xy}\cdot\tau_{xy}]\cdot\langle C(\tau_{xy})\rangle\end{aligned} \tag{18}$$

These are discussed in detail in Sec. 8.7.

As a final note, the incoherent terms reduce to somewhat simpler forms when observations are made in the forward direction, $\varphi_f^2 \ll 1$:

$$\begin{aligned}\left\langle \mathrm{BRDF}^{(2\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{FK}}_{\mathrm{incoherent}} &= \frac{16\pi^2}{\lambda^4}\frac{\cos^4[(\theta_f+\theta_i)/2]}{\cos(\theta_i)\cos(\theta_f)}\cdot\delta_{\alpha,\beta}\cdot R(\theta_{\mathrm{loc}})\cdot\langle S(f_x,0)^{(2\mathrm{D})}\rangle\\ \left\langle \mathrm{BRDF}^{(1\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{FK}}_{\mathrm{incoherent}} &= \frac{16\pi^2}{\lambda^3}\frac{\cos^4[(\theta_f+\theta_i)/2]}{\cos(\theta_i)\cos(\theta_f)}\cdot\delta_{\alpha,\beta}\cdot R(\theta_{\mathrm{loc}})\cdot\langle S(f_x)^{(1\mathrm{D})}\rangle\end{aligned} \tag{19}$$

Moderately Rough Surfaces In moderately rough surfaces, where $g \approx 1$, the power-series expansion of the second exponential in Eq. (15) cannot be cut off after the first two terms, and higher terms must be included. Beckmann and Spizzichino[1] illustrate this procedure for a gaussian $\langle C(\tau)\rangle$ and a gaussian bivariate distribution (see also Refs. 11 and 13).

A gaussian autocovariance function is rarely, if ever, observed in polished optical surfaces, although it is very convenient for analytic and experimental investigations. For example, O'Donnell and Mendez have made artificially rough grating-like surfaces of this type by superimposing speckle patterns, and have used them to make ingenious scattering studies of rough surfaces.[11]

Very Rough Surfaces In very rough surfaces, where $g \gg 1$, the coherent term vanishes for a gaussian bivariate distribution, and we revert to Eq. (8) which then involves the limit of the scattering integral:

$$\lim_{\langle D(\tau_{xy})\rangle\to\infty}\left\{\int_{-\infty}^{+\infty} d\tau_{xy}\exp[i2\pi\mathbf{f}_{xy}\cdot\tau_{xy}]\cdot\exp\left[-\frac{1}{2}(2\pi f_z)^2\langle D(\tau_{xy})\rangle\right]\right\} \tag{20}$$

which is determined by the indicial behavior of $<D(\tau_{xy})>$. In the special case where the structure function is isotropic and quadratic

$$\lim_{\tau \to o} \langle D(\tau_{xy}) \rangle = \sigma_M^2 \tau_{xy}^{\ 2} \tag{21}$$

where σ_M is the dimensionless root mean square (rms) value of the surface gradient of a 2D surface or the rms value of surface slope of a 1D surface. It is easy to see that this quadratic dependence leads to values of $<\mathfrak{S}>$ that are proportional to λ^2 in 2D and λ^1 in 1D, in which case the <BRDF> is independent of the radiation wavelength. In other words, a quadratic structure function leads to geometric-optics results.

In fact, the resulting scattering pattern is a mapping of the slope distribution of the surface roughness, including the doubling of the deflection angle on reflection.[1,2] The form of the scattering pattern depends on the form of the bivariate distribution involved. For example, a gaussian bivariate distribution leads to a gaussian pattern, while a gamma distribution leads to scattering patterns involving modified Bessel functions.[13]

If the indicial behavior of $<D>$ is not quadratic, the form of the <BRDF>'s depend on λ and the elegant geometrical-optics limits are not achieved. Mathematically, this occurs because such surfaces are not differentiable at $\tau = 0$ and so have no well-defined "slope."

Fractal Surfaces

Introduction Fractal surfaces have structure functions of the form

$$\langle D(\tau_{xy}) \rangle_{\text{fractal}} = T^2 \left| \frac{\tau_{xy}}{T} \right|^N \qquad 0 < N < 2 \tag{22}$$

where T is a length parameter called the topothesy.[16,17] Physically, T is the separation of surface points whose connecting chord has an rms slope of unity. Because Eq. (22) is proportional to T^{2-N} where $N < 2$, a perfectly smooth surface occurs when $T \to 0$. On the other hand, because $N = 2$ is excluded, very rough fractal surfaces do not lead to a geometrical-optics result.

The number N is the fractal index, which is related to the Hausdorff or Hausdorff-Besicovitch dimension D',[16,17]

$$\begin{aligned} D' &= (4-N)/2 \qquad N = 4 - 2D' \\ 1 &< D' < 2 \qquad 0 < N < 2 \end{aligned} \tag{23}$$

D' can also be expressed in terms of the Hurst dimension or coefficient, but the connection depends on the dimensionality of the problem.[18]

Fractal Forms of the Scattering Integrals In the case of statistically isotropic surfaces, structure functions of the form of Eq. (22) lead to expressions for the incoherent scattering integrals which may be written as

$$\begin{aligned} \langle \mathfrak{S}(\mathbf{f}_{xy})^{(2D)} \rangle &= 2\pi \int_0^\infty \tau_{xy}\, d\tau_{xy}\, J_0(2\pi f_{xy} \tau_{xy}) \cdot \sigma^2 \exp\left[-\left| \frac{\tau_{xy}}{\rho} \right|^N \right] \\ \langle \mathfrak{S}(f_x)^{(1D)} \rangle &= \int_{-\infty}^{+\infty} d\tau_x \exp\left[i 2\pi f_x \tau_x \right] \cdot \sigma^2 \exp\left[-\left| \frac{\tau_x}{\rho} \right|^N \right] \end{aligned} \tag{24}$$

where

$$\sigma = 1 \ \text{(dimensionless)} \qquad \rho = \left[\frac{2}{(2\pi f_z T)^2} \right]^{1/N} \cdot T \tag{25}$$

are "pseudo" roughness and correlation length parameters. These do not play true physical roles in the case of fractals, but are artificial quantities introduced here to enable us to write Eq. (24) in form of a Fourier transform of a covariance function that will appear later as the power exponential (PEX) model.

The integrals in Eq. (24) are symmetric bell-shaped functions of f_{xy} and f_x that are flat at low spatial frequencies and fall off with inverse-power-law tails at high spatial frequencies. The 2D expression cannot be expressed in terms of known functions, while the 1D form can be written in terms of centered symmetric Lévy stable distributions of order α, that is, $L_\alpha(X)$, where:[17]

$$\langle \Im(f_x)^{(1D)} \rangle = 2\pi\sigma^2\rho \cdot L_N(Y) \qquad Y = 2\pi f_x \rho \tag{26}$$

Nolan[19] gives the computer program "STABLE" for this in terms of general stable distribution functions f_{Nolan}:

$$\langle \Im(f_x)^{(1D)} \rangle = 2\pi\sigma^2\rho \cdot f_{\text{Nolan}}(x|\alpha, \beta, \gamma, \delta, k) \tag{27}$$

$$x = |f_x|, \quad \alpha = N, \quad \beta = 0, \quad \gamma = 1/(2\pi\rho), \quad \delta = 0, \quad k = 0 \text{ or } 1$$

On the other hand, the low- and high-frequency limits of the 1D and 2D forms can be expressed in simple closed form. In the 1D case:

$$\begin{aligned} \langle \Im(|f_x| << 1/2\pi\rho)^{(1D)} \rangle &= \sigma^2\rho \cdot 2\Gamma((1+N)/N) \\ \langle \Im(|f_x| >> 1/2\pi\rho)^{(1D)} \rangle &= \sigma^2\rho \cdot 2^N\sqrt{\pi}\,\frac{\Gamma((1+N)/2)}{\Gamma((2-N)/2)} \cdot \frac{N}{(2\pi|f_x|\rho)^{N+1}} \end{aligned} \tag{28a}$$

and in the isotropic 2D case:

$$\begin{aligned} \langle \Im(|f_{xy}| << 1/2\pi\rho)^{(2D)} \rangle &= \sigma^2\rho^2 \cdot \pi\,\Gamma((2+N)/N) \\ \langle \Im(|f_{xy}| >> 1/2\pi\rho)^{(2D)} \rangle &= \sigma^2\rho^2 \cdot 2^{N+1}\pi\,\frac{\Gamma((2+N)/2)}{\Gamma((2-N)/2)} \cdot \frac{N}{(2\pi|f_{xy}|\rho)^{N+2}} \end{aligned} \tag{28b}$$

It follows from the Fourier transform nature of Eq. (8) that the areas under each of these curves in frequency space is simply σ^2. This plus the asymptotic properties of the $<\Im>$'s given above capture most of the physical properties of the <BRDF> of interest.

The case $N = 1$, $D' = 3/2$ is called the Brownian fractal, which falls between the Cantor set ($D' = 0.63093\ldots$) and the Sierpinski gasket ($D' = 1.5850\ldots$). The Brownian fractal has the virtue of leading to the simple analytic expressions for the diffraction integrals valid for all spatial frequencies:

$$\langle \Im(f_x)^{(1D)} \rangle_{N=1} = \frac{2\sigma^2\rho}{1+(2\pi f_x\rho)^2} \qquad \langle \Im(f_{xy})^{(2D)} \rangle_{N=1} = \frac{2\pi\sigma^2\rho^2}{[1+(2\pi f_{xy}\rho)^2]^{3/2}} \tag{29}$$

where, for fractal surfaces, σ and ρ are given by Eq. (25).

8.5 THE RAYLEIGH-RICE (RR) OR SMALL-PERTURBATION APPROXIMATION

Results

The small-perturbation method is an alternative to the Fresnel-Kirchhoff method discussed above. Its first-order form was originally derived by Rice[20] using the Rayleigh hypothesis, and hence the name Rayleigh-Rice. Peake[2,21] was the first to derive the expression for an arbitrary

surface material and the results have been rederived many times in the literature. These Rayleigh-Rice results have been extended to higher orders[22–24], and in its more general form is called the small-perturbation method.

The lowest-order perturbation theory results are[2]

$$\left\langle \mathrm{BRDF}(\mathbf{f}_{xy})^{(2\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{RR}}_{\mathrm{incoherent}} = \frac{16\pi^2}{\lambda^4}\cos(\theta_i)\cos(\theta_f)\cdot Q^{RR}_{\alpha\to\beta}\cdot\langle S(\mathbf{f}_{xy})^{(2\mathrm{D})}\rangle$$
$$\left\langle \mathrm{BRDF}(f_x)^{(1\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{RR}}_{\mathrm{incoherent}} = \frac{16\pi^2}{\lambda^3}\cos(\theta_i)\cos(\theta)_f\cdot Q^{RR}_{\alpha\to\beta}\cdot\delta_{\alpha,\beta}\cdot\langle S(f_x)^{(1\mathrm{D})}\rangle \tag{30}$$

The RR form of the coherent term is complicated and can be found in the literature.[5,25]

The Q's are the material-polarization factors similar to those appearing in the FK calculations. In contrast with the approximation made in the FK case, however, they do not separate into distinct angular and reflectivity factors. In particular,[2]

$$Q^{\mathrm{RR}}_{\alpha\to\beta} = \left|A^{\mathrm{RR}}_{\alpha\to\beta}\right|^2$$
$$A^{\mathrm{RR}}_{s\to s} = \frac{[\mu-1][B(\theta_i)B(\theta_f)\cos(\varphi_f)-\mu\sin(\theta_i)\sin(\theta_f)]-\mu^2(\varepsilon-1)\cos(\varphi_f)}{[B(\theta_i)+\mu\cos(\theta_i)][B(\theta_f)+\mu\cos(\theta_f)]}$$
$$A^{\mathrm{RR}}_{s\to p} = \frac{\varepsilon(\mu-1)B(\theta_i)-\mu(\varepsilon-1)B(\theta_f)}{[B(\theta_i)+\mu\cos(\theta_i)][B(\theta_f)+\varepsilon\cos(\theta_f)]}\sin(\varphi_f) \tag{31}$$
$$A^{\mathrm{RR}}_{p\to s} = \frac{\mu(\varepsilon-1)B(\theta_i)-\varepsilon(\mu-1)B(\theta_f)}{[B(\theta_i)+\varepsilon\cos(\theta_i)][B(\theta_f)+\mu\cos(\theta_f)]}\sin(\varphi_f)$$
$$A^{\mathrm{RR}}_{p\to p} = \frac{(\varepsilon-1)[\varepsilon\sin(\theta_i)\sin(\theta_f)-B(\theta_i)B(\theta_f)\cos(\varphi_f)]+\varepsilon^2(\mu-1)\cos(\varphi_f)}{[B(\theta_i)+\varepsilon\cos(\theta_i)][B(\theta_f)+\varepsilon\cos(\theta_f)]}$$

where $B(\theta)=\sqrt{\varepsilon\mu-\sin^2(\theta)}$ and index of refraction $=\sqrt{\varepsilon\mu}$. The full ε–μ dependencies are useful for checking the duality of the results.

The Q^{RR}'s are closely related to the Fresnel reflection coefficients in Eqs. (11) and (12). For nonmagnetic materials, $\mu=1$ and

$$Q^{\mathrm{RR}}_{s\to s} = \sqrt{R_s(\theta_i)R_s(\theta_f)}\cdot\cos^2(\varphi_f)$$
$$Q^{\mathrm{RR}}_{\alpha\to\beta}(\mathrm{specular}) = R_\alpha(\theta_i)\cdot\delta_{\alpha,\beta} \tag{32}$$

On the other hand, for a perfectly reflecting (PEC) surface,

$$Q^{\mathrm{RR}}_{s\to s} = \cos^2(\varphi_f) \qquad Q^{\mathrm{RR}}_{s\to p} = \left[\frac{\sin(\varphi_f)}{\cos(\theta_f)}\right]^2$$
$$Q^{\mathrm{RR}}_{p\to p} = \left[\frac{\cos(\varphi_f)-\sin(\theta_i)\sin(\theta_f)}{\cos(\theta_i)\cos(\theta_f)}\right]^2 \qquad Q^{\mathrm{RR}}_{p\to s} = \left[\frac{\sin(\varphi_f)}{\cos(\theta_i)}\right] \tag{33}$$

In the special case of a perfectly reflecting surface measured in the plane of incidence we get the elegant results:

$$\left\langle \mathrm{BRDF}^{(2\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{RR}}_{\mathrm{incoherent}} = \frac{16\pi^2}{\lambda^4}\cos(\theta_i)\cos(\theta_f)\cdot Q^{\mathrm{RR}}_{\alpha\to\beta}\cdot\langle S(f_x,0)^{(2\mathrm{D})}\rangle$$

$$\left\langle \mathrm{BRDF}^{(1\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{RR}}_{\mathrm{incoherent}} = \frac{16\pi^2}{\lambda^3}\cos(\theta_i)\cos(\theta_f)\cdot Q^{\mathrm{RR}}_{\alpha\to\beta}\cdot\delta_{\alpha,\beta}\cdot\langle S(f_x)^{(1\mathrm{D})}\rangle \tag{34}$$

$$Q^{\mathrm{RR}}_{s\to s}=1 \quad Q^{\mathrm{RR}}_{s\to p}=Q^{\mathrm{RR}}_{p\to s}=0 \quad Q^{\mathrm{RR}}_{p\to p}=\left(\frac{1-\sin(\theta_i)\sin(\theta_f)}{\cos(\theta_i)\cos(\theta_f)}\right)^2$$

which may be compared with the FK result in Eq. (19) with $R(\theta) = 1$.

Again, the reader is alerted to the fundamental distinction between $<S(f_x, 0)^{(2D)}>$ and $<S(f_x)^{(1D)}>$, appearing here. They may be mathematically related for an isotropically rough surface, but they are never equal.

Comparison of RR and FK Results

The Rayleigh-Rice results are inherently a smooth-surface approximation for a statistically stationary random surface, so that the proper comparison is with the Fresnel-Kirchhoff results for slightly rough surfaces in Eq. (17) and the RR results in Eq. (30).

In the limit of paraxial scattering, $\theta_f \approx \theta_I$ and $\varphi_f \approx 0$, the two sets of results become identical and can be written in the common form:

$$\left\langle \mathrm{BRDF}^{(2\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{FK,\,RR}}_{\mathrm{incoherent}} \to \frac{16\pi^2}{\lambda^4}\cos^2(\theta_i)\cdot R_\alpha(\theta_i)\cdot\left\{\begin{array}{ll}1 & \alpha=\beta\\ \left(\dfrac{\sin(\varphi_f)}{\cos(\theta_i)}\right)^2 & \alpha\neq\beta\end{array}\right\}\cdot\langle S(f_x,f_y)^{(2\mathrm{D})}\rangle \tag{35a}$$

$$\left\langle \mathrm{BRDF}^{(1\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{FK,\,RR}}_{\mathrm{incoherent}} \to \frac{16\pi^2}{\lambda^3}\cos^2(\theta_i)\cdot R_\alpha(\theta_i)\cdot\delta_{\alpha,\beta}\cdot\langle S(f_x)^{(1\mathrm{D})}\rangle$$

where $R_\alpha(\theta_i)$ is given by Eq. (11).

In the case of fractal surfaces the paraxial results are

$$\left\langle \mathrm{BRDF}^{(2\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{FK,\,RR}}_{\mathrm{incoherent}} \to \frac{1}{\lambda^2}\cdot R_\alpha(\theta_i)\cdot\left\{\begin{array}{ll}1 & \alpha=\beta\\ \left(\dfrac{\sin(\varphi_f)}{\cos(\theta_i)}\right)^2 & \alpha\neq\beta\end{array}\right\}\cdot\langle\Im(f_x,f_y)^{(2\mathrm{D})}\rangle \tag{35b}$$

$$\left\langle \mathrm{BRDF}^{(1\mathrm{D})}_{\alpha\to\beta}\right\rangle^{\mathrm{FK,\,RR}}_{\mathrm{incoherent}} \to \frac{1}{\lambda}\cdot R_\alpha(\theta_i)\cdot\delta_{\alpha,\beta}\cdot\langle\Im(f_x)^{(1\mathrm{D})}\rangle$$

where the $<\Im>$'s are given in Eqs. (24) et seq. Later, in "The J-K model" section we discuss the high-frequency forms of the <BRDF> that follow from these results.

A nice feature of the paraxial results in Eq. (35) is that they satisfy the conservation of energy. In the case of statistically stationary surfaces this occurs via

$$\int d\omega_s\frac{dP}{d\omega_s}=\frac{\lambda^2}{R(\theta_i)}\int d\mathbf{f}_{xy}\langle\mathrm{BRDF}^{(2\mathrm{D})}\rangle^{\mathrm{FK,\,RR}}_{\mathrm{total}}=(1-g)+g=1$$

$$\int d\theta_s\frac{dP}{d\theta_s}=\frac{\lambda}{R(\theta_i)}\int df_x\langle\mathrm{BRDF}^{(1\mathrm{D})}\rangle^{\mathrm{FK,\,RR}}_{\mathrm{total}}=(1-g)+g=1 \tag{36}$$

where the terms (1–g) and g come from the coherent and incoherent components.

The differences between the FK and RR results that appear at larger deflection angles are attributed to the inherently paraxial approximation of the FK calculations. In particular, the FK results for rougher surfaces do not satisfy the conservation of energy due to their neglect of multiple scattering and shadowing effects.[26]

On the other hand, the RR or lowest-order perturbation theory results are known to have intrinsic limitations at grazing angles, especially for p-polarized radiation.[27] The RR results also may not satisfy the conservation of energy because of the phenomenon of roughness-induced absorption.[28]

8.6 EFFECTS OF FINITE ILLUMINATION AREA

The discussion above has assumed that the illuminated surface area is infinite, which is the meaning of the limits $\pm\infty$ in the integrals, $\langle\Im\rangle$, appearing in Eqs. (8) et seq.

In general, the effects of the finite rectangular illumination area, $L_x \times L_y$, can be taken into account by convolving the infinite-illumination forms of the <BRDF> with the system-response (SR) or point-spread function

$$\text{System response}(f_x, f_y) = \frac{L_x L_y}{\lambda^2}\left[\frac{\sin(\pi f_x L_x)}{\pi f_x L_x}\right]^2\left[\frac{\sin(\pi f_y L_y)}{\pi f_y L_y}\right]^2 \tag{37}$$

which becomes $\delta(f_x)\delta(f_y)$ in the limit $L_x, L_y \gg \lambda$.[29]

When the L's are much larger than the correlation length of the surface roughness, the incoherent scattering pattern is a broad and "smooth" function of spatial frequency and is unaffected by the convolution with the relatively sharp system response function.

This argument breaks down when there are sharp features in the <BRDF>. An example of this occurs in the smooth-surface limit of statistically stationary surfaces, which exhibit a delta-function coherent-scattering peak as in Eq. (17). That delta function is then smeared into the expected sinc^2 pattern by convolution with the system response.

Fractal scattering does not display a separable coherent component but does become increasingly bunched in the specular direction when the topothesy is sufficiently small. In that limit the observed scattering is again affected significantly by convolution with the system response.

The non-vanishing width of the system response function plays an important role in the discussion of surface-finish specification in Sec. 8.8.

8.7 SURFACE STATISTICS

Second-Order Statistical Functions

The ensemble-average scattered power can be written in terms of three second-order statistical functions: the structure function, $\langle D(\tau)\rangle$, the surface autocovariance function (ACF), $\langle C(\tau)\rangle$, and the power spectral density (PSD) $\langle S(f)\rangle$. Equation (18) gives the PSD in terms of the ACF, but it can also be written directly in terms of the surface profile according to

$$\begin{aligned}\langle S(f_x)^{(1D)}\rangle &= \lim_{L_o\to\infty}\left\langle\frac{1}{L_o}\left|\int_{-L_o/2}^{+L_o/2} dx \exp[i2\pi f_x x]\cdot Z(x)\right|^2\right\rangle \\ \langle S(\mathbf{f}_{xy})^{(2D)}\rangle &= \lim_{A_o\to\infty}\left\langle\frac{1}{A_o}\left|\int_{A_o} d\mathbf{r}_{xy} \exp[i2\pi\mathbf{f}_{xy}\cdot\mathbf{r}_{xy}]\cdot Z(\mathbf{r}_{xy})\right|^2\right\rangle\end{aligned} \tag{38}$$

where $-\infty < f_x, f_{xy} < +\infty$. This is the basis for the periodogram estimate of the one-sided profile spectrum[30]:

$$\hat{S}^*(f_n) = 2 \cdot \frac{D}{N} \left| \sum_{m=0}^{N-1} \exp[i 2\pi mn/N] \cdot W(m) \cdot Z(mD) \right|^2 K(m)$$
$$f_n = \frac{n}{ND} \qquad n = 1, \ldots, \frac{N}{2} \tag{39}$$

where the "hat" on S means that it is an estimate, and the asterisk and the factor of two on the right mean that the negative spatial frequencies have been folded over and added into the positive frequencies. $W(n)$ is a real bell-shaped window function that eliminates the ringing that would otherwise appear in the estimate due to the sharp edges of the data window, and $K(m)$ is a book-keeping factor that equals unity everywhere except at the end points, where it equals 1/2.

In the above, D is the sample spacing of the measured data, and the range of spatial frequencies included in the measurement is $(1/ND) \le f_n \le 1/2D$, where $1/2D$ is the Nyquist frequency of the measurement. As written, N is even, although a similar expression holds for odd N.

Properties of Power Spectra

The power spectra show how the variance of the surface roughness is distributed over surface spatial frequencies. In particular,

$$(\sigma^2)^{(2D)} = \langle Z(x, y)^2 \rangle = \int_{-\infty}^{+\infty} d\mathbf{f}_{xy} \langle S(\mathbf{f}_{xy})^{(2D)} \rangle = \langle C(0) \rangle$$
$$(\sigma^2)^{(1D)} = \langle Z(x)^2 \rangle = \int_{-\infty}^{+\infty} df_x \langle S(f_x)^{(1D)} \rangle = \langle C(0) \rangle \tag{40}$$

In other words, the roughness of a statistically stationary surface measured over a surface area is the same as that measured over any linear profile across it.

The 2D spectrum is what appears in surface-scattering measurements, while 1D spectrum appears in surface profile measurements. Both depend only on the magnitude of their spatial-frequency arguments. However, 1D and 2D spectra are distinctly different—they even have different dimensions: $<S^{(2D)}>$ is $[L^4]$, while $<S^{(1D)}>$ is $[L^3]$. What is not true is that the 1D form is a simple slice of the 2D form; that is, $<S(f_x)^{(1D)}>$ *does not equal* $<S(f_x, 0)^{(2D)}>$. Instead, the 1D form can be derived from the 2D form by integration,

$$\langle S(f_x)^{(1D)} \rangle = \int_{-\infty}^{+\infty} df_y \langle S(f_x, f_y)^{(2D)} \rangle \tag{41}$$

but the 2D form cannot be derived from the 1D form without providing further information about the 2D form. This is usually given in terms of its symmetry properties.

Incidentally, it follows from Eqs. (35) and (41) that the 1D scattering pattern equals the 2D pattern integrated over an long, narrow slit parallel to the y axis in Fig. 1.

If the surface is statistically isotropic, $<S^{(1D)}>$ and $<S^{(2D)}>$ are related by the integral transforms

$$\langle S(f_{xy})^{(2D)} \rangle = -\frac{1}{\pi} \int_{f_{xy}}^{\infty} \frac{df_x}{\sqrt{f_x^2 - f_{xy}^2}} \frac{d}{df_x} \langle S(f_x)^{(1D)} \rangle$$
$$\langle S(f_x)^{(1D)} \rangle = 2 \int_{f_x}^{\infty} \frac{f_{xy} df_{xy}}{\sqrt{f_{xy}^2 - f_x^2}} \langle S(f_{xy})^{(2D)} \rangle \tag{42}$$

The first is the inverse-Abel or "half derivative" transform and the second is the Abel transform or "half integral" transform.[31]

The transforms in Eq. (42) are useful since they allow profile measurements, which are inherently 1D, to be translated into the 2D spectra which appear in scatterometry and practical applications.[32] They also permit the transformation of the high-frequency behavior of the spectra of one dimensionality to be transformed into the high-frequency behavior of the other without knowledge of their low-frequency behavior.[32]

An important example of this is the case of inverse-power-law high-frequency tails,

$$\langle S(f_{xy})^{(2D)}\rangle = \frac{J}{f_{xy}^{m}} \qquad \langle S(f_x)^{(1D)}\rangle = \frac{K}{|f_x|^{m-1}}$$
$$K = \frac{\Gamma[1/2]\Gamma[(m-1)/2]}{\Gamma[m/2]} \cdot J \qquad m > 2 \tag{43}$$

which is the essence of the so-called J-K model discussed in the "The J-K Model" section.

Finish Models

General Remarks The magnitudes of the spatial frequencies $|f|$ appearing in the PSDs discussed above cover the range from 0 to $+\infty$. Real world measurements, however, include only a lesser range of spatial frequencies, $f_{min}<|f|<f_{max}$, where f_{min} and f_{max} are determined by the details of the measurement process.

In scatterometry the bandwidth limits are determined by the radiation wavelength and the maximum and minimum collection angles according to Eq. (2). In profilometry the minimum spatial frequency is the reciprocal of the trace length of the measurement, and the maximum is the reciprocal of twice the uniform sampling interval—that is, the Nyquist frequency of the measurement.

Surface finish models are parametric models that are fitted to experimental data. This condenses the measured data into a set of discrete finish parameters, smooths the measured data within the measurement bandpass, and—depending on one's degree of trust in the model—can be used to extrapolate the data outside the measurement range.

In this chapter we consider four elementary models: The fractal model discussed above, and the ABC, PEX and J-K models considered below. These models have been chosen since each shows an inverse-power-law high-frequency tail displayed by many real surfaces.

The Fractal Model The fractal model is defined by the structure function $D(\tau)=T^2|\tau/T|^N$ appearing in Eqs. (8) and (9), et seq. This two-parameter "model" follows from the geometrical scaling of fractal or self-affine surface roughness. Since there is no intrinsic limitation on its degree of roughness in this case, it is more properly described by the FK rather than the RR calculations, leading to the results given in the "Fractal Surfaces" section.

The ABC Model A very useful pair of spectra that satisfy the integral transforms in Eq. (42) is the "ABC" model:

$$\langle S(f_x)^{(1D)}\rangle = \frac{A}{[1+(Bf_x)^2]^{C/2}} \qquad \langle S(f_{xy})^{(2D)}\rangle = \frac{A'}{[1+(Bf_{xy})^2]^{(C+1)/2}}$$
$$A' = \frac{\Gamma[(C+1)/2]}{\Gamma[1/2]\Gamma[C/2]} \cdot AB \qquad \sigma^2 = \frac{\Gamma[1/2]\Gamma[(C-1)/2]}{\Gamma[C/2]} \cdot \frac{A}{B} \qquad C > 1 \tag{44}$$

Here σ is the rms roughness parameter that describes its vertical character, $B/(2\pi)$ is the roughness "correlation length" that characterizes its transverse character, and C is the spectral index that determines its high-frequency behavior.

The corresponding ACF, obtained by taking the Fourier transform of $\langle S(f_x)^{(1D)}\rangle$, is

$$\langle C(\tau)\rangle_{ABC} = \sqrt{2\pi}\frac{2A}{B}\frac{2^{-C/2}}{\Gamma[C/2]}\left(2\pi\frac{|\tau|}{B}\right)^{(C-1)/2}\cdot K_{(C-1)/2}\left(2\pi\frac{|\tau|}{B}\right) \quad C>0 \tag{45}$$

where K_n is a modified Bessel function.[33] For this reason the "ABC" model is also called the K-correlation model.[30] When $C = 2, 4, 6, \ldots$, it reduces to simple algebraic expressions. For $C = 2$, and 4, for example,

$$\begin{aligned}\langle C(\tau)\rangle_{ABC}|_{C=2} &= \pi\frac{A}{B}\exp\left[-2\pi\frac{|\tau|}{B}\right]\\ \langle C(\tau)\rangle_{ABC}|_{C=4} &= \frac{\pi}{2}\frac{A}{B}\exp\left[-2\pi\frac{|\tau|}{B}\right]\cdot\left[1+2\pi\frac{|\tau|}{B}\right]\end{aligned} \tag{46}$$

where the $C = 2$ form is the well-known two-sided exponential. When $C \to \infty$ the covariance function in Eq. (45) becomes gaussian.

The PEX Model Another three-parameter model with an inverse power-law power spectrum is the power exponential model:

$$\langle C(\tau)\rangle_{PEX} = \sigma^2\exp\left[\left|\frac{\tau}{\rho}\right|^N\right] \quad 0<N<2 \tag{47}$$

This model is identical with the ABC model for $N = 1$ and $C = 2$, but otherwise they are different. Some of the mathematical properties of the 1D and 2D spectra of the PEX model have been given earlier in connection with fractal surfaces. In particular, Eqs. (28*a*) and (28*b*) give the low- and high-frequency forms, and Eq. (29) gives explicit results for $N = 1$.

Note that the ABC model only requires that $C > 1$ to be statistically stationary. This admits faster high-frequency falloffs than are permitted for the fractal and PEX models, which translate to $1 < C < 3$. This means that surfaces with $C \geq 3$ only fit the ABC model.

The J-K Model In the limit of long correlation lengths, the ABC, PEX, and fractal model each reduces to what we call the J-K model, defined in Eq. (43). This can be viewed as a new two-parameter finish model, where the magnitudes of J and m, or equivalently, K and n, are determined directly from experimental data without reference to any underlying model. On the other hand, the values of J and K can be written in terms of the parameters of the ABC, PEX, or fractal models leading to these high-frequency forms. For the fractal surfaces, for example,

$$K = \frac{m-2}{4\cdot\pi^{m-1}}\cdot\frac{\Gamma[1/2]\Gamma[(m-1)/2]}{\Gamma[(4-m)/2]}\cdot T^{4-m} \qquad S(f_x) = \frac{K}{|f_x|^{m-1}} \tag{48}$$

where $2 < m < 4$. This allows the topothesy T of a fractal scatterer to be determined from its high-frequency tail.

The observation of an inverse-power-law spectrum over a limited bandwidth does not guarantee that the surface is fractal. To do that one would have to observe low-frequency behavior conforming to Eqs. (24) and (25) as well, and confirm the unique wavelength and angular dependencies they imply.[34] Until then, power-law scattering over a finite bandwidth can at best be called "fractal-like" rather than fractal.

8.8 SURFACE FINISH SPECIFICATION

Performance Measures

It is desirable to express performance requirements on reflecting surfaces in terms of surface-finish parameters that can be measured by scatterometry or profilometry. One can concoct a wide variety of image-based performance measures.[35] For example, earlier we invoked an ambitious measure of image degradation based on the reduction of the on-axis image intensity, rather than the simpler measure based on the integrated image intensity suggested below.[36,37]

The simplest practical measure appears to place an upper limit on the average total scattering outside the specular core,

$$\langle \varepsilon^{\mathrm{FK,\,RR}} \rangle^{(2\mathrm{D})} = \frac{1}{R(\theta_i)} \int_{\substack{\text{outside} \\ \text{core}}}^{\infty} d\omega_f \cos(\theta_f) \langle \mathrm{BRDF}_{\alpha\to\alpha}^{(2\mathrm{D})} \rangle^{\mathrm{FK,\,RR}} = \frac{\lambda^2}{R(\theta_i)} \int_{\substack{\text{outside} \\ \text{core}}}^{\infty} d\mathbf{f}_{xy} \langle \mathrm{BRDF}_{\alpha\to\alpha}^{(2\mathrm{D})} \rangle^{\mathrm{FK,\,RR}}$$
$$\langle \varepsilon^{\mathrm{FK,\,RR}} \rangle^{(1\mathrm{D})} = \frac{1}{R(\theta_i)} \int_{\substack{\text{outside} \\ \text{core}}}^{\infty} d\theta_f \cos(\theta_f) \langle \mathrm{BRDF}_{\alpha\to\alpha}^{(1\mathrm{D})} \rangle^{\mathrm{FK,\,RR}} = \frac{\lambda}{R(\theta_i)} \int_{\substack{\text{outside} \\ \text{core}}}^{\infty} df_x \langle \mathrm{BRDF}_{\alpha\to\alpha}^{(1\mathrm{D})} \rangle^{\mathrm{FK,\,RR}} \tag{49}$$

For small correlation lengths the BRDF is flat at low frequencies, the omitted parts of the integrations in Eq. (49) can be neglected, and so

$$\langle \varepsilon^{\mathrm{FK,\,RR}} \rangle^{(2\mathrm{D})} = \langle \varepsilon^{\mathrm{FK,\,RR}} \rangle^{(1\mathrm{D})} = \left(4\pi \cos(\theta_i) \frac{\sigma}{\lambda} \right)^2 = g \tag{50}$$

where σ is the intrinsic rms roughness of the surface given by Eq. (40). In the earlier literature this result is called the total integrated scatter (TIS). This simple and beautiful expression for the image error permeates the wave-optics and microwave literature.[15]

In the limit of large correlation lengths, which is required to display inverse-power-law behavior, the BRDFs appearing in Eq. (49) diverge at low spatial frequencies. This leads to very different forms for the <ε>'s, which now depend on the bandwidth limits included in the error calculation.

In the J-K language of Eq. (43),

$$\langle \varepsilon_{\rho > L_{xy}}^{(2\mathrm{D})} \rangle = \left(4\pi \frac{\cos(\theta_i)}{\lambda} \right)^2 \cdot \frac{2\pi}{m-2} \cdot J L_{xy}^{m-2} \qquad \langle \varepsilon_{\rho > L_x}^{(1\mathrm{D})} \rangle = \left(4\pi \frac{\cos(\theta_i)}{\lambda} \right)^2 \cdot \frac{2}{m-2} \cdot K L_x^{m-2} \tag{51}$$

where L_{xy} and L_x are the *radii* of the excluded regions in Eq. (49).

Note that for statistically stationary surfaces the surface becomes perfectly smooth when $\sigma \to 0$, while for fractal surfaces this occurs when $T \to 0$.

Numerical Illustration

In an earlier paper we discussed the measurements of a silicon cylinder made with the LTP profiling instrument at Brookhaven National Laboratory.[37] These were fitted to the two-sided profile spectrum

$$S(f_x)^{(1\mathrm{D})} = \frac{K}{|f_x|^{m-1}} = \frac{3.32 \times 10^{-9}}{|f_x|^{1.61}} \mu\mathrm{m}^3 \qquad 10^{-5} < |f_x| < 10^{-1}\ \mu\mathrm{m}^{-1} \tag{52}$$

If fractal, this corresponds to $T = 8.36 \times 10^{-3}$ nm. If the surface is isotropic, the corresponding (2D) spectrum is

$$S(f_{xy})^{(2\mathrm{D})} = \frac{J}{f_{xy}^m} = \frac{1.45 \times 10^{-9}}{f_{xy}^{2.61}} \mu\mathrm{m}^4 \tag{53}$$

These allow us to evaluate the errors associated with the use of this mirror in 1D and 2D geometries.

If $\lambda = 10(-4)$ μm (0.1 nm), $\theta = (\pi/2) - 10^{-3}$ (i.e., 1 mrad glancing incidence), and $L_x = L_o = 0.1$ m,

$$\langle \varepsilon^{(2D)} \rangle = 26.5\% \quad \langle \varepsilon^{(1D)} \rangle = 19.3\% \tag{54}$$

The corresponding errors at $\lambda = 0.6328$ μm and at normal incidence are smaller than these by a factor of 0.025.

These results indicate that for the parameters used, this mirror would perform marginally well as a glancing-incidence x-ray mirror, but very well as a normal-incidence mirror at visible wavelengths, both in 1D and 2D applications.

Statistical Fluctuations

The discussion to this point has been concerned with ensemble average quantities $<U>$. Individual, deterministic measurements of U will fluctuate about this average by an amount measured by the dimensionless quantity

$$\gamma_U^2 = \frac{\langle (U - \langle U \rangle)^2 \rangle}{\langle U \rangle^2} = \frac{\langle U^2 \rangle}{\langle U \rangle^2} - 1 \tag{55}$$

The limit $\gamma_U \to 0$ indicates a perfect measurement while $\gamma_U \to 1$ is particularly bad.

An important example of this is the inverse-power-law sum that appears in the periodogram and effective mean-square roughness in Eqs. (49) through (51) for the J-K model:

$$U(n) = \sum_{j=1}^{\infty} \frac{1}{j^n} \quad \gamma_U = \frac{\sqrt{\zeta(2n)}}{\zeta(n)} \tag{56}$$

where $\zeta(n)$ is the Riemann zeta function. For the brownian fractal, $n = 2$, for example, $\gamma_U = \sqrt{(2/5)} = 0.632\ldots$. The Tchebycheff inequality then indicates that the sum U may be rather broadly distributed about $<U>$ except for n near unity.

γ_U vanishes when $n \to 1$ because the number of degrees of freedom included in the sum becomes infinite, and it approaches unity in the opposite limit of $n \to \infty$, since the sum then includes only a single term with two degrees of freedom, or a "single speckle."

If the fluctuations in $<\varepsilon>$ are unacceptably large, the lowest-order statistical description must be replaced by a deterministic version. Steps in this direction have been taken by Mori et al., Mimura et al., and Yamauchi et al.[38–40], for very high-performance x-ray mirrors. They have reported very accurate profile measurements of highly polished mirrors which they have correlated with image quality measurements made using the 1-km beam line at SPring-8. Unfortunately, the discussion of this interesting and important work lies outside the scope of the present chapter.

8.9 RETROSPECT AND PROSPECT

This chapter outlines methods for understanding the performance of mirror surfaces in terms of statistical models of their surface topography. We illustrate this making use of simple models that exhibit an inverse-power-law fall off at high spatial frequencies. Obvious follow-on steps are to expand the database, to relate residual roughness to finishing methods, to explore different and composite models, and examine measurement errors and instrumental effects in metrology.[41–44]

It is pointed out that the utility of certain statistical parameters may be limited by broad confidence limits. This suggests that a deterministic approach may be desirable for demanding applications, especially involving one-of-a-kind surfaces. Even so, the statistical approach provides deep insight into the physics involved, offers a pre-screening methodology, and will remain the lingua franca of this wide and diverse field in the future.

CREOL, The College of Optics and Photonics
University of Central Florida
Orlando, Florida

9.1 GLOSSARY

A	transversal area
C	correlation function
c	speed of light
D	diffusion constant
$\mathbf{D}$	degree of polarization
$\mathbf{E}$	field amplitude
$\mathbf{e}$	polarization direction
F	scattering form amplitude
f	forward-scattering amplitude
G	pair correlation function
g	asymmetry parameter
I	field intensity
$\mathbf{I}$	Stokes vector
$\mathbf{J}$	diffuse flux
$\mathbf{k}$	wave vector
K_B	Boltzman constant
$K_{K\text{–}M}$	effective absorption coefficient
l_a	absorption length
l_s	scattering length
l^*	transport mean free path
N	number of particles
n	refractive index
P	scattering phase function
$\mathbf{q}$	scattering wavevector

$\mathbf{r}, \mathbf{R}$	vector position
S	static structure factor
S	scattering potential
$\mathbf{s}$	specific direction
S_{K-M}	effective scattering coefficient
T	absolute temperature
t	time
T_{ab}	transmission coefficient
U	diffuse energy density
V	volume
v	volume fraction
ε	dielectric constant
η	shear viscosity
θ	scattering angle
λ	wavelength of light
μ_a	absorption coefficient
μ_s	scattering coefficient
ρ	number density
σ	scattering cross-section
ω	frequency
Ω	solid angle

9.2 INTRODUCTION

Electromagnetic radiation impinging on matter induces oscillating charges that can be further regarded as secondary sources of radiation. The morphological details and the microscopical structure of the probed medium determine the frequency, intensity, and polarization properties of this re-emitted (scattered) radiation. This constitutes the basis of a long history of applications of light scattering as a characterization tool in biology, colloid chemistry, solid state physics, and so on.

A substantial body of applications deals with light scattering by particles. These smaller or larger ensembles of molecules have practical implications in many industries where they are being formed, transformed, or manipulated. Since the early works of Tyndall and Lord Rayleigh,[1] the study of light scattering by molecules and small particles has been consistently in the attention of many investigators. Classical reviews of the field are the books by van de Hulst,[2] Kerker,[3] Bayvel and Jones,[4] Bohren and Huffman;[5] we also note the recent survey of techniques and theoretical treatments by Jones.[6] Why and how the light is scattered by small particles has already been described in Chap. 7, "Scattering by Particles," by Craig F. Bohren in this volume. Discussions on subjects related to light scattering can also be found in chapters like Chap. 5, "Coherence Theory," by William H. Carter and Chap. 12, "Polarization," by Jean M. Bennett.

For the topic of this chapter, light scattering by individual particles constitutes the building block of more complicated physical situations. When the three-dimensional extent of the medium that scatters the light is much larger than the typical size of a local inhomogeneity (scattering center), the physical process of wave interaction with matter can be classified as volume scattering. In this regime, the measured radiation originates from many different locations dispersed throughout the volume. Depending upon the structural characteristics of the medium, various scattering centers can act as secondary, independent sources of radiation (*incoherent scattering*) or they can partially add their contributions in a collective manner (*coherent scattering*). Another situation of interest happens when, for highly disordered systems, light is scattered successively at many locations throughout the volume (*multiple scattering*). All these three aspects of volume scattering will be discussed in this chapter.

In practice, particles very rarely exist singly and, depending on the illuminated volume or the volume seen by the detection system, scattering by a large number of particles needs to be considered. The simplest situation is that of *incoherent scattering*. When the fields scattered by different centers are completely independent, the measured intensity results from an intensity-based summation of all individual contributions. The ensemble of particles is described by temporal and spatial statistics which does not show up in scattering experiments; one can say that the volume scattering does not resolve the spatial arrangement of scattering centers.

When the scattering centers are sufficiently close, the phases of wavelets originating from individual scattering centers are not independent. This is the case of collective or *coherent scattering*. One faces the problem of expanding the scattering theories to ensembles of particles that can have certain degree of spatial or temporal correlations. A transition sets in from independent to coherent scattering regime. The situation is common for gels or composites which scatter light due to local inhomogeneities of the refractive index with length scales of the order of wavelength and where spatial correlations between the scattering centers are encountered. This is the basis of one of the most successful application of volume scattering: the observation of structural characteristics of inhomogeneous systems.

In the case of highly disordered systems, the light propagation can be subject of scattering at many different locations within the probed volume and a *multiple-scattering* regime sets in. For a long time, the intensity and phase fluctuations determined by multiple light scattering were regarded as optical "noise" that degrades the radiation by altering its coherence, broadening the beam, and decreasing its intensity. Experimentalists were trying to avoid it as much as possible and the development of comprehensive theories was not sufficiently motivated. Over the last two decades, however, remarkable advances in fundamental understanding and experimental methodologies proved that multiple scattering of waves is a source for unexplored physics leading to essentially new applications. New phenomena have been discovered and a series of experimental techniques have been implemented using particular coherent, polarization, temporal, and spectral properties of multiple scattered light. This revival of interest has been stimulated by the use of highly coherent sources in remote sensing and, especially, by considerable advances in solid-state physics. Many features of multiple scattered light are common to other classical waves like sound, heat, or microwaves but several analogies with electron transport phenomena have been at the core of this renewed interest in the propagation of optical waves in random systems.[7]

There is also another situation, which is often encountered in optics, when waves propagate through media with abrupt changes in their optical properties. Waves passing through inhomogeneous media with defined boundaries usually suffer surface scattering. In principle, scattering at rough surfaces can be considered as a limiting case of wave propagation and it is significant in various practical situations; this topic has been separately discussed in Chap. 8, "Surface Scattering," by Eugene L. Church and Peter Z. Takacs in this volume.

9.3 GENERAL THEORY OF SCATTERING

The schematic of a typical scattering experiment is depicted in Fig. 1, where a plane wave $\mathbf{E}^0$ with the wavevector $k=\omega/c$ is incident on a spatially random medium occupying a finite volume V. Light is scattered by local inhomogeneities of the dielectric constant $\varepsilon(\mathbf{r})$ and a basic theory of scattering aims at providing the link between the experimentally accessible intensity $I_s(\mathbf{R})=|\mathbf{E}_s(\mathbf{R})|^2$ and the microscopic structure of the random medium.

The starting point of the theory is to describe the total electric field $\mathbf{E}(\mathbf{r})$ as a summation of the incoming and scattered fields and to consider that it satisfies the equation $(\nabla^2+k^2)\mathbf{E}(\mathbf{r})=-4\pi S(\mathbf{r})\mathbf{E}(\mathbf{r})$, where $\mathbf{S}(\mathbf{r})$ represents a generic scattering potential. This equation can be converted into an integral one and, for $\mathbf{R}$ sufficiently far from the scattering volume where the associated Green function simplifies, one eventually obtains the general result[3,8]

$$\mathbf{E}_s(\mathbf{R})=\frac{e^{ikR}}{R}\frac{k^2}{4\pi}\int_{(V)}d\mathbf{r}\{-\mathbf{k}_s\times[\mathbf{k}_s\times(\varepsilon(\mathbf{r})-1)\cdot\mathbf{E}(\mathbf{r})]\}e^{-i\mathbf{k}_s\cdot\mathbf{r}} \tag{1}$$

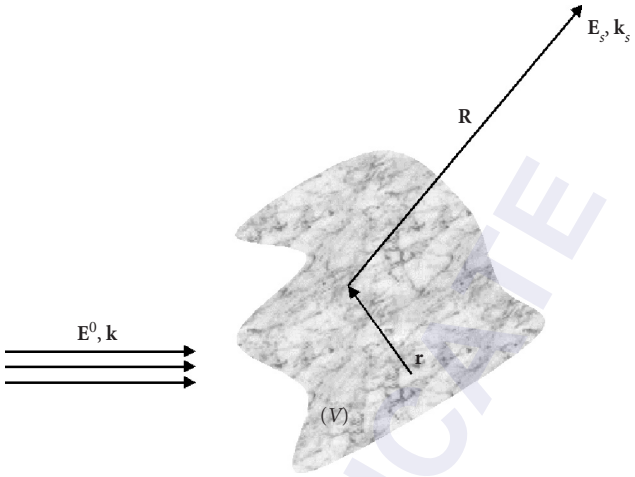

FIGURE 1 Schematic representation of the incident $\mathbf{k}$ and scattered $\mathbf{k}_s$ beams in a generic scattering experiment.

This expression represents the scattered field as an outgoing spherical wave that depends on the direction and magnitude of the total field inside the scattering volume V.

Approximate solutions can be obtained for the case of weak fluctuations of the dielectric constant. One can expand the field $\mathbf{E}(\mathbf{r})=\mathbf{E}^0(\mathbf{r})+\mathbf{E}_1(\mathbf{r})+\mathbf{E}_2(\mathbf{r})+\cdots$ in terms of increasing orders of the scattering potential and use successive approximations of $\mathbf{E}(\mathbf{r})$ in Eq. (1) to obtain the so-called Born series. In the spirit of a first iteration, one replaces $\mathbf{E}(\mathbf{r})$ with $\mathbf{E}^0(\mathbf{r})$ and obtains the first Born approximation that describes the regime of single scattering.

Alternatively, one can write $\mathbf{E}(\mathbf{r})=\exp[\Psi(\mathbf{r})]$ and develop the series solution for $\Psi(\mathbf{r})$ in terms of increasing orders of the scattering potential. This is the Rytov's series of exponential approximations, an alternative to the algebraic series representation of the Born method. The two approaches are almost equivalent, however, preference is sometimes given to Rytov's method because an exponential representation is believed to be more appropriate to describe waves in line-of-sight propagation problems.[9–11]

It is worth pointing out here that Eq. (1) can be regarded as an integral equation for the total field and, because the total field is a superposition of the incident field and contributions originating from scattering from all volume V, this generic equation includes all possible multiple scattering effects.[8,12]

9.4 SINGLE SCATTERING

Incoherent Scattering

When a sparse distribution of scattering centers is contained in the volume V, all the scattering centers are practically exposed only to the incident field, $\mathbf{E}(\mathbf{r})=\mathbf{E}^0(\mathbf{r})=E^0\mathbf{e}^0e^{i\mathbf{k}\cdot\mathbf{r}}$ where E^0 is the field magnitude, $\mathbf{e}^0$ is the polarization direction, and $\mathbf{k}$ is the wave vector. A considerable simplification is introduced when the magnitude of the scattered field is much smaller than that of the incident field, such that the total field inside the medium can be everywhere approximated with the incident field. This is the condition of the first Born approximation for tenuous media that practically neglects multiple scattering effects inside the scattering volume V. From Eq. (1), it follows that

$$\mathbf{E}_s(\mathbf{R})=E^0\frac{e^{ikR}}{R}\frac{k^2}{4\pi}\int_{(V)}d\mathbf{r}[\mathbf{e}^s\cdot(\varepsilon(\mathbf{r})-1)\cdot\mathbf{e}^0]e^{-i\mathbf{k}_s\cdot\mathbf{r}} \tag{2}$$

For instance, in the case of a system of N identical particles, Eq. (2) is evaluated to give

$$\mathbf{E}_s(\mathbf{R}) = E^0 \frac{e^{ikR}}{R} \frac{k^2}{4\pi} \sum_{j=1}^{N} e^{-i\mathbf{k}_s \cdot \mathbf{r}_j} \int_{(V_j)} d\mathbf{r} [\mathbf{e}^s \cdot (\boldsymbol{\varepsilon}(\mathbf{r}) - 1) \cdot \mathbf{e}^0] e^{-i\mathbf{k}_s \cdot \mathbf{r}} \tag{3}$$

where V_j is the volume of the jth particle located at $\mathbf{r}_j$. In terms of the scattering wavevector $\mathbf{q} = \mathbf{k}_s - \mathbf{k}$, the integral in Eq. (3) has the meaning of single-scattering amplitude of the jth particle, $F(\mathbf{q}) = |f| \cdot B(\mathbf{q})$, and depends on the forward scattering amplitude f and a scattering amplitude normalized such that $B(0) = 1$. As explained in Chap. 7 in this volume, the ratio between the refractive index of the particles n_p and of the suspending medium n_s determine the scattering strength f of an individual scatterer while its shape and size are accounted for in $B(\mathbf{q})$.

For a collection of discrete scattering centers the total scattered intensity of Eq. (3) factorizes like:[13]

$$I(\mathbf{q}) = \left(E_i \frac{e^{ikR}}{R} \frac{k^2}{4\pi} \right)^2 NF^2(\mathbf{q}) \sum_{i,j=1}^{N} e^{-i\mathbf{q} \cdot (\mathbf{r}_i - \mathbf{r}_j)} : NP(\mathbf{q}) S(\mathbf{q}) \tag{4}$$

where we separated the single-scattering form factor $P(\mathbf{q})$ from the interference function or the static structure factor $S(\mathbf{q}) = \sum_{i,j=1}^{N} e^{-i\mathbf{q} \cdot (\mathbf{r}_i - \mathbf{r}_j)}$. The structure factor quantifies the phase-dependent contributions due to different locations of scattering centers. When an ensemble average is taken over the volume V and after separating out the diagonal terms, the static structure factor can be written as[13,14]

$$S(\mathbf{q}) = 1 + \langle e^{-i\mathbf{q} \cdot (\mathbf{r}_i - \mathbf{r}_j)} \rangle = 1 + \rho \int G(\mathbf{r}) e^{-i\mathbf{q} \cdot \mathbf{r}} d\mathbf{r} \tag{5}$$

in terms of the pair-correlation function $G(\mathbf{r})$ (where $\mathbf{r}$ is the vectorial distance between two particles), describing the statistical properties of the spatial arrangement of scattering centers. It is through $S(\mathbf{q})$ that the link is made between the statistical mechanics description of the inhomogeneities and the measurable quantities in a scattering experiment.

As can be seen from Eq. (5), for the case of particles separated by distances much larger than the wavelength, $S(\mathbf{q})$ becomes unity; the situation corresponds to $G(\mathbf{r}) \equiv 1$, i.e., constant probability to find scattering centers anywhere in the scattering volume. This regime characterized by $S(\mathbf{q}) = 1$ is also called the incoherent case of volume scattering where $I(\mathbf{q})$ is a simple, intensity-based summation of individual contributions originating from different scattering centers.

Coherent Scattering

For higher volume fractions of particles, the pair-correlation function depends on both the particle size and their concentration. The estimation of the pair-correlation functions—and, therefore, the evaluation of an explicit form for the structure factor—is a subject of highest interest and is usually approached through various approximations.[15]

Typical structure factors are shown in Fig. 2 for increasing volume fractions of spherical particles with radius r_0. These results are based on the Percus-Yevick approximation,[16,17] which has the advantage of being available in a closed mathematical form but the trend shown in Fig. 2 is rather general. Note that the strength of the interparticle interactions is practically measured by the magnitude of the first peak in $S(q)$.[13,14]

In general, wave-scattering experiments can be used to infer the pair-correlation function of the scattering centers in a random medium and, meanwhile, the characteristic of an individual scattering event. In an ideal experiment where one has access to all the values of $I(\mathbf{q})$ and the single-scattering phase function $P(\mathbf{q})$ is known, Eq. (3) can be inverted by standard methods.[17,18] Capitalizing on conventional types of single-scattering form factors, various inversion schemes have been implemented to extract the structure factor from the values of angular-resolved intensity.[19]

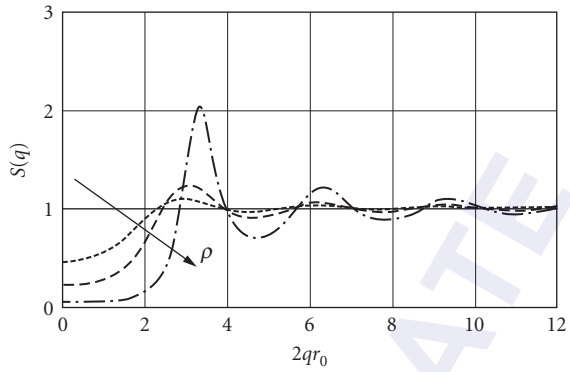

FIGURE 2 Typical structure factors corresponding to systems of identical spherical particles with increasing volume fractions as indicated. The horizontal line at $S(q)=1$ corresponds to the independent scattering approximation.

Convergence and stability in the presence of noise are the major requirements for a successful inversion procedure and a subsequent Fourier analysis to provide a description of the pair-correlation function. Of course, for systems of nonspherical particles or when the system exhibits structural anisotropies, a fully vectorial inverse problem needs to be approached.

The factorization approximation of Eq. (4) has found numerous applications in optical-scattering experiments for characterization of colloidal, polymeric, and complex micellar systems. Numerous static and dynamic techniques were designed to probe the systems at different length and time scales. For example, reaction kinetics or different phase transitions have been followed on the basis of angular and/or temporal dependence of the scattered intensity.[19] Another significant body of applications deals with light-scattering studies of aggregation phenomena.[20–22]

We should not conclude this section without mentioning here the similarities between volume light scattering and other scattering-based procedures such as x-ray and neutron scattering. Of course, the "scattering potentials" and the corresponding length scales are different in these cases but the collective scattering effects can be treated in a similar manner. From a practical viewpoint, however, light scattering has the appealing features of being noninvasive and, most of the time, easier to implement.

The average power scattered by a single particle is usually evaluated using the physical concept of total scattering cross-section $\sigma = k^{-4}\int_0^{2k} P(q)q\,dq$.[2,3,18] For a system with a number density $\rho = N/V$ of scattering centers, the regime of scattering is characterized by a *scattering length* $l_s = 1/\rho\sigma$. When the extent over which the wave encounters scattering centers is less than this characteristic scattering length l_s, we deal with the classical single-scattering regime. Note that the system of particles can be in the single-scattering regime and exhibit both independent or collective scattering. From the general theory of scattering it follows that the details of the scattering-form factor depend on the size of scattering particle compared to the wavelength. The deviation of the scattering-form factor from an isotropic character is characterized by the asymmetry parameter $g = \langle\cos(\theta)\rangle = 1 - 2\langle q^2\rangle/(2k)^2$, where $\langle q^2\rangle = k^{-2}\int_0^{2k} p(q)q^3\,dq$.[2,18]

As we have seen in the preceding section, when the particles are closely packed the scattering centers are not independent, i.e., they are sufficiently close that the fields scattered by different centers are partially in phase, collective scattering is considered through the static structure factor $S(q)$. The effect of wave coupling to an individual particle can therefore be isolated from the statistical mechanics description of the particle locations in the volume. In this regime, one can consider the dispersion of correlated particles as a collection of pseudo-scattering centers, *equivalent particles*, that are characterized by a modified single-scattering form factor $P(q)S(q)$. There is no interaction

between these fictitious particles and a corresponding single-scattering phase function can also be defined to be:

$$\widetilde{P(q)} = \frac{k^2 |f|^2 \cdot |B(q)|^2 S(q)}{\int_0^{2k} |f|^2 \cdot |B(q)|^2 S(q) q \, dq} \tag{6}$$

The asymmetry parameter of these pseudo-particles can be written as

$$\tilde{g} = 1 - \frac{\int_0^{2k} |f|^2 \cdot |B(q)|^2 S(q) q^3 dq}{2k^2 \int_0^{2k} |f|^2 \cdot |B(q)|^2 S(q) q \, dq} \tag{7}$$

The equivalent-particle concept is illustrated in Fig. 3, where both the phase function and asymmetry parameters are presented for the specific case of silica particles suspended in water. This simplifying representation of coherent scattering effects is useful to further interpret complex, multiple scattering phenomena.

Dynamic Scattering

So far, we limited the discussion to the case where the scattering potential varies across the volume V but, at a certain location, it remains constant in time. However, many physical systems are such that the volume distribution of scattering centers fluctuates in time and, therefore, gives rise to temporal fluctuations of the scattered radiation, i.e., to dynamic scattering. A complete analysis of light scattering involves the autocorrelation function of the dielectric constant fluctuations $\langle \varepsilon^*(\mathbf{r}, 0), \varepsilon(\mathbf{r}, t) \rangle$ that manifests itself in the statistics of the temporal fluctuations of the measured light intensity. Evaluation of such correlation functions requires knowledge of the transport properties of the volume medium and is based on statistical mechanics and many-body theory. In spite of the rather complex phenomenology, different photon correlation techniques have been successfully implemented in studies of reacting systems, molecular dynamics, or atmospheric scintillations.

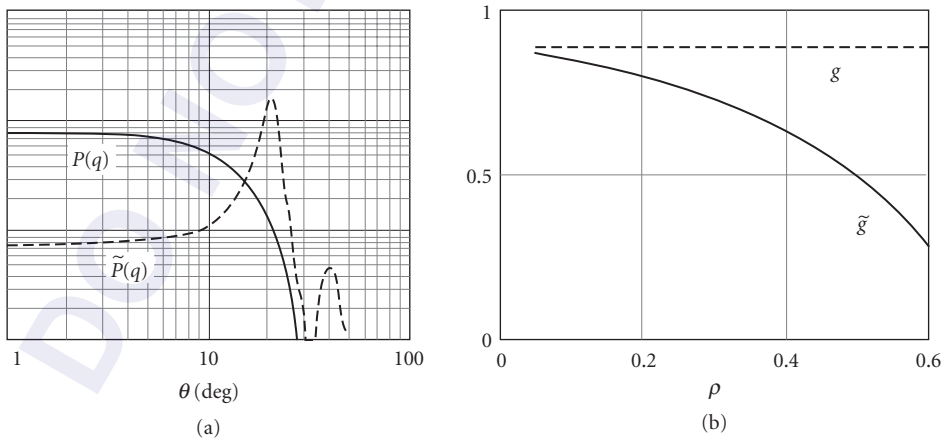

FIGURE 3 (*a*) Single scattering form factor $P(q)$ corresponding to silica particles of 0.476 μm placed in water and illuminated with $\lambda = 0.633$ μm and the form factor $P(q)$ of an equivalent particle corresponding to a collection of such particles at the volume fraction $\rho = 0.5$. (*b*) Values of the asymmetry parameter for one silica particle and for a colection of of particles with an increasing volume fraction as indicated.

The benchmarks of the dynamic light scattering have been set in the seventies.[23,24] An interesting and useful particularity stems from the fact that, based on dynamic scattering, one can actually measure mechanical properties in the scattering volume without knowledge of the refractive index. Random motion of scattering centers induces small Doppler frequency shifts which, in turn, produce an overall broadening of the incident spectrum of light. The detection methods for such spectral changes depend primarily on the time scales of interest and range from high-resolution spectroscopy for very fast phenomena to various mixing or beating techniques for processes slower than about 1 ms.

Based on comparing the scattering signal with itself at increasing time intervals, photon correlation spectroscopy (PCS) has emerged as a successful technique for the study of volume distributions of small particles suspended in fluids.[25] Practically, one deals with the time-dependent fluctuations of the speckle pattern and the goal is to determine the temporal autocorrelation function $\langle E(0)E^*(t)\rangle$, which probes the microscopic dynamics. For instance, in the simple case of a monodisperse and noninteracting system of brownian particles, $\langle E(0)E^*(t)\rangle$ is a single exponential that depends on the diffusion constant $D=k_BT/6\pi\eta r_0$. Knowing the absolute temperature T and the shear viscosity η of the solvent, one can infer the particle radius r_0. Similar to the case of static scattering discussed previously, refinements can be added to the analysis to account for possible dynamic structuring, polydispersivity as well as asphericity effects.[19,23,26]

9.5 MULTIPLE SCATTERING

When optical waves propagate through media with random distributions of the dielectric constant or when they encounter extended regions containing discrete scatterers or random continuum, one needs to solve a wave equation in the presence of large number of scattering centers; this is a difficult task and, as we will discuss, a series of simplifying approaches have been proposed. A survey of multiple scattering applications is presented by van de Hulst.[27]

Effective-Medium Representation

Some physical insight is given by a simple model, which describes the wave attenuation due to scattering and absorption in terms of an effective dielectric constant. Without explicitly involving multiple scattering, one considers the wave propagation through an homogeneous *effective-medium* which is defined in terms of averaged quantities. The effective permittivity ε_{eff} is calculated by simply considering the medium as a distribution of spheres with permittivity ε embedded in a continuum background of permittivity ε_0. If a wave with the wavelength much larger than the characteristic length scales (size of inhomogeneity and mean separation distance) propagates through a volume random medium, the attenuation due to scattering can be neglected; therefore, a frequency-independent dielectric constant will appropriately describe the medium. Based on an induced dipoles model, the Maxwell-Garnett mixing formula relates the effective permittivity to the volume fraction v of spheres $\varepsilon_{\text{eff}}=\varepsilon(1+2va)/(1-va)$, where $a=(\varepsilon-\varepsilon_0)/(\varepsilon+2\varepsilon_0)$.[28]

In recent developments, the wave propagation through highly scattering media has been described by including multiple scattering interactions in a mean-field approach. This is simply done by considering that the energy density is uniform when averaged over the correlation length of the microstructure.[29] Through this effective medium, a "coherent" beam propagates with a propagation constant that includes the attenuation due to both absorption and scattering. In general, the propagation of the coherent beam is characterized by a complex index of refraction associated with the effective medium and a nontrivial dispersion law can be determined by resonant scattering.[30] It is worth mentioning that, in the long-wavelength limit, the attenuation due to scattering is negligible and the classical mixture formula for the effective permittivity applies.

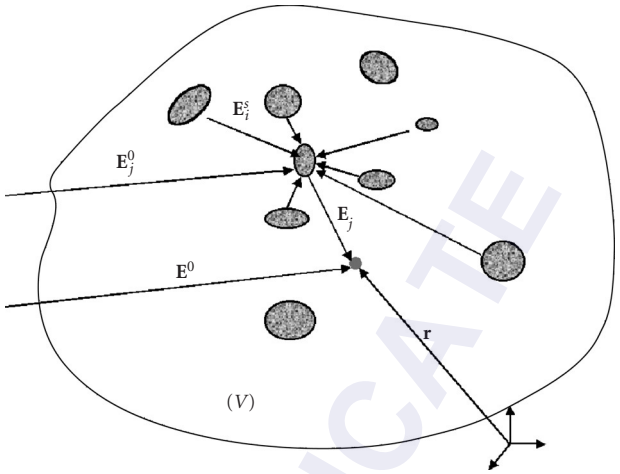

FIGURE 4 The field at $\mathbf{r}$ is a summation of the incident filed $\mathbf{E}^0$ and contributions $\mathbf{E}_j$ from all other scattering centers; in turn, the effective field on each particle consists of an incident contribution $\mathbf{E}_j^0$ and contributions $\mathbf{E}_i^s$ from all other scattering centers.

Analytical Theory of Multiple Scattering

A rigorous description of multiple light-scattering phenomena can be made if statistical considerations are introduced for quantities such as variances and correlation functions for $\varepsilon(\mathbf{r})$ and general wave equations are subsequently produced. The advantage of an analytical theory is that the general formulation does not require a priori assumptions about the strength of individual scattering events nor about the packing fraction of scattering centers. The drawback, however, is that, in order to deal with the complexity of the problem, one needs to use quite involved approximations and, sometimes, rather formal representations.

Multiple Scattering Equations As shown in Fig. 4, when the field $\mathbf{E}^0$ is incident on a random distribution of N scattering centers located at $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N$ throughout the scattering volume V, the total field at one particular location inside V is the sum of the incident wave and the contributions from all the other particles

$$\mathbf{E} = \mathbf{E}^0 + \sum_{j=1}^{N} \mathbf{E}_j \tag{8}$$

the field scattered from the jth particle depends on the effective field incident on this particle and its characteristics (scattering potential) S_j

$$\mathbf{E}_j = \mathrm{S}_j \left(\mathbf{E}_j^0 + \sum_{i=1, i\neq j}^{N} \mathbf{E}_i^s \right) \tag{9}$$

It follows from Eqs. (8) and (9) that the total field can be formally written as

$$\mathbf{E} = \mathbf{E}^0 + \sum_{j=1}^{N} \mathrm{S}_j \left(\mathbf{E}_j^0 + \sum_{j=1}^{N} \sum_{i=1, i\neq j}^{N} \mathrm{S}_i \mathbf{E}_i^s \right) \tag{10}$$

which is a series of contributions from the incident field, single scattering, and increasing orders of multiple scattering.[18] In principle, knowing the scattering characteristics S_j of individual centers (this includes strength and location), one can develop the analytical approach by involving chains of successive scattering paths. From the summations in Eq. (10), by neglecting the scattering contributions that contain a scatterer more than once, Twersky has developed an expanded representation of multiple scattering which is practical only for cases of low-order scattering.[31]

Approximations of Multiple Scattering Rigorous derivation of multiple scattering equations using the Green's function associated with the multiple-scattering process and a system-transfer-operator approach (the T-matrix formalism) can be found in.[32–34] However, in many cases of practical interest, a very large number of scattering centers needs to be involved and it is impossible to obtain accurate descriptions for either the T-matrix or the Green's function.

When large ensembles of scatterers are involved, a statistical description of the multiple scattering equations is appropriate. Probability density functions for finding scattering centers at different locations are determined by radial distribution function in a similar way as discussed in the context of correlated scattering. This expresses both the constraint on the particle locations and the fact that they are impenetrable. By using configuration-averaging procedures, self-consistent integral equations can be obtained for the average and fluctuating parts of the field produced through multiple scattering. When such a procedure is applied to Eq. (10),

$$\langle \mathbf{E} \rangle = \mathbf{E}^0 + \int S_j \mathbf{E}_j^0 G(\mathbf{r}_j) d\mathbf{r}_j + \int\int S_i S_j \mathbf{E}_i^0 G(\mathbf{r}_i) G(\mathbf{r}_j) d\mathbf{r}_i d\mathbf{r}_j + \cdots \tag{11}$$

a hierarchy of integral equations is generated and successive approximations are obtained by truncating the series at different stages. In fact, this expanded form has a more physically understandable representation in terms of the average field $\langle \mathbf{E}_j \rangle$ at the location of a generic particle j:

$$\langle \mathbf{E} \rangle = \mathbf{E}^0 + \int S_j \langle \mathbf{E}_j \rangle G(\mathbf{r}_j) d\mathbf{r}_j \tag{12}$$

Foldy was the first to introduce the concept of configurational averaging and used the joint probability distribution for the existence of a given configuration of scattering centers to average the resulting wave over all possible configurations.[35] However, Foldy's approximation is appropriate for wave propagation in sparse media with a small fractional volume of scatterers.

A comprehensive discussion on multiple scattering equations and various approaximations can be found in Tsang's book[34] including the quasi-crystalline approximation[36] and coherent potential[37] approximations.

Radiative Transfer

The drawback of an analytical theory of multiple scattering is that it is too complicated; for systems with volume disorder often encountered in realistic situations, the scattering phenomena depends essentially on the ratio between the characteristic length scales of the system and the radiation wavelength. A statistical description in terms of such characteristic scattering lengths is usually sufficient. In general, the particular location, orientation, and size of a scattering center is irrelevant and the underlying wave character seems to be washed out. Because energy is transported through multiple scattering processes, what matters is only the energy balance. Of course, this approach cannot account for subtle interference and correlation effects but refinements can be developed on the basis of a microscopic interpretation of radiative transfer.[38]

A comprehensive mathematical description of the nonstationary radiative transport is given by both Chandrasekhar[39] and Ishimaru.[18] The net effect of monochromatic radiation flow through a medium with a density ρ of scattering centers is expressed in terms of a modified Stokes vector

$$\mathbf{I}(\mathbf{r}, \mathbf{s}, t) = [\langle E_1^* E_1 \rangle + \langle E_2^* E_2 \rangle, \langle E_1^* E_1 \rangle - \langle E_2^* E_2 \rangle, Re\{\langle E_1^* E_2 \rangle\}, Im\{\langle E_1^* E_2 \rangle\}]^T$$

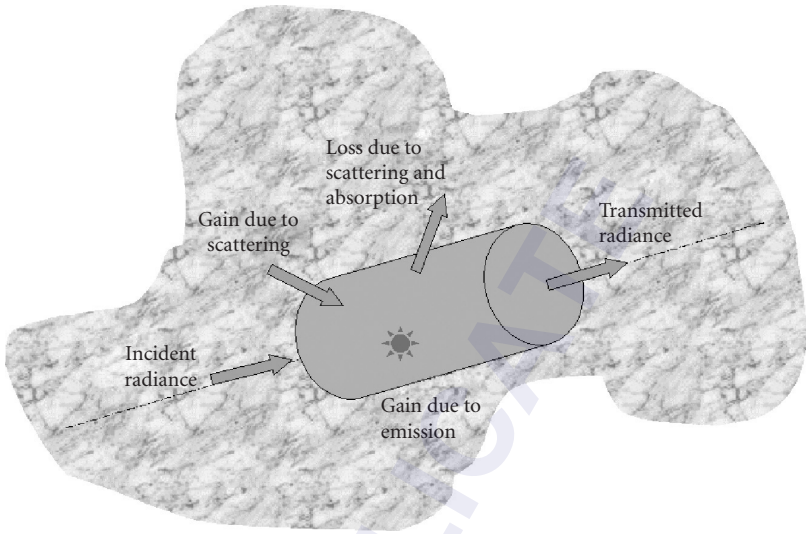

FIGURE 5 Loss-gain balance in a differential volume element; the incident radiance is attenuated by both absorption inside and scattering out of the volume element but it can be increased by ambient scattering and emission within the volume.

This quantity is a vectorial equivalent to the radiance where each element can be defined as the amount of energy in a given state that, at the position **r**, flows per second and per unit area in the direction **s**. When radiation propagates over the distance *ds*, there is a loss of specific intensity due to both scattering and absorption $d\mathbf{I} = -\rho(\sigma_{sc} + \sigma_{abs})\mathbf{I}ds$. In the mean time, there is a gain of specific intensity due to scattering from a generic direction **s**′ into the direction **s** quantified by the tensoral scattering phase function (Mueller matrix) $P(\mathbf{s}', \mathbf{s})$. Also, there could be an increase, $\varepsilon(\mathbf{r}, \mathbf{s}, t)$, of specific intensity due to emission within the volume of interest and the net loss-gain balance which is illustrated in Fig. 5, and represents the nonstationary radiative transfer equation:[18]

$$\left[\frac{1}{c}\frac{\partial}{s\partial t} + \mathbf{s}\cdot\nabla + \rho(\sigma_{sc} + \sigma_{abs})\right]\mathbf{I}(\mathbf{r}, \mathbf{s}, t) = \rho\sigma_{sc}\int P(\mathbf{s}', \mathbf{s})(\mathbf{r}, \mathbf{s}, t)d\Omega + \varepsilon(\mathbf{r}, \mathbf{s}, t) \tag{13}$$

No analytical solution exists for the transfer equation and, in order to solve specific problems, one needs to assume functional forms for both the phase function and the specific intensity. Various methods have been used to approach the transient scalar RTE.[40–43] Cheung and Ishimaru[44] and Kim et al.[45] approached the steady state vector RTE using a Fourier analysis. Vaillon et al.[46] used a vector Monte Carlo method to analyze the radiative transfer in a particle-laden semitransparent medium. Jiang et al. presented a model for the atmospheric radiative transfer with polarization for remote-sensing applications.[47] Ma and Ishimaru used an eigenvalue-eigenfunction technique to solve numerically the vector radiative transfer equation.[48] To solve the problem of polarized pulse propagation in random media, Ishimaru et al.[49] used the discrete-ordinates method by expanding the Stokes vector in a Fourier series. Successive orders of approximation are obtained by spherical harmonic expansion of the specific intensity; for instance, the so-called P_1 approximation is obtained when the diffuse radiance is expressed as a linear combination of an isotropic radiance and a second term modulated by a cosine.[18]

Diffusion Approximation Perhaps one of the most widely used treatment for multiple light scattering is the diffusion approach. When (i) absorption is small compared to scattering, (ii) scattering is almost isotropic, and (iii) the radiance is not needed close to the source or boundaries

then the diffusion theory can be used as an approximation following from the general radiative transfer theory. To get insight into the physical meaning of this approximation it is convenient to define quantities that are directly measurable such as the diffuse energy density (average radiance) $U(\mathbf{r}, t)=\int_{4\pi}\mathbf{I}_0(\mathbf{r}, \mathbf{s}, t)d\Omega$ and the diffuse flux $\mathbf{J}(\mathbf{r}, t)=\int_{4\pi}\mathbf{I}(\mathbf{r}, \mathbf{s}, t)\mathbf{s}d\Omega$. In the diffusion approximation, the diffuse radiance is approximated by the first two terms of a Taylor's expansion:[8,50]

$$\mathbf{I}_0(\mathbf{r}, \mathbf{s}, t)\approx U(\mathbf{r}, t)+\frac{3}{4\pi}\mathbf{J}(\mathbf{r}, t)\cdot\mathbf{s} \tag{14}$$

and the following differential equation can be written for the average radiance

$$D\nabla^2U(\mathbf{r}, t)-\mu_aU\left(\mathbf{r}, t\right)-\frac{\partial U(\mathbf{r}, t)}{\partial t}=S(\mathbf{r}, t) \tag{15}$$

The isotropic source density is denoted by $S(\mathbf{r}, t)$ and D is the diffusion coefficient which is defined in units of length as

$$D=\frac{1}{3[\mu_a+\mu_s(1-g)]} \tag{16}$$

in terms of the absorption μ_a and μ_s scattering coefficients. The diffusion equation is solved subject to boundary conditions and source specifics; most appealing is the fact that analytical solutions can be obtained for reflectance and transmittance calculations.

Because the phase function is characterized by a single anisotropy factor, the diffusion approximation provides mathematical convenience. Through renormalization, an asymmetry-corrected scattering cross-section that depends only on the average cosine of scattering angle defines the diffusion coefficient in Eq. (16) and, therefore, an essentially anisotropic propagation problem is mapped into an almost isotropic (diffusive) model.

The photon migration approach based on the diffusion approximation has been very successful in describing the interaction between light and complex fluids[51] or biological tissues.[52,53] It is instructive to note that three length scales characterize the light propagation in this regime: the absorption length $l_a=\mu_a^{-1}$ which is the distance traveled by a photon before it is absorbed, the scattering length $l_s=\mu_s^{-1}$ which is the average distance between successive scattering events, and the transport mean free path $l^*=l_s/(1-g)$ that defines the distance traveled before the direction of propagation is randomized. In experiments that are interpreted in the frame of the diffusion approximation, l^* is the only observable quantity and, therefore, the spatial and temporal resolution are limited by l^* and l^*/c, respectively.

Under appropriate boundary conditions, such as a mixed boundary condition in which the diffuse energy density vanishes linearly on a plane, the steady state diffusion equation can be solved and the photon flux is obtained from Fick's law.[54] Assuming an average energy transport velocity, the path length dependence of the energy flux can be evaulated yielding a path length probability distribution, $p(s)$, which can be regarded as the probability distribution of optical path lengths that correspond to waves that have traveled through the medium along closed loops and have also accumulated a total momentum transfer equal to $4\pi/\lambda$.

Low-Order Flux Models for Radiative Transfer In an effort to describe the optical properties of highly scattering materials while reducing the computational difficulties, simplifying *flux models* have been designed for the radiative energy transport. A volume scattering medium consisting of a collection of scattering centers is described as homogeneous material characterized by effective scattering and absorption properties that are determined by its internal structure.

In this approach, the fundamental equation of radiative transfer is based on the balance between the net flux change, the flux input, and flux continuing out in an infinitesimal volume. Assuming two diffusing components, a one-dimensional model based on plane symmetry for unit cross-section has been initially proposed by Schuster.[55] One of the most successful extensions of this model is the so-called

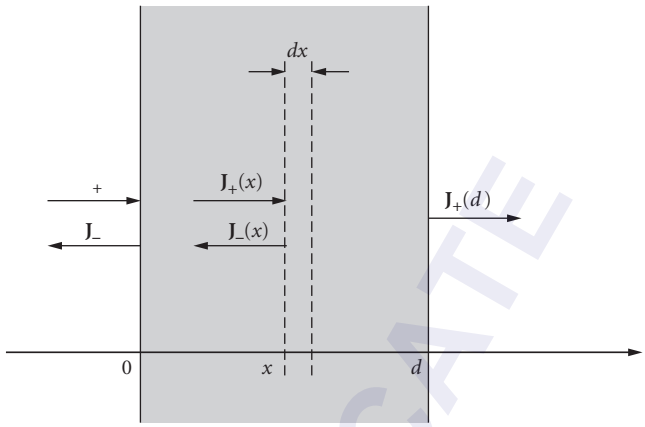

FIGURE 6 The two-flux approximation applied to radiative transfer through a diffusive layer.

Kubelka-Munk theory[56] which relates the phenomenological, effective scattering S_{K-M} and absorption K_{K-M} coefficients to measurable optical properties such as diffuse reflectance or transmittance.

The two-flux model, Kubelka-Munk theory, is schematically illustrated in Fig. 6. Diffuse radiation is assumed to be incident on the slab; the diffuse radiant flux in the positive x direction is $\mathbf{J}_+$ while the one returning as a result of scattering is $\mathbf{J}_-$. The net flux balance at a distance x across an infinitesimal layer of thickness dx is

$$\begin{aligned} d\mathbf{J}_+ &= -(K_{K-M}+S_{K-M})\mathbf{J}_+ dx + s\mathbf{J}_+ dx \\ d\mathbf{J}_- &= +(K_{K-M}+S_{K-M})\mathbf{J}_- dx - s\mathbf{J}_+ dx \end{aligned} \tag{17}$$

where the coefficient K_{K-M} determines the flux attenuation due to absorption while S_{K-M} accounts for the net flux scattered between forward and backward directions. The solution of the simultaneous differential equations of the first order in one dimension is obtained by applying the boundary conditions for the layer shown in Fig. 6. The diffuse reflectance of the substrate at $x=d$ can also be accounted for and expressions for the total diffuse reflection and transmission are found for a specific application. In practical applications of the Kubelka-Munk theory, the effective scattering and absorption parameters are inferred by iteration from measurements of diffuse reflectance or transmission.

A considerable body of work was dedicated to relate the Kubelka-Munk parameters to microstructure and to incorporate both the single- and multiple-scattering effects. Refinements and higher-order flux models have also been developed. A more accurate model that accounts for the usual condition of collimated incident radiation was elaborated by J. Reichman.[57] A four-flux model has been developed that includes certain anisotropy of the scattered radiation.[58] A six-flux model was implemented to incorporate the effect of particle shape and interparticles correlation.[59] In spite of the fact that it is based on empirical determination of coefficients and that its range of applicability is rather unclear, the simple-to-implement Kubelka-Munk theory makes reasonably good description of experiments and has found applications in areas such as coatings, paper, paints, pigments, medical physics, and atmospheric physics.

Specific Effects in Multiple Light Scattering

The effects associated with light propagation through multiple scattering media depend on the scale of observation. An interesting analogy exists between optical and electron waves propagation in mesoscopic systems and, based on recent developments in solid state physics, useful insights have

been provided for a range of multiple scattering phenomena.[7,60] It is clear now that multiple light scattering in volume disorder does not merely scramble a coherent incident wave. In fact, the apparent randomness of the scattered field conceals intriguing and sometimes counter intuitive effects such as the enhancement of the backscattered intensity and a range of correlations and statistics of vector waves.

Weak Localization Until recently, the coherent light propagating through random media has been considered to be somehow *degraded,* losing its coherence properties. However, recent experiments have brought evidence of the enhanced backscattering of light due to interference between the waves taking time-reversed paths,[61] an effect which is associated with the more general phenomenon for the weak localization of waves in random media.[62,63] First found in solid state physics more than 30 years ago, this phenomenon is applicable to all classical waves. Surveys of the state of the art in the optical counterpart of weak localization can be found in Refs. 64 and 65.

When coherent light is scattered by a medium with volume randomness, interference effects between the scattered waves which traveled through the medium along different paths occur. The result is a random pattern of interference called *laser speckle*. Because the correlations in this granular pattern extend over angular scales of typically 10^{-3} rad or less, when the individual scatterers are allowed to move over distances of the order of the wavelength or more, the distribution of intensities in the speckle pattern is rapidly averaged out and becomes essentially flat. So far, however, it is well understood and widely recognized that one kind of interference still survives in this average. This is the interference of the waves emerging from the medium in directions close to exact backscattering and which have traveled along the *same path* but in *opposite* directions.

The pairs of time-reversed light paths have some particularities which can be easily understood in the general context of the waves scattered by random media. In Fig. 7, the main contributions to scattering from a dense distribution of scatterers are presented together with their angular dependence. In the narrow angle of interest, the single scattering $I^{(s)}$ and the ladder term of multiple scattering $I^{(\mathrm{ml})}$ are practically constant. The third, cyclical term $I^{(\mathrm{mc})}$, however, corresponds to the paired (or coherent) scattering channels and, being an interference term, has a definite angular structure.

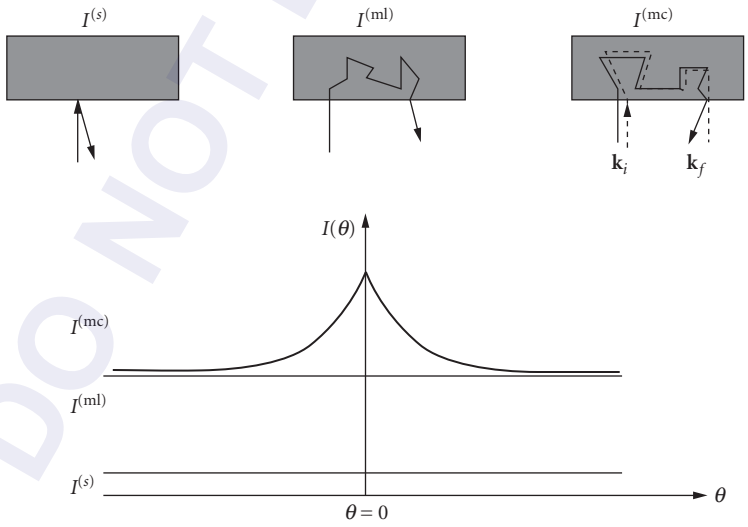

FIGURE 7 A schematic illustration of the origin of coherent backscattering. The classical contributions to backscattering are $I^{(s)}$ and $I^{(\mathrm{ml})}$; in addition, constructive interference occurs between reversed multiple scattering paths that have the same incident wave vector $\mathbf{k}_i$ and exit wave vector $\mathbf{k}_f$.

The existence of such a cyclical term (an idea originated from Watson[66]) is based on the fact that each scattering channel, involving a multitude of scattering centers, has its own coherent channel corresponding to the same sequence of scattering centers but time reversed. In the backward direction, the contribution of $I^{(mc)}$ equals that of $I^{(ml)}$ but its magnitude vanishes quickly away from this direction.

The angular profile of $I^{(mc)}$ can be qualitatively described by taking into account the interference between two light paths as shown in Fig. 7. The two time reversed paths have the same initial and final wave vectors, $\mathbf{k}_i$ and $\mathbf{k}_f$, and develop inside the medium through the same scattering centers. Under stationary conditions, the two outgoing waves corresponding to these paths are coherent and can interfere constructively for a special choice of $\mathbf{k}_i$ and $\mathbf{k}_f$. If the positions of the first and the last scatterer in the sequence are $\mathbf{r}_i$ and $\mathbf{r}_f$, respectively, the total phase shift between the two waves is $\mathbf{q}(\mathbf{r}_i-\mathbf{r}_f)$, where $\mathbf{q}$ is the momentum transfer $\mathbf{k}_i+\mathbf{k}_f$. Close to the backward direction ($\mathbf{k}_f=-\mathbf{k}_i$), the two waves add coherently and the interference may be described by a weighting factor $\cos[(\mathbf{k}_i+\mathbf{k}_f)(\mathbf{r}_i-\mathbf{r}_f)]$, which is controlled by the interparticle distance $|\mathbf{r}_i-\mathbf{r}_f|$. One can say that the coherence between the time-reversed sequences is lost for angles $\theta>\lambda/|\mathbf{r}_i-\mathbf{r}_f|$ and this actually sets the angular width of the cyclical term $I^{(mc)}$. The detailed angular profile of $I^{(mc)}$ is determined by the probability distribution function for $|\mathbf{r}_i-\mathbf{r}_f|$ and, based on a diffusive model for light propagation in a semi-infinite medium, an approximate formula was given in Ref. 67:

$$I^{(mc)}=[1-e^{-3.4ql^*}]/3.4ql^* \tag{18}$$

It should be noted that the intensities which contribute to classical backscattering, i.e., $I^{(s)}$ and $I^{(ml)}$, correspond to incoherent channels of scattering, they add up on an intensity basis and, upon ensemble average, all angular dependences are washed out as seen in Fig. 7. As can be seen from Eq. (18), the angular shape of the coherent backscattering peak can be used to measure l^* for a specific multiple scattering medium.

Correlations in Speckle Patterns One of the significant discoveries in mesoscopic physics is the phenomenon of conductance fluctuations which arises from correlations between the transmission probabilities for different output and input modes. In multiple light scattering, the same phenomenon shows up in the form of correlations between the intensities of light transmitted in different directions such as the case schematically depicted in Fig. 8. A nice feature of the optical scattering is that in contrast with electronic conductance experiments, one has access to both angular

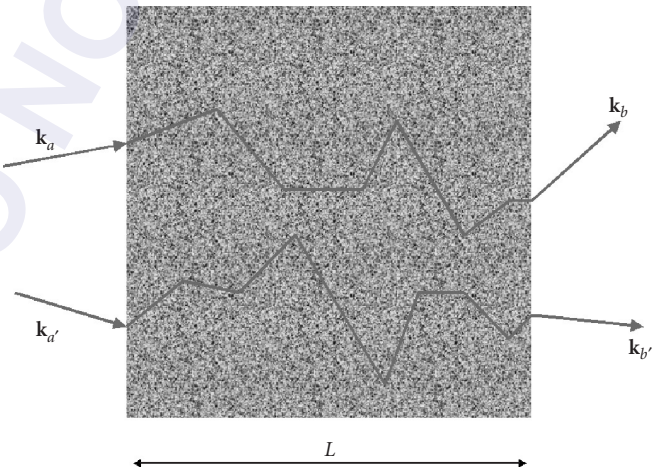

FIGURE 8 Scattering geometry containing two different wave trajectories.

dependence and angular integration of transmittance. A rich assortment of correlation functions of the different transmission quantities can be studied and their magnitudes, decay rates, etc., open up novel possibilities for multiple light scattering-based characterization and tomographic techniques.[68,69] These measurements exploit the spatial, spectral, and temporal resolution accessible in optical experiments.[70]

In a medium with volume disorder, optical waves can be thought to propagate through *channels* (propagating eigenmodes) defined angularly by one coherence area having the size of a speckle spot. The energy is coupled in and out of the medium through a number of $2\pi A/\lambda^2$ such channels where A is the transversal size of the medium. The transmission coefficient T_{ab} of one channel is defined as the ratio between the transmitted intensity in mode b and the incident intensity in mode a at a fixed optical frequency ω. An average transmission through the medium $\langle T_{ab} \rangle$ can be evaluated by ensemble averaging over different realizations of disorder and, for purely elastic scattering, it can be shown that $\langle T_{ab} \rangle \sim l^*/L$. The motion of scatterers, the frequency shift of the incident wave, and the variation of angle of incidence and/or detection, introduce phase shifts (momentum differences) in different propagating channels. Surprising and novel features are found when one studies carefully how various T_{ab} channels are correlated with one another. A general function $C_{aba'b'} = \langle \delta T_{ab} T_{a'b'} \rangle$ can be designed to evaluate the correlation between changes in the transmission coefficients $\delta T_{ab} = T_{ab} - \langle T_{ab} \rangle$ and, to the lowest order in the disorder parameter $1/kl$, it can be shown to be a summation of three different terms.[71] The first term C^1, *short-range correlations,* represents the large local intensity fluctuations specific to speckle patterns and exhibits an angular *memory* effect: when the incident beam is tilted by a small angle, the transmitted speckle pattern will, in average, follow provided that the tilt angle is not too large.[72,73] The second term C^2, *long-range correlations,* arises from paths that cross at a certain scattering site; it is smaller than C^1 by a factor $1/\sum T_{ab}$ and decays very slowly with the momentum difference.[74] Finally, a uniform positive correlation which is independent of momentum differences is included in C^3, *conductance correlations,* and it is determined by the less probable case of two crossings in propagation channels. This small correlation term (of the order of $1/\sum (T_{ab})^2$) causes just a shift in background, i.e., the spatially averaged intensity in each speckle pattern is always a little darker or brighter than the total intensity averaged over many disorder realizations in the sample. These fluctuations do not decrease when averaging is done over larger and larger spatial regions and they are the optical analogue of the universal conductance fluctuations in electronic systems.[71,75]

Depolarization A common interpretation of multiple scattering effects assumes depolarization of the incident field. However, when coherent radiation interacts with scattering media, there is always a fixed phase and amplitude relationship between orthogonal electric field components at a given frequency at any point in time and space. Of course, these relationships may vary as a function of time, spatial coordinate, frequency, and material morphology. If, upon ensemble average, there is no correlation between any pair of orthogonal field components, the field is said to be unpolarized. A degree of polarization is defined as

$$\mathrm{D} = \frac{\left(\mathrm{I}_1^2 + \mathrm{I}_2^2 + \mathrm{I}_3^2\right)^{1/2}}{\mathrm{I}_0} \tag{19}$$

where I_i are the ensemble averaged Stokes vector elements. This ensemble average can take the form of spatial, temporal, or frequency average or can also be the result of averaging over different material realizations.[76] For a static medium illuminated by polarized light, depolarization occurs when path length differences contributing to a particular point exceed the coherence length of the illuminating light. It is interesting to note that the measured degree of polarization will be a function of the detection geometry, decreasing with increasing the detector's size and integration time.

Based on symmetry considerations, van de Hulst[2] finds the Mueller matrix for single scattering on a collection of randomly oriented identical particles each of which has a plane of symmetry to be diagonal with $P_{22} = P_{33} \neq P_{44}$. For spheres in exact forward scattering $P_{22} = P_{44} = 1$. In multiple scattering

however, this relation is not true anymore. It is expected that when light of arbitrary incident polarization impinges on an optically thick, multiple scattering medium it emerges diffusely and totally depolarized. When increasing the optical density, the transfer matrix evolves toward that of a total depolarizer which has all elements equal to zero except for P_{11}. This depolarization process will depend on the size parameter of the scattering particles. Owing to a smaller scattering anisotropy for the particles with the size parameter close to 1, the total depolarization stage is reached at higher optical densities than for larger particles. Two different regimes can be identified in terms of optical density d/l^*: (i) a steep decay for low optical densities, which corresponds to the attenuation of ballistic photons, and (ii) a slower decay for large optical densities, corresponding to the diffusive regime. The effective coefficient of attenuation depends only on the volume fraction of the scattering medium.

For an arbitrary input state of polarization, the output state of polarization can be obtained from $\mathbf{I}_{\text{out}} = P\mathbf{I}_{\text{in}}$. In the case of a diagonal transfer matrix, the renormalized output Stokes vector is

$$\mathbf{I}_{\text{out}} = \begin{bmatrix} 1 & \mathbf{I}_1 P_{22} & \mathbf{I}_2 P_{33} & \mathbf{I}_3 P_{44} \end{bmatrix}^T \tag{20}$$

The degree of polarization of the scattered light can be obtained from Eq. (20) using Eq. (19) for any input state. The characteristics of the depolarization will depend both on the input state of polarization and the dominant scattering regime, exhibiting different behavior in the Mie and Rayleigh (ka $\ll$1) regimes. The depolarizing behavior of multiple scattering, as a function of sample thickness is exemplified in Fig. 9*a* and *b* for linear and circular inputs, respectively. As can be seen, for samples 2 and 3 in Fig. 9*a* and *b* the slope for linear input is always steeper than for circular input, indicating that circularly polarized light is less depolarized than linearly polarized light for the same sample thickness.

It is expected that, as soon as the diffusive regime is reached, multiple scattering will completely depolarize the incident optical wave. Knowing the complete Mueller matrix, the state of polarization of scattered light can be estimated for any input state of polarization. A detailed analysis can also predict which type of illumination is better preserved while propagating through the scattering medium. This is particularly important in applications such as long-range target identification where one must take into account depolarization effects due to propagation.

10.1 GLOSSARY

A_{ba}	Einstein coefficient for spontaneous emission
a_0	Bohr radius
B_{if}	Einstein coefficient between initial state, $\|i\rangle$, and final state, $\|f\rangle$
E_{DC}	Dirac Coulomb term
E_{hf}	hyperfine energy
E_n	eigenvalue of quantum state n
$E(t)$	electric field at time t
$E(\omega)$	electric field at frequency ω
e	charge on the electron
ED	electric dipole term
EQ	electric quadrupole term
$\langle f\|\mathbf{V}'\|i\rangle$	matrix element of perturbation V'
g_a	degeneracy of ground level
g_b	degeneracy of excited level
g_N	gyromagnetic ratio of nucleus
H_{so}	spin-orbit interaction Hamiltonian
$\hbar$	Planck's constant
I	nuclear spin
$I(t)$	emission intensity at time t
$\mathbf{j}$	total angular momentum vector given by $\mathbf{j}=\boldsymbol{l} \pm \frac{1}{2}$
l_i	orbital state
M_N	mass of nucleus N
MD	magnetic dipole term
m	mass of the electron

$n_\omega(T)$	equilibrium number of photons in a blackbody cavity radiator at angular frequency ω and temperature T
QED	quantum electrodynamics
R_∞	Rydberg constant for an infinitely heavy nucleus
$R_{\mathrm{nl}}^{(r)}$	radial wavefunction
s	spin quantum number with the value $\frac{1}{2}$
s_i	electron spin
T	absolute temperature
W_{ab}	transition rate in absorption transition between states $\|a\rangle$ and $\|b\rangle$
W_{ba}	transition rate in emission transition from state $\|b\rangle$ to state $\|a\rangle$
Z	charge on the nucleus
$\alpha = e^2/4\pi\varepsilon_0\hbar c$	fine structure constant
ε_0	permittivity of free space
μ_B	Bohr magneton
$\rho(\omega)$	energy density at frequency ω
$\zeta(r)$	spin-orbit parameter
τ_R	radiative lifetime
ω	angular frequency
$\Delta\omega$	natural linewidth of the transition
$\Delta\omega_D$	Doppler width of transition
ω_k	mode k with angular frequency ω

Spectroscopic measurements have played a key role in the development of quantum theory. This chapter presents a simple description of the quantum basis of spectroscopic phenomena, as a prelude to a discussion of the application of spectroscopic principles in atomic, molecular, and solid-state physics. A brief survey is presented of the multielectron energy-level structure in the three phases of matter and of the selection rules which determine the observation of optical spectra. Examples are given of the fine-structure, hyperfine-structure, and spin-orbit splittings in the spectra of atoms, molecules, and solids. Solid-state phenomena considered will include color center, transition metal, and rare earth ion spectra.

The intrinsic or homogeneous lineshapes of spectra are determined by lifetime effects. Other dephasing processes, including rotational and vibrational effects, lead to splitting and broadening of spectra. There are also sources of inhomogeneous broadening associated with Doppler effects in atomic and molecular spectra and crystal field disorder in solids. Methods of recovering the homogeneous lineshape include sub-Doppler laser spectroscopy of atoms, optical hole burning, and fluorescence line narrowing.

Finally, the relationship between linewidth and lifetime are discussed and the effects of time-decay processes outlined. The consequences of measurements in the picosecond and subpicosecond regime are described. Examples of vibrational relaxation in molecular and solid-state spectroscopy are reviewed.

10.2 INTRODUCTORY COMMENTS

Color has been used to enhance the human environment since the earliest civilizations. Cave artists produced spectacular colorations by mixing natural pigments. These same pigments, burned into the surfaces of clays to produce color variations in pottery, were also used to tint glass. The explanation of the coloration process in solids followed from Newton's observation that white light contains all the colors of the rainbow,[1] the observed color of a solid being complementary to that absorbed

from white light by the solid. Newton measured the wavelength variation of the refractive index of solids, which is responsible for dispersion, and his corpuscular theory of light explained the laws of reflection and refraction.[1] The detailed interpretation of polarization, diffraction, and interference followed from the recognition that light was composed of transverse waves, the directions of which were related to the direction of the electric field in Maxwell's electromagnetic theory:[2,3] the electronic constituents of matter are set into transverse oscillation relative to the propagating light beam. Subsequently, Einstein introduced the photon in explaining the photoelectric effect.[4] Thus the operating principles of optical components in spectrometers, such as light sources, mirrors, lenses, prisms, polarizers, gratings, and detectors, have been with us for a long time.

Many significant early developments in quantum physics led from optical spectroscopic studies of complex atoms. After Bohr's theory of hydrogen,[5] the quantum basis of atomic processes developed apace. One of Schrödinger's first applications of wave mechanics was in the calculations of atomic energy levels and the strengths of spectroscopic transitions.[6] Schrödinger also demonstrated the formal equivalence of wave mechanics and Heisenberg's matrix mechanics. Extensions of spectroscopy from atomic physics to molecular physics and solid-state physics more or less coincided with the early applications of quantum mechanics in these areas.

A survey of the whole of spectroscopy, encompassing atoms, molecules, and solids, is not the present intent. Rather it is hoped that by choice of a few critical examples the more general principles linking optical spectroscopy and the structure of matter can be demonstrated. The field is now vast: Originally the exclusive domain of physicists and chemists, optical spectroscopy is now practiced by a variety of biophysicists and biochemists, geophysicists, molecular biologists, and medical and pharmaceutical chemists with applications to proteins and membranes, gemstones, immunoassay, DNA sequencing, and environmental monitoring.

10.3 THEORETICAL PRELIMINARIES

The outstanding success of the Bohr theory was the derivation of the energy-level spectrum for hydrogenic atoms:

$$E_n = -\frac{mZ^2e^4}{2(4\pi\varepsilon_0)^2n^2\hbar^2} = -\frac{Z^2hc}{n^2}R_\infty \tag{1}$$

Here the principal quantum number n is integral; $h = 2\pi\hbar$ is Planck's constant; Z is the charge on the nucleus, m and e are, respectively, the mass and charge on the electron; and ε_0 is the permittivity of free space. The Rydberg constant for an infinitely heavy nucleus, R_∞, is regarded as a fundamental atomic constant with approximate value 10,973,731 m^{-1}. Equation (1) is exactly the relationship that follows from the boundary conditions required to obtain physically realistic solutions for Schrödinger's time-independent equation for one-electron atoms. However, the Schrödinger equation did not account for the *fine structure* in the spectra of atoms nor for the splittings of spectral lines in magnetic or electric fields.

In 1927 Dirac developed a relativistic wave equation,[7] which introduced an additional angular momentum for the spinning electron of magnitude $s^*\hbar$, where $s^* = \sqrt{s(s+1)}$ and the spin quantum number s has the value $s = \frac{1}{2}$. The orbital and spin angular momenta are coupled together to form a total angular momentum vector $\mathbf{j}$, given by $\mathbf{j} = \boldsymbol{l} \pm \frac{1}{2}$. In the hydrogenic ground state $|nl\rangle = |10\rangle$, this spin-orbit coupling yields a value of $\mathbf{j} = \frac{1}{2}$ only, giving the $1S_{1/2}$ level. In the first excited state, for which $n = 2$ the $l = 0$, $\mathbf{j} = \frac{1}{2}$ is represented by $2S_{1/2}$, while $l = 1$ leads to $\mathbf{j} = \frac{3}{2}(2P_{3/2})$ and $\mathbf{j} = \frac{1}{2}(2P_{1/2})$ levels, these two levels being separated by the fine structure interval.[8] The Dirac form of the Coulomb energy, expressed as an expansion in powers of $Z \times$ the fine structure constant, $\alpha = (e^2/4\pi\varepsilon_0\hbar c)$, is then

$$E_{DC} = -\frac{Z^2}{n^2}R_\infty hc\left[1 + \frac{(Z\alpha)^2}{n}\left(\frac{1}{\mathbf{j}+\frac{1}{2}} - \frac{3}{4n}\right) + O((Z\alpha)^4)\right] \tag{2}$$

The second term in the bracket in Eq. (2) is the spin-orbit correction to the energies, which scales as $(Z^4\alpha^2)/n^3$. In the case of hydrogenic atoms this relativistic coupling removes the $nP_{1/2} - nP_{3/2}$ and $nD_{3/2} - nD_{5/2}$ degeneracy, but does not split the $nS_{1/2}$ level away from the $nP_{1/2}$ level. A further relativistic correction to Eq. (1) involves replacing the electronic mass in R_∞ by the reduced mass of the electron $\mu = mM/(M + m)$, which introduces a further shift of order $(m/M)_N(1-(Z\alpha/2n)^2)E_{DC}$. Here M_N is the mass of the nucleus.

There are two further energy-level shifts.[9] The so-called quantum electrodynamic (QED) shifts include contributions due to finite nuclear size, relativistic recoil, and radiative corrections, collectively described as the Lamb shift, as well as terms due to electron self-energy and vacuum polarization. The Lamb shift raises the degeneracy of the $nS_{1/2} - nP_{1/2}$ levels. Overall, the QED shift scales as $\alpha(Z\alpha)^4/n^3$.[10] The interaction of the electronic and nuclear magnetic moments gives rise to hyperfine structure in spectra. The hyperfine contribution to the electronic energies for a nucleus of mass M_N, nuclear spin I, and gyromagnetic ratio g_N, is given by

$$E_{hf} = \alpha^2\left(\frac{Z^3}{n^3}\right)\left(\frac{g_N m}{M_N}\right)hcR_\infty \frac{F(F-1)-I(I+1)-j(j+1)}{j(j+2)(2l+1)} \tag{3}$$

where $\mathbf{j} = \boldsymbol{l} + \mathbf{s}$ is the total electronic angular momentum and $\mathbf{F} = \mathbf{I} + \mathbf{j}$ is the total atomic angular momentum. E_{hf} scales as $Z^3\alpha^2/n^3$ and is larger for S-states than for higher-orbit angular momentum states. More generally, all the correction terms scale as some power of Z/n, demonstrating that the shifts are greatest for $n = 1$ and larger nuclear charge. Experiments on atomic hydrogen are particularly important, since they give direct tests of relativistic quantum mechanics and QED.

10.4 RATES OF SPECTROSCOPIC TRANSITION

The rates of transitions may be determined using time-dependent perturbation theory. Accordingly, it is necessary to consider perturbations which mix stationary states of the atom. The perturbations are real and oscillatory in time with angular frequency ω and have the form

$$H_1 = V\ \exp(-i\omega t) + V^*\ \exp(\omega t) \tag{4}$$

where V is a function only of the spatial coordinates of the atom. In the presence of such a time-dependent perturbation, the Schrödinger equation

$$(H_0 + H_1)\Psi = i\hbar\frac{\delta\Psi}{\delta t} \tag{5}$$

has eigenstates

$$\Psi = \sum_n c_n(t)|nlm\rangle\ \exp(-iE_n t/\hbar) \tag{6}$$

which are linear combinations of the n stationary solutions of the time-independent Schrödinger equation, which have the eigenvalues E_n. The time-dependent coefficients, $c_m(t)$, indicate the extent of mixing between the stationary state wavefunctions $|nlm\rangle$. The value of $|c_j(t)|^2$, the probability that the electronic system, initially in state i, will be in a final state f after time t is given by

$$|c_f(t)|^2 = 4\left|\frac{V_{fi}}{\hbar}\right|^2 \frac{\sin^2\frac{1}{2}(\omega_{fi}-\omega)t}{(\omega_{fi}-\omega)^2} \tag{7}$$

for an absorption process in which the final state f is higher in energy than the initial state i. This expression defines the Bohr frequency condition,

$$\hbar\omega = E_f - E_i \tag{8}$$

and $\omega_{fi} = (E_f - E_i)/\hbar$. Obviously, $|c_f(t)|^2$ has a maximum value when $\omega_{fi} = \omega$, showing that the probability of an absorption transition is maximum when $E_f - E_i = \hbar\omega$. The emission process comes from the V^* exp (ωt) term in Eq. (4): the signs in the numerator and denominator of Eq. (7) are then positive rather than negative. For the probability to be significant then requires that $\omega_{fi} + \omega = 0$, so that the final state f is lower in energy than the initial state. If the radiation field has a density of oscillatory modes $u(\omega)$ per unit frequency range, then Eq. (7) must be integrated over the frequency distribution. The transition rate is then

$$W_{fi} = \frac{2\pi}{\hbar^2} |V_{fi}^{\omega}|^2 \, u(\omega_{fi}) \tag{9}$$

in which the V_{fi}^{ω} indicates that only a narrow band of modes close to $\omega = \omega_{fi}$ has been taken into account in the integration. This equation, which gives the probability of a transition from $|i\rangle \rightarrow |f\rangle$ per unit time, is known as Fermi's golden rule.

In Eq. (9) $V_{fi} = \langle f|V|i\rangle$ and $V_{fi}^* = \langle f|V^*|i\rangle$ determine the transition probabilities for absorption and emission between the initial i and final states f. In fact $|V_{fi}^{\omega}|$ and $|V_{if}^{\omega *}|$ are identical and the transition probabilities for absorption and emission are equal. For the kth mode with angular frequency ω_k the perturbation takes the form

$$V_k^{\omega} \cong \sum_i \left(e\mathbf{r}_i \cdot E_k^0 + \frac{e}{2m}(\mathbf{l}_i + 2\mathbf{s}_i) \cdot B_k^0 + \tfrac{1}{2} e\mathbf{r}_i \cdot \mathbf{r}_i \cdot kE_k^0 \right) \tag{10}$$

The first term in Eq. (10) is the electric dipole (ED) term. The second and third terms are the magnetic dipole (MD) and electric quadrupole terms (EQ), respectively. The relative strengths of these three terms are in the ratio $(ea_0)^2 : (\mu_B/c)^2 : ea_0^2/\lambda^2$ where a_0 and μ_B are the Bohr radius and Bohr magneton, respectively. These ratios are then approximately $1 : 10^{-5} : 10^{-7}$. Since the electromagnetic energy per unit volume contained in each mode, including both senses of polarization, is given by $2\varepsilon_0\kappa|E_k^0|^2$, the energy density, $\rho(\omega)$, per unit volume per unit angular frequency is just $4\varepsilon_0\kappa|E_k^0|^2 u_k(\omega)$. Hence, from Eq. (9) and using only the first term of Eq. (10) the electric dipole transition rate is determined as

$$W_{if} = \frac{\pi}{2\varepsilon_0\kappa\hbar^2} \sum_k \left| \langle f| \sum_i e\mathbf{r}_i \cdot \hat{\boldsymbol{\varepsilon}}_k |i\rangle \right|^2 \rho(\omega) \tag{11}$$

where the summations are over the numbers of electrons, i, and polarization vectors, $\mathbf{k}$. For randomly polarized radiation Eq. (11) becomes

$$W_{if} = \frac{2\pi}{6\varepsilon_0\kappa\hbar^2} \left| \langle f| \sum_i e\mathbf{r}_i |i\rangle \right|^2 \rho(\omega) \tag{12}$$

If the radiation has all the $\mathbf{E}_\mathbf{k}$ vectors pointing along the z-direction then only this mode is taken into account and

$$W_{if} = \frac{\pi}{2\varepsilon_0\kappa\hbar^2} \left| \langle f| \sum_i ez_i |i\rangle \right|^2 \rho(\omega) \tag{13}$$

These relationships, Eqs. (12) and (13), are used subsequently in discussing experimental techniques for measuring optical absorption and luminescence spectra. They result in the selection rules that govern both polarized and unpolarized optical transitions.

For the most part the succeeding discussion is concerned with radiative transitions between the ground level a and an excited level b. These levels have degeneracies g_a and g_b with individual ground and excited states labeled by $|a_n\rangle$ and $|b_m\rangle$, respectively. The probability of exciting a transition from state $|a_n\rangle$ to state $|b_m\rangle$ is the same as that for a stimulated transition from $|b_m\rangle$ to $|a_n\rangle$. The transition rates in absorption, W_{ab}, and in emission, W_{ba}, are related through

$$g_a W_{ab} = g_b W_{ba} \tag{14}$$

assuming the same energy density for the radiation field in absorption and emission. Since the stimulated transition rate is defined by

$$W_{ab} = B_{ab}\rho(\omega) \tag{15}$$

the Einstein coefficient B_{ab} for stimulated absorption is directly related to the squared matrix element $|\langle b_m|\Sigma_i|er_i|a_n\rangle|^2$. Furthermore, the full emission rate is given by

$$W_{ba} = A_{ba}[1+n_\omega(T)] \tag{16}$$

where $n_\omega(T)$ is the equilibrium number of photons in a blackbody cavity radiator at angular frequency ω and temperature T. The first term in Eq. (16) (i.e., A_{ba}) is the purely spontaneous emission rate, related to the stimulated emission rate by

$$A_{ba} = 2B_{ba}u_k(\omega)\hbar\omega_k \tag{17}$$

Equation (17) shows that the spontaneous transition probability is numerically equal to the probability of a transition stimulated by one photon in each electromagnetic mode, **k**. Similarly the stimulated absorption rate is given by

$$W_{ab} = B_{ab}\rho(\omega) = \frac{g_b}{g_a}A_{ba}n_\omega(T) \tag{18}$$

These quantum mechanical relationships show how the experimental transition rates, for both polarized and unpolarized radiation, are determined by the mixing of the states by the perturbing oscillatory electric field. Since the radiative lifetime τ_R is the reciprocal of the Einstein A coefficient for spontaneous emission [i.e., $\tau_R = (A_{ba})^{-1}$] we see the relationship between luminescence decaytime and the selection rules via the matrix element $|\langle b_m|\Sigma_i er_i|a_n\rangle|$.

10.5 LINESHAPES OF SPECTRAL TRANSITIONS

Consider the excitation of optical transitions between two nondegenerate levels $|a\rangle$ and $|b\rangle$. The instantaneous population of the upper level at some time t after the atomic system has been excited with a very short pulse of radiation of energy $\hbar\omega_{ab}$ is given by

$$N_b(t) = N_b(0)\exp(-A_{ba}t) \tag{19}$$

where A_{ba} is the spontaneous emission rate of photons from level $|b\rangle$ to level $|a\rangle$. Since the energy radiated per second $I(t) = A_{ba}N_b(t)\hbar\omega_{ab}$, the emission intensity at time t, and frequency ω_{ba} is given by $I(t) = I(0)\exp(-t/\tau_R)$, where the radiative decaytime τ_R is defined as the reciprocal of the *spontaneous decay rate*, i.e., $\tau_R = (1/A_{ba})$. The expectation value of the time that the electron spends in the excited state, $\langle t\rangle$, is calculated from

$$\langle t\rangle = \frac{1}{N_b(0)}\int_{-8}^{+\infty} N_b(t)\,dt = (A_{ba})^{-1} = \tau_R \tag{20}$$

This is just the average time, or *lifetime,* of the electron in the excited state. In consequence, this simple argument identifies the radiative decaytime with the lifetime of the electron in the excited state. Typically, for an allowed electric dipole transition $\tau_R \sim 10^{-8}$ s.

The radiation from a collection of atoms emitting radiation at frequency ω_{ba} at time $t > 0$ has an associated electric field at some nearby point given by

$$E(t) = E_0\exp(i\omega_{ba}t)\exp(-t/2\tau_R) \tag{21}$$

(i.e., the electric field oscillates at the central frequency of the transition on the atom). The distribution of frequencies in $E(t)$ is obtained by Fourier analyzing $E(t)$ into its frequency spectrum, from which

$$E(\omega)=\frac{E_0}{\sqrt{(\omega_{ab}-\omega)^2+(2\tau_R)^{-2}}}\exp\left[i\phi(\omega)\right] \tag{22}$$

where $\phi(\omega)$ is a constant phase factor. Since $I(t) \simeq E(t)^2$ we obtain the intensity distribution of frequencies given by

$$I(\omega)=\frac{I_0}{(\omega_{ab}-\omega)^2+(2\tau_R)^{-2}} \tag{23}$$

This classical argument shows that the distribution of frequencies in the transition has a *lorentzian* shape with full width at half maximum (FWHM), $\Delta\omega$, given by

$$\Delta\omega=\frac{1}{\tau_R}=A_{ba} \tag{24}$$

An identical lineshape is derived from wave mechanics using time-dependent perturbation theory. This relationship between the *natural linewidth* of the transition, $\Delta\omega$, and the radiative decaytime, τ_R, is related to the uncertainty principle. The time available to measure the energy of the excited state is just $\langle t\rangle$; the width in energy of the transition is $\Delta E=\hbar\Delta\omega$. Hence $\Delta E\langle\tau\rangle=\hbar\Delta\omega\tau_R=\hbar$ follows from Eq. (24). For $\tau_R\cong 10^{-8}$ s the energy width $\Delta E/c\simeq 5\times10^{-2}\,\mathrm{m}^{-1}$. Hence the natural linewidth of a transition in the visible spectrum is $\Delta\lambda\simeq 2\times10^{-3}$ nm.

The broadening associated with the excited state lifetime is referred to as *natural* or *homogeneous* broadening. There are other processes which modulate the energy levels of the atom thereby contributing to the overall decay rate, τ^{-1}. It is this overall decay rate, $\tau^{-1}>\tau_R^{-1}$, which determines the width of the transition. Examples of such additional processes include lattice vibrations in crystals and the vibrations/rotations of molecules. In gas-phase spectroscopy, random motion of atoms or molecules leads to inhomogeneous broadening via the Doppler effect. This leads to a Gaussian spectral profile of FWHM given by

$$\Delta\omega_D=\frac{4\pi}{c}\left(\frac{2kT}{M}\ln 2\right)^{1/2}\omega_{ba} \tag{25}$$

showing that the Doppler width varies as the square root of temperature and is smaller in heavier atoms. In solids, distortions of the crystal field by defects or growth faults lead to strain which is manifested as inhomogeneous broadening of spectra. The resulting lineshape is also gaussian. The great power of laser spectroscopy is that spectroscopists recover the true homogeneous width of a transition against the background of quite massive inhomogeneous broadening.

10.6 SPECTROSCOPY OF ONE-ELECTRON ATOMS

Figure 1*a* shows the energy level structure of atomic hydrogen for transitions between $n = 3$ and $n = 2$ states, i.e., the Balmer α-transition. Electric dipole transitions are indicated by vertical lines. The relative strengths of the various lines are indicated by the lengths of the vertical lines in Fig. 1*b*. Also shown in Fig. 1*b* is a conventional spectrum obtained using a discharge tube containing deuterium atoms cooled to $T = 50$ K. This experimental arrangement reduces the Doppler width of the Balmer α-transition at 656 nm to 1.7 GHz. Nevertheless, only three transitions $2P_{3/2}\rightarrow 3D_{5/2}$, $2S_{1/2}\rightarrow 3P_{1/2}$, and $2P_{1/2}\rightarrow 3D_{3/2}$ are resolved.[11] However, sub-Doppler resolution is possible using laser saturation spectroscopy.[12] Figure 1*c* shows the Doppler-free Balmer α-spectrum to comprise

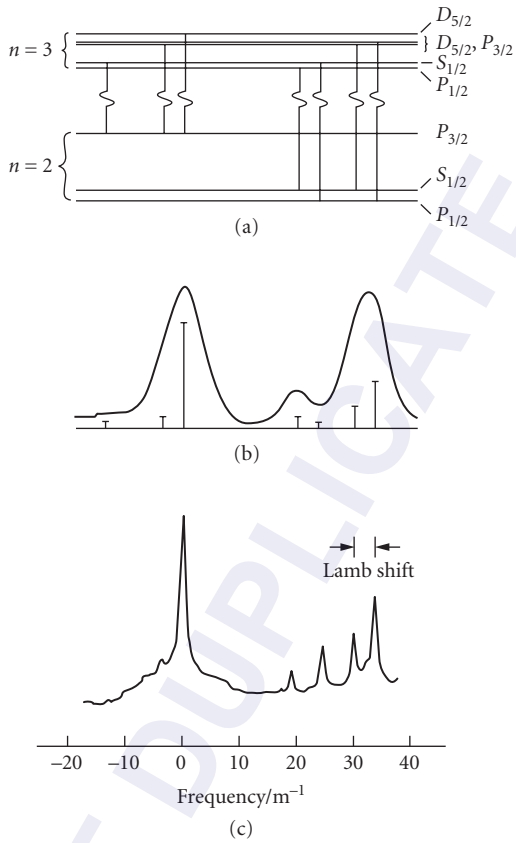

FIGURE 1 (*a*) The structure of the $n = 3$ and $n = 2$ levels of hydrogen showing the Balmer α-transitions. (*b*) A low resolution discharge spectrum of deuterium cooled to 50 K. (*c*) A Doppler-free spectrum of the Balmer α-spectrum of hydrogen. (*After Hänsch et al.*[12])

comparatively strong lines due to $2P_{3/2} \rightarrow 3D_{5/2}$, $2S_{1/2} \rightarrow 3P_{1/2}$, $2S_{1/2} \rightarrow 3P_{3/2}$, and $2P_{1/2} \rightarrow 3D_{3/2}$ transitions, as well as a very weak $2P_{3/2} \rightarrow 3D_{3/2}$ transition. Also evident is a cross-over resonance between the two transitions involving a common lower level $2S_{1/2}$, which is midway between the $2S_{1/2} \rightarrow 3P_{1/2}$, $3P_{3/2}$ transitions. The splitting between $2P_{3/2}$, $2P_{1/2} \rightarrow 3D_{3/2}$ transitions measures the spin-orbit splitting in the $n = 2$ state, which from Eq. (2) is about 36.52 m^{-1}. The Lamb shift is measured from the splitting between $2S_{1/2} \rightarrow 3P_{3/2}$ and $2P_{1/2} \rightarrow 3D_{3/2}$ lines to be 3.53 m^{-1}, which compares well with the original microwave measurement (3.537 m^{-1}).[13] Subsequently, Hänsch et al.[14] made an interferometric comparison of a Balmer α-line with the 632.8-nm line from He-Ne locked to a component of $^{129}I_2$, thereby deriving a value of R_∞ of 10973731.43(10) m^{-1}, at that time an order of magnitude improvement in accuracy on previous values. Neither the $2S_{1/2}$ nor $2P_{1/2}$ hfs was resolved in this experiment, both splittings being less than the system resolution of *ca* 0.05 m^{-1}. This probably followed from the use of pulsed dye lasers where the laser linewidth exceeds by factors of 10 the linewidth available from single-frequency continuous wave (CW) dye lasers. Subsequent measurements using CW dye lasers standardized against I_2-stabilized He-Ne lasers gave further improvements in the value of R_∞.[15,16] Also using the Balmer α-transition Stacey et al[17] have studied the isotope shifts between spectra from

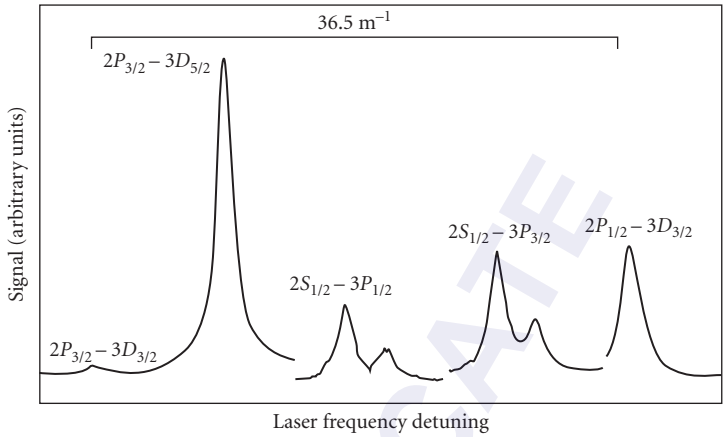

FIGURE 2 Showing hyperfine structure splittings of the $2S_{1/2} \rightarrow 3P_{3/2}$, $3D_{3/2}$ transition in hydrogen. (*After Stacey*.[17])

hydrogen, deuterium, and tritium. The spectrum shown in Fig. 2 reveals the $2S_{1/2}$ hyperfine splitting on the $2S_{1/2} \rightarrow P_{3/2}$ and $2S_{1/2} \rightarrow 3D_{3/2}$ transitions. These measurements yield isotope shifts of 124259.1(1.6) MHz and 41342.7(1.6) MHz for *H-D* and *D-T,* respectively, which accord well with theoretical values.

The literature on H-atom spectroscopy is vast, no doubt fueled by the unique relationship between experimental innovation and fundamental tests of relativistic quantum mechanics and QED. This chapter is not a comprehensive survey. However, it would be seriously remiss of the author to omit mention of three other categories of experimentation. The first experimental arrangement uses crossed atomic and laser beams: a well-collimated beam of atoms propagates perpendicular to a laser beam which, after traversing the atomic beam, is reflected to propagate through the atomic beam again in the opposite direction. The interaction between the counter-propagating beams and the atoms in the atomic beam is signaled by a change in the beam flux. The atomic beam replaces the discharge unit used in conventional atomic spectroscopy, thereby reducing errors due to the electric fields in discharges. This experiment is the optical analogue of the Lamb-Retherford radio-frequency experiment[13] and has been much used by workers at Yale University.[18] They reported a value of $R_\infty = 10973731.573(3)$ m^{-1} in experiments on the Balmer β-transition ($n = 2$ to $n = 4$).

There have been several other studies of the Balmer β-transition, which has a narrower natural linewidth than the Balmer α-transition. However, because it is weaker than the Balmer α-transition, Wieman and Hänsch used a polarization scheme to enhance the sensitivity of the saturation absorption scheme.[19] Finally, the metastable $2S_{1/2}$ level may decay spontaneously to the $1S_{1/2}$ ground state with the emission of two photons with energies that sum to the energy separation between $1S_{1/2}$ and $2S_{1/2}$. Such a process has a radiative decaytime of 0.14 s, giving a natural linewidth for the $2S_{1/2} \rightarrow 1S_{1/2}$ transition of order 1 Hz! The probability of a two-photon absorption transition is quite low. However, as with laser absorption saturation spectroscopy, two-photon absorption experiments are made feasible by Doppler-free resolution. Wieman and Hänsch[20] used an amplified CW laser beam at 243 nm to excite a two-photon absorption transition, which they detected by observing the Lyman α-emission at 121 nm. In addition, part of the laser beam was split off and used to measure simultaneously the Balmer β-spectrum. The coupled experiment permitted a direct measurement of the ground-state Lamb shift of 8161(29) MHz. Ferguson and his colleagues developed standard cells using $^{130}Te_2$ lines for studies of the Balmer β-and $1S_{1/2} \rightarrow 2S_{1/2}$ transitions.[10,21]

10.7 MULTIELECTRON ATOMS

In order to calculate the energy level spectrum of a multielectron atom we require a suitable hamiltonian describing the interaction of all the electrons with the nucleus and with each other. A convenient starting point is the simplified Dirac equation for a one-electron atom, viz.,

$$H = H_0 + H_{so} \tag{26}$$

where H_0 is the simplified hamiltonian for the electron in the field of a nucleus of charge Ze at rest, i.e.,

$$H_0 = \frac{p^2}{2m} - \frac{Ze^2}{4\pi\varepsilon_0 r} \tag{27}$$

and $H_{so} = -\zeta(r)\mathbf{l}\cdot\mathbf{s}$ is the spin-orbit hamiltonian. Wavefunctions which satisfy Eq. (27) are

$$\psi_{nlm_l}(r) = R_{nl}^{(r)} Y_l^m(\theta\phi) \tag{28}$$

where the labels n, l, and m are quantum numbers which characterize the eigenstates. The eigenvalues, given in Eq. (1), depend only on the principal quantum number n, which takes positive integral values. The quantum number l characterizing the orbital angular momentum also takes integral values, $l = 0, 1, 2, 3, \ldots, (n-1)$, whereas m_l measures the z-component of the orbital angular momentum. There are $2l+1$ integral values of l given by $m = 1, (l-1), (l-2), \ldots, -(l-1), -l$, and for a given value of n there are several different orbital states with identical energy. H_{so}, among other interactions, raises this degeneracy.

It is convenient to represent the orbital wavefunction ψ_{nlm} by the ket $|nlm\rangle$. Including spin angular momentum we represent a *spin orbital* by $|nlsmm_s\rangle$ or more simply by $|nlmm_s\rangle$. Recalling the brief discussion of the coupled representation, whereby $j = l + s$, an equally valid representation is $|nljm_j\rangle$. Indeed the new basis states $|nljm_j\rangle$ are just linear combinations of the $|nlmm_s\rangle$ basis states.[8] Each wavefunction has a definite parity. The parity of wavefunctions is important in determining the selection rules of spectra. The inversion operator P_i, defined by $P_i f(r) = f(-r)$ for any function of r, gives the following result

$$P_i|nlm\rangle = (-1)^l|nlm\rangle \tag{29}$$

Hence, for even values of l the wavefunctions are said to have even parity since they do not change sign under inversion of coordinates. For l odd the wavefunctions have odd parity. The strength of an optical transition is determined by a matrix element $\langle\psi_b|\mu|\psi_a\rangle$, where the integration is taken over the volume of the atom. In the electric dipole approximation, $\mu = -er$ so that the matrix element is zero except that the wavefunction ψ_a and ψ_b have opposite parity. This defines the Laporte selection rule which states that the parity of a state must change from odd to even (or vice versa) in an electric dipole transition.

The hamiltonian for multielectron atoms is a sum over all N electrons of one-electron operators [see Eq. (1)] plus an electron-electron Coulomb repulsion between electrons i and j separated by a distance r_{ij}. Hence we may write this as

$$H = \sum_i \left(\frac{P_i^2}{2m} - \frac{Ze^2}{4\pi\varepsilon_0 r_i} + \zeta(r_i)\mathbf{l}_i\cdot\mathbf{s}_i \right) + \sum_{i\neq j} \frac{e^2}{4\pi\varepsilon_0 r_{ij}} \tag{30}$$

The computational complexity militates in favor of an approximate solution because the spin-orbit and electron-electron interactions are not spherically symmetric. In consequence, the first stage of the approximation to Eq. (30) is in the form

$$H = \sum_i \frac{p_i^2}{2m} + V_i'(r_i) + \zeta(r_i)\mathbf{l}_i\cdot\mathbf{s}_i \tag{31}$$

where $V_i'(r_i)$ is a spherically symmetric one-electron operator which represents the potential energy of the ith electron in the field of the nucleus and all the electrons. The first two terms in this sum constitute the orbital hamiltonian, H_0, a sum of one-electron hydrogen-like hamiltonians [Eq. (27)], but with a more complicated radial potential energy function, $V'(r)$. The radial and angular parts of each one-electron hamiltonian are separable and we write orbital functions

$$R'_{nl}(r_i)Y_l^m(\theta, \phi) = |nlm\rangle \tag{32}$$

However, $R'_{nl}(r_i)$ is the solution of the radial equation involving the central potential, $V'(r_i)$, which is characterized by the quantum numbers n and l. In consequence, the energy of the one-electron state also depends on both n and l. The complete spin orbital is characterized by four quantum numbers including spin (i.e., $u = |nlmm_s\rangle$) and the many electron eigenstate of H_0 is a product of one-electron states

$$U = \prod_i |nlmm_s\rangle_i \tag{33}$$

The energy E_u of this product state is

$$E_u = \sum_i E_{n_i l_i} \tag{34}$$

which depends on the set of $n_i l_i$ values. However, since E_u does not depend on m_l and m_s these eigenstates have a large degeneracy.

Experimentally, the complete wavefunctions of electrons are antisymmetric under the exchange of orbital and spin coordinates of any two electrons. The product wavefunction, Eq. (33), does not conform to the requirement of interchange symmetry. Slater solved this problem by organizing the spin orbitals into an antisymmetric N-electron wavefunction in determinantal form.[22] The application of the Hartree-Fock variational approach to determine the central field potential consistent with the best Slater wavefunctions is described in detail by Tinkham.[23] There are many different sets of energy eigenfunctions that can be chosen; the net result is that the eigenstates of H_0 can be classified by a set of quantum numbers LSM_LM_S for each $(n_i l_i)$ electron configuration, where $L = \Sigma_i l_i$ and $S = \Sigma_i s_i$. That the eigenfunctions must be antisymmetric restricts the number of possible L and S values for any given configuration. Since $J = L + S$ is also a solution of H_0, we can represent the eigenstates of the configuration by the ket $|LSM_LM_S\rangle$ or alternatively by $|LSJM_j\rangle$ where the eigenstates of the latter are linear combinations of the former.

There is a particular significance to the requirement of antisymmetric wavefunctions in the Slater determinantal representation. A determinant in which any two rows or columns are identical has the value of zero. In the present context, if two one-electron states are identical, then two columns of the Slater determinant are identical, and the wavefunction is identically zero. This is a statement of the Pauli exclusion principle: no two electrons in an atom can occupy identical states (i.e., can have the same four quantum numbers). The Slater wavefunctions indicate those one-electron states which are occupied by electrons. To see how this works consider two equivalent electrons in p-states on an atom. For $n = n'$ for both electrons, the l-values may be combined vectorially to give $L = 2$, 1, and 0. Similarly, the two electron spins, $s = \frac{1}{2}$, may be combined to give $S = 1$ or 0. The antisymmetric requirement on the total wavefunction means that the symmetric orbitals $D(L = 2)$ and $S(L = 0)$ states can only be combined with the antisymmetric spin singlet, $S = 0$. The resulting spin orbitals are represented by ^1D and ^1S. In contrast the antisymmetric P state must be combined with the spin triplet, which is a symmetric function, yielding the antisymmetric spin orbital, ^3P. However, for two inequivalent p-electrons in an excited state of the atom both spin singlet and spin triplet states are possible for the S, P, and D orbital states.

10.8 OPTICAL SPECTRA AND THE OUTER ELECTRONIC STRUCTURE

Optical spectroscopy probes those electronic transitions associated with a small number of electrons outside the closed shells of electrons. This gives further simplification to the computational problem since the multielectron hamiltonian

$$H = \sum_i \frac{p_i^2}{2m} + V'(r_i) + \zeta(r_i) l_i \cdot s_i + \sum_{i>j} \left(\frac{e^2}{4\pi\varepsilon_0 r_i} \right) \tag{35}$$

is summed only over the outer electrons where each of these electrons moves in the central field of the nucleus and the inner closed-shell electrons, $V'(r_i)$. Neglecting the smallest term due to the spin-orbit interaction, the hamiltonian in Eq. (35) takes the form $H_0 + H'$, where H_0 is a sum of one-electron hamiltonian with the radial potential functions $V'(r_i)$ and H' is the energy of the Coulomb interaction between the small number of outer electrons. The corrections to the one-electron energies are then the diagonal matrix elements $\langle n_i l_i m_i m_{si} | H' | n_i l_i m_i m_{si} \rangle$, expressed either in terms of Racah parameters, A, B, C, or Slater parameters, F_0, F_2, F_4 . . . .[24] Transition metal ion energy levels are normally described in terms of the Racah parameters and rare earth ion energy levels in terms of the Slater functions. The effect of H' is to split each configuration $(n_i l_i)$ into a number of LS terms for each of which there are $(2L + 1)(2S + 1)$ distinct energy eigenstates. We represent the energy eigenstates by the kets $|(n, l)LSJM_J\rangle$, which are defined as linear combinations of the $|(n_i l_i)LSM_L M_S\rangle$ states.

Returning briefly to the $(np)^2$ configuration (characteristic of the Group-4 elements, C, Si, Ge, etc. of the Periodic Table) it is noted that the diagonal matrix elements evaluated in terms of the Slater parameters are given by $E(^1D) = F_0 + F_2$, $E(^1S) = F_0 + 10F_2$, and $E(^3P) = F_0 - 5F_2$. For different atoms it is the relative values of F_0 and F_2 which change through the series $(2p)^2$, $(3p)^2$, $(4p)^2$, etc. Note that it is the term with maximum multiplicity, ^3P, which is lowest in energy in conformity with Hund's rule. A similar situation arises for the $(np)^4$ configuration of, for example, atomic O, S, and Se which might equally and validly be considered as deriving from two holes in the $(np)^2$ configuration. The general conclusion from this type of analysis is that the energy level structures of atoms in the same period of the Periodic Table are identical, with the principal differences being the precise energies of the eigenstates. This is evident in Fig. 3, the term scheme for atomic Li, which has the outer electron configuration $(2S)^1$; this may be looked on as a pseudo-one-electron atom. There is a general spectroscopic similarity with atomic hydrogen, although the $(ns)^1 - (np)^1$ splittings are much larger than in hydrogen. The $3S_{1/2} \leftrightarrow 2S_{1/2}$ transition is forbidden in Li just as the $2S_{1/2} \leftrightarrow 1S_{1/2}$ transition is in hydrogen. However, it is unlikely to be observed as a two-photon process in emission because the $3S_{1/2} \rightarrow 2P_{3/2,\,1/2}$ and $2P_{3/2,\,1/2} \rightarrow 2S_{1/2}$ transitions provide a much more effective pathway to the ground state.

The comparison between Li and Na is much more complete as Figs. 3 and 4 show: assuming as a common zero energy the ground state, the binding energies are $E(2S_{1/2}, \text{Li}) = 43{,}300\ \text{cm}^{-1}$ and $E(3S_{1/2}, \text{Na}) = 41{,}900\ \text{cm}^{-1}$. The energies of the corresponding higher lying nS, nP, and nD levels on Li are quite similar to those of the $(n + 1)S$, $(n + 1)P$, and $(n + 1)D$ levels on Na. This similarity in the energy level structure is reflected in the general pattern of spectral lines, although the observed wavelengths are a little different. For example, the familiar D lines in the emission spectrum of Na occur at $\lambda \simeq 589.9$ nm whereas the corresponding transition in Li occur at 670.8 nm.

Examination of the term schemes for a large number of elements reveal striking similarities between elements in the same group of the Periodic Table, due to this structure being determined by the number of electrons outside the closed shell structure. These term diagrams also reveal a very large number of energy levels giving rise to line spectra in the ultraviolet, visible, and infrared regions of the spectrum. The term diagrams are not very accurate. Tables of accurate energy levels determined from line spectra have been compiled by Moore[25] for most neutral atoms and for a number of ionization states of the elements. This comprehensive tabulation reports energy levels to a very large principal quantum number ($n \cong 10, 11$).

The term diagram of the neutral Tl atom, $(6p)^1$ configuration (see Fig. 5) shows two interesting features in comparison with those for alkali metals (see Figs. 3 and 4). In the $(6p)^1$ state the spin-orbit splitting into $6P_{1/2}$ and $6P_{3/2}$ levels amounts to almost 8000 cm^{-1} whereas the spin-orbit splitting

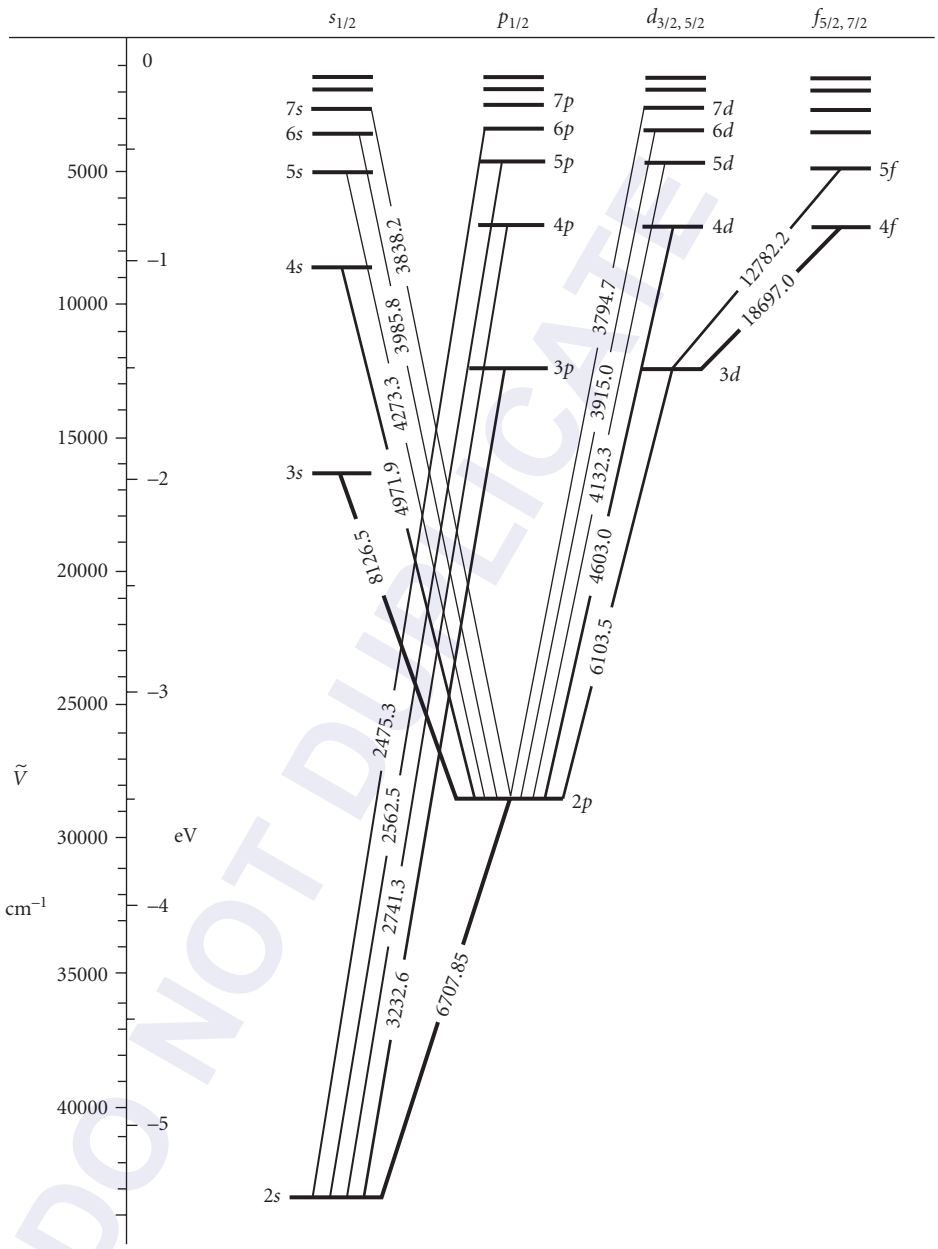

FIGURE 3 The term diagram of atomic Li, in which the slanted lines indicate the observed electric dipole transitions and the numbers on the lines are the wavelengths in Ångstrom units. (*After Grotian*.[26])

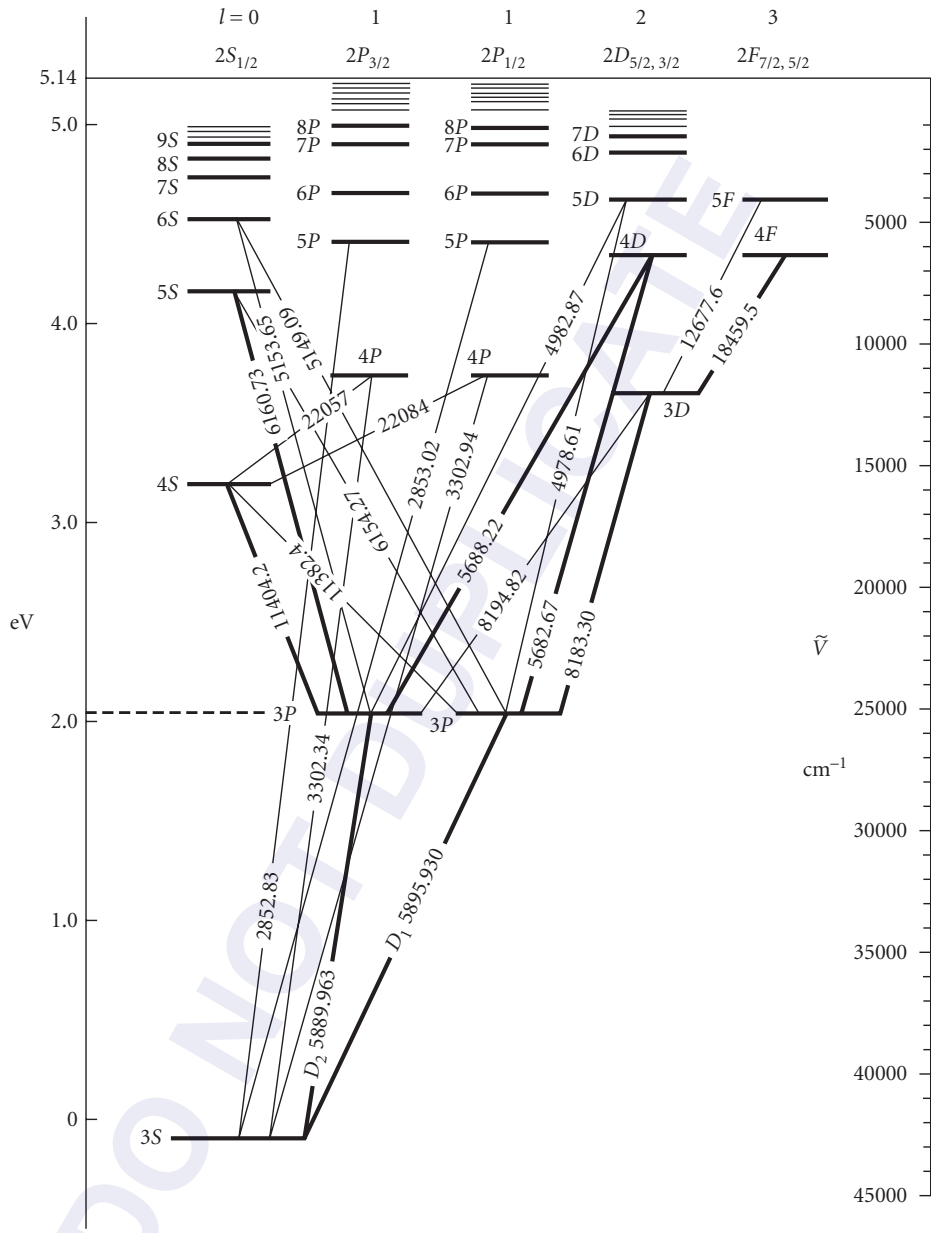

FIGURE 4 The term diagram of atomic Na. (*After Grotian.*[26])

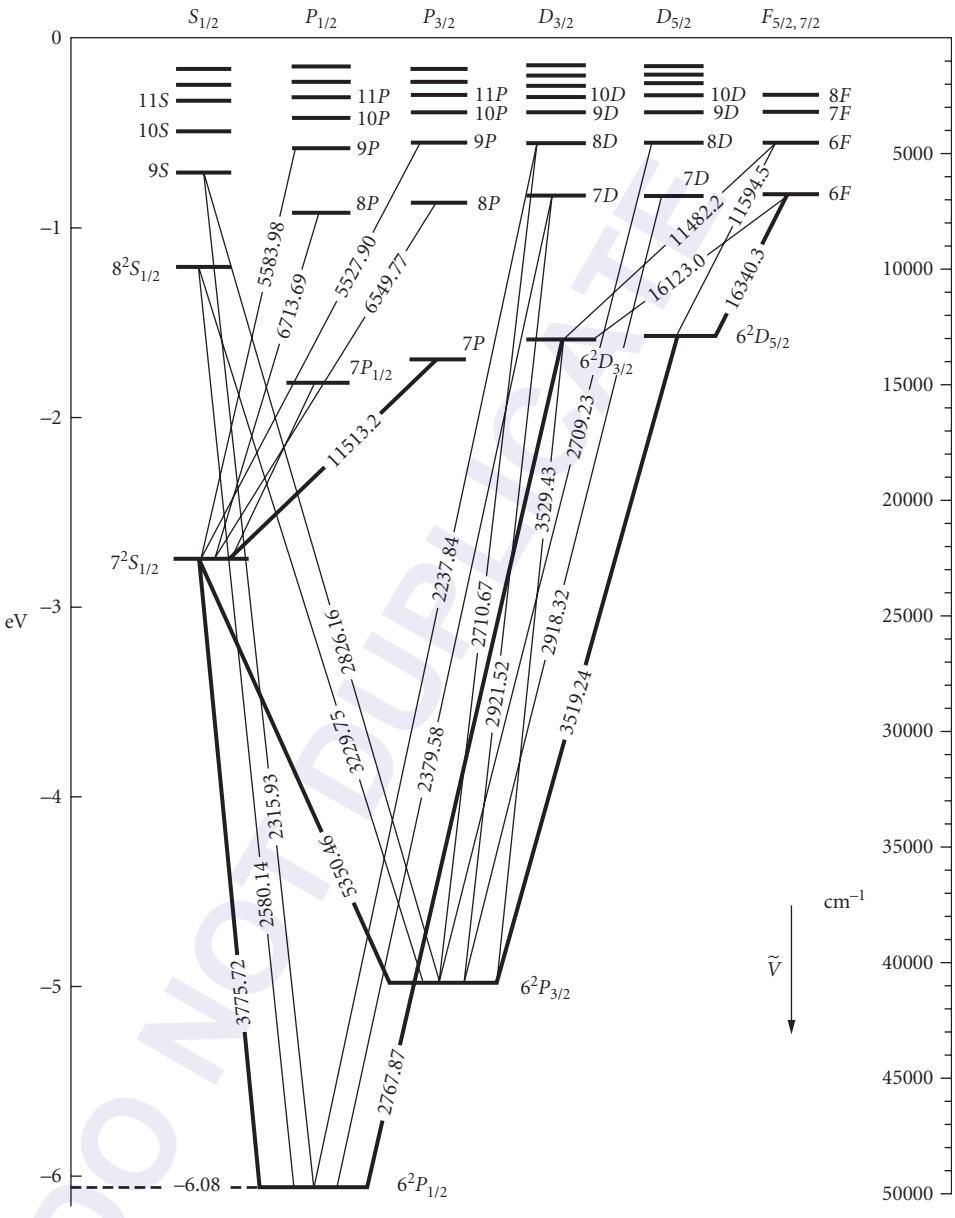

FIGURE 5 The term diagram of neutral Tl. (*After Grotian.*[26])

between the $3P_{1/2}$ and $3P_{3/2}$ levels of Na is only 17 cm^{-1}. This reflects the (Z^4/n^3) dependence of the spin-orbit coupling constant. Furthermore, when Tl is in the $7S_{1/2}$ state it can decay radiatively via transitions to either $6P_{3/2}$ or $6P_{1/2}$, each with a distinct transition probability. The relative probability of these transitions is known as the branching ratio for this mode of decay. Other examples of branching are apparent in Fig. 5: the branching ratios are intrinsic properties of the excited state.

10.9 SPECTRA OF TRI-POSITIVE RARE EARTH IONS

The rare earth elements follow lanthanum (Z = 57) in the Periodic Table from cerium (Z = 58), which has the outer electron configuration $4f^15d^16s^2$ to ytterbium (Z = 70) with electron configurations $4f^{13}5d^16s^2$. In the triply charged state in ionic crystals all *5d* and *6s* electrons are used in ionic bonding and the many energy levels of these rare earth $(RE)^{3+}$ ions are due to the partially filled *4f* shell. The number of electrons in the *4f* shell for each trivalent ion and the ground-state configuration is indicated in Table 1. The energy levels of the unfilled $4f''$ shells spread out over some 40,000 cm^{-1}, giving rise to numerous radiative transitions with energies in the visible region. A remarkable feature of the $4f^n$ electrons is that they are shielded by the outer *5s* and *5d* shells of electrons, with the result that *4f* electrons are not strongly affected by interactions with neighboring ions in crystals. In consequence, the energy levels of the *4f* electrons in crystals are essentially the free ion levels characterized by quantum numbers *L*, *S*, and *J*. As with the free ions the $R.E.^{3+}$ ions in crystals have very sharp energy levels which give rise to very sharp line spectra. The crystal field interaction does split the RE^{3+} ion levels, but this splitting is very much smaller than the splittings between the free-ion levels. Hence for rare earth ions in different crystals the gross features of the optical spectra are unchanged.

As discussed in Sec. 10.6 the eigenstates of the *4f* electrons are calculated using the central field approximation from which each *4f* electron state is characterized by the ket $|n=4,\ l=3 m_l m_s\rangle$. The effect of the Coulomb repulsion between electrons, $H' = \sum_i e^2/4\pi\varepsilon_0 r_{ij}$, is to split the energy levels of the $4f^n$ configuration into different *LS* terms, with wavefunctions characterized by kets $|LSM_L M_S\rangle$. The magnitudes of the electrostatic interaction for each *LS* level are expressed as sums of Slater electron-electron integrals F_k, with $k = 0, 2, 4$, and 6 for *4f* electrons. Since F_0 contributes equally to all *LS* states of the same $4f^n$ configuration, this term can be neglected. Generally, these Slater integrals are regarded as adjustable parameters with magnitudes determined by fitting to the measured line spectra. The values of the F_k integrals for $4f^n$ ions in many crystals vary by only about 2 percent from those obtained for free ions; they also vary slightly depending on the nature of the surrounding ions. The next largest term in the hamiltonian, after H', is spin-orbit coupling. If the spin-orbit coupling

TABLE 1 The Number of Electrons (*n*) and Ground State of Tri-positive Rare Earth Ions

Ion	*n* (in ed^n)	Ground state

Yb^{3+}	13	$^2F_{7/2}$

energy is much smaller than the energy separation in the *LS* term then the spin-orbit interaction can be written as ζLS and the wavefunctions are characterized by $|LSJM_J\rangle$. The additional energy of the *J*-multiples are given by the Landé interval formula

$$E_J = \frac{\zeta}{2}[J(J+1) - L(L+1) - S(S+1)] \tag{36}$$

from which it is evident that the separation between adjacent levels is given by $J\zeta$ where *J* refers to the upper *J* value. However, deviations from this Landé interval rule do occur because of mixing of different *LS*-terms when spin-orbit coupling and electron-electron interaction are of similar magnitudes. Clear examples of this are obtained from the spectra of $Pr^{3+}(4f^2)$ and $Tm^{3+}(4f^{12})$.

As representative of the type of spectra observed from R.E.$^{3+}$ ions in ionic crystals we consider just one example: $Nd^{3+}(4f^3)$ in $Y_3Al_3O_{12}$(YAG). The Nd^{3+}-YAG material is important as the gain medium. Nd^{3+} has a multitude of levels many of which give rise to sharp line emission spectra. A partial energy level structure is shown in Fig. 6. The low-temperature emission is from the $^4F_{3/2}$ level

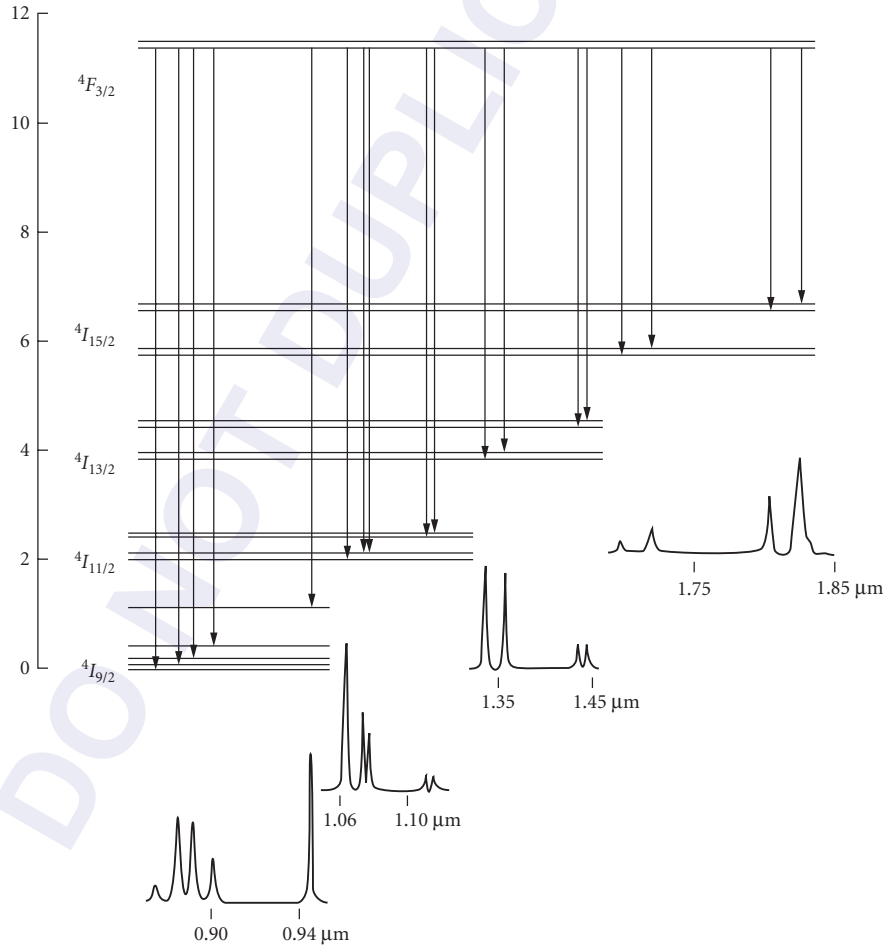

FIGURE 6 The low-temperature photoluminescence spectrum from the $^4F_{3/2}$ level of Nd^{3+} in $Y_3Al_5O_{12}$ and the corresponding energy level structure. (*After Henderson and Imbusch.*[8])

to all the ^4I_J levels of the Nd^{3+} ion. The spectra in Fig. 6 also show the splittings of the ^4I_J levels by the crystal field, corresponding to the energy-level splitting patterns given in the upper portion of Fig. 6. Depending upon crystal quality these lines can be quite narrow with half-widths of order a few gigahertz. Nevertheless the low-temperature width in the crystal is determined by the distribution of internal strains and hence the lines are in homogeneously broadened. The natural linewidth of rare earth ion spectra is of the order of a few megahertz. By using optical hole burning (OHB), which is similar to the saturated absorption spectroscopy discussed earlier for atomic hydrogen, it is possible to eliminate the inhomogeneous broadening and recover the homogeneous lineshape of the spectrum. In principle, the natural width is determined by lifetime processes of which there are more numerous sources in crystals than in atomic vapors. Indeed the width may be determined by random modulation of the optical lineshape by photons and by both nuclear and electronic spins of neighboring ions. The two most general techniques for determining the homogeneous widths of optical transitions in solids are optical holeburning and fluorescence line narrow (FLN). Examples of these techniques are discussed in Chap. 2 of Vol. V.

10.10 VIBRATIONAL AND ROTATIONAL SPECTRA OF MOLECULES

A consultation of any one of the tables of data in Moore's compilation[25] shows that the energy level schemes of most atoms are complex. This is confirmed by the associated atomic spectra. Considerable interpretive simplication is afforded by the construction of term diagrams (e.g., Figs. 3 to 5), on which a very large number of lines may be associated with a much smaller number of terms, each term corresponding to an energy level of the atom. The observed spectral lines are due to transitions between pairs of terms (not all pairs) which occur subject to an appropriate selection rule. The spectra of even simple molecules measured with low-dispersion show characteristic band spectra which are even more complicated than the most complex atomic spectra. These band spectra, when studied at higher spectral resolution, are observed to consist of an enormous number of closely spaced lines. At first acquaintance, such band spectra appear to be so complex as to defy interpretation. Order can be brought to the riot of spectral components by constructing term schemes for molecules involving electronic, vibrational, and rotational energy terms, which enable the molecular spectroscopist to account for each and every line.

Molecular physics was a research topic to which quantum mechanics was applied from the very earliest times. Heitler and London developed the valence band theory of covalency in the H_2-molecule in 1927.[27] The theory shows that with both electrons in 1s states there are two solutions to the hamiltonian

$$E_{\pm} = 2E(1\mathrm{H}) + \frac{K \pm \mathfrak{I}}{1 \pm \mathcal{S}} \tag{37}$$

where $E(1H)$ is the energy of an electron in the ground state of atomic hydrogen, K is the Coulomb interaction due to the mutual actions of charges distributed over each atom, $\mathfrak{I}$ is the exchange energy, and $\mathcal{S}$ is the overlap integral. The exchange energy is a purely quantum mechanical term, representing the frequency with which the deformation of the wavefunctions by their mutual interaction oscillates from one atom to another. The positive sign refers to the symmetric combination of orbital wavefunctions for the two hydrogen atoms. Since the overall wavefunction must be antisymmetric, the combined spin states must be antisymmetric (i.e., the spin singlet $S = 0$; this state is labeled $^1\Sigma_g$). The evaluation of the integrals in Eq. (37) as a function of internuclear separation leads to Fig. 7 for the spin singlet state. This $^1\Sigma_g$ ground state has a potential energy minimum of about 4.8 eV (experimentally) with the nuclei separated by 0.75 nm, relative to the total energy of the two hydrogen atoms at infinity. The theoretical value of the binding energy on the valence band model is only 3.5 eV.[27] The negative sign in Eq. (37) guarantees that in the state characterized by the antisymmetric combination of orbital states and $S = 1$, i.e., $^3\Sigma_u$, the energy is monotonically ascending,

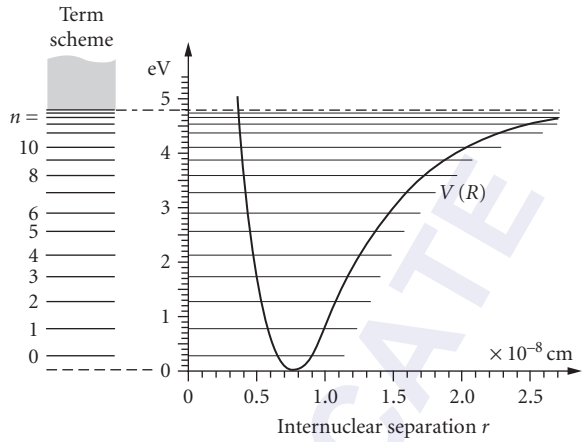

FIGURE 7 The internuclear potential, $V(R - R_o)$, in the ground state $^1\Sigma_g$ of the hydrogen molecule.

corresponding to repulsion between the two hydrogen atoms for all values of R. In such a state the molecule dissociates.

The energy versus internuclear separation curve in Fig. 7 represents the effective potential well, in which the protons oscillate about their mean positions. This is the potential used in the Born-Oppenheimer treatment of the molecular vibrations in the spectra of diatomic molecules.[28] The potential function may be written as a Taylor expansion

$$V(R-R_0)=V_0+(R-R_0)\left(\frac{dV}{d(R-R_0)}\right)_0+\frac{(R-R_0)^2}{2}\left(\frac{d^2V}{d(R-R_0)^2}\right)_0$$
$$+\frac{(R-R_0)^3}{6}\left(\frac{d^3V}{d(R-R_0)^3}\right)_0$$

where the subscript 0 refers to values of the differentials *at* $R = R_0$ and higher terms have been ignored. For a molecule in stable equilibrium the potential energy is a minimum and the force at $R = R_0$ must be zero. In consequence, the potential energy function may be written as

$$V(R-R_0)=\frac{1}{2}(R-R_0)^2\left(\frac{d^2V}{d(R-R_0)^2}\right)_0+\frac{1}{6}(R-R_0)^3\left(\frac{d^3V}{d(R-R_0)^3}\right)_0 \tag{38}$$

after setting $V_0 = 0$.

The excited states of H_2 are constructed on the assumption that only one electron is excited in the transition: the appropriate configurations may be written as (1*s*, 2*s*), (1*s*, 2*p*), (1*s*, 3*s*), etc. The electronic states of the molecule are then suitable combinations of the atomic states and categorized according to the total orbital angular momentum determined by vector addition of individual electronic orbital momenta. These orbital angular momentum states are designated as Σ, Π, Λ, etc. when the total angular momentum quantum number is 0, 1, 2, etc. Thus the electronic state in Fig. 7 is described as the $^1\Sigma_g$ (ground state) and the lowest lying excited state as $^3\Sigma_u$, where the subscripts *g* and *u* indicate even (gerade) and odd (ungerade) parity of the orbital states, respectively. The first excitation states associated with the (1*s*, 2*s*) molecular configuration, designated as $^1\Sigma_g$ and $^3\Sigma_u$, have energies

$$E_{\pm}=E(1\mathrm{H})+E(2\mathrm{H})+\frac{K\pm\Im}{1\pm\mathcal{S}} \tag{39}$$

Because the charge distributions are different in the atomic 1*s* and 2*s* states, the values of K and $\Im$ are also different in the (1*s*, 2*s*) configuration relative to the ground configuration. Obviously, as the orbital degeneracy of the molecular configuration increases so does the number of molecular levels resulting from the configuration. For example, there are six molecular levels associated with (1*s*, *np*) configuration, ten associated with (1s, *nd*), and so on. Roughly speaking, half of these levels will have a potential minimum in a graph of electronic potential energy versus internuclear separation (e.g., Fig. 7), and are associated with "bonding" orbitals of the molecule. In the other levels the force between the constituent atoms is repulsive for all values of the internuclear separation. In such orbitals the molecules will tend to dissociate.

The potential energy curve for a molecular bonding orbital (e.g., Fig. 7) is of the form given by Eq. (38). In the lowest order approximation this relation defines a potential well which is harmonic in the displacements from the equilibrium value. Of course, not all values of the potential energy, $V(R - R_0)$, are permitted: the vibrational energy of the molecule is quantized, the quantum number n having integral values from $n = 0$ to infinity. The energy levels are equally spaced with separations $h\nu_v$. The second term is an anharmonic term which distorts the parabolic shape relative to the harmonic oscillator. There are two important differences between the quantized harmonic and anharmonic oscillators. First, where there is an infinite number of levels in the former, there is only a finite number of vibrational states for an anharmonic molecule. Second, the levels are not equally spaced in the anharmonic oscillator, except close to the potential minimum. For this reason the anharmonic oscillator will behave like a harmonic oscillator for relatively small values of the vibrational quantum number. It is normal to assume harmonic vibrations in the Born-Oppenheimer approximation.[28]

Molecular spectra fall into three categories, according as they occur in the far infrared (20 to 100 μm), near infrared (800 to 2000 nm), or visible/near ultraviolet (750 to 150 nm) region. Spectra excited by radiation in the infrared region are associated with changes in the rotational energy of the molecule. Spectra in the near-infrared region correspond to simultaneous changes in the rotational and vibrational energy of the molecule. Finally, the visible and ultraviolet spectra signal simultaneous changes in the rotational, vibrational, and electronic energies of the molecule. The latter category has the greatest potential complexity since in interpreting such visible/ultraviolet spectra we must, in principle, solve the molecular hamiltonian containing terms which represent electronic, vibrational, and rotational energies.

If we simplify the molecular problem somewhat we may represent the stationary states of a molecule by a linear sum of three energy terms: an electronic term determined by a quantum number n, a vibrational term determined by a quantum number v, and a rotational term determined by a quantum number r. The band spectra emitted by molecules are then characterized by three different kinds of excitations: electronic, vibrational, and rotational with frequencies in the ratio $\nu_{el} : \nu_v : \nu_r = 1 : \sqrt{m/M} : m/M$, where m is the electronic mass and M is the reduced molecular mass. In an optical transition the electronic configuration (nl) changes, and generally we expect the vibrational/rotational state to change also. In consequence, for a particular electronic transition, we expect splittings into a number of vibrational components, each of which is split into a number of rotational components. Using the rough ratio rule given previously, and assuming the Rydberg to be a characteristic electronic transition, we find spectral splittings of 500 cm^{-1} and 60 cm^{-1} to characterize the vibrational and rotational components, respectively. Since the quantized energy levels of the harmonic oscillator and rigid rotor are given by

$$E_v = \left(n + \frac{1}{2}\right) h\nu_v \tag{40}$$

$$E_r = r(r+1)h\nu_r \tag{41}$$

where $\nu_v = (1/2\pi)\sqrt{k/M}$ and $\nu_r = \hbar/4\pi I$, in which k is the "spring" constant and $I = Ml^2$ is the moment of inertia for a dumbbell-shaped molecule of length l, and applying to the usual selection rules for electronic ($\Delta l = \pm 1$, with $\Delta j = 0, \pm 1$), vibrational ($\Delta v = \pm 1\ \pm 2, \ldots$), and rotational ($\Delta r = 0, \pm 1$) transitions, we expect transitions at the following frequencies

$$\nu = \nu_0 + (n'' - n')/\nu_v + [r''(r''+1) - r'(r'+1)]\nu_r \tag{42}$$

where the superscript primes and double primes refer to final and initial states. For simplicity we have assumed that the vibrational spring constants and rotational moments of inertia are unchanged in the transitions. The number of potential transition frequencies is obviously very large and the spectrum consists of very many closely spaced lines. Of course, the vibrational/rotational structure may be studied directly in microwave spectroscopy.[29] An early account of the interpretation of such spectra was given by Ruark and Urey.[30] For many years such complex spectra were recorded photographically; as we discuss in later sections, Fourier transform spectroscopy records these spectra electronically and in their finest detail. Subsequent detailed accounts of the energy levels of molecular species and their understanding via spectroscopic measurements have been given by Slater, Hertzberg, and others.[31–33]

An example of the complexities of band spectra, for a simple diatomic molecule, is given in Fig. 8, in this case for the photographically recorded β-bands ($2\Pi \rightarrow 3\Sigma$) of the nitric oxide molecule. Under low dispersion band spectra are observed (see Fig. 8*a*) which break down into line spectra under very high resolution (see Fig. 8*b*). This band system is emitted in transitions having common initial and final electronic states, with all the electronic states corresponding to a multiplet in atomic spectra. The electronic energy difference determines the general spectral range in which the bands are observed. However, the positions of the individual bands are determined by the changes in the vibrational quantum numbers. The spectra in Fig. 8 are emission spectra: the bands identified in Fig. 8*a* by (n', n'') are so-called *progressions* in which the transition starts on particular vibrational levels $(n' = 0)$ of the upper electronic state and ends on a series of different vibrational levels (n'') of the lower electronic level. Such n' progressions measure the vibrational energy level differences in the lower electronic levels. Specifically identified in Fig. 8*a* are band progressions $n' = 0 \rightarrow n'' = 4, 5, 6, 7 \ldots$ and $n' = 1 \rightarrow n'' = 10, 11, 12 \ldots$. Also evident, but not identified in Fig. 8*a*, are *sequences* of lines in which the difference in vibrational quantum number $n' - n''$ is a constant. For example, either side of the (0, 4) band can be seen $\Delta n = -4$ and -3 sequences, respectively.

The (0, 7) band is shown under much higher spectral resolution in Fig. 8*b,* revealing a plethora of closely spaced lines associated with the rotational structure. For transitions in which the vibrational quantum number changes by some multiple of unity, i.e., $\Delta n = 1, 2, 3, \ldots$, the rotational quantum number changes by $\Delta r = 0$ and ± 1. The three branches of the rotational spectrum have the following positions (measured in cm^{-1}):

$$R = A + 2B(r+1) \qquad \text{for } \Delta r = -1 \text{ and } r = 0, 1, 2 \ldots \tag{43a}$$

$$Q = A + Cr \qquad \text{for } \Delta r = 0 \quad \text{and } r = 0, 1, 2 \ldots \tag{43b}$$

$$P = A - 2Br \qquad \text{for } \Delta r = +1 \text{ and } r = 1, 2, 3 \ldots \tag{43c}$$

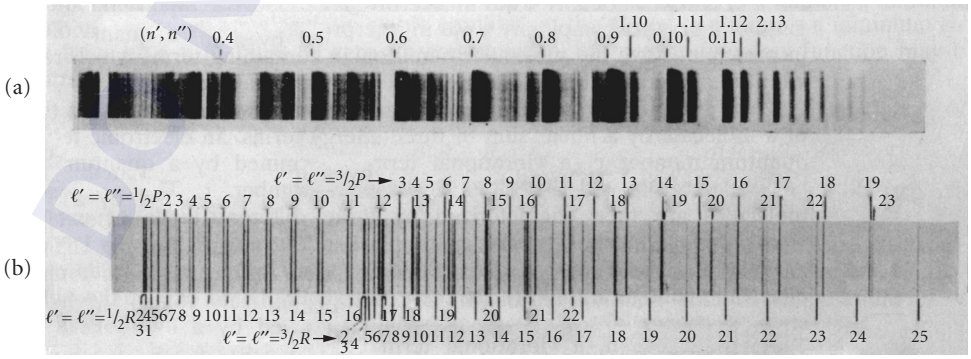

FIGURE 8 Characteristic band spectra of the diatomic NO molecule under conditions of (*a*) low resolution and (*b*) high resolution. (*After Ruark and Urey.*[30])

where in each case r refers to the rotational quantum number in the final electronic-vibrational state, $A=\overline{\upsilon}_e+\overline{\upsilon}_v$, and $B=\hbar/4\pi cl$. In consequence, if $C=0$, the Q-branch consists of a single line at $Q(r)=\nu_e+\nu_v$, and the P- and R-branches shift linearly to lower and higher wavenumbers, respectively, relative to the Q-branch for increasing values of r. The spectra in Fig. 8 show that for the NO molecule $C\neq 0$ so that the lines in the P- and R-branches are shifted by $\pm 2B$ relative to the Q-branch lines. The particular Q-branches are defined by $l'=l''=r+\frac{1}{2}$ with r being either 0 or 1, i.e., $l'=l''=\frac{1}{2}$ or $\frac{3}{2}$. The $C\neq 0$ implies that the Eqs. (41) and (43) are inaccurate and additional rotational energy terms must be included even for vibrational states close to the bottom of the potential well (i.e., small n-values). Roughly the rotational term in Eq. (43) must be multiplied by $1-(2\hbar^2(r+1)^2/4\pi^2I^2)$, which has the further consequence that the separations of lines in the P- and R-branches corresponding to particular values of r increase with increasing r. A detailed analysis of Fig. 8*b* shows this to be the case.

10.11 LINESHAPES IN SOLID STATE SPECTROSCOPY

There are many modes of vibration of a crystal to which the optical center is sensitive. We will concentrate on one only, the breathing mode in which the ionic environment pulsates about the center. The variable for the lattice state, the so-called configurational coordinate, is labeled as Q. For the single mode of vibration the system oscillates about its equilibrium value Q_0^a in the ground state and Q_0^b in the excited state. The ground and excited state configurational coordinate curves are assumed to have identical harmonic shapes, and hence vibrational frequencies for the two states. This is illustrated in Fig. 9. In the Born-Oppenheimer approximation the optical center-plus-lattice system is represented in the electronic ground state by the product function[28]

$$\Phi_a(r_i, Q)=\Psi_a(r_i, Q_0^a)\chi_a(Q) \tag{44}$$

and in the electronic excited state by

$$\Phi_b(r_i, Q)=\Psi_b(r_i, Q_0^b)\chi_b(Q) \tag{45}$$

The first term in the product is the electronic wavefunction, which varies with the electronic positional coordinate r_i, and hence is an eigenstate of $H_0=\sum_i(p_i^2/2m)+V'(r_i)$, and is determined at the equilibrium separation Q_0^a. The second term in the product wavefunction is $\chi_a(Q)$, which is a function of the configurational coordinate Q. The entire ionic potential energy in state a is then given by

$$E^a(Q)=E_0^a+V_a(Q) \tag{46}$$

The $E^a(Q)$ in Fig. 9 is a harmonic potential function. This is an approximation to the potential used in Eq. (38) and illustrated in Fig. 7. A similar expression obtains for $E^b(Q)$. This representation of the Born-Oppenheimer approximation is often referred to as the *configurational coordinate model.*[39]

Treating the electronic energy of the ground state E_0^a as the zero of energy, we write the ionic potential energy in the ground state as

$$E^a(Q)=\frac{1}{2}M\omega^2(Q-Q_0^a)^2 \tag{47}$$

and in the excited state as

$$E_0^b(Q)=E_{ab}+\frac{1}{2}M\omega^2(Q-Q_0^a)^2-(2S)^{1/2}\hbar\omega\left(\frac{M\omega}{\hbar}\right)^{1/2}(Q-Q_0^a) \tag{48}$$

where E_{ab} is essentially the peak energy in an absorption transition between states $|a\rangle$ and $|b\rangle$ with the lattice at the coordinate, Q_0^a, where the Huang-Rhys parameter S is defined as

$$S=\frac{E_{\text{dis}}}{\hbar\omega}=\frac{1}{2}\frac{M\omega^2}{\hbar\omega}(Q_0^b-Q_0^a)^2 \tag{49}$$

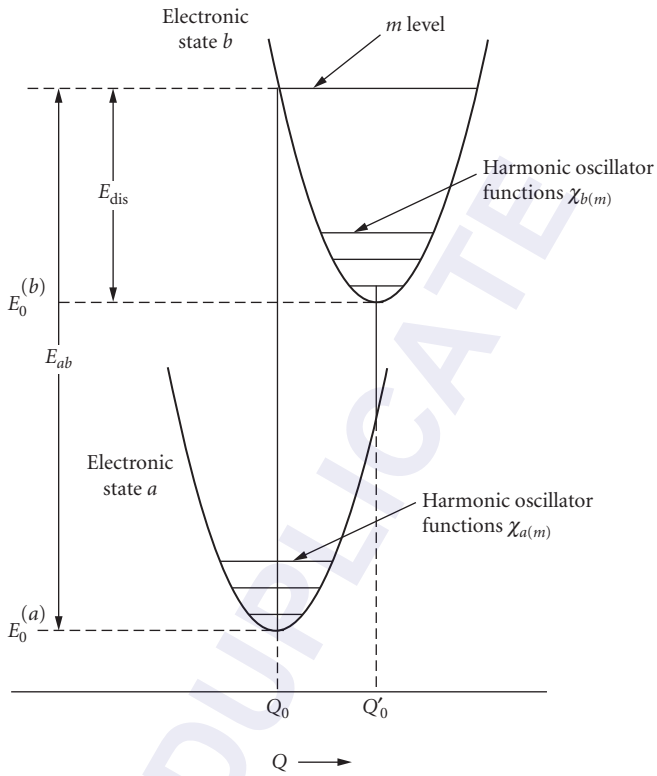

FIGURE 9 A configurational coordinate diagram showing the interionic potential in the harmonic approximation for electronic states $|a\rangle$ and $|b\rangle$. (*After Henderson and Imbusch.*[8])

If the vertical line from $Q=Q_0^a$ in Fig. 9 intersects the upper configurational coordinate curve at the vibrational level n' then

$$E_{\text{dis}} = S\hbar\omega = \left(n' + \frac{1}{2}\right)\hbar\omega \tag{50}$$

The shapes of absorption and emission spectra are found to depend strongly on the difference in electron-lattice coupling between the states, essentially characterized by $(Q_0^b - Q_0^a)$ and by E_{dis}.

The radiative transition rate between the states $|a, n'\rangle \rightarrow |b, n''\rangle$, where n' and n'' are vibrational quantum numbers, is given by[8]

$$W(a, n' - b, n'') = |\langle \psi_b(r_i, Q_0^a)\chi_b(n'')|\mu|\psi_a(r_i, Q_0^a)\chi_a(n')\rangle|^2 \tag{51}$$

It can be written as

$$W(a, n' - b, n'') = W_{ab}\,|\langle \chi_b(n'')|\chi_a(n')\rangle|^2 \tag{52}$$

where W_{ab} is the purely electronic transition rate. The shape function of the transition is determined by the square of the vibrational overlap integrals, which are generally not zero. The

absorption bandshape at $T = 0$ K, where only the $n' = 0$ vibrational level is occupied, is then given by

$$I_{ab}(E) = I_0 \Sigma_{n''} \frac{S^{n''} \exp(-S)}{n''!} \delta(E_0 + n''\hbar\omega - E) \tag{53}$$

where $E_0 = E_{b0} - E_{a0}$ is the energy of the transition between the zero vibrational levels of electronic states a and b. This is usually referred to as the *zero-phonon transition,* since $\Sigma_{n''} S^{n''} \exp(-S)/n''! = 1$. I_0 is the total intensity of the transition, which is independent of S. The intensity of the zero-phonon transition I_{00} is given by

$$I_{00} = I_0 \exp(-S) \tag{54}$$

so that if $S = 0$ all the intensity is contained in the zero-phonon transition. On the other hand, when S is large, the value of I_{00} tends to be zero and the intensity is concentrated in the *vibrational sidebands.* The single configurational coordinate model is relevant to the case of electron-vibrational structure in the spectra of molecules and the intensities so calculated fit observations rather well.

The net effect of this analysis is given in Fig. 10, which represents the absorption case when $S = 2$. At $T = 0$ we see a strong zero-phonon line, even stronger phonon-assisted transitions at $n'' = 1$ and 2, and then decreasing intensity in the phonon sidebands at $n'' = 3, 4, 5, \ldots$. These individual transitions are represented by the vertical lines in this predicted spectrum. The envelope of these sidebands, given by the solid line, represents the effects of adding a finite width, $n''\hbar\omega$, to each sideband feature.

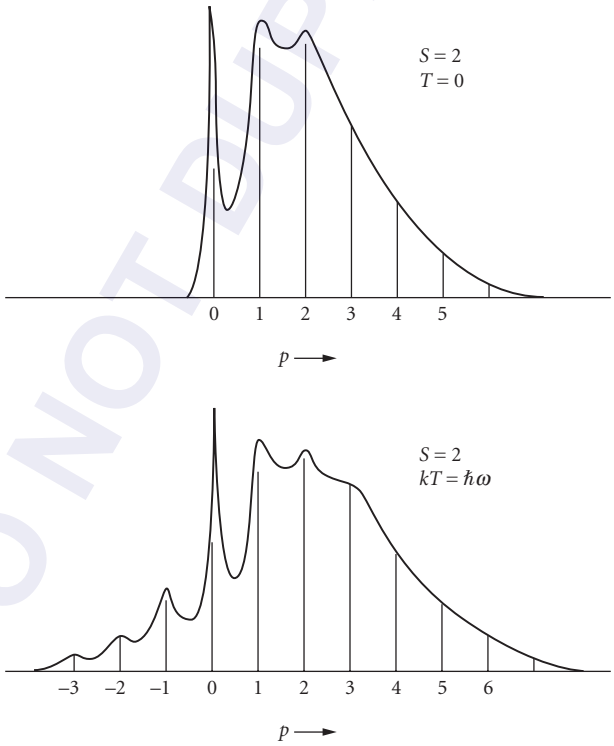

FIGURE 10 Showing the zero-phonon line and the Stokes shifted sideband on one side of the zero-phonon line at $T = 0$. When the temperature is raised the anti-Stokes sidebands appear on the other side of the zero-phonon line. (*After Henderson and Imbusch.*[8])

The effect is to smear out the structure, especially at larger phonon numbers. Also in Fig. 10 we show the effect of temperature on the sideband shape in absorption, which is to reveal structure at lower energies than that of the zero-phonon line. Although the lineshape changes, the total intensity is independent of temperature, whereas the zero-phonon line intensity is given by

$$I_{00} = I_0 \exp\left[-S \coth\left(\frac{\hbar\omega}{2kT}\right)\right] \tag{55}$$

which decreases with increasing temperature. For values of $S \ll 1$, the phonon sideband intensity increases according to $I_0 S \coth(\hbar\omega/2kT)$. These effects are also shown in Fig. 10.

Three examples of the optical bandshapes in solid state spectra are considered. Figure 11 shows the luminescence spectrum of the molecular ion O_2^- in KBr measured at 77 K.[34] The O_2^- ion emits in the visible range from 400 to 750 nm, and the spectrum shown corresponds to the vibrational sidebands corresponding to $n'' = 5$ up to 13. The optical center is strongly coupled, $S = 10$, to the internal vibrational mode of the O_2^- ion with energy $\hbar\omega \simeq 1000\ \text{cm}^{-1}$. However, as the detail of the $n'' = 8$ electronic vibrational transition is shown at $T = 4.2$ K, there is also weak coupling $S \simeq 1$ to the phonon spectrum of the KBr, where the maximum vibrational frequency is only about 200 cm^{-1}.

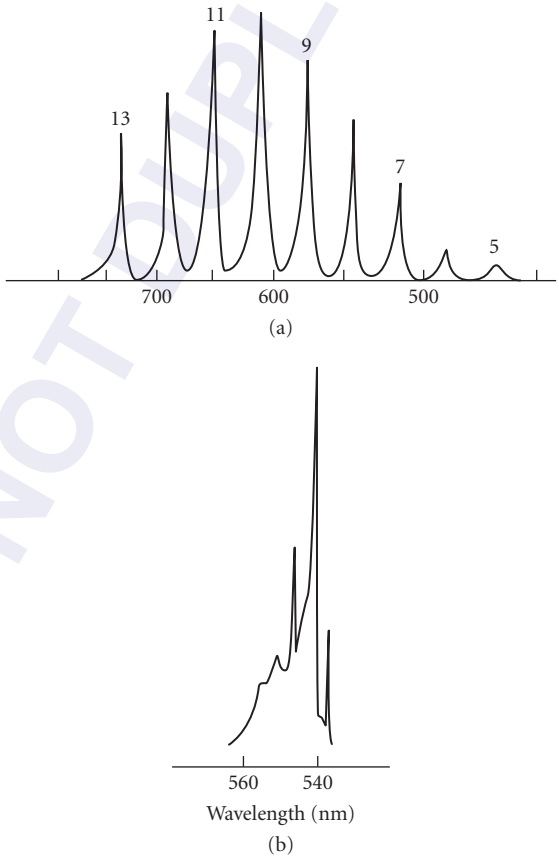

FIGURE 11 Photoluminescence spectrum of O_2^- in KBr at 77 K. *(After Rebane and Rebane.[34])*

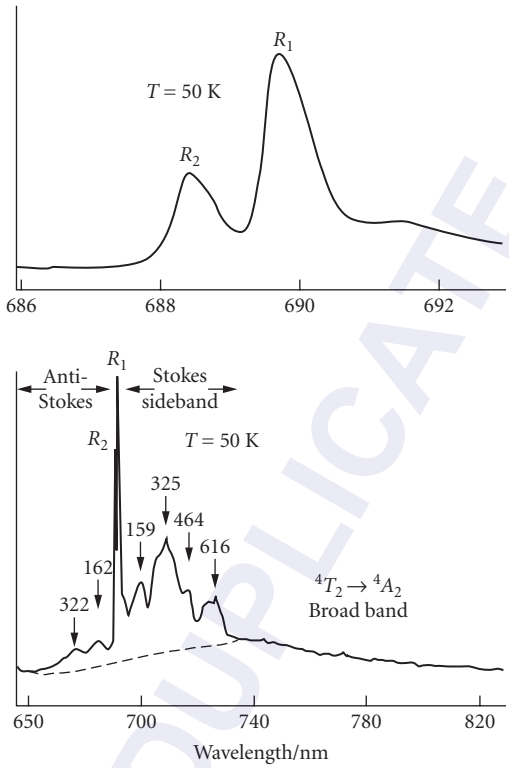

FIGURE 12 The photoluminescence spectrum of Cr^{3+} ions in $Y_3Ga_5O_{12}$.

The Cr^{3+} ion occupies a central position in the folklore of solid state spectroscopy. In yttrium gallium garnet, $Y_3Ga_5O_{12}$, the Cr^{3+} ion occupies a Ga^{3+} ion site at the center of six octahedrally-disposed O^{2-} ions. The crystal field at this site is intermediate in strength[8] so that the ^2E and $^4T_2$ states are mixed by the combined effects of spin-orbit coupling and zero-point vibrations. The emission then is a composite spectrum of $^2E \rightarrow {}^4A_2$ transition and $^4T_2 \rightarrow {}^4A_2$ transition, with a common radiative lifetime.[35] The composite spectrum, in Fig. 12, shows a mélange of the *R*-line and its vibronic sideband, $^2E \rightarrow {}^4A_2$ transition with $S \sim 0.3$, and the broadband $^4T_2 \rightarrow {}^4A_2$ transition for which $S \sim 6$.[36] Understanding this particular bandshape is complex.[35–37]

The final example, in Fig. 13, shows the absorption and emission spectra of *F*-centers in KBr.[38] This is a strongly coupled system with $S \simeq 30$. Extension of the configurational coordinate model to the luminescence spectrum shows that the absorption and emission sidebands are mirror images of each other in the zero-phonon line. With *S* small (less than 6) there is structure in absorption and emission. However for *S* large, there is no structure, at least when a spectrum of vibrational modes interacts with the electronic states. The *F*-center represents strong coupling to a band of vibrational frequencies rather than to a single breathing mode of vibration. The effect of this is to broaden the spectrum to look like the envelope encompassing the spectrum of sharp sidebands shown in Fig. 10. In this case the zero-phonon line position is midway between the peaks in the absorption and emission bands of the *F*-center in KBr. Note also that as the temperature is raised the bands broaden and the peak shifts to longer wavelengths.

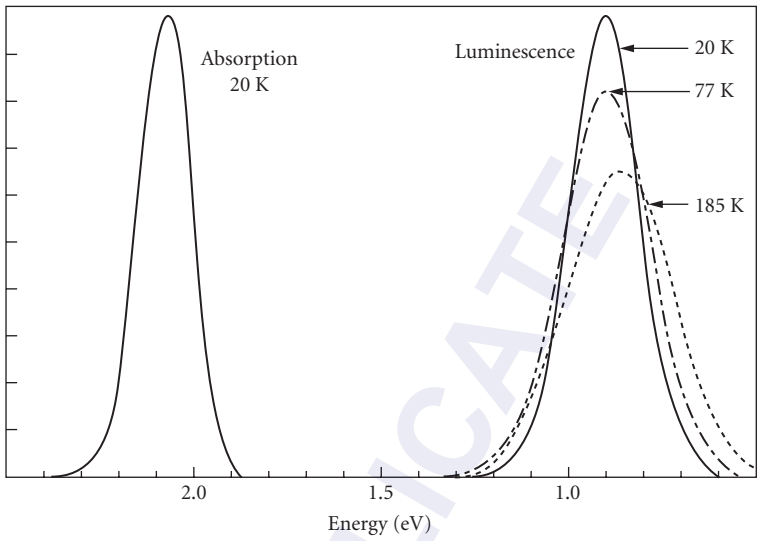

FIGURE 13 Optical absorption and photoluminescence of *F*-centers in KBr. (*After Gebhardt and Kuhnert.*[37])

ANALOG OPTICAL SIGNAL AND IMAGE PROCESSING

Joseph W. Goodman

Department of Electrical Engineering
Stanford University
Stanford, California

11.1 GLOSSARY

$C(\tau)$	cross-correlation function
d, z	distances
f	focal length
f_X, f_Y	spatial frequencies
$H(f_X, f_Y)$	transfer function
$I(x, y)$	intensity distribution
i	square root of negative one
$\mathbf{M}$	matrix
$t_A(x, y)$	amplitude transmittance of a transparency
$U(x, y)$	phasor representation of a monochromatic field
$\mathbf{u}, \mathbf{v}$	vectors
V	velocity of propagation
x, y	spatial coordinates
θ_B	Bragg angle
λ	wavelength
Λ	period of grating
ν	optical frequency
τ	time delay

11.2 INTRODUCTION

The function of signal and image processing systems is the modification of signals and images to allow information extraction by a human observer or, alternatively, to allow fully automatic information extraction without human intervention. The origins of optical information processing are several, but certainly the invention of various techniques for visualizing the phase distribution of optical wavefronts qualifies (e.g., Ref. 1), as do the famous Abbe-Porter experiments.[2,3] Starting in the 1950s, more general information processing tasks were undertaken with the help of optics.[4,5] This chapter presents an overview of such methods.

Optical systems are of interest both for digital processing of information and for analog processing of information. Our attention here will be restricted only to analog processing operations, which are far more mature and well developed than digital optical methods.

Certain basic assumptions will be used throughout and are detailed here. First, monochromatic optical signals will be represented by complex phasor field distributions, with the direction of phasor rotation being assumed to be clockwise. Similarly, time-varying optical fields will be represented by complex analytic signals, again with the direction of rotation in the complex plane being clockwise. In both cases the underlying real signals are recoverable as the real part of the complex representations. In all cases, a small-angle assumption will be employed, allowing paraxial approximations to be used. Polarization effects will generally be ignored, it being assumed that a scalar theory of light propagation is sufficiently accurate for our purposes.[6] The intensity of the optical waves, which is proportional to power density and is the observable quantity in an optical experiment, is defined as the squared magnitude of the complex fields.

It is very important to distinguish at the start between *coherent* and *incoherent* optical systems. For a review of optical coherence concepts, see Chap. 5 of this volume. For our purposes, we will regard an optical signal as coherent if the various optical contributions that produce an output add on an amplitude basis, with fixed and well-defined relative phases. Signals will be regarded as incoherent if the various contributions that add to produce an output at any point have time-varying phase relations, and therefore must add on an intensity or average-power basis.

11.3 FUNDAMENTAL ANALOG OPERATIONS

The fundamental components of any linear processing operation are addition and multiplication. We consider each of these operations separately.

Addition

Analog addition takes place in optical systems when light waves or wave components are superimposed. The exact nature of the addition depends on whether the optical components are mutually coherent or incoherent. In the coherent case, addition of complex phasor field components takes place. Thus if the $U_n(x, y)$ represent various optical field components that are superimposed at a given point (x, y) at the output, the resultant optical field $U(x, y)$ is given by

$$U(x, y) = \sum_n U_n(x, y) \tag{1}$$

Note that the result of such a superposition depends on the phases of the individual components.

On the other hand, if the various optical contributions at (x, y) are mutually incoherent, the addition takes place on an intensity basis. The resultant intensity $I(x, y)$ is given by

$$I(x, y) = \sum_n I_n(x, y) \tag{2}$$

where the $I_n(x, y)$ are the component intensity contributions. In this case the component intensity contributions are always positive and real, as is the resultant intensity.

In view of the above two equations, an important point can now be made. Coherent optical systems are *linear in complex amplitude,* while incoherent optical systems are *linear in intensity*. The design of an analog processing system thus depends fundamentally on whether the illumination used in the system is coherent or incoherent.

Multiplication

Analog multiplication takes place in optical systems as light passes through an absorbing or phase-shifting structure. If we define the complex amplitude transmittance $t_A(x, y)$ of a transmitting structure as the ratio of the transmitted complex field to the incident complex field, then analog multiplication in a coherent system is represented by

$$U_t(x, y) = t_A(x, y)U_i(x, y) \tag{3}$$

where $U_i(x, y)$ is the incident optical field and $U_t(x, y)$ is the transmitted optical field.

When the optical system is incoherent, then we define an intensity transmittance $t_I(x, y)$ as the ratio of the transmitted optical intensity to the incident optical intensity. Analog multiplication in such systems is represented by

$$I_t(x, y) = t_I(x, y)I_i(x, y) \tag{4}$$

Thus we have seen that the fundamental analog operations of addition and multiplication are quite naturally available in optical systems. It should be kept in mind that the operation of integration is just a generalization of addition, involving addition of an infinite number of infinitesimal components.

11.4 ANALOG OPTICAL FOURIER TRANSFORMS

Perhaps the most fundamental optical analog signal- and image-processing operation offered by optical systems is the Fourier transform. Such transforms occur quite simply and naturally with coherent optical systems. While Fourier sine and cosine transforms can be performed with incoherent light, the methods used are more cumbersome than in the coherent case and the numbers of resolvable spots involved in the images and transforms are more restricted. Therefore we focus here on Fourier transforms performed by coherent optical systems. The Fourier transform is normally two-dimensional in nature (image processing), although it can be restricted to a single dimension if desired (signal processing).

Focal-Plane-to-Focal-Plane Geometry

The optical system required to perform a two-dimensional Fourier transform is remarkably simple as shown in Fig. 1. We begin with a spatially coherent source of quasi-monochromatic light (a source that is both spatially and temporally coherent). The light from that point source is collimated by a positive lens and a transparency of the image to be Fourier transformed is introduced in the front

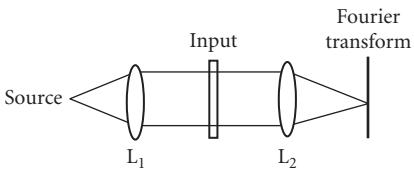

FIGURE 1 Simple optical system for performing a two-dimensional Fourier transform.

focal plane of a second positive lens (L_2). Under such conditions, the complex field appearing across the rear focal plane of that lens can be shown to be the two-dimensional Fourier transform of the complex field transmitted by the input transparency, as given by

$$U_f(x, y) = \frac{1}{i\lambda f}\int\int_{-\infty}^{\infty} U_i(\xi, \eta)\exp\left[-i\frac{2\pi}{\lambda f}(x\xi + y\eta)\right]d\xi\, d\eta \tag{5}$$

Here λ is the optical wavelength, f is the focal length of the second lens, U_f is the field distribution across the back focal plane of lens L_2, and U_i is the field transmitted by the transparency in the front focal plane.

An intuitive explanation for the occurrence of this elegant relationship between the fields in the two focal planes can be presented as follows. If we were to mathematically Fourier transform the fields transmitted by the input transparency, each such Fourier component could be recognized as a different plane wave component of the transmitted field. Each such Fourier component represents a plane wave traveling in a unique direction with respect to the optical axis. Such representations are the basis for the so-called angular spectrum of plane waves often used in the analysis of optical wavefields (see, for example, Ref. 6, p. 48). Now consider the effect of the positive lens on a single Fourier component, i.e., a plane wave traveling at a particular angle with respect to the optical axis. As that plane wave passes through the lens L_2, it is changed into a spherical wave converging toward a focus in the rear focal plane, in a particular location determined by that plane wave's propagation direction. Thus the intensity of light at a given coordinate in the rear focal plane is proportional to the energy contained by the input wavefield at a particular Fourier spatial frequency. Hence the distribution of energy across the rear focal plane is a representation of the distribution of energy across the various spatial frequencies contained in input transparency.

Other Fourier Transform Geometries

A slightly more general configuration is one in which the input transparency is placed at an arbitrary distance d in front of the lens L_2, while the field is again considered in the rear focal plane of that lens. The relation between the input and output fields remains of the general form of a two-dimensional Fourier transform, but with the complication that a multiplicative quadratic phase factor is introduced, yielding a relation between input and focal-plane fields given by

$$U_f(x, y) = \frac{\exp\left[i\frac{k}{2f}\left(1-\frac{d}{f}\right)(x^2+y^2)\right]}{i\lambda f}\int\int_{-\infty}^{\infty} U_i(\xi, \eta)\exp\left[-\frac{i2\pi}{\lambda f}(x\xi + y\eta)\right]d\xi\, d\eta \tag{6}$$

Three additional Fourier transform geometries should be mentioned for completeness. One is the case of an object transparency placed directly against the lens in Fig. 1, either in front or in back of the lens. This is a special case of Eq. (6), with d set equal to 0, yielding

$$U_f(x, y) = \frac{\exp\left[i\frac{k}{2f}(x^2+y^2)\right]}{i\lambda f}\int\int_{-\infty}^{\infty} U_i(\xi, \eta)\exp\left[-\frac{i2\pi}{\lambda f}(x\xi + y\eta)\right]d\xi\, d\eta \tag{7}$$

Another situation of interest occurs when the object transparency is located behind the lens L_2, a distance d from the focal plane, as shown in Fig. 2. In this case the relationship between the fields transmitted by the object and incident on the focal plane becomes

$$U_f(x, y) = \frac{\exp\left[i\frac{k}{2d}(x^2+y^2)\right]}{i\lambda d}\frac{f}{d}\int\int_{-\infty}^{\infty} U_i(\xi, \eta)\exp\left[-\frac{i2\pi}{\lambda d}(x\xi + y\eta)\right]d\xi\, d\eta \tag{8}$$

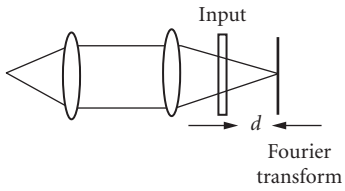

FIGURE 2 Fourier transform geometry with the object behind the lens.

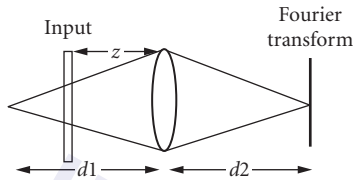

FIGURE 3 Fourier transform geometry using a single lens.

Note that now the scaling distance in the Fourier kernel is d, rather than the focal length f. Therefore, by moving the object toward or away from the focal plane, the transform can be made smaller or larger, respectively.

While the Fourier transform plane in all the above examples has been the rear focal plane of the lens L_2, this is not always the case. The more general result states that the Fourier transform always appears in the plane where the original point-source of illumination is imaged by the optical system. In the previous examples, which all involved a collimating lens L_1 before the object transparency, the source was indeed imaged in the rear focal plane of L_2, where we asserted the Fourier transform lies. However, in the more general case depicted in Fig. 3, the point source of light lies in plane P_1 and its image lies in plane P_2, which for this geometry is the Fourier transform plane. A single lens L_1 performs both imaging of the source and Fourier transformation of the fields transmitted by the input transparency. If the input is placed to the right of the lens, at distance d from the image of the source, then the Fourier transform relation is identical to that presented in Eq. (8), for it does not matter what optical system illuminated the transparency with a converging spherical wave, only what distance exists between the input and the plane where the source is imaged.

If the input transparency is placed to the left of the single lens, as shown in Fig. 3, the resulting relationship between the fields transmitted by the object U_i and the fields across the plane where the source is imaged, U_f, becomes

$$U_f(x, y) = \frac{d_1}{i\lambda d_2(d_1 - z)} \exp\left\{i\frac{k}{2}\left(\frac{1}{d_2} - \frac{zd_1}{d_2^2(d_1 - z)}\right)\right\} \times \int\int_{-\infty}^{\infty} U_i(\xi, \eta) \exp\left\{-i\frac{2\pi d_1}{\lambda d_2(d_1 - z)}[x\xi + y\eta]\right\} d\xi\, d\eta \tag{9}$$

where the meanings of z, d_1, and d_2 are shown in Fig. 3, and $k = 2\pi/\lambda$. In this relation, d_1 and d_2 are connected through the lens law, $1/d_1 + 1/d_2 = 1/f$. It can be shown quite generally that the effective distance d associated with the Fourier transform kernel is $d = d_2/d_1(d_1 - z)$, while the quadratic phase factor is that associated with a diverging spherical wave in the transform plane that appears to have originated on the optical axis in the plane of the input transparency.

11.5 SPATIAL FILTERING

Given that Fourier transforms of optical fields occur so directly in coherent optical systems, it seems natural to consider the intentional manipulation of such spectra for the purposes of signal or image processing. Given that a signal or image has been introduced into the coherent optical system, either by means of photographic film or by means of an electronically or optically controlled spatial light modulator (see Chap. 6, "Acousto-Optic Devices," in Vol. V), the idea is to insert in the plane where the Fourier transform occurs a transparency (again either film or a spatial light modulator) which intentionally alters the fields transmitted through that plane. A second Fourier transforming lens

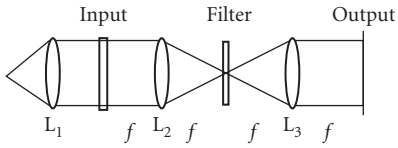

FIGURE 4 Spatial filtering system based on double Fourier transform.

then returns the observer to an image plane, where the filtered version of the input can be measured or extracted. The simplest geometry from the conceptual point of view is that shown in Fig. 4.

The lens L_1 is again a collimating lens, the lens L_2 is a Fourier transforming lens, and the lens L_3 is a second Fourier transforming lens. The fact that a sequence of two Fourier transforms takes place, rather than a Fourier transform followed by an inverse Fourier transform, results simply in an inversion of the image at the output of the system.

Systems of this type form the basis for coherent optical spatial filtering, although the detailed geometry of the layout may vary. We will discuss several such spatial filtering problems in later sections. For the moment it suffices to say that if a filtering system is desired to have a transfer function $H(f_X, f_Y)$ then the amplitude transmittance of the transparency inserted in the Fourier plane should be

$$t_A(\xi, \eta) = H\left(\frac{\xi}{\lambda f}, \frac{\eta}{\lambda f}\right) \tag{10}$$

where λ has been defined, f is the focal length of the Fourier transforming lenses (assumed identical), and (ξ, η) represent the spatial coordinates in the filter plane.

11.6 COHERENT OPTICAL PROCESSING OF SYNTHETIC APERTURE RADAR DATA

The earliest serious application of coherent optics to signal processing was to the problem of processing data gathered by synthetic aperture radars. We explain the synthetic aperture principle, and then discuss optical signal-processing architectures that have been applied to this problem.

The Synthetic Aperture Radar Principle

The synthetic-aperture radar problem is illustrated in Fig. 5. An aircraft carrying a stable local oscillator and a side-looking antenna flies a straight-line path, illuminating the terrain with microwave energy and detecting the returned energy reflected and scattered from that terrain. In the simplest case, resolution in range (i.e., perpendicular to the aircraft flight path) is obtained by pulse echo timing, the usual radar range–measurement technique. Resolution in azimuth (the direction parallel to the flight path) is obtained by processing the Doppler-shifted returns, as will be explained. For the purpose of explaining the azimuth imaging, we neglect the pulsed nature of the radiation emitted by the aircraft, an approximation allowable because of the pulse-to-pulse coherence of the signals. The goal of the system is to obtain a two-dimensional image of the microwave reflectivity of the ground illuminated by the aircraft. The resolution of the system is not limited by the size of the antenna that is carried by the aircraft—in fact resolution increases as the size of the antenna is decreased. The system coherently combines the signals received along a portion of the flight path, thereby synthesizing the equivalent of a much longer antenna array.

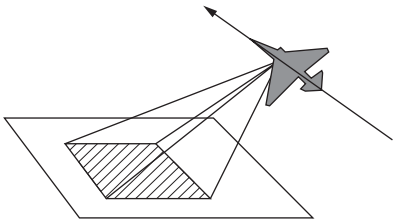

FIGURE 5 Aircraft flight path.

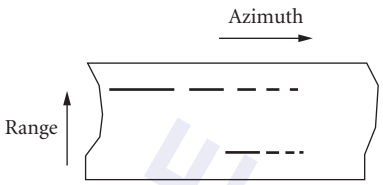

FIGURE 6 Recording format for signals received.

If we consider the signal received at the aircraft as a function of time, originating from a single point scatterer on the ground, that signal will suffer an upward frequency shift as the aircraft approaches the scattered and a downward frequency shift as the aircraft flies away from the scatterer. This chirping signal is beat against the stable local oscillator in the aircraft, a bias is added, and the new signal is then recorded on a strip of film. Figure 6 shows the recording format. In the vertical direction, different scatterers are separated by the pulse echo timing, each being imaged on a separate horizontal line of the film. In the horizontal direction, the time histories of the chirping azimuth signals from different scatterers are recorded.

The signal recorded from a single scatterer is in fact an off-axis one-dimensional Fresnel zone plate, and as such is capable of imaging light in the horizontal direction to a focus. Such a focus constitutes the azimuthal image of the point scatterer that gave rise to this zone plate. However, the chirp rates, and therefore the focal lengths, of the zone plates produced by scatterers at different ranges are unfortunately not the same. The focal length is in fact proportional to the distance of the scatterer from the aircraft. Thus the focal points of scatterers at different ranges from the aircraft lie on a tilted plane with respect to the film plane, whereas the range images lie in the plane of the film. Thus the optical processing system must be designed to bring the two different images into coincidence.

Optical Processing Systems

The earliest system used for optical processing of synthetic aperture radar data is illustrated in Fig. 7.[7] This processor uses a conical optical element, called an axicon, to change the focal lengths of all horizontal zone plates to infinity, thus moving the azimuth image to infinity. A cylindrical lens is placed one focal length from the film to likewise move the range image to infinity, and a spherical lens is placed one focal length from the final image plane to bring the infinitely distant azimuth and range planes back to a common focus.

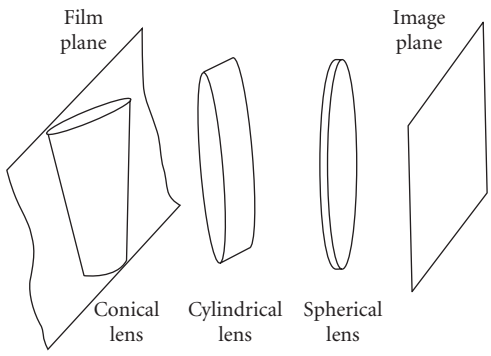

FIGURE 7 Processor using an axicon.

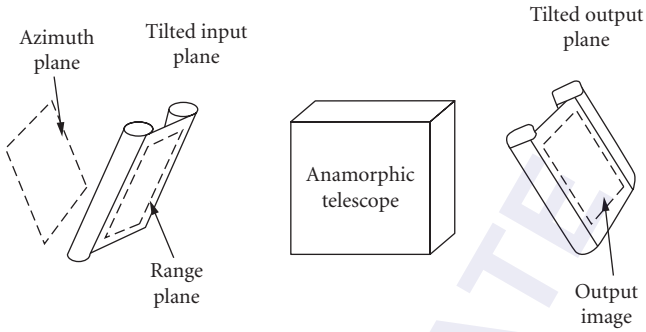

FIGURE 8 The tilted-plane processor.

The magnification achieved by such a system is a function of range, so the output is recorded through a vertical slit. As the input film is drawn through the system, an output film strip is likewise drawn past the slit in synchronism, with the result that an image with proper magnification is recorded at the output.

Following the use of such an optical system to produce images, a far more sophisticated processing system known as the "tilted-plane processor" was developed.[8] The architecture of this system is illustrated in Fig. 8. In this case an anamorphic telescope is used to bring the range and azimuth planes into coincidence with a constant magnification, allowing a full two-dimensional image to be recorded at the output at one time. Again motion of the input film and the output film takes place in synchronism, but the throughput of the system is much higher due to the absence of the output slit.

From the very fundamental work on processing synthetic aperture radar signals at the University of Michigan during the late 1950s and early 1960s came a multitude of extraordinary inventions, including holograms with an off-axis reference wave and the holographic matched filter, or Vander Lugt filter, discussed in Sec. 11.8.

11.7 COHERENT OPTICAL PROCESSING OF TEMPORAL SIGNALS

An important subclass of information-processing operations is those that are applied to one-dimensional signals that are functions of time. Such signals can be processed by coherent optical-filtering systems once a suitable transducer is found to convert time-varying voltages representing the signals into space-varying wavefields. The best developed and most common of such transducers is the acousto-optic cell.[9,10]

Acousto-Optic Cells for Inputting Signals

A time-varying electrical signal can be changed to an equivalent one-dimensional space-varying distribution of field strength by means of acousto-optic devices. In bulk form, such devices consist of a transducer, to which a time-varying voltage representing an RF signal is applied, and a transparent medium into which compressional waves are launched by the transducer. The RF signal is assumed to contain a carrier frequency, which generates a dynamic grating and, when illuminated by coherent light, produces a number of different diffraction orders, of which the +1 and −1 orders are of primary interest. Any modulation, in amplitude or phase, that may be carried by the RF signal is transferred to the spatial distributions of these diffraction orders.

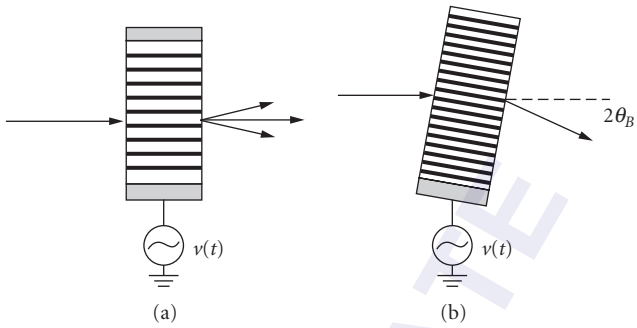

FIGURE 9 Acousto-optic diffraction in the (*a*) Raman-Nath and (*b*) Bragg regimes.

Acousto-optic diffraction is characterized as either *Raman-Nath* diffraction or *Bragg* diffraction, depending on the relations that exist between the cell thickness and the period of the acoustic wave generated by the RF carrier. For cells that are sufficiently thin, Raman-Nath diffraction takes place. The acousto-optic cell then acts like a thin phase grating, generating a multitude of diffraction orders. For cells that are sufficiently thick, Bragg diffraction takes place. In this case, high diffraction efficiency into a single grating order can be achieved if the acoustic grating is illuminated at the Bragg angle θ_B which satisfies

$$\sin\frac{\theta_B}{2}=\frac{\lambda}{2\Lambda} \tag{11}$$

In this case most of the optical power is transferred to the +1 diffraction order, and other orders, including the −1 and 0 orders can be neglected.

Figure 9 illustrates Raman-Nath and Bragg diffraction from an acousto-optic cell. $v(t)$ represents the voltage driving the cell transducer. For modern-day signal-processing applications, which involve very high microwave frequencies, the Bragg cell is invariably used, and the situation on the right-hand side of the figure is the one of interest.

The signal $v(t)$ is of the form (in complex notation)

$$v(t)=A(t)\exp\left[-i(2\pi\nu_0 t+\theta(t))\right] \tag{12}$$

where $A(t)$ is the amplitude modulation of the carrier, $\theta(t)$ is the phase modulation of the carrier, and ν_0 is the center frequency. If the speed of propagation of acoustic waves in the medium of the Bragg cell is V, then emerging from the right of that cell will be a spatial complex field distribution of the form

$$U(x,\,t)=A(x-Vt)\exp\left[-i\theta(x-Vt)\right] \tag{13}$$

where the dependence on y is suppressed due to uniformity of U in that dimension. Thus the temporal structure of the signal $v(t)$ has been changed to a spatial structure of the optical field $U(x, t)$.

The Bragg Cell Spectrum Analyzer

The most common use of coherent optics for signal processing is a method for finding and displaying the frequency (Fourier) spectrum of the electrical signal $v(t)$ applied to the cell. To construct such a spectrum analyzer, we follow the Bragg cell of Fig. 9 with a positive lens, which then Fourier transforms the wavefield emerging from the cell, as shown in Fig. 10. A detector array placed in the Fourier

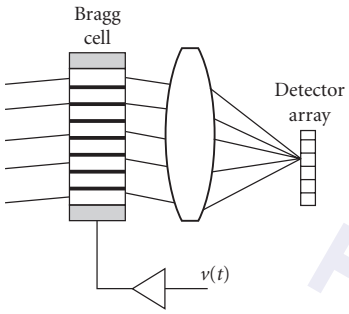

FIGURE 10 Bragg cell spectrum analyzer.

plane then measures the amount of signal power present in each frequency bin subtended by a detector element. Note the spectrum analysis is performed over a finite sliding window, namely, the window of time stored in the Bragg cell itself. Figure 10 shows a diagram illustrating the Bragg cell spectrum analyzer.

Assuming perfect optics, the resolution of such a spectrum analyzer is determined by the diffraction limit associated with the space window that is being transformed. The spatial dimension of a resolution element is given by $\Delta x = (\lambda f/L)$ where L is the length of the cell and f is again the focal length of the lens. Given the mapping from time to space that takes place in the cell, it follows that the temporal resolution of the spectrum analyzer (in hertz) is $\Delta \nu = (V/L)$.

Bragg cell spectrum analyzers have been built with center frequencies of more than 1 GHz, with bandwidths approaching 1 GHz, and time bandwidth products (equivalent to the number of resolvable spectral elements) of the order of 1000. While the vast majority of work on this type of spectrum analyzer has used bulk devices (e.g., bulk Bragg cells, discrete lenses, etc.), work has also been carried out on integrated versions. Such devices use planar waveguides rather than free-space propagation, surface acoustic waves rather than bulk acoustic waves, integrated optic lenses, etc. Such systems are more compact than those based on bulk approaches, but their performance is so far somewhat inferior to that of the more conventional bulk systems.

The chief difficulty encountered in realizing high-performance Bragg cell spectrum analyzers is the dynamic range that can be achieved. The dynamic range refers to the ratio of the largest spectral component that can be obtained within the limit of tolerable nonlinear distortion, to the smallest spectral component that can be detected above the noise floor.

Acousto-Optic Correlators

Many signal detection problems require the realization of correlators that produce cross-correlations between a local reference signal and an incoming unknown signal. A high cross-correlation between the reference and the unknown signal indicates a high degree of similarity between the two signals, while a low correlation indicates that the two signals are not very similar. Thus correlators play an important role in signal detection and recognition.

Given two complex-valued signals $\upsilon_1(t)$ and $\upsilon_2(t)$, the cross-correlation between those signals is defined as

$$C(\tau) = \int_{-\infty}^{\infty} \upsilon_1(t)\upsilon_2^*(t-\tau)dt \tag{14}$$

When υ_1 and υ_2 are identical, $C(\tau)$ achieves a peak value at the relative delay τ that causes the two signals to be identically aligned in time.

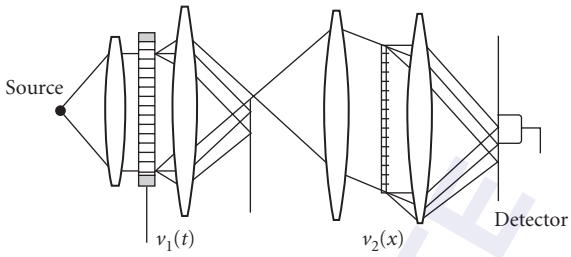

FIGURE 11 The time integrating correlator.

Two distinctly different architectures have been developed for using acousto-optic systems for cross-correlating wideband signals. We discuss each of these techniques separately.

The Space-Integrating Correlator The older of the two architectures is known as the space-integrating correlator. As the name indicates, the integration inherent in the correlation operation is carried out over space. The variable delay τ is achieved by allowing one signal to slip past the other in time.

Figure 11 shows the structure of a time-integrating correlator. One of the signals, $v_1(t)$, is introduced by means of an input Bragg cell. Spatial filtering is used to eliminate any residual of the zeroth and unwanted first diffraction orders, retaining only a single first order. The second signal, the reference $v_2(t)$, is stored on a transparency, complete with a spatial carrier frequency representing the center frequency and acting as a high-frequency amplitude- and phase-modulated grating. The integration over space is provided by the final output lens. The particular diffraction order used in the final transparency is chosen to yield the conjugate of $v_2(t)$. A point detector is used at the output, and different relative delays between the two signals are achieved simply by allowing $v_1(t)$ to slide through the Bragg cell.

The Time-Integrating Correlator A different approach to realizing the temporal cross-correlation operation is the so-called time-integrating correlator.[11,12] The architecture of a time-integrating correlator is illustrated in Fig. 12. Spatial filtering selects one component that has undergone zeroth-order diffraction by the first cell and first-order diffraction by the second, and another component that has undergone first-order diffraction by the first cell and zeroth-order by the second. These two components interfere on a time-integrating detector array.

As the name implies, the correlation integration is in this case carried out by temporal integration on an array of time-integrating detectors. Note that the two electrical signals are introduced at opposite ends of the Bragg cells, with the result that at each spatial position on the Bragg cell pair the two signals have been delayed relative to one another by different amounts, thus introducing the

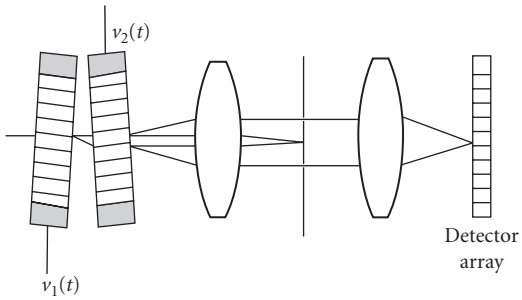

FIGURE 12 Time-integrating correlator.

relative delay required in the correlation integral. The lens on the right images the pair of Bragg cells onto the detector array. Thus different detector elements measure the interference of the two signals with different relative delays, one portion of which yields

$$\mathrm{Re}\{C(x)\} = \mathrm{Re}\left\{\int_T v_1\left[t-\left(\frac{x+L/2}{V}\right)\right] v_2^*\left[t+\left(\frac{x-L/2}{V}\right)\right] dt\right\} \tag{15}$$

which is the real part of the correlation integral of interest. Here L represents the length of the Bragg cells, V the velocity of propagation of acoustic waves, T the total integration time of the detector, and x is the position of a particular detector on the detector array at the output. Note that for the position x on the detector array the two signals have been delayed relative to each other by the amount

$$\tau = \frac{2x}{V} \tag{16}$$

Other variants of both space-integrating and time-integrating correlators are known but will not be presented here. Likewise, many architectures for other types of acousto-optic signal processing are known. The reader may wish to consult Ref. 13 for more details.

11.8 OPTICAL PROCESSING OF TWO-DIMENSIONAL IMAGES

Because optical systems are fundamentally two-dimensional in nature, they are well suited to processing two-dimensional data. The most important type of two-dimensional data is imagery. Thus we consider now the application of optical information processing systems to image processing. The applications of optical processing in this area can be divided into two categories: (1) pattern detection and recognition, and (2) image enhancement.

Optical Matched Filtering for Pattern Recognition

By far the most well-known approach to pattern recognition is by means of the matched filter.[14] While this approach has many known defects in the pattern recognition application, it nonetheless forms the basis for many other more sophisticated approaches.

The Matched Filter A linear invariant filter is said to be "matched" to a certain spatial image $s(x, y)$ if the impulse response (point-spread function) $h(x, y)$ of that filter is of the form

$$h(x, y) = s^*(-x, -y) \tag{17}$$

When a general signal $v(x, y)$ is applied to the input of such a filter, the output (the convolution of the input and the impulse response) is given by

$$\begin{aligned} w(x, y) &= \int\int_{-\infty}^{\infty} v(\xi, \eta) h(x-\xi, y-\eta)\, d\xi\, d\eta \\ &= \int\int_{-\infty}^{\infty} v(\xi, \eta) s^*(\xi-x, \eta-y)\, d\xi\, d\eta \end{aligned} \tag{18}$$

which is the *cross-correlation* between the signals $v(x, y)$ and $s(x, y)$. Thus the output of a matched filter is the cross-correlation between the input signal and the signal for which the filter is matched.

In the frequency domain, the convolution relation becomes a simple product relation. The frequency domain equivalent of Eq. (18) is

$$W(f_X, f_Y) = H(f_X, f_Y)V(f_X, f_Y) = S^*(f_X, f_Y)V(f_X, f_Y) \tag{19}$$

Thus the transfer function of the matched filter is the complex conjugate of the spectrum of the signal to which the filter is matched.

The coherent optical realization of the matched filter utilizes a system identical with that shown previously in Fig. 4, where the Fourier domain transparency is one with amplitude transmittance proportional to $S^*(f_X, f_Y)$. The output of the filter, appearing at the plane on the far right in Fig. 4, consists of a bright spot at each location where the signal $s(x, y)$ is located within the input field.

Prior to 1964, a key difficulty in the realization of matched filtering systems was the construction of the Fourier domain filter with the proper amplitude transmittance. To control the amplitude and phase transmittance through the Fourier plane in a relatively complicated manner was often beyond the realm of possibility. However, in 1964 Vander Lugt published his classic paper on holographically recorded matched filters, and many new applications became possible.

The Vander Lugt Filter The method introduced by Vander Lugt[15] for recording matched filters is shown in Fig. 13. It is assumed that a mask can be constructed with amplitude transmittance proportional to the desired impulse response $s^*(-x, -y)$, which in pattern recognition problems is often real and positive. That mask is illuminated by coherent light and Fourier transformed by a positive lens. In the Fourier domain, the spectrum $S^*(f_X, f_Y)$ is allowed to interfere with an angularly inclined reference wave, often a plane wave. The result is an intensity pattern with a high spatial frequency carrier, which is amplitude modulated by the amplitude distribution associated with the incident spectrum, and phase modulated by the phase distribution of that spectrum. This recording is in fact a Fourier hologram of the desired point-spread function[16] (see also Chap. 33, "Holography and Holographic Instruments," in this volume). The film used for recording in the Fourier domain responds to the incident optical intensity. With proper processing of the film, one of the grating orders of the resulting transparency yields a field component proportional to the desired field,

$$t_A(\xi, \eta) \approx S^*\left(\frac{\xi}{\lambda f}, \frac{\eta}{\lambda f}\right) \exp(-i2\pi\alpha\eta) \tag{20}$$

where (ξ, η) are the spatial coordinates in the filter plane, and α is the spatial frequency of the carrier. Thus the transmittance required for realizing the matched filter has been achieved, with the exception of the linear exponential term, which serves simply to shift the desired output off the optical axis.

The filter constructed as above is placed in the Fourier domain of the system in Fig. 4 and provided the correct region of the output plane in that figure is examined, the matched filter response is found. In a second region of the output plane, mirror symmetric with the matched filter region, the convolution of the signal $s(x, y)$ and the input $v(x, y)$ can be found.

Prior to Vander Lugt's invention the only matched filters that could be realized in practice were filters with very simple transfer functions $S^*(f_X, f_Y)$. The significance of the Vander Lugt filter is that it extends the domain for which filters can be realized to those with reasonably simple impulse responses $s(-x, -y)$, a case more typically encountered in pattern recognition.

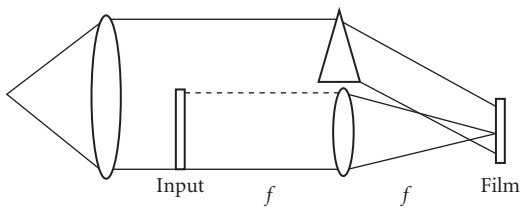

FIGURE 13 Recording a Vander Lugt filter.

Deficiencies of the Matched Filter Concept While the Vander Lugt filter provides an elegant solution to the problem of realizing coherent optical matched filters, nonetheless the use of coherent optics for pattern recognition has been very restricted in its applications. A major reason for this limited applicability can be traced to deficiencies of the matched filter concept itself, and is not due to the methods used for optical realization. The matched filter, in its original form, is found to be much too sensitive to parameters for which lack of sensitivity would be desired. This includes primarily rotation of the image and scale change of the image. Thus a matched filter that responds perfectly to the desired signal in its original rotation and scale size may not respond at all to that signal when it is rotated and magnified or demagnified.

Many attempts have been made to remove these undesired sensitivities of the matched filter (see for example, Refs. 17 and 18). These include the use of Mellin transforms and polar coordinate transformations to remove scale-size sensitivity and rotation sensitivity, and the use of circular harmonic decompositions to remove rotation sensitivity. These attempts have had varying degrees of success, but unfortunately they generally destroy one insensitivity that is present for a conventional matched filter, namely, insensitivity to translation of the signal. For a conventional matched filter, when an input $s(x, y)$ is translated, the resulting bright spot at the output translates in response. Realization of rotation invariance generally removes translation insensitivity, a serious loss.

Unfortunately, to date there have been no commercially successful applications of coherent optical matched filtering to pattern recognition, although several attempts to commercialize the technology have been made.

Coherent Optical Image Enhancement

Coherent optical spatial filtering systems can also be applied to the problem of image enhancement.[4] Image enhancement problems come in a wide variety of types, ranging from simple operations, such as the suppression of periodic noise in a nonperiodic image, to more complex operations, such as restoring an image that has been degraded by a known blur. We focus here on image restoration, since it is the most challenging of these problems.

The Inverse Filter A common type of image restoration problem arises when an image produced by an incoherent imaging system has been blurred by a known, space-invariant, linear point-spread function. Let $i(x, y)$ represent the intensity of the blurred image, $o(x, y)$ represent the intensity of the object, and $b(x, y)$ represent the intensity point-spread function of the blur. These three quantities are related through a convolution equation,

$$i(x,y)=\int\int_{-\infty}^{\infty} b(x-\xi,\, y-\eta)o(\xi,\, \eta)d\xi\, d\eta \tag{21}$$

The frequency domain equivalent is the relation

$$I(f_X, f_Y) = B(f_X, f_Y)O(f_X, f_Y) \tag{22}$$

where I, O, and B are the Fourier transforms of the lowercase quantities. The quantity B is the transfer function of the blur, and is assumed to be perfectly known.

Examination of Eq. (22) suggests an obvious approach to image restoration. Convolve the blurred image $i(x, y)$ with a kernel that provides a deblurring transfer function that is the reciprocal of the blur transfer function, i.e., having a transfer function given by $H(f_X, f_Y)=B^{-1}(f_X, f_Y)$. For obvious reasons, such a filter is referred to as an *inverse filter*. The restored image then is given, in the frequency domain, by

$$\begin{aligned} R(f_X, f_Y) &= [B(f_X, f_Y)O(f_X, f_Y)]H(f_X, f_Y) \\ &= [B(f_X, f_Y)O(f_X, f_Y)]B^{-1}(f_X, f_Y) \\ &= O(f_X, f_Y) \end{aligned} \tag{23}$$

Returning to the space domain we see that result of the image restoration operation is perfect recovery of the original object $o(x, y)$.

The inverse filter is an elegant mathematical solution to the restoration problem, but it lacks practicality. Many problems exist, both with the concept and with its implementation. The conceptual flaw, which is the most serious drawback, arises because the problem formulation completely neglected the inevitable presence of noise in the image $i(x, y)$. The inverse filter boosts those spatial frequency components the most that were suppressed the most by the blur. In such regions of the frequency domain there is little or no image information to be boosted, but there is always noise, which then is amplified to the point that it dominates the restored image.

Other problems arise due to the very large dynamic range required of the deblurring filter transfer function in many cases. For the above reasons, the inverse filter is never used in practice, although it is an important concept to be aware of.

The Wiener Filter The Wiener filter overcomes many of the difficulties of the inverse filter by explicitly including noise in the basic imaging model. In this case the detected image intensity is represented by

$$i(x, y) = \int\int_{-\infty}^{\infty} b(x-\xi, y-\eta) o(\xi, \eta) d\xi d\eta + n(x, y) \tag{24}$$

where $o(x, y)$ and $n(x, y)$ are regarded as statistically stationary random processes. The goal of the restoration process is now to choose a restoration filter that will minimize the mean-squared error between the restored image $r(x, y)$ and the original object $o(x, y)$. The solution to this problem can be shown to be a restoration filter having a transfer function of the form

$$H(f_X, f_Y) = \frac{B^*(f_X, f_Y)}{\left|B(f_X, f_Y)\right|^2 + \dfrac{P_N(f_X, f_Y)}{P_O(f_X, f_Y)}} \tag{25}$$

where P_N and P_O represent the power spectral densities of the respective noise and object random processes.

The Wiener filter provides a balance between uncompensated blur and residual noise in just such a way as to minimize mean-squared error. Note that at spectral locations where the object power is much greater than the noise power, the Wiener filter approaches an inverse filter, while at spectral locations where the noise power dominates, the Wiener filter behaves as a matched filter with considerable attenuation.

Coherent Optical Realization of Inverse and Wiener Filters While the inverse filter is primarily of theoretical interest, nonetheless there is much to be learned from consideration of how one might realize an approximation to such a filter. In general, the transfer function $B(f_X, f_Y)$ is complex-valued, or at least has sign reversals implying 180° phase shifts at some frequencies. This implies that the inverse filter must control both the magnitude and the phase of the transmitted fields. In most cases this implies a holographic filter and possibly a second absorbing filter.

The exact blur impulse response is assumed to be known. From a blurred image of a known point source, a photographic record of the blur impulse response can be obtained. If a filter is recorded in the geometry of Fig. 13, with the blur impulse response placed in the plane labeled "input," then an interferometrically generated transparency results, one component of amplitude transmittance being proportional to the conjugate of the blur transfer function

$$t_A(\xi, \eta) \approx B^*(f_X, f_Y) \exp(-i2\pi\alpha\eta) \tag{26}$$

where α is again a carrier frequency introduced by the offset reference wave. Passage of the blurred image through a coherent optical filtering system with this transfer function will correct any

frequency-domain phase shifts associated with the blur, but will not restore the magnitude of the object spectrum correctly.

To correct the spectral magnitudes we require an additional transparency to be sandwiched with the above holographic filter. This filter can be generated in a number of ways, but the easiest to understand is a method that rests on properties of the photographic process. If a photographic emulsion is exposed to an optical intensity $I(\xi, \eta)$, then over a certain dynamic range the amplitude transmittance of the resulting negative transparency will be of the form

$$t_A(\xi, \eta) = K[I(\xi, \eta)]^{-\gamma/2} \tag{27}$$

where γ is the so-called gamma of the photographic process. If the intensity to which the emulsion is exposed is simply the intensity in the Fourier transform of the blur transfer function, as obtained by optically Fourier transforming the blur spread function (for example, as in the system of Fig. 13 but with the reference wave blocked), then if a gamma equal to 2 is achieved with the photographic processing, the second transparency will have amplitude transmittance

$$t_A(\xi, \eta) = K\left|B\left(\frac{\xi}{\lambda f}, \frac{\eta}{\lambda f}\right)\right|^{-2} \tag{28}$$

If the two transparencies discussed above are now placed in contact, the overall amplitude transmittance will be the product of the two individual transmittances, and the effective filter transfer function realized by the coherent optical processor will be

$$H(f_X, f_Y) = \frac{B^*(f_X, f_Y)}{\left|B(f_X, f_Y)\right|^2} = \frac{1}{B(f_X, f_Y)} \tag{29}$$

which is precisely the transfer function of the desired inverse filter. However, in practice there will be errors in this filter due to the limited dynamic range of the photographic media.

To realize an approximation to the Wiener filter, a different recording method can be used. In this case the full holographic recording system illustrated in Fig. 13 is used, including the reference beam. However, the intensity of the reference beam is made weak compared with the peak intensity of the $|B|^2$ component. Furthermore, the recording is arranged so that the exposure falls predominantly in a range where the amplitude transmittance of the developed transparency is proportional to the logarithm of the intensity incident during exposure. Now if amplitude transmittance is proportional to the logarithm of incident exposure, the changes of amplitude transmittance, which lead to diffraction of light by the transparency, will obey

$$\Delta t_A = \beta \Delta(\log E) \approx \beta \frac{\Delta E}{\bar{E}} \tag{30}$$

where ΔE represents changes in exposure, $\bar{E}$ represents the average exposure about which the fluctuations occur, and β is a proportionality constant. Restricting attention to the proper portion of the output plane, the following identifications can be made:

$$\begin{aligned} \Delta E &\propto \hat{B}^* \exp(-i2\pi\alpha\eta) \\ \bar{E} &\propto |\hat{B}|^2 + K \end{aligned} \tag{31}$$

where $|\hat{B}|^2$ is the squared magnitude of the blur transfer function, normalized to unity at the origin, while K is the ratio between the reference beam intensity and the maximum value of $|B|^2$. Neglecting the exponential term which leads to offset from the origin in the output plane, the amplitude transmittance of the deblurring filter becomes

$$\Delta t_A = \frac{\hat{B}^*}{|\hat{B}|^2 + K} \tag{32}$$

which is precisely the form of the Wiener filter for a constant ratio K of noise power spectral density to signal power spectral density.

Thus the Wiener filter has been achieved with a single holographic filter. If the signal-to-noise ratio in the blurred image is high, then the reference beam intensity should be much less than the object beam intensity ($K \ll 1$). Bleached filters of this kind can also be made.

11.9 INCOHERENT PROCESSING OF DISCRETE SIGNALS

The previous problems examined have all involved signals and images that are continuous functions of time or space. We turn attention now to signals that are sampled or discrete functions of time or space.

Background

A continuous signal $u(t)$ is sampled at times separated by Δt yielding a set of P samples $u(k\ \Delta t)$, which we represent by the column vector

$$\mathbf{u} = \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_P \end{bmatrix} \tag{33}$$

For discrete signals, the continuous operations associated with convolution and correlation become matrix-vector operations. Thus any linear transformation of an input signal $\mathbf{u}$ is represented by

$$\mathbf{v} = \mathbf{M}\mathbf{u} \tag{34}$$

where $\mathbf{v}$ is a length Q output vector containing samples of the output signal, and $\mathbf{M}$ is a $P \times Q$ matrix

$$\mathbf{M} = \begin{bmatrix} m_{11} & m_{12} & \cdots & m_{1P} \\ m_{21} & m_{22} & \cdots & m_{2P} \\ \vdots & \vdots & \vdots & \vdots \\ m_{Q1} & m_{Q2} & \cdots & m_{QP} \end{bmatrix} \tag{35}$$

In the sections that follow we examine some of the optical approaches that have been proposed and demonstrated for this kind of operation.

The Serial Incoherent Matrix-Vector Multiplier

An important starting point is provided by the serial incoherent matrix-vector multiplier invented by Bocker[19] (see also Ref. 20), and illustrated in Fig. 14. The elements of the vector $\mathbf{u}$ are applied as current pulses, with heights proportional to the u_i, to an LED. Light from the LED floods the matrix mask, which contains $Q \times P$ cells, each with an intensity transmittance proportional to a different m_{ij}. The light transmitted by the matrix mask then falls on a two-dimensional CCD detector array, used in an unusual mode of operation. Charges are transferred horizontally along the rows of the detector array. In the first clock cycle, when the first element of the input vector is generated by the LED, the charge deposited in the first column of the detector array can be represented by a vector with elements $c_{1j} = m_{1j}u_1$. This set of charge packets is now transferred one column to the right, and

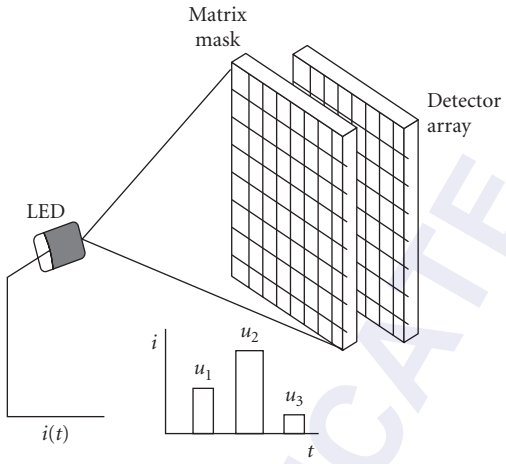

FIGURE 14 Serial matrix-vector multiplier.

the second pulse of light, proportional to u_2 is emitted. In the second column of the detector array a new charge is added to each of the existing charges, yielding a new set of charges $c_{2j} = m_{1j}u_1 + m_{2j}u_2$. After P clock cycles the column on the far right-hand side of the detector array contains a charge vector $\mathbf{c} = \mathbf{Mu}$, which within a proportionality constant is the desired output vector $\mathbf{v}$.

Thus the elements of the output vector are obtained in parallel from the right-hand column of the detector array. To compute the output vector, P cycles of the system are necessary, one for each element of the input vector. Multiplications are performed optically by passage of light through the matrix mask, while additions are performed electrically by charge addition.

The Parallel Matrix-Vector Multiplier

A fundamentally faster system for performing the matrix-vector product was discovered in 1978.[21] The architecture of this system is shown in Fig. 15.

The elements of the vector **u** are now entered in parallel as brightness values on an array of LEDs or laser diodes. The optics, not shown here, spread the light from each source in the vertical direction

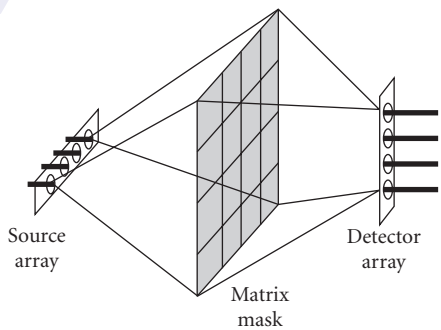

FIGURE 15 Parallel matrix-vector multiplier.

to cover the height of the matrix mask, while imaging each source onto an individual column in the horizontal direction. Passage of the light through the matrix mask multiplies the input vector, element by element, by the elements of the row vectors of the mask. The second set of optics, again not shown, adds the light transmitted by each row of the mask, placing an intensity on each element of the detector array that is proportional to the sum of the products produced by one row of the mask or, equivalently, the inner product of the input vector and a unique row vector of the matrix. In this case the detectors are of the nonintegrating type, and nearly instantaneously produce an output current proportional to an element of the output vector **v**. In this way a series of input vectors can be flowed through the system at high speed.

In this case both the multiplications and the additions are performed optically. A different output vector can be obtained with each cycle of the system. The result is a fundamentally faster system.

Systems of this type have had a broad impact on optical signal processing, with applications ranging from photonic switching[22] to neural networks.[23]

The Outer Product Processor

Another fundamentally different architecture is represented by the outer product processor,[24] shown in Fig. 16.

The goal in this case is to calculate the outer product **C** of two matrices **A** and **B**. Illustrating with a simple 3×3 example, the outer product is defined by the equation

$$\mathbf{C} = \begin{bmatrix} a_{11} \\ a_{21} \\ a_{31} \end{bmatrix} \begin{bmatrix} b_{11} & b_{12} & b_{13} \end{bmatrix} + \begin{bmatrix} a_{12} \\ a_{22} \\ a_{32} \end{bmatrix} \begin{bmatrix} b_{21} & b_{22} & b_{23} \end{bmatrix} + \begin{bmatrix} a_{13} \\ a_{23} \\ a_{33} \end{bmatrix} \begin{bmatrix} b_{31} & b_{32} & b_{33} \end{bmatrix} \tag{36}$$

The system of Fig. 16 accomplishes this operation by use of two Bragg cell arrays oriented in orthogonal directions, and a time-integrating two-dimensional detector array. A column of **A** is entered in parallel on the first Bragg cell array, and a row of **B** on the second. The first box labeled "optics" images one array onto the other (with appropriate spatial filtering as needed to convert phase to intensity). The second box labeled "optics" images that product onto the detector array. In one cycle of the system, one of the outer products in the summation of Eq. (36) is accumulated on the elements of the detector array. In this example, three cycles are necessary, with addition of charge at the detector, to accumulate the full outer product of the matrices. More generally, if **A** is $P \times Q$ (i.e., P rows and Q columns) and **B** is $Q \times P$, then the detector array should be $P \times P$ in size, and Q cycles are required to obtain the full outer product.

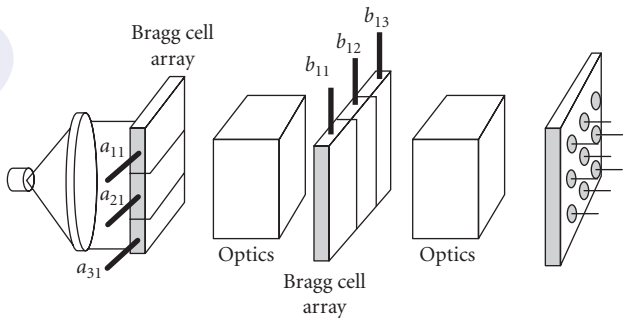

FIGURE 16 Outer product processor.

Other Discrete Processing Systems

A multitude of other discrete processing systems have been proposed throughout the 1980s and 1990s. Worth special mention here are the optical systolic matrix-vector processor of Caulfield et al.[25] and the SAOBIC processor of Guilfoyle.[26] We refer the reader to the original references for details.

11.10 CONCLUDING REMARKS

Analog optical signal and image processing were strong areas of research during three decades, the 1960s through the 1980s. Many ingenious systems were devised, each motivated by one or more applications. With some exceptions, these systems seldom survived for the particular application they were conceived for, but often they led to new applications not envisioned by their inventors. The majority of applications of this technology have been to defense-related problems. Research emphasis has shifted away from analog signal processing, as described above, towards the application of optics to providing interconnects between and within digital computers. However, the intellectual base formed by previous analog processing experience continues to strongly influence work in other, more modern disciplines, including integrated optics, modern microscopy, coherence tomography, ultrafast optical pulses, and digital image processing.

12

POLARIZATION*

Jean M. Bennett†

Research Department
Michelson Laboratory
Naval Air Warfare Center
China Lake, California

12.1 GLOSSARY

c	velocity of light
d	thickness
E	electric field
$\mathbf{k}$	wave vector ($k = 2\pi/\lambda$)
k	extinction coefficient
m	number of reflections
N	retardation per wavelength
n	real refractive index
$\tilde{n}$	complex refractive index
$\hat{\mathbf{n}}$	unit normal vector
P	degree of polarization
p	parallel polarization
R	intensity reflection coefficient
r	amplitude reflection coefficient
$\mathbf{r}$	position vector
s	senkrecht or perpendicular polarization
t	amplitude transmission coefficient
t	time
z	cartesian coordinate
$\alpha, \beta, a, b, c, d$	intermediate parameters
α	absorption coefficient

*This material was originally prepared under the auspices of the U.S. government and is not subject to copyright.
†Deceased.

γ	$2\pi nd \cos \theta/\lambda$
δ	phase angle
ε	dielectric constant
η	effective refractive index
θ_B	Brewster angle
θ	angle
κ	absorption index
λ	wavelength
ρ	extinction ratio
σ	conductivity
ω	radian or angular frequency
∇	laplacian operator
0	first medium
1	second medium

The material on polarization is abridged from the much more complete treatment by Bennett and Bennett.[1] Information on polarizers is found in Chap. 13, "Polarizers," in this volume.

12.2 BASIC CONCEPTS AND CONVENTIONS

Optical polarization was discovered by E. L. Malus in 1808. A major triumph of nineteenth- and early twentieth-century theoretical physics was the development of electromagnetic theory and the demonstration that optical polarization is completely described by it. This theory is phenomenological in that instead of trying to explain why materials have certain fundamental characteristics, it concentrates on the resulting properties which any material with those characteristics will display. In the optical case, the polarization and all other optical properties of a material are determined by two or more phenomenological parameters called *optical constants.* Electromagnetic theory has little or nothing to say about *why* a material should have these particular optical constants or *how* they are related to its atomic character. This problem has been extensively investigated in twentieth-century solid-state physics and is still only partially understood. It is clear, however, that the optical constants are a function not only of the atomic nature of the material, i.e., its position in the periodic table, but are also quite sensitive to how it is prepared. Perhaps *optical parameters* would be a better term than optical constants. Nevertheless, the concept of optical constants is an extremely useful one and makes it possible to predict quantitatively the optical behavior of a material and, under certain conditions, to relate this behavior to nonoptical parameters.

Since the optical constants are so fundamental, differences in their definition are particularly unfortunate. The most damaging of these differences arise from an ambiguity in the initial derivation. Maxwell's equations, which form the basis of electromagnetic theory, result in the wave equation, which in mks units is

$$\nabla^2 \mathbf{E} = \frac{\varepsilon}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2} + \frac{4\pi\sigma}{c^2}\frac{\partial \mathbf{E}}{\partial t} \tag{1}$$

where ∇^2 = laplacian operator
$\mathbf{E}$ = electric field vector of traveling wave
t = time
c = velocity of light
σ = conductivity of material at frequency of wave motion
ε = dielectric constant of material at frequency of wave motion

A solution to this equation is

$$\mathbf{E} = \mathbf{E}_0 \exp\left[i(\omega t + \delta)\right] \exp(-i\mathbf{k}\cdot\mathbf{r}) \exp\left(-\frac{\alpha z}{2}\right) \tag{2}$$

where $\mathbf{E}_0$ = amplitude of wave
ω = angular frequency of wave
δ = phase vector
$\mathbf{k}$ = wave vector
$\mathbf{r}$ = position vector
z = direction wave is traveling
α = absorption coefficient

The wave vector $\mathbf{k}$ is assumed to be real and equal to $(2\pi/\lambda_m)\hat{\mathbf{n}}$, where λ_m is the wavelength in the medium in which the wave is traveling and $\mathbf{n}$ is a unit vector in the k direction.* Equation (2) can also be written in terms of $\tilde{n}$, the complex index of refraction, defined as

$$\tilde{n} = n - ik \tag{3}$$

where n is the index of refraction and k the extinction coefficient. In this form, Eq. (2) is

$$E = E_0 \exp\left[i\omega\left(t - \frac{\tilde{n}z}{c}\right)\right] \tag{4}$$

when $\delta = 0$. By setting the imaginary part of the exponent equal to zero one obtains

$$z = \frac{c}{n}t \tag{5}$$

To show that Eq. (4) represents a wave traveling in the positive z direction with phase velocity c/n, we note that the phase ϕ of the wave in Eq. (4) is $\omega t - (\omega\tilde{n}z)/c = \phi$. For a wave propagating with a constant phase, $d\phi = 0$, so that $\omega\, dt - (\omega\tilde{n}/c)\, dz = d\phi = 0$, and hence the phase velocity $\upsilon_p = dz/dt = c/n$.[2] The amplitude of the wave at z is, from Eq.(4),

$$|E| = E_0 e^{-2\pi kz/\lambda} \tag{6}$$

where λ is the wavelength in vacuum. The wave is thus exponentially damped, and the amplitude penetration depth, or distance below an interface at which the *amplitude* of the wave falls to $1/e$ times its initial value, is $z = \lambda/2\pi k$. The absorption coefficient α, or the reciprocal of the distance in which the *intensity* of the wave falls to $1/e$ times its initial value, is

$$\alpha = \frac{4\pi k}{\lambda} \tag{7}$$

This development follows that commonly given by those working at optical or radio frequencies. The confusion in the definition of the optical constants arises because an equally valid solution to Eq. (1) is

$$E' = E_0 \exp\left[-i\omega\left(t - \frac{\tilde{n}'z}{c}\right)\right] \tag{8}$$

*Frequently the wave vector is taken to be complex, that is, $\tilde{\mathbf{k}} = (2\pi/\lambda_m - i\alpha/2)\mathbf{n}$, and Eq. (2) is written $\mathbf{E} = \mathbf{E}_0 \exp[i(\omega t + \delta)] \exp(-i\mathbf{k}'\cdot\mathbf{r})$.

which also represents an exponentially damped wave traveling in the $+z$ direction *provided that the complex index of refraction is defined to be*

$$\tilde{n}' = n + ik \tag{9}$$

where the primes indicate the alternative solution. When the wave equation arises in quantum mechanics, the solution chosen is generally the negative exponential, i.e., Eq. (8) rather than Eq. (4). Solid-state physicists working in optics thus often define the complex index of refraction as the form given in Eq. (9) rather than that in Eq. (3). Equally valid, self-consistent theories can be built up using either definition, and as long as only intensities are considered, the resulting expressions are identical. However, when phase differences are calculated, the two conventions usually lead to contradictory results. Even worse, an author who is not extremely careful may not consistently follow either convention, and the result may be pure nonsense. Some well-known books might be cited in which the authors are not even consistent from chapter to chapter.

There are several other cases in optics in which alternative conventions are possible and both are found in the literature. Among these, the most distressing are the use of a left-handed rather than a right-handed coordinate system, which makes the p and s components of polarized light have the same phase change at normal incidence (see Sec. 12.3), and defining the optical constants so that they depend on the angle of incidence, which makes the angle of refraction given by Snell's law real for an absorbing medium. There are many advantages to be gained by using a single set of conventions in electromagnetic theory. In any event, an author should *clearly* state the conventions being used and then *stay with them*.

Finally, the complex index of refraction is sometimes written

$$\tilde{n} = n(1 - i\kappa) \tag{10}$$

In this formulation the symbol κ is almost universally used instead of k, which is reserved for the imaginary part of the refractive index. Although k is more directly related to the absorption coefficient α than κ [see Eq. (7)] and usually makes the resulting expressions slightly simpler, in areas such as attenuated total reflection, the use of κ results in a simplification. To avoid confusion between k and κ, if Eq. (10) is used, κ could be called the *absorption index* to distinguish it from the extinction coefficient k, and the absorption coefficient α.

12.3 FRESNEL EQUATIONS

The Fresnel equations are expressions for the reflection and transmission coefficients of light at nonnormal incidence. In deriving these equations, the coordinate system assumed determines the signs in the equations and therefore the phase changes on reflection of the p and s components. In accordance with the Muller convention,[3] we shall assume that the coordinate system is as shown in Fig. 1. In this system, the angle of incidence is θ_0, and the angle of refraction is θ_1. The *s component* of polarization is the plane of vibration of the E wave which is perpendicular to the plane of the paper, and the *p component* is the plane of vibration which is in the plane of the paper.* (The plane of incidence is in the plane of the paper.) The positive directions for the vibrations are indicated in Fig. 1 by the dots for E_s, E_s', and E_s'' and by the arrows for the corresponding p components. Note that the positive direction for E_p'' is as shown in the figure because of the *mirror-image effect*.

*Unfortunately, when Malus discovered that light reflected at a certain angle from glass is, as he said, "polarized," he defined the plane of polarization" of the reflected light as the plane of incidence. Since the reflected light in this case has its E vector perpendicular to the plane of incidence, the "plane of polarization" is perpendicular to the plane in which the E vector vibrates. This nomenclature causes considerable confusion and has been partially resolved in modern terminology by discussing the *plane of vibration* of the E vector and avoiding, insofar as possible, the term *plane of polarization*. In this chapter, when specifying the direction in which light is polarized, we shall give the direction of vibration, *not* the direction of polarization.

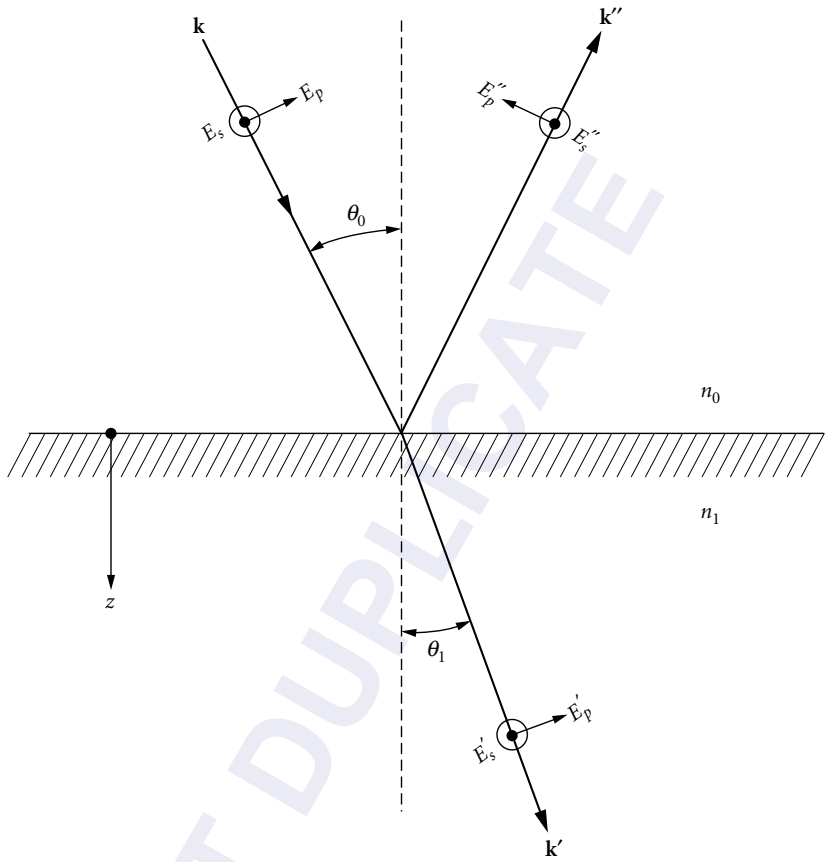

FIGURE 1 Coordinate system for measuring the E vectors of a plane wave reflected and refracted at a boundary between a medium of refractive index n_0 and a medium of refractive index n_1 (may be absorbing). The positive direction for the coordinates of the E_s, E_s', and E_s'' components is out of the paper, and that for the coordinates of the E_p components is in the plane of the paper, as indicated by the arrows. The wave vector **k,** the direction the wave is traveling z, and angles of incidence and refraction θ_0 and θ_1 are also shown. (*Modified from Mutter.*[3])

By convention, one always looks *against the direction of propagation of the wave* so that the positive direction of E_p is to the right and the positive direction of E_p'' is also to the right. The positive directions of the reflected E vectors are not the same as the actual directions of the reflected E vectors. These latter directions will depend on the refractive index of the material and may be either positive or negative. For example, if $n_1 > n_0$, at normal incidence E_s'' will be in the negative direction and E_p'' will be in the positive direction. Thus we say that there is a phase change on reflection of 180° for the s wave and a phase change of 0° for the p wave.

With this coordinate system, the Fresnel amplitude reflection coefficients for a single interface, obtained from Eq. (4) by setting up and solving the boundary-value problem, can be written

$$\frac{E_s''}{E_s} \equiv r_s = \frac{n_0 \cos\theta_0 - n_1 \cos\theta_1}{n_0 \cos\theta_0 + n_1 \cos\theta_1} \tag{11}$$

and

$$\frac{E_p''}{E_p} \equiv r_p = \frac{n_1 \cos\theta_0 - n_0 \cos\theta_1}{n_1 \cos\theta_0 + n_0 \cos\theta_1} \tag{12}$$

The amplitude transmission coefficients are

$$\frac{E_s'}{E_s} \equiv t_s = \frac{2n_0 \cos\theta_0}{n_0 \cos\theta_0 + n_1 \cos\theta_1} \tag{13}$$

and

$$\frac{E_p'}{E_p} \equiv t_p = \frac{2n_0 \cos\theta_0}{n_1 \cos\theta_0 + n_0 \cos\theta_1} \tag{14}$$

Other forms of the Fresnel amplitude reflection and transmission coefficients containing only the angles of incidence and refraction are somewhat more convenient. These relations can be derived using Snell's law

$$\frac{\sin\theta_0}{\sin\theta_1} = \frac{n_1}{n_0} \tag{15}$$

to eliminate n_0 and n_1 from Eqs. (1) to (14):

$$r_s = \frac{-\sin(\theta_0 - \theta_1)}{\sin(\theta_0 + \theta_1)} \tag{16}$$

$$r_p = \frac{\tan(\theta_0 - \theta_1)}{\tan(\theta_0 + \theta_1)} \tag{17}$$

$$t_s = \frac{2\sin\theta_1 \cos\theta_0}{\sin(\theta_0 + \theta_1)} \tag{18}$$

$$t_p = \frac{2\sin\theta_1 \cos\theta_1}{\sin(\theta_0 + \theta_1)\cos(\theta_0 - \theta_1)} \tag{19}$$

For nonabsorbing materials the intensity reflection coefficients R_s and R_p are simply the squares of Eqs. (16) and (17):

$$R_s = r_s^2 = \frac{\sin^2(\theta_0 - \theta_1)}{\sin^2(\theta_0 + \theta_1)} \tag{20}$$

$$R_p = r_p^2 = \frac{\tan^2(\theta_0 - \theta_1)}{\tan^2(\theta_0 + \theta_1)} \tag{21}$$

and, at normal incidence,

$$R_s = R_p = \frac{(n_0 - n_1)^2}{(n_0 + n_1)^2} \tag{22}$$

from Eqs. (11) and (12). In the lower part of Fig. 2, R_s and R_p are given as a function of angle of incidence for various values of the refractive-index ratio n_1/n_0 with k_1 for the material equal to zero.

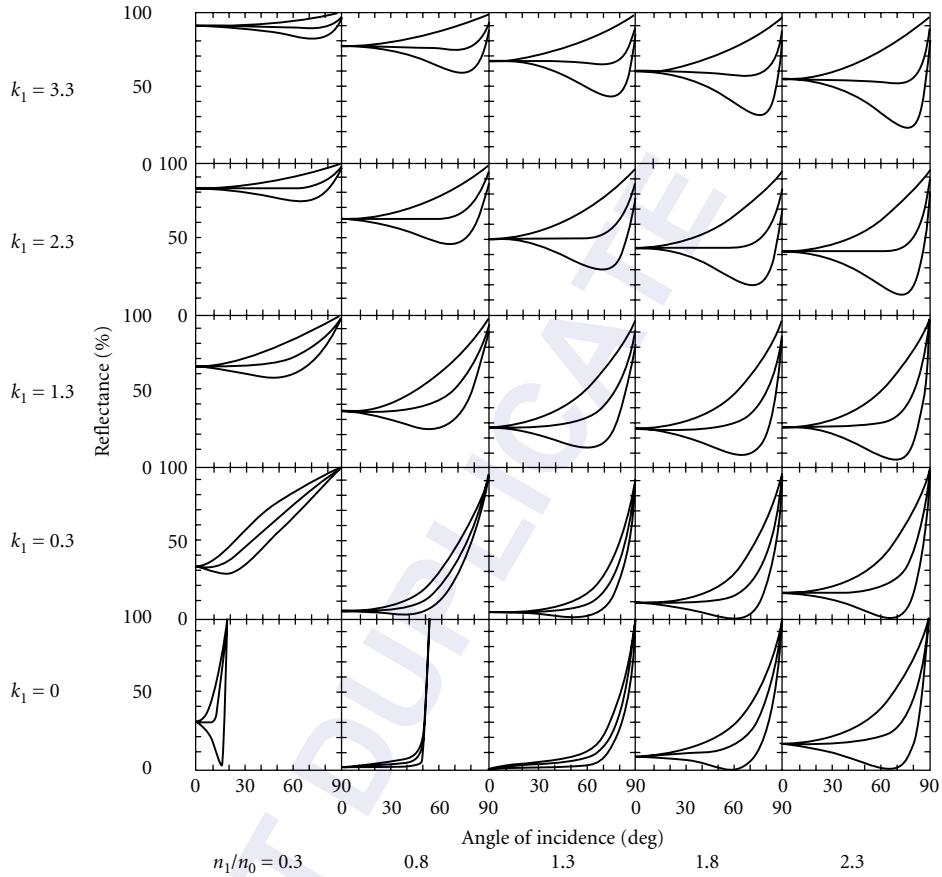

FIGURE 2 R_s (upper curves), R_p (lower curves), and $R_{av} = (R_s + R_p)/2$ as a function of angle of incidence for various values of the refractive-index ratio n_1/n_0 and k_1. The incident medium, having refractive index n_0, is assumed to be nonabsorbing. (*Modified from Hunter.*[4])

The curves for $n_1/n_0 = 1.3$, 1.8, and 2.3 show that the normal-incidence reflectance increases as n_1 increases. The curves for $n_1/n_0 = 0.3$ and 0.8 and $k_1 = 0$ have no physical significance as long as the incident medium is air. However, they are representative of *intenal reflections* in materials of refractive index $n_0 = 3.33$ and 1.25, respectively when the *other* medium is air ($n_1 = 1$).

The intensity transmission coefficients T_s and T_p are obtained from the Poynting vector and for nonabsorbing materials are

$$T_s = 1 - R_s = \frac{n_1 \cos\theta_1}{n_0 \cos\theta_0} t_s^2 = \frac{4 n_0 n_1 \cos\theta_0 \cos\theta_1}{(n_0 \cos\theta_0 + n_1 \cos\theta_0)^2} = \frac{\sin 2\theta_0 \sin 2\theta_1}{\sin^2(\theta_0 + \theta_1)} \tag{23}$$

$$\begin{aligned} T_p &= 1 - R_p = \frac{n_1 \cos\theta_1}{n_0 \cos\theta_0} t_p^2 = \frac{4 n_0 n_1 \cos\theta_0 \cos\theta_1}{(n_1 \cos\theta_0 + n_0 \cos\theta_1)^2} \\ &= \frac{\sin 2\theta_0 \sin 2\theta_1}{\sin^2(\theta_0 + \theta_1)\cos^2(\theta_0 - \theta_1)} \end{aligned} \tag{24}$$

These coefficients are for light passing through a single boundary and hence are of limited usefulness. In actual cases, the light is transmitted through a slab of material where there are two boundaries generally multiple reflections within the material, and sometimes interference effects when the boundaries are smooth and plane-parallel.

The intensity transmission coefficient T_{sample} for a slab of transparent material in air is given by the well-known Airy equation[5] when the sample has smooth, plane-parallel sides and coherent multiple reflections occur within it:

$$T_{\text{sample}} = \frac{1}{1+[4R_{s,p}/(1-R_{s,p})^2]\sin^2\gamma} \tag{25}$$

where

$$\gamma = \frac{2\pi n_1 d\cos\theta_1}{\lambda} \tag{26}$$

The values of R_s and R_p can be determined from Eqs. (20) to (22); d is the sample thickness, λ the wavelength, n_1 the refractive index of the material, and θ_1 the angle of refraction. Equation (25) holds for all angles of incidence including the Brewster angle, where $R_p = 0$ [see Eq. (48)]. The Airy equation predicts that at a given angle of incidence the transmission of the sample will vary from a maximum value of 1 to a minimum value of $(1-R_{s,p})^2/(1+R_{s,p})^2$ as the wavelength or the thickness is changed. If the sample is very thick, the oscillations in the transmittance will occur at wavelengths very close together and hence will be unresolved. A complete oscillation occurs every time γ changes by π, so that the wavelength interval $\Delta\lambda$ between oscillations is

$$\Delta\lambda \approx \frac{\lambda^2}{2n_1 d\cos\theta_1} \tag{27}$$

An an example, a sample 1 mm thick with an index of 1.5 at 5000 Å will have transmission maxima separated by 0.83 Å when measured at normal incidence ($\cos\theta_1 = 1$). These maxima would not be resolved by most commercial spectrophotometers. In such a case, one would be measuring the average transmission $T_{\text{sample,av}}$:

$$T_{\text{sample,av}} = \frac{1-R_{s,p}}{1-R_{s,p}} \tag{28}$$

For nonabsorbing materials, this is the same value as that which would be obtained if the multiply reflected beams did not coherently interfere within the sample. If the sample is wedge-shaped, so that no multiply reflected beams contribute to the measured transmittance, T_{sample} is simply T_s^2 or T_p^2 and can be calculated from Eq. (23) or (24).

When the material is absorbing, i.e., has a complex refractive index, it is not so easy to calculate the reflectance and transmittance since the angle of refraction is complex. However, Snell's law [Eq. (15)] and Fresnel's equations (11) and (12) are sometimes used with complex values of n_1 and θ_1. The resulting amplitude reflection coefficients are written

$$r_s = |r_s|e^{i\delta_s} \tag{29}$$

and

$$r_p = |r_p|e^{i\delta_p} \tag{30}$$

where $|r_s|$ and $|r_p|$ are the magnitudes of the reflectances and δ_s and δ_p are the phase changes on reflection. The intensity reflection coefficients are

$$R_{s,p} = r_{s,p}r_{s,p}^* \tag{31}$$

An alternative approach is to use the method of effective indexes to calculate R_s and R_p. In the medium of incidence, which is assumed to be nonabsorbing, the effective indexes η_{0s} and η_{0p} for the *s* and *p* components are

$$\eta_{0s} = n_0 \cos\theta_0 \tag{32}$$

$$\eta_{0p} = \frac{n_0}{\cos\theta_0} \tag{33}$$

where n_0 generally equals 1 for air. In the absorbing material both η's are complex and can be written, according to the Bernings,[6,7]

$$\tilde{\eta}_{1s} = \tilde{n}_1 \cos\theta_1 \tag{34}$$

$$\tilde{\eta}_{1p} = \frac{\tilde{n}_1}{\cos\theta_1} \tag{35}$$

where $\tilde{n}_1 = n_1 - ik_1$ is the complex refractive index of the material, and

$$\cos\theta_1 = \left[\frac{(\alpha_1^2 + \beta_1^2)^{1/2} + \alpha_1}{2}\right]^{1/2} - i\left[\frac{(\alpha_1^2 + \beta_1^2)^{1/2} - \alpha_1}{2}\right]^{1/2} \tag{36}$$

$$\alpha_1 = 1 + \left(\frac{n_0 \sin\theta_0}{n_1^2 + k_1^2}\right)^2 (k_1^2 - n_1^2) \tag{37}$$

and

$$\beta_1 = -2n_1 k_1 \left(\frac{n_0 \sin\theta_0}{n_1^2 + k_1^2}\right)^2 \tag{38}$$

Abelès' method[8] also uses effective indexes for the absorbing material, but they are calculated differently:

$$\tilde{\eta}_{1s} = a - ib \tag{39}$$

$$\tilde{\eta}_{1p} = c - id \tag{40}$$

where

$$a^2 - b^2 = n_1^2 - k_1^2 - n_0^2 \sin^2\theta_0 \tag{41}$$

$$ab = n_1 k_1 \tag{42}$$

$$c = a\left(1 + \frac{n_0^2 \sin^2\theta_0}{a^2 + b^2}\right) \tag{43}$$

$$d = b\left(1 - \frac{n_0^2 \sin^2\theta_0}{a^2 + b^2}\right) \tag{44}$$

In both methods employing effective indexes, the amplitude reflection coefficients are

$$r_s = \frac{\eta_{0s} - \eta_{1s}}{\eta_{0s} + \eta_{1s}} \tag{45}$$

$$r_p = \frac{\eta_{1p} - \eta_{0p}}{\eta_{1p} + \eta_{0p}} \tag{46}$$

which are equivalent to Eqs. (29) and (30) and reduce to Eqs. (11) and (12) when $k_1 = 0$. The intensity reflection coefficients are given by Eq. (31), as before. At normal incidence,

$$R_s = R_p = \frac{(n_0 - n_1)^2 + k_1^2}{(n_0 + n_1)^2 + k_1^2} \tag{47}$$

Values of R_s and R_p are plotted as a function of angle of incidence in Fig. 2 for various values of n_1 and k_1. (The incident medium is assumed to be air with $n_0 = 1$ unless otherwise noted.) As n_1 increases with $k_1 > 0$ held constant, the magnitudes of R_s and R_p at normal incidence both decrease. As k_1 increases with n_1 held constant, the magnitudes of R_s and R_p at normal incidence both increase. Tables of R_s and R_p for various values of n_1 and k_1 are given for angles of incidence from 0 to 85° by Holl.[9]

The absolute phase changes on reflection δ_s and δ_p are also of interest in problems involving polarization. When the material is nonabsorbing, the phase changes can be determined from the amplitude reflection coefficients, Eqs. (11) and (12); when $\theta_0 = 0$ and $n_1 > n_0$, $\delta_s = 180°$ and $\delta_p = 360°$.* This is an apparent contradiction since at normal incidence the *s* and *p* components should be indistinguishable. However, the problem is resolved by recalling that by convention we are always looking against the direction of propagation of the light (see Fig. 1). To avoid complications, the phase change on reflection at normal incidence (often defined as β) is identified with δ_s.

For a dielectric, if $n_0 < n_1$, δ_s remains 180° for all angles of incidence from 0 to 90°, as can be seen from the numerator of Eq. (11). However, there is an abrupt discontinuity in δ_p, as can be seen from Eq. (12). If $n_0 < n_1$, $\delta_p = 360°$* at normal incidence and at larger angles for which the numerator of Eq. (12) is positive. Since cos θ_0 becomes increasingly less than cos θ_1 as θ_0 increases, and since $n_1 > n_0$, there will be an angle for which $n_1 \cos \theta_0 = n_0 \cos \theta_1$. At this angle δ_p undergoes an abrupt change from 360° to 180°, and it remains 180° for larger angles of incidence. At the transition value of θ_0, which is called the *Brewster angle* θ_B since $R_p = 0$,

$$\tan \theta_B = \frac{n_1}{n_2} \tag{48}$$

(This angle is also called the *polarizing angle* since $\theta_0 + \theta_1 = 90°$.)

The phase changes δ_s and δ_p are not simply 360° or 180° for an absorbing material. At normal incidence it follows from Eq. (45) that

$$\tan \delta_s = \frac{2n_0 k_1}{n_0^2 - n_1^2 - k_1^2} \tag{49}$$

so that $\delta_s = 180°$ only if $k_1 = 0$. As before, $\delta_p = \delta_s + 180°$, as seen by comparing Eqs. (45) and (46). At nonnormal incidence

$$\tan \delta_s = \frac{2\eta_{0s} b}{\eta_{0s}^2 - a^2 - b^2} \tag{50}$$

*Since 360° and 0° are indistinguishable, many optics books state that $\delta_p = 0°$ for dielectrics at normal incidence, but this makes the ellipsometric parameter $\Delta = \delta_p - \delta_s < 0$, which is incompatible with ellipsometric conventions—see Chap. 16, "Ellipsometry."

and

$$\tan\delta_p = \frac{-2\eta_{0p}d}{c^2 + d^2 - \eta_{0p}^2} \tag{51}$$

where the relations for a, b, c, and d have been given in Eqs. (41) to (44). The following relations between these quantities may also prove helpful:

$$a^2 + b^2 = [(n_1^2 - k_1^2 - n_0^2 \sin^2\theta_0)^2 + 4n_1^2k_1^2]^{1/2} \tag{52}$$

$$c^2 + d^2 = \frac{(n_1^2 + k_1^2)^2}{a^2 + b^2} \tag{53}$$

$$b^2 = \frac{n_1^2 - k_1^2 - n_0^2 \sin^2\theta_0}{2} + \frac{a^2 + b^2}{2} \tag{54}$$

Figure 3 shows how δ_s and δ_p change as a function of angle of incidence for an absorbing material. At normal incidence they are 180° apart because of the mirror-image effect, mentioned previously. As the angle of incidence increases, δ_p approaches δ_s, and at the *principal angle* $\bar{\theta}$ the two quantities differ by only 90°. At grazing incidence they coincide.

The reflectance R_p does not reach zero for an absorbing material as it does for a dielectric, but the angle for which it is a minimum is called the *pseudo-Brewster angle* θ_B'. Two other angles closely associated with the pseudo-Brewster are also of interest. The angle for which the ratio R_p/R_s is a minimum is sometimes called the *second Brewster angle*. It is generally only slightly larger than θ_B'. The *principal angle* $\bar{\theta}$, at which $\delta_p - \delta_s = 90°$, is always larger than the second Brewster angle and θ_B'. For most metals θ_B' and $\bar{\theta}$ are only a fraction of a degree apart but it is possible for them to differ by as much as 45°.[9] There is no polarizing angle as such for an absorbing material because the angle of refraction is complex.

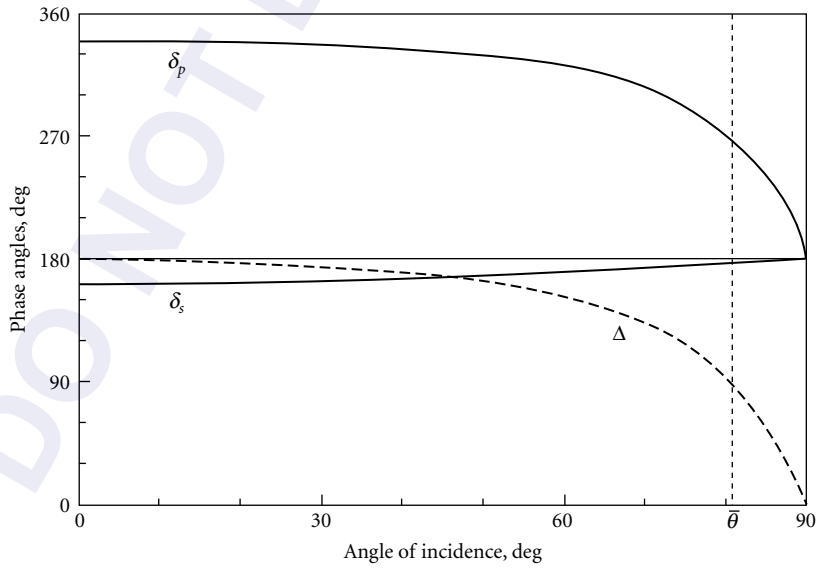

FIGURE 3 Phase changes on reflection δ_s and δ_p and phase difference $\Delta = \delta_p - \delta_s$ as a function of angle of incidence for an absorbing material. The principal angle, for which $\Delta = 90°$, is also shown. (*Bennett and Bennett.*[10])

12.4 BASIC RELATIONS FOR POLARIZERS

A linear* polarizer is anything which when placed in an incident unpolarized beam produces a beam of light whose electric vector is vibrating primarily in one plane, with only a small component vibrating in the plane perpendicular to it. If a polarizer is placed in a plane-polarized beam and is rotated about an axis parallel to the beam direction, the transmittance T will vary between a maximum value T_1 and a minimum value T_2 according to the law

$$T = (T_1 - T_2)\cos^2\theta + T_2 \tag{55}$$

Although the quantities T_1 and T_2 are called the *principal transmittances*, in general $T_1 \gg T_2$; θ is the angle between the plane of the principal transmittance T_1 and the plane of vibration (of the electric vector) of the incident beam. If the polarizer is placed in a beam of unpolarized light, its transmittance is

$$T = \frac{1}{2}(T_1 + T_2) \tag{56}$$

so that a perfect polarizer would transmit only 50 percent of an incident unpolarized beam.†

When two identical polarizers are placed in an unpolarized beam, the resulting transmittance will be

$$T_{||} = \frac{1}{2}(T_1^2 + T_2^2) \tag{57}$$

when their principal transmittance directions are parallel and will be

$$T_{\perp} = T_1 T_2 \tag{58}$$

when they are perpendicular. In general, if the directions of principal transmittance are inclined at an angle θ to each other, the transmittance of the pair will be

$$T_\theta = \frac{1}{2}(T_1^2 + T_2^2)\cos^2\theta + T_1 T_2 \sin^2\theta \tag{59}$$

The polarizing properties of a polarizer are generally defined in terms of its *degree of polarization* P‡,§

$$P = \frac{T_1 - T_2}{T_1 + T_2} \tag{60}$$

or its *extinction ratio* ρ_p

$$\rho_p = \frac{T_2}{T_1} \tag{61}$$

When one deals with nonnormal-incidence reflection polarizers, one generally writes P and ρ_p in terms of R_p and R_s, the reflectances of light polarized parallel and perpendicular to the plane of incidence, respectively. As will be shown in Sec. 12.5, R_s can be equated to T_1 and R_p to T_2, so that

*Circular polarizers are discussed in Sec. 12.7.

†Jones[11] has pointed out that a perfect polarizer can transmit more than 50 percent of an incident unpolarized beam under certain conditions.

‡Bird and Shurcliff[12] distinguish between *degree of polarization,* which is a constant of the light beam, and *polarizance,* which is a constant of the polarizer. The polarizance is defined as being equal to the degree of polarization the polarizer produces in an incident monochromatic beam that is unpolarized. In practice, incident beams are often slightly polarized, so that the polarizance values differ slightly from the ideal degree of polarization. Other authors have not followed this distinction.

§Authors dealing with topics such as scattering from aerosols sometimes define *degree of polarization* (of the scattered light) in terms of the Stokes vectors (Sec. 12.8) as $P = (S_1^2 + S_2^2 + S_3^2)^{1/2}/S_0$.

Eqs. (60) and (61) become $P = (R_s - R_p)/(R_s + R_p)$ and $\rho_p = R_p/R_s$. If either ρ_p or P is known, the other can be deduced since

$$P = \frac{1-\rho_p}{1+\rho_p} \tag{62}$$

and

$$\rho_p = \frac{1-P}{1+P} \tag{63}$$

If one is determining the degree of polarization or the extinction ratio of a polarizer, the ratio of $T_\perp$ to $T_\parallel$ can be measured for two identical polarizers in unpolarized light. From Eqs. (57) and (58),

$$\frac{T_\perp}{T_\parallel} = \frac{T_1 T_2}{(T_1^2 + T_2^2)/2} \approx \frac{2T_2}{T_1} = 2\rho_p \tag{64}$$

if $T_2^2 \ll T_1^2$. If a perfect polarizer or a source of perfectly plane-polarized light is available, T_2/T_1 can be determined directly by measuring the ratio of the minimum to the maximum transmittance of the polarizer. Other relations for two identical partial polarizers are given by West and Jones,[13] as well as the transmittance $T_{\theta ab}$ of two dissimilar partial polarizers a and b whose principal axes are inclined at an angle θ with respect to each other. This latter expression is

$$T_{\theta ab} = \frac{1}{2}(T_{1a}T_{1b} + T_{2a}T_{2b})\cos^2\theta + \frac{1}{2}(T_{1a}T_{2b} + T_{1b}T_{2a})\sin^2\theta \tag{65}$$

where the subscripts 1 and 2 refer to the principal transmittances, as before.

Spectrophotometric measurements can involve polarizers and dichroic samples. Dichroic (optically anisotropic) materials are those which absorb light polarized in one direction more strongly than light polarized at right angles to that direction. (Dichroic materials are to be distinguished from birefringent materials, which may have different refractive indices for the two electric vectors vibrating at right angles to each other but similar, usually negligible, absorption coefficients.) When making spectrophotometric measurements, one should know the degree of polarization of the polarizer and how to correct for instrumental polarization. This latter quantity may arise from nonnormal-incidence reflections from a grating, dispersing prism, or mirrors. Light sources are also sometimes polarized. Simon,[14] Charney,[15] Gonatas et al.,[16] and Wizinowich[17] suggest methods for dealing with imperfect polarizers, dichroic samples, and instrumental polarization. In addition, when a dichroic sample is placed between a polarizer and a spectrophotometer which itself acts like an imperfect polarizer, one has effectively three polarizers in series. This situation has been treated by Jones,[18] who showed that anomalies can arise when the phase retardation of the polarizers takes on certain values. Mielenz and Eckerle[19] have discussed the accuracy of various types of polarization attenuators.

12.5 POLARIZATION BY NONNORMAL-INCIDENCE REFLECTION (PILE OF PLATES)

Pile-of-plates polarizers make use of reflection or transmission of light at nonnormal incidence, frequently near the Brewster or polarizing angle [Eq. (48) in Sec. 12.3]. The extinction ratio and "transmittance" of these polarizers can be calculated directly from the Fresnel equations. Some simplifications occur for nonabsorbing or slightly absorbing plates. Equations (20) and (21) give the values of the intensity reflection coefficients R_s and R_p for light vibrating perpendicular to the plane of incidence (s component) and parallel to the plane of incidence (p component). The angle of refraction θ_1 in those equations is related to the refractive index n of the material by

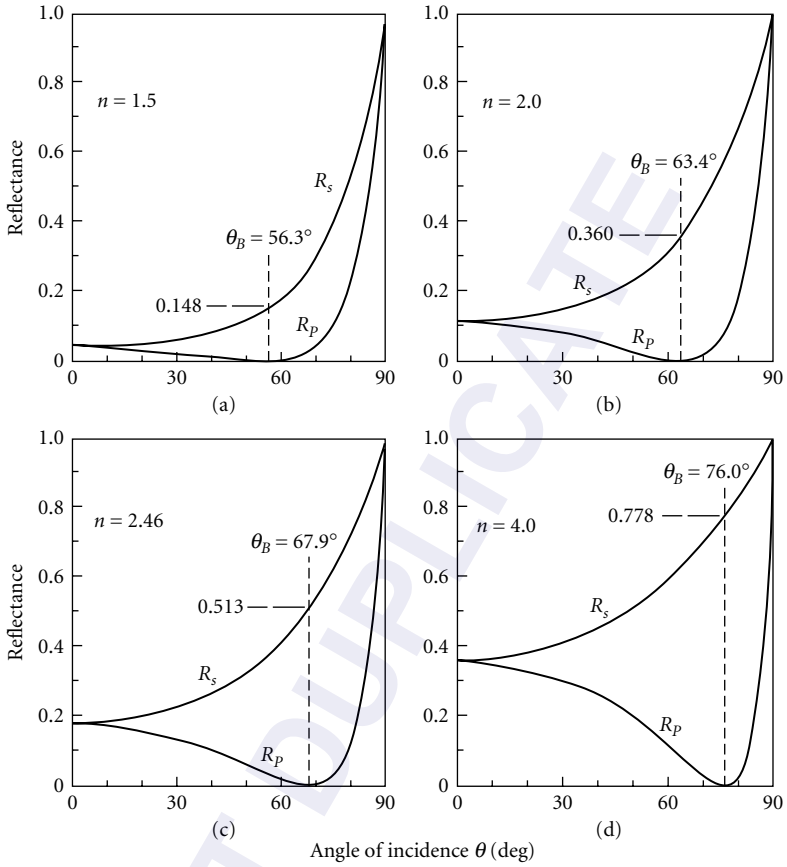

FIGURE 4 Reflectance of light polarized parallel R_p and perpendicular R_s to the plane of incidence from materials of different refractive index n as a function of angle of incidence: (*a*) $n = 1.5$ (alkali halides in ultraviolet and sheet plastics in infrared); (*b*) $n = 2.0$ (AgCl in infrared); (*c*) $n = 2.46$ (Se in infrared); and (*d*) $n = 4.0$ (Ge in infrared). The Brewster angle θ_B (at which R_p goes to 0) and the magnitude of R_s at θ_B are also indicated.

Snell's law [Eq. (15)*]. At the Brewster angle $R_p = 0$, so that the reflected light is, in principle, completely plane-polarized. This is the basis for all Brewster angle reflection polarizers.

Let us now see how the characteristics of a reflection polarizer depend on its refractive index. In Fig. 4 the reflectances R_s and R_p have been plotted for different values of the refractive index, roughly representing alkali halides in the ultraviolet and sheet-plastic materials, silver chloride, selenium, and germanium in the infrared. The Brewster angle, given by Eq. (48), is also indicated, as well as the magnitude of R_s at the Brewster angle. We note from these graphs that if light is polarized by a single reflection from a nonabsorbing material, the polarizer with the highest refractive index will have the largest throughput. In reflection polarizers, the quantity R_s is essentially the principal "transmittance" of the polarizer [T_1 in Eqs. (55) to (65)] except that it must be multiplied by the reflectance of any other mirrors used to return the beam to its axial position.

*Since we are assuming that the medium of incidence is air, $n_0 = 1$ and $n_1 = n$, the refractive index of the material.

The reflectance R_p can be equated to T_2, the minimum "transmittance" of the polarizer, so that the extinction ratio ρ_p of a reflection polarizer [Eq. (61)] is $\rho_p = R_p/R_s$. If R_p is really zero at the Brewster angle, the extinction ratio will be zero for all materials *independent of the value of n*. If a given extinction ratio is desired, for example, 10^{-3} [corresponding to 99.8 percent polarization; see Eq. (62)], then the convergence angle of the light beam must be small so that all the angles of incidence lie within about ±1° of the Brewster angle. The convergence angle depends only weakly on the refractive index for this case, varying from ±1.2° for $n = 1.5$ to ± 0.8° for $n = 4.0$.

If a good extinction ratio is required for a beam of larger convergence angle, two polarizing reflections may be used. Then all the exponents in Fig. *5a* are doubled, and the convergence angles for a given extinction ratio are greatly increased. To obtain a value of 10^{-3} with two reflections, the angle of incidence must be within about ± 6° of the Brewster angle for values of n less than 3.5; for $n = 4$ it is reduced slightly and becomes more asymmetric (+4.0 and −5.2°). A disadvantage of having two reflections from the polarizing materials is that the throughput is reduced. All the values of

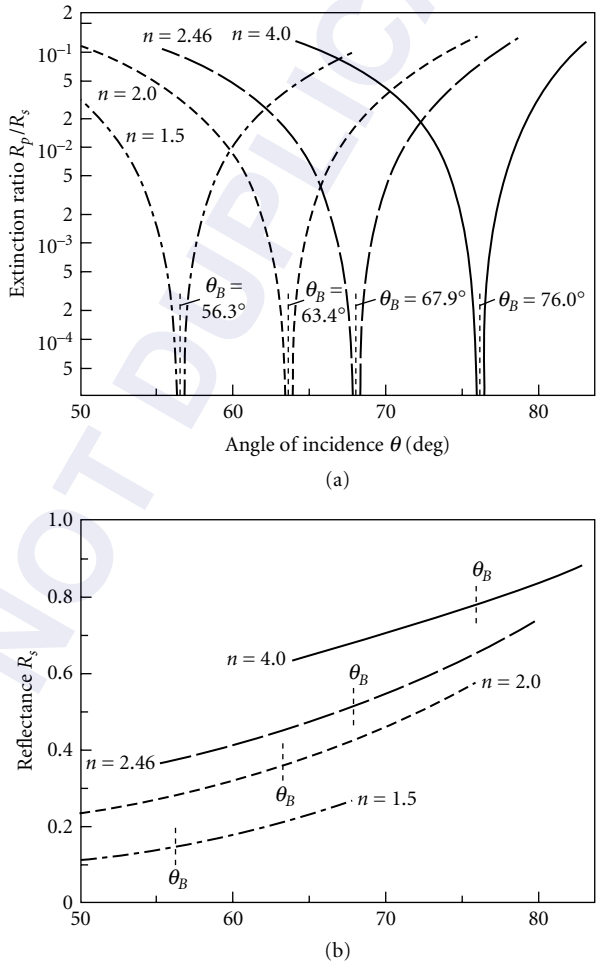

FIGURE 5 (*a*) Reflectance R_s and (*b*) extinction ratio R_p/R_s for materials of different refractive index at angles near the Brewster angle θ_B. A single surface of the material is assumed.

R_s in Fig. 5*b* are squared, so that for $n = 4$, $R_s = 0.78$ but $R_s^2 = 0.61$; for smaller refractive indexes the reduction in throughput is much greater.

The information shown graphically in Figs. 4 and 5 is given analytically in a paper by Azzam[20] who is concerned about the angular sensitivity of Brewster-angle reflection polarizers, particularly those made with silicon or germanium plates. Also, Murty and Shukla[21] show analytically that the shadowy extinction patterns sometimes seen with a crossed Brewster angle reflection polarizer and analyzer are caused by light incident on the surfaces at angles different from the Brewster angle.

Although in many cases multiple reflections within a plate degrade its polarizing properties, this is not true for Brewster angle reflection polarizers. For multiple reflections within a plane-parallel plate of material

$$(R_{s,p})_{\text{plate}} = \frac{2R_{s,p}}{1+R_{s,p}} \tag{66}$$

assuming no interference or absorption; R_s and R_p are given by Eqs. (20) and (21). Multiple reflections have a minor effect on the extinction ratio but the increase in R_s is appreciable. To fulfill the conditions of Eq. (66), the plate must have plane-parallel sides and be unbacked. We are also assuming that the plate is thick or nonuniform enough for interference effects within it to be neglected.

All the preceding discussion applies only to nonabsorbing materials. If a small amount of absorption is present, R_p will have a minimum that is very close to zero and the material will still make a good reflection polarizer. However, if the extinction coefficient k becomes appreciable, the minimum in R_p will increase and the polarizing efficiency will be degraded. By referring to Fig. 2 one can see roughly what the ratio of R_p to R_s will be for a given set of optical constants. Exact values of R_p and R_s can be calculated from n and k using Eqs. (45), (46), (31), and the other pertinent relations in Sec. 12.3. When choosing materials for possible use as metallic reflection polarizers, one wants the largest difference between R_s and R_p and the smallest magnitude of R_p at the minimum. Thus, ideally n should be much larger than k.

The Abelès condition[22] applies to the amplitude reflectances r_s and r_p for either dielectrics or metals at 45° angle of incidence. At this angle

$$r_s^2 = r_p \tag{67}$$

and

$$2\delta_s = \delta_p \tag{68}$$

where the δ's are the absolute phase changes on reflection for the p and s components (see Sec. 12.3). Relation in Eq. (67) is frequently applied to the intensity reflectances R_s and R_p, which are directly related to the amplitude reflectances [Eqs. (20), (21), and (31)].

12.6 POLARIZATION BY NONNORMAL-INCIDENCE TRANSMISSION (PILE OF PLATES)

The theory of Brewster angle transmission polarizers follows directly from that given for reflection polarizers. Table 1 lists the relations giving the s and p transmittances of the polarizers with various assumptions about multiple reflections, interference, absorption, etc.* All these relations contain R_s and R_p, the reflectances at a single interface, which are given at the bottom of the table.

At the Brewster angle, R_p at a single interface equals zero, and the transmittances of the plates can be expressed in terms of the refractive index of the material and the number of plates. The relations for the s and p transmittances at this angle are given in Table 2. Most references that contain

*Transmission polarizers in which the multiply internally reflected beams are coherent and produce interference effects are discussed in Chap. 13, "Polarizers."

TABLE 1 Transmittances and Degree of Polarization for a Single Plate and Multiple Plates at any Angle of Incidence in Terms of R_s and R_p for a Single Surface*

	One Plate (Two Surfaces)	*m* Plates (2*m* Surfaces)	
	$(T_{s,p})_{\text{sample}}$	$(T_{s,p})_{\text{sample}}$	$P=\dfrac{T_p-T_s}{T_p+T_s}=\dfrac{1-T_s/T_p}{1+T_s/T_p}$

§Formula of Provostaye and Desains.[23]
¶Also holds for coherent multiple reflections averaged over one period of $\sin^2\gamma$.

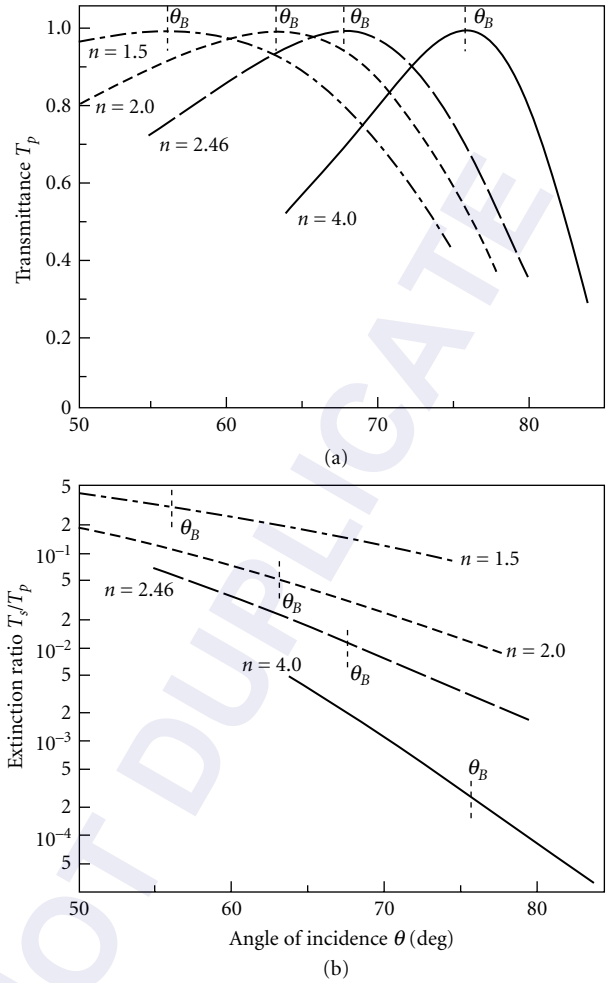

FIGURE 6 (*a*) Transmittance and (*b*) extinction ratio of four plane-parallel plates of refractive index n as a function of angle of incidence, for angles near the Brewster angle. Assumptions are multiple reflections but no interference within each plate and no reflections between plates.

an expression for the degree of polarization of a pile of plates give the formula of Provostaye and Desains,[23] which assumes an infinite series of multiple reflections between all surfaces, i.e., multiple reflections within and between plates. This assumption is not valid for most real transmission polarizers (see Chap. 13, "Polarizers," specifically Brewster Angle Transmission Polarizers).

For most parallel-plate polarizers it is reasonable to assume incoherent multiple reflections within each plate and no reflections between plates. Figure 6 shows the principal transmittance (*p* component) and extinction ratio for several four-plate polarizers having the refractive indexes indicated.* The extinction ratio improves considerably with increasing refractive index. It is also

*The extinction ratio of a pile of m plates (no multiple reflections between plates) is simply the product of the extinction ratios of the individual plates.

improved by using the plates at an angle of incidence slightly above the Brewster angle. This procedure, which is most helpful for high refractive index plates, reduces the transmission per plate so that a trade-off is required between losses resulting from absorption or scattering when many plates are used and the reflectance loss per plate when only a few plates are used above the Brewster angle. In some cases significant improvements have been achieved by following the latter course.[24]

When the number of plates of a given refractive index is increased, the transmittance is unaffected (in the absence of absorption) and the extinction ratio is greatly increased, as shown in the earlier polarization chapter.[1] In the absence of absorption, comparable transmittances and extinction ratios are obtained with a large number of low-refractive-index plates or a small number of high refractive index plates. Small amounts of absorption decrease the transmittance, but have little effect on the extinction ratio.[1] Tuckerman[25] has derived exact expressions for light reflected from or transmitted through a pile of absorbing plates. He has also noted mistakes that have been perpetuated in some of the formulas for light reflected from or transmitted through a pile of nonabsorbing plates.

A figure of merit giving the variation of the extinction ratio with angle of incidence can be defined as in Fig. 7, where the ordinate is the extinction ratio at a given angle of incidence divided by the extinction ratio at the Brewster angle. The angles of incidence are referred to the Brewster angle, and curves for different values of the refractive index are shown. These curves are calculated from the ratio

$$\frac{\left(\frac{T_s}{T_p}\right)_\theta}{\left(\frac{T_s}{T_p}\right)_{\theta_B}} = \frac{\left(\frac{1-R_s}{1+R_s}\frac{1+R_p}{1-R_p}\right)_\theta}{\left(\frac{1-R_s}{1+R_s}\right)^{\theta_B}} \tag{69}$$

and are for a single transparent film or plate having multiple incoherent internal reflections within the material. As an example of how to use the graphs, consider an optical system having a two-plate germanium polarizer with a refractive index of 4.0. If the angles of incidence vary from −1.4 to +1.5° around the Brewster angle, the ratio of the extinction ratios will vary between $1.10^2 = 1.21$ and

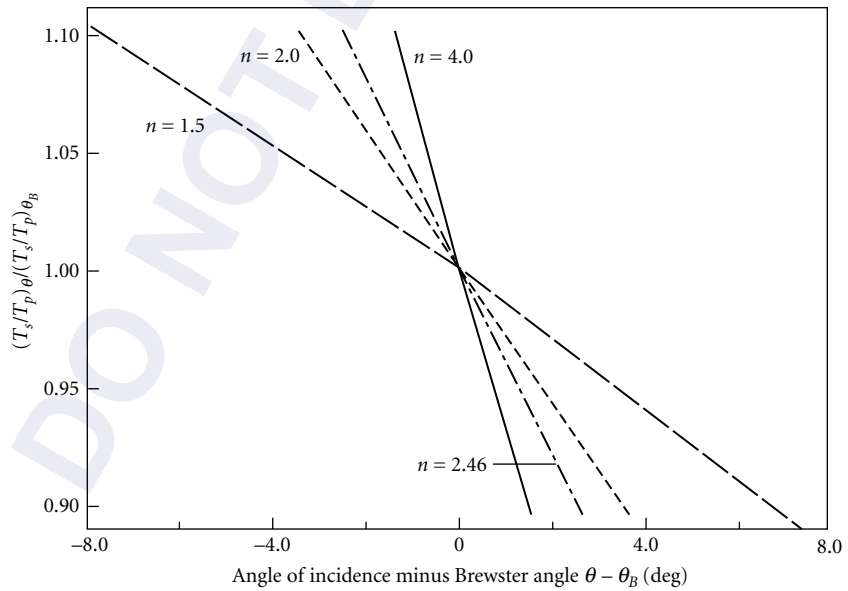

FIGURE 7 Variation of extinction ratio (per film) as a function of angle near the Brewster angle $\theta - \theta_B$. The ordinate is the extinction ratio at θ divided by the extinction ratio at θ_B.

$0.90^2 = 0.81$, respectively. (For m plates it would be 1.10^m and 0.90^m.) Thus, in order to restrict the percent variation of the extinction ratio to a given value, one must use a smaller acceptance angle when using more plates.

We have assumed that there are multiple incoherent reflections within each plate and no multiple reflections between plates. The difference in extinction ratios for a series of four plates with and without internal reflections is shown in Fig. 8. The principal transmittance is essentially the same as in Fig. 6 for values of T_p above 0.70 (and only about 0.025 lower when T_p drops to 0.30). However, the extinction ratio of high-refractive-index materials is much better without multiple internal reflections; for low-refractive-index materials the difference in extinction ratios is small.

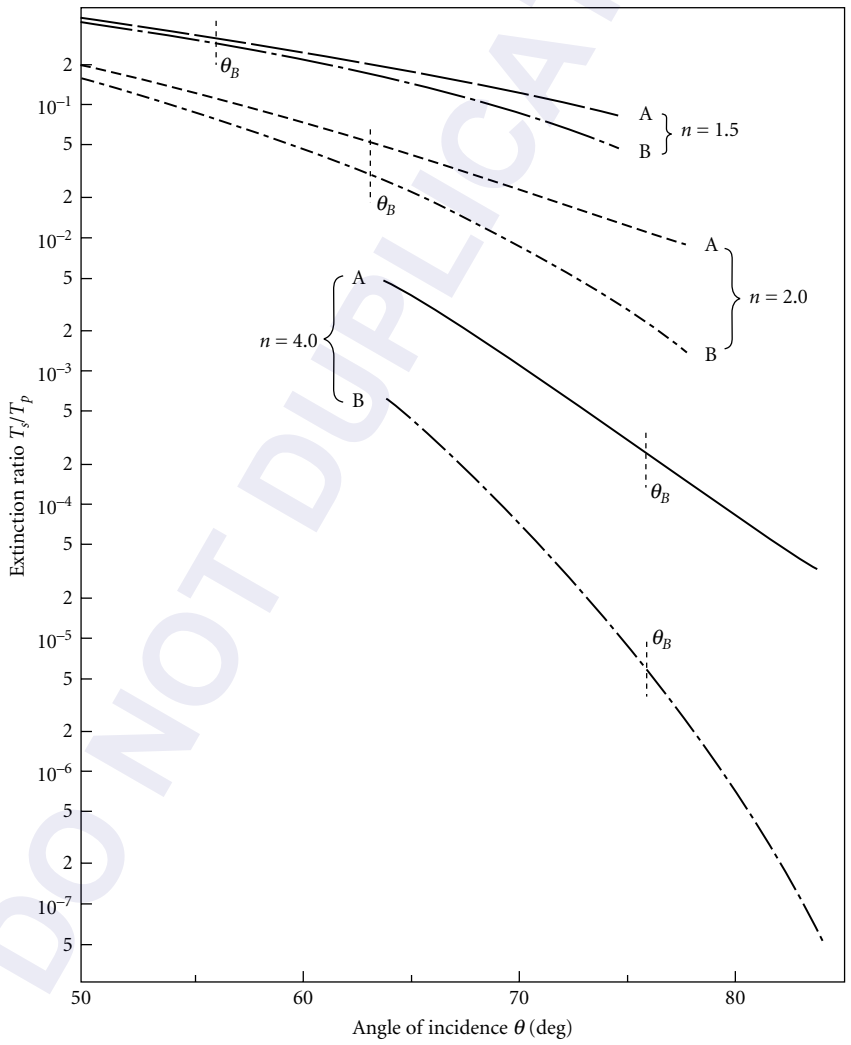

FIGURE 8 Extinction ratio of four plane-parallel plates of refractive index n as a function of angle of incidence for angles near the Brewster angle. Assumptions are *A*, multiple reflections but no interference within each plate and no reflections between plates; *B*, no multiple reflections within each plate or between plates. The transmittances for conditions *A* and *B* are essentially identical (see Fig. 6*a*).

The effect of multiple reflections on the extinction ratio can readily be seen from the three relations for the transmittances of the *p* and *s* components:

No multiple reflections:

$$(T_{s,p})_{\text{sample}} = (1-R_{s,p})^{2m} = 1-2mR_{s,p}+2m^2R^2_{s,p}-mR^2_{s,p}+\cdots \tag{70}$$

Multiple reflections within plates:

$$(T_{s,p})_{\text{sample}} = \left(\frac{1-R_{s,p}}{1+R_{s,p}}\right)^m = 1-2mR_{s,p}+2m^2R^2_{s,p}+\cdots \tag{71}$$

Multiple reflections within and between plates:

$$(T_{s,p})_{\text{sample}} = \frac{1-R_{s,p}}{1+(2m-1)R_{s,p}} = 1-2mR_{s,p}+4m^2R_{s,p}-2mR^2_{s,p}+\cdots \tag{72}$$

At the Brewster angle, $R_p = 0$, $T_p = 1$, and the extinction ratio will be smallest, i.e., highest degree of polarization, for the smallest values of the *s* transmittance. The first three terms in Eqs. (70) and (71) are identical, but Eq. (70) has an additional negative term in R_s^2 and so it will give a slightly smaller value of the *s* transmittance. Equation (72), from which the formula of Provostaye and Desains was derived, has twice as large a third term as the other two equations, and the negative fourth term is only l/2*m* of the third term, so that it does not reduce the overall value of the expression appreciably. Thus, Eq. (72) gives an appreciably larger value of the *s* transmittance, but fortunately it is a limiting case and is rarely encountered experimentally.

12.7 QUARTER-WAVE PLATES AND OTHER PHASE RETARDATION PLATES

A retardation plate is a piece of birefringent, uniaxial (or uniaxial-appearing) material in which the ordinary and extraordinary rays travel at different velocities. Thus, one ray is retarded relative to the other, and the path $N\lambda$ between the two rays is given by

$$N\lambda = \pm d(n_e - n_o) \tag{73}$$

where n_o = refractive index of ordinary ray
n_e = refractive index of extraordinary ray
d = physical thickness of plate
λ = wavelength

The positive sign is used when $n_e > n_o$, that is, a positive uniaxial crystal, and the negative sign is used for a negative uniaxial crystal, for which $n_e < n_o$. Since $N\lambda$ is the path difference between the two rays, N can be considered the retardation expressed in fractions of a wavelength. For example, $N = 1/4$ for a quarter-wave (or $\lambda/4$) plate, 1/2 for a half-wave (or $\lambda/2$) plate, 3/4 for a three-quarter-wave (or $3\lambda/4$) plate, etc.

The phase difference between two rays traveling through a birefringent material is $2\pi/\lambda$ times the path difference, so that the phase retardation δ is

$$\delta = 2\pi N = \pm\frac{2\pi d(n_e - n_o)}{\lambda} \tag{74}$$

Thus, phase differences of $\pi/2$, π, and $3\pi/2$ are introduced between the two beams in quarter-wave, half-wave, and three-quarter-wave plates, respectively.

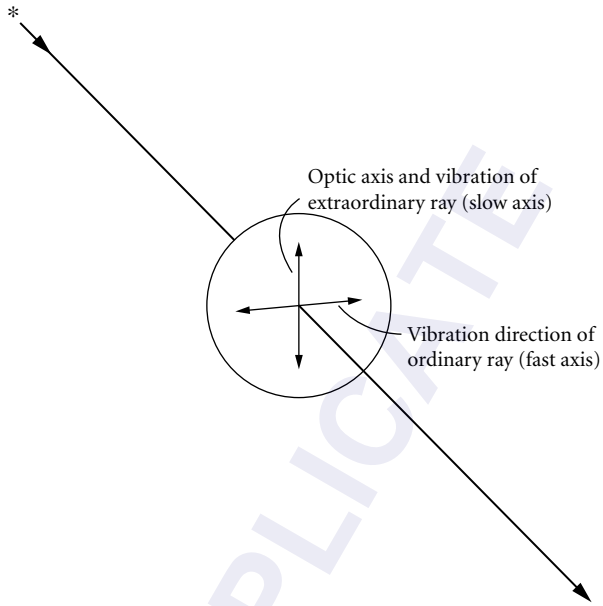

FIGURE 9 Light incident normally on the front surface of a retardation plate showing the vibration directions of the ordinary and extraordinary rays. In a positive uniaxial crystal, the fast and slow axes are as indicated in parentheses; in a negative uniaxial crystal, the two axes are interchanged.

A retardation plate can be made from a crystal which is cut so that the optic axis lies in a plane parallel to the face of the plate, as shown in Fig. 9. Consider a beam of unpolarized or plane-polarized light normally incident on the crystal. It can be resolved into two components traveling along the same path through the crystal but vibrating at right angles to each other. The ordinary ray vibrates in a direction perpendicular to the optic axis, while the extraordinary ray vibrates in a direction parallel to the optic axis. In a positive uniaxial crystal $n_e > n_o$, so that the extraordinary ray travels more slowly than the ordinary ray. The fast axis is defined as the direction in which the faster-moving ray vibrates; thus in a positive uniaxial crystal, the fast axis (ordinary ray) is perpendicular to the optic axis while the slow axis, (extraordinary ray) coincides with the optic axis. For a negative uniaxial crystal the fast axis coincides with the optic axis.

Figure 10 shows how the state of polarization of a light wave changes after passing through retardation plates of various thicknesses when the incident light is plane-polarized at an azimuth of 45° to the fast axis of the plate. If the plate has a retardation of $\lambda/8$, which means that the ordinary and extraordinary waves are out of phase by $\pi/4$ with each other, the transmitted light will be elliptically polarized with the major axis of the ellipse coinciding with the axis of the original plane-polarized beam. As the retardation gradually increases (plate gets thicker for a given wavelength or wavelength gets shorter for a given plate thickness), the ellipse gradually turns into a circle, but its major axis remains at 45° to the fast axis of the retardation plate. For a retardation of $\lambda/4$, the emerging light is right-circularly polarized. As the retardation continues to increase, the transmitted light becomes elliptically polarized with the major axis of the ellipse lying perpendicular to the plane of the incident polarized beam, and then the minor axis of the ellipse shrinks to zero and plane-polarized light is produced when the retardation becomes $\lambda/2$. As the retardation increases further, the patterns change in opposite order and the polarized light is left-circularly polarized when the retardation equals $3\lambda/4$. Finally, when the retardation is a full wave, the incident plane-polarized light is transmitted unchanged although the slow wave has now been retarded by a full wavelength relative to the fast wave.

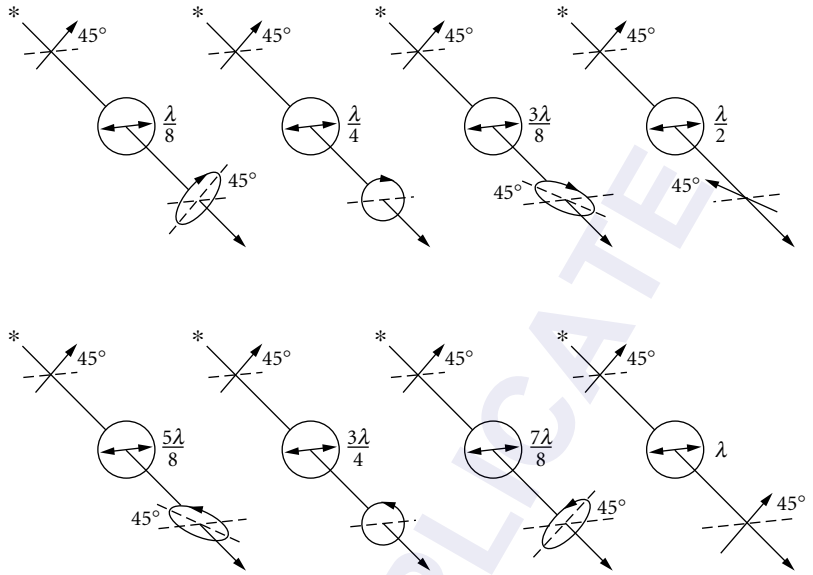

FIGURE 10 State of polarization of a light wave after passing through a crystal plate whose retardation is indicated in fractions of a wavelength (phase retardation $2\pi/\lambda$ times these values) and whose fast axis is indicated by the double arrow. In all cases the incident light is plane-polarized at an azimuth of 45° to the direction of the fast axis.

The most common type of retardation plate is the quarter-wave plate. Figure 11 shows how this plate affects the state of polarization of light passing through it when the fast axis is positioned in the horizontal plane and the azimuth of the incident plane-polarized light is changed from $\theta = 0°$ to $\theta = 90°$. When $\theta = 0°$, only the ordinary ray (for a positive birefringent material) passes through the plate, so that the state of polarization of the beam is unchanged. When θ starts increasing, the transmitted beam is elliptically polarized with the major axis of the ellipse lying along the fast axis of the $\lambda/4$ plate; $\tan\theta = b/a$, the ratio of the minor to the major axis of the ellipse. In the next case, $\theta = 15°$ and $\tan\theta = 0.268$, and so the ellipse is long and narrow. When the plane of vibration has rotated to an azimuth of 45°, the emerging beam is right-circularly polarized (the same situation as that shown in the second part of Fig. 10). For values of θ between 45° and 90°, the light is again elliptically polarized, this time with the major axis of the ellipse lying along the direction of the slow axis of the $\lambda/4$ plate. The angle shown in the figure is 60°, and $\tan 60° = 1.732$, so that b/a (referred to the fast axis) is greater than unity. When θ increases to 90°, the plane of vibration coincides with the slow axis and the transmitted

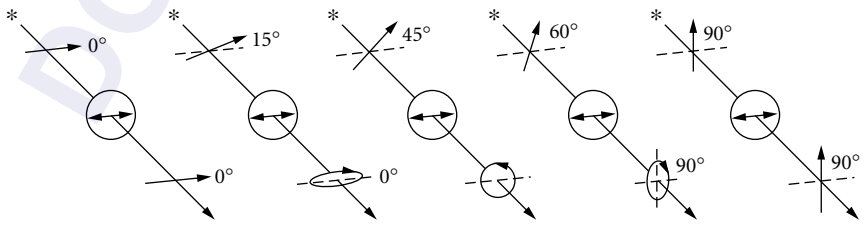

FIGURE 11 State of polarization of a light wave after passing through a $\lambda/4$ plate (whose fast axis is indicated by the double arrow) for different azimuths of the incident plane-polarized beam.

light is again plane-polarized. As θ continues to increase, the transmitted patterns repeat those already described and are symmetric about the slow axis, but the direction of rotation in the ellipse changes from right-handed, to left-handed, so that left-circularly polarized light is produced when $\theta = 135°$.

The definition of right- and left-circularly polarized light should be clear from Figs. 10 and 11. When the rotation is *clockwise* with the observer looking *opposite to the direction of propagation,* the light is called *right-circularly polarized*; if the rotation is *counterclockwise,* the light is called *left-circularly polarized*.[26] When circularly polarized light is reflected from a mirror, the direction of propagation is reversed, so that the sense of the circular polarization changes; i.e., left-circularly polarized light changes on reflection into right-circularly polarized light and vice versa. Therefore, in experiments involving magnetic fields in which the sense of the circularly polarized light is important,[27,28] it is important to know which kind one started with and how many mirror reflections occurred in the rest of the light path. Cyclotron resonance experiments can sometimes be used to determine the sense of the circular polarization.[28] Another method utilizing a polarizer and $\lambda/4$ plate has been described by Wood.[29]

The behavior of a half-wave plate in a beam of plane-polarized light is completely different from that of a quarter-wave plate; the transmitted light is always plane-polarized. If the incident plane of vibration is at an azimuth θ with respect to the fast axis of the $\lambda/2$ plate, the transmitted beam will be rotated through an angle 2θ relative to the azimuth of the incident beam. The case showing $\theta = 45°$ where the phase of vibration is rotated through 90° is illustrated in the fourth part of Fig. 10. In this situation the extraordinary beam is retarded by half a wavelength relative to the ordinary beam (for a positive birefringent material), hence the name, half-wave plate. If the polarizer is fixed and the $\lambda/2$ plate is rotated (or vice versa), the plane of vibration of the transmitted beam will rotate at twice the frequency of rotation of the $\lambda/2$ plate.

Quarter-wave plates are useful for analyzing all kinds of polarized light. In addition, they are widely employed in experiments using polarized light, e.g., measurements of the thickness and refractive index of thin films by ellipsometry or measurements of optical rotary dispersion, circular dichroism, or strain birefringence. Polarizing microscopes, interference microscopes, and petrographic microscopes are usually equipped with $\lambda/4$ plates. In some applications the $\lambda/4$ plate is needed only to produce circularly polarized light, e.g., for optical pumping in some laser experiments, or to convert a partially polarized light source into one which appears unpolarized, i.e., has equal amplitudes of vibration in all azimuths. For these and similar applications, one can sometimes use a circular polarizer which does not have all the other properties of a $\lambda/4$ plate (see Pars. 73 to 76 in Ref. 1).

The customary application for a $\lambda/2$ plate is to rotate the plane of polarization through an angle of 90°. In other applications the angle of rotation can be variable. Automatic-setting ellipsometers or polarimeters sometimes employ rotating $\lambda/2$ plates in which the azimuth of the transmitted beam rotates at twice the frequency of the $\lambda/2$ plate.

12.8 MATRIX METHODS FOR COMPUTING POLARIZATION

In dealing with problems involving polarized light, it is often necessary to determine the effect of various types of polarizers (linear, circular, elliptical, etc.), rotators, retardation plates, and other polarization-sensitive devices on the state of polarization of a light beam. The Poincaré sphere construction is helpful for giving a qualitative understanding of the problem; for quantitative calculations, one of several forms of matrix calculus can be used. The matrix methods are based on the fact that the effect of a polarizer or retarder is to perform a linear transformation (represented by a matrix) on the vector representation of a polarized light beam. The advantage of these methods over conventional techniques is that problems are reduced to simple matrix operations; thus since one does not have to think through the physics of every problem, the probability of making an error is greatly reduced. The most common forms of matrix calculus are the Mueller calculus and the Jones calculus, but the coherency-matrix formulation is also gaining popularity for dealing with problems involving partially polarized light. We give here a brief description of the Poincaré sphere and the

different matrix methods, indicating how they are used, the different types of problems for which they are helpful, and where complete descriptions of each may be found.

The *Poincaré sphere* is a useful device for visualizing the effects of polarizers and retarders on a beam of polarized light. The various states of polarization are represented on the sphere as follows. The equator represents various forms of linear polarization, the poles represent right- and left-circular polarization,* and other points on the sphere represent elliptically polarized light. Every point on the sphere corresponds to a different polarization form. The radius of the sphere indicates the intensity of the light beam (which is usually assumed to be unity). The effects of polarizers and retarders are determined by appropriate displacements on the sphere. Partially polarized light or absorption may be dealt with approximately by ignoring the intensity factor, since one is generally interested only in the state of polarization; however, the construction is most useful when dealing with nonabsorbing materials. Good introductory descriptions of the Poincaré sphere, including references, can be found in *Polarized Light* by Shurcliff,[30†] *Ellipsometry and Polarized Light* by Azzam and Bashara,[31] and *Polarized Light in Optics and Spectroscopy* by **K**liger Lewis and Randall;[32‡] illustrative examples and problems are given in Sutton and Panati.[33] More comprehensive treatments are given by Ramachandran and Ramaseshan[34‡] and Jerrard[35‡] and include numerous examples of applications to various types of problems. The new book *Polarized Light, Fundamentals and Applications* by Collett[36] has a comprehensive 35-page chapter on the mathematical aspects of the Poincaré sphere; this material can be best understood after reading some of the introductory descriptions of the Poincaré sphere. The main advantage of the Poincaré sphere, like other graphical methods, is to reveal by essentially a physical argument which terms in exceedingly complex equations are negligible or can be made negligible by modifying the experiment. It is characteristic of problems in polarized light that the trigonometric equations are opaque to inspection and yield useful results only after exact calculation with the aid of a computer or after complex manipulation and rather clever trigonometric identities. The Poincaré sphere thus serves as a guide to the physical intrepretation of otherwise obscure polarization phenomena. It can be used for solving problems involving retarders or combinations of retarders,[30,32,36–39] compensators, half-shade devices, and depolarizers,[34] and it has also been applied to ellipsometric problems[40] and stress-optical measurements.[41]

The Poincaré sphere is based on the Stokes vectors, which are sometimes designated S_0, S_1, S_2, and S_3. The physical interpretation of the vectors is as follows. S_0 is the intensity of the light beam, corresponding to the radius of the Poincaré sphere. S_1 is the difference in intensities between the horizontal and vertical polarization components of the beam; when S_1 is positive, the preference is for horizontal polarization, and when it is negative, the preference is for vertical polarization.§ S_2 indicates preference for +45° or −45° polarization, depending upon whether it is positive or negative, and S_3 gives the preference for right- or left-circular polarization. The Stokes vectors S_1, S_2, and S_3 are simply the three cartesian coordinates of a point on the Poincaré sphere: S_1 and S_2 are perpendicular to each other in the equatorial plane, and S_3 points toward the north pole of the sphere.¶ Thus, any state of polarization of a light beam can be specified by these three Stokes vectors. The intensity vector S_0 is related to the other three by the relation $S_0^2 = S_1^2 + S_2^2 + S_3^2$ when the beam is completely polarized. If the beam is partially polarized, $S_0^2 > S_1^2 + S_2^2 + S_3^2$. Good introductory material on Stokes vectors is given by Shurcliff,[30] Azzam and Bashara,[31] Kliger et al.,[32] Sutton and Panati,[33] and Walker.[42] A comprehensive discussion of the Stokes vectors has been given by Collett.[36] Rigorous definitions of the simple vectors and those for partially coherent light can be found in Born and Wolf;[43] other authors are cited by Shurcliff[30] and Collett.[36] Stokes vectors are generally used in conjunction with the Mueller calculus, and some examples of applications will be given there. We note here that Budde[44] has demonstrated a method for experimentally determining the Stokes vectors and other polarization parameters from a Fourier analysis of measured quantities. Ioshpa and Obridko[45] have proposed a photoelectric

*Right-circularly polarized light is defined as a *clockwise* rotation of the electric vector when the observer is looking *against the direction the wave is traveling.*

†Schurcliff and Kliger, Lewis, and Randall have the S_3 axis pointing down, so that the upper pole represents left-circular polarization. The more logical convention, followed by most others, is for the upper pole to represent right-circular polarization.

‡The notation is similar to that used by Schurcliff,[30] with the upper pole representing left-circular polarization.

§Some authors dealing with light scattering from aerosols define S_1 as positive when the preference is for vertical polarization.

¶See Shurcliff and Kliger, Lewis and Randall footnote, p. 5.26.

method for simultaneously and independently measuring the four Stokes parameters. Collett[46] has developed a method for measuring the four Stokes vectors using a single circular polarizer. Azzam and coworkers[47–51] have built, tested, analyzed, and calibrated a four-detector photopolarimeter for measuring normalized Stokes vectors of a large number of polarization states, and have given a physical meaning to the rows and columns in the instrument matrix. Other methods for measuring Stokes parameters are discussed by Collett.[36] Hauge[52] has surveyed different types of methods for completely determining the state of polarization of a light beam using combinations of Stokes vectors.

The matrix methods for solving problems involving polarized light have certain properties in common. All use some type of representation for the original light beam (assumed to be a plane wave traveling in a given direction) that uniquely describes its state of polarization. Generally the beam is completely polarized, but for some of the matrix methods it can also be unpolarized or partially polarized or its phase may be specified. The beam encounters one or more devices which change its state of polarization. These are called *instruments* and are represented by appropriate matrices. After the instruments operate on the light beam, it emerges as an outgoing plane wave in an altered state of polarization. The basic problem for all the methods is to find a suitable representation for the incident plane wave (usually a two- or four-component column vector), and the correct matrices (2×2 or 4×4) to represent the instruments. Once the problem is set up, one can perform the appropriate matrix operations to obtain a representation for the outgoing plane wave. Its properties are interpreted in the same way as the properties of the incident plane wave.

An introduction to the Jones and Mueller calculus is given by Shurcliff,[30] Azzam and Bashara,[31] and Kliger et al.,[32] and an excellent systematic and rigorous discussion of all the matrix methods has been given by O'Neill[53] and Collett.[36] All references contain tables of vectors for the various types of polarized beams and tables of instrument matrices. More complete tables are given by Sutton and Panati.[33] In the Mueller calculus the beam is represented by the four-component Stokes vector, written as a column vector. This vector has all real elements and gives information about *intensity* properties of the beam. Thus it is not able to handle problems involving phase changes or combinations of two beams that are coherent. The instrument matrix is a 4×4 matrix with all real elements. In the Jones calculus, the Jones vector is a two-component column vector that generally has complex elements. It contains information about the *amplitude* properties of the beam and hence is well suited for handling coherency problems. However, it cannot handle problems involving depolarization, as the Mueller calculus can. The Jones instrument matrix is a 2×2 matrix whose elements are generally complex.

Shurcliff[30] has noted some additional differences between Jones calculus and Mueller calculus. The Jones calculus is well suited to problems involving a large number of similar devices arranged in series in a regular manner and permits an investigator to arrive at an answer expressed explicitly in terms of the number of such devices. The Mueller calculus is not suited for this type of problem. The Jones instrument matrix of a train of transparent or absorbing nondepolarizing polarizers and retarders contains no redundant information. The matrix contains four elements each of which has two parts, so that there are a total of eight constants, none of which is a function of any other. The Mueller instrument matrix of such a train contains much redundancy; there are 16 constants but only 7 of them are independent.

In order to handle problems involving partially coherent polarized light, coherency-matrix formalism has been developed. In this system the beam is represented by a 4×4 matrix called a *coherency* or *density matrix,* which is the time average of the product of the Jones vector with its hermitian conjugate. The instrument matrices are the same as those used in the Jones calculus. O'Neill[53] and Born and Wolf[43] have good basic descriptions of coherency-matrix formalism; later extensions of the theory are given by Marathay.[54,55]

There have been some modifications of the various matrix methods. Priebe[56] has introduced an operational notation for the Mueller matrices that facilitates the analysis by simplifying the functional description of a train of optical components. Collins and Steel[57] have suggested a modification of the Jones calculus in which the light vector is expressed as the sum of two circularly polarized (rather than linearly polarized) components. Schmieder[58] has given a unified treatment of Jones calculus and Mueller calculus including the coherency matrix and has shown that if the Stokes parameters are ordered in a different way from that customarily used, familiar relationships

are preserved and the rotation matrix looks like a rotation matrix rather than like a rearranged one. Tewarson[59] presents a generalized reciprocity equation expressing an algebraic relationship between the parameters of an optical system and its reciprocal system and has verified the equation for both plane-polarized and circularly polarized light beams. Since his equation follows from the reciprocity law in the Mueller calculus, that law is verified also. Cernosek[60] presents a simple geometric method based on the properties of quaternions to give a quick, quantitative analysis of the effect of any combination of linear retarders and rotators on the state of polarization of a system.

Among the applications of Mueller calculus and Jones calculus to problems involving polarized light, McCrackin[61] has used both matrix methods to analyze instrumental errors in ellipsometry, and Hellerstein[62] has used Mueller calculus to study the passage of linearly, circularly, and elliptically polarized light through a Sénarmont polariscope. Azzam and Bashara[63] have used Jones calculus to give a unified analysis of errors in ellipsometry, including effects of birefringence in cell windows, imperfect components, and incorrect azimuth angles. Azzam[64] also describes a simple photopolarimeter with rotating polarizer and analyzer for measuring Jones and Mueller matrices.

POLARIZERS

Jean M. Bennett*

Research Department
Michelson Laboratory
Naval Air Warfare Center
China Lake, California

13.1 GLOSSARY

D	optical density
d	grid spacing
e	extraordinary
i	angle of incidence
i	semicone angle
M	positive integer
m	number of plates
N	1/4, 1/2
n	refractive index
o	ordinary
S	cut angle
T	intensity transmittance
α	faces angle or angle between normal and optical axis
α_i	absorption coefficient for ith component
β	angle between normal and optical axis
γ	maximum variation plane of vibration
δ	deviation angle
Δn	change in retardation
Δn	$n_e - n_o$
λ	wavelength
ν	frequency (wave number)
ϕ	angle ϕ
ϕ	angle to wave normal

*Deceased.

13.2 PRISM POLARIZERS

The material on prism polarizers is abridged from the much more complete treatment by Bennett and Bennett.[1] Basic relations for polarizers are given in Sec. 12.4 of Chap. 12, "Polarization."

Double Refraction in Calcite

Although many minerals, specifically those which do not have a cubic crystal structure, are doubly refracting, nearly all polarizing prisms used in the visible, near-ultraviolet, and near-infrared regions of the spectrum are made from optical calcite, which exhibits strong birefringence over a wide wavelength range. Polarizing prisms made from other birefringent crystals are used primarily in the ultraviolet and infrared at wavelengths for which calcite is opaque (see Sec. 13.7).

Next to quartz, calcite is the most widely distributed of all minerals and usually occurs in an impure polycrystalline form as marble, limestone, or chalk. Optical calcite, or Iceland spar, which is quite rare, originally came from a large deposit on the east coast of Iceland. This source is now exhausted, and optical calcite now comes principally from Mexico, Africa, and Siberia. It has been grown artificially by a hybrid gel-solution method,[2] but maximum edge lengths are only 3 to 4 mm.

Although calcite is much softer than glass, with care it can be worked to an excellent polish. Surfaces flat to one-fifth fringe, or even, with care, one-tenth fringe, which are free from surface defects or perceptible turned edges can be produced using more or less conventional pitch-polishing techniques.[3] Such techniques fail only for surfaces normal to the optic axis, in which case pitch polishing tends to cleave out small tetrahedra. Such surfaces can be polished to a lower surface quality using cloth polishers.

Crystals of calcite are negative uniaxial and display a prominent double refraction. The material can easily be cleaved along three distinct planes, making it possible to produce rhombs of the form shown in Fig. 1. At points *B* and *H*, a given face makes an angle of 101°55′ with each of the other two. At all the other points, two of the angles are 78°5′ and one is 101°55′. The *optic axis HI*, the direction in the crystal along which the two sets of refracted waves travel at the same velocity, makes equal

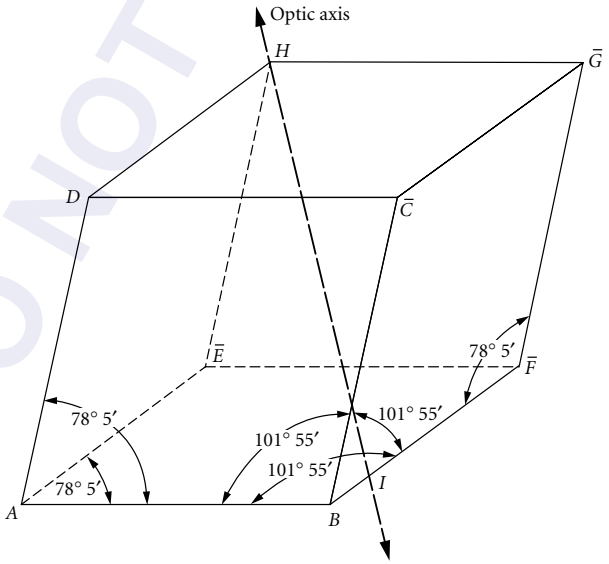

FIGURE 1 Schematic representation of a rhombohedral calcite crystal showing the angles between faces. The optic axis passes through corner *H* and point *I* on side *BF*.

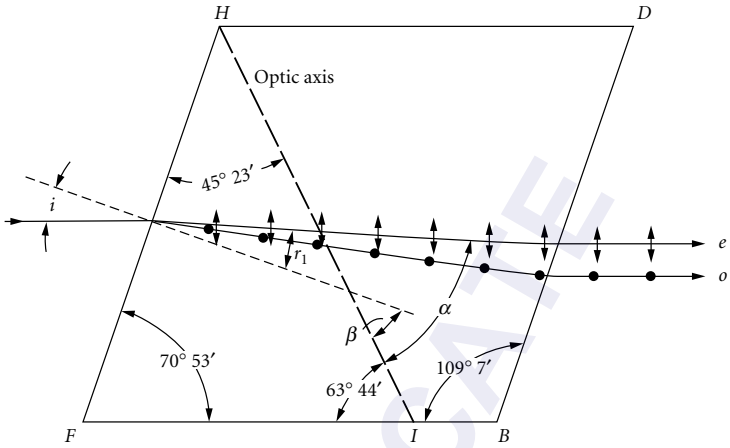

FIGURE 2 Side view of a principal section for the calcite rhomb in Fig. 1. The direction of the optic axis and the angles of the principal section are indicated. The angle of incidence is i, angle of refraction is r, angle between the e ray and the optic axis is α, and angle between the normal to the surface and the optic axis is β. The directions of vibration of the e and o rays are in the plane of the paper and perpendicular to it, respectively.

angles with all three faces at point H.* Any plane, such as $DBFH$, which contains the optic axis and is perpendicular to the two opposite faces of the rhomb $ABCD$ and $EFGH$ is called a *principal section*. A side view of the principal section $DBFH$ is shown in Fig. 2. If light is incident on the rhomb so that the plane of incidence coincides with a principal section, the light is broken up into two components polarized at right angles to each other. One of these, the ordinary ray o, obeys Snell's law and has its plane of vibration (of the electric vector) perpendicular to the principal section. The second, the extraordinary ray e, has its plane of vibration parallel to the principal section. The refraction of the extraordinary ray in some cases violates Snell's law, at least in its simple form. The anomalous deflection of the ray is caused by the wavefront becoming ellipsoidal, so that the direction of propagation of the light is not along the wave normal. This ellipticity causes the velocity of the light in the crystal, and hence its refractive index, to be a function of angle. If light is incident on rhomb face $EFGH$ parallel to edge BF of the rhomb, the o and e rays, both of which lie in a principal section, are as shown in Fig. 2. As the angle of incidence is changed in Fig. 2 so that the direction taken by the o ray approaches that of the optic axis HI, the separation between the e and o rays decreases. If the rhomb is rotated about an axis parallel to HD, the e ray will precess about the o ray. However, unlike the o ray, it will not remain in the plane of incidence unless this plane coincides with the principal section.

The plane containing the o ray and the optic axis is defined as the *principal plane of the o ray*, and that containing the e ray and the optic axis as the *principal plane of the e ray*. In the case discussed earlier, the two principal planes and the principal section coincide. In the general case, they may all be different. However, in all cases, the o ray is polarized with its plane of vibration perpendicular to its principal plane and the e ray with its plane of vibration in its principal plane (see Fig. 2). In all cases, the vibration direction of the e ray remains perpendicular to that of the o ray.

The value of the index of refraction of the e ray which differs most from that of the o ray, i.e., the index when the e ray vibrations are parallel to the optic axis, is called the *principal index for the extraordinary ray* n_e. Snell's law can be used to calculate the path of the e ray through a prism for this case. Snell's law can always be used to calculate the direction of propagation of the ordinary ray.

Table 1 lists values of n_o and n_e for calcite, along with the two absorption coefficients a_o and a_e, all as a function of wavelength. Since $n_e < n_o$ in the ultraviolet, visible and infrared regions, calcite is a

*The direction of the optic axis in a uniaxial crystal such as calcite or crystalline quartz can be determined by observing the crystal between crossed polarizers. If the alignment is correct, so that the optic axis is parallel to the line of sight, there will be concentric colored circles with a black cross superimposed.[4]

[a]Refractive indexes n_o and n_e are the ordinary and extraordinary rays, respectively, and the corresponding absorption coefficients are $\alpha_o = 4\pi k_o/\lambda\,\mathrm{cm}^{-1}$ and $\alpha_e = 4\pi k_e/\lambda\,\mathrm{cm}^{-1}$, where the wavelength λ is in centimeters. In the table, the wavelength is in micrometers.
[b]Uzan et al., Ref. 5; α_o and α_e were calculated from the reported values of k_o and k_e.
[c]Ballard et al., Ref. 6.
[d]Schellman et al., Ref. 7; α_e was calculated from the optical density for the extraordinary ray.
[e]Bouriau and Lenoble, Ref. 8; reported absorption coefficient in this paper was for both *o* and *e* rays. α_o was calculated by assuming $\alpha_e = 0$.
[f]Ballard et al., Ref. 9.

negative uniaxial crystal. However, at wavelengths shorter than 1520 Å in the vacuum ultraviolet, the birefringence $n_e - n_o$ becomes positive, in agreement with theoretical predictions.[5,10] For additional data in the 0.17- to 0.19-μm region, see Uzan et al.[11] The range of transparency of calcite is approximately from 0.214 to 3.3 μm for the extraordinary ray but only from about 0.23 to 2.2 μm for the ordinary ray.

If the principal plane of the *e* ray and the principal section coincide (Fig. 2), the wave normal (*but not the e ray*) obeys Snell's law, except that the index of refraction n_ϕ of this wave is given by[12,13]

$$\frac{1}{n_\phi^2} = \frac{\sin^2\phi}{n_e^2} + \frac{\cos^2\phi}{n_o^2} \tag{1}$$

where ϕ is the angle between the direction of the *wave normal* and the optic axis ($\phi \le 90°$). When $\phi = 0°$, $n_\phi = n_o$, and when $\phi = 90°$, $n_\phi = n_e$. The angle of refraction for the wave normal is $\phi - \beta$, where β is the angle the normal to the surface makes with the optic axis. Snell's law for the extraordinary-ray *wave normal* then becomes

$$n \sin i = \frac{n_e n_o \sin(\phi - \beta)}{(n_o^2 \sin^2\phi + n_e^2 \cos^2\phi)^{1/2}} \tag{2}$$

where i is the angle of incidence of light in a medium of refractive index n. Since all other quantities in this equation are known, ϕ is uniquely determined but often must be solved for by iteration. Once ϕ is known, the angle of refraction r for the extraordinary ray can be determined as follows. If α is the angle the ray makes with the optic axis ($\alpha \le 90°$), then $r = \alpha - \beta$ and[13]

$$\tan\alpha = \frac{n_o^2}{n_e^2} \tan\phi \tag{3}$$

Although the angle of refraction of the extraordinary ray determines the path of the light beam through the prism, one must use the angle of refraction of the *wave normal*, $\phi - \beta$, in Fresnel's equation [Eq. (21) in Chap. 12, "Polarization"] when calculating the reflection loss of the *e* ray at the surface of the prism.

For the special case in which the optic axis is parallel to the surface as well as in the plane of incidence, α and ϕ are the complements of the angles of refraction of the ray and wave normal, respectively. If the light is normally incident on the surface, ϕ and α are both 90° and the extraordinary ray is undeviated and has its minimum refractive index n_e. In other cases for which the optic axis is not parallel to the surface, the extraordinary ray is refracted even for normal incidence.

If the plane of incidence is neither in a principal section nor perpendicular to the optic axis, it is more difficult to determine the angle of refraction of the extraordinary ray. In such cases, Huygens' construction is helpful.[13–15]

Types of Polarizing Prisms and Definitions

In order to make a polarizing prism out of calcite, some way must be found to separate the two polarized beams. In wavelength regions where calcite is absorbing (and hence only a minimum thickness of calcite can be used), this separation has been made simply by using a very thin calcite wedge cut so that the optic axis is parallel to the faces of the wedge to enable the *e* and *o* rays to be separated by a maximum amount. The incident light beam is restricted to a narrow pencil. Calcite polarizers of this type can be used at wavelengths as short as 1900 Å.[16] In more favorable wavelength regions, where the amount of calcite through which the light passes is not so critical, more sophisticated designs are usually employed. Such prisms can be divided into two main categories, *conventional polarizing prisms* (Secs. 13.3 and 13.4) and *polarizing beam-splitter prisms* (Sec. 13.5), and a third category, *Feussner prisms* (Sec. 13.6).

In conventional polarizing prisms, only light polarized in one direction is transmitted. This is accomplished by cutting and cementing the two halves of the prism together in such a way that the other beam suffers total internal reflection at the cut. It is usually deflected to the side, where it is absorbed by a coating containing a material such as lampblack. Since the ordinary ray, which has the higher index, is the one usually deflected, the lampblack is often mixed in a matching high-index binder such as resin of aloes ($n_D = 1.634$) or balsam of Tolu ($n_D = 1.628$) to minimize reflections.[17] When high-powered lasers are used, the coating is omitted to avoid overheating the prism, and the light is absorbed externally.

Conventional polarizing prisms fall into two general categories: *Glan types* (Sec. 13.3) and *Nicol types* (Sec. 13.4), which are illustrated in Fig. 3. Glan types have the optic axis in the plane of the entrance face. If the principal section is parallel to the plane of the cut, the prism is a Glan-Thompson design (sometimes called a Glazebrook design); if perpendicular, a Lippich design; and if 45°, a Frank-Ritter design. In Nicol-type prisms, which include the various Nicol designs and the Hartnack-Prazmowsky, the principal section is perpendicular to the entrance face, but the optic axis is neither parallel nor perpendicular to the face.

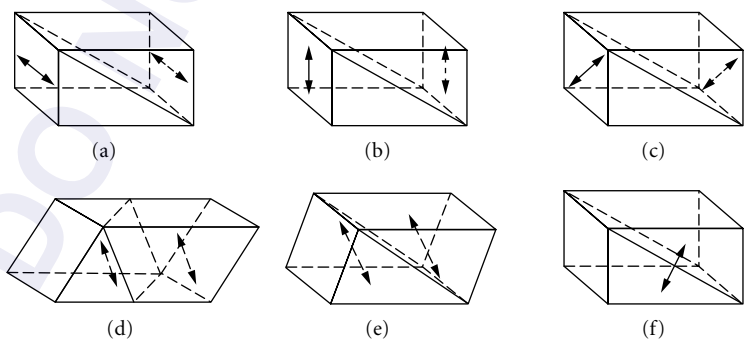

FIGURE 3 Types of conventional polarizing prisms. Glan types: (*a*) Glan-Thompson, (*b*) Lippich, and (*c*) Frank-Ritter; Nicol types: (*d*) conventional Nicol, (*e*) Nicol, Halle form, and (*f*) Hartnack-Prazmowsky. The optic axes are indicated by the double-pointed arrows.

Air-spaced prisms can be used at shorter wavelengths than cemented prisms, and special names have been given to some of them. An air-spaced Glan-Thompson prism is called a Glan-Foucault, and an air-spaced Lippich prism, a Glan-Taylor. In common practice, either of these may be called a Glan prism. An air-spaced Nicol prism is called a Foucault prism. Double prisms can also be made, thus increasing the prism aperture without a corresponding increase in length. Most double prisms are referred to as double Frank-Ritter, etc., but a double Glan-Thompson is called an Ahrens prism.

In polarizing beam-splitter prisms, two beams, which are polarized at right angles to each other, emerge but are separated spatially. The prisms have usually been used in applications for which both beams are needed, e.g., in interference experiments, but they can also be used when only one beam is desired. These prisms are also of two general types, illustrated in Fig. 10; those having the optic axis in the two sections of the prism perpendicular and those having them parallel. Prisms of the first type include the Rochon, Sénarmont, Wollaston, double Rochon, and double Sénarmont. Prisms of the second type are similar to the conventional polarizing prisms but usually have their shape modified so that the two beams emerge in special directions. Examples are the Foster, the beam-splitting Glan-Thompson, and the beam-splitting Ahrens.

The Feussner-type prisms, shown in Fig. 12, are made of isotropic material, and the film separating them is birefringent. For negative uniaxial materials the ordinary ray rather than the extraordinary ray is transmitted. These prisms have the advantage that much less birefringent material is required than for the other types of polarizing prisms, but they have a more limited wavelength range when calcite or sodium nitrate is used because, for these materials, the extraordinary ray is transmitted over a wider wavelength range than the ordinary ray.

The amount of flux which can be transmitted through a prism or other optical element depends on both its angular aperture and its cross-sectional area. The greater the amount of flux which can be transmitted, the better the *throughput* or *light-gathering power* (sometimes called *étendue* or *luminosity*) of the system.[18,19] If a pupil or object is magnified, the convergence angle of the light beam is reduced in direct ratio to the increase in size of the image. The maximum throughput of a prism is thus proportional to the product of the prism's solid angle of acceptance and its cross-sectional area perpendicular to the prism axis. Hence, a large Glan-Taylor prism having an 8° field angle may, if suitable magnification is used, have a throughput comparable to a small Glan-Thompson prism with a 26° field angle. In general, to maximize prism throughput in an optical system, both the angular aperture and clear aperture (diameter of the largest circle perpendicular to the prism axis which can be included by the prism) should be as large as possible.

The quantities normally specified for a prism are its clear aperture, field angle, and length-to-aperture (L/A) ratio. The *semifield angle* is defined as the maximum angle to the prism axis* at which a ray can strike the prism and still be completely polarized *when the prism is rotated about its axis*. The field angle is properly twice the semifield angle.† (Some manufacturers quote a "field angle" for their polarizing prisms which is not symmetric about the prism axis and is thus in most cases unusable.) The *length-to-aperture* (L/A) *ratio* is the ratio of the length of the prism base (parallel to the prism axis) to the minimum dimension of the prism measured perpendicular to the prism base. For a square-ended prism, the L/A ratio is thus the ratio of prism length to width.

In determining the maximum angular spread a light beam can have and still be passed by the prism, both the field angle and the L/A ratio must be considered, as illustrated in Fig. 4. If the image of a point source were focused at the center of the prism, as in Fig. *4a*, the limiting angular divergence of the beam would be determined by the field angle $2i$ of the prism.‡ However, if an extended

*The prism axis, which is parallel to its base, is not to be confused with the optic axis of the calcite.

†In many prism designs, there is asymmetry about the prism axis, so that although light transmitted at a given angle to the prism axis may be completely polarized for one prism orientation, it will not be completely polarized when the prism is rotated about its axis. Thus, the semifield angle is not necessarily the largest angle at which completely polarized light can be transmitted by the prism in any orientation.

‡We are assuming that the prism is wide enough to ensure that the sides of the prism do not limit the angular width of the beam.

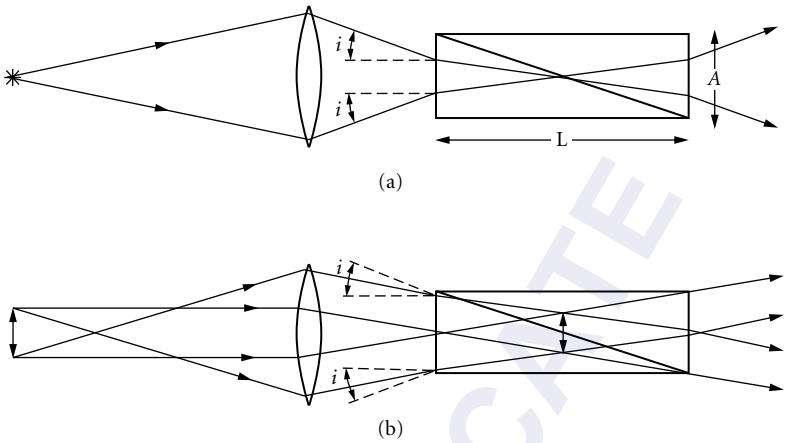

FIGURE 4 The effect of field angle and length-to-aperture ratio of a prism polarizer on the maximum angular beam spread for (*a*) a point source and (*b*) an extended source. The field angle is $2i$, and $L/A = 3$. The field angle is exaggerated for clarity.

source were focused there (Fig. 4*b*), the limiting angular divergence would be determined by the L/A ratio, not the field angle.

The field angle of a polarizing prism is strongly wavelength-dependent. For example, a Glan prism having an 8° field angle at 0.4 μm has only a 2° field angle at 2 μm. In designing optical systems in which polarizing prisms are to be used, the designer must allow for this variation in field angle. If he does not, serious systematic errors may occur in measurements made with the system.

13.3 GLAN-TYPE PRISMS

Most prisms used at the present time are of the Glan type. Although they require considerably more calcite than Nicol types of comparable size, they are optically superior in several ways: (1) Since the optic axis is perpendicular to the prism axis, the index of the extraordinary ray differs by a maximum amount from that of the ordinary ray. Thus, a wider field angle or a smaller L/A ratio is possible than with Nicol types. (2) The light is nearly uniformly polarized over the field; it is not for Nicol types. (3) There is effectively no lateral displacement in the apparent position of an axial object viewed through a (perfectly constructed) Glan-type prism. Nicol types give a lateral displacement. (4) Since off-axis wander results in images which have astigmatism when the prism is placed in a converging beam, Glan types have slightly better imaging qualities than Nicol types.

Two other often-stated advantages of Glan-type prisms over Nicol types appear to be fallacious. One is that the slanting end faces of Nicol-type prisms have higher reflection losses than the square-ended faces of Glan types. Since the extraordinary ray vibrates in the plane of incidence and hence is in the *p* direction, increasing the angle of incidence toward the polarizing angle should decrease the reflection loss. However, the index of refraction for the extraordinary ray is higher in Nicol-type prisms (Glan types have the minimum value of the extraordinary index), so the reflection losses are actually almost identical in the two types of prisms. The second "advantage" of Glan-type prisms is that the slanting end faces of the Nicol type supposedly induce elliptical polarization. This widely stated belief probably arises because in converging light the field in Nicol-type polarizers is not uniformly polarized, an effect which could be misinterpreted as ellipticity (see "Landolt Fringe" in Sec. 13.4). It is possible that strain birefringence could be introduced in the surface layer of a calcite prism by some optical polishing techniques resulting in

ellipticity in the transmitted light, but there is no reason why Nicol-type prisms should be more affected than Glan types.

Glan-Thompson-Type Prisms

Glan-Thompson-type prisms may be either cemented or air-spaced. Since, as was mentioned previously, an air-spaced Glan-Thompson-type prism is called a Glan-Foucault or simply a Glan prism,* the name Glan-Thompson prism implies that the prism is cemented. Both cemented and air-spaced prisms, however, have the same basic design. The cemented prisms are optically the better design for most applications and are the most common type of prisms in use today. The Glan-Thompson prism is named for P. Glan,[20] who described an air-spaced Glan-Thompson-type prism in 1880, and for S. P. Thompson,[21] who constructed a cemented version in 1881 and modified it to its present square-ended design in 1882.[22] These prisms are also sometimes called Glazebrook prisms because R. T. Glazebrook[23] demonstrated analytically in 1883 that when rotated about its axis, this prism gives the most uniform rotation of the plane of polarization for a conical beam of incident light. The cut in a Glan-Thompson-type prism is made parallel to the optic axis, which may either be parallel to two sides, as in Fig. 3*a*, or along a diagonal. The end faces are always perpendicular to the axis of the prism and contain the optic axis.

The extinction ratio† obtainable with a good Glan-Thompson-type prism equals or exceeds that of any other polarizer. Ratios of 5 parts in 100,000 to 1 part in 1 million can be expected although values as high as 1 part in 3×10^7 have been reported for small selected apertures of the prism.[24] The small residuals result mainly from imperfections in the calcite or from depolarizaton by scattering from the prism faces,[24] although if the optic axis is not strictly in the plane of the end face, or if the optic axes in the two halves of the prism are not accurately parallel, the extinction ratio will be reduced. Also, the extinction ratio may depend strongly upon which end of the prism the light is incident. When prisms are turned end for end, changes in the extinction ratio of as much as a factor of 6 have been reported.[24]

When measuring the extinction ratio, it is essential that none of the unwanted ordinary ray, which is internally reflected at the interface and absorbed or scattered at the blackened side of the prism, reach the detector. King and Talim[25] found that they had to use two 4-mm-diameter apertures and a distance of 80 mm between the photomultiplier detector and prism to eliminate the *o*-ray scattered light. With no limiting apertures and a 20-mm distance, their measured extinction ratio was in error by a factor of 80.

The field angle of the prism depends both on the cement used between the two halves and on the angle of the cut, which is determined by the *L*/*A* ratio. Calculation of the field angle is discussed in "Field Angle" section on p. 13.12 and by Bennett and Bennett.[1] Very large field angles can be obtained with Glan-Thompson prisms. For example, if the *L*/*A* ratio is 4, the field angle can be nearly 42°. Normally, however, smaller *L*/*A* ratios are used. The most common types of cemented prisms are the long form, having an *L*/*A* ratio of 3 and a field angle of 26°, and the short form, having an *L*/*A* ratio of 2.5 and a field angle of 15°.

Transmission In Fig. 5 the transmission of a typical Glan-Thompson prism is compared with curves for a Glan-Taylor prism and a Nicol prism. The Glan-Thompson is superior over most of the range, but its transmission decreases in the near ultraviolet, primarily because the cement begins to absorb. Its usable transmission range can be extended to about 2500 Å by using an ultraviolet-transmitting cement. Highly purified glycerin, mineral oil, castor oil, and Dow Corning DC-200 silicone oil, which because of its high viscosity is not as subject to seepage as lighter oils, have been used as cements in the ultraviolet, as have dextrose, glucose, and *gédamine* (a urea formaldehyde resin in butyl alcohol).

*An air-spaced Lippich prism, the Glan-Taylor (see "Glan-Taylor Prism" section on p. 13.12), has similar optical properties to the Glan-Foucault prism but better transmission. It is also called a Glan prism.

†The extinction ratio is the ratio of the maximum to the minimum transmittance when a polarizer is placed in a plane polarized beam and is rotated about an axis parallel to the beam direction.

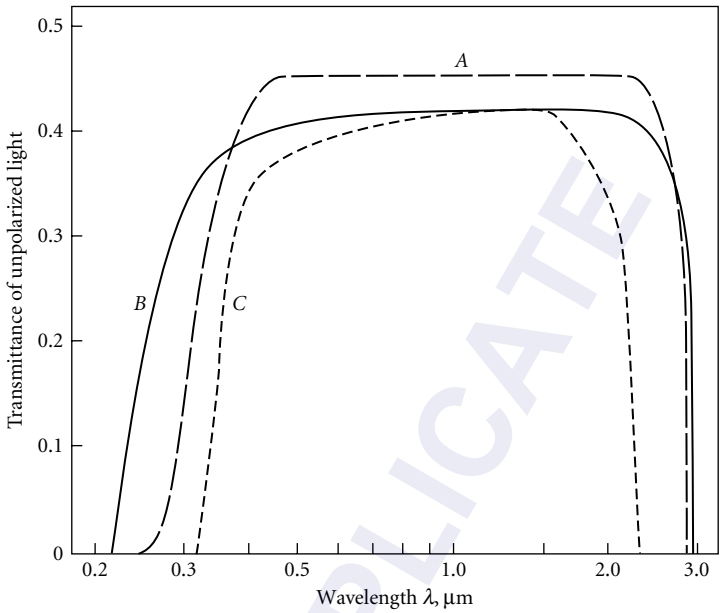

FIGURE 5 Transmittance curves for typical polarizing prisms: *A*, Glan-Thompson, *B,* Glan-Taylor, and *C,* Nicol prism. (*Measured by D. L. Decker, Michelson Laboratory.*) In the visible and near-infrared regions the Glan-Thompson has the best energy throughput. In the near ultraviolet the Glan-Thompson may still be superior because the Glan-Taylor has such an extremely small field angle that it may cut out most of the incident beam.

Transmission curves for 1-mm thicknesses of several of these materials are shown in Fig. 6, along with the curve for Canada balsam, a cement formerly widely used for polarizing prisms in the visible region.[8] *Gédamine*, one of the best of the ultraviolet-transmitting cements, has an index of refraction $n_D = 1.465_7$ and can be fitted to the dispersion relation[8]

$$n = 1.464 + \frac{0.0048}{\lambda^2} \tag{4}$$

where the wavelength λ is in micrometers.

Figure 7 shows ultraviolet transmission curves for Glan-Thompson prisms with *L*/*A* ratios of 2.5 and 3 which are probably cemented with *n*-butyl methacrylate, a low-index polymer that has largely replaced Canada balsam. Better ultraviolet transmission is obtained with a Glan-Thompson prism cemented with DC-200 silicone oil. Air-spaced prisms can be used to nearly 2140 Å in the ultraviolet, where calcite begins to absorb strongly. Transmission curves for two such prisms are shown in Fig. 7. The Glan-Taylor, which is an air-spaced prism of the Lippich design, has a higher ultraviolet transmission than the Glan-Foucault, an air-spaced Glan-Thompson prism. The reason for this difference is that multiple reflections occur between the two halves of the Glan-Foucault prism, resulting in a lowered transmission, but are largely absent in the Glan-Taylor design (see "Glan-Taylor Prism" section on p. 13.12).

The infrared transmission limit of typical Glan-Thompson prisms is about 2.7 μm although they have been used to 3 μm.[26] The same authors report using a 2.5-cm-long Glan-Thompson prism in the 4.4- to 4.9-μm region.

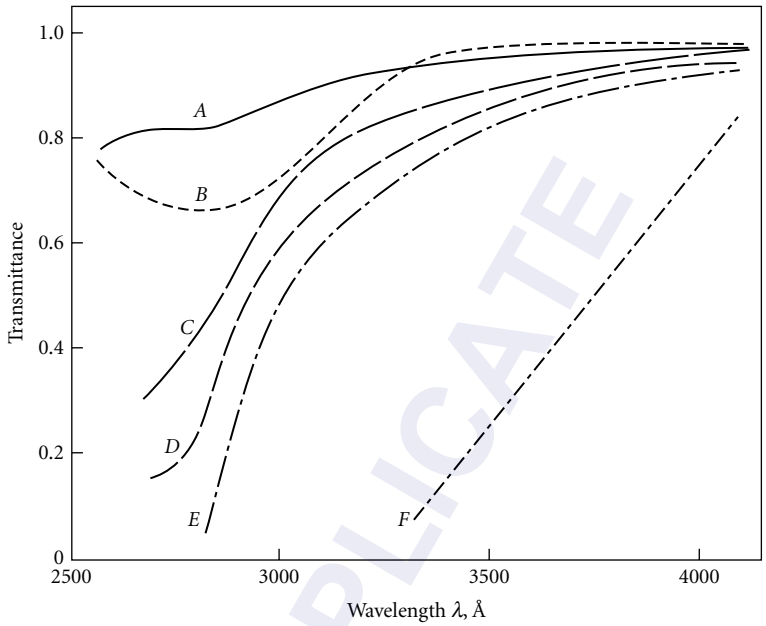

FIGURE 6 Transmittance curves for 1-mm thicknesses of various cements: *A*, crystalline glucose, *B*, glycerine, *C*, gédamine (urea formaldehyde resin in butyl alcohol), *D*, Rhodopas N60A (polymerized vinyl acetate in alcohol), *E*, urea formaldehyde, and *F*, Canada balsam. (*Modified from Bouriau and Lenoble.*[8]) The transmittance of these materials is adequate at longer wavelengths.

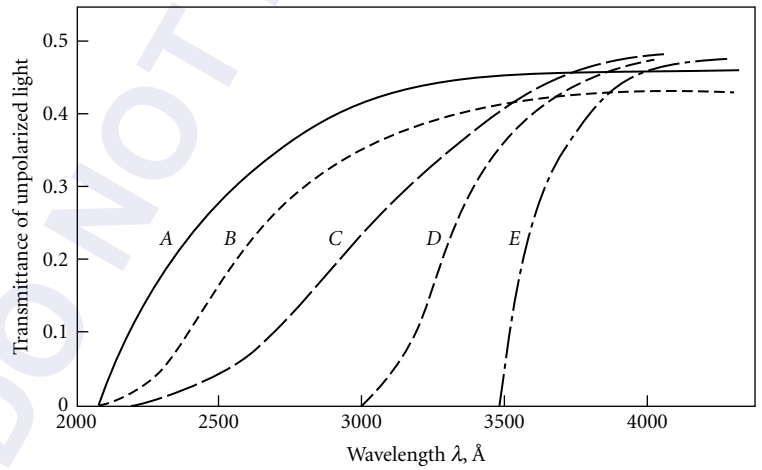

FIGURE 7 Ultraviolet transmittance curves for various Glan-Thompson and air-spaced prisms: *A*, Glan-Taylor (air-spaced Lippich-type prism), *B*, Glan-Foucault (air-spaced Glan-Thompson prism), *C*, Glan-Thompson prism with *L*/*A* ratio of 2 cemented with DC-200 silicone oil. *D*, Glan-Thompson prism with *L*/*A* ratio of 2.5 probably cemented with *n*-butyl methacrylate, and *E*, Glan-Thompson prism similar to *D* except with $L/A = 3$. (*Modified from curves supplied by Karl Lambrecht Corporation, Chicago.*)

Field Angle Since many prism polarizers are used with lasers that have parallel beams of small diameter, field-angle effects are not as important as previously when extended area sources were used. Extensive calculations of the field angles for a Glan-Thompson prism are included in the earlier polarization chapter.[1]

Other Glan-Thompson-Type Prisms Other types of Glan-Thompson-type prisms include the Ahrens prism (two Glan-Thompson prisms placed side-by-side), Glan-Foucault prism (an air-spaced Glan-Thompson prism), Grosse prism (an air-spaced Ahrens prism), and those constructed of glass and calcite. Information about these prisms can be found in the earlier polarization chapter.[1]

Lippich-Type Prisms

Lippich[27] (1885) suggested a polarizing-prism design similar to the Glan-Thompson but with the optical axis in the entrance face and at right angles to the intersection of the cut with the entrance face (Fig. 3*b*).* For this case, the index of refraction of the extraordinary ray is a function of angle of incidence and can be calculated from Eq. (1) after ϕ, the complement of the angle of refraction of the wave normal is determined from Eq. (2). In the latter equation, β, the angle normal to the surface makes with the optic axis, is 90° since the optic axis is parallel to the entrance face. Since the directions of the ray and the wave normal no longer coincide, the ray direction must be calculated from Eq. (3). Lippich prisms are now little-used because they have small field angles, except for two; the air-spaced Lippich, often called a Glan-Taylor prism, and the Marple-Hess prism (two Glan-Taylor prisms back-to-back) that is described in "Marple-Hess Prism" section on p. 13.13. Further information about all Lippich-type prisms is given in the earlier polarization chapter.[1]

Glan-Taylor Prism The Glan-Taylor prism, first described in 1948 by Archard and Taylor,[29] has substantial advantages over its Glan-Thompson design counterpart, the Glan-Foucault prism (see "Other Glan-Thompson-Type Prisms" section earlier). Since air-spaced prisms have a very small field angle, the light must be nearly normally incident on the prism face, so that the difference in field angles between the Glan-Taylor and Glan-Foucault prisms (caused by the difference in the refractive index of the extraordinary ray) is negligible.

The major advantages of the Glan-Taylor prism are that its calculated transmission is between 60 and 100 percent higher than that of the Glan-Foucault prism and the intensity of multiple reflections between the two sides of the cut always a principal drawback with air-spaced prisms, is reduced to less than 10 percent of the value for the Glan-Foucault prism.

The calculated and measured transmittances of a Glan-Taylor prism are in reasonable agreement, but the measured transmittance of a Glan-Foucault prism (Fig. 7) may be considerably higher than its theoretical value.[29] Even so, the transmission of the Glan-Taylor prism is definitely superior to that of the Glan-Foucault prism, as can be seen in Fig. 7. Extinction ratios of better than 1 part in 10^3 are obtainable for the Glan-Taylor prism.[30]

A final advantage of the Glan-Taylor prism is that it can be cut in such a way as to conserve calcite. Archard and Taylor[29] used the Ahrens method of spar cutting described by Thompson[22] and found that 35 percent of the original calcite rhomb could be used in the finished prism.

In a modified version of the Glan-Taylor prism becoming popular for laser applications, the cut angle† is increased, the front and back faces are coated with antireflection coatings, and portions of the sides are either covered with absorbing black glass plates or highly polished to let the unwanted beams escape.[30] The effect of increasing the cut angle is twofold: a beam normally incident on the prism face will have a smaller angle of incidence on the cut and hence a smaller reflection loss at

*The Lippich prism should not be confused with the Lippich half-shade prism, which is a device to determine a photometric match point. The half-shade prism consists of a Glan-Thompson or Nicol prism placed between the polarizer and analyzer such that it intercepts half the beam and is tipped slightly in the beam. The prism edge at the center of the field is highly polished to give a sharp dividing line. The eye is focused on this edge; the disappearance of the edge gives the photometric match point.[28]

†The cut angle is the acute angle the cut makes with the prism base.

the cut than a standard Glan-Taylor prism, but, at the same time, the semifield angle will be reduced throughout most of the visible and near-infrared regions.

A new type of air-spaced prism[31] has a very high transmittance for the extraordinary ray. It resembles the Glan-Taylor prism in that the optic axis is parallel to the entrance face and at right angles to the intersection of the cut with the entrance face. However, instead of striking the prism face at normal incidence, the light is incident at the Brewster angle for the extraordinary ray (54.02° for the 6328-Å helium-neon laser wavelength), so that there is no reflection loss for the *e* ray at this surface. Since the ordinary ray is deviated about 3° more than the extraordinary ray and its critical angle is over 4° less, it can be totally reflected at the cut with tolerance to spare while the extraordinary ray can be incident on the cut at only a few degrees beyond its Brewster angle. Thus this prism design has the possibility of an extremely low light loss caused by reflections at various surfaces. A prototype had a measured transmission of 0.985 for the extraordinary ray at 6328 Å.[31] If the prism is to be used with light sources other than lasers, its semifield angle can be calculated.[1]

A major drawback to the Brewster angle prism is that since the light beam passes through a plane-parallel slab of calcite at nonnormal incidence, it is displaced by an amount that is proportional to the total thickness of the calcite. Some of the prisms are made with glass in place of calcite for the second element. In this case, the beam will usually be deviated in addition to being displaced. Measurements on a calcite-glass prototype at 6328 Å showed that the output beam was laterally displaced by several millimeters with an angular deviation estimated to be less than 0.5°.[31]

Marple-Hess Prism If a larger field angle is required than can be obtained with a Glan-Taylor prism, a Marple-Hess prism may be used. This prism, which was first proposed in 1960 as a double Glan-Foucault by D. T. F. Marple of the General Electric Research Laboratories and modified to the Taylor design by Howard Hess of the Karl Lambrecht Corporation,[32] is effectively two Glan-Taylor prisms back-to-back. The analysis for this prism is made in the same way as for the Glan-Taylor prism (see "Glan-Taylor Prism" section earlier) and Lippich-type prisms in general, keeping in mind that the refractive index of the "cement" is 1 since the components are air-spaced.

Since the ordinary ray is totally reflected for all angles of incidence by one or the other of the two cuts, the field angle is symmetric about the longitudinal axis of the prism and is determined entirely by the angle at which the extraordinary ray is totally reflected at one of the two cuts. This angle can be readily calculated.[1] The field angle is considerably larger than for the Glan-Foucault or Glan-Taylor prism and does not decrease as the wavelength increases.

Unlike the Glan-Foucault or Glan-Taylor prisms, which stop being efficient polarizers when the angle of incidence on the prism face becomes too large, the Marple-Hess prism continues to be an efficient polarizer as long as the axial ordinary ray is not transmitted. If the prism is used at a longer wavelength than the longest one for which it was designed (smallest value of n_o used to determine the cut angle), the value of n_o will be still smaller and the critical angle for the axial ordinary ray will not be exceeded. Thus the axial *o* ray will start to be transmitted before off-axis rays get through. When this situation occurs, it only makes matters worse to decrease the convergence angle. Thus, there is a limiting long wavelength, depending on the cut angle, beyond which the Marple-Hess prism is not a good polarizer. At wavelengths shorter than the limiting wavelength, the Marple-Hess prism has significant advantages over other air-spaced prism designs.

It is not easy to make a Marple-Hess prism, and the extinction ratio in the commercial model is given as between 1×10^{-4} and 5×10^{-5}, somewhat lower than for a Glan-Taylor prism.[30] On the other hand, even though the Marple-Hess prism has an increased L/A ratio, 1.8 as compared to 0.85 for a Glan-Taylor prism, its ultraviolet transmission is still superior to commercially available ultraviolet-transmitting Glan-Thompson prisms of comparable aperture.

Frank-Ritter-Type Prisms

The third general category of Glan-type polarizing prisms is the Frank-Ritter design. Prisms of this type are characterized by having the optic axis in the plane of the entrance face, as in other Glan-type prisms, but having the cut made at 45° to the optic axis (Fig. 3*c*) rather than at 0°, as in Glan-Thompson

prisms, or at 90°, as in Lippich prisms. Frank-Ritter prisms are particularly popular in the Soviet Union, and over 80 percent of the polarizing prisms made there have been of this design.[33] Usually double prisms comparable to the Ahrens modification of the Glan-Thompson are used,[1] primarily because from a rhombohedron of Iceland spar two Frank-Ritter double prisms can be obtained but only one Ahrens of the same cross-section or one Glan-Thompson of smaller cross-section.[33] However, this apparent advantage can be illusory since Iceland spar crystals often are not obtained as rhombs. For example, if the natural crystal is in the form of a plate, it may be less wasteful of material to make a Glan-Thompson or Ahrens prism than a Frank-Ritter prism.[33]

Optically Frank-Ritter prisms should be similar to Glan-Thompson and Ahrens types, although the acceptance angle for a given L/A ratio is somewhat smaller since the refractive index of the extraordinary ray is larger than n_e in the prism section containing the longitudinal axis and perpendicular to the cut. In practice, the degree of polarization for a Frank-Ritter prism seems to be quite inferior to that of a good Glan-Thompson or even an Ahrens prism.[33]

Use of Glan-Type Prisms in Optical Systems

Several precautions should be taken when using Glan-type prisms in optical systems: (1) the field angle of the prism should not be exceeded, (2) there should be an adequate entrance aperture so that the prism does not become the limiting aperture of the optical system, and (3) baffles should be placed preceding and following the prism to avoid incorrect collection of polarized light or extraneous stray light. The reason why these precautions are important are discussed in the earlier polarization chapter.[1]

Common Defects and Testing of Glan-Type Prisms

Several common defects are found in the construction of Glan-type prisms and limit their performance:

1. The axial beam is displaced as the prism is rotated. This defect called *squirm,* results when the optic axes in the two halves of the prism are not strictly parallel. A line object viewed through the completed prism will oscillate as the prism is turned around the line of sight.[34]

2. The axial ray is deviated as the prism is rotated. This defect is caused by the two prism faces not being parallel. A residual deviation of 3 minutes of arc is a normal tolerance for a good Glan-Thompson prism; deviations of 1 minute or less can be obtained on special order.

3. The optic axis does not lie in the end face. This error is often the most serious, since if the optic axis is not in the end face and the prism is illuminated with convergent light, the planes of vibration of the transmitted light are no longer parallel across the face of the prism. This effect, which in Nicol-type prisms gives rise to the Landolt fringe, is illustrated in the following practical case.[35] For a convergent beam of light of semicone angle i, the maximum variation of the plane of vibration of the emergent beam is $\pm\gamma$, where, approximately,

$$\tan\gamma = n_e \sin i \tan\phi \tag{5}$$

and ϕ is the angle of inclination of the optic axis to the end face, caused by a polishing error. For $i = 3°$ and $p = 5°$, the plane of vibration of the emergent beam varies across the prism face by ± 23 minutes of arc. Thus, good extinction cannot be achieved over the entire aperture of this prism even if nearly parallel light is incident on it. The field angle is also affected if the optic axis is not in the end face or is not properly oriented in the end face, but these effects are small.

4. The cut angle is incorrect or is different in the two halves of the prism. If the cut angle is slightly incorrect, the field angle may be decreased. This error is particularly important in Glan-Foucault or Glan-Taylor prisms, for which the angular tolerances are quite severe, and a small change in cut angle for these prisms may greatly alter the field angle, as discussed in "Glan-Taylor Prism" section on p. 13.12 and Ref. 1. If the cut angles are different in the two halves of the prism, the field angle will change when the prism is turned end-for-end. The field angle is determined by the cut angle in the half of the prism toward the incident beam. Differences in the two cut angles may also cause a beam deviation. If the angles in the two halves differ by a small angle α that makes the end

faces nonparallel, the beam will be deviated by an angle $\delta = \alpha(n_e - 1)$.[35] If instead, the end faces are parallel and the difference in cut angle is taken up by the cement layer which has a refractive index of approximately n_e, there will be no deviation. However, if the prism is air-spaced, the deviation δ' caused by a nonparallel air film is approximately $\delta' = \alpha n_e$, illustrating one reason why air-spaced prisms are harder to make than conventional Glan-Thompson prisms.[35]

5. The transmittance is different when the prism is rotated through 180°. A potentially more serious problem when one is making photometric measurements is that the transmission of the prism may not be the same in two orientations exactly 180° apart.[36] This effect may be caused by the presence of additional light outside the entrance or exit field angle, possibly because of strain birefringence in the calcite.

Two factors which limit other aspects of polarizer performance in addition to the extinction ratio are *axis wander*, i.e., variation of the azimuth of the transmitted beam over the polarizer aperture, and the ellipticity of the emergent polarized beams[25] caused by material defects in the second half of the prism. Further details are discussed in the earlier polarization chapter.[1]

In order to determine the cut angle, field angle, parallelism of the prism surfaces, thickness and parallelism of the air film or cement layer, and other prism parameters, one can use the testing procedures outlined by Decker et al.,[37] which require a spectrometer with a Gauss eyepiece, laser source, and moderately good polarizer. (Other testing procedures have been suggested by Archard.[35]) Rowell et al.[38] have given a procedure for determining the absolute alignment of a prism polarizer. However, they failed to consider some polarizer defects, as pointed out by Aspnes[39] who gives a more general alignment procedure that compensates for the prism defects. (There is also a response from Rowell.[40]) Further information about testing Glan-type prisms and reasons why prism errors are important can be found in the earlier polarization chapter.[1]

13.4 NICOL-TYPE PRISMS

Nicol-type prisms are not generally used at the present time, as Glan types are optically preferable. However, they were the first kind made and were once so common that Nicol became a synonym for polarizer. There is much more calcite wastage in making Glan-type prisms than in making the simpler Nicol types so that, even though Glan polarizers were developed in the nineteenth century, it was only following the recent discoveries of new calcite deposits that they became popular. Many of the older instruments are still equipped with Nicol prisms so they will be briefly described here.

Conventional Nicol Prism

The first polarizing prism was made in 1828 by William Nicol[41] a teacher of physics in Edinburgh. By cutting a calcite rhomb diagonally and symmetrically through its blunt corners and then cementing the pieces together with Canada balsam, he could produce a better polarizer than any known up to that time. A three-dimensional view of Nicol's prism is shown in Fig. 3*d*. The cut is made perpendicular to the principal section (defined in "Double Refraction in Calcite" in Sec. 13.2), and the angle is such that the ordinary ray is totally reflected and only the extraordinary ray emerges. When the rhomb is intact, the direction of polarization can be determined by inspection. However, the corners are sometimes cut off, making the rhomb difficult to recognize.

The principal section of Nicol's original prism is similar to that shown in Fig. 2 except that the ordinary ray is internally reflected at the cut along diagonal *BH*. The cut makes an angle of 19°8′ with edge *BF* in Fig. 2 and an angle of about 90° with the end face of the rhomb. Since the obtuse angle is 109°7′ (Fig. 3*d*), the angle between the cut and the optic axis is 44°36′. The field of the prism is limited on one side by the angle at which the ordinary ray is no longer totally reflected from the balsam film, about 18.8° from the axis of rotation of the prism, and on the other by the angle at which the extraordinary ray is totally reflected by the film, about 9.7° from the axis. Thus the total angle is about 28.5° but is not by any means symmetric about the axis of rotation; the field angle (see "Types of Polarizing Prisms and Definitions" in Sec. 13.2) is only $2 \times 9.7° = 19.4°$.

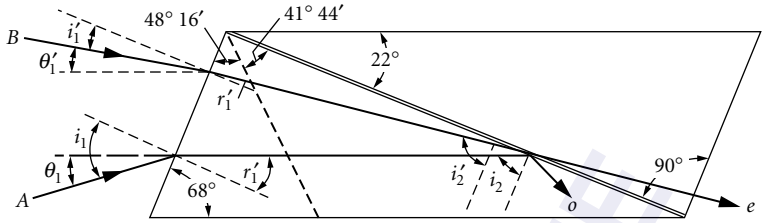

FIGURE 8 Principal section of a conventional Nicol prism with slightly trimmed end faces. Ray *A* gives the limiting angle θ_1 beyond which the ordinary ray is no longer totally internally reflected at the cut; ray *B* gives the limiting angle θ_1' for which the extraordinary ray starts to be totally internally reflected at the cut.

In order to produce a somewhat more symmetric field and increase the field angle, the end faces of Nicol prisms are usually trimmed to an angle of 68°. This practice was apparently started by Nicol himself.[22] If the cut is made at 90° to the new face, as shown in Fig. 8, the new field angle is twice the smaller of θ_1 and θ_1'. The field angles are computed as described in the earlier polarization chapter.[1]

Trimmed Nicol-Type Prisms

The angle at which the cut is made in a Nicol-type prism is not critical. The field angle is affected, but a useful prism will probably result even if the cut is made at an angle considerably different from 90°. The conventional trimmed Nicol, discussed in "Conventional Nicol Prism" section earlier, is shown again in Fig. 9*a*. In this and the other five parts of the figure, principal sections of various prisms are

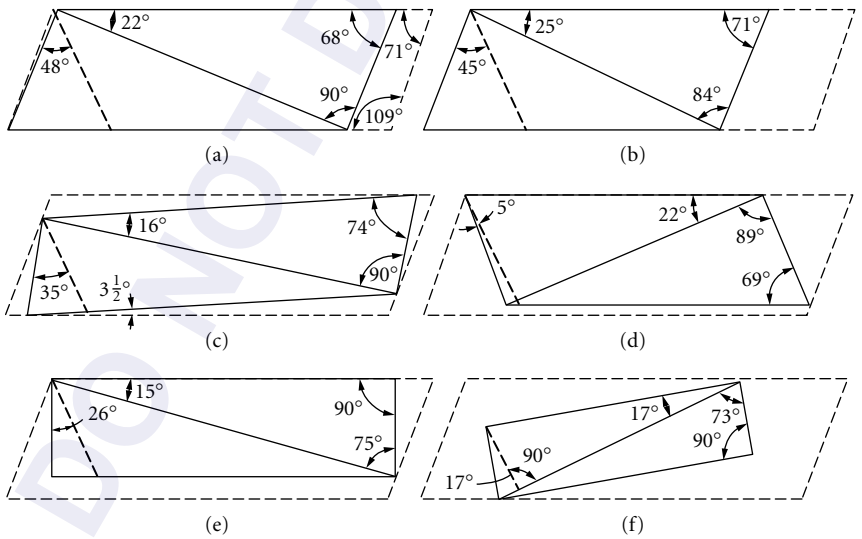

FIGURE 9 Principal sections of various types of trimmed cemented Nicol prisms shown superimposed on the principal section of a cleaved calcite rhomb (see Fig. 2): (*a*) conventional trimmed Nicol; (*b*) Steeg and Reuter shortened Nicol (*Thompson*[22]); (*c*) Ahrens Nicol (*Thompson*[22]); (*d*) Thompson reversed Nicol (*Thompson*[42]); (*e*) square-ended Nicol; and (*f*) Hartnack-Prazmowski reversed Nicol. In all cases, the angle between the prism face and the optic axis (*heavy dashed line*), the angle of the cut, and the acute angle of the rhomb are indicated.

shown superimposed on the principal section of the basic calcite rhomb (Fig. 2). Thus, it is clear how much of the original rhomb is lost in making the different types of trimmed Nicols.

In the Steeg and Reuter Nicol shown in Fig. 9*b*, the rhomb faces are not trimmed, and the cut is made at 84° to the faces instead of 90°, giving a smaller *L*/*A* ratio. The asymmetry of the field which results is reduced by using a cement having a slightly higher index than Canada balsam.

Alternately, in the Ahrens Nicol shown in Fig. 9*c*, the ends are trimmed in the opposite direction, increasing their angles with the long edges of the rhomb from 70°53′ to 74°30′ or more. By also trimming the long edges by 3°30′, the limiting angles are made more symmetric about the prism axis.

Thompson Reversed Nicol In the Thompson reversed Nicol shown in Fig. 9*d*, the ends are heavily trimmed so that the optic axis lies nearly in the end face. As a result, the blue fringe is thrown farther back than in a conventional Nicol, and although the resulting prism is shorter, its field angle is actually increased.

Nicol Curtate, or Halle, Prism The sides of the calcite rhomb may also be trimmed so that they are parallel or perpendicular to the principal section. Thus, the prism is square (or sometimes octagonal). This prism is of the Halle type[43,44] and was shown in Fig. 3*e*. Halle, in addition, used thickened linseed oil instead of Canada balsam and altered the angle of the cut. In this way he reduced the length-to-aperture ratio from about 2.7 to 1.8 and the total acceptance angle from 25° to about 17°. Such shortened prisms cemented with low-index cements are often called Nicol curtate prisms (curtate means shortened).

Square-Ended Nicol The slanting end faces on conventional Nicol prisms introduce some difficulties, primarily because the image is slightly displaced as the prism is rotated. To help correct this defect, the slanting ends of the calcite rhomb can be squared off, as in Fig. 9*e*, producing the so-called square-ended Nicol prism. The angle at which the cut is made must then be altered since the limiting angle θ_1 for an ordinary ray depends on the angle of refraction at the end face in a conventional prism, in which the limiting ray travels nearly parallel to the prism axis inside the prism (ray *A* in Fig. 8). If the cut remained the same, the limiting value of θ_1 would thus be zero. However, if the cut is modified to be 15° to the sides of the prism, the total acceptance angle is in the 24° to 27° range, depending on the type of cement used.[22]

Some image displacement will occur even in square-ended Nicol prisms since the optic axis is not in the plane of the entrance face. Therefore, the extraordinary ray will be bent even if light strikes the entrance face of the prism at normal incidence. There is considerable confusion on this point in the literature.[22,45]

Hartnack-Prazmowski Prism A reversed Nicol which has the cut at 90° to the optic axis[46] is shown in Figs. 3*f* and 9*f*. If it is cemented with linseed oil, the optimum cut angle calculated by Hartnack is 17° to the long axis of the prism, giving a total acceptance angle of 35° and an *L*/*A* ratio of 3.4.[22] If Canada balsam is used, the cut should be 11°, in which case the total acceptance angle is 33° and the *L*/*A* ratio is 5.2.

Foucault Prism A modified Nicol prism in which an air space is used between the two prism halves instead of a cement layer[47] consists of a natural-cleavage rhombohedron of calcite which has been cut at an angle of 51° to the face. The cut nearly parallels the optic axis. Square-ended Foucault-type prisms, such as the Hofmann prism, have also been reported.[22] The angle at which the cut is made can be varied slightly in both the normal Foucault prism and the Hofmann variation of it. In all designs the *L*/*A* ratio is 1.5 or less, and the total acceptance angle about 8° or less. The prisms suffer somewhat from multiple reflections, but the principal trouble, as with all Nicol prisms, is that the optic axis is not in the plane of the entrance face. This defect causes various difficulties, including nonuniform polarization across the field and the occurrence of a Landolt fringe (discussed next and Ref. 1) when two Nicol-type prisms are crossed.

Landolt Fringe If an intense extended light source is viewed through crossed polarizing prisms, careful observation will reveal that the field is not uniformly dark. In Nicol-type prisms the darkened field is crossed by a darker line whose position is an extremely sensitive function of the angle between the polarizer and analyzer. Other types of polarizing prisms also exhibit this anomaly but to a lesser extent. The origin of the Landolt fringe is given in the earlier polarization chapter[1] and the references cited therein.

13.5 POLARIZING BEAM-SPLITTER PRISMS

The three classic polarizing beam-splitter prisms are the Rochon, Sénarmont, and Wollaston, shown in perspective in Fig. 10*a* to 10*c* and in side view in Fig. 11*a* to 11*c*. In addition, any polarizing prism can be used as a polarizing beam splitter by changing the shape of one side and removing the absorbing coating from its surface. Two examples of such prisms are the Foster prism, in which the ordinary and extraordinary rays emerge at right angles to each other, and the beam-splitting Glan-Thompson prism, in which the ordinary ray emerges normal to one side (Figs. 10*d* and *e* and 11*d* and *e*). Another prism of this type, the beam-splitting Ahrens prism, is a double beam-splitting Glan-Thompson prism (see "Other Glan-Thompson-Type Prisms" in Sec. 13.3).

In polarizing prisms, the optic axes are always parallel to each other in the two halves of the prism. By contrast, the optic axes in the two halves of the Rochon, Sénarmont, and Wollaston polarizing beam-splitter prisms are at right angles to each other. Crystal quartz is often used to make these beam splitters, and such prisms can be used down to the vacuum ultraviolet. In applications not requiring such short wavelengths, calcite is preferable because it gives a greater angular separation of the beams (typically 10° as compared to 0.5° for quartz) and does not produce optical rotation.

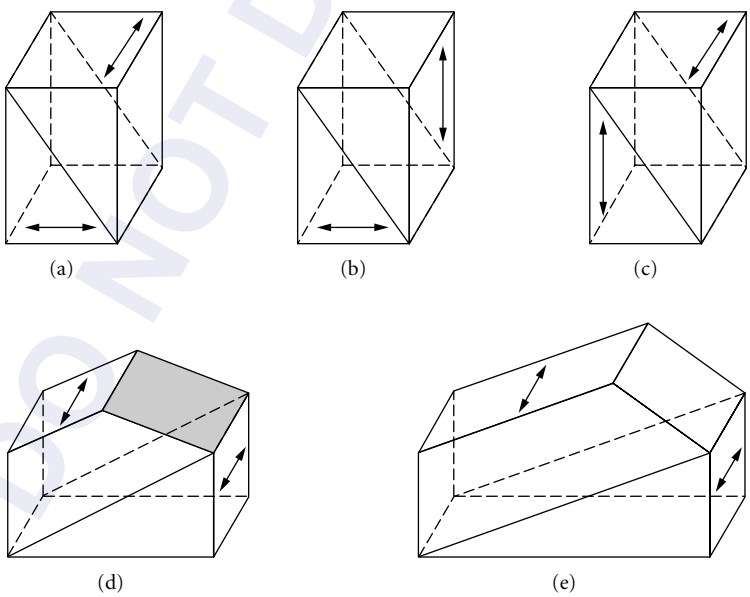

FIGURE 10 Three-dimensional views of various types of polarizing beam-splitter prisms: (*a*) Rochon; (*b*) Sénarmont; (*c*) Wollaston; (*d*) Foster (shaded face is silvered); and (*e*) beam-splitting Glan-Thompson.

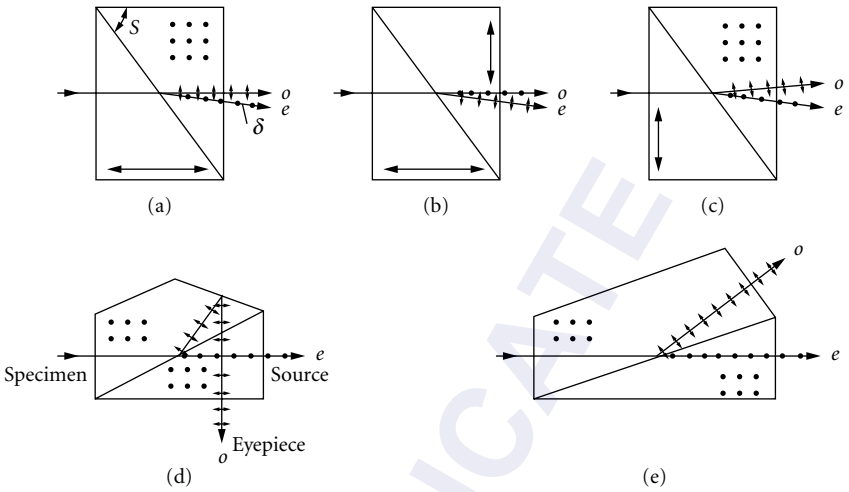

FIGURE 11 Side views of the polarizing beam-splitter prisms in Fig. 10. The directions of the optic axes are indicated by the dots and the heavy double-pointed arrows. The angle of the cut for the Rochon prism is *S*. When the Foster prism is used as a microscope illuminator, the source, specimen, and eyepiece are in the positions indicated.

Rochon Prism

The Rochon prism, invented in 1783,[48] is the most common type of polarizing beam splitter. It is often used in photometric applications in which both beams are utilized. It is also used as a polarizing prism in the ultraviolet, in which case one of the beams must be eliminated, e.g., by imaging the source beyond the prism and blocking off the deviated image.

The paths of the two beams through the prism are shown in Fig. 11*a*. A ray normally incident on the entrance face travels along the optic axis in the first half of the prism, so that both ordinary and extraordinary rays are undeviated and have the same refractive index n_o. The second half of the prism has its optic axis at right angles to that in the first half, but the ordinary ray is undeviated since its refractive index is the same in both halves. The extraordinary ray, however, has its minimum index in the second half, so that it is refracted at the cut according to Snell's law (see "Double Refraction in Calcite" in Sec. 13.2). Since the deviation angle depends on the ratio n_e/n_o, it is a function of wavelength. If the angle of the cut is *S*, to a good approximation the beam deviation δ of the extraordinary ray depends on the cut angle in the following manner, according to Steinmetz et al.,[49]

$$\tan S = \frac{n_o - n_e}{\sin\delta} + \frac{\sin\delta}{2n_e} \tag{6}$$

This relation holds for light normally incident on the prism face. The semifield angle $i_{\max}$ is given by[49]

$$\tan i_{\max} = \frac{1}{2}(n_e - n_o)\cot S \tag{7}$$

If the prism is to be used as a polarizer, the light should be incident as shown. Rochon prisms also act as polarizing beam splitters when used backward, but the deviation of the two beams is then slightly less.

When a Rochon prism is used backward, both the dispersion and the optical activity (for quartz) will adversely affect the polarization. Thus, one generally uses a Rochon in the normal manner. However, an exception occurs when a quartz Rochon is to be used as an analyzer. In this case it is

best to reverse the prism and use a detector that is insensitive to polarization to monitor the relative intensities of the two transmitted beams.

A Rochon prism is achromatic for the ordinary ray but chromatic for the extraordinary ray. Since total internal reflection does not occur for either beam, the type of cement used between the two halves of the prism is less critical than that used for conventional polarizing prisms. Canada balsam is generally used, although the two halves are sometimes optically contacted for high-power laser applications or for use in the ultraviolet at wavelengths shorter than 3500 Å. Optically contacted crystalline-quartz Rochon prisms can be used to wavelengths as short as 1700 Å, and a double Rochon of MgF_2 has been used to 1300 Å in the vacuum ultraviolet.[49] Optically contacted single Rochon prisms of MgF_2 have also been constructed, and the transmission of one has been measured from 1400 Å to 7 μm.[50] Ultraviolet-transmitting cements such as *gédamine* can be used to extend the short-wavelength limit of calcite prisms to about 2500 Å (see "Transmission" in Sec. 13.3).

Defects Quartz and calcite Rochon prisms suffer from several defects. Quartz exhibits optical activity when light is transmitted through it parallel to the optic axis, and although two mutually perpendicular, polarized beams will emerge from a quartz Rochon prism used in the conventional direction, their spectral composition will not faithfully reproduce the spectral compositions of the horizontal and vertical components of the input. If such a prism is used backward, different wavelengths emerge from the prism vibrating in different planes. Hence the output consists of many different polarizations instead of the desired two.[51]

Calcite Rochon prisms do not exhibit optical activity but are difficult to make, since when calcite surfaces are cut normal to the optic axis, small tetrahedra tend to cleave out from the surface during pitch polishing. These tetrahedra may also cleave out during attempts to clean the prisms, and occasionally glass plates are cemented to such surfaces to prevent damage. Some image distortion will occur in calcite prisms; if nonnormally incident rays pass through the prism, both beams will be distorted along their directions of vibration; i.e., the undeviated beam (*o* ray), which vibrates in a vertical plane, will be distorted vertically, and the deviated beam (*e* ray), which vibrates in a horizontal plane, will be distorted horizontally.[51]

Glass-Calcite Rochons Some of the difficulties mentioned in the preceding section can be minimized or eliminated by making the entrance half of the Rochon prism out of glass of matching index instead of quartz or calcite. Both *o* and *e* rays travel along the same path and have the same reflective index in this half of the prism, so that the birefringent qualities of the quartz or calcite are not being used and an isotropic medium would serve just as well. By properly choosing the index of the glass, either the ordinary or the extraordinary ray can be deviated, and glasses are available for matching either index of calcite reasonably well over much of the visible region.[51] The extraordinary ray always suffers some distortion in its direction of vibration, but the distortion of the ordinary ray can be eliminated in the glass-calcite construction. By properly choosing the refractive index of the glass we can determine whether the *e* ray will be the deviated or the undeviated beam. (Some distortion also arises for deviated beams in the direction of the deviation because of Snell's law and cannot be corrected in this way.) Another method of obtaining an undeviated beam was used by Hardy;[52] unable to find a glass with refractive index and dispersion matching those of calcite, he selected a glass with the correct dispersive power and then compensated for the difference in refractive index by putting a slight wedge angle on the calcite surface. Now a wider selection of glasses is available, but glass-calcite prisms cannot be made strictly achromatic over an extended wavelength range, and thermally induced strains caused by the difference in expansion coefficients in the two parts of the prism may be expected unless the cement yields readily.

Total Internal Reflection in Rochons When normal Rochon prisms are used as polarizers, one of the beams must be screened off and eliminated. This restriction might be removed by making the cut between halves of the prism at a sufficiently small angle for the extraordinary ray to be totally reflected. Calculations indicate that this approach should be feasible,[53] but it has apparently not been followed.

Sénarmont Prism

The Sénarmont polarizing beam splitter, shown in Figs.10*b* and 11*b*, is similar to the Rochon prism except that the optic axis in the exit half of the prism is coplanar with the optic axis in the entrance half, i.e., at right angles to the Rochon configuration. As a result, light whose plane of vibration is initially vertical is deviated in the Sénarmont prism, while in the Rochon prism the deviated beam has its plane of vibration horizontal (assuming no optical activity in either case) (compare Fig.11*a* and *b*). The amount of the deviation in the Sénarmont prism is slightly less than in the Rochon because the extraordinary ray does not have its minimum refractive index [Eq. (1)].

An alternate form of Sénarmont prism, the right-angle Sénarmont or Cotton polarizer,[54] consists of only the first half of the Sénarmont prism. Unpolarized light normally incident on the prism face is totally internally reflected at the hypotenuse and is then resolved into two planes of vibration, one parallel to the optic axis and the other perpendicular to it. Double refraction will then occur just as in a normal Sénarmont prism. Such a prism has a transmission equivalent to that of an optically contacted Sénarmont or Rochon but is much less expensive.

Wollaston Prism

The Wollaston prism (Figs. 10*c* and 11*c*) is a polarizing beam splitter, also used as a polarizing prism in the vacuum ultraviolet,[55] that deviates both transmitted beams. The deviations, indicated in Fig. 11*c*, are nearly symmetrical about the incident direction, so that the Wollaston has about twice the angular separation of a Rochon or Sénarmont prism. A normally incident beam is undeviated upon entering the prism, but the *o* ray, vibrating perpendicular to the optic axis, has a refractive index n_o while the *e* ray, vibration parallel to the optic axis has its minimum (or principal) index n_e. At the interface the *e* ray becomes the *o* ray and vice versa because the direction of the optic axis in the second half is perpendicular to its direction in the first half. Thus the original *o* ray enters a medium of lower refractive index and is refracted away from the normal at the cut, while the original *e* ray passes into a medium of higher refractive index and is refracted toward the normal. On leaving the second half of the prism, both rays are refracted away from the normal, so that their divergence increases.

The deviation of each beam is chromatic in Wollaston prisms, which are most commonly used to determine the relative intensities of two plane-polarized components. Since the light never travels along the optic axis, optical activity does not occur and the relative intensities of the two beams are always proportional to the intensities of the horizontal and vertical polarization components in the incident beam. For an *L*/*A* ratio of 1.0, the angular separation between beams is about 1° for a crystalline-quartz Wollaston prism; it can be as high as 3°30′ for an *L*/*A* ratio of 4.0. With a calcite prism, the beams would have an angular separation of about 19° for an *L*/*A* ratio of 1.0, but severe image distortion and lateral chromatism results when such large angular separations are used. These effects can be minimized or the angular separation can be increased for a given *L*/*A* ratio by using a three-element Wollaston prism, a modification, apparently suggested by Karl Lambrecht.[30] Divergences as large as 30° can be obtained.[1]

The ellipticity in the emergent polarized beams has been measured by King and Talim.[25] For calcite Wollaston prisms, the ellipticities were in the 0.004° to 0.025° range, comparable to those of Glan-Thompson prisms ("Common Defects and Testing of Glan-Type Prism" in Sec. 13.3). Larger values, between 0.12° and 0.16°, were measured for crystalline-quartz Wollaston prisms. The major contribution, which was from the combined optical activity and birefringence in the quartz rather than from defects within the crystal, cannot be avoided in quartz polarizers.

Foster Prism

This prism, shown in a three-dimensional view in Fig. 10*d* and in cross-section in Fig. 11*d*, can be used to form two plane-polarized beams separated by 90° from each other.[56] Its construction is similar to that of a Glan-Thompson prism except that one side is cut at an angle and silvered to reflect the ordinary ray out the other side.

The Foster prism is often used backward as a polarizing microscope illuminator for observing reflecting specimens. For this application, the light source is at *e* in Fig. 11*d*, and unpolarized light enters the right-hand face of the prism. The ordinary ray (not shown) is reflected at the cut and absorbed in the blackened side of the prism, while the extraordinary ray is transmitted undeviated out the left face of the prism. It then passes through the microscope objective and is reflected by the specimen, returning on its same path to the prism. Light that is unchanged in polarization will be transmitted undeviated by the prism along the path to the light source. If, however, the plane of vibration has been rotated so that it is at right angles to the optic axis (in the plane of the figure), the light will be reflected into the eyepiece. The prism thus acts like a crossed polarizer-analyzer combination.

If a correctly oriented quarter-wave plate is inserted in the beam between the prism and the microscope objective, the light striking the sample will be circularly polarized, and, after being reflected back through the quarter-wave plate, it will be linearly polarized again but with the plane of vibration rotated by 90°. This light is vibrating perpendicular to the optic axis and will be reflected into the eyepiece, giving bright-field illumination. Foster prisms used in this manner introduce no astigmatism since the light forming the image enters and leaves the prism normal to the prism faces and is reflected only by plane surfaces.

Beam-Splitting Glan-Thompson Prism

If a prism design similar to the Foster is used but the side of the prism is cut at an angle so that the ordinary ray, which is deflected, passes out normal to the surface of the prism rather than being reflected, the prism is called a beam-splitting Glan-Thompson prism (Figs. 10*e* and 11*e*). Since no refraction occurs for either beam, the prism is achromatic and nearly free from distortion. The angle between the two emerging beams is determined by the angle of the cut between the two halves of the prism and hence depends on the *L*/*A* ratio of the prism. For an *L*/*A* ratio of 2.414, the angle is 45°. The field angle around each beam is calculated for different *L*/*A* ratios just as for a conventional Glan-Thompson prism. By making the prism double, i.e., a beam-splitting Ahrens prism, the incident beam can be divided into three parts, one deflected to the left, one to the right, and one undeviated.

13.6 FEUSSNER PRISMS

The polarizing prisms discussed so far require large pieces of birefringent material, and the extraordinary ray is the one usually transmitted. Feussner[57] suggested an alternate prism design in which only thin plates of birefringent material are required and the ordinary ray rather than the extraordinary ray is transmitted for negative uniaxial materials. A similar suggestion was apparently made by Sang in 1837, although he did not publish it until 1891.[58] In essence, Feussner's idea was to make the prisms isotropic and the film separating them birefringent, as shown in Fig. 12. The isotropic

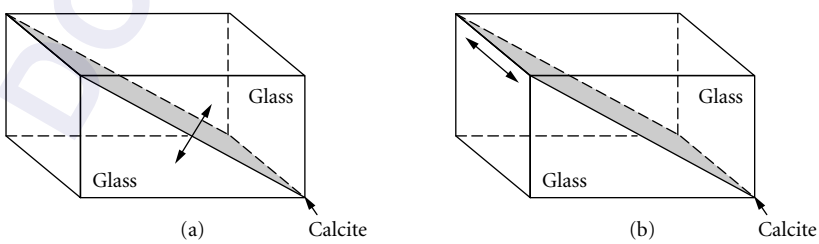

FIGURE 12 Types of Feussner prisms: (*a*) original Feussner prism and (*b*) Bertrand type. The arrows indicate the orientation of the optic axis in the calcite (or other birefringent material).

prisms should have the same refractive index as the higher index of the birefringent material so that for negative uniaxial materials e.g., calcite or sodium nitrate, the ordinary ray is transmitted and the extraordinary ray totally internally reflected. Advantages of this design are (1) since the ordinary ray is transmitted, the refractive index does not vary with angle of incidence and hence the image is anastigmatic, (2) large field angles or prisms of compact size can be obtained, and (3) the birefringent material is used economically. Furthermore, because the path length of the ray through the birefringent material is short, a lower-quality material can be used.

Disadvantages are (1) for both calcite and sodium nitrate, the extraordinary ray is transmitted over a larger wavelength range than the ordinary ray so that Feussner prisms do not transmit over as large a wavelength range as conventional prisms, and (2) the thermal-expansion coefficients of the isotropic and birefringent materials are different, making thermally induced strains likely. Solutions to the second problem are to use a thixotropic cement, which flows more readily with increasing stress, or to enclose the system in a metal sleeve and use oil instead of cement. If the ordinary index is matched by the oil, the birefringent material does not even need to be polished very well. Even a cleavage section of calcite can be used, with only a tolerable loss in angular field.[59]

Feussner suggested orienting the optic axis of the birefringent slab perpendicular to the cut, as indicated in Fig. 12*a*. Since the thermal expansion of the slab is the same in all directions perpendicular to the optic axis, thermally induced strains are minimized in this way. Field angles for Feussner prisms employing calcite and sodium nitrate slabs are given in the earlier polarization chapter.[1]

Shortly after Feussner's article was published, Bertrand[60] pointed out that the optic axis of the birefringent slab should be parallel to the entrance face of the prism to give the maximum difference between the refractive indices of the ordinary and extraordinary rays. A prism made in this way, sometimes called a Bertrand-type Feussner prism, is shown in Fig. 12*b*.

Since sodium nitrate is easily obtainable and has a birefringence even larger than that of calcite, attempts have been made to produce polarizing prisms of this material by Wulff,[61] Stöber,[62–64] Tzekhovitzer,[65] West,[66] Huot de Longchamp,[67] and Yamaguti.[68,69] However, it is not only deliquescent but also very soft, so that although large single crystals can be obtained, they are difficult to work. They can be crystallized in the desired orientation from a melt using a technique discovered by West.[66] When sodium nitrate crystallizes from a melt on a mica cleavage surface, one of its basal planes is oriented parallel to the mica cleavage and hence its optic axis is perpendicular to the mica surface. West reports growing single crystals as large as $38 \times 19 \times 2$ cm using this technique. Yamaguti[68,69] has produced polarizing prisms of sodium nitrate by placing thin, closely spaced glass plates on edge on a mica sheet and then immersing the assembly in a melt of sodium nitrate. The thin single crystal thus formed was annealed and cemented between glass prisms to form a Bertrand-type Feussner prism. Conceivably, the sodium nitrate could have been grown directly between the glass prisms themselves, but when such thick pieces of glass are used, it is difficult to avoid setting up strains in the crystal and consequently reducing the polarization ratio. Yamaguti used SK5 glass prisms ($n_D = 1.5889$) cut at an angle of 23° to form his polarizing prism and reports a field of view of 31°, symmetric about the normal to the entrance face.

Another possible birefringent material suitable for a Feussner prism is muscovite mica, and such prisms have actually been constructed and tested.[70,71] A 6° field angle can be obtained,[59] which is adequate for many optical systems illuminated by lasers.

13.7 NONCALCITE POLARIZING PRISMS

Polarizing prisms made of materials other than calcite have been used primarily in the ultraviolet region at wavelengths for which calcite is opaque. Prism materials used successfully in this region include crystalline quartz, magnesium fluoride, sodium nitrate, and ammonium dihydrogen phosphate. Rutile polarizing prisms have been used beyond the calcite cutoff in the infrared. A new prism material, yttrium orthovanadate, has been used to make high-transmission polarizers for the

visible and near-infrared spectral regions.[72] Properties of this material were described in the earlier polarization chapter.[1]

Rochon or Wollaston prisms (see "Rochon Prism" and "Wollaston Prism" in Sec. 13.5) are sometimes made of crystalline quartz for use in the far ultraviolet. The short-wavelength cutoff of the quartz is variable, depending on the impurities present, but can be as low as 1600 Å.

By utilizing magnesium fluoride instead of quartz for the polarizing prisms, the short-wavelength limit can be extended to 1300 Å. Magnesium fluoride transmits to about 1125 Å, but below 1300 Å its birefringence decreases rapidly and changes sign at 1194 Å.[55,73] Although it is the most birefringent material available in this region, MgF_2 has a much smaller birefringence than that of calcite; hence, a small cut angle and large *L/A* ratio for the prism are unavoidable. Since absorption does occur, it is desirable to minimize the length of the prism. Johnson[55] solved this problem by constructing a MgF_2 Wollaston prism which requires only half the path length necessary for a Rochon prism. However, both beams are deviated, creating instrumental difficulties.

Steinmetz et al.[49] constructed a double Rochon prism of MgF_2 which has the same *L*/*A* ratio as the Wollaston prism but does not deviate the desired beam. Problems with the prism included fluorescence, scattered light, and nonparallelism of the optic axes.[1] In principle, however, a MgF_2 double Rochon polarizing prism should be an efficient, high-extinction-ratio, on-axis polarizer for the 1300- to 3000-Å wavelength range and should also be useful at longer wavelengths. Morris and Abramson[50] reported on the characteristics of optically contacted MgF_2 single Rochon prisms.

A different type of polarizer suggested by Chandrasekharan and Damany[74] to take the place of a Rochon or Wollaston prism in the vacuum ultraviolet consisted of a combination of two MgF_2 lenses, one planoconcave and the other planoconvex of the same radius of curvature, combined so that their optic axes were crossed. The combination acted as a convergent lens for one polarization and as a divergent lens for the other. It had the advantage that the polarized beam remained on axis and was focused. A measured degree of polarization of 98.5 percent was obtained at 1608 Å, in good agreement with the calculated value.

Prism polarizers can also be constructed for use in the infrared at wavelengths longer than those transmitted by calcite. Rutile, TiO_2, a positive uniaxial mineral with a large birefringence and good transmittance to 5 μm in the infrared, has been used by Landais[75] to make a Glan-Foucault-type crystal polarizer. Since rutile has a positive birefringence (in contrast to the negative birefringence of calcite), the ordinary ray is transmitted undeviated and the extraordinary ray is reflected out one side. Other characteristics are given in the earlier Polarization chapter.[1]

13.8 DICHROIC AND DIFFRACTION-TYPE POLARIZERS

Some of the most useful polarizers available employ either dichroism or diffraction effects. These polarizers come in sheet form, sometimes in large sizes, are easily rotated, and produce negligible beam deviation. Also, they are thin, lightweight, and rugged, and most can be made in any desired shape. The cost is generally much less than that of a prism-type polarizer. Furthermore, both types are insensitive to the degree of collimation of the beam, so that dichroic or diffraction-type polarizers can be used in strongly convergent or divergent light.

A dichroic* material is one which absorbs light polarized in one direction more strongly than light polarized at right angles to that direction. Dichroic materials are to be distinguished from birefringent materials, which may have different refractive indexes for the two electric vectors vibrating at right angles to each other but similar (usually negligible) absorption coefficients.

*The term *dichroic* is also used in three other ways: (1) to denote the change in color of a dye solution with change in concentration, (2) to denote a color filter that has two transmission bands in very different portions of the visible region and hence changes color when the spectral distribution of the illuminating source is changed, and (3) to denote an interference filter that appears to be of a different color when viewed in reflected or transmitted light.

Various materials are dichroic, either in their natural state or in a stretched condition. The most common materials used as dichroic polarizers are stretched polyvinyl alcohol sheets treated with absorbing dyes or polymeric iodine, commonly marketed under the trade name Polaroid. These and similar materials are discussed in the following section. Another type of dichroic polarizer is prepared by rubbing a glass or plastic surface in a single direction and then treating it with an appropriate dye. Polarizers of this type are sold under the trade name Polacoat and will be described in "Dichoric Polarizing Coating" section on p. 13.28. In certain portions of the infrared spectral region, calcite is strongly dichroic and makes an excellent high-extinction polarizer.[76] Pyrolytic graphite is electrically and optically anisotropic and has been successfully used as an infrared polarizer; it is described in "Pyrolytic-Graphite Polarizers" section on p. 13.28. Other materials which exhibit dichroism in the infrared include single-crystal tellurium,[77] ammonium nitrate,[78] mica, rubber under tension, polyvinyl alcohol, and polyethylene.[79] In the visible region, gold, silver, and mercury in the form of microcrystals,[80] needles of tellurium,[81] graphite particles,[82] and glasses containing small elongated silver particles[83] are all dichroic.

A sodium nitrate polarizer described by Yamaguti[84] is not dichroic in the strict sense of the word but acts like a dichroic polarizer. Roughened plates of SK5 glass are bonded together by a single crystal of sodium nitrate, which has a refractive index for the ordinary ray nearly equal to that of the glass. The extraordinary ray has a much lower index, so that it is scattered out of the beam by the rough surfaces, leaving the ordinary ray to be transmitted nearly undiminished. (Yamaguti has also made Feussner prisms out of single-crystal sodium nitrate described in Sec. 13.6.)

Diffraction-type polarizers include diffraction gratings, echelettes, and wire grids. These are all planar structures that have properties similar to those of dichroic polarizers except that they transmit one component of polarization and reflect the other when the wavelength of the radiation is much longer than the grating or grid spacing. Wire grid and grating polarizers are covered in "Wire-Grid and Grating Polarizers" section on p. 13.30.

None of these polarizers has as high a degree of polarization as the prism polarizers of Secs. 13.1 to 13.5. Thus it is frequently necessary to measure the polarizing properties of the particular polarizer used. A source of plane-polarized light is desirable for such a measurement. Lacking that, one of the procedures described in "Measuring Polarization of Imperfect Polarizers" section on p. 13.33 can be followed if there are two identical imperfect polarizers. Alternate methods are also described which are applicable to two nonidentical imperfect polarizers.

Sheet Polarizers

Various types of sheet polarizers have been developed by Edwin H. Land and coworkers at the Polaroid Corporation, Cambridge, Mass. Sheet polarizers are also available from several European companies. The J sheet polarizer, the first type available in America (around 1930), consisted of submicroscopic needles of herapathite oriented parallel to one another in a sheet of cellulose acetate. Since this type of polarizer, being microcrystalline, had some tendency to scatter light, it was superseded by H and K sheet molecular polarizers, which exhibit virtually no scattering. The most widely used sheet polarizer is the H type, which consists of a sheet of polyvinyl alcohol that has been unidirectionally stretched and stained with iodine in a polymeric form. The K type is made by heating a sheet of polyvinyl alcohol in the presence of a catalyst to remove some of the water molecules and produce the dichromophore polyvinylene. It was developed primarily for applications where resistance to high temperature and high humidity are necessary. Another type of polarizing sheet, made from a combination of the H and K types, has an absorption maximum at about 1.5 μm in the infrared and is designated as HR Polaroid.

The history of the development of the various kinds of sheet polarizers has been given by Land,[81] their chemical composition by Land and West,[80] and their optical performance by Shurcliff,[82] Baumeister and Evans,[85] Land and West,[80] and Land.[81] In addition, Blake et al.[86] mention the HR infrared polarizer, and Makas[87] describes the modified H-film polarizer for use in the near ultraviolet. Baxter et al.[88] describe a technique for measuring the optical density of high-extinction polarizers in the presence of instrumental polarization.

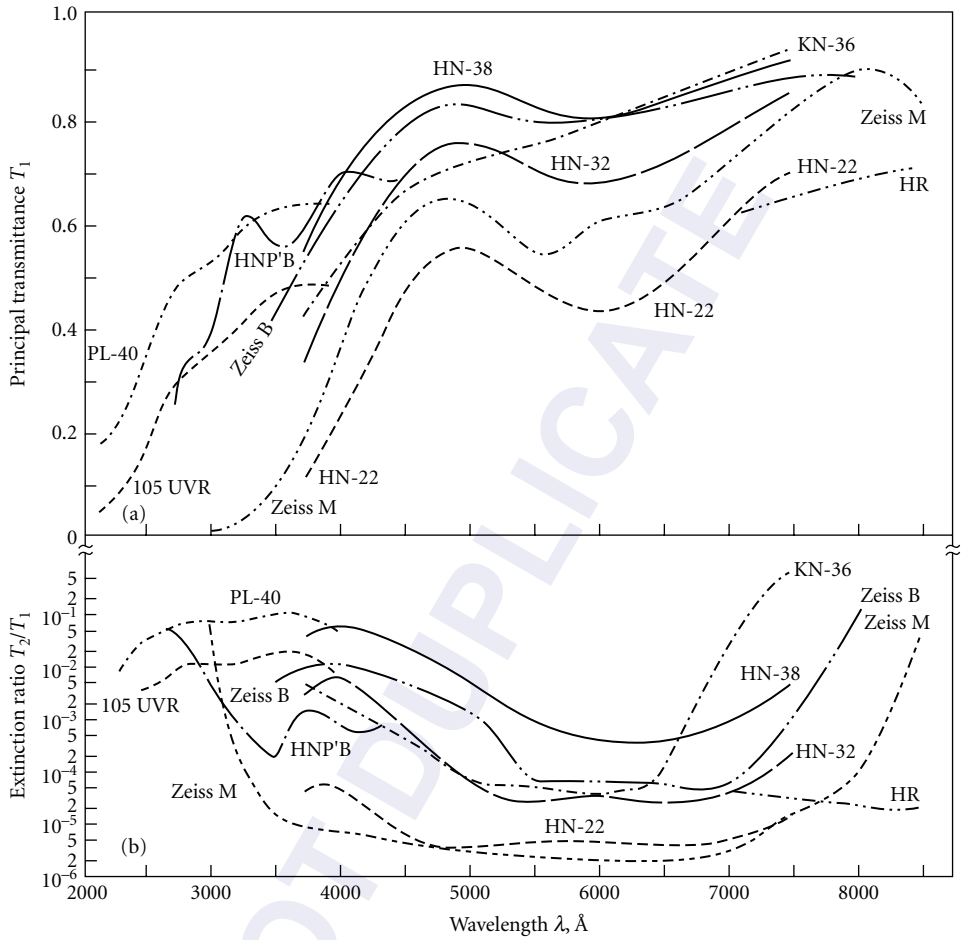

FIGURE 13 (*a*) Principal transmittance and (*b*) extinction ratio for various types of dichroic polarizers: Polaroid sheet polarizers HN-22, HN-32, HN-38, and KN-36; Zeiss (Oberkochen) Bernotar and Micro Polarization filters; and Polacoat PL-40 and 105 UVR polarizing filters. The last is stated to have a transmittance (for unpolarized light) of 32 percent at 5460 Å. (*Modified from curves of Shurcliff,*[82] *Baumeister and Evans,*[85] *Jones,*[89] *Haase,*[90] *and McDermott and Novick.*[91])

Figure 13 shows the principal transmittance T_1 and extinction ratio T_2/T_1 of various types of H and K sheet polarizers used in the visible and near ultraviolet.[82,85,89] In addition, curves for two sheet polarizers manufactured by Zeiss and two types of polarizing filters from Polacoat (see "Dichroic Polarizing Coatings" section on p. 13.28) are shown. The letter N in the designation of the Polaroid sheets stands for neutral (to distinguish them from sheet polarizers prepared from colored dyes), and the number 22, 32, etc., indicates the approximate transmittance of unpolarized visible light. Figure 14 gives the principal transmittance and extinction ratio of a typical plastic laminated HR infrared polarizer.[82,89] Sometimes the optical density D of a polarizer is plotted instead of its transmittance. The relation between these two quantities is

$$D = \log \frac{1}{T} \tag{8}$$

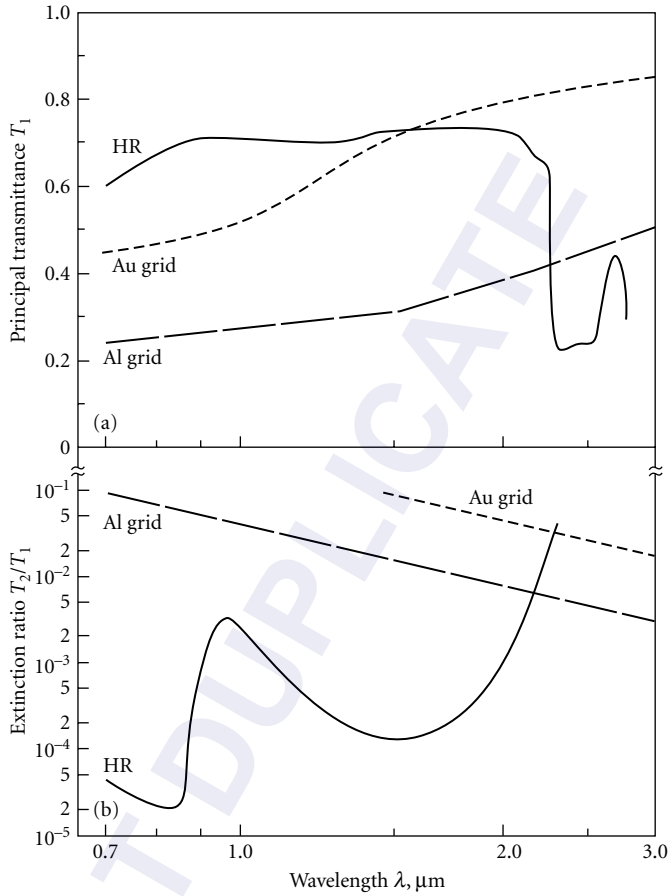

FIGURE 14 (*a*) Principal transmittance and (*b*) extinction ratio for plastic laminated HR infrared polarizer (*modified from curves of Shurcliff,*[82] *and Jones,*[89]) and two wire grid polarizers with 0.463-μm grating spacings (*Bird and Parrish,*[92]).

The extinction ratio of the HN-22 Polaroid compares favorably with that of Glan-Thompson prisms throughout the visible region, but the transmission of the Glan-Thompson is superior. In the ultraviolet, the new HNP′B material has a reasonably good extinction ratio (about 10^{-3} or better) for wavelengths longer than 3200 Å. It is a specially purified form of HN-32, and its properties match those of the standard HNT-32 Polaroid at wavelengths longer than 4500 Å. Optical properties of various types of Polaroid dichroic polarizers have been described by Trapani.[93] According to West and Jones,[48] the extinction ratio for a dichroic polarizer of the Polaroid type has a practical limit of about 10^{-5} because, as the concentration of dichromophore is increased beyond a certain value, the optical density no longer increases proportionately. Gunning and Foschaar[94] have described a method for the controlled bleaching of the iodine dichromophore in iodine-polyvinyl alcohol polarizers to achieve an increased internal transmission of up to 95 percent for the principal transmittance of linearly polarized light in the 5000- to 6000-Å wavelength region. This is achieved at the expense of degrading the extinction ratio and drastically affecting the short wavelength performance of the polarizer. Baum[95] describes the application of sheet polarizers to liquid crystal displays and problems encountered in this application.

If Polaroids are used in applications where beam deviation is important, they should be checked for possible deviation. Most Polaroids, which are laminated in plastic sheets, do produce a slight beam deviation that can be observed through a telescope as a shift in the image position when the Polaroid is rotated. The amount of the deviation varies from point to point on the Polaroid and can be much worse if the material is mounted between glass plates. It is possible to order specially selected sheet Polaroid laminated between polished glass plates that deviates the beam by only about 5 seconds of arc.

Sheet polarizers made of stretched polyvinyl alcohol that has been stained with iodine or various dyes are also made in countries outside the United States, as described in the earlier polarization chapter.[1]

King and Talim[25] have measured the axis wander and ellipticity of beams transmitted by various types of sheet polarizers in the same way as for Glan-Thompson prisms ("Common Defects and Testing of Glan-Type Prisms" in Sec. 13.3). They found considerable variations from one type of sheet polarizer to another and also over a single sheet. Details are given in the earlier chapter on polarization.[1]

Dichroic Polarizing Coatings

Beilby-layer polarizers[82] are dichroic coatings that can be applied to the surface of glass or plastic. The process was developed by Dreyer,[96] who founded the company which manufactures Polacoat polarizing filters. There are three main steps in the production of these polarizers. First, the substrate (quartz, glass, plastic, etc.) is rubbed along parallel lines with filter paper, cotton, or rouge to produce a preferred surface orientation. (The affected region of minute scratches extends to a depth of less than 1 μm.) Then the sheet is rinsed and treated with a solution of dichroic molecules e.g., a 0.5 percent solution of methylene blue in ethanol or one or more azo dyes, and then dried in a controlled fashion. Presumably the molecules line up preferentially along the rubbing direction, resulting in a greater absorption for light, polarized in that direction. As a final step, the surface is treated with an acidic solution, often that of a metallic salt such as stannous chloride, which can increase the dichroism and produce a more neutral color. A protective coating over the polarized surface provides mechanical protection for the fragile layer with no loss in transmission. McDermott and Novick[91] give a somewhat more complete description of the Polacoat process, and Anderson[97] has investigated the absorption of methylene blue molecules on a unidirectionally polished surface. References to patents and related work are given by Shurcliff.[82]

The principal transmittance and extinction ratio of two standard Polacoat coatings, PL-40 and 105 UVR (32 percent transmission of unpolarized light at 5460 Å), are shown in Fig. 13. These curves are taken from the data of McDermott and Novick.[91] Polacoat 105 UVR coating comes in various densities; the data shown are for the highest-density material with the best extinction ratio.* A major advantage of Polacoat over sheet Polaroid is that it does not bleach upon exposure to intense ultraviolet radiation.

Kyser[99] tested a stock PL40 polarizing filter on fused quartz and found that it produced a large quantity of scattered light of the unwanted component. This light was dispersed spectrally and was scattered at angles up to about 20° as though the scratches on the rubbed surface were acting like rulings on a diffraction grating. There was relatively little of the unwanted component on axis; most of it was scattered at larger angles. Despite these difficulties, Polacoat PL40 polarizers appear to be the best large-aperture transmission-type polarizers available for work in the 2000- to 3000-Å wavelength range in the ultraviolet.

Pyrolytic-Graphite Polarizers

Pyrolytic graphite has a large anisotropy in both the electric conductivity and in the optical properties. If the E vector of an electromagnetic wave is pointing in the direction of the c-axis of the graphite, the absorption coefficient is a minimum, the reflectance is also a minimum, and hence

*The company literature[98] is somewhat misleading in that the transmittance of this material is stated to be 35 percent, but the transmission curve (for unpolarized light) given in the bulletin does not rise above 30 percent until the wavelength becomes longer than 6500 Å

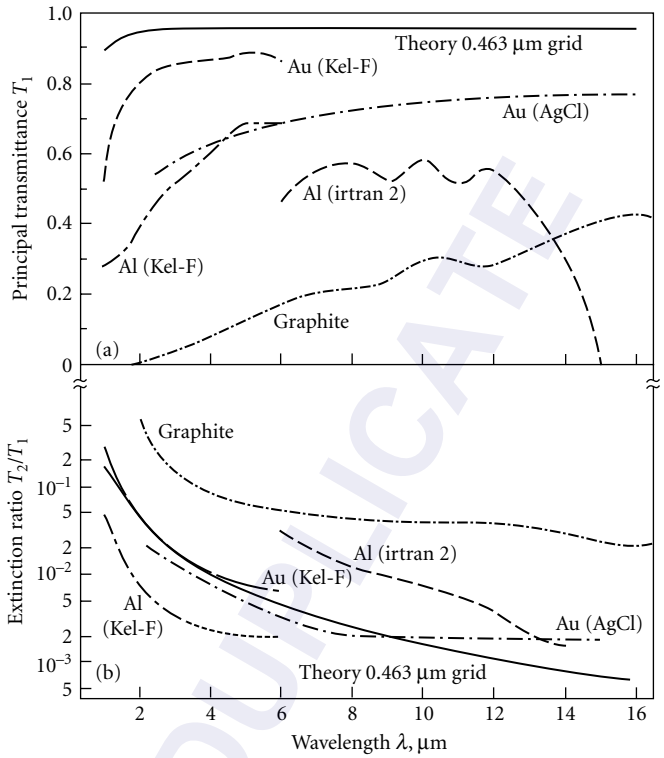

FIGURE 15 (*a*) Principal transmittance and (*b*) extinction ratio for a pyrolytic-graphite polarizer (*Rupprecht* et al.[100]) and various wire-grid polarizers. (*Bird and Parrish,*[92] *Perkin-Elmer,*[101] *and Young* et al.[102]) The substrate materials and metals used for the grids are indicated. Theoretical curves (*solid lines*) calculated from relations given in Ref. 1 with $n = 1.5$ and $d = 0.463$ are also shown for comparison.

the transmittance is a maximum. If the E vector lies in the plane perpendicular to the c direction, the absorption is a maximum, reflectance is a maximum, and transmittance is a minimum. Thus, pyrolytic graphite should be a good material from which to make a dichroic polarizer if a thin foil is cut and polished to contain the c-axis. Several such polarizers have been made by Rupprecht et al.[100]; two had thicknesses of 9.2 μm, and a third was 4.2 μm thick. The transmittances T_1 of the thinner one and T_1 and T_2 of the two thicker ones were determined using one of the methods described in Par. 49 of the earlier Polarization chapter.[1] The principal transmittance and extinction ratio for one of the 9.2-μm-thick ones are shown in Fig. 15 for infrared wavelengths from 2 to 16 μm, along with curves for various wire-grid polarizers (see "Wire Grid and Grating Polarizers" section next). In the far infrared out to 600 μm, T_1 gradually increases to 0.50 and T_2/T_1 drops down to the 10^{-3} range.[100] The transmittance of the thinner pyrographite polarizer was larger than the curve shown, but its extinction ratio, although not given, was probably poorer. Pyrolytic-graphite polarizers have the advantages of being planar and thus easily rotatable, having large acceptance angles, and having reasonably high transmittances and good extinction ratios in the far infrared. However, in the shorter-wavelength region shown in Fig. 15, they are inferior to all the wire-grid polarizers. In addition, they are fragile, and the largest clear aperture obtained by Rupprecht et al.[100] was about 12 mm diameter.

Wire-Grid and Grating Polarizers

Wire grids* have a long history of use as optical elements to disperse radiation and detect polarization in far-infrared radiation and radio waves.[92] They transmit radiation whose E vector is vibrating perpendicular to the grid wires and reflect radiation with the E vector vibrating parallel to the wires when the wavelength λ is much longer than the grid spacing d. When λ is comparable to d, both components are transmitted. For grids made of good conductors, absorption is negligible. Various aspects of the theory of reflection and transmission of radiation by wire grids are summarized in the earlier polarization chapter.[1] In addition to that theoretical treatment, Casey and Lewis[104,105] considered the effect of the finite conductivity of the wires on the transmission and reflection of wire-grid polarizers when the light was polarized parallel to the wires. Mohebi, Liang, and Soileau[106] extended the treatment to the case for which light was polarized both parallel and perpendicular to the wires; they also calculated the absorption of the wire grids as a function of d/λ. In addition, they measured the absorption and surface damage of wire-grid polarizers consisting of aluminum strips (0.84-μm period) deposited on ZnSe substrates at 10.6 μm, 1.06 μm, and 0.533 μm. Stobie and Dignam[107] calculated the amplitude transmission coefficients for parallel and perpendicular components and relative phase retardation between them, both as a function of λ/d. Burton[108] proposed using wire-grid polarizers in the form of cylinders and paraboloids instead of planar structures in infrared interferometers, but did not show any experimental measurements.

Figure 16 shows values of the calculated principal transmittance and extinction ratio for various values of the refractive index n as a function of λ/d. These curves were calculated from relations given in the earlier polarization chapter.[1] It is clear that the shortest wavelength for which a given grid will act as a useful polarizer is $\lambda \approx 2d$. Also, the best performance is obtained with the lowest refractive index substrate. Since absorption in the substrate material has been neglected, principal transmittances measured for real materials will be lower than the calculated values, but the extinction ratios should be unaffected. If one must use a high refractive index substrate such as silicon or germanium, the performance of the grid can be considerably improved by applying an antireflection coating to the substrate *before* depositing the conducting strips, since a perfectly antireflected substrate acts like an unsupported grid.[109] However, if the antireflecting layer is laid down *over* the grid strips, the performance of the wire-grid polarizer is degraded.[1]

Many people have built and tested wire-grid polarizers including Bird and Parrish,[92] Young et al.,[102] Hass and O'Hara,[110] Hilton and Jones,[111] Auton,[109] Vickers et al.,[112] Cheo and Bass,[113] Auton and Hutley,[114] Costley et al.,[115] Beunen et al.,[116] Leonard,[117] Sonek et al.,[118] Eichhorn and Magner,[119] and Novak et al.[120] In addition, two types of wire grids are manufactured commercially by Buckbee Mears (see Ref. 110) and Perkin-Elmer,[101] and a third type composed of 152 μm-diameter tungsten wires spaced 800 to the inch has been mentioned, but no performance characteristics have been given.[121] Hwang and Park[122] measured the polarization characteristics of two-dimensional wire mesh (64 μm and 51 μm spacings) at a laser wavelength of 118.8 μm. The different wire-grid polarizers are listed in Table 2, and the principal transmittances and extinction ratios of several are shown in Figs. 14 and 15.

The polarizers with grid spacings of 1.69 μm and less were all made by evaporating the grid material at a very oblique angle onto a grating surface which had been prepared either by replicating a diffraction grating with the appropriate substrate material (silver bromide, Kel-F, polymethyl methacrylate, etc.) or by ruling a series of lines directly onto the substrate (Irtran 2 and Irtran 4). The oblique evaporation (8° to 12° from the surface) produced metallic lines on the groove tips which acted like the conducting strips of the theory, while the rest of the surface was uncoated and became the transparent region between strips. Larger grid spaces (4 to 25.4 μm) were produced by a photoetching process, and one 25.4-μm grid was made by an electroforming process. Still larger grid spacings were achieved by wrapping wires around suitable mandrels.

If a wire-grid polarizer is to be used in the near infrared, it is desirable to have the grid spacing as small as possible. Bird and Parrish[92] succeeded in obtaining a very good extinction ratio in the 2- to 6-μm wavelength region with an aluminum-coated Kel-F substrate (Figs. 14 and 15). Unfortunately,

Wire grid is being used here, as is customary, to denote a planar structure composed of a series of parallel wires or strips. Renk and Genzel[103] and a few others use the term to designate a two-dimensional array with two series of elements arranged at right angles to each other. They call a one-dimensional array a wire or strip grating.

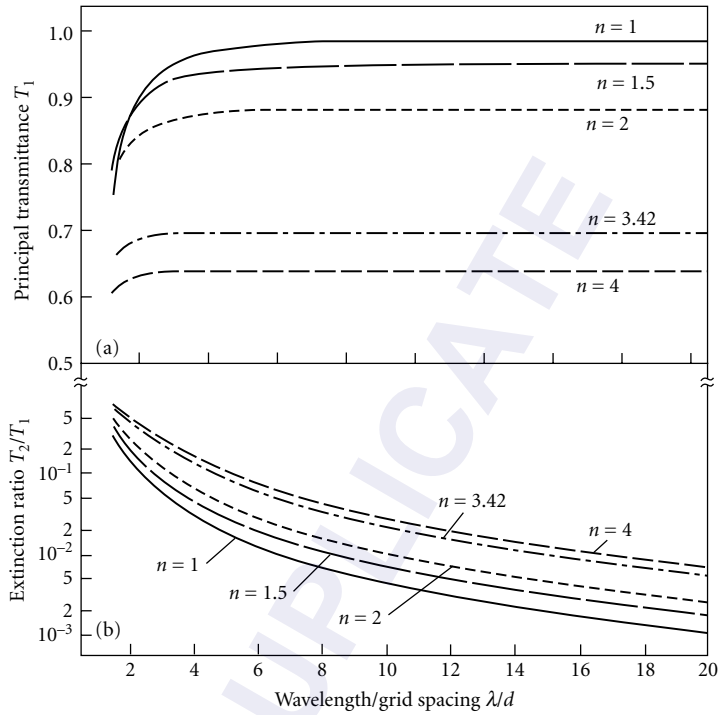

FIGURE 16 (*a*) Principal transmittance and (*b*) extinction ratio as a function of λ/d calculated from relations given in Ref. 1 for various values of n for the substrate. Substrate indexes correspond approximately to an antireflected substrate of air, organic plastic, silver chloride, silicon, and germanium.

Kel-F $(CF_2CFCl)_n$, has absorption bands at 7.7 to 9.2 μm and 10.0 to 11.0 μm, making the polarizer useless in these regions, but it can be used at longer wavelengths out to 25 μm.[92] Polyethylene would be an excellent substrate material since it has fewer absorption bands than Kel-F, but its insolubility in common solvents makes it much more difficult to use for replicating gratings.[110] It does, however, make an excellent substrate material for photoetched grids.[109]

For infrared wavelengths longer than about 24 μm, a photoetched grid with 1-μm-wide lines (close to the present limit for the photoetching process) and a 2-μm spacing should have an extinction ratio of 5×10^{-3} or better if the refractive index of the substrate is about 1.5—for example, polyethylene. The extinction ratio would continue to decrease; i.e., the polarization properties would improve as the wavelength is increased. At very long wavelengths, grids with a larger spacing would have a high degree of polarization. The important factor is the ratio of wavelength to grid spacing, which should be kept as large as possible (Fig. 16*b*).

One definite advantage of the wire-grid polarizer is that it can be used in sharply converging beams, i.e., systems with high numerical apertures. Young et al.[102] found no decrease in percent of polarization for an Irtran 2 polarizer at 12 μm used at angles of incidence from 0° to 45°. They did find, however, that the transmittance decreased from 0.55 at normal incidence to less than 0.40 at 45° incidence.

If a grid were to be used at a single wavelength, one might possibly make use of interference effects in the substrate to increase the transmission.[109] If the substrate has perfectly plane-parallel surfaces, it will act like a Fabry-Perot interferometer and transmit a maximum amount of light when twice the product of the thickness and refractive index is equal to an integral number of wavelengths. The 0.25-mm-thick pressed polyethylene substrates used by Auton[109] were not uniform enough to show interference effects, but the Mylar film backing on the Buckbee Mears electroformed grid did show interference effects.[110]

TABLE 2 Types of Wire-Grid Polarizers

Grid spacing, μm	Grid material	Substrate	Wavelength range, μm	Reference
0.115	Evaporated Al	Quartz	0.2–0.8	Sonek et al.[118]
0.347	Evaporated Au	Silverchloride	2.5–30	Perkin-Elmer[101]
0.22–0.71	Evaporated Al	KRS-5	3–15, 3.39, 10.6	Auton and Hutley[114]
0.22–0.45	Evaporated Al	CaF_2	3–10, 3.39	Auton and Hutley[114]
0.42	Evaporated Al	Glass	3–5	Auton and Hutley[114]
0.463	Evaporated Au	Kel-F	1.5–10*	Bird and Parrish[92]
0.463	Evaporated Al	Kel-F	0.7–15*	Bird and Parrish[92]
0.463	Evaporated Al	Polymethyl methacrylate	l–4000†	Hass and O'Hara[110]
1.67	Evaporated Al	Irtran 2	6–14	Young et al.[102]
1.67	Evaporated Al	Irtran 4	8–19	Young et al.[102]
1.69	Evaporated Al	Polyethylene	2.9–200‡	Hass and O'Hara[110]
2	Evaporated Cr	Silicon	10.6	Cheo and Bass[113]

*Strong absorption bands near 8.3 and 10.5 μm.
†Strong absorption bands between 5.7 and 12.5 μm.
‡Absorption bands between 6 and 15.5 μm.

Lamellar eutectics of two phases consist of thin needles of a conducting material embedded in a transparent matrix. The material is made by a controlled cooling process in which there is a unidirectional temperature gradient. This method of cooling orients conducting needles parallel to the temperature gradient, and hence the material can act like a wire-grid polarizer. Weiss and coworkers[123–125] have grown eutectic alloys of InSb and NiSb in which the conducting needles of NiSb are approximately 1 μm in diameter and approximately 50 μm long. A degree of polarization of more than 99 percent has been reported. Other eutectic alloys of InAs, GaSb, and InSb containing conducting needlelike crystals of Ni, Fe, Mn, Cr, and Co (or their compounds) have also been investigated. An advantage of this type of polarizer is that its performance can be optimized at a specific wavelength, e.g., that of a CO_2 laser line, by choosing the thickness of the crystalline film so that there will be an interference maximum at the desired wavelength.[126] Recently, Saito and Miyagi[127] have proposed using a thin film of anodized aluminum with implanted metallic columns to make a high-performance polarizer. Their theoretical calculations suggest that this type of polarizer should have a large extinction ratio and low loss in the infrared.

In summary, wire grids are very useful infrared polarizers, particularly for wavelengths much greater than the grid spacing. They are compact and easily rotatable and can be used with sharply converging beams. A major advantage is the extreme breadth of the wavelength band over which they have good polarizing properties. The long-wavelength limit is set by the transmission of the substrate material rather than by the loss of polarization of the grid. The short-wavelength limit is

determined by the grid spacing; if gratings with smaller spacings could be successfully replicated and coated, the short-wavelength limit could be pushed closer to the visible region.

Another possible method of producing plane-polarized light is by using diffraction gratings or echelette gratings. Light reflected from diffraction gratings has long been known to be polarized, but the effect is generally small and extremely wavelength-dependent.[128,129] However, Roumiguieres[130] predicted that under certain conditions (rectangular groove grating with equal groove and land spacings and small groove depth), a high polarizing efficiency could be obtained. For wavelengths in the range $1.1 < \lambda/d < 1.7$, over 80 percent of the light polarized parallel to the grooves should be reflected in the zero order at a 50° angle of incidence and less than 5 percent of the other polarization. His predictions were verified by Knop[131] who fabricated gold-coated photoresist gratings as well as an electroplated nickel master grating. Knop's measured reflectances of the two polarized components were within ±3 percent of the predicted values. In general, one tries to avoid polarization in the diffracted light to obtain high efficiencies in a blazed grating since polarization effects are frequently associated with grating anomalies.[132,133]

In contrast to diffraction gratings, echelette gratings, have been found to produce an appreciable amount of plane-polarized light. Experimental studies have been made by Peters et al.,[134] Hadni et al.,[135,136] and Mitsuishi et al.,[137] as discussed in the earlier Polarization chapter.[1] The theory of the polarization of light reflected by echelette gratings in the far-infrared and microwave regions has been given by Janot and Hadni[138] and Rohrbaugh et al.[139] A general numerical technique published by Kalhor and Neureuther[140] should be useful for calculating the polarization effects of echelette gratings of arbitrary groove shape used in the visible region.

Measuring Polarization of Imperfect Polarizers

In determining the principal transmittance, extinction ratio, and other properties of an imperfect polarizer, the effects of source polarization, instrumental polarization, and sensitivity of the detector to the plane of polarization must either be measured or eliminated from the calculations. This is easy if an auxiliary polarizer is available that has a much higher degree of polarization than the one to be measured. In such a case, the "perfect" polarizer can be placed in the beam, and the transmittances T_1 and T_2 for the unknown polarizer can be measured directly.* Source polarization, instrumental polarization, and variation of detector response with plane of polarization can all be lumped together as a product. If this product is different in the horizontal and vertical planes, the ratio of the signals obtained when the "perfect" polarizer is oriented horizontally and vertically will not equal unity. One should always take more than the minimum number of measurements, i.e., introduce redundancy, to make sure that no systematic errors are present.

If a high-quality polarizer is not available, two polarizers having unknown properties may be used instead. Several procedures have been described in detail in the earlier polarization chapter.[1] The method of Hamm et al.[141] which yields the extinction ratio of each polarizer and the instrumental polarization was described in detail and a brief summary of the method of Kudo et al.[142] was given. The methods of Hamm et al.,[141] Horton et al.,[143] and Schledermann and Skibowski[144] were specifically developed for non-normal incidence reflection polarizers (see "Brewster Angle Reflection Polarizers" section in Sec. 13.9).

13.9 NON-NORMAL-INCIDENCE REFLECTION AND TRANSMISSION POLARIZERS

By far the largest class of polarizers used in the infrared and ultraviolet spectral regions (where dichroic sheet polarizers and calcite polarizing prisms cannot be used) is the so-called *pile-of-plates polarizers* from which light is reflected (or transmitted) at non-normal incidence. Since most of these polarizers operate at angles near the Brewster or polarizing angle [see Eq. (48) in Chap. 12, "Polarization"], they are frequently called Brewster angle polarizers. The plane-parallel plates which are used for Brewster angle transmission polarizers (see "Brewster Angle Transmission Polarizers" section on p. 13.38) are generally thick enough to ensure that although multiple reflections occur within each plate, the

*When using an air-spaced polarizing prism, extreme care should be taken not to exceed the acceptance angle of the prism.

coherence of the light beam is lost and there are no interference effects. However, another class of non-normal-incidence transmission polarizers makes use of interference effects to enhance their polarizing properties. These include interference polarizers (see "Interference Polarizers" section on p. 13.39) and polarizing beam splitters (see "Polarizing Beam Splitters" section on p. 13.41). These thin-film devices are discussed in much more detail in Chap. 7, "Optical Properties of Films and Coatings," in Vol. IV by Jerzy A. Dobrowolski. A relation which is frequently used in connection with non-normal-incidence reflectance measurements is the Abelès condition, discussed in the following section.

Brewster Angle Reflection Polarizers

Most reflection-type polarizers are made of plates which are either nonabsorbing or only slightly absorbing. The angle of incidence most often used is the Brewster angle at which the reflection of the *p* component, light polarized parallel to the plane of incidence, goes to 0. Thus the reflected light is completely plane polarized with the electric vector vibrating perpendicular to the plane of incidence (*s* component). Curves showing the reflectance and extinction ratio for various materials and angles near the Brewster angle are given in Fig. 5 of Chap. 12, "Polarization." The polarizing efficiency of reflection-type polarizers can be experimentally determined using any of the methods given in Par. 49 of the earlier polarization chapter;[1] the methods of Hamm et al.,[141] Horton et al.,[143] and Schledermann and Skibowski[144] were specifically developed for polarizers of this type.

Brewster angle reflection polarizers for the infrared are made from the semiconductors silicon, germanium, and selenium which are transparent beyond their absorption edges and have high refractive indexes. Table 3 lists various infrared polarizers which have been described in the literature. All involve external reflections except the Ge-Hg polarizer described by Harrick,[145] in which light undergoes two or four reflections within a bar of germanium. While Harrick's polarizer has attractive features, it depends on maintaining polarization in the germanium, so that great care must be taken to obtain material with a minimum of strain birefringence.

In the ultraviolet, materials such as LiF, MgF_2, CaF_2, and $A1_2O_3$, can be used as polarizers. Biotite, a form of mica, has also been found to perform very well in the 1000- to 6000-Å region. In the extreme ultraviolet, metallic films, particularly Au, Ag, and Al, have been used as polarizers. Table 4 lists various non-normal-incidence ultraviolet reflection polarizers as well as authors who have made calculations and measurements on various materials for ultraviolet polarizers.

TABLE 3 Infrared Brewster Angle Reflection Polarizers

Material	Description	Reference
Ge-Hg	Multiple internal reflections in Ge immersed in Hg	Harrick[145]
Ge	Single external reflection from 1-cm-thick polished Ge single crystal	Edwards and Bruemmer[146]
Ge	Proposed parallel and antiparallel arrangements of two Ge plates	Krízek[147]
Ge	Double-beam system: beam 1, single reflection; beam 2, one transmission, one reflection	Craig et al.[148]
Ge	Axial arrangement with reflections from two Ge wedges and two Al mirrors	Bor and Brooks[149]
Se	Reflections from two cast-Se films on roughened glass plates	Pfund[150]
Se	Axial arrangement with reflections from two Se films evaporated on NaCl and one Ag mirror	Barchewitz and Henry[151]
Se	Large-aperture, axial, venetian-blind arrangement with one or two reflections from evaporated Se films on roughened glass plates (additional reflections from Al mirrors)	Takahashi[152]
Si	Single reflection from polished single crystal Si	Walton and Moss[153]
Si	Axial arrangement with reflection from two Al mirrors and polished Si plate with roughened back	Baumel and Schnatterly[154]
PbS	Axial arrangement with reflections from two chemically deposited PbS films and one Al film	Grechushnikov and Petrov[155]
CdTe	Single plate	Leonard[117]
$Al + A1_2O_3$	Multiple reflections from $A1_2O_3$ coated with metal at 10.6 μm (calculations only)	Cox and Hass[156]
$Ti + SiO_2$	Multiple reflections from dielectric coated Ti at 2.8 μm (calculations only)	Thonn and Azzam[157]

TABLE 4 Ultraviolet Reflection Polarizers and Polarization Measurements

Material	Description	Wavelength range, Å	Reference
Al_2O_3, Al, Au, ZnS, glass, and others	Calculated values of R_s and $(R_s/R_p)_{max}$ vs. wavelength for a single reflection	500–2000	Hunter[158]
Al_2O_3, Al, glass, and others	Calculated values of R_s and $(R_s - R_p)/(R_s + R_p)$ vs. angle of incidence for a single reflection; also principal angle and related angles	584	Damany[159]
Al_2O_3, CaF_2, LiF, and Pyrex	Measured optical constants; calculated R_s and $(R_s - R_p)/(R_s + R_p)$ vs. angle of incidence and wavelength for a single reflection	200–2000	Stephan et al.[160]
Al_2O_3 and CaF_2	Measured $(R_s - R_p)/(R_s + R_p)$ vs. angle of incidence at selected wavelengths for a single reflection; used both materials as single-reflection polarizers	1026–1600	de Chelle and Merdy[161]
LiF, Al_2O_3, MgF_2, SiO, ZnS	Used single-reflection LiF polarizer at Brewster angle to measure R_s and R_s/R_p for various materials; best polarizers were Al_2O_3 and MgF_2	1216	McIlrath[162]
Al, Ag, Au, MgF_2, SiO, ZnS	Measured polarization of uncoated aluminum grating and optical constants of all materials listed	304–1216	Cole and Oppenheimer[163]
Al, Au	Determined polarization of Au- and Al-coated gratings by measuring reflectance of Au and fused-silica mirrors at 45°	600–2000	Uzan et al.[164]
Al, Au, glass	Measured average reflectance and degree of polarization of Al, Au, and glass as a function of angle of incidence; measured polarization of a glass grating and an Al-coated grating	584	Rabinovitch et al.[165]
MgF_2	Measured R_p/R_s at 60° for a single reflection and compared it with calculated values	916, 1085, 1216	Sasaki and Fukutani[166]
MgF_2 + Al	Calculated performance, constructed axial triple-reflection polarizer and analyzer of MgF_2-coated Al, and measured transmission	1216	Winter et al.[167]
MgF_2, MgF_2 + Al	Calculated performance, constructed triple-reflection polarizer of a MgF_2 plate and two MgF_2-coated Al mirrors, and measured transmission	300–2000	Hass and Hunter[168]
MgF_2, MgF_2 + Al	Constructed four-reflection polarizers of a MgF_2 plate and three MgF_2-coated Al mirrors, no performance properties measured; polarizer part of the UV spectrometer and polarimeter for the NASA Solar Maximum Mission	1150-visible	Spencer et al.[169]

TABLE 4 Ultraviolet Reflection Polarizers and Polarization Measurements (*Continued*)

Material	Description	Wavelength range, Å	Reference
MgF_2 Au, and other metals	Calculated values of R_s and $(R_s/R_p)_{max}$ vs. angle of incidence and wavelength for one and more reflections for a variety of materials	300–2000	Hunter[170]
Au, Ag	Measured R_p/R_s at 45° for a single reflection and compared it with calculated values; measured R_p/R_s for a platinized grating	500–1300	Hamm et al.[141]
Au	Used single-reflection Au mirror at 60° as polarizer (Brewster angle about 55°)	600–1200	Ejiri[171]
Au	Used axial arrangement of eight Au mirrors at 60° as polarizer and analyzer to measure polarization of synchrotron radiation; determined polarizing properties of each polarizer	500–1000	Rosenbaum et al.[172]
Au	Constructed axial triple-reflection Au polarizer, measured extinction ratio and transmission for different angles of incidence on Au plates	500–5000	Horton et al.[143]
Au	Reflection from two cylindrical gold mirrors in a Seya-Namioka monochromator; measured polarization ratio	1200–3000	Rehfeld et al.[173]
Au	Calculated performance of a polarizer made of 2 concave Au-coated spherical mirrors used off axis, constructed polarizer, no measurements made of polarization or transmission	584	Van Hoof[174]
Au	Constructed a 4-reflection Au-coated polarizer of Van Hoof's design (2 plane, 2 spherical mirrors), measured transmission and degree of polarization	400–1300	Hibst and Bukow[175]
Au	Constructed a single-reflection Au-coated polarizer and measured the polarizing efficiency	584	Khakoo et al.[176]
Biotite	Constructed axial polarizer and analyzer each with 61° Brewster angle reflection from biotite and two reflections from MgF_2-coated Al mirrors; measured transmission and extinction ratio	1100–6000	Robin et al.[177]
Biotite	Constructed two polarizers: (1) axial polarizer with two 60° reflections from biotite and 30° reflection from MgF_2-coated Al mirror; (2) displaced-beam polarizer with 60° reflections from two biotite plates; measured degree of polarization of various gratings	1000–2000	Matsui and Walker[178]

The most versatile non-normal-incidence reflection polarizer would be one which does not deviate or displace the beam from its axial position. One convenient arrangement would be a symmetric three-reflection system in which the light is incident on one side of a triangle, reflected to a plane mirror opposite the apex, and back to the other side of the triangle, as was done by Horton et al.,[143] and Barchewitz and Henry.[151] If the polarizer must have a good extinction ratio and the light beam is highly convergent, two of the reflections could be from the polarizing material and the third from a silvered or aluminized mirror. If the beam is highly collimated or more throughput is required, only one reflection may be from the polarizing material. The throughput can also be increased by using a plane-parallel plate for the polarizing reflection. The major drawback to a reflection polarizer is the extreme length of the device required to accommodate a beam of large cross-sectional area. For example, if a germanium polarizer were used at the Brewster angle (76°) and the beam width were about 25 mm, each Ge plate would have to be about 25 mm × 100 mm and the overall length of the polarizer would be greater than 200 mm if a three-reflection axial arrangement such as that described above were used.

The Abelès condition,[179] which applies to the amplitude reflectance at 45° angle of incidence (see Sec. 12.5 in Chap. 12, "Polarization") is useful for testing the quality of reflection polarizers. Schulz and Tangherlini[180] apparently rediscovered the Abelès condition and used the ratio $R_s^2/R_p = 1$ as a test to evaluate their reflecting surfaces. They found that surface roughness made the ratio too small but annealing the metal films at temperatures higher than 150°C made the ratio larger than unity. Rabinovitch et al.[165] made use of the Abelès condition to determine the polarization of their Seya-Namioka vacuum-ultraviolet monochromator. They measured the reflectance at 45° of a sample whose plane of incidence was perpendicular or parallel to the exit slit. From these measurements they deduced the instrumental polarization by assuming the Abelès condition. Values of instrumental polarization obtained using carefully prepared gold and fused-silica samples were in excellent agreement, showing that neither of these materials had surface films which invalidated the Abelès condition. Surface films usually have relatively little effect on the Abelès condition in the visible region[181] but become important in the vacuum ultraviolet. Hamm et al.[141] eliminated the effect of instrumental polarization from their measurements of the reflectance of a sample in unpolarized light at 45° angle of incidence by making use of the Abelès condition. Although Mcllrath[162] did not refer to the Abelès condition as such, he used it to determine the instrumental polarization of his vacuum-ultraviolet apparatus so he could measure the absolute reflectance of a sample at 45° angle of incidence. Thonn and Azzam[157] have calculated the polarizing properties of dielectric-coated metal mirrors at 2.8 μm in the infrared. Reflections from 2, 3, or 4 such mirrors at the Brewster angle should give excellent performance, although the polarizer would be quite long.

Brewster Angle Transmission Polarizers

To help overcome the beam-deviation problem and the extreme length of reflection-type polarizers, Brewster angle polarizers are often used in transmission, particularly in the infrared, where transparent materials are available. At the Brewster angle, all of the *p* component and an appreciable fraction of the *s* component are transmitted. Thus, several plates must be used to achieve a reasonable degree of polarization. The higher the refractive index of the plates, the fewer are required.

Tables 1 and 2 in Chap. 12, "Polarization" give equations for the transmittances and degree of polarization for a single plate and multiple plates at any angle of incidence in terms of R_s and R_p for a single surface, as well as these same quantities at the Brewster angle. Conn and Eaton[182] have shown that the formulas which assume incoherent multiple reflections within each plate and none between plates give the correct degree of polarization for a series of Zapon lacquer films ($n = 1.54$) and also for a series of eight selenium films, whereas the formula of Provostaye and Desains[183] predicted values which were much too low. These authors also point out that the number of multiply reflected beams between plates that enter the optical system depends on the spacing between plates and the diaphragm used to limit the number of beams. One can use a fanned arrangement, as suggested by Bird and Shurcliff,[184] to eliminate these multiply reflected beams. Internal reflections within each plate can be removed by wedging the plates.[184]

Most of the infrared Brewster angle transmission polarizers described in the literature have been made of selenium, silver chloride, or polyethylene sheet; they are listed in Table 5. For wavelengths

TABLE 5 Infrared Brewster Angle Transmission Polarizers

Material	Description	Wavelength range, μm	Reference
Se	5 or 6 unbacked films (4 μm thick) at 65° angle of incidence (Brewster angle 68.5°)	2–14	Elliott and Ambrose[185] Elliott et al.[186]
Se	5 unbacked films at 65° incidence (different method of preparation from above)		Ames and Sampson[187]
Se	8 unbacked films at the Brewster angle		Conn and Eaton[182]
Se	Se films (3–8 μm thick) evaporated on one side of collodion films; 68.5° angle of incidence	1–15	Barchewitz and Henry[151]
Se	1–6 unbacked films (1.44–8 μm thick) at 68° angle of incidence	Visible-20	Duverney[188]
Se	3 unbacked films (0.95 μm thick) at 71° angle of incidence	6–17	Hertz[189]
Se	5 Formvar films coated on both sides with Se (various thicknesses) at 65° angle of incidence	1.8–3.2	Buijs[190]
Se	Unbacked films (different method of preparation from Elliott et al.[186])		Bradbury and Elliott[191]
Se	4 to 6 pleated unsupported films (4–8 μm thick) at the Brewster angle	2.5–25	Greenler et al.[192]
AgCl	3 plates (1 mm thick) at 63.5° angle of incidence	Visible-15	Wright[193]
AgCl	6–12 plates (0.05 mm thick) at 60–75° angle of incidence	2–20	Newman and Halford[78]
AgCl	6 plates (0.5 mm thick) at 63.5° stacked in alternate directions		Makas and Shurcliff[194]
AgCl	Suggest 6 wedge-shaped plates at 68° stacked in alternate directions in a fanned arrangement		Bird and Shurcliff[184]
AgCl	2 V-shaped plates (3.2 mm thick) at 77° angle of incidence; large aperture		Bennett et al.[195]
KRS-5	1–3 thallium bromide-iodide plates (1 and 4 mm thick) at polarizing angle	1–15	Lagemann and Miller[196]
ZnS	4 glass plates (0.1 mm thick) coated on both sides with uniform ZnS films of same thickness (several sets of plates to cover extended wavelength range)	Visible-6	Huldt and Staflin[197]
ZnSe	6 plates, extinction ratio of 800 at 4 μm	4	Leonard et al.[198]
Ge	1 single-crystal Ge plate (0.8 mm thick) at 76° angle of incidence		Meier and Günthard[199]
Ge	2 plates (1 mm thick) in an X-shaped arrangement at 76° angle of incidence		Harrick[200]
Ge	3 plates (2 wedged) at the Brewster angle	2–6	Murarka and Wilner[201]
Polyethylene	12 sheets (8 μm thick) at the Brewster angle	6–20 (absorption bands 6–14)	Smith et al.[202]
Polyethylene	9–15 sheets (20–50 μm thick) at the Brewster angle (55°)	30–200	Mitsuishi et al.[137]
Polyethylene	4 sheets at the Brewster angle	200–350	Hadni et al.[136]
Polyethylene	12 sheets (5 μm thick) at the Brewster angle	1.5–13 (selected wavelengths)	Walton and Moss[153]
Polyethylene	1–15 stretched sheets (12.7 μm thick) at the Brewster angle	10.6	Rampton and Grow[203]
Polyethylene	20 sheets (30 μm thick) at the Brewster angle	45–200	Munier et al.[204]
Polyethylene	25–30 sheets at the Brewster angle	54.6	Hilton and Jones[111]
Melinex	11–13 polyethylene terephthalate (Melinex) sheets (4.25–9 μm thick) at the Brewster angle	1–5	Walton et al.[205]

TABLE 6 Ultraviolet Brewster Angle Transmission Polarizers

Material	Description	Wavelength range, Å	Reference
LiF	4–8 plates (0.3–0.8 mm thick) at 60° angle of incidence (Brewster angle 55.7–58.7°) stacked in alternate directions	1200–2000	Walker[206]
LiF	8 plates	1100–3000	Hinson[207]
LiF	8 plates (0.25–0.38 mm thick) at 60° angle of incidence stacked in groups of 4 in alternate directions	1200–2000	Heath[208]
CaF_2	4 to 8 wedged plates stacked in alternate directions in fanned arrangement at 65° angle of incidence (Brewster angle 56.7)	1500–2500	Schellman et al.[209]
Al	Calculations of polarizing efficiency for 1000-Å-thick unbacked Al film, 1000- and 500-Å Al films each covered with 30-Å Al_2O_3 and 100-Å Au films	300–800	Hunter[158]

longer than 3 μm, where calcite polarizing prisms become highly absorbing, to about 10 μm, beyond which wire-grid polarizers have good extinction ratios, Brewster angle transmission polarizers are the most useful, since the better-extinction, on-axis reflection-type polarizers (see "Brewster Angle Reflection Polarizers" section on p. 13.34) are impossibly long. Some of the interference polarizers described in the following sections "Interference Polarizers" and "Polarizing Beam Splitters" are superior if the beam-convergence angle is small. Ultraviolet Brewster angle transmission polarizers are not nearly as common; LiF and CaF_2 have mainly been used from about 1500 to 2500 Å (see Table 6). In the wavelength region where calcite polarizing prisms are usable (>2140 Å), Brewster angle polarizers have the advantage of a larger linear aperture and less absorption.

Low-absorption glass pile-of-plates polarizers have been used in the visible spectral region by Weiser,[210] in preference to more absorbing Glan-Thompson prism polarizers, to increase the power output of giant-pulse ruby lasers. Weinberg[211] calculated the degree of polarization of glass and silver chloride plates, but he did not calculate the transmittance of his polarizers.

Interference Polarizers

When the sheets or films constituting a non-normal-incidence transmission polarizer are thin and have very smooth surfaces, the internally reflected beams can interfere constructively or destructively. In this case, the transmittance of the *p* component remains unity at the Brewster angle (where $R_p = 0$) and only oscillates slightly (with respect to wavelength) for angles close to the Brewster angle. However, the *s* transmittance varies from a maximum of unity to a minimum of $(1-R_s)^2/(1+R_s)^2$ whenever λ changes by an amount that will make the quantity $(nd \cos \theta_1)/\lambda$ in Eq. (26) in Chap. 12, "Polarization" change by 1/2.* These transmittance oscillations are only ±0.225 for a single film of refractive index 1.5 but can become as large as ±0.492 when $n = 4.0$. Since the *p* transmittance remains essentially constant, the extinction ratio will vary cyclically with the *s* transmittance, as can be seen in the upper curve of Fig. 17 for a 2.016-μm-thick selenium film.

If a transmission polarizer with a good extinction ratio is needed for use over a limited wavelength range, it can be made of several uniform films of a thickness that yields a minimum extinction ratio in the given wavelength region. The extinction ratio for a series of *m* films is $(T_s/T_p)^m$ when there are no multiple reflections between them. In this way only *half* as many films would be needed to achieve a given extinction ratio as would be necessary if interference effects were not present. This rather surprising result can be seen from the expressions for $(T_s)_{\text{sample}}$ for *m* plates with and without interference effects in Table 2 in Chap. 12, "Polarization." Assuming no multiple

*The approximate expression for this wavelength interval $\Delta\lambda$ (assuming that the oscillations are sufficiently close together for $\lambda_1\lambda_2 \approx \lambda_2$) is given in Eq. (27) in Chap. 12, "Polarization."

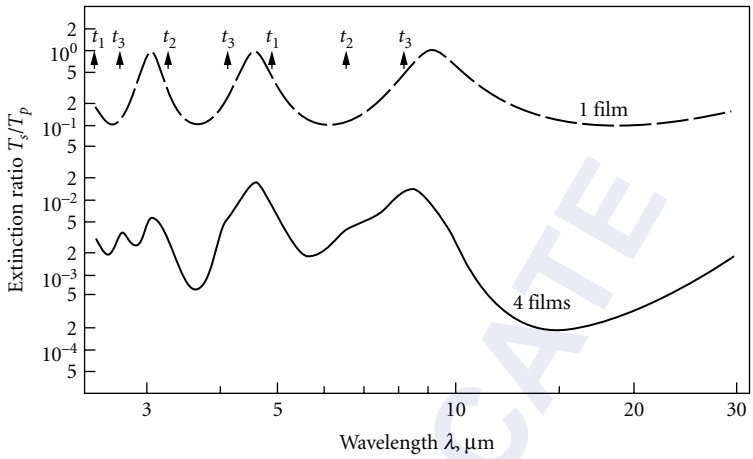

FIGURE 17 Calculated extinction ratios for a series of selenium films ($n = 2.46$) as a function of wavelength from 2.5 to 30 μm. Light is incident at the Brewster angle, 67.9°, and multiply reflected beams interfere within the film. The upper curve is for a single film 2.016 μm thick; arrows indicate positions of maxima for three thinner films: $t_1 = 1.080$ μm, $t_2 = 1.440$ μm, and $t_3 = 1.800$ μm. The lower curve is the extinction ratio for the four films in series assuming no reflections between films. The calculated p transmittance for each film (and for four films in series) is unity at the Brewster angle.

reflections between plates, the expressions are $[2n^2/(n^4+1)]^{2m}$ and $[2n^2/(n^4+1)]^m$, respectively. Hertz[189] achieved a degree of polarization of 99.5 percent in the 6- to17-μm region using three unbacked selenium films 0.95 μm thick. Conn and Eaton[182] obtained only a slightly better performance with eight thicker nonuniform selenium films.

As can be seen in Fig. 17, the calculated extinction ratio for the 2.016-μm-thick film goes to unity at 3.0, 4.6, and 9.2 μm, indicating that the *s* as well as the *p* transmittance at these wavelengths is unity. This ratio will remain unity at the above wavelengths if there are several nonabsorbing films of the same thickness. Even if the films have slightly different thicknesses, or if their surfaces are somewhat rough, interference effects may still persist, adversely affecting polarizer performance. Such effects have been observed by Elliott et al.,[186] Barchewitz and Henry,[151] Duverney,[188] Mitsuishi et al.,[137] and Walton et al.[205]

By choosing films of appropriate thicknesses, interference effects can be used to advantage. The lower curve in Fig. 17 shows the extinction ratio obtained if four selenium films of thicknesses 1.08, 1.44, 1.80, and 2.02 μm are used at the Brewster angle as a transmission polarizer. (The wavelengths at which maxima occur for the three thinner films are indicated by arrows in the upper portion of the figure.) In this example the extinction ratio for the four films in series is better than 2×10^{-2} from 2.5 to 30 μm and at most wavelengths is better than 10^{-2} (corresponding to a degree of polarization in excess of 98 percent). In the 11- to 27-μm wavelength region the extinction ratio is better than 10^{-3}. Four thick or nonuniform selenium films without interference effects have a calculated extinction ratio of about 10^{-2}, and six films are required to change this ratio to 10^{-3}. Thus, in the 11- to 27-μm wavelength region, *four* selenium films of appropriate thicknesses *with interference* have a superior extinction ratio to *six* selenium films *without interference.* If one wishes to optimize the extinction ratio over a more limited wavelength range, the film thicknesses can be adjusted accordingly and the extinction ratio improved. Unfortunately, the gain in extinction ratio is offset by a more sensitive angular function than that shown in Fig. 7 in Chap. 12., "Polarization," so that the incident beam must be very well collimated.

Interference effects can also be used to advantage in other types of non-normal-incidence polarizers. Bennett et al.[212] made a transmission polarizer from a series of four germanium films

(ranging in thickness from 0.164 to 0.593 μm), evaporated onto strain-free plates of sodium chloride. The plates were inclined at the Brewster angle for germanium and arranged in the form of an X so that the polarizer would have a large square aperture and would not deviate the beam. An extinction ratio better than 3×10^{-3} was measured at 2.5 μm, and the plates transmitted from 2 to 13 μm. (Calculated extinction ratios in this wavelength range vary from 1×10^{-3} to 2×10^{-4} for radiation incident at the Brewster angle.)

Polarizers consisting of a high refractive index transparent film on a lower refractive index transparent substrate have been suggested for use in the visible wavelength region by Schröder[213] and Abelès.[214] These still have a Brewster angle where $R_p = 0$, and furthermore R_s at this angle is greatly increased over its value for an uncoated low refractive index substrate. Thus, a large-aperture, high-efficiency polarizer with no absorption losses is possible, which should find numerous applications in laser systems. One polarizer of this type, suggested independently by Schröder and by Abelès, would consist of high refractive index titanium dioxide films ($n \approx 2.5$) evaporated onto both sides of a glass substrate ($n = 1.51$). At the Brewster angle, 74.4°, $R_s \approx 0.8$, making this polarizer equivalent to one made from a material of refractive index 4 ($\theta_B = 76.0°$ as shown in Fig. 4 in Chap. 12, "Polarization").* Two glass plates coated on both sides with TiO_2 films should have an extinction ratio of about 1.6×10^{-3} at 5500 Å and about twice that value at the extreme ends of the visible region, according to Abelès.[214] Schröder[213] measured the degree of polarization as a function of angle of incidence for one such TiO_2-coated glass plate and found values comparable to the calculated ones. Kubo[215] calculated the degree of polarization, reflectance, and transmittance (as a function of angle of incidence and wavelength) of a glass plate ($n = 1.50$) covered with a thin transparent film of index, 2.20. His results are similar to those of Abelès and Schröder.

Schopper,[216] Ruiz-Urbieta and Sparrow,[217–219] and Abelès[220] have also investigated making non-normal-incidence reflection polarizers from a thin transparent or absorbing film deposited onto an absorbing substrate. Zaghloul and Azzam[221] proposed using silicon films on fused silica substrates as reflection polarizers for different mercury spectral lines in the visible and ultraviolet regions. Abelès designed some specialized reflection polarizers for use in the vacuum ultraviolet. Unfortunately the wavelength range covered by such a polarizer is very narrow; for one polarizer it was 25 Å at a wavelength of 1500 Å. However, the spectral range could possibly be increased by using several thin films instead of one.

Multilayer film stacks have also been used to produce non-normal-incidence reflection or transmission polarizers by Buchman et al.[222] Buchman[223] later improved the design performance of his polarizers by adding antireflection layers between the repeating groups of layers. Although this type of polarizer has a relatively narrow operating bandwidth, a small angular acceptance, tight wavelength centering, and layer thickness uniformity requirements, it can be used successfully in high power laser systems as shown by Refermat and Eastman.[224] Songer[225] described how to design and fabricate a Brewster angle multilayer interference polarizer out of a titanium dioxide, silicon dioxide multilayer on BK 7 glass for use in a 1.06-μm laser beam. Blanc, Lissberger, and Roy[226] designed, built, and tested multilayer zinc sulfide-cryolite-coated glass and quartz polarizers for use with a pulsed 1.06-μm laser. Recently, Maehara et al.[227] have reported excellent performance for a pair of polarizers coated with 21 ruthenium and silicon films on a silicon wafer over a wide wavelength range in the soft x-ray region. In several designs of multilayer film stacks, both the reflected and transmitted beams are used; they are discussed in the following section.

Polarizing Beam Splitters

Polarizing beam splitters are a special form of non-normal-incidence interference polarizers in which the beam is incident on a multilayer dielectric stack at 45°. The transmitted beam is almost entirely plane-polarized in the *p* direction, while the reflected beam is nearly all plane-polarized

*We are assuming no multiply reflected beams within the substrate in either case.

in the *s* direction. Generally the alternating high and low refractive index dielectric layers are deposited onto the hypotenuses of two right-angle prisms, which are then cemented together to form a cube. The beam enters a cube face normally and strikes the multilayers on the hypotenuse (the high refractive index layer is next to the glass), and the reflected and transmitted beams emerge normal to cube faces, being separated by 90°. Clapham et al.[228] have a good discussion of polarizing beam splitters, which were invented by S. M. MacNeille[229] and developed by Banning.[230] Banning's beam splitter was made with three zinc sulfide and two cryolite layers on each prism; the polarization for white light was greater than 98 percent over a 5°-angle on each side of the normal to the cube face for both the reflected and transmitted beams. Variations on this design have since been proposed by Dobrowolski and Waldorf,[231] Monga et al.,[232] and Mouchart et al.,[233] primarily to improve the laser damage resistance of the device and increase the angular field of view. Dobrowolski and Waldorf[231] designed and built a polarizing beam splitter consisting of a multilayer coating of HfO_2 and SiO_2 deposited onto fused silica and immersed in a water cell that acted like the MacNeille cube. Tests with a 0.308 μm excimer laser showed a high laser damage threshold. The multi-wavelength polarizing beam splitters designed by Monga et al.[232] could be made in large sizes and could withstand high laser power levels. The modified MacNeille cube polarizers designed by Mouchart et al.[233] had angular fields of view that could be increased to about ±10° when the polarizers were used with monochromatic light sources.

Lees and Baumeister[234] designed a frustrated total internal reflection beam splitter that had a multilayer dielectric stack deposited onto the hypotenuse of a prism. Their designs, for use in the infrared spectral region, consisted of multilayer stacks of PbF_2 and Ge deposited onto a germanium prism and covered by a second germanium prism. Azzam[235] designed polarization-independent beam splitters for 0.6328 μm and 10.6 μm using single-layer coated zinc sulfide and germanium prisms. The devices were found to be reasonably achromatic and their beam-splitting ratio could be varied over a wide range with little degradation in polarization properties. Azzam[236] also proposed coating a low-refractive-index dielectric slab on both sides with high-refractive-index dielectric films to make an infrared polarizing beam splitter.

Various high- and low-refractive-index materials have been successfully used in the multilayer stacks. In addition to zinc sufilde and cryolite on glass by Banning[230] and Schröder and Schläfer,[237] layers of a controlled mixture of silicon dioxide and titanium dioxide have been alternated with pure titanium dioxide on fused-silica prisms by Pridatko and Krylova,[238] thorium dioxide and silicon dioxide have been used on fused-silica prisms by Sokolova and Krylova,[239] chiolite (a mixture of sodium and aluminum fluorides) and lead fluoride have been used on fused-silica prisms by Turner and Baumeister,[240] bismuth oxide and magnesium fluoride have been used on EDF glass prisms by Clapham et al.,[228] and zirconium oxide and magnesium fluoride have been used on dense flint-glass prisms by Clapham et al.[228] The calculations involved in optimizing these beam splitters for good polarizing characteristics, achromaticity, and relative insensitivity to angle of incidence are quite involved. Clapham et al.[228] and Turner and Baumeister[240] discuss various calculational techniques frequently used. Clapham[241] also gives the measured characteristics of a high-performance achromatic polarizing beam splitter made with zirconium oxide and magnesium fluoride multilayers.

Although polarizing beam splitters are generally designed so that the *s* and *p* polarized beams emerge at right angles to each other, Schröder and Schläfer[237] have an ingenious arrangement in which a half-wave plate and mirror are introduced into the path of the reflected beam to make it parallel to the transmitted beam and of the same polarization. Other optical schemes to accomplish the same purpose have been described in a later paper.[242]

For some purposes it is desirable to have a beam splitter that is insensitive to the polarization of the incident beam. Baumeister[243] has discussed the design of such beam splitters made from multilayer dielectric stacks of alternating low- and high-refractive-index materials. One of his designs is composed of six dielectric layers for which the extinction ratio T_s/T_p varies from 0.93 to 0.99 in a bandwidth of about 800 Å, with a ±1° variation in the angle of incidence. In principle, any multilayer filter which is nonreflecting at normal incidence will be nonpolarizing at all angles of incidence, according to Baumeister.[244] Costich[245] has described filter designs for use in the near infrared which are relatively independent of polarization at 45° angle of incidence.

13.10 RETARDATION PLATES

Introduction

The theory of retardation plates and especially quarter-wave retarders is given in Chap. 12, "Polarization." The basic relation for retardation plates, Eq. (73) in that section, is

$$N\lambda = d(n_e - n_o) \tag{9}$$

where n_o = refractive index of the ordinary ray, n_e = refractive index of the extraordinary ray, d = physical thickness of the plate, and λ = wavelength.

Retardation plates are generally made of mica, stretched polyvinyl alcohol, and quartz, although other stretched plastics such as cellophane, Mylar, cellulose acetate, cellulose nitrate, sapphire, magnesium fluoride, and other materials can also be used (see West and Makas[246]). Polyvinyl alcohol in sheet form transmits well into the ultraviolet beyond the cutoff for natural mica and is thus particularly useful for ultraviolet retardation plates, according to McDermott and Novick.[91] As suggested by Jacobs et al.,[247] permanent birefringence can be thermomechanically induced in the borosilicate optical glass ARG-2, making it an attractive alternate to natural crystalline quartz and mica for large aperture wave plates for laser systems. Refractive indexes and birefringences of some materials are listed in Tables 7 and 8. The birefringences reported for mica and apophyllite should be considered as approximate, since they are measurements made on single samples. There is good reason to believe that the birefringence of apophyllite may be different for other samples, (see "Achromatic Retardation Plates" section on p. 13.48). Although calcite would seem at first to be a good material for retardation plates, its birefringence is so high that an extremely thin piece, less than 1 μm, would be required for a single $\lambda/4$ retardation plate. If a "first-order" or multiple-order plate were constructed (see sections "First-Order Plates" on p. 13.46 and "Multiple-Order Plates" on p. 13.47), or if calcite were used as one component of an achromatic retardation plate (see "Achromatic Retardation Plates" section), the tolerance on the thickness would be very stringent.

Retardation plates are generally made of a single piece of material, although when the thickness required for a plate is too small, two thicker pieces may be used with the fast axis of one aligned parallel to the slow axis of the other to cancel out all but the desired retardation. Plates which are a little too thin or a little too thick may be rotated about an axis parallel or perpendicular to the optic axis

TABLE 7 Refractive Indices of Selected Materials at 5893 Å[248]

Material	n_o	n_e
Positive Uniaxial Crystals		
Ice, H_2O	1.309	1.313
Sellaite, MgF_2	1.378	1.390
Apophyllite, $2[KCa_4Si_8O_{20}(F, OH)\cdot 8H_2O]$	1.535±	1.537±
Crystalline quartz, SiO_2	1.544	1.553

to change the retardation to the desired amount, as suggested by Gieszelmann et al.,[267] and Daniels.[268] There are also some novel circular polarizers and polarization rotators for use in the far ultraviolet (see the papers by Mcllrath,[162] Saito et al.,[269] and Westerveld et al.[270]), far infrared (Richards and Smith,[271] Johnston,[272] and Gonates et al.[273]), and visible region (Lostis,[274] and Greninger[275]).

Achromatic retardation plates which have the same retardation over a range of wavelengths can be made from two or more different materials or from two or more plates of the same material whose axes are oriented at appropriate angles with respect to each other. These latter devices are known as composite plates (see "Composite Retardation Plates" section on p. 13.52 and the earlier polarization chapter[1]), and although they can change plane-polarized light into circularly polarized light, they do not have all the other properties of true retardation plates. By far the most achromatic $\lambda/4$ retarders are devices, such as the Fresnel rhomb, which obtain their retardation from internal reflections at angles greater than the critical angle.

Mica retardation plates are mentioned in "Mica Retardation Plates" section and are discussed in detail in the earlier polarization chapter,[1] which includes the theory of multiple reflections; "Crystalline Quartz Retardation Plates" section on p. 13.46 is devoted to various types of crystalline-quartz retardation plates, and "Achromatic Retardation Plates" section on p. 13.48 covers all achromatic retardation plates, except those of the rhomb-type; the latter are mentioned in "Rhombs as Achromatic $\lambda/4$ Retarders" section on p. 13.52 and in detail by Bennett[276] and also in the earlier polarization chapter.[1] Various types of composite plates and unusual retardation plates are also described in detail in Ref. 1.

Methods for making and testing quarter-wave plates including ways of splitting mica, how to distinguish between fast and slow axes, methods for measuring retardations close to $\lambda/4$, and the tolerance on plate thickness have all been described in detail in the earlier polarization chapter.[1] An additional paper by Nakadate[277] shows how Young's fringes can be used for a highly precise measurement of phase retardation.

Waveplates are all sensitive to some degree to temperature changes, variations in the angle of incidence, coherence effects in the light beam, and wavelength variations. Multiple-order plates are much more sensitive than "first-order" or single-order plates. Hale and Day[278] discuss these effects for various types of waveplates and suggest designs that are less sensitive to various parameters.

Most retardation plates are designed to be used in transmission, generally at normal incidence. However, there are also reflection devices that act as quarter-wave and half-wave retarders and polarization rotators. In the vacuum ultraviolet, Westerveld et al.[270] produced circularly polarized light by using Au-coated reflection optics. Saito et al.[269] used an evaporated Al mirror as a retardation plate at 1216 Å, Lyman α radiation, following earlier work by Mcllrath.[162] Greninger[275] showed that a three-mirror device could be used in place of a half-wave plate to rotate the plane of polarization of a plane-polarized beam and preserve the collinearity of input and output beams. Johnston[272] used a different three-mirror arrangement for the same application in the far-infrared. Thonn and Azzam[157] designed three-reflection half-wave and quarter-wave retarders from single-layer dielectric coatings on metallic film substrates. They showed calculations for ZnS-Ag film-substrate retarders used at 10.6 μm. Previously Zaghloul, Azzam, and Bashara[279,280] had proposed using a SiO_2 film on Si as an angle-of-incidence tunable reflection retarder for the 2537-Å mercury line in the ultraviolet spectral region. Kawabata and Suzuki[281] showed that a film of MgF_2 on Ag was superior to Zaghloul et al.'s design at 6328 Å. They also performed calculations using A1, Cu, and Au as the metals and concluded that Ag worked best.

Mica Retardation Plates

Mica quarter-wave plates can be made by splitting thick sheets of mica down to the appropriate thickness, as described by Chu et al.,[282] and in the earlier polarization chapter.[1] Since the difference between the velocities of the ordinary and extraordinary rays is very small, the mica sheets need not be split too thin; typical thicknesses lie in the range 0.032–0.036 mm for yellow light. The fast and slow axes of a mica quarter-wave plate can be distinguished using Tutton's test, as mentioned in Strong's book,[283] and the retardation can be measured using one of several rather simple tests.[1]

If the mica sheets are used without glass cover plates, multiply reflected beams in the mica can cause the retardation to oscillate around the value calculated from the simple theory, as described in the earlier polarization chapter.[1] Fortunately this effect can be eliminated in one of several ways.[1] Mica does have one serious drawback. There are zones in the cleaved mica sheets which lie at angles to each other and which do not extinguish at the same angle, as noted by Smith.[284] Thus, extinction cannot be obtained over the whole sheet simultaneously. In very critical applications such as ellipsometry, much better extinction can be obtained using quarter-wave plates made of crystalline quartz ("Crystalline Quartz Retardation Plates" section next), which do not exhibit this effect. Properties of mica quarter-wave plates and methods for making and testing all $\lambda/4$ plates are discussed in detail in the earlier polarization chapter.[1]

Crystalline-Quartz Retardation Plates

Crystalline quartz is also frequently used for retardation plates, particularly those of the highest quality. It escapes the problem of zones with different orientations like those found in mica. The thickness of quartz required for a single quarter-wave retardation at the 6328-Å helium-neon laser line is about 0.017 mm, much too thin for convenient polishing. If the plate is to be used in the infrared, single-order quarter-wave plates are feasible (see "Single-Order Plates in the Infrared" section). Two types of quartz retardation plates are generally employed in the visible and ultraviolet regions: so-called "first-order" plates made of two pieces of material "First-Order Plates section" which are the best for critical applications, and multiple-order plates made of one thick piece of crystalline quartz (see "Multiple-Order Plates," "Sensitivity to Temperature Changes," and "Sensitivity to Angle of Incidence" sections). The multiple-order plates are generally not used for work of the highest accuracy since they are extremely sensitive to small temperature changes (see "Sensitivity to Temperature Changes" section) and to angle of incidence. Also, they have $\lambda/4$ retardation only at certain wavelengths; at other wavelengths the retardation may not even be close to $\lambda/4$.

When using any of the different types of retardation plates at a single wavelength, the methods for measuring the retardation and for distinguishing between fast and slow axes given in the earlier polarization chapter[1] can be used.

"First-Order" Plates A so-called "first-order" plate is made by cementing together two nearly equal thicknesses of quartz such that the fast axis of one is aligned parallel to the slow axis of the other (both axes lie in planes parallel to the polished faces). The plate is then polished until the difference in thickness between the two pieces equals the thickness of a single $\lambda/4$ plate. The retardation of this plate can be calculated from Eq. (9) by setting d equal to the *difference in thickness* between the two pieces. The "first-order" plate acts strictly like a single-order quarter-wave plate with respect to the variation of retardation with wavelength, temperature coefficient of retardation, and angle of incidence.

The change in phase retardation with temperature at 6328 Å, as calculated from equations given in the earlier polarization chapter,[1] is 0.0091°/°C, less than one-hundredth that of the 1.973-mm multiple-order plate discussed in "Sensitivity to Temperature Changes" section on p. 13.48. The change in retardation with angle of incidence* at this wavelength is also small: $(\Delta N)_{10°} = 0.0016$, as compared with 0.18 for the thick plate (see "Sensitivity to Angle of Incidence" section on p. 13.48).

A "first-order" quartz $\lambda/4$ plate has several advantages over a mica $\lambda/4$ plate: (1) Crystalline quartz has a uniform structure, so that extinction can be obtained over the entire area of the plate at a given angular setting. (2) Since the total plate thickness is generally large, of the order of 1 mm or so, the coherence of the multiple, internally reflected beams is lost and there are no oscillations in the transmitted light or in the phase retardation. (3) Crystalline quartz is not pleochroic, except in the infrared, so that the intensity transmitted along the two axes is the same. (4) Crystalline quartz transmits farther into the ultraviolet than mica, so that "first-order" plates can be used from about 0.185–2.0 μm (see Table 8).

*Grechushnikov[285] has an incorrect relation for the change in phase retardation with angle of incidence [his Eq. (2)]. He assumed that the retardations in the two halves of the plate add rather than subtract, yielding a retardation comparable to that of a thick quartz plate.

Single-Order Plates in the Infrared Although a crystalline-quartz retardation plate which is $\lambda/4$ in the visible is too thin to make from a single piece of material, the thickness required for such a plate is larger in the infrared. Jacobs and coworkers[267] describe such a $\lambda/4$ plate for use at the 3.39-μm helium-neon laser line. They measured the birefringence of quartz at this wavelength and found it to be 0.0065 ± 0.0001, so that the thickness required for the plate was 0.1304 mm. The actual plate was slightly thinner (0.1278 mm), so that it was tipped at an angle of 10° (rotating it about an axis parallel to the optic axis) to give it exactly $\lambda/4$ retardation (see "Sensitivity to Angle of Incidence" section on p. 13.48). Maillard[262] has also measured the birefringence of quartz at 3.39 μm and 3.51 μm and obtained values of 0.00659 and 0.00642, respectively (both ±0.00002), in agreement with Jacobs' value. These data lie on a smooth curve extrapolated from the values of Shields and Ellis.[251]

A problem encountered when using crystalline quartz in the infrared is that, in general, the ordinary and extraordinary rays have different absorption coefficients; thus it may be impossible to construct a perfect wave plate regardless of the relative retardation between the rays. For an absorbing wave plate to have a retardation of exactly $\lambda/4$, the requirement

$$\left(\frac{n_o+1}{n_e+1}\right)^2 \exp\left[-\frac{(\alpha_e-\alpha_o)\lambda}{8(n_e-n_o)}\right]=1 \tag{10}$$

must be met;[267] α_e and α_o are the absorption coefficients for the extraordinary and ordinary rays, respectively. At wavelengths shorter than 3.39 μm, the birefringence is small enough for it to be possible to approximate the condition in Eq. (10) closely whenever $\alpha_e \approx \alpha_o$. Values of these quantities are given by Drummond.[286] Gonatas et al.[273] concluded that, in the far infrared and submillimeter wavelength region, the effect of different absorption coefficients in the crystalline quartz was small and could be corrected.

Another problem which occurs for crystalline quartz and also for sapphire[273] in the infrared is that the Fresnel reflection coefficients are slightly different for the ordinary and extraordinary rays since the refractive indexes and absorption coefficients are in general different. One possible solution is to deposit isotropic thin films on the crystal surfaces.[273] The refractive index of these films is chosen to balance the anisotropic absorption effect by making the Fresnel reflection coefficients appropriately anisotropic. On the other hand, if anisotropic Fresnel reflection proves to be undesirable, it can be greatly diminished by using an antireflection coating, as suggested by Gieszelmann et al.[267]

If a single-order crystalline-quartz plate is to be used for a continuous range of wavelengths, both the phase retardation and the transmittance of the ordinary and extraordinary rays will oscillate as a function of wavelength because of multiple coherent reflections in the quartz. The separation between adjacent maxima in the phase retardation can be calculated from Eq. (144) in the earlier polarization chapter.[1] Using $\lambda = 3.3913$ μm, $n \approx 1.4881$, and $d = 127.8$ μm, $\Delta\lambda = 0.03024$ μm, an amount which should be well-resolved with most infrared instruments. Thus, if a wave plate is to be used over a range of wavelengths, it would be well to antireflect the surfaces to eliminate the phase oscillations.

Multiple-Order Plates Thick plates made from crystalline quartz are sometimes used to produce circularly polarized light at a single wavelength or a discrete series of wavelengths. The plate thickness is generally of the order of one or more millimeters so that the retardation is an integral number of wavelengths plus $\lambda/4$, hence the name multiple-order wave plate. This plate acts like a single $\lambda/4$ plate provided it is used only at certain specific wavelengths; at other wavelengths it may not even approximate the desired retardation. For example, a 1.973-mm-thick quartz plate was purchased which had an order of interference $N = 28.25$ at 6328 Å. From Eq. (9) and Table 8, this plate would have $N = 30.52$ at 5890 Å, and would thus be an almost perfect half-wave plate at this latter wavelength.

If a multiple-order plate is used to produce circularly polarized light at unspecified discrete wavelengths e.g., to measure circular or linear dichroism, it can be placed following a polarizer and oriented at 45° to the plane of vibration of the polarized beam. When the wavelengths are such that N calculated from Eq. (9) equals 1/4, 3/4, or in general $(2M - 1)/4$ (where M is a positive integer),

the emerging beam will be alternately right and left circularly polarized. The frequency interval $\Delta\nu$ between wavelengths at which circular polarization occurs is

$$\Delta\nu = \frac{1}{2d(n_e - n_o)} \tag{11}$$

where $\nu = 1/\lambda$. If the birefringence is independent of wavelength, the retardation plate will thus produce circularly polarized light at equal intervals on a frequency scale and can conveniently be used to measure circular dichroism, as described by Holzwarth.[287]

In order to approximately calibrate a multiple-order retardation plate at a series of wavelengths, it can be inserted between crossed polarizers and oriented at 45° to the polarizer axis. Transmission maxima will occur when the plate retardation is $\lambda/2$ or an odd multiple thereof; minima will occur when the retardation is a full wave or multiple thereof. If the axes of the two polarizers are parallel, maxima in the transmitted beam will occur when the plate retardation is a multiple of a full wavelength. The birefringence of the retardation plate can be determined by measuring the wavelengths at which maxima or minima occur if the plate thickness is known. Otherwise d can be measured with a micrometer, and an approximate value of $n_e - n_o$ can be obtained.

Palik[288] made and tested a 2.070-mm-thick CdS plate for the 2- to 15-μm infrared region and also made thick retardation plates of SnSe, sapphire, and crystalline quartz to be used in various parts of the infrared. Holzwarth[287] used a cultured-quartz retardation plate 0.8 mm thick to measure circular dichroism in the 1850- to 2500-Å region of the ultraviolet; Jaffe et al.[289] measured linear dichroism in the ultraviolet using a thick quartz plate and linear polarizer.

Sensitivity to Temperature Changes Small temperature changes can have a large effect on the retardation of a multiple-order plate. The method for calculating this effect was given earlier in the polarization chapter.[1] For the 1.973-mm-thick quartz plate mentioned in Multiple-Order Plates" section (N = 28.25 at 6328 Å), the phase retardation will decrease 1.03° for each Celsius degree increase in temperature. If the temperature of the wave plate is not controlled extremely accurately, the large temperature coefficient of retardation can introduce sizable errors in precise ellipsometric measurements in which polarizer and analyzer settings can be made to ±0.01°.

Sensitivity to Angle of Incidence The effect of angle of incidence (and hence field angle) on the retardation was calculated in the earlier polarization chapter.[1] It was shown there that the change in phase retardation with angle of incidence, $2\pi(\Delta N)_\theta$, is proportional to the total thickness of the plate (which is incorporated into N) and the square of the angle of incidence when the rotation is about an axis parallel to the optic axis. If the 1.973-mm-thick plate mentioned previously is rotated parallel to the optic axis through an angle of 10° at a wavelength of 6328 Å, the total retardation changes from 28.25 to 28.43, so that the $\lambda/4$ plate is now nearly a $\lambda/2$ plate.

If the plate had been rotated about an axis *perpendicular* to the direction of the optic axis, in the limit when the angle of incidence is 90°, the beam would have been traveling along the optic axis; in this case the ordinary and extraordinary rays would be traveling with the same velocities, and there would have been *no retardation* of one relative to the other. For any intermediate angle of incidence the retardation would have been *less than* the value at normal incidence. The relation for the retardation as a function of angle of incidence is not simple, but the retardation will be approximately as angle-sensitive as it was in the other case. An advantage of rotation about either axis is that, with care, one can adjust the retardation of an inexact wave plate to a desired value. Rotation about an axis *parallel* to the optic axis will *increase* the retardation, while rotation about an axis *perpendicular* to the optic axis will *decrease* the retardation.

Achromatic Retardation Plates

Achromatic retardation plates are those for which the phase retardation is independent of wavelength. The name arose because when a plate of this type is placed between polarizers, it does not appear colored and hence is achromatic, as shown by Gaudefroy.[290] In many applications, a truly

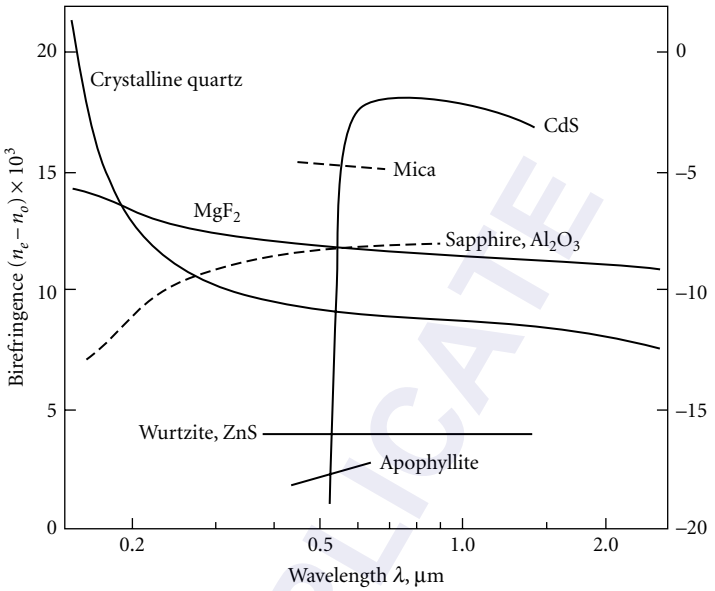

FIGURE 18 Birefringence of various optical materials as a function of wavelength. The scale at the left is for materials having a positive birefringence (*solid curves*), and the scale at the right is for materials with a negative birefringence (*dashed curves*).

achromatic retardation plate is not required. Since the wavelength of light changes by less than a factor of 2 across the visible region, a quarter- or half-wave mica plate often introduces only tolerable errors even in white light. The errors that do occur cancel out in many kinds of experiments.

Achromatic retardation plates can be made in various ways. The most achromatic are based on the principle of the Fresnel rhomb, in which the phase retardation occurs when light undergoes two or more total internal reflections (see next section "Rhombs as Achromatic $\lambda/4$ Retarders" and Ref. 1). A material with the appropriate variation of birefringence with wavelength can also be used. Such materials are uncommon, but plates of two or more different birefringent materials can be combined to produce a reasonably achromatic combination. Composite plates, consisting of two or more plates of the same material whose axes are oriented at the appropriate angles, can be used as achromatic circular polarizers or achromatic polarization rotators,[1] although they do not have all the properties of true $\lambda/4$ or $\lambda/2$ plates. One unusual achromatic half-wave plate is described in the earlier polarization chapter.[1]

The simplest type of achromatic retardation plate could be made from a single material if its birefringence satisfied the requirement that $(n_e - n_o)/\lambda$ be independent of wavelength, i.e., that $n_e - n_o$ be directly proportional to λ. This result follows from Eq. (9) since $d(n_e - n_o)/\lambda$ must be independent of λ to make N independent of wavelength. (The plate thickness d is constant.) The birefringences of various materials are listed in Table 8 and plotted in Figs. 18 and 19. Only one material, the mineral apophyllite, has a birefringence which increases in the correct manner with increasing wavelength.[264*] A curve of the phase retardation vs. wavelength for a quarter-wave apophyllite plate is shown as curve *D* in Fig. 20. Also included are curves for other so-called achromatic $\lambda/4$ plates as well as for simple $\lambda/4$ plates of quartz and mica. The phase retardation of apophyllite is not as constant with λ as that of the rhomb-type retarders, but it is considerably more constant than that of the other "achromatic" $\lambda/4$ plates. Since the birefringence of apophyllite is small, a $\lambda/4$ plate needs

*For materials having a negative birefringence the requirement is that $-(n_e - n_o)$ be proportional to λ.

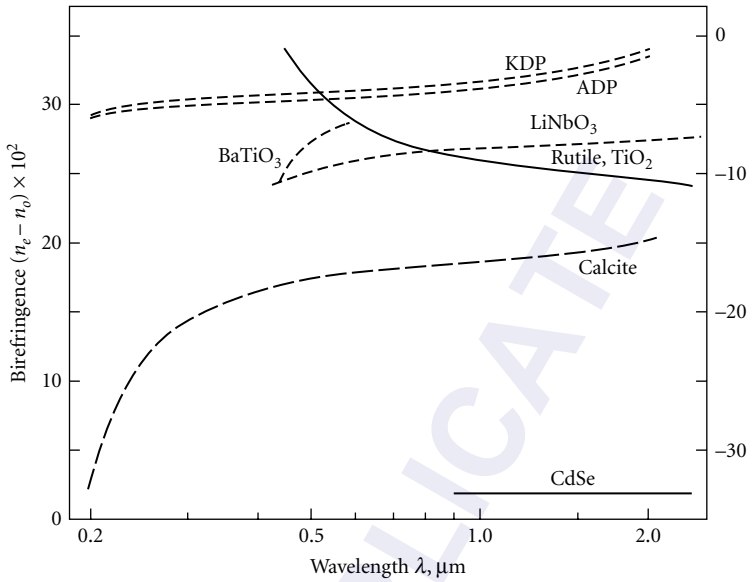

FIGURE 19 Birefringence of various optical materials which have larger birefringences than those shown in Fig. 18. The scale at the left is for materials having a positive birefringence (*solid curves*), and the scale at the right is for materials with a negative birefringence (*dashed curves*).

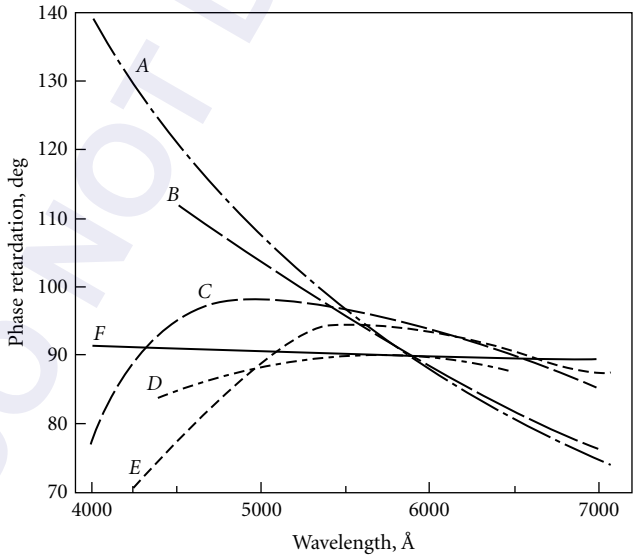

FIGURE 20 Curves of the phase retardation vs. wavelength for $\lambda/4$ plates: *A*, quartz; *B*, mica; *C*, stretched plastic film; *D*, apophyllite; and *E*, quartz-calcite achromatic combination. Curve *F* is for a Fresnel rhomb but is representative of all the rhomb-type devices. (*After Bennett.*[276])

a thickness of about 56.8 μm, which is enough for it to be made as a single piece rather than as a "first-order" plate. Unfortunately optical-grade apophyllite is rare, the sample for which data are reported here having come from Sweden. There is some indication that the optical properties of other apophyllite samples may be different. Isotropic, positive, and negative-birefringent specimens have been reported by Deer et al.[291] According to them, the optical properties of apophyllite are often anomalous, some specimens being isotropic, uniaxial negative, or even biaxial with crossed dispersion of optic axial planes. Whether many samples have the favorable birefringence of the Swedish sample is uncertain.

Certain types of plastic film stretched during the manufacturing process have birefringences which are nearly proportional to wavelength and can serve as achromatic retardation plates if they have the proper thickness, as pointed out by West and Makas.[246] Curve *C* in Fig. 20 is the retardation of a stretched cellulose nitrate film as measured by West and Makas.[246] A combination of stretched cellulose acetate and cellulose nitrate sheets with their axes parallel will also make a reasonably achromatic $\lambda/4$ plate over the visible region. The advantages of using stretched plastic films for retardation plates are that they are cheap, readily available, have a retardation which is uniform over large areas, and can be used in strongly convergent light. However, each sheet must be individually selected since the birefringence is a strong function of the treatment during the manufacturing process and the sheets come in various thicknesses, with the result that their retardations are not necessarily $\lambda/4$ or $\lambda/2$. Also, Ennos[292] found that while the magnitude of the retardation was uniform over large areas of the sheets, the direction of the effective crystal axis varied from point to point by as much as 1.5° on the samples he was testing. Thus, film retarders appear to be excellent for many applications but are probably not suitable for measurements of the highest precision.

A reasonably achromatic retardation plate can be constructed from pairs of readily available birefringent materials such as crystalline quartz, sapphire, magnesium fluoride, calcite, or others whose birefringences are listed in Table 8. Assume that the plate is to be made of materials *a* and *b* having thicknesses d_a and d_b, respectively (to be calculated), and that it is to be achromatized at wavelengths λ_1 and λ_2. From Eq. (9) we can obtain the relations

$$\begin{aligned} N\lambda_1 &= d_\alpha \Delta n_{1a} + d_b \Delta n_{1b} \\ N\lambda_2 &= d_a \Delta n_{2a} + d_b \Delta n_{2b} \end{aligned} \tag{12}$$

where $N = 1/4$ for a $\lambda/4$ plate, 1/2 for a $\lambda/2$ plate, etc., and the Δn's are values of $n_e - n_o$ for the particular materials at the wavelengths specified; Δn will be positive for a positive uniaxial crystal and negative for a negative uniaxial crystal. (A positive uniaxial material can be used with its fast axis crossed with that of another positive uniaxial material; in this case the first material will have a negative Δn.) Equations (12) can be solved for d_a and d_b:

$$d_\alpha = \frac{N(\lambda_1 \Delta n_{2b} - \lambda_2 \Delta n_{1b})}{\Delta n_{1a} \Delta n_{2b} - \Delta n_{1b} \Delta n_{2a}} \quad d_b = \frac{N(\lambda_2 \Delta n_{1a} - \lambda_1 \Delta n_{2a})}{\Delta n_{1a} \Delta n_{2b} - \Delta n_{1b} \Delta n_{2a}} \tag{13}$$

As an example of a compound plate, let us design a $\lambda/4$ plate of crystalline quartz and calcite and achromatize it at wavelengths $\lambda_1 = 0.508$ μm and $\lambda_2 = 0.656$ μm. Quartz has a positive birefringence and calcite a negative birefringence (Table 8) so that Δn_{1a} and Δn_{2a} (for quartz) are positive Δn_{1b} and Δn_{2b} (for calcite) are negative. Equations (13) are satisfied for $d_{qtz} = 426.2$ μm and $d_{calc} = 21.69$ μm; thus the phase retardation is exactly 90° at these two wavelengths. An equation of the form of those in Eqs. (12) is now used to calculate *N* for all wavelengths in the visible region using birefringence values listed in Table 8, and the results are plotted as curve *E* in Fig. 20. Although the achromatization for this quartz-calcite combination is not as good as can be obtained with a rhomb-type device or apophyllite, the phase retardation is within ±5° of 90° in the wavelength region 4900–7000 Å and is thus much more constant than the retardation of a single mica or quartz $\lambda/4$ plate. Better two-plate combinations have been calculated by Beckers,[249] the best being MgF_2-ADP and MgF_2-KDP, which have maximum deviations of ±0.5 and ±0.4 percent, respectively, compared with ±7.2 percent

for a quartz-calcite combination over the same 4000- to 7000-Å wavelength region. The thicknesses of the materials which are required to produce $\lambda/4$ retardation* are $d_{MgF_2} = 113.79\,\mu m$, $d_{ADP} = 26.38\,\mu m$, and $d_{MgF_2} = 94.47\,\mu m$, $d_{KDP} = 23.49\,\mu m$. Since the ADP and KDP must be so thin, these components could be made in two pieces as "first-order" plates.

Other two-component compound plates have been proposed by Chandrasekharan and Damany,[261] Gaudefroy,[290] Ioffe and Smirnova,[293] and Mitchell.[294] The paper by Ioffe and Smirnova describes a quartz-calcite combination similar to the one illustrated earlier, but it contains various numerical errors which partially invalidate the results.

If better achromatization is desired and one does not wish to use a rhomb-type $\lambda/4$ device, three materials can be used which satisfy the relations

$$\begin{aligned} N\lambda_1 &= d_a\Delta n_{1a} + d_b\Delta n_{1b} + d_c\Delta n_{1c} \\ N\lambda_2 &= d_a\Delta n_{2a} + d_b\Delta n_{2b} + d_c\Delta n_{2c} \\ N\lambda_3 &= d_a\Delta n_{3a} + d_b\Delta n_{3b} + d_c\Delta n_{3c} \end{aligned} \tag{14}$$

where the Δn's are birefringences of the various materials at wavelengths λ_1, λ_2, and λ_3.

Instead of using only three wavelengths, Beckers[249] suggested that the thicknesses can be optimized such that the maximum deviations from achromatization are minimized over the entire wavelength interval desired. In this way, he obtained a three-component combination of quartz, calcite, and MgF_2 which has a retardation of a full wavelength and a maximum deviation of only ±0.2 percent over the 4000- to 7000-Å wavelength region. The maximum deviation of slightly different thicknesses of these same three materials rises to ±2.6 percent if the wavelength interval is extended to 3000–11,000 Å. Chandrasekharan and Damany[261] have designed a three-component $\lambda/4$ plate from quartz, MgF_2, and sapphire for use in the vacuum ultraviolet. Title[295] has designed achromatic combinations of three-element, four-element, nine-element, and ten-element waveplates using Jones matrix techniques. The nine-element combination is achromatic to within 1° from 3500 to 10,000 Å. He constructed and tested several waveplate combinations, and they performed as designed.

Rhombs as Achromatic $\lambda/4$ Retarders

The simplest stable, highly achromatic $\lambda/4$ retarder with a reasonable acceptance angle and convenient size appears to be a rhomb-type retarder. Several types are available; the choice of which one to use for a specific application depends on (1) the geometry of the optical system (can a deviated or displaced beam be tolerated?), (2) wavelength range, (3) degree of collimation of the beam, (4) beam diameter (determining the aperture of the retarder), (5) space available, and (6) accuracy required. Table 9 summarizes the properties of the various achromatic rhombs. This subject has been covered in detail by Bennett[276] and is condensed from that reference in the earlier polarization chapter.[1] Anderson[296] has compared the retardation of a CdS $\lambda/4$ plate and a Fresnel rhomb in the 10-μm CO_2 laser emission region. Wizinowich[297] used a Fresnel rhomb along with some additional optics to change an unpolarized light beam from a faint star object into linearly polarized light to improve the throughput of a grating spectrograph and make it independent of the input polarization.

Composite Retardation Plates

A composite retardation plate is made up of two or more elements of the same material combined so that their optic axes are at appropriate angles to each other. Some of the composite plates have nearly all the properties of a true retardation plate, whereas others do not. In the earlier polarization chapter,[1]

*Beckers' tables II to V give the thickness of materials required to produce one full-wave retardation. To obtain values of thicknesses for $\lambda/4$ retardation, for example, multiply all d values in the table by 0.25. The percent deviations should remain unchanged.

TABLE 9 Properties of Achromatic Rhombs[275]

Name	Light Path	Internal Angle of Incidence, deg	Material	Refractive Index		Variation of Phase Retardation			
						With Wavelength		With Angle of Incidence	
				n	Wave-Length, Å	Var., deg	Wave-Length, Å	Var., deg	Angle, deg
Fresnel rhomb	Translated	54.7	Crown glass	1.511	5893	2.5	3650–7682	9.1	−7 to +7
Coated Fr. rhomb	Translated	51.5	Crown glass	1.5217	5461	0.4	3341–5461	2.5	−4 to +6
	Translated	54.0	Fused quartz	1.4880	3000	0.7	2148–3341	<0.5	−1.5 to +1.5

composite plates were described which produced circularly polarized light at a given wavelength, those which acted as achromatic circular polarizers, and those which acted as achromatic polarization rotators or pseudo $\lambda/2$ plates. The effect of combining several birefringent plates with their axes at arbitrary angles to each other can be easily understood using the Poincaré sphere. A general treatment of this subject has been given by Ramachandran and Ramaseshan.[298]

13.11 VARIABLE RETARDATION PLATES AND COMPENSATORS

Variable retardation plates can be used to modulate or vary the phase of a beam of plane-polarized light, to measure birefringence in mineral specimens, flow birefringence, or stress in transparent materials, or to analyze a beam of elliptically polarized light such as might be produced by transmission through a birefringent material or by reflection from a metal or film-covered surface. The term compensator is frequently applied to a variable retardation plate since it can be used to compensate for the phase retardation produced by a specimen. Common types of variable compensators include the Babinet and Soleil compensators, in which the total thickness of birefringent material in the light path is changed, the Sénarmont compensator,[1] which consists of a fixed quarter-wave plate and rotatable analyzer to compensate for varying amounts of ellipticity in a light beam, and tilting-plate compensators,[1] with which the total thickness of birefringent material in the light beam is changed by changing the angle of incidence. Electro-optic and piezo-optic modulators can also be used as variable retardation plates since their birefringence can be changed by varying the electric field or pressure. However, they are generally used for modulating the amplitude, phase, frequency, or direction of a light beam, in particular a laser beam, at frequencies too high for mechanical shutters or moving mirrors to follow. Information on electro-optic materials and devices is contained in the chapter on electro-optic modulators by Georgeanne M. Purvinis and Theresa A. Maldonado (Chap. 7 in Vol. V) and in the earlier polarization chapter.[1]

Babinet Compensator

There are many devices which compensate for differences in phase retardation by having a variable thickness of a birefringent material (such as crystalline quartz) in the light beam, as discussed by Johansen,[299] and Jerrard.[300] One such device, described by Hunt,[301] can compensate for a residual

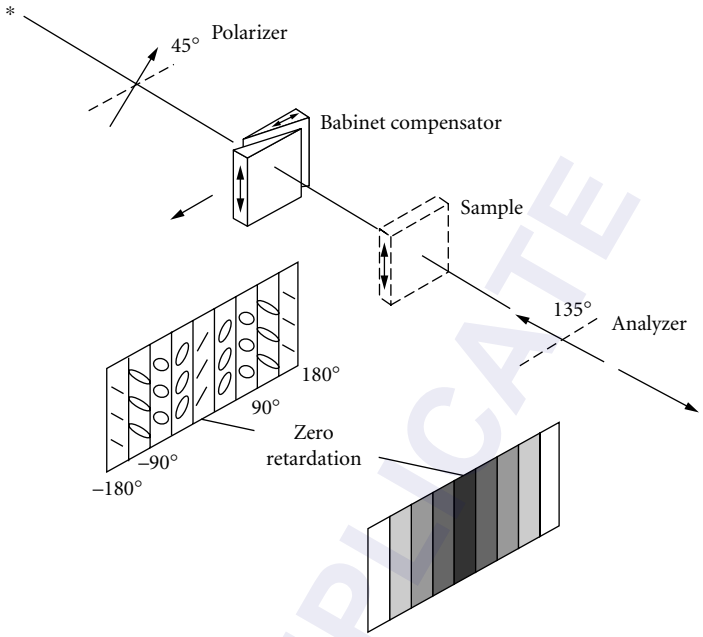

FIGURE 21 Arrangement of a Babinet compensator, polarizer, and analyzer for measuring the retardation of a sample. The appearance of the field after the light has passed through the compensator is shown to the left of the sample position. Retardations are indicated for alternate regions. After the beam passes through the analyzer, the field is crossed by a series of dark bands, one of which is shown to the left of the analyzer.

wedge angle between the entrance and exit faces of birefringent optical components such as optical modulators and waveplates.

The most common variable retardation plates are the Babinet compensator and the Soleil compensator. The Babinet compensator was proposed by Babinet in 1837 and later modified by Jamin; references to the voluminous early literature are given by Partinngton.[302] Ellerbroek and Groosmuller[303] have a good description of the theory of operation (in German), and Jerrard[304–306] and Archard[307] describe various optical and mechanical defects of Babinet compensators.

The Babinet compensator, shown schematically in Fig. 21, consists of two crystalline-quartz wedges, each with its optic axis in the plane of the face but with the two optic axes exactly 90° apart. One wedge is stationary, and the other is movable by means of a micrometer screw in the direction indicated by the arrow, so that the total amount of quartz through which the light passes can be varied uniformly. In the first wedge, the extraordinary ray vibrates in a horizontal plane and is retarded relative to the ordinary ray (crystalline quartz has a positive birefringence; see Table 8). When the rays enter the second wedge, the ray vibrating in the horizontal plane becomes the ordinary ray and is advanced relative to the ray vibrating in the vertical plane. Thus, the total retardation is proportional to the difference in thickness between the two wedges:

$$N\lambda = (d_1 - d_2)(n_e - n_o) \tag{15}$$

where N = retardation in integral and fractional parts of a wavelength
d_1, d_2 = thickness of the first and second wedges where light passes through
n_o, n_e = ordinary and extraordinary refractive indexes for crystalline quartz

If light polarized at an angle of 45° to one of the axes of the compensator passes through it, the field will appear as shown in Fig. 21; the wedges have been set so there is zero retardation at the center of the field. (If the angle α of the incident plane-polarized beam were different from 45°, the beam retarded or advanced by 180° in phase angle would make an angle of 2α instead of 90° with the original beam.) When an analyzer whose axis is crossed with that of the polarizer is used to observe the beam passing through the compensator, a series of light and dark bands is observed in monochromatic light. In white light only one band, that for which the retardation is zero, remains black. All the other bands are colored. These are the bands for which the retardation is multiples of 2π (or, expressed in terms of path differences, integral numbers of wavelengths). On one side of the central black band one ray is advanced in phase relative to the other ray; on the other side it is retarded. If one wedge is moved, the whole fringe system translates across the field of view. The reference line is scribed on the stationary wedge so that it remains in the center of the field. Information on calibrating and using a Babinet compensator is given in the earlier polarization chapter.[1]

Soleil Compensator

The Soleil compensator (see Wood[308] and Ditchburn[309]), sometimes called a Babinet-Soleil compensator, is shown in Fig. 22. It is similar to the Babinet compensator in the way it is used, but instead of having a field crossed with alternating light and dark bands in monochromatic light, the

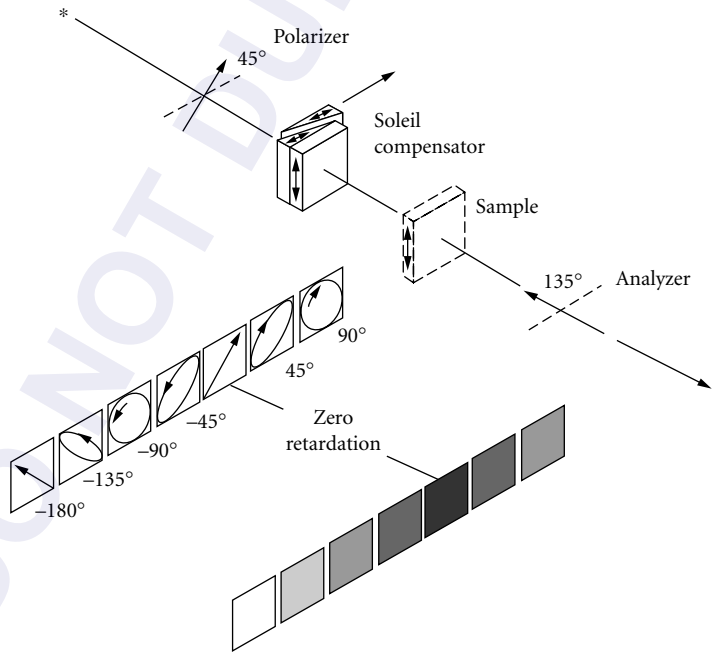

FIGURE 22 Arrangement of a Soleil compensator, polarizer, and analyzer for measuring the retardation of a sample. The appearance of the field after the light has passed through the compensator is shown to the left of the sample position. After the beam passes through the analyzer, the field appears as one of the shades of gray shown to the left of the analyzer.

field has a uniform tint if the compensator is constructed correctly. This is because the ratio of the thicknesses of the two quartz blocks (one composed of a fixed and a movable wedge) is the same over the entire field. The Soleil compensator will produce light of varying ellipticity depending on the position of the movable wedge. Calibration of the Soleil compensator is similar to that of the Babinet compensator.[1] The zero-retardation position is found in the same manner except that now the entire field is dark. The compensator is used in the same way as a Babinet compensator with the uniformly dark field (in white light) of the Soleil corresponding to the black zero-retardation band in the Babinet.

The major advantage of the Soleil compensator is that a photoelectric detector can be used to make the settings. The compensator is offset a small amount on each side of the null position so that equal-intensity readings are obtained. The average of the two drum positions gives the null position. Photoelectric setting can be much more precise than visual setting, but this will not necessarily imply increased accuracy unless the compensator is properly constructed. Since Soleil compensators are composed of three pieces of crystalline quartz, all of which must be very accurately made, they are subject to more optical and mechanical defects than Babinet compensators. Jerrard[310–312] has described many of these defects in detail. Ives and Briggs[313] found random departures of about ±1.5° from their straight-line calibration curve of micrometer reading for extinction vs. wedge position. This variation was considerably larger than the setting error with a half-shade plate and was attributed to variations in thickness of the order of $\pm\lambda/4$ along the quartz wedges.

Soleil compensators have been used for measurements of retardation in the infrared. They have been made of crystalline quartz, cadmium sulfide, and magnesium fluoride (see the work of Palik[257,314] and Palik and Henvis[252]). A by-product of this work was the measurement of the birefringence of these materials in the infrared.

Two other uniform-field compensators have been proposed. Jerrard,[311] following a suggestion by Soleil, has taken the Babinet wedges and reversed one of them so the light passes through the thicker portions of each wedge. This reversed Babinet compensator is less subject to mechanical imperfections than the Soleil compensator but does produce a small deviation of the main beam. Hariharan and Sen[315] suggest double-passing a Babinet compensator (with a reflection between the two passes) to obtain a uniform field.

13.12 HALF-SHADE DEVICES

It is sometimes necessary to measure accurately the azimuth of a beam of plane-polarized light, i.e., the angle the plane of vibration makes with a reference coordinate system. This can be done most easily by using a polarizer as an analyzer and rotating it to the position where the field appears the darkest. The analyzer azimuth is then exactly 90° from the azimuth of the plane-polarized beam. A more sensitive method is to use a photoelectric detector and offset on either side of the extinction position at angles where the intensities are equal. The average of these two angles is generally more accurate than the value measured directly, but care must be taken to keep the angles small so that asymmetries will not become important.

Before the advent of sensitive photoelectric detectors, the most accurate method of setting on a minimum was to use a half-shade device as the analyzer or in conjunction with the analyzer. The device generally consisted of two polarizers having their axes inclined at an angle α to each other (angle fixed in some types and variable in others). As the device was rotated, one part of the field became darker while the other part became lighter. At the match position, both parts of the field appeared equally bright. The Jellett-Cornu prism, Lippich, and Laurent half shades, Nakamura biplate, and Savart plate are examples of half-shade devices.[1]

Ellipticity half-shade devices are useful for detecting very small amounts of ellipticity in a nominally plane-polarized beam and hence can indicate when a compensator has completely converted elliptically polarized light into plane-polarized light. Two of these devices are the Bravais biplate

and the Brace half-shade plate. Half-shade devices for both plane and elliptically polarized light are described in detail in the earlier polarization chapter.[1]

13.13 MINIATURE POLARIZATION DEVICES

Polarization Devices for Optical Fibers

Single-mode optical fiber-type polarizers are important devices for optical fiber communication and fiber sensor systems. These polarizers have been made by a variety of techniques. Polarizers have been made by bending[316] or by tapering[317] a birefringent fiber to induce differential attenuation in the orthogonal modes. In most cases a fiber was polished laterally and some device was placed in contact with the exposed guiding region of the fiber to couple out the unwanted polarization. Bergh et al.[318] used a birefringent crystal as the outcoupling device and obtained a high extinction ratio polarizer. Optical fiber polarizers made with a metal film coated onto the polished area to eliminate the unwanted polarization state seem to be preferred because they are stable and rugged. The original version by Eickhoff[319] used the thin cladding remaining after polishing as the buffer layer, but it had an insufficient extinction ratio. Other designs using metal coatings were suggested by Gruchmann et al.,[320] and Hosaka et al.[321] Feth and Chang[322] used a fiber polished into its core to which a superstrate coated with a very thin metal layer was attached by an index-matching oil. Yu and Wu[323] gave a theoretical analysis of metal-clad single-mode fiber-type polarizers. Dyott et al.[324] made a metal-fiber polarizer from an etched D-shaped fiber coated with indium.

In the above approaches, either expensive components are used or the structure of the polarizer is complicated and fragile. Lee and Chen[325] suggested a new way of fabricating high-quality metal-clad polarizers by polishing a fiber ~0.4 μm into its core and then overcoating it with a 265-nm MgF_2 film as the buffer layer followed by a 100-nm Al film. Polarizers fabricated in this way had an average extinction ratio of 28 dB with a 2-dB insertion loss at a 0.63-μm wavelength or a 34-dB extinction ratio with a 3-dB insertion loss at 0.82 μm[325]

Other devices for optical fibers have also been designed. Ulrich and Johnson[326] made a single-mode fiber-optical polarization rotator by mechanically twisting successive half-wave fiber sections in alternating directions; Hosaka et al.'s fiber circular polarizer[327] was composed of a metal-coated fiber polarizer and a $\lambda/4$ platelet fabricated on a birefringent fiber; polished-type couplers acting as polarizing beam splitters were made by Snyder and Stevenson.[328] The patent literature contains references to other polarization devices for optical fibers.

Polarization Devices for Integrated Circuits

Small and highly efficient polarization devices are also needed for integrated circuits. Some such devices have been proposed and fabricated. Uehara et al.[329] made an optical waveguiding polarizer for optical fiber transmission out of a plate of calcite attached to borosilicate glass into which a three-dimensional high-index region had been formed by ion migration to act as the waveguide. Mahlein[330] deposited a multilayer dielectric film onto a glass superstrate which was then contacted to a planar waveguide to couple out the TM polarization. This paper contains a good description of the polarizer design as well as extensive references. Suchoski et al.[331] fabricated low-loss, high-extinction polarizers in $LiNbO_3$ by proton exchange. Noé et al.[332] achieved automatic endless polarization control with integrated optical Ti:$LiNbO_3$ polarization transformers. This was a better method of matching polarization states between two superposed waves than techniques that had been used previously. Finally Baba et al.[333] proposed making a polarizer for integrated circuits out of periodic metal-dielectric laminated layers (Lamipol structures). Their experiments with Al-SiO_2 structures were encouraging. Patents have been filed for other polarization devices for integrated circuits.

MUELLER MATRICES

Russell A. Chipman

College of Optical Sciences
University of Arizona
Tucson, Arizona

14.1 GLOSSARY

A	analyzer vector
d	diattenuation parameters, set of three
d_i	magnitude of polarization parameters via matrix roots
D	diattenuation
D	diagonal matrix
D_i	differential polarization parameters via matrix roots
DD	diagonal depolarizer Mueller matrix
Dep	depolarization
DI	depolarization index
DoCP	degree of circular polarization
DoLP	degree of linear polarization
DoP	degree of polarization
e	ellipticity
E	extinction ratio
E	Jones vector
E_x, E_y	electric field components
ED	elliptical diattenuator Mueller matrix
EP	elliptical polarizer Mueller matrix
ER	elliptical retarder Mueller matrix
G	Mueller matrix generators for polarization properties
H	hermitian coherency matrix
$\hat{\mathbf{H}}$	horizontal polarized Stokes vector, 0°, normalized
$\mathbf{H}_p$	hermitian coherency matrix of a physical Mueller matrix
HLP	horizontal linear polarizer Mueller matrix
HQWLR	quarter-wave linear retarder Mueller matrix, horizontal fast axis

HWLR	half-wave linear retarder Mueller matrix
i	$\sqrt{-1}$
I	inhomogeneity of a Mueller matrix
I	identity matrix
ID	ideal depolarizer Mueller matrix
J	Jones matrix
$j_{xx}, j_{xy}, j_{yx}, j_{yy}$	Jones matrix elements
k	propagation vector
LCP	left circular polarizer Mueller matrix
LD	linear diattenuator operator
LD	linear diattenuator Mueller matrix
LDR	homogeneous linear diattenuator and retarder Mueller matrix
LP(θ)	linear polarizer Mueller matrix transmitting along axis θ
M	Mueller matrix
$\hat{\mathbf{M}}$	normalized Mueller matrix
$\mathbf{M}_D$	diattenuator Mueller matrix
$\mathbf{M}_N$	nondepolarizing Mueller matrix, Mueller-Jones matrix
$\mathbf{M}_P$	physical Mueller matrix
$\mathbf{M}_R$	retarder Mueller matrix
$\mathbf{M}_{\text{refl}}, \mathbf{M}_{\text{refr}}$	Mueller matrices for reflection and refraction
$m_{00}, m_{01}, \ldots, m_{33}$	Mueller matrix elements
n_1, n_2	refractive indices of modes
O	orthogonal matrix
P	polarizance
P	high-order matrix root of Mueller matrix
PD	partial depolarizer Mueller matrix
PDL	polarization-dependent loss
q	index for a sequence of polarization elements
q	index for mode order
Q	index limit
QWLR	quarter-wave linear retarder Mueller matrix
QWRCR, QWLCR	quarter-wave circular retarder Mueller matrix, right and left fast mode
$\mathbf{R}_M$	rotational change of basis matrix for Stokes vectors
RCP	right circular polarizer Mueller matrix
Re	real part
s	Stokes three-vector
S	Stokes vector
$\hat{\mathbf{S}}$	normalized polarized Stokes vector
$\mathbf{S}'$	exiting Stokes vector
$\mathbf{S}_{\max}, \mathbf{S}_{\min}$	incident Stokes vectors of maximum and minimum intensity transmittance
S_0, S_1, S_2, S_3	Stokes vector elements
t	thickness
t	time
T	transpose, superscript
T	intensity transmittance

T_{avg}	intensity transmission averaged over all incident polarization states
T_{max}	maximum intensity transmittance
T_{min}	minimum intensity transmittance
Tr	trace of a matrix
U	unitary matrix
U	Jones / Mueller transformation matrix
$\hat{\mathbf{U}}$	unpolarized Stokes vector, normalized
v	eigenvectors
$\hat{\mathbf{V}}$	vertical polarized Stokes vector, 90°, normalized
VD	variable partial depolarizer Mueller matrix
VQWLR	quarter-wave linear retarder Mueller matrix, vertical fast axis
$\{\hat{\mathbf{x}}, \hat{\mathbf{y}}\}$	Stokes vector coordinate basis
z	spatial coordinate
δ	retardance, radians
δ_H, δ_{45}, δ_R	retardance components: horizontal, 45°, right
ε	latitude on Poincaré sphere
θ	orientation angle: (1) polarizer axis, (2) retarder fast axis, (3) major axis of polarization ellipse
λ	wavelength
λ	eigenvalue
ρ	amplitudes of a complex number
$\boldsymbol{\sigma}_i$	identity matrix, $i = 0$, and normalized Pauli spin matrices, $i = 1, 2, 3$
ϕ	phase of a complex number
χ	angle between the eigenpolarizations on the Poincaré sphere
ω	angular frequency
$\otimes$	tensor product
†	hermitian adjoint
•	dot product, matrix multiplication
$\|\|$	norm of a vector

14.2 CONVENTIONS

All angles are in radians unless the degree sign (°) is used. Retardance is specified in radians throughout. The last Stokes vector element, S_3, is positive for a right circularly polarized component and negative for a left circularly polarized component. All vectors and matrices are represented by bold characters.

14.3 OBJECTIVES

This chapter surveys the Mueller matrix and its properties. The Mueller matrix has become the principal quantity used in polarimetric measurements of optical and polarization elements. For optical design and theoretical analyses, particularly of interferometers, Jones matrices and coherence matrices are often preferred. Mueller matrices are straightforward to measure and dominate experimental studies.

Despite the Mueller matrix's straightforward definition, the relation between the polarization properties and the matrix elements is complex, particularly when depolarization is involved.

Several issues are addressed:

1. Determining the Mueller matrix from the specification of a polarization element.
2. Given the Jones matrix for a polarization element, determine the corresponding Mueller matrix.
3. Given a Mueller matrix, determine if there is a corresponding Jones matrix and calculate this Jones matrix.
4. Given a Mueller matrix, determine the corresponding polarization properties of diattenuation, retardance, and depolarization.
5. Given a 4×4 matrix which violates the constraints on Mueller matrices, find the closest Mueller matrices.

This chapter supports Chap. 15, "Polarimetry" which assumes much of the material here. Chapter 15 is principally concerned with measuring Stokes parameters and Mueller matrices; this chapter treats Mueller matrix calculations and data reduction.

14.4 STOKES PARAMETERS AND MUELLER MATRICES

Several calculi have been developed for analyzing polarization, including those based on the Jones matrix, coherency matrix, Mueller matrix, and other matrices.[1–10] Of these methods, the Mueller calculus is most generally suited for describing irradiance-measuring instruments, including most polarimeters, radiometers, and spectrometers.

The set of four linear equations relating incident and exiting Stokes parameters was first introduced by Soleillet in 1929.[11] Hans Müller of MIT formulated these equations as a 4×4 matrix times a Stokes vector in his class notes, an Optical Society of America meeting abstract, and in a technical report but he never published a journal article.[12] His graduate student Parke developed the matrix properties in great detail.[13,14] R. Clark Jones became aware of the work prior to publication and was the first to use the term and spelling Mueller matrix in a journal article.[15] In keeping with current practice, we will refer to this matrix as the Mueller matrix, although it is sometimes referred to as the Stokes matrix.[16]

In the Mueller calculus, the Stokes vector **S** describes the polarization state of a light beam, and the Mueller matrix **M** describes the polarization-altering characteristics of a sample. This sample may be a surface, a polarization element, an optical system, or some other light/matter interaction which produces a reflected, refracted, diffracted, or scattered light beam. Chapter 15 "Polarimetry" contains a detailed description of Stokes vector properties.

14.5 THE STOKES PARAMETERS AND THE POINCARÉ SPHERE

The Stokes parameters (Stokes vector) can be normalized by its flux S_0, and used to define the Stokes three-vector **s,**

$$\hat{\mathbf{S}} = \frac{\mathbf{S}}{S_0} = \begin{pmatrix} 1 \\ s_1 \\ s_2 \\ s_3 \end{pmatrix} = \begin{pmatrix} 1 \\ \mathbf{s} \end{pmatrix} \qquad \mathbf{s} = \{s_1, s_2, s_3\} \tag{1}$$

For unpolarized light $\mathbf{s} = \{0, 0, 0\}$ and the magnitude of $\mathbf{s}$,

$$|\mathbf{s}| = \sqrt{s_1^2 + s_2^2 + s_3^2} = 0 \tag{2}$$

For a completely polarized polarization state, $|\mathbf{s}| = 1$. The vector $\mathbf{s}$ is the coordinates of $\hat{\mathbf{S}}$ on the unit Poincaré sphere. The introduction of $\mathbf{s}$ allows the polarization state to be specified irrespective of the flux. Completely polarized states $\mathbf{s}_a$ and $\mathbf{s}_b$ are orthogonal when

$$\mathbf{s}_a = -\mathbf{s}_b \tag{3}$$

Orthogonal states have opposite helicity (the electric fields rotate clockwise and counterclockwise) and the orientations of the polarization ellipse major axes are 90° apart.

The Poincaré sphere is a geometrical construction for the representation of Stokes vectors and polarization ellipses where the Stokes three-vector is plotted in a three-dimensional space with axes $\{S_1, S_2, S_3\}$ as shown in Fig 1.

Each point on the surface of the Poincaré sphere can be parameterized by angles $\{\theta, \varepsilon\}$ where θ is the orientation of the major axis of the polarization ellipse and ε is the latitude; sin ε is the degree of circular polarization,

$$\mathbf{S}(\theta, \varepsilon) = \begin{pmatrix} 1 \\ \cos(2\theta)\cos\varepsilon \\ \sin(2\theta)\cos\varepsilon \\ \sin\varepsilon \end{pmatrix} \tag{4}$$

Linearly polarized Stokes parameters are located around the Poincaré sphere equator, $\{\cos(2\theta), \sin(2\theta), 0\}$, where θ is the orientation of linear polarization. The north pole $\{0, 0, 1\}$ represents right circularly polarized light and the south pole $\{0, 0, -1\}$ left circularly polarized light. The sphere's center $\{0, 0, 0\}$ represents unpolarized light. The set of spheres centered on the origin each contain partially polarized states with a degree of polarization equal to the radius r. The surface at radius one,

$$r = 1 = \sqrt{s_1^2 + s_2^2 + s_3^2} \tag{5}$$

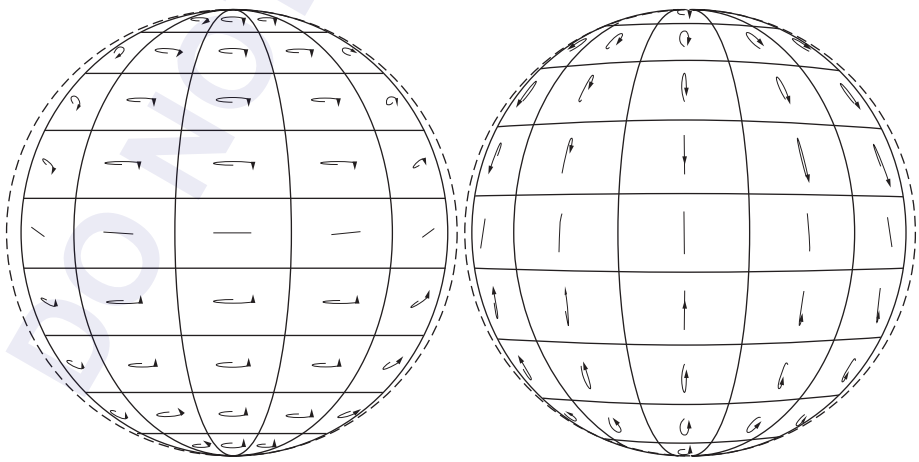

FIGURE 1 View of the Poincaré sphere along the $+S_1$ axis (*a*) and along the $-S_1$ axis (*b*) with the polarization ellipses associated with different locations indicated.

represents all possible states of (completely) polarized light. θ is one half the latitude on a traditional globe because, for incoherent light, a rotation of 180° returns the polarization state to its initial state; rotate a linear polarizer through 180° and the polarization states repeat. Notice that on the Poincaré sphere, the locations for 0° linearly polarized light (nominally horizontal {1, 0, 0}) and 45° linearly polarized light {0, 1, 0} are 90° apart while horizontal and vertical {−1, 0, 0} linearly polarized light are diametrically opposite, 180° apart. Orthogonal polarization states are at opposite points on the sphere surface.

The Stokes parameters have an unusual coordinate system because the S_1, S_2, and S_3 axes do not represent polarization states 90° apart, the traditional definition of orthogonal vectors. The Stokes parameter coordinate system is a clever and effective representation of incoherent light because equal amounts of orthogonal polarized fluxes, when combined, yield unpolarized light. Due to the properties of this coordinate system, the four Stokes parameters do not transform as a vector, and cannot be considered as a true *vector*. The Stokes parameters do add as vectors and are operated on by Mueller matrices like vectors; thus the widespread use of the term Stokes vector.

In current practice, the Poincaré sphere is used three different ways:

1. To represent a polarization state
2. To represent diattenuation by indicating the Stokes parameters of maximum transmission, and the diattenuation magnitude as distance from the origin
3. To represent retardance by indicating the axis through the origin of the fast and slow axes (eigenpolarizations), or by representing retardance within a three dimensional *retardance space* with components $\{\delta_x, \delta_{45}, \delta_R\}$

14.6 MUELLER MATRICES

The Mueller matrix is a 4 × 4 matrix with real-valued elements.[10,14] The Mueller matrix **M** for a polarization-altering device is defined as the matrix which transforms an incident Stokes vector **S** into the exiting (reflected, transmitted, or scattered) Stokes vector **S′**,

$$\mathbf{M}\cdot\mathbf{S}=\mathbf{S}'=\begin{pmatrix} m_{0,0} & m_{0,1} & m_{0,2} & m_{0,3} \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{2,1} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{3,1} & m_{3,2} & m_{3,3} \end{pmatrix} \bullet \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} = \begin{pmatrix} S'_o \\ S'_1 \\ S'_2 \\ S'_3 \end{pmatrix}$$

$$= \begin{pmatrix} S_0 m_{0,0} + S_1 m_{0,1} + S_2 m_{0,2} + S_3 m_{0,3} \\ S_0 m_{1,0} + S_1 m_{1,1} + S_2 m_{1,2} + S_3 m_{1,3} \\ S_0 m_{2,0} + S_1 m_{2,1} + S_2 m_{2,2} + S_3 m_{2,3} \\ S_0 m_{3,0} + S_1 m_{3,1} + S_2 m_{3,2} + S_3 m_{3,3} \end{pmatrix} \tag{6}$$

Each element of the incident **S** is related to the four elements of **S′** by the elements of **M**. Since the elements of **S** and **S′** are irradiances, the elements of **M** are dimensionless ratios of irradiances. Since irradiances are real, the elements of **M** are real valued, not complex numbers. When the Mueller matrix is known, then the exiting polarization state is known for an arbitrary incident polarization state. Our convention numbers the subscripts from 0 to 3 to match the corresponding Stokes vector subscripts.

The Mueller matrix $\mathbf{M}(\mathbf{k}, \lambda)$ for a device is always a function of the direction of propagation **k** and wavelength λ.

14.7 SEQUENCES OF POLARIZATION ELEMENTS

The Mueller matrix **M** associated with a beam path through a sequence (cascade) of polarization elements $q = 1, 2, \ldots, Q$ is the right-to-left product of the individual matrices $\mathbf{M}_q$,

$$\mathbf{M} = \mathbf{M}_Q \bullet \mathbf{M}_{Q-1} \bullet \ldots \mathbf{M}_q \bullet \ldots \mathbf{M}_2 \bullet \mathbf{M}_1 = \prod_{q=Q,-1}^{1} \mathbf{M}_q \tag{7}$$

In evaluating cascades of Mueller matrices, the associative rule for matrix multiplication can be applied,

$$(\mathbf{M}_3 \bullet \mathbf{M}_2) \bullet \mathbf{M}_1 = \mathbf{M}_3 \bullet (\mathbf{M}_2 \bullet \mathbf{M}_1) \tag{8}$$

and adjacent matrices grouped in any order for multiplication.

14.8 POLARIZATION ELEMENTS' PROPERTIES IN THE MUELLER CALCULUS

For ideal polarization elements, the polarization properties are readily defined. For real polarization elements, the precise description of the polarization properties is more complex. Polarization elements such as polarizers, retarders, and depolarizers have three general polarization properties: diattenuation, retardance, and depolarization, and a typical element displays some amount of all three. Diattenuation arises when the intensity transmittance of an element is a function of the incident polarization state.[17] The diattenuation D of a device is defined in terms of the maximum T_{max} and minimum T_{min} intensity transmittances,

$$D = \frac{T_{max} - T_{min}}{T_{max} + T_{min}} \tag{9}$$

For an ideal polarizer, $D = 1$. When $D = 0$, all incident polarization states are transmitted with equal attenuation. For an ideal retarder the polarization states change upon transmission but T_{max} and T_{min} are equal and $D = 0$. The quality of a polarizer is often expressed in terms of the related quantity, the extinction ratio E,

$$E = \frac{T_{max}}{T_{min}} = \frac{1+D}{1-D} \tag{10}$$

where the ideal polarizer has $E = \infty$.

Retardance is the phase change a device introduces between its eigenpolarizations (eigenstates). For a birefringent retarder with refractive indices n_1 and n_2, and thickness t, the retardance δ expressed in radians is

$$\delta = \frac{2\pi(n_1 - n_2)t}{\lambda} \tag{11}$$

Depolarization describes the coupling by a device of incident polarized light into depolarized light in the exiting beam. For example, depolarization occurs when light transmits through milk or scatters from clouds. Multimode optical fibers generally depolarize the light. Depolarization is intrinsically associated with scattering and a loss of coherence in the polarization state. A small amount of depolarization is associated with the scattered light from all optical components.

14.9 ROTATION OF AN ELEMENT ABOUT THE OPTICAL AXIS

When a polarization element with Mueller matrix **M** is rotated about the incident beam of light by an angle θ such that the angle of incidence is unchanged (for example, for a normal-incidence beam, rotating the element about the normal), the resulting Mueller matrix $\mathbf{M}(\theta)$ is

$$\mathbf{M}(\theta)=\mathbf{R}_M(\theta)\bullet\mathbf{M}\bullet\mathbf{R}_M(-\theta)=\begin{pmatrix}1&0&0&0\\0&\cos 2\theta&-\sin 2\theta&0\\0&\sin 2\theta&\cos 2\theta&0\\0&0&0&1\end{pmatrix}\bullet\begin{pmatrix}m_{00}&m_{01}&m_{02}&m_{03}\\m_{10}&m_{11}&m_{12}&m_{13}\\m_{20}&m_{21}&m_{22}&m_{23}\\m_{30}&m_{31}&m_{32}&m_{33}\end{pmatrix}\bullet\begin{pmatrix}1&0&0&0\\0&\cos 2\theta&\sin 2\theta&0\\0&-\sin 2\theta&\cos 2\theta&0\\0&0&0&1\end{pmatrix} \tag{12}$$

where $\mathbf{R}_M$ is the rotational change of basis matrix for Stokes vectors and Mueller matrices.

14.10 NONPOLARIZING MUELLER MATRICES

A nonpolarizing matrix does not change the polarization state of any incident polarization vector; only the amplitude and/or phase change. The Mueller Matrix for a nonabsorbing, nonpolarizing sample is the identity matrix **I**,

$$\mathbf{I}=\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{pmatrix} \tag{13}$$

I is the Mueller matrix for vacuum and the approximate Mueller matrix for air. For a neutral density filter or polarization-independent absorption or loss, the Mueller matrix has $T_{\max} = T_{\min} = T$, and the resulting Mueller matrix is proportional to the identity matrix and can be expressed in terms of our notation for linear diattenuators, $\mathbf{LD}(T_{\max}, T_{\min}, \theta)$, as

$$\mathbf{LD}\,(T,\,T,\,0)=T\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&1\end{pmatrix} \tag{14}$$

14.11 MUELLER MATRICES OF IDEAL POLARIZERS

First, the properties of an example ideal polarizer are examined. Tables of ideal polarizer Mueller matrices are presented followed by equations for linear and elliptical ideal polarizers.

An ideal polarizer has a transmittance of one for its principal state and a transmittance of zero for the orthogonal "blocked" state.

Consider the Mueller matrix for a horizontal linear polarizer (**HLP**), which we also express as **LD** (1, 0, 0) for linear diattenuator, $T_{max} = 1$, $T_{min} = 0$, orientation of transmission axis 0,

$$\mathbf{HLP} = \mathbf{LD}\,(1, 0, 0) = \frac{1}{2}\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{15}$$

When operating on the Stokes vector for horizontal linearly polarized light,

$$\mathbf{HLP} \bullet \hat{\mathbf{H}} = \frac{1}{2}\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \bullet \begin{pmatrix} 1 \\ 1 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 \\ 1 \\ 0 \\ 0 \end{pmatrix} \tag{16}$$

horizontally polarized light exits without loss. Vertically polarized incident light is completely blocked,

$$\mathbf{HLP} \bullet \hat{\mathbf{V}} = \frac{1}{2}\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \bullet \begin{pmatrix} 1 \\ -1 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} \tag{17}$$

In fact, **H** and **V** are the two eigenpolarizations of **HLP**. Eigenpolarizations are the eigenvectors which correspond to physically realizable Stokes vectors. For **HLP** the remaining two eigenvectors are nonphysical as Stokes vectors since $S_0 = 0$,

$$\begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix} \quad \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix} \tag{18}$$

For an arbitrary incident Stokes vector,

$$\mathbf{HLP} \bullet \mathbf{S} = \mathbf{S}' = \frac{1}{2}\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \bullet \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} = \frac{1}{2}\begin{pmatrix} S_0 + S_1 \\ S_0 + S_1 \\ 0 \\ 0 \end{pmatrix} = \frac{S_0 + S_1}{2}\begin{pmatrix} 1 \\ 1 \\ 0 \\ 0 \end{pmatrix} \tag{19}$$

Since the first two rows of **M** are equal, the first two elements of **S′** are equal, the S_2 and S_3 characteristics of the incident light are lost, and the exiting light is always horizontally linearly polarized. Table 1 lists the Mueller matrices for the six basis polarization states and the general linear polarizer.

TABLE 1 Mueller Matrices for Ideal Polarizers for the Basis Polarization States

Type of Polarizer	Symbol	Mueller Matrix
Horizontal linear polarizer	HLP	$\frac{1}{2}\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$
Vertical linear polarizer	VLP	$\frac{1}{2}\begin{pmatrix} 1 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$
45° linear polarizer	LP(45°)	$\frac{1}{2}\begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$
135° linear polarizer	LP(135°)	$\frac{1}{2}\begin{pmatrix} 1 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$
Right circular polarizer	RCP	$\frac{1}{2}\begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix}$
Left circular polarizer	LCP	$\frac{1}{2}\begin{pmatrix} 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 \end{pmatrix}$
Linear polarizer with transmission axis oriented at angle θ, measured positive when rotating counterclockwise from the x-axis looking into the beam	LP(θ)	$\frac{1}{2}\begin{pmatrix} 1 & \cos 2\theta & \sin 2\theta & 0 \\ \cos 2\theta & \cos^2 2\theta & \sin 2\theta \cos 2\theta & 0 \\ \sin 2\theta & \sin 2\theta \cos 2\theta & \sin^2 2\theta & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$

For an elliptical polarizer which transmits a polarization state with the major axis of the ellipse oriented at θ located at latitude ϕ on the Poincaré sphere, $-\pi/2 \le \phi \le \pi/2$, the Mueller matrix $\mathbf{EP}(\theta, \phi)$ is

$$\mathbf{EP}(\theta,\phi)=\frac{1}{2}\begin{pmatrix} 1 & \cos 2\theta \cos\phi & 2\cos\theta \sin\theta \cos\phi & \sin\phi \\ \cos 2\theta \cos\phi & \cos^2 2\theta \cos^2\phi & \frac{1}{2}\sin 4\theta \cos^2\phi & \frac{1}{2}\cos 2\theta \cos\phi \sin\phi \\ 2\cos\theta \sin\theta \cos\phi & \frac{1}{2}\sin 4\theta \cos^2\phi & \sin^2 2\theta \cos^2\phi & 2\cos\theta \sin\theta \cos\phi \sin\phi \\ \sin\phi & \frac{1}{2}\cos 2\theta \sin 2\phi & 2\cos\theta \sin\theta \cos\phi \sin\phi & \sin^2\phi \end{pmatrix} \quad (20)$$

14.12 RETARDER MUELLER MATRICES

Retarders have two polarization states which are transmitted in the incident polarization state (eigenpolarizations) but with different optical path lengths (phases). Birefringent retarders divide incident light into two modes with orthogonal polarizations and delay one mode with respect to the other due to birefringence, the refractive index difference between the modes. Other retarding interactions include the following: reflections from metals, reflection and transmission through multilayer thin films, stress birefringence, and interactions with diffraction gratings. These interactions also are often diattenuating.

Retarders are specified by the optical path difference between the eigenpolarizations (the retardance δ) and the eigenpolarization states, either the state with the smaller optical path length (the fast axis) or the larger optical path (the slow axis). Retardance is specified in this chapter in radians, so $\delta = 2\pi$ indicates one wavelength of optical path difference. Note that *axis* implies a linear polarization state, but the fast eigenpolarization may be elliptical or circular and the term "axis" is still applied. The most common retarders in practice are quarter-wave linear retarders and half-wave linear retarders. Quarter-wave linear retarders are most commonly used to convert between linear and circularly polarized light. Half-wave linear retarders are most commonly used to rotate the plane of linear polarization.

In the Mueller calculus, retarders are represented by real unitary matrices of the form

$$\mathbf{M}_{\text{retarder}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & & & \\ 0 & & 3\times 3 \text{ rotation} & \\ 0 & & \text{matrix} & \end{pmatrix} \tag{21}$$

where, except for the $\mathbf{M}_{0,0}$ element, the first row and column are zero. Real unitary matrices are called *orthogonal matrices*. The definition of a unitary matrix **U** is a matrix whose hermitian adjoint (complex conjugate of the matrix transpose) equals its matrix inverse,

$$\mathbf{U}^{\dagger} = (\mathbf{U}^{T})^{*} = \mathbf{U}^{-1} \tag{22}$$

For a real matrix, the complex conjugate of a matrix equals the matrix, so the transpose of an orthogonal matrix **O** equals its inverse,

$$\mathbf{O}^{T} = \mathbf{O}^{-1} \tag{23}$$

This equation *tests if a Mueller matrix is a pure retarder*. Orthogonal matrices such as retarder Mueller matrices are rotation matrices. The lower right 3×3 elements form a rotation matrix in $\{S_1, S_2, S_3\}$ space showing how retarders operate on Stokes vectors as a rotation of the Poincaré sphere. The retardance δ of a pure retarder Mueller matrix in radians is

$$\delta = \arccos\left(\frac{m_{0,0} + m_{1,1} + m_{2,2} + m_{3,3}}{2} - 1\right) = \arccos\left(\frac{\mathbf{Tr}(\mathbf{M})}{2} - 1\right) \tag{24}$$

The Mueller matrices for quarter wave retarders with fast axes corresponding to the six basis polarization states are given in Table 2. Table 3 lists the half wave retarder Mueller matrices corresponding to the basis polarization states.

The Mueller matrix for a quarter-wave linear retarder with fast axis at angle θ, $\mathbf{QWLR}(\theta)$ is

$$\mathbf{QWLR}(\theta) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos^2 2\theta & \cos 2\theta \sin 2\theta & -\sin 2\theta \\ 0 & \cos 2\theta \sin 2\theta & \sin^2 2\theta & \cos 2\theta \\ 0 & \sin 2\theta & -\cos 2\theta & 0 \end{pmatrix} \tag{25}$$

TABLE 2 Quarter Wave Retarder Mueller Matrices for the Basis Polarization States

Type of Retarder	Symbol	Mueller Matrix
Horizontal quarter-wave Linear retarder	HQWLR	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -1 & 0 \end{pmatrix}$
Vertical quarter-wave Linear retarder	VQWLR	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$
45° quarter-wave Linear retarder	QWLR(45°)	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}$
135° quarter-wave Linear Retarder	QWLR(135°)	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix}$
Quarter-wave right Circular retarder	QWRCR	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$
Quarter-wave left circular retarder	QWLCR	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$

TABLE 3 Half-Wave Retarder Mueller Matrices for the Basis Polarization States

Type of Retarder	Symbol	Mueller Matrix
Horizontal or vertical half-wave linear retarder (same matrix)	HHWLR	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}$
45° or 135° half-wave linear retarder	HWLR(45°)	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}$
Right or left half-wave circular retarder	RHWCR	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$

Similarly a half wave linear retarder with fast axis at angle θ, **HWLR**(θ), has the matrix

$$\mathbf{HWLR}(\theta)=\begin{pmatrix}1&0&0&0\\0&\cos 4\theta&\sin 4\theta&0\\0&\sin 4\theta&-\cos 4\theta&0\\0&0&0&-1\end{pmatrix}=\mathbf{HWLR}\left(\theta+\frac{\pi}{2}\right) \tag{26}$$

The Mueller matrix is the same for a horizontal half-wave linear retarder and a vertical half-wave linear retarder or for other pairs 90° apart because both half-wave retarders perform the same transformation on Stokes vectors.

The Mueller matrix **LR**(δ, θ) for a linear retarder with retardance δ and fast axis oriented at an angle θ is

$$\mathbf{LR}(\delta,\ \theta)=\begin{pmatrix}1&0&0&0\\0&\cos^2(2\theta)+\cos(\delta)\sin^2(2\theta)&(1-\cos(\delta))\cos(2\theta)\sin(2\theta)&-\sin(\delta)\sin(2\theta)\\0&(1-\cos(\delta))\cos(2\theta)\sin(2\theta)&\cos(\delta)\cos^2(2\theta)+\sin^2(2\theta)&\cos(2\theta)\sin(\delta)\\0&\sin(\delta)\sin(2\theta)&-\cos(2\theta)\sin(\delta)&\cos(\delta)\end{pmatrix} \tag{27}$$

Elliptical retarders (**ER**) are commonly specified in two ways: (1) by specifying horizontal, 45°, and circular retardance components: δ_H, δ_{45}, δ_R, or (2) by retardance, δ, orientation, θ, and latitude, ε, of the fast eigenstates using Poincaré sphere coordinates. In terms of retardance components, the magnitude of the retardance is

$$\delta=\sqrt{\delta_H^2+\delta_{45}^2+\delta_R^2}\qquad \mathbf{S}_{\text{fast}}=\begin{pmatrix}1\\ \delta_H/\delta\\ \delta_{45}/\delta\\ \delta_R/\delta\end{pmatrix} \tag{28}$$

The ideal retarder Mueller matrix expressed in terms of retardance components is

$$\mathbf{ER}(\delta_H,\ \delta_{45},\ \delta_R)=\begin{pmatrix}1&0&0&0\\0&\dfrac{\delta_H^2+\left(\delta_{45}^2+\delta_R^2\right)C}{\delta^2}&\dfrac{\delta_{45}\delta_H T}{\delta^2}-\dfrac{\delta_R S}{\delta}&\dfrac{\delta_H\delta_R T}{\delta^2}+\dfrac{\delta_{45}S}{\delta}\\0&\dfrac{\delta_{45}\delta_H T}{\delta^2}+\dfrac{\delta_R S}{\delta}&\dfrac{\delta_{45}^2+\left(\delta_R^2+\delta_H^2\right)C}{\delta^2}&\dfrac{\delta_R\delta_{45}T}{\delta^2}-\dfrac{\delta_H S}{\delta}\\0&\dfrac{\delta_H\delta_R T}{\delta^2}-\dfrac{\delta_{45}S}{\delta}&\dfrac{\delta_R\delta_{45}T}{\delta^2}+\dfrac{\delta_H S}{\delta}&\dfrac{\delta_R^2+\left(\delta_{45}^2+\delta_H^2\right)C}{\delta^2}\end{pmatrix} \tag{29}$$

$$C=\cos\delta,\ S=\sin\delta,\ T=1-\cos\delta$$

In terms of the Poincaré sphere parameters: retardance, δ, orientation, θ, and latitude, ε, of the fast eigenstates, the elliptical retarder Mueller matrix has a long equation given by the following matrix product:

$$\mathbf{ER}(\delta,\ \theta,\ \varepsilon)=\mathbf{LR}(\varepsilon,\ \theta+45^\circ)\bullet\mathbf{LR}(\delta,\theta)\bullet\mathbf{LR}(\varepsilon,\ \theta-45^\circ) \tag{30}$$

Here is a list of the matrix elements,

$$\begin{pmatrix} m_{0,0} \\ m_{0,1} \\ m_{0,2} \\ m_{0,3} \\ m_{1,0} \\ m_{1,1} \\ m_{1,2} \\ m_{1,3} \\ m_{2,0} \\ m_{2,1} \\ m_{2,2} \\ m_{2,3} \\ m_{3,0} \\ m_{3,1} \\ m_{3,2} \\ m_{3,3} \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ \frac{1}{8}\left(2+6\cos\delta-\cos(\delta-2\varepsilon)+2\cos 2\varepsilon-\cos(\delta+2\varepsilon)+8\cos^2(\varepsilon)\cos 4\theta \sin^2\left(\frac{\delta}{8}\right)\right) \\ \sin\delta\sin\varepsilon+\cos^2\varepsilon\sin^2\frac{\delta}{2}\sin 4\theta \\ \cos(\varepsilon)\left(2\cos 2\theta\sin^2\frac{\delta}{2}\sin\varepsilon-\sin\delta\sin 2\theta\right) \\ 0 \\ -\sin\delta\sin\varepsilon+\cos^2\varepsilon\sin^2\frac{\delta}{2}\sin 4\theta \\ \frac{1}{8}\left(2+6\cos\delta-\cos(\delta-2\varepsilon)+2\cos 2\varepsilon-\cos(\delta+2\varepsilon)-8\cos^2(\varepsilon)\cos 4\theta \sin^2\left(\frac{\delta}{8}\right)\right) \\ \cos\varepsilon\left(\cos 2\theta\sin\delta+2\sin^2\frac{\delta}{2}\sin\varepsilon\sin 2\theta\right) \\ 0 \\ \cos\varepsilon\left(2\cos 2\theta\sin^2\frac{\delta}{2}\sin\varepsilon+\sin\delta\sin 2\theta\right) \\ \cos\varepsilon\left(-\cos 2\theta\sin\delta+2\sin^2\frac{\delta}{2}\sin\varepsilon\sin 2\theta\right) \\ \cos^2\frac{\delta}{2}-\cos 2\varepsilon\sin^2\frac{\delta}{2} \end{pmatrix} \tag{31}$$

The Mueller matrix for half-wave elliptical and linear retarders **HWR** simplifies to the following form:

$$\mathbf{HWR}(\delta_H, \delta_{45}, \delta_R) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1+2d_1^2 & 2d_2d_1 & 2d_1d_3 \\ 0 & 2d_2d_1 & -1+2d_2^2 & 2d_2d_3 \\ 0 & 2d_3d_1 & 2d_2d_3 & -1+2d_3^2 \end{pmatrix} \tag{32}$$

$$\sqrt{d_1^2+d_2^2+d_3^2}=1 \quad d_1=\frac{\delta_H}{\pi} \quad d_2=\frac{\delta_{45}}{\pi} \quad d_3=\frac{\delta_R}{\pi}$$

14.13 RETARDER MUELLER MATRICES AMBIGUITIES AND RETARDER SPACE

Retarders can be represented as points in a three-dimensional retarder space $\{\delta_H, \delta_{45}, \delta_R\}$ as in Fig. 2. In this space, all quarter-wave elliptical retarders lie on a sphere of radius $\pi/2$, all half-wave retarders on a sphere of radius π, and so on. All Mueller matrices on spheres of radius $2\pi n$, where n is an integer, the retarder order, have the identity matrix as their Mueller matrix, as does the point at the origin. The retarder space is similar to the Poincaré sphere except the retardance components are plotted instead of the Stokes vector, so the size of the space is not limited to a radius of one.

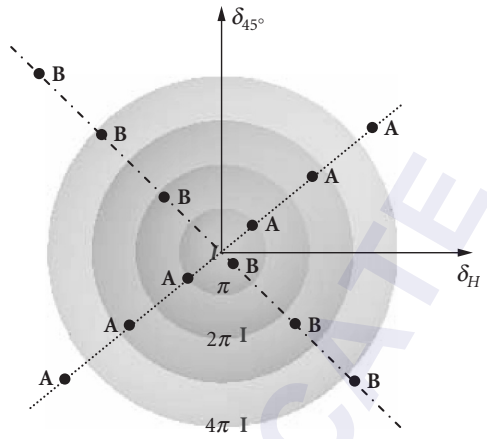

FIGURE 2 Retarder space is a Poincaré sphere like space which represents retarder fast axes $\{\delta_H, \delta_{45}, \delta_R\}$ as points in a three-dimensional space. All half-wave retarders at the points indicated by A's have the same Mueller matrix; all retarders at points B share the same Mueller matrix.

Retarder Mueller matrices have an ambiguity with regard to retarder order n, the integer part or half integer part of the number of waves of retardance. The Mueller matrix relates incident Stokes vectors to transmitted Stokes vectors. There is a family of retarders which will perform the same transformation on all polarization states. For example, a retarder with retardance $\delta = 0$ leaves all polarization states unchanged. Similarly when all polarization states exit a retarder with $\delta = 2\pi$, or $n2\pi$, all polarization states are returned to the incident polarization state. As another example, a quarter-wave retarder rotates the Poincaré sphere $\pi/2$ radians clockwise about an axis. A three-quarter-wave retarder with the orthogonal axis rotates the Poincaré sphere $3\pi/2$ radians counterclockwise, has the same Mueller matrix and transmits the same Stokes vectors. As a third example, half-wave retarders with orthogonal axes rotate the Poincaré sphere by half a rotation in opposite directions and have the same Mueller matrix. So in general all Mueller matrices with retardance $2\pi n + \delta$ and a particular normalized fast axis $\{\delta_H, \delta_{45}, \delta_R\}$ and all Mueller matrices with retardance $2\pi m - \delta$ and the orthogonal normalized fast axis $\{-\delta_H, -\delta_{45}, -\delta_R\}$ have the same Mueller matrix (m and n integers). This is shown in Fig. 2 by the set of half-wave retarder locations with **A**'s. Another set of elliptical retarders with the same Mueller matrix are indicated by the set of **B**'s.

The surfaces of various sets of retarders in the 16-dimensional space of Mueller matrices have an interesting topology due to the retarder ambiguity. In a narrow Mobius strip, the edge is nearly a circle which goes around twice before returning to its starting point. Similarly going around the equatorial plane of the half-wave retarders, the Mueller matrices for the corresponding half-wave linear retarders repeat twice. When plotted in the 16-dimensions of the Mueller matrix space, the half-wave retarders circle twice in a perfect circle for one 180° rotation of the fast axis. The linear retarder Mueller matrices for a retardance slightly different from π circle twice slightly offset and outline the edges of a Mobius strip. This doubling is a consequence of the fact that when all the linear retarders are plotted as points in the Mueller matrix space, they form a two-dimensional surface which is topologically equivalent to a Klein bottle, a single-sided surface with Mobius strip cross-sections. Similarly when all elliptical retarders are plotted in the Mueller matrix space, they form a higher-dimensional Klein bottle with a three-dimensional surface. To summarize, any plane through the origin of the retarder space in Fig. 2 maps to a Klein bottle in the Mueller matrix space, and the entire space maps to the higher-dimensional Klein bottle.

14.14 TRANSMITTANCE AND DIATTENUATION

Polarizers and partial polarizers are characterized by the property diattenuation, which describes the magnitude of the variation of the transmitted irradiance as a function of the incident polarization state. The diattenuation magnitude D, usually referred to as the *diattenuation*, is a function of the maximum, T_{max}, and minimum, T_{min}, transmittances of a polarization element,

$$D = \frac{T_{max} - T_{min}}{T_{max} + T_{min}} = \frac{\sqrt{m_{1,0}^2 + m_{2,0}^2 + m_{3,0}^2}}{m_{0,0}} \qquad 0 \le D \le 1 \tag{33}$$

The diattenuation has the useful property that D varies from 1 for a polarizer to 0 for an element which transmits all polarization states equally, such as a retarder or a nonpolarizing interaction.

The transmitted irradiance of a Mueller matrix and its diattenuation depends only on the first row, $m_0 = \{m_{0,0}, m_{0,1}, m_{0,2}, m_{0,3}\}$, because these are the only elements which affect S_0'. The diattenuation is not linear in T_{min}/T_{max} as shown in Fig. 3.

To find T_{max} and T_{min}, first the incident Stokes vectors is normalized so $S_0 = 1$. The transmittance $T(\mathbf{S})$ of a device with Mueller matrix $\mathbf{M}$ depends on the incident polarization state and is the ratio of the exiting flux to the incident flux,

$$\mathbf{T}(\mathbf{M}, \hat{\mathbf{S}}) = \frac{S_0'}{S_0} = \frac{(\mathbf{M} \bullet \hat{\mathbf{S}})_0}{S_0} = \frac{m_{0,0} s_0 + m_{0,1} s_1 + m_{0,2} s_2 + m_{0,3} s_3}{s_0} \tag{34}$$

which depends on the dot product of the first row of the Mueller matrix with the incident Stokes vector. The dependence of the transmission on incident polarization state is characterized by a set of three diattenuation parameters, $\mathbf{d}$, defined as

$$\mathbf{d} = \frac{\{m_{0,1}\ m_{0,2}\ m_{0,3}\}}{m_{0,0}} = \{d_H, d_{45}, d_R\} \tag{35}$$

The diattenuation parameters have three components corresponding to the three components of the Stokes vector, *x/y,* 45°/135°, right/left, each of which characterizes how the transmission varies with each of the Stokes vector component. The diattenuation parameter set $\mathbf{d}$ is often called the

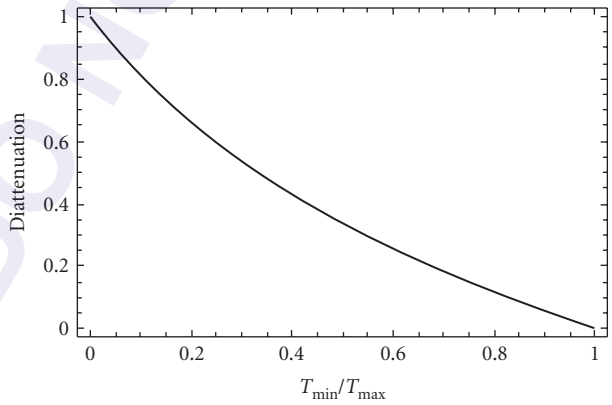

FIGURE 3 Relationship between the diattenuation and the extinction ratio, T_{min}/T_{max}.

diattenuation vector, but like the Stokes vector, **d** is not a true vector. Diattenuation parameters do not add. For a Stokes three-vector **s**, the transmission function T is

$$T(\mathbf{M},\,\mathbf{s}) = \frac{s_0'}{s_0} = m_{0,0} + m_{0,1}\,s_1 + m_{0,2}\,s_2 + m_{0,3}\,s_3 = m_{0,0}(1 + \mathbf{d}\bullet\mathbf{s}) \tag{36}$$

The average transmission, formed by averaged over all polarized Stokes vectors, is $m_{0,0}$. The average transmission is also the transmission for unpolarized incident light, $\mathbf{s}_U = \{0,0,0\}$. The polarization-dependent variation of the transmission is contained in the dot product term between the incident Stokes three-vector and the diattenuation vector, $\mathbf{s} \bullet \mathbf{d}$. The maximum transmission, $T_{\max}$, occurs when the dot product is maximized, which occurs when **s** and **d** are parallel, and the magnitude of S_0' is as large as possible. The incident normalized Stokes vectors with maximum transmittance, $S_{\max}$, and minimum transmittance, $S_{\min}$, are

$$\mathbf{s}_{\max} = \frac{\mathbf{d}}{|\mathbf{d}|} \quad \hat{\mathbf{S}}_{\max} = \frac{1}{D}\begin{pmatrix} D \\ d_x \\ d_{45} \\ d_R \end{pmatrix} \quad \mathbf{s}_{\min} = \frac{-\mathbf{d}}{|\mathbf{d}|} \quad \hat{\mathbf{S}}_{\min} = \frac{1}{D}\begin{pmatrix} D \\ -d_x \\ -d_{45} \\ -d_R \end{pmatrix} \tag{37}$$

yielding

$$T_{\max} = m_{0,0}(1+D) \quad T_{\min} = m_{0,0}(1-D) \tag{38}$$

Therefore the diattenuation of any Mueller matrix is

$$D(\mathbf{M}) = \frac{T_{\max} - T_{\min}}{T_{\max} + T_{\min}} = \frac{\sqrt{m_{0,1}^2 + m_{0,2}^2 + m_{0,3}^2}}{m_{0,0}} \tag{39}$$

For an ideal polarizer the minimum transmission is zero, $D=1$, $T_{\min} = m_{0,0}(1-D) = 0$.

Linear polarization sensitivity or *linear diattenuation* LD(**M**) characterizes the variation of intensity transmittance with incident linear polarization states:

$$\mathrm{LD}(\mathbf{M}) = \frac{\sqrt{m_{0,1}^2 + m_{0,2}^2}}{m_{0,0}} \tag{40}$$

Linear polarization sensitivity is frequently specified as a performance parameter in remote sensing systems designed to measure incident power independently of any linearly polarized component present in scattered earth-light.[18] Note that LD(**M**) = 1 identifies **M** as a linear analyzer; **M** is not necessarily a linear polarizer, but may represent a linear polarizer followed by some other polarization element.

Diattenuation in fiber optic components and systems is often characterized by the *polarization-dependent loss* (*PDL*) specified in decibels:

$$\mathrm{PDL}(\mathbf{M}) = 10\log_{10}\frac{T_{\max}}{T_{\min}} \tag{41}$$

14.15 POLARIZANCE

The polarizance ($P(\mathbf{M})$) is the degree of polarization (DoP) of the transmitted light when unpolarized light $\hat{\mathbf{U}}$ is incident,[3]

$$P(\mathbf{M}) = \mathrm{DoP}(\mathbf{M}\bullet\hat{\mathbf{U}}) = \frac{\sqrt{m_{1,0}^2 + m_{2,0}^2 + m_{3,0}^2}}{m_{0,0}} \tag{42}$$

The exiting polarization state, $\mathbf{S}_p(\mathbf{M})$, is the first column of $\mathbf{M}$,

$$\mathbf{S}_p(\mathbf{M}) = \mathbf{M}\bullet\mathbf{U} = \begin{pmatrix} m_{0,0} & m_{0,1} & m_{0,2} & m_{0,3} \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{2,1} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{3,1} & m_{3,2} & m_{3,3} \end{pmatrix} \bullet \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} m_{0,0} \\ m_{1,0} \\ m_{2,0} \\ m_{3,0} \end{pmatrix} \tag{43}$$

The polarizance does not necessarily equal the diattenuation. Nor does $\mathbf{S}_p$ necessarily equal, $\vec{\mathbf{S}}_{\max}$, the incident state of maximum transmittance.

14.16 MUELLER MATRICES OF DIATTENUATORS

The Mueller matrix for a partial polarizer (homogeneous diattenuator) with intensity transmittances T_x and T_y and eigenpolarizations along the x and y axes, $\mathbf{LD}(T_x, T_y, 0)$ is

$$\mathbf{LD}(T_x, T_y, 0) = \frac{1}{2}\begin{pmatrix} T_x + T_y & T_x - T_y & 0 & 0 \\ T_x - T_y & T_x + T_y & 0 & 0 \\ 0 & 0 & 2\sqrt{T_x T_y} & 0 \\ 0 & 0 & 0 & 2\sqrt{T_x T_y} \end{pmatrix} \tag{44}$$

Ideal diattenuators have two different intensity transmittances $T_{\max}$ and $T_{\min}$, for two orthogonal linear eigenpolarizations; thus the name "di" "attenuator". A linear diattenuator oriented at angle θ has the Mueller matrix

$$\mathbf{LD}(T_{\max}, T_{\min}, \theta) = \frac{1}{2}\begin{pmatrix} A & B\cos 2\theta & B\sin 2\theta & 0 \\ B\cos 2\theta & A\cos^2 2\theta + C\sin^2 2\theta & (A-C)\cos 2\theta \sin 2\theta & 0 \\ B\sin 2\theta & (A-C)\cos 2\theta \sin 2\theta & C\cos^2 2\theta + A\sin^2 2\theta & 0 \\ 0 & 0 & 0 & C \end{pmatrix} \tag{45}$$

where

$$A = T_{\max} + T_{\min} \qquad B = T_{\max} - T_{\min} \qquad C = 2\sqrt{T_{\max} T_{\min}} \tag{46}$$

Ideal diattenuators have no retardance, although in practice most diattenuators have some retardance. An example of a pure linear diattenuator without retardance is transmission into a transparent dielectric; $T_{\max}$ and $T_{\min}$ are then given by intensity Fresnel coefficients. Reflection at metal surfaces acts as a diattenuator with retardance.

Ideal diattenuator Mueller matrices are hermitian matrices; they have real eigenvalues. A hermitian matrix equals the complex conjugate of its transpose, its hermitian adjoint, $\mathbf{H} = \mathbf{H}^{\dagger} = (\mathbf{H}^{T})^{*}$. But since Mueller matrices are real, $\mathbf{H}^{*} = \mathbf{H}$, ideal diattenuator Mueller matrices equal their transpose,

$$\mathbf{H} = \mathbf{H}^{T} \tag{47}$$

The general equation for a diattenuator, either linear, elliptical, or circular, expressed in terms of the first row of the Mueller matrix is

$$\text{Diattenuator}(d_H, d_{45}, d_R, Ta_{\text{avg}}) =$$

$$T_{\text{avg}} \begin{pmatrix} 1 & d_H & d_{45} & d_R \\ d_H & A & 0 & 0 \\ d_{45} & 0 & A & 0 \\ d_R & 0 & 0 & A \end{pmatrix} + \frac{T_{\text{avg}}(1-A)}{D^2} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & d_H^2 & d_{45}d_H & d_H d_R \\ 0 & d_{45}d_H & d_{45}^2 & d_{45}d_R \\ 0 & d_H d_R & d_{45}d_R & d_R^2 \end{pmatrix} \tag{48}$$

$$D = \sqrt{d_H^2 + d_{45}^2 + d_R^2} \qquad A = \sqrt{1 - d_H^2 - d_{45}^2 - d_R^2} \qquad T_{\text{avg}} = \frac{T_{\max} + T_{\min}}{2}$$

14.17 NORMALIZING A MUELLER MATRIX

Mueller matrices are normalized by dividing $\mathbf{M}$ by $m_{0,0}$, the transmission for unpolarized light, and also the transmission when the input state is averaged over the entire Poincaré sphere. The normalized Mueller matrix $\bar{\mathbf{M}}$ has an average transmission of one,

$$\bar{\mathbf{M}} = \frac{\mathbf{M}}{m_{0,0}} = \begin{pmatrix} 1 & m_{0,1}/m_{0,0} & m_{0,2}/m_{0,0} & m_{0,3}/m_{0,0} \\ m_{1,0}/m_{0,0} & m_{1,1}/m_{0,0} & m_{1,2}/m_{0,0} & m_{1,3}/m_{0,0} \\ m_{2,0}/m_{0,0} & m_{2,1}/m_{0,0} & m_{2,2}/m_{0,0} & m_{2,3}/m_{0,0} \\ m_{3,0}/m_{0,0} & m_{3,1}/m_{0,0} & m_{3,2}/m_{0,0} & m_{3,3}/m_{0,0} \end{pmatrix} \tag{49}$$

Normalization limits all element values to the range $-1 \le m_{i,j} \le 1$. Measured Mueller matrix data is frequently normalized to facilitate comparison of Mueller matrix polarization properties with the average transmission removed. It facilitates comparison to Mueller matrices tabulated in the literature. Normalizing Mueller matrix images or spectra simplifies *eyeballing* the data; with the flux variations removed, diattenuation, retardance, and depolarization variations are easier to see.

Normalizing by a different value, $k/m_{0,0}$ sets the average transmission to k, such as $k = 1/2$ for an ideal polarizer. A Mueller matrix $\hat{\mathbf{M}}$ normalized, so the maximum transmission is one is

$$\hat{\mathbf{M}} = \frac{\mathbf{M}}{m_{0,0} + \sqrt{m_{0,1}^2 + m_{0,2}^2 + m_{0,3}^2}} = \frac{\mathbf{M}}{T_{\max}} \tag{50}$$

14.18 COORDINATE SYSTEM FOR THE MUELLER MATRIX

Consider a Mueller polarimeter consisting of a polarization generator which illuminates a sample, and a polarization analyzer which collects the light exiting the sample in a particular direction. We wish to characterize the polarization modification properties of the sample for a particular incident and exiting beam through the Mueller matrix. The incident polarization states are specified by Stokes vectors defined relative to an $\{\hat{\mathbf{x}}, \hat{\mathbf{y}}\}$ coordinate system orthogonal to the propagation

direction of the incident light. Similarly, the exiting light's Stokes vector is defined relative to an $\{\hat{\mathbf{x}}', \hat{\mathbf{y}}'\}$ coordinate system orthogonal to its propagation direction. For transmission measurements where the beam exits undeviated, the orientations of $\{\hat{\mathbf{x}}, \hat{\mathbf{y}}\}$ and $\{\hat{\mathbf{x}}', \hat{\mathbf{y}}'\}$ will naturally be chosen to be aligned, $(\hat{\mathbf{x}} = \hat{\mathbf{x}}', \hat{\mathbf{y}} = \hat{\mathbf{y}}')$. The global orientation of $\{\hat{\mathbf{x}}, \hat{\mathbf{y}}\}$ is arbitrary, and the measured Mueller matrix varies systematically if $\{\hat{\mathbf{x}}, \hat{\mathbf{y}}\}$ and $\{\hat{\mathbf{x}}', \hat{\mathbf{y}}'\}$ are rotated together.

When the exiting beam emerges in a different direction from the incident beam, orientations must be specified for both sets of coordinates. For measurements of reflection from a surface, a logical choice sets $\{\hat{\mathbf{x}}, \hat{\mathbf{y}}\}$ and $\{\hat{\mathbf{x}}', \hat{\mathbf{y}}'\}$ to the $\{\hat{\mathbf{s}}, \hat{\mathbf{p}}\}$ orientations for the two beams. Other Mueller matrix measurement configurations may have other obvious arrangements for the coordinates. All choices, however, are arbitrary, and lead to different Mueller matrices. Let a Mueller matrix $\mathbf{M}$ be defined relative to a particular $\{\hat{\mathbf{x}}, \hat{\mathbf{y}}\}$ and $\{\hat{\mathbf{x}}', \hat{\mathbf{y}}'\}$. Let another Mueller matrix $\mathbf{M}(\theta_1, \theta_2)$ for the same measurement conditions have its $\hat{\mathbf{x}}$ axis rotated by θ_1 and x' axis rotated by θ_2, where $\theta > 0$ indicates a counterclockwise rotation looking into the beam ($\hat{\mathbf{x}}$ into $\hat{\mathbf{y}}$). These Mueller matrices are related by the equation

$$\mathbf{M}(\theta_1, \theta_2) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos 2\theta_2 & -\sin 2\theta_2 & 0 \\ 0 & \sin 2\theta_2 & \cos 2\theta_2 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \bullet \begin{pmatrix} m_{0,0} & m_{0,1} & m_{0,2} & m_{0,3} \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{2,1} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{3,1} & m_{3,2} & m_{3,3} \end{pmatrix} \bullet \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos 2\theta_1 & \sin 2\theta_1 & 0 \\ 0 & -\sin 2\theta_1 & \cos 2\theta_1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{51}$$

When $\theta_1 = \theta_2$, the coordinates rotate together, the eigenvalues are preserved, the circular polarization properties are preserved, and the linear properties are shifted in orientation. When $\theta_1 \neq \theta_2$, the matrix properties are qualitatively different; the eigenvalues of the matrix change. If the eigenpolarizations of $\mathbf{M}$ were orthogonal, they may not remain orthogonal. After we perform data reduction on the matrix, the basic polarization properties couple in a complex fashion. For example, linear diattenuation in $\mathbf{M}$ yields a circular retardance component in $\mathbf{M}(\theta_1, \theta_2)$. The selection of the coordinate systems for the incident and exiting beams is not important for describing exiting polarization states, but is crucial for properly identifying polarization characteristics of the sample.

14.19 MUELLER MATRICES FOR REFRACTION

Reflections and refractions at homogenous and isotropic interfaces, typical glass or metal interfaces, have *s* and *p* eigenpolarizations. The polarization is a combination of diattenuation and retardance, with the eigenpolarizations aligned with the *s* and *p* planes. Let *s* be aligned with *x* and *p* with *y*. T_s is the *s*-intensity reflectance or transmittance and T_p is the *p*-intensity reflectance or transmittance. The retardance between the *s* and *p* states is δ. T_s, T_p, δ are determined from Fresnel equations or from a thin-film coating calculation. The Mueller matrix is the product of the diattenuator and retarder Mueller matrices,

$$\begin{aligned} \mathbf{LDR}(D, \delta, 0) &= \frac{T_{\max} + T_{\min}}{2} \begin{pmatrix} 1 & D & 0 & 0 \\ D & 1 & 0 & 0 \\ 0 & 0 & \sqrt{1-D^2}\cos\delta & \sqrt{1-D^2}\sin\delta \\ 0 & 0 & -\sqrt{1-D^2}\sin\delta & \sqrt{1-D^2}\cos\delta \end{pmatrix} \\ &= \frac{1}{2} \begin{pmatrix} T_s + T_p & T_s - T_p & 0 & 0 \\ T_s - T_p & T_s + T_p & 0 & 0 \\ 0 & 0 & 2\sqrt{T_s T_p}\cos\delta & 2\sqrt{T_s T_p}\sin\delta \\ 0 & 0 & -2\sqrt{T_s T_p}\sin\delta & 2\sqrt{T_s T_p}\cos\delta \end{pmatrix} \end{aligned} \tag{52}$$

For transmission at an uncoated interface, $\delta = 0$, but for thin-film-coated interfaces, such as anti-reflection coatings or beam-splitter coatings, the retardance is nonzero. If the plane of incidence is not vertical, the Mueller rotation operator is applied. Refraction Mueller matrices are homogeneous; the eigenpolarizations, the *s* and *p* polarizations, are orthogonal.

14.20 MUELLER MATRICES FOR REFLECTION

In most optics notation, including this chapter, a sign change occurs in the coordinate system after reflection to maintain a right-handed coordinate system after the propagation vector has changed direction. After reflection, the S_2 component of Stokes vectors (linearly polarized light at 45°/135°) and the S_3 component (circularly polarized light) change sign. The S_2 component changes sign during reflection (diffuse or specular) because the *z*-component of the light propagation vector (the component parallel to the sample surface normal) changes sign. To maintain a right-handed coordinate system, one of the transverse coordinates must change sign as well. Choosing *x*, the spatial coordinates (*x, y, z*) switch to (*–x, y, –z*) after reflection or scatter from a sample; *z* is the direction of propagation before reflection which changes to *–z* after reflection. The change of coordinates dictates that a beam polarized at an angle of 45° which reflects polarized in the same global plane is described as having a 135° orientation in the coordinates following reflection.

Picture a Stokes polarimeter measuring in transmission; now rotate that polarimeter around *z* axis and move it to measure in reflection and you should see how the 45° component has changed sign. In addition, the helicity (i.e., handedness) of all circular and elliptical states changes sign upon reflection. Right circular polarization reflects as left circular polarization, and vice versa.

First let *s* be aligned with *x* and *p* with *y*. R_s is the *s*-intensity reflectance and R_p is the *p*-intensity reflectance. The retardance between the *s* and *p* states is δ. R_s, R_p, δ are determined from Fresnel equations or from a thin-film coating calculation. The reflection Mueller matrix is

$$\frac{1}{2}\begin{pmatrix} R_s+R_p & R_s-R_p & 0 & 0 \\ R_s-R_p & R_s+R_p & 0 & 0 \\ 0 & 0 & -2\sqrt{R_sR_p}\cos\delta & -2\sqrt{R_sR_p}\sin\delta \\ 0 & 0 & 2\sqrt{R_sR_p}\sin\delta & -2\sqrt{R_sR_p}\cos\delta \end{pmatrix} \tag{53}$$

With this convention for reflection, the equation for rotating the Mueller matrix, **M**, of a sample measured by a polarimeter in a reflection configuration about its normal is

$$\mathbf{M}_R(\theta) = \mathbf{R}(\theta)\bullet\mathbf{M}\bullet\mathbf{R}(\theta)$$

$$= \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos 2\theta & -\sin 2\theta & 0 \\ 0 & \sin 2\theta & \cos 2\theta & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} m_{0,0} & m_{0,1} & m_{0,2} & m_{0,3} \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{2,1} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{3,1} & m_{3,2} & m_{3,3} \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos 2\theta & -\sin 2\theta & 0 \\ 0 & \sin 2\theta & \cos 2\theta & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{54}$$

compared to

$$\mathbf{M}_T(\theta) = \mathbf{R}(\theta)\bullet\mathbf{M}\bullet\mathbf{R}(-\theta) \tag{55}$$

for Mueller matrices in transmission. For example, the Mueller matrix of a transmission polarizer with its transmission axis oriented at 20° and the Mueller matrix of a reflection polarizer oriented at 20° are different since polarized light exits the reflection polarizer oriented at –20° in the reflection coordinates (20° in the incident coordinates). In essence the reflection polarizer Mueller matrix is

analyzing at 20° but polarizing at −20°. For the special cases of linear polarizer matrices oriented at 0° or 90° and linear retarders oriented at 0° or 90°, this transformation results in Mueller matrices which are the same for transmission and reflection.

The normalized reflection Mueller matrices for weakly polarizing diffuse reflecting samples, those with diattenuation, retardance, and depolarization close to zero, are close to the Mueller matrix for an ideal reflector,

$$\mathbf{M}_{\text{refl}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \tag{56}$$

14.21 CONVERSION BETWEEN MUELLER MATRICES AND JONES MATRICES

Jones matrices form an alternative and very useful representation of sample polarization, particularly because Jones matrices have simpler properties and are more easily manipulated and interpreted. The complication in mapping Mueller matrices onto Jones matrices and vice versa is that Mueller matrices cannot represent absolute phase and Jones matrices cannot represent depolarization. Thus, only nondepolarizing Mueller matrices have corresponding Jones matrices. All Jones matrices have corresponding Mueller matrices, but because the absolute phase is not represented, the mapping is many Jones matrices to one Mueller matrix.

Both Jones matrices and Mueller matrices can calculate the polarization properties of sequences of nondepolarizing interactions, the effect of cascading a series of diattenuators and retarders. When this same polarization element sequence is calculated by Jones matrices and alternatively by Mueller matrices, the answer is the same diattenuating and retarding properties. Either method is suitable.

Jones vectors and Jones matrices are commonly represented with two different sign conventions for the phase. Electromagnetic waves are commonly written with two different conventions, either the phase decreases with time $(kz-\omega t-\phi)$, the convention adopted here, or the phase increases with time $(wt-kz+\phi)$. Depending on the choice, various plus and minus signs must be adjusted in the Jones vectors for circularly and elliptically polarized light and in the various Jones matrices. Both conventions are in widespread use so care is necessary when taking Jones matrices from different sources. In this chapter, the phase decreases with time, so a monochromatic plane wave propagating in the z direction has the form

$$\mathbf{E}(z,\, t) = \text{Re}\left\{ \begin{pmatrix} E_x \\ E_y \end{pmatrix} e^{i(kz-\omega t-\phi)} \right\} = \begin{pmatrix} E_x \\ E_y \end{pmatrix} \cos(kz-\omega t-\phi) \tag{57}$$

A wave is *advanced* by *subtracting* from the phase. A wave is delayed or retarded by adding to the phase.

A Jones matrix **J** is transformed into a Mueller matrix by the relation

$$\mathbf{M} = \mathbf{U}(\mathbf{J} \otimes \mathbf{J}^*)\mathbf{U}^{-1} \tag{58}$$

in which ⊗ represents the tensor product and **U** is the Jones/Mueller transformation matrix:[9,10,19,20]

$$\mathbf{U} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & -1 \\ 0 & 1 & 1 & 0 \\ 0 & i & -i & 0 \end{pmatrix} = (\mathbf{U}^{-1})^{\dagger} \tag{59}$$

where the hermitian adjoint is represented by †. All Jones matrices of the form $\mathbf{J}' = e^{i\phi}\mathbf{J}$ transform to the same Mueller matrix. Consider a Jones matrix with complex elements expressed in polar coordinate form

$$\mathbf{J} = \begin{pmatrix} \phi_{x,x} & \phi_{x,y} \\ \phi_{y,x} & \phi_{y,y} \end{pmatrix} = \begin{pmatrix} \rho_{x,x}e^{i\phi_{x,x}} & \rho_{x,y}e^{i\phi_{x,y}} \\ \rho_{y,x}e^{i\phi_{y,x}} & \rho_{y,y}e^{i\phi_{y,y}} \end{pmatrix} \tag{60}$$

The tensor product $(\mathbf{J} \otimes \mathbf{J}^*)$ gives a fourth rank second-order tensor $\{2 \times 2 \times 2 \times 2\}$,

$$(\mathbf{J} \otimes \mathbf{J}^*) = \begin{pmatrix} \rho_{x,x}e^{i\phi_{x,x}} \begin{pmatrix} \rho_{x,x}e^{-i\phi_{x,x}} & \rho_{x,y}e^{-i\phi_{x,y}} \\ \rho_{y,x}e^{-i\phi_{y,x}} & \rho_{y,y}e^{-i\phi_{y,y}} \end{pmatrix} & \rho_{x,y}e^{i\phi_{x,y}} \begin{pmatrix} \rho_{x,x}e^{-i\phi_{x,x}} & \rho_{x,y}e^{-i\phi_{x,y}} \\ \rho_{y,x}e^{-i\phi_{y,x}} & \rho_{y,y}e^{-i\phi_{y,y}} \end{pmatrix} \\ \rho_{y,x}e^{i\phi_{y,x}} \begin{pmatrix} \rho_{x,x}e^{-i\phi_{x,x}} & \rho_{x,y}e^{-i\phi_{x,y}} \\ \rho_{y,x}e^{-i\phi_{y,x}} & \rho_{y,y}e^{-i\phi_{y,y}} \end{pmatrix} & \rho_{y,y}e^{i\phi_{y,y}} \begin{pmatrix} \rho_{x,x}e^{-i\phi_{x,x}} & \rho_{x,y}e^{-i\phi_{x,y}} \\ \rho_{y,x}e^{-i\phi_{y,x}} & \rho_{y,y}e^{-i\phi_{y,y}} \end{pmatrix} \end{pmatrix} \tag{61}$$

This tensor is contracted to a second rank fourth-order (4×4) tensor.

$$(\mathbf{J} \otimes \mathbf{J}^*) = \begin{pmatrix} \rho_{x,x}^2 & \rho_{x,x}\rho_{x,y}e^{i(\phi_{x,x}-\phi_{x,y})} & \rho_{x,y}\rho_{x,x}e^{i(\phi_{x,y}-\phi_{x,x})} & \rho_{x,y}^2 \\ \rho_{x,x}\rho_{y,x}e^{i(\phi_{x,x}-\phi_{y,x})} & \rho_{x,x}\rho_{y,y}e^{i(\phi_{x,x}-\phi_{y,y})} & \rho_{x,y}\rho_{y,x}e^{i(\phi_{x,y}-\phi_{y,x})} & \rho_{x,y}\rho_{y,y}e^{i(\phi_{x,y}-\phi_{y,y})} \\ \rho_{y,x}\rho_{x,x}e^{i(\phi_{y,x}-\phi_{x,x})} & \rho_{y,x}\rho_{x,y}e^{i(\phi_{y,x}-\phi_{x,y})} & \rho_{y,y}\rho_{x,x}e^{i(\phi_{y,y}-\phi_{x,x})} & \rho_{y,y}\rho_{x,y}e^{i(\phi_{y,y}-\phi_{x,y})} \\ \rho_{y,x}^2 & \rho_{y,x}\rho_{y,y}e^{i(\phi_{y,x}-\phi_{y,y})} & \rho_{y,y}\rho_{y,x}e^{i(\phi_{y,y}-\phi_{y,x})} & \rho_{y,y}^2 \end{pmatrix} \tag{62}$$

which when multiplied with $\mathbf{U}$ gives the Mueller matrix elements as follows:

$$\mathbf{U}\bullet(\mathbf{J} \otimes \mathbf{J}^*)\bullet\mathbf{U}^{-1} = \begin{pmatrix} m_{0,0} \\ m_{0,1} \\ m_{0,2} \\ m_{0,3} \\ m_{1,0} \\ m_{1,1} \\ m_{1,2} \\ m_{1,3} \\ m_{2,0} \\ m_{2,1} \\ m_{2,2} \\ m_{2,3} \\ m_{3,0} \\ m_{3,1} \\ m_{3,2} \\ m_{3,3} \end{pmatrix} = \begin{pmatrix} \frac{1}{2}\left(\rho_{x,x}^2 + \rho_{x,y}^2 + \rho_{y,x}^2 + \rho_{y,y}^2\right) \\ \frac{1}{2}\left(\rho_{x,x}^2 - \rho_{x,y}^2 + \rho_{y,x}^2 - \rho_{y,y}^2\right) \\ \rho_{x,x}\rho_{x,y}\cos(\phi_{x,x}-\phi_{x,y}) + \rho_{y,x}\rho_{y,y}\cos(\phi_{y,x}-\phi_{y,y}) \\ \rho_{x,x}\rho_{x,y}\sin(\phi_{x,x}-\phi_{x,y}) + \rho_{y,x}\rho_{y,y}\sin(\phi_{y,x}-\phi_{y,y}) \\ \frac{1}{2}\left(\rho_{x,x}^2 + \rho_{x,y}^2 - \rho_{y,x}^2 - \rho_{y,y}^2\right) \\ \frac{1}{2}\left(\rho_{x,x}^2 - \rho_{x,y}^2 - \rho_{y,x}^2 + \rho_{y,y}^2\right) \\ \rho_{x,x}\rho_{x,y}\cos(\phi_{x,x}-\phi_{x,y}) - \rho_{y,x}\rho_{y,y}\cos(\phi_{y,x}-\phi_{y,y}) \\ \rho_{x,x}\rho_{x,y}\sin(\phi_{x,x}-\phi_{x,y}) - \rho_{y,x}\rho_{y,y}\sin(\phi_{y,x}-\phi_{y,y}) \\ \rho_{x,x}\rho_{y,x}\cos(\phi_{x,x}-\phi_{y,x}) + \rho_{x,y}\rho_{y,y}\cos(\phi_{x,y}-\phi_{y,y}) \\ \rho_{x,x}\rho_{y,x}\cos(\phi_{x,x}-\phi_{y,x}) - \rho_{x,y}\rho_{y,y}\cos(\phi_{x,y}-\phi_{y,y}) \\ \rho_{x,y}\rho_{y,x}\cos(\phi_{x,y}-\phi_{y,x}) + \rho_{x,x}\rho_{y,y}\cos(\phi_{x,x}-\phi_{y,y}) \\ -\rho_{x,y}\rho_{y,x}\sin(\phi_{x,y}-\phi_{y,x}) + \rho_{x,x}\rho_{y,y}\sin(\phi_{x,x}-\phi_{y,y}) \\ -\rho_{x,x}\rho_{y,x}\sin(\phi_{x,x}-\phi_{y,x}) - \rho_{x,y}\rho_{y,y}\sin(\phi_{x,y}-\phi_{y,y}) \\ -\rho_{x,x}\rho_{y,x}\sin(\phi_{x,x}-\phi_{y,x}) + \rho_{x,y}\rho_{y,y}\sin(\phi_{x,y}-\phi_{y,y}) \\ -\rho_{x,y}\rho_{y,x}\sin(\phi_{x,y}-\phi_{y,x}) - \rho_{x,x}\rho_{y,y}\sin(\phi_{x,x}-\phi_{y,y}) \\ -\rho_{x,y}\rho_{y,x}\cos(\phi_{x,y}-\phi_{y,x}) + \rho_{x,x}\rho_{y,y}\cos(\phi_{x,x}-\phi_{y,y}) \end{pmatrix} \tag{63}$$

An equivalent method to convert Jones matrices to Mueller matrices utilizes dot products with two Pauli spin matrices to determine each Mueller matrix element, $m_{i,j}$,

$$m_{i,j} = \frac{1}{2}\mathrm{Tr}(\mathbf{J}\cdot\boldsymbol{\sigma}_i\cdot\mathbf{J}^{\dagger}\cdot\boldsymbol{\sigma}_j) \tag{64}$$

where Tr is the trace of the matrix and

$$\boldsymbol{\sigma}_i = \left\{\begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix},\ \begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix},\ \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix},\ \begin{pmatrix}0 & -i\\ i & 0\end{pmatrix}\right\} \quad i = 0,\ 1,\ 2,\ 3 \tag{65}$$

are the identity matrix and normalized Pauli spin matrices.

Nondepolarizing Mueller matrices are transformed into the equivalent Jones matrices using the following relations:

$$\mathbf{J} = \begin{pmatrix} j_{x,x} & j_{x,y} \\ j_{y,x} & j_{y,y} \end{pmatrix} = \begin{pmatrix} \rho_{x,x}e^{i\phi_{x,x}} & \rho_{x,y}e^{i\phi_{x,y}} \\ \rho_{y,x}e^{i\phi_{y,x}} & \rho_{y,y}e^{i\phi_{y,y}} \end{pmatrix} \tag{66}$$

where the amplitudes are

$$\begin{aligned} \rho_{x,x} &= \frac{1}{\sqrt{2}}\sqrt{m_{0,0}+m_{0,1}+m_{1,0}+m_{1,1}} \quad \rho_{x,y} = \frac{1}{\sqrt{2}}\sqrt{m_{0,0}-m_{0,1}+m_{1,0}-m_{1,1}} \\ \rho_{y,x} &= \frac{1}{\sqrt{2}}\sqrt{m_{0,0}+m_{0,1}-m_{1,0}-m_{1,1}} \quad \rho_{y,y} = \frac{1}{\sqrt{2}}\sqrt{m_{0,0}-m_{0,1}-m_{1,0}+m_{1,1}} \end{aligned} \tag{67}$$

and the relative phases are

$$\begin{aligned} \phi_{x,x}-\phi_{x,y} &= \arctan\left(\frac{m_{0,3}+m_{1,3}}{m_{0,2}+m_{1,2}}\right) \quad \phi_{y,x}-\phi_{x,x} = \arctan\left(\frac{m_{3,0}+m_{3,1}}{m_{2,0}+m_{2,1}}\right) \\ \phi_{y,y}-\phi_{x,x} &= \arctan\left(\frac{m_{3,2}-m_{2,3}}{m_{2,2}+m_{3,3}}\right) \end{aligned} \tag{68}$$

The phase $\phi_{x,x}$ is not determined but is the "reference phase." These equations are not unique and other equivalent forms can be derived.

For example, a special case occurs if $j_{x,x} = 0$; then both the numerator and denominator of the arctan are zero and the phase equations fail. The transformation equations can then be recast in closely related forms to use the phase of another Jones matrix element as the "reference phase."

14.22 NONDEPOLARIZING MUELLER MATRICES AND MUELLER-JONES MATRICES

Nondepolarizing Mueller matrices are the set of Mueller matrices for which completely polarized incident light [DoP(**S**)=1] is transmitted as completely polarized for all incident polarization states and have a depolarization index of one [Eq. (96)]. Nondepolarizing Mueller matrices are a subset of the Mueller matrices. Jones matrices can only represent nondepolarizing interactions. The nondepolarizing Mueller matrices are Mueller matrices with corresponding Jones matrices; thus nondepolarizing Mueller matrices are also called Mueller-Jones matrices.

An ideal polarizer is nondepolarizing when if the incident beam is polarized, the exiting beam is also polarized. Similarly an ideal retarder is nondepolarizing. The nondepolarizing Mueller matrices comprise the Mueller matrices for the matrix product of all arbitrary sequences of diattenuation and retardance. A Mueller-Jones matrix must satisfy the following condition for all θ and ϕ,

$$\mathrm{DoP}(\mathbf{M}\bullet\mathbf{S})=\mathrm{DoP}\left(\begin{pmatrix} m_{0,0} & m_{0,1} & m_{0,2} & m_{0,3} \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{2,1} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{3,1} & m_{3,2} & m_{3,3} \end{pmatrix}\bullet\begin{pmatrix} 1 \\ \cos 2\theta\cos\phi \\ \sin 2\theta\cos\phi \\ \sin\phi \end{pmatrix}\right)=1 \tag{69}$$

One necessary, but not sufficient, condition for nondepolarizing Mueller matrices is[21]

$$\begin{aligned}\mathrm{Tr}\,(\mathbf{M}\bullet\mathbf{M}^T)=4\,m_{0,0}^2=m_{0,0}^2+m_{0,1}^2+m_{0,2}^2+m_{0,3}^2+m_{1,0}^2+m_{1,1}^2+m_{1,2}^2+m_{1,3}^2 \\ +m_{2,0}^2+m_{2,1}^2+m_{2,2}^2+m_{2,3}^2+m_{3,0}^2+m_{3,1}^2+m_{3,2}^2+m_{3,3}^2\end{aligned} \tag{70}$$

In a typical imaging optical system, depolarization is an undesirable characteristic for lens and mirror surfaces, filters, and polarization elements. Depolarization is associated with scattering, and optical surfaces are carefully fabricated and coated to minimize scattering. Depolarization is generally very small from high-quality optical surfaces. Thus the majority of optical surfaces are well described by nondepolarizing Mueller matrices.

14.23 HOMOGENEOUS AND INHOMOGENEOUS POLARIZATION ELEMENTS

A nondepolarizing Mueller matrix is *homogeneous* if the two Stokes vector eigenpolarizations are orthogonal, and *inhomogeneous* otherwise. A nondepolarizing Mueller matrix $\mathbf{M}_N$ can be factored into a cascade of a diattenuator Mueller matrix $\mathbf{M}_D$ followed by a retarder Mueller matrix $\mathbf{M}_R$ or into a cascade of the same retarder followed by a different diattenuator $\mathbf{M}'_D$,[22]

$$\mathbf{M}_N=\mathbf{M}_R\mathbf{M}_D=\mathbf{M}'_D\mathbf{M}_R \tag{71}$$

The magnitude of the diattenuation of $\mathbf{M}_D$ and $\mathbf{M}'_D$ are equal. We define the diattenuation of $\mathbf{M}$ as the diattenuation of $\mathbf{M}_D$, and the retardance of $\mathbf{M}$ as the retardance of $\mathbf{M}_R$. For a homogeneous device, $\mathbf{M}_D = \mathbf{M}'_D$ and the eigenvectors of $\mathbf{M}_R$ and $\mathbf{M}_D$ are equal. Thus the retardance and diattenuation of a homogeneous Mueller matrix are "aligned," giving it substantially simpler properties than the inhomogeneous Mueller matrices. A necessary condition for a homogeneous Mueller matrix is

$$m_{0,1}=m_{1,0}, m_{0,2}=m_{2,0}, m_{0,3}=m_{3,0} \tag{72}$$

then, $P(\mathbf{M})=D(\mathbf{M})$.

The inhomogeneity of a Mueller matrix is characterized by the inhomogeneity index $I(\mathbf{M})$,

$$I(\mathbf{M})=\frac{\sqrt{\hat{\mathbf{S}}_1\bullet\hat{\mathbf{S}}_2}}{2}=\cos(\chi/2) \tag{73}$$

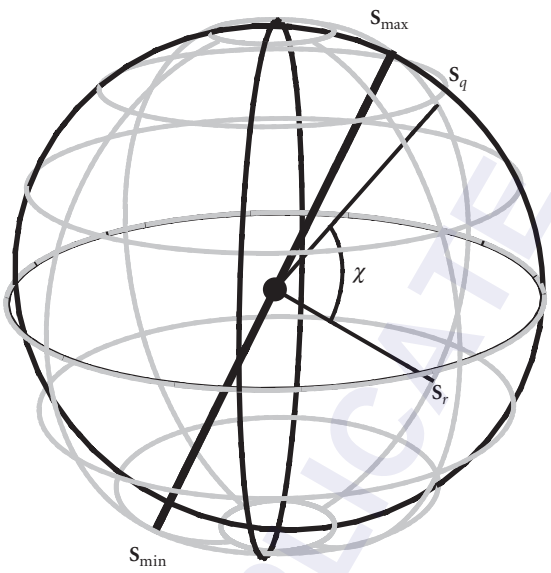

FIGURE 4 The principal Stokes vectors associated with an inhomogeneous polarization element mapped on the Poincarè sphere. The incident Stokes vectors of maximum $\mathbf{S}_{max}$ and minimum $\mathbf{S}_{min}$ intensity transmittance are diametrically opposite on the Poincarè sphere (indicating orthogonal polarization states) while the eigenpolarizations $\mathbf{S}_q$ and $\mathbf{S}_r$ are separated by the angle χ.

where $\hat{\mathbf{S}}_q$ and $\hat{\mathbf{S}}_r$ are normalized polarized Stokes vector eigenpolarizations of a Mueller matrix and χ is the angle between the eigenpolarizations on the Poincarè sphere measured from the center of the sphere as illustrated in Fig. 4. $I(\mathbf{M})$ varies from zero for orthogonal eigenpolarizations to one for degenerate (equal) eigenpolarizations.

The product of an arbitrary sequence of nondepolarizing Mueller matrices is another nondepolarizing Mueller matrix.

14.24 MUELLER MATRICES NEAR THE IDENTITY MATRIX, WEAK POLARIZATION ELEMENTS

The Mueller matrices of weak polarization elements are close to the 4×4 identity matrix. The properties of weak Mueller matrices are much simpler than general Mueller matrices because the retardance, diattenuation, and depolarization are close to zero. These simpler properties will be utilized later in the analysis of Mueller matrix properties by their matrix roots.

Some important examples of such weakly polarizing elements would be the lens surfaces and mirror surfaces in lenses, microscopes, and telescopes, where the polarization properties are not zero due to Fresnel equations, antireflection coatings, or mirrored surfaces, but the effects are often well below 5 percent.

The structure of the Mueller calculus and the properties of these weak elements can be explored by performing Taylor series on the Mueller matrix expressions with respect to diattenuation or retardance. Weak retarders have a retardance near zero. Performing a Taylor series expansion on

the general equation for an elliptical retarder and keeping the first-order terms yields the following simple expression for weak retarders:

$$\lim_{\delta_H,\delta_{45},\delta_R\to 0}\mathbf{LR}(\delta_H,\ \delta_{45},\ \delta_R)=\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & 1 & \delta_R & -\delta_{45}\\ 0 & -\delta_R & 1 & \delta_H\\ 0 & \delta_{45} & -\delta_H & 1\end{pmatrix} \tag{74}$$

Similarly, a first-order Taylor series expansion on the general diattenuator expression yields

$$\lim_{d_H,d_{45},d_R\to 0}\mathbf{D}(d_H,\ d_{45},\ d_R,\ T_{\text{avg}})=T_{\text{avg}}\begin{pmatrix}1 & d_H & d_{45} & d_R\\ d_H & 1 & 0 & 0\\ d_{45} & 0 & 1 & 0\\ d_R & 0 & 0 & 1\end{pmatrix} \tag{75}$$

Combining these yields the weak diattenuators and retarder Mueller matrix form

$$\mathbf{WDR}(d_H,\ d_{45},\ d_R,\ \delta_H,\ \delta_{45},\ \delta_R,\ T_{\text{avg}})=T_{\text{avg}}\begin{pmatrix}1 & d_H & d_{45} & d_R\\ d_H & 1 & \delta_R & -\delta_{45}\\ d_{45} & -\delta_R & 1 & \delta_H\\ d_R & \delta_{45} & -\delta_H & 1\end{pmatrix} \tag{76}$$

These three equations are only correct to first order. Higher-order terms, which are present when these parameters are not infinitesimal, are calculated from the exact equations presented earlier.

So weak diattenuators are symmetric in the top row and first column. Weak retarders are antisymmetric in the off-diagonal lower right 3×3 elements. The presence of antisymmetric components in the top row and column and symmetric components in the lower right 3×3 elements of weak polarization element Mueller matrices indicates the presence of depolarization.

14.25 MATRIX ROOTS OF NONDEPOLARIZING MUELLER MATRICES

In this section an order-independent representation of Mueller-Jones matrices is developed using *matrix generators* to provide additional insights into the polarization properties of Mueller matrices. This matrix-generator approach is extended in the Sec. 14.31.

The matrix decompositions in Eq. (71) are order-dependent; the retardance occurs before the diattenuation or vice versa. Because the retardance and diattenuation components in general do not commute, the result is order-dependent.

An order-independent representation was developed for the Jones calculus by Jones with his *N* matrices, which represented Jones matrices with differential amounts of the three diattenuation and three retardance degrees of freedom. Jones approached the problem by considering propagation through a dichroic (diattenuating) and birefringent (retarding) anisotropic crystal and analyzed the Jones matrices as the path length t is cut into many (N) short lengths of t/N as N approaches infinity.

The same method is applicable to nondepolarizing Mueller-Jones matrices $\mathbf{M}_N$. Dividing the path length in half ($N = 2$) corresponds to taking the square root of $\mathbf{M}_N$; this matrix square root has half the magnitude of the polarization properties of $\mathbf{M}_N$. For example, the square root of a quarter-wave retarder is an eighth-wave retarder with the same eigenpolarizations. The square root of a diattennuator with transmissions 1 and 0.64 has transmissions 1 and 0.8. For a square matrix, multiple

matrix square roots exist; a 4×4 matrix has 2^4 square roots. A real matrix square root always exists which is closer than $\mathbf{M}_N$ to the identity matrix. Taking the series of these matrix roots

$$\sqrt[n]{\mathbf{M}_N} \qquad n = 2, 3, 4, \ldots \tag{77}$$

yields a matrix sequence which approaches the identity matrix. The direction in which this sequence approaches the identity matrix depends on the ratio of polarization parameters and identifies the $\mathbf{M}_N$ as linearly or elliptically diattenuating or retarding. The matrix properties in the vicinity of the identity matrix, as shown in Sec. 14.24 are particularly simple.

The differential Mueller matrices for diattenuation and retardance corresponding to the N matrices are presented below. They are obtained by taking high-order roots of Mueller matrices or by using differential values for the diattenuation and retardance in the equations for the basis retarder and diattenuator Mueller matrices. Such differential matrices are also known as *generators* and differ from the identity matrix by infinitesimal amounts which *point* in the direction of a particular polarization property.

The Mueller matrix generators describe infinitesimal amounts of each polarization property. There are three generators for diattenuation, $\mathbf{G}_1(d_1)$, $\mathbf{G}_2(d_2)$, and $\mathbf{G}_3(d_3)$, and three generators for retardance $\mathbf{G}_4(d_4)$, $\mathbf{G}_5(d_5)$, and $\mathbf{G}_6(d_6)$. The three diattenuation generators along with their first-order expansions and second-order terms are the following:

$$\mathbf{G_1}(d_1) = \begin{pmatrix} 1 & d_1 & 0 & 0 \\ d_1 & 1 & 0 & 0 \\ 0 & 0 & \sqrt{1-d_1} & 0 \\ 0 & 0 & 0 & \sqrt{1-d_1} \end{pmatrix} \approx \begin{pmatrix} 1 & d_1 & 0 & 0 \\ d_1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} + \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & -d_1^2 & 0 \\ 0 & 0 & 0 & -d_1^2 \end{pmatrix} \tag{78}$$

$$\mathbf{G_2}(d_2) = \begin{pmatrix} 1 & 0 & d_2 & 0 \\ 0 & \sqrt{1-d_2} & 0 & 0 \\ d_2 & 0 & 1 & 0 \\ 0 & 0 & 0 & \sqrt{1-d_2} \end{pmatrix} \approx \begin{pmatrix} 1 & 0 & d_2 & 0 \\ 0 & 1 & 0 & 0 \\ d_2 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} + \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -d_2^2 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -d_2^2 \end{pmatrix} \tag{79}$$

$$\mathbf{G_3}(d_3) = \begin{pmatrix} 1 & 0 & 0 & d_3 \\ 0 & \sqrt{1-d_3} & 0 & 0 \\ 0 & 0 & \sqrt{1-d_3} & 0 \\ d_3 & 0 & 0 & 1 \end{pmatrix} \approx \begin{pmatrix} 1 & 0 & 0 & d_3 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ d_3 & 0 & 0 & 1 \end{pmatrix} + \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -d_3^2 & 0 & 0 \\ 0 & 0 & -d_3^2 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{80}$$

The equation for the general diattenuator is

$$\begin{aligned} \mathbf{M}_D(d_0, d_1, d_2, d_3) &= d_0 \lim_{N\to\infty}\left\{\left[\mathbf{G}_1\left(\frac{d_1}{N}\right)\mathbf{G}_2\left(\frac{d_2}{N}\right)\mathbf{G}_3\left(\frac{d_3}{N}\right)\right]^N\right\} \\ &= d_0 \lim_{N\to\infty}\left\{\left(\prod_{i=1}^{3} G_i\left(\frac{d_i}{N}\right)\right)\right\}^N \end{aligned} \tag{81}$$

The d_i are the diattenuation parameters and are restricted to the range

$$-1 \le d_1, d_2, d_3 \le 1 \tag{82}$$

and d_0 is an overall constant. For ideal polarizers,

$$\sqrt{d_1^2+d_2^2+d_3^2}=1 \qquad d_0=\frac{1}{2} \tag{83}$$

The generators for retarders are as follows:

$$\mathbf{G}_4(d_4)=\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&\cos d_4&\sin d_4\\0&0&-\sin d_4&\cos d_4\end{pmatrix}\approx\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&1&d_4\\0&0&-d_4&1\end{pmatrix}-\frac{1}{2}\begin{pmatrix}0&0&0&0\\0&0&0&0\\0&0&d_4^2&0\\0&0&0&d_4^2\end{pmatrix} \tag{84}$$

$$\mathbf{G}_5(d_5)=\begin{pmatrix}1&0&0&0\\0&\cos d_5&0&-\sin d_5\\0&0&1&0\\0&\sin d_5&0&\cos d_5\end{pmatrix}\approx\begin{pmatrix}1&0&0&0\\0&1&0&-d_5\\0&0&1&0\\0&d_5&0&1\end{pmatrix}-\frac{1}{2}\begin{pmatrix}0&0&0&0\\0&d_5^2&0&0\\0&0&0&0\\0&0&0&d_5^2\end{pmatrix} \tag{85}$$

$$\mathbf{G}_6(d_6)=\begin{pmatrix}1&0&0&0\\0&\cos d_6&\sin d_6&0\\0&-\sin d_6&\cos d_6&0\\0&0&0&1\end{pmatrix}\approx\begin{pmatrix}1&0&0&0\\0&1&d_6&0\\0&-d_6&1&0\\0&0&0&1\end{pmatrix}-\frac{1}{2}\begin{pmatrix}0&0&0&0\\0&d_6^2&0&0\\0&0&d_6^2&0\\0&0&0&0\end{pmatrix} \tag{86}$$

The parameters d_1, d_2, and d_3 are the retardance components in radians and are not limited in range. The general elliptical retarder has the form

$$\mathbf{M}_R(d_4,d_5,d_6)=\lim_{N\to\infty}\left\{\left[\mathbf{G}_4\left(\frac{d_4}{N}\right)\mathbf{G}_5\left(\frac{d_5}{N}\right)\mathbf{G}_6\left(\frac{d_6}{N}\right)\right]^N\right\}=\lim_{N\to\infty}\left\{\left(\prod_{i=4}^{6}\mathbf{G}_i\left(\frac{d_i}{N}\right)\right)\right\}^N \tag{87}$$

The retardance generators are periodic in the retardances d_i,

$$\mathbf{G}_i(d_i+\pi)=\mathbf{G}_i(d_i) \qquad i=4,5,6 \tag{88}$$

Combining these, the general nondepolarizing Mueller matrix $\mathbf{M}_N$ (Mueller-Jones matrix), an inhomogeneous diattenuator and retarder, has the form

$$\mathbf{M}_N(d_0,\ldots,d_6)=d_0\lim_{N\to\infty}\left(\prod_{i=1}^{6}\mathbf{G}_i\left(\frac{d_i}{N}\right)\right)^N \tag{89}$$

This representation is order-independent; the product of the six $\mathbf{G}_i(d_i)$ with differential d_i/N can be taken in any order of the six i, prior to raising to the Nth power.

The d_i for a Mueller-Jones matrix $\mathbf{M}_N$ are determined by calculating a high-order matrix root. For the majority of Mueller-Jones matrices, as the root order $N\to\infty$ the matrix root approaches a constant times the identity matrix with small first-order deviations, D_i, corresponding to the first-order terms above, as

$$\sqrt[N]{\mathbf{M}_N}=d_0\begin{pmatrix}1&D_1&D_2&D_3\\D_1&1&D_6&-D_5\\D_2&-D_6&1&D_4\\D_3&D_5&-D_4&1\end{pmatrix} \tag{90}$$

Due to the inexact nature of computer arithmetic, in practice N is set large enough that the matrix root is very close to the identity matrix without losing accuracy due to round off errors in calculations, which occurs when N is very large. Setting $10^4 < q < 10^9$ usually works well. The D_i are scaled by the matrix root order N,

$$d_i = N D_i \tag{91}$$

yielding the magnitudes of the diattenuation and retardance parameters.

For any Mueller-Jones matrix, $\mathbf{M}_N(d_0, \ldots, d_6,)$, varying one of the d_i generates a family of $\mathbf{M}_N$ where only a single polarization property varies. Varying each of the d_i one at a time generates a family of orthogonal trajectories through $\mathbf{M}_N$. Thus the set $\{d_0, d_1, d_2, d_3, d_4, d_5, d_6\}$ comprises a coordinate system for the Mueller-Jones matrices. Within the 15-dimensional space of normalized Mueller matrices, the Mueller-Jones matrices, parameterized by $\{d_1, d_2, d_3, d_4, d_5, d_6\}$ form an open six-dimensional surface embedded on a 15-dimensional hypersphere of radius $\sqrt{3}$, the surface where the depolarization index equals one.

A homogeneous nondepolarizing Mueller matrix has the same eigenvectors for its diattenuation (hermitian) and retarding (unitary) parts, and the corresponding condition on the Mueller roots is

$$\{d_1, d_2, d_3\} = k\{d_4, d_5, d_6\} \tag{92}$$

where k is a real constant, the ratio of the diattenuation to the retardance.

14.26 DEPOLARIZATION AND THE DEPOLARIZATION INDEX

Depolarization is the reduction of the degree of polarization of light. In the Mueller calculus depolarization can be pictured as a coupling of polarized into unpolarized light, where polarized light is incident and the exiting Stokes vector can be mathematically separated into a fully polarized and an unpolarized Stokes vector. Lenses, mirrors, filters, and other typical optical elements exhibit very small amounts of depolarization, typically less than a few tenths of a percent. In contrast, the depolarization of most diffusely reflecting objects such as paints, metal and wood surfaces, natural materials, and the like is significant, varying from a few to 100 percent (i.e., complete depolarization).

Two single-valued depolarization matrices, the depolarization index and the average degree of polarization, have been introduced to describe the degree to which a Mueller matrix depolarizes incident states.[23–25] However, such single-number matrices cannot describe the complexity of depolarization associated with a Mueller matrix.

Consider three Mueller matrices of the following forms:

$$\mathbf{ID} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \quad \mathbf{PD} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & a & 0 & 0 \\ 0 & 0 & a & 0 \\ 0 & 0 & 0 & a \end{pmatrix} \quad \mathbf{DD} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & a & 0 & 0 \\ 0 & 0 & b & 0 \\ 0 & 0 & 0 & c \end{pmatrix} \tag{93}$$

Matrix **ID** is the ideal depolarizer; only unpolarized light exits the depolarizer. Matrix **PD** is the partial depolarizer; all fully polarized incident states exit with their incident polarization ellipse, but with a degree of polarization DoP(**PD**•**S**) = a. The diagonal depolarizer matrix **DD** represents a variable partial depolarizer; the degree of polarization of the exiting light is a function of the incident state. Physically, depolarization is closely related to scattering and usually has its origin in retardance or diattenuation which is rapidly varying in time, space, or wavelength.

Of the 16 degrees of freedom in the Mueller matrix, 1 corresponds to loss, 3 to diattenuation, and 3 to retardance. The remaining 9 degrees of freedom describe depolarization.

14.27 DEGREE OF POLARIZATION SURFACES AND MAPS

The degree of polarization is a measure of the randomness of polarization in a light beam, a property characterized by how much of this beam may be blocked by a polarizer. Degree of polarization maps and surfaces represent this dependence of depolarization on incident polarization state.[26] For the typical depolarizer, different incident polarization states are depolarized by different amounts.

$$\mathrm{DoP}(\mathbf{M}\bullet\mathbf{S}(\theta,\varepsilon)) = \mathrm{DoP}\left(\begin{pmatrix} m_{0,0} & m_{0,1} & m_{0,2} & m_{0,3} \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{2,1} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{3,1} & m_{3,2} & m_{3,3} \end{pmatrix} \bullet \begin{pmatrix} 1 \\ \cos 2\theta \ \cos\varepsilon \\ \sin 2\theta \ \cos\varepsilon \\ \sin\varepsilon \end{pmatrix}\right) \tag{94}$$

Degree of polarization surfaces are formed from a nonuniform contraction of the Poincaré sphere corresponding to the depolarization properties of a Mueller matrix. The DoP surface for a Mueller matrix M is formed by moving normalized Stokes vectors **S** on the surface of the Poincaré sphere radially inward to a distance DoP(**S′**=**M**•**S**) from the origin, plotted for all incident **S** on the surface of the Poincaré sphere. The DoP surface results from the product of a scalar, the DoP, and a vector, (s_1, s_2, s_3), formed from the Stokes three-vector,

$$\mathrm{DoPsurface}(\mathbf{M},\ \mathbf{S}) = \frac{\sqrt{S_1'(\mathbf{M},\ \mathbf{S})^2 + S_2'(\mathbf{M},\ \mathbf{S})^2 + S_3'(\mathbf{M},\ \mathbf{S})^2}}{S_0'(\mathbf{M},\ \mathbf{S})}\,(s_1, s_2, s_3) \tag{95}$$

for all $(s_1^2 + s_2^2 + s_3^2)^{1/2} = 1$.

The DoP map for a Mueller matrix is a two-dimensional plot, such as a contour plot or density plot, of the DoP of exiting light as a function of the incident polarized state and represents a "flattened" DoP surface. In this paper, the DoP map is plotted with axes θ (polarization ellipse major axis orientation) and DoCP, but there is some flexibility in the parameterization of the polarized Stokes vectors. In general the DoP map provides easier visualization of maxima, minima, saddles, and other features of the depolarization variation than the DoP surface.

Fig. 5 shows depolarization maps for a liquid crystal cell's Mueller matrices measured at 2, 3, and 4 V at 550 nm in laboratory.[27] The cell is an untwisted nematic cell (Fredericksz cell) with fast and slow axes at 45°/135° used as a variable linear retarder for polarization control. The depolarization characteristics change significantly with applied voltage and incident polarization state. At 2 V, the maximum DoP (white area) occurs for a slightly elliptical state located just above the 135° linear state on the Poincaré sphere; a second DoP maximum occurs near 45°. At 0 V the liquid crystal (LC) directors will be parallel to one of these axes throughout the cell. So the least depolarization is occurring along the direction the LC molecules are aligned at the two surfaces. As the voltage increases, the molecules near the center of the cell gap rotate toward the cell normal while simultaneously the retardance decreases. Both maxima drift away from the fast/slow axes as the voltage increases while the depolarization, a measure of order, decreases the most around 90°. Unfortunately, polarization controllers are usually operated midway between the fast and slow axes and miss the DoP maxima.

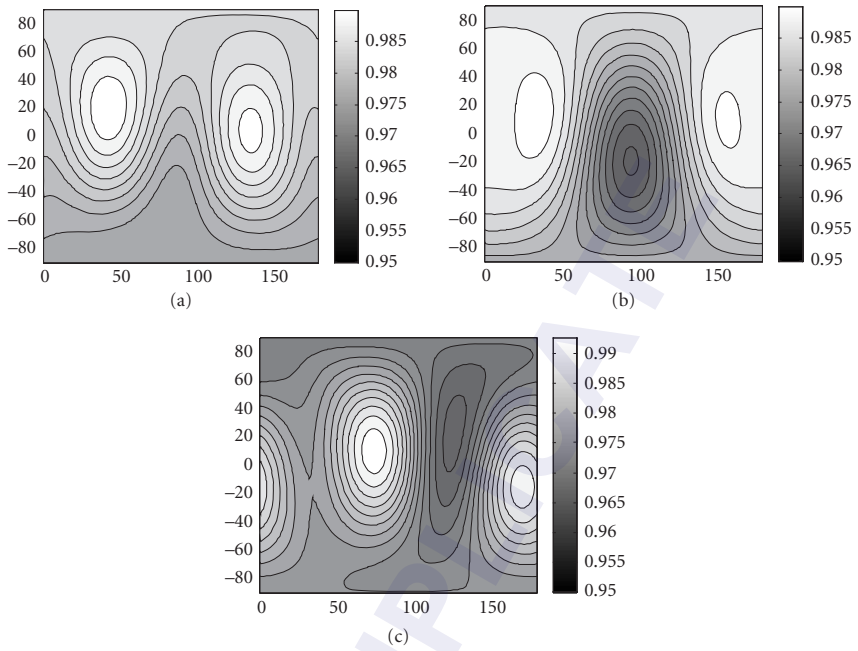

FIGURE 5 DoP maps for an untwisted nematic liquid crystal cell at (*a*) 2 V, (*b*) 3 V, and (*c*) 4 V. The DoP varies between 0.965 and 0.991 as the voltage and incident polarization state varies. At low voltages, the low depolarization states are close to the fast and slow axes. As the voltage increases, these DoP maps (lighter gray) drift away.

14.28 THE DEPOLARIZATION INDEX

One figure of merit of the depolarization characteristics of a Mueller matrix is the depolarization index DI(**M**) introduced by Gil and Bernabeu.[23,24] DI(**M**) is the euclidian distance of the normalized Mueller matrix $\mathbf{M}/m_{0,0}$ from the ideal depolarizer:

$$\mathrm{DI}(\mathbf{M}) = \left\| \frac{\mathbf{M}}{m_{0,0}} - \mathbf{ID} \right\| = \frac{\sqrt{\left(\sum_{i,j} m_{i,j}^2 \right) - m_{0,0}^2}}{\sqrt{3}\, m_{0,0}} \tag{96}$$

DI(**M**) varies from zero for the ideal depolarizer to 1 for all nondepolarizing Mueller matrices, including all pure diattenuators, pure retarders, and any sequences composed from them.

14.29 THE AVERAGE DEGREE OF POLARIZATION

The average degree of polarization, averageDoP, is the arithmetic mean of the degree of polarization of the exiting light when averaged over the Poincaré sphere,[25]

$$\mathrm{averageDoP}(\mathbf{M}) = \frac{\int_0^{\pi} \int_{-\pi/2}^{\pi/2} \mathrm{DoP}(\mathbf{M} \bullet \mathbf{S}(\theta, \varepsilon)) \cos(\varepsilon) d\theta d\varepsilon}{4\pi} \tag{97}$$

$\mathbf{S}(\theta, \varepsilon)$ the Stokes vector parameterized by orientation of polarization θ and latitude ε, in radians on the Poincare sphere, is

$$\mathbf{S}(\theta, \varepsilon) = \begin{pmatrix} 1 \\ \cos(2\theta)\cos(\varepsilon) \\ \sin(2\theta)\cos(\varepsilon) \\ \sin(\varepsilon) \end{pmatrix} \tag{98}$$

The averageDoP varies from zero to one and provides a summary of the depolarizing property in a single number. When averageDoP is equal to one the exiting light is always completely polarized indicating a nondepolarizing Mueller matrix. Values near one indicates little depolarization. When averageDoP equals zero the exiting light is completely depolarized; only unpolarized light exits the interaction.

The DI and the averageDoP are often equal and usually quite close. The averageDoP is the easier metric to understand; it provides the mean DoP of the exiting light averaged over the Poincaré sphere, the expected value. The DI has a clear geometric meaning in the Mueller matrix configuration space, being the fractional distance of a Mueller matrix along a line segment from the ideal depolarizer to the hypersphere of nondepolarizing Mueller matrices, so it remains a useful and meaningful parameter, but more useful for theoretical studies of the Mueller calculus than for representing the depolarization of an optical element.

14.30 DETERMINING MUELLER MATRIX PROPERTIES

Given a Mueller matrix, measured or calculated, a natural question is "what are the polarization properties of this matrix?" Algorithms for the properties of Jones matrices were developed decades ago.[1,15,28–30] For Mueller matrices, the algorithm development was challenging and work continues in this area.[13,14,16,24,31–37]

A matrix decomposition expresses a matrix as a function of other matrices which indicate useful properties. For example, the polar decomposition of a Jones matrix expresses **J** as the matrix product of a hermitian matrix and a unitary matrix, corresponding to a diattenuator (partial polarizer) and retarder.[21,22] Jones' N-matrix decomposition of the Jones matrix divided the Jones matrix into a large number of identical matrix components infinitesimally close to the identity matrix and provided a simple description of Jones matrix properties.[15]

The Mueller matrix has 16 degrees of freedom and thus can be described by 16 unique properties. The Mueller roots decomposition presented in the following section is a generalization of Jones' method to the Mueller matrix and provides an order-independent decomposition. The decomposition of Lu and Chipman, presented in the following section, expresses the Mueller matrix as the product of pure diattenuator, pure retarder, and depolarizer Mueller matrices.[30] The three components could occur in any specified order but the values of the components changed based on the order.

14.31 GENERATORS FOR DEPOLARIZATION

The generator method for describing polarization properties of Mueller-Jones matrices extends to depolarizing Mueller matrices by adding nine additional generators to span the remaining nine degrees of freedom.[38] These nine generators have been divided into three families of three generators corresponding to the three diattenuation and retardance degrees

of freedom. The nine generators for depolarization in exact, first- and second-order representations are as follows:

$$\mathbf{G}_7(d_7)=\begin{pmatrix} 1 & d_7 & 0 & 0 \\ -d_7 & 1-d_7 & 0 & 0 \\ 0 & 0 & \sqrt{1-d_7^2} & 0 \\ 0 & 0 & 0 & \sqrt{1-d_7^2} \end{pmatrix} \approx \begin{pmatrix} 1 & d_7 & 0 & 0 \\ -d_7 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} + \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & -d_7^2 & 0 \\ 0 & 0 & 0 & -d_7^2 \end{pmatrix} \tag{99}$$

$$\mathbf{G}_8(d_8)=\begin{pmatrix} 1 & 0 & d_8 & 0 \\ 0 & \sqrt{1-d_8^2} & 0 & 0 \\ -d_8 & 0 & 1 & 0 \\ 0 & 0 & 0 & \sqrt{1-d_8^2} \end{pmatrix} \approx \begin{pmatrix} 1 & 0 & d_8 & 0 \\ 0 & 1 & 0 & 0 \\ -d_8 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} + \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -d_8^2 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -d_8^2 \end{pmatrix} \tag{100}$$

$$\mathbf{G}_9(d_9)=\begin{pmatrix} 1 & 0 & 0 & d_9 \\ 0 & \sqrt{1-d_9^2} & 0 & 0 \\ 0 & 0 & \sqrt{1-d_9^2} & 0 \\ -d_9 & 0 & 0 & 1 \end{pmatrix} \approx \begin{pmatrix} 1 & 0 & 0 & d_9 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ -d_9 & 0 & 0 & 1 \end{pmatrix} + \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -d_9^2 & 0 & 0 \\ 0 & 0 & -d_9^2 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{101}$$

$$\mathbf{G}_{10}(d_{10})=\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \sqrt{1-d_{10}^2} & d_{10} \\ 0 & 0 & d_{10} & \sqrt{1-d_{10}^2} \end{pmatrix} \approx \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & d_{10} \\ 0 & 0 & d_{10} & 1 \end{pmatrix} + \frac{1}{2}\begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & -d_{10}^2 & 0 \\ 0 & 0 & 0 & -d_{10}^2 \end{pmatrix} \tag{102}$$

$$\mathbf{G}_{11}(d_{11})=\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & \sqrt{1-d_{11}^2} & 0 & d_{11}\\ 0 & 0 & 1 & 0\\ 0 & d_{11} & 0 & \sqrt{1-d_{11}^2}\end{pmatrix}\approx\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & 1 & 0 & d_{11}\\ 0 & 0 & 1 & 0\\ 0 & d_{11} & 0 & 1\end{pmatrix}+\frac{1}{2}\begin{pmatrix}0 & 0 & 0 & 0\\ 0 & -d_{11}^2 & 0 & 0\\ 0 & 0 & 0 & 0\\ 0 & 0 & 0 & -d_{11}^2\end{pmatrix} \tag{103}$$

$$\mathbf{G}_{12}(d_{12})=\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & \sqrt{1-d_{12}^2} & d_{12} & 0\\ 0 & d_{12} & \sqrt{1-d_{12}^2} & 0\\ 0 & 0 & 0 & 1\end{pmatrix}\approx\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & 1 & d_{12} & 0\\ 0 & d_{12} & 1 & 0\\ 0 & 0 & 0 & 1\end{pmatrix}+\frac{1}{2}\begin{pmatrix}0 & 0 & 0 & 0\\ 0 & -d_{12}^2 & 0 & 0\\ 0 & 0 & -d_{12}^2 & 0\\ 0 & 0 & 0 & 0\end{pmatrix} \tag{104}$$

The final three degrees of freedom describe the depolarization along the matrix diagonal elements: $m_{1,1}, m_{2,2}, m_{3,3}$:

$$\begin{aligned}\mathbf{G}(d_{13})&=\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & -\sqrt{\frac{3}{2}}d_{13}+\sqrt{1-d_{13}^2} & 0 & 0\\ 0 & 0 & \sqrt{\frac{3}{2}}d_{13}+\sqrt{1-d_{13}^2} & 0\\ 0 & 0 & 0 & \sqrt{1-d_{13}^2}\end{pmatrix}\\ &=\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & 1-\sqrt{\frac{3}{2}}d_{13} & 0 & 0\\ 0 & 0 & 1+\sqrt{\frac{3}{2}}d_{13} & 0\\ 0 & 0 & 0 & 1\end{pmatrix}-\frac{1}{2}\begin{pmatrix}0 & 0 & 0 & 0\\ 0 & d_{13}^2 & 0 & 0\\ 0 & 0 & d_{13}^2 & 0\\ 0 & 0 & 0 & -d_{13}^2\end{pmatrix}\end{aligned} \tag{105}$$

$$\begin{aligned}\mathbf{G}(d_{14})&=\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & \frac{d_{14}}{\sqrt{2}}+\sqrt{1-d_{14}^2} & 0 & 0\\ 0 & 0 & \frac{d_{14}}{\sqrt{2}}+\sqrt{1-d_{14}^2} & 0\\ 0 & 0 & 0 & -\sqrt{2}d_{14}+\sqrt{1-d_{14}^2}\end{pmatrix}\\ &=\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & 1+\frac{d_{14}}{\sqrt{2}} & 0 & 0\\ 0 & 0 & 1+\frac{d_{14}}{\sqrt{2}} & 0\\ 0 & 0 & 0 & 1-\sqrt{2}d_{14}\end{pmatrix}-\frac{1}{2}\begin{pmatrix}0 & 0 & 0 & 0\\ 0 & d_{14}^2 & 0 & 0\\ 0 & 0 & d_{14}^2 & 0\\ 0 & 0 & 0 & d_{14}^2\end{pmatrix}\end{aligned} \tag{106}$$

$$\mathbf{G}(d_{15})=\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & 1-d_{15} & 0 & 0\\ 0 & 0 & 1-d_{15} & 0\\ 0 & 0 & 0 & 1-d_{15}\end{pmatrix} \tag{107}$$

TABLE 4 Polarizing and Depolarizing Degrees of Freedom

	Horizontal and Vertical	45° and 135°	Right and Left
Diattenuation	d_1	d_2	d_3
Retardance	d_4	d_5	d_6
Amplitude depolarization	d_7	d_8	d_9
Phase depolarization	d_{10}	d_{11}	d_{12}
	Orthogonal 1	Orthogonal 2	Radial
Diagonal depolarization	d_{13}	d_{14}	d_{15}

Combining the 9 depolarizing generators with the 6 nondepolarizing generators yields an order-independent equation for Mueller matrices in terms of 15 polarization parameters,

$$\begin{aligned}\mathbf{M} &= d_0 \lim_{N\to\infty}\left[\mathbf{G}_1\left(\frac{d_1}{N}\right)\mathbf{G}_2\left(\frac{d_2}{N}\right)\mathbf{G}_3\left(\frac{d_3}{N}\right)\mathbf{G}_4\left(\frac{d_4}{N}\right)\mathbf{G}_5\left(\frac{d_5}{N}\right)\mathbf{G}_6\left(\frac{d_6}{N}\right)\mathbf{G}_7\left(\frac{d_7}{N}\right)\mathbf{G}_8\left(\frac{d_8}{N}\right)\right.\\ &\left.\mathbf{G}_9\left(\frac{d_9}{N}\right)\mathbf{G}_{10}\left(\frac{d_{10}}{N}\right)\mathbf{G}_{11}\left(\frac{d_{11}}{N}\right)\mathbf{G}_{12}\left(\frac{d_{12}}{N}\right)\mathbf{G}_{13}\left(\frac{d_{13}}{N}\right)\mathbf{G}_{14}\left(\frac{d_{14}}{N}\right)\mathbf{G}_{15}\left(\frac{d_{15}}{N}\right)\right]^N \\ &= d_0 \lim_{N\to\infty}\left(\prod_{i=1}^{15}\mathbf{G}_i\left(\frac{d_i}{N}\right)\right)^N\end{aligned} \tag{108}$$

As any single parameter is scanned in value, it generates a trajectory through the space of Mueller matrices where just one polarization property is changing. Thus Eq. (108) provides a coordinate system for depolarizing and nondepolarizing Mueller matrices in terms of the individual polarization parameters. The names of the polarization properties are given in Table 4. $\mathbf{G}_7$, $\mathbf{G}_8$, and $\mathbf{G}_9$ share the same first-order matrix elements as diattenuation and affect the flux of the light; thus the name amplitude diattenuation. $\mathbf{G}_{10}$, $\mathbf{G}_{11}$, and $\mathbf{G}_{12}$ share the same first-order matrix elements as retardance and do not affect the flux of the light; thus the name phase diattenuation.

The final three depolarization degrees of freedom lie along the matrix diagonal. In most depolarizing samples these are the largest components of the depolarization. Several different bases can be considered for these degrees of freedom. The uniform depolarizer is a depolarizer which depolarized all polarization states equally. Combining the uniform depolarizer with any nondepolarizing Mueller matrix should move that matrix straight toward the ideal depolarizer in a radial direction in the 15-dimensional normalized Mueller matrix space. This uniform depolarizer generator is chosen as the final generator, $\mathbf{G}_{15}$. $\mathbf{G}_{13}$, $\mathbf{G}_{14}$, and $\mathbf{G}_{15}$ are an orthogonal basis for the diagonal matrix elements.

The degree of polarization maps associated with the individual depolarization generators are shown in Fig. 6. Nonphysical regions with the degree of polarization greater than one are hatched; physical regions are solid. All of the generators except $\mathbf{G}_{15}$ have DoP maps where half the area has a value below one and half is above one (hatched). Thus $\mathbf{G}_7$ through $\mathbf{G}_{14}$ are nonphysical Mueller matrices by themselves. Only when they are combined with an equal or greater amount of $\mathbf{G}_{15}$, do they form physical Mueller matrices with DoP values always equal to or less than one. $\mathbf{G}_{15}$ is an essential component of any depolarizing Mueller matrix.

The algorithm for the decomposition of Mueller matrix $\mathbf{M}$ into matrix root parameters d_i has four steps. First, $\mathbf{M}$ is normalized so its average transmission is one,

$$\hat{\mathbf{M}} = \frac{\mathbf{M}}{m_{0,0}} = \begin{pmatrix} 1 & m_{0,1}/m_{0,0} & m_{0,2}/m_{0,0} & m_{0,3}/m_{0,0} \\ m_{1,0}/m_{0,0} & m_{1,1}/m_{0,0} & m_{1,2}/m_{0,0} & m_{1,3}/m_{0,0} \\ m_{2,0}/m_{0,0} & m_{2,1}/m_{0,0} & m_{2,2}/m_{0,0} & m_{2,3}/m_{0,0} \\ m_{3,0}/m_{0,0} & m_{3,1}/m_{0,0} & m_{3,2}/m_{0,0} & m_{3,3}/m_{0,0} \end{pmatrix} \tag{109}$$

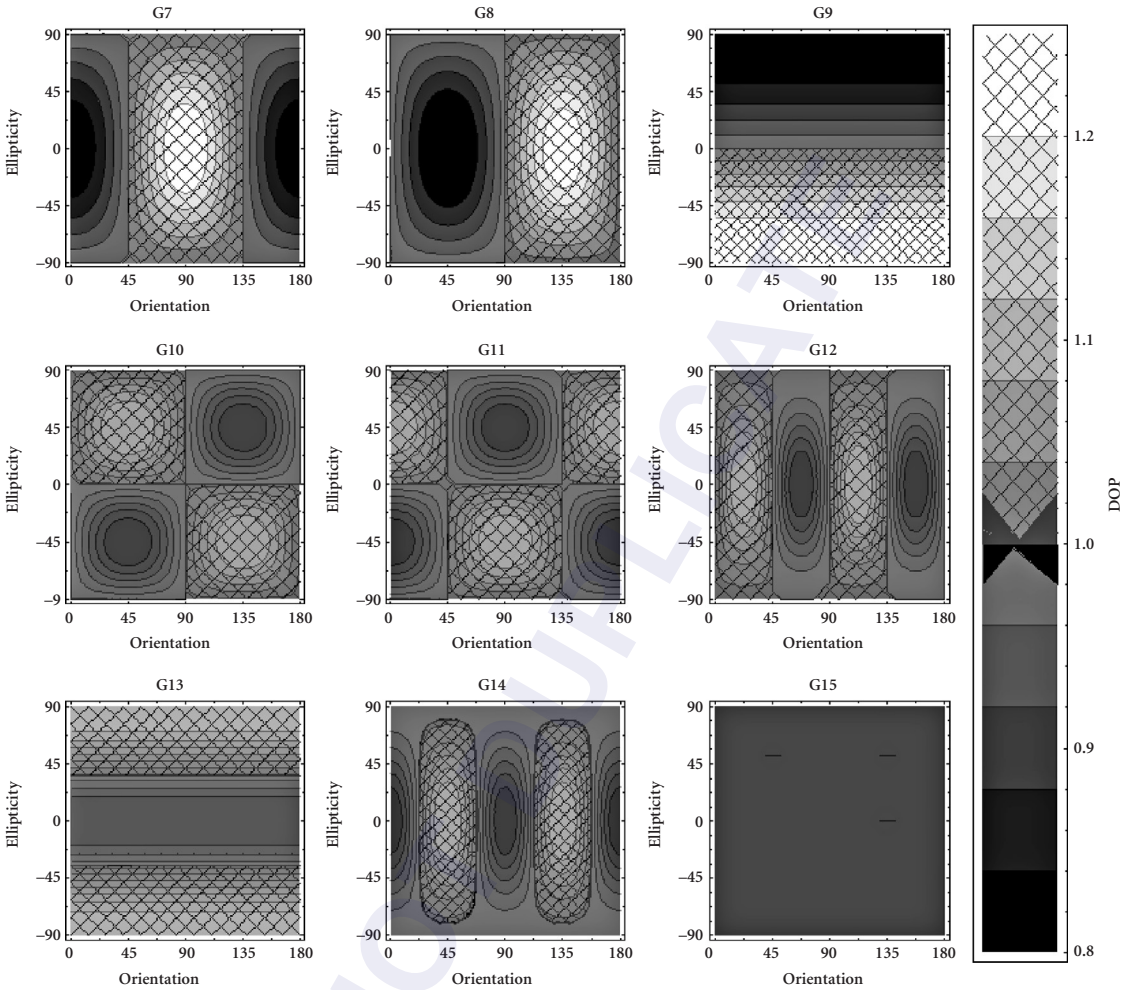

FIGURE 6 Degree of polarization maps associated with the depolarization generators $\mathbf{G}_7$–$\mathbf{G}_{15}$ for a value of $d_i = 0.2$. Hatched areas indicate incident polarization states where the exiting Stokes vector has a DoP > 1. $\mathbf{G}_{15}$, radial depolarization, has a constant map.

Normalizing $\mathbf{M}$ separates the property of the average transmission (nonpolarizing) from the remaining 15 polarizing properties. Second, a high-order matrix root of $\hat{\mathbf{M}}$ is calculated,

$$\mathbf{P} = \sqrt[q]{\hat{\mathbf{M}}} \tag{110}$$

For the majority of Mueller matrices, $\mathbf{P}$ approaches a constant d_0 times the identity matrix as $q \to \infty$

$$\lim_{q\to\infty} \sqrt[q]{\hat{\mathbf{M}}} = d_0 \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{111}$$

Due to the inexact nature of computer arithmetic, in practice q is selected as a large enough number such that **P** is very close to the identity matrix without losing accuracy due to round off errors in calculations. Setting $10^4 < q < 10^9$ usually works well.

Third, the difference between **P** and the identity matrix is decomposed into 15 terms, corresponding to 15 polarization properties,

$$\mathbf{P} = \begin{pmatrix} P_{0,0} & P_{0,1} & P_{0,2} & P_{0,3} \\ P_{1,0} & P_{1,1} & P_{1,2} & P_{1,3} \\ P_{2,0} & P_{2,1} & P_{2,2} & P_{2,3} \\ P_{3,0} & P_{3,1} & P_{3,2} & P_{3,3} \end{pmatrix} = d_0 \begin{pmatrix} 1 & D_1 + D_7 & D_2 + D_8 & D_3 + D_9 \\ D_1 - D_7 & 1 - f_{13} & D_6 + D_{12} & -D_5 + D_{11} \\ D_2 - D_8 & -D_6 + D_{12} & 1 - f_{14} & D_4 + D_{10} \\ D_3 - D_9 & D_5 + D_{11} & -D_4 + D_{10} & 1 - f_{15} \end{pmatrix} \tag{112}$$

where the D_i are very small numbers which decrease linearly with large N. D_{13}, D_{14}, and D_{15} are more complex due to our selection of diagonal depolarization generators,

$$d_{13} = \frac{f_{13} - f_{14}}{\sqrt{6}} \qquad d_{14} = \frac{-\sqrt{2} f_{13} + \sqrt{2} f_{14} + 2\sqrt{2} f_{15}}{6} \qquad d_{15} = \frac{f_{13} + f_{14} + f_{15}}{3} \tag{113}$$

Finally, the D_i are scaled by the matrix root order q,

$$d_i = q D_i \tag{114}$$

yielding the magnitudes of the polarization parameters.

One method to ensure the proper matrix root is calculated is to calculate the appropriate matrix square or cube root, then repeatedly apply the square or cube root function to generate high-order roots. Higham has addressed finding the real square roots of real matrices.[39,40]

Several classes of Mueller matrices and their matrix roots require special consideration. For ideal polarizers ($T_{max} = 1$, $T_{min} = 0$), the Mueller matrix squared equals the Mueller matrix, then the high-order matrix roots do not approach the identity matrix. But when T_{min} is infinitesimally increased above zero, the high-order matrix roots do approach the identity matrix.

Some highly depolarizing Mueller matrices have a negative determinant. The Mueller matrices generated by Eq. (108) span most of the space of physically realizable Mueller matrices. The determinant of normalized Mueller matrices vary over the range

$$\frac{-1}{27} \le \det(\mathbf{M}) \le 1 \tag{115}$$

Since **P** has a positive determinant, its high-order powers can never equal a matrix with negative determinant. Unfortunately, the Mueller matrices spanned by Eq. (108) do not cover the small number of negative determinant Mueller matrices, an issue beyond the scope of this chapter.

The high-order roots of the majority of Mueller matrices are well behaved in approaching the identity matrix. The boundary between these classes is an area of ongoing investigation. An alternative form for the depolarization generators for the matrix diagonal is the following:

$$\mathbf{G}'(d_{13}) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 - d_{13} & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{116}$$

$$\mathbf{G}'(d_{14}) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 - d_{14} & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{117}$$

$$\mathbf{G}'(d_{15}) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1-d_{15} \end{pmatrix} \tag{118}$$

14.32 INTERPRETATION OF ARBITRARY MUELLER MATRICES, THE POLAR DECOMPOSITION OF MUELLER MATRICES

When simulating polarization elements, polarimeters, and optical systems, typically the Mueller matrices are nondepolarizing. Measured Mueller matrices have depolarization at some level; usually low for optical systems or much higher for light scattered from rough surfaces. To understand these matrices, it is desirable to interpret the Mueller matrices in terms of standard polarization elements. Given a Mueller matrix and access to a well-stocked inventory of polarization elements, diattenuator, retarder, and depolarizer could be combined to perform equivalent polarization transformations.

One common algorithm for Mueller matrix decomposition is the Lu-Chipman polar decomposition which represents an arbitrary depolarizing Muller matrix as the product of a pure diattenuator, a pure retarder, and a depolarizer Mueller matrices.[22] The algorithm is complex; only a few steps will be outlined here; the reader is referred to other treatments of this algorithm and comments on its properties.[10,37,41]

In this generalized polar decomposition, depolarizing Mueller matrices are expressed as the product of the three matrix factors: diattenuation, retardance, and depolarization,

$$\mathbf{M} = \mathbf{M}_\Delta \bullet \mathbf{M}_R \bullet \mathbf{M}_D \tag{119}$$

$\mathbf{M}_D$ is the diattenuator Mueller matrix and $\mathbf{M}_R$ is the retarder Mueller matrix. For the purpose of the Lu-Chipman decomposition algorithm, the depolarization Mueller matrix $\mathbf{M}_\Delta$ has the form

$$\mathbf{M}_\Delta = \begin{pmatrix} 1 & 0 & 0 & 0 \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{1,2} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{1,3} & m_{2,3} & m_{3,3} \end{pmatrix} = \begin{pmatrix} 1 & \vec{0}^T \\ \vec{\mathbf{P}}_\Delta & \mathbf{m}_\Delta \end{pmatrix} \tag{120}$$

The submatrix $\mathbf{m}_\Delta$ is symmetric, so it does not contain any retardance. The first column contains a polarizance term. The first step is to form $\mathbf{M}_D$ from the top row of $\mathbf{M}$ and then remove the diattenuation via

$$\mathbf{M}' = \mathbf{M} \bullet \mathbf{M}_D^{-1} = \mathbf{M}_\Delta \bullet \mathbf{M}_R \tag{121}$$

Extensive manipulations are then required to form $\mathbf{M}_R$ and $\mathbf{M}_\Delta$, and these are used to define the retardance and depolarization.

The Lu-Chipman decomposition algorithm has several disadvantages: (1) It is an order-dependent representation, so the polarization properties depend on which of the six polarization element sequence permutations is chosen. (2) Some highly depolarizing Mueller matrices have negative determinants; these negative determinant Mueller matrices form a very small subset of Mueller matrices, but they cannot be decomposed with the generalized polar decomposition.[41] (3) The form for the depolarizer $\mathbf{M}_\Delta$ is peculiar, combining depolarization and polarizance, and sometimes $\mathbf{M}_\Delta$ which are by themselves nonphysical Mueller matrices are generated.

The advantage of this algorithm is that as a well-defined procedure, the values of diattenuation and retardance returned are carefully specified and reproducible. The results can be readily communicated between different groups.

Regarding the order-dependence of the algorithm, it makes sense to put the depolarizing part of the decomposition last (on the left). When fully polarized light is incident, the degree of polarization is not changed by $\mathbf{M}_D$ or $\mathbf{M}_R$, so $\mathbf{M}_\Delta$ performs all the depolarizing. Two of the other five permutations are obtained by straightforward manipulations:

$$\mathbf{M} = \mathbf{M}_{\Delta 2} \bullet \mathbf{M}_{D2} \bullet \mathbf{M}_{R2} = \mathbf{M}_\Delta \bullet (\mathbf{M}_R \bullet \mathbf{M}_D \bullet \mathbf{M}_R^T) \bullet \mathbf{M}_R \tag{122}$$

$$\mathbf{M} = \mathbf{M}_{R3} \bullet \mathbf{M}_{\Delta 3} \bullet \mathbf{M}_{D3} = \mathbf{M}_R \bullet (\mathbf{M}_R^T \bullet \mathbf{M}_\Delta \bullet \mathbf{M}_R) \bullet \mathbf{M}_D \tag{123}$$

Straightforward relationships for the other three permutations are not easily obtained:

$$\mathbf{M} = \mathbf{M}_{D4} \bullet \mathbf{M}_{R4} \bullet \mathbf{M}_{\Delta 4} \tag{124}$$

$$\mathbf{M} = \mathbf{M}_{R5} \bullet \mathbf{M}_{\Delta 5} \bullet \mathbf{M}_{D5} \tag{125}$$

$$\mathbf{M} = \mathbf{M}_{D6} \bullet \mathbf{M}_{\Delta 6} \bullet \mathbf{M}_{R6} \tag{126}$$

14.33 PHYSICALLY REALIZABLE MUELLER MATRICES

Mueller matrices form a subset of the 4×4 real matrices. A 4×4 real matrix is not a physically realizable Mueller matrix if it can operate on an incident Stokes vector to produce a vector with degree of polarization greater than one ($S_0^2 < S_1^2 + S_2^2 + S_3^2$), which represents a physically unrealizable polarization state. Similarly, a Mueller matrix cannot output a state with negative flux. Conditions for physical realizability have been studied extensively in the literature, and many necessary conditions have been published.[33,34,42–47] The following four necessary conditions for physical realizability are among the more general of those published:[31,44]

1. $\mathrm{Tr}(\mathbf{M}\mathbf{M}^T) \le 4\mathbf{m}_{0,0}^2$
2. $m_{0,0} \ge |m_{i,j}|$
3. $m_{0,0}^2 \ge b^2$
4. $(m_{0,0} - b)^2 \ge \sum_{j=1}^{3} \left(m_{0,j} - \sum_{k=1}^{3} m_{j,k} a_k \right)$

where $b = \sqrt{m_{0,1}^2 + m_{0,2}^2 + m_{0,3}^2}$, $a_j = m_{0,j}/b$, and Tr indicates the trace of a matrix.

Another condition for physical realizability is that the matrix can be expressed as a sum of nondepolarizing Mueller matrices. The Mueller matrix for a passive device $T_{\max} \le 1$, a device without gain, must satisfy the relation $T_{\max}\, m_{0,0} = \sqrt{m_{0,1}^2 + m_{0,2}^2 + m_{0,3}^2} \le 1$.

In the 16-dimensional space of Mueller matrices, the matrices for ideal polarizers, ideal retarders, and other nondepolarizing elements lie on the boundary between the physically realizable Mueller matrices and the unrealizable nonphysical matrices. Thus, a small amount of noise in the measurement of a Mueller matrix for a polarizer or retarder may yield a marginally unrealizable matrix.

When calculating a Mueller matrix **M** from a set of flux measurements, there is error present due to nonidealities in the system. When error is present, it is often the case that the reconstructed **M** is nonphysical, i.e., it is not possible to generate this **M** using real components such as polarizers, retarders, and depolarizers. In this case degree of polarization is outside the range of 0 to 1, and/or the intensity is negative. The "nearest" physical matrix to **M** may be found, both to reduce the error when extracting polarization parameters, and to give a quantifiable metric for the error in the measurement of **M**.

Depolarization in Mueller matrices results from the addition of nondepolarizing Mueller matrices. The set of all normalized physically realizable Mueller matrices is thus formed from the convex hull of all the nondepolarizing Mueller matrices.

A requirement for a physically realizable Mueller matrix is that the complex hermitian matrix **H** known as the coherency matrix derived from **M** has non-negative eigenvalues.[39,48]

$$\mathbf{H} = \frac{1}{2}\sum_{j=0}^{3}\sum_{i=0}^{3} m_{ij}(\boldsymbol{\sigma}_i \otimes \boldsymbol{\sigma}_j^*) \tag{127}$$

where the $\boldsymbol{\sigma}$'s are the normalized Pauli matrices:

$$\boldsymbol{\sigma}_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad \boldsymbol{\sigma}_1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad \boldsymbol{\sigma}_2 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad \boldsymbol{\sigma}_3 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \tag{128}$$

and $\otimes$ indicates the outer product function flattened into a matrix, i.e.,

$$\boldsymbol{\sigma}_i \otimes \boldsymbol{\sigma}_j^* = \begin{pmatrix} \boldsymbol{\sigma}_{i,0,0}\boldsymbol{\sigma}^*_{j,0,0} & \boldsymbol{\sigma}_{i,0,0}\boldsymbol{\sigma}^*_{j,0,1} & \boldsymbol{\sigma}_{i,0,1}\boldsymbol{\sigma}^*_{j,0,0} & \boldsymbol{\sigma}_{i,0,1}\boldsymbol{\sigma}^*_{j,0,1} \\ \vdots & \ddots & & \vdots \\ \vdots & & \ddots & \vdots \\ \boldsymbol{\sigma}_{i,1,0}\boldsymbol{\sigma}^*_{j,1,0} & \cdots & \cdots & \boldsymbol{\sigma}_{i,1,1}\boldsymbol{\sigma}^*_{j,1,1} \end{pmatrix} \tag{129}$$

The Mueller matrix is reconstructed from **H** as

$$m_{i,j} = \mathrm{Tr}\{\mathbf{H} \bullet (\sigma_i \otimes \sigma_j)^*\} \tag{130}$$

If any of the four eigenvalues of **H** are negative, then **M** is not physical. *This is the fundamental test for physical M.* Often when a Mueller matrix is measured in the presence of noise, the Mueller Matrix is close to physical. Usually three of the four eigenvalues are positive, and one is small and negative.

Two methods are presented to construct a physical Mueller matrix $\mathbf{M}_p$ from a physical Mueller matrix **M**:(1) One method first calculates the hermitian matrix $\mathbf{H}_p$ corresponding to the closest $\mathbf{M}_p$ via optimization in the coherency matrix domain.[48] Various metrics can define the meaning of *closest*. (2) A faster method finds $\mathbf{H}_p$ which has all nonnegative eigenvalues (i.e., is positive semidefinite).

Method 1

To calculate the closest $\mathbf{M}_p$, the first step is to construct a positive semidefinite matrix $\mathbf{H}_{\mathrm{opt}}$ from a Cholesky decomposition of the Mueller matrix **M**,

$$\mathbf{M} = \mathbf{C}^\dagger \bullet \mathbf{C} \tag{131}$$

where † indicates conjugate transpose, and **C** is an upper triangular matrix. If the Cholesky decomposition of **M** exists, then **M** must be positive semidefinite. To preserve the magnitude of $\mathbf{H}_{\mathrm{opt}}$, its Cholesky decomposition is normalized by a constant,

$$\mathbf{H}_{\mathrm{opt}} = \frac{2\mathbf{C}^\dagger \bullet \mathbf{C}}{\mathrm{Tr}(\mathbf{C}^\dagger \bullet \mathbf{C})} \tag{132}$$

where **C** is given by

$$\mathbf{C} = \begin{pmatrix} h_1 & h_5 + ih_6 & h_{1,1} + ih_{1,2} & h_{1,5} + ih_{1,6} \\ 0 & h_2 & h_7 + ih_8 & h_{13} + ih_{1,4} \\ 0 & 0 & h_3 & h_9 + ih_{1,0} \\ 0 & 0 & 0 & h_4 \end{pmatrix} \tag{133}$$

To perform the optimization, $\mathbf{H}_{opt}$ (having 16 variable parameters $h_1 - h_{16}$) is formed via Eqs. (132) and (133), and the 16 h parameters are varied until the difference metric between $\mathbf{M}_p$ and $\mathbf{M}$ is minimized. A starting point for the 16 parameters can be selected as $\mathbf{H}_{init}$,

$$\mathbf{H}_{init} = \frac{2\sqrt{H}(\sqrt{H})^{\dagger}}{\mathrm{Tr}(\sqrt{H}(\sqrt{H})^{\dagger})} \tag{134}$$

The Cholesky decomposition of $\mathbf{H}_{init}$ yields the upper triangular matrix $\mathbf{C}_{init}$, and the 16 starting values. By minimizing the Frobenius distance F_d between $\mathbf{M}_p$ and $\mathbf{M}$,

$$F_d = \frac{\left\|\mathbf{M}-\mathbf{M}_p\right\|}{\left\|\mathbf{M}+\mathbf{M}_p\right\|} \tag{135}$$

where ||.|| is any appropriate matrix norm. The euclidean norm for Mueller matrix $\mathbf{M}$ is

$$\left\|\mathbf{M}\right\| = \sqrt{\sum_{i=0}^{3}\sum_{j=0}^{3} m_{i,j}^2} \tag{136}$$

Method 2

The Cholesky decomposition method is computationally intenstive. A more expedient method for generating a physical $\mathbf{M}_p$ is to find the eigenvalues $\{\lambda_1, \lambda_2, \lambda_3, \lambda_4\}$ and eigenvectors $\{\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3, \mathbf{v}_4\}$ of $\mathbf{H}$. Any negative eigenvalues are set to zero. The set of positive definite eigenvalues are formed into a diagonal matrix $\mathbf{D}$:

$$\mathbf{D} = \begin{pmatrix} \lambda_1' & 0 & 0 & 0 \\ 0 & \lambda_2' & 0 & 0 \\ 0 & 0 & \lambda_3' & 0 \\ 0 & 0 & 0 & \lambda_4' \end{pmatrix} \tag{137}$$

$$\text{where } \lambda_i' = \begin{cases} \lambda_i & \text{if } \lambda_i \geq 0 \\ 0 & \text{if } \lambda_i < 0 \end{cases}$$

and the eigenvectors are formed into a square unitary matrix $\mathbf{U}$,

$$\mathbf{U} = \begin{pmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \mathbf{v}_3 \\ \mathbf{v}_4 \end{pmatrix} \tag{138}$$

A new physically realizable $\mathbf{H}_p$ is formed as the product

$$\mathbf{H}_p = \mathbf{U} \bullet \mathbf{D} \bullet \mathbf{U}^{-1} \tag{139}$$

per the Eigen decomposition theorem.[49,50] Finally $\mathbf{M}_p$ is derived from $\mathbf{H}_p$ via Eq. (130) yielding a dramatically faster algorithm. This $\mathbf{M}_p$ is not necessarily the closest one to the original nonphysical $\mathbf{M}$.

14.34 ACKNOWLEDGMENTS

In preparing this chapter extensive use has been made of the works of some of the author's students and other collaborators and they deserve particular credit: Shih-Yau Lu, Karlton Crabtree, Brian deBoo, Karen Tweitmeyer, Garam Yun, and Neil Beaudry.

15 POLARIMETRY

Russell A. Chipman

College of Optical Sciences
University of Arizona
Tucson, Arizona

15.1 GLOSSARY

A	analyzer vector
a	analyzer vector element
a	semimajor axis of ellipse
A, B, C	principal axes for a dielectric tensor
BRDF	bidirectional reflectance distribution function
b	semiminor axis of ellipse
$\mathbf{C}_M$	covariance matrix
d	liquid crystal cell gap
D	diagonal matrix
D	diattenuation
DoCP	degree of circular polarization
DoLP	degree of linear polarization
DoP	degree of polarization
E	extinction ratio
e	ellipticity
EM	error metric
I	inhomogeneity of a Mueller matrix
I	first Stokes element, S_0, flux
i, j, k	summation indices
k	propagation vector
L, L_2	condition number of a matrix
LP	linear polarizer
M	Mueller matrix
$\vec{\mathbf{M}}$	Mueller vector
MMBRDF	Mueller matrix bidirectional reflectance distribution function
$\mathbf{M}_R$	polarimeter's estimate of the Mueller matrix
$\mathbf{M}_R$, $\mathbf{M}_T$	beamsplitter Mueller matrix in reflection and transmission

$\mathbf{M}_S$	sample Mueller matrix
$m_{00}, m_{01},\ldots, m_{33}$	Mueller matrix elements
Δn	birefringence
n_1, n_2	refractive indices of a birefringent medium
$\mathbf{P}$	flux measurement vector
P	polarizance
P	flux measurement
PAF	polarization aberration function
PSM	point spread matrix
QWLR	quarter-wave linear retarder
Q, R	index limit
Q	second Stokes vector element, S_1
q	index for a sequence of polarization elements
r	index for polarimeter variables
$\mathbf{S}$	Stokes vector
$\mathbf{S}'$	exiting Stokes vector
$\mathbf{S}_m$	measured Stokes vector
S_0, S_1, S_2, S_3	Stokes vector elements
$\mathbf{S}_p, \mathbf{S}_u$	polarized and unpolarized part of Stokes vector
SD	standard deviation
T	transpose, superscript
$T_{\max}$	maximum intensity transmittance
$T_{\min}$	minimum intensity transmittance
t	time
t	thickness
$\mathbf{U}$	Jones/Mueller transformation matrix
U	third Stokes vector element, S_2
$\mathbf{U}, \mathbf{V}$	unitary matrices
V	fourth Stokes vector element, S_3
$\mathbf{W}$	polarimetric measurement matrix
$\mathbf{W}^{-1}$	polarimetric data-reduction matrix
$\mathbf{W}_P^{-1}$	pseudoinverse of $\mathbf{W}$
α	liquid crystal cell rubbing direction
β	bistatic angle
γ, δ	angles of scatter
$\delta\mathbf{M}_k$	error in Mueller matrix element
$<\delta\mathbf{M}>$	mean
$<\delta\mathbf{W}>$	corrections to polarimetric measurement matrix
δ	retardance
ε	eccentricity
$\tilde{\boldsymbol{\varepsilon}}$	dielectric tensor
η	azimuth of ellipse
θ	Euler angle
θ	orientation angle
θ_i, ϕ_I	angles of incidence

θ_s, ϕ_s	angles of scatter
Θ_1, Θ_2	pretilt at liquid crystal cell input and output
κ_p	condition number
λ	wavelength
μ_k	singular values
φ	Euler angle
Φ	liquid crystal cell twist angle
ϕ	phase of a complex number
ψ	Euler angle
Ω	solid angle, steradians
•	dot product, matrix multiplication

15.2 OBJECTIVES

The principles of polarization measurements are surveyed in this chapter. One of the primary difficulties in performing accurate polarization measurements is the systematic errors due to nonideal polarization elements. Therefore, the polarimetric measurement and data-reduction process is formulated to incorporate arbitrary polarization elements calibrated by measurement of their transmitted and analyzed Stokes vectors. Polarimeter optimization is addressed through the minimization of the condition number. First derivatives of the polarimetric measurement matrix provide an error analysis method. Methods for polarization modulation are compared. The chapter concludes with a survey of polarimeter applications including the following sections: "Ellipsometry and Generalized Ellipsometry," "Liquid Crystal Cell and System Testing," "Polarization Aberrations," "Remote Sensing," "Polarization Light Scattering," "Ophthalmic Polarimetry."

Throughout this chapter, quantities are formulated in terms of the Stokes vector and Mueller matrix, as these usually comprise the most appropriate representation of polarization for radiometric measurements.

15.3 POLARIMETERS

Polarimeters are optical instruments for measuring the polarization properties of light beams and samples. Polarimetry, the science of polarization measurement, is most simply characterized as *radiometry with polarization elements*. Accurate polarimetry requires careful attention to all the issues necessary for accurate radiometry, together with many additional polarization issues which must be mastered to accurately determine polarization properties from polarimetric measurements.

Typical applications of polarimeters include the following: remote sensing of the earth and astronomical bodies, calibration of polarization elements, measurements of the thickness and refractive indices of thin films (ellipsometry), spectropolarimetric studies of materials, and alignment of polarization-critical optical systems such as liquid crystal displays and projectors. Polarimeters are divided into several categories.

15.4 LIGHT-MEASURING POLARIMETERS

Light-measuring polarimeters measure the polarization state of a beam of light and its polarization characteristics: the Stokes vector, the direction of oscillation of the electric field vector for a linearly polarized beam, the helicity of a circularly polarized beam, the elliptical parameters of an elliptically polarized beam, and the degree of polarization.

A light-measuring polarimeter utilizes a set of polarization elements placed in a beam of light in front of a radiometer. The light beam is analyzed by this set of polarization state analyzers, and a set of flux measurements is acquired. The polarization characteristics of the light beam are determined from these measurements by data-reduction algorithms (see "Data Reduction for Light-measuring Polarimeters").

15.5 SAMPLE-MEASURING POLARIMETERS

Sample-measuring polarimeters determine the relationship between the polarization states of incident and exiting beams for a sample. The term *exiting beam* is general and in different measurements might describe beams which are transmitted, reflected, diffracted, scattered, or otherwise modified. The term sample is also an inclusive term used in a broad sense to describe a general light-matter interaction or sequence of such interactions and applies to practically anything.

Measurements are acquired using a set of polarization elements located between a source and sample and the exiting beams are analyzed with a separate set of polarization elements between the sample and radiometer. Samples of great interest include surfaces, thin films on surfaces, polarization elements, optical elements, optical systems, natural scenes, biological samples, and industrial samples.

Accurate polarimetric measurements can be made only if the polarization generator and polarization analyzer are well calibrated. To perform accurate polarimetry, the polarization elements need not be ideal or of the highest quality. If the Mueller matrices of the polarization components are known from careful calibration, the systematic errors due to nonideal polarization elements are removed during the data reduction (see "Polarimetric Measurement Equation and Polarimetric Data-Reduction Equation").

15.6 COMPLETE AND INCOMPLETE POLARIMETERS

A light-measuring polarimeter is *complete* if a Stokes vector can be determined from its measurements. An *incomplete* light-measuring polarimeter cannot be used to determine a Stokes vector. For example, a polarimeter which employs a rotating polarizer in front of a detector does not determine the circular polarization content of a beam, and is incomplete. Similarly, a sample-measuring polarimeter is complete if it is capable of measuring the full Mueller matrix, and incomplete otherwise. Complete polarimeters are referred to as Stokes polarimeters or Mueller polarimeters.

15.7 POLARIZATION GENERATORS AND ANALYZERS

A *polarization generator* consists of a light source, optical elements, and polarization elements to produce a beam of known polarization state. A polarization generator is specified by the Stokes vector **S** of the exiting beam. A *polarization analyzer* is a configuration of polarization elements, optical elements, and a detector which performs a flux measurement of a particular polarization component in an incident beam. A polarization analyzer is characterized by a Stokes-like *analyzer vector* **A** which specifies the incident polarization state which is analyzed, the state which produces the maximal response at the detector. Sample-measuring polarimeters require polarization generators and polarization analyzers, while light-measuring polarimeters only require polarization analyzers. Frequently the terms "polarization generator" and "polarization analyzer" refer just to the polarization elements in the generator and analyzer. It is important to distinguish between elliptical (and circular) generators and elliptical analyzers for a given state because they generally have different

polarization characteristics and different Mueller matrices (see "Elliptical and Circular Polarizers and Analyzers").

15.8 CLASSES OF POLARIMETERS

Polarimeters operate by acquiring measurements with a set of polarization analyzers. The following sections classify polarimeters by the four broad methods by which these multiple measurements are most often acquired. A complete Stokes polarimeter requires a minimum of four flux measurements with a set of linearly independent polarization generators in order to set up four equations in four unknowns, the four Stokes parameters. Many Stokes polarimeters use more than four flux measurements to improve signal to noise and/or reduce systematic errors.

15.9 TIME-SEQUENTIAL MEASUREMENTS

In a time-sequential polarimeter, the series of flux measurements are taken sequentially in time. Between measurements, the polarization generator and analyzer are changed. Time-sequential polarimeters frequently employ rotating polarization elements or filter wheels containing a set of analyzers. A time-sequential polarimeter generally employs a single source and single detector or focal plane.

15.10 POLARIZATION MODULATION

Polarization modulation polarimeters contain a polarization modulator, a rapidly changing polarization element. The output of the analyzer is a rapidly fluctuating irradiance on which polarization information is encoded. Polarization parameters are determined by lock-in amplifiers or by frequency-domain digital signal processing techniques. For example, a rapidly spinning polarizer produces a modulated output which allows the flux and the degree of linear polarization to be read with a DC voltmeter and an AC voltmeter. The most common high-speed polarization modulator in general use is the photoelastic modulator.

15.11 DIVISION OF APERTURE

Division of aperture polarimeters use multiple polarization analyzers operating side by side. The aperture of the polarimeter beam is subdivided. Each beam propagates through a separate polarization analyzer to a separate detector. The detectors are usually synchronized to acquire measurements simultaneously. This is similar in principle to the polarizing glasses used in three-dimensional movie systems, where different analyzers are placed over each eye, sometimes a 45° and a 135° polarizer, sometimes a right and left circular analyzer, presenting two different perspective views simultaneously to each eye.

15.12 DIVISION OF AMPLITUDE

Division-of-amplitude polarimeters utilize beam splitters to divide the measured beam and direct the component beams to multiple analyzers and detectors. A division-of-amplitude polarimeter can acquire its measurements simultaneously, providing advantages for rapidly changing scenes

or measurements from moving platforms. Many division-of-amplitude polarimeters use polarizing beam splitters to simultaneously divide and analyze the beam.

15.13 SPECTROPOLARIMETERS

Polarimeters can be combined with monochromators or spectrometers to measure Stokes vector spectra or Mueller matrix spectra. Because grating monochromators have large diattenuation which varies rapidly with wavelength, the monochromator should be configured to use only a single polarization.

15.14 IMAGING POLARIMETERS

When the polarimeter's detector is a focal plane array, a series of images acquired with different analyzers (the raw images) can be reduced to measure a Stokes vector image or a Mueller matrix image.

Imaging polarimeters are particularly susceptible to misalignment of the raw images since polarization properties are determined from the difference between flux measurements. Such misalignment causes polarization artifacts in the image on account of spurious polarization mixed with the actual polarization.

Raw image misalignments occur due to source motion, polarimeter motion, vibration, and beam wander from slight wedge in rotating components. Polarization artifacts are largest in areas where the image intensity is changing the fastest, around object edges and near point sources. The edges of objects are usually where the angles of incidence and angles of scatter are larger. The largest polarization is typically expected around these areas, but due to vibration, image motion, and image misalignment, these are also the areas where the data is most suspect. Other errors result from imperfect polarization elements, and detector noise.

When the source flux fluctuates between raw images, a uniform polarization error occurs across the entire image. Source fluctuations are a serious problem in outdoor Stokes imagery because sunlight fluctuates due to cloud motion.

Many of the polarization images and spectra presented in conferences and publications are inaccurate. In our polarization laboratory where rigorous polarimeter-operating procedures are in place, still about a quarter of our data is discarded as dubious and remeasured. It is recommended that all polarization measurements be approached with a degree of skepticism until the measurement system and measurement circumstances are clearly understood and appropriate tests and calibrations are provided.

15.15 DEFINITIONS

Analyzer an element whose intensity transmission is proportional to the content of a specific polarization state in the incident beam. Analyzers are placed before the detector in polarimeters. The polarization state emerging from an analyzer is not necessarily the same as the incident state being analyzed.

Birefringence the material property of having two refractive indices associated with one propagation direction. For each propagation direction within a birefringent medium, there are two modes of propagation with orthogonal polarization states and with different refractive indices n_1 and n_2. The birefringence Δn is $|n_1 - n_2|$.

Depolarization any process which couples polarized light into partially polarized light. Depolarization is intrinsically associated with scattering and with diattenuation and retardance which vary in space, time, and/or wavelength.

Diattenuation the property of an optical element or system whereby the flux of the exiting beam depends on the polarization state of the incident beam. The transmitted intensity is a maximum P_{max} for one incident state, and a minimum P_{min} for the orthogonal state. The diattenuation is defined as $(P_{max} - P_{min})/(P_{max} + P_{min})$. Polarizers have a diattenuation of one, while ideal retarders have a diattenuation of zero. Diattenuation is an essential property of analyzers.

Diattenuator any polarization element which displays diattenuation. Polarizers have a diattenuation very close to one, but nearly all optical interfaces are weak diattenuators. Examples of diattenuators include the following: polarizers and dichroic materials, as well as metal and dielectric interfaces with reflection and transmission differences described by Fresnel equations; thin films (homogeneous and isotropic); and diffraction gratings.

Eigenpolarization a polarization state transmitted unaltered by a polarization element except for a change of amplitude and phase. Every nondepolarizing polarization element has two eigenpolarizations. Any incident light not in an eigenpolarization state is transmitted in a polarization state different from the incident state. Eigenpolarizations are eigenvectors of the corresponding Mueller or Jones matrix which correspond to physical polarization states.

Ellipsometry a polarimetric technique which uses the change in the polarization state upon reflection or transmission to characterize the complex refractive index of surfaces and interfaces, and refractive indices and thicknesses of thin films.[1]

Fast axis the eigenpolarization of a retarder which exits the device first. For a linear retarder, the axis is a line at a particular angle, such as 0° and 180°. For an elliptical or circular retarder, it is the corresponding elliptical polarization.

Homogeneous polarization element an element whose eigenpolarizations are orthogonal. Its eigenpolarizations are the states of maximum and minimum transmittance and also of maximum and minimum optical path length. A homogeneous element is classified as linear, circular, or elliptical depending on the form of the eigenpolarizations.

Inhomogeneous polarization element an element whose eigenpolarizations are not orthogonal. The diattenuation axis and retardance axis are not aligned. Such an element will also display different polarization characteristics for forward and backward propagating beams. The eigenpolarizations are generally not the states of maximum and minimum transmittance. Often inhomogeneous elements cannot be simply classified as linear, circular, or elliptical.

Ideal polarizer a polarizer with an intensity transmittance of one for its principal state and zero for its orthogonal state.

Linear polarizer a device which, when placed in an incident unpolarized beam, produces a beam of light whose electric field vector is oscillating primarily in one plane, with only a small component in the perpendicular plane.[2]

Nonpolarizing element an element which does not change the polarization state of light beams. The polarization state of the output light is equal to the polarization state of the incident light. The Jones matrix or Mueller matrix of a nonpolarizing element is proportional to the identity matrix.

Partially polarized light light containing an unpolarized component; cannot be extinguished by an ideal polarizer.

Polarimeter an optical instrument for the determination of the polarization state of a light beam, or the polarization-altering properties of a sample.

Polarimetry the science of measuring the polarization state of a light beam and the diattenuating, retarding, and depolarizing properties of materials.

Polarization (1) the polarization state of a light beam; (2) any process which alters the polarization state of a beam of light, including diattenuation, retardance, depolarization.

Polarization coupling any conversion of light from one polarization state into another state.

Polarized light light in a fixed, elliptically (including linearly or circularly) polarized state. Polarized light can be extinguished by an ideal polarizer. For polychromatic polarized light, the polarization ellipses associated with each spectral component have identical ellipticity, orientation, and helicity.

Polarizer a strongly diattenuating optical element designed to transmit light in a specified polarization state independent of the incident polarization state. The transmission of the extinguished eigenpolarization is near zero.

Polarization element any optical element used to control the polarization state of light. This includes polarizers, retarders, and depolarizers.

Pure diattenuator a diattenuator with zero retardance and no depolarization.

Pure retarder a retarder with zero diattenuation and no depolarization.

Retardance a polarization-dependent phase change associated with a polarization element or system. The phase (optical path length) of the output beam depends on the polarization state of the input beam. The optical path length (phase) of the transmitted beam is a maximum for one eigenpolarization, and a minimum for the other eigenpolarization. Other states show polarization coupling. Strictly speaking, retardance is measured in radians, but it may also be expressed equivalently as an optical path difference (length) or in fractions of a wavelength (unitless).

Retardation plate a retarder constructed from a plane parallel plate or plates of linearly birefringent material.

Retarder a polarization element designed to produce a specified phase difference between the exiting beams for two orthogonal incident polarization states (the eigenpolarizations of the element). For example, a quarter-wave linear retarder has as its eigenpolarizations two orthogonal linearly polarized states which are transmitted in their incident polarization states but with a 90° (quarter wavelength) relative phase difference (optical path length difference) introduced.

Slow axis the eigenpolarization of a retarder orthogonal to the fast axis.

Spectropolarimetry the spectroscopic study of the polarization properties of materials. Conventional spectroscopy measures the reflectance or transmission of a sample as a function of wavelength. Spectropolarimetry also measures the diattenuating, retarding, and depolarizing properties as a function of wavelength. Complete characterization of these properties is obtained by measuring the Mueller matrix of the sample as a function of wavelength.

Waveplate a retardation plate.

15.16 STOKES VECTORS AND MUELLER MATRICES

Several systematic methods of calculation have been developed for analyzing polarization, including those based on the Jones matrix, coherency matrix, and Mueller matrix.[3–8] Of these methods, the Mueller calculus is most suited for describing irradiance-measuring instruments, including most

polarimeters, radiometers, and spectrometers. The Mueller calculus is primarily used in this chapter. The properties of the Mueller matrix are described in Chap. 14 "Mueller Matrices."

In the Mueller calculus, a Stokes vector **S** describes the polarization state of a light beam, and a Mueller matrix **M** describes the polarization-altering characteristics of a sample. This sample may be a surface, a polarization element, an optical system, or some other light/matter interaction which produces a reflected, refracted, diffracted, or scattered light beam. Vectors and matrices are represented with bold characters.

15.17 PHENOMENOLOGICAL DEFINITION OF THE STOKES VECTOR

The Stokes vector **S** describes the polarization state of a light beam. **S** is defined relative to the following six flux measurements P performed with ideal polarizers in front of a radiometer.[3]

P_H	horizontal linear polarizer (0°)
P_V	vertical linear polarizer (90°)
P_{45}	45° linear polarizer
P_{135}	135° linear polarizer
P_R	right circular polarizer
P_L	left circular polarizer

The Stokes vector is defined as

$$\mathbf{S} = \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} = \begin{pmatrix} P_H + P_V \\ P_H - P_V \\ P_{45} - P_{135} \\ P_R - P_L \end{pmatrix} = \begin{pmatrix} I \\ Q \\ U \\ V \end{pmatrix} \tag{1}$$

where S_0, S_1, S_2, and S_3 (or alternatively I, Q, U, and V) are the four Stokes vector elements or Stokes parameters. The Stokes vector does not need to be measured by these six ideal measurements; the method must reproduce the Stokes vector defined by these measurements. Ideal polarizers are not required. Further, the Stokes vector is a function of wavelength, position on the object, and the light's direction of emission or scatter. Thus, a Stokes vector measurement is an average over area, solid angle, and wavelength, as is any radiometric measurement. The Stokes vector is defined relative to a local x-y coordinate system in the plane perpendicular to the light's propagation vector, established by the polarimeter. The coordinate system is right-handed; the cross-product $\hat{x} \times \hat{y}$ of the basis vectors points in the direction of propagation of the beam.

15.18 POLARIZATION PROPERTIES OF LIGHT BEAMS

From the Stokes vector, the following polarization parameters are defined.[6,9–11]

$$\text{Flux} \qquad P = S_0 \tag{2}$$

$$\text{Degree of polarization} \qquad \text{DoP} = \frac{\sqrt{S_1^2 + S_2^2 + S_3^2}}{S_0} \tag{3}$$

$$\text{Degree of linear polarization} \qquad \text{DoLP} = \frac{\sqrt{S_1^2 + S_2^2}}{S_0} \tag{4}$$

$$\text{Degree of circular polarization} \qquad \text{DoCP} = \frac{|S_3|}{S_0} \tag{5}$$

The Stokes vector for a partially polarized beam (DoP < 1) can be considered as a superposition of a completely polarized Stokes vector $\mathbf{S}_P$ and an unpolarized Stokes vector $\mathbf{S}_U$.[11]

$$\mathbf{S} = \mathbf{S}_P + \mathbf{S}_U = \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} = S_0\,\text{DoP}\begin{pmatrix} 1 \\ S_1/(S_0\,\text{DoP}) \\ S_2/(S_0\,\text{DoP}) \\ S_3/(S_0\,\text{DoP}) \end{pmatrix} + (1-\text{DoP})S_0\begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix} \tag{6}$$

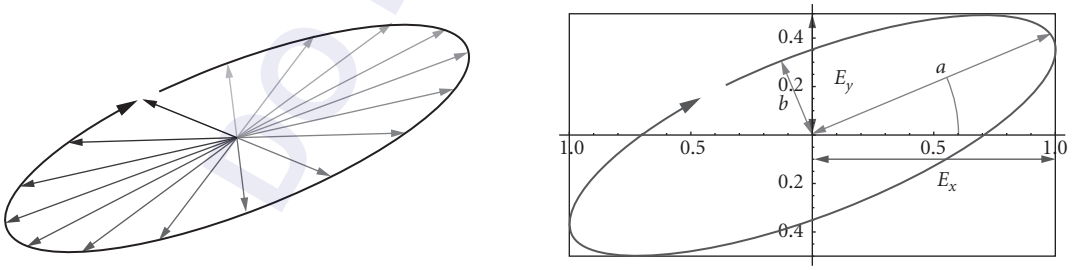
There is no polarization element which performs this separation into polarized and unpolarized light components; a polarizer will always transmit half the unpolarized component. The polarized portion of the beam represents a net polarization ellipse traced by the electric field vector as a function of time as shown in Fig. 1. The polarization ellipse is uniquely described by four parameters. One is the phase at $t=0$, and the other three are selected from the following list: the magnitude of the semimajor axis a, semiminor axis b, orientation of the major axis ψ (azimuth of the ellipse) measured counterclockwise from the x axis, and eccentricity, and ellipticity.

$$\text{Ellipticity} \qquad e = \frac{b}{a} = \frac{S_3}{S_0 + \sqrt{S_1^2 + S_2^2}} \tag{7}$$

$$\text{Orientation of major axis, azimuth} \qquad \psi = \frac{1}{2}\arctan\left(\frac{S_2}{S_1}\right) \tag{8}$$

$$\text{Eccentricity} \qquad \varepsilon = \sqrt{1-e^2} \tag{9}$$

The ellipticity is the ratio of the minor to the major axis of the corresponding electric field polarization ellipse, and varies from 0 for linearly polarized light to 1 for circularly polarized light. The polarization ellipse is alternatively described by its eccentricity, which is zero for circularly polarized light, increases as the polarization ellipse becomes thinner, and is one for linearly polarized light. The polarization ellipse strictly refers to the light's electric field.



(a) (b)

FIGURE 1 The tip of the electric field vector rotating as a function of time traces the polarization ellipse (*a*). The polarization ellipse parameters (*b*).

15.19 MUELLER MATRICES

The Mueller matrix **M** for a polarization-altering device is defined as the matrix which transforms an incident Stokes vector **S** into the exiting Stokes vector **S′**,

$$\mathbf{S}' = \begin{pmatrix} S'_0 \\ S'_1 \\ S'_2 \\ S'_3 \end{pmatrix} = \mathbf{M} \bullet \mathbf{S} \begin{pmatrix} m_{0,0} & m_{0,1} & m_{0,2} & m_{0,3} \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{2,1} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{3,1} & m_{3,2} & m_{3,3} \end{pmatrix} \bullet \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} \tag{10}$$

The Mueller matrix is a 4×4 matrix with real-valued elements. The Mueller matrix $\mathbf{M}(\mathbf{k}, \lambda)$ for a device is always a function of the direction of propagation **k** and wavelength λ. The Mueller matrix is an appropriate formalism for characterizing polarization measurements because it contains within its elements all of the polarization properties (diattenuation, retardance, depolarization) and their form (linear, circular, elliptical). When the Mueller matrix is known, then the exiting polarization state is known for an arbitrary incident polarization state. Chapter 14, "Mueller Matrices" contains tables of Mueller matrices for common polarization elements. Other Mueller matrix tables are found in many references including the following: Shurcliff,[3] Gerrard and Burch,[4] Azzam and Bashara,[9] Theocaris and Gdoutos,[5] and Goldstein.[12] The Mueller Matrix chapter contains a detailed discussion of the polarization properties and methods for calculating these properties from the Mueller matrix.

The Mueller matrix **M** associated with a beam path through a sequence (cascade) of polarization elements $q = 1, 2, \ldots, Q$ is the right-to-left product of the individual matrices $\mathbf{M}_q$,

$$\mathbf{M} = \mathbf{M}_Q \bullet \mathbf{M}_{Q-1} \bullet \ldots \mathbf{M}_q \bullet \ldots \mathbf{M}_2 \bullet \mathbf{M}_1 = \prod_{q=Q,-1}^{1} \mathbf{M}_q \tag{11}$$

15.20 DATA REDUCTION FOR LIGHT-MEASURING POLARIMETERS

This section presents a general formulation of the measurement and data-reduction procedure for a light-measuring polarimeter. The objective of Stokes polarimetry is to determine the Stokes parameters from a series of radiometric measurements. The data reduction is a linear estimation process, and lends itself to efficient solution using linear algebra, usually with a least-squares estimator to find the best match to the data. Similar developments are found in Thie,[13] Azzam,[14] and Stenflo.[15]

Stokes vectors and related polarization parameters for a beam are determined by measuring the flux transmitted through a set of polarization analyzers. Each analyzer determines the flux of one polarization component in the incident beam. Since a polarization analyzer does not contain ideal polarization elements, the analyzer must be calibrated, and the calibration data used in the data reduction. The polarizer in an analyzer does not need $T_{\min}$ to equal zero; it never does, and this leakage will be corrected in the data reduction. The measured values are related to the incident Stokes vector and the analyzers by the polarimetric measurement equation. A set of linear equations, the data-reduction equations, is then solved to determine the Stokes parameters for the beam.

The *polarization analyzer* consists of the polarization elements used for analyzing the polarization state, any other optical elements (lenses, mirrors, etc.) following the analyzer, and the polarimeter's detector. The polarization effects from all elements are included in the measurement and data-reduction procedures. A polarization analyzer is characterized by an *analyzer vector* containing four elements, defined analogously to a Stokes vector. Let P_H be the flux measurement measured by the detector (the current or voltage generated) when one unit of horizontally polarized light is incident.

Similarly P_V, P_{45}, P_{135}, P_R, and P_L are the detector's flux measurements for the corresponding incident polarized beams with unit flux. Then the analyzer vector **A** is

$$\mathbf{A}=\begin{pmatrix} a_0 \\ a_1 \\ a_2 \\ a_3 \end{pmatrix}=\begin{pmatrix} P_H+P_V \\ P_H-P_V \\ P_{45}-P_{135} \\ P_R-P_L \end{pmatrix} \tag{12}$$

Note that in the absence of noise, $P_H + P_V = P_{45} + P_{135} = P_R + P_L$. The response P of the polarization analyzer to an arbitrary polarization state **S** is a dot product

$$P=\mathbf{A}\bullet\mathbf{S}=a_0S_0+a_1S_1+a_2S_2+a_3S_3 \tag{13}$$

A Stokes vector measurement is a set of measurements acquired with a set of polarization analyzers placed into the beam. Let the total number of analyzers be Q, with each analyzer $\mathbf{A}_q$ specified by index $q = 0, 1, \ldots, Q - 1$. We assume the incident Stokes vector is the same for all polarization analyzers. The qth measurement generates an output $P_q = \mathbf{A}_q \bullet \mathbf{S}$. A polarimetric measurement matrix **W** is defined as a $Q \times 4$ matrix with the qth row containing the analyzer vector $\mathbf{A}_q$,

$$\mathbf{W}=\begin{pmatrix} a_{0,0} & a_{0,1} & a_{0,2} & a_{0,3} \\ a_{1,0} & a_{1,1} & a_{1,2} & a_{1,3} \\ \vdots & \vdots & \vdots & \vdots \\ a_{Q-1,0} & a_{Q-1,1} & a_{Q-1,2} & a_{Q-1,3} \end{pmatrix} \tag{14}$$

The Q measured fluxes are arranged in a measurement vector $\mathbf{P} = \{P_0, P_1, \ldots, P_{Q-1}\}^T$. **P** is related to **S** by the polarimetric measurement equation

$$\mathbf{P}=\begin{pmatrix} P_0 \\ P_1 \\ \vdots \\ P_{Q-1} \end{pmatrix}=\mathbf{W}\bullet\mathbf{S}=\begin{pmatrix} a_{0,0} & a_{0,1} & a_{0,2} & a_{0,3} \\ a_{1,0} & a_{1,1} & a_{1,2} & a_{1,3} \\ \vdots & \vdots & \vdots & \vdots \\ a_{Q-1,0} & a_{Q-1,1} & a_{Q-1,2} & a_{Q-1,3} \end{pmatrix}\bullet\begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} \tag{15}$$

During calibration of the polarimeter, the objective is the accurate determination of **W**.

To calculate the Stokes vector from the data, the inverse of **W** is determined and applied to the measured data. The measured value for the incident Stokes vector $\mathbf{S}_m$ is related to the data by the polarimetric data-reduction matrix $\mathbf{W}^{-1}$,

$$\mathbf{W}^{-1}\bullet\mathbf{P}=\mathbf{S}_m \tag{16}$$

This is the *polarimetric measurement equation*. Three considerations in the solution of this equation are the existence, rank, and uniqueness of the matrix inverse $\mathbf{W}^{-1}$.

The simplest case is when four measurements are performed. If $Q = 4$ and if four linearly independent analyzer vectors are used, then **W** is of rank four, and $\mathbf{W}^{-1}$ exists, is unique and nonsingular. Data reduction is performed by Eq. (16); the polarimeter measures all four elements of the incident Stokes vector.

When $Q > 4$, **W** is not square and $\mathbf{W}^{-1}$ is not unique; multiple $\mathbf{W}^{-1}$ exist. $\mathbf{S}_m$ is overdetermined; there are more equations than unknowns. In the absence of noise, the different $\mathbf{W}^{-1}$ all yield the same $\mathbf{S}_m$. Because noise is always present, the optimum $\mathbf{W}^{-1}$ is desired. The least squares estimate for $\mathbf{S}_m$ utilizes a particular matrix inverse, the pseudoinverse $\mathbf{W}_P^{-1}$ of **W**,

$$\mathbf{W}_P^{-1}=(\mathbf{W}^T\mathbf{W})^{-1}\,\mathbf{W}^T \tag{17}$$

The optimal estimate of **S** is

$$\mathbf{S} = \mathbf{W}_P^{-1} \bullet \mathbf{P} = (\mathbf{W}^T \bullet \mathbf{W})^{-1} \bullet \mathbf{W}^T \bullet \mathbf{P} \tag{18}$$

When **W** is of rank three or less, the polarimeter is *incomplete*. The optimal matrix inverse is the pseudoinverse, but only three or fewer *properties* of the Stokes vector elements are determined; the projection of the Stokes vector onto three or fewer directions is measured. If these directions align with the Stokes basis vectors, then these Stokes vector elements are measured, but in general, linear combinations of elements are measured.

15.21 SAMPLE-MEASURING POLARIMETERS FOR MEASURING MUELLER MATRIX ELEMENTS

This section contains a general formulation of Mueller matrix measurement which is an extension of the Stokes vector method of the preceding section. The Mueller matrix is always a function of wavelength, angle of incidence, and location on the sample. These are assumed fixed here for simplicity; this method can be generalized to these more general cases. Figure 2 is a block diagram of a sample-measuring polarimeter. The polarization state generator (PSG) prepares polarization states incident on a sample. The light beam exiting the sample is analyzed by the polarization state analyzer (PSA), and the flux at the detector measured.

The objective is to determine several or all of the sample's Mueller matrix **M** elements through a sequence $q = 0, 1, \ldots, Q-1$ of polarimetric measurements. The polarization generator prepares a set of polarization states with a sequence of Stokes vectors $\mathbf{S}_q$. The Stokes vectors exiting the sample are $\mathbf{M} \bullet \mathbf{S}_q$. These exiting states are analyzed by the qth polarization state analyzer $\mathbf{A}_q$, yielding the qth measured flux $P_q = \mathbf{A}_q^T \bullet \mathbf{M} \bullet \mathbf{S}_q$. Each measured flux is assumed to be a linear function of the sample's Mueller matrix elements (nonlinear optical interactions such as frequency doubling are not treated by the present formulation). A set of linear equations is developed from the set of polarimetric measurements to solve for the Mueller matrix elements.

For example, consider a measurement taken with horizontal linear polarizers as the generator and the analyzer. As Eq. (11) shows, the measured flux only depends on the Mueller matrix elements $m_{0,0}$, $m_{0,1}$, $m_{1,0}$, and $m_{1,1}$,

$$P = \mathbf{A}^T \bullet \mathbf{M} \bullet \mathbf{S} = \frac{1}{2}(1, 1, 0, 0) \begin{pmatrix} m_{0,0} & m_{0,1} & m_{0,2} & m_{0,3} \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{2,1} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{3,1} & m_{3,2} & m_{3,3} \end{pmatrix} \bullet \begin{pmatrix} 1 \\ 1 \\ 0 \\ 0 \end{pmatrix} \tag{19}$$

$$= \frac{m_{0,0} + m_{0,1} + m_{1,0} + m_{1,1}}{2}$$

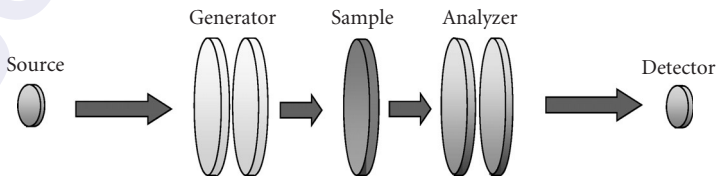


FIGURE 2 A sample-measuring polarimeter consists of a source, polarization state generator (PSG), the sample, a polarization state analyzer (PSA), and the detector. (See also color insert.)

As another example, the four Mueller matrix elements $m_{0,0}$, $m_{0,1}$, $m_{1,0}$, and $m_{1,1}$ can be measured using four measurements with ideal horizontal (**H**) and vertical (**V**) linear polarizers. Four measurements P_0, P_1, P_2, and P_3 are taken with (generator/analyzer) settings of (**H**/**H**), (**V**/**H**), (**H**/**V**), and (**V**/**V**), determining the following combinations of Mueller matrix elements,

$$\begin{aligned} P_0 &= (m_{0,0} + m_{0,1} + m_{1,0} + m_{1,1})/4 \qquad P_1 = (m_{0,0} - m_{0,1} + m_{1,0} - m_{1,1})/4 \\ P_2 &= (m_{0,0} + m_{0,1} - m_{1,0} - m_{1,1})/4 \qquad P_3 = (m_{0,0} - m_{0,1} - m_{1,0} + m_{1,1})/4 \end{aligned} \tag{20}$$

These four equations are solved for the Mueller matrix elements as

$$\begin{pmatrix} m_{0,0} \\ m_{0,1} \\ m_{1,0} \\ m_{1,1} \end{pmatrix} = \begin{pmatrix} P_0 + P_1 + P_2 + P_3 \\ P_0 - P_1 + P_2 - P_3 \\ P_0 + P_1 - P_2 - P_3 \\ P_0 - P_1 - P_2 + P_3 \end{pmatrix} \tag{21}$$

Other Mueller matrix elements are determined using different combinations of generator and analyzer states. The four matrix elements at the corners of a rectangle in the Mueller matrix $\{m_{0,0}, m_{0,i}, m_{j,0}, m_{j,i}\}$ can be determined from four measurements using a $\pm i$-generator and $\pm j$-analyzer. For example, a pair of right and left circularly polarizing generators and a pair of 45° and 135° oriented analyzers determine elements $m_{0,0}$, $m_{0,3}$, $m_{2,0}$, $m_{2,3}$.

In practice, the data-reduction equations are far more complex than these examples because many more measurements are involved with nonideal polarization elements. The following section contains a systematic method for calculation of data-reduction equations based on calibration data for the generator and analyzer.

15.22 POLARIMETRIC MEASUREMENT EQUATION AND POLARIMETRIC DATA-REDUCTION EQUATION

This section develops data-reduction equations to calculate Mueller matrices from arbitrary sequences of measurements. The algorithm uses either ideal or calibrated values for the polarization generator and analyzer vectors. The data-reduction equations are straightforward matrix-vector multiplication on a data vector. This method is an extension of the data-reduction methods presented in "Data Reduction for Light-Measuring Polarimeters".

A Mueller matrix polarimeter takes Q measurements identified by index $q = 0, 1, \ldots, Q-1$. For the qth measurement, the generator produces a beam with Stokes vector $\mathbf{S}_q$ and the beam exiting the sample is analyzed by analyzer vector $\mathbf{A}_q$. The measured flux P_q is related to the sample Mueller matrix by

$$\begin{aligned} P_q &= \mathbf{A}_q^T \mathbf{M} \mathbf{S}_q = (a_{q,0} \quad a_{q,1} \quad a_{q,2} \quad a_{q,3}) \bullet \begin{pmatrix} m_{0,0} & m_{0,1} & m_{0,2} & m_{0,3} \\ m_{1,0} & m_{1,1} & m_{1,2} & m_{1,3} \\ m_{2,0} & m_{2,1} & m_{2,2} & m_{2,3} \\ m_{3,0} & m_{3,1} & m_{3,2} & m_{3,3} \end{pmatrix} \bullet \begin{pmatrix} S_{q,0} \\ S_{q,1} \\ S_{q,2} \\ S_{q,3} \end{pmatrix} \\ &= \sum_{j=0}^{3} \sum_{k=0}^{3} a_{q,j} m_{j,k} S_{q,k} \end{aligned} \tag{22}$$

This equation is rewritten as a vector-vector dot product.[16,17] First, the Mueller matrix is flattened into a 16×1 *Mueller vector* $\vec{\mathbf{M}} = (m_{0,0}, m_{0,1}, m_{0,2}, m_{0,3}, m_{1,0}, \ldots, m_{3,3},)^T$. A 16×1 polarimetric measurement vector $\mathbf{W}_q$ for the qth measurement is defined as follows:

$$\begin{aligned}\mathbf{W}_q &= (w_{q,0,0},\ w_{q,0,1},\ w_{q,0,2},\ w_{q,0,3},\ w_{q,1,0}, \ldots\ldots\ w_{q,3,3})^T \\ &= (a_{q,0}\ S_{q,0},\ a_{q,0}\ S_{q,1},\ a_{q,0}\ S_{q,2},\ a_{q,0}\ S_{q,3},\ a_{q,1}\ S_{q,0}, \ldots\ldots, a_{q,3}\ S_{q,3})^T\end{aligned} \tag{23}$$

where $w_{q,j,k} = a_{q,j} s_{q,k}$. The qth measured flux is the dot product

$$P_q = \mathbf{W}_q \bullet \vec{\mathbf{M}} = \begin{pmatrix} a_{q,0}S_{q,0} \\ a_{q,0}S_{q,1} \\ a_{q,0}S_{q,2} \\ a_{q,0}S_{q,3} \\ a_{q,1}S_{q,0} \\ a_{q,1}S_{q,1} \\ \vdots \\ a_{q,3}S_{q,3} \end{pmatrix} \bullet \begin{pmatrix} m_{0,0} \\ m_{0,1} \\ m_{0,2} \\ m_{0,3} \\ m_{1,0} \\ m_{1,1} \\ \vdots \\ m_{3,3} \end{pmatrix} = \begin{pmatrix} w_{q,0,0} \\ w_{q,0,1} \\ w_{q,0,2} \\ w_{q,0,3} \\ w_{q,1,0} \\ w_{q,1,1} \\ \vdots \\ w_{q,3,3} \end{pmatrix} \bullet \begin{pmatrix} m_{0,0} \\ m_{0,1} \\ m_{0,2} \\ m_{0,3} \\ m_{1,0} \\ m_{1,1} \\ \vdots \\ m_{3,3} \end{pmatrix} \tag{24}$$

The full sequence of Q measurements is described by the $Q \times 16$ polarimetric measurement matrix $\mathbf{W}$, where the qth row is $\mathbf{W}_q$. The polarimetric measurement equation relates the measurement vector $\mathbf{P}$ to the sample Mueller vector as

$$\mathbf{P} = \mathbf{W} \bullet \vec{\mathbf{M}} = \begin{pmatrix} P_0 \\ P_1 \\ \vdots \\ P_{Q-1} \end{pmatrix} = \begin{pmatrix} w_{0,0,0} & w_{0,0,1} & \cdots & w_{0,3,3} \\ w_{1,0,0} & w_{1,0,1} & \cdots & w_{1,3,3} \\ \vdots & \vdots & & \vdots \\ w_{Q-1,0,0} & w_{Q-1,0,1} & \cdots & w_{Q-1,3,3} \end{pmatrix} \bullet \begin{pmatrix} m_{0,0} \\ m_{0,1} \\ \vdots \\ m_{3,3} \end{pmatrix} \tag{25}$$

If $\mathbf{W}$ contains 16 linearly independent rows, all 16 elements of the Mueller matrix can be determined. When $Q = 16$, the matrix inverse is unique and the Mueller matrix elements are determined from the polarimetric data-reduction equation

$$\vec{\mathbf{M}} = \mathbf{W}^{-1} \bullet \mathbf{P} \tag{26}$$

Often, $Q > 16$, and $\vec{\mathbf{M}}$ is overdetermined. The optimal (least-squares) polarimetric data-reduction equation for $\vec{\mathbf{M}}$ uses the pseudoinverse $\mathbf{W}_P^{-1}$ of $\mathbf{W}$,

$$\vec{\mathbf{M}} = (\mathbf{W}^T \bullet \mathbf{W})^{-1} \bullet \mathbf{W}^T \bullet \mathbf{P} = \mathbf{W}_P^{-1} \bullet \mathbf{P} \tag{27}$$

The advantages of this procedure are as follows: First, this procedure does not assume that the set of states of polarization state generator and analyzer have any particular form. For example, the polarization elements in the generator and analyzer do not need to be rotated in uniform angular increments, but can comprise an arbitrary sequence. Second, the polarization elements are not assumed to be ideal polarization elements or have any particular imperfections. If the polarization generator and analyzer vectors are determined through a calibration procedure, the effects of nonideal polarization elements are corrected in the data reduction. Third, the procedure readily treats overdetermined measurement sequences (more than 16 measurements for the full Mueller matrix), providing a least-squares solution. Finally, a matrix-vector form of data reduction is readily implemented and easily understood.

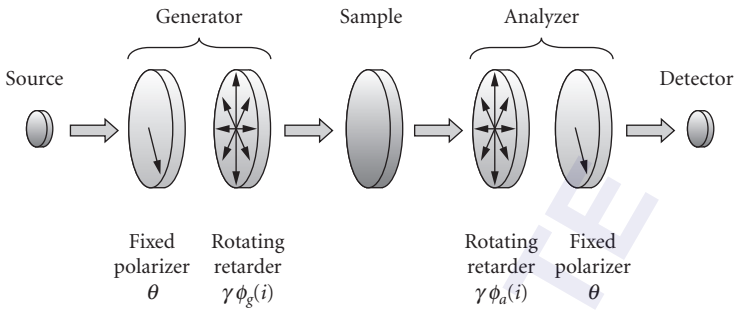

FIGURE 3 The dual rotating retarder polarimeter consists of a source, a fixed linear polarizer, a retarder which rotates in steps, the sample, a second retarder which rotates in steps, a fixed linear polarizer, and the detector. (See also color insert.) (*After Ref. 18.*)

15.23 DUAL ROTATING RETARDER POLARIMETER

The dual rotating retarder Mueller matrix polarimeter shown in Fig. 3[18] is one of the most common Mueller polarimeters. Light from the source passes first through a fixed linear polarizer, then through a rotating linear retarder, the sample, a rotating linear retarder, and finally through a fixed linear polarizer. In the most common configuration, the polarizers are parallel, and the retarders are rotated in angular increments of five-to-one. This five-to-one ratio encodes all 16 Mueller matrix elements onto the amplitudes and phases of 12 distinct frequencies in the detected signal. This configuration was first described by Azzam[16] who provides an explanation of how the ratios one-to-one, two-to-one, three-to-one, and four-to-one all yield incomplete polarimeters. Thus five-to-one is the first integer ratio yielding a complete Mueller matrix polarimeter. The data reduction can be performed using the polarimetric data-reduction matrix method of the preceding section, or alternatively the detected signal can be Fourier analyzed, and the Mueller matrix elements calculated from the Fourier coefficients.[19]

This polarimeter configuration has several design advantages. Since the polarizers do not move, the polarizer in the generator accepts only one polarization state from the source optics, making the measurement immune to source polarization and polarization aberrations from optics prior to the polarizer. If the polarizer did rotate, and if the beam incident on it were elliptically polarized, a systematic modulation of intensity would be introduced which would require compensation in the data reduction. Similarly, the polarizer in the analyzer does not rotate; only one polarization state is transmitted through the analyzing optics and onto the detector. Any diattenuation in the analyzing optics and any polarization sensitivity in the detector will not affect the measurements.

Optimal values for the retardances are near $2\pi/3$ rad ($\lambda/3$ waveplates).[19] If $\delta_1 = \delta_2 = \pi$ rad (half-wave linear retarders), only linear states are generated and analyzed, and the last row and column of the sample Mueller matrix are not measured.

Hauge and Broch[20,21] developed an algorithm to compensate for the linear diattenuation and linear retardance of the retarders. Goldstein and Chipman[22] treat five errors, the retardances of the two retarders, and orientation errors of the two retarders and one of the polarizers, in a small angle approximation good for small errors. Chenault, Pezzaniti, and Chipman[23] extended this method to larger errors.

15.24 INCOMPLETE SAMPLE-MEASURING POLARIMETERS

Incomplete sample-measuring polarimeters do not measure the full Mueller matrix of a sample and thus provide incomplete information regarding the polarization properties of a sample. Often the full Mueller matrix is not needed. For example, many birefringent samples have considerable linear retardance and insignificant amounts of other polarization forms. The magnitude of the retardance

can be measured, assuming all the other polarization effects are small, using much simpler configurations than a Mueller matrix polarimeter, such as the circular polariscope.[5] Similarly, homogeneous and isotropic interfaces, such as dielectrics, metals, and thin films, should only display linear diattenuation and linear retardance aligned with the *s-p* planes. These interfaces do not need characterization of their circular diattenuation and circular retardance. So most ellipsometers characterize the diattenuation and retardance associated with *s* and *p* without providing the full Mueller matrix.[1,6,9]

15.25 NONIDEAL POLARIZATION ELEMENTS

Polarization elements used in polarimetry require a level of characterization beyond what is normally provided by vendors at the time of this writing. For retarders, vendors usually only specify the linear retardance. For polarizers, usually only the two principal transmittances or the extinction ratio is given. For polarization critical applications, this is inadequate. In the following sections, common defects of polarization elements are described. The Mueller calculus is recommended as an appropriate means of describing complex behaviors and shortcomings.

For ideal polarization elements, the polarization properties are readily defined. For real polarization elements, the precise description is more complex. Polarization elements such as polarizers, retarders, and depolarizers have three general polarization properties: diattenuation, retardance, and depolarization; a typical element displays some amount of all three. Diattenuation occurs when the intensity transmittance is a function of the incident polarization state.[24] The diattenuation D is defined in terms of the maximum T_{max} and minimum T_{min} intensity transmittances, as

$$D = \frac{T_{max} - T_{min}}{T_{max} + T_{min}} \tag{28}$$

For an ideal polarizer, $D = 1$. When $D = 0$, all incident polarization states are transmitted with equal attenuation. The quality of a polarizer is often expressed in terms of the related quantity, the extinction ratio E,

$$E = \frac{T_{max}}{T_{min}} = \frac{1 + D}{1 - D} \tag{29}$$

Retardance is the phase difference a device introduces between its eigenpolarizations (eigenstates). For a birefringent retarder with refractive indices n_1 and n_2 and thickness t, the retardance δ expressed in radians is

$$\delta = \frac{2\pi |n_1 - n_2| t}{\lambda} \tag{30}$$

Depolarization describes the coupling by a device of incident polarized light into depolarized light in the exiting beam. Depolarization occurs when light transmits through milk or scatters from clouds. Multimode optical fibers generally depolarize the light. Depolarization is intrinsically associated with scattering and a loss of coherence of the polarization state. A small amount of depolarization is associated with the scattered light from all optical components. The depolarization varies as a function of the incident polarization state.[25]

15.26 ELLIPTICAL AND CIRCULAR POLARIZERS AND ANALYZERS

There are few good and convenient circularly or elliptically polarizing mechanisms, whereas linear polarizers are simple, inexpensive, and of high quality. Therefore, most circular and elliptical polarizers incorporate linear polarizers to perform the polarizing, and retarders to convert between

polarization states. For such compound devices, the distinction between a polarizer and an analyzer is significant. This is illustrated by three examples: (1) a left circular polarizer (and horizontal linear analyzer) constructed from a horizontal linear polarizer **LP**(0°) followed by a quarter-wave linear retarder with the fast axis oriented at 135°, **QWLR**(135°) Eq. (31), (2) a left circular analyzer (and horizontal linear polarizer) constructed from a **QWLR**(45°) followed by a horizontal linear polarizer **LP**(0°) Eq. (32), and (3) a homogeneous left circular polarizer (and left circular analyzer) constructed from a **QWLR**(135°), then an **LP**(0°), followed by a **QWLR**(45°) Eq. (33). The three Mueller matrix equations and the exiting polarization states for arbitrary incident states are as follows:

$$\begin{aligned}\mathbf{QWLR}(135°)\bullet\mathbf{LP}(0°)\bullet\mathbf{S}&=\begin{pmatrix}1&0&0&0\\0&0&0&1\\0&0&1&0\\0&-1&0&0\end{pmatrix}\bullet\frac{1}{2}\begin{pmatrix}1&1&0&0\\1&1&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\bullet\begin{pmatrix}S_0\\S_1\\S_2\\S_3\end{pmatrix}\\&=\frac{1}{2}\begin{pmatrix}1&1&0&0\\0&0&0&0\\0&0&0&0\\-1&-1&0&0\end{pmatrix}\bullet\begin{pmatrix}S_0\\S_1\\S_2\\S_3\end{pmatrix}=\frac{1}{2}\begin{pmatrix}S_0+S_1\\0\\0\\-S_0-S_1\end{pmatrix}\end{aligned}\tag{31}$$

$$\begin{aligned}\mathbf{LP}(0°)\bullet\mathbf{QWLR}(45°)\bullet\mathbf{S}&=\frac{1}{2}\begin{pmatrix}1&1&0&0\\1&1&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\bullet\begin{pmatrix}1&0&0&0\\0&0&0&-1\\0&0&1&0\\0&1&0&0\end{pmatrix}\bullet\begin{pmatrix}S_0\\S_1\\S_2\\S_3\end{pmatrix}\\&=\frac{1}{2}\begin{pmatrix}1&0&0&-1\\1&0&0&-1\\0&0&0&0\\0&0&0&0\end{pmatrix}\bullet\begin{pmatrix}S_0\\S_1\\S_2\\S_3\end{pmatrix}=\frac{1}{2}\begin{pmatrix}S_0-S_3\\S_0-S_3\\0\\0\end{pmatrix}\end{aligned}\tag{32}$$

$$\begin{aligned}&\mathbf{QWLR}(135°)\bullet\mathbf{LP}(0°)\bullet\mathbf{QWLR}(45°)\bullet\mathbf{S}\\&=\begin{pmatrix}1&0&0&0\\0&0&0&1\\0&0&1&0\\0&-1&0&0\end{pmatrix}\frac{1}{2}\begin{pmatrix}1&1&0&0\\1&1&0&0\\0&0&0&0\\0&0&0&0\end{pmatrix}\frac{1}{2}\begin{pmatrix}1&0&0&0\\0&0&0&-1\\0&0&1&0\\0&1&0&0\end{pmatrix}\begin{pmatrix}S_0\\S_1\\S_2\\S_3\end{pmatrix}\\&=\frac{1}{2}\begin{pmatrix}1&0&0&-1\\0&0&0&0\\0&0&0&0\\-1&0&0&1\end{pmatrix}\bullet\begin{pmatrix}S_0\\S_1\\S_2\\S_3\end{pmatrix}=\frac{1}{2}\begin{pmatrix}S_0-S_3\\0\\0\\-S_0+S_3\end{pmatrix}\end{aligned}\tag{33}$$

The device in Eq. (31) transmits only left circularly polarized light, because the S_0 and S_3 have equal magnitude and opposite sign; thus it is a left circular polarizer. However, the transmitted flux $(S_0 + S_1)/2$ is the flux of horizontal linearly polarized light in the incident beam, making it a horizontal linear analyzer.

Similarly, the transmitted flux in Eq. (32), $(S_0 - S_3)/2$, is the flux of incident left circularly polarized light, making this combination a left circular analyzer. The final polarizer makes the Eq. (32) device a horizontal linear polarizer, although this is not the standard Mueller matrix for horizontal linear polarizers found in tables. Thus an analyzer for a state does not necessarily transmit that state;

its transmitted flux is proportional to the amount of the analyzed state in the incident beam. The examples in Eqs. (31) and (32) are inhomogeneous polarization elements because the eigenpolarizations are not orthogonal. Equation (31) has left circular and vertically polarized eigenpolarizations. Equation (32) has horizontal and right circularly polarized eigenpolarizations. The characteristics of both devices are different for propagation in opposite directions.

The Eq. (33) device is both a left circular polarizer and a left circular analyzer; it has the same characteristics for propagation in opposite directions. The eigenpolarizations are orthogonal, left and right circularly polarized, so this device is a homogeneous left circular polarizer. This is the left circular polarizer Mueller matrix commonly found in tables; however, it is not the most common implementation.

15.27 COMMON DEFECTS OF POLARIZATION ELEMENTS

Here we list some common defects found in real polarization elements.

1. Polarizers have nonideal diattenuation since $T_{\min} > 0$ and also nonideal transmission since $T_{\max} < 1$.[2,25,26]
2. Retarders have the incorrect retardance. Thus, there will be some deviation from a quarter-wave or a half-wave of retardance, for example, because of fabrication errors or a change in wavelength or temperature.
3. Retarders usually have some diattenuation. This may occur due to differences in the absorption coefficients (dichroism). Birefringent retarders have diattenuation due to the difference of the Fresnel coefficients at normal incidence for the two eigenpolarizations since $n_1 \neq n_2$. This can be reduced by antireflection coatings.
4. Polarizers usually have some retardance; there is an optical path length difference between the transmitted (principal) eigenpolarization and the small amount leaked of the secondary eigenpolarization. For example, sheet polarizers and wire-grid polarizers show substantial retardance when the secondary state is not completely extinguished.
5. The polarization properties vary with angle of incidence; for example, Glan-Thompson polarizers polarize over only a 4° field of view.[2] Birefringent retarders commonly show a quadratic variation of retardance with angle of incidence; the retardance increases along one axis and decreases along the orthogonal axis.[27,28] For polarizing beam-splitter cubes, the axis of the transmitted linear polarization rotates when the light is incident from outside of the normal plane (the plane of the face normals and the beam-splitting interface normal).
6. The polarization properties vary with wavelength; for simple retarders made from a single birefringent plate, the retardance varies approximately as 1/wavelength. Other components have more complex dependence.
7. For polarizers, the *analyzed state* and the *transmitted state* can be different. Consider a polarizing device formed from a linear polarizer oriented at 0° followed by a linear polarizer oriented at 2°. Incident light linearly polarized at 0° has the highest transmittance for all possible polarization states and is the analyzed state. The exiting beam is linearly polarized at 2°, the only state exiting the device. The transmitted state is an eigenpolarization; the analyzed state isn't. This *rotation* between the analyzed and transmitted states of a polarizer frequently occurs, for example, when the crystal axes of a birefringent polarizing prism assembly, such as a Glan-Thompson polarizer, are misaligned.
8. A nominally "linear" element may be slightly elliptical (have elliptical eigenpolarizations). For example, a crystal quartz linear retarder waveplate with the optical crystal axis not quite parallel with the surface becomes an elliptical retarder due to quartz's optical activity. A compound waveplate with two or more birefringent crystals whose fast axes are not exactly 0° or 90°

apart is a retarder with slightly elliptical eigeonplarizations. Similarly a circular element may be slightly elliptical. For example, an inhomogeneous circular polarizer formed from a linear polarizer followed by a quarter-wave linear retarder at 45° [see Eq. (31)] becomes an elliptical polarizer as the retarder's fast axis is rotated or as the retardance changes with wavelength.

9. The eigenpolarizations of a polarization element may not be orthogonal; that is, a polarizer may transmit linearly polarized light at 0° without change of polarization while extinguishing linearly polarized light oriented at 88°. Such a polarization element is referred to as *inhomogeneous*.[3,29] Sequences of polarization elements, such as optical isolator assemblies, often are inhomogeneous. The circular polarizer in Eq. (31) is inhomogeneous.
10. A polarization element may depolarize, coupling polarized light into an unpolarized component. A polarizer or retarder with a small amount of depolarization, when illuminated by a completely polarized beam, will have a small amount of unpolarized light in the transmitted beam. Such a transmitted beam can no longer be extinguished by an ideal polarizer. Depolarization results from fabrication errors such as surface roughness, bulk scattering, random strains and dislocations, and thin-film microstructure. Pinholes in a polarizer allow unpolarized light into the transmitted beam.
11. Multiply reflected beams and other "secondary" beams may be present with undesired polarization properties. For example, the multiply reflected beams inside a birefringent waveplate have various retardances. Antireflection coatings will reduce this effect in one waveband, but may increase these problems with multiple reflections in other wavebands.

The preceding list is by no means comprehensive but should serve as a warning to those with demanding polarization element applications. In particular, the performance of polarizing beamsplitting cubes and of liquid crystal cells have been found to be far from ideal.[30]

15.28 POLARIZATION MODULATORS, RETARDANCE MODULATORS

Time-sequential polarimeters require rapid variation of the polarization state in a controlled manner. This section reviews the principal polarization modulation technologies. Several varieties of retardance modulators are in widespread use. The only common diattenuation modulator is the spinning polarizer.

Variable retarders generally have either a fixed retardance with variable axis (i.e., motor driven rotating waveplate), or a variable retardance with a fixed axis (i.e., liquid crystal retarder, electrooptical modulator, or photoelastic modulator).

In a retardance modulator, at least one of the two (often degenerate or equal) modes' refractive indices change. If polarized light is launched into the mode with varying refractive index, a phase modulator results. For polarization modulation, the incident state must be in a combination of the modes, usually equally distributed between the two modes. An amplitude (intensity) modulator is produced by placing an additional polarizer after a polarization modulator, oriented between the two modes.

15.29 ROTATING RETARDERS

Retarders with fast axes rotated by rotary stages are the gold standard for accurate polarimetry. Crystal and polymer retarders are fabricated to high accuracy and uniformity. Rotary stages can locate the fast axis angle to one arc second or better. Alternatively retarders can be continuously rotated, usually using DC brushless motors, with high uniformity and repeatability. Smith[19] discusses the optimization of rotating retarder Mueller matrix polarimeters.

The disadvantages of rotating retarders are the size of the motors, their cost, and the relatively low rotation speeds (less than 1000 revolutions per second).

15.30 PHOTO-ELASTIC MODULATORS

Photo-elastic modulators (PEMs) use oscillating stress birefringence in a resonant crystal driven by a sound wave. An isotropic optical material such as glass becomes birefringent when compressed along one axis.[31,32] This is stress-induced birefringence, or the photoelastic effect. A variable retarder can be constructed by compressing glass, but a large amount of power is needed to slowly modulate stress-induced birefringence. PEMs use a mechanically resonant bar with a high mechanical quality factor Q of 10^3 to 10^4. A piezoelectric transducer (PZT) is coupled to the glass or fused silica bar, and a standing sound wave that oscillates at the bar's fundamental frequency is induced, causing a rapid sinusoidal modulation of the birefringence. This reduces power requirement for a quarter wave or half wave of retardance to less than 0.5 W.[33] The positive and negative parts of the sine correspond to retardance fast axes 90° apart.

PEMs have been in use for over 25 years as a method of polarization modulation in a variety of research and industrial applications. The principal supplier of PEMs is Hinds Instruments (Hillsboro, Oregon). The benefits of PEMs include low operating voltages, large apertures, and wide angular acceptance.[34,35] Because PEMs are constructed from glass, fused silica, and other transparent materials, transmittance over a wide spectral range is straightforward. Polarimetric sensitivities (i.e., precision) of about 3 parts in 10^6 have been obtained for solar astronomy applications.[36,37,38]

A single PEM oscillating between 0° and 90° fast axes in front of a polarizer can measure S_0, S_2, and S_3, but not S_1. Complete Stokes vector measurement requires two PEMs, optimally 45° apart. Complete Mueller matrix measurement requires two PEMs in the generator with axes nominally 45° apart and two PEMs in the analyzer nominally 45° apart. Another common configuration measures S_0, S_1, and S_2 but not S_3 by placing a PEM between two quarter-wave linear retarders whose axes are at ±45° to the PEM axis. When linearly polarized light is incident, linearly polarized light exits with a rapidly modulated orientation. This retarder/PEM/retarder assembly operates as a circular retardance modulator.

Typical PEM frequencies are in the tens of kHz for glass elements several centimeters in size. Smaller elements have higher frequencies and larger elements lower frequencies. The instantaneous retardance is spatially nonuniform, varying as a half period cosine across the aperture, thus varying quadratically about the center of the aperture.

PEMs which modulate at frequencies suitable for interfacing with cameras are impracticably large, so PEMs are used almost exclusively with single channel detectors acquiring hundreds of thousands of measurements per second.

Because of the PEM's high Q and extremely stable frequency operation, they excel at the measurement of low birefringence in glass, such as for glass for liquid crystal (LC) cells.[39,40,41]

15.31 LIQUID CRYSTAL RETARDERS

Two types of liquid crystal cells for polarization modulation are in widespread use: untwisted nematic cells and ferroelectric cells.

Untwisted nematic liquid crystal cells, Fredericksz cells, are available as polarization modulators. These liquid crystal variable retarders (LCVRs) are electrically tunable waveplates with retardance in the range of zero to several waves. The Fredericksz cell configuration is different from the twisted nematic configuration typically used in liquid crystal displays. There are four components (Fig. 4): two glass plates which form a cavity, indium tin oxide transparent electrodes coating on the outside of the plates, a polyimide layer on the inside of each plate which acts to align the liquid crystal molecules parallel to the plates, and a high birefringence liquid crystal material sandwiched between the plates. When no voltage is applied, the liquid crystal molecules' directions are aligned in one direction parallel to the plates and the retardance is at a maximum. When a voltage differential is applied between the plates, an electric field is induced which supplies a torque to the liquid crystal molecules, increasing the angle of the molecules with respect to the plates; the retardance is decreased, as shown in Fig. 5. When the majority of the molecules are nearly perpendicular to the

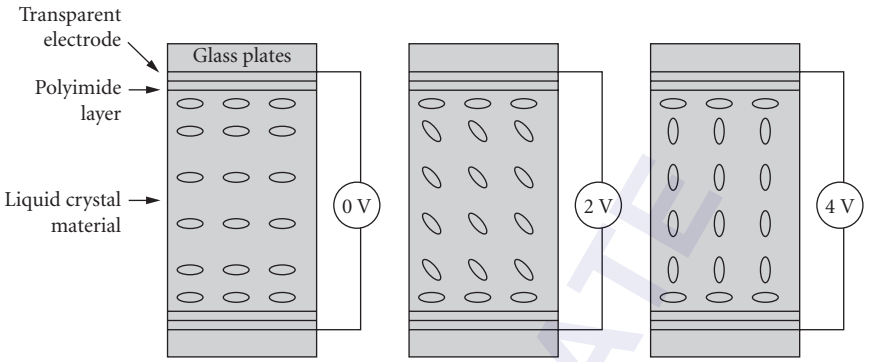

FIGURE 4 Liquid crystal cell composition and liquid crystal orientation as a function of applied voltage, varying from maximum retardance (left) to minimum (right).

plates, retardance is at a minimum. The molecules near the plates are unable to fully rotate, and so the retardance doesn't quite get to zero.

If a DC electric field is applied continuously, impurity ions in the liquid crystal material migrate toward the plates and may damage the liquid crystal structure. Once at the plates, the ions create a permanent electric field which reduces the dynamic range of the device. To avoid this problem an alternating square wave voltage at approximately 1 kHz is applied.

Retardance is a nonlinear function of applied voltage, and the relationship is highly variable from device to device, so that individual calibration of each device is required. Although optical quality and surface figure are generally very good, spatial uniformity is often poor due to the difficulty of obtaining an even distribution of the liquid crystal material between the plates. Transmission of LC

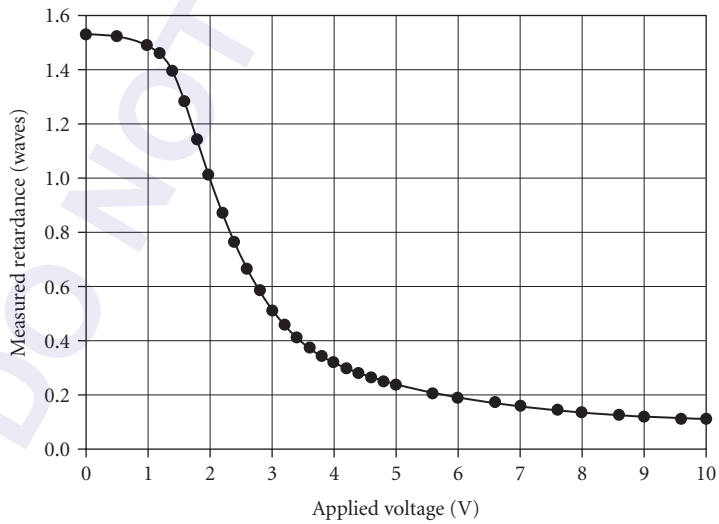

FIGURE 5 Typical retardance vs. voltage curve for a liquid crystal variable retarder.

cells without polarizers is fairly high (typically 80 to 90 percent), but can vary with applied voltage. Temperature dependence is typically 0.5 percent per °C, a significant issue. The variation of retardance with angle of incidence is large, typically 2° to 4° of retardance per degree angle of incidence! Also the liquid crystal material scatters, causing some depolarization.

Switching time in LCVRs is highly variable, depending on cell thickness, liquid crystal viscosity, temperature, and applied voltage. Switching time is asymmetric: when voltage and thus electric field is increased, the torque applied to the molecules determines the response time, but when voltage is decreased a slower mechanical restoring force bringing the molecules to equilibrium determines response time. LCVR switching time is measured by placing the LC cell between two polarizers with its axis at 45°, sending light through the assembly onto a photodiode, then modulating the cell from low to high voltage amplitude with a sinusoidal or square wave. The detected signal is observed with an oscilloscope while sweeping the signal frequency. The onset of hysteresis indicates the switching time. LCVR switching times are typically on the order of 5 to 100 ms. Vendor specifications are often misleading and should be independently tested.

LCVRs exhibit significant nonuniformity in polarization parameters across the clear aperture, with 5 percent typical. Retardance variation has many causes: cell thickness variations, temperature nonuniformity, variation of surface charge on the electrodes, and nonuniform squeezing when charge is applied. The depolarization index is usually significant, typically between 1 and 10 percent. Depolarization has several causes: bulk scattering, the glass spacer balls, and a small high-frequency oscillation of the LC molecules in response to the kHz square wave drive voltage. The large variation in uniformity and depolarization index observed among individual lots of LCVRs results from the handmade quality of most cells (Refs. 42 and 43, Chap. 7).

Fredericksz cells are small and inexpensive relative to the other retardance modulators: rotating retarders, electro-optical modulators, PEMs, and magneto-optical modulators. Thus LCVRs appear to be the ideal modulators for most applications. But they have many difficult and nonideal characteristics. Thus they are relegated to mainly qualitative applications, such as intensity modulation or low-accuracy polarization state control. It is likely that more polarimeter development projects based on LC cells have failed, than those using any other polarization modulation technology. Significant time and resources are necessary to develop accurate LC-based polarimetry.

15.32 ELECTRO-OPTICAL MODULATORS

Electro-optic modulators use the electric field across the modulating material to induce retardance. The two principal mechanisms are the Pockels effect and the Kerr effect. The electric field is generally produced by placing the crystal within a capacitor. The electro-optic effects are relatively weak so the modulator crystal aperture is generally small, the path length long, and the associated voltages large, hundreds or thousands of volts. Modulation speeds can be very high, in the hundreds of megahertz, or when operating in waveguides, modulation can be produced in the tens of gigahertz. Lithium niobate, potassium dihydrogen phosphate (KDP), and ammonium dihydrogen phosphate (ADP) are common electro-optic modulator materials.

15.33 MAGNETO-OPTICAL MODULATORS

Circular retardance modulators using the magneto-optical effect are produced by placing a high Verdet coefficient material, such as yttrium iron garnet, in a solenoid and varying the magnetic field. Large apertures are easily achieved. High currents are required and switching times are fairly slow.

Magneto-optic materials are primarily used in Faraday isolators, which allow light to pass in one direction and block the counter-propagating light. The corresponding magneto-optical modulators have not been widely commercialized.

15.34 FIBER SQUEEZERS

For fiber optic polarimetry, fiber squeezers are a fast, economical, widely deployed retardance modulator.[44,45] When a fiber is squeezed mechanically, retardance is introduced both because the core becomes elliptical and due to the stress-optic effect. Retardance is linearly proportional to the force applied. Piezoelectric transducers can modulate fiber squeezer polarization at rates up to 30 KHz with low insertion loss.

The polarization state through long fibers, such as fiber communication links between cities, tends to drift as a function of time, quickly if the fibers are moved. One important application of fiber squeezers is to maintain the exiting polarization in a fixed state.

General Photonics (Chino, California) is a leading supplier of fiber squeezers and associated polarimeters, polarization mode dispersion controllers, depolarizers, and other fiber squeezer-based devices.

15.35 POLARIMETER DESIGN METRICS

Several methods have been developed for evaluating the suitability of a polarimeter configuration for Stokes or Mueller matrix measurement. Such methods are needed to select the sets of generators and analyzer states, determine optimum values for retarders and rotation angles, and obtain a deeper understanding of how the polarization parameters will be measured by a particular polarimeter. The following development closely follows Twietmeyer[43] and Twietmeyer and Chipman.[46]

The rank and null space of the polarimetric measurement matrix **W** identifies a polarimeter as complete or incomplete. The rank of **W** should be four for a complete Stokes polarimeter and 16 for a complete Mueller matrix polarimeter. Any polarization state which lies partially or wholly in the null space of **W** cannot be measured. A complete polarimeter has no null space. When **M** has components in the null space, the data reduction returns a nearby reconstruction in the range of **W**.

Each row of **W** forms one basis vector in the reconstruction of **M**, that is, the measured intensity at each polarimeter state is the projection of **M** onto the corresponding basis vector. For an effective reconstruction, there should be minimum correlation between basis vectors; they should be linearly independent, widely distributed, and well balanced in magnitude. For an overspecified system with $Q > 16$, the basis vectors provide redundant coverage of the polarization space, improving performance in the presence of noise. Basis states may be chosen to lie more densely in directions where most information about **M** is desired. For example, polarimeters to measure stress birefringence are most interested in linear retardance, so the basis states can be selected to improve the signal to noise on those parameters at the expense of diattenuation and depolarization accuracy.

For a general purpose polarimeter which measures a wide variety of arbitrary **M**, the polarimetric measurement matrix should be as far from singular as possible; it should be *well conditioned*. Various linear algebra metrics quantify this distance from singular. The most widely used is κ_p, the condition number based on the L_p norm of the matrix **W**, defined as[47]

$$\kappa_p(\mathbf{W}) = \left\|\mathbf{W}\right\|_p \left\|\mathbf{W}^{-1}\right\|_p \tag{34}$$

where the bars signify the p-norm

$$\left\|\mathbf{W}\right\|_p = \sup_{x \in D(W)} \frac{\left\|\mathbf{W}\bullet\mathbf{x}\right\|_p}{\left\|\mathbf{x}\right\|_p} \text{(matrix } p\text{-norm)} \qquad \left(\left\|\mathbf{x}\right\|_p\right)^p = \sum_i x_i^p \text{(vector } p\text{-norm)} \tag{35}$$

and where **x** is a vector, $D(\mathbf{W})$ is the domain of **W**, and sup is the supremum (limiting maximum value). Minimization of the condition number of **W** is a standard optimization method for polarimeters.

Four different condition number definitions are in general use: the L_1 condition number ($p = 1$) based on the maximum absolute column sum; the L_∞ condition number ($p = \infty$) based on the maximum absolute row sum; the L_2 condition number ($p = 2$) based on the euclidean length of the rows of **W**; and the frobenius norm (applicable where **W** is square and invertible) based on the determinant of **W**. Though the various condition numbers differ for a given matrix, they are similarly bounded,[47] and so provide equivalent utility. In polarimetry the L_2 condition number is preferred. The range of the L_2 condition number varies from 1 (perfect conditioning, the identity matrix) to infinity (singular matrices).

Further insight into the conditioning of **W** is obtained from its singular value decomposition (SVD) which was introduced to polarimeter design by Tyo[48] and Sabatke et al.[49] The SVD factors any $N \times K$ matrix **W** as

$$\mathbf{W} = \mathbf{U} \bullet \mathbf{D} \bullet \mathbf{V}^T = \mathbf{U} \bullet \begin{pmatrix} \mu_1 & & & & \\ & \mu_2 & & & \\ & & \ddots & & \\ & & & \mu_{K-1} & \\ & & & & \mu_K \\ 0 & 0 & \cdots & 0 & 0 \\ & & \vdots & & \end{pmatrix} \bullet \mathbf{V}^T \tag{36}$$

where **U** and **V** are $N \times N$ and $K \times K$ unitary matrices, and **D** is an $N \times K$ diagonal matrix. The diagonal elements μ_k are the singular values. The rank of **W** is the number of nonzero singular values. Those columns of **U** associated with nonzero singular values form an orthonormal basis for the range of **W**; those columns of **V** associated with zero-valued singular values form an orthonormal basis for the null space of **W**. The columns of **V** associated with nonzero singular values form an orthonormal basis which spans the full vector space of **W** and thus reconstructs $\vec{\mathbf{M}}$. Each singular value gives the relative strength of the corresponding vector in this basis set, and the columns of **U** form a mapping from the **V** basis set back to the original basis set of **W**. Further, since

$$\mathbf{P} = \mathbf{W} \bullet \mathbf{M} = \mathbf{U} \bullet \begin{pmatrix} u_1 & 0 & 0 & 0 \\ 0 & u_2 & 0 & 0 \\ & & \ddots & \\ 0 & 0 & 0 & u_{16} \\ & & \vdots & \end{pmatrix} \bullet \mathbf{V}^T \bullet \vec{\mathbf{M}} \tag{37}$$

the rows of **U** corresponding to zero-valued singular values describe sets of flux measurements which are not generated by any Mueller matrix, so their presence in a polarimetric measurement can only be due to noise. Based on this interpretation, any basis vector in **V** which is associated with a relatively small singular value is near the null space and likely has little information content; such small singular values predominantly amplify noise into the reconstruction of **M**. Error sources which produce projections (flux vectors) which are similar to the flux vectors generated by the basis vectors in **V** (particularly those which correspond to large singular values) will couple strongly into the reconstruction of **M**. The L_2 condition number is equal to the ratio of the largest to smallest singular values,[50] and thus minimizing the condition number is equivalent to equalizing, to the extent possible, the range of singular values so that the basis vectors have wide distribution and similar weight.

For a four measurement Stokes polarimeter, the Stokes vectors representing each of the four analyzer states, when plotted on the Poincaré sphere, define a tetrahedron which is generally irregular. The volume of the tetrahedron is proportional to the determinant of **W**, and is maximized when the vertices form a regular tetrahedron. In this case the maximum distance from a vertex to any point on the sphere is minimized, and the condition number is also at a minimum.

15.36 SINGULAR VALUE DECOMPOSITION EXAMPLES

Two examples of the application of the condition number to Mueller matrix polarimeters follow: the first is an example of an optimum polarimeter, the second is nearly singular. Consider a Mueller matrix polarimeter which uses four generator states $\mathbf{V}_1$, $\mathbf{V}_2$, $\mathbf{V}_3$, $\mathbf{V}_4$, located at the vertices of a regular tetrahedron on the Poincaré sphere, with associated Stokes vectors

$$\mathbf{V}_1 = \{1, 1, 0, 0\} \quad \mathbf{V}_2 = \left\{1, -\frac{1}{3}, \frac{2\sqrt{2}}{3}, 0\right\} \quad \mathbf{V}_3 = \left\{1, -\frac{1}{3}, \frac{-\sqrt{2}}{3}, \sqrt{\frac{2}{3}}\right\} \quad \mathbf{V}_4 = \left\{1, -\frac{1}{3}, -\frac{\sqrt{2}}{3}, -\sqrt{\frac{2}{3}}\right\} \tag{38}$$

The analyzer states are also chosen as $\mathbf{V}_1$, $\mathbf{V}_2$, $\mathbf{V}_3$, $\mathbf{V}_4$. Sixteen measurements are acquired at each of the combinations of generator and analyzer. This polarimeter is one member of the set of 16-measurement Mueller matrix polarimeters with minimum condition number, so it can be considered an optimum configuration. The corresponding 16 singular values are

$$\left\{4, \frac{4\sqrt{3}}{3}, \frac{4\sqrt{3}}{3}, \frac{4\sqrt{3}}{3}, \frac{4\sqrt{3}}{3}, \frac{4\sqrt{3}}{3}, \frac{4\sqrt{3}}{3}, \frac{4}{3}, \frac{4}{3}, \frac{4}{3}, \frac{4}{3}, \frac{4}{3}, \frac{4}{3}, \frac{4}{3}, \frac{4}{3}, \frac{4}{3}\right\} \tag{39}$$

and the condition number, equal to the quotient of the first and last singular values, is 3. Each of the 16 columns of **U** represents a different orthogonal component used to reconstruct a measured Mueller matrix. In the presence of white noise, the Mueller matrix component corresponding to the first column will be measured with the highest signal to noise, about $\sqrt{3}$ times better than the next six components (columns) from **U**, and about three times better than the last nine Mueller matrix components.

As an example of a polarimeter with a nearly singular polarimetric measurement matrix, the second row of **W**, (generate $\mathbf{V}_1$, analyze $\mathbf{V}_2$),

$$\{1.0, -0.333, 0.943, 0, 1.0, -0.333, 0.943, 0, 0, 0, 0, 0, 0, 0, 0, 0\} \tag{40}$$

will be replaced with a vector

$$\{1, 1.0, 0.0005, 0, 1.0, 1.0, 0.0005, 0, 0, 0, 0, 0, 0, 0, 0, 0\} \tag{41}$$

nearly equal to the first row of **W**,

$$\{1, 1, 0, 0, 1, 1, 0, 0, 0, 0, 0, 0, 0, 0, \mathbf{0}, 0\} \tag{42}$$

so that these two rows are nearly linearly dependent. Examining the resulting singular values,

$$\begin{aligned}\{&4.0557, 2.7273, 2.3094, 2.3094, 2.3094, 2.3094, 2.0221, 1.4988, 1.3333,\\ &1.3333, 1.3333, 1.3333, 1.3333, 1.3333, 1.3333, 0.0004\}\end{aligned} \tag{43}$$

the last singular value is close to zero and the condition number is about 10,000. Whenever the measured flux contains the pattern corresponding to the last row of $\mathbf{V}^T$, this component will be amplified by about 10,000 during the data reduction relative to the other 15 components of the Mueller

matrix and will usually dominate the measurement. In the presence of random noise, the measured Mueller matrix will be close to the 16th column of **U** (partitioned into a 4×4 "Mueller matrix"), and so the measurement will be inaccurate.

In summary, components corresponding to very small singular values are greatly amplified in the matrix inverse and can overwhelm the remainder of the Mueller matrix in the polarimetric data reduction.

15.37 POLARIMETER ERROR ANALYSIS

When operating a polarimeter, **W** is not known exactly and may have changed since calibration. For example, a rotating retarder may have inconsistent orientation, rays may take different paths through the polarimeter for different samples, or the spectral distribution of the measured light may vary. Measurement error is present due to detector noise and source fluctuation. Eqs. (18) and (27) may be modified to include these effects as follows:

$$(\mathbf{W}+\delta\mathbf{W})\bullet\mathbf{M}+\delta\mathbf{P}=\mathbf{P}_M \tag{44}$$

where $\delta\mathbf{W}$ is an $N \times 16$ matrix representing the difference between the actual and calibrated **W**, $\delta\mathbf{P}$ is an $N \times 1$ vector representing intensity measurement error, and $\mathbf{P}_M$ is the $N \times 1$ vector of fluxes measured in the presence of error. $\mathbf{M}_R$, the polarimeter's estimate of **M**, is then calculated using the calibration data as

$$\begin{aligned}\mathbf{M}_R &= \mathbf{W}_p^{-1}\bullet\mathbf{P}_M \\ &= \mathbf{W}_p^{-1}\bullet((\mathbf{W}+\delta\mathbf{W})\bullet\mathbf{M}+\delta\mathbf{P}) \\ &= \mathbf{M}+\delta\mathbf{M}=\mathbf{M}+\mathbf{W}_p^{-1}\bullet(\delta\mathbf{W}\bullet\mathbf{M}+\delta\mathbf{P})\end{aligned} \tag{45}$$

where $\delta\mathbf{M}$ is the difference between the measured $\mathbf{M}_R$ and the actual **M**. There are two error terms in $\delta\mathbf{M}$, one dependent on $\delta\mathbf{W}$ and **M**, and the other on $\delta\mathbf{P}$.

Small errors may be described by a first-order Taylor expansion. The error for the *j*th component of the *i*th polarimeter state, having *R* variables x_r which may be subject to error (such as a retardance magnitude), each with nominal value ϕ_r, and error magnitude δ_r, is

$$\delta\mathbf{W}_{i,j} \approx \sum_{r=1}^{R} \delta_{r,i,j} \left.\frac{\partial\mathbf{W}_{i,j}}{\partial x_r}\right|_{x_r=\phi_r} \tag{46}$$

The error in the fluxes **P** is assumed independent of the polarimeter elements, and is given by

$$\delta\mathbf{P}_i = \varepsilon_i \tag{47}$$

where ε_i is the error in the *i*th intensity measurement. The error in reconstructing each of the $k = 1,\ldots,16$ elements of **M** in terms of the errors in the instrument and detection process is then

$$\delta\mathbf{M}_k = \sum_{i=1}^{N} \mathbf{W}_{k,i}^{-1} \bullet \left[\sum_{j=1}^{16} \sum_{r=1}^{R} \delta_{r,i,j} \left.\frac{\partial\mathbf{W}_{i,j}}{\partial x_r}\right|_{x_r=\phi_r} \bullet \mathbf{M}_j \right] + \sum_{i=1}^{N} \mathbf{W}_{k,i}^{-1} \varepsilon_i \qquad k=1,\ldots,16 \tag{48}$$

The mean (expectation) and standard deviation (SD) of the error [$<\delta\mathbf{M}>$ and SD($\delta\mathbf{M}$)] may be estimated when the polarimeter state variables and the statistics of the error sources are approximately known.

The error due to a known systematic (nonzero mean error) source may be compensated by estimating $\delta\mathbf{W}$ (e.g., using ideal Mueller matrices to model the polarimeter) and then forming a new polarimetric measurement matrix $\mathbf{W}_q = \mathbf{W} + <\delta\mathbf{W}>$. For example, when using a liquid crystal retarder with a known profile of retardance magnitude as a function of temperature, a new $\mathbf{W}_q$ may be recalculated at every use given the ambient temperature.

A covariance matrix can optimize a polarimeter in the presence of known error. This method has been applied to random measurement noise in Stokes polarimetry by Sabatke et al.[49] and Twietmeyer,[46] and to random instrument noise in Stokes polarimetry by Tyo.[48] The covariance matrix is a symmetric matrix which describes the correlation between random variables which have been centered about their means. For Mueller matrix polarimetry, the elements of the 16×16 covariance matrix, $\mathbf{C}_\mathbf{M}$, are

$$\mathbf{C}_{\mathbf{M},j,k} = \langle \delta M_j \, \delta M_k \rangle - \langle \delta M_j \rangle \langle \delta M_k \rangle \qquad j, k = 1,\ldots,16 \tag{49}$$

One useful error metric (EM) is the sum of the diagonal elements,

$$\mathrm{EM} = \sum_i \mathbf{C}_{\mathbf{M},ii} \tag{50}$$

EM is a function of the polarimeter configuration, the number of states, the Mueller matrix of the sample, and the statistical properties of the error sources. Minimization of EM with respect to a polarimeter variable may be used to compute the variable's optimal value in the presence of known error.

15.38 THE MUELLER MATRIX FOR POLARIZATION COMPONENT CHARACTERIZATION

The Mueller matrix provides detailed characterization of a polarization element.[3,9] Using Mueller matrix functions, all of the previous performance defects and more can be specified. Thus, when using polarization elements in critical applications such as polarimetry, knowledge of its Mueller matrix is desirable. This is analogous to having the interferogram of a lens to ensure that it is of suitable quality for incorporation into a critical imaging system.

15.39 RETRO-REFLECTION TESTING AND CORRECTION FOR SUPPLEMENTAL OPTICS

Some reflective optical components are tested near normal incidence, such as corner cube retro reflectors, liquid crystal on silicon panels (LCOS), and other reflective spatial light modulators. Retro-reflection testing requires the insertion of a low polarization, ideally nonpolarizing, beam splitter in front of the sample, as shown in Fig. 6. The polarimeter measures the Mueller matrix of everything between the generator and the analyzer. This is the *polarization critical region*, where any significant polarization from beam splitters, mirrors, lenses, and the like, needs to be characterized and accounted for in data reduction.

In Fig. 6, a portion of the beam from the polarization state generator reflects from a nonpolarizing beam splitter and is normally incident on the sample; the remainder is removed in a beam dump. The light reflected from the sample divides at the beam splitter and the transmitted portion continues through the polarization analyzer to the focal plane. The focal plane acquires a series of raw images of the sample, and from the set of raw images the Mueller matrix image of all the optics in the polarization critical region is calculated pixel by pixel.

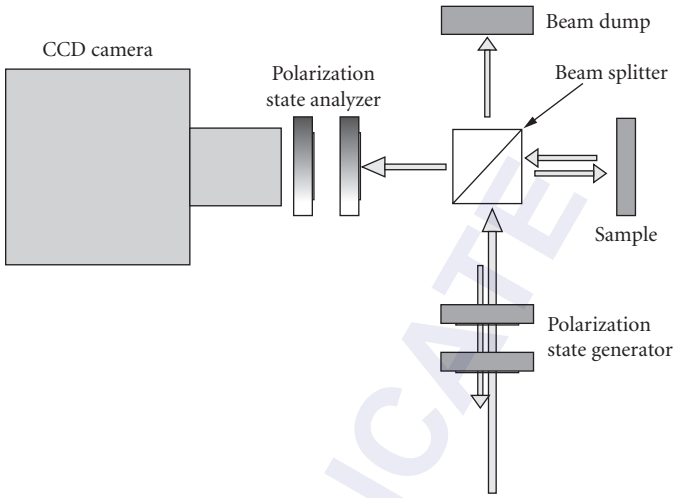

FIGURE 6 Imaging polarimeter configured for retro reflection testing using a nonpolarizing beam splitter and beam dump. (See also color insert.)

To obtain the Mueller matrix image of the sample, contributions from the reflection off the nonpolarizing beam splitter and transmission through the nonpolarizing beam splitter must be calibrated and removed. The ideal nonpolarizing beam splitter should have no polarization, its retardance and diattenuation should be zero; the Mueller matrix would be the identity matrix for both reflection and transmission. In practice, commercially available nonpolarizing beam splitters always have some diattenuation and retardance.

The sample Mueller matrix $\mathbf{M}_S$ is determined from the measured Mueller matrix, $\mathbf{M}_{\text{measured}}$, where $\mathbf{M}_T$ is the beam splitter in transmission and $\mathbf{M}_R$ is the beam splitter in reflection,

$$\mathbf{M}_{\text{measured}} = \mathbf{M}_T \bullet \mathbf{M}_S \bullet \mathbf{M}_R \tag{51}$$

$\mathbf{M}_T$ and $\mathbf{M}_R$ are measured during sample compartment calibration at each wavelength. $\mathbf{M}_S$ is determined as

$$\mathbf{M}_S = (\mathbf{M}_T)^{-1} \bullet \mathbf{M}_{\text{measured}} \bullet (\mathbf{M}_R)^{-1} \tag{52}$$

The compensation must be cautiously applied, with all instrumental variables such as collimation, vignetting, stray light, and angle of incidence carefully considered.

The same method is applicable to lenses, mirrors, and other supplemental optics used to manipulate the beams through the sample compartment. Once the Mueller matrices for the optics before $\mathbf{M}_1$ and after $\mathbf{M}_2$ are calibrated, their matrix inverses can be applied during data reduction,

$$\mathbf{M}_S = (\mathbf{M}_2)^{-1} \bullet \mathbf{M}_{\text{measured}} \bullet (\mathbf{M}_1)^{-1} \tag{53}$$

15.40 APPLICATIONS OF POLARIMETRY

Polarimetry and ellipsometry have found application in nearly all areas of science and technology with several tens of thousands of papers detailing various applications. The following summarizes a few of the principal applications and introduces some of the books, reference works, and review papers which provide gateways into the subject.

15.41 ELLIPSOMETRY AND GENERALIZED ELLIPSOMETRY

Ellipsometry is the application of polarimetry to the determination of the optical properties of surfaces and interfaces. Example applications are refractive index and thin-film thickness measurement, and investigations of processes at surfaces such as contamination and corrosion. Chapter 16, "Ellipsometry," by Rasheed M. A. Azzam treats ellipsometry fundamentals. A more extensive treatment is found in the textbook by Azzam and Bashara.[6,9] SPIE Milestone Series by Azzam[51] is a collection of historical papers. Calculation of the polarization properties of thin films is presented in the chapter by Dobrowolski,[52] and also in the text by Macleod.[53]

Ellipsometry is a well-established technique for determining optical properties such as refractive indices, absorption coefficients, and film thicknesses of material samples by measuring polarization changes that occur on reflection and refraction.[6] In ellipsometer systems, the measurement configuration is varied, and the polarization change measured. Configuration changes include illumination angle, wavelength, and sample orientation. A forward calculation based on a model, such as the thin-film reflectance or transmission equations, has its free parameters optimized to provide the best fit to the data.

The recent development of generalized ellipsometry or biaxial ellipsometry uses measurements of the complete Jones matrix or Mueller matrix to determine the optical properties of more general anisotropic structures such as birefringent crystals and polarizing films.[54–68] Generalized ellipsometry measures the optical constants of materials such as anisotropic films, and multilayer stacks of anisotropic films, birefringent crystals, and polarizing materials. With the widespread adoption of biaxial multilayer films in liquid crystal projectors for control of retardance as a function of field of view and wavelength, accurate characterization of anisotropic materials has become more important. The need for such types of ellipsometric instruments has increased with the rapid evolution of liquid crystal displays, new materials and fabrication techniques, and nanostructured materials.

The optical constants of anisotropic materials are conveniently expressed in the form of the dielectric tensor $\tilde{\boldsymbol{\varepsilon}}$. For nonoptically active, non-magneto-optic materials with aligned retardance and diattenuation, the dielectric tensor is symmetric and can be expressed as a rotated diagonal matrix of the form

$$\tilde{\boldsymbol{\varepsilon}} = \mathbf{R}^{-1}(\varphi, \theta, \psi) \bullet \begin{bmatrix} (n_x + i\kappa_x)^2 & 0 & 0 \\ 0 & (n_y + i\kappa_y)^2 & 0 \\ 0 & 0 & (n_z + i\kappa_z)^2 \end{bmatrix} \bullet \mathbf{R}(\varphi, \theta, \psi) \tag{54}$$

where $n_x + i\kappa_x$, $n_y + i\kappa_y$, and $n_z + i\kappa_z$ are the complex refractive indices along the principal axes, and $\mathbf{R}$ is a rotation matrix through Euler angles φ, θ, and ψ with respect to the laboratory coordinates as represented in Fig. 7.[69]

Characterizing such an anisotropic multilayer thin film requires measuring up to 10 parameters for each layer, 9 that specify the dielectric tensor and 1 for thickness. Multiple measurements must be acquired which span a suitably large range of incident and azimuthal (about the surface normal) angles so that each optical constant to be determined has a distinct effect on the measurements. Changes to the optical constants need to cause distinct changes to the ellipsometric dataset. Each dielectric tensor and thickness parameter must significantly change the polarization within the range of illumination angles, so that ellipsometric data points are not a linear combination of previous measurements. By simultaneously measuring a large range of both incident and azimuthal angles, the components of the dielectric tensor can be determined from a single Mueller matrix image.[68] Figures 8 and 9 show Mueller matrix imaging polarimeters with converging beams operating in reflection and transmission for generalized ellipsometry. Figure 10 is an example Mueller matrix image of an LC projector biaxial field correcting film.

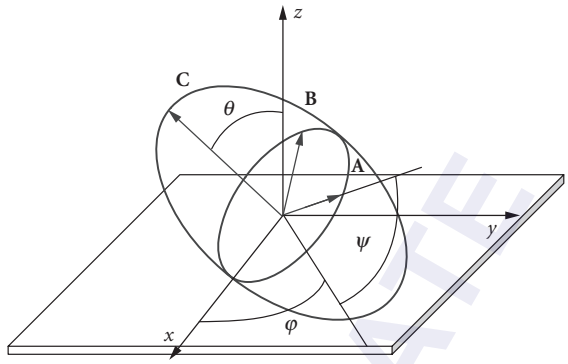

FIGURE 7 Example of a biaxial index ellipsoid with principal axes oriented at an arbitrary orientation along orthogonal vectors **A**, **B**, and **C**.

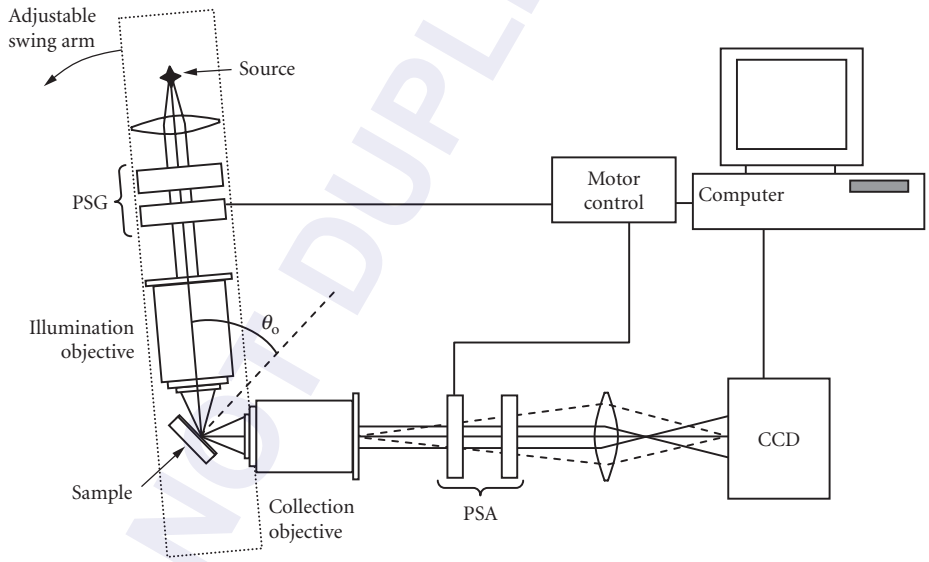

FIGURE 8 Mueller matrix imaging polarimeter configured for reflection generalized ellipsometry with the inclusion of two microscope objectives in the sample compartment. The microscope objective's exit pupil is imaged onto the CCD so that each pixel receives light which reflected at a different angle of incidence and azimuth.

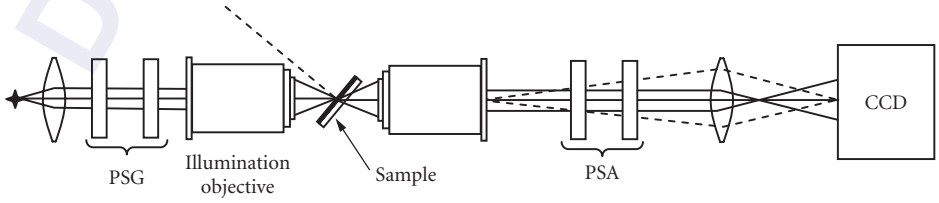

FIGURE 9 This Mueller matrix imaging polarimeter configured for transmission-generalized ellipsometry uses two microscope objectives to obtain polarization change as a function of angle of incidence.

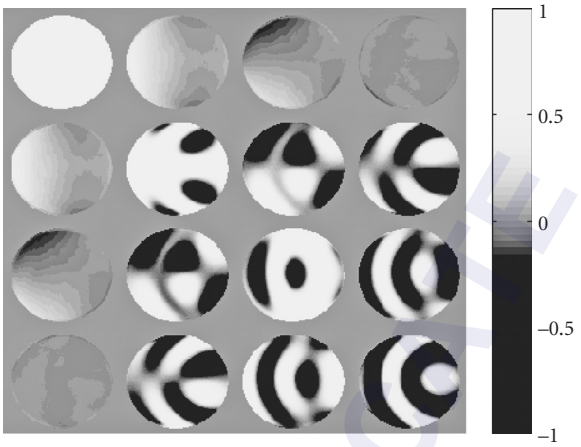

FIGURE 10 Angle of incidence Mueller matrix image of a field widening film for liquid crystal projector systems. The retardance is engineered to vary opposite to the LC, greatly increasing the field of view before artifacts, such as color shifts, occur in the display. The film's optical properties, such as thickness and refractive indices, can be reverse engineered from such measurements by generalized ellipsometry.

Biaxial materials have tensor components that vary with direction and can only be fully characterized if measurements are performed while both the incident and the azimuthal (about the normal) angle of the illuminating light varies with respect to the sample. Dielectric tensor information can also be obtained by measuring at multiple wavelengths and fitting a parameterized dispersion relationship based on a physical model of the dielectric tensor.[66,70]

Several methods for calculating the reflection and transmission properties for arbitrary anisotropic multilayer structures have been developed, including the Berremann calculus and related methods derived by Yeh, Mansuripur, and Schubert.[71–74]

15.42 LIQUID CRYSTAL CELL AND SYSTEM TESTING

Liquid crystal (LC) displays of all types are polarization critical optical systems, where the systems are readily put out of specifications by misalignment of polarization elements, poor polarization element quality, stress birefringence, depolarization and scattering, LC cell defects, and a myriad of other issues. Such displays include laptop displays, computer monitors, conference room projectors, direct view and projection televisions, and the myriad of small displays in watches, calculators, cell phones, and the like. Mueller matrix polarimetry and imaging polarimetry are important methods to provide detailed diagnostics of LCs and the associated optical systems.

Polarization measurements made on liquid crystal (LC) cells are particularly useful for determining the key physical parameters of the cell, namely the cell gap, rubbing direction, twist angle, and pretilt angles of the LC as shown in Fig. 11. The cell gap is the thickness of the LC layer between the two glass plates. The rubbing direction describes the azimuth angle (orientation angle) of the LC director at the top glass surface, and the twist angle describes the change in orientation angle of the LC director through the thickness of the cell, such that the orientation angle at the bottom glass is the top-glass rubbing direction plus the twist angle. The pretilt

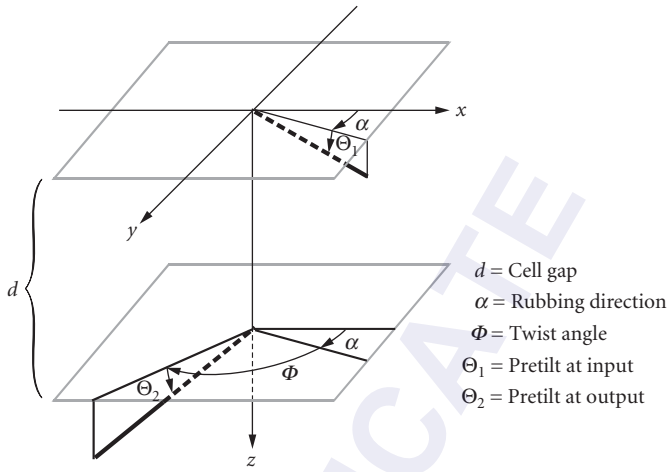

FIGURE 11 Parameters describing a twisted nematic liquid crystal cell can be measured by multiangle Mueller matrix polarimetry.

angles describe the polar angle (tilt angle) of the LC directors at the glass plate interfaces. By adjusting these parameters, LC panel manufactures can tune their design for the desired response time, color properties, and useable field-of-view. By making polarization measurements of the cell at a variety of incident angles and/or wavelength, and applying curve-fitting techniques, these key parameters can be measured, such as by the AxoScan Mueller matrix polarimeter from Axometrics, Inc. (Huntsville, Alabama).

LCs operate as electrically addressable variable retarders. With the inclusion of polarizers and color filters, pixilated LC arrays (LC panels) serve as color image generators. Several performance specifications of an LC system are critical. The contrast ratio is the ratio of the on-screen illuminance in the white state to the intensity in the dark state. A high contrast ratio depends on the dark state intensity being nearly zero, which requires that all polarization properties are nearly ideal so the beam is well extinguished at the final polarizer. The efficiency of the system is the ratio of the output intensity to the source intensity in the white state. Spatial uniformity characterizes the variations in brightness of the dark and bright states across the aperture.

The contrast ratio and efficiency of the LC projector are a function of the polarization properties of the components in the light valve: the polarizer, beam splitter, LC, and analyzer, as well as the étendue, color balancing, and many other factors. Determination of the polarization properties of each component allows for modeling of system performance, and, in the case of poor system performance, diagnosing which elements are the source of the problem.

The Mueller matrix is especially useful for characterization of LC display system components because sequences of elements behave as the product of their Mueller matrices. Thus the Mueller matrix of an LC panel can be combined with the matrices for beam splitters, dichroic filters, and other components to understand their polarization interactions and tolerance of combinations of optical elements.

Polarization testing of LCs provides important information augmenting radiometric testing. Polarization testing of LC panels requires illuminating the panels with a variety of incident polarization states and measuring the corresponding output polarization states. These additional states are not normally used during LC system operation so their usage for testing appears extraneous until the diagnostic value of retardance and depolarization maps is realized; these parameters directly determine performance properties of the LCs. Radiometric testing measures the LC performance, treating the LC as a black box. Imaging polarimetry quantifies desired and undesired polarization properties enabling better diagnosis of LC problems, problems more difficult to isolate using

TABLE 1 Performance Specification Issues Related to Polarization Causes and LC Defects

Defect	Possible Polarization Causes
Low contrast	Depolarization Incorrect trim retarder Misalignment of liquid crystal, trim retarder, or PBS
Low brightness	Incorrect retardance Oxidized reflector High levels of depolarization
Poor uniformity	Spatial variation in retardance magnitude Spatial variation of retardance orientation Temperature-induced retardance variations

radiometric testing alone. Table 1 and Table 2 summarize the relationship of these polarization properties with several LC performance defects. In Table 1, LC system defects are paired with the related polarization properties which can cause the defect. Many display problems are the direct result of nonideal polarization properties. Table 2 lists some nonideal LC polarization properties and the associated effects.

Depolarization adversely affects LC system performance in different ways than incorrect retardance or retardance nonuniformity. With depolarization, a fraction of the exiting light can be treated as unpolarized light [Eq. (6)]; this is the depolarized component. Fifty percent of the depolarized light will pass through the analyzer and 50 percent will be blocked, so the fraction of leaked light is, at minimum,

$$\text{Leakage} = \frac{1 - \text{DoP}}{2} \tag{55}$$

In the dark state, the leaked depolarized light increases the dark state intensity, and if significant, has a severe effect on the contrast ratio. In the white state half of the depolarized light is blocked by the analyzer decreasing the white state brightness, a less critical problem than dark state leakage. For high contrast, the LC panel must have very low levels of depolarization.

Scattering is a common cause of depolarization in liquid crystals. Liquid crystal depolarization also arises from spatial averaging; micron-scale retardance variations cause adjacent parts of the beam to emerge with different polarization states which average at the polarimeter resulting in a depolarized component in the measurement. An imaging polarimeter measures the average retardance within each of its pixels and any subpixel retardance variations are measured as depolarization. Temperature variations, electric field variations, edge effects in pixels, and disclinations in the LC all cause depolarization.

In any polarimeter measurement, small values of depolarization need to be critically evaluated to ensure the depolarization is due to the device under test and is not due to noise or calibration error within the polarimeter. All polarimeter measurements have some depolarization noise or bias.

TABLE 2 Polarization Defects and Resulting Onscreen Effects

Polarization Property	On-Screen Effect
Retardance spatial nonuniformity	Spatial variation of brightness, color, or contrast
Nonzero dark state retardance	Reduced contrast and color saturation
Incorrect retardance orientation or magnitude	Reduced brightness and contrast
Spectral variation of retardance	Wavelength-dependant contrast and brightness
Depolarization	Reduced contrast and brightness

Typical twisted nematic LC cells cannot be driven to zero retardance, suffering some residual retardance due to thin boundary layers of liquid crystal along the alignment layers as shown in Fig. 3. This residual retardance is usually compensated by placing an additional "trim retarder" over the LC panel.[75] The trim retarder introduces retardance equal in magnitude to the LC's single pass retardance with the retardance axis rotated 90°.[75] Such a retarder combines with the LC retardance yielding a retardance of zero.

While a trim retarder can be used to reduce the effect of dark state retardance, depolarization cannot be compensated; it must be reduced to acceptable levels during LC device development and fabrication.

15.43 POLARIZATION ABERRATIONS

Polarimetry is useful in optical metrology for measuring the polarization aberrations of optical systems and for characterizing optical and polarization components. Optical systems modify the polarization state of light due to reflections, refractions, and other interactions. Lenses and mirrors have polarization properties described by the Fresnel equations and associated multilayer thin-film equations. For many optical systems, such as camera lenses and Cassegrain telescopes, these polarization aberrations are small, but not necessarily negligible. Other optical systems, with large angles of incidence, diffraction gratings, beam splitters, or other significantly polarizing components, have significant and often troublesome polarization aberrations.

Each ray path through the optical system can be characterized by its polarization matrix. Polarization ray–tracing is the technique of calculating the polarization matrices for ray paths through optical systems.[24,76–79] Diffraction image formation of polarization-aberrated beams is then handled by vector extensions to diffraction theory.[80–85] Polarimeters, particularly imaging polarimeters, can measure the Mueller matrices of ray paths through optical systems determining the polarization aberrations. These polarization aberrations frequently have similar functional forms to the geometrical aberrations, since they arise from similar geometrical considerations of surface shape and angle of incidence variation.[85–92]

Optical system polarization aberrations can be measured by placing the system in the sample compartment of a Mueller matrix imaging polarimeter. Usually the exit pupil is imaged, giving the polarization aberration function (**PAF**) a Mueller matrix as a function of pupil coordinates. Then maps are generated of linear diattenuation, linear retardance, and other metrics. Figure 12 shows the diattenuation and retardance polarization aberrations measured through a pair of 0.55 numerical aperture microscope objectives; collimated light enters the pupil of the first objective, focuses at the focal point of the second objective, and is recollimated, like Fig. 9 without the sample. The lengths of the lines in the images correspond to the magnitude of the diattenuation and retardance.

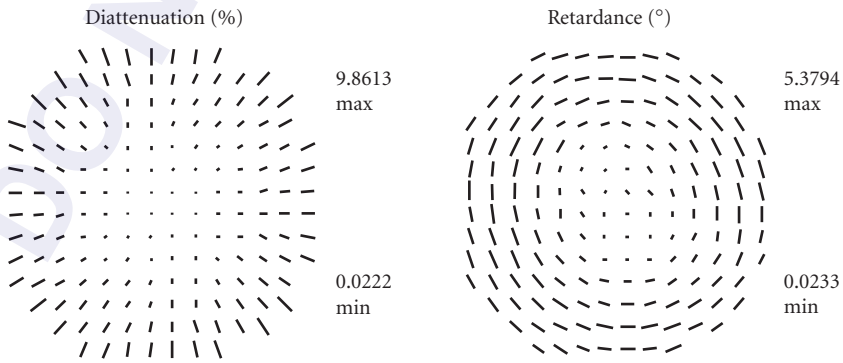

FIGURE 12 The polarization aberrations transmitting through a pair of microscope objectives is represented by these linear diattenuation and linear retardance pupil maps.

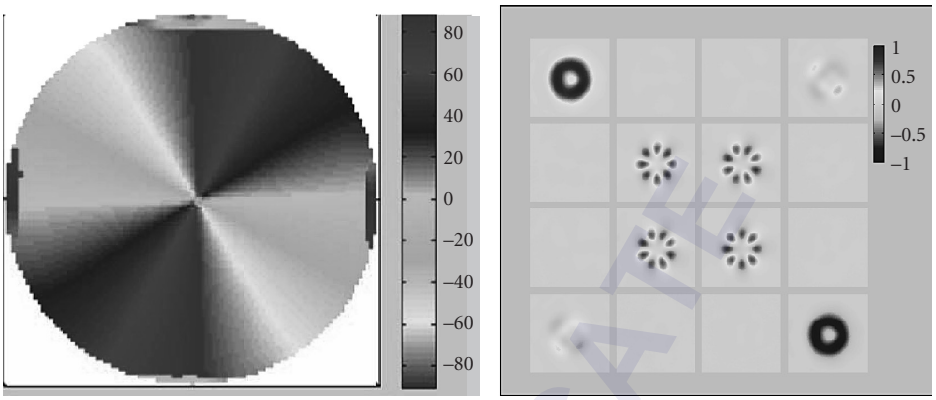

FIGURE 13 The orientation of the fast axis of the half wave vortex retarder rotates by 360° around the pupil (*a*). The Point spread matrix describes the polarization dependence of the point spread function as a Mueller matrix image (*b*).

The microscope objective pair has up to 5.4° of spatially varying retardance and 0.1 of spatially varying diattenuation. When placed between crossed linear polarizers, this pair of objectives will leak about 0.15 percent of the incident flux, averaged over the pupil.

When significant polarization aberrations are present, an optical system illuminated with a uniform polarization state will have polarization variations within the point spread function. To characterize these variations and the dependence of the point spread function on the incident polarization state, a Mueller matrix imaging polarimeter focusses on the image of a point object and measures the point spread matrix (**PSM**) as a Mueller matrix image. Measured **PSM** with large polarization aberration is shown in Fig. 13. A vortex retarder was placed in the pupil of an imaging system with a large f/# image on a camera focal plane, and a Mueller matrix image acquired. This vortex retarder is half-wave linear retarder whose fast axis varies as a function of pupil angle.[93] The pupil image on the left side shows the retardance orientation varying by 360° around the pupil. The right side contains the **PSM**. When the Stokes vector of the incident light is multiplied by the **PSM**, the resulting Stokes vector function describes the flux (point spread function) and polarization state variations within the image as a Stokes vector image. Figure 14 shows the point spread function for a fixed incident polarization state and several analyzers, demonstrating the polarization variations within the point spread function.

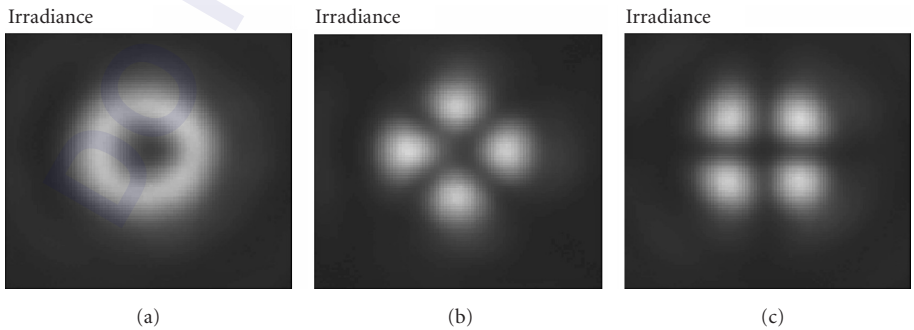

FIGURE 14 The measured point spread function of the vortex retarder completely changes with the analyzed polarization state: (*a*) no analyzer; (*b*) horizontal linear analyzer; and (*c*) vertical linear analyzer. Horizontal linearly polarized light is input.

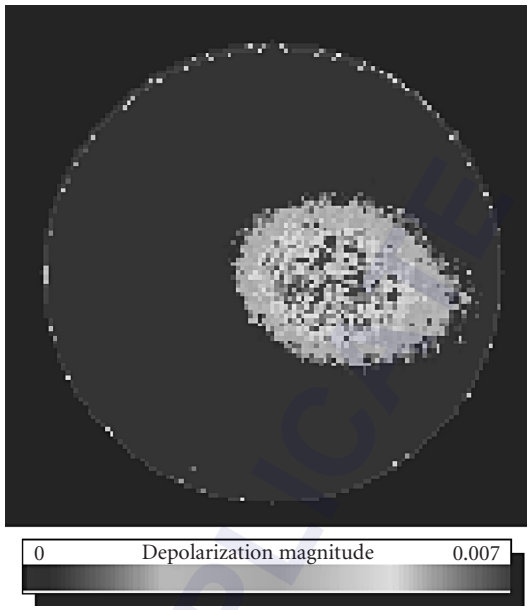

FIGURE 15 Depolarization index of lens with coating damage on the right center causing about 0.005 depolarization.

Figure 15 shows another polarization aberration measurement example.[94] The lens coatings became damaged by heat and began flaking off. The resulting Mueller matrix pupil image shows a few tenths of a percent depolarization in the damaged area. The undamaged area has a depolarization of only a few hundredths of a percent, more typical of coated lenses.

15.44 REMOTE SENSING

Polarimetry is an important remote sensing technique which complements spectroscopic or hyperspectral imaging. The sunlight which illuminates the earth is essentially unpolarized, but the scattered light has a surprisingly large degree of polarization, which is mostly linear polarization.[7,94–97] Visible light scattered from forest canopy, cropland, meadows, and similar features frequently has a degree of polarization of 20 percent or greater in the visible range.[98,99] Light reflecting from mudflats and water can have a degree of polarization greater than 50 percent, particularly for light incident near Brewster's angle. The magnitude of the degree of linear polarization depends on many variables, including the angle of incidence, the angle of scatter, the wavelength, and the weather. The polarization from a site varies from day to day even if the angles of incidence and scatter remain the same; these variations are caused by changes in the earth's vegetation, cloud cover, humidity, rain, and standing water. Polarization is complex to interpret but it conveys useful information.

Light scattered from dense white clouds is nearly unpolarized due to multiple scattering.[7,96] Scattering from thin aerosols is partially polarized. Hyperspectral imaging combined with Mie scattering theory can determine the mean particle size and the imaginary part of the refractive index of an aerosol. Adding multiangle polarimetric data at visible and shortwave infrared wavelengths provides additional information on the real part of the aerosol refractive index, n_r, and particle size variances, with greater sensitivity than intensity measurements alone. This has been demonstrated with the airborne research scanning polarimeter (RSP),[100,101] through theoretical sensitivity studies,[102] and with the space-borne Polarization and Directionality of Earth's Reflectances (POLDER) instrument.[103] POLDER spatial resolution is 6 to 7 km, with degree of linear polarization (DoLP) uncertainty of ~2 percent.[104]

The Aerosol Polarimeter Sensor (APS) instrument for NASA's Glory mission, using similar design concepts as the airborne RSP, will provide very accurate multi-anglepolarimetric measurements (linear polarization uncertainty ~0.2 percent), but in a coarse resolution (6 to 20 km) due to nonimaging operation.[105]

Many factors affect the accuracy of imaging polarimeters.[106] Polarization aberrations of the optics (instrumental polarization) is addressed through accurate calibration and removal of systematic errors. Many remote sensing polarimeters use different analyzers over different detectors whose signals are then subtracted to measure polarization, and are thus susceptible to gain variations and pixel sensitivity drift. Ongoing detector cross-calibration is desirable. Spatial displacements on the ground between the locations where different polarization orientations are measured gives rise to *polarization artifacts*, also known as *false polarization.* Spatial misregistration between the measurements comprising a polarization measurement is particularly problematic in the presence of scene gradients.

15.45 POLARIZATION LIGHT SCATTERING

Polarization light scattering is the application of polarimetry to scattered light.[107,108] The scattering characteristics of a sample are generally described by its bidirectional reflectance distribution function, BRDF $(\theta_i, \phi_i, \theta_s, \phi_s, \lambda)$, depicted in Fig. 16, which is the ratio of the scattered flux in a particular direction (θ_s, ϕ_s) to the flux of an incident beam from direction (θ_i, ϕ_i),[109]

$$\text{BRDF}(\theta_i, \phi_i, \theta_s, \phi_s), = \frac{dL_s(\theta_s, \phi_s)}{dE_i(\theta_i, \phi_i)} \tag{56}$$

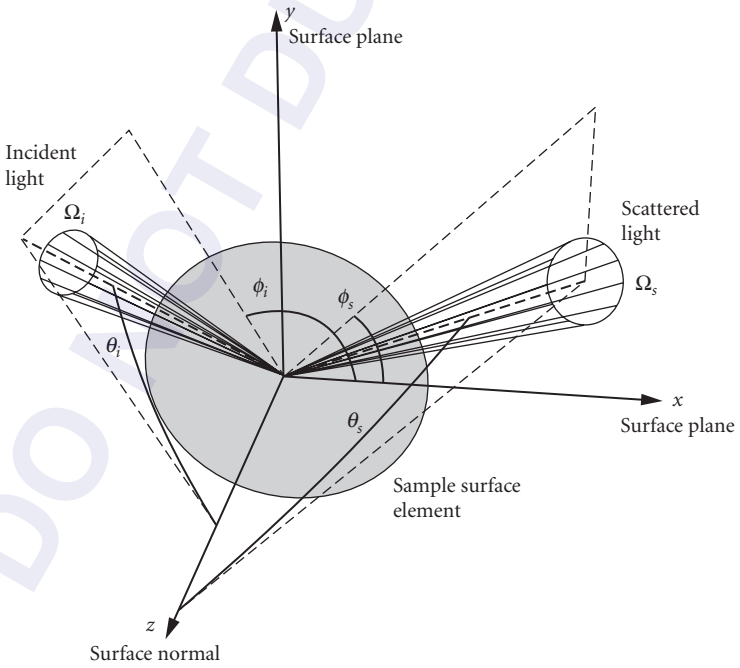

FIGURE 16 The BRDF angle nomenclature: The incident light has an angle of incidence θ_i and azimuth angle ϕ_i and subtends solid angle Ω_i. The scattered light has an angle of scatter θ_s and azimuth angle ϕ_s and subtends solid angle Ω_s.

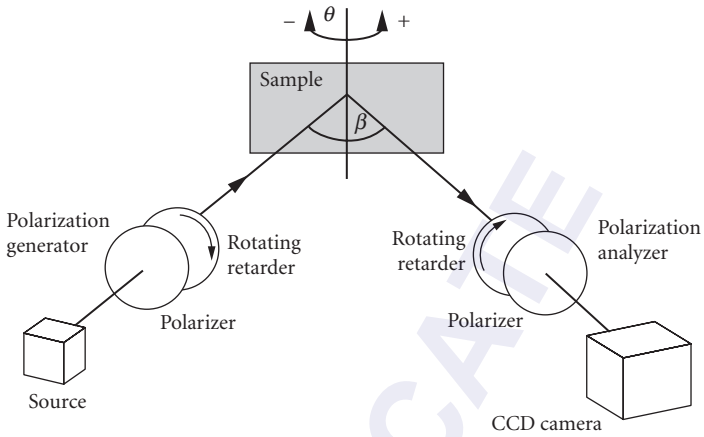

FIGURE 17 Mueller matrix imaging polarimeter for in-plane **MMBRDF** measurements, with bistatic angle β between the polarization generator arm and analyzer arm.

This standard BRDF definition makes no reference to the incident or scattered polarization state so the BRDF function contains no polarization information. The BRDF can be generalized to a Mueller matrix bidirectional reflectance distribution function, or **MMBRDF**(θ_i, ϕ_i, θ_s, ϕ_s, λ), the Mueller matrix relating incident and scattered beams in arbitrary directions,[25]

$$\mathbf{MMBRDF}(\theta_i, \varphi_i, \theta_s, \varphi_s) = \begin{pmatrix} m_{0,0}(\theta_i, \varphi_i, \theta_s, \varphi_s) & \cdots & m_{0,3}(\theta_i, \varphi_i, \theta_s, \varphi_s) \\ \vdots & \ddots & \vdots \\ m_{3,0}(\theta_i, \varphi_i, \theta_s, \varphi_s) & \cdots & m_{3,3}(\theta_i, \varphi_i, \theta_s, \varphi_s) \end{pmatrix} \tag{57}$$

Then the BRDF function is the $m_{0,0}$ element of the **MMBRDF**(θ_i, ϕ_i, θ_s, ϕ_s, λ).

Scattered light is a sensitive indicator of surface conditions; a small amount of surface roughness may reduce the specular power by less than a percent while increasing the scattered power by orders of magnitude. The retardance, diattenuation, and depolarization of the scattered light similarly provide sensitive indicators of light scattering conditions, such as uniformity of refractive index, orientation of surface defects, texture, strain and birefringence at an interface, subsurface damage, coating microstructure, and the degree of multiple scattering. Figure 17 depicts a polarimeter configured for polarization scattered light measurements.

Frequently the last 15 **MMBRDF** elements are normalized (divided) by the $m_{0,0}$ element which simplifies the interpretation of polarization properties associated with scattering by adjusting these elements to a −1 to 1 scale.

Figure 18 shows two examples **MMBRDF** from DeBoo.[25] Concrete is nearly lambertian and the $m_{1,1}$ element (labeled $m_{0,0}$ elsewhere in this chapter) varies little with angle. The gold-coated diffuser has a more distinct specular peak at $\theta = 0$, and becomes more diattenuating and depolarizing as θ varies away from zero.

15.46 OPHTHALMIC POLARIMETRY

The human visual system is polarization insensitive; an observer cannot discern between unpolarized light and polarized light of various states. The structures of the eye are, however, diattenuating, retarding, and depolarizing.

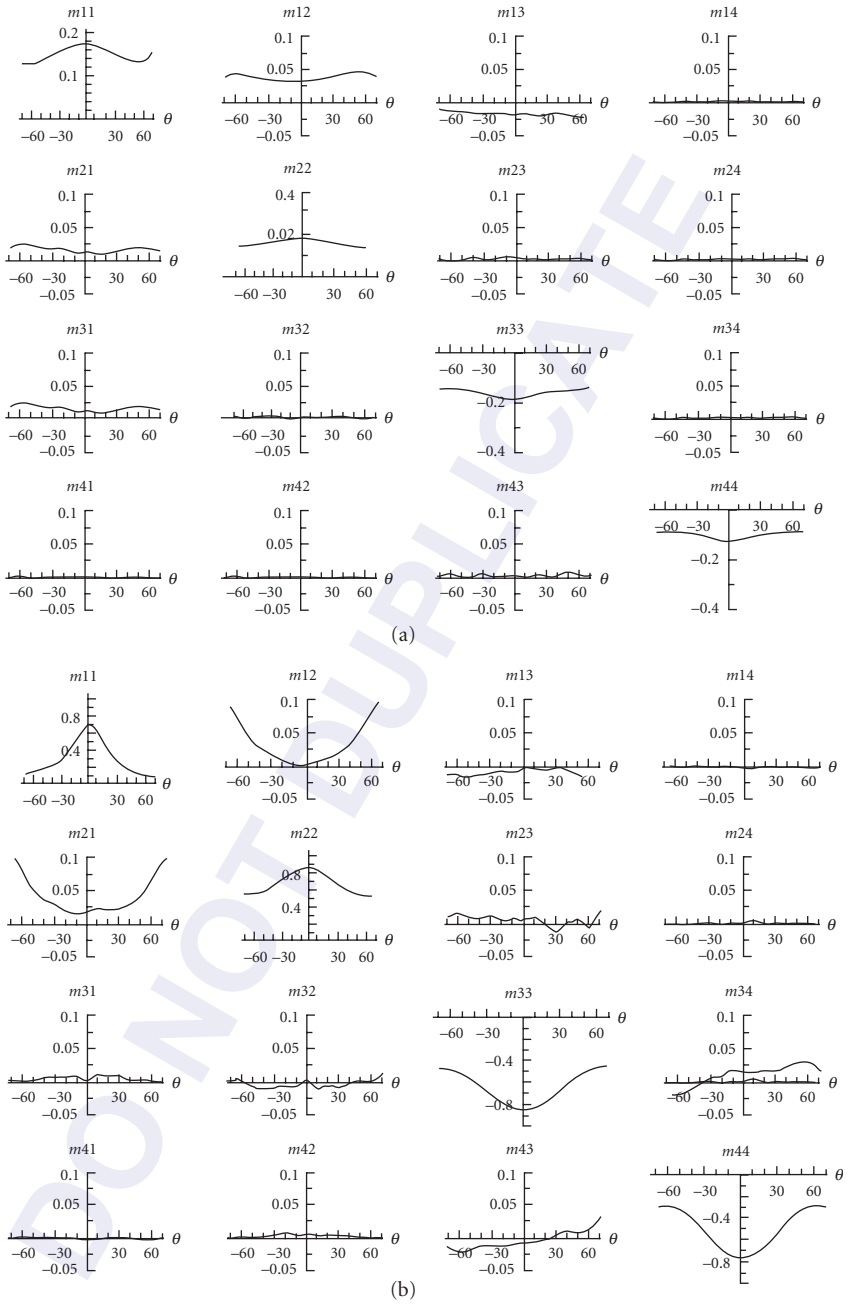

FIGURE 18 (*a*) In-plane Mueller matrix BRDF for scattering from concrete measured at 808 nm as a normalized Mueller matrix spectrum. In this figure, the Mueller matrix index runs from 1 to 4. The $m_{2,4}$, $m_{4,2}$, $m_{3,4}$, and $m_{4,3}$ elements are nearly zero indicating the absence of linear retardance. The positive $m_{1,2}$ and $m_{2,1}$ elements indicate diattenuation in the *s*-*p* orientations such that *s* has the larger diffuse reflectance. (*b*) The same for a gold-coated diffuser. The $m_{3,4}$, and $m_{4,3}$ elements are nonzero indicating linear retardance between the *s*-*p* components.

The eye's strongest polarization effects are found in the cornea, retinal nerve fiber layer, and Henle's layer. These anisotropic structures contain long thin parallel-oriented cylinders (such as collagen fibrils or microtubules), uniformly distributed within the surrounding medium, with dimensions smaller than the wavelength of visible light. Wiener[110] demonstrated in his theory of mixed dielectrics that due to the small difference in refractive index between cylinders and medium, this type of structure has different refractive indices for light polarized parallel and perpendicular to the cylinder axes, an effect termed *form birefringence.* The retardance increases linearly with propagation distance.[111] Hemenger deduced that these structures also have greater absorption for light oscillating parallel to the cylinders (similar to a wire grid polarizer), so that diattenuation increases with propagation distance, an effect termed *form dichroism*.[112] Other models have described diattenuation and retardance with structured ocular tissues.[113,114]

The interaction of polarized light with retinal tissue has been actively explored to detect subtle changes in the tissue microstructure. A healthy retina has an ordered microstructure.[115] The more ordered a structure, the larger the diattenuation and retardance should be. As these cellular structures become disordered in certain disease states, the diattenuation and retardance are expected to decrease and the depolarization to increase.

Direct measurements of retinal polarization have been performed using a variety of techniques. Van Blokland[116] was the first to obtain a complete Mueller matrix with a single pixel and demonstrated significant retinal depolarization. Imaging methods include camera-based retinal polarimeters,[117–119] scanning laser polarimetery methods, and polarization-sensitive optical coherence tomography. Retinal images are assembled through appropriate reconstruction of the detector signal.[120–122]

A retinal polarimeter, the GDx Nerve Fiber Analyzer (Carl Zeiss Meditec, Dublin California) has been commercially available since the late 1990s and is FDA approved for the measurement of retinal nerve fiber layer thickness and its thinning for the purpose of diagnosing the progression of glaucoma. The GDx is a scanning laser ophthalmoscope measuring linear retardance only, an incomplete polarimeter. The linear retardance is used to estimate the thickness of the retinal nerve fiber layer, which aids in diagnosis and monitoring of glaucoma.[123–125] As an incomplete polarimeter, the GDx is increasingly inaccurate as depolarization and diattenuation increase.[118]

Elsner, Burns, and their coworkers have demonstrated the utility of depolarization images to provide higher contrast for deep tissue scattering abnormalities that occur in age-related macular degeneration, central serous chorioretinopathy, and other maculopathies. These abnormalities include drusen, pools of fluid, pigmentation changes, and abnormal vasculature. Lara and Dainty[126] have reported a complete retinal polarimeter incorporating multiple polarizing beam splitters and detectors.

Polarization-sensitive optical coherence tomography (OCT) generates three-dimensional retinal polarization images.[127–129] The OCT repeatedly scans with different polarization states illuminating the sample. De Boer has measured the birefringence distribution through the retina and demonstrated that the birefringence of the nerve fiber layer is not uniform. The polarization of the reference beam must be closely matched at the detector for useful fringe visibility. Thus polarization OCT is limited in the measurement of depolarization since multiply scattered incoherent light is rejected in OCT.

15.47 ACKNOWLEDGMENTS

In preparing this chapter, extensive use was made of the works of some of the author's students and other collaborators and they deserve particular credit: Brian de Boo, Karen Twietmeyer, Justin Wolfe, Neil Beaudry, Ann Elsner (Univ. Indiana), Matt Smith (Axometrics), and Dave Diner (NASA/JPL).

16.1 GLOSSARY

$\mathbf{A}$	instrument matrix
D_ϕ	film thickness period
d	film thickness
$\mathbf{E}$	electrical field
$\mathbf{E}_0$	constant complex vector
$f()$	function
$\mathbf{I}$	interface scattering matrix
k	extinction coefficient
$\mathbf{L}$	layer scattering matrix
N	complex refractive index $= n - jk$
n	real part of the complex refractive index
R	reflection coefficient
r	reflection coefficient
S_{ij}	scattering matrix elements
s, p	subscripts for polarization components
X	$\exp(-j2\pi d/D_\phi)$
Δ	ellipsometric angle
ϵ	dielectric function
$\langle\epsilon\rangle$	psuedo dielectric function
ρ	$R_p/R_s = \tan\psi \exp(j\Delta) = \chi_i/\chi_r$
ϕ	angle of incidence
χ_i	E_{is}/E_{ip}
χ_r	E_{rs}/E_{rp}
ψ	ellipsometric angle

16.2 INTRODUCTION

Ellipsometry is a nonperturbing optical technique that uses the change in the state of polarization of light upon reflection for the in-situ and real-time characterization of surfaces, interfaces, and thin films. In this chapter we provide a brief account of this subject with an emphasis on modeling and instrumentation. For extensive coverage, including applications, the reader is referred to several monographs,[1–4] handbook,[5] collected reprints,[6] conference proceedings,[7–15] and general and topical reviews.[16–32]

In ellipsometry, a collimated beam of monochromatic or quasi-monochromatic light, which is polarized in a known state, is incident on a sample surface under examination, and the state of polarization of the reflected light is analyzed. From the incident and reflected states of polarization, ratios of complex reflection coefficients of the surface for the incident orthogonal linear polarizations parallel and perpendicular to the plane of incidence are determined. These ratios are subsequently related to the structural and optical properties of the ambient-sample interface region by invoking an appropriate model and the electromagnetic theory of reflection. Finally, model parameters of interest are determined by solving the resulting inverse problem.

In ellipsometry, one of the two copropagating orthogonally polarized waves can be considered to act as a reference for the other. Inasmuch as the state of polarization of light is determined by the superposition of the orthogonal components of the electric field vector, an ellipsometer may be thought of as a common-path polarization interferometer. And because ellipsometry involves only relative amplitude and relative phase measurements, it is highly accurate. Furthermore, its sensitivity to minute changes in the interface region, such as the formation of a submonolayer of atoms or molecules, has qualified ellipsometry for many applications in surface science and thin-film technologies.

In a typical scheme, Fig. 1, the incident light is linearly polarized at a known but arbitrary azimuth and the reflected light is elliptically polarized. Measurement of the ellipse of polarization of the reflected light accounts for the name ellipsometry, which was first coined by Rothen.[33] (For a discussion of light polarization, the reader is referred to Chap. 12 in this volume. For a historical background on ellipsometry, see Rothen[34] and Hall.[35])

For optically isotropic structures, ellipsometry is carried out only at oblique incidence. In this case, if the incident light is linearly polarized with the electric vector vibrating parallel p or perpendicular s to the plane of incidence, the reflected light is likewise p- and s-polarized, respectively. In other words, the p and s linear polarizations are the eigenpolarizations of reflection.[36] The associated eigenvalues are the complex amplitude reflection coefficients R_p and R_s. For an arbitrary input state with phasor electric-field components E_{ip} and E_{is}, the corresponding field components of the reflected light are given by

$$E_{rp} = R_p E_{ip} \qquad E_{rs} = R_s E_{is} \tag{1}$$

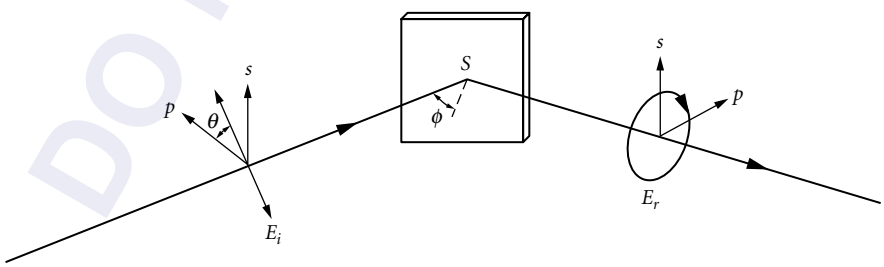

FIGURE 1 Incident linearly polarized light of arbitrary azimuth θ is reflected from the surface S as elliptically polarized. p and s identify the linear polarization directions parallel and perpendicular to the plane of incidence and form a right-handed system with the direction of propagation. ϕ is the angle of incidence.

By taking the ratio of the respective sides of these two equations, one gets

$$\rho = \chi_i / \chi_r \tag{2}$$

where

$$\rho = R_p / R_s \tag{3}$$

$$\chi_i = E_{\text{is}} / E_{\text{ip}} \qquad \chi_r = E_{\text{rs}} / E_{\text{rp}} \tag{4}$$

χ_i and χ_r of Eqs. (4) are complex numbers that succinctly describe the incident and reflected polarization states of light;[37] their ratio, according to Eqs. (2) and (3), determines the ratio of the complex reflection coefficients for the *p* and *s* polarizations. Therefore, ellipsometry involves pure polarization measurements (without account for absolute light intensity or absolute phase) to determine ρ. It has become customary in ellipsometry to express ρ in polar form in terms of two *ellipsometric angles* ψ and $\Delta (0 \le \psi \le 90°, 0 \le \Delta < 360°)$ as follows

$$\rho = \tan\psi \exp(j\Delta) \tag{5}$$

$\tan\psi = |R_p| / |R_s|$ represents the relative amplitude attenuation and $\Delta = \arg(R_p) - \arg(R_s)$ is the differential phase shift of the *p* and *s* linearly polarized components upon reflection.

Regardless of the nature of the sample, ρ is a function,

$$\rho = f(\phi, \lambda) \tag{6}$$

of the angle of incidence ϕ and the wavelength of light λ. Multiple-angle-of-incidence ellipsometry[38–43] (MAIE) involves measurement of ρ as a function of ϕ, and spectroscopic ellipsometry[3,22,27–31] (SE) refers to the measurement of ρ as a function of λ. In variable-angle spectroscopic ellipsometry[43] (VASE) the ellipsometric function ρ of the two real variables ϕ and λ is recorded.

16.3 CONVENTIONS

The widely accepted conventions in ellipsometry are those adopted at the 1968 Symposium on Recent Developments in Ellipsometry following discussions of a paper by Muller.[44] Briefly, the electric field of a monochromatic plane wave traveling in the direction of the *z* axis is taken as

$$\mathbf{E} = \mathbf{E}_0 \exp(-j2\pi Nz/\lambda) \exp(j\omega t) \tag{7}$$

where $\mathbf{E}_0$ is a constant complex vector that represents the transverse electric field in the $z = 0$ plane, *N* is the complex refractive index of the optically isotropic medium of propagation, ω is the angular frequency, and *t* is the time. *N* is written in terms of its real and imaginary parts as

$$N = n - jk \tag{8}$$

where $n > 0$ is the refractive index and $k \ge 0$ is the extinction coefficient. The positive directions of *p* and *s* before and after reflection form a right-handed coordinate system with the directions of propagation of the incident and reflected waves, Fig. 1. At normal incidence ($\phi = 0$), the *p* directions in the incident and reflected waves are antiparallel, whereas the *s* directions are parallel. Some of the consequences of these conventions are as follows:

1. At normal incidence, $R_p = -R_s$, $\rho = -1$, and $\Delta = \pi$.
2. At grazing incidence, $R_p = R_s$, $\rho = 1$, and $\Delta = 0$.
3. For an abrupt interface between two homogeneous and isotropic semi-infinite media, Δ is in the range $0 \le \Delta \le \pi$, and $0 \le \psi \le 45°$.

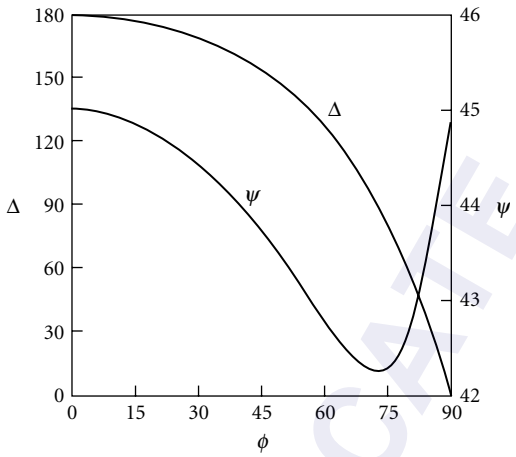

FIGURE 2 Ellipsometric parameters ψ and Δ of an air/Au interface as functions of the angle of incidence ϕ. The complex refractive index of Au is assumed to be $0.306 - j2.880$ at 564-nm wavelength. ψ, Δ, and ϕ are in degrees.

As an example, Fig. 2 shows ψ and Δ vs. ϕ for light reflection at the air/Au interface, assuming $N = 0.306 - j2.880$ for Au[45] at $\lambda = 564$ nm.

16.4 MODELING AND INVERSION

The following simplifying assumptions are usually made or implied in conventional ellipsometry: (1) the incident beam is approximated by a monochromatic plane wave; (2) the ambient or incidence medium is transparent and optically isotropic; (3) the sample surface is a plane boundary; (4) the sample (and ambient) optical properties are uniform laterally but may change in the direction of the normal to the ambient-sample interface; (5) the coherence length of the incident light is much greater than its penetration depth into the sample; and (6) the light-sample interaction is linear (elastic), hence frequency-conserving.

Determination of the ratio of complex reflection coefficients is rarely an end in itself. Usually, one is interested in more fundamental information about the sample than is conveyed by ρ. In particular, ellipsometry is used to characterize the optical and structural properties of the interfacial region. This requires that a stratified-medium model (SMM) for the sample under measurement be postulated that contains the sample physical parameters of interest. For example, for visible light, a polished Si surface in air may be modeled as an optically opaque (semi-infinite) Si substrate which is covered with a SiO_2 film, with the Si and SiO_2 phases assumed uniform, and the air/SiO_2 and SiO_2/Si interfaces considered as parallel planes. This is often referred to as the three-phase model. More complexity (and more layers) can be built into this basic SMM to represent such finer details as the interfacial roughness and phase mixing, a damage surface layer on Si caused by polishing, or the possible presence of an outermost contamination film. Effective medium theories[46–54] (EMTs) are used to calculate the dielectric functions of mixed phases based on their microstructure and component volume fractions; and the established theory of light reflection by stratified structures[55–60] is employed to calculate the ellipsometric function for an assumed set of model parameters. Finally, values of the model parameters are sought that best match the measured and computed values of ρ. Extensive data (obtained, e.g., using VASE) is required to determine the parameters of more complicated samples. The latter task, called the

inverse problem, usually employs linear regression analysis,[61–63] which yields information on parameter correlations and confidence limits. Therefore, the full practice of ellipsometry involves, in general, the execution and integration of three tasks: (1) polarization measurements that yield ratios of complex reflection coefficients, (2) sample modeling and the application of electromagnetic theory to calculate the ellipsometric function, and (3) solving the inverse problem to determine model parameters that best match the experimental and theoretically calculated values of the ellipsometric function.

Confidence in the model is established by showing that complete spectra can be described in terms of a few wavelength-independent parameters, or by checking the predictive power of the model in determining the optical properties of the sample under new experimental conditions.[27]

The Two-Phase Model

For a single interface between two homogeneous and isotropic media, 0 and 1, the reflection coefficients are given by the Fresnel formulas[1]

$$r_{01p} = (\epsilon_1 S_0 - \epsilon_0 S_1)/(\epsilon_1 S_0 + \epsilon_0 S_1) \tag{9}$$

$$r_{01s} = (S_0 - S_1)/(S_0 + S_1) \tag{10}$$

in which

$$\epsilon_i = N_i^2 \qquad i = 0, 1 \tag{11}$$

is the dielectric function (or dielectric constant at a given wavelength) of the *i*th medium,

$$S_i = (\epsilon_i - \epsilon_0 \sin^2 \phi)^{1/2} \tag{12}$$

and ϕ is the angle of incidence in medium 0 (measured from the interface normal). The ratio of complex reflection coefficients which is measured by ellipsometry is

$$\rho = [\sin\phi \tan\phi - (\epsilon - \sin^2\phi)^{1/2}]/[\sin\phi \tan\phi + (\epsilon - \sin^2\phi)^{1/2}] \tag{13}$$

where $\epsilon = \epsilon_1/\epsilon_0$. Solving Eq. (13) for ϵ gives

$$\epsilon_1 = \epsilon_0 \{\sin^2\phi + \sin^2\phi \tan^2\phi [(1-\rho)/(1+\rho)]^2\} \tag{14}$$

For light incident from a medium (e.g., vacuum, air, or an inert ambient) of known ϵ_0, Eq. (14) determines, concisely and directly, the complex dielectric function ϵ_1 of the reflecting second medium in terms of the measured ρ and the angle of incidence ϕ. This accounts for an important application of ellipsometry as a means of determining the optical properties (or *optical constants*) of bulk absorbing materials and opaque films. This approach assumes the absence of a transition layer or a surface film at the two-media interface. If such a film exists, ultrathin as it may be, ϵ_1 as determined by Eq. (14) is called the pseudo dielectric function and is usually written as $\langle \epsilon_1 \rangle$. Figure 3 shows lines of constant ψ and lines of constant Δ in the complex ϵ plane at $\phi = 75°$.

The Three-Phase Model

This often-used model, Fig. 4, consists of a single layer, medium 1, of parallel-plane boundaries which is surrounded by two similar or dissimilar semi-infinite media 0 and 2. The complex amplitude reflection coefficients are given by the Airy-Drude formula[64,65]

$$R = (r_{01\nu} + r_{12\nu} X)/(1 + r_{01\nu} r_{12\nu} X) \qquad \nu = p, s \tag{15}$$

$$X = \exp[-j2\pi(d/D_\phi)] \tag{16}$$

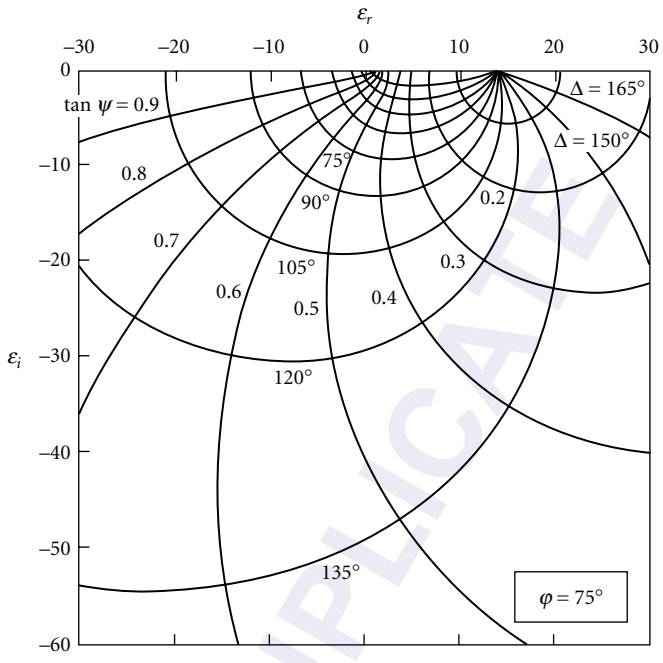

FIGURE 3 Contours of constant tan ψ and constant Δ in the complex plane of the relative dielectric function ϵ of a transparent medium/absorbing medium interface.

r_{ijv} is the Fresnel reflection coefficient of the ij interface ($ij = 01$ and 12) for the v polarization, d is the layer thickness, and

$$D_\phi = (\lambda/2)(1/S_1) \tag{17}$$

where λ is the vacuum wavelength of light and S_1 is given by Eq. (12). The ellipsometric function of this system is

$$\rho = (A + BX + CX^2)/(D + EX + FX^2) \tag{18}$$

$$\begin{aligned} A &= r_{01p} & B &= r_{12p} + r_{01p}r_{01s}r_{12s} & C &= r_{12p}r_{01s}r_{12s} \\ D &= r_{01s} & E &= r_{12s} + r_{01p}r_{01s}r_{12p} & F &= r_{12s}r_{01p}r_{12p} \end{aligned} \tag{19}$$

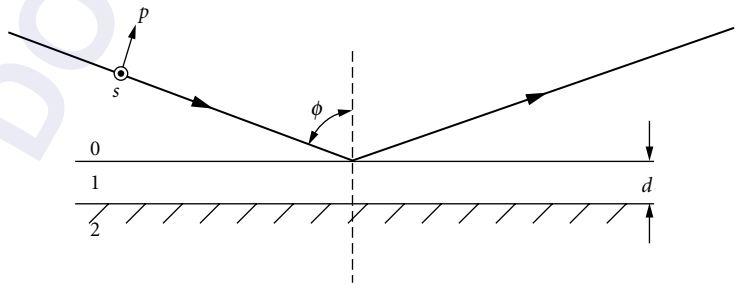

FIGURE 4 Three-phase, ambient-film-substrate system.

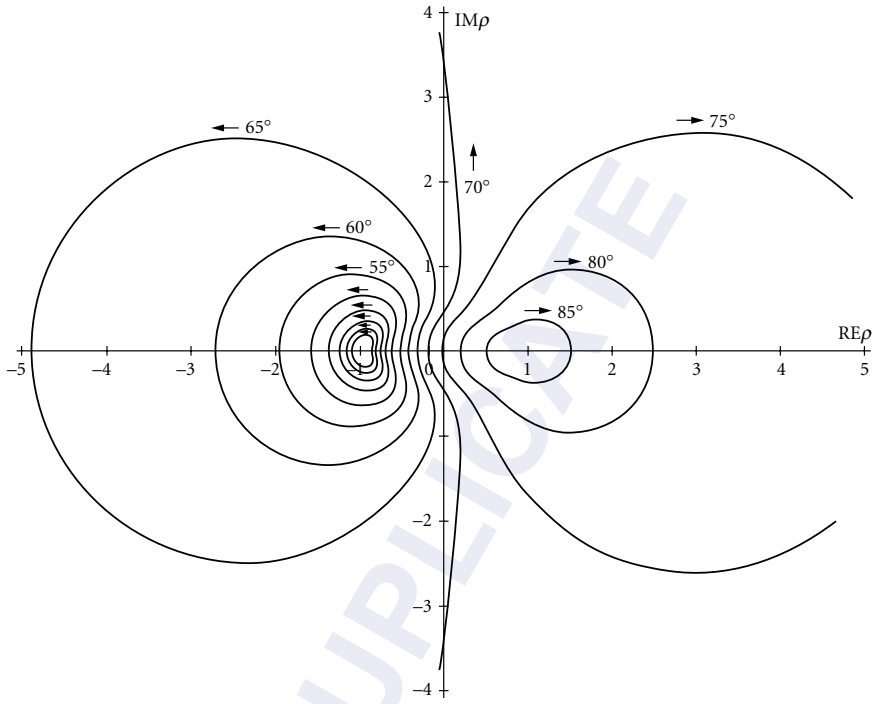

FIGURE 5 Family of constant-angle-of-incidence contours of the ellipsometric function ρ in the complex plane for light reflection in air by the SiO_2/Si film-substrate system at 633-nm wavelength. The contours are for angles of incidence from 30° to 85° in steps of 5°. The arrows indicate the direction of increasing film thickness.[66]

For a transparent film, and with light incident at an angle ϕ such that $\epsilon_1 > \epsilon_0 \sin^2\phi$ so that total reflection does not occur at the 01 interface, D_ϕ is real, and X, R_p, R_s, and ρ become periodic functions of the film thickness d with period D_ϕ. The locus of X is the unit circle in the complex plane and its multiple images through the conformal mapping of Eq. (18) at different values of ϕ give the constant-angle-of-incidence contours of ρ. Figure 5 shows a family of such contours[66] for light reflection in air by the SiO_2–Si system at 633-nm wavelength at angles from 30° to 85° in steps of 5°. Each and every value of ρ, corresponding to all points in the complex plane, can be realized by selecting the appropriate angle of incidence and the SiO_2 film thickness (within a period).

If the dielectric functions of the surrounding media are known, the dielectric function ϵ_1 and thickness d of the film are obtained readily by solving Eq. (18) for X,

$$X = \{-(B-\rho E) \pm [(B-\rho E)^2 - 4(C-\rho F)(A-\rho D)]^{1/2}\}/2(C-\rho F) \tag{20}$$

and requiring that[66,67]

$$|X| = 1 \tag{21}$$

Equation (21) is solved for ϵ_1 as its only unknown by numerical iteration. Subsequently, d is given by

$$d = [-\arg(X)/2\pi]D_\phi + mD_\phi \tag{22}$$

where m is an integer. The uncertainty of an integral multiple of the film thickness period is often resolved by performing measurements at more than one wavelength or angle of incidence and requiring that d be independent of λ or ϕ.

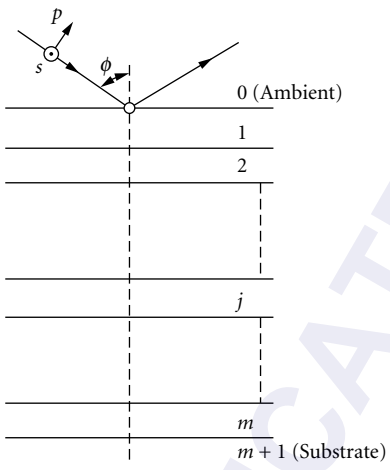

FIGURE 6 Light reflection by a multilayer structure.[1]

When the film is absorbing (semitransparent), or the optical properties of one of the surrounding media are unknown, more general inversion methods[68–72] are required which are directed toward minimizing an error function of the form

$$f = \sum_{i=1}^{N} [(\psi_{im} - \psi_{ic})^2 + (\Delta_{im} - \Delta_{ic})^2] \tag{23}$$

where ψ_{im}, ψ_{ic} and Δ_{im}, Δ_{ic} denote the ith measured and calculated values of the ellipsometric angles, and N is the total number of independent measurements.

Multilayer and Graded-Index Films

For an outline of the matrix theory of multilayer systems refer to Chap. 7, "Optical Properties of Films and Coatings," in Vol. IV. For our purposes, we consider a multilayer structure, Fig. 6, that consists of m plane-parallel layers sandwiched between semi-infinite ambient and substrate media (0 and $m + 1$, respectively). The relationships between the field amplitudes of the incident (i), reflected (r), and transmitted (t) plane waves for the p or s polarizations are determined by the scattering matrix equation[73]

$$\begin{bmatrix} E_i \\ E_r \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} E_t \\ 0 \end{bmatrix} \tag{24}$$

The complex-amplitude reflection and transmission coefficients of the entire structure are given by

$$\begin{aligned} R &= E_r / E_i = S_{21} / S_{11} \\ T &= E_t / E_i = 1 / S_{11} \end{aligned} \tag{25}$$

The scattering matrix $\mathbf{S} = (S_{ij})$ is obtained as an ordered product of all the interface $\mathbf{I}$ and layer $\mathbf{L}$ matrices of the stratified structure,

$$\mathbf{S} = \mathbf{I}_{01}\mathbf{L}_1\mathbf{I}_{12}\mathbf{L}_2 \cdots \mathbf{I}_{(j-1)j}\mathbf{L}_j \cdots \mathbf{L}_m\mathbf{I}_{m(m+1)} \tag{26}$$

and the numbering starts from layer 1 (in contact with the ambient) to layer m (adjacent to the substrate) as shown in Fig. 6. The interface scattering matrix is of the form

$$\mathbf{I}_{ab} = (1/t_{ab}) \begin{bmatrix} 1 & r_{ab} \\ r_{ab} & 1 \end{bmatrix} \tag{27}$$

where r_{ab} is the local Fresnel reflection coefficient of the $ab[j(j+1)]$ interface evaluated [using Eqs. (9) and (10) with the appropriate change of subscripts] at an incidence angle in medium a which is related to the external incidence angle ϕ in medium 0 by Snell's law. The associated interface transmission coefficients for the p and s polarizations are

$$\begin{aligned} t_{abp} &= 2(\epsilon_a \epsilon_b)^{1/2} S_a / (\epsilon_b S_a + \epsilon_a S_b) \\ t_{abs} &= 2S_a / (S_a + S_b) \end{aligned} \tag{28}$$

where S_j is defined in Eq. (12). The scattering matrix of the jth layer is

$$\mathbf{L}_j = \begin{bmatrix} Y_j^{-1} & 0 \\ 0 & Y_j \end{bmatrix} \tag{29}$$

$$Y_j = X_j^{1/2} \tag{30}$$

and X_j is given by Eqs. (16) and (17) with the substitution $d = d_j$ for the thickness, and $\epsilon_1 = \epsilon_j$ for the dielectric function of the jth layer.

Except in Eqs. (28), a polarization subscript $\nu = p$ or s has been dropped for simplicity. In reflection and transmission ellipsometry, the ratios $\rho_r = R_p / R_s$ and $\rho_t = T_p / T_s$ are measured. Inversion for the dielectric functions and thicknesses of some or all of the layers requires extensive data, as may be obtained by VASE, and linear regression analysis to minimize the error function of Eq. (23).

Light reflection and transmission by a graded-index (GRIN) film is handled using the scattering matrix approach described here by dividing the inhomogeneous layer into an adequately large number of sublayers, each of which is approximately homogeneous. In fact, this is the most general approach for a problem of this kind because analytical closed-form solutions are only possible for a few simple refractive-index profiles.[74–76]

Dielectric Function of a Mixed Phase

For a microscopically inhomogeneous thin film that is a mixture of two materials, as may be produced by coevaporation or cosputtering, or a thin film of one material that may be porous with a significant void fraction (of air), the dielectric function is determined using EMTs.[46–54] When the scale of the inhomogeneity is small relative to the wavelength of light, and the domains (or grains) of different dielectrics are of nearly spherical shape, the dielectric function of the mixed phase ϵ is given by

$$\frac{\epsilon - \epsilon_h}{\epsilon + 2\epsilon_h} = v_a \frac{\epsilon_a - \epsilon_h}{\epsilon_a + 2\epsilon_h} + v_b \frac{\epsilon_b - \epsilon_h}{\epsilon_b + 2\epsilon_h} \tag{31}$$

where ϵ_a and ϵ_b are the dielectric functions of the two component phases a and b with volume fractions v_a and v_b and ϵ_h is the host dielectric function. Different EMTs assign different values to ϵ_h. In the Maxwell Garnett EMT,[47,48] one of the phases, say b, is dominant ($v_b \gg v_a$) and $\epsilon_h = \epsilon_b$. This reduces the second term on the right-hand side of Eq. (31) to zero. In the Bruggeman EMT,[49] v_a and v_b are comparable, and $\epsilon_h = \epsilon$, which reduces the left-hand side of Eq. (31) to zero.

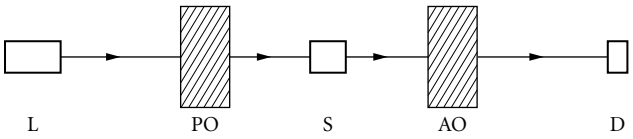

FIGURE 7 Generic ellipsometer with polarizing optics PO and analyzing optics AO. L and D are the light source and photodetector, respectively.

16.5 TRANSMISSION ELLIPSOMETRY

Although ellipsometry is typically carried out on the reflected wave, it is possible to also monitor the state of polarization of the transmitted wave, when such a wave is available for measurement.[77–81] For example, by combining reflection and transmission ellipsometry, the thickness and complex dielectric function of an absorbing film between transparent media of the same refractive index (e.g., a solid substrate on one side and an index-matching liquid on the other) can be obtained analytically.[79,80] Polarized light transmission by a multilayer was discussed previously under "Multilayer and Graded-Index Films." Transmission ellipsometry can be carried out at normal incidence on optically anisotropic samples to determine such properties as the natural or induced linear, circular, or elliptical birefringence and dichroism. However, this falls outside the scope of this chapter.

16.6 INSTRUMENTATION

Figure 7 is a schematic diagram of a generic ellipsometer. It consists of a source of collimated and monochromatic light L, polarizing optics PO on one side of the sample S, and polarization analyzing optics AO and a (linear) photodetector D on the other side. An apt terminology[25] refers to the PO as a polarization state generator (PSG) and the AO plus D as a polarization state detector (PSD).

Figure 8 shows the commonly used polarizer-compensator-sample-analyzer (PCSA) ellipsometer arrangement. The PSG consists of a linear polarizer with transmission-axis azimuth P and a linear retarder, or compensator, with fast-axis azimuth C. The PSD consists of a single linear polarizer, that functions as an analyzer, with transmission-axis azimuth A followed by a photodetector D.

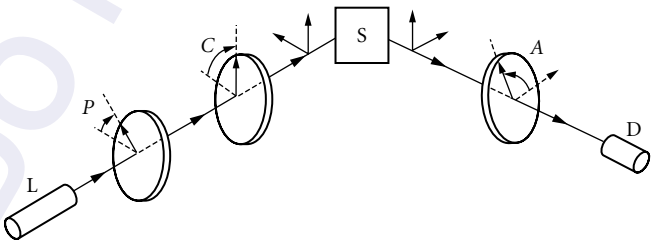

FIGURE 8 Polarizer-compensator-sample-analyzer (PCSA) ellipsometer. The azimuth angles P of the polarizer, C of the compensator (or quarter-wave retarder), and A of the analyzer are measured from the plane of incidence, positive in a counterclockwise sense when looking toward the source.[1]

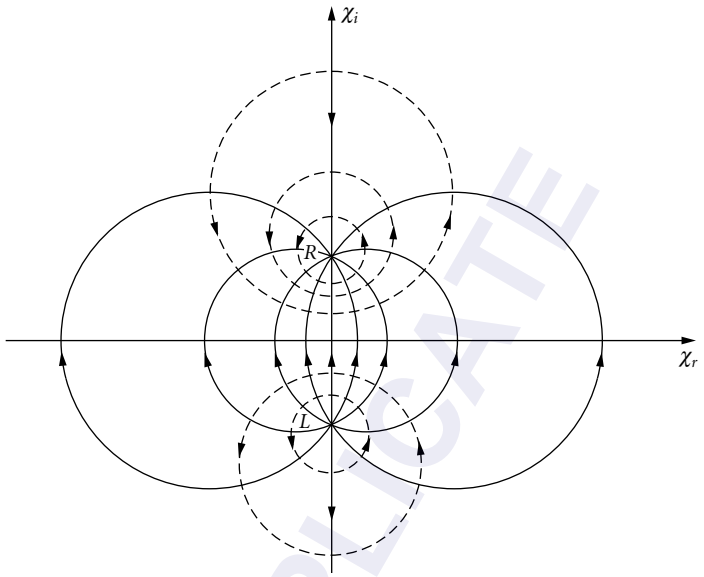

FIGURE 9 Constant C, variable *P* contours (continuous lines), and constant *P* − *C*, variable *C* contours (dashed lines) in the complex plane of polarization for light transmitted by a polarizer-compensator (PC) polarization state generator.[1]

All azimuths *P*, *C*, and *A*, are measured from the plane of incidence, positive in a counterclockwise sense when looking toward the source. The state of polarization of the light transmitted by the PSG and incident on S is given by

$$\chi_i = [\tan C + \rho_c \tan(P - C)]/[1 - \rho_c \tan C \tan(P - C)] \tag{32}$$

where $\rho_c = T_{cs}/T_{cf}$ is the ratio of complex amplitude transmittances of the compensator for incident linear polarizations along the slow *s* and fast *f* axes. Ideally, the compensator functions as a quarter-wave retarder (QWR) and $\rho_c = -j$. In this case, Eq. (32) describes an elliptical polarization state with major-axis azimuth *C* and ellipticity angle $-(P - C)$. (The tangent of the ellipticity angle equals the minor-axis-to-major-axis ratio and its sign gives the handedness of the polarization state, positive for right-handed states.) All possible states of total polarization χ_i can be generated by controlling *P* and *C*. Figure 9 shows a family of constant *C,* variable *P* contours (continuous lines) and constant *P* − *C*, variable *C* contours (dashed lines) as orthogonal families of circles in the complex plane of polarization. Figure 10 shows the corresponding contours of constant *P* and variable *C*. The points *R* and *L* on the imaginary axis at (0, +1) and (0, −1) represent the right- and left-handed circular polarization states, respectively.

Null Ellipsometry

The PCSA ellipsometer of Fig. 8 can be operated in two different modes. In the null mode, the output signal of the photodetector D is reduced to zero (a minimum) by adjusting the azimuth angles *P* of the polarizer and *A* of the analyzer with the compensator set at a fixed azimuth *C*. The choice $C = \pm 45°$ results in rapid convergence to the null. Two independent nulls are reached for each compensator setting. The two nulls obtained with $C = +45°$ are usually referred to as the nulls in zones 2 and 4; those for $C = -45°$ define zones 1 and 3. At null, the reflected polarization is linear and is

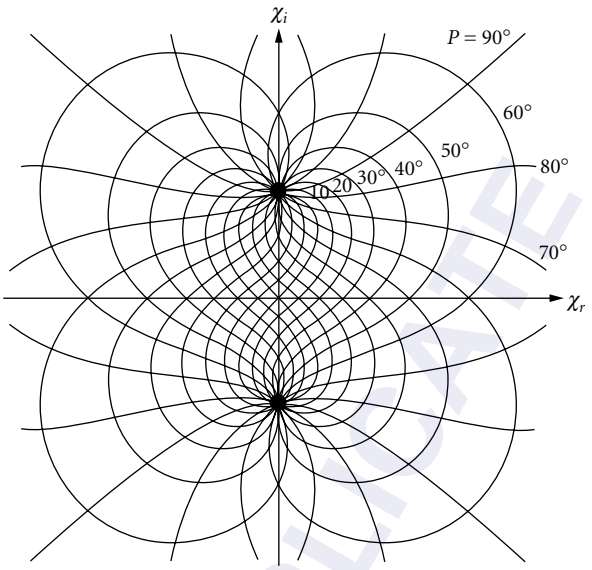

FIGURE 10 Constant *P*, variable *C* contours in the complex plane of polarization for light transmitted by a polarizer-compensator (PC) polarization state generator.[1]

crossed with the transmission axis of the analyzer; therefore, the reflected state of polarization is given by

$$\chi_r = -\cot A \tag{33}$$

where A is the analyzer azimuth at null. With the incident and reflected polarizations determined by Eqs. (32) and (33), the ratio of complex reflection coefficients of the sample for the *p* and *s* linear polarizations ρ is obtained by Eq. (2). Whereas a single null is sufficient to determine ρ in an ideal ellipsometer, results from multiple nulls (in two or four zones) are usually averaged to eliminate the effect of small component imperfections and azimuth-angle errors. Two-zone measurements are also used to determine ρ of the sample and ρ_c of the compensator simultaneously.[82–84] The effects of component imperfections have been considered extensively.[85]

The null ellipsometer can be automated by using stepping or servo motors[86,87] to rotate the polarizer and analyzer under closed-loop feedback control; the procedure is akin to that of nulling an ac bridge circuit. Alternatively, Faraday cells can be inserted after the polarizer and before the analyzer to produce magneto-optical rotations in lieu of the mechanical rotation of the elements.[88–90] This reduces the measurement time of a null ellipsometer from minutes to milliseconds. Large (±90°) Faraday rotations would be required for limitless compensation. Small ac modulation is often added for the precise localization of the null.

Photometric Ellipsometry

The polarization state of the reflected light can also be detected photometrically by rotating the analyzer[91–95] of the PCSA ellipsometer and performing a Fourier analysis of the output signal I of the linear photodetector D. The detected signal waveform is simply given by

$$I = I_0(1 + \alpha \cos 2A + \beta \sin 2A) \tag{34}$$

and the reflected state of polarization is determined from the normalized Fourier coefficients α and β by

$$\chi_r = [\beta \pm (1-\alpha^2-\beta^2)^{1/2}]/(1+\alpha) \tag{35}$$

The sign ambiguity in Eq. (35) indicates that the rotating-analyzer ellipsometer (RAE) cannot determine the handedness of the reflected polarization state. In the RAE, the compensator is not essential and can be removed from the input PO (i.e., the PSA instead of the PCSA optical train is used). Without the compensator, the incident linear polarization is described by

$$\chi_i = \tan P \tag{36}$$

Again, the ratio of complex reflection coefficients of the sample ρ is determined by substituting Eqs. (35) and (36) in Eq. (2). The absence of the wavelength-dependent compensator makes the RAE particularly qualified for SE. The dual of the RAE is the rotating-polarizer ellipsometer which is suited for real-time SE using a spectrograph and a photodiode array that are placed after the fixed analyzer.[31]

A photometric ellipsometer with no moving parts, for fast measurements on the microsecond time scale, employs a photoelastic modulator[96–100] (PEM) in place of the compensator of Fig. 8. The PEM functions as an oscillating-phase linear retarder in which the relative phase retardation is modulated sinusoidally at a high frequency (typically 50 to 100 kHz) by establishing an elastic ultrasonic standing wave in a transparent solid. The output signal of the photodetector is represented by an infinite Fourier series with coefficients determined by Bessel functions of the first kind and argument equal to the retardation amplitude. However, only the dc, first, and second harmonics of the modulation frequency are usually detected (using lock-in amplifiers) and provide sufficient information to retrieve the ellipsometric parameters of the sample.

Numerous other ellipsometers have been introduced[25] that employ more elaborate PSDs. For example Fig. 11 shows a family of rotating-element photopolarimeters[25] (REP) that includes the RAE. The column on the right represents the Stokes vector and the fat dots identify the Stokes

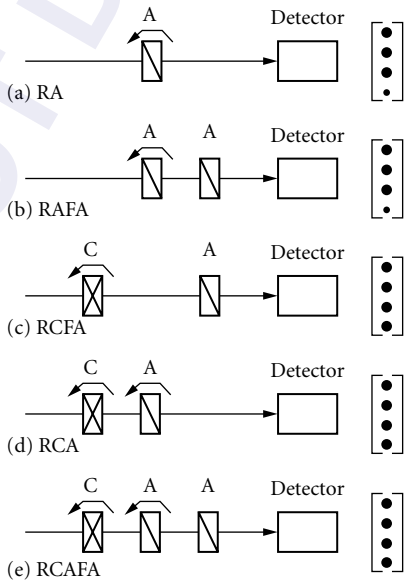

FIGURE 11 Family of rotating-element photo-polarimeters (REP) and the Stokes parameters that they can determine.[25]

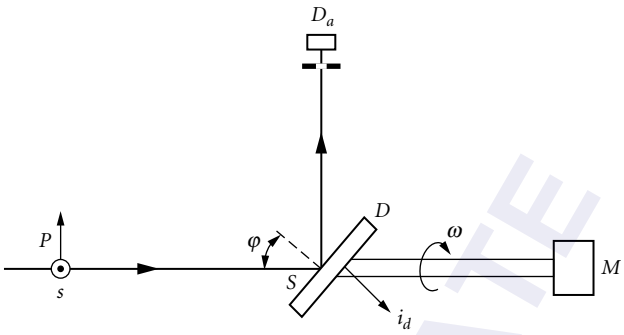

FIGURE 12 Rotating-detector ellipsometer (RODE).[102]

parameters that are measured. (For a discussion of the Stokes parameters, see Chap. 12 in this volume of the *Handbook*.) The simplest complete REP, that can determine all four Stokes parameters of light, is the rotating-compensator fixed-analyzer (RCFA) photopolarimeter originally invented to measure skylight polarization.[101] The simplest handedness-blind REP for totally polarized light is the rotating-detector ellipsometer[102,103] (RODE), Fig. 12, in which the tilted and partially reflective front surface of a solid-state (e.g., Si) detector performs as polarization analyzer.

Ellipsometry Using Four-Detector Photopolarimeters

A new class of fast PSDs that measure the general state of partial or total polarization of a quasi-monochromatic light beam is based on the use of four photodetectors. Such PSDs employ the division of wavefront, the division of amplitude, or a hybrid of the two, and do not require any moving parts or modulators. Figure 13 shows a division-of-wavefront photopolarimeter (DOWP)[104] for

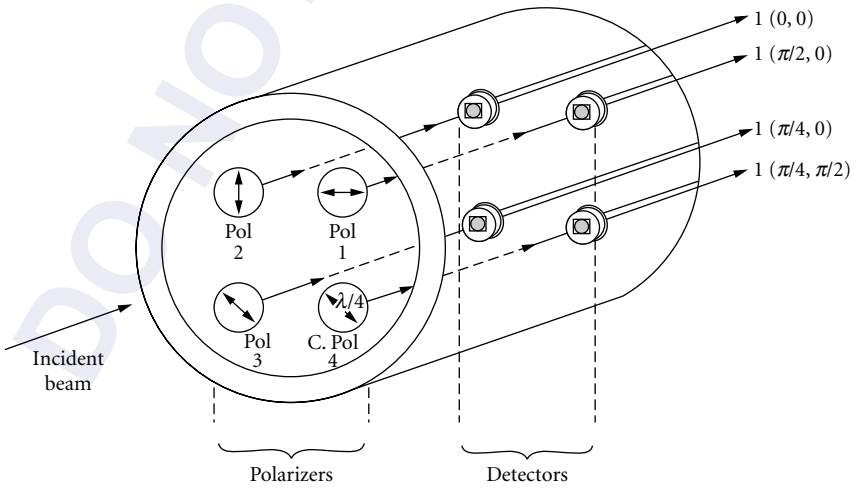

FIGURE 13 Division-of-wavefront photopolarimeter for the simultaneous measurement of all four Stokes parameters of light.[104]

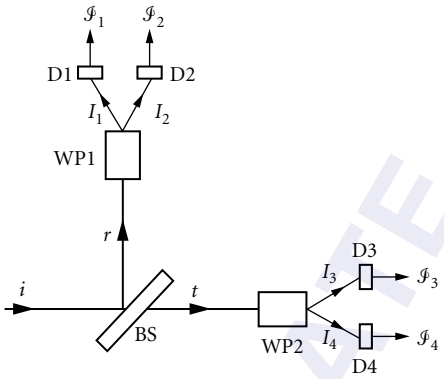

FIGURE 14 Division-of-amplitude photopolarimeter (DOAP) for the simultaneous measurement of all four Stokes parameters of light.[107]

performing ellipsometry with nanosecond laser pulses. The DOWP has been adopted recently in commercial automatic polarimeters for the fiber-optics market.[105,106]

Figure 14 shows a division-of-amplitude photopolarimeter[107,108] (DOAP) with a coated beam splitter BS and two Wollaston prisms WP1 and WP2, and Fig. 15 represents a recent implementation[109] of that technique. The multiple-beam-splitting and polarization-altering properties of grating diffraction are also well-suited for the DOAP.[110,111]

The simplest DOAP consists of a spatial arrangement of four solid-state photodetectors Fig. 16, and no other optical elements. The first three detectors (D_0, D_1, and D_2) are partially specularly reflecting and the fourth (D_3) is antirefiection-coated. The incident light beam is steered in such a way that the plane of incidence is rotated between successive oblique-incidence reflections, hence

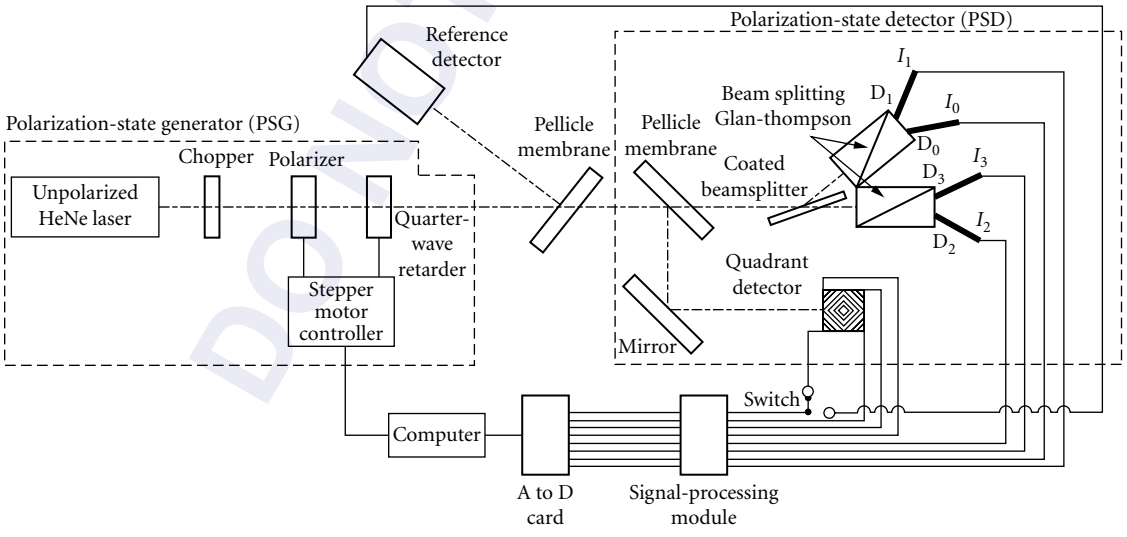

FIGURE 15 Recent implementation of DOAP.[109]

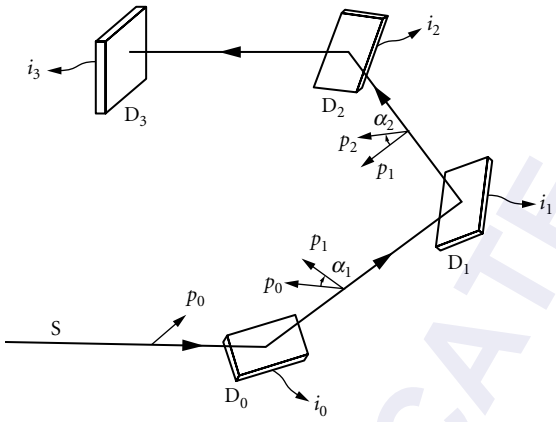

FIGURE 16 Four-detector photopolarimeter for the simultaneous measurement of all four Stokes parameters of light.[112]

the light path is nonplanar. In this four-detector photopolarimeter[112–117] (FDP), and in other DOAPs, the four output signals of the four linear photodetectors define a current vector $\mathbf{I} = [I_0\ I_1\ I_2\ I_3]^t$ which is linearly related,

$$\mathbf{I} = \mathbf{AS} \tag{37}$$

to the Stokes vector $\mathbf{S} = [S_0\ S_1\ S_2\ S_3]^t$ of the incident light, where t indicates the matrix transpose. The 4×4 instrument matrix $\mathbf{A}$ is determined by calibration[115] (using a PSG that consists of a linear polarizer and a quarter-wave retarder). Once $\mathbf{A}$ is determined, $\mathbf{S}$ is obtained from the output signal vector by

$$\mathbf{S} = \mathbf{A}^{-1}\mathbf{I} \tag{38}$$

where $\mathbf{A}^{-1}$ is the inverse of $\mathbf{A}$. When the light under measurement is totally polarized (i.e., $S_0^2 = S_1^2 + S_2^2 + S_3^2$), the associated complex polarization number is determined in terms of the Stokes parameters as[118]

$$\chi = (S_2 + jS_3)/(S_0 + S_1) = (S_0 - S_1)/(S_2 - jS_3) \tag{39}$$

For further information on polarimetry, see Chap. 15 in this volume.

Ellipsometry Based on Azimuth Measurements Alone

Measurements of the azimuths of the elliptic vibrations of the light reflected from an optically isotropic surface, for two known vibration directions of incident linearly polarized light, enable the ellipsometric parameters of the surface to be determined at any angle of incidence. If θ_i and θ_r represent the azimuths of the incident linear and reflected elliptical polarizations, respectively, then[119–121]

$$\tan 2\theta_r = (2\tan\theta_i \tan\psi \cos\Delta)/(\tan^2\psi - \tan^2\theta_i) \tag{40}$$

A pair of measurements (θ_{i1}, θ_{r1}) and (θ_{i2}, θ_{r2}) determines ψ and Δ via Eq. (40). The azimuth of the reflected polarization is measured precisely by an ac-null method using an ac-excited Faraday

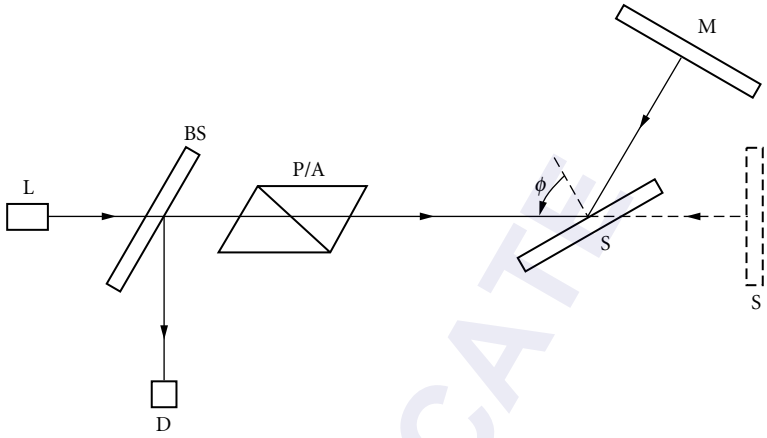

FIGURE 17 Return-path ellipsometer. The dashed lines indicate the configuration for perpendicular-incidence ellipsometry on optically anisotropic samples.[126]

cell followed by a linear analyzer.[119] The analyzer is rotationally adjusted to zero the fundamental-frequency component of the detected signal; this aligns the analyzer transmission axis with the minor or major axis of the reflected polarization ellipse.

Return-Path Ellipsometry

In a return-path ellipsometer (RPE), Fig. 17, an optically isotropic mirror M is placed in, and perpendicular to, the reflected beam. This reverses the direction of the beam, so that it retraces its path toward the source with a second reflection at the test surface S and second passage through the polarizing/analyzing optics P/A. A beam splitter BS sends a sample of the returned beam to the photodetector D. The RPE can be operated in the null or photometric mode.

In the simplest RPE,[122,123] the P/A optics consists of a single linear polarizer whose azimuth and the angle of incidence are adjusted for a zero detected signal. At null, the angle of incidence is the principal angle, hence $\Delta = \pm 90°$, and the polarizer azimuth equals the principal azimuth, so that the incident linearly polarized light is reflected circularly polarized. Null can also be obtained at a general and fixed angle of incidence by adding a compensator to the P/A optics. Adjustment of the polarizer azimuth and the compensator azimuth or retardance produces the null.[124,125] In the photometric mode,[126] an element of the P/A is modulated periodically and the detected signal is Fourier-analyzed to extract ψ and Δ.

RPEs have the following advantages: (1) the same optical elements are used as polarizing and analyzing optics; (2) only one optical port or window is used for light entry into and exit from the chamber in which the sample may be mounted; and (3) the sensitivity to surface changes is increased because of the double reflection at the sample surface.

Perpendicular-Incidence Ellipsometry

Normal-incidence reflection from an optically isotropic surface is accompanied by a trivial change of polarization due to the reversal of the direction of propagation of the beam (e.g., right-handed circularly polarized light is reflected as left-handed circularly polarized). Because this change of polarization is not specific to the surface, it cannot be used to determine the properties of the

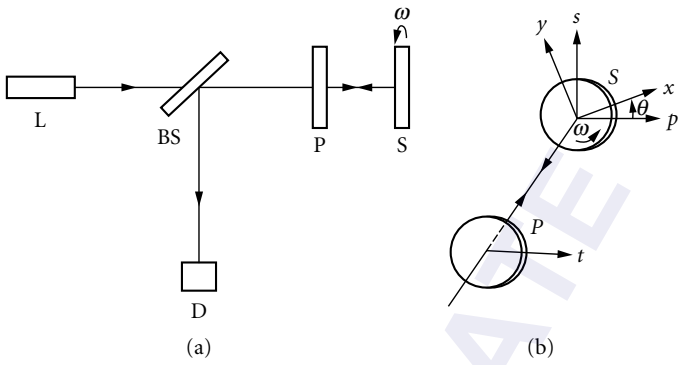

FIGURE 18 Normal-incidence rotating-sample ellipsometer (NIRSE).[128]

reflecting structure. This is why ellipsometry of isotropic surfaces is performed at oblique incidence. However, if the surface is optically anisotropic, perpendicular-incidence ellipsometry (PIE) is possible and offers two significant advantages: (1) simpler single-axis instrumentation of the return-path type with common polarizing/analyzing optics, and (2) simpler inversion for the sample optical properties, because the equations that govern the reflection of light at normal incidence are much simpler than those at oblique incidence.[127,128]

Like RPE, PIE can be performed using null or photometric techniques.[126–132] For example, Fig. 18 shows a simple normal-incidence rotating-sample ellipsometer[128] (NIRSE) that is used to measure the ratio of the complex principal reflection coefficients of an optically anisotropic surface S with principal axes x and y. (The incident linear polarizations along these axes are the eigenpolarizations of reflection.) If we define

$$\eta = (R_{xx} - R_{yy})/(R_{xx} + R_{yy}) \tag{41}$$

then

$$\eta = \{a_2 \pm j[8a_4(1-a_4) - a_2^2]^{1/2}\}/2(1-a_4) \tag{42}$$

R_{xx} and R_{yy} are the complex-amplitude principal reflection coefficients of the surface, and a_2 and a_4 are the amplitudes of the second and fourth harmonic components of the detected signal normalized with respect to the dc component. From Eq. (41), we obtain

$$\rho = R_{yy}/R_{xx} = (1-\eta)/(1+\eta) \tag{43}$$

PIE can be used to determine the optical properties of bare and coated uniaxial and biaxial crystal surfaces.[127–130,133]

Interferometric Ellipsometry

Ellipsometry using interferometer arrangements with polarizing optical elements has been suggested and demonstrated.[134–136] Compensators are not required because the relative phase shift is obtained by the unbalance between the two interferometer arms; this offers a distinct advantage for SE. Direct display of the polarization ellipse is possible.[134–136]

16.7 JONES-MATRIX GENERALIZED ELLIPSOMETRY

For light reflection at an anisotropic surface, the *p* and *s* linear polarizations are not, in general, the eigenpolarizations of reflection. Consequently, the reflection of light is no longer described by Eqs. (1). Instead, the Jones (electric) vectors of the reflected and incident waves are related by

$$\begin{bmatrix} E_{rp} \\ E_{rs} \end{bmatrix} = \begin{bmatrix} R_{pp} & R_{ps} \\ R_{sp} & R_{ss} \end{bmatrix} \begin{bmatrix} E_{ip} \\ E_{is} \end{bmatrix} \tag{44}$$

or, more compactly,

$$\mathbf{E}_r = \mathbf{R}\mathbf{E}_i \tag{45}$$

where **R** is the nondiagonal reflection Jones matrix. The states of polarization of the incident and reflected waves, described by the complex variables χ_i and χ_r of Eqs. (4), are interrelated by the bilinear transformation[85,137]

$$\chi_r = (R_{ss}\chi_i + R_{sp})/(R_{ps}\chi_i + R_{pp}) \tag{46}$$

In generalized ellipsometry (GE), the incident wave is polarized in at least three different states (χ_{i1}, χ_{i2}, χ_{i3}) and the corresponding states of polarization of the reflected light (χ_{r1}, χ_{r2}, χ_{r3}) are measured. Equation (46) then yields three equations that are solved for the normalized Jones matrix elements, or reflection coefficients ratios,[138]

$$\begin{aligned} R_{pp}/R_{ss} &= (\chi_{i2} - \chi_{i1}H)/(-\chi_{r1} + \chi_{r2}H) \\ R_{ps}/R_{ss} &= (H-1)/(-\chi_{r1} + \chi_{r2}H) \\ R_{sp}/R_{ss} &= (\chi_{i2}\chi_{r1} - \chi_{i1}\chi_{r2}H)/(-\chi_{r1} + \chi_{r2}H) \\ H &= (\chi_{r3} - \chi_{r1})(\chi_{i3} - \chi_{i2})/(\chi_{i3} - \chi_{i1})(\chi_{r3} - \chi_{r2}) \end{aligned} \tag{47}$$

Therefore, the nondiagonal Jones matrix of any optically anisotropic surface is determined, up to a complex constant multiplier, from the mapping of three incident polarizations into the corresponding three reflected polarizations. A PCSA null ellipsometer can be used. The incident polarization χ_i is given by Eq. (32) and the reflected polarization χ_r is given by Eq. (33). Alternatively, the Stokes parameters of the reflected light can be measured using the RCFA photopolarimeter, the DOAP, or the FDP, and χ_r is obtained from Eq. (39). More than three measurements can be taken to overdetermine the normalized Jones matrix elements and reduce the effect of component imperfections and measurement errors. GE can be performed based on azimuth measurements alone.[139] The main application of GE has been the determination of the optical properties of crystalline materials.[138–143]

16.8 MUELLER-MATRIX GENERALIZED ELLIPSOMETRY

The most general representation of the transformation of the state of polarization of light upon reflection or scattering by an object or sample is described by[1]

$$\mathbf{S}' = \mathbf{M}\mathbf{S} \tag{48}$$

where **S** and **S′** are the Stokes vectors of the incident and scattered radiation, respectively, and **M** is the real 4 × 4 Mueller matrix that succinctly characterizes the linear (or elastic) light-sample interaction.

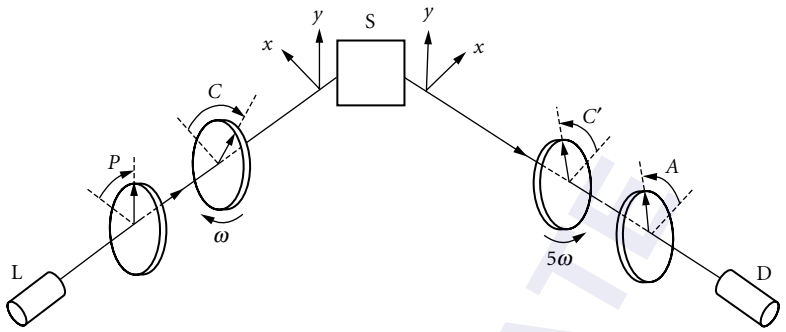

FIGURE 19 Dual-rotating-retarder Mueller-matrix photopolarimeter.[145]

For light reflection at an optically isotropic and specular (smooth) surface, the Mueller matrix assumes the simple form[144]

$$\mathbf{M} = r\begin{bmatrix} 1 & a & 0 & 0 \\ a & 1 & 0 & 0 \\ 0 & 0 & b & c \\ 0 & 0 & -c & b \end{bmatrix} \tag{49}$$

In Eq. (49), r is the surface power reflectance for incident unpolarized or circularly polarized light, and a, b, c are determined by the ellipsometric parameters ψ and Δ as:

$$a = -\cos 2\psi \qquad b = \sin 2\psi \cos \Delta \qquad \text{and} \qquad c = \sin 2\psi \sin \Delta \tag{50}$$

and satisfy the identity $a^2 + b^2 + c^2 = 1$.

In general (i.e., for an optically anisotropic and rough surface), all 16 elements of **M** are nonzero and independent.

Several methods for Mueller matrix measurements have been developed.[25,145–149] An efficient scheme[145–147] uses the PCSC′A ellipsometer with symmetrical polarizing (PC) and analyzing (C′A) optics, Fig. 19. All 16 elements of the Mueller matrix are encoded onto a single periodic detected signal by rotating the quarter-wave retarders (or compensators) C and C' at angular speeds in the ratio 1:5. The output signal waveform is described by the Fourier series

$$I = a_0 + \sum_{n=1}^{12} (a_n \cos nC + b_n \sin nC) \tag{51}$$

where C is the fast-axis azimuth of the slower of the two retarders, measured from the plane of incidence. Table 1 gives the relations between the signal Fourier amplitudes and the elements of the

TABLE 1 Relations Between Signal Fourier Amplitudes and Elements of the Scaled Mueller Matrix **M′**

n	0	1	2	3	4	5	6
a_n	$m'_{11} + \frac{1}{2}m'_{12} + \frac{1}{2}m'_{21} + \frac{1}{4}m'_{22}$	0	$\frac{1}{2}m'_{12} + \frac{1}{4}m'_{22}$	$-\frac{1}{4}m'_{43}$	$-\frac{1}{2}m'_{44}$	0	$\frac{1}{2}m'_{44}$
b_n		$m'_{14} + \frac{1}{2}m'_{24}$	$\frac{1}{2}m'_{13} + \frac{1}{4}m'_{23}$	$-\frac{1}{4}m'_{42}$	0	$-m'_{41} - \frac{1}{2}m'_{42}$	0
n	7	8	9	10	11	12	
a_n	$\frac{1}{4}m'_{43}$	$\frac{1}{8}m'_{22} + \frac{1}{8}m'_{33}$	$\frac{1}{4}m'_{34}$	$\frac{1}{2}m'_{21} + \frac{1}{4}m'_{22}$	$-\frac{1}{4}m'_{34}$	$\frac{1}{8}m'_{22} - \frac{1}{8}m'_{33}$	
b_n	$-\frac{1}{4}m'_{42}$	$-\frac{1}{8}m'_{23} + \frac{1}{8}m'_{32}$	$-\frac{1}{4}m'_{24}$	$\frac{1}{2}m'_{31} + \frac{1}{4}m'_{32}$	$\frac{1}{4}m'_{24}$	$\frac{1}{8}m'_{23} + \frac{1}{8}m'_{32}$	

The transmission axes of the polarizer and analyzer are assumed to be set at 0 azimuth, parallel to the scattering plane or the plane of incidence.

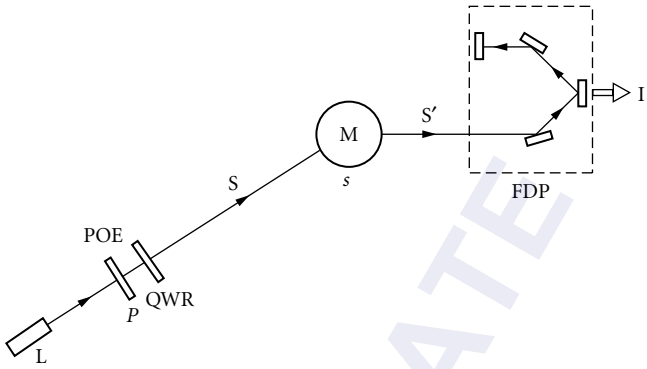

FIGURE 20 Scheme for Mueller-matrix measurement using the four-detector photopolarimeter.[152]

Mueller matrix **M′** which differs from **M** only by a scale factor. Inasmuch as only the normalized Mueller matrix, with unity first element, is of interest, the unknown scale factor is immaterial. This dual-rotating-retarder Mueller-matrix photopolarimeter has been used to characterize rough surfaces[150] and the retinal nerve-fiber layer.[151]

Another attractive scheme for Mueller-matrix measurement is shown in Fig. 20. The FDP (or equivalently, any other DOAP) is used as the PSD. Fourier analysis of the output current vector of the FDP, **I**(*C*), as a function of the fast-axis azimuth *C* of the QWR of the input PO readily determines the Mueller matrix **M,** column by column.[152,153]

16.9 APPLICATIONS

The applications of ellipsometry are too numerous to try to cover in this chapter. The reader is referred to the books and review articles listed in the bibliography. Suffice it to mention the general areas of application. These include: (1) measurement of the optical properties of materials in the visible, IR, and near-UV spectral ranges. The materials may be in bulk or thin-film form and may be optically isotropic or anisotropic.[3,22,27–31] (2) Thin-film thickness measurements, especially in the semiconductor industry.[2,5,24] (3) Controlling the growth of optical multilayer coatings[154] and quantum wells.[155,156] (4) Characterization of physical and chemical adsorption processes at the vacuum/solid, gas/solid, gas/liquid, liquid/liquid, and liquid/solid interfaces.[26,157] (5) Study of the oxidation kinetics of semiconductor and metal surfaces in various gaseous or liquid ambients.[158] (6) Electrochemical investigations of the electrode/electrolyte interface.[18,19,32] (7) Diffusion and ion implantation in solids.[159] (8) Biological and biomedical applications.[16,20,151,160]

17.1 GLOSSARY

a, b	first and second lenses
AChr	axial chromatic aberration
AST	astigmatism
b	factor
bfl	back focal length
C_o	scaling factor
c	curvature
C_1	scaling factor
C_2	scaling factor
CC	conic constant
CMA_s	sagittal coma
CMA_t	tangential coma
D_{ep}	diameter of entrance pupil
d_o	distance from object to loupe
d_e	distance from loupe to the eye
E	irradiance
efl	effective focal length
ep	eyepiece
FN	F-number
f	focal length
h	height above axis
H_i	height of ray intercept in image plane
K	shape factor
i	image
$J_1()$	Bessel function of the first kind
k	$2\pi/\lambda$

L	length
MP	magnifying power [cf. linear lateral longitudinal magnification]
m	linear, lateral magnification
m_{oc}	nodal-point to optical-center magnification
$\bar{m}$	linear, longitudinal magnification
MTF	modulation transfer function
M	factor
n	refractive index
NA	numerical aperture
o	object
obj	objective
P	partial dispersion
P_i	principal points
p	$=s_d/f_a$
$\tilde{\mathfrak{R}}$	peak normalized spectral weighting function
s	object to image distance
SA3	third-order spherical aberration
SAC	secondary angular spectrum
s_i	image distance
s_{ot}	optical tube length
s_o	object distance
TPAC	transverse primary chromatic aberration
t	thickness
u	slope
V	Abbe number or reciprocal dispersion
υ	φ-normalized reciprocal object distance $1/s_o\varphi$
x, y, z	cartesian coordinates
β	angular blur diameter
δ	depth of focus
ζ	sag
$\Delta\theta$	angular blur tolerance
θ	field of view
λ	wavelength
ν	spatial frequency
ϕ	lens power
r	radius
σ	standard deviation of the irradiance distribution
τ	transmission
Ω	normalized spatial frequency

17.2 INTRODUCTION

This chapter provides a basic understanding of using lenses for image formation and manipulation. The principles of image formation are reviewed first. The effects of lens shape, index of refraction, magnification, and F-number on the image quality of a singlet lens are discussed in some detail. Achromatic doublets and more complex lens systems are covered next. A representative variety of lenses is analyzed

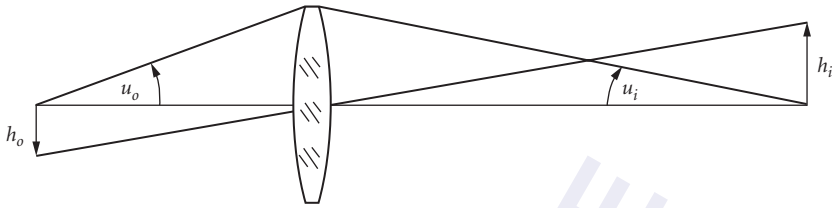

FIGURE 1 Imaging by a simple lens.

and discussed. Performance that may be expected of each class of lens is presented. The section concludes with several techniques for rapid estimation of the performance of lenses. Refer to Chap. 1 "Geometrical Optics," in this volume for further discussion of geometrical optics and aberrations.

17.3 BASICS

Figure 1 illustrates an image being formed by a simple lens. The object height is h_o and the image height is h_i with u_o and u_i being the corresponding slope angles. It follows from the Lagrange invariant that the *lateral magnification* is defined to be

$$\begin{aligned} m &\equiv \frac{h_i}{h_o} \\ &= \frac{(nu)_0}{(nu)_i} \end{aligned} \tag{1}$$

where n_o and n_i are the refractive indices of the medium in which the object and image lie, respectively. By convention, a height is positive if above the optical axis and a ray angle is positive if its slope angle is positive. Distances are positive if the ray propagates left to right. Since the Lagrange invariant is applicable for paraxial rays, the angle nu should be understood to mean n tan u. This interpretation applies to all paraxial computations. For an *aplanatic* lens, which is free of spherical aberration and linear coma, the magnification can by the *optical sine theorem* be given by

$$\begin{aligned} m &\equiv \frac{h_i}{h_o} \\ &= \frac{n_o \sin u_o}{n_i \sin u_i} \end{aligned} \tag{2}$$

If the object is moved a small distance ∂s_o longitudinally, the corresponding displacement of the image ∂s_i can be found by the differential form of the basic imaging equation and leads to an equation analogous to the Lagrange invariant. The *longitudinal magnification* is then defined as

$$\begin{aligned} \bar{m} &\equiv \frac{\partial s_i}{\partial s_o} \\ &= \frac{(nu^2)_0}{(nu^2)_i} \\ &= m^2 \left[\frac{n_i}{n_o} \right] \end{aligned} \tag{3}$$

The following example will illustrate one application of m and $\bar{m}$. Consider that a spherical object of radius r_o is to be imaged as shown in Fig. 2. The equation of the object is $r_o^2 = y_o^2 + z^2$, where z is measured along the optical axis and is zero at the object's center of curvature. Letting the surface sag

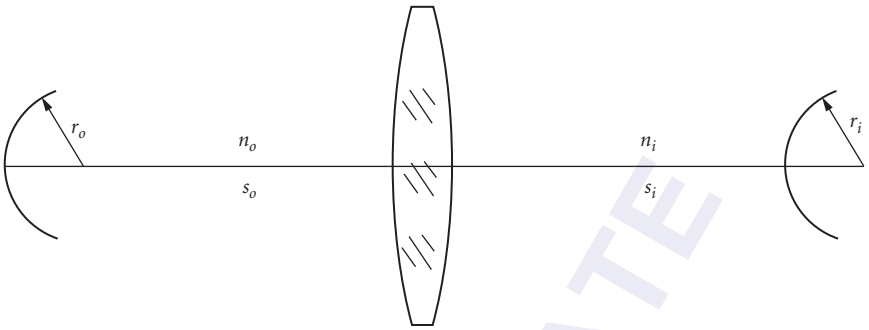

FIGURE 2 Imaging of a spherical object by a lens.

as measured from the vertex plane of the object be denoted as ζ_o the equation of the object becomes $r_o^2 = (r_o - \zeta_o)^2 + y_o^2$ since $z = r_o - \zeta_o$. In the region near the optical axis, $\zeta_o^2 \ll r_o^2$, which implies that $r_o \approx y_o^2/2\zeta_o$. The image of the object is expressed in the transverse or lateral direction by $y_i = my_o$ and in the longitudinal or axial direction by $\zeta_i = \bar{m}\zeta_o = \zeta_o m^2(n_i/n_o)$. In a like manner, the image of the spherical object is expressed as $r_i \approx (y_i)^2/2\zeta_i$. By substitution, the sag of the image is expressed by

$$\begin{aligned} r_i &\equiv \frac{n_o y_o^2}{2n_i \xi_o} \\ &= r_o\left[\frac{n_o}{n_i}\right] \end{aligned} \tag{4}$$

Hence, in the paraxial region about the optical axis, the radius of the image of a spherical object is independent of the magnification and depends only on the ratio of the refractive indices of the object and image spaces.

When an optical system as shown in Fig. 3 images a tilted object, the image will also be tilted. By employing the concept of lateral and longitudinal magnification, it can be easily shown that the

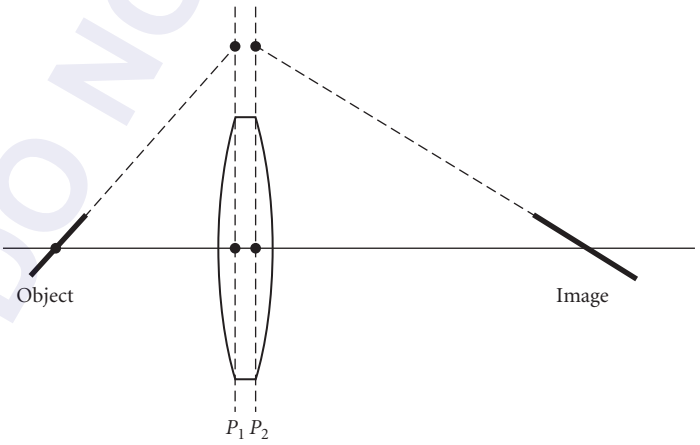

FIGURE 3 Imaging of a tilted object illustrating the Scheimpflug condition.

intersection height of the object plane with the first principal plane P_1 of the lens must be the same as the intersection height of the image plane with the second principal plane P_2 of the lens. This principle is known as the *Scheimpflug condition.*

The object-image relationship of a lens system is often described with respect to its *cardinal points,* which are the *principal and focal points* (conceived by Carl Gauss in 1841) and *nodal points* (conceived by Johann Listing in 1845). Gauss demonstrated that, so far as paraxial rays are concerned, a lens of any degree of complexity can be replaced by its cardinal points, viz., two principal points and two focal points, where the distances from the principal points to their respective focal points being the focal lengths of the lens. This was the first formal definition of the focal length of a lens system. The properties of the cardinal points and related points are as follows:

- *Principal points:* the axial intersection points of conjugate planes P_1 and P_2 where these *principal planes* are related by unit lateral magnification. A ray incident at height h on P_1 will exit P_2 at the same height. When $n_i \neq n_o$, a ray incident at the first principal point with angle u will exit the second principal point with angle $u(n_i/n_o)$.
- *Nodal points:* conjugate points related by unit angular magnification ($m = u_i/u_o$). Nodal points are the axial intersection points of conjugate planes N_1 and N_2 where these *nodal planes* are related, by application of the Lagrange invariant, lateral magnification ($m = n_i/n_o$). A ray incident at height h on N_1 will exit N_2 at $h(n_i/n_o)$.
- *Focal points:* anterior or front (f_1) and posterior or rear (f_2) focal points are the axial intersections of the respective focal planes, which are not conjugate. Any ray parallel to the optical axis, and entering the lens from the left, will intersect the axis at f_2. Any ray parallel to the optical axis, and entering the lens from the right, will intersect the axis at f_1. When $n_i \neq n_o$, the distance $f_1 N_1$ equals the posterior focal length $P_2 f_2$ and the distance $N_2 f_2$ equals the anterior focal length $P_1 f_1$.
- *Antiprincipal points:* the axial intersection points of conjugate planes where these *antiprincipal planes* are related by negative unit lateral magnification. An example is a lens used at $m = -1$ where the object and image planes are located at twice the focal length from the principal points.
- *Antinodal points:* conjugate points related by negative unit angular magnification ($m = -u_i/u_o$).

Although imaging can be done solely using n_i/n_o and either the principal point and planes, or the nodal point and planes, it is customary and easier to use a mixed set, that is, principal planes and nodal points. In this manner, the lateral and angular magnifications are both unity. This is particularly useful when performing graphical ray tracing. In addition, the image location and magnification can be determined in the following manner:

- Trace a horizontal ray from the object tip to the first principal plane.
- Transfer to the second principal plane.
- Trace the ray through the second focal point.
- Trace a second ray from the object tip through the first focal point and to the intersection with the first principal plane.
- Transfer to the second principal plane.
- Project this ray horizontally until it intersects the first ray.

The intersection is the image height and locates the image plane. Magnification is the ratio of image height to object height. There are several alternative graphical ray-tracing method that can determine image height and location. One alternative is to trace a ray from the object tip to the first nodal point, and then project the ray exiting the second nodal point to intersect with the second ray mentioned above.

The focal length of a lens is related to the power of the lens by

$$\phi = \frac{n_o}{f_o} = \frac{n_i}{f_i} \tag{5}$$

This relationship is important in such optical systems as underwater cameras, cameras in space, and the like. For example, it is evident that the field of view is decreased for a camera in water.

The *lens law* can be expressed in several forms. If s_o and s_i are the distance from the object to the first principal point and the distance from the second principal point to the image, then the relationship between the object and the image is given by

$$\phi = \frac{n_i}{s_i} + \frac{n_o}{s_o} \tag{6}$$

Should the distance be measured with respect to the nodal points, the imaging equation becomes

$$\phi = \frac{n_o}{s_i} + \frac{n_i}{s_o} \tag{7}$$

When the distances are measured from the focal points, the image relationship, known as the *Newtonian imaging equation,* is given by

$$f_1 f_2 = s_o s_i \tag{8}$$

The power of a spherical refracting surface, with curvature c and n being the refractive index following the surface, is given by

$$\phi = c(n - n_0) \tag{9}$$

It can be shown that the power of a single thick lens in air is

$$\phi_{\text{thick}} = \phi_1 + \phi_2 - \phi_1 \phi_2 \frac{t}{n} \tag{10}$$

where t is the thickness of the lens. The distance from the first principal plane to the first surface is $-(t/n)\phi_2 f_1$ and the distance from the second principal point to the rear surface is $-(t/n)\phi_1 f_2$. The power of a thin lens ($t \to 0$) in air is given by

$$\phi_{\text{thin}} = (n-1)(c_1 - c_2) \tag{11}$$

17.4 STOPS AND PUPILS

The *aperture stop* or *stop* of a lens is the limiting aperture associated with the lens that determines how large an axial beam may pass through the lens. The stop is also called an *iris.* The *marginal ray* is the extreme ray from the axial point of the object through the edge of the stop. The *entrance pupil* is the image of the stop formed by all lenses preceding it when viewed from object space. The *exit pupil* is the image of the stop formed by all lenses following it when viewed from image space. These pupils and the stop are all images of one another. The *principal ray* is defined as the ray emanating from an off-axis object point that passes through the center of the stop. In the absence of pupil aberrations, the principal ray also passes through the center of the entrance and exit pupils.

As the obliquity angle of the principal ray increases, the defining apertures of the components comprising the lens may limit the passage of some of the rays in the entering beam thereby causing the stop not to be filled with rays. The failure of an off-axis beam to fill the aperture stop is called v*ignetting.* The ray centered between the upper and lower rays defining the oblique beam is called the *chief ray.* When the object moves to large off-axis locations, the entrance pupil often has a highly distorted shape, may be tilted, and/or displaced longitudinally and transversely. Due to the vignetting and pupil aberrations, the chief and principal rays may become displaced from one another. In some cases, the principal ray is vignetted.

The *field stop* is an aperture that limits the passage of principal rays beyond a certain field angle. The image of the field stop when viewed from object space is called the *entrance window* and is called the *exit window* when viewed from image space. The field stop effectively controls the field of view of the lens system. Should the field stop be coincident with an image formed within or by the lens system, the entrance and exit windows will be located at the object and/or image(s).

A *telecentric stop* is an aperture located such that the entrance and/or exit pupils are located at infinity. This is accomplished by placing the aperture in the focal plane. Consider a stop placed at the front focal plane of a lens. The stop image or exit pupil is located at infinity and the principal ray exits the lens parallel to the optical axis. This feature is often used in metrology since the measurement error is reduced when compared to conventional lens systems because the centroid of the blur remains at the same height from the optical axis even as the focus is varied.

17.5 F-NUMBER AND NUMERICAL APERTURE

The focal ratio or F-number (FN) of a lens is defined as the effective focal length divided by the entrance pupil diameter D_{ep}. When the object is not located at infinity, the effective FN is given by

$$\mathrm{FN}_{\mathrm{eff}} = \mathrm{FN}_{\infty}(1-m) \tag{12}$$

where m is the magnification. For example, for a simple positive lens being used at unity magnification ($m = -1$), the $\mathrm{FN}_{\mathrm{eff}} = 2\mathrm{FN}_{\infty}$. The *numerical aperture* of a lens is defined as

$$\mathrm{NA} = n_i \sin U_i \tag{13}$$

where n_i is the refractive index in which the image lies and U_i is the slope angle of the marginal ray exiting the lens. If the lens is aplanatic, then

$$\mathrm{FN}_{\mathrm{eff}} = \frac{1}{2\mathrm{NA}} \tag{14}$$

The T-number of a lens is the effective FN divided by the square root of the transmittance of the lens and is used for radiometric computations; however, the FN should be used when computing depth of focus and depth of field discussed in Sec. 17.21.

17.6 MAGNIFIER OR EYE LOUPE

The typical magnifying glass, or *loupe,* comprises a singlet lens and is used to produce an erect but virtual magnified image of an object. The magnifying power of the loupe is stated to be the ratio of the angular size of the image when viewed through the magnifier to the angular size without the magnifier. By using the thin-lens model of the human eye, the magnifying power (MP) can be shown to be given by

$$\mathrm{MP} = \frac{25\,\mathrm{cm}}{d_e + d_o - \phi d_e d_o} \tag{15}$$

where d_o is the distance from the object to the loupe, d_e is the separation of the loupe from the eye, and $\phi = 1/f$ is the power of the magnifier. When d_o is set to the focal length of the lens, the virtual image is placed at infinity and the magnifying power reduces to

$$\mathrm{MP} = \frac{25\,\mathrm{cm}}{f} \tag{16}$$

Should the virtual image be located at the near viewing distance of the eye (about 25 cm), then

$$\mathrm{MP} = \frac{25\,\mathrm{cm}}{f} + 1 \tag{17}$$

Typically simple magnifiers are difficult to make with magnifying powers greater than about 10×.

17.7 COMPOUND MICROSCOPES

For magnifying power greater than that of a simple magnifier, a compound microscope, which comprises an objective lens and an eyepiece, may be used. The objective forms an aerial image of the object at a distance s_{ot} from the rear focal point of the objective. The distance s_{ot} is called the *optical tube length* and is typically 160 mm. The objective magnification is

$$\mathrm{MP}_{obj} = \frac{s_{ot}}{f_{obj}} \tag{18}$$

The image formed is further magnified by the eyepiece which has a MP_{ep} = 250 mm/f_{ep}. The total magnifying power of the compound microscope is given by

$$\begin{aligned} \mathrm{MP} &= \mathrm{MP}_{obj}\mathrm{MP}_{ep} \\ &= \frac{160}{f_{obj}} \cdot \frac{250}{f_{ep}} \end{aligned} \tag{19}$$

Typically, f_{ep} = 25 mm, so its MP 10. Should the objective have a focal length of 10 mm, the total magnifying power of the microscope is 16× times 10×, or 160×.

17.8 FIELD AND RELAY LENSES

Field lenses are placed at (or near) an image location for the purpose of optically relocating the pupil or to increase the field-of-view of the optical system. For example, a field lens may be used at the image plane of an astronomical telescope such that the field lens images the objective lens onto the eyepiece. In general, the field lens does not contribute to the aberrations of the system except for distortion and field curvature. Since the field lens must be positive, it adds inward curving Petzval. For systems having a small detector requiring an apparent increase in size, the field lens is a possible solution. The detector is located beyond the image plane such that it subtends the same angle as the objective lens when viewed from the image point. The field lens images the objective lens onto the detector.

Relay lenses are used to transfer an image from one location to another such as in a submarine periscope or borescope. It is also used as a means to erect an image in many types of telescopes and other such instruments. Often relay lenses are made using two lens groups spaced about a stop, or an image of the system stop, in order to take advantage of the principle of symmetry, thereby minimizing the comatic aberrations and lateral color. The relayed image is frequently magnified.

17.9 APLANATIC SURFACES AND IMMERSION LENSES

Abbe called a lens an aplanat that has an equivalent refractive surface which is a portion of a sphere with a radius r centered about the focal point. Such a lens satisfies the Abbe sine condition and implies that the lens is free of spherical and coma near the optical axis. Consequently, the maximum

possible numerical aperture (NA) of an aplanat is unity, or an FN = 0.5. In practice, an FN less than 0.6 is difficult to achieve. For an aplanat,

$$\mathrm{FN} = \frac{1}{2 \cdot \mathrm{NA}} \tag{20}$$

It can be shown that three cases exist where the spherical aberration is zero for a spherical surface. These are: (1) the trivial case where the object and image are located at the surface, (2) the object and image are located at the center of curvature of the surface, and (3) the object is located at the aplanatic point. The third case is of primary interest. If the refractive index preceding the surface is n_o and following the surface is n_i then the object is located a distance s_o from the surface as expressed by

$$s_o = \frac{r(n_o + n_i)}{n_o} \tag{21}$$

and the image is located at

$$s_i = \frac{r(n_o + n_i)}{n_i} \tag{22}$$

An immersion lens or contact lens can be formed from an aplanatic surface and a plano surface. Figure 4 illustrates a hemispherical magnifier that employs the second aplanatic case. The resultant magnification is n_i if in air or n_i/n_o otherwise. A similar magnifier can be constructed by using a hyperhemispherical surface and a plano surface as depicted in Fig. 5. The lateral magnification is n_i^2. This lens, called an *Amici lens,* is based upon the third aplanatic case. The image is free of all orders of spherical aberration, third-order coma, and third-order astigmatism. Axial color is also absent from the hemispherical magnifier. These magnifiers are often used as a means to make a detector appear larger and as the first component in microscope objectives.

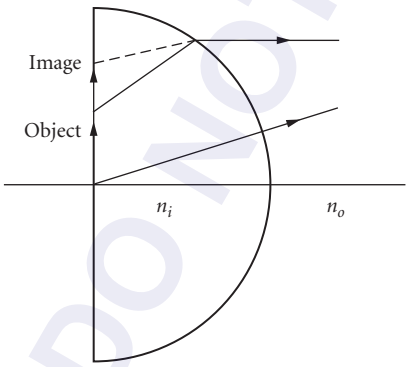

FIGURE 4 Aplanatic hemispherical magnifier with the object and image located at the center of curvature of the spherical surface. This type of magnifier has a magnification of n_i/n_o which can be used as a contact magnifier or as an immersion lens.

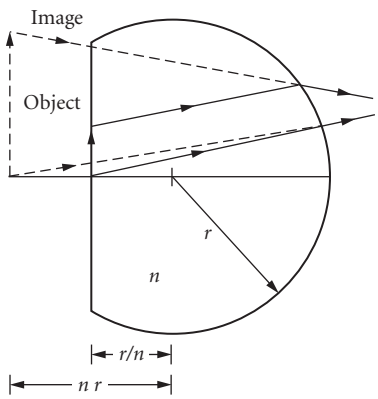

FIGURE 5 Aplanatic hyperhemispherical magnifier or Amici lens has the object located at the aplanatic point. The lateral magnification is $(n_i/n_0)^2$.

17.10 SINGLE ELEMENT LENS

It is well known that the spherical aberration of a lens is a function of its shape factor or bending. Although several definitions for the shape factor have been suggested, a useful formulation is

$$\mathcal{K} = \frac{c_1}{c_1 - c_2} \tag{23}$$

where c_1 and c_2 are the curvatures of the lens with the first surface facing the object. By adjusting the lens bending, the spherical aberration can be seen to have a minimum value.

The power of a thin lens or the reciprocal of its focal length is given by

$$\phi = \frac{(n-1)c_1}{\mathcal{K}} \tag{24}$$

When the object is located at infinity, the shape factor for minimum spherical aberration can be represented by

$$\mathcal{K} = \frac{n(2n+1)}{2(n+2)} \tag{25}$$

The resultant third-order spherical aberration of the marginal ray in angular units is

$$\text{SA3} = \frac{n^2 - (2n+1)\mathcal{K} + (1+2/n)\mathcal{K}^2}{16(n-1)^2(\text{FN})^3} \tag{26}$$

or after some algebraic manipulations,

$$\text{SA3} = \frac{n(4n-1)}{64(n+2)(n-1)^2(\text{FN})^3} \tag{27}$$

where, for a thin lens, the FN is the focal length f divided by the lens diameter, which in this case is the same as entrance pupil diameter D_{ep}. Inspection of this equation illustrates that smaller values of spherical aberration are obtained as the refractive index increases.

When the object is located at a finite distance s_o, the equations for the shape factor and residual spherical aberration are more complex. Recalling that the magnification m is the ratio of the object distance to the image distance and that the object distance is negative if the object lies to the left of the lens, the relationship between the object distance and the magnification is

$$\frac{1}{s_o\phi} = \frac{m}{1-m} \tag{28}$$

where m is negative if the object distance and the lens power have opposite signs. The term $1/s_o\phi$ represents the reduced or ϕ-normalized reciprocal object distance υ, that is, s_o is measured in units of focal length ϕ^{-1}. The shape factor for minimum spherical aberration is given by

$$\mathcal{K} = \frac{n(2n+1)}{2(n+2)} + \frac{2(n^2-1)}{n+2}\left(\frac{m}{1-m}\right) \tag{29}$$

and the resultant third-order spherical aberration of the marginal ray in angular units is

$$\text{SA3} = \frac{1}{16(n-1)^2(\text{FN})^3}\left[n^2 - (2n+1)\mathcal{K} + \frac{n+2}{n}\mathcal{K}^2 + (3n+1)(n-1)\left(\frac{m}{1-m}\right)\right.$$
$$\left. - \frac{4(n^2-1)}{n}\left(\frac{m}{1-m}\right)\mathcal{K} + \frac{(3n+2)(n-1)^2}{n}\left(\frac{m}{1-m}\right)^2\right] \tag{30}$$

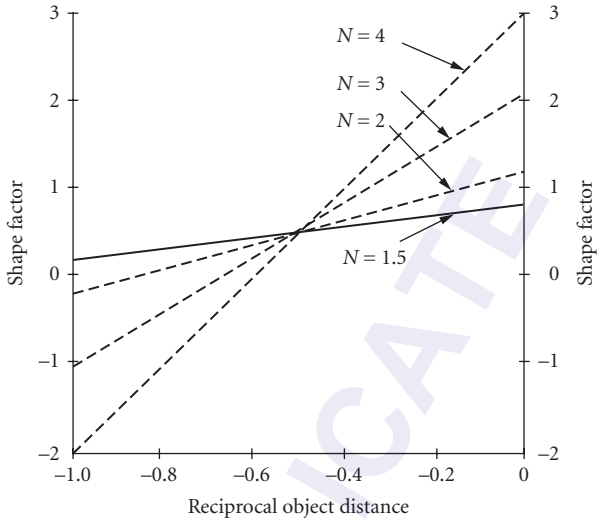

FIGURE 6 The shape factor for a single lens is shown for several refractive indexes as a function of reciprocal object distance υ where the distance is measured in units of focal length.

where FN is the effective focal length of the lens f divided by its entrance pupil diameter. When the object is located at infinity, the magnification becomes zero and the above two equations reduce to those previously given.

Figure 6 illustrates the variation in shape factor as a function of υ for refractive indices of 1.5 to 4 for an FN = 1. As can be seen from the figure, lenses have a shape factor of 0.5 regardless of the refractive index when the magnification is −1 or $\upsilon = -0.5$. For this shape factor, all lenses have biconvex surfaces with equal radii. When the object is at infinity and the refractive index is 4, lenses have a meniscus shape toward the image. For a lens with a refractive index of 1.5, the shape is somewhat biconvex, with the second surface having a radius about 6 times greater than the first surface radius.

Since the minimum-spherical lens shape is selected for a specific magnification, the spherical aberration will vary as the object-image conjugates are adjusted. For example, a lens having a refractive index of 1.5 and configured for $m = 0$ exhibits a substantial increase in spherical aberration when the lens is used at a magnification of −1. Figure 7 illustrates the variation in the angular spherical aberration as both a function of refractive index and reciprocal object distance when the lens bending is for minimum spherical aberration with the object located at infinity. As can be observed from Fig. 7, the ratio of the spherical aberration, when $m = -0.5$ and $m = 0$, increases as n increases. Figure 8 shows the variation in angular spherical aberration when the lens bending is for minimum spherical aberration at a magnification of −1. In a like manner, Fig. 9 presents the variation in angular spherical aberration for a convex-plano lens with the plano side facing the image. The figure can also be used when the lens is reversed by simply replacing the object distance with the image distance.

Figures 7 to 9 may provide useful guidance in setting up experiments when the three forms of lenses are available. The so-called "off-the-shelf" lenses that are readily available from a number of vendors often have the convex-plano, equal-radii biconvex, and minimum spherical shapes.

Figure 10 shows the relationship between the third-order spherical aberration and coma, and the shape factor for a thin lens with a refractive index of 1.5, stop in contact, and the object at infinity. The coma is near zero at the minimum spherical aberration shape. The shape of the lens as a function of shape factor is shown at the top of the figure.

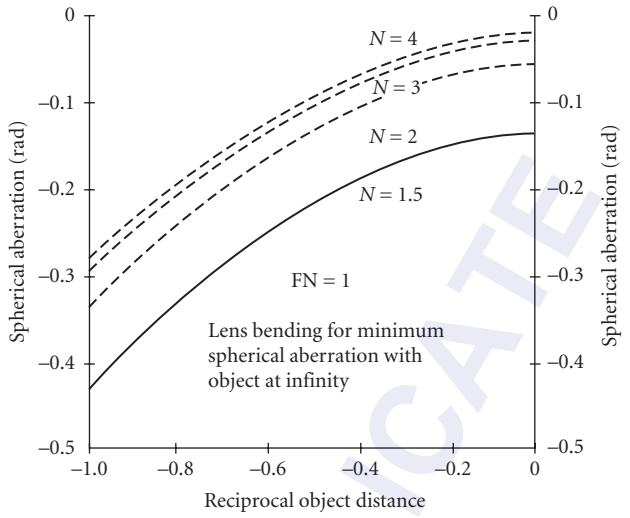

FIGURE 7 Variation of angular spherical aberration as a function of reciprocal object distance υ for various refractive indices when the lens is shaped for minimum spherical aberration with the object at infinity. Spherical aberration for a specific FN is determined by dividing the aberration value shown by $(FN)^3$.

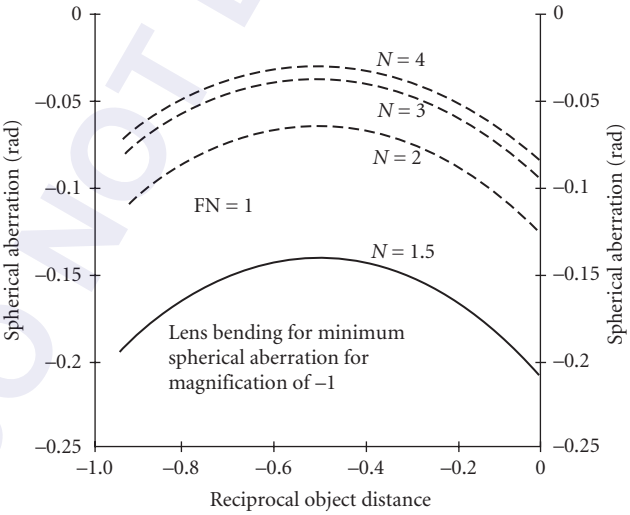

FIGURE 8 Variation of angular spherical aberration as a function of reciprocal object distance υ for various refractive indices when the lens is shaped for minimum spherical aberration for a magnification of –1. Spherical aberration for a specific FN is determined by dividing the aberration value shown by $(FN)^3$.

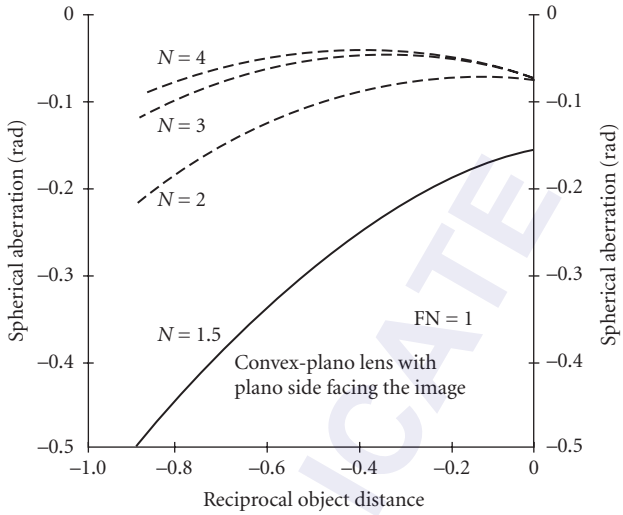

FIGURE 9 Variation of angular spherical aberration as a function of reciprocal object distance υ for various refractive indices when the lens has a convex-plano shape with the plano side facing the object. Spherical aberration for a specific FN is determined by dividing the aberration value shown by $(FN)^3$.

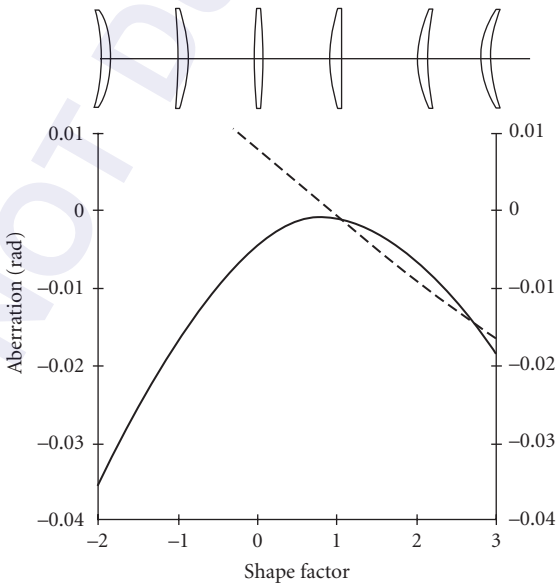

FIGURE 10 Variation of spherical aberration (solid curve) and coma (dashed line) as a function of shape factor for a thin lens with a refractive index of 1.5, stop in contact with the lens, and the object at infinity. The shape of the lens as the shape factor changes is shown at the top of the figure.

For certain cases, it is desirable to have a single lens with no spherical aberration. A useful form is the plano-convex, with the plano side facing the object, if the convex side is figured as a conic surface with a conic constant of $-n^2$. Caution should be exercised when using this lens form at other than infinite object distances; however, imaging at finite conjugates can be accomplished by using two lenses with their plano surfaces facing one another and the magnification being determined by the ratio of the focal lengths. It should be noted that for this lens form, the actual thickness of the lenses is not important and that the inclusion of the conic surface does not alter the focal length.

The off-axis performance of a lens shaped for minimum spherical aberration with the object at infinity can be estimated by using the following equations. Assuming that the stop is in contact with the lens, the third-order angular sagittal coma is given by

$$\mathrm{CMA}_s = \frac{\theta}{16(n+2)(\mathrm{FN})^2} \tag{31}$$

where the field angle θ is expressed in radians. The tangential coma is three times the sagittal coma or $\mathrm{CMA}_t = 3 \cdot \mathrm{CMA}_s$. The diameter of the angular astigmatic blur formed at best focus is expressed by

$$\mathrm{AST} = \frac{\theta^2}{\mathrm{FN}} \tag{32}$$

The best focus location lies midway between the sagittal and tangential foci. An estimate of the axial angular chromatic aberration is given by

$$\mathrm{AChr} = \frac{1}{2V(\mathrm{FN})} \tag{33}$$

where V is the Abbe number of the glass and $V = (n_2 - 1)/(n_3 - n_1)$ with $n_1 < n_2 < n_3$.

If a singlet is made with a conic or fourth-order surface, the spherical aberration is corrected by the aspheric surface, and the bending can be used to remove the coma. With the stop in contact with the lens, the residual astigmatism and chromatic errors remain as expressed by the preceding equations. Figure 11 depicts the shapes of such singlets for refractive indices of 1.5, 2, 3, and 4. Each lens has a unity focal length and an FN of 10. Table 1 presents the prescription of each lens where CC_2 is the conic constant of the second surface.

The *optical center* of a thick lens is located where a nodal ray crosses the optical axis of the lens. A *nodal ray* is aimed at the first nodal point, passes through the lens undeviated (although translated), and appears to emerge from the lens from the second nodal point. It can be shown that the distance from the first surface vertex to the optical center is $t/[1-(c_1/c_2)]$ where t is the thickness of the lens.

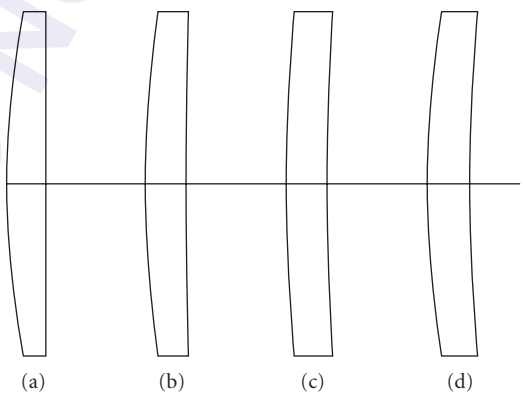

FIGURE 11 Variation of shape of singlets when the spherical aberration is corrected by the conic constant and the coma by the bending .

TABLE 1 Prescription of Singlets Corrected for Both Spherical Aberration and Coma

Lens	R_1	Thickness	R_2	Index	CC_2
a	0.55143	0.025	−5.27966	1.5	−673.543
b	0.74715	0.025	2.90553	2.0	23.2435
c	0.88729	0.025	1.56487	3.0	0.86904
d	0.93648	0.025	1.33421	4.0	0.24340

A remarkable property of the optical center is its wavelength independence (*n* does not appear in the preceding equation). This means that the spatial position of the optical center is fixed, where in contrast, the spatial positions of the six cardinal points are a function of wavelength because of their dependence upon *n*.

The optical center point (plane) is conjugate with the nodal points (planes); however, while the nodal points are related by unit angular magnification, the nodal-point to optical-center magnification (m_{OC}) is not necessarily unity. In general, m_{OC} is the ratio of the nodal ray slope angles at the first nodal point and the optical center. For a single thick lens, the magnification m_{OC} can be readily shown to be given by

$$m_{OC} = (r_1 - r_2)/[N(r_1 - r_2) - t(N-1)]$$

All rotationally symmetric lenses have an optical center just as they possess the six cardinal points. Since the optical center is conjugate with N_1 and N_2, the optical center can justifiably be considered also as a cardinal point. Should the aperture stop be located at the optical center, then the entrance pupil will be located at the first nodal point and the exit pupil will be located at the second nodal point with a unity pupil magnification. This statement is true whether the lens is of symmetrical or unsymmetrical design. When $n_o \neq n_i$, the exit pupil magnification will be n_o/n_i rather than unity.

17.11 LANDSCAPE LENSES AND THE INFLUENCE OF STOP POSITION

The first lens used for photography was designed in 1812 by the English scientist W. H. Wollaston about a quarter of a century before the invention of photography. He discovered that a meniscus lens with its concave surface toward the object could produce a much flatter image field than the simple biconvex lens commonly used at that time in the camera obscuras. This lens became known as the landscape lens and is illustrated in Fig. 12. Wollaston

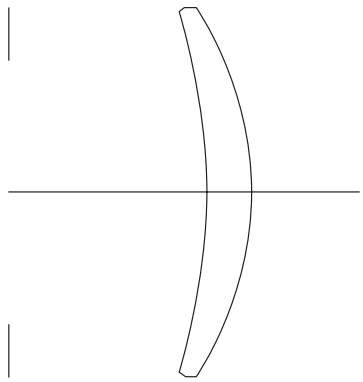

FIGURE 12 Landscape lens with the aperture stop located to the left of the lens.

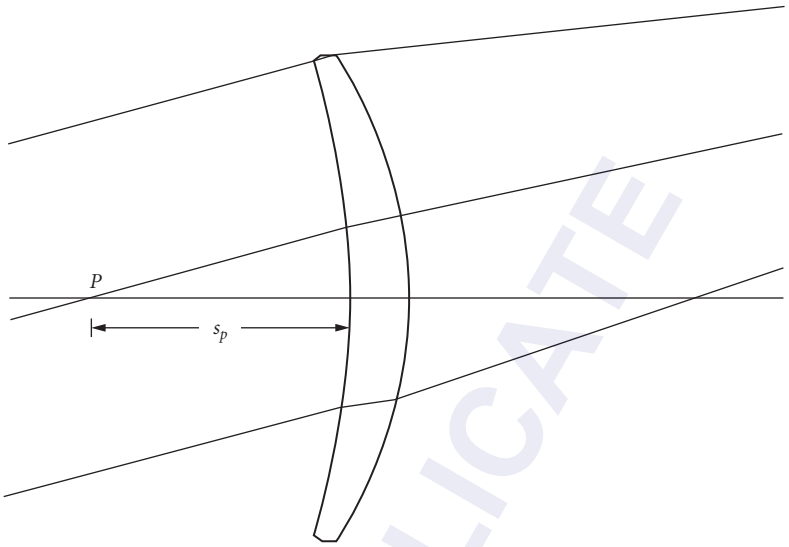

FIGURE 13 Rays traced at a given obliquity where the intersection of a given ray with the optical axis is *P*, located a distance s_p from the front surface of the lens.

realized that if the stop was placed an appropriate amount in front of the lens and the F-number was made to be modest, the image quality would be improved significantly over the biconvex lens.

The rationale for this can be readily seen by considering the influence on the residual aberrations of the lens by movement of the stop. Functionally, the stop allows certain rays in the oblique beam to pass through it while rejecting the rest. By simple inspection, it is clear that the movement of the stop (assuming a constant FN is maintained) will not affect the axial aberrations, while the oblique aberrations will be changed. In order to understand the influence of stop movement on the image quality, a graphical method was devised by R. Kingslake in which he traced a number of rays in the meridional plane at a given obliquity angle as illustrated in Fig. 13. A plot is generated that relates the intercept height of each real ray at the image plane H_i to the distance s_p from the intersection of the ray with optical axis *P* to the front surface of the lens. Each ray can be viewed as the principal ray when the stop is located at the intersection point *P*. This $H_i - s_p$ plot provides significant insight into the effect upon image quality incurred by placement of the stop. The shape of the curve provides information about the spherical aberration, coma, tangential field curvature, and distortion. Spherical aberration is indicated by an S-shaped curve, while the curvature at the principal ray point is a gauge of the coma. The coma is zero at inflection points. When the curve is a straight line, both coma and spherical aberration are essentially absent. The slope of the curve at the principal ray point is a measure of the tangential field curvature or the sag of the tangential field, that is, astigmatism. The difference in height of the real and gaussian principal rays in the image plane is distortion. For situations where the curve does not exhibit spherical aberration, it is impossible to correct the coma by shifting the stop.

Since a simple meniscus lens has stop position and lens bending as degrees of freedom, only two aberrations can be corrected. Typically, coma and tangential field curvature are chosen to be corrected, while axial aberrations are controlled by adjusting the FN of the lens. The $H_i - s_p$ plot for the lens shown in Fig. 13 is presented in Fig. 14, where the field angle is 10° and the image height is expressed as a percent of the gaussian image height. The lens has a unity focal length,

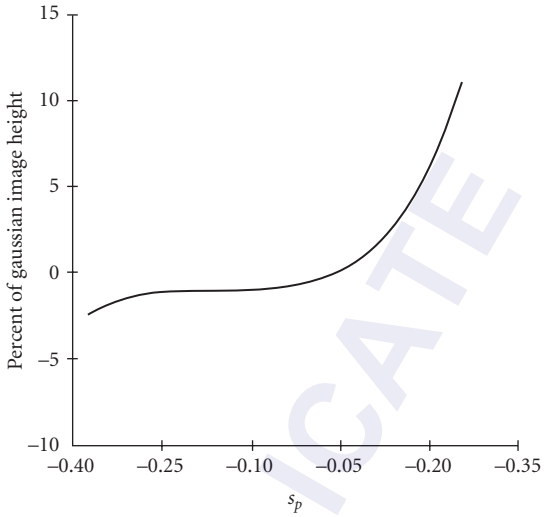

FIGURE 14 The image height H_i of each ray traced in Fig. 13 is plotted against the intersection length s_p to form the $H_i - s_p$ plot. H_i is expressed as a percent of the gaussian image height as a direct measure of distortion.

and the lens diameter is 0.275. Table 2 contains the prescription of the lens. Examination of this graph indicates that the best selection for stop location is when the stop is located at $s_p = -0.1505$ (left of the lens). For this selection, the coma and tangential astigmatism will be zero since the slope of the curve is zero and an inflection point is located at this stop position. Figure 15 shows the astigmatic field curves which clearly demonstrate the flat tangential image field for all field angles. Other aberrations cannot be controlled and must consequently be tolerated. When this lens is used at F/11, the angular blur diameter is less than 300 μrad. It should be noted that this condition is generally valid for only the evaluated field-angle obliquity and will likely be different at other field angles. Nevertheless, the performance of this lens is often acceptable for many applications.

An alternate configuration can be used where the lens is in front of the stop. Such configuration is used to conserve space since the stop would be located between the lens and the image. The optical performance is typically poorer due to greater residual spherical aberration.

The principle demonstrated by the $H_i - s_p$ plot can be applied to lenses of any complexity as a means to locate the proper stop position. It should be noted that movement of the stop will not affect the coma if spherical aberration is absent nor will astigmatism be affected if both spherical aberration and coma have been eliminated.

17.12 TWO-LENS SYSTEMS

Figure 16 illustrates the general imaging problem where an image is formed of an object by two lenses at a specified magnification and object-to-image distance. Most imaging problems can be solved by using two *equivalent* lens elements. An equivalent lens can comprise one lens or multiple lenses and may be represented by the principal planes and power of a single thick lens. All distances are measured from the principal points of each equivalent lens element. For simplicity, the lenses shown in Fig. 16 are thin lenses. If the magnification m, object-image distance s, and lens powers ϕ_a and ϕ_b are known, then the equations for s_1, s_2, and s_3 are given by

$$s_1 = \frac{\phi_b(s - s_2) - 1 + m}{m\phi_a + \phi_b}$$

$$s_2 = \frac{s}{2}\left[1 \pm \sqrt{1 - \frac{4\left[sm(\phi_a + \phi_b) + (m-1)^2\right]}{s^2 m \phi_a \phi_b}}\right] \tag{34}$$

$$s_3 = s - s_1 - s_2$$

The equation for s_2 indicates that zero, one, or two solutions may exist.

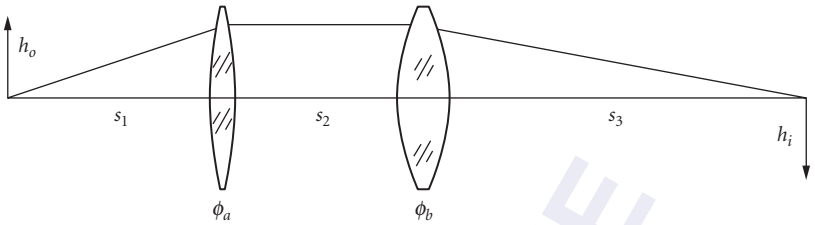

FIGURE 16 General imaging problem where the image is formed by two separated lenses.

If the magnification and the distances are known, then the lens powers can be determined by

$$\phi_a = \frac{s+(s_1+s_2)(m-1)}{ms_1s_2}$$

and

$$\phi_b = \frac{s+s_1(m-1)}{s_2(s-s_1-s_2)} \tag{35}$$

It can be shown that only certain pairs of lens powers can satisfy the magnification and separation requirements. Commonly, only the magnification and object-image distance are specified with the selection of the lens powers and locations to be determined. By utilizing the preceding equations, a plot of regions of all possible lens power pairs can be generated. Such a plot is shown as the shaded region in Fig. 17 where $s = 1$ and $m = -0.2$.

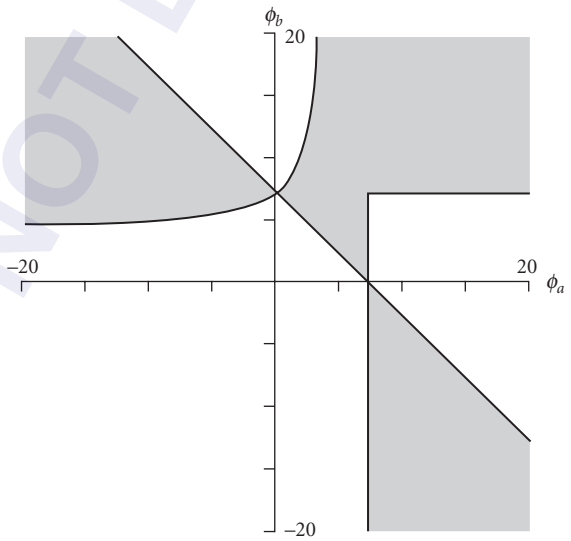

FIGURE 17 Shaded regions indicate all possible power pairs for the two lenses used for imaging. The solution space may be limited by physical considerations such as maximum aperture.

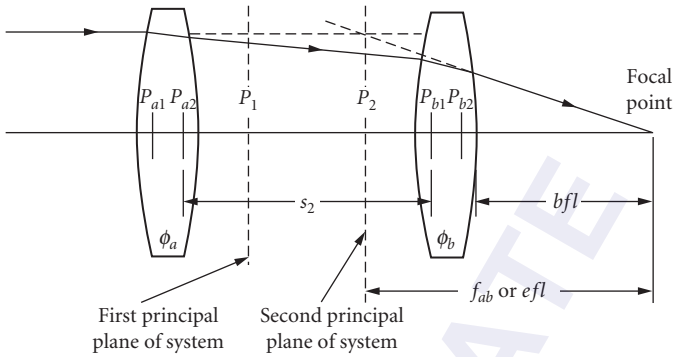

FIGURE 18 Combination of two thick lenses illustrating the principal points of each lens and the system, the f_{ab} or efl, and the bfl. Distances are measured from the principal points with the exception of the bfl.

Examination of this plot can assist in the selection of lenses that may likely produce better performance by, for example, selecting the minimum power lenses. The potential solution space may be limited by placing various physical constraints on the lens system. For example, the allowable lens diameters can dictate the maximum powers that are reasonable. Lines of maximum power can then be plotted to show the solution space.

When s_1 becomes very large compared to the effective focal length efl of the lens combination, the optical power of the combination of these lenses is expressed by

$$\phi_{ab} = \phi_a + \phi_b - s_2\phi_a\phi_b \tag{36}$$

The effective focal length is ϕ_{ab}^{-1} or

$$f_{ab} = \frac{f_a f_b}{f_a + f_b - s_2} \tag{37}$$

and the back focal length is given by

$$\text{bfl} = f_{ab}\left(\frac{f_a - s_2}{f_a}\right) \tag{38}$$

The separation between lenses is expressed by

$$s_2 = f_a + f_b - \frac{f_a f_b}{f_{ab}} \tag{39}$$

Figure 18 illustrates the two-lens configuration when thick lenses are used. The principal points for the lens combination are denoted by P_1 and P_2, P_{a1} and P_{a2} for lens *a,* and P_{b1} and P_{b2} for lens *b.* The distance between the principal points of a lens is called a *hiatus.* With the exception of the back focal length, all distances are measured from the principal points of each lens element or the combined lens system, as shown in the figure. For example, s_2 is the distance from P_{a2} to P_{b1}. The bfl is measured from the final surface vertex of the lens system to the focal point.

17.13 ACHROMATIC DOUBLETS

The singlet lens suffers from axial chromatic aberration, which is determined by the Abbe number *V* of the lens material and its FN. A widely used lens form that corrects this aberration is the achromatic doublet as illustrated in Fig. 19. An achromatic lens has equal focal lengths in *c* and *f* light.

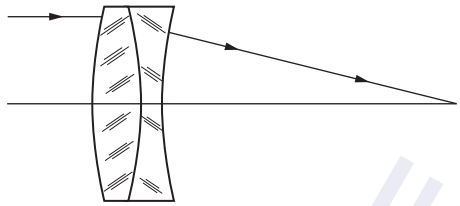

FIGURE 19 Typical achromatic doublet lens.

This lens comprises two lens elements where one element with a high V-number (crown glass) has the same power sign as the doublet and the other element has a low V-number (flint glass) with opposite power sign. Three basic configurations are used. These are the cemented doublet, broken contact doublet, and the widely airspaced doublet (dialyte). The degrees of freedom are two lens powers, glasses, and shape of each lens.

The resultant power of two thin lenses in close proximity, $s_2 \rightarrow 0$, is $\phi_{ab} = \phi_a + \phi_b$ and the transverse primary chromatic aberration TPAC is

$$\text{TPAC} = -yf_{ab}\left[\frac{\phi_a}{V_a} + \frac{\phi_b}{V_b}\right] \tag{40}$$

where y is the marginal ray height. Setting TPAC = 0 and solving for the powers of the lenses yields

$$\phi_a = \frac{V_a}{f_{ab}(V_a - V_b)} \tag{41}$$

and

$$\phi_b = \frac{-V_b\phi_a}{V_a} \tag{42}$$

The bending or shape of a lens is expressed by $c = c_1 - c_2$ and affects the aberrations of the lens. The bending of each lens is related to its power by $c_a = \phi_a/(n_a - 1)$ and $c_b = \phi_b(n_b - 1)$. Since the two bendings can be used to correct the third-order spherical and coma, the equations for these aberrations can be combined to form a quadratic equation in terms of the curvature of the first surface c_1. Solving for c_1 will yield zero, one, or two solutions for the first lens. A linear equation relates c_1 to c_2 of the second lens.

While maintaining the achromatic correction of a doublet, the spherical aberration as a function of its shape (c_1) is described by a parabolic curve. Depending upon the choices of glasses, the peak of the curve may be above, below, or at the zero spherical aberration value. When the peak lies in the positive spherical aberration region, two solutions with zero spherical aberration exist in which the solution with the smaller value of c_1 is called the left-hand solution (Fraunhofer or Steinheil forms) and the other is called the right-hand solution (Gaussian form). Two additional solutions are possible by reversal of the glasses. These two classes of designs are denoted as crown-in-front and flint-in-front designs. Depending upon the particular design requirements, one should examine all four configurations to select the most appropriate. The spherical aberration curve can be raised or lowered by the selection of the V difference or the n difference. Specifically, the curve will be lowered as the V difference is increased or if the n difference is reduced. As for the thin singlet lens, the coma will be zero for the configuration corresponding to the peak of the spherical aberration curve.

Although the primary chromatic aberration may be corrected, a residual chromatic error often remains and is called the secondary spectrum, which is the difference between the ray intercepts in d and c spectral lines. Figure 20*a* illustrates an F/5 airspaced doublet that exhibits well-corrected spherical light and primary chromatic aberrations and has notable secondary color. The angular secondary spectrum for an achromatic thin-lens doublet is given by

$$\text{SAC} = \frac{-(P_a - P_b)}{2(\text{FN})(V_a - V_b)} \tag{43}$$

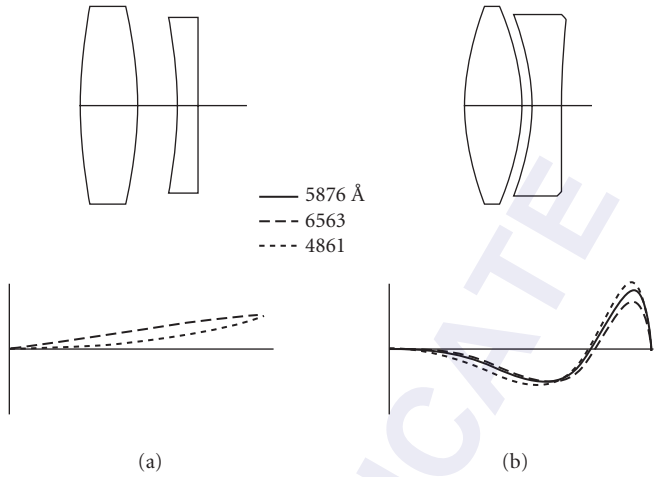

FIGURE 20 An F/5 airspaced doublet using conventional glasses is shown in (*a*) and exhibits residual secondary chromatic aberration. A similar lens is shown in (*b*) that uses a new glass to effectively eliminate the secondary color.

where $P = (n_\lambda - n_c)(n_f - n_c)$ is the partial dispersion of a lens material. In general, the ratio $(P_a - P_b)/(V_a - V_b)$ is nearly a constant which means little can be done to correct the SAC. A few glasses exist that allow $P_a - P_b \approx 0$, but the $V_a - V_b$ is often small, which results in lens element powers of rather excessive strength in order to achieve achromatism. Figure 20*b* shows an F/5 airspaced doublet using a relatively new pair of glasses that have a small $P_a - P_b$ and a more typical $V_a - V_b$. Both the primary and secondary chromatic aberration are well corrected. Due to the relatively low refractive index of the crown glass, the higher power of the elements results in spherical aberration through the seventh order. Almost no spherochromatism (variation of spherical aberration with wavelength) is observed. The 80 percent blur diameter is almost the same for both lenses and is 0.007. Table 3 contains the prescriptions for these lenses.

TABLE 3 Prescriptions for Achromatic Doublets Shown in Fig. 20

4	94.310		Air

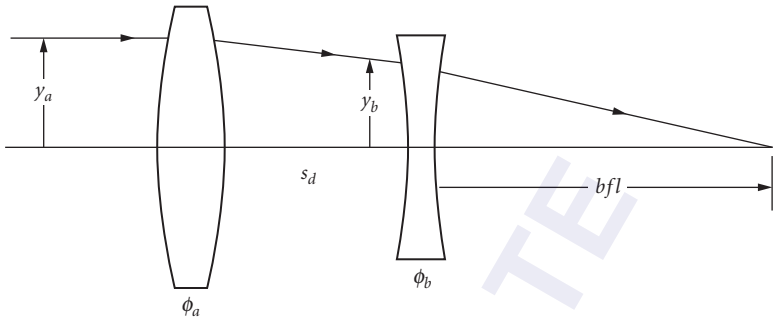

FIGURE 21 Widely separated achromatic doublet known as the dialyte lens.

When the separation between the lens elements is made a finite value, the resultant lens is known as a *dialyte* and is illustrated in Fig. 21. As the lenses are separated by a distance s_d, the power of the flint or negative lens increases rapidly. The distance s_d may be expressed as a fraction of the crown-lens focal length by $p = s_d/f_a$. Requiring the chromatic aberration to be zero implies that

$$\frac{y_a^2}{f_a V_a} + \frac{y_b^2}{f_b V_b} = 0 \tag{44}$$

By inspection of the figure and the definition of p, it is evident that $y_b = y_a(1 - p)$ from which it follows that

$$f_b V_b = -f_a V_a (1-p)^2 \tag{45}$$

The total power of the dialyte is

$$\phi = \phi_a + \phi_b (1-p) \tag{46}$$

Solving for the focal lengths of the lenses yields

$$f_a = f_{ab}\left[1 - \frac{V_b}{V_a(1-p)}\right] \tag{47}$$

$$f_b = f_{ab}(1-p)\left[1 - \frac{V_b(1-p)}{V_b}\right] \tag{48}$$

The power of both lenses increases as p increases.

The typical dialyte lens suffers from residual secondary spectrum; however, it is possible to design an airspaced achromatic doublet with only one glass type that has significantly reduced secondary spectrum. Letting $V_a = V_b$ results in the former equations becoming

$$f_a = \frac{p f_{ab}}{p-1} \qquad f_b = -p f_{ab}(p-1) \qquad s_d = p f_a \qquad \text{bfl} = -f_{ab}(p-1) \tag{49}$$

When $f_{ab} > 0$, then p must be greater than unity, which means that the lens is quite long. The focal point lies between the two lenses, which reduces its general usefulness. This type of lens is known as the Schupmann lens, based upon his research in the late 1890s. Several significant telescopes, as well as eyepieces, have employed this configuraton. For $f_{ab} < 0$, the lens can be made rather compact and is sometimes used as the rear component of some telephoto lenses.

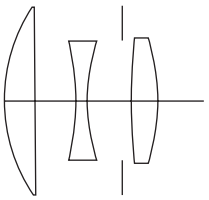

FIGURE 22 Typical triplet lens.

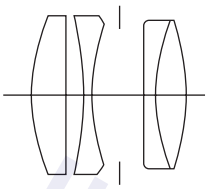

FIGURE 23 Typical Tessar lens.

17.14 TRIPLET LENSES

In 1893, a new type of triplet lens for photographic applications was invented by the English designer H. Dennis Taylor. He realized that the power of two lenses in contact of equal, but opposite, power is zero, as is its Petzval sum. As the lenses are separated, the system power becomes positive since the negative lens contributes less power. The Petzval sum remains zero, since it does not depend upon the marginal ray height. In order to overcome the large aberrations of such a configuration, Taylor split the positive lens into two positive lenses and placed one on each side of the negative lens. A stop is often located between the negative and rear-positive lenses. Figure 22 illustrates a typical triplet lens. The triplet can be used at reasonably large apertures (>F/4) and moderately large fields of view (>±25°).

The triplet has eight degrees of freedom which are the three powers, two airspaces, and three lens bendings. The lens powers and airspaces are used to control the axial and lateral chromatic aberrations, the Petzval sum, the focal length, and the ratio of the airspaces. Spherical aberration, coma, and astigmatism are corrected by the lens bendings. Distortion is usually controlled by the airspace ratio or the choice of glasses. Consequently, the triplet has exactly the number of degrees of freedom to allow correction of the basic aberrations and maintain the focal length.

The design of a triplet is somewhat difficult since a change of any surface affects every aberration. The choice of glass is important and impacts the relative aperture, field of view, and overall length. For example, a large ΔV produces a long system. It should be noted that a triplet corrected for third-order aberrations by using the degrees of freedom almost always leads to a lens with poor performance. A designer normally leaves a certain amount of residual third-order aberrations to balance the higher-order terms. The process for thin-lens predesign is beyond the scope of this *Handbook*; however, it may be found in various references comprising the bibliography.

A few years later, Paul Rudolph of Zeiss developed the Tessar, which resembles the triplet, with the rear lens replaced by an achromatic doublet. The Tessar shown in Fig. 23 was an evolution of Rudolph's anastigmats which were achromatic lenses located about a central stop. The advantage of the achromatic rear component is that it allows reduction of the zonal spherical aberration and the oblique spherical aberration, and reduces the separation of the astigmatic foci at other than the design maximum field angle. Performance of the Tessar is quite good and has generally larger relative apertures at equivalent field angles than the triplet. A variety of lenses were derived from the triplet and the Tessar in which the component lenses were made into doublets or cemented triplets.

17.15 SYMMETRICAL LENSES

In the early 1840s, it was recognized that lenses that exhibit symmetry afford various benefits to the lens designer. The first aberration acknowledged to be corrected by the symmetry principle was distortion. It can also be shown that coma and lateral color are necessarily corrected by a symmetrical lens construction. Although the principle of symmetry implies that the lens be

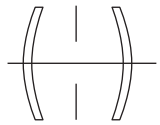

FIGURE 24 The periscopic lens illustrates the earliest form of symmetrical lenses. It is formed by placing two landscape lenses about a central stop. Symmetry removes the aberrations of coma, distortion, and lateral color.

operated at a magnification of −1, the degree to which the aberrations are upset by utilizing the lens at other conjugates is remarkably small. This principle forms the basis of most wide-field-of-view lenses.

One of the earliest symmetrical lenses was the Periscopic (Periskop) lens invented by C. A. Steinheil in 1865. Figure 24 shows an F/11 Periscopic lens constructed from the landscape lens discussed previously. Symmetry corrects for coma and distortion, while the spacing of the lenses and their shapes are selected to produce a flat tangential astigmatic field. Since the stop position for the landscape lens was chosen to yield a flat tangential astigmatic field, essentially no change in the lens separation is necessary even though the Periscopic lens is being used at infinite conjugates. No correction for spherical aberration can be made. When used at other than unit magnification, some optical improvement can be achieved by making the stop slightly asymmetrical and/or having a different shape for the front or rear lens. This lens has continued to find application throughout this century.

By 1866, Dallmeyer in England and Steinheil and von Seidel in Germany both invented the Rapid Rectilinear lens that could be used at apertures of up to F/6. The lens has two cemented achromats about a central stop. Use of the doublet allows correction of the axial chromatic and spherical aberrations. Glass selection is of importance in the design. Typically, the Δn between the glasses should be large while the ΔV should be relatively small. The positive lens is located nearest the stop and has the lower refractive index. A notable characteristic of the lens is that the aberrations are reasonably stable over a broad range of object distances.

It should be noted that vignetting is often used in these and other lens types to control the higher-order aberrations that are often observed at large field angles. Although a loss in illumination occurs, the gain in resolution is often worthwhile.

The airspaced dialyte lens comprises four lenses symmetrically arranged about a central stop. The rear portion of the lens is an achromatic doublet that has five degrees of freedom (an air space, two powers, and two bendings) which may be used to control the focal length, spherical aberration, axial chromatic aberration, astigmatism, and the Petzval sum. With a like pair of lenses mounted in front of the stop, the symmetry corrects the coma, distortion, and lateral color. When used at infinite conjugates, the resultant residuals of the aberrations can be controlled by deviating somewhat from perfect symmetry of the air spaces about the stop. Lenses of this type can provide useful performance with apertures approaching F/4 and fields of view of about ±20° or so.

17.16 DOUBLE-GAUSS LENSES

In the early 1800s, Gauss described a telescope objective comprising a pair of meniscus lenses with one having positive power and the other negative power. An interesting aspect of his lens is that the spherochromatism is essentially constant. Although this lens found little acceptance, in 1888, Alvan Clark of Massachusetts placed a pair of the Gauss lenses around a central stop to create a high-aperture, wide-field-of-view lens. This lens form is known as the Double-Gauss lens and is the basis of almost every

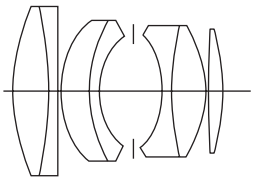

FIGURE 25 Unsymmetrical Double-Gauss or Biotar lens introduced as the Leica Summitar in 1939.

high-aperture lens developed to date. An example of this lens was patented by Richter in 1933 and can cover a field of view of ±45° at F/6.

In 1896, Paul Rudolph of Zeiss developed the Planar which reduces the often serious oblique spherical aberration and the separation of the astigmatic foci at intermediate field angles. Rudolph placed a buried surface into the thick negative elements to control the chromatic aberration. A buried surface is defined as the interface between two glasses that have the same refractive index n_d at the central wavelength, but have significantly different Abbe numbers. Such a surface has no effect upon the monochromatic aberrations or the lens system power, but does allow the inclusion of a wide range of chromatic aberration to compensate for that caused by the rest of the lens.

Many Double-Gauss lenses are symmetrical; however, it was discovered that if the lens was made unsymmetrical, then an improvement in performance could be realized. This lens form is often called the Biotar. A large portion of 35-mm camera lenses are based upon this design form or some modification thereof. Figure 25 shows the configuration of the Leica Summitar introduced in 1939.

It is the general nature of meniscus lens systems of this type to exhibit little coma, distortion, or lateral color; however, oblique spherical aberration is often observed to increase to significant levels as the field angle increases. Oblique spherical aberration can be recognized in transverse ray plots as the S shape of spherical aberration, but with the S becoming increasingly stronger as the field angle increases. As the aperture is increased beyond about F/8, the outer negative elements must be thickened dramatically and achromatic surfaces must necessarily be included.

17.17 PETZVAL LENSES

In 1839, Petzval designed a new type of lens that comprises a front objective with an achromatic, airspaced doublet as the rear elements. The Petzval lens has found great application in projectors and as a portrait lens. Both spherical aberration and coma can be well-corrected, but the lens configuration causes the Petzval sum to be undercorrected, which results in the field of view being limited by the astigmatism. The Petzval-field curves inward and may be corrected by including a *field flattener lens* in close proximity to the image plane. A typical example of a Petzval lens is shown in Fig. 26.

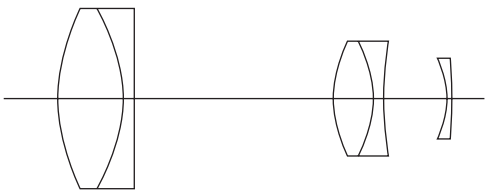

FIGURE 26 Typical Petzval lens.

17.18 TELEPHOTO LENSES

A telephoto lens provides an effective focal length efl that is longer than its overall length s_{ol} as measured from the front of the lens to the image plane. The telephoto ratio is defined as s_{ol}/efl, thus a lens with a ratio less than one is a telephoto lens. The basic concept of a telephoto lens is illustrated by the dialyte lens configuration in which a negative lens is inserted between the objective lens and the image plane. This concept goes back to Kepler, but Peter Barlow developed the idea in the early 1800s by including a negative achromat in telescopes to increase their magnification. Barlow type lenses are widely used today. As the telephoto ratio is made smaller, the design of the lens becomes more difficult, primarily due to the Petzval sum increasing.

When most telephoto lenses are used to view objects that are relatively close, the image quality degrades rapidly due to the typical unsymmetrical lens configuration. Some modern telephoto lenses include one or more elements that move as the lens is focused for the purpose of aberration correction.

17.19 INVERTED OR REVERSE TELEPHOTO LENSES

A reverse telephoto lens has a telephoto ratio greater than unity and exhibits a shorter focal length than its overall length, a larger bfl than is provided by normal lenses of the same efl, lenses with generally large apertures and wide fields of view, and lens elements of physically larger size that allow easier manufacture and handling. The basic configuration has a large negative lens located in front of a positive objective lens. Since the negative lens makes the object appear closer to the objective lens, the resultant image moves beyond the focal point, thereby making the bfl greater than the efl.

An extreme form of the reverse telephoto lens is the fish-eye or sky lens. Such lenses have a total field of view of 180° or more. The image formed by these lenses has very large barrel distortion. Recalling that the image height for a distortionless lens on a flat image surface is $f \tan \theta$, the reverse telephoto lens has mapping relationships such as $f\theta$ and $f \sin \theta$. When the barrel distortion is given by $f \sin \theta$, the illumination across the image will be constant if such effects as vignetting and stop/pupil distortion are absent. Barrel distortion has the effect of compressing the outer portions of the image toward the central portion, thereby increasing the flux density appropriately.

After World War II, the Russian designer M. M. Roosinov patented a double-ended reverse-telephoto lens that was nearly symmetrical with large negative lenses surrounding a pair of positive lenses with a central stop. Although the back focal length is quite short, it provides relatively large aperture with a wide field of view and essentially no distortion. Lenses of this type have found significant use in aerial photography and photogrammetry.

17.20 PERFORMANCE OF REPRESENTATIVE LENSES

Figures 27 to 38 present the performance of lenses, selected generally from the patent literature, representing a variety of lens types. The measures of performance provided in each figure have been selected for utilization purposes. Diffraction effects have not been included.

Each figure is divided into four sections *a* to *d.* Section *a* is a drawing of the lens showing the aperture stop. Section *b* contains two set of plots. The *solid* line is for the distortion versus field of view (θ) in degrees while the *dashed* lines show the transmission of the lens versus field of view for three F-numbers. Transmission in this case is *one minus the fractional vignetting.* No loss for coatings, surface reflection, absorption, and the like is included. The rms diameter of the geometric point source image versus field-of-view for three F-numbers is presented in section *c.* The spot sizes are in angular units and were calculated for the central wavelength only, that is, monochromatic values. Note that the ordinate is logarithmic. The final section, *d,* contains angular transverse ray plots in all three colors for both the on-axis and near-extreme field angles with y_{ep} being measured in the

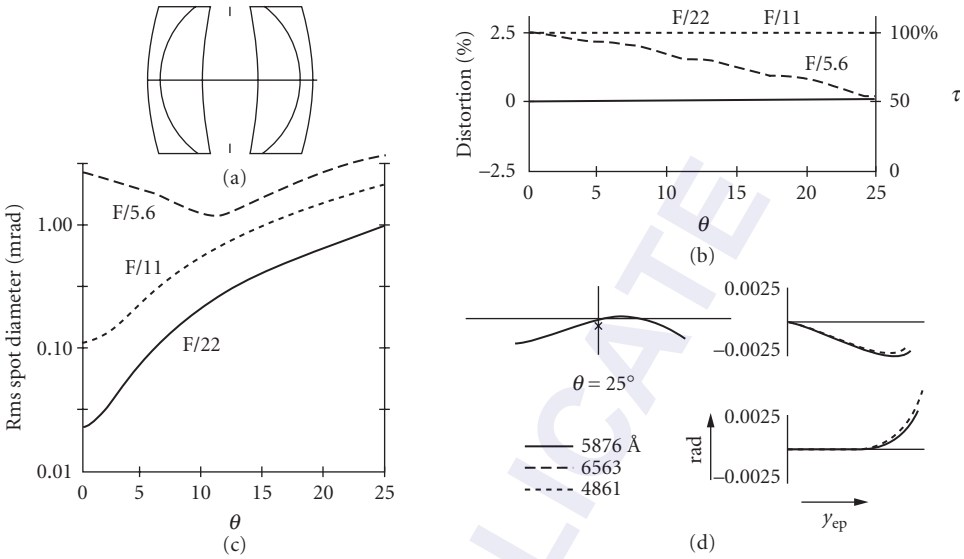

FIGURE 27 Rapid Rectlinear: This lens is an aplanat which is symmetrical with the rear half corrected for spherical aberration and flat tangential field. A compact configuration is realized by having a large amount of coma in each half. Symmetry removes the lens system coma, distortion, and lateral color. This type of lens is one of the most popular camera lenses ever made.

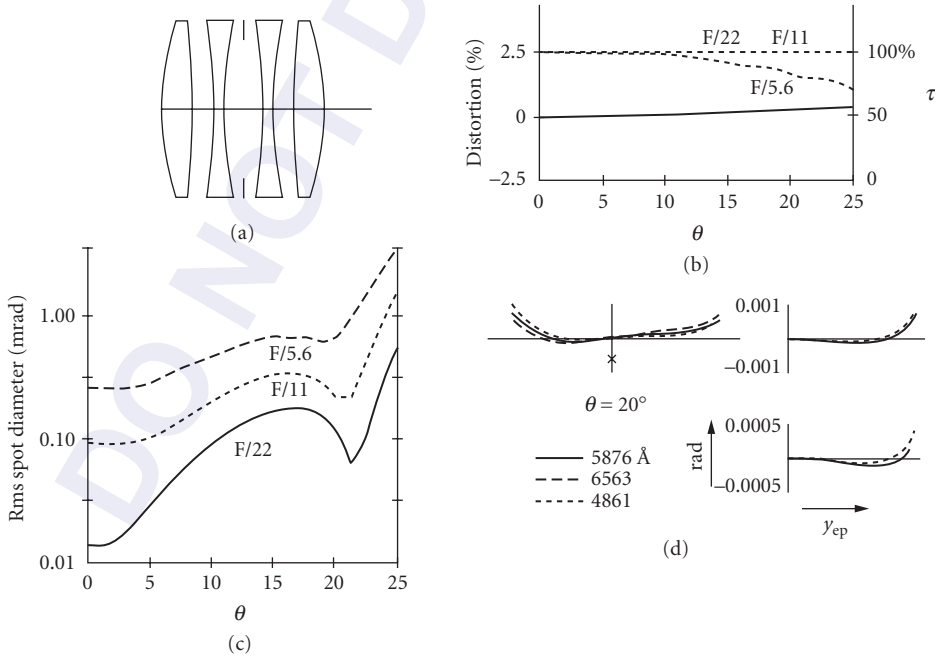

FIGURE 28 Celor : F/5.6 with 50° total field of view. Also known as an airspaced dialyte lens. (*After R . Kingslake, Lens Design Fundamentals, Academic Press, New York, 1978, p. 243.*)

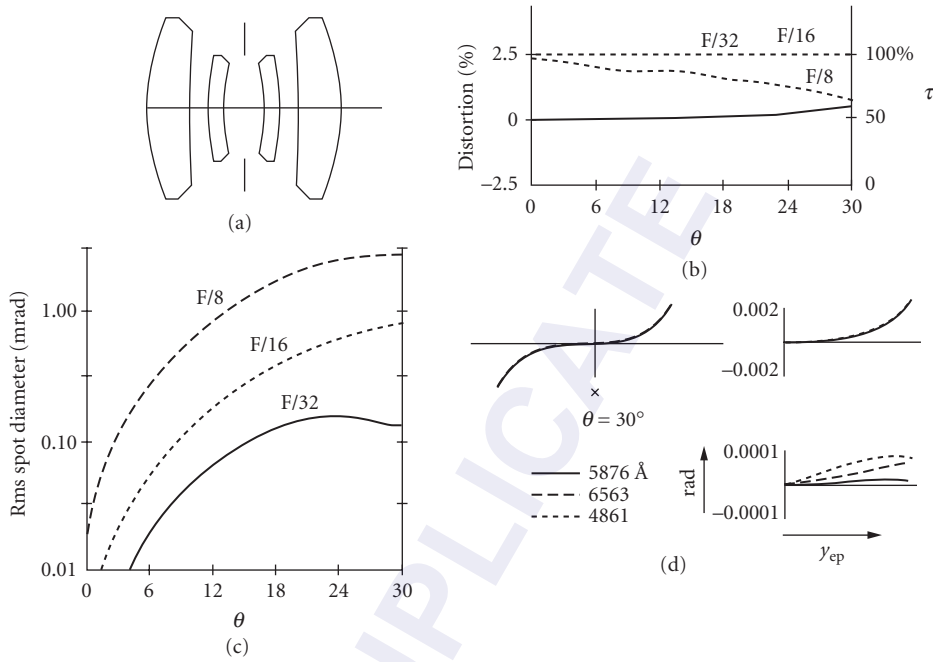

FIGURE 29 Symmetrical double anastigmat or gauss homocentric objective: basic form of Double-Gauss lens using a pair of gauss telescope objectives. First patented by Alvan Clark in 1888, USP 399,499. (*After R. Kingslake, Lens Design Fundamentals, Academic Press New York, 1978, pp. 224–250.*)

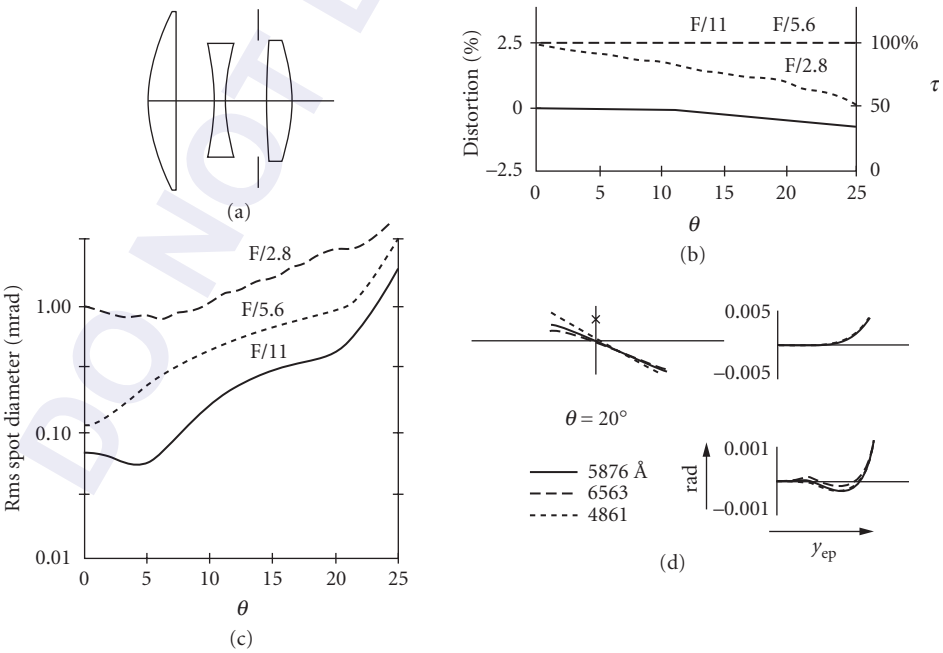

FIGURE 30 Triplet: F/2.8 with 50° total field of view. (*Tronnier, USP 3,176,582.*)

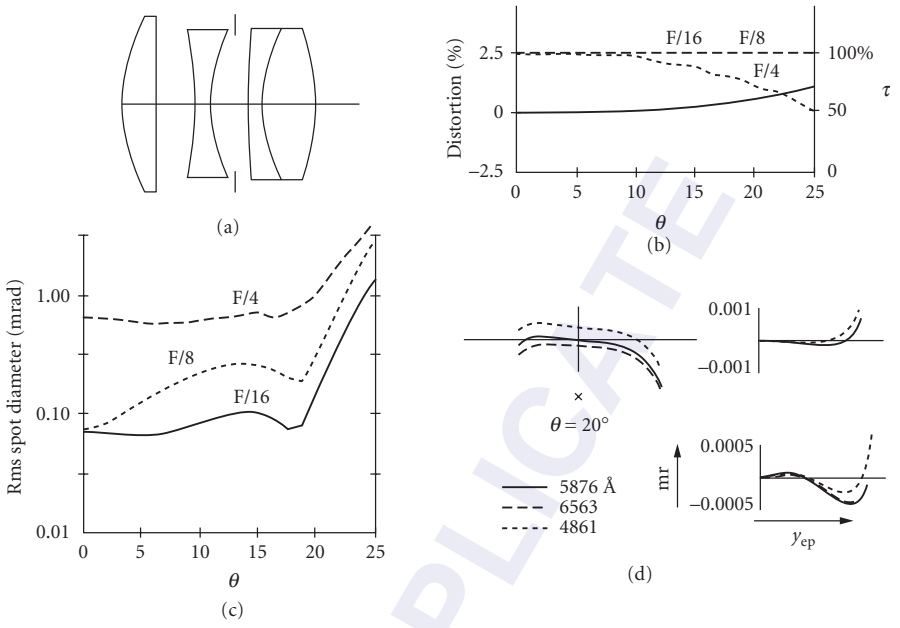

FIGURE 31 Tessar: F/4 with 50° total field of view. (*Tronnier, USP 2,084,714, 1937.*)

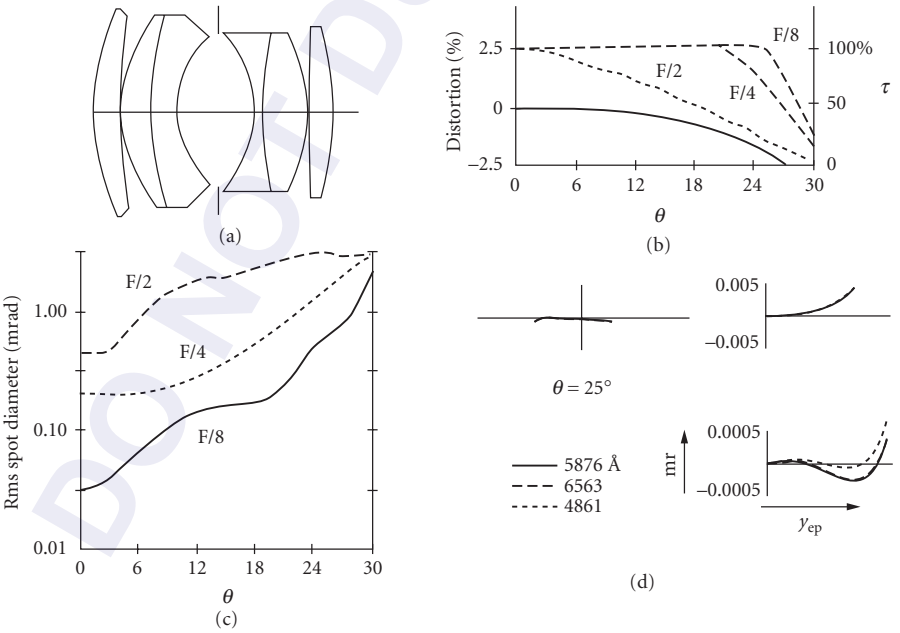

FIGURE 32 Unsymmetrical Double-Gauss: This lens was designed in 1933 for Leitz and was called the Summar. F/2 with 60° total field of view. This lens was replaced by the Leitz Summitar in 1939, due to rapidly degrading off-axis resolution and vignetting. Compare this lens with the lens shown in Fig. 33. (*Tronnier, USP 2,673,491.*)

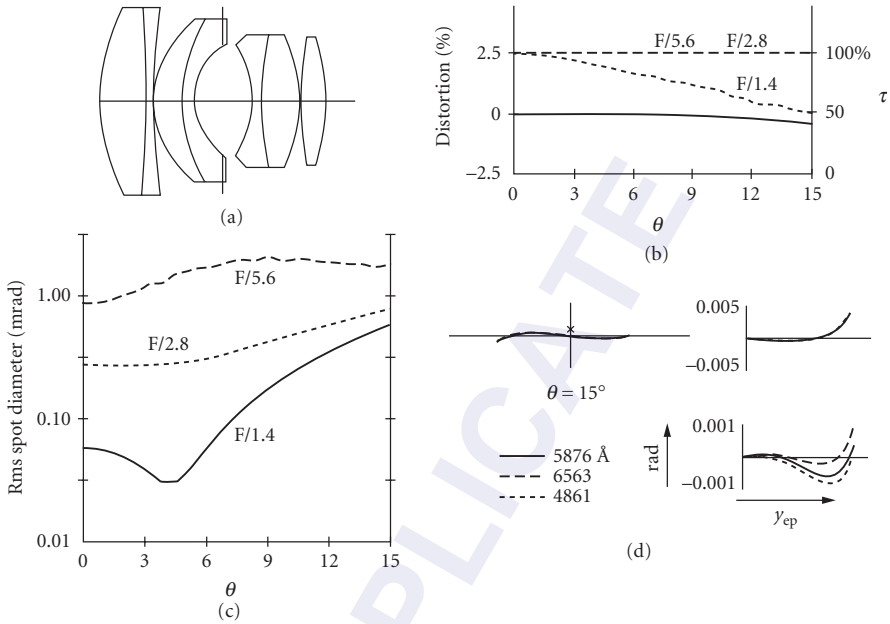

FIGURE 33 Unsymmetrical Double-Gauss: This lens type was designed in 1939 for Leitz and was called the F/2 Summitar. Kodak had a similar lens called the F/1.9 Ektar. A later example of this design form is shown and operates at F/1.4 with 30° total field of view. (*Klemp, USP 3,005,379.*)

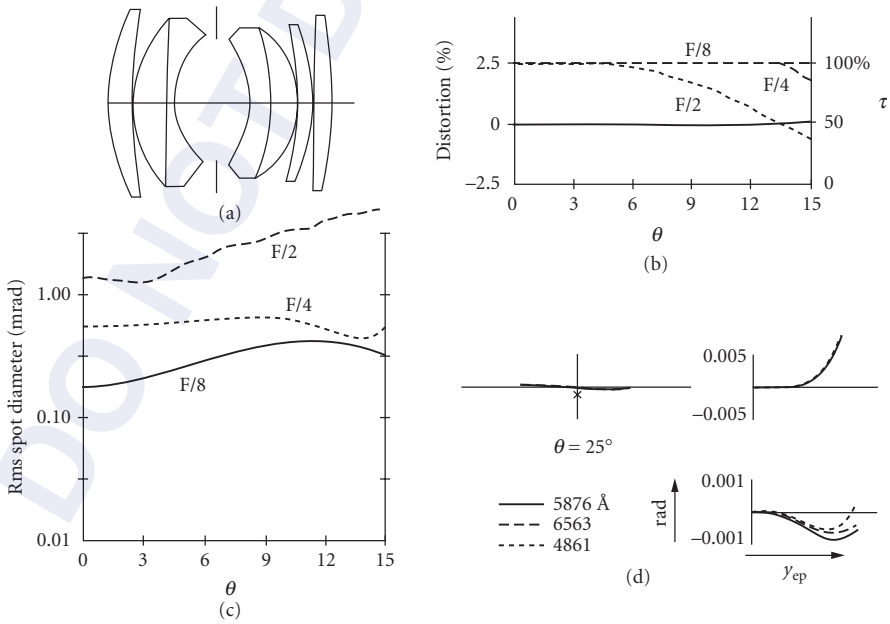

FIGURE 34 Unsymmetrical Double-Gauss: F/1.75 with 50° total field of view. Similar to the 1949 Leitz F/1.5 Summarit. This lens has a split rear element which produces improved resolution of the field of view and less vignetting than the earlier Summar type lens. (*Cook, USP 2,959,102.*)

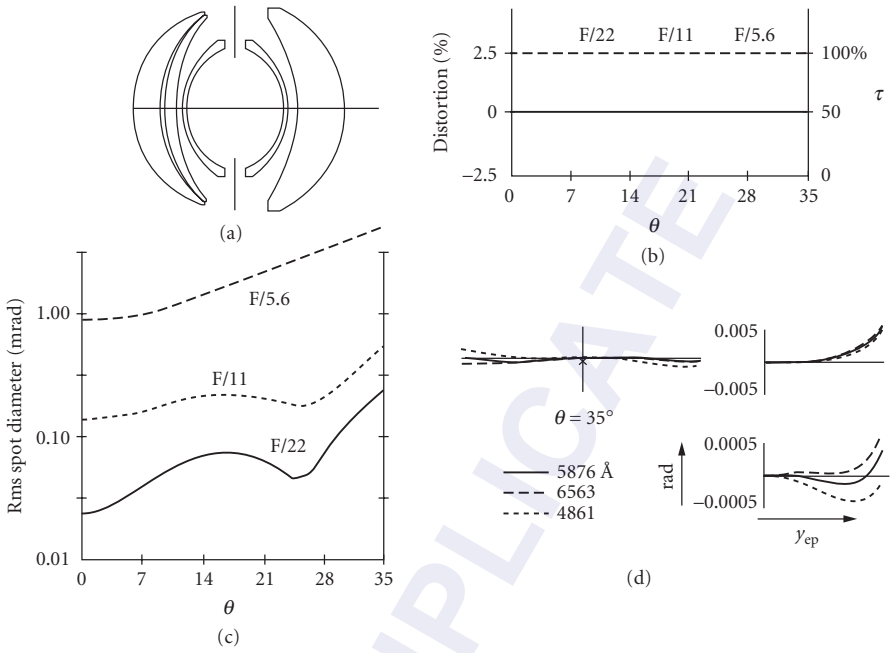

FIGURE 35 Unsymmetrical Double-Gauss: F/5.6 with 70° field of view. This lens is a variant of the 1933 Zeiss F/6.3 Topogon (*USP 2,031,792*) and is the Bausch & Lomb Metrogon. The principal difference is the splitting of the front element. (*Rayton, USP 2,325,275.*)

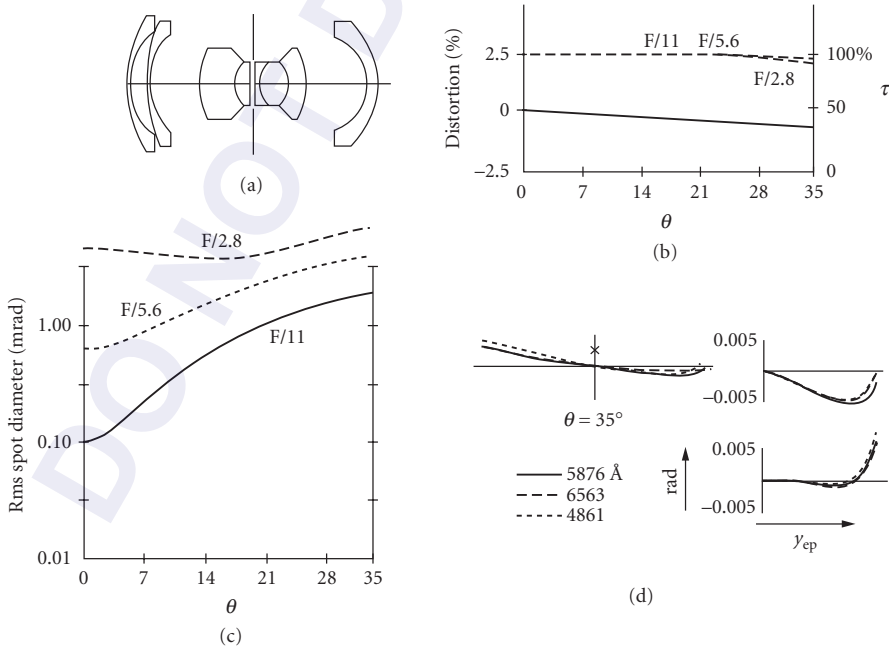

FIGURE 36 Reverse Telephoto: This lens was developed by Zeiss in 1951 and is known as the Biogon. It operates at F/2.8 with 70° field of view. This lens comprises two reverse-telephoto objectives about a central stop. (*Bertele, USP 2,721,499.*)

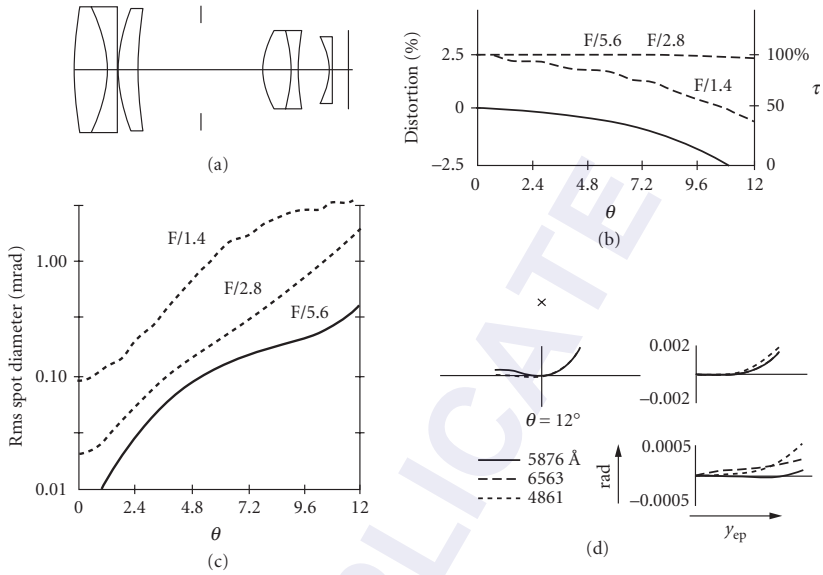

FIGURE 37 Petzval: Example of Kodak projector lens operating at F/1.4 with 24° total field of view. The front lens group has its power shared between a cemented doublet and a singlet for aberration correction. Note that the aperture stop is located between the front and rear groups rather than the more common location at the front group. Resolution in the region near the optical axis is very good although it falls off roughly exponentially. The limiting aberrations are oblique spherical and cubic coma. (*Schade, USP 2,541,484.*)

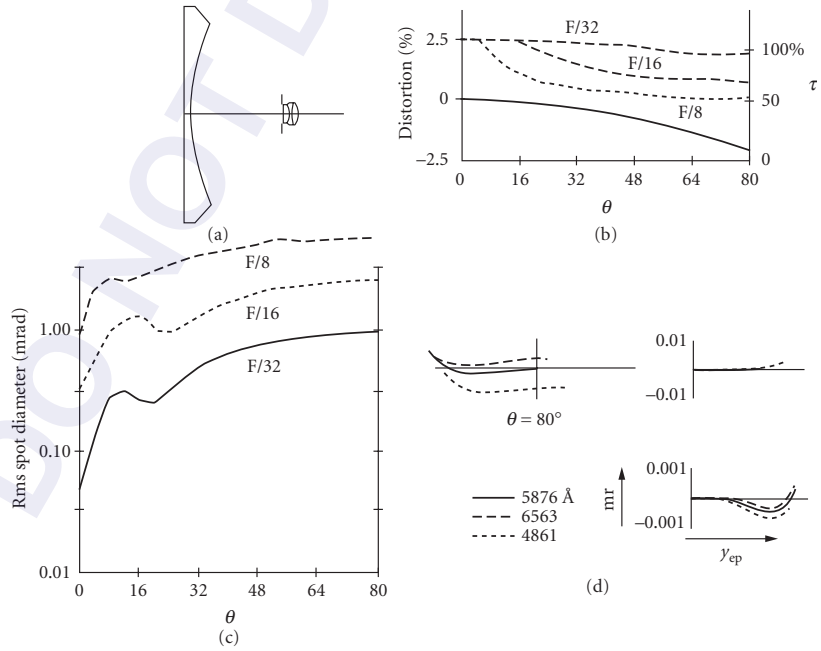

FIGURE 38 Fish-eye: The Hill Sky lens was manufactured by Beck of London in 1924. The lens has moderate resolution and enormous distortion characteristic of this type of lens. (*Merte, USP 2,126,126.*)

entrance pupil. The lower right plot shows the axial aberrations while the upper left plot represents the tangential/meridional aberrations and the upper right plot presents the sagittal aberrations. The X included on some of the tangential plots represents the location of the paraxial principal ray which also provides a measure of the distortion. The legend indicating the relationship between line type and wavelength is included.

The linear spot size is computed by multiplying the efl by the angular spot size. This value can be compared against the diffraction-limited spot size given by $2.44(\lambda/D_{ep})$. If the geometric spot is several times *smaller* than the diffraction-limited spot, then the lens may be considered to be diffraction-limited for most purposes. If the geometric spot is several times *larger,* then the lens performance is controlled by the geometric spot size for most applications.

17.21 RAPID ESTIMATION OF LENS PERFORMANCE

Singlet

Figure 39 is a nomogram that allows quick estimation of the performance of a single refracting lens, with the stop at the lens, as a function of refractive index *N,* dispersion *V,* F-number, and field of view θ. Chart A estimates the angular blur diameter β resulting from a singlet with bending for minimum spherical aberration. The angular chromatic blur diameter is given by Chart B. The three rows of FN values below the chart represent the angular blur diameter that contains the indicated

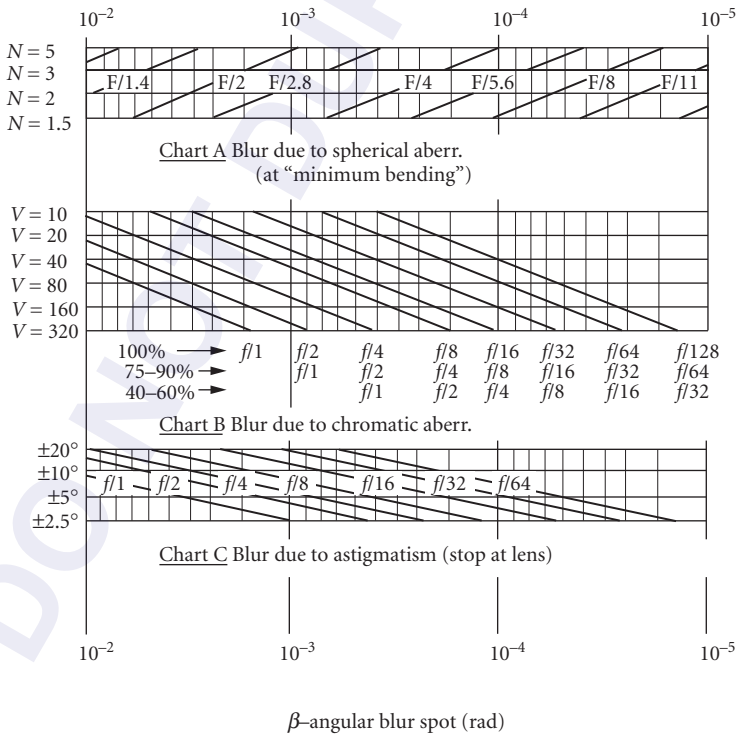

FIGURE 39 Estimation of single lens spot size as a function of refractive index, dispersion, F-number, and field of view. (*Smith, Modern Optical Engineering, McGraw-Hill, New York, 1990, p. 458.*)

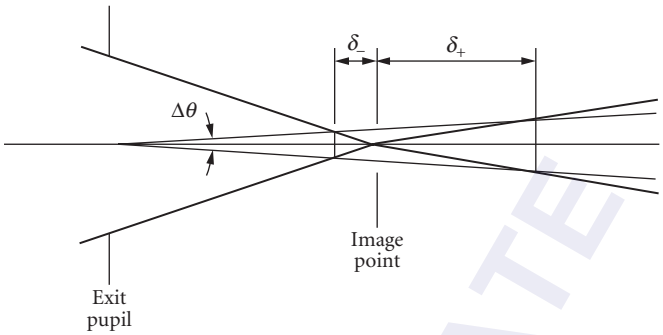

FIGURE 40 Geometric relationships for determining the geometric depth of focus of a lens .

percentage of the total energy. Chart C shows the blur diameter due to astigmatism. Coma for a singlet bent for minimum spherical aberration with the stop at the lens is approximately

$$\frac{\theta}{16\cdot(N+2)\cdot(\mathrm{FN})^2} \tag{50}$$

Depth of Focus

The *depth of focus* of an optical system is expressed as the axial displacement that the image may experience before the resultant image blur becomes excessive. Figure 40 shows the geometric relationship of the angular blur tolerance $\Delta\theta$ to the depth of focus $\delta_{\pm}$. If the entrance pupil diameter is D_{ep} and the image distance is s_i then the depth of focus is

$$\delta_{\pm} = \frac{s_i^2 \Delta\theta}{D_{\mathrm{ep}} \pm s_i \Delta\theta} \tag{51}$$

or when $\delta \ll s_i$, the depth of focus becomes

$$\delta = \frac{s_i^2 \Delta\theta}{D_{\mathrm{ep}}} \tag{52}$$

When $s_i = f$, then

$$\delta = f \Delta\theta \,\mathrm{FN} \tag{53}$$

The *depth of field* is distance that the object may be moved without causing excessive image blur with a fixed image location. The distance at which a lens may be focused such that the depth of field extends to infinity is $s_o = D_{\mathrm{ep}}/\Delta\theta$ and is called the hyperfocal distance.

If the lens system is diffraction-limited, then the depth of focus according to the Rayleigh criterion is given by

$$\delta = \pm \frac{\lambda}{2 n_i \sin^2 u_i} \tag{54}$$

Diffraction-Limited Lenses

It is well known that the shape of the image irradiance of an incoherent, monochromatic point source formed by an aberration-free, circularly-symmetric lens system is described by the Airy pattern

$$E(r) = C_0 \left[\frac{2 J_1(k D_{\mathrm{ep}} r/2)}{k D_{\mathrm{ep}} r} \right]^2 \tag{55}$$

where J_1 is the first-order Bessel function of the first kind, D_{ep} is the diameter of the entrance pupil, k is $2\pi/\lambda$, r is the radial distance from the center of the image to the observation point, and C_0 is a scaling factor. The angular radius β_{DL} of the first dark ring of the image is $1.22(\lambda/D_{ep})$. A common measure for the resolution is Lord Rayleigh's criterion that asserts that two point sources are just resolvable when the maximum of one Airy pattern coincides with the first dark ring of the second Airy pattern, that is, an angular separation of β_{DL}. Figure 41 presents a nomogram that can be used to make a rapid estimate of the diameter of angular or linear blur for a diffraction-limited system.

The modulation transfer function (MTF) *at a specific wavelength* λ for a circular entrance pupil can be computed by

$$\mathrm{MTF}_{\lambda}(\Omega)=\frac{2}{\pi}\left[\arccos\Omega-\Omega\sqrt{1-\Omega^2}\right] \qquad \text{for } 0\le\Omega\le1 \tag{56}$$

where Ω is the normalized spatial frequency (ν/ν_{co}) with the maximum or cut-off frequency ν_{co} being be by $1/\lambda_o$ FN.

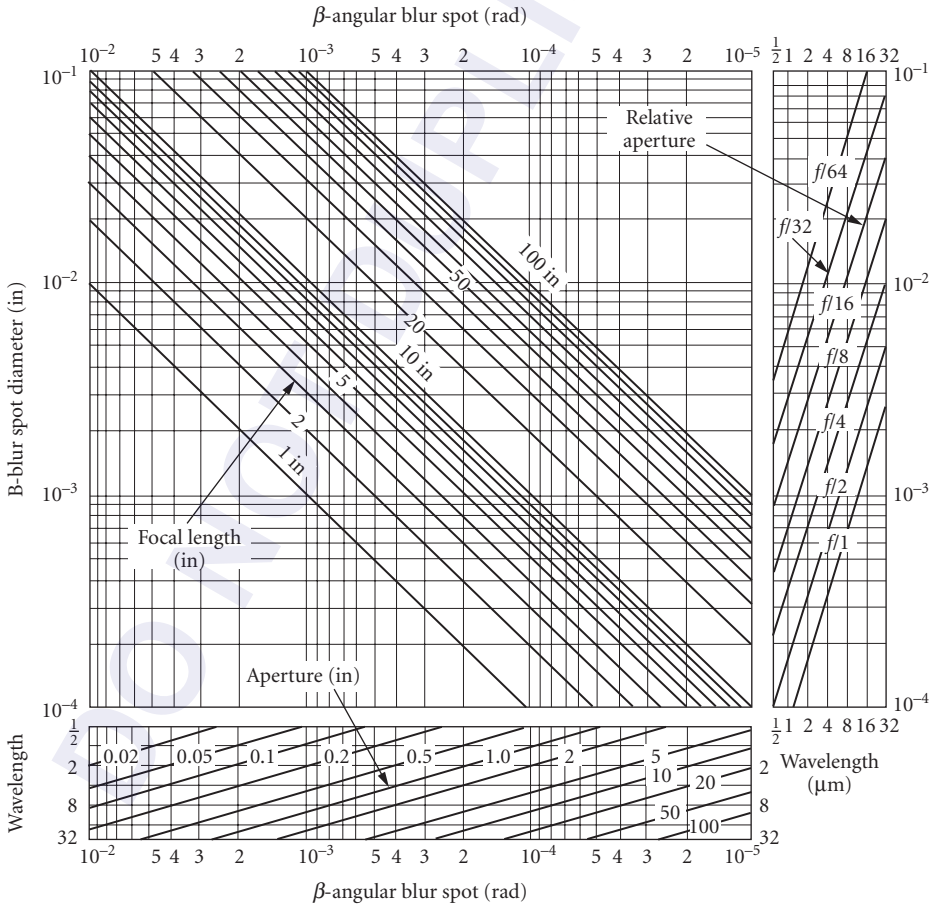

FIGURE 41 Estimation of the spot diameter for a diffraction-limited lens system. The diameter is that of the first dark ring of the Airy disk. (*Smith, Modern Optical Engineering, McGraw-Hill, New York, 1990, p. 458.*)

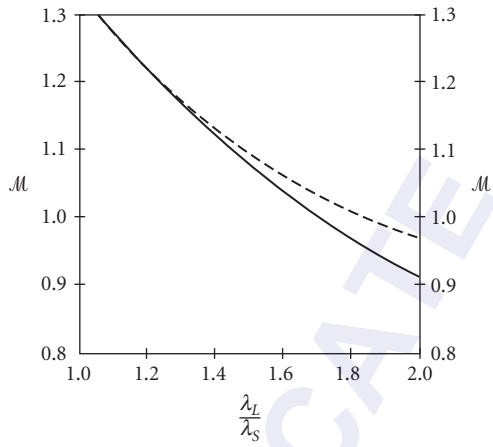

FIGURE 42 Variation of $\mathcal{M}$ with λ_L/λ_S or $b + 1$ for $\tilde{\mathfrak{R}}(\lambda) = 1$ as the solid curve and $\tilde{\mathfrak{R}}(\lambda) = \lambda/\lambda_S$ as the dashed curve.

Should the source be polychromatic and the lens system be aberration-free, then the perfect-image irradiance distribution of a point source can be written as

$$E(r) = C_1 \int_0^\infty \tilde{\mathfrak{R}}(\lambda) \left[\frac{2J_1(kD_{ep}r/2)}{kD_{ep}r} \right]^2 d\lambda \tag{57}$$

where $\tilde{\mathfrak{R}}(\lambda)$ is the peak normalized spectral weighting factor and C_1 is a scaling factor.

A quick estimation of this ideal irradiance distribution can be made by invoking the central limit theorem to approximate this distribution by a Gaussian function, that is,

$$E(r) \approx C_2 e^{-(r^2/2\sigma^2)} \tag{58}$$

where C_2 is a scaling constant and σ^2 is the estimated variance of the irradiance distribution. When $\tilde{\mathfrak{R}}(\lambda) = 1$ in the spectral interval λ_S to λ_L and zero otherwise with $\lambda_s < \lambda_L$, an estimate of can be written as

$$\sigma = \frac{\mathcal{M}\lambda_L}{\pi D_{ep}} \tag{59}$$

where $\mathcal{M} = 1.335 - 0.625\text{b} + 0.025b^2 - 0.0465b^3$ with $b = (\lambda_L/\lambda_s) - 1$. Should $\tilde{\mathfrak{R}}(\lambda) = \lambda/\lambda_L$ in the spectral interval λ_S to λ_L and zero otherwise, which approximates the behavior of a quantum detector, $\mathcal{M} = 1.\ 335 - 0.65b + 0.385b^2 - 0.099b^3$. The Gaussian estimate residual error is less than a few percent for $b = 0.5$ and remains useful even as $b \to 0$. Figure 42 contains plots of $\mathcal{M}$ for both cases of $\tilde{\mathfrak{R}}(\lambda)$, where the abscissa is λ_L/λ_S. A useful estimation of the modulation transfer function for this *polychromatic* lens system is given by

$$\text{MTF}(\nu) \approx e^{-2(\pi\sigma\nu)^2} \tag{60}$$

where ν is the spatial frequency. This approximation overestimates the MTF somewhat at lower spatial frequencies, while being rather a close fit at medium and higher spatial frequencies. The reason for this is that the central portion of the irradiance distribution is closely matched by the gaussian approximation, while the irradiance estimation beyond several Airy radii begins to degrade, therefore impacting the lower spatial frequencies. Nevertheless, this approximation can provide useful insight into expected performance limits.

18.2 INTRODUCTION

If collimated (parallel) light rays from an infinitely distant point source fall incident on the input end of a lens system, rays exiting from the output end will show one of three characteristics: (1) they will converge to a real point focus outside the lens system, (2) they will appear to diverge from a virtual point focus within the lens system, or (3) they will emerge as collimated rays that may differ in some characteristics from the incident collimated rays. In cases 1 and 2, the paraxial imaging properties of the lens system can be modeled accurately by a characteristic focal length and a set of fixed principal surfaces. Such lens systems might be called *focusing* or *focal* lenses, but are usually referred to simply as *lenses*. In case 3, a single finite focal length cannot model the paraxial characteristics of the lens system; in effect, the focal length is infinite, with the output focal point an infinite distance behind the lens, and the associated principal surface an infinite distance in front of the lens. Such lens systems are referred to as *afocal*, or without focal length. They will be called *afocal lenses* here, following the common practice of using "lens" to refer to both single element and multielement lens systems. They are the topic of this chapter.

The first afocal lens was the galilean telescope (to be described later), a visual telescope made famous by Galileo's astronomical observations. It is now believed to have been invented by Hans Lipperhey in 1608.[1] Afocal lenses are usually thought of in the context of viewing instruments or attachments to change the effective focal length of focusing lenses, whose outputs are always collimated. In fact, afocal lenses can form real images of real objects. A more useful distinction between focusing and afocal lenses concerns which optical parameters are fixed, and which can vary in use. Focusing lenses have a fixed, finite focal length, can produce real images for a wide range of object distances, and have a linear magnification which varies with object distance. Afocal lenses have a fixed magnification which is independent of object distance, and the range of object distances yielding real images is severely restricted.

This chapter is divided into six sections, including this introduction. Section 18.3 reviews the gaussian (paraxial) image-forming characteristics of afocal lenses and compares them to the properties of focusing lenses. The importance of the optical invariant in designing afocal lenses is discussed. Section 18.4 reviews the keplerian telescope and its descendants, including both infinite conjugate and finite conjugate variants. Section 18.5 discusses the galilean telescope and its descendants. Thin-lens models are used in the Secs. 18.4 and 18.5 to define imaging characteristics and design principles for afocal lenses. Section 18.6 reviews relay trains and periscopes. The final section reviews reflecting and catadioptric afocal lenses.

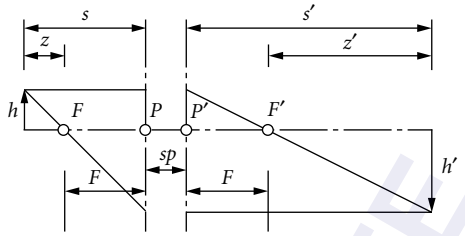
This chapter is based on an earlier article by Wetherell.[2] That article contains derivations of many of the equations appearing here, as well as a more extensive list of patents illustrating different types of afocal lens systems.

18.3 GAUSSIAN ANALYSIS OF AFOCAL LENSES

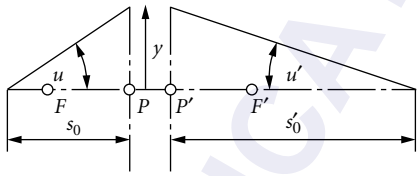
Afocal lenses differ from focusing lenses in ways that are not always obvious. It is useful to review the basic image-forming characteristics of focusing lenses before defining the characteristics unique to afocal lenses.

Focusing Lenses

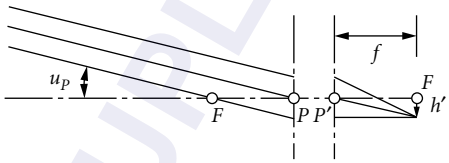
In this chapter, all lens elements are assumed to be immersed in air, so that object space and image space have the same index of refraction. Points in object space and image space are represented by two rectangular coordinate systems (x, y, z) and (x', y', z'), with the prime indicating image space. The z- and z' axes form a common line in space, the *optical axis* of the system. It is assumed, unless noted otherwise, that all lens elements are rotationally symmetric with respect to the optical axis. Under these conditions, the imaging geometry of a focusing lens can be defined in terms of two principal



(a) Finite conjugate model of focusing lens



(b) Computing image tilt with scheimpflug rule



(c) Infinite conjugate model of focusing lens

FIGURE 1 Imaging geometry of focusing lenses.

points P and P', two focal points F and F', and a single characteristic focal length f, as shown in Fig. 1. P, P', F, and F' all lie on the optical axis.

The focal points F and F', will be the origins for the coordinate systems (x, y, z) and (x', y', z'). If the origins are at P and P', the coordinates will be given as (x, y, s) and (x', y', s'), where $s = z - f$ and $s' = z' + f$. Normal right-hand sign conventions are used for each set of coordinates, and light travels along the z axis from negative z toward positive z', unless the optical system has internal mirrors. Figure l*a* illustrates the terminology for finite conjugate objects.

Object points and image points are assumed to lie in planes normal to the optical axis, for paraxial computations. *Object distance* is specified by the axial distance to the object surface, z or s, and *image distance* by z' or s'. The two most commonly used equations relating image distance to object distance are

$$\frac{1}{s'} - \frac{1}{s} = \frac{1}{f} \tag{1}$$

and

$$zz' = -f^2 \tag{2}$$

For infinitely distant object points, $z' = 0$ and $s' = f$, and the corresponding image points will lie in the focal plane at F'.

To determine the actual distance from object plane to image plane, it is necessary to know the distance sp between P and P'. The value of sp is a constant specific to each real lens system, and may be either positive [moving object and image further apart than predicted by Eq. (1) or (2)] or negative (moving them closer together).

For rotationally symmetric systems, off-axis object and image coordinates can be expressed by the *object height h* and *image height h′*, where $h^2 = x^2 + y^2$ and $h'^2 = x'^2 + y'^2$. Object height and image height are related by the *linear magnification m*, where

$$m = \frac{h'}{h} = \frac{s'}{s} = \frac{z' + f}{z - f} \tag{3}$$

Since the product zz' is a constant, Eq. (3) implies that magnification varies with object distance.

The *principal surfaces* of a focusing lens intersect the optical axis at the principal points P and P'. In paraxial analysis, the principal surfaces are planes normal to the optical axis; for real lenses, they may be curved. The principal surfaces are conjugate image surfaces for which $m = +1.0$. This property makes the raytrace construction shown in Fig. l*a* possible, since a ray traveling parallel to the optical axis in either object or image space must intersect the focal point in the conjugate space, and must also intersect both principal surfaces at the same height.

In real lenses, the object and image surfaces may be tilted or curved. Planes normal to the optical axis are still used to define object and image positions for off-axis object points, and to compute magnification. For tilted object surfaces, the properties of the principal surfaces can be used to relate object surface and image surface tilt angles, as shown in Fig. 1*b*. Tilted object and image planes intersect the optical axis and the two principal planes. The tilt angles with respect to the optical axis, u and u', are defined by meridional rays lying in the two surfaces. The points at which conjugate tilted planes intercept the optical axis are defined by s_a and s'_a, given by Eq. (1). Both object and image planes must intersect their respective principal surfaces at the same height y, where $y = s_a \tan u = s'_a \tan u'$. It follows that

$$\frac{\tan u'}{\tan u} = \frac{s_a}{s'_a} = \frac{1}{m_a} \tag{4}$$

The geometry of Fig. 1*b* is known as the *Scheimpflug condition*, and Eq. (4) is the *Scheimpflug rule*, relating image to object tilt. The magnification m_a applies only to the axial image.

The height off axis of an infinitely distant object is defined by the principal ray angle u_p measured from F or P, as shown in Fig. l*c*. In this case, the image height is

$$h' = f \tan u_p \tag{5}$$

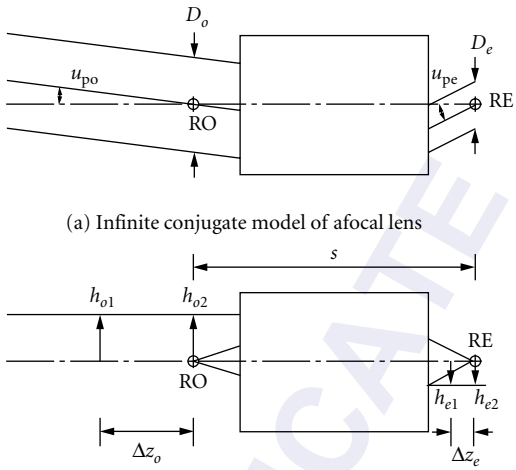
A focusing lens which obeys Eq. (5) for all values of u_p within a specified range is said to be *distortion-free*: if the object is a set of equally spaced parallel lines lying in an object plane perpendicular to the optical axis, it will be imaged as a set of equally spaced parallel lines in an image plane perpendicular to the optical axis, with line spacing proportional to m.

Equations (1) through (5) are the basic gaussian imaging equations defining a perfect focusing lens. Equation (2) is sometimes called the *newtonian* form of Eq. (1), and is the more useful form for application to afocal lens systems.

Afocal Lenses

With afocal lenses, somewhat different coordinate system origins and nomenclature are used, as shown in Fig. 2. The object and image space reference points RO and RE are at conjugate image points. Since the earliest and most common use for afocal lenses is as an aid to the eye for viewing distant objects, image space is referred to as *eye space*. Object position is defined by a right-hand coordinate system (x_o, y_o, z_o) centered on reference point RO. Image position in eye space is defined by coordinates (x_e, y_e, z_e) centered on RE.

Because afocal lenses are most commonly used for viewing distant objects, their imaging characteristics are usually specified in terms of *angular magnification M, entrance pupil* diameter D_o, and total field of view. Figure 2*a* models an afocal lens used at infinite conjugates. Object height off axis is



(a) Infinite conjugate model of afocal lens

(b) Finite conjugate model of afocal lens

FIGURE 2 Imaging geometry of focusing lenses.

defined by the principal ray angle u_{po}, and the corresponding image height is defined by u_{pe}. Objects viewed through the afocal lens will appear to be magnified by a factor M, where

$$\tan u_{pe} = M \tan u_{po} \tag{6}$$

If M is negative, as in Fig. 2*a*, the image will appear to be inverted. [Strictly speaking, since RO and RE are separated by a distance S, the apparent magnification seen by an eye at RE with and without the afocal lens will differ slightly from that indicated by Eq. (6) for nearby objects.][2]

The imaging geometry of an afocal lens for finite conjugates is illustrated in Fig. *2b*. Since a ray entering the afocal lens parallel to the optical axis will exit the afocal lens parallel to the optical axis, it follows that the linear magnification m relating object height h_o and image height h_e must be invariant with object distance. The linear magnification m is the inverse of the angular magnification M:

$$m = \frac{h_e}{h_o} = \frac{1}{M} \tag{7}$$

The axial separation Δz_e of any two images h_{e1} and h_{e2} is related to the separation Δz_o of the corresponding objects h_{o1} and h_{o2} by

$$\Delta z_e = m^2 \Delta z_o = \frac{\Delta z_o}{M^2} \tag{8}$$

It follows that any convenient pair of conjugate image points can be chosen as reference points RO and RE. Given the location of RO, the reference point separation S, and the magnifications $m = 1/M$, the imaging geometry of a rotationally symmetric distortion-free afocal lens can be given as

$$x_e = m x_o = \frac{x_o}{M} \qquad y_e = m y_o = \frac{y_o}{M} \qquad z_e = m^2 z_o = \frac{z_o}{M^2} \tag{9}$$

Equation (9) is a statement that coordinate transformation between object space and eye space is rectilinear for afocal lenses, and is solely dependent on the *afocal magnification M* and the location

of two conjugate reference points RO and RE. The equations apply (paraxially) to all object and image points independent of their distances from the afocal lens. Any straight line of equally spaced object points will be imaged as a straight line of equally spaced image points, even if the line does not lie in a plane normal to the optical axis. Either RO or RE may be chosen arbitrarily, and need not lie on the axis of symmetry of the lens system, so long as the z_o- and z_e axes are set parallel to the axis of symmetry.

A corollary of invariance in lateral and axial linear magnification is invariance in angular magnification. Equation (6) thus applies to any ray traced through the afocal system, and to tilted object and image surfaces. In the latter context, Eq. (6) can be seen as an extension of Eq. (4) to afocal lenses.

The *eye space pupil diameter* D_e is of special importance to the design of visual instruments and afocal attachments: D_e must usually be large enough to fill the pupil of the associated instrument or eye. The *object space pupil* diameter D_o is related to D_e by

$$D_e = \frac{D_o}{M} = mD_o \tag{10}$$

(The more common terminology *exit pupil* and *entrance pupil* will be used later in this chapter.)

Subjective Aspects of Afocal Imagery

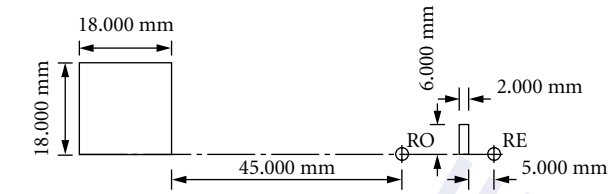
The angular magnification M is usually thought of in terms of Eq. (6), which is often taken to indicate that an afocal lens projects an image which is M-times as large as the object. (See, for example, Fig. 5.88 in Hecht and Zajac.)[3] Equation (9) shows that the image height is actually $1/M$-times the object height (i.e., smaller than the object when $|M| > 1$). Equation (9) also shows, however, that the image distance is reduced to $1/M^2$-times the object distance, and it is this combination of linear height reduction and quadratic distance reduction which produces the subjective appearance of magnification. Equation (6) can be derived directly from Eq. (9).

$$\tan u_{\text{pe}} = \frac{y_e}{z_e} = \frac{y_o/M}{z_o/M^2} = M \tan u_{\text{po}}$$

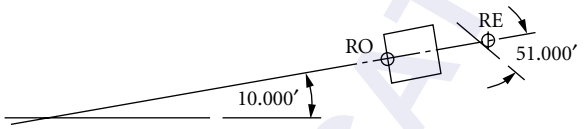
Equation (9) is therefore a more complete model than Eq. (6) for rotationally symmetric, distortion-free afocal lenses.

Figure 3 illustrates two subjective effects which arise when viewing objects through afocal lenses. In Fig. 3*a* for which $M = +3\times$, Eq. (9) predicts that image dimensions normal to the optical axis will be reduced by 1/3, while image dimensions along the optical axis will be reduced by 1/9. The image of the cube in Fig. 3*a* looks three times as tall and wide because it is nine times closer, but it appears compressed by a factor of 3 in the axial direction, making it look like a cardboard cutout. This subjective compression, most apparent when using binoculars, is intrinsic to the principle producing angular magnification, and is independent of pupil spacing in the binoculars.

Figure 3*a* assumes the optical axis is horizontal within the observer's reference framework. If the axis of the afocal lens is not horizontal, the afocal lens may create the illusion that horizontal surfaces are tilted. Figure 3*b* represents an $M = +7\times$ afocal lens whose axis is tilted 10° to a horizontal surface. Equation (6) can be used to show that the image of this surface is tilted approximately 51° to the axis of the afocal lens, creating the illusion that the surface is tilted 41° to the observer's horizon. This illusion is most noticeable when looking downward at a surface known to be horizontal, such as a body of water, through a pair of binoculars.



(a) Image of 18-mm cube formed by +3× afocal lens



(b) Horizontal surface imaged by +7× afocal lens whose axis is tilted 10° to horizon

FIGURE 3 Subjective aspects of afocal imagery.

Afocal Lenses and the Optical Invariant

Equations (6) and (7) can be combined to yield

$$h_e \tan u_{\text{pe}} = h_o \tan u_{\text{po}} \tag{11}$$

which is a statement of the optical invariant as applied to distortion-free afocal lenses. Neither u_{po} nor u_{pe} is typically larger than 35°–40° in distortion-free afocal lenses, although there are examples with distortion where $u_{\text{po}} \rightarrow 90°$. Given a limit on one angle, Eq. (11) implies a limit on the other angle related to the ratio $h_o/h_e = D_o/D_e$. Put in words, *the ratio D_o/D_e cannot be made arbitrarily large without a corresponding reduction in the maximum allowable field of view*. All designers of afocal lens systems *must* take this fundamental principle into consideration.

18.4 KEPLERIAN AFOCAL LENSES

A simple afocal lens can be made up of two focusing lenses, an *objective* and an *eyepiece*, set up so that the rear focal point of the objective coincides with the front focal point of the eyepiece. There are two general classes of simple afocal lenses, one in which both focusing lenses are positive, and the other in which one of the two is negative. Afocal lenses containing two positive lenses were first described by Johannes Kepler in *Dioptrice*, in 1611,[4] and are called *keplerian*. Lenses containing a negative eyepiece are called *galilean*, and will be discussed separately. Generally, afocal lenses contain at least two powered surfaces. The simplest model for an afocal lens consists of two thin lenses.

Thin-Lens Model of a Keplerian Afocal Lens

Figure 4 shows a thin-lens model of a keplerian telescope. The focal length of its objective is f_o and the focal length of its eyepiece is f_e. Its properties can be understood by tracing two rays, ray 1 entering the objective parallel to the optical axis, and ray 2 passing through F_o, the front focal

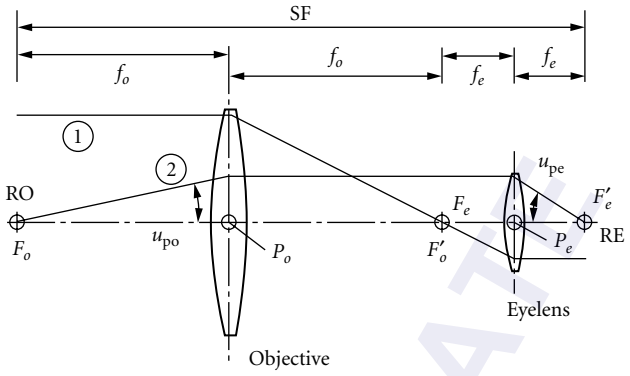


FIGURE 4 Thin-lens model of keplerian afocal lens.

point of the objective. Ray 1 leads directly to the linear magnification m, and ray 2 to the angular magnification M:

$$m = -\frac{f_e}{f_0} \qquad M = -\frac{f_o}{f_e} = \frac{\tan u_{\text{pe}}}{\tan u_{\text{po}}} \tag{12}$$

Equation (12) makes the relationship of afocal magnification to the Scheimpflug rule of Eq. (4) more explicit, with focal lengths f_o and f_e substituting for s_a and s'_a.

The second ray shows that placing the reference point RO at F_o will result in the reference point RE falling on F'_e, the rear focal point of the eyepiece. The reference point separation for RO in this location is

$$\text{SF} = 2f_e + 2f_o = 2(1-M)f_e = 2(1-m)f_o \tag{13}$$

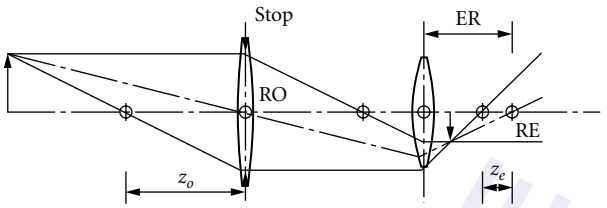
Equation (13) can be used as a starting point for calculating any other locations for RO and RE, in combination with Eq. (9).

One additional generalization can be drawn from Fig. 4: the ray passing through F_o will emerge from the objective parallel to the optical axis. It will therefore also pass through F'_e even if the spacing between objective and eyepiece is increased to focus on nearby objects. Thus the angular magnification remains invariant, if u_{po} is measured from F_o and u_{pe} is measured from F'_e, even when adjusting the eyepiece to focus on nearby objects makes the lens system depart from being strictly afocal.

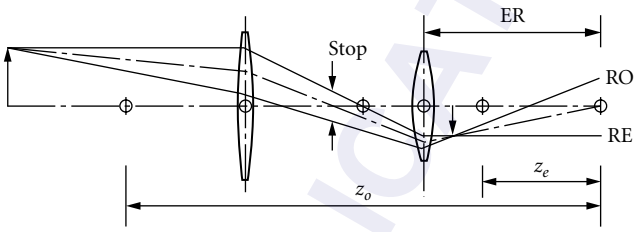
The simple thin-lens model of the keplerian telescope can be extended to systems composed of two real focusing lenses if we know their focal lengths and the location of each lens' front and rear focal points. Equation (12) can be used to derive M, and SF can be measured. Equation (9) can then be used to compute both finite and infinite conjugate image geometry.

Eye Relief Manipulation

The earliest application of keplerian afocal lenses was to obtain magnified views of distant objects. To view distant objects, the eye is placed at RE. An important design consideration in such instruments is to move RE far enough away from the last surface of the eyepiece for comfortable viewing. The distance from the last optical surface to the exit pupil at RE is called the *eye relief* ER. One way to increase eye relief ER is to move the entrance pupil at RO toward the objective. Most telescopes and binoculars have the system stop at the first surface of the objective, coincident with the entrance pupil, as shown in Fig. 5*a*.



(a) RO placed at objective



(b) RO and RE at same point

FIGURE 5 Increasing eye relief ER by moving stop.

In the thin-lens model of Fig. 5*a*, RO is moved a distance $z_o = f_o$ to place it at the objective. Thus RE must move a distance $z_e = f_o/M^2 = -f_e/M$, keeping in mind that M is negative in this example. Thus for a thin-lens keplerian telescope with its stop at the objective, the eye relief ER_k is

$$\mathrm{ER}_k = \frac{(M-1)}{M} f_e \tag{14}$$

It is possible to increase the eye relief further by placing the stop inside the telescope, moving the location of RO into virtual object space. Figure 5*b* shows an extreme example of this, where the virtual location of RO has been matched to the real location of RE. For this common-pupil-position case, the eye relief $\mathrm{ER}_{\mathrm{cp}}$ is

$$\mathrm{ER}_{\mathrm{cp}} = \frac{(M-1)}{(M+1)} f_e \tag{15}$$

A price must be paid for locating the stop inside the afocal lens, in that the elements ahead of the stop must be increased in diameter if the same field of view is to be covered without vignetting.

The larger the magnitude of M, the smaller the gain in ER yielded by using an internal stop. To increase the eye relief further, it is necessary to make the objective and/or the eyepiece more complex, increasing the distance between F_o and the first surface of the objective, and between the last surface of the eyepiece and F_e'. If this is done, placing RO at the first surface of the objective will further increase ER.

Figure 6 shows a thin-lens model of a telephoto focusing lens of focal length f_t. For convenience, a zero Petzval sum design is used, for which $f_1 = f$ and $f_2 = -f$. Given the telephoto's focal length f_t and the lens separation d, the rest of the parameters shown in Fig. 6 can be defined in terms of the constant $C = d/f_t$. The component focal length f, back focal length bfl, and front focal length ffl, are given by

$$f = f_t C^{1/2} \qquad \mathrm{bfl} = f_t(1 - C^{1/2}) \qquad \mathrm{ffl} = f_t(1 + C^{1/2}) \tag{16}$$

and the total physical length ttl and focal point separation sf are given by

$$\mathrm{ttl} = f_t(1 + C - C^{1/2}) \qquad \mathrm{sf} = f_t(2 + C) \tag{17}$$

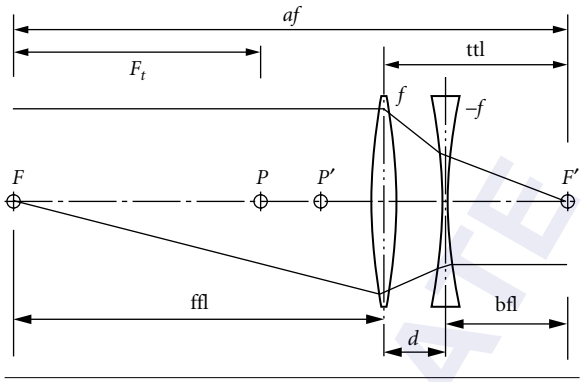


FIGURE 6 Zero Petzval sum telephoto lens.

The maximum gain in eye relief will be obtained by using telephoto designs for both objective and eyepiece, with the negative elements of each facing each other. Two cases are of special interest. First, ttl can be minimized by setting $C = 0.25$ for both objective and eyepiece. In this case, the eye relief ER_{ttl} is

$$ER_{ttl} = 1.5\frac{(M-1)}{M} f_e = 1.5ER_k \tag{18}$$

Second, sf can be maximized by setting $C = 1.0$ for both objective and eyepiece. This places the negative element at the focal plane, merging the objective and eyepiece negative elements into a single negative field lens. The eye relief in this case, ER_{sf}, is

$$ER_{sf} = 2.0\frac{(M-1)}{M} = 2.0ER_k \tag{19}$$

Placing a field lens at the focus between objective and eyepiece can be problematical, when viewing distant objects, since dust or scratches on the field lens will be visible. If a reticle is required, however, it can be incorporated into the field lens. Equations (14), (18), and (19) show that significant gains in eye relief can be made by power redistribution. In the example of Eq. (18), the gain in ER is accompanied by a reduction in the physical length of the optics, which is frequently beneficial.

Terrestrial Telescopes

Keplerian telescopes form an inverted image, which is considered undesirable when viewing earthbound objects. One way to make the image erect, commonly used in binoculars, is to incorporate erecting prisms. A second is to insert a relay stage between objective and eyepiece, as shown in Fig. 7. The added relay is called an *image erector*, and telescopes of this form are called *terrestrial telescopes*. (The keplerian telescope is often referred to as an *astronomical telescope*, to distinguish it from terrestrial telescopes, since astronomers do not usually object to inverted images. *Astronomical* has become ambiguous in this context, since it now more commonly refers to the very large aperture reflecting objectives found in astronomical observatories. *Keplerian* is the preferred terminology.) The terrestrial telescope can be thought of as containing an objective, eyepiece, and image erector, or as containing two afocal relay stages.

There are many variants of terrestrial telescopes made today, in the form of binoculars, theodolites, range finders, spotting scopes, rifle scopes, and other military optical instrumentation. All are offshoots of the keplerian telescope, containing a positive objective and a positive eyepiece, with intermediate

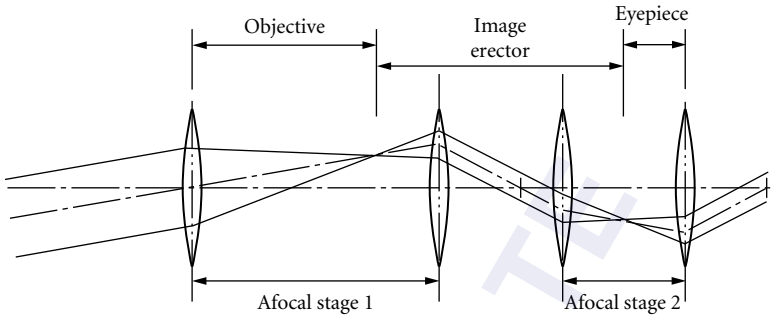

FIGURE 7 Terrestrial telescope.

relay stages to perform special functions. Patrick[5] and Jacobs[6] are good starting points for obtaining more information.

Field-of-View Limitations in Keplerian and Terrestrial Telescopes

The maximum allowable eye space angle u_{pe} and magnification M set an upper limit on achievable fields of view, in accordance with Eq. (11). MIL-HDBK-141[7] lists one eyepiece design for which the maximum $u_{pe} = 36°$. If $M = 7\times$, using that eyepiece allows a 5.9° maximum value for u_{po}. It is a common commercial practice to specify the total field of view FOV as the width in feet which subtends an angle $2u_{po}$ from 1000 yd away, even when the pupil diameter is given in millimeters. FOV is thus given by

$$\text{FOV} = 6000 \tan u_{po} = \frac{6000}{M} \tan u_{pe} \tag{20}$$

For our 7× example, with u_{pe} = 36°, FOV = 620 ft at 1000 yd. For commercial 7 × 50 binoculars ($M = 7\times$ and $D_o = 50$ mm), FOV = 376 ft at 1000 yd is more typical.

Finite Conjugate Afocal Relays

If an object is placed in contact with the front surface of the keplerian telescope of Fig. 5, its image will appear a distance ER_k behind the last surface of the eyepiece, in accordance with Eq. (14). There is a corresponding *object relief* distance $OR_k = M^2 ER_k$ defining the position of an object that will be imaged at the output surface of the eyepiece, as shown in Fig. 8. OR_k and ER_k define the portions of object space and eye space within which real images can be formed of real objects with a simple keplerian afocal lens.

$$OR_k = M(M-1)f_e \tag{21}$$

Object relief is enlarged by the power redistribution technique used to extend eye relief. Thus there is a minimum total length design corresponding to Eq. (18), for which the object relief OR_{ttl} is

$$OR_{ttl} = 1.5M(M-1)f_e \tag{22}$$

and a maximum eye relief design corresponding to Eq. (19), for which OR_{sf}

$$OR_{sf} = 2.0M(M-1)f_e \tag{23}$$

is also maximized.

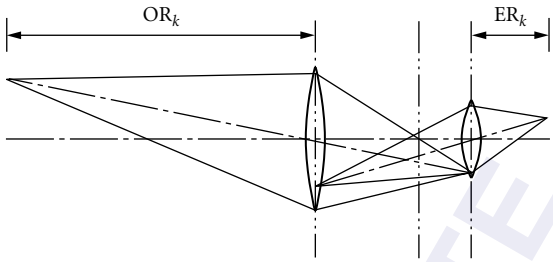

FIGURE 8 Finite conjugate keplerian afocal lens showing limits on usable object space and image space.

Figure 9 shows an example of a zero Petzval sum finite conjugate afocal relay designed to maximize OR and ER by placing a negative field lens at the central infinite conjugate image. Placing the stop at the field lens means that the lens is *telecentric* (principal rays parallel to the optical axis) in both object and eye space. As a result, magnification, principal ray angle of incidence on object and image surface, and cone angle are all invariant over the entire range of OR and ER for which there is no vignetting. Magnification and cone angle invariance means that object and image surfaces can be tilted with respect to the optical axis without introducing keystoning or variation in image irradiance over the field of view. Having the principal rays telecentric means that object and image position can be adjusted for focus without altering magnification. It also means that the lens can be defocused without altering magnification, a property very useful for unsharp masking techniques used in the movie industry.

One potential disadvantage of telecentric finite conjugate afocal relays is evident from Fig. 9: to avoid vignetting, the apertures of both objective and eyepiece must be larger than the size of the associated object and image. While it is possible to reduce the diameter of either the objective or the eyepiece by shifting the stop to make the design nontelecentric, the diameter of the other lens group becomes larger. Afocal relays are thus likely to be more expensive to manufacture than focusing lens relays, unless object and image are small.

Finite conjugate afocal lenses have been used for alignment telescopes,[8] for laser velocimeters,[9] and for automatic inspection systems for printed circuit boards.[10] In the last case, invariance of magnification, cone angle, and angle of incidence on a tilted object surface make it possible to measure the volume of solder beads automatically with a computerized video system. Finite conjugate afocal lenses are also used as Fourier transform lenses.[11] Brief descriptions of these applications are given in Wetherell.[2]

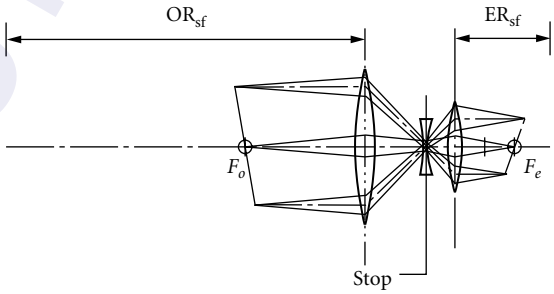

FIGURE 9 Finite conjugate afocal relay configured to maximize eye relief ER and object relief OR. Stop at common focus collimates principal rays in both object space and eye space.

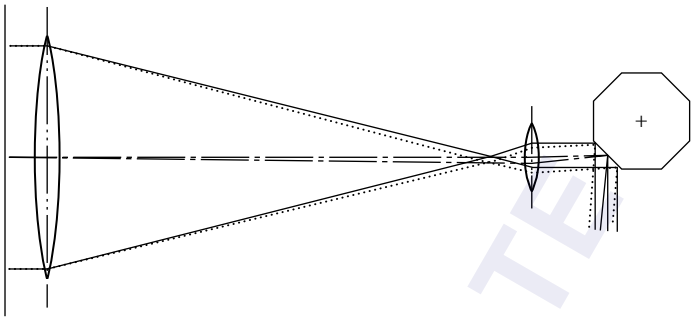

FIGURE 10 Afocal lens scanner geometry.

Afocal Lenses for Scanners

Many optical systems require scanners, and if the apertures of the systems are large enough, it is preferable to place the scanner inside the system. Although scanners have been designed for use in convergent light, they are more commonly placed in collimated light (see Chap. 30, "Scanners," in this volume, Marshall,[12] and Chap. 7 in Lloyd,[13] for descriptions of scanning techniques). A large aperture objective can be converted into a high magnification keplerian afocal lens with the aid of a short focal length eyepiece collimator, as shown in Fig. 10, providing a pupil in a collimated beam in which to insert a scanner. For the polygonal scanner shown, given the desired scan angle and telescope aperture diameter, Eq. (11) will define the combination of scanner facet size and number of facets needed to achieve the desired scanning efficiency. Scanning efficiency is the time it takes to complete one scan divided by the time between the start of two sequential scans. It is tied to the ratio of facet length to beam diameter, the amount of vignetting allowed within a scan, the number of facets, and the angle to be scanned.

Two limitations need to be kept in mind. First, the optical invariant will place an upper limit on M for the given combination of D_o and u_{po}, since there will be a practical upper limit on the achievable value of u_{pe}. Second, it may be desirable in some cases for the keplerian afocal relay to have enough barrel distortion so that Eq. (6) becomes

$$u_{pe} = Mu_{po} \tag{24}$$

An afocal lens obeying Eq. (24) will convert a constant rotation rate of the scan mirror into a constant angular scan rate for the external beam. The same property in "f-theta" focusing lenses is used to convert a constant angular velocity scanner rotation rate into a constant linear velocity rate for the recording spot of light.

The above discussion applies to scanning with a point detector. When the detector is a linear diode array, or when a rectangular image is being projected onto moving film, the required distortion characteristics for the optical system may be more complex.

Imaging in Binoculars

Most commercial binoculars consist of two keplerian afocal lenses with internal prismatic image erectors. Object and image space coordinates for binoculars of this type are shown schematically in Fig. 11. Equation (9) can be applied to Fig. 11 to analyze their imaging properties. In most binoculars, the spacing S_o between objectives differs from the spacing S_e between eyepieces, and S_o may be either larger or smaller than S_e. Each telescope has its own set of reference points, ROL and REL for the left telescope, and ROR and RER for the right. Object space is a single domain with a single origin O. The object point at z_o, midway between the objective axes, will be x_{oL} units to the right

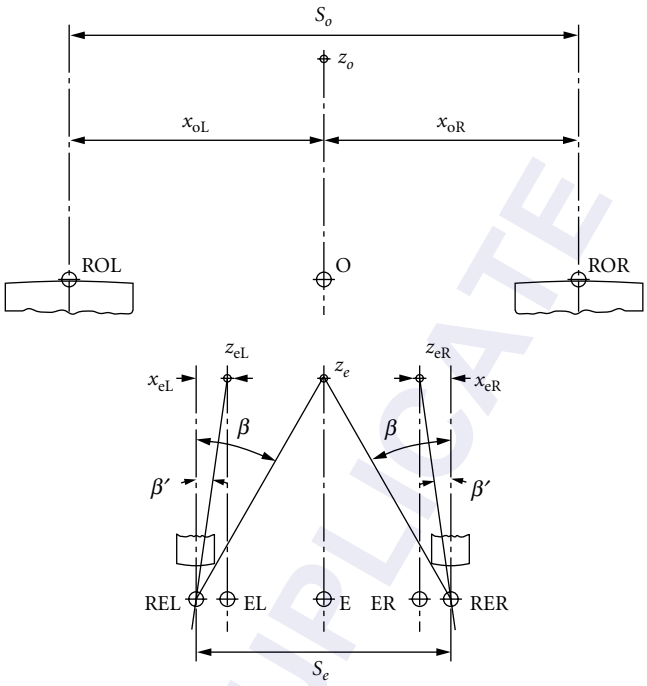

FIGURE 11 Imaging geometry of binoculars.

of the left objective axis, and x_{oR} units to the left of the right objective axis. In an ideal binocular system, the images of the object formed by the two telescopes would merge at one point, z_e units in front of eye space origin E. This will happen if $S_o = MS_e$, so that $x_{eL} = x_{oL}/M$ and $x_{eR} = x_{oR}/M$. In most modern binoculars, however, $S_o \ll MS_e$, and separate eye space reference points EL and ER will be formed for the left and right eye. As a result, each eye sees its own eye space, and while they overlap, they are not coincident. This property of binoculars can affect stereo acuity[2] and eye accommodation for the user.

It is normal for the angle at which a person's left-eye and right-eye lines of sight converge to be linked to the distance at which the eyes focus. (In my case, this linkage was quite strong before I began wearing glasses.) Eyes focused for a distance z_e normally would converge with an angle β, as shown in Fig. 11. When $S_o \ll MS_e$, as is commonly the case, the actual convergence angle β' is much smaller. A viewer for whom focus distance is strongly linked to convergence angle may find such binoculars uncomfortable to use for extended periods, and may be in need of frequent focus adjustment for different object distances.

A related but more critical problem arises if the axes of the left and right telescopes are not accurately parallel to each other. Misalignment of the axes requires the eyes to twist in unaccustomed directions to fuse the two images, and refocusing the eyepiece is seldom able to ease the burden. Jacobs[6] is one of the few authors to discuss this problem. Jacobs divides the axes misalignment into three categories: (1) misalignments requiring a divergence D of the eye axes to fuse the images, (2) misalignments requiring a convergence C, and (3) misalignments requiring a vertical displacement V. The tolerance on allowable misalignment in minutes of arc is given by Jacobs as

$$D = 7.5/(M-1) \qquad C = 22.5/(M-1) \qquad V = 8.0/(M-1) \tag{25}$$

Note that the tolerance on C, which corresponds to convergence to focus on nearby objects, is substantially larger than the tolerances on D and V.

18.5 GALILEAN AND INVERSE GALILEAN AFOCAL LENSES

The combination of a positive objective and a negative eyepiece forms a *galilean* telescope. If the objective is negative and the eyepiece positive, it is referred to as an *inverse galilean* telescope. The galilean telescope has the advantage that it forms an erect image. It is the oldest form of visual telescope, but it has been largely replaced by terrestrial telescopes for magnified viewing of distant objects, because of field-of-view limitations. In terms of number of viewing devices manufactured, there are far more inverse galilean than galilean telescopes. Both are used frequently as power-changing attachments to change the effective focal length of focusing lenses.

Thin-Lens Model of a Galilean Afocal Lens

Figure 12 shows a thin-lens model of a galilean afocal lens. The properties of galilean lenses can be derived from Eqs. (9), (12), and (13). Given that f_e is negative and f_o is positive, M is positive, indicating an erect image. If RO is placed at the front focal point of the objective, RE is a virtual pupil buried inside the lens system. In fact, galilean lenses cannot form real images of real objects under any conditions, and at least one pupil will always be virtual.

Field of View in Galilean Telescopes

The fact that only one pupil can be real places strong limitations on the use of galilean telescopes as visual instruments when $M \gg 1x$. Given the relationship $\Delta z_o = M^2 \Delta z_e$, moving RE far enough outside the negative eyepiece to provide adequate eye relief moves RO far enough into virtual object space to cause drastic vignetting at even small field angles. Placing RE a distance ER behind the negative lens moves RO to the position shown in Fig. 13, SF′ units behind RE, where

$$\mathrm{SF}' = (M^2 - 1)\mathrm{ER} - (M-1)^2 f_e \tag{26}$$

In effect, the objective is both field stop and limiting aperture, and vignetting defines the maximum usable field of view. The maximum acceptable object space angle u_{po} is taken to be that for the principal ray which passes just inside D_o, the entrance pupil at the objective. If the F-number of the objective is $\mathrm{FN}_{\mathrm{ob}} = f_o/D_o$, then

$$\tan u_{\mathrm{po}} = \frac{-f_e}{2\mathrm{FN}_{\mathrm{ob}}(\mathrm{MER} + f_e - Mf_e)} \tag{27}$$

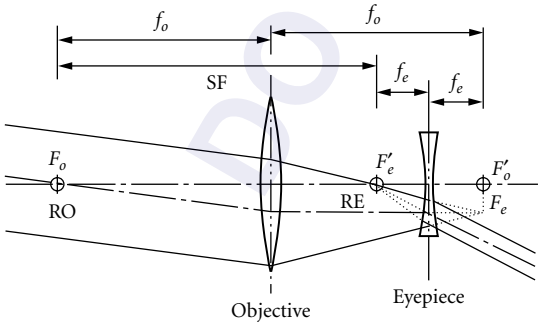

FIGURE 12 Thin-lens model of galilean afocal lens.

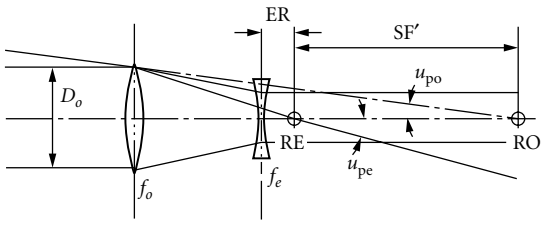

FIGURE 13 Galilean field-of-view limitations.

For convenience, assume ER $= -f_e$. In this case, Eq. (27) reduces to

$$\tan u_{po} = \frac{1}{2\mathrm{FN}_{ob}(2M-1)} \tag{28}$$

For normal achromatic doublets, $\mathrm{FN}_{ob} \geq 4.0$. For $M = 3x$, in this case, Eq. (28) indicates that $u_{po} \leq 1.43°$ (FOV ≤ 150 ft at 1000 yd). For $M = 7x$, $u_{po} \leq 0.55°$ (FOV ≤ 57.7 ft at 1000 yd). The effective field of view can be increased by making the objective faster and more complex, as can be seen in early patents by von Rohr[14] and Erfle.[15] In current practice, galilean telescopes for direct viewing are seldom made with M larger than $1.5x - 3.0x$. They are more typically used as power changers in viewing instruments, or to increase the effective focal length of camera lenses.[16]

Field of View in Inverse Galilean Telescopes

For inverse galilean telescopes, where $M \ll 1x$, adequate eye relief can be achieved without moving RO far inside the first surface of the objective. Inverse galilean telescopes for which $u_{po} \to 90°$ are very common in the form of security viewers[17] of the sort shown in Fig. 14, which are built into doors in hotel rooms, apartments, and many houses. These may be the most common of all optical systems more complex than eyeglasses. The negative objective lens is designed with enough distortion to allow viewing of all or most of the forward hemisphere, as shown by the principal ray in Fig. 14.

Inverse galilean telescopes are often used in camera view finders.[18] These present reduced scale images of the scene to be photographed, and often have built in arrangements to project a frame of lines representing the field of view into the image. Inverse galilean power changers are also used to increase the field of view of submarine periscopes and other complex viewing instruments, and to reduce the effective focal length of camera lenses.[19]

Anamorphic Afocal Attachments

Afocal attachments can compress or expand the scale of an image in one axis. Such devices are called *anamorphosers*, or *anamorphic afocal attachments*. One class of anamorphoser is the cylindrical galilean telescope, shown schematically in Fig. 15*a*. Cox[20] and Harris[21] have patented representative examples. The keplerian form is seldom if ever used, since a cylindrical keplerian telescope would introduce image inversion in one direction. Anamorphic compression can also be obtained using two prisms, as shown in Fig. 15*b*. The adjustable magnification anamorphoser patented by Luboshez[22] is a good example of prismatic anamorphosers. Many anamorphic attachments were developed in the 1950s for the movie industry for use in wide-field cameras and projectors. An extensive list of both types will be found in Wetherell.[2]

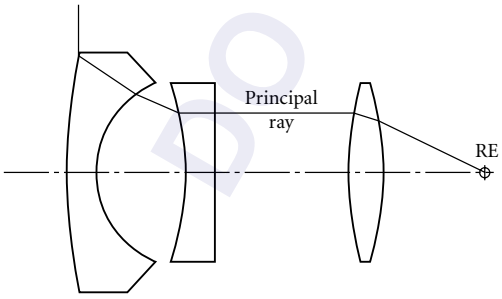

FIGURE 14 Inverse galilean security viewer with hemispheric field of view.

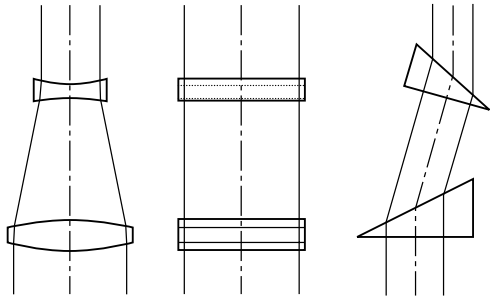

FIGURE 15 Anamorphic afocal attachments.

Equation (9) can be modified to describe anamorphic afocal lenses by specifying separate afocal magnifications M_x and M_y for the two axes. One important qualification is that separate equations are needed for object and image distances for the x and y planes. In general, anamorphic galilean attachments work best when used for distant objects, where any difference in x-axis and y-axis focus falls within the depth of focus of the associated camera lens. If it is necessary to use a galilean anamorphoser over a wide range of object distances, it may be necessary to add focus adjustment capabilities within the anamorphoser.

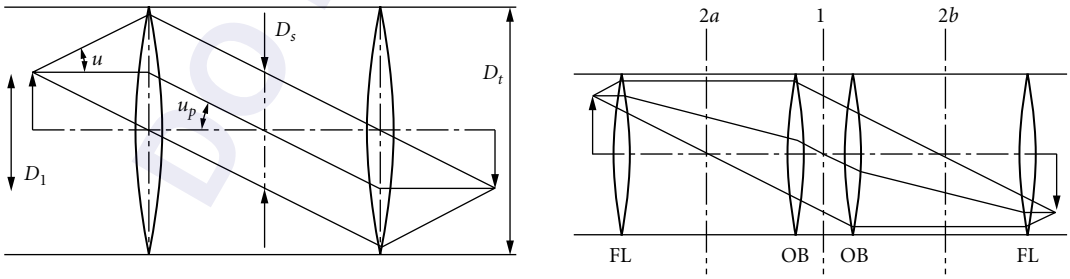
18.6 RELAY TRAINS AND PERISCOPES

There are many applications where it is necessary to perform remote viewing because the object to be viewed is in an environment hostile to the viewer, or because the object is inaccessible to the viewer without unacceptable damage to its environment. Military applications[5] fall into the former category, and medical applications[23] fall into the latter. For these applications, instrumentation is needed to *collect* light from the object, *transport* the light to a location more favorable for viewing, and *dispense* the light to the viewing instruments or personnel. Collecting and dispensing optical images is done with focusing lenses, typically. There are three image transportation techniques in common use today: (1) sense the image with a camera and transport the data electronically, (2) transport the light pattern with a coherent fiber optics bundle, and (3) transport the light pattern with a relay lens or train of relay lenses. The first two techniques are outside the scope of this chapter. *Relay trains*, however, are commonly made up of a series of unit power afocal lenses, and are one of the most important applications of finite conjugate afocal lenses.

Unit Power Afocal Relay Trains

Several factors are important in designing relay trains. First, it is desirable to minimize the number of relay stages in the relay train, both to maximize transmittance and to minimize the field curvature caused by the large number of positive lenses. Second, the outside diameter of the relay train is typically restricted (or a single relay lens could be used), so the choice of image and pupil diameter within the relay is important. Third, economic considerations make it desirable to use as many common elements as possible, while minimizing the total number of elements. Fourth, it is desirable to keep internal images well clear of optical surfaces where dust and scratches can obscure portions of the image. Fifth, the number of relay stages must be either odd or even to ensure the desired output image orientation.

Figure 16 shows thin-lens models of the two basic afocal lens designs which can be applied to relay train designs. Central to both designs is the use of symmetry fore and aft of the central stop to control coma, distortion, and lateral color, and matching the image diameter D_i and stop diameter D_s to



(a) Minimum number of lenses

(b) Minimum tube diameter

FIGURE 16 Basic unit power afocal relay designs.

maximize the stage length to diameter ratio. In paraxial terms, if $D_i = D_s$, then the marginal ray angle u matches the principal ray angle u_p, in accordance with the optical invariant. If the relay lens is both aplanatic and distortion free, a better model of the optical invariant is

$$D_i \sin u = D_s \tan u_p \tag{29}$$

and either the field of view $2u_p$ or the numerical aperture NA = $n \sin u$ must be adjusted to match pupil and image diameters. For some applications, maximizing the optical invariant which can pass through a given tube diameter D_t in a minimum number of stages is also critical.

If maximizing the ratio $D_i \sin u/D_t$ is not critical, Fig. 16*a* shows how the number of elements can be minimized by using a keplerian afocal lens with the stop at the common focus, eliminating the need for field lenses between stages. The required tube diameter in this example is at least twice the image diameter. If maximizing $D_i \sin u/D_t$ is critical, field lenses FL must be added to the objectives OB as shown in Fig. 16*b*, and the field lenses should be located as close to the image as possible within limits set by obstructions due to dirt and scratches on the field lens surfaces. Symmetry fore and aft of the central stop at 1 is still necessary for aberration balancing. If possible within performance constraints, symmetry of OB and FL with respect to the planes 2a and 2b is economically desirable, making OB and FL identical.

For medical instruments, where minimizing tube diameter is critical, variants of the second approach are common. The rod lens design[24] developed by H. H. Hopkins[25] can be considered an extreme example of either approach, making a single lens so thick that it combines the functions of OB and FL. Figure 17*a* shows an example from the first of two patents by McKinley.[26,27] The central element in each symmetrical cemented triplet is a sphere. Using rod lenses does maximize the optical invariant which can be passed through a given tube diameter, but it does not eliminate field curvature. It also maximizes weight, since the relay train is almost solid glass, so it is most applicable to small medical instruments.

If larger diameter relays are permissible, it is possible to correct field curvature in each relay stage, making it possible to increase the number of stages without adding field curvature. Baker[28] has patented the lens design shown in Fig. 17*b* for such an application. In this case, field lens and objective are identical, so that an entire relay train can be built using only three different element forms. Pupil and image diameters are the same, and pupil and image are interchangeable.

For purposes of comparison, the two designs shown in Fig. 17 have been scaled to have the same image diameter (2.8 mm) and numerical aperture (0.10), with component focal lengths chosen so that $D_s = D_i$. Minimum tube diameter is 4.0 mm for the rod lens and 5.6 mm for the Baker relay. The image radius of curvature is about 20 mm for the rod relay and about −368 mm for the Baker relay (i.e., field curvature is overcorrected). Image quality for the rod relay is 0.011 waves rms on axis and 0.116 waves rms at full field, both values for best focus, referenced to 587-nm wavelength. For the Baker relay, the corresponding values are 0.025 and 0.056 waves rms, respectively. The Baker design used for this comparison was adapted from the cited patent, with modern glasses substituted for types no longer available. No changes were made to the design other than refocusing it and scaling it to match the first-order parameters of the McKinley design. Neither design necessarily represents the best performance which can be obtained from its design type, and both should be evaluated

in the context of a complete system design where, for example, the field curvature of the McKinley design may be compensated for by that of the collecting and dispensing objectives. Comparing the individual relay designs does, however, show the price which must be paid for either maximizing the optical invariant within a given tube diameter or minimizing field curvature.

Periscopes

Periscopes are relay trains designed to displace the object space reference point RO a substantial distance away from the eye space reference point RE. This allows the observer to look over an intervening obstacle, or to view objects in a dangerous environment while the observer is in a safer environment. The submarine periscope is the archetypical example. Many other examples can be found in the military[5] and patent[2] literature.

The simplest form of periscope is the pair of fold mirrors shown in Fig. 18*a*, used to allow the viewer to see over nearby obstacles. Figure 18*b* shows the next higher level of complexity, in the form of a rear-view vehicle periscope patented[29] by Rudd.[30] This consists of a pair of cylindrical mirrors in a roof arrangement. The cylinders image one axis of object space with the principal purpose of compensating for the image inversion caused by the roof mirror arrangement. This could be considered to be a keplerian anamorphoser, except that it is usually a unit power magnifier, producing no anamorphic compression. Beyond these examples, the complexity of periscopes varies widely.

The optics of complex periscopes such as the submarine periscope can be broken down into a series of component relays. The core of a submarine periscope is a pair of fold prisms arranged like the mirrors in Fig. 18*a*. The upper prism can be rotated to scan in elevation, while the entire periscope is rotated to scan in azimuth, typically. The main optics is composed of keplerian afocal relays of different magnification, designed to transfer an erect image to the observer inside the submarine, usually at unit net magnification. Galilean and inverse galilean power changers can be inserted between the upper prism and main relay optics to change the field of view. Variants of this arrangement will be found in other military periscopes, along with accessories such as reticles or image intensifiers located at internal foci. Optical design procedures follow those for other keplerian afocal lenses.

18.7 REFLECTING AND CATADIOPTRIC AFOCAL LENSES

Afocal lenses can be designed with powered mirrors or combinations of mirrors and refractors. Several such designs have been developed in recent years for use in the photolithography of microcircuits. All-reflecting afocal lenses are classified here according to the number of powered mirrors they contain. They will be reviewed in order of increasing complexity, followed by a discussion of catadioptric afocal systems.

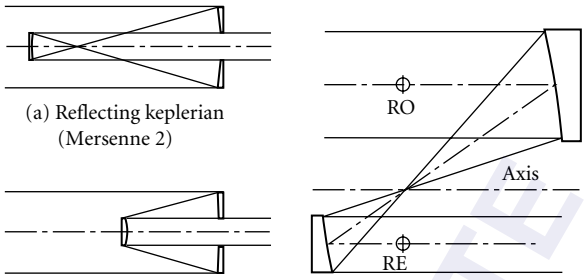

FIGURE 19 Reflecting Galilean.

Two-Powered-Mirror Afocal Lenses

The simplest reflecting afocal lenses are the variants of the galilean and keplerian telescopes shown in Fig. 19*a* and 19*b*. They may also be thought of as afocal cassegrainian and gregorian telescopes. The galilean/cassegrainian version is often called a *Mersenne* telescope. In fact, both galilean and keplerian versions were proposed by Mersenne in 1636,[31] so his name should not be associated solely with the galilean variant.

Making both mirrors parabolic corrects all third-order aberrations except field curvature. This property of *confocal parabolas* has led to their periodic rediscovery,[32,33] and to subsequent discussions of their merits and shortcomings.[34–36] The problem with both designs, in the forms shown in Fig. 19*a* and 19*b*, is that their eyepieces are buried so deeply inside the design that their usable field of view is negligible. The galilean form is used as a laser beam expander,[37] where field of view and pupil location is not a factor, and where elimination of internal foci may be vital.

Eccentric pupil versions of the keplerian form of confocal parabolas, as shown in Fig. 19*c*, have proven useful as lens attachments.[38] RO, RE, and the internal image are all accessible when RO is set one focal length ahead of the primary, as shown. It is then possible to place a field stop at the image and pupil stops at RO and RE, which very effectively blocks stray light from entering the following optics. Being all-reflecting, confocal parabolas can be used at any wavelength, and such attachments have seen use in infrared designs.

Three-Powered-Mirror Afocal Lenses

The principle which results in third-order aberration correction for confocal parabolas also applies when one of the parabolas is replaced by a classical cassegrainian telescope (parabolic primary and hyperbolic secondary), as shown in Fig. 20, with two important added advantages. First, with one negative and two positive mirrors, it is possible to reduce the Petzval sum to zero, or to leave a small

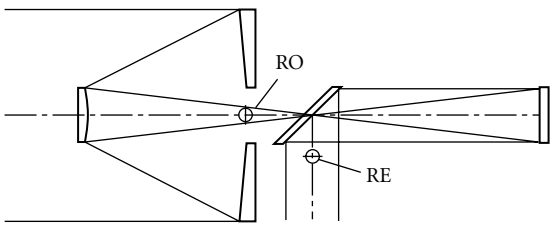

FIGURE 20 Three-powered-mirror afocal lenses.

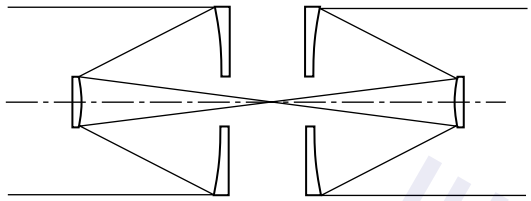
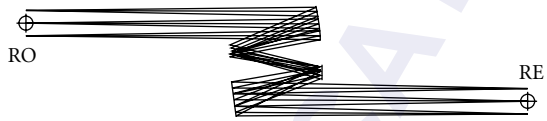


(a) Centered pupil confocal Cassegrains



(b) Eccentric pupil confocal Cassegrains

FIGURE 21 Four-powered-mirror afocal lenses.

residual of field curvature to balance higher-order astigmatism. Second, because the cassegrainian is a telephoto lens with a remote front focal point, placing the stop at the cassegrainian primary puts the exit pupil in a more accessible location. This design configuration has been patented by Offner,[39] and is more usefully set up as an eccentric pupil design, eliminating the central obstruction and increasing exit pupil accessibility.

Four-Powered-Mirror Afocal Lenses

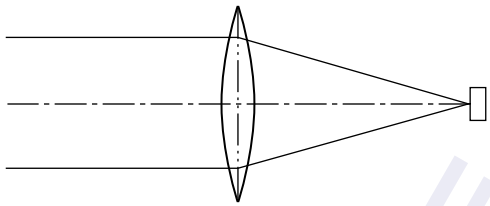
The confocal parabola principle can be extrapolated one step further by replacing both parabolas with classical cassegrainian telescopes, as shown in Fig. 21*a*. Each cassegrainian is corrected for field curvature independently, and the image quality of such *confocal cassegrainians* can be quite good. The most useful versions are eccentric pupil. Figure 21*b* shows an example from Wetherell.[40] Since both objective and eyepiece are telephoto designs, the separation between entrance pupil RO and exit pupil RE can be quite large. An afocal relay train made up of eccentric pupil confocal cassegrainians will have very long collimated paths. If the vertex curvatures of the primary and secondary mirrors within each cassegrainian are matched, the relay will have zero field curvature, as well. In general, such designs work best at or near unit magnification.

Unit Power Finite Conjugate Afocal Lenses

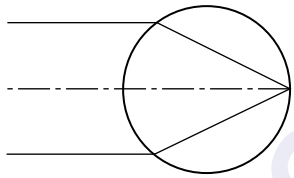
The simplest catadioptric afocal lens is the cat's-eye retroreflector shown in Fig. 22*a*, made up of a lens with a mirror in its focal plane. Any ray entering the lens will exit parallel to the incoming ray but traveling in the opposite direction. If made with glass of index of refraction $n = 2.00$, a sphere with one hemisphere reflectorized (Fig. 22*b*) will act as a perfect retroreflector for collimated light entering the transparent hemisphere. Both designs are, in effect, unit power ($M = -1.00$) afocal lenses. Variations on this technique are used for many retroreflective devices.

Unit power relays are of much interest in photolithography, particularly for microcircuit manufacturing, which requires very high resolution, low focal ratio unit power lenses. In the *Dyson lens,*[41] shown in Fig. 23*a*, the powered surfaces of the refractor and the reflector are concentric, with radii R and r given by

$$\frac{R}{r} = \frac{n}{(n-1)} \tag{30}$$



(a) Cat's eye retroreflector



(b) Spherical cat's eye ($n = 2.0$)

FIGURE 22 Afocal retroreflector designs.

where n is the index of refraction of the glass. At the center point, spherical aberration and coma are completely corrected. In the nominal design, object and image are on the surface intersecting the center of curvature, displaced laterally to separate object from image sensor (this arrangement is termed *eccentric field*, and is common to many multimirror lens systems). In practice, performance of the system is limited by off-axis aberrations, and it is desirable to depart from the nominal design to balance aberrations across the field of view.[42]

The unit power all-reflecting concentric design shown in Fig. 23*b* is patented[43] by Offner.[44] It was developed for use in manufacturing microcircuits, and is one of the most successful finite conjugate afocal lens designs in recent years. The spheres are concentric and the plane containing object and image surfaces passes through the common center of curvature. It is an all-reflecting, unit power equivalent of the refracting design shown in Fig. 9. Object and image points are eccentric field, and this is an example of the *ring field* design concept, where axial symmetry ensures good correction throughout a narrow annular region centered on the optical axis. As with the Dyson lens, having an eccentric field means performance is limited by off-axis aberrations. Correction of the design can be improved at the off-axis point by departing from the ideal design to balance on-axis and off-axis aberrations.[45]

NONDISPERSIVE PRISMS[1,2]

William L. Wolfe

College of Optical Sciences
University of Arizona
Tucson, Arizona

19.1 GLOSSARY

δ	angular deviation
ϕ	phase
ω	radian frequency of rotation
A, B, C, D, d	prism dimensions
t	time
x, y	rectangular components
α	angle
1, 2	prism number

19.2 INTRODUCTION

Prisms of various shapes and sizes are used for folding, inverting, reverting, displacing, and deviating a beam of light, whether it be collimated, converging, or diverging.

Prisms, rather than mirrors, are often used for the applications discussed here, since they make use of reflecting coatings at what amounts to an interior surface. The coatings can be protected on their backs by other means, and do not tarnish with age and exposure. Even better, some prisms do not need such coatings if the (internal) angle of incidence exceeds the critical angle.

In these applications, chromatism is to be avoided. Thus, the arrangements either make use of perpendicular incidence or compensating angles of incidence.

Almost all of these prisms are meant to be used with collimated beams. Most of the operations are somewhat equivalent to the use of plane parallel plates, which displace but do not deviate a

collimated beam. However, such plates have both chromatism and spherical aberration in a convergent beam.

Dispersing prisms are discussed in Chap. 20 by George J. Zissis and polarizing prisms in Chap. 13 by Jean M. Bennett, both in this volume of the *Handbook*.

19.3 INVERSION, REVERSION

A reverted image shifts the image left for right. An inverted image is upside down. A reinverted image or inverted-reverted image does both.

The best two references on this subject are the Frankford Arsenal book called *Design of Fire Control Optics*,[1] and Jacobs' book called *Optical Engineering*.[2] Many of the diagrams shown here have been taken from the former since they provide direct design information as well as descriptions of the performance of the prism.

19.4 DEVIATION, DISPLACEMENT

The beam, in addition to being inverted and/or reverted, can also be displaced and/or deviated. Displacement means that the beam has been translated in x or y, but it has not changed the direction in which it was traveling. Deviation indicates that the beam has been caused to change its direction. Deviation is measured in angular measure; displacement in linear measure. If a beam has been deviated, displacement is not important. If a beam has been displaced, it usually has not been deviated. Although the two can occur simultaneously, it seldom happens in optical prisms.

19.5 SUMMARY OF PRISM PROPERTIES

Table 1 is a listing of the prisms that are described in this section. The first column provides the name of the prism. The second column indicates whether the image is reverted. The third column indicates whether the image has been inverted. The fourth column indicates how much the image has been displaced as a ratio of the critical prism dimension A. The next column gives the amount of deviation, and the last column provides comments.

19.6 PRISM DESCRIPTIONS

Each diagram shows at least one view of the prism and a set of dimensions. The *A* dimension is a reference dimension. It is always 1.00, and the rest of the dimensions are related to it. The refractive index is almost always taken as 1.5170, a representative value for glass in the visible. Prism dimensions can change somewhat if the refractive index is modestly different from the chosen value. However, if a material like germanium is used, the prism might be drastically different.

TABLE 1 Summary of Prism Properties

Prism	Reverts	Inverts	Displaces	Deviates	Comments
Right angle	Yes	No	—	90	Simplest
	No	Yes

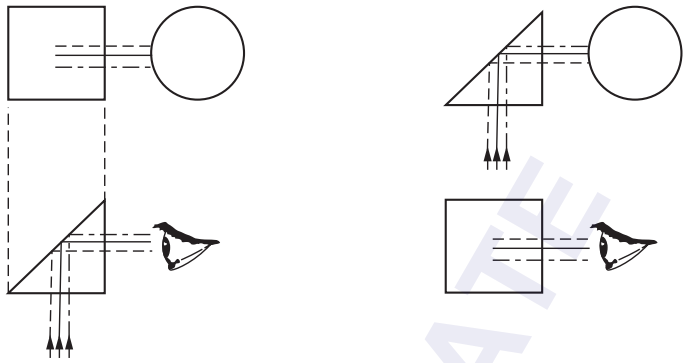
D120	No	No	—	110–130	

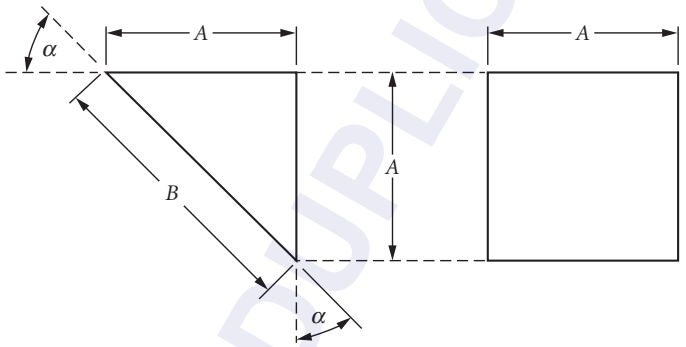
Right-Angle Prism

Perhaps the simplest of the deviating prisms is the right-angle prism. Light enters one of the two perpendicular faces, as shown in Fig. 1*a*, reflects off the diagonal face, and emerges at 90° from the other perpendicular face. The beam has been rotated by 90°, and the image has been inverted. If the prism is used in the other orientation, shown in Fig. 1*b*, then the image is reverted. The internal angle of incidence is 45°, which is sufficient for total internal reflection (as long as the refractive index is greater than 1.42).

Porro Prism

A Porro prism, shown in Fig. 2, has a double reflection and may be considered to be two right-angle prisms together. They are often identical. Often, two Porro prisms are used together to invert and revert the image. The incidence angles are the same as with the right-angle prism, so that total internal reflection takes place with refractive indices larger than 1.42. It is a direct-vision prism.





$A = 1.00$ $\alpha = 45°$ $d = A = 1.00$

$B = 1.4142A = 1.4142$ $d/n = 0.6592$

$n = 1.5170$

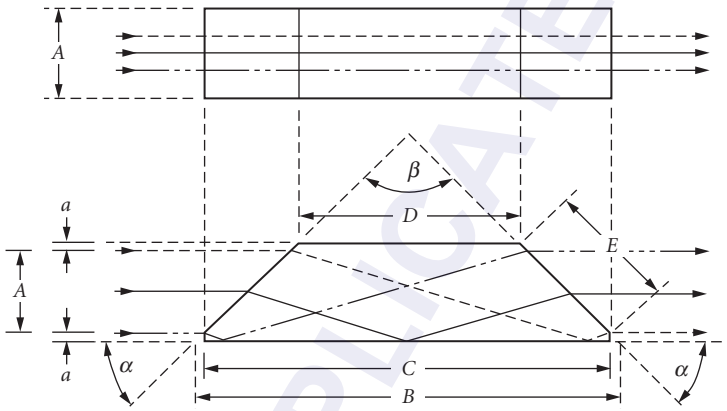
$b = 0.5773A = 0.5773$
$d = 5.1962A = 5.1962$
$d/n = 3.4253$
$n = 1.5170$

FIGURE 5 Abbe direct-vision prism—B.

Dove Prism

A Dove prism (also known as a Harting-Dove prism) does not deviate or displace an image but it can be used to either invert or revert an image. It must be placed in parallel light. Such a prism is shown in Fig. 6.



$A = 1.00$

$\alpha = 45°$

$a = 0.05$

$$B = (A + 2a)\left\{\frac{\sqrt{n^2 - \sin^2\alpha} + \sin\alpha}{\sqrt{n^2 - \sin^2\alpha} - \sin\alpha} + 1\right\}$$

$\beta = 90°$

$$d = \frac{n\,(A + 2a)}{\sin\alpha\left\{\sqrt{n^2 - \sin^2\alpha} - \sin\alpha\right\}}$$

$= 4.2271\,(A + 2a) = 4.6498$

$= 3.3787\,(A + 2a) = 3.7165$

$C = B - 2a = 4.5498$

$d/n = 2.4499$

$D = B - 2(A + 2a) = 2.4498$

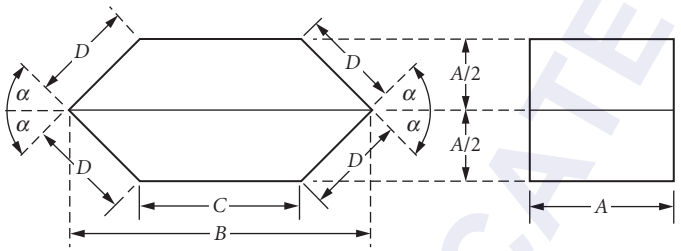
$n = 1.5170$

$$E = \frac{a + A}{\cos\alpha} = 1.4142\,(A + a) = 1.4849$$

FIGURE 6 Harting-Dove prism.

Double Dove

Two Dove prisms are glued together. The length is halved, but the height is doubled. It performs the same functions as a single Dove in almost the same way. It is shown in Fig. 7.



$A = 1.00$

$$B = \frac{A}{2}\left\{\frac{\sqrt{n^2 - \sin^2\alpha} + \sin\alpha}{\sqrt{n^2 - \sin^2\alpha} - \sin\alpha} + 1\right\}$$

$= 2.1136A = 2.1136$

$C = B - A = 1.1136$

$$D = \frac{A}{2\cos\alpha} = 0.7071A = 0.7071$$

$\alpha = 45°$

$$d = \frac{nA}{2\sin\alpha\left\{\sqrt{n^2 - \sin^2\alpha} - \sin\alpha\right\}}$$

$= nAC = 1.6893$

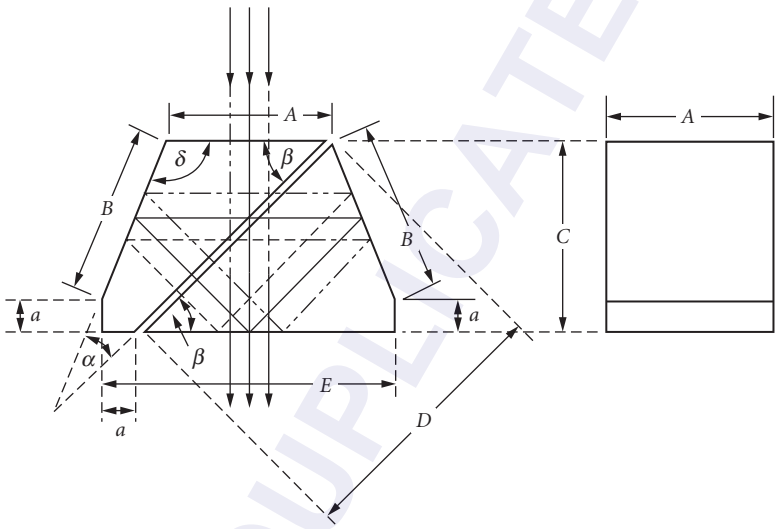
$d/n = 1.1135$

$n = 1.5170$

FIGURE 7 Double Dove prism.

Pechan Prism

The Pechan prism (shown in Fig. 8) performs the same function as the Dove, but it can do it in converging or diverging beams. The surfaces marked *B* are silvered and protected. The surfaces bordering the air space are unsilvered.

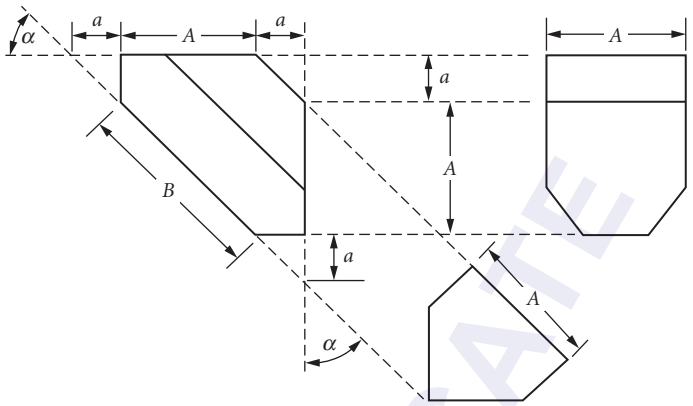


$A = 1.00$	$\alpha = 22°30'$	$a = 0.2071A = 0.2071$
$B = 1.0824A = 1.0824$	$\beta = 45°$	$d = 4.6213A = 4.6213$
$C = 1.2071A = 1.2071$	$\gamma = 67°30'$	$d/n = 3.0464$
$D = 1.7071A = 1.7071$	$\delta = 112°30'$	$n = 1.5170$
$E = 1.8284A = 1.8284$		

FIGURE 8 Pechan prism.

Amici (Roof) Prism

This more complex arrangement of surfaces inverts the image, reverts it, and deviates it 90°. It is shown in Fig. 9. Since this prism makes use of the roof effect, it has the same angles as both the right-angle and Porro prisms, and exhibits total internal reflection for refractive indices larger than 1.42.



$A = 1.00$
$B = 1.4142A = 1.4142$

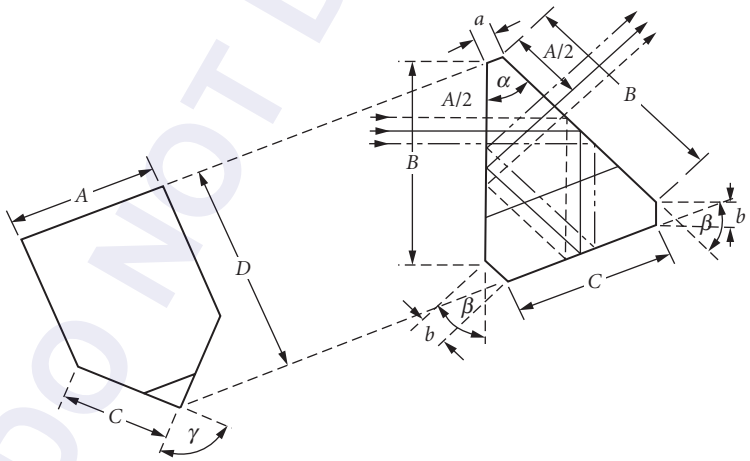
$\alpha = 45°$

$a = 0.3536A = 0.3536$
$d = 1.7071A = 1.7071$
$d/n = 1.1253$
$n = 1.5170$

FIGURE 9 Amici (roof) prism.

Schmidt Prism

The prism will invert and revert the image, and it will deviate it through 45°. It is shown in Fig. 10.



$A = 1.00$
$B = 1.4142A + 0.5412a = 1.4683$

		$n = 1.5170$

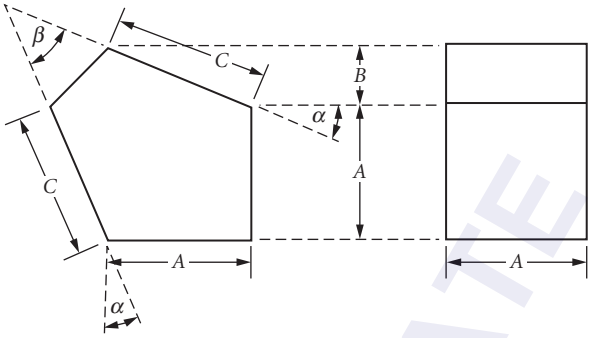
FIGURE 11 Leman prism.

Penta Prism

A penta prism has the remarkable property that it always deviates a beam by exactly 90° in the principal plane. This is akin to the operation of a cube corner. The two reflecting surfaces of the penta prism, shown in Fig. 12, must be reflectorized, as the angles are 22.5° and therefore require a refractive index of 2.62 or greater for total internal reflection. Some penta-prisms are equipped with a roof to revert the image.



$A = 1.00$
$B = 0.4142A = 0.4142$
$C = 1.0824A = 1.0824$

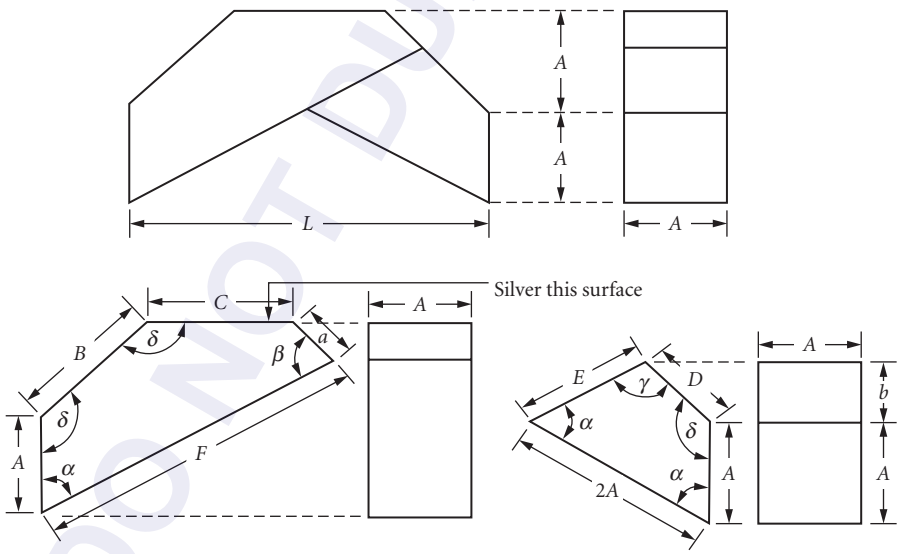
$\alpha = 22°30'$
$\beta = 45°$

$a = 3.4142A = 3.4142$
$d/n = 2.2506$
$n = 1.5170$

FIGURE 12 Penta prism.

Reversion Prism

This prism operates like an Abbe prism, type A, but does not require parallel light. It is shown in Fig. 13.



$A = 1.00$
$B = 1.4142A$
$C = 1.4641A$
$D = 0.8966A$
$E = 1.2679A$
$F = 3.2679A$
$L = 3.4641A$

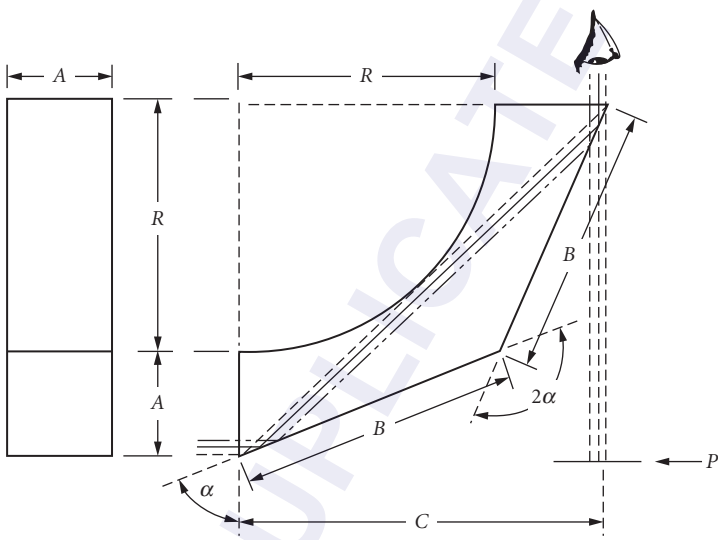
$\alpha = 60°$
$\beta = 75°$
$\gamma = 105°$
$\delta = 135°$

$a = 0.5176A$
$b = 0.6340A$
$d = 5.1962A$
$d/n = 3.4253A$
$n = 1.5170$

FIGURE 13 Reversion prism.

Wollaston Prism

This prism does not invert, revert, or displace. It does deviate a beam by 90°, allowing a tracing to be made. It is shown in Fig. 14.



$A = 1.00$ $\alpha = 67°30'$ $d = 2R = 4.8284A = 4.8284$

$B = 2.6131A = 2.6131$ $d/n = 3.1829$

$C = 3.4142A = 3.4142$ $n = 1.5170$

$R = 2.4142A = 2.4142$

FIGURE 14 Wollaston prism.

Carl Zeiss Prism System

This arrangement of three prisms allows the image to be reverted, inverted, and displaced, but not deviated. The amount of displacement is adjustable. The system is shown in Fig. 15.

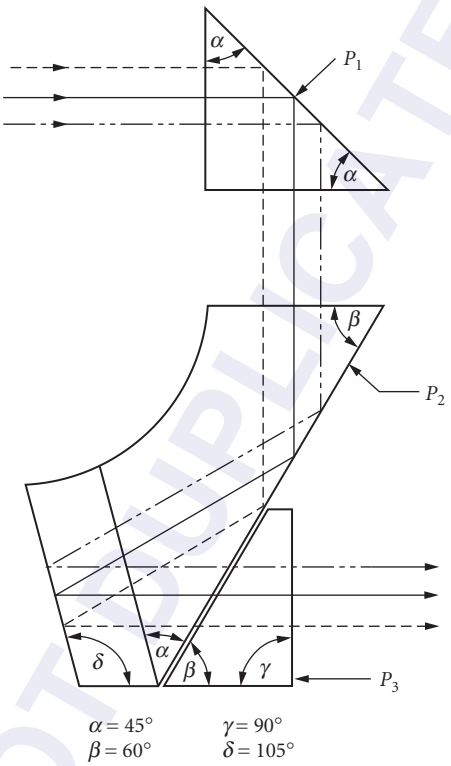


FIGURE 15 Carl Zeiss prism system.

Goerz Prism System

This is an alternate to the Zeiss system. It does the same things. It is shown in Fig. 16.

$\alpha = 22°30'$
$\beta = 45°$
$\gamma = 90°$

$d = 4.4142A = 4.4142$
$d/n = 2.9098$
$n = 1.5170$

FIGURE 23 Frankford Arsenal prism 7.

Brashear-Hastings Prism

This device, shown in Fig. 24, inverts an image without changing the direction of the beam. Since this is a relatively complicated optical element, it does not see much use.

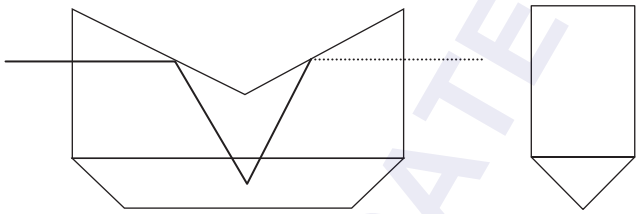

FIGURE 24 Brashear-Hastings prism.

Rhomboidal Prism

A rhomboidal prism, as shown in Fig. 25, displaces the beam without inverting, reverting, deviating, or otherwise changing things. The reflecting analog is a pair of mirrors at 45°.

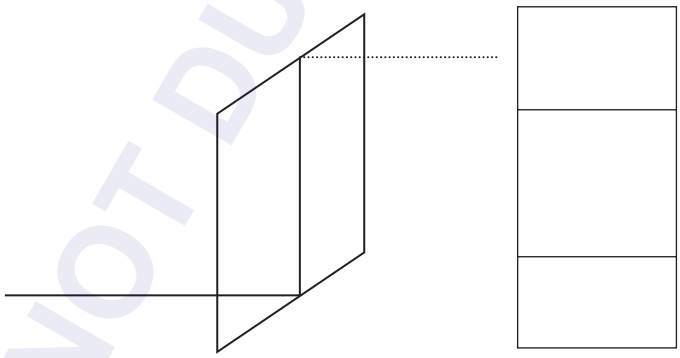

FIGURE 25 Rhomboidal prism.

Risley Prisms

Risley prisms are used in two ways. If they are slightly absorbing, they can be used as variable attenuators by translating one with respect to the other perpendicular to their apexes.[3] They can also be rotated to generate a variety of angular deviations.[4] A single prism deviates the beam according to its wedge angle and refractive index. If rotated in a circle about an axis perpendicular to its face, it will rotate the beam in a similar circle. A second, identical prism in series with it, as shown in Fig. 26, can double the angle of the beam rotation and generate a circle of twice the radius. If they rotate in opposite directions, one motion is canceled and a line is generated. In fact, all sorts of Lissajous-type figures can be obtained; some are shown in Fig. 27. The equations that govern the patterns are

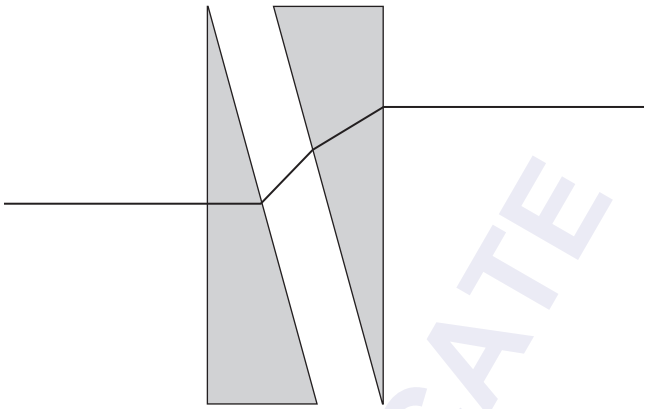

FIGURE 26 Risley prisms.

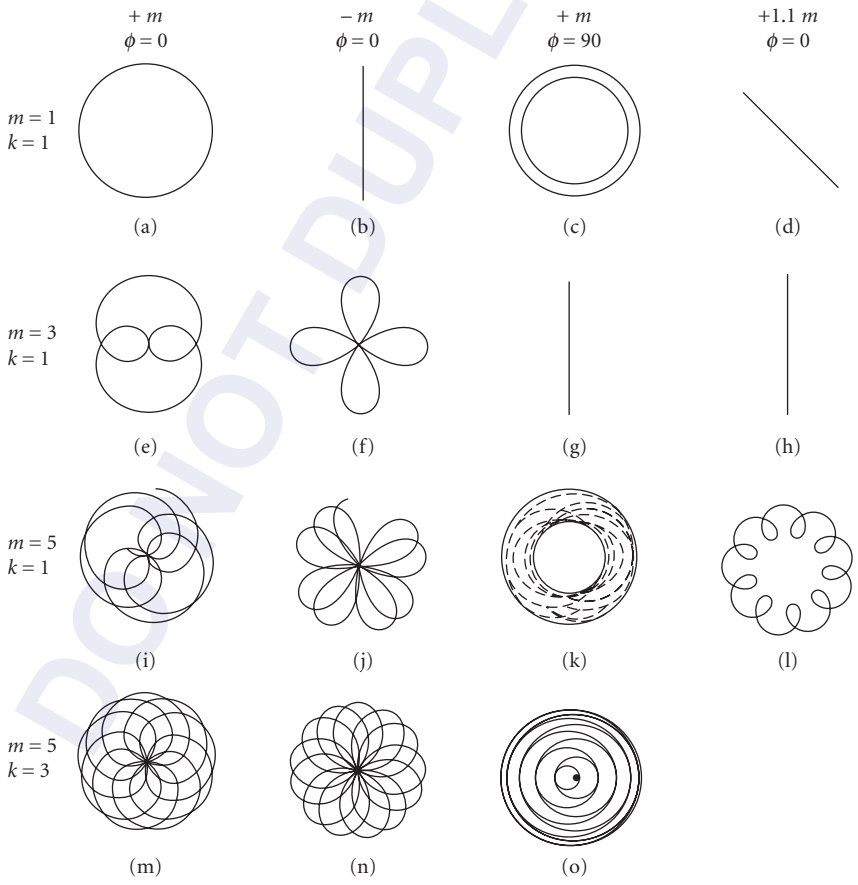

FIGURE 27 Risley prism patterns.

$$\delta_x = \delta_1 \cos\omega_1 t + \delta_2 \cos(\omega_2 t + \phi) \tag{1}$$

$$\delta_y = \delta_1 \sin\omega_1 t + \delta_2 \sin(\omega_2 t + \phi) \tag{2}$$

where δ_x and δ_y are the beam deviations, δ_1 and δ_2 are the individual prism deviations, ω is the rotation rate, t is time, and ϕ is the phase of the prism position. For relatively monochromatic applications, the prisms can be "fresnelled," as shown in Fig. 28, and the mirror analogs, shown in Fig. 29, can also be used.

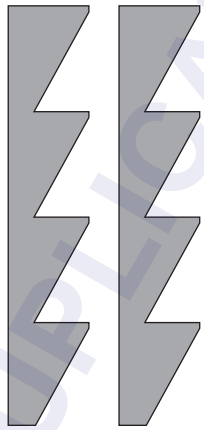

FIGURE 28 Fresnel Risleys.

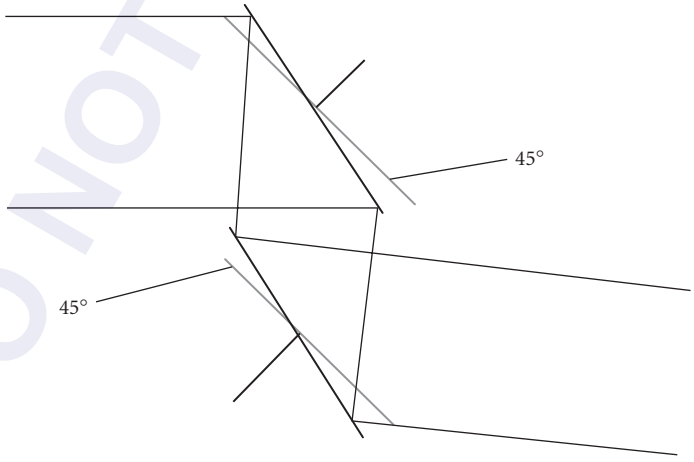

FIGURE 29 Risely mirrors.

Retroreflectors

The familiar reflective cube corner (not corner cube), that sends a ray back in the direction from which it came, has its refractive analog, as shown in Fig. 30. The angles are adjusted so that total internal reflection occurs. The angular acceptance range can be large.

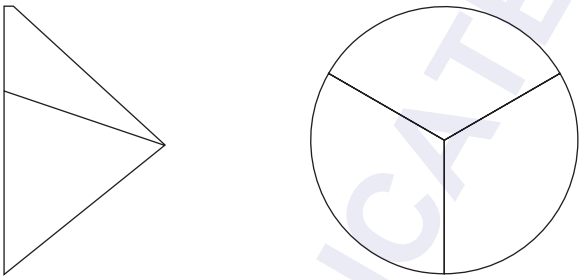

FIGURE 30 Retroreflectors.

General Deviation Prisms

Figure 31 shows a 40°-deviation prism. Other angles are obtainable with appropriate changes in the prism manufacture, as shown, for example, in Figs. 32 and 33.

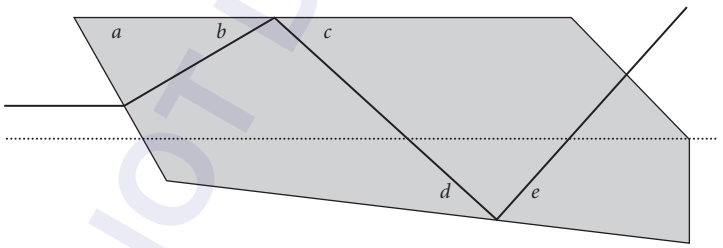

FIGURE 31 40°-deviation prism—D40.

W	prism width
β	angle
γ	angle

20.2 INTRODUCTION

Spectroradiometers (Fig. 1) are radiometers designed specifically to allow determination of the wavelength distribution of radiation. This category of measurement systems usually consists of those in which separation of the radiation into its spectral components, or *dispersion*, is accomplished by the use of an optical element possessing a known functional dependence on wavelength—specifically, prisms and diffraction gratings. (Interferometers can also provide spectral dispersion as is discussed in Chap. 32, "Interferometers," by Parameswaran Hariharan.)

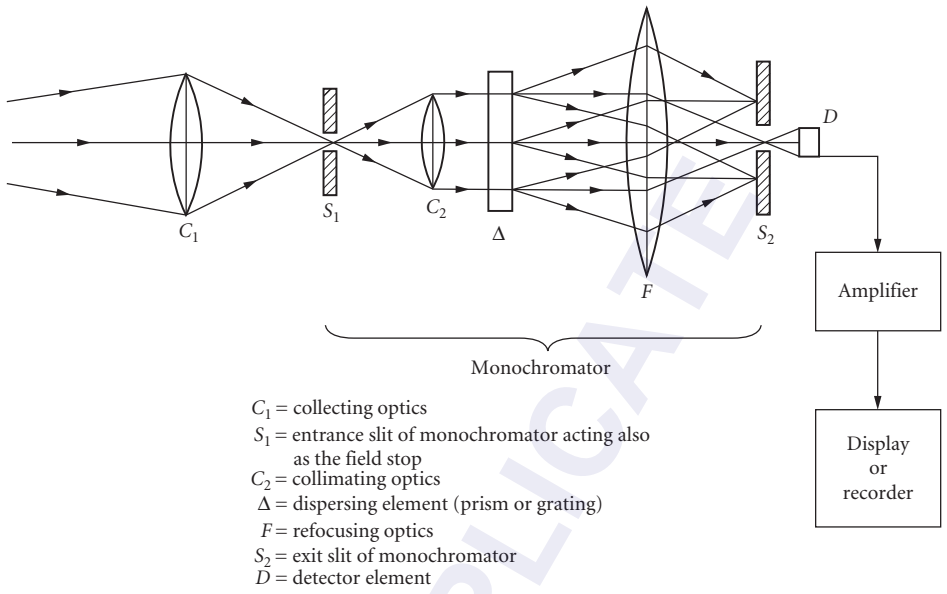

FIGURE 1 Basic spectroradiometer.

20.3 PRISMS[1,2,3]

The wavelength dependence of the index of refraction is used in prism spectrometers. Such an optical element disperses parallel rays or collimated radiation into different angles from the prism according to wavelength. Distortion of the image of the entrance slit is minimized by the use of plane wave illumination. Even with plane wave illumination, the image of the slit is curved because not all of the rays from the entrance slit can traverse the prism in its principal plane. A prism is shown in the position of minimum angular deviation of the incoming rays in Fig. 2. At minimum angular deviation, maximum power can pass through the prism. For a prism adjusted to the position of minimum deviation,

$$r_1 = r_2 = A_p/2 \tag{1}$$

and

$$i_1 = i_2 = (D_p + A_p)/2 \tag{2}$$

where D_p = angle of minimum deviation for the prism
A_p = angle of the prism
r_1 and r_2 = internal angles of refraction
i_1 and i_2 = angles of entry and exit

The angle of minimum deviation D_p varies with wavelength. The angular dispersion is defined as $dD_p/d\lambda$, while the linear dispersion is

$$dx/d\lambda = F\,dD_p/d\lambda \tag{3}$$

where F is the focal length of the camera or imaging lens and x is the distance across the image plane. It can be shown[1] that

$$dD_p/d\lambda = (B/W)(dn/d\lambda) \tag{4}$$

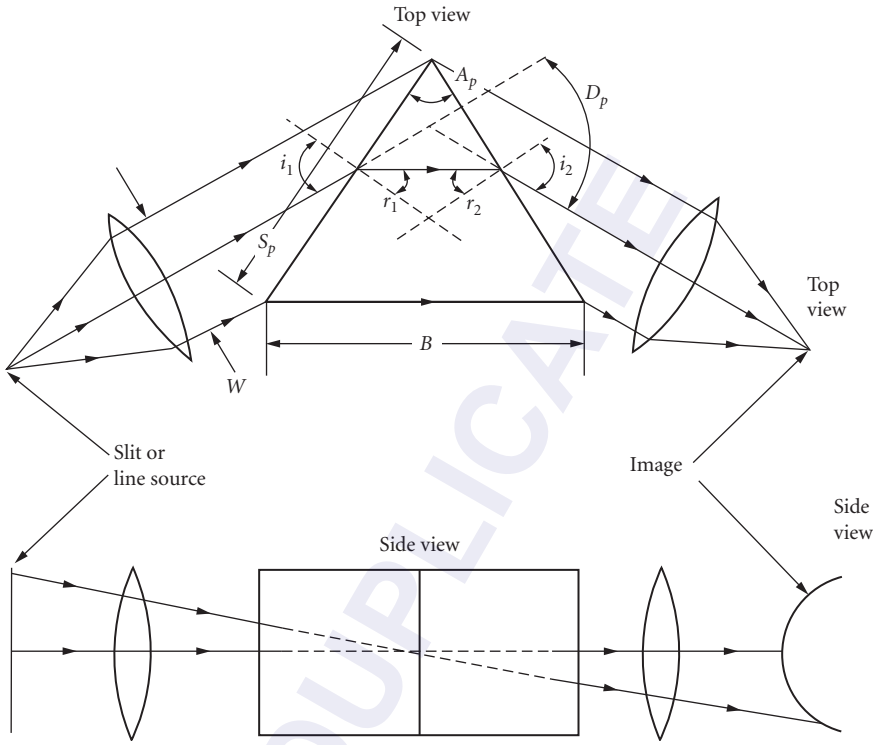

FIGURE 2 Elementary prism spectrometer schematic. W is the width of the entrance beam; S_p is the length of the prism face; and B is the prism base length.

where B = base length of the prism
W = width of the illumination beam
n = index of refraction
$dx/d\lambda = F(B/W)(dn/d\lambda)$

The resolving power RP of an instrument may be defined as the smallest resolvable wavelength difference, according to the Rayleigh criterion, divided by the average wavelength in that spectral region. The limiting resolution is set by diffraction due to the finite beam width, or effective aperture of the prism, which is rectangular. Thus,

$$\mathrm{RP}_p = B(dn/d\lambda) \tag{5}$$

If the entire prism face is not illuminated, then only the illuminated base length must be used for B.

20.4 GRATINGS

A grating is an n-slit system used in Fraunhofer diffraction with interference arising from division of the incident plane wave front. Thus it is a multiple beam interferometer described by

$$p\lambda = d(\sin\theta + \sin\phi) \tag{6}$$

where p = order number (= 0, 1, 2,…) of the principal maxima
d = the grating constant or spacing (the distance between adjacent slits)
ϕ = angle of incidence
θ = angle of diffraction

The most common case is that of normal incidence, that is, $\phi = 0$, so that

$$p\lambda = d \sin\theta \tag{7}$$

and the irradiance distribution is

$$E = E_o\{\sin[(\pi w \sin\theta)/\lambda]/[(\pi w \sin\theta)/\lambda]\}^2 \times \{\sin[(N\pi d \sin\theta)/\lambda]/\sin[(\pi d \sin\theta)/\lambda]\}^2 \tag{8}$$

where w is the slit width and N is the number of slits or grooves. This equation is often written as

$$E = E_0[(\sin\beta)/\beta]^2[(\sin N\gamma)/\sin\gamma]^2 \tag{9}$$

which can be considered to be

$$E = \text{constant} \times \text{single-slit diffraction function} \times N\text{-slit interference function} \tag{10}$$

These considerations are for unblazed gratings. For a diffraction grating, the angular dispersion is given (for constant angle ϕ) by

$$dD_g/d\lambda \quad \text{or} \quad d\theta/d\lambda = p/(d\cos\theta) \tag{11}$$

The resolving power is given by

$$\text{RP}_g = pN \tag{12}$$

20.5 PRISM AND GRATING CONFIGURATIONS AND INSTRUMENTS

Classical

There are several basic prism and grating configurations and spectrometer designs which continue to be useful. One of the oldest spectrometer configurations is shown in Fig. 3.[1] Reflective interactions and prism combinations are used in Figs. 4, 5, and 6. Dispersion without deviation is realized in Figs. 7 and 8, while half-prisms are used in Fig. 9 in an arrangement which uses smaller prisms but still attains the same beam width. A few classical prism instrumental configurations are shown in Figs. 10, 11, and 12. Multiple-pass prism configurations are illustrated in Figs. 13 and 14.[4,5]

A well-known example of a single beam double-pass prism infrared spectrometer was the Perkin-Elmer Model 112 instrument shown in Fig. 15. Infrared radiation from a source is focused by mirrors M_1 and M_2 on the entrance slit S_1 of the monochromator. The radiation beam from S_1, path 1, is collimated by the off-axis paraboloid M_3 and a parallel beam traverses the prism for a first refraction. The beam is reflected by the Littrow mirror M_4, through the prism for a second refraction, and focused by the paraboloid, path 2, at the corner mirror M_6. The radiation returns along path 3, traverses the prism again, and is returned along path 4 for reflection by mirror M_7 to the exit slit S_2. By this double dispersion, the radiation is spread out along the plane of S_2. The radiation of the frequency interval which passes through S_2 is focused by mirrors M_8 and

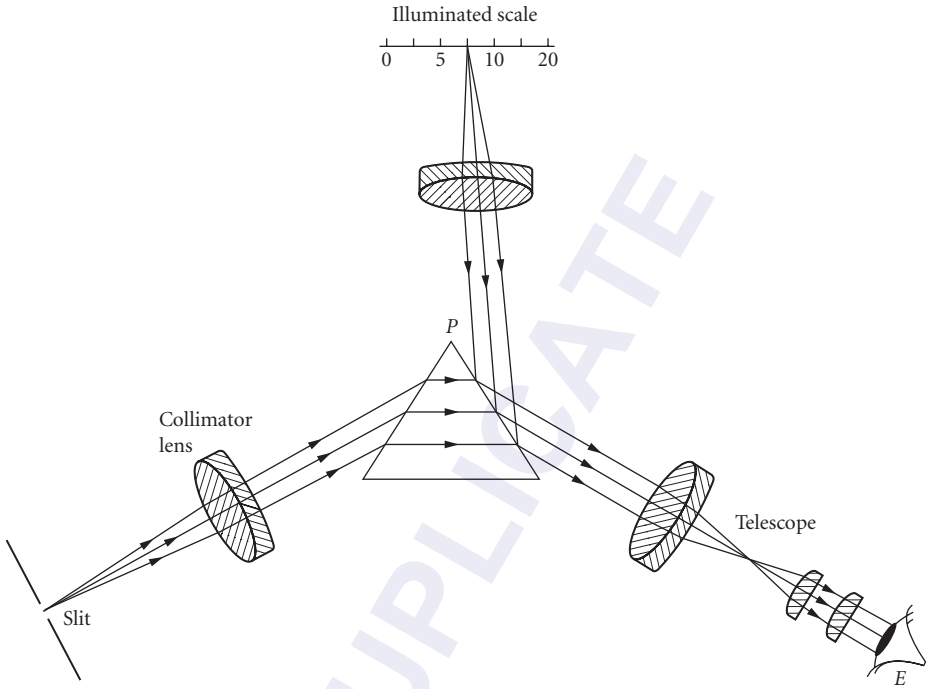

FIGURE 3 Bunsen-Kirchhoff spectrometer. An illuminated scale is reflected from the prism face into the telescope.

M_9 on the thermocouple TC. The beam is chopped by CH, near M_6, to produce a voltage (at the thermocouple) which is proportional to the radiant power or intensity of the beam. This voltage is amplified and recorded by an electronic potentiometer. Motor-driven rotation of Littrow mirror M_4 causes the infrared spectrum to pass across exit slit S_2 permitting measurement of the radiant intensity of successive frequencies.

Gratings can be used either in transmission or reflection.[6] Another interesting variation comes from their use in plane or concave reflection form. The last was treated most completely by Rowland, who achieved a useful combination of focusing and grating action. He showed that the radius of curvature of the grating surface is the diameter of a circle (called the Rowland circle). Any source placed on the

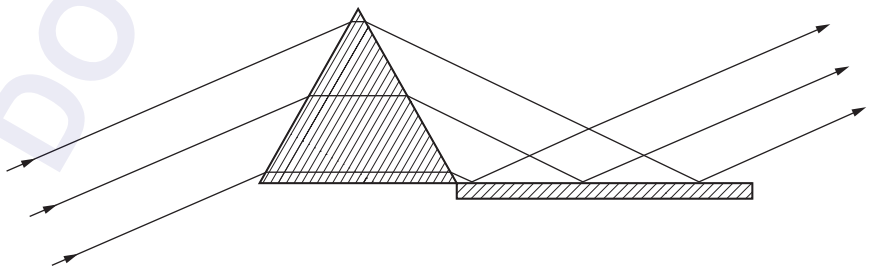

FIGURE 4 Wadsworth constant-deviation, prism-mirror arrangement. The beam enters the prism at minimum deviation and emerges displaced but not deviated from its original direction.

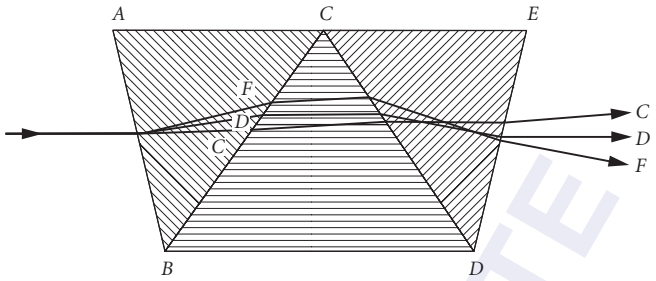

FIGURE 5 Amici prism. The central ray *D* enters and leaves parallel to the base. The *C* and *F* rays are deviated and dispersed.

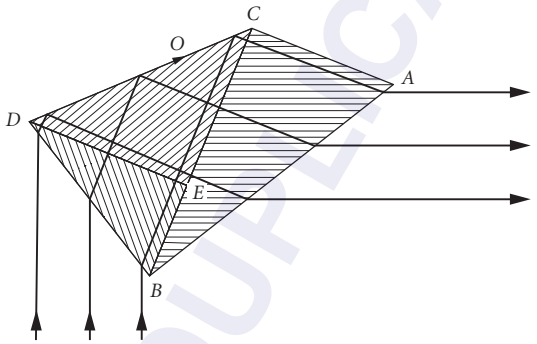

FIGURE 6 Pellin–Broca prism. The prism is equivalent to two 30° prisms, *ABC* and *BED*, and one 45° prism, *DEC*, but is made in one place. The beam shown, entering at minimum deviation, emerges at 90° deviation to its entrance direction.

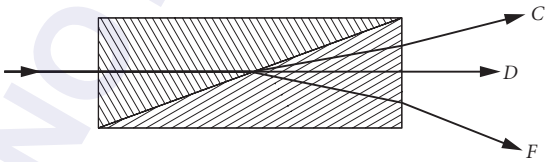

FIGURE 7 Zenger prism. The central ray *D* is undeviated. The *C* and *F* rays are deviated and dispersed.

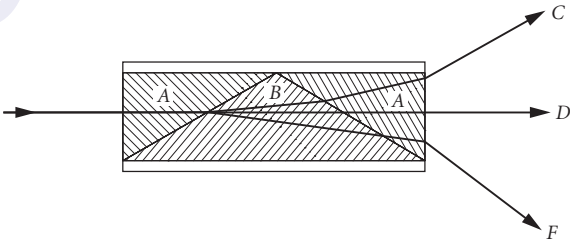

FIGURE 8 Wernicke prism. This arrangement is essentially two Zenger prisms, back-to-back.

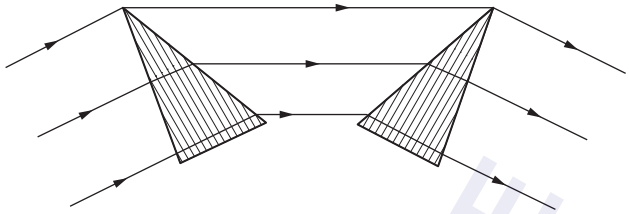

FIGURE 9 Young–Thollon half prisms. The passage of a beam at minimum deviation is shown.

circle will be imaged on the circle, with dispersion, if the rulings are made so that d is constant on the secant to the grating-blank (spherical) surface. The astigmatism acts so that a point source on a Rowland circle is imaged as a vertical line perpendicular to the plane of the circle. Rowland invented and constructed the first concave grating mounting, illustrated in Fig. 16.[1]

If dispersion is sufficiently large, one may find overlapping of the lines from one order with members of the spectra belonging to a neighboring order. Errors and imperfections in the ruling of gratings can produce spurious images which are called "ghosts." Also, the grooves in a grating can be shaped so as to send more radiation along a preferred direction corresponding to an order other than the zero order. Such gratings are said to be blazed in that order. These issues and many more involved in the production of gratings by ruling engines were thoroughly discussed by Harrison in his 1973 paper "The Diffraction Grating—An Opinionated Appraisal."[7]

Six more grating configurations[1] which are considered to be "classics" are

1. *Paschen-Runge*, illustrated in Fig. 17. In this arrangement, one or more fixed slits are placed to give an angle of incidence suitable for the uses of the instrument. The spectra are focused along the Rowland circle $P\,P'$, and photographic plates, or other detectors, are placed along a large portion of this circle.

2. *Eagle*, shown in Fig. 18. This is similar to the Littrow prism spectrograph. The slit and plate holder are mounted close together on one end of a rigid bar with the concave grating mounted on the other end.

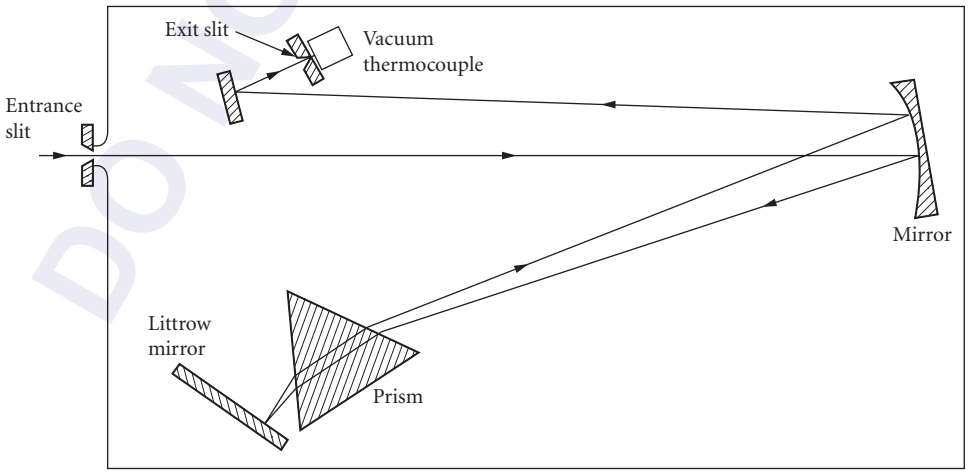

FIGURE 10 Infrared spectrograph of the Littrow-type mount with a rock salt prism.

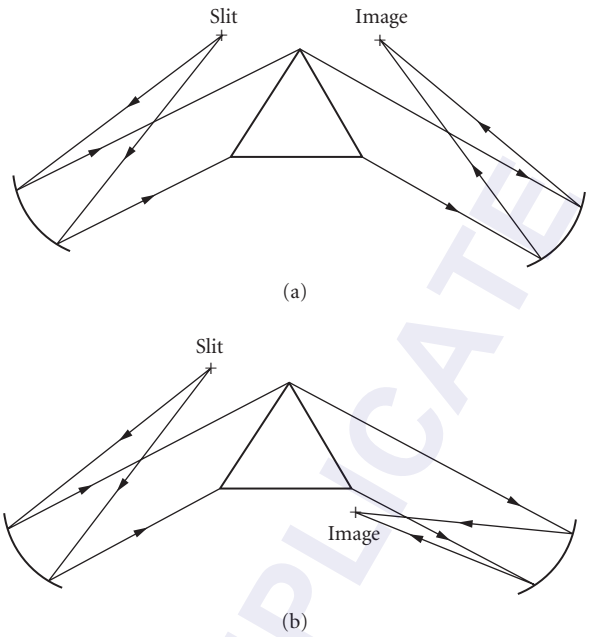

FIGURE 11 Mirror spectrometer with two choices of the location of the image. Arrangement (*b*) leads to smaller aberrations than arrangement (*a*) and is used in the Czerny-Turner mount.

3. *Wadsworth*, shown in Fig. 19. The Rowland circle is not used in this mounting in which the grating receives parallel light.

4. *Ebert-Fastie*, shown in Fig. 20. The Ebert-Fastie features a single, spherical, collimating mirror and a grating placed symmetrically between the two slits. The major advantage of the Ebert system is the fact that it is self-correcting for spherical aberration. With the use of curved slits, astigmatism is almost completely overcome.

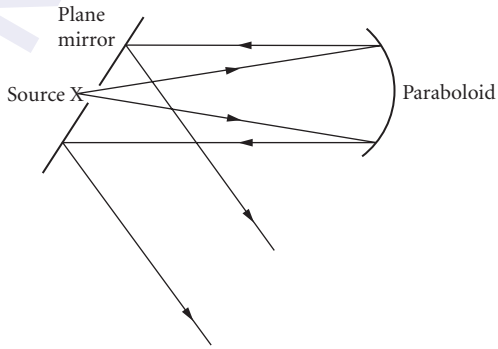

FIGURE 12 Pfund mirror. The use of a plane mirror to avoid astigmatism in the use of a paraboloidal mirror.

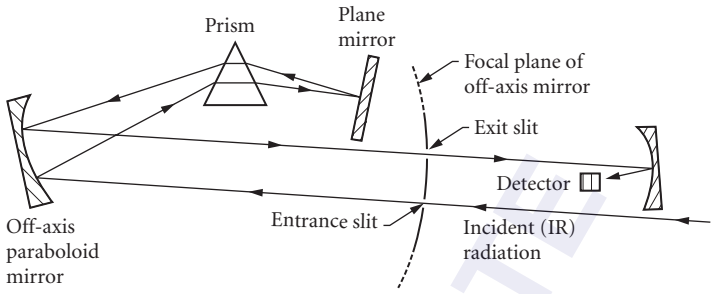

FIGURE 13 Double-pass monochromator.

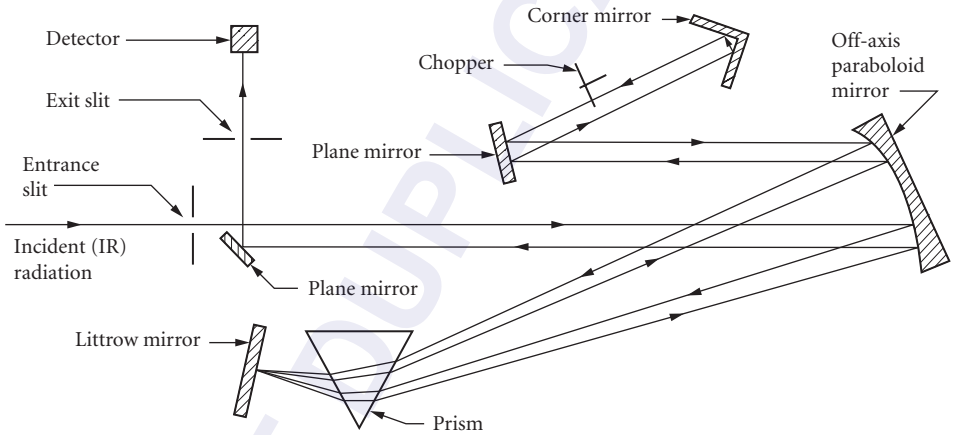

FIGURE 14 Perkin-Elmer Model 99 double-pass monochromator.

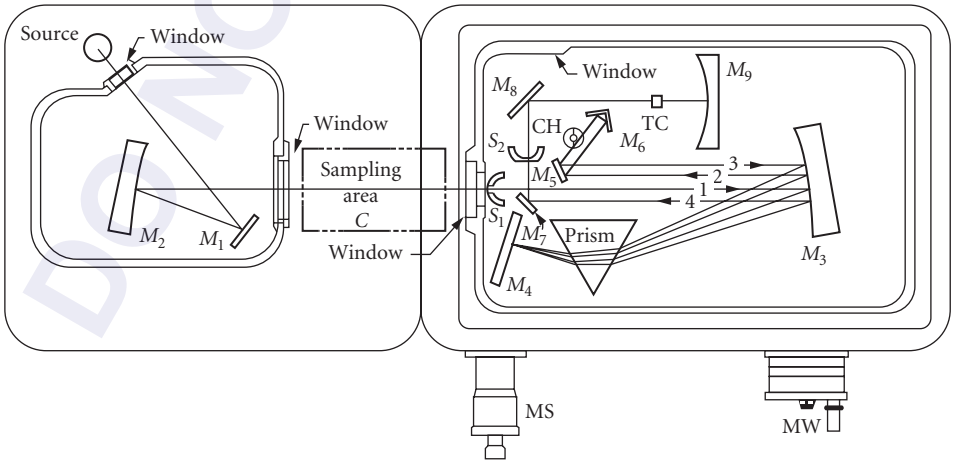

FIGURE 15 Perkin-Elmer Model 112 single-beam double-pass infrared spectrometer.

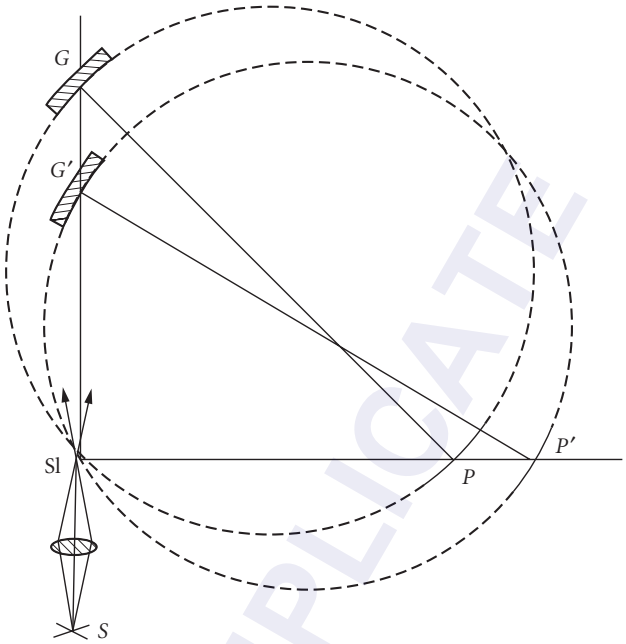

FIGURE 16 Rowland mounting of the concave grating. The grating plate-holder bar, which slides on the two perpendicular ways, is shown in two positions, *GP* and *G′P′*. The slit SI and source *S* remain fixed.

5. *Littrow*, shown in Fig. 10. The Littrow system has slits on the same side of the grating to minimize astigmatism. An advantage of the Littrow mount, therefore, is that straight slits can be used. In fact, such slits may be used even for a spherical collimating mirror if the aperture is not too large. Its greatest disadvantage is that it does not correct for spherical aberration—not too serious a defect for long focal-length/small-aperture instruments. If an off-axis parabola is used to collimate the light, aberrations are greatly reduced.

6. *Pfund*, shown in Figs. 12 and 21. This is an on-axis, Pfund-type grating instrument.[5] Incident infrared radiation, focused by a collimating lens on the entrance slit and modulated by a chopper, passes through the central aperture of plane mirror M_1. Reflected by the paraboloidal mirror P_1, it emerges as a parallel beam of radiation, which is reflected by mirror M_1 to the grating. The grating is accurately located on a turntable, which may be rotated to scan the spectrum. From the grating, the diffracted beam, reflected by mirror M_2, is focused by a second paraboloid P_2 through the central aperture of mirror M_2 to the exit slit. The emerging beam is then focused by the ellipsoidal mirror M_3 on the detector.

An off-axis, double-pass grating instrument is illustrated in Fig. 22.[6]

Combinations of prisms and gratings are not uncommon. An illustrative and complex prism-grating, double-monochromator spectrometer designed by Unicam Instruments, Ltd. is shown in Fig. 23.[5] The prism monochromator has four interchangeable prisms, and the grating monochromator has two interchangeable gratings. The two monochromators, ganged by cams which are linear in wave number, are driven by a common shaft. The instrument can be used either as a prism-grating double monochromator, or as a prism spectrometer by blanking the grating monochromator. Gratings, prisms, and cams can be automatically interchanged by means of push buttons.

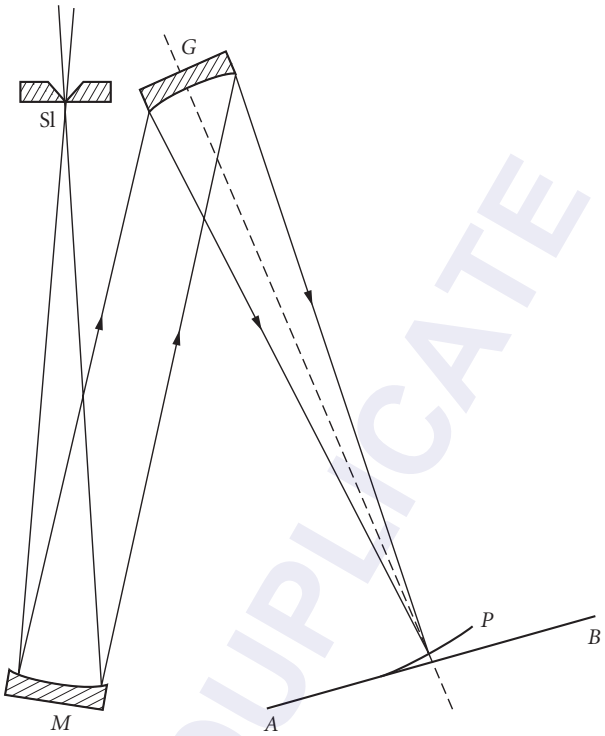

FIGURE 19 Wadsworth mounting of the concave grating. Sl is the entrance slit, *G* is the concave grating, *M* is the concave mirror, *P* is the plate holder, and *AB* is the rail for the plate holder. To minimize aberrations, one must locate the slit close to the grating.

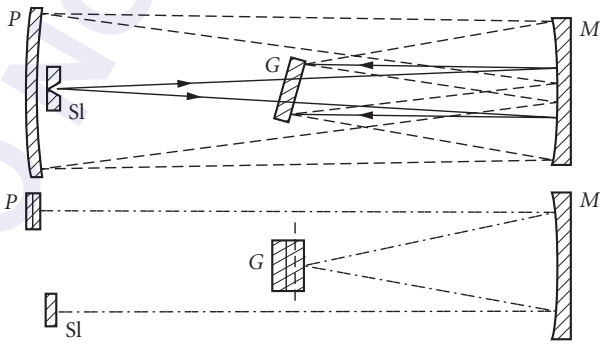

FIGURE 20 Ebert mounting of the plane grating designed by Fastie. Sl is the entrance slit, *G* is the grating, *M* is the concave mirror, and *P* is the photographic plate. The horizontal section is at the top and the vertical section is at the bottom.

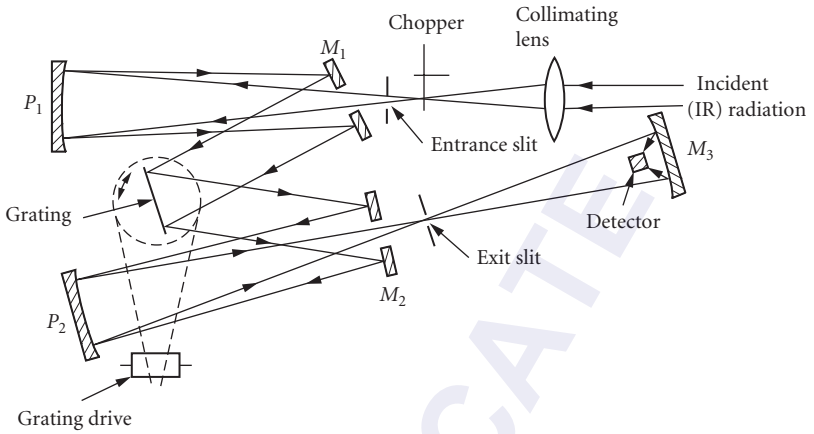

FIGURE 21 On-axis Pfund grating spectrograph.

Magnetically operated slits, programmed by a taped potentiometer, provide a constant energy background. A star-wheel, time-sharing, beam attenuator is used in the double-beam photometer.

Contemporary

In recent years there has been more attention paid to total system design and integration for specific purposes and applications, as for analytical atomic and molecular spectroscopy in analytical chemistry. Thus the conventional dispersive elements are often used in the classical configurations with variations. Innovations have come especially in designs tailored for complete computer control; introduction of one- and two-dimensional detector arrays as well as new detector types (especially for signal matching); the use of holographic optical elements either alone or combined with holographic gratings; and special data-processing software packages, displays, and data storage systems. This is the case also for interferometric systems as discussed in Chap. 32, "Interferometers," by Parameswaran Hariharan.

21.1 GLOSSARY

APE	annealed proton exchange
CATV	cable television
CVD	chemical vapor deposition
CMOS	complementary metal oxide semiconductor
DBR	distributed Bragg reflector
DFB	distributed feedback
$\vec{E}$	electric field of propagating light
FOG	fiber optic gyroscope
Gb/s	gigabits per second
$\vec{H}$	magnetic field of propagating light
IO	integrated optics
IOC	integrated optic circuit
L_c	coupling length of directional coupler
LED	light-emitting diode
Mb/s	megabits per second
MMIC	monolithic millimeter-wave integrated circuit
MZ	Mach-Zehnder
n	index of refraction
OEIC	optoelectronic integrated circuit
r_{ij}	electro-optic tensor element
PIC	photonic integrated circuit
RF	radio frequency
SOI	silicon-on-insulator

t_{cutoff}	waveguide thickness for cutoff of first odd mode
TE	transverse electric mode
TM	transverse magnetic mode
V_π	voltage for π radian phase shift in electro-optic modulator
VLSI	very large scale integration
WDM	wavelength division multiplexing
β	propagation constant of waveguide mode
ε_m	field amplitude of mode m
η	coupling efficiency between modes
θ_{crit}	critical angle for total internal reflection
Λ	spatial period of periodic feature along waveguide
λ	vacuum wavelength of propagating light
λ_{PL}	photoluminescence peak wavelength of semiconductor

21.2 INTRODUCTION

The field of integrated optics is concerned with the theory, fabrication, and applications of guided wave optical devices and circuits. These structures guide light along the surface of a wafer typically using dielectric waveguides that confine light to lateral dimensions on the scale of the optical wavelength. Guided wave devices that perform passive operations analogous to classic optics, such as reflecting, beam splitting, attenuating and spectral filtering, can be formed using microelectronic-based fabrication techniques. By fabricating devices in active materials such as ferroelectrics, modulators, and switches based on the classic electro-optic effect can be formed. Compound semiconductors such as GaAs or InP additionally allow for the detection of light, and generation and amplification of light with light-emitting diodes (LEDs), lasers, and optical amplifiers. Extremely compact passive and active optical devices have also recently been demonstrated in silicon, taking explicit advantage of the highly advanced very large scale integration (VLSI) process technology developed for electronics. The monolithic integrate of optically interconnected passive and active devices in a multicomponent circuit is referred to as an *integrated optic circuit* (IOC) or a *photonic integrated circuit* (PIC), with the latter term usually applied to active semiconductor-based circuits. In semiconductor materials, purely electronic devices such as transistors can be integrated as well to form what is often referred to as an optoelectronic integrated circuit (OEIC).

Progress in the field of integrated optics has been rapid since its inception[1] in 1969. Much of this progress is due the availability of increasingly high-quality materials, microelectronic-processing equipment and techniques, and the overall rapid advancement and deployment of fiber optic systems. Interest in integrated optics stems from its numerous advantages over other optical technologies. Integrated optics devices interface efficiently with optical fibers, and can reduce cost in complex circuits by eliminating the need for separate, individual packaging of each circuit element. They also offer smaller size and weight, lower power consumption, improved reliability, and often larger electrical modulation bandwidths compared to their bulk-optic counterparts.

The applications for integrated optics are widespread. Generally these applications involve interfacing with single-mode fiber optic systems such as digital and analog communications, but also include RF signal processing using optical techniques, laser beam control, and navigational and biomedical sensors. Integrated optics is viewed in the marketplace as a key enabling technology for high-speed digital optical fiber telecommunications, cable television (CATV) signal distribution, and fiber optic gyroscopes (FOG), and it will certainly continue to have a major impact on progress in broadband information distribution and connectivity.

This chapter reviews the integrated optics (IO) field, beginning with a brief review of IO device physics and fabrication techniques. A phenomenological description of IO circuit elements, both passive and active, is given, followed by a discussion of IO applications and system demonstrations.

The chapter concludes with a short look at future trends. Due to the brevity of this chapter relative to the work in the field, much of the coverage is necessarily limited. The reader is referred to Refs. 2–17 for more detailed information at a variety of levels.

21.3 DEVICE PHYSICS

Optical Waveguides

Central to integrated optics is the concept of guiding light in dielectric waveguide structures with dimensions comparable to the wavelength of the guided light. In this section we present only a brief survey of the relevant physics and analysis techniques used to study their properties. The reader is referred to a number of excellent texts dealing with this topic for a more comprehensive treatment.[2–6]

A dielectric waveguide confines light to the core of the waveguide by somehow reflecting power back toward the waveguide core that would otherwise diffract or propagate away. While any means of reflection can accomplish this end (e.g., glancing-incidence partial reflections from interfaces between different media can serve as the basis for *leaky* waveguides), the most common technique employs a 100 percent *total internal reflection* from the boundary of a high-index core and a lower-index cladding material. As light propagates down the axis of such a structure, the waveguide cross section can also be viewed as a lens-like phase plate that provides a larger retardation in the core region. Propagation down the guide then resembles a continuous refocusing of light that would otherwise diffract away.

The pedagogical structure used to illustrate this phenomenon is the symmetric slab waveguide, composed of three layers of homogeneous dielectrics as shown in Fig. 1. It is well known that propagation in slab structures can be analyzed using either a ray-optics approach, or through the use of interface boundary conditions applied to the simple solutions of Maxwell's equations in each homogeneous layer of the structure.[2–6] In the ray-optics description, the rays represent the phase fronts of two intersecting plane waves propagating in the waveguide core region. Since the steady-state field has a well-defined phase at each point, a finite set of discrete modes arises from the self-consistency condition that, after propagation and two reflections from the core-cladding boundaries, any phase front must rejoin itself with an integral multiple of a 2π phase shift. For a given core thickness, there will be a limited discrete number of propagation angles in the core that satisfy this criterion, with the lower bound on the angle given by the critical angle for total internal reflection, $\theta_{\text{crit}} = \sin^{-1}(n_0/n_1)$. In general, a thicker and higher-index waveguide core will admit a larger number of confined solutions or *bound* modes. Figure 1 shows both the fundamental even mode and the first higher order,

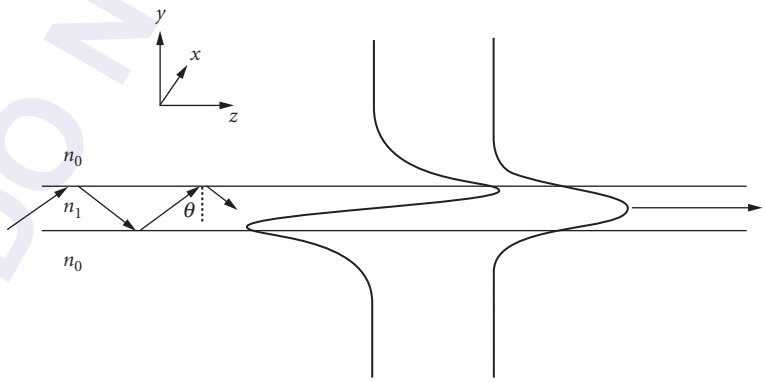

FIGURE 1 A symmetric three-layer slab waveguide. The fundamental even and first odd mode are shown.

odd mode. If the dimensions are small enough, only one bound mode for each polarization state will exist and the guide is termed a *single-mode* waveguide. Care must be exercised to include the angle-dependent phase shift upon total internal reflection, referred to as the Goos-Hanchen shift, that can be viewed as a displaced effective reflection plane.[2] The quantity $\beta = (2\pi n_1/\lambda)\cdot\sin\theta$, referred to as the propagation constant, is the z projection of the wave vector and thus governs the phase evolution of the field along the length of the guide. In addition to the discrete set of bound modes, plane waves can also enter from one side and pass at an angle *through* such a structure, and form a continuous set of *radiation* modes. In an asymmetrical structure, some of the radiation modes may be propagating on one side of the guide, but evanescent on the other. From a mathematical point of view, the set of all bound and radiation modes in a nondissipative structure form a complete set for expansion of any electromagnetic field in the structure. Analysis techniques will be discussed in more detail below.

The slab waveguide in Fig. 1 employed total internal reflection from an abrupt index discontinuity for confinement. Some fabrication techniques for waveguides, particularly in glasses or electro-optic materials such as $LiNbO_3$, achieve the high-index core by impurity diffusion or implantation, leading to a *graded* index profile. Here a field solution will usually be required to properly describe the modes and the ray paths become curved, but total internal reflection is still responsible for confinement.

Most useful integrated optics devices require waveguide confinement not just in a two-dimensional slab, but in a stripe or channel geometry. While recognizing that the vector nature of the electromagnetic field makes the rigorous analysis of a particular structure quite cumbersome, the reader can appreciate that the same phenomenon of confinement by reflection will be operative in two dimensions as well. Figure 2 shows the cross sections of the most common stripe or channel waveguide types used in integrated optics. Common to the cross section for all these structures is a region on the waveguide axis containing higher index material than the surrounding cladding areas. The diffused waveguide may require a full two-dimensional analysis, but a common technique for the approximate analysis of high-aspect-ratio channel guides such as in Fig. 2*a*, *b*, *c*, and *d*, is the *effective index method*.[2,3,18] In this technique a slab waveguide analysis is applied sequentially to the two dimensions. First three separate vertical problems are solved to obtain the modal phase index $n_{mode} \equiv \beta\cdot\lambda/2\pi$ for a given polarization mode in each lateral region as if it were an infinite

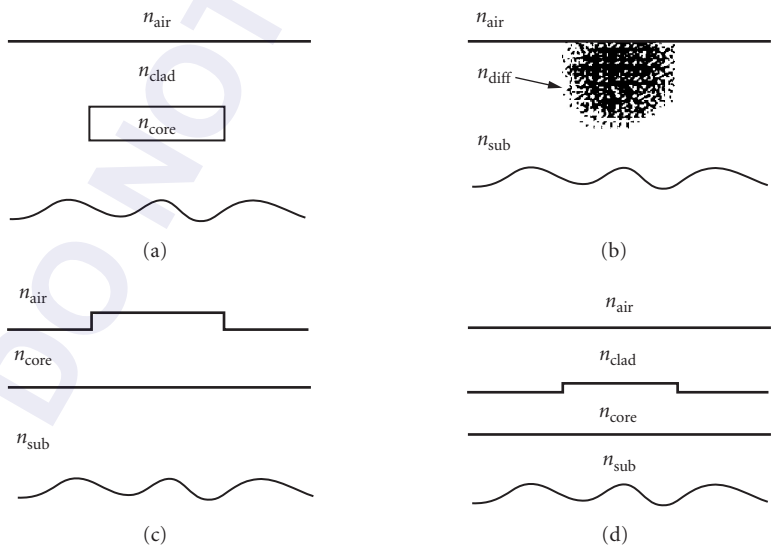

FIGURE 2 Various types of channel or stripe waveguides .

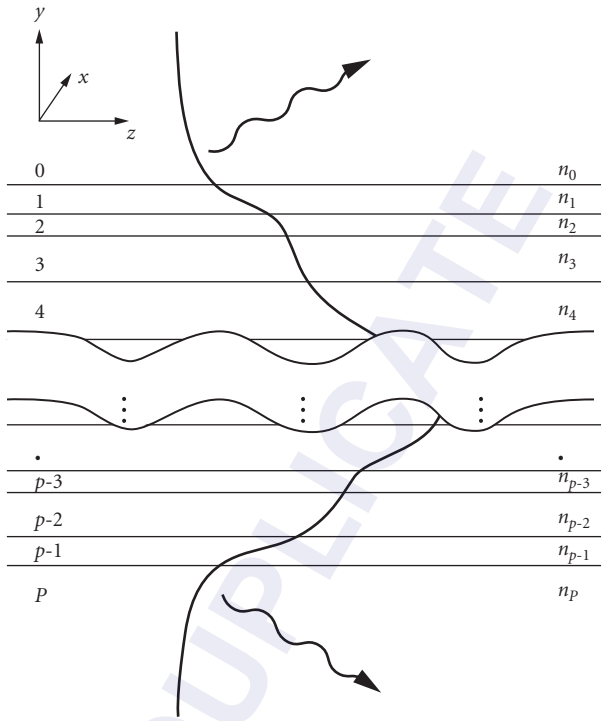

FIGURE 3 A general multilayer slab waveguide structure.

slab. These indices are then used as input to a final "effective" slab waveguide problem in the lateral dimension using the opposite polarization boundary conditions. Since the properties of multilayer slab waveguides play an important role in waveguide analysis, a more comprehensive general formulation is outlined below. This task is more tractable using the field solutions of Maxwell's equations than the ray-optics approach.

A general multilayer slab is shown in Fig. 3. Since the wave equation in this case is separable, we need only consider a two-dimensional problem in the y direction perpendicular to the layers, and a propagation direction z. Here we will consider the concept of a mode in such a structure to be quantified in physical terms as a solution to Maxwell's equations whose sole dependence on the coordinate in the propagation direction z is given by $e^{i\beta z}$. This translates to a requirement that the *shape* of the field distribution in the y direction, perpendicular to layers, remain unchanged with propagation. In this manner we can easily generalize to leaky structures or materials exhibiting loss or gain, where β may be complex to allow for the scaling of the mode amplitude with propagation, but the relative mode profile in the perpendicular y direction still remains constant. These latter solutions are not normalizable or "proper" in the sense of mathematical completeness, but are very useful in understanding propagation behavior in such structures.

Since the field in each homogeneous layer m is well known to be $e^{\pm i\vec{k}_m\cdot\vec{r}}$, with $|\vec{k}_m| = 2\pi n_m/\lambda$ for the (generally complex) index of refraction n_m, the general solution to the field amplitude in each layer m is

$$\varepsilon_m = \left[a_m e^{iq_m y} + b_m e^{-iq_m y} \right] e^{i\beta z} \tag{1}$$

where $q_m \equiv \left[(2\pi n_m/\lambda)^2 - \beta^2 \right]^{1/2}$. Inspection of the vector Maxwell's equations reveals that the general vector solution in the multilayer slab can be broken down into the superposition of a TE

(transverse electric) and a TM (transverse magnetic) solution.[2,3] The TE (TM) solution is characterized by having only one component of the electric (magnetic) field that points in the x direction, parallel to the layers and perpendicular to the propagation direction z. The mode field amplitude ε_m in Eq. (1) refers to the E_x or the H_x field for the TE and TM case, respectively.

In a very simple exercise, for each of these cases one can successively match boundary conditions for continuous tangential $\vec{E}$ and $\vec{H}$ across the interfaces to provide the coefficients a_{m+1} and b_{m+1} in each layer $m+1$ based upon the value of the coefficients in the preceding layer m,

$$\begin{bmatrix} a_{m+1} \\ b_{m+1} \end{bmatrix} = \begin{bmatrix} \frac{1}{2}\left(1+\frac{q_m\gamma_m}{q_{m+1}\gamma_{m+1}}\right)e^{-i(q_{m+1}-q_m)y_m} & \frac{1}{2}\left(1-\frac{q_m\gamma_m}{q_{m+1}\gamma_{m+1}}\right)e^{-i(q_{m+1}+q_m)y_m} \\ \frac{1}{2}\left(1-\frac{q_m\gamma_m}{q_{m+1}\gamma_{m+1}}\right)e^{i(q_{m+1}+q_m)y_m} & \frac{1}{2}\left(1+\frac{q_m\gamma_m}{q_{m+1}\gamma_{m+1}}\right)e^{i(q_{m+1}-q_m)y_m} \end{bmatrix} \cdot \begin{bmatrix} a_m \\ b_m \end{bmatrix} \tag{2}$$

where y_m are the coordinates of the interfaces between layers m and $m+1$, and $\gamma_m \equiv 1$ for TE modes and $\gamma_m \equiv n_m^{-2}$ for TM modes. The wave is assumed evanescently decaying or outward leaking on one initial side of the arbitrary stack of complex-index layers, that is $b_0 = 0$ on the uppermost layer. When the lowermost "cladding" layer $m = p$ is reached, one again demands that only the coefficient b_p of the evanescently decaying, or possibly the outward leaking, component be nonzero, which recursively provides the eigenvalue equation $a_p(\beta) = 0$ for the eigenvalues β_j. Arbitrarily letting $a_0 = 1$, this can be written explicitly as

$$a_p(\beta) = [1 \quad 0] \cdot \left[\prod_{m=p-1}^{m=0} \mathbf{M}_m(\beta)\right] \cdot \begin{bmatrix} 1 \\ 0 \end{bmatrix} = \mathbf{0} \tag{3}$$

where $\mathbf{M}_m(\beta)$ is the matrix appearing in Eq. (2). This method is essentially the one described for real propagation constants by Kogelnik,[2] who further provides important variational and perturbative expressions for determining the changes in propagation constants due to local changes in materials properties as might be used for modulation. In practice Eq. (3) is solved numerically in the form of two equations (for the real and imaginary parts of a_p) in two unknowns (the real and imaginary parts of β). Once the complex solutions β_j are obtained using standard root-finding routines, the spatial profiles are easily calculated for each mode j by actually evaluating the coefficients for the solutions using the relations above with $a_0 = 1$, for example.

Application of Eq. (3) to the simple symmetric slab of Fig. 1 with thickness t, and real core index n_1 and cladding index n_0 can be reduced with some trigonometric half-angle identities to a simple set of equations with intuitive solutions by graphical construction.[19] Defining new independent variables $r \equiv t/2[(2\pi n_1/\lambda)^2 - \beta^2]^{1/2}$ and $s \equiv t/2\,[\beta^2 - (2\pi n_0/\lambda)^2]^{1/2}$, one must simultaneously solve for positive r and s the equation

$$r^2 + s^2 = (\pi t/\lambda)^2\,(n_1^2 - n_0^2) \tag{4}$$

and either one of the following equations:

$$s = \frac{\gamma_1}{\gamma_0} \cdot r \cdot \begin{cases} \tan(r) & \text{(even modes)} \\ -\cot(r) & \text{(odd modes)} \end{cases} \tag{5}$$

where again $\gamma_m \equiv 1$ for TE modes and $\gamma_m \equiv n_m^{-2}$ for TM modes.

By plotting the circles described by Eq. (4) and the functions in Eq. (5) in the (r,s) plane, intersections provide the solutions (r_j, s_j) for mode j, yielding β_j from the definition of either r or s. This construction is shown in Fig. 4 for TE modes, where Eq. (4) has been parametrized with $u \equiv (\pi t/\lambda)\,(n_1^2 - n_0^2)^{1/2}$. Due to the presence of γ_m in Eq. (5), the TE and TM modes will have different propagation constants, leading to waveguide birefringence.

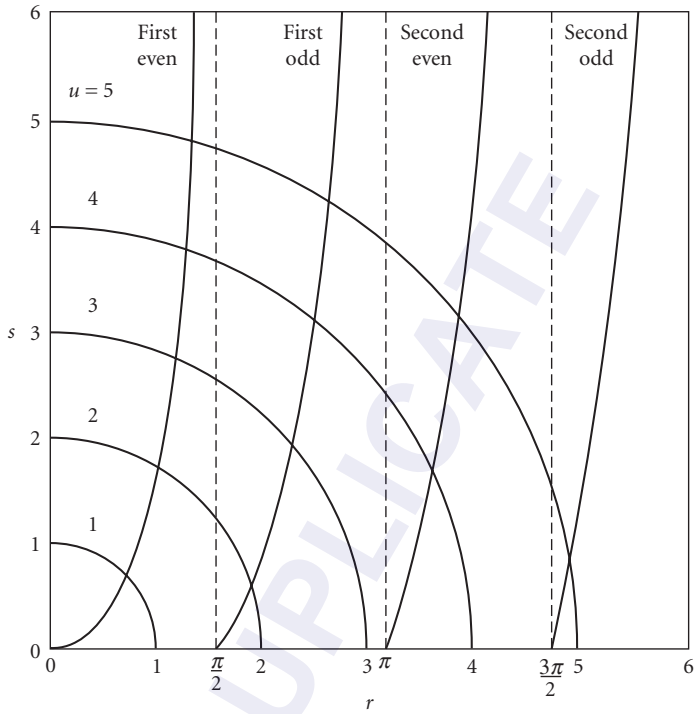

FIGURE 4 A graphical solution for the symmetric three-layer slab waveguide. For an arbitrary value of the parameter u, solutions are found at the intersections of the circular arcs and the transcendental functions as shown.

It is easy to see from the zero-crossing of Eq. (5) at $r = \pi/2$ that the cutoff of the first odd mode occurs when the thickness reaches a value

$$t_{\text{cutoff}} = (\lambda/2)\cdot(n_1^2 - n_0^2)^{-1/2} \tag{6}$$

Another important feature of the symmetric slab is the fact that neither the TE nor TM fundamental (even) mode is ever cut off. This is not true for asymmetric guides. More complicated structures are easily handled using Eq. (2), and one can also approximate graded-index profiles using the multi layer slab. However, analytical solutions also exist[1] for a number of interesting graded-index profiles, including parabolic, exponential, and "cosh^{-2}" index profiles.

Once the modes of a waveguide are known, there are many physical phenomena of interest that can be easily calculated. Quite often the propagation constant is required to evaluate the phase evolution of guided-wave components. In other cases the frequency dependence of the propagation constant is required to get the group velocity, $v_g = [\partial\beta/\partial\omega]^{-1}$, which determines quantities such as the flow of energy or the mode spacing in resonators. In other cases, the designer may need to know the electric field amplitude, or perhaps the fraction of the propagating energy, that lies within a certain layer of the waveguide system.

One critical application lies in evaluating how light couples between guided-wave components with different modal structure, or from free space into a guided-wave component. For example, it is easy to show from the mathematical completeness of the waveguide modes[2–4] that the energy

efficiency η of the coupling from a field ε_{inj} injected at the input facet of the waveguide into a particular TE mode ε_m of a waveguide is given by

$$\eta = \frac{|\int \varepsilon_m^*(y)\varepsilon_{\text{inj}}(y)dy|^2}{\int|\varepsilon_m(y)|^2\,dy \cdot \int|\varepsilon_{\text{inj}}(y)|^2\,dy} \tag{7}$$

Another mathematical formalism, called coupled-mode theory,[2,3,9] is one of the most important design tools for the guided-wave device designer and allows for the calculation of the coupling between parallel waveguides as in a directional coupler. It also allows for the evaluation of coupling between distinct modes of a waveguide when a longitudinal perturbation along the propagation direction destroys the exact mode orthogonality. An important example of the latter is when the perturbation is periodic as in a corrugated-waveguide grating where the grating allows for phase matching between modes with different propagation constants. Waveguide gratings are used to form wavelength selective coupling as in Bragg reflectors, distributed feedback lasers, and other grating-coupled devices. The comprehensive treatment of these phenomena is beyond the scope of this chapter, and the reader is referred to the references cited above. In some instances, evaluating the performance of devices where radiation plays a significant role may be tedious using a modal analysis, and numerical techniques such as the *beam propagation method* (BPM) are used to actually launch waves through the structure to evaluate radiation losses in waveguide bends, branches, or complicated splitters.[20]

Index of Refraction and Active Index-Changing Mechanisms

Index of Refraction Waveguide analysis and design requires precise knowledge of the material index of refraction. One of the most common electro-optic materials is $LiNbO_3$, a uniaxial birefringent crystal whose index can be characterized by providing the wavelength-dependent ordinary and extraordinary indices n_o and n_e. They are given by[21]

$$n_{o,e}^2 = A_{o,e} + \frac{B_{o,e}}{D_{o,e} - \lambda^2} + C_{o,e}\lambda^2 \tag{8}$$

where $A_o = 4.9048$
$B_o = -0.11768$
$C_o = -0.027169$
$D_o = 0.04750$
$A_e = 4.5820$
$B_e = -0.099169$
$C_e = -0.021950$
$D_e = 0.044432$

Glasses are also common substrate materials, but compositions and indices are too varied to list here; indices usually lie in the range of 1.44 to 1.65, and are mildly dispersive. Commonly deposited dielectrics are SiO_2 and Si_3N_4, with indices of ~1.44 and ~2.0 at 1.55 μm. The reader is referred to various tables in the literature for more detail.[21]

InP and GaAs are by far the most common substrates for IO devices in semiconductors. The usual epitaxial material on GaAs substrates is $Al_xGa_{1-x}As$, which is nearly lattice-matched for all values of x, with GaAs at $x = 0$ providing the narrowest bandgap. For photon energies below the absorption edge, the index of refraction of this material system is given by[22]

$$n_{\text{AlGaAs}}(E, x) = \left[1 + \gamma(E_f^4 - E_\Gamma^4) + 2\gamma(E_f^2 - E_\Gamma^2)E^2 + 2\gamma E^4 \cdot \ln\left(\frac{E_f^2 - E^2}{E_\Gamma^2 - E^2}\right)\right]^{1/2} \tag{9}$$

where $E = 1.2398/\lambda$ is the incident photon energy,

$$\gamma = \frac{E_d}{4E_0^3(E_0^2 - E_\Gamma^2)} \quad \text{and} \quad E_f = (2E_0^2 - E_\Gamma^2)^{1/2} \tag{10}$$

where $E_0(x) = 3.65 + 0.871x + 0.179x^2$

$E_d(x) = 36.1 - 2.45x$

$E_\Gamma(x) = 1.424 + 1.266x + 0.26x^2$

For devices fabricated on InP substrates, common in telecommunications applications for devices in the 1.3-μm and 1.55-μm bands, the most common epitaxial material is a quaternary alloy composition $In_xGa_{1-x}As_yP_{1-y}$. In this case the material is only lattice matched for the specific combination $y = 2.917x$, and this lattice-matched alloy can be characterized by its photoluminescence wavelength λ_{PL} under low intensity optical excitation. The index of this quaternary allow is given by[23]

$$n_Q(E, E_{PL}) = \left(1 + \frac{A_1}{1 - \left(\frac{E}{E_{PL} + E_1} \right)^2} + \frac{A_2}{1 - \left(\frac{E}{E_{PL} + E_2} \right)^2} \right)^{1/2} \tag{11}$$

where $E = 1.2398/\lambda$ and $E_{PL} = 1.2398/\lambda_{PL}$ are, respectively, the incident photon energy and photoluminescence peak photon energy for λ in micrometer and $A_1(E_{PL})$, $A_2(E_{PL})$, E_1, E_2 are fitted parameters given by

$$A_1 = 13.3510 - 5.4554 \cdot E_{PL} + 1.2332 \cdot E_{PL}^2$$

$$A_2 = 0.7140 - 0.3606 \cdot E_{PL}$$

$$E_1 = 2.5048 \text{ eV} \quad \text{and} \quad E_2 = 0.1638 \text{ eV}$$

For application to the binary InP, the value of the photoluminescence peak should be taken as $\lambda_{PL} = 0.939$ μm.

Many integrated optics devices rely on active phenomena such as the electro-optic effect to alter the real or imaginary index of refraction. This index change is used to achieve a different device state, such as the tuning of a filter, the switching action of a waveguide switch, or the induced absorption of an electroabsorption modulator. Below, a brief survey is provided of the most commonly exploited index-changing phenomena.

Linear Electro-Optic Effect The linear electro-optic or Pockels effect refers to the change in the optical dielectric permittivity experienced in noncentrosymmetric ordered materials that is *linear* with applied quasi-static electric field. This relation is commonly expressed using the dielectric *impermeability* $(1/n^2)_{ij} \equiv \varepsilon_0 \, \partial E_i / \partial D_j$ appearing in the *index ellipsoid* equation for propagation in anisotropic crystals.[24] Convention employs symmetry arguments to contract all the $(1/n^2)_{ij}$ to only six independent values which are then denoted by a single subscript $(1/n^2)_i$ for $i = 1, \ldots, 6$. In the *principal axes* coordinate system, the impermeability is diagonalized and $(1/n^2)_i = 0$ for $i = 4, 5, 6$ in the absence of an applied electric field, with the value of $(1/n^2)_{ij}$ providing the inverse square of the index for optical fields polarized along each axis $i = 1, 2, 3$. For an electric field expressed in the

principal axes coordinate system, the changes in the coefficients are then evaluated using the 6 × 3 *electro-optic tensor* **r**

$$\Delta\left(\frac{1}{n^2}\right)_i = \sum_{j=1}^{3} r_{ij} E_j \qquad i = 1,\ldots,6 \tag{12}$$

With an applied field, the equation for the index ellipsoid in general must be *rediagonalized* to again yield $(1/n^2)_i = 0$ for $i = 4, 5, 6$. This provides a new set of principal axes and the coefficients in the new index ellipsoid equation provide the altered value of the refractive index along each new principal axis.

For a particular crystal, symmetry also limits the number of nonzero r_{ij} that are possible. In the cubic zinc-blend III-V compounds there are only three equal nonzero components $r_{63} = r_{52} = r_{41}$ and the analysis is relatively easy. As a specific example, consider a static field **E** applied along the (001) direction, surface normal to the wafers commonly used for epitaxial growth. The re-diagonalized principal axes in the presence of the field become the (001) direction (z axis), the (011) direction (x axis), and the $(01\bar{1})$ direction (y axis); the latter two directions are the cleavage planes and are thus common directions for propagation. The respective index values become

$$\begin{aligned} n_x &= n_0 - \frac{1}{2} n_0^3 r_{41} \mathbf{E} \\ n_y &= n_0 + \frac{1}{2} n_0^3 r_{41} \mathbf{E} \\ n_z &= n_0 \end{aligned} \tag{13}$$

If we thus consider a slab guide on a (001) substrate and propagation in the (011) direction, the applied field would produce a phase retardation for TE-polarized light of $\Delta\phi = \pi/\lambda\, n_0^3 r_{41} \mathbf{E} \cdot L$ after a propagation length L. With values of $r_{41} \sim 1.4 \times 10^{-10}$ cm/V, micron-scale waveguide structures in GaAs or InP lead to retardations in the range of 10°/V·mm. This TE retardation could be used as a phase modulator, or in a Mach-Zehnder (MZ) interferometer to provide intensity modulation. For fields applied in other directions such as the (011), the principal axes are rotated away from the (011) and $(01\bar{1})$ directions. Propagation along a cleavage direction can then alter the polarization state, a phenomenon that also has device implications as will be discussed in more detail later.

In the case of $LiNbO_3$ and $LiTaO_3$, two of the most common integrated optic materials for electro-optic devices, the dielectric tensor is more complex and the materials are also birefringent in the absence of an applied field. There are eight nonzero components to the electro-optic tensor, $r_{22} = -r_{12} = -r_{61}$, $r_{51} = r_{42}$, $r_{13} = r_{23}$, and r_{33}. For $LiNbO_3$, the largest coefficient is $r_{33} \sim 30.8 \times 10^{-10}$ cm/V. Both retardation and polarization changes are readily achieved, and the reader is referred to Chap. 7, "Electro-Optic Modulators," Vol. V of this *Handbook* or the literature for a comprehensive treatment of the properties of these and other materials.[24,25]

The electro-optic effect in these materials is associated with field-induced changes in the positions of the constituent atoms in the crystal, and the resulting change in the crystal polarizability. The absorption induced by the conventional electro-optic effect is thus negligible. Below, both free-carrier and field-induced absorption effects that are readily observed in semiconductors will be described.

Carrier Effects In semiconductors, other powerful index-changing mechanisms are available related to the interaction of the optical field with the free electrons or holes. The simplest of these is the plasma contribution resulting from the polarizability of the mobile carriers. This mechanism is important in active integrated optical devices in both compound semiconductors and in silicon, where in the latter case it provides one of the only viable technique for modulation. According to the simple Drude model,[26] this is given for each carrier species by $\Delta n \approx -N \cdot e^2 \lambda^2 / (8\pi^2 \varepsilon_0 n c^2 m^*)$ in MKS units, where N and m^* are the carrier concentration and effective mass, e is the electronic charge, and ε_0 is the free-space permittivity. This can produce index changes approaching $\Delta n \sim -0.01$ at $10^{18}/\text{cm}^3$ electron-/hole-injected carrier density at 1.5-μm wavelengths. Static index shifts can also be achieved by impurity doping of the semiconductor, and can be exploited for waveguide design. Near the bandgap of the semiconductor, there are additional strong index changes with variations in the

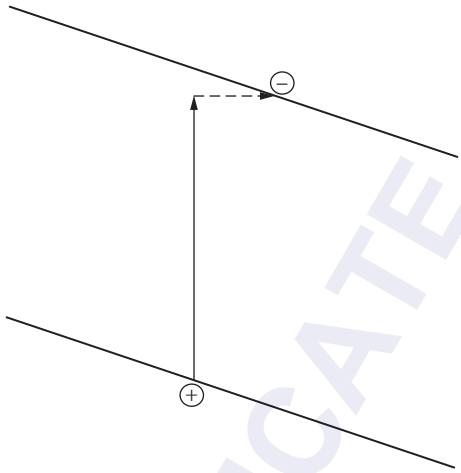

FIGURE 5 Franz-Keldysh effect. Electron can complete transition to the tilted conduction band by tunneling.

carrier density that arise from the associated dramatic changes in the optical loss or gain. Since these correspond to changes in the imaginary index, the Kramers-Kronig relation dictates that changes also occur in the real index. In the spectral region for gain in the semiconductor, these changes are comparable in magnitude and of the same sign as the free-carrier index contribution. These changes are responsible for chirping in the output of modulated semiconductor lasers, and also strongly influence their sensitivity to feedback. They can dramatically impact the static and dynamic performance of semiconductor devices and PICs that employ gain media.

In addition to the effects described above arising from changing carrier populations, the electronic transitions that generate the free carriers can be modified by an applied electric field. For optical frequencies close to these transitions, this can give rise both to electroabsorption and to an enhanced electro-optic effect, which shall be termed electrorefraction, due to the Stark effect on the carrier-generating transitions. In bulk material, the induced absorption is termed the Franz-Keldysh effect,[27] and can be viewed as a tunneling effect. For an electron in the valence band with insufficient energy to complete a transition to the conduction band, the field can be viewed as adding a potential to the bands that effectively tilts them in space as shown in Fig. 5. If the excited carrier also traversed a short distance down-field from its initial location, it would have sufficient energy to complete the transitions. This distance depends on the tilt, and thus the strength of the applied field. Since carriers can not be precisely localized according to the Heisenberg uncertainty principle, there is a finite amplitude for completing the transition that is an increasing function of electric field. For fields on the order of 10^5 V/cm, absorption values of ~100 cm^{-1} can be readily achieved in material that is quite transparent at zero field. According to the Kramers-Kronig relations, in addition to the absorption described above, this will also induce a change in the real index that will be positive below the band edge and can be used for phase modulation.

In the case of quantum wells, carrier-induced effects can be enhanced due to the forced carrier proximity arising from confinement in the wells. *Excitonic* effects, resulting from the coulombic attraction between electrons and holes, produce sharp features in the absorption spectrum near the band gap that can be dramatically altered by an applied electric field. This quantum-confined Stark effect (QCSE) can enhance both electroabsorptive and electrorefractive effects.[28,29] This suggests that more compact, lower-drive voltage devices are possible when quantum wells are employed, a fact that has been confirmed experimentally. However, in both the bulk and especially the quantum well case, care must be taken to operate at an optical frequency where strong electroabsorptive or electrorefractive effects are operative but the zero-field background absorption is

not prohibitively high. Another issue that impacts the design of devices based on electroabsorption is the requirement for removal of the photogenerated carriers to prevent screening of the applied field and band-filling which result in saturation. While the vast majority of QCSE devices have been demonstrated in compound semiconductors due to their direct bandgap, recent work has demonstrated that the effect is also operative in quantum wells at the direct bandgap of indirect gap materials such as Ge, providing impetus for further studies of QCSE device applications in the silicon-germanium materials system.[30]

Thermal Effects In virtually all materials, the optical path length of a given section of waveguide will increase with temperature. This is the combination of both the physical expansion of the material and the change of the index of refraction with temperature. While both are significant, in most integrated-optic materials the latter effect is dominant. In SiO_2 on Si, for example, this mechanism provides a useful means of index change, and numbers on the order of $\Delta n \sim 10^{-5}$/°C are observed. This effect has been used to form a variety of thermo-optic switches and filters, but a significant disadvantage for many applications is the inherent slow speed and high power dissipation. In semiconductors, this index change is more than an order of magnitude larger, and leads to frequency shifts in filter devices and single-longitudinal-mode laser of $\Delta f \sim 10$ GHz/°C.

Nonlinear Effects Another class of index changes results from the nonlinear optical effects caused by the incident optical fields themselves. This is treated in depth in other portions of this *Handbook*,[31] but two phenomena will be mentioned here. The first is closely related to the electro-optic effect discussed earlier, where now the applied field giving rise to the index change is no longer "quasi-static" but is in fact the optical field itself. The response of the medium is in general not the same at optical frequencies, but the same symmetry arguments and contracted tensor approach is employed.

An exemplary phenomenon related to this kind of nonlinearity is second harmonic generation. The polarization resulting from the incident field at ω multiplied by the index oscillating at ω generates second harmonic components at 2ω. This frequency doubling can occur in waveguides, but great care must be taken to achieve *phase matching* where each locally generated frequency-doubled field propagates in such a way as to add coherently to frequency-doubled fields generated farther along the guide. This requires either that the dispersive properties of the materials and guide geometry allow $n(\omega) = n(2\omega)$, or that the frequency-doubled light radiates away from the guide at an angle to allow phase matching of the z component of the wavevector, or that a periodic domain reversal be introduced into the crystal to allow phase matching. This latter approach, often referred to as quasi-phase matching, has generated considerable interest recently. In this approach, the optic axis of the crystal is periodically reversed with a period equal to $\lambda/2$ the difference in the index of refraction of the fundamental and second harmonic. To date, the most promising results are in $LiTaO_3$, $LiNbO_3$, and KTP. In $LiNbO_3$, periodic domain reversal has been obtained by the application of 100 μs pulsed electric fields of 24 kV/mm using a 2.8 μm-period segmented electrode that is subsequently removed.[32] The domain reversal in $LiTaO_3$ can be obtained on a few-micron scale by proton exchange or electron bombardment. KTP has a higher nonlinear coefficient, but the material is not as well developed. Lower efficiencies have been obtained.

This nonlinear mechanism can be used not just for second harmonic generation, but also for sum and difference frequency generation using input signals of different frequencies.

A second application of nonlinear optics to integrated structures involves a higher order of nonlinearity referred to four-wave mixing, or in some situations as self-phase modulation. The change in index in these cases arises from the *product* of two optical fields. If all fields are the same frequency, this is termed *degenerate*, and if only one field is present, it becomes self-phase modulation with the index change driven by the *intensity* of the incident wave. This nonlinearity has been of interest in research aimed at creating all-optical logic devices. Here the intensity of either the input signal or a separate gating signal can determine the output port of a Mach-Zehnder or directional coupler switch, for example.[33] Recent work has also shown that parametric amplification can be accomplished in guided-wave structures when the waveguide is properly constructed to allow phase matching of the resulting fields,[34] suggesting the potential for compact, low-noise amplification in new regions of the spectrum.

21.4 INTEGRATED OPTICS MATERIALS AND FABRICATION TECHNOLOGY

Ion-Exchanged Glass Waveguides

Passive integrated optic devices can be fabricated in certain glass substrates using the ion-exchange technique.[35,36] In this fabrication process, a sodium-rich glass substrate is placed in a mixture of molten nitrate salts containing alkali cations, such as Cs^+, Rb^+, Li^+, K^+, Ag^+, and Tl^+. During this process, sodium ions at the surface of the host glass are replaced with the alkali cations, resulting in a local increase in the refractive index. Channel waveguides are realized by selectively masking the glass surface. The index change and the diffusion depth are a function of host material composition, the specific alkali cation being used, the temperature, and the diffusion time. The exchange process can be substantially enhanced by applying an electric field across the wafer while the substrate is immersed in the salt bath .

Multimode devices are typically fabricated using thallium ion exchange in borosilicate glasses.[37] The high polarizability of the thallium ions results in a large index change (>0.1) while providing low propagation losses (0.1 dB/cm). However, thallium-sodium ion exchange has two significant drawbacks. Thallium is extremely toxic, and it also has a large ionic radius compared to sodium (1.49 Å compared to 0.95 Å), resulting in low diffusion coefficients and low mobility. It is therefore necessary to process the waveguides at high bath temperatures approaching the glass transition temperature of the host material (500°C) for long diffusion times (10 hours) with high applied electric fields (>100 V/cm) to achieve deep multimode waveguides that efficiently couple to commercially available multimode fiber (50 to 100 μm core size). Finding suitable masking materials is a challenge.

Single-mode devices are typically realized using either Ag^+–Na^+, K^+–Na^+, or Cs^+–K^+ exchange.[29,30] The first two processes have been extensively studied and are well understood; however, they each appear to have drawbacks. Ag^+–Na^+ exchanged waveguides are somewhat lossy (0.5 dB/cm) due to a tendency for silver reduction in the host material. K^+–Na^+ exchanged waveguides are typically highly stressed and prone to surface scattering that increases the propagation loss. Although not as extensively studied, Cs^+–K^+ exchanged waveguides show great promise. These waveguides are nearly stress free, low loss (< 0.1 dB/cm), reproducible, and can be buried using a two-step exchange process. The two-step process further reduces the propagation loss and results in efficient fiber-waveguide coupling (<0.1 dB loss per interface).

Thin Film Oxides

In recent years there has been substantial interest in IO devices fabricated in thin-film dielectrics on silicon substrates. This is due in part to the excellent surface quality, large-area wafers and mechanical integrity of silicon itself. However, this interest also stems in some cases from the availability of mature silicon-processing technology developed by the electronic integrated circuit industry. IO technology on silicon substrates is usually carried out in SiO_2, and there are two generic approaches to the Si/SiO_2 fabrication that have proven capable of producing very high performance IO devices. IO devices using both approaches are characterized by waveguides that are extremely low loss and are easily matched in mode characteristics to optical fibers used for transmission, thereby providing very efficient coupling.

The first approach borrows more from the technology of optical fiber manufacture than it does from the Si electronics industry.[38] Using a technique known as flame hydrolysis (FHD), a "soot" of SiO_2 is deposited on a Si wafer to a depth of 50 to 60 μm, followed by a thinner layer of a SiO_2/GeO_2 mix to form what will become the high-index waveguide core. This material is consolidated at ~1300°C for several hours down to roughly half its original thickness, and then the waveguide core layer is patterned using reactive ion etching to form square cross-section waveguide cores. Then FHD is again used, followed by more consolidation, to form the upper cladding layers. Typical index differences for the core material are in the range of 0.25 to 0.75 percent, with core dimensions of 6 to 8 μm square.

A measure of the material quality that was available using this approach is given by some of the extraordinary early devices results obtained. IO power splitters were fabricated to sizes of 1×128 using seven stages and a total of 127 Y-branch 1×2 splitters and a total device length of 5 cm. Total *fiber-to-fiber* excess loss for this device was 3.2 dB with a standard deviation of 0.63 dB.[39] A large variety of devices has been made using this technique.

Another technique for Si/SiO_2 fabrication employs film-deposition technology borrowed from silicon electronics processing.[40] First a base SiO_2 layer is deposited using high-pressure steam to a thickness of ~15 μm to prevent leakage to the high-index Si substrate. The waveguide and cladding layers are deposited using low-pressure chemical vapor deposition, either from silane and oxygen, or from tetraethylorthosilane and ammonia. Phosphine is added to increase the index, with guide cores typically containing 6.5 to 8 percent phosphine. The wafer is usually annealed at 1000°C to relieve strain and to densify the films. Waveguide losses below 0.05 dB/cm being reported[41] using this technique, and a large variety of devices have been demonstrated using this approach, including splitters, couplers, and WDM devices. One of the interesting features of this approach to fabrication is that it readily lends itself to the inclusion of other thin films common in Si processing. One such film is Si_3N_4 and this has been used as a high index core for waveguides with much larger core-cladding index step. Such waveguides can generate tightly confined modes that are a much closer match to the modes commonly found in active semiconductor components such as lasers. This feature has been used in a novel mode converter device[42] that adiabatically transforms from the smaller mode into the larger, fiber-matched mode commonly employed in Si/SiO_2 IOCs.

In some instances, slow response *active* devices have been fabricated in Si/SiO_2 technology using thermal effects to achieve local index changes in one arm of a Mach-Zehnder interferometer. This can either be used as a thermo-optic switch or as a tuning element in WDM components. The heating elements in these devices comprises a simple metal-film-resistive heater deposited directly on the upper surface of the wafer.

Another characteristic feature of IOCs in Si/SiO_2 is a degree of birefringence that results from the compressive stress induced in the film by the Si substrate after cooling down from the high-temperature film deposition or consolidation. Typical amounts of birefringence are $n_{TE} - n_{TM} = 3 \times 10^{-4}$. This birefringence can cause wavelength shifts with input polarization in WDM components, and techniques to counteract it include stress removal by adding strain-relief grooves in the film, or stress compensation by adding a counteracting stress-inducing film on the surface of the guide, or the explicit introduction of birefringence-compensating waveguide elements.

The Si/SiO_2 technology has matured to a point where it is commonly used in telecommunications for passive devices such as wavelength demultiplexing circuits that will be discussed later in this chapter, and active thermo-optic device circuits continue to be explored.

Silicon Photonics Fabrication and Materials

Recent years have seen a strong increase in research and development of *silicon photonics* where light is guided in silicon layers that are transparent in the important telecommunications window from 1.2 to 1.6 μm.[43–46] The most common approach to waveguide design directly uses silicon-on-insulator (SOI) technology, which provides for a layer of single-crystal silicon with thicknesses in the 0.1- to 5-μm range, separated from the underlying silicon substrate by a buried oxide (BOX) layer of SiO_2 with a thickness typically in the 1- to 2-μm range. Typical waveguide structures fabricated in the SOI system are shown in Fig. 6.

SOI has become a mainstream VLSI electronics technology offering reduced electrical parasitics for high-performance microprocessor applications, and the most common SOI wafer-fabrication method is the SMARTCUT technique, developed at CEA/LETI in France, and commercialized by Soitec.[47] This technique works by implanting hydrogen in a first substrate and growing oxide on a second substrate. After the two substrates are wafer bonded, a rapid annealing step expands the hydrogen, creating an accurate cleave plane and leaving a uniform silicon film on top of the oxide. High-quality SOI wafers are now available to the silicon photonics community in sizes up to 12 in (300 mm), and this materials system immediately brings to bear the unprecedented process

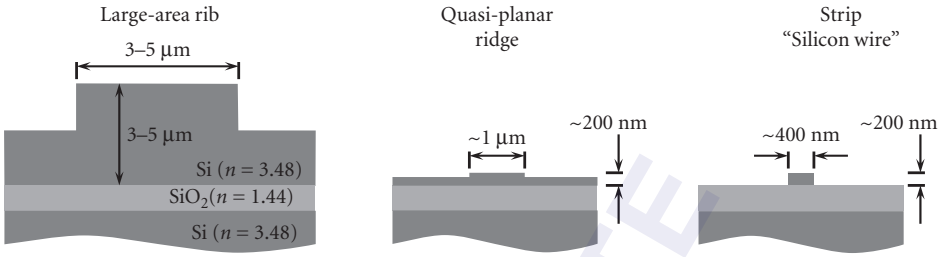

FIGURE 6 Typical silicon-on-insulator (SOI) waveguide structures.

precision associated with VLSI complementary metal-oxide-semiconductor (CMOS) technology. This precision is not just in lithography, etching, and feature size, now at the 65-nm node and still shrinking, but also in the remarkable versatility in materials sequencing that allows for exotic dielectrics and multilayer metallizations.

One of the distinctive features of the SOI system is the extremely high index contrast available for waveguides, for example, with $n_{Si} = 3.475$ and $n_{SiO_2} = 1.444$ at 1.55 μm. As illustrated in Fig. 7, this allows for extremely small waveguides with cross-sectional areas below 0.1 μm^2.[46] This feature enables extremely compact passive devices, and also enables high-performance active devices by concentrating the mode on the index-changing region. However, the same high index contrast also leads to significant scattering losses from fabrication-induced waveguide sidewall roughness, which becomes increasingly challenging in very small cross-section waveguides. Larger mode devices in SOI have shown losses in the ~0.1 dB/cm range,[48] while maximally vertically confined shallow ridge guides have losses of ~0.4 dB/cm,[49] and several decibels per centimeter is more typical for most tightly confined "wire" waveguides.

The principle active index-changing mechanism used in silicon photonics is the plasma index contribution from free electronics and holes in the silicon. As will be illustrated later in discussions of devices, these free-carrier populations and locations can be controlled in a variety of diode and field-effect structures. The ability to harness the precision of VLSI CMOS technology to predictably

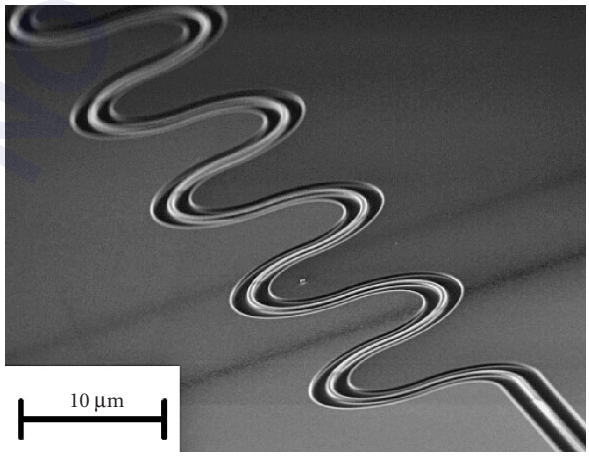

FIGURE 7 Example of losses for high-index-contrast "wire" waveguides: For 6.5-μm radius bends, losses are 0.0043 dB per 180° turn as demonstrated by Vlasov et al., IBM.[86]

engineer very high confinement waveguides together with precision dynamic control of free carriers in transistor-like device geometries has recently resulted in a number of high-performance modulator designs. While historically silicon has not been viewed as a high-performance active optical material, these and other advances have caused a serious reexamination of the potential of silicon as a powerful medium for PICs.

$LiNbO_3$ and $LiTaO_3$

The majority of the integrated optics R&D from 1975 to 1985 and the majority of the currently commercial integrated optics product offerings utilize $LiNbO_3$ as the substrate material. A number of excellent review papers detailing R&D efforts in $LiNbO_3$ are available.[50–54] $LiNbO_3$ is an excellent electro-optic material with high optical transmission in the visible and near infrared, a relatively large refractive index ($n = 2.15 - 2.2$), and a large electro-optic coefficient ($r_{33} = 30.8 \times 10^{-10}$ cm/V). Probably most important, but frequently overlooked, is the widespread availability of high-quality $LiNbO_3$ wafers. Hundreds of tons of $LiNbO_3$ is produced annually for the fabrication of surface acoustic wave (SAW) devices. This large volume has resulted in well-developed crystal growth and wafer-processing techniques. In addition, $LiNbO_3$ wafers are at least an order of magnitude less expensive than they would be if integrated optics was the only user of this material. High-quality 3- and 4-in optical-grade $LiNbO_3$ wafers are now available from multiple vendors.

$LiNbO_3$ is a uniaxial crystal which is capable of supporting an extraordinary polarization mode for light polarized along the optic axis (z axis) and an ordinary polarization mode for light polarized in the x-y plane. $LiNbO_3$ is slightly birefringent with $n_e = 2.15$ and $n_o = 2.20$. $LiNbO_3$ devices can be fabricated on x-, y-, and z-cut wafers. Phase modulators, fiber gyro circuits, and Mach-Zehnder interferometers are typically fabricated on x-cut, y-propagating wafers, and operate with the TE (extraordinary) mode. Push-pull devices, such as delta-beta directional coupler switches, are typically fabricated on z-cut, y-propagating wafers and operate with the TM (extraordinary) mode. Both configurations utilize the strong r_{33} electro-optic coefficient. Devices that require two phase-matched modes for operation are typically fabricated on x-cut, z-propagating wafers.

The majority of $LiNbO_3$ integrated optic devices demonstrated to date have been fabricated using the titanium in-diffusion process.[55] Titanium strips of width 3 to 10 μm and thickness 500 to 1200 Å are diffused into the $LiNbO_3$ at 950 to 1050°C for diffusion times of 5 to 10 hours.[56,57] The titanium diffusion results in a local increase in both the ordinary and extraordinary refractive indices so that both TE and TM modes can be supported for any crystal orientation. Titanium thickness and strip width typically need to be controlled to ± 1 percent and ± 0.1 μm, respectively, for reproducible device performance. Due to the high processing temperatures that approach the Curie temperature of $LiNbO_3$, extreme care must be taken to prevent Li_2O out-diffusion[58,59] and ferroelectric domain inversion, both of which significantly degrade device performance. Photorefractive optical damage[60] also needs to be considered when utilizing Ti-diffused devices for optical wavelengths shorter than 1 μm. Optical damage typically prevents the use of Ti-diffused devices for optical power greater than a few hundred micro Watts at 800-nm wavelength, although the problem can be reduced by utilizing MgO-doped $LiNbO_3$ wafers. Optical damage is typically not a problem at 1300 and 1550 nm for optical powers up to 100 mW.

An alternative process for fabricating high-quality waveguides in $LiNbO_3$ is the annealed proton exchange (APE) process.[61,62] In the APE process, a masked $LiNbO_3$ wafer is immersed in a proton-rich source (benzoic acid is typically used) at temperatures between 150 and 245°C and times ranging from 10 to 120 minutes. The wafer is then annealed at temperatures between 350 and 400°C for 1 to 5 hours. During the initial acid immersion, lithium ions from the wafer are exchanged with hydrogen ions from the bath in the unmasked region, resulting in a stress-induced waveguide that supports only the extraordinary polarization mode. Proton-exchanged waveguides that are not subjected to further processing are practically useless due to temporal instabilities in the modal propagation constants, high propagation loss, DC drift, and a much-reduced electro-optic coefficient. However, it has been demonstrated[62] that proper postannealing results in extremely high quality waveguides that are stable, low-loss, and electro-optically efficient.

The APE process has recently become the fabrication process of choice for the majority of applications currently in production. Since the APE waveguides only support the extraordinary polarization mode, they function as high-quality polarizers with polarization extinction in excess of 60 dB.[63] As described later in this chapter, high-quality polarizers are essential for reducing the drift in fiber optic gyroscopes and minimizing nonlinear distortion products in analog links. APE waveguides exhibit low propagation losses of 0.15 dB/cm for wavelengths ranging from 800 to 1550 nm. APE $LiNbO_3$ devices exhibit stable performance for optical powers of 10 mW at 800 nm and 200 mW at 1300 and 1550 nm. The APE process can also be used to fabricate devices in $LiTaO_3$ for applications requiring higher optical powers (up to 200 mW) at 800 nm.[64] In addition to offering performance advantages, the APE process also appears to be the more manufacturable process. It is relatively easy to scale the APE process so that it can handle 25-wafer lots with no degradation in device uniformity. The fiber pigtailing requirements are also substantially reduced when packaging APE devices since these devices only support a single polarization mode.

After the waveguides have been fabricated in the $LiNbO_3$ wafer, electrodes need to be deposited on the surface. One-μm-thick gold is typically used for lumped-electrode devices while 5-μm-thick gold is typically used for traveling-wave devices to reduce RF resistive losses. The lift-off process and electron-beam deposition is typically used for lumped-electrode devices while up-plating is typically used for realizing the thicker gold electrodes. Better than 0.5-μm layer-to-layer registration is required for optimum device performance. As shown in Fig. 10, electrodes on x-cut $LiNbO_3$ are usually placed along side the waveguide so that the horizontal component of the electric field interacts with the propagating TE mode. Electrodes on z-cut $LiNbO_3$ are placed on top of the waveguide so that the vertical component of the electric field interacts with the propagating TM mode. An SiO_2 buffer layer (0.1–1 μm thick) is required between the optical waveguide and the electrode on all z-cut devices to reduce metal-loading loss. A thick (1 μm) SiO_2 buffer layer is also utilized on some x- and z-cut devices to reduce the velocity mismatch between the microwave and optical waves in high-speed traveling-wave modulators. A thin layer of amorphous silicon is also utilized on some z-cut devices to improve device stability over temperature.

III-V Materials and Fabrication Technology

In this section we will briefly review some of the epitaxial growth and fabrication techniques that are used to make PICs in III-V materials, with a primary focus on InP-based devices.

III-V Epitaxial Crystal Growth The epitaxial growth of III-V optoelectronic materials has evolved during the last several decades from nearly exclusive use of manually controlled liquid-phase epitaxial (LPE) growth to a variety of highly versatile computer-automated vapor and beam-growth techniques. These include atmospheric-pressure and low-pressure metal-organic vapor-phase epitaxy (MOVPE), hydride and chloride vapor-phase epitaxy (VPE), molecular beam epitaxy (MBE), chemical beam epitaxy (CBE), and metal-organic molecular beam epitaxy(MOMBE). Detailed descriptions of reactor design and growth chemistry are beyond the scope of this section, and the interested reader is referred to recent texts and conference proceedings for the most current information.[65]

One of the critical criteria for evaluating crystal growth is the uniformity, both in thickness and in epitaxial composition. Layer thickness changes of several percent can lead to nanometer-scale wavelength changes in grating-based lasers and filter devices. Similarly, compositional changes leading to a 10-nm shift in the photoluminescence peak wavelength of the guide layers, which is not at all uncommon, can also result in nanometer-scale wavelength shifts in distributed feedback (DFB) laser emission wavelengths, in addition to potential undesirable gain-peak mismatches that may result from the λ_{PL} shift itself.

Proper reactor geometry, sometimes with substrate rotation, have been shown capable of percent-level uniformity both in MOVPE and in the beam techniques. One difficulty associated with latter lies in the ballistic "line-of-sight" growth which prevents regrowth over reentrant mesa geometries or overhanging mask surfaces often encountered in PIC and laser fabrication, while

MOVPE and especially VPE offer outstanding coverage over a wide range of morphologies. Other criteria to be considered are the doping capabilities. The lower growth temperatures associated with MBE, CBE and MOMBE enable very abrupt changes in doping level, and highly concentrated doping sheets that are desirable for high-speed transistors in OEICs, for example. Both the vapor and beam techniques have successfully grown semi-insulating Fe-doped InP, a material that is playing an increasingly pivotal role in photonic devices.

The typical PIC processing involves the growth of a base structure that is followed by processing and regrowths. During both the base wafer and regrowths, selective area growth is often employed where a patterned dielectric film is used to prevent crystal growth over protected areas. This film is typically SiO_2 or Si_3N_4 deposited by CVD or plasma-assisted CVD. This technique is readily used with MOVPE, but care must be taken to keep a substantial portion of the field open for growth to avoid the formation of polycrystalline deposits on the dielectric mask. Caution must be exercised during regrowths over mesas or other nonplanar geometries, as well as in the vicinity of masked surfaces. Gross deviations from planarity can occur due to overshoots of crystal growth resulting from crystal-orientation-dependent growth rates on the various exposed surfaces.

III-V Etching Technology A fundamental step in III-V PIC processing is mesa etching for definition of the optical waveguides. This is usually accomplished by patterning a stripe etch mask on a base wafer that has a number of epitaxial layers already grown, and removing some of the layers in the exposed regions to leave a mesa comprised of several of the epitaxial layers. The etching process can either be a "wet" chemical etchant, or a "dry" plasma-type etch.

Wet etching refers to the use of an acid bath to attack the unprotected regions of a surface. The acids that are commonly used to etch III-V materials[66] also tend to significantly undercut a photoresist pattern, and hence photoresist is usually used only in broad-area features or in shallow etches where undercutting is not a concern. For precise geometries such as waveguide stripes, another masking material such as SiO_2 or Si_3N_4 is first deposited and patterned with photoresist and plasma etching, or HF etching (for SiO_2).

In some instances it is required that the etchants be nonselective, uniformly removing layers regardless of composition. This is usually the case when etching a mesa through a multilayer active region to form a buried heterostructure laser. Br-based etchants, such as bromine in percent-level concentration in methanol, tend to be very good in this regard. This etchant, along with many of the nonselective etchants, will form a reentrant 54.7° (111A) face mesa for stripes along the (011) direction (with a nonundercutting mask) and will form an outward-sloping 54.7° walled mesa for stripes along the $(01\bar{1})$ direction. Other etchants, with varying degrees of nonselectivity and crystallographic behavior, include mixtures of HBr, CH_3COOH, or HCl, CH_3COOH, and H_2O_2.[67]

In fabricating precise geometries in III-V integrated optic or PIC devices, it is often desirable to remove specific layers while leaving others, or control mesa heights to a very high degree of precision. The combination of material-selective etchants and the inclusion of special etch-stop layers offers a convenient and precise means of achieving this. Hundred-Å-thick layers of InGaAsP can easily halt InP etches even after many microns of etching. Extensive compilations have been made of etches for the InP-based compounds,[52] and the most common selective InP etches are HCl-based. Typical mixtures are HCl and H_3PO_4 in ratios ranging from 3:1 to 1:3, with the lower HCl content leading to less undercutting and slower etch rates. The HCl-based etchants are highly crystallographic in nature,[68] and can produce mesas with nearly vertical walls or outward sloping walls, depending on the mesa stripe orientation.

A common selective etch for removing InGaAsP or InGaAs while only weakly attacking InP are mixtures of H_2SO_4, H_2O_2, and H_2O in a ratio of X:1:1 with X typically ranging from 3 to 30. Selectivities in the range of 10:1 and typically much higher are readily achieved. Other selective etchants for InGaAsP are based on HNO_3 or mixtures of KOH, $K_2Fe(CN)_6$, and H_2O.

Dry etching techniques, such as reactive ion etching (RIE) or other variants such as chemically assisted reactive ion beam etching (CAIBE), also play a key role in III-V PIC processing. These have often been carried out using Cl_2-based mixtures with O_2 and Ar,[69] while in other cases the reactive chlorine is derived from compounds such as CCl_2F_2. Excellent results have also been obtained with methane/hydrogen mixtures or ethane/hydrogen.[70] In these latter cases Ar is also often used as a

sputtering gas to remove interfering redeposited compounds. Reactive ion etching has been used both to form mesa and facet structures as well as in transferring grating patterns into semiconductors through an etch mask.

The appeal of reactive ion etching is the lack of mask undercutting that can usually be achieved, allowing very high lateral precision with the promise of reproducible submicron mesa features. In addition, the ability to create vertical wall-etched facets through a variety of different composition epitaxial layers suggests the possibility of integrated resonator or reflecting and coupling structures without the use of gratings. This approach has been used to form corner reflectors,[71] square-geometry ring-resonators,[72] and a variety of complex waveguide patterns using beam splitters.[73] Another recent application has been the use of etched-facet technology to create gratings, not as an interfacial corrugation *along* the waveguide, but as a grating in the other dimension *at the end surface* of a waveguide for two-dimensional "free-space" grating spectrometers.[74,75]

Grating Fabrication Many of the PICs employ corrugated-waveguide grating-based resonators or filters, and the most common technique for fabricating these gratings involves a "holographic" or interferometric exposure using a short wavelength laser source. Here a thin (typically 500 to 1000Å thick) layer of photoresist is spun on a wafer surface and exposed with two collimated, expanded beams from a blue or UV laser at an appropriate angle to form high-contrast fringes at the desired pitch. Since the illuminating wavelength is precisely known, and angles are easily measured in the milliradian range, the typical corrugation in the 2000Å-period range can be fabricated to arm-strong-level precision in period. The resist is developed and then functions as an etch mask for the underlying layers. This etching can be either a wet etch (commonly using *HBr*-based etchants), or a dry reactive ion etch. Commonly used lasers are HeCd at 325 nm or one of the UV lines of an Argon ion laser at 364 nm. Electron-beam lithography has also been successfully applied to the generation of gratings for III-V integrated optic devices.

Active-Passive Transitions Compound semiconductors are appealing for PICs in large part due to their ability to emit, amplify, and detect light. However, waveguide elements that perform these functions are not low loss without excitation, and are generally not suitable for providing passive interconnections between circuit elements. One of the most fundamental problems to overcome is the proper engineering and fabrication of the coupling between active waveguides, containing lower bandgap material, and passive waveguides composed of higher bandgap material.

Most PICs demonstrated to date have employed some form of butt-coupling, where an active waveguide of one vertical and/or lateral structure mates end-on with a passive waveguide of a different vertical and/or lateral structure. Butt-coupling offers design simplicity, flexibility, and favorable fabrication tolerances. The most straightforward approach for butt-coupling involves the selective removal of the entire active waveguide core stack using selective wet chemical etching, followed by a regrowth of a mated, aligned passive waveguide structure. The principal advantage of such an approach is the independent selection of compositional and dimensional design parameters for the two guides.

Another approach to butt-coupling, often called "offset quantum wells" or "active layer removal," employs a largely continuous passive waveguide structure with a thin active layer (usually of quantum wells) residing on top, which is selectively removed on the portions of the structure which are to be passive. Using material-selective wet chemical etches, the thin MQW stack can be removed with very high reproducibility and precision, and the dimensional control is thus placed in the original computer-automated MOVPE growth of the base wafer. The removal of the thin active layer constitutes only a small perturbation of the continuous guide core constituted by the lower, thicker layer, and efficient coupling can be achieved.[76]

Two powerful alternatives to the butt-coupling variants discussed above are *selective area epitaxy* and *quantum-well intermixing.* These techniques provide for longitudinal modification in the effective bandgap of quantum-well-containing waveguides by altering the dimensions or profile of the quantum well along the length of a waveguide. Selective area epitaxy accomplishes this by the inclusion of growth-inhibiting masks, such as SiO_2, laterally adjacent to the waveguide during MOVPE growth. The resulting local increase in vapor-phase reactants, combined with surface diffusion along

the growth-inhibiting mask, leads to an increased growth rate in regions adjacent to the lateral masks. This leads to thicker quantum wells with correspondingly lower bandgaps from quantum confinement, making these regions suitable for gain media or absorption along a waveguide which is transparent in regions with no masks. By controlling the degree of enhancement, regions of transparency, regions suitable for electroabsorption or QCSE, and regions suitable for gain or absorption can all be formed along a guide with remarkably smooth continuity between regions. This technique has been highly successful in PICs comprising an integrated DFB laser and electroabsorption modulator.[77]

The quantum-well intermixing accomplishes a similar end by implanting regions and diffusing impurities or vacancies into the quantum-well region of a waveguide to intermix the boundaries of the wells and barriers. This intermixing smoothes the rectangular well into a rounded profile and also can change the average composition of the well, leading to a higher bandgap which can be used for longitudinally differentiating gain regions, modulation regions, and transparent regions.[78] Although not in as wide commercial use, this method has the advantage that the various regions are large-area materials modifications allowing for standard materials characterization techniques, in contrast to the selective area epitaxy approaches which require difficult characterization of narrow stripe regions.

Yet another approach to coupling between two different waveguides employs directional coupling in the vertical plane between epitaxial layers serving as the cores of the two distinct waveguides. This type of vertical coupling can either be accomplished using the principle of intersecting dispersion curves, or through the use of a corrugated-waveguide grating to achieve phase matching. Vertical coupler structures may be useful for wide-tuning applications, since a small change of effective index for one mode can lead to a large change in coupling wavelength.[79]

Organic Polymers

Polymer films are a relatively newer class of materials for integrated optics.[80] Polymers offer much versatility, in that molecular engineering permits many different materials to be fabricated; they can be applied by coating techniques to many types of substrates, and their optical and electro-optical properties can be modified in a variety of ways. Applications range from optical interconnects, in which passive guides are used in an optical PC board arrangement, to equivalents of IOCs and OEICs. Polymer devices are also being explored for third-order nonlinear applications.

Numerous methods for fabricating polymer waveguide electro-optic devices have been reported. One attractive technique consists of spin-coating a three-layer polymer sandwich over a metal film, often on a semiconductor (Si) substrate. The three polymer layers form a symmetric planar waveguide; the middle layer is electro-optic, due to the presence of a guest molecule that imparts the electro-optic property, or the use of a side-chain polymer. The sample is overcoated with metal and the entire structure is heated near the glass transition temperature and poled at an electric field of typically 150 V/μm. The poling aligns the nonlinear molecules in the middle polymer layer, thereby inducing the Pockels effect and a birefringence. Typical values of index and birefringence are 1.6 and 0.05, respectively. Electro-optic coefficients are in the 16 to 38 pm/V range. Channel waveguides are subsequently defined by a variety of methods. An attractive technique is photobleaching, in which the waveguide region is masked with a metal film and the surrounding area exposed to UV light. This exposure alters the molecules/linking in the active layer, thereby reducing the refractive index and providing lateral confinement. Losses in such guides are typically in the 1dB/cm range.

The basic IO modulators have been demonstrated in a variety of polymers. Of particular note are traveling wave modulators with a 3-dB bandwidth of 40 GHz and a low-frequency V pi of 6 V,[81] and work illustrating the high-frequency potential of polymers up to modulation frequencies of 110 GHz.[82] Relative to $LiNbO_3$, polymer modulators can have higher overlap factors because the lower metal layer provides vertical, well-confined signal fields. However, the relatively low index of polymers and their comparable electro-optic coefficient to $LiNbO_3$ implies a lower electro-optic efficiency. Polymers do provide a better velocity match of optical and electromagnetic velocities which can result in very high frequency performance as described above.

For polymers to fulfill their potential, a number of material and packaging issues must be addressed. First, it is highly desirable to develop polymers that overcome the long-term relaxation of the electro-optic effect typical of many of the early reports. Development of polymers with transition temperatures in the 300°C range (so they can withstand the temperatures typical of device processing and packaging) is also highly desirable. Work on polyimide is particularly promising in this area. Recent work has demonstrated encouraging results with devices processed at lower temperatures that exhibit long-term stability at elevated operating temperatures of 85°C.[83]

21.5 CIRCUIT ELEMENTS

Passive Devices

This section provides a phenomenological description of the most common passive and active IO devices. Detailed descriptions of the device theoretical properties as well as typical characteristics can be found in Refs. 2–6.

Passive devices form many of the fundamental building blocks for IOCs and PICs, and passive waveguides also comprise the interconnections between devices. Passive devices are defined as those dielectric waveguide structures which involve neither application of electrical signals, generation or detection of light, nor nonlinear optical effects. This section will focus on the most important structures: waveguide bends, polarizers, fiber-to-chip coupling, power splitters, and filters.

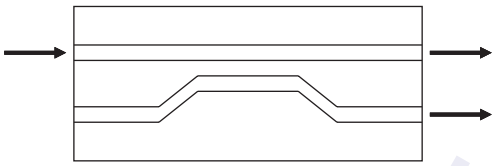
Waveguide bends, such as those illustrated in Figs. 7, 10, 11, 12, 14, 15, 19, 22, 25, and 26, are needed to laterally offset modulators and other devices, and also to increase device-packing density. Waveguide bends lead to radiation or leakage from the guide, and analytical treatments reveal that the induced losses decrease exponentially with radius of curvature in a manner that is very sensitive to the index difference between the core and cladding of the guide.[84,85] The most widely used bend is based on an S-bend geometry described by a raised cosine function.[2] This structure minimizes the tendency of light in a dielectric waveguide to "leak" as the guide's direction is altered by starting with a small bend (large effective bend radius and then increasing the bend rate until the midpoint of the offset, then following the pattern in reverse through the bend completion.

Since the index difference between the guide and surrounding dielectric material is often small (10^{-3} to 10^{-4}) bends must be gradual (effectively a few degrees) to keep losses acceptably (< 0.5 dB) small. In $LiNbO_3$, offsets of 100 μm require linear distances of typically 3 mm. In semiconductor research device work, designs with high index steps are sometimes used to form small-radius bends and ion beam etching has been utilized to form reflective micromirrors[73] at 45° to the guide to create a right-angle bend. While compact, to date these have generally been relatively lossy compared to their bending waveguide counterparts.

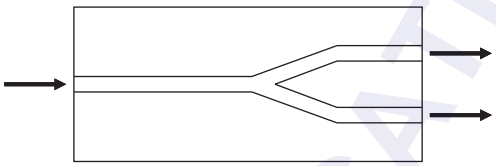
As noted earlier, silicon photonics carries a very high index contrast of $\Delta n \sim 2$, which also allows for extremely tight waveguide radii, as illustrated in Fig. 7, without introducing the bending losses that often limit the size of weaker index contrast materials systems.[86] This can provide a dramatic increase in the density of possible PICs developed in the SOI system.

Polarizers are necessary for polarization-sensitive devices such as many electro-optic modulators and for polarization-sensitive applications such as fiber gyroscopes. Polarizers can be formed on dielectric waveguides that support both TE and TM propagation by forming overlays that selectively couple one polarization out of the guide. For example, a plasmon polarizer formed on $LiNbO_3$ by overcoating the guide with a Si_3N_4/Au/Ag thin-film sandwich selectively attenuates the TM mode.[87] In some materials it is possible to form waveguides that only support one polarization (the other polarization is not guided and radiates into the substrate). By inserting short (millimeter) lengths of such guides in circuits or alternatively forming entire circuits from these polarizing guides, high extinction can be obtained. For example, annealed proton exchange waveguides (APE) in $LiNbO_3$ exhibit polarization extinction ratios of at least 60 dB.[88]

Guided wave devices for splitting light beams are essential for most IOCs. Figure 8 illustrates the two common splitters: a directional coupler and a Y junction. The figure illustrates 3-dB coupling (1X2),



Directional coupler



Y-splitter

and by cascading such devices and using variations on the basic designs it is possible to fabricate N × N structures. IO splitters of complexity 8 × 8 are commercially available in glass.

The operation of the directional coupler is analogous to the microwave coupler and is described by the coupled mode equations. The coupling strength is exponentially dependent of the ratio of the guide spacing and the effective tail length of the guided mode. Thus when guides are far apart (typically greater than 10 μm in weakly guided glass and ferroelectric devices) as in the left-most portion of the structure in Fig. 8, there is negligible coupling. When the guides are close together (typically a few microns), power will couple to the adjacent guide. The fraction of power coupled is sinusoidally dependent on the ratio of the interaction length to the coupling length L_c. L_c is typically 0.5–10 mm and is defined as the length for full power transfer from an incident guide to a coupled guide. The 3-dB coupling illustrated requires an interaction length of half L_c.[2–6] Operation of this device is symmetric; light incident in any one of the four inputs will result in 3-dB splitting of the output light. However, if coherent light is incident on both input guides simultaneously, the relative power out of the two output guides will depend on the phase and power relationship of the incident signals.

The Y splitter illustrated in Fig. 8 operates on a modal evolution principle. Light incident on the junction from the left will divide symmetrically so that the fundamental mode of each output branch is excited. Branching circuit design follows closely from the design of waveguide bends. In low index contrast systems, the Y-junction angle is typically a few degrees and the interaction length is a few millimeter. Operation of this device is not symmetric with respect to loss. If coherent light is incident on both guides from the right, the amount of light exiting the single guide will depend on the power and phase relationship of the optical signals as they enter the junction area. If coherent light is only incident in one arm of the junction from the right it will experience a fundamental 3-dB loss in propagation to the left to the single guide. This is due to the asymmetric modal excitation of the junction. (see the next section, "Active Devices").

An extremely important issue in integrated optics is the matching of the waveguide mode to the mode of the fiber coupled to the guide. Significant mode mismatch causes high insertion loss, whereas a properly designed waveguide mode can have coupling loss well under 1 dB. As illustrated in Eq. (7), the proper design requires optimizing the overlap integral of the optical fields in the two media. Often some sort of index matching between the two materials is also employed to minimize additional reflective losses. Figure 9 illustrates the issue with mode profiles in the two transverse directions for a Ti indiffused guide. In general the IO mode is asymmetric relative to the fiber mode. It should be noted that the loss obtained on a pigtailed fiber-chip joint is also highly determined by the precision and stability of the mechanical method of attaching the fiber to the chip. Most techniques use some sort of carrier block for the fiber (e.g., a Si V-groove) and attach the block to the IO chip.

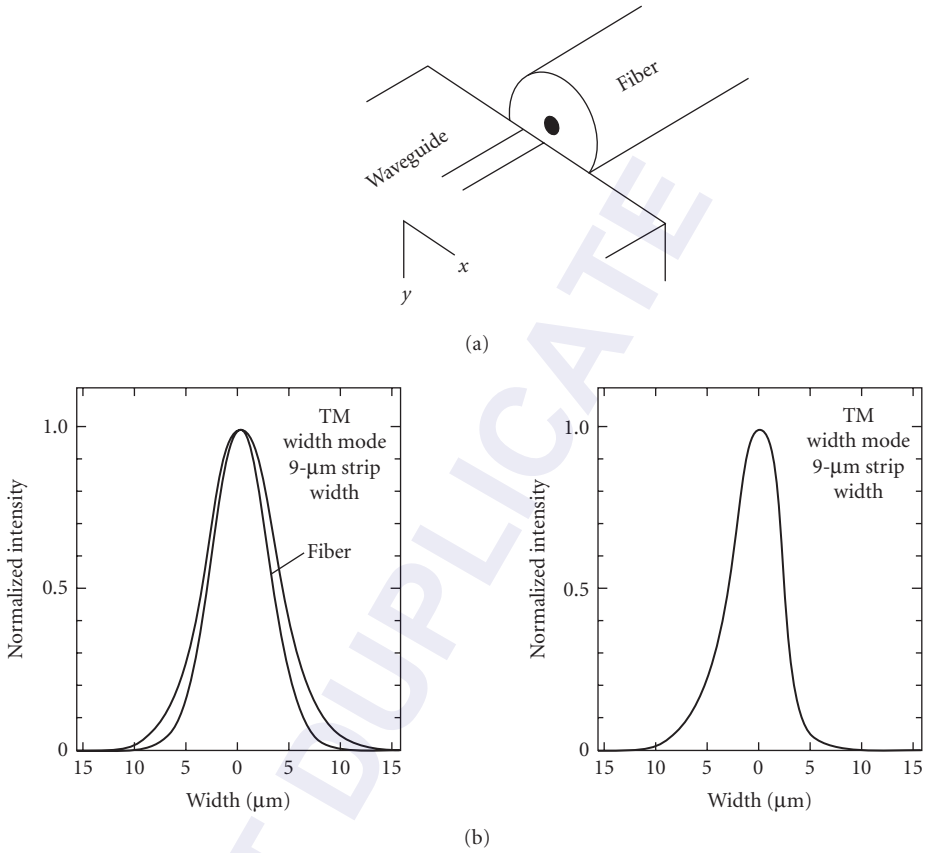

FIGURE 9 Mode-matching illustrated by coupling a Ti-indiffused guide to an optical fiber. Mode profiles are shown both in width and depth for the waveguide.

Performance on commercially available devices is typically <1-dB coupling loss per interface with robust performance over at least the −30 to 60°C range.

Filters are another critical passive IO component used to selectively pass, block, or route predetermined wavelengths or bands of the input optical spectrum. Filters most often use interferometric concepts to achieve the desired effect. For example, a simple unequal-arm Mach-Zehnder filter can be constructed by combining two Y-splitters where the two arms in the interconnecting region have different path lengths as illustrated in Fig. 10. Combining the two paths reveals trivially that the resulting transmission of the device will have an amplitude response that is sinusoidal in frequency, or an intensity transmission given by

$$I(\omega) = I_0 \cos^2\left(\frac{n\omega(L_2 - L_1)}{2c}\right) \tag{14}$$

By cascading such filters, a large variety of passband characteristics can be realized.

IO filters are important for wavelength division multiplexed (WDM) optical communications, where they are commonly used to combine different frequency channels together in multiplexers and to separate the different frequency channels in demultiplexers. Sophisticated multipath variants of the unequal arm interferometer are commonly used for this purpose, and are referred to as

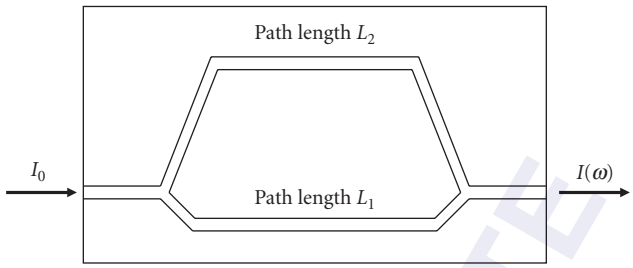

FIGURE 10 Unequal arm Mach-Zehnder interference filter.

arrayed-waveguide gratings (AWGs), waveguide grating routers (WGRs), or phasars.[89–91] A multiport WGR is shown in Fig. 11 where each input to a primary star coupler expands in the laterally unguided portion of the star to uniformly illuminate each output waveguide of the primary star. The path lengths of each guide in the array between the primary and secondary star are incremented in length by an integral multiple of some base wavelength. At this wavelength, upon arrival at the input to the secondary star, each wave has the same phase relation to its neighbors that it had at the output to the first star coupler and reciprocity demands that this focus the beam, as a phased array, back to the corresponding single waveguide at the secondary star output. However, a slight change in wavelength will produce a phase tilt across this phased array, and the focus will go to a different output waveguide. In this manner, the device operates as a demultiplexer. The incremental length difference between adjacent guides in the region between the two stars functions just as a grating would in a bulk-optic equivalent of this device. The design illustrated here also has useful cyclical mapping between input and output ports that can be useful in wavelength-based switching schemes.

AWG designs have been successfully executed both in the Si/SiO_2 and InP-based technologies with extraordinary performance. Commercially available devices provide out of band rejection in excess of 30 dB, polarization-independent operation, typical channel spacings of 50 GHz or 100 GHz, and fiber-to-fiber insertion losses below 2.5 dB. Research devices have demonstrated as many as 4200 channels with spacings as narrow as 5 GHz.[92] By properly designing the input ports in the coupler regions, nearly ideal flat bandpass characteristics can be obtained at the expense of a few additional dB of insertion loss. The precision waveguide spacing on the inputs and outputs also enables fiber

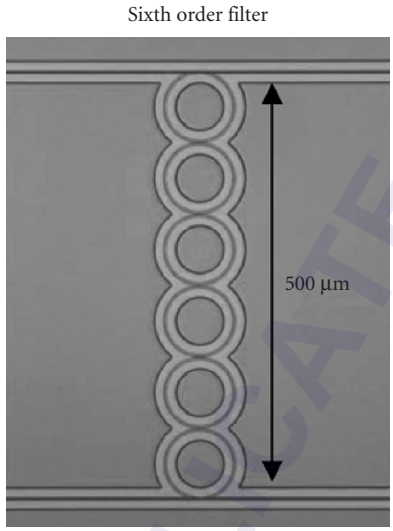

FIGURE 12 Experimental realization of a cascaded ring channel drop filter.

ribbon array connections. IO devices that perform this function have become instrumental for cost-effective deployment of high-channel-count WDM optical communications systems.

Another filter design that is becoming increasingly explored is based upon ring resonators, as illustrated in Fig. 12. Here weak directional couplers are used to couple the ring to the two straight waveguides, allowing coupling between the two straight waveguides only at the sharp resonant frequency of the rings, with other nonresonant frequencies bypassing the rings and remaining in their original input waveguide. As with the unequal-arm Mach-Zehnder filter, rings can be cascaded between two waveguides to provide flat bandpass characteristics with very sharp edges and high out-of-band rejection.[93]
