Chichilnisky and Wandell[289] located equilibrium boundary planes by presenting stimuli varying in both intensity and chromaticity on various backgrounds, and then asking subjects to classify them into red-green, blue-yellow, and white-black opponent-color categories. They found that the opponent-color classification boundaries were not coplanar. Wuerger, Atkinson, and Cropper[22] determined the null planes for the four unique hues using a hue-selection task in which subjects selected the equilibrium hue from an array of colors. They concluded that unique green and unique red planes in a space defined by the color monitor phosphors were not coplanar, consistent with the previous findings, but

that unique blue and unique yellow could form a single plane. However, they did not try to fit their data with curved surfaces, as might be suggested by previous work.

In summary, unique red and green are not colinear in two-dimensional color space or coplanar in three, and the unique blue "vector" or "plane" is curved. As we discuss below, failures of colinearity or coplanarity imply that either a bipolar color-opponent mechanism is not a single mechanism or it is a single but nonlinear mechanism, while curved vectors and planes imply failures of additivity within single mechanisms.

Linearity of Color-Opponent Mechanisms

Tests of linearity For the spectral sensitivities of color-opponent mechanisms to be generalizable implicitly or explicitly, the color-opponent mechanisms must be linear and additive. This assumption is made in many accounts of zero crossings and/or in descriptions of valence functions as linear combinations of the cone fundamentals.[11,18,19,24,29,76,278,279,306–308]

Larimer, Krantz, and Cicerone[307,309] specifically tested whether the equilibrium colors behaved additively under dark adapted conditions. They tested two predictions of additivity: (1) that equilibrium colors should be intensity-invariant (the so-called "scalar invariance law"), and (2) that mixtures of equilibrium hues should also be in equilibrium ("the additivity law"). Another consequence of these predictions is that the chromatic response or valence function should be a linear combination of the cone fundamentals.[75] For R/G opponency, Larimer, Krantz, and Cicerone[307] found that the spectral position of the blue and yellow equilibrium hues were intensity-invariant over a range of 1 to 2 log units, and that mixtures of red/green equilibrium hues remained in red/green equilibrium. These results suggest that R/G color opponency is additive. Additivity for the R/G mechanism has also been reported in other studies[310,311] and is consistent with the R/G valence functions being linear combinations of the cone spectral sensitivities.[12,286,312]

Several studies, however, suggest that linearity fails for the R/G mechanism. The curvilinear unique blue vector[16,305] implies that mixtures of lights that individually appear unique blue and therefore in R/G equilibrium will not be in equilibrium when they are mixed—as is required for additivity. Similarly, the nonplanar red-green color categories[289] also imply failures of additivity. Ayama, Kaiser, and Nakatsue[313] carried out an additivity test for red valence and found that while additivity was found for some pairs of wavelength within separate R valence lobes (400 paired with 440 nm and 610 paired with 680 nm) failures were found between lobes (400 paired with 680 nm) for 3 out of 4 observers. Ingling et al.[314] found that the short-wavelength shape of the R valence lobe was dependent on the technique used to measure it. If the redness of the violet light was assessed by matching rather than by cancellation, the estimate of redness was as much as 30 times less. Ingling, Barley, and Ghani[287] analyzed previous R/G hue cancellation and hue-scaling data and found them to be inconsistent with the linear model.

By contrast, most evidence suggests that the B/Y color-opponent mechanism is nonlinear. Larimer, Krantz, and Cicerone[309] found that equilibrium green was approximately intensity-invariant, but that equilibrium red was not, becoming more bluish-red as the target intensity was increased. Moreover, although mixtures of B/Y equilibrium hues remained in equilibrium as their overall intensity changed, the equilibria showed an intensity-dependence. Other results also suggest that B/Y color opponency is nonlinear. The unique green and red vectors are not colinear in two dimensions of color space[16,305] and the unique green and unique red planes are not coplanar.[22,289] These failures of colinearity and coplanarity suggest that the B and the Y valence function have different spectral sensitivities, but the same neutral or balance point. The failure of additivity is consistent with the fact that the B/Y valence functions cannot be described by a linear combination of the cone fundamentals; instead some form of nonlinearity must be introduced.[286,309] Elzinga and de Weert[315] found failures of intensity-invariance for equilibrium mixtures and attributed the failures to a nonlinear (power) transform of the S-cone input. Ayama and Ikeda[316] found additivity failures for combinations of several wavelength pairs. Ingling, Barley, and Ghani[287] found that previous B/Y hue cancellation and hue-scaling data were inconsistent with the linear model. Knoblauch and Shevell[317] found that the B/Y nonlinearity might be related to the signs of the cone signals changing with luminance.

Interestingly, the B/Y mechanism behaves linearly in protanopes and deuteranopes, which suggests that the nonlinearity might depend in some way on L–M.[318,319]

Why linearity? This question of whether color-opponent mechanisms are linear or nonlinear was originally formulated when it was still considered plausible that cone signals somehow fed directly into color-opponent channels without modification. Given our current knowledge of receptoral adaptation and postreceptoral circuitry, that hope now seems somewhat optimistic. Receptoral adaptation is an essentially nonlinear process, so that unless the adaptive states of all three cone types are held approximately constant (or they somehow change together as perhaps in the case of invariant hues), linearity will fail.

Tests that have found linearity have used elaborate experimental strategies to avoid the effects of adaptation. Larimer, Krantz, and Cicerone,[307,309] for example, used dark-adapted conditions and presented the stimuli for only 1 second once every 21 seconds. This protracted procedure succeeded in achieving additivity in the case of the red/green equilibrium experiments but not in the case of the blue/yellow ones.

It would be a mistake to conclude from results like these that color opponency and color appearance are, in general, additive with respect to the cone inputs. Experiments like those of Larimer, Krantz, and Cicerone[307,309] demonstrate additivity, but only under very specific conditions. While the results are important, because they provide information about the properties of the "isolated" postreceptoral mechanisms, they are not necessarily relevant to natural viewing conditions under which the mechanisms may well behave nonlinearly with respect to the cone inputs.

Bezold-Brücke Effect and Invariant Hues Hue depends upon light intensity. Although a linear explanation of such hue changes has been suggested (see, e.g., Fig. 4 on p.74 of Hurvich[283]), it now seems clear that these changes reflect underlying nonlinearities in the visual response. These nonlinearities arise in part because the cone outputs are nonlinear functions of intensity, but they may also reflect inherent nonlinearities within the color-appearance mechanisms themselves and the way in which they combine cone signals. The dependence of hue on intensity is revealed clearly by the Bezold-Brücke effect,[320,321] which is illustrated in Fig. 33 using prototypical data from Purdy.[322] As the intensity of a spectral light is increased, those with wavelengths shorter than 500-nm shift in appearance toward that of an invariant blue hue of approximately 474 nm, while those with wavelengths

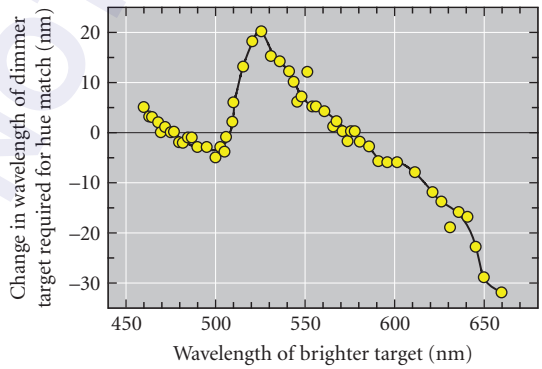

FIGURE 33 Bezold-Brücke effect. Data replotted from Fig. 1 of Purdy[322] illustrating the changes in apparent hue as the light level increases, a phenomenon known as the Bezold-Brücke hue shift. The graph shows the change in the wavelength of a 100-td target from that of the 1000-td target required to match the hue of the 1000-td target plotted as a function of the wavelength of the more intense target.

longer than about 520 nm shift in appearance toward that of the invariant yellow of approximately 571 nm. Intermediate spectral colors shift to an invariant green of approximately 506 nm.

The invariant hues are usually assumed to coincide with the unique hues of color-opponent theory,[283] yet when the coincidence is tested, small discrepancies are found in some[284,322,323] but not all[307,309] studies (see also Ref. 296). Although invariant hues are often interpreted as being the zero crossings of cone-opponent mechanisms,[136] they are also consistent with models that incorporate just receptor adaptation.[323,324] As Vos[323] pointed out, if hue invariance and unique hues reflect different underlying processes, their approximate agreement may serve an important purpose.

Color Appearance and Chromatic Adaptation In the Bezold-Brücke effect, the level of adaptation is varied by increasing or decreasing the intensity of spectral lights of fixed wavelength. Under such conditions, as noted in the previous section, the appearances of some wavelengths are invariant with intensity. If, however, the state of chromatic adaptation is varied by superimposing the spectral lights on a chromatic background, their color appearance will change. In general, the appearances of targets superimposed on an adapting background move away from the appearance of the adapting wavelength. Thus, a target that appears yellow when viewed alone will appear reddish if superimposed on a middle-wavelength adapting background or greenish if superimposed on a long-wavelength one.[325–327] Similarly, the appearance of a superimposed target of the *same* wavelength as the adapting background will move toward the appearance of the equilibrium yellow hue. Indeed, on intense adapting fields of 560, 580, and 600 nm, Thornton and Pugh[107] showed that the spectral position of equilibrium yellow for a superimposed target coincided with the adapting field wavelength. However, this agreement breaks down on longer wavelength fields. Long-wavelength flashes presented on long-wavelength fields appear red, not equilibrium yellow.[65,328,329]

Historically, changes in color appearance with adaptation were thought to be consistent with von Kries adaptation,[330] in which the gain of each photoreceptor is attenuated in proportion to the background adaptation. However, von Kries adaptation cannot completely account for the changes in color appearance[77,331–333] (but see Ref. 334). In particular, asymmetric color matches, in which targets presented on different adapting backgrounds are adjusted to match in hue, do not survive proportional changes in overall intensity—as they should if the von Kries coefficient law holds.[335]

Jameson and Hurvich[336] proposed that the adapting field alters color appearance in two ways. First, by changing the cone sensitivities in accordance with von Kries adaptation, and second by an additive contribution to the appearance of the incremental mixture. For example, a red background tends to make an incremental target appear greener because it selectively adapts the L- cones, but it also tends to make it appear redder because it adds to the target. Color-appearance models of this sort remain in vogue (see Ref. 337). Figure 15 shows a case where a model with both gain control at the cones and an additive term accounts for much but not all of the variance in an asymmetric matching data set.

The details of this two-stage theory have been contentious, despite the fact that all authors are in essential agreement that much of the effect of the background is removed from the admixed background and test. Walraven,[325,338] using 1.5° diameter targets superimposed on 7° diameter backgrounds, determined the equilibrium mixtures of incremental 540 and 660 nm targets on various 660 nm backgrounds. He found that the equilibria were consistent with von Kries adaptation produced by the background, but that the color appearance of the background was completely discounted, so that it made no additive contribution to the appearance of the incremental target. By contrast, Shevell, using thin annuli or transiently presented 150-ms targets that were contiguous with the background, found that the background is not discounted completely and instead makes a small additive contribution to the target.[326,327,339] Walraven[338] suggested that Shevell's results reflected the fact that his conditions hindered the easy separation of the incremental target from the background. Yet, later workers came to similar conclusions as Shevell.[340–342] However, although the background is not entirely discounted, its additive contribution to color appearance is much less than would be expected from its physical admixture.[327,343] Thus, a discounting mechanism must be playing some role. Indeed, the failure of complete discounting is small compared to the magnitude of the additive term, so that the failure is very much a second-order effect.

Color Appearance and Chromatic Detection and Discrimination Several attempts have been made to link explicitly the cone-opponent effects evident in field sensitivity and field adaptation detection experiments with changes in color appearance measured under the same conditions.

On a white, xenon field, Thornton and Pugh[164] showed that the L–M cone-opponent detection implied by the Sloan notch is consistent with the suprathreshold color opponency implied by red-green hue equilibria. Thus, the wavelength of the notch, which is assumed to occur when the L–M cone-opponent signals are equal, coincided with an R/G equilibrium hue. A comparable convergence was found for 430- and 570-nm mixtures and the suprathreshold yellow-blue equilibrium locus.

S-cone thresholds on bichromatic mixtures of spectral blue and yellow fields are subadditive (see Fig. 26). According to the Pugh and Mollon[231] cone-opponent model, the greatest sensitization should occur when the opposing signals at the second site are in balance; that is, when the S- and L+M-cone signals are equal and opposite. In an attempt to link these cone-opponent effects to the color opponency of Hering, two groups have suggested that the background mixture that yields the lowest threshold, which is therefore the balance point of the cone-opponent at the second site, should also be the mixture that is in blue-yellow equilibrium (i.e., the mixture that appears neither yellow nor blue).

Pugh and Larimer[228] investigated the detection sensitivity of π_1/π_3 on field mixtures that appeared to be in yellow-blue equilibrium. They reasoned that if such mixtures are also null stimuli for the cone-opponent S–(L+M) second site, then detection sensitivity should depend only on first-site adaptation. Their results were consistent with their hypothesis, since field mixtures in yellow-blue equilibrium never produced superadditivity, a characteristic assumed to be due to second-site adaptation (see "Field Additivity" in Sec. 11.5). However, Polden and Mollon[227] looked specifically at the relationship between the maximum sensitization and the contribution of the longer wavelength component of the field mixture and found that it approximately followed a $V(\lambda)$ spectral sensitivity. By contrast, the comparable equilibrium hue settings for long-wavelength fields fell much more steeply with wavelength for fields longer than 590 nm, implying that different underlying spectral sensitivities operate in the two cases.

Rinner and Gegenfurtner[344] looked at the time course of adaptation for color appearance and discrimination and identified three processes with half lives of less than 10 ms, 40 to 70 ms, and 20 s. The slow and intermediate adaptation processes were common to color appearance and discrimination, but the fast process affected only color appearance. However, in an extensive study, Hillis and Brainard[78] compared the effects of chromatic adaptation on color discrimination and asymmetric color matching. Pedestal discrimination measurements made as a function of pedestal intensity on five different chromatic backgrounds were used to estimate the response-intensity curves on each background. These response-intensity curves were then used to predict pairs of light that should match on different pairs of backgrounds. The agreement they found between the predicted asymmetric matches and measured ones suggests that color appearance and discriminability on different uniform backgrounds are controlled by the same underlying mechanism.[78] A follow-up study reached the same conclusion about the effect of habituation on "unstructured" spatiotemporal contrast,[82] although this study did not probe performance with test stimuli likely to tap purported higher-order chromatic mechanisms.

Overall, the results of these experiments are somewhat equivocal, but the majority of experiments find some correspondence between the effects of adaptation on color detection and discrimination on the one hand, and its effects on color appearance on the other. Given, however, that the discrimination and appearance processes have very different spectral sensitivities, this correspondence must break down under some conditions of chromatic adaptation, at least if the signals that control the adaptation of mechanisms depend strongly on the output of those same mechanisms. Of note here is that Hillis and Brainard did find clear dissociations of the effect of adaptation on discrimination and on appearance when the stimuli contained sufficient spatial structure to be perceived as illuminated surfaces.[345] Elucidation of the nature of this dissociation awaits further investigation.

Color Appearance and Habituation The results of Webster and Mollon[32,79] were used as an example in subsection "Appearance Field Measurements and Second-Site Adaptation" in Sec. 11.4. Briefly, they

found that contrast adaptation produced changes in appearance that were selective for the habituating axis whether that axis was in the equiluminant plane or not. This finding is a potentially important difference between the effects of habituation on color appearance and its effects on detection, since only the appearance data provides clear evidence for higher-order mechanisms that are sensitive to both chromatic and luminance modulations. The detection data measured after habituation suggest that the chromatic and luminance mechanisms behave independently.[241] Determining conclusively whether this comparison across studies reflects a dissociation between habituation effects on thresholds and appearance, or instead represents a difference between the processing of near-threshold and suprathreshold test stimuli, could be resolved by applying the logic developed by Hillis and Brainard[78,82] to data collected for the full set of stimulus conditions studied by Webster and Mollon.[32,79]

Webster and Mollon[32,79] suggested two models that might account for their data. In the first, they replaced the three color mechanisms tuned to the three cardinal directions of color space with many mechanisms with tuning that varied according to a Gaussian distribution around each of the three cardinal directions. They found that they could account for the individual data by varying the standard deviations of the Gaussian distributions. In the second, they assumed that there were just three mechanisms, but that their tuning could be modified by adaptation. With adaptation, inhibition was assumed to build up between the mechanisms to decorrelate the input signals and reduce redundancy (see also Refs. 242–244). These models can also be applied to chromatic detection data.

Luminance and Brightness Brightness matching functions are broader than luminous efficiency functions measured using techniques such as HFP or MDB that produce additive results (see subsection "Sensitivity to Spectral Lights" in Sec. 11.5) and are thought to measure the sensitivity of the luminance channel.[115,118,122,346]

Figure 34 shows examples of a brightness matching function measured by direct brightness matching (red line) and luminous efficiency measured by flicker photometry (black line) replotted from Wagner and Boynton.[122] The brightness matching function is relatively more sensitive in the blue and orange spectral regions and slightly less sensitive in the yellow. These differences are usually attributed to a chromatic contribution to brightness but not to luminance.[11,122,347]

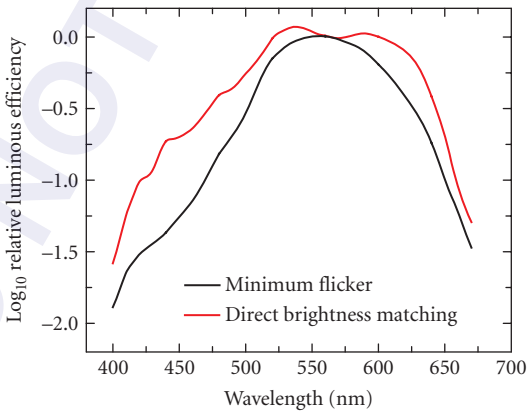

FIGURE 34 Luminous efficiency and brightness. Mean matching data for three subjects replotted from Figs. 6 and 8 of Wagner and Boynton[122] obtained either using flicker photometry (black line) or using direct brightness matching (red line). The discrepancies are consistent with a chromatic contribution to brightness matching but not to flicker photometric matching.[120,122]

Mechanisms of Color Constancy

The literature on mechanisms of color appearance is closely tied to a phenomenon known as "color constancy." The need for color constancy stems from two observations. First, our normal use of color appearance is to associate colors with objects. Second, the stimulus reflected to the eye from a fixed object depends not only on the object's intrinsic reflectance properties but also on the spectrum of the illumination. When the illuminant changes, so does the spectrum of the reflected light. If the visual system did not compensate for this change to stabilize the appearance of objects, it would not be possible to use color appearance as a reliable guide to object properties.

Empirically, color constancy is studied in much the same way as color appearance, using techniques of asymmetric matching, hue cancellation, or hue scaling. Papers published under the rubric of color constancy, however, have tended to employ stimulus conditions designed to model scenes consisting of illuminated objects and to emphasize context changes induced by manipulating the illuminant, rather than the simpler test-stimuli-on-background configurations favored for working out mechanistic accounts of color appearance.[348–353] The evidence supports the empirical generalization that when the illuminant is varied in a manner typical of the variations that occur in the natural environment, the visual system adapts to compensate for the physical change in reflected light, and thus to stabilize color appearance. That is, constancy in the face of naturally occurring illumination changes is good.[352,353] At the same time, it is important to note that constancy is not perfect: objects do not appear exactly the same across illumination changes. Moreover, other scene manipulations, such as those that change the reflectance of objects near the one of interest, also affect color appearance, even in rich scenes.[354] Figure 1 shows examples of this latter type of effect for simple stimulus configurations; these may be regarded as failures of constancy. Several recent reviews treat empirical studies of color constancy in more detail.[355–357]

Considerable theoretical attention has been devoted to modeling human color constancy. Much of this work is in the computational tradition, in which the theorist starts not with experimental data but rather by asking how constancy could in principle be achieved (or approximated), given the information about object reflectance properties that is available in the retinal image.[358–363]

With a few exceptions, work in the computational tradition does not connect explicitly with the mechanistic account of processing that we have developed in this chapter. Rather the work seeks to elucidate the sources of information in an image that could contribute to constancy. This is then used both to guide experiments[354] as well as in models whose purpose is to explicitly predict color appearance.[364–367] A particular promise of this approach is that it generalizes naturally as scene complexity increases, allowing (for example) predictions of the effects of manipulations in complex three-dimensional scenes using the principles developed for simpler scene configurations.[368–370]

A limitation of computational models is that they do not, in and of themselves, provide much insight about how neural mechanisms might act to provide constancy. Not surprisingly, then, there is also an important line of theoretical work that attempts to understand constancy in terms of the action of the first- and second-site mechanisms of adaptation that we have reviewed in this chapter.

Land's retinex theory[371–374] may be understood as a computational model that incorporates first-site cone-specific gain control to stabilize the representation of object color. Several authors have shown that for natural illuminant changes, such first-site gain control provides excellent, although not perfect, compensation for the effect of illumination changes on the light reflected from natural objects as long as the gains are set correctly for the scene illumination.[375–378] Moreover, asymmetric matching data from experiments conducted using rich, naturalistic stimuli are well fit by postulating first-site gain control.[352] Webster and Mollon[379] (see also Ref. 380) extended this general line of thinking by showing that following first-site cone-specific adaptation with a second-site process that is sensitive to image contrast can improve the degree of compensation for the physical effect of illuminant changes. As we have reviewed in subsections "Appearance Field Measurements and Second Site Adaptation" in Sec. 11.4 and "Color Appearance and Habituation" in Sec. 11.5, it has also been established that contrast adaptation affects color appearance,[32,79,379,381] which provides a connection between human performance and the observation that contrast adaptation can help achieve color constancy.

A number of authors[382–384] have emphasized that it is clarifying, in the context of understanding constancy and more generally adaptation, to distinguish two questions. First, what parameters of visual processing (e.g., first-site gains, subtractive terms, second-site gains) are affected by contextual factors. That is, what can adapt? Second, what are the particular contextual features that act to set each of the adaptable parameters? Our understanding of these aspects is less developed. For example, it is not obvious how theories based on data obtained with spatially uniform adapting fields should be generalized to predict the adapted state for image contexts that have rich spatial and temporal structure. Simple hypotheses for generalization include the idea that a weighted average of the cone coordinates of the image might play the role of the uniform field, as might the most luminous image region. Ideas of this sort are implicit, for example, in Land's retinex theory. Explicit tests of hypotheses of this nature for rich scenes, however, have not revealed simple scene statistics sufficient to predict the visual system's state of adaptation.[354] Indeed, understanding what image statistics are used by the visual system to achieve constancy, and connecting the extraction of these statistics explicitly to mechanistic sites of adaptation is a primary focus of current research on constancy. In this regard, the computational work may provide critical guidance, as at the heart of each computational theory is an analysis of where in the retinal image the most valuable information about the illumination may be found. Zaidi[385] and Golz and MacLeod,[386] for example, translate analyses of image statistics that carry information about the illuminant into mechanistic terms.

Color and Contours

In the natural world, differently colored regions are usually delimited by contours across which there is also a luminance difference. If the luminance difference is removed, the contour becomes indistinct, and it becomes more difficult to discriminate the chromatic differences between the two regions. For example, Boynton, Hayhoe, and MacLeod[387] showed that color discrimination is severely impaired if the difference between two regions is dependent on only the S cones, and Eskew and Boynton[388] showed that the contour remains indistinct even for chromaticity differences up to twice threshold. For two regions separated by a border defined by S cones (i.e., if the regions are tritan pairs), "melting" of the border[389] and "chromatic diffusion" between the regions[388] have been reported.

Figure 35*a* shows two examples of chromatic regions filling in an area bordered by a luminance contour. These are versions of the "Boynton illusion" (see p. 287 of Ref. 15 and http://www.yorku.ca/eye/boynton.htm). The yellow areas, which are discriminated from the white background mainly by S cones, appear to fill-in the black borders as you move further away from the figure. The filling-in illustrates the tendency of luminance contours to constrain the spatial extent of signals mediated by the chromatic pathways.

Figure 35*b* shows four examples of a related illusion, which is known as the watercolor illusion or effect.[390–392] If an area is delineated by a darker outer chromatic contour flanked by a brighter inner chromatic contour, then the brighter color spreads faintly into the inner area.[393] This faint coloration resembles a "watercolor" wash.

The "Gap" Effect and Luminance Pedestals The gap effect is a well-known phenomenon described by Boynton, Hayhoe, and MacLeod.[387] A small gap introduced between two juxtaposed test fields improves their discriminability if the fields differ only in S-cone excitation, impairs it if they differ only in luminance, and can result in a small improvement if they differ only in L- and M-cone excitation at constant luminance (i.e., in L–M excitation).[387,394] The small gap that separates the tritan pair and improves discriminability can be produced either by a luminance difference or by an L–M chromatic difference.[395]

The improvement in chromatic discriminability caused by gaps can be related to the improvement in chromatic sensitivity when a luminance pedestal or contour is coincident with the chromatic stimulus[169,177,194,269,271,272]—the so-called "crossed" pedestal facilitation described above (see subsection "Pedestal Experiments" in Sec. 11.5). Moreover, as also noted above, the crossed facilitation survives if the luminance pedestal is replaced by a thin ring[169] (see also Ref. 177). Montag[394] compared the gap

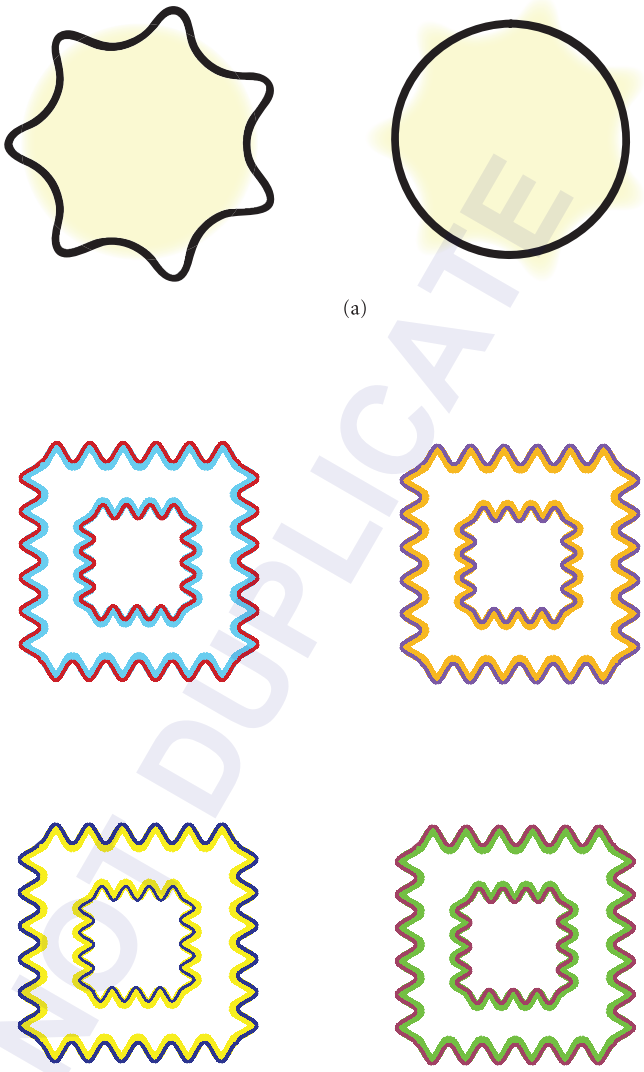

FIGURE 35 Boynton and watercolor illusions. (*a*) Two examples of the Boynton illusion. In the left picture, a star-shaped black outline is superimposed on a circular yellow area, while in the right picture a circular black outline is superimposed on a star-shaped yellow area. As you move away from the picture, the yellow areas appear to fill the black outlines. These are variations of an illusion attributed to Robert M. Boynton by Peter Kaiser, see: http://www.yorku.ca/eye/boynton.htm. (*b*) Four examples of the watercolor illusion.[390–392] Each square is outlined by a pair of juxtaposed sinuous contours. The similar colors of the inner contour of each larger square and the outer contour of each smaller square fill in the intervening space with a faint color (which looks like a watercolor wash). Inspired by a version of the watercolor illusion designed by Akiyoshi Kitaoka, see: http://www.psy.ritsumei.ac.jp/~akitaoka/watercolorillusionsamples.jpg.

effect with facilitation produced by adding thin lines of the same orientation to gratings at half-cycle intervals. He found that the detection of S-cone gratings was facilitated by placing dark lines at the midpoints between the peaks and troughs of the gratings (i.e., where the luminance of the grating is equal to the mean luminance of the stimulus—zero crossings of the spatially varying factor in the stimulus), but that the facilitation declined to zero as the lines were moved toward the peaks and troughs. A comparable but smaller effect was found for equiluminant L- and M-cone modulated gratings, while the detection of luminance gratings was always impaired. Montag suggested that the gap effect and pedestal enhancement may be complementary effects.[394] Indeed, Gowdy, Stromeyer, and Kronauer[396] reported that the facilitation of L–M detection by luminance pedestals is markedly enhanced if the luminance grating is square-wave rather than sinusoidal. They argued that the square-wave produces an abrupt border across which the L–M mechanism is somehow able to compare chromatic differences.

Color Appearance and Stabilized Borders The importance of contours on color appearance is made clear in experiments in which the retinal image is partially or wholly stabilized. When the retinal image is wholly stabilized, the color and brightness of the stimulus fades until it is no longer seen.[397] The color appearance of partially stabilized images in which stabilized and unstabilized borders are combined can be entirely independent of the local quantal absorptions. Krauskopf[398] found that when the border between a disc and a surrounding annulus is stabilized, and the outer border of the annulus unstabilized, the disc "disappears" and its color is filled in by the color of the annulus. When, for example, the border between a green, 529-nm annulus, and an orange, 640-nm disc, is stabilized, the disc appears green. These changes are not restricted to the stabilized disc. Unstabilized targets presented on stabilized discs also change their color appearance as the color of the disc fills in to the color of the annulus.[399] For example, if the annulus is yellow and the stabilized disc is either red or green, both discs fill in to take on the yellow color of the annulus. Unstabilized yellow targets presented in the center of the stabilized discs, however, take on the color appearance complementary to actual color of the disc, so that the yellow target on a green disc appears red, and the yellow target on a red disc appears green. Such changes are consistent with the local contrast signals at the target edges determining the filled-in appearance of the yellow target (see Experiment 4 of Ref. 400).

It has also been reported that stabilized boundaries can produce colors that appear reddish-green and yellowish-blue, and so violate the predictions of the opponent-colors theory that opposed colors (red and green, or yellow and blue) cannot be perceived simultaneously. These "forbidden colors" were produced by presenting two vertical stripes side-by-side, with their common border stabilized, but their outer borders unstabilized. When the juxtaposed stripes were red and green, most observers reported that the merged stripes appeared reddish-green or greenish-red, and when the stripes were blue and yellow most observers reported that they appeared bluish-yellow[401] (see Experiment 3 of Ref. 400). Forbidden colors were also reported by some subjects in another study, but only when the stripes were equiluminant.[402]

The results obtained using stabilized and unstabilized borders add to the view that color appearance need not be a local retinal phenomenon. A crucial question, then, is whether the changes in color appearance caused by image stabilization also influence phenomena that are ostensibly more low-level, and thus more likely to be local, such as detection. Two experiments have addressed this question. Nerger, Piantanida, and Larimer[403] found that when a red disk was surrounded by a yellow annulus, stabilizing the edge between the two fields on the retina caused the yellow to fill in, making the disk appear yellow too. This filling-in affected the color appearance of small tests added to the disk, but it did not affect their increment threshold. The results for S-cone flicker detection, somewhat surprisingly, suggest that filling-in can change S-cone flicker sensitivity. Previously, Wisowaty and Boynton,[404] using flickering tritan pairs to isolate the S-cone response, had found that yellow background adaptation reduces the S-cone modulation sensitivity compared to no background adaptation. Piantanida[405] showed that the reduction in S-cone flicker sensitivity caused by a yellow field could also be caused by a dark field that only appeared yellow because its outer border with a yellow annulus was stabilized. In a related experiment, Piantanida and Larimer,[400] compared S-cone modulation sensitivities on yellow and green fields, and found that the S-cone modulation sensitivity was

lower on the yellow field. Again, this sensitivity difference depended upon the field appearance rather than upon its spectral content. Thus, the reduced sensitivity was found not only on the yellow field but also on a green field that appeared yellow because its border with a surrounding yellow annulus was stabilized. Similarly, the increased sensitivity was found not only on the green field but also on a yellow field that appeared green because its border with a surrounding green annulus was stabilized. The differences between studies may indicate that different sites of limiting noise act to limit detection in the different tasks.

Contours and Aftereffects Daw[406] showed that the saliency of colored after-images depended upon the presence of an aligned monochrome image. Thus, adaptation to a colored image produces a clear afterimage if the after-image is aligned with a monochrome image with the same contours, but produces a poor after-image if the two are misaligned. Figure 36 demonstrates this effect.

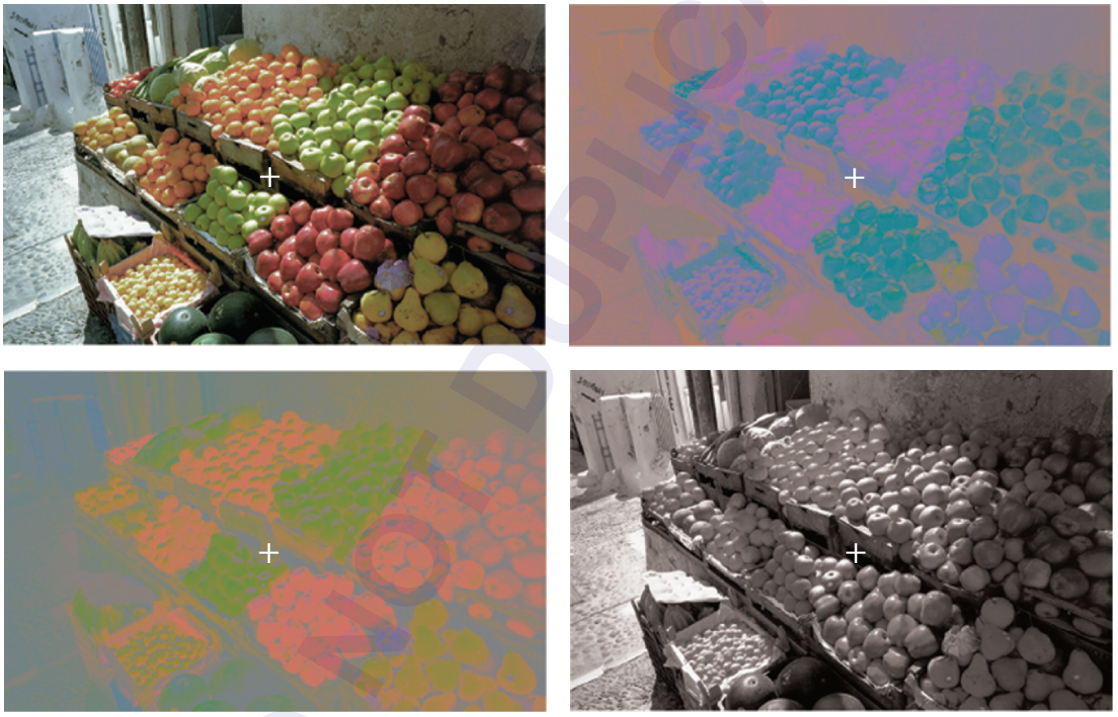

FIGURE 36 Color and contour. Four different images of a fruit stall are shown. The full color image (top left) has been decomposed into its chromatic (bottom left) and luminance components (bottom right). The image on the top right is the complementary or inverse of the chromatic image. Notice that the details of the image are much better preserved in the luminance image than in the chromatic image. The chromatic information, although important for object discrimination and identification, is secondary to the perception of form. Color fills-in the picture delineated by the luminance information. This can be demonstrated by fixating the cross in the center of the complementary chromatic image (top right) for several seconds, and then diverting your gaze quickly to the cross in the center of the luminance image (bottom right). You should see a correctly colored version of the picture. Notice that if you shift your gaze slightly, so that the after-image no longer aligns precisely with the luminance image, the color disappears. You can also try adapting to the chromatic image (bottom left) and repeating the experiment. The effects are stronger with projected CRT versions of the images and successive presentation, which can be seen at http://www.cvrl.org. Color scene after Fig. 1.14A of Sharpe et al.[477] from an original by Minolta Corp. A version of this aftereffect demonstration was first described in 1962 by Nigel Daw.[406] Other examples of this illusion along with instructions about how to produce comparable images can be found at: http ://www.johnsadowski.com/color_illusion_tutorial.html.

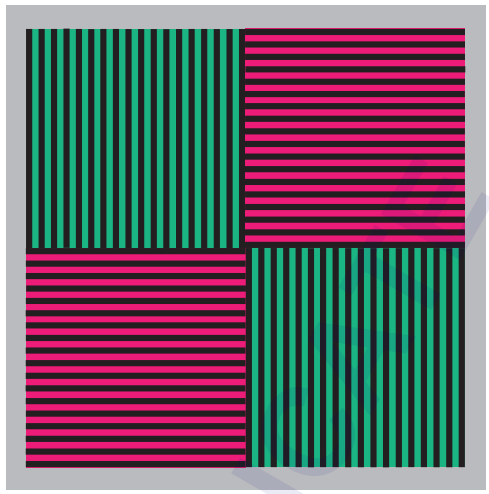
Impressive demonstrations of the influence of contours on after-images have recently been produced by van Lier and Vergeer[407] and van Lier, Vergeer, and Anstis.[408] Their demonstrations show that colored stimuli can produce different after-image colors at the same retinal location, depending on the positioning of contours presented with the after-image. In one version, observers adapt to a plaid pattern made up of blue, green, orange, and purple squares, and then view, together with the after-image, either horizontal or vertical contours aligned with the borders of the squares. The color of the after-image changes with the orientation of the contours, because the "mean" after-image along the horizontal rows and along the vertical columns is different, thanks to the arrangement of the adapting squares in the plaid. The demonstration can be seen at: http://www-psy.ucsd.edu/~sanstis/SAai.html.

McCollough Effect The McCollough effect is a well-known orientation-contingent color after-effect.[409] After prolonged viewing of colored "adapting" gratings of, say, vertical or horizontal orientation, neutral, black-and-white test gratings of the same orientation take on the complimentary hue of the adapting grating. For example, following adaptation to red horizontal and green vertical gratings, horizontal and vertical black-and-white gratings appear, respectively, slightly greenish and reddish (see Fig. 37).

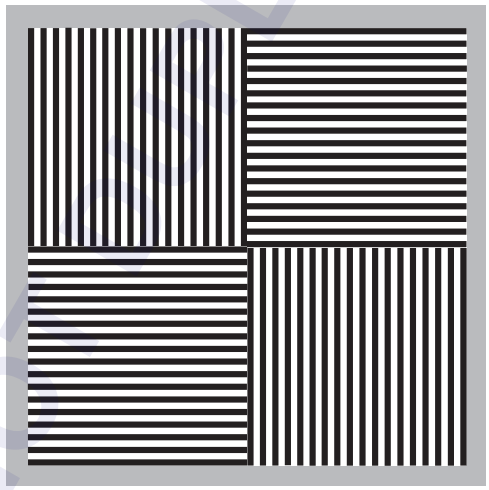
The McCollough effect can persist undiminished for many days provided that test gratings are not viewed.[410] This prolonged effect is distinct from colored afterimages, such as the effect demonstrated in the previous subsection, which decline relatively quickly. Vul, Krizay, and MacLeod[411] have recently identified two processes in the generation of the McCollough effect. The first process behaves like a leaky integrator, and produces an effect that declines exponentially with a time constant of roughly 30 s. The second process behaves like a perfect integrator, and produces an effect that shows no decay.[411] Several lines of evidence suggest that the McCollough effect is generated relatively early in the visual pathway. First, the McCollough effect exhibits little interocular transfer.[409,412,413] Second, it can by produced by alternating red-striped and green-striped adapting patterns at rates as high as 50 Hz, frequencies at which the colored patterns cannot be consciously perceived.[414] Third, it is dependent on the spectral content of the inducing stimuli, not their color appearance.[415] These findings suggest that the "adaptation" has an effect that occurs at a relatively early visual site that precedes binocularity, is able to respond high-frequency flicker, and retains some veridical information about the spectral content of lights. However, the contingency of the McCollough effect on grating orientation suggests that the site cannot be earlier than primary visual cortex, V1, where orientation selectivity is first clearly established.[416,417] There is an extensive literature on the McCollough effect (e.g., Refs. 418–423).

Multiplexing Chromatic and Achromatic Signals Information about color and contour may be transmitted—at least in part—by the same postreceptoral pathways. The ways in which these mixed signals are demultiplexed may give rise to some of the color and border phenomena described in the previous subsections. The evidence for the color-luminance multiplexing comes mainly from knowledge of the spatial properties of neuronal receptive fields in the early visual pathway. Cone-opponent, center-surround mechanisms that are also spatially opponent encode not only chromatic information, which is dependent upon the difference between the spectral sensitivities of their center and surround, but also "achromatic" information, which is dependent on the sum of their spectral sensitivities. For color, the center and surround behave synergistically producing a low-pass response to spatial variations in chromaticity, but for luminance they behave antagonistically producing a more band-pass response to spatial variations in luminance.[149–151] This type of multiplexing can, in principle, apply to any mechanism that is both chromatically and spatially opponent, but it is most often considered in the context of P-cells or midget ganglion cells, which make up as much as 80 percent of the primate ganglion cell population.[424] These cells are chromatically opponent with opposed L- and M-cone inputs,[36] but also respond to spatial differences in luminance.[425,426] In the fovea, they may be chromatically opponent simply by virtue of having single L- or M-cone centers [427,428] and mixed surrounds.[429–431] How segregated the L- and M-cone inputs are to P-cell surrounds and to P-cell centers in the periphery remains controversial.[432–440]

The multiplexing of color and luminance signals may just be an unwanted and unused artifact of having both spatial and chromatic opponency in P-cells. Indeed, Rodieck[441] has argued that the L–M



(a)



(b)

FIGURE 37 McCollough effect. View the upper colored image (*a*) for several minutes letting your gaze fall on different colored areas for several seconds at a time. Look next at the lower monochrome image (*b*).

opponent system is mediated instead by a population of so-called Type II cells with coincident centers and surrounds, which are chromatically but not spatially opponent. For the multiplexing of color and luminance signals in cells with concentric center-surrounds to be unambiguously useful to later visual stages, the signals must be decoded. Several decoding strategies have been suggested, most of which depend on the chromatic signal being spatially low-pass filtered by the center-surround interaction, and the luminance signal being spatially band-pass filtered. Because of this filtering, signals between adjacent mechanisms will, in general, change slowly if the signals are chromatic and rapidly if they are achromatic. Thus, the chromatic and luminance signals can be decoded by spatially

low-pass or band-pass filtering, respectively, across adjacent mechanisms.[149,150] In such a scheme, low spatial-frequency luminance information and high spatial-frequency chromatic (edge) information is lost. The high-frequency luminance or edge information can be used both in "filling-in" the low spatial frequency luminance information, and to define missing chromatic edges. Several well-known visual illusions, such as the Craik-O'Brien-Cornsweet illusion (see Ref. 442), are consistent with filling-in, while others, such as the Boynton illusion (see Fig. 35*a*), are consistent with luminance edges defining chromatic borders.

Simple mechanisms for decoding the luminance and chromatic signals that difference or sum center-surround chromatically opponent neurons have been proposed.[153,443–445] Such mechanisms are, in fact, mathematically related to decoding using matched spatial filters.[445] In one version, spatially superimposed opponent cells with different cone inputs are either summed or differenced.[153] The band-pass luminance signal is decoded by summing +Lc–Ms and +Mc–Ls to give +(L+M)c–(L+M)s and by summing –Mc+Ls and –Lc+Ms to give –(L+M)c+(L+M)s, both of which are also bandpass and, in principle, achromatic (where c = center, s = surround). The low-pass chromatic signal is decoded by differencing +Lc–Ms and –Mc+Ls to give (+L–M)c,s and by differencing –Lc+Ms and +Mc–Ls to give (+M–L)c,s, both of which have spatially coincident centers and surrounds. These combination schemes are illustrated in Fig. 38. As Kingdom and Mullen[446] point out, superimposed centers with

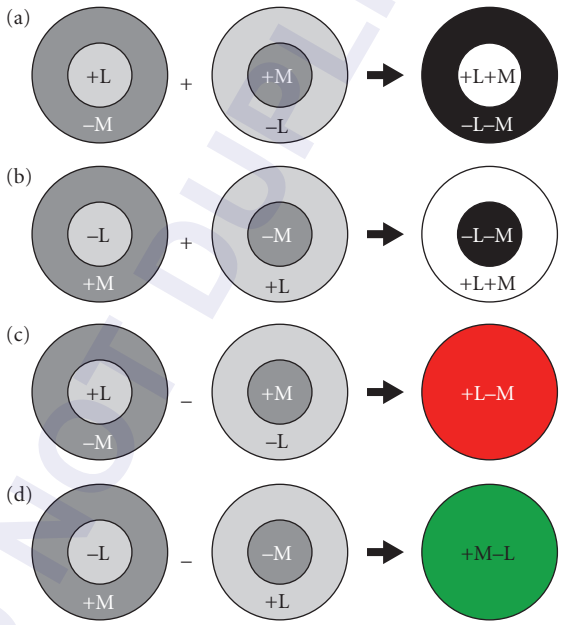


FIGURE 38 Double-duty L–M center-surround opponency. Achromatic and chromatic information can be demultiplexed from LM-cone-opponent center-surround mechanisms by summing or differencing different types of mechanisms. Spatially opponent On and Off center achromatic mechanisms can be produced by summing, respectively, either (*a*) L and M On-center mechanisms, or (*b*) L and M Off-center mechanisms. Spatially nonopponent L–M and M–L chromatic mechanisms can be produced by differencing, respectively, either (*c*) L and M On-center mechanisms, or (*d*) L and M Off-center mechanisms. See Fig. 24 of Lennie and D'Zmura[478] and Fig. 2 of Kingdom and Mullen.[446]

different cone inputs must be spatially offset, simply because two cones cannot occupy the same space. They found that such offsets produce significant crosstalk between the decoded luminance and chromatic outputs. However, this problem is mitigated somewhat by the blurring of the image by the eye's optics, and, in the case of chromatic detection, by neural blurring (see Fig. 7 of Ref. 200).

In another version of the decoding mechanism, De Valois and De Valois[18] added S-cone inputs to generate spectral sensitivities more consistent with opponent-colors theory (see subsection "Spectral Properties of Color-Opponent Mechanisms" in Sec. 11.5). Billock,[445] by contrast, opposed P-cells of the same sign in both the center and surround, thus directly generating double-opponent cells. This can be achieved by differencing (e.g., +L–M in the center differenced from +L–M in the surround) or by summing (e.g., +L–M in the center summed with –L+M in the surround).

The importance of multiplexing in spatially and chromatically opponent mechanisms, and, in particular, in P-cells, remains controversial. Clearly, the P-cells, which make up 80 percent of the ganglion cells and have small receptive fields, must be important for spatial, achromatic vision, but their importance for color vision, while likely, is not yet firmly established. Speculative arguments have been based on the phylogenetically recent duplication of the M/L-cone photopigment gene, which is thought to have occurred about 30 to 40 million years ago after the divergence of Old and New World primates.[447] The typical argument is that the color opponency in P-cells is parasitic on an "ancient" system that before the duplication detected only luminance contrast.[448] However, this raises the possibility that the "decoding" of color information might be done simply to remove it and so improve image fidelity rather than to provide a color signal.

Many psychophysical experiments have attempted to elucidate the properties of the P-cells by employing equiluminant stimuli.[449] The idea is that these stimuli silence the M-cells and thus reveal the properties of the P-cells. If we accept this logic, there is still, of course, an important limitation to these experiments: they do not, by their design, provide any information about how the P-cells respond to luminance modulation. Thus, these experiments can provide only a partial characterization of the P-cells' response.

11.6 CONCLUSIONS

In Sections 11.3 and 11.4, we introduced basic mechanistic models for color discrimination and color appearance. Section 11.5 reviewed evidence that both supports the basic model and indicates areas where it is deficient. Here we summarize what we see as the current state of mechanistic models of color vision.

Low-Level and Higher-Order Color-Discrimination Mechanisms

Test methods provide clear evidence for the existence of three low-level "cardinal" postreceptoral mechanisms: L–M, S–(L+M), and L+M in detection and discrimination experiments (see subsection "Test Sensitivities" in Sec. 11.5). This simple picture is complicated by evidence that L–M and L+M may have small S-cone inputs (see subsection "Sensitivity to Different Directions of Color Space" in Sec. 11.5), but nevertheless the weight of the evidence suggests that just three bipolar cardinal mechanisms (or six unipolar mechanisms—see next section "Unipolar versus Bipolar Chromatic Mechanisms") are sufficient to understand the preponderance of the data. Consistent with the existence of cardinal mechanisms, near-threshold color-discrimination experiments, with one exception,[241] require only four or five unipolar detection mechanisms.[179,197,260] Field methods (see subsection "Field Sensitivities" in Sec. 11.5) also confirm the importance of the three cardinal mechanisms. This agreement across methods provides strong psychophysical evidence for the independent existence of these mechanisms.

Test methods provide little or no evidence for the existence of "higher-order" (or noncardinal) mechanisms. Evidence for higher-order mechanisms comes almost entirely from field methods carried

out mainly in the DKL equiluminance plane using detection and habituation,[241] detection and noise masking,[245,248,450] discrimination and habituation,[241,255] texture segmentation and noise,[451] and image segmentation and noise.[452] In contrast, three experiments using detection and noise carried out with stimuli specified in cone contrast space found little or no evidence for higher-order mechanisms.[175,179,246]

In principal, the choice of space should not influence the results. However, the choice of space used to represent the data does tend to affect the ensemble of stimuli studied, in the sense that stimuli that uniformly sample color directions when they are represented in one space do not necessarily do so when they are represented in another. Another concern is that experiments carried out at nominal equiluminance are liable to luminance artifacts, since the elimination of luminance signals is, in practice, difficult to achieve. Aside from limits on calibration precision or inaccuracies introduced by the assumption that the 1924 CIE $V(\lambda)$ function (i.e., candelas/m^2) defines equiluminance, a recurring difficulty in producing truly equiluminant stimuli is that the luminance spectral sensitivity varies not only with chromatic adaptation and experimental task, but also shows large individual differences (see subsection "Luminance" in Sec. 11.5). Moreover, the luminance channel almost certainly has cone-opponent inputs (see Fig. 25). Finally, even when the luminance mechanism is silenced, the low-level L–M mechanism may have a small S-cone input, which will rotate the mechanism axis away from the cardinal axis.

These concerns notwithstanding, the results of field methods also suffer from an inherent ambiguity. Just because noise masking or habituation alters the detection spectral sensitivity does not necessarily reveal transitions between multiple higher-order mechanisms. Such changes can also result if the simple model used to characterize mechanisms fails to capture, for example, low-level interactions and nonlinearities. Indeed, Zaidi and Shapiro[243] have suggested that such "failures" might actually be an adaptive orthogonalization among cardinal mechanisms that reduces sensitivity to the adapting stimulus and improves sensitivity to the orthogonal direction. Moreover, noise masking can produce rotated detection contours by changing the balance of noise at the first and second sites (see subsection "Sites of Limiting Noise" in Sec. 11.3) without the need to invoke high-order mechanisms.

Of course, it would be absurd to suppose that higher-order color mechanisms do not exist in some form. They are clearly found in more "cognitive" experiments such as Stroop or reverse-Stroop experiments, which show clearly the effects of color categorization (e.g., Ref. 453). The central question with respect to color discrimination, however, is how such mechanisms can be revealed and investigated psychophysically using conventional threshold techniques. For example, if the site of limiting noise precedes higher-order mechanisms for most stimulus conditions, this may not be possible. In that case, the study of higher-order mechanisms will require the use of appearance or other experimental tasks in addition to knowledge of the input characteristics.

On the other hand, some discrimination tasks do provide clear evidence for higher-order mechanisms. Zaidi and Halevy[454] showed that the discrimination thresholds for an excursion in color space away from a background, the chromaticity of which was modulated at 0.46 Hz along a circle in the DKL equiluminant-color plane, depended on the direction of the background color change. Discrimination was consistently worse if the excursion was in the same direction as the background color change, than if it was in the opposite direction. Since this effect was independent of the actual background chromaticity, the effect is inconsistent with there being a limited number of cardinal mechanisms. More generally, Flanagan, Cavanagh, and Favreau[31] used the tilt after-effect to investigate the spectral properties of the orientation-selective mechanisms thought to underlie the after-effect. They found that the orientation-selectivity occurs independently in each of the three cardinal mechanisms, but they also found evidence for secondary orientation-selective mechanisms at other directions in color space. In addition, they found evidence for another orientation-selective mechanism that was nonselective for color directions in any color direction. Other experiments that suggest high-order mechanisms include visual search,[455] color appearance,[32,79,456] and the motion coherence of plaid patterns.[457] A unified understanding of when and why higher-order mechanisms are revealed experimentally remains an important question for the field.

Unipolar versus Bipolar Chromatic Mechanisms

The strong implication that cone-opponent and color-opponent mechanisms may be unipolar rather than bipolar came first from physiology. The inhibitory range of LGN opponent cells

(i.e., the extent of decreases in firing rate from the resting or spontaneous level) is seldom more than 10 to 20 impulses per second, compared with an excitatory range of several hundred (i.e., the extent of increases in firing rate from the resting level).[458] Consequently, cells of both polarities (i.e., L–M and M–L) are required in a push-pull relationship to encode fully both poles of a cone-opponent response. By the cortex, the low spontaneous firing rates of cortical neurons makes cells effectively half-wave rectifiers, because they cannot encode inhibitory responses.[459,460] Thus, the bipolar L–M, M–L, S–(L+M), and (L+M)–S cone-opponent mechanisms must become unipolar |L–M|, |M–L|, |S–(L+M)|, and |(L+M)–S| cone-opponent mechanisms, while the bipolar R/G and B/Y mechanism become unipolar R, G, B, and Y mechanisms.

Behavioral evidence for unipolar mechanisms at the cone-opponent level is sparse in the case of the L–M mechanism, because the opposite polarity L–M and M–L detection mechanisms have similar cone weights (see subsection "Detection contours in the L, M Plane" in Sec. 11.5), so in many ways they behave like a unitary bipolar mechanism.[34] Nevertheless, there is some evidence that the |L–M| and |M–L| poles behave differently. In particular, habituations to sawtooth chromaticity modulations can selectively elevate thresholds for |L–M| or |M–L| targets.[14,461] Sankeralli and Mullen[462] raised detection threshold using unipolar masking noise and found that masking was most evident when the test and noise had the same polarity (thus, |L–M| noise selectively masks an |L–M| test, and |M–L| noise selectively masks an |M–L| test). Other evidence suggests that |L–M| and |M–L| are separate mechanisms at the fovea.[396,463] Evidence for separate mechanisms is also apparent in the peripheral retina, where the |L–M| mechanism predominates.[176,178,464]

There is better evidence for the existence of unipolar S-cone mechanisms. Sawtooth chromaticity modulations selectively elevate thresholds for |S–(L+M)| or |(L+M)–S| targets,[14,461] as do unipolar |S–(L+M)| or |(L+M)–S| masks.[462] Other evidence shows that (1) the spatial summation for S-cone incremental and decremental flashes differs,[465] (2) the longer wavelength field sensitivity for transient tritanopia is different for incremental and decremental flashes, which indicates different L- and M-cone inputs for the two S cone polarities,[466] and (3) habituation or transient adapting flashes have differential effects on S increment and S decrement thresholds.[467,468] There is also ample physiological and anatomical evidence that S-cone ON and OFF pathways are distinct (e.g., Ref. 2). For a recent review, see Ref. 34.

Eskew[34] takes the more philosophical stance that a psychophysical mechanism should be defined as a univariant mechanism, the output of which is a "labeled line."[469,470] This means that a bipolar cone-opponent mechanism cannot by definition be a unitary mechanism, since it can exist in two discriminable states (positive and negative).

Discrepancies between Color-Discrimination and Color-Appearance Mechanisms

Much evidence indicates that color-discrimination and color-appearance mechanisms are distinct, at least given the linking hypotheses currently used to connect mechanism properties to performance.[14,16–22] As with color-discrimination mechanisms, much color appearance data may be accounted for by postulating three postreceptoral mechanisms. But the detailed properties of these mechanisms differ from those of the color-discrimination mechanisms.

In general, excitation of single cone-opponent mechanisms along cardinal directions does not give rise to the perceptions expected of isolated color-opponent mechanisms. Thus, the modulation of L–M around white produces a red/magenta to cyan color variation, whereas modulation of S around white produces a purple to yellow/green modulation.[31,32]

In specific tests of the relationship between color-discrimination and color-appearance mechanisms, unique hues, which correspond to the null vector of color-appearance mechanisms (see subsection "Spectral Properties of Color-Opponent Mechanisms" in Sec. 11.5), have been compared with the null vectors of color-discrimination mechanisms. Webster et al.[298] plotted pairs of unique colors of different saturation in DKL space. They found that only the unique red pair aligned with one of the cone-opponent axes, the L–M axis. The blue and yellow pair aligned roughly along an intermediate axis, but the green pair was not colinear with the red pair. Thus, unique blue and yellow, in particular,

must reflect the joint activity of L–M and S–(L+M). Chichilnisky and Wandell[289] and Wuerger, Atkinson, and Cropper[22] found that their four unique hue planes did not correspond to the null planes of color-discrimination mechanisms. Using a hue-naming technique, De Valois et al.[21] found that hue names are also not easily related to modulations of color-discrimination mechanisms (see Fig. 31).

The inconsistencies between color-discrimination and color-appearance mechanisms strongly suggest that the two are fundamentally different. But can they be considered to be mechanisms at different levels of a common serial processing stream or are they even more distinct? And if they do act serially, how might they be related? The simplified three-stage zone model described in the next section suggests that they could be parts of a common serial process and, at least for R/G, very simply related.

Three-Stage Zone Models

As noted in the Introduction (see section "The Mechanistic Approach" in Sec. 11.2), linear three-stage Müller zone models,[23] in which the second stage is roughly cone-opponent and the third stage color-opponent, have been proposed by Judd[24] and more recently by Guth[29] and De Valois, and De Valois.[18]

The De Valois and De Valois[18] three-stage zone model is an interesting example based on physiological and anatomical assumptions about the relative numerosity of cone inputs to center-surround-opponent neurons. In their indiscriminate-surround model, neurons are assumed to have single cone inputs to their centers and mixed cone inputs to their surrounds (in the ratio of 10L:5M:S). Consequently, both the L–M and M–L cone-opponent stages have −S inputs, as a result of which the third color-opponent stage with an S input to R/G is arguably not needed (see Guth[471] and De Valois and De Valois[472]). [The dangers of assuming that cone weights can be simply related to relative cone numerosity were discussed before in the context of luminous efficiency (see subsection "Luminance" in Sec. 11.5).] The spectral sensitivities of the De Valois and De Valois[18] third-stage color-opponent mechanisms are shown in Fig. 32, as dashed black lines. Despite their physiologically based approach, the De Valois and De Valois[18] zone model inevitably derives from earlier psychophysical models, partly because there are only a limited number of ways in which the cone fundamentals can be linearly combined to produce plausible cone-opponent and color-opponent spectral sensitivities. As well as three-stage models, there are also many examples of two-stage models, in which the second stage is designed to account either for color-discrimination or for color-appearance data in isolation.[8–13,15]

As an exercise, we next provide an illustrative example of a linear three-stage zone model based on a few very simple assumptions about the signal transformations at each stage. Our goal was to see if we could derive plausible estimates of the zero crossings of opponent-colors theory without resorting to speculative physiological models or psychophysical data fitting.

First zone At the first stage, we assume the Stockman and Sharpe[28] cone fundamentals: $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$, the spectral sensitivities of which are labelled Stage 1 in Fig. 4. These functions are normalized to unity peak.

Second zone At the second stage, we assume classical cone opponency. In the case of L–M (and M–L), we assign equal cone weights, thus yielding $\bar{l}(\lambda)-\bar{m}(\lambda)$, and its opposite-signed pair $\bar{m}(\lambda)-\bar{l}(\lambda)$. This is consistent with the evidence from psychophysical detection experiments for equal L- and M-cone contrast weights into L–M (see subsection "Sensitivity to Different Directions of Color Space" in Sec. 11.5). Note that the zero crossing of this cone-opponent L–M mechanism is 549 nm, which is far from unique yellow. For the zero crossing to be near the 580 nm—the unique yellow assumed at the next stage—the relative M:L cone weight would have to be increased from 1 to 1.55 (see, e.g., Fig. 7.4 of Ref. 15).

In the case of S–(L+M) and (L+M)–S, we assign half the weight to M as to L (in accordance with many other models) and then scale both by 0.69 to give equal weights (in terms of peak spectral sensitivity) to S and L+0.5M, thus yielding $\bar{s}(\lambda)-0.69[\bar{l}(\lambda)+0.5\bar{m}(\lambda)]$ and its opposite signed pair $0.69[\bar{l}(\lambda)+0.5\bar{m}(\lambda)]-\bar{s}(\lambda)$. The zero crossing of this mechanism is 486 nm, which is closer to unique blue (a zero crossing of R/G) than to unique green (a zero crossing of Y/B). For a *linear* Y/B to have a zero crossing near unique green, the B pole must have a contribution from M or L. The cone weights

into the cone-opponent mechanisms assumed at the second level are consistent with psychophysical measurements of color detection and discrimination estimates (e.g., Table 18.1 of Ref. 89).

The spectral sensitivities of the cone-opponent pairs are labelled Stage 2 in Fig. 4. (The L–M sensitivities have also been scaled by 2.55 in accordance with the proposals for the next stage.)

Third zone At the third stage, we sum the outputs of the second-stage mechanisms (or equivalently oppose ones of different signs), to give four color-opponent mechanisms (see also Refs. 29 and 18). The L–M cone-opponent input to the third stage is weighted by 2.55, so that R/G is zero for an equal-quantum white light, thus:

Red [L–M summed with S–(L+M)]

$$2.55[\bar{l}(\lambda)-\bar{m}(\lambda)]+(\bar{s}(\lambda)-0.69[\bar{l}(\lambda)+0.5\bar{m}(\lambda)])=1.86\bar{l}(\lambda)-2.90\bar{m}(\lambda)+\bar{s}(\lambda)$$

$$\text{(bipolar) or } |1.86\bar{l}(\lambda)-2.90\bar{m}(\lambda)+\bar{s}(\lambda)|\text{(unipolar)}$$

Green [M–L and (L+M)–S summed]

$$2.55[\bar{m}(\lambda)-\bar{l}(\lambda)]+(0.69[\bar{l}(\lambda)+0.5\bar{m}(\lambda)]-\bar{s}(\lambda))=-1.86\bar{l}(\lambda)+2.90\bar{m}(\lambda)-\bar{s}(\lambda)$$

$$\text{(bipolar) or } |-1.86\bar{l}(\lambda)+2.90\bar{m}(\lambda)-\bar{s}(\lambda)|\text{(unipolar)}$$

R/G is required to be zero for an equal-quantal white, because otherwise, according to opponent-colors theory, such whites would appear colored (see Ref. 283). Initially, we used the same weights for the cone-opponent inputs to B/Y and Y/B, thus:

Blue [M–L summed with S–(L+M)]

$$2.55[\bar{m}(\lambda)-\bar{l}(\lambda)]+(\bar{s}(\lambda)-0.69[\bar{l}(\lambda)+0.5\bar{m}(\lambda)])=-3.24\bar{l}(\lambda)+2.21\bar{m}(\lambda)+\bar{s}(\lambda)$$

$$\text{(bipolar) or } |-3.24\bar{l}(\lambda)+2.21\bar{m}(\lambda)+\bar{s}(\lambda)|\text{(unipolar)}$$

Yellow [L–M summed with (L+M)–S]

$$2.55[\bar{l}(\lambda)-\bar{m}(\lambda)]+(0.69[\bar{l}(\lambda)+0.5\bar{m}(\lambda)]-\bar{s}(\lambda))=3.24\bar{l}(\lambda)-2.21\bar{m}(\lambda)-\bar{s}(\lambda)$$

$$\text{(bipolar) or } |3.24\bar{l}(\lambda)-2.21\bar{m}(\lambda)-\bar{s}(\lambda)|\text{(unipolar)}$$

The spectral sensitivities of the color-opponent mechanisms are labelled Stage 3 in Fig. 4. The R/G mechanism yields reasonable estimates of unique blue (477 nm) and unique yellow (580 nm), and the B/Y mechanism yields a reasonable estimate of unique green (504 nm).

One potential problem, however, is that the opposing poles of B/Y and Y/B are unbalanced (as they also are in the De Valois and De Valois model), so that B/Y and Y/B will produce a nonzero response to an equal-quantum white. Given that Y > B, the white field would be expected to appear yellowish. This imbalance can be corrected by decreasing the relative contributions of Y perhaps after the half-wave rectification of B/Y into unipolar B and Y mechanisms. Alternatively, it can be corrected by decreasing the weights of the L- and M-cone inputs into B/Y and into Y/B. For this illustrative example, we choose the latter correction and accordingly scale the weights of the L- and M-inputs into Y/B by 0.34 to give a zero response to white, so that:

Blue [M–L summed with S–(L+M)] becomes

$$-1.10\bar{l}(\lambda)+0.75\bar{m}(\lambda)+\bar{s}(\lambda)\text{(bipolar) or } |-1.10\bar{l}(\lambda)+0.75\bar{m}(\lambda)+\bar{s}(\lambda)|\text{ (unipolar)}$$

Yellow [L–M summed with (L+M) –S] becomes

$$1.10\bar{l}(\lambda)-0.75\bar{m}(\lambda)-\bar{s}(\lambda)\text{(bipolar) or } |1.10\bar{l}(\lambda)-0.75\bar{m}(\lambda)-\bar{s}(\lambda)|\text{(unipolar)}$$

The spectral sensitivities of the Y/B and B/Y color-opponent pair are shown in the lower right panel of Fig. 4 as dashed lines. The correction shifts unique green to 510 nm. Such post hoc adjustments are inevitably somewhat speculative, however. Moreover, given that B/Y is clearly nonlinear (see subsection "Linearity of Color-Opponent Mechanisms" in Sec. 11.5), any mechanism that adjusts the balance of B/Y is also likely to be nonlinear.

Nonetheless, this example demonstrates that plausible estimates of the zero crossings of third-stage color opponency can be generated by making a few very simple assumptions about the transformations at the cone-opponent and color-opponent stages. But, how close are the R/G and B/Y spectral sensitivities to color-appearance data at wavelengths removed from the zero crossings? Figure 32 compares the R/G and B/Y spectral sensitivities with color valence data. Figure 32*a* shows as red circles R/G valence data from Ingling et al.[314] scaled to best (least-squares) fit the R/G spectral sensitivity. As can be seen, the agreement between R/G and the valence data is remarkably good. Figure 32*b*, shows B/Y valence data for three subjects (AW, JF, and LK, dark blue triangles, purple inverted triangles, and light blue squares, respectively) from Werner and Wooten[286] each scaled to best (least-squares) fit B/Y. Consistent with their own failed attempts to find linear combinations of cone fundamentals to describe their B/Y valence data,[286] our B/Y spectral sensitivity agrees only approximately with the data for AW and LK, and poorly with the data for JF.

Also shown in Fig. 32 are the spectral sensitivities of R/G and B/Y color-opponent mechanisms proposed by De Valois and De Valois[18] scaled to best fit our functions. Their R/G and B/Y functions agree poorly with our functions and with the valence data. In contrast, our R/G spectral sensitivity agrees well with the proposal by Ingling et al.,[314] which was based on the valence data shown in Fig. 32*a* (see also Ref. 12).

In summary, simple assumptions about signal transformations at the second and third stages yield a reasonable estimate of the spectral sensitivity of the R/G color-opponent mechanism. Perhaps, then, the R/G mechanism does reflect a cortical summing of the chromatic responses of double-duty L–M center-surround neurons and S–(L+M) neurons as has been suggested before.[18,29] In contrast, the B/Y mechanism cannot be accounted for so simply, and may reflect much more complex nonlinear transformations (see subsection "Linearity of Color-Opponent Mechanisms" in Sec. 11.5). These differences between R/G and B/Y could be linked to the idea that the R/G mechanism represents the opportunistic use of an existing or perhaps slightly modified neural process following the relatively recent emergence of separate L- and M-cone photopigment genes,[447] whereas the B/Y mechanism is some more ancient neural process.[448]

Figure 39 shows a speculative "wiring" diagram of the three-stage Müller zone model.

Final Remarks

Although the three-stage zone model provides a way to integrate the separate two-stage models required for discrimination and for appearance, it is important to note several limitations.

First, as formulated, it does not account for the nonlinearities in unique hue and hue-scaling judgments described in "Linearity of Color-Opponent Mechanisms" in Sec. 11.5. It is possible that explicitly incorporating nonlinearities in the contrast-response functions of each stage could remedy this, but this remains an open question.

Second, the model as outlined just above is for a single state of adaptation. We know that adaptive processes act at both the first and second stages and, with the three-stage models, the effects of these would be expected to propagate to the third stage and thus affect both discrimination and appearance in a common fashion. Although some data, reviewed in "Color Appearance and Chromatic Detection and Discrimination" in Sec. 11.5, suggest that this is the case, further investigation on this point is required. In addition, test on pedestal data for crossed conditions suggest that somewhere in the processing chain there may be additional cross mechanism adaptive effects. Such effects have also been suggested to play a role in appearance data.[381]

Third, the model as formulated does not explicitly account for effects of the temporal and spatial structure of the stimuli. These components could certainly be added, but whether this can be done in a parsimonious fashion that does justice to the empirical phenomena is not clear. If our mechanistic understanding of color vision is to be applied to natural viewing, then its extension to handle the

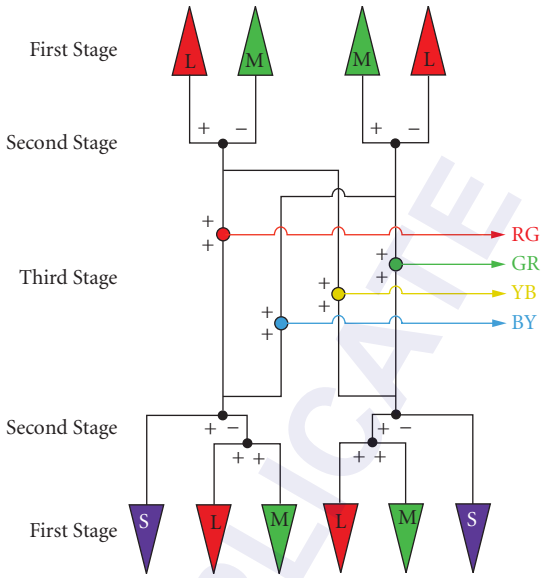

FIGURE 39 Three-stage Müller zone model. *First stage:* L-, M-, and S-cone photoreceptors (top and bottom). *Second stage:* L–M and M–L cone opponency (top) and S–(L+M) and (L+M)–S cone opponency (bottom). *Third stage:* Color opponency (center) is achieved by summing the various cone-opponent second-stage outputs.

complexity of natural retinal stimulation must be a high priority. At the same time, this is a daunting problem because of the explosion in stimulus parameters and the difficulties in controlling them adequately that occur when arbitrary spatiotemporal patterns are considered for both test and field.

Finally, we do not know whether models of this sort can provide a unified account of data across a wider range of tasks than simple threshold and appearance judgments.

Despite these unknowns and limitations, the type of three-stage model described here provides a framework for moving forward. It remains to be seen whether a model of this type will eventually provide a unified account of a wide range data, or whether what will be required, as was the case with Stiles' π-mechanism model which preceded it, is a reconceptualization of the nature of the psychophysical mechanisms and/or the linking hypotheses that connect them to behavioral data.

11.7 ACKNOWLEDGMENTS

The first author acknowledges a significant intellectual debt to Rhea Eskew not only for his writings on this subject, but also for the many discussions over many years about color detection and discrimination. He also acknowledges the support of Sabine Apitz, his wife, without whom this chapter could not have been written; and the financial support of the Wellcome Trust, the BBSRC, and Fight for Sight. The second author acknowledges the support of NIH R01 EY10016. The authors are grateful to Bruce Henning for helpful discussions, proofreading and help with Fig. 20, and Caterina Ripamonti for help with Fig. 16. They also thank Rhea Eskew, Bruce Henning, Ken Knoblauch, and Caterina Ripamonti for helpful comments on the manuscript.

ASSESSMENT OF REFRACTION AND REFRACTIVE ERRORS AND THEIR INFLUENCE ON OPTICAL DESIGN

B. Ralph Chou

School of Optometry
University of Waterloo
Waterloo, Ontario, Canada

12.1 GLOSSARY

Definitions

Accommodation. The increase of refractive power of the eye by changing the shape of the crystalline lens that enables focusing of the eye on a near object.

Amblyopia. Reduced visual acuity that is not improved with corrective lenses and occurs in the absence of anatomical or pathological anomalies in the eye.

Ametropia. A refractive condition of the unaccommodated eye in which light from optical infinity does not focus on the retina.

Aniseikonia. A relative difference in the perceived size and/or shape of the images in the two eyes.

Anisometropia. Unequal refractive state in the two eyes, which may result in aniseikonia.

Aphakia. Absence of the crystalline lens from the eye.

Astigmatism. Refractive state of the eye in which rays from a point object form two line images at different distances from the retina.

Back vertex power. Reciprocal of the distance in meters between the pole of the back surface of a lens and the axial position of the image formed of an infinitely distant object. The unit of BVP is the **diopter** (or reciprocal meter).

Base curve of a contact lens. The radius of curvature of the ocular surface of a contact lens.

Base curve of a spectacle lens. The power of the flattest meridian on the front surface of a spectacle lens. Alternatively, for a spectacle lens design, the reference surface power for a series of lenses of different back vertex powers.

Emmetropia. Refractive state of an unaccommodated eye in which light from an infinitely distant object is focused on the retina.

Far point. A point in the object space of an ametropic eye which is conjugate to the retina.

Presbyopia. Reduced ability to accommodate, usually due to age-related changes in the crystalline lens.

Prismatic effect. The deviation of a ray of light as it passes through an optical system, considered as if due to a prism of known deviating power that replaces the optical system. The unit of prismatic effect is the **prism diopter**, which is 1 cm of displacement per meter of travel of the ray along the optical axis.

Rimless mounting. A system of mounting spectacle lenses in which there is no frame; all parts for resting the spectacles on the nose and ears are attached directly to the lenses.

Visual acuity. Clinical measure of the minimum angle of resolution of the eye, with or without corrective lenses.

Working distance. Distance of the object of regard in front of the eye, usually considered 40 cm for reading and other near tasks.

Symbols

f	spectacle lens focal length
F	spectacle lens power
F_v	back vertex power of a spectacle lens
F_x	effective back vertex power of a spectacle lens displaced a distance x
K	keratometry reading of corneal curvature
L	axial length of the eye
P	power of intraocular implant lens
x	displacement distance of a spectacle lens
P_H	prismatic effect in a lens of power F at a point x cm from the optical center

Equations

Equation (1) is the lens effectivity equation which is used to adjust the power of a spectacle lens when it is moved a distance x meter from its original position.

F_x	effective back vertex power of a spectacle lens displaced a distance x
F_v	original back vertex power of the spectacle lens
x	displacement distance of the spectacle lens

Equation (2) estimates the spectacle correction needed after cataract extraction.

F	back vertex power of the postoperative spectacle lens
F_{old}	back vertex power of the preoperative spectacle lens

Equation (3) is the SRKII formula for power of an intraocular lens needed to produce emmetropia in an eye after cataract removal.

P	IOL power
$A1$	a constant
K	keratometer reading of the central corneal curvature
L	axial length of the eye in mm

Equation (4) is Prentice's Rule.

P_H	prismatic effect
x	distance in cemtimeters of the point on the lens through which the line of sight passes from the optical center of the lens
F	the back vertex power of the lens

Equation (5) is the exact expression for spectacle magnification of a spectacle lens.

M	magnification
d_v	distance between the back vertex of the lens and the cornea

F back vertex power of the spectacle lens
t axial thickness of the spectacle lens in meters
n index of refraction of the lens
F_1 front surface power of the lens

Equation (6) is the approximate formula for spectacle magnification.

12.2 INTRODUCTION

At the beginning of the twenty-first century, much of the information upon which we rely comes to us through vision. Camera view finders, computer displays, liquid crystal displays at vehicle controls, and optical instruments are only a few examples of devices in which refractive error and its correction can have important implications for both their users and optical designers. The options for correction of refractive error are many and varied; each has its advantages and disadvantages when the use of optical devices is considered. Most observers are binocular, and whether one or both eyes are fully or optimally corrected may affect one's ability to use a given optical device or instrument. In addition, the optical and physiological changes associated with aging of the eye may also have a profound effect on visual performance.

12.3 REFRACTIVE ERRORS

As described by Charman[1] in Chap. 1, the eye consists of two refractive elements, the cornea and the crystalline lens, which are separated by the watery aqueous humor, and the gel-like vitreous humor, which fills the rest of the eyeball between the crystalline lens and the retina (Fig. 1). The cornea provides approximately one-third of the optical power of the eye and the crystalline lens the remainder. Light entering the cornea from optical infinity ideally is focused through the dioptrics of the eye onto the retina, where it stimulates the photoreceptors and triggers the cascade of neurophysiological processes leading to the visual percept. An eye in which the retinal image is in sharp focus is described as emmetropic. The shape of the crystalline lens can be changed through the action of intraocular muscles in the process called *accommodation*. Accommodation increases the power of the eye so that light from a "near" object at a finite distance in front of the eye is sharply focused on the *retina*. The neural mechanisms governing accommodation affect the neural control of convergent and divergent eye movement. This ensures that as the eyes fixate on a near object, both eyes form images that overlap, giving rise to a single binocular percept. The crystalline lens continues to grow throughout life and physical changes within it gradually cause a loss of flexibility which reduces the amplitude of accommodation. The clinical onset of *presbyopia* (old eye) is marked by the inability to maintain focus on a target viewed at distance of 40 cm in front of the eye. This normally occurs at the age of 40 to 50 years.

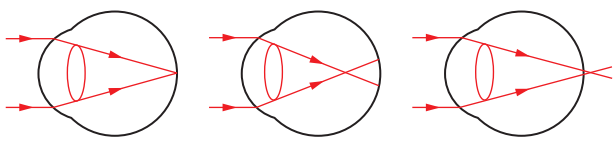

FIGURE 1 Focusing collimated light in emmetropic, myopic, and hyperopic eyes.

The failure to accurately focus light from a remote object onto the retina is referred to as *ametropia*.[1] Ametropia or refractive error is present in many eyes. Uncorrected ametropia has been identified as one of the leading treatable causes of blindness around the world.[2] The degree of ametropia is quantified by the optical power F of the spectacle lens that "corrects" the focus of the eye by bringing light from the distant object to focus at the retina. The dioptric power of the lens is given by the reciprocal of its focal length f: $F = 1/f$. The unit of focal power is the *diopter*, abbreviated as D, which has dimensions of reciprocal meters. Most spectacle lenses can be regarded as thin lenses,[3] and the power of superimposed thin lenses can be found as the algebraic sum of the powers of the individual lenses. This is convenient in ophthalmic applications such as measurement of refractive error and the use of "trial" corrections made with combinations of loose or trial case lenses.

Types of Refractive Error

An unaccommodated eye which focuses light from a distant object onto the retina is *emmetropic* and requires no corrective lenses (Fig. 1).

A "near sighted" or *myopic* eye focuses light in front of the retina (Fig. 1). The myope sees closer objects in focus, but distant objects are blurred. Myopia is corrected by lenses of negative power that diverge light.

A "far sighted" or *hyperopic* eye focuses light behind the retina (Fig. 1). The hyperope can exercise accommodation to increase the power of the eye and focus the image of a distant object clearly on the retina. Nearer objects can also be seen clearly by exercising more accommodation, but the increased effort to maintain accommodation and a single binocular percept may result in symptoms of "eyestrain" and blurred near point vision. If accommodative fatigue occurs, the observer's ability to maintain a clearly focused image of the distant object is lost, and blur at both distance and near results. Measurement of the refractive error of a hyperope often results in a finding of apparent emmetropia when accommodation is being exercised (latent hyperopia) and varying degrees of manifest hyperopia when control of accommodation is lost. Hyperopia is corrected by lenses of positive power that converge light.

The foregoing discussion assumes that the dioptrics of the eye bring collimated light to a point focus. However, most eyes are *astigmatic*, that is, the optical components form two line foci that are usually perpendicular to one another. *Astigmatism* results in blur for all object distances, and the greater the astigmatism, the greater the blur. If the orientation of the line foci is in a direction away from the horizontal and vertical, the effects of ocular astigmatism on vision may be very serious, hindering development of the visual system.

Astigmatism is corrected with a *spherocylindrical lens* (Fig. 2), which usually has one spherical and one toric surface. Optically, the cylinder component brings the two line foci of the eye together,

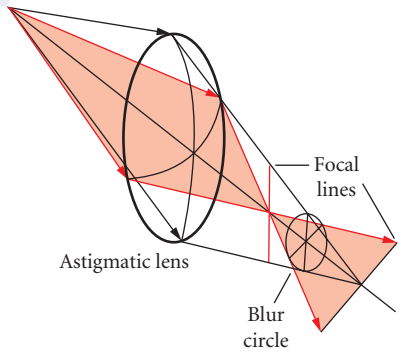

FIGURE 2 The astigmatic pencil formed by a spherocylindrical lens.

and the sphere component places the superimposed line foci on the retina. In clinical practice, the lens prescription is written in terms of *sphere*, *cylinder*, and *axis*. The position of the cylinder axis is specified using the trigonometric coordinate system centered on the eye as seen by the examiner, with 0° to the examiner's right or the patient's left, in what is referred to as the TABO or Standard Notation.[3] For example, the prescription +1.00 – 2.50 × 030 corresponds to a +1.00 D spherical lens (sometimes designated +1.00 DS) superimposed on a –2.50 D cylindrical lens with its axis at 30° (sometimes designated –2.00 DC × 030). Occasionally, for clinical reasons, astigmatism may be corrected by the *spherical equivalent lens*, a spherical lens that causes the line foci to straddle the retina. The power of the spherical equivalent is calculated as the sum of the sphere plus one-half of the cylinder in the spectacle prescription. The spherical equivalent of the above prescription would be –0.25 D.

Spectacle lenses are usually manufactured in quarter diopter steps. By ophthalmic convention, spectacle prescriptions are written with a plus or minus sign and to two decimal places. When the power is less than ±1.00 D, a 0 is written before the decimal point, for example, +0.25 D.

Refractive errors are usually one of these simple types because the curvatures of the various refractive surfaces of the eye vary slowly over the area of the entrance pupil.[4,5] In some instances, however, *irregular astigmatism* may occur and no lens of any type can produce sharp vision. These are usually cases of eye injury or disease, such as distortion of the cornea in advanced keratoconus, corneal scarring after severe trauma, corneal dystrophy, disruption of the optics of the crystalline lens due to cataract, and traumatic damage to the lens. Tilting or displacement of the crystalline lens and distortion of the cornea following rigid contact lens wear may also lead to irregular refraction.[6] Williams[7] has described a case of irregular refraction due to tilting of the retina.

12.4 ASSESSMENT OF REFRACTIVE ERROR

In ophthalmic practice, the measurement of refractive error or ocular refraction is an iterative process in which a series of tests is employed to refine the results until a satisfactory end point is reached. The usual starting point is an objective test where no patient interaction is required, followed by subjective tests that require patient responses. Clinical tests are generally accurate to within ±0.25 D, which is comparable to the depth of field of the human eye.[8]

Objective Tests

Objective tests require only that the patients fix their gaze upon a designated target, normally located at a distance of 6 m from the eye so that with accurate fixation there is a negligible amount of accommodation being exercised. Three common tests are keratometry, direct ophthalmoscopy, and retinoscopy.

Keratometry measures the curvature of the front surface of the cornea. A bright object, the *keratometer mire*, is reflected by the cornea (1st Purkinje image) and its magnification determined from the lateral displacement of a doubled image of the mire.[9] The curvature of the corneal surface (*K* reading) in its principal meridians is read from a calibrated dial along with the axis of any corneal astigmatism. The total power of the cornea may be estimated from the *K* reading, and the corneal astigmatism may be used to predict the total amount and orientation of the astigmatism of the whole eye. Various rules of thumb have been developed (e.g., Javal's rule) to estimate the total astigmatism from the keratometric readings of normal eyes. This is due to the observation that large degrees of ocular astigmatism are almost always due to the cornea. In an *aphakic* eye, from which the crystalline lens has been removed, the corneal astigmatism is the ocular astigmatism.

Although primarily designed to view the retina of the living eye, the *direct ophthalmoscope* can also be used to estimate refractive error. Light is directed from a source in the ophthalmoscope through the pupil to illuminate the patient's retina. The examiner views the resulting image through lenses of varying power until a clear view of the retina is obtained. The algebraic sum of the lens power

and refractive error of the examiner is the patient's refractive error. When astigmatism is taken into account, this result is a crude estimate of the spherical equivalent of the patient's ocular refraction and is not sufficiently accurate to prescribe a corrective lens power. It may be helpful in assessing the refractive error of incommunicative patients when other methods cannot be employed.

The most common objective measurement of ocular refraction is retinoscopy. The retinoscope is designed to view the red reflex in the pupil as light is reflected from the retina. This is the same red reflex that often is seen in flash photographs of faces. The retinoscope is held at a known *working distance* from the eye, and the examiner observes the red reflex through the peephole in the retinoscope mirror as the retinoscope beam is moved across the patient's eye. Vignetting of the beam by the pupils of the patient and the examiner results in a movement of the reflex across the pupil. The direction and speed of the reflex motion depends on the patient's refractive error.[10]

Most refractionists use either a slightly divergent or collimated retinoscope beam at a working distance of 50 or 66 cm from the eye. If the red reflex moves in the same direction as the beam, this is a "with" movement and indicates that the retina is conjugate to a point closer than the working distance. As lenses with increasing plus power are interposed in 0.25 D increments, the with movement becomes faster until the end point is reached where a lens neutralizes the refractive error and the reflex moves infinitely fast or instantly fills the pupil when the beam touches the edge of the pupil. The next lens in the sequence should cause the reflex motion to reverse direction. The patient's refractive error is the value of the end point lens minus the working distance correction (+2.00 D for 50 cm working distance and +1.50 D for 66 cm). When the red reflex shows an "against" movement (it moves in the opposite direction to the retinoscope beam), the retina is conjugate to a point farther than the working distance.

Neutralization is achieved by interposing lenses of increasing minus power until the reflex shows a with movement. The end point lens is one incremental step back in power; with this lens, the reflex instantly fills the pupil when the beam touches the edge of the pupil. The patient's refractive error is calculated by correcting for the examiner's working distance.

The shape and motion of the reflex can be used to determine the axis of astigmatism. Once the two principal meridians of the eye are identified, the refractive error is measured in each separately. The sphere, cylinder, and axis components of the ocular refraction can then be calculated.

Retinoscopy provides an estimate of the refractive error very quickly, but requires some skill. A streak-shaped beam can facilitate the process in many patients, but retinoscopic findings may still vary from the true ocular refraction in some patients.

Automated equipment has been developed to determine the refractive error and corneal curvature without depending on the examiner's skill or judgment. Autokeratometers and autorefractors are frequently used to provide a starting point for the subjective refraction. More recently, aberrometers, instruments that measure ocular aberrations as well as the paraxial ocular refraction, have entered the ophthalmic market.

Subjective Techniques

The final refinement of the refractive findings in an oculovisual examination is usually obtained through subjective refraction. Although many techniques have been developed over the years, in practice only two or three are used. These methods rely on patient interaction to determine the sphere, cylinder, and axis components of the refractive error.

Subjective methods rely on the use of a visual acuity chart and trial lenses that can be placed in a trial frame worn by the patient, or a phoropter, a mechanical device that contains a range of powers of spherical and cylindrical lenses, prisms and accessory filters and lenses. The visual acuity chart may be either printed or projected and contains letters, numbers, or pictographs arranged in a sequence of sizes from large at the top to small at the bottom. The target size is rated according to the distance at which the finest detail within it would subtend 1 min of arc. Both recognition and resolution of detail within the target are required to read the smallest characters on the chart. The *visual acuity* is a representation of the minimum angle of resolution of the eye viewing the chart with or without corrective lenses. For example, an eye with a 1.5 min minimum angle of resolution should just read

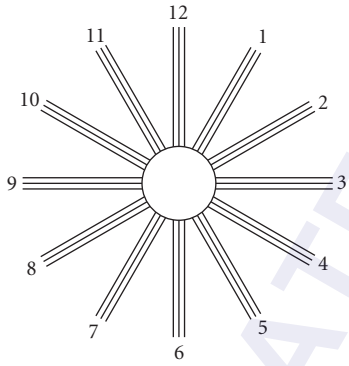

FIGURE 3 The astigmatic dial.

a target rated for 9 m or 30 ft when viewed at a distance of 6 m or 20 ft. The visual acuity would be recorded as 6/9 in metric, or 20/30 in imperial units. The refractive error can be estimated as the quotient of the denominator in imperial units divided by 100—in this example the refractive error would be approximately ±0.30 D spherical equivalent. We usually expect ametropic patients with healthy eyes to have corrected visual acuity of 6/4.5 (20/15) or 6/6 (20/20). Rabbetts[11] has an excellent review of the design and use of visual acuity charts.

Subjective refraction usually begins with the patient's retinoscopic finding or previous spectacle correction in the phoropter or trial frame. Sometimes it may be preferable or necessary to add plus lenses in 0.25 D steps before the unaided eye to blur or fog the patient, then reduce lens power or add minus power incrementally until the best possible visual acuity is achieved with a spherical lens power (unfogging).

The astigmatism is measured next. If the patient has an equivalent sphere lens in front of the eye, vision is fogged while viewing the astigmatic dial, which is a chart with radial lines arranged in 30° intervals (Fig. 3). The patient identifies the line that appears clearest or darkest; the line corresponds to the line focus nearest to the retina and its orientation allows for calculation of the axis of the astigmatism. Since the chart looks like an analog clock dial, the hour value times 30 gives the approximate axis value, where 12 o'clock has the value 0 for the TABO axis notation. Cylinder power is added with this axis position until all lines appear equally dark or clear.

Refinement of the astigmatic correction is achieved with the *Jackson cross-cylinder* check test. This uses a spherocylindrical lens with equal but opposite powers in its principal meridians; normally a ±0.25 D or ±0.50 D lens is used. The Jackson cross-cylinder lens is designed to rotate around one of its principal meridians to check cylinder power and around an axis 45° from that meridian to check cylinder axis orientation. The patient looks through the spherocylinder correction and Jackson cross-cylinder lens and notes changes in clarity of small letters on the acuity chart as the cross cylinder is flipped and adjustments are made first to the axis position, then the cylinder power until both cross-cylinder orientations give the same degree of clarity. The sphere is then adjusted for best corrected visual acuity. Further adjustments may be made to equalize the visual acuity between the two eyes before the final corrective power is confirmed with trial lenses and frame.

Presbyopia

Presbyopia or "old eye" is the refractive condition in which the ability to accommodate or focus the eyes on a near target is reduced. This is an age-related phenomenon due to the gradually increasing rigidity of the crystalline lens. It generally becomes clinically significant in the mid to late 40s; absolute presbyopia occurs by the late 50s when there is no accommodation. The onset of presbyopia is

earlier among hyperopes whose first symptom is the inability to focus on distant objects that were previously seen clearly without corrective lenses. Myopes can compensate for early presbyopia by removing their corrective lenses to view near objects. Presbyopia is corrected by adding positive power (the reading addition or add) to the distance correction until the patient is able to achieve the desired near visual acuity for reading. Single vision reading glasses or bifocal lenses may be prescribed for near work.

The added power may be determined either objectively using techniques such as dynamic retinoscopy or subjectively using a variety of techniques.[12]

12.5 CORRECTION OF REFRACTIVE ERROR

The Art of Prescribing

Ametropia is usually corrected by placing a lens in front of the eye that will focus light from a distant object onto the axial position that is conjugate to the retina of the ametropic eye. This position is the *far point* or *punctum remotum* of the eye. Near objects can then be seen clearly through the lens by exercising accommodation.

The fact that humans usually have two functioning eyes and the frequent occurrence of astigmatism in ametropia require eye care practitioners to consider a given patient's binocular status and visual needs in addition to the refractive errors of the eyes. Prescribing corrective lenses is therefore as much an art as a science.

The spatial distortion inherent in astigmatic corrections can cause adaptation problems, whether or not the patient is well adapted to spectacle correction. As a result, most practitioners will try to minimize the amount of cylindrical correction that is needed for clear comfortable vision. In some cases, particularly in first corrections, the spherical equivalent may be preferred over even a partial correction of the astigmatism to facilitate adaptation to the lenses.

Younger ametropes may find vision slightly more crisp when they exercise a small degree of accommodation when looking at a distant target. Beginning refractionists often err in "over minusing" patients who accommodate during the refraction. The methods of subjective refraction are designed to minimize this tendency. While absolute presbyopes may be expected to require a full distance correction, and one expects myopic individuals will normally require full correction of their ametropia, younger hyperopes may often show a manifest error that is considerably lower than what can be found in cycloplegic refraction. They may require a partial correction until they learn to relax their accommodation when looking at distant objects.

Anatomical and neuromuscular anomalies of extraocular muscles that control eye movement may result in ocular deviations, both latent and manifest, that affect the ability of the visual system to provide a clear binocular visual percept for all target distances in all directions of gaze through corrective lenses. Differential *prismatic effects* may lead to double vision when the patient looks in certain directions or at certain distances in front of the eyes. The practitioner may need to modify the lens prescription in order to provide comfortable vision.

As presbyopia develops, a reading addition is required to maintain single clear binocular vision during near visual tasks like reading. The power of the add usually is chosen so that the patient uses about one-half of the available accommodation when reading. Addition power is determined using a standardized testing distance of 40 cm, then adjusted using trial lenses and the patient's preferred working distance for near vision tasks. The design of the lenses (bifocal, multifocal, invisible bifocal, single vision readers) to be prescribed largely depends on the wearer's visual tasks, intended use of the lenses, and need for eye protection.

It should be noted that presbyopes are not the only ones who can benefit from using bifocals and reading glasses. Since these corrections can reduce the demand for accommodation, they may be prescribed for younger patients who have anomalous accommodation and complain of eyestrain, visual discomfort, and even double vision. Finally, some individuals with low degrees of myopia often find that they are most comfortable when reading without any spectacle correction at all.

Spectacle Correction

Optical Considerations Spectacles have been in use for at least 700 years, although it was only after the late nineteenth century that they were generally used to correct distance vision. Prior to that time, the lenses were self-selected mostly to aid in reading, and rarely for distance correction. The now familiar *bent* shape of modern spectacle lenses was not generally adopted until the early 1900s.

Spectacle lenses are often treated as thin lenses and it is often assumed that their exact position in front of the eyes is not critical. These assumptions apply to the majority of patients who have low-to-moderate refractive errors. It is only when we consider lenses for correction of high refractive error that thick lens optics must be used.

Spectacle lenses are specified by their *back vertex power*, which is the reciprocal of the distance from the pole of the ocular or back surface of the lens to its second focal point. The powers of phoropter and trial case lenses are also given as back vertex powers. The *focimeter* or *lensometer* is an instrument used to measure the back vertex power of spectacle lenses.[13]

The back vertex power of a corrective lens depends on the *vertex distance*, which is the distance between the back surface of the lens and the cornea. The vertex distance is typically between 12 and 15 mm. When the vertex distance of the phoropter or trial frame used in determining a patient's refractive error differs from the actual vertex distance of the corrective lenses placed in the spectacle frame, the back vertex power of the lenses can be modified using the formula

$$F_x = \frac{F_v}{1 - xF_v} \tag{1}$$

where x is the distance in meters between the vertex distance of the refraction and the vertex distance of the spectacles ($x > 0$ when the spectacles are moved closer to the eye). It can be shown that changes in vertex distance of 1 or 2 mm are insignificant unless the lens power is greater than 8.00 D.[14]

Of all the parameters that are considered in designing spectacle lenses, the most significant is the *base curve*, which defines the lens form. The base curve is adjusted so that the lens forms images of distant objects near the far point of the wearer's eye in all directions of gaze. Ideally the image surface coincides with the far point sphere of the eye, so that the same spectacle prescription is required in all fields of gaze.[15] In practice, this means that the lens design will minimize unwanted oblique astigmatism and control curvature of field. Many corrected curve or best form lens designs have been developed, each with its own assumptions about vertex distance, field size, thickness, material, and relative importance of the Seidel aberrations, using spherical curves in the principal meridians of the lens. High plus power lenses must be made with aspheric curves to achieve adequate performance. Astigmatic lenses are made in minus cylinder form, with a spherical front surface and toric back.

The introduction of computer-aided design and computer numerically controlled (CNC) surfacing machines has led to the free form surfacing technology of today's ophthalmic lens industry. By specifying the deviation of both lens surfaces from reference spherical surfaces at many points, a diamond cutter can be used to form any desired surface shape. Double aspheric lenses which may provide optimal visual performance for wearers of any spectacle correction can be made readily with this technology.

Spectacle Lens Materials Spectacle lenses of all types are available in many glass and plastic materials. The final choice of material for a given pair of lenses depends on the diameter and thickness of the lenses (which determine their weight), the need for impact and scratch resistance, and the sensitivity of the wearer to color fringes caused by transverse chromatic aberration. The glass lenses of the twentieth century have been largely replaced by plastics, the most common being CR39 with a refractive index of 1.498. Polycarbonate (index 1.586) is frequently used because of its high impact resistance for protective lenses for occupational and sports use and for patients with high refractive errors. This material requires scratch-resistant coatings because of its soft surface and it suffers from chromatic aberration. Trivex (index 1.53) is a recently introduced plastic material that is more impact resistant than CR39 and can be used in *rimless mountings* and high power prescriptions where polycarbonate shows poorer performance. High index urethane lenses have largely replaced the high index glass lenses of the late 1900s with refractive indices of 1.6 to 1.74 available. Many

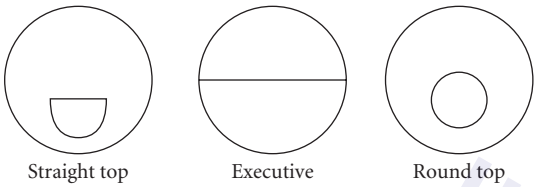

FIGURE 4 Common bifocal styles.

lenses are supplied with antireflection coatings to enhance visual performance and cosmetic appearance; the coating can significantly reduce impact resistance.[16–18] Tints can be applied for cosmetic, protective, or vision enhancement purposes.[19]

Presbyopic Corrections Most presbyopic patients prefer a bifocal correction in which the top part of the spectacle lens provides the distance correction and an area in the lower part, the *segment*, contains the correction for near vision. The difference between the segment and distance power is the add of the bifocal. Adds typically range from +1.00 D to +2.50 D, with the power increasing with age. A small minority of patients prefer separate pairs of glasses for distance use and reading.

The most common bifocal segments are the *straight top*, *Executive*, and *round* top designs shown in Fig. 4. Although many segment designs were developed in the early 1900s, only a few remain commercially available. All plastic bifocals are one piece, that is, the distance and near powers are achieved by changing the surface curvature on one side of the lens. Glass Executive bifocals are also one piece, but the straight top and round top styles are made by fusing a high index glass button into a countersink in the front surface of a lower index glass lens. They are referred to as fused bifocals. Bifocal segments are normally placed so that the top of the segment (the segment line) is at the edge of the lower eyelid. This allows comfortable near vision with minimal downgaze and keeps the segment as inconspicuous as possible. The style and width of the bifocal segment used is mainly determined by the wearer's visual needs at near, particularly with regard to width of the near visual field, as well as cosmetic appearance.

Patients with adds greater than +1.75 D often find that objects at a distance of 50 to 60 cm appear blurred through both the distance and segment portions of their bifocals. A trifocal lens that contains an intermediate segment between the distance and near parts of the lens allows for clear vision at arm's-length distance. Trifocals are positioned with the top line at or just below the lower edge of the pupil.

Special occupational multifocal lenses can be prescribed for presbyopes who need to see intermediate or near objects overhead. These lenses contain an intermediate or near add in the upper part of the lens in addition to the usual bifocal or trifocal segment. They are often referred to as occupational trifocal or quadrifocal lenses, respectively. Such lenses are recommended for presbyopic mechanics, electricians, plumbers, carpenters, painters, and librarians, among others. The *progressive addition lens* or *PAL* is an increasingly popular alternative to bifocal and trifocal lenses. The PAL design (Fig. 5) features a continuously varying power in the lens from the distance visual point, the pupil position when looking at distance, to the near visual point that is used to read. Originally a single aspheric progressive surface on the front of the lens was used, but more recent designs that take advantage of freeform surfacing technology have incorporated the power progression on either or both surfaces. Clear vision is achieved not only at the distance and near visual points, but also through a narrow optical corridor or umbilicus that joins them.

Outside of the distance and near vision zones and the corridor, the changes in surface shape result in distorted blurred images. The myriad of PAL designs in the ophthalmic lens market represents the many solutions to designing the progressive surface(s) to optimize single clear binocular vision through as much of the lens as possible. Some manufacturers claim to include preference for head or eye movements to view objects to the side, differences in prismatic effect between the eyes, and other factors in their designs.[20] Although marketed as lineless bifocals, PALs have proven popular because they hide the fact the wearer is old enough to need a reading prescription and provide clear vision at

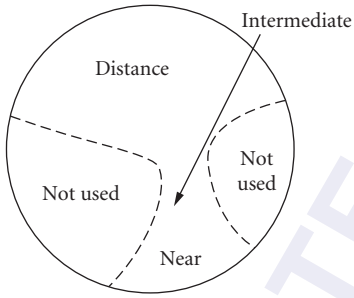

FIGURE 5 A progressive addition lens (PAL) has a large area of distance prescription power and an area of addition power connected by a narrow corridor. Areas to either side of the corridor and reading area are less usable due to blur induced by the progressive power surface.

all distances once the patient has learned to use them. The lens must be properly positioned in front of the eyes and the patient instructed on how to use it. Most patients adapt quickly to their PALs and prefer them to conventional bifocals despite the extra cost.

Recently PAL technology has been adapted for both patients approaching presbyopia as well as advanced presbyopes, who work with computer displays. These office lenses focus on arm's length and near working distances to provide a wider intermediate field of view than can be achieved in the corridor of a PAL. Prepresbyopes with complaints of eyestrain and presbyopes suffering "bifocal neck" while working at a computer display may find that these lens designs relieve their symptoms. Since the lenses have the intermediate portion in front of the pupil in the straight ahead gaze position, the head need not be tilted backward to enable the wearer to see the screen. Musicians, hairdressers, and other workers who require wide clear intermediate fields may also find these lenses useful.

Contact Lenses

A contact lens can be considered as a spectacle lens with a zero vertex distance. The spectacle lens power must be adjusted for the change in vertex distance from the spectacle plane; in practice lens powers under 5 D are not adjusted for vertex distance since the change in power is less than 0.25 D. The contact lens power will be more positive or less negative than the spectacle lens power. Since the contact lens is supported by the cornea, the fit of the contact lens must be assessed to ensure that the back surface of the contact lens is supported without significantly affecting the shape of the cornea. The tear layer between the cornea and the contact lens may affect the fit as well as the power of the contact lens.

Most contact lenses are prescribed for cosmetic reasons and many patients ask for them in sports activity. Patients with very high refractive errors often find that contact lenses provide better quality of vision, particularly with regard to magnification effects and extent of the visual field, than spectacles. They are also much more comfortable than when wearing thick, heavy spectacle lenses.

The main contraindications for wearing contact lenses are dry eye and allergies.

Rigid Contact Lenses The first contact lenses were made from polymethylmethacrylate (PMMA). This plastic has very good optical and physical properties, but is impermeable to oxygen. Contact lenses had to be designed so that the overall diameter and the curvature of the back surface (the base curve of the contact lens) allowed a lens to move over the eye with the blink and permit tear fluid to be exchanged under the lens. This allowed enough oxygen to reach the cornea to maintain its physiology. Poorly fitting PMMA lenses could cause many problems related to disrupted corneal physiology due to hypoxia, including hypoesthesia, edema, surface irregularities, and overwear syndrome.

Deformation of the cornea could also occur, especially in corneal astigmatism, if the base curve did not provide a good mechanical fit to the toric corneal surface.

Modern rigid lenses made of gas permeable materials[21] have greatly reduced many of the problems caused by PMMA. These biocompatible materials transmit oxygen and can be made larger and thinner than PMMA lenses without adversely affecting corneal physiology. With less movement, the lenses are more comfortable, although initially there is a period of adaptation. Adaptation usually occurs over a few weeks as the patient starts wearing the lenses for a few hours each day, then gradually increases the wearing time. Eventually most patients wear their contact lenses between 10 and 14 hours a day; some patients may attempt extended wear, when the lenses are worn continuously for several days. Once adapted, the patient must continue to wear the lenses on a schedule that maintains the eyes' adaptation.

Rigid lenses do not conform to the shape of the underlying cornea. Thus, the tears filling the space between the ocular surface of the contact lens and the cornea form a *tear lens*. The sum of the power of the tear lens plus the power of the contact lens itself must equal the vertex adjusted power of the spectacle correction. Very thin gas permeable lenses tend to flex and change shape on the eye because of lid pressure and the tear lens. Most contact lens fitters will use trial lenses to estimate how the lens behaves on the eye and thus choose a base curve and lens power that will provide both a good physical fit and optimal vision correction.

Because the tears and cornea have almost the same index of refraction, the optical power of the cornea is replaced by that of the front surface of the tear layer beneath the lens. A spherical base curve therefore effectively masks the corneal astigmatism that often contributes most of the refractive astigmatism in ametropia. As a result, many patients with moderate astigmatism can be managed satisfactorily with spherical contact lenses, provided that an acceptable fit of the base curve to the cornea can be achieved. If the astigmatism is too great, or if a suitable physical fit cannot be achieved, rigid contact lenses with toric front and/or back surfaces can be used. In these cases, the lenses must be oriented using prism ballast in which prism power is ground into the lens so that the thicker base edge is at the bottom of the lens—its orientation is maintained by gravity.

Rigid lenses, particularly those made of PMMA, will change the shape of the cornea.[22] The curvature change may vary from day to day, making it difficult to determine a spectacle prescription for use when the patient is not wearing the contact lenses. This is described as spectacle blur. In extreme cases, the warped cornea may have a permanent irregular astigmatism. *Orthokeratology* is a clinical approach to reducing or eliminating refractive error by corneal molding with rigid contact lenses.[23] The procedure involves a series of contact lenses with successively flatter base curves to reduce corneal curvature. After several months, the patient experiences a mild reduction of 1 or 2 D of myopia. This is a temporary (i.e., several hours) effect. Retainer lenses must be worn for several hours each day to prevent the cornea from rebounding to its original shape.

Most rigid lenses are made with a handling tint, often a very light blue, brown, or green, to facilitate locating a lens dropped on the floor or countertop. The tint should not affect the wearer's colour perception. The right lens of a pair is normally identified with a dot engraved on the front surface. Lenses must be cleaned and disinfected with special care solutions after each wearing. The fit of the lens should be checked every year. The expected service life of a rigid gas permeable contact lens is 2 to 3 years.

Hydrogel Lenses Soft or hydrogel contact lenses were introduced in the 1970s and today they dominate the contact lens market. A hydrogel is a polymer that is able to absorb a significant amount of water.[21] Although brittle and fragile when dry, a hydrogel becomes soft and flexible when hydrated. The first commercially successful lens, the Bausch & Lomb Soflens®, was made of hydroxyethylmethacrylate (HEMA), which contains 38.6 percent water by weight when fully hydrated. Manufacturers have since developed HEMA derivatives with water content up to 77 percent.[24] A hydrogel lens that is saturated with ophthalmic saline solution buffered to the pH of the tears will smoothly drape over the cornea if an appropriate base curve has been selected. The base curve of the lens is determined from the value of K, the corneal curvature measured by a keratometer. A trial lens of known power with this base curve is placed on the eye and an over refraction is performed to determine the final contact lens power. A properly sized hydrogel lens will cover the entire cornea

and overlap the sclera by about 1 mm; the peripheral flattening of the cornea is accommodated by flattening of the edge zone of the ocular surface of the contact lens. The optic zone of the lens, where the base curve is found, covers most of the cornea.

Most soft contact lenses are spherical with small amounts of astigmatism being corrected with the equivalent sphere of the prescription. Because a hydrogel lens conforms more to the shape of the cornea than a rigid lens, higher amounts of astigmatism must be corrected with a toric lens. Maintaining the orientation of a toric lens on the eye is a challenge, since interaction of the lens with the underlying cornea, the tear layer, and the action of the lids will influence how it sits on the eye. Various methods have been used by manufacturers to stabilize lens position.

Soft lenses can be worn on a daily, disposable/frequent replacement basis. In daily wear, the lenses are worn up to 12 to 14 hours a day and removed each night. The lenses must be cleaned and disinfected before they are worn again. Cleaning with digital rubbing of the lens surfaces removes mucous deposits while disinfection eliminates infectious agents. These lenses can be worn for about 1 year. Disposable or frequent replacement lenses are worn between 1 day and several weeks on a daily basis, then discarded. They are prescribed for patients who experience rapid build-up of protein deposits or who have limited access to cleaning and sterilizing solutions. Extended wear lenses are worn up to a week at a time before being removed for cleaning and disinfection. Their higher water content and reduced thickness increase oxygen permeability but make them more susceptible to damage when handled. Extended wear lenses are usually replaced monthly.

One important advantage of hydrogel over rigid lens materials is that the lens is comfortable to wear with little or no adaptation time. Tear exchange is not as important since hydrogel transmits oxygen to the cornea. Thin lenses with high water content transmit significantly more oxygen. The lenses do not dislodge easily, making them ideal for sports activity; however, it has been reported that hydrogel lenses worn in chlorinated pool water exhibit significantly more microbial colonization than lenses that were never worn in the pool. This may increase the risk of bacterial keratitis if the lenses are worn in water sports.[25] Lenses worn in water sports should be discarded as soon as possible after the activity is finished.[26]

In the last few years, silicone hydrogel lenses have entered the market. Silicone hydrogel has very high oxygen transmissivity, but is stiffer than HEMA-based hydrogel. Initially there is more awareness of the lens in situ; however, the oxygen permeability of these lenses has largely eliminated many of the complications of earlier hydrogel lenses.

Most soft contact lenses are either clear or have a slight handling tint. Cosmetic lenses with an overall tint can be used to make light irides appear in different colors. Lenses with arrays of tinted dots can be used to change the color appearance of dark irides with varying degrees of success. Novelty tints can be used to change the appearance of the eye (e.g., slit pupils, "unnatural" pupil color); however, there is a controversy over whether such lenses should only be supplied through eye care practitioners because of serious risks to eye health.[27] Similar types of lens can be used to disguise scarred or disfigured eyes due to damage or disease.[28]

Contact Lenses for Presbyopia Presbyopia has become an important clinical problem as patients who began wearing their contact lenses in the 1970s and 1980s enter their 40s or 50s. The quality of vision and convenience of a largely spectacle-free life are compromised. Reading glasses worn over the contact lenses is a simple approach, but defeats the purpose of having contacts in the first place.

Monovision is the practice of fitting one eye for distance correction and the other for near. This approach reduces the need for spectacles, but relies on the patient's ability to suppress the vision of one or the other eye when looking at a given target. The resulting reduction of binocular vision may create more serious problems involving depth and space perception.

Bifocal contact lenses have met with varying degrees of success. Alternating vision rigid contact lenses have a segment ground into the lens. When the patient looks at a near object the lower eyelid moves the lens over the cornea to bring the segment in front of the pupil. The theory of this design is seldom found in practice.

The simultaneous vision lenses are more successful. Both the distance portion and the segment are within the pupil so that superimposed clear and blurred images of distant and near objects are seen. There is a resultant loss of clarity and contrast. A diffractive contact lens design uses concentric

rings cut into the base curve of the lens to provide a near correction while the front surface curvature provides the distance correction simultaneously.[29]

For a more detailed discussion of contact lens optics and technology, see Chap. 20.

Refractive Surgery

The desire of many ametropic patients to be free of both spectacles and contact lenses has driven the development of refractive surgery to reduce or neutralize ametropia. Earlier procedures that used incisions in the cornea to alter its shape (radial keratotomy) have since been largely abandoned due to complications including corneal perforation[30] and the possibility of rupture of the compromised cornea.[31] More recently, the excimer laser has been used in *photorefractive keratectomy* (*PRK*) and *laser in-situ keratomileusis* (*LASIK*) to reshape the cornea. These procedures are not without risks of compromised vision and complications include stromal haze, regression of refractive effect, infection, and optical and/or mechanical instability of the corneal flap in LASIK.[30] Almost all patients achieve visual acuity of at least 20/40 (6/12) and most achieve postoperative visual acuity of at least 20/20 (6/6). LASIK results in increased higher-order ocular aberrations; a new wavefront-guided LASIK procedure improves on this result.[32] A more detailed description of PRK and LASIK can be found in Chap. 16.

Extremely high myopia (over 12.00 D) may be treated by clear lens exchange in which the crystalline lens is extracted and an intraocular lens of suitable power is implanted. Phakic lens implants have also been used in either the anterior chamber or posterior chamber.

Low myopes can achieve visual acuity of better than 20/40 (6/12) when treated with intrastromal corneal rings (ICR). Circular arcs are implanted concentrically to the optical axis of the cornea in the stroma of the peripheral cornea to flatten the corneal curvature mechanically. The procedure is at least partly reversed by removal of the rings.

None of these procedures is guaranteed to result in perfect vision. All have some deleterious effect on quality of vision (glare, loss of contrast, increased higher-order aberrations[30]) and none eliminates the need for glasses for certain visually demanding tasks. As these patients become presbyopic, they will still require some form of reading prescription.

Aphakia and Pseudophakia

Cataract is the general term for a crystalline lens that loses transparency because of aging or injury. Cortical cataract is seen in the outer layers of the crystalline lens, the cortex, and may comprise general haze, punctuate or wedge shaped opacities, and bubbles. In earlier stages, cortical cataract does not greatly affect visual acuity that is measured with high contrast targets, but there may be a significant reduction of contrast sensitivity. Patients may complain of glare in bright sunlight and difficulty reading. Nuclear cataract often appears as a gradual yellowing of the core of the crystalline lens. This is thought to arise from photochemical changes in the lens crystalline proteins triggered by long-term chronic exposure to ultraviolet radiation.[33] Visual consequences include reduced color discrimination and visual acuity.

Treatment of cataract is by surgical removal of the crystalline lens. *Intracapsular cataract extraction* (*ICCE*) is the removal of the lens and its surrounding lens capsule. ICCE has been largely replaced by *extracapsular cataract extraction* (*ECCE*) in which the lens is removed, but the capsule remains in the eye. Phacoemulsification is a procedure for breaking up the lens with an ultrasonic probe to facilitate ECCE. A very small incision near the edge of the cornea is required for ECCE, whereas a much larger circumferential incision is required for ICCE. Consequently, the potential for optical and physical postoperative complications in ECCE is much smaller than for ICCE. Approximately one in three patients who undergo ECCE will experience postoperative opacification of the lens capsule. This is remedied by an in-office YAG laser capsulotomy to open a hole in the posterior capsule to restore a clear optical path to the retina.[34] An eye which has had its lens removed is described as *aphakic*.

Postsurgical Correction Since the crystalline lens contributes about one-third of the optical power of the eye (see Chap. 1), the aphakic eye requires a high plus optical correction whose approximate power is

$$F = +11.25 + 0.62\,F_{\text{old}} \tag{2}$$

where F_{old} is the preoperative equivalent spectacle correction.[35] This can be provided in the form of spectacles, contact lenses, or intraocular lens implants.

Aphakic spectacle corrections, sometimes referred to as cataract lenses, are heavy, thick, and cosmetically unattractive. They also have significant optical problems including distortion, field curvature, and oblique astigmatism that cannot be minimized using best-form principles, high magnification, and ring scotoma arising from prismatic effect in the periphery.[36] Aspheric lenses and lenticular designs can minimize some of these effects, but aphakic spectacle corrections remain problematic.

Contact lenses provide much better visual performance for aphakic patients. Cosmetic appearance is improved and most of the problems due to the aberrations and prismatic effects of spectacle lenses are eliminated. The magnification is closer to that of the phakic eye, making spatial adaptation and hand-eye coordination easier.[37] The optical advantages are somewhat offset by the difficulties of fitting these lenses due to the thick optical center and the challenge of providing sufficient oxygen to maintain corneal physiology.

Except in rare cases, most patients with clinically significant cataracts now have their natural crystalline lenses replaced with *intraocular lenses* (*IOLs*). They are described as being *pseudophakic*. In general, posterior chamber IOLs that are implanted in the lens capsule after ECCE, provide better optical performance than anterior chamber lenses that are fixed in the anterior chamber angle or clipped to the iris following ICCE. The power of the IOL is determined from the keratometric measurement of corneal curvature and the axial length of the eye, as determined by ultrasound A-scan. There are many formulas for estimating the power of the IOL. One of the most widely used, the SRK II formula is

$$P = A1 - 0.9\,K - 2.5\,L \tag{3}$$

where P is the IOL power needed for emmetropia, $A1$ is a constant that varies according to the axial length of the eye L in millimeters, and K is the keratometer reading of central corneal curvature.[38] IOLs for astigmatism and bifocal IOLs have also been produced and recently designs incorporating wavefront correction have been introduced. IOL formulas have also been developed for use with patients who have undergone LASIK.[39] A more detailed discussion of the optics and clinical considerations of IOLs is found in Chap. 21.

12.6 BINOCULAR FACTORS

Convergence and Accommodation

In most individuals the two eyes have similar refractive errors. When looking at a distant object, the amount of defocus is therefore similar in both eyes and accommodation to view a near object results in retinal images that appear similar in size and clarity. (It is assumed that both eyes will accommodate by the same amount.) The visual system has an easier task to fuse the two retinal images into a single binocular percept.

Ideally, corresponding points in the two retinal images would be fused into a single perceived image. However, binocular fusion does not require exactly matching images. When a single point in the retina of one eye is stimulated, an area of retina in the other eye surrounding the corresponding point will give rise to a single fused percept when any point in this area is stimulated. This is called *Panum's area*. The size of Panum's area varies with location in the retina. It is very small in the macula and increases toward the periphery of the retina. Disparities between the two points are used by the visual system to determine stereoscopic depth.

Control of the extraocular muscles is neurologically linked to the process of accommodation. As accommodation increases, the eyes converge so that near objects can be seen as a single binocular percept. When the patient accommodates while wearing corrective lenses, the lines of sight pass through off-axis points of the lens and prismatic effect will alter the amount of convergence needed to maintain fusion. Myopes experience less convergence demand while hyperopes experience more; the amount of this difference from the emmetropic convergence demand can be estimated for each eye using Prentice's rule:

$$P_H = xF \tag{4}$$

where P_H is the prismatic effect in *prism diopters* along the horizontal direction, x is the distance in centimeters along the horizontal meridian of the line of sight from the optical center of the lens, and F is the power of the corrective lens in the horizontal meridian.

The foregoing discussion assumes that the ametropia is spherical. If the ametropia is astigmatic, it is open to question whether accommodation is driven to focus on one or the other principal meridian or on the circle of least confusion (spherical equivalent). Most writers assume that focus is to the spherical equivalent in the interval of Sturm.

A more extensive discussion of binocular factors in found in Chap. 13.

Anisometropia and Aniseikonia

Anisometropia is considered clinically significant when the spherical equivalent refractive error of the two eyes differs by 1.00 D or more.[40] Whether corrected or uncorrected, anisometropia can lead to significant problems with binocular vision for the patient.

Uncorrected Ametropia In uncorrected ametropia, depending on the refractive errors of the two eyes and the distance of the object of regard, one retinal image or the other may be in focus, or neither, since both eyes accommodate by the same amount. If the patient is a young child, the eye that more frequently has a clear retinal image will develop normally; however, the eye that tends to have a blurred image more of the time is likely to develop *amblyopia*. This is often the case where one eye is hyperopic and the other emmetropic, or if both eyes are hyperopic but to different degrees. If one eye is myopic and the other emmetropic, the child may learn to use the myopic eye for near objects and the emmetropic one for distant objects, in which case there is no amblyopia, but binocular fusion and stereopsis may not develop normally.

Corrected Ametropia When anisometropia is corrected, accommodation brings both retinal images of a near object into focus; however, differences in prismatic effect in off-axis gaze and in retinal image size may lead to problems with binocular vision, particularly fusion. This is particularly a problem when the patient looks down to read. Although the visual system has the capacity to fuse images with substantial horizontal disparities, it is extremely limited when disparities in the vertical meridian are encountered. In downward gaze the lines of sight pass through a spectacle lens approximately 1.0 cm below the optical center. Many patients experience visual discomfort when the vertical prismatic imbalance between the eyes is about 1 prism diopter (this unit is often written as $^{\Delta}$) and vertical diplopia (double vision) when it is over 2^{Δ}. While a younger patient can avoid this problem by tipping the chin down so that the lines of sight pass through the paraxial zone of the lens in the vertical meridian, presbyopic anisometropes would need either bifocals or PALs with slab-off prism in the near portion of the lens with more minus or less plus distance power or a separate pair of single vision reading glasses.[40] Bifocal contact lenses, monovision, or reading glasses with contact lenses may avoid the problem altogether, but may cause other complications with the patient's vision.

Aniseikonia Anisometropia corrected with spectacles almost invariably results in *aniseikonia*, a condition in which binocular fusion is difficult or impossible because of the disparity in size of the retinal or cortical images from the two eyes.

The spectacle magnification M of a spectacle lens is given by the formula

$$M = \frac{1}{1 - d_v F} \frac{1}{1 - \frac{t}{n} F_1} \tag{5}$$

where d_v is the distance between the back vertex of the spectacle lens and the cornea, F is the back vertex power of the lens, t is the axial thickness of the lens, n its refractive index, and F_1 its front surface power. The first factor is the power factor, the magnification due to a thin lens of power F at distance d_v in front of the cornea and the second is the shape factor, the magnification due to an afocal lens with front surface power F_1, index n, and thickness t. For thin lenses the equation can be written as

$$M = 1 + d_v F + \frac{t}{n} F_1 \tag{6}$$

using a thin lens approximation.[41]

Aniseikonia can be measured with a space eikonometer or estimated from the refractive error. The percentage difference in image size is between 1 and 1.5 percent per diopter of anisometropia and can be attributed to differences in refractive power of the eyes rather than axial length. When relative spectacle magnification is calculated on the basis of axial versus refractive ametropia, aniseikonia must arise from differences between the eyes in refractive ametropia. Size lenses, afocal lenses with magnification, can be used to determine the amount of change in spectacle magnification of the corrective lenses needed to neutralize the aniseikonia. The spectacle magnification formula can then be used to calculate the new lens parameters needed to modify the shape factor of the lens.[41]

Aniseikonia is relatively rare; however, cataract surgery and corneal refractive surgery often induces it particularly when only one eye is operated. Clinicians require more understanding of this clinical phenomenon than is assumed in their training. The reader is referred to Remole and Robertson's book on this subject[42] as well as the Web site www.opticaldiagnostics.com/info/aniseikonia.html[43] for further information.

12.7 CONSEQUENCES FOR OPTICAL DESIGN

Designers of optical equipment must take into account that many potential users of their devices will have ametropia, either corrected or uncorrected, and perhaps presbyopia as well. While each refractive condition has its challenges, the combination can make for a great deal of discomfort and inconvenience when using optical equipment. For example, digital point-and-shoot cameras have LCD panels to display images as well as control menus and exposure information. The panel is also used to aim the camera. Most users will hold the device approximately 40 cm from the eyes—viewing the display is uncomfortable and difficult, particularly if the user is wearing bifocal or PAL spectacles. It is also important to determine whether the device is to be used monocularly or binocularly. In the latter case, the optical design must allow for convergence of the eyes and the possible change in convergence demand if the user has to accommodate. A further complication is the size of the exit pupil of the device: as patients age, their pupil size decreases and results in vignetting of the exit beam. Human visual performance factors must be considered carefully in the design of future optical devices.

BINOCULAR VISION FACTORS THAT INFLUENCE OPTICAL DESIGN

Clifton Schor

School of Optometry
University of California
Berkeley, California

13.1 GLOSSARY

Accommodation. Change in focal length or optical power of the eye produced by change in power of the crystalline lens as a result of contraction of the ciliary muscle. This capability decreases with age.

Ametrope. An eye with a refractive error.

Aniseikonia. Unequal perceived image sizes from the two eyes.

Baseline. Line intersecting the entrance pupils of the two eyes.

Binocular disparity. Differences in the perspective views of the two eyes.

Binocular fusion. Act or process of integrating percepts of retinal images formed in the two eyes into a single combined percept.

Binocular parallax. Angle subtended by an object point at the nodal points of the two eyes.

Binocular rivalry. Temporal alternation of perception of portions of each eye's visual field when the eyes are stimulated simultaneously with targets composed of dissimilar colors or different contour orientations.

Center of rotation. A pivot point within the eye about which the eye rotates to change direction of gaze.

Concomitant. Equal amplitude synchronous motion or rotation of the two eyes in the same direction.

Conjugate. Simultaneous motion or rotation of the two eyes in the same direction.

Convergence. Inward rotation of the two eyes.

Corresponding retinal points. Regions of the two eyes, which when stimulated result in identical perceived visual directions.

Cyclopean eye. A descriptive term used to symbolize the combined view points of the two eyes into a single location midway between them.

Cyclovergence. Unequal torsion of the two eyes.

Disconjugate. Simultaneous motion or rotation of the two eyes in opposite directions.

Divergence. Outward rotation of the two eyes.

Egocenter. Directional reference point for judging direction relative to the head from a point midway between the two eyes.

Emmetrope. An eye with no refractive error.

Entrance pupil. The image of the aperture stop formed by the portion of an optical system on the object side of the stop. The eye pupil is the aperture stop of the eye.

Extraretinal cues. Nonvisual information used in space perception.

Eye movement. A rotation of the eye about its center of rotation.

Fixation. The alignment of the fovea with an object of interest.

Focus of Expansion. The origin of velocity vectors in the optic flow field.

Frontoparallel plane. Plane that is parallel to the face and orthogonal to the primary position of gaze.

Haplopia. Perception of a single target by the two eyes.

Heterophoria. Synonymous with phoria.

Horopter. Locus of points in space whose images are formed on corresponding points of the two retinas.

Hyperopia. An optical error of the eye in which objects at infinity are imaged behind the retinal surface while the accommodative response is zero.

Midsagittal plane. Plane that is perpendicular to and bisects the baseline. The plane vertically bisecting the midline of the body.

Motion parallax. Apparent relative displacement or motion of one object or texture with respect to another that is usually produced by two successive views by a moving observer of stationary objects at different distances.

Myopia. An optical error of the eye in which objects at infinity are imaged in front of the retinal surface while the accommodative response is zero.

Nonconcomitant. Unequal amplitudes of synchronous motion or rotation of the two eyes in the same direction.

Optic flow. Pattern of retinal image movement.

Percept. That which is perceived.

Perception. The act of awareness through the senses, such as vision.

Perspective. Variations of perceived size, separation, and orientation of objects in 3-D space from a particular viewing distance and vantage point.

Phoria. An error of binocular alignment revealed when one eye is occluded.

Primary position of gaze. Position of the eye when the visual axis is directed straight ahead and is perpendicular to the frontoparallel plane.

Retinal disparity. Difference in the angles formed by two targets with the entrance pupils of the eyes.

Shear. Differential displacement during motion parallax of texture elements along an axis perpendicular to meridian of motion.

Skew movement. A vertical vergence or vertical movement of the two eyes in opposite directions.

Stereopsis. The perception of depth stimulated by binocular disparity.

Strabismus. An eye turn or misalignment of the two eyes during attempted binocular fixation.

Tilt. Amount of angular rotation in depth about an axis in the frontoparallel plane—synonymous with orientation.

Torsion. Rotation of the eye around the visual axis.

Vantage point. Position in space of the entrance pupil through which 3-D space is transformed by an optical system with a 2-D image or view plane.

Visual field. The angular region of space or field of view limited by the entrance pupil of the eye, the zone of functional retina, and occlusion structures such as the nose and orbit of the eye.

Visual plane. Any plane containing the fixation point and entrance pupils of the two eyes.

Yoked movements. Simultaneous movement or rotation of the two eyes in the same direction.

13.2 COMBINING THE IMAGES IN THE TWO EYES INTO ONE PERCEPTION OF THE VISUAL FIELD

The Visual Field

Optical designs that are intended to enhance vision usually need to consider limitations imposed by having two eyes and the visual functions that are made possible by binocular vision. When developing an optical design it is important to tailor it to specific binocular functions that you wish to enhance or at least not limit binocular vision. Binocular vision enhances visual perception in several ways. First and foremost, it expands the visual field.[1] The horizontal extent of the visual field depends largely on the placement and orientation of eyes in the head. Animals with laterally placed eyes have panoramic vision that gives them a full 360° of viewing angle. The forward placement of our eyes reduces the visual field to 190°. Eye movements let us expand our field of view. The forward placement of the eyes adds a large region of binocular overlap so that we can achieve another binocular function, stereoscopic depth perception. The region of binocular overlap is 114° and the remaining monocular portion is 37° for each eye. Each eye sees slightly more of the temporal than nasal-visual field and they also see more of the ipsilateral than the contralateral side of a binocularly viewed object.

Visual perception is not uniform throughout this region. The fovea or central region of the retina is specialized to allow us to resolve fine detail in the central 5° of the visual field. Eye movements expand the regions of available space. They allow expansion of the zone of high resolution, and accommodation expands the range of distances within which we can have high acuity and clear vision from viewing distances ranging from as near as 5 cm in the very young to optical infinity.[2] The peripheral retina is specialized to aid us in locomotor tasks such as walking so that we can navigate safely without colliding with obstacles. It is important that optical designs allow users to retain the necessary visual to perform tasks aided by the optical device.

Perceived Space

Space perception includes our perception of direction, distance, orientation, and shape of objects; object trajectories with respect to our location; sensing body orientation, location, and motion in space; and heading. These percepts can be derived from a 2-D image projection on the two retinas of a 3-D object space. Reconstruction of a 3-D percept from a 2-D image requires the use of information within the retinal image that is geometrically constrained by the 3-D nature of space. Three primary sources of visual or vision-related information are used for this purpose and they include monocular information, binocular information, and extraretinal or motor information. Monocular visual or retinal cues include familiarity with size and shape of objects, linear perspective and shape distortions, texture density, shading, partial image occlusion or overlap, size expansion and optic flow patterns, and motion parallax.[3] Binocular information is also available, including stereoscopic depth sensed from combinations of horizontal and vertical disparity, and motion in depth.[4] Extraretinal cues include accommodation, convergence, and gaze direction of the eyes. Many of these cues are redundant and provide ways to check their consistency, and to sense their errors that can be corrected by adaptably reweighting their emphasis or contribution to the final 3-D percept.

Monocular Cues Static monocular cues include familiarity with size and shape of objects, linear perspective and shape distortions, texture density, partial image occlusion or overlap.[3] Linear perspective refers to the distortions of the retinal image that result from the projection or imaging of a 3-D object located at a finite viewing distance onto a 2-D surface such as the retina. Texture refers to a repetitive pattern of uniform size and shape such as a gravel bed. Familiarity with the size and shape of a target allows us to sense its distance and orientation. As targets approach us and change their orientation, even though the retinal image expands and changes shape, the target appears to maintain a constant perceived size and rigid shape. Retinal image shape changes are interpreted as changes in object orientation produced by rotations about three axes. Texture density can indicate which axes the object is rotated about. Rotation about the vertical axis produces tilt and causes a compression of texture along

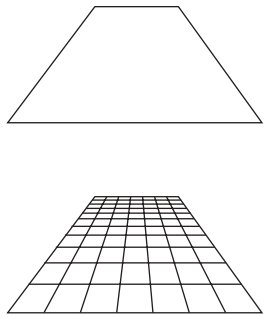

FIGURE 1 When the edges of an object are parallel, they meet at a point in the retinal image plane called the vanishing point.

the horizontal axis. Rotation about the horizontal axis produces slant and it causes a compression of texture along the vertical axis. Rotation about the *z* axis produces roll or torsion and causes a constant change in orientation of all texture elements. Combinations of these rotations cause distortions or foreshortening of images; however, if the distortions are decomposed into three rotations, the orientation of rigid objects can be computed. The gradient of compressed texture varies inversely with target distance. If viewing distance is known, the texture density gradient is a strong cue to the amount of slant about a given axis.

Perspective cues arising from combinations of observer's view point, object distance, and orientation can contribute to perception of distance and orientation. Perspective cues utilize edge information that is extrapolated until it intersects another extrapolated edge of the same target (Fig. 1).[5] When the edges of an object are parallel, they meet at a point in the retinal image plane called the vanishing point. Normally we do not perceive the vanishing point directly, and it needs to be derived by extrapolation. It is assumed that the line of sight directed at the vanishing point is parallel to the edges of the surface such as a roadway that extrapolates to the same vanishing point. As with texture density gradients, perspective distortion of the retinal image increases with object proximity. If the viewing distance is known, the amount of perspective distortion is an indicator of the amount of slant or tilt about a given axis.

Depth ordering can be computed from image overlap. This is a very powerful cue and can override any of the other depth cues, including binocular disparity. A binocular version of form overlap is called DaVinci stereopsis where the overlap is compared between the two eyes' views.[6] Because of their lateral separation, each eye sees a slightly different view of 3-D objects. Each eye perceives more of the ipsilateral side of the object than the contralateral side. Thus for a given eye, less of the background is occluded by a near object on the ipsilateral than the contralateral side. This binocular discrepancy is sufficient to provide a strong sense of depth in the absence of binocular parallax.

Kinetic Cues Kinetic monocular motion cues include size expansion, optic flow patterns, and motion parallax. Distance of targets that we approach becomes apparent from the increased velocity of radial flow of the retina (loom).[7] Motion of texture elements across the whole image contributes to our perception of shape and location of objects in space. The relative motion of texture elements in the visual field is referred to as optic flow and this flow field can be used to segregate the image into objects at different depth planes as well as to perceive the shape or form of an object. Motion parallax is the shear of optic flow in opposite directions resulting from the translation of our view point.[8] Movies that pan the horizon yield a strong sense of 3-D depth from the motion parallax they produce between near and far parts of 3-D objects. Two sequential views resulting from a lateral shift in the viewpoint (motion parallax) are analogous to two separate and simultaneous views from two eyes with separate viewpoints (binocular disparity). Unlike horizontal disparity, the shear

between sequential views by itself is ambiguous, but once we know which way our head is translating, we can correctly identify the direction or sign of depth.[9] The advantage of motion parallax over binocular disparity is that we can translate in any meridian, horizontal or vertical, and get depth information, while stereo only works for horizontal disparities.[8]

Motion perception helps us to determine where we are in space over time. Probably the most obvious application is to navigation and heading judgments (Fig. 2). Where are we headed, and can

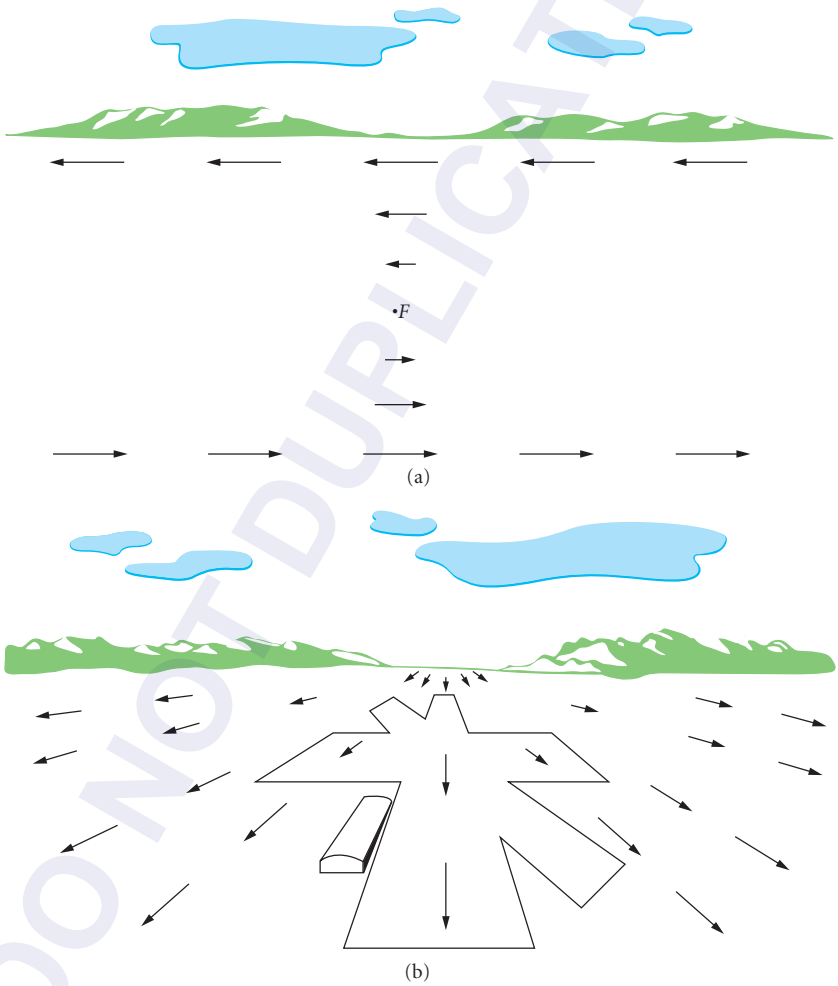

FIGURE 2 (*a*) Motion Parallax. Assume that an observer moving toward the left fixates a point at *F*. Objects nearer than *F* will appear to move in a direction opposite to that of the movement of the observer; objects farther away than *F* will appear to move in the same direction as the observer. The length of the arrows signifies that the apparent velocity of the optic flow is directly related to the distance of objects from the fixation point. (*b*) Motion perspective. The optical flow in the visual field as an observer moves forward. The view is that as seen from an airplane in level flight. The direction of apparent movement in the terrain below is signified by the direction of the motion vectors (arrows); speed of apparent motion is indicated by the length of the motion vectors. The expansion point in the distance from which motion vectors originate is the heading direction.

we navigate to a certain point in space? Generally we perceive a focus of expansion in the direction we are heading as long as our eyes and head remain fixed.[7,10–13] These types of judgments occur whenever we walk, ride a bicycle, or operate a car. Navigation also involves tasks to intercept or avoid moving objects. For example, you might want to steer your car around another car or avoid a pedestrian walking across the crosswalk. Or you may want to intercept something such as catching or striking a ball. Another navigation task is anticipation of time of arrival or contact. This activity is essential when pulling up to a stop sign or traffic light. If you stop too late you enter the intersection and risk a collision. These judgments are also made while walking down or running up a flight of stairs. Precise knowledge of time to contact is essential to keep from stumbling. Time to contact can be estimated from the distance to contact divided by the speed of approach. It can also be estimated from the angular subtence of an object divided by its rate of expansion.[14] The task is optimal when looking at a surface that is in the frontoparallel plane, and generally we are very good at it. It looks like we use the rate of expansion to predict time of contact since we make unreliable judgments of our own velocity.[15]

Another class of motion perception is self- or ego-motion.[16] It is related to the vestibular sense of motion and balance and it tells us when we are moving. Self-motion responds to vestibular stimulation as well as visual motion produced by translational and rotational optic flow of large fields. Finally, we can use binocular motion information to judge the trajectory of a moving object and determine if it will strike us in the head or not. This motion in depth results from a comparison of the motion in one eye to the other. The visual system computes the direction of motion from the amplitude ratio and relative direction of horizontal retinal image motion (Fig. 3).[17] If horizontal motion in the two

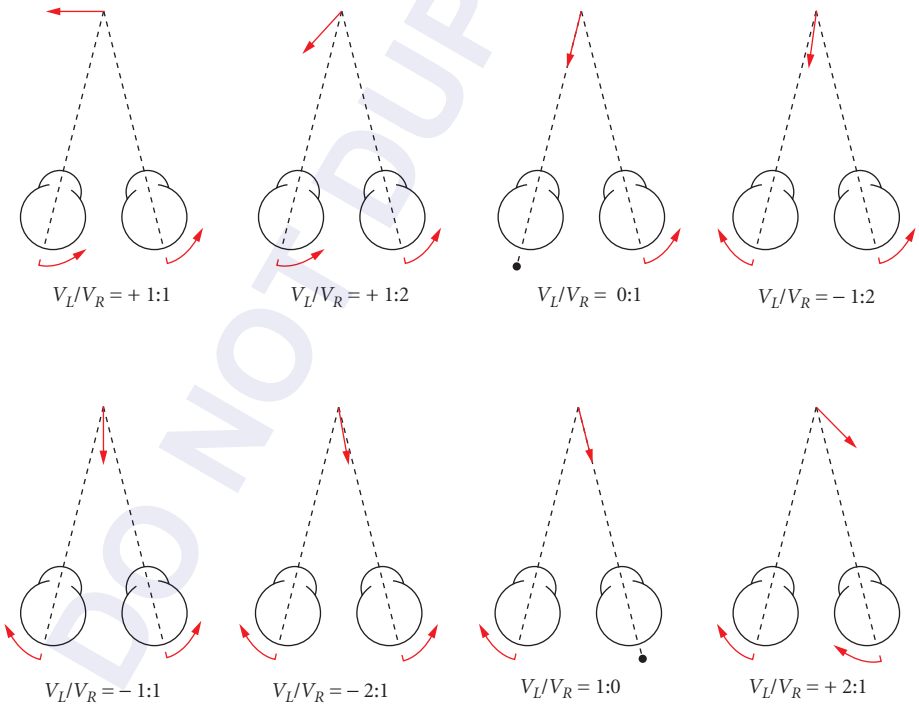

FIGURE 3 Motion in depth. Relative velocities of left and right retinal images for different target trajectories. When the target moves along a line passing between the eyes, its retinal images move in opposite directions in the two eyes; when the target moves along a line passing wide of the head, the retinal images move in the same direction, but with different velocities. The ratio (V_l/V_r) of left- and right-eye image velocities provides an unequivocal indication of the direction of motion in depth relative to the head.

eyes is equal in amplitude and direction, it corresponds to an object moving in the frontoparallel plane. If the horizontal retinal image motion is equal and opposite, the object is moving toward us in the midsagittal plane and will strike us between the eyes. If the motion has any disconjugacy at all, it will strike us. A miss is indicated by yoked, albeit noncomitant, motion.

Binocular Cues and Extraretinal Information from Eye Movements Under binocular viewing conditions, we perceive a single view of the world as though seen by a single cyclopean eye, even though the two eyes receive slightly different retinal images. The binocular percept is the average of monocularly sensed shapes and directions (allelotropia). The benefit of this binocular combination is to allow us to sense objects as single with small amounts of binocular disparity so that we can interpret depth from the stereoscopic sense. Interpretation of the effects of prism and magnification upon perceived direction through an instrument needs to consider how the visual directions of the two eyes are combined. If we only had one eye, direction could be judged from the nodal point of the eye, a site where viewing angle in space equals visual angle in the eye, assuming the nodal point is close to the radial center of the retina. However, two eyes present a problem for a system that operates as though it has only a single cyclopean eye. The two eyes have view points separated by approximately 6.5 cm. When the two eyes converge accurately on a near target placed along the midsagittal plane, the target appears straight ahead of the nose, even when one eye is occluded. In order for perceived egocentric direction to be the same when either eye views the near target monocularly, there needs to be a common reference point for judging direction. This reference point is called the cyclopean locus or egocenter, and is located midway on the interocular axis. The egocenter is the percept of a reference point for judging visual direction with either eye alone or under binocular viewing conditions.

Perceived Direction

Direction and distance can be described in polar coordinates as the angle and magnitude of a vector originating at the egocenter. For targets imaged on corresponding retinal points, this vector is determined by the location of the retinal image and by the direction of gaze that is determined by the average position of the two eyes (conjugate eye position). The angle the two retinal images form with the visual axes is added to the conjugate rotational vector component of binocular eye position (the average of right- and left-eye position). This combination yields the perceived egocentric direction. Convergence of the eyes, which results from disconjugate eye movements, has no influence on perceived egocentric direction. Thus, when the two eyes fixate near objects to the left or right of the midline in asymmetric convergence, only the conjugate component of the two eyes' positions contributes to perceived direction. These facets of egocentric direction were summarized by Hering[18] as five laws of visual direction, and they have been restated by Howard.[19] The laws are mainly concerned with targets imaged on corresponding retinal regions (i.e., targets on the horopter).

We perceive space with two eyes as though they were merged into a single cyclopean eye. This merger is made possible by a sensory linkage between the two eyes that is facilitated by the anatomical superposition or combination of homologous regions of the two retinas in the visual cortex. The binocular overlap of the visual fields is very specific. Unique pairs of retinal regions in the two eyes (corresponding points) must receive images of the same object so that these objects can be perceived as single and at the same depth as the point of fixation. This requires that retinal images must be precisely aligned by the oculomotor system with corresponding retinal regions in the two eyes. As described in Sec. 13.8, binocular alignment is achieved by yoked movements of the eyes in the same direction (version) and by movements of the eyes in opposite direction (vergence). Slight misalignment of similar images from corresponding points is interpreted as depth. Three-dimensional space can be derived geometrically by comparing the small differences between the two retinal images that result from the slightly different vantage points of the two eyes caused by their 6.5-cm separation. These disparities are described as horizontal, vertical, and torsional as well as distortion or shear differences between the two images. The disparities result from surface shape,

depth, and orientation with respect to the observer as well as direction and orientation (torsion) of the observer's eyes.[20] These disparities are used to judge the layout of 3-D space and to sense the solidness or curvature of surfaces. Disparities are also used to break through camouflage in images such as seen in tree foliage.

Binocular Visual Direction—Corresponding Retinal Points and the Horopter Hering[18] defined binocular correspondence by retinal locations in the two eyes, which when stimulated, resulted in a percept in identical visual directions. For a fixed angle of convergence, projections of corresponding points along the equator and midline of the eye converge upon real points in space. In other cases, such as oblique eccentric locations of the retina, corresponding points have visual directions that do not intersect in real space. The horopter is the locus in space of real objects or points whose images can be formed on corresponding retinal points. It serves as a reference throughout the visual field for the same depth or disparity as at the fixation point. To appreciate the shape of the horopter, consider a theoretical case in which corresponding points are defined as homologous locations on the two retinas. Thus corresponding points are equidistant from their respective foveas. Consider binocular matches between the horizontal meridians or equators of the two retinas. Under this circumstance, the visual directions of corresponding points intersect in space at real points that define the longitudinal horopter. This theoretical horopter is a circle whose points will be imaged at equal eccentricities from the two foveas on corresponding points except for the small arc of the circle that lies between the two eyes.[22] While the theoretical horopter is always a circle, its radius of curvature increases with viewing distance. This means that its curvature decreases as viewing distance increases. In the limit, the theoretical horopter is a straight line at infinity that is parallel to the interocular axis. Thus a surface representing zero disparity has many different shapes depending on the viewing distance. The consequence of this spatial variation in horopter curvature is that the spatial pattern of horizontal disparities is insufficient information to specify depth magnitude or even depth ordering or surface shape. It is essential to know viewing distance to interpret surface shape and orientation from depth related retinal image disparity. Viewing distance could be obtained from extraretinal information such as the convergence state of the eyes, or from retinal information in the form of vertical disparity as described further.

The empirical or measured horopter differs from the theoretical horopter in two ways.[22] It can be tilted about a vertical axis and its curvature can be flatter or steeper than the Vieth-Muller circle. This is a circle that passes through the fixation point in the midsagittal plane and the entrance pupils of the two eyes. Points along this circle are imaged at equal retinal eccentricities from the foveas of the two eyes. The tilt of the empirical horopter can be the result of a horizontal magnification of the retinal image in one eye. Image points of a frontoparallel surface subtend larger angles in the magnified images. A similar effect occurs when no magnifier is worn and the fixation plane is tilted toward one eye. The tilt causes a larger image to be formed in one eye than the other. Thus magnification of a horizontal row of vertical rods in the frontoparallel plane causes the plane of the rods to appear tilted to face the eye with the magnifier.

How does the visual system distinguish between a surface fixated in eccentric gaze that is in the frontoparallel plane (parallel to the face), but tilted with respect to the Vieth-Muller circle, and a plane fixated in forward gaze, that is tilted toward one eye? Both of these planes project identical patterns of horizontal retinal image disparity, but they have very different physical tilts in space. In order to distinguish between them, the visual system needs to know the horizontal gaze eccentricity. One way is to register the extraretinal eye position signal, and the other is to compute gaze eccentricity from the vertical disparity gradient associated with eccentrically located targets. It appears that the latter method is possible, since tilt of a frontoparallel plane can be induced by a vertical magnifier before one eye (the induced effect). The effect is opposite to the tilt produced by placing a horizontal magnifier before the same eye (the geometric effect). If both a horizontal and vertical magnifier are placed before one eye, in the form of an overall magnifier, no tilt of the plane occurs. Interestingly, in eccentric gaze, the proximity to one eye causes an overall magnification of the image in the nearer eye, and this could be sufficient to allow observers to make accurate frontoparallel settings in eccentric gaze (Fig. 4). Comparison of vertical and horizontal magnification seems to be sufficient to disambiguate tilt from eccentric viewing.

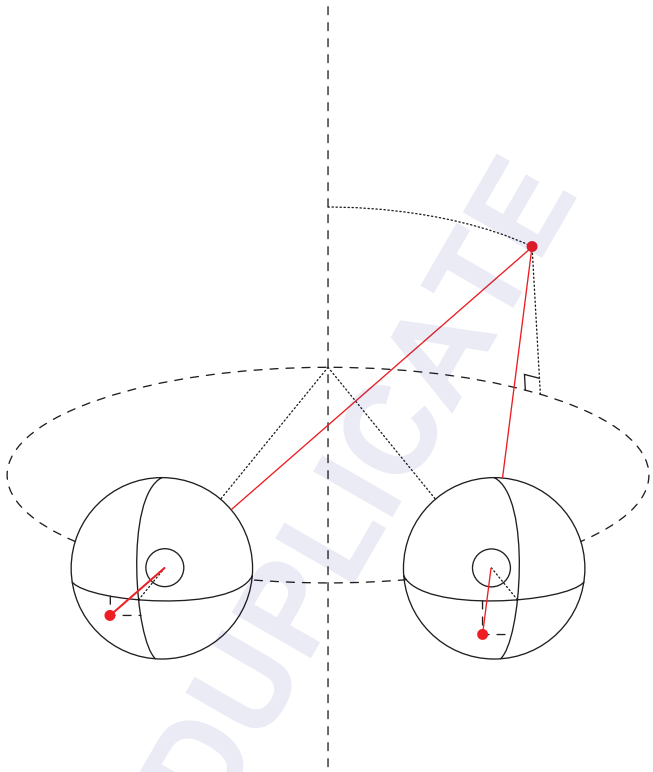

FIGURE 4 The horopter. The theoretical horopter or Vieth-Muller circle passes through the fixation point and two entrance pupils of the eyes. The theoretical vertical horopter is a vertical line passing through the fixation point in the midsagittal plane. Fixation on a tertiary point in space produces vertical disparities because of greater proximity to the ipsilateral eye. (*Reprinted by permission from Tyler and Scott.*[21])

Flattening of the horopter from a circle to an ellipse results from nonuniform magnification of one retinal image. If the empirical horopter is flatter than the theoretical horopter, corresponding retinal points are more distant from the fovea on the nasal than temporal hemiretina. Curvature changes in the horopter can be produced with nonuniform magnifiers such as prisms (Fig. 5). A prism magnifies more at its apex than its base. If base-out prism is placed before the two eyes, the right half of the image is magnified more in the left eye than in the right eye and the left half of the image is magnified more in the right eye than in the left eye. This causes flat surfaces to appear more concave and the horopter to be less curved or more convex.

The Vertical Horopter The theoretical vertical point horopter for a finite viewing distance is limited by the locus of points in space where visual directions from corresponding points will intersect real objects.[21] These points are described by a vertical line in the midsagittal plane that passes through the Vieth-Muller circle. Eccentric object points in tertiary gaze (points with both azimuth and elevation) lie closer to one eye than the other eye. Because they are imaged at different vertical eccentricities from the two foveas, tertiary object points cannot be imaged on theoretically corresponding retinal points. However, all object points at an infinite viewing distance can be imaged on corresponding retinal regions and at this infinite viewing distance, the vertical horopter becomes a plane.

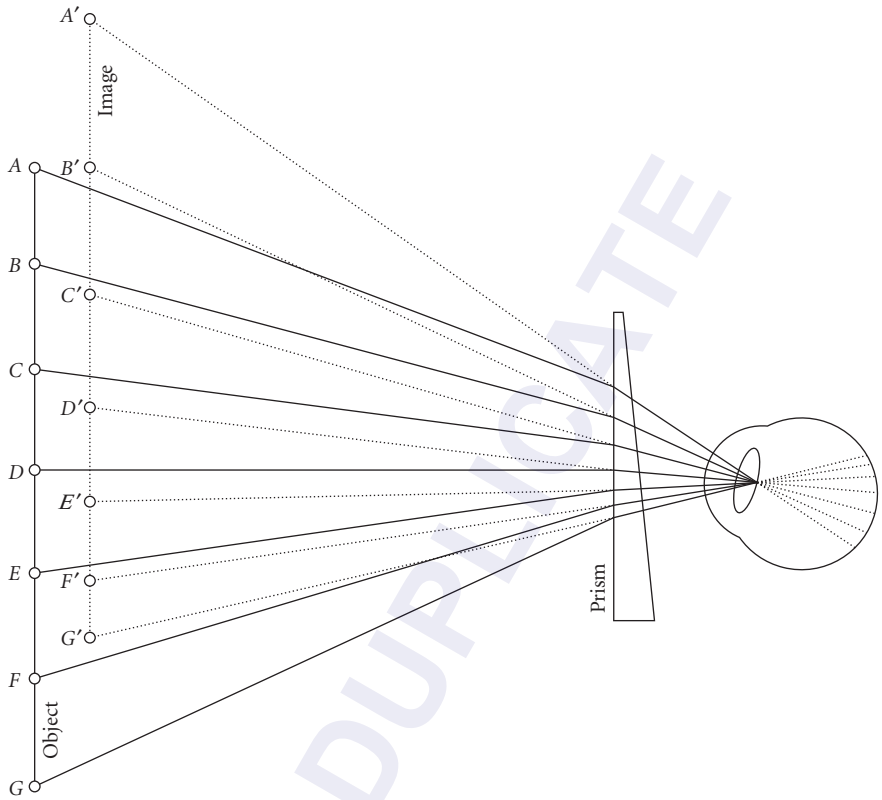

FIGURE 5 Figure showing nonuniform magnification of a prism. Disparateness of retinal images, producing stereopsis.

The empirical vertical horopter is declinated (top slanted away from the observer) in comparison to the theoretical horopter. Helmholtz[23] reasoned that this was because of a horizontal shear of the two retinal images which causes a real vertical plane to appear inclinated toward the observer. Optical infinity is the only viewing distance that the vertical horopter becomes a plane. It is always a vertical line at finite viewing distances. Targets that lie away from the midsagittal plane always subtend a vertical disparity due to their unequal proximity and retinal image magnification in the two eyes. The pattern of vertical disparity varies systematically with viewing distance and eccentricity from the midsagittal plane. For a given target height, vertical disparity increases with horizontal eccentricity from the midsagittal plane and decreases with viewing distance. Thus a horizontally extended target of constant height will produce a vertical disparity gradient that increases with eccentricity. The gradient will be greater at near than far viewing distances. It is possible to estimate viewing distance from the vertical disparity gradient or from vertical disparity at a given point if target eccentricity is known. This could provide a retinal source of information about viewing distance to allow the visual system to scale disparity to depth and to compute depth ordering. Several investigators have shown that modifying vertical disparity can influence the magnitude of depth (scaling) and surface slant, such that vertical disparity is a useful source of information about viewing distance that can be used to scale disparity and determine depth ordering.

Stereopsis

Three independent variables involved in the calculation of stereodepth are retinal image disparity, viewing distance, and the separation in space of the two viewpoints (i.e., the baseline or interpupillary distance) (Fig. 6). In stereopsis, the relationship between the linear depth interval between two objects and the retinal image disparity that they subtend is approximated by the following expression

$$\Delta d = \frac{\eta \times d^2}{2a}$$

where η is retinal image disparity in radians, d is viewing distance, $2a$ is the interpupillary distance and Δd is the linear depth interval. $2a$, d, and Δd are all expressed in the same units (e.g., meters). The formula implies that in order to perceive depth in units of absolute distance (e.g., meters), the visual system utilizes information about the interpupillary distance and the viewing distance. Viewing distance could be sensed from the angle of convergence[24] or from other retinal cues such as oblique or vertical disparities. These disparities occur naturally with targets in tertiary directions from the point of fixation.[25–30]

The equation illustrates that for a fixed retinal image disparity, the corresponding linear depth interval increases with the square of viewing distance and that viewing distance is used to scale the

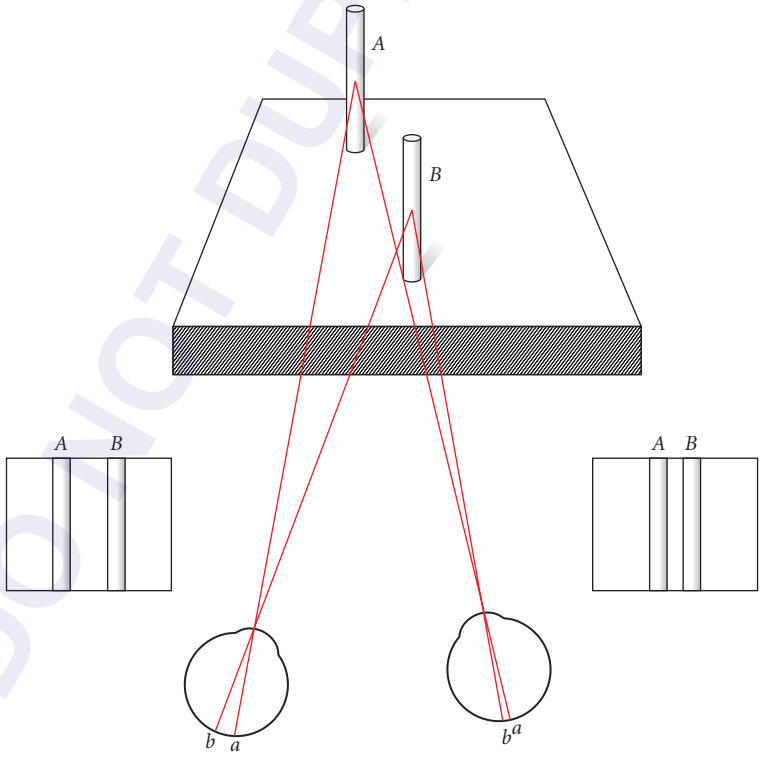

FIGURE 6 The differences in the perspective views of the two eyes produce binocular that can be used to perceive depth.

horizontal disparity into a linear depth interval. When objects are viewed through base-out prisms that stimulate additional convergence, perceived depth should be reduced by underestimates of viewing distance. Furthermore, the pattern of zero retinal image disparities described by the curvature of the longitudinal horopter varies with viewing distance. It can be concave at near distances and convex at far distances in the same observer.[22] Thus, without distance information, the pattern of retinal image disparities across the visual field is insufficient to sense either depth ordering (surface curvature) or depth magnitude.[25] Similarly, the same pattern of horizontal disparity can correspond to different slants about a vertical axis presented at various horizontal gaze eccentricities.[22] Convergence distance and direction of gaze are important sources of information used to interpret slant from disparity fields associated with slanting surfaces.[31] Clearly, stereodepth perception is much more than a disparity map of the visual field.

Binocular Fusion and Suppression

Even though there is a fairly precise point-to-point correspondence between the two eyes for determining depth in the fixation plane, images in the two eyes can be combined into a single percept when they are anywhere within a small range or retinal area around corresponding retinal points. Thus a point in one eye can be combined perceptually with a point imaged within a small area around its corresponding retinal location in the other eye. These ranges are referred to as Panum's fusional area (PFA) and they serve as a buffer zone to eliminate diplopia for small disparities near the horopter. PFA allows for the persistence of single binocular vision in the presence of constant changes in retinal image disparity caused by various oculomotor disturbances. For example, considerable errors of binocular alignment (>15 arc min) may occur during eye tracking of dynamic depth produced either by object motion or by head and body movements.[32] Stereopsis could exist without singleness but the double images near the fixation plane would be a distraction. The depth of focus of the human eye serves a similar function. Objects that are nearly conjugate to the retina appear as clear as objects focused precisely on the retina. The buffer for the optics of the eye is much larger than the buffer for binocular fusion. The depth of focus of the eye is approximately 0.75 D. Panum's area, expressed in equivalent units, is only 0.08 meter angles or approximately one tenth the magnitude of the depth of focus. Thus we are more tolerant of focus errors than we are of convergence errors.

Fusion is only possible when images have similar size, shape, and contrast polarity. This similarity ensures that we only combine images that belong to the same object in space. Natural scenes contain many objects that are at a wide range of distances from the plane of fixation. Some information is coherent, such as images formed within Panum's fusional areas. Some information is fragmented, such as partially occluded regions of space resulting in visibility to only one eye. Finally, some information is uncorrelated because it is either ambiguous or in conflict with other information, such as the superposition of separate diplopic images arising from objects seen by both eyes behind or in front of the plane of fixation. One objective of the visual system is to preserve as much information from all three sources as possible to make inferences about objective space without introducing ambiguity or confusion of space perception. In some circumstances conflicts between the two eyes are so great that conflicting percepts are seen alternately every 4 s (binocular rivalry suppression) or in some cases one image is permanently suppressed such as when you look through a telescope with one eye while the other remains open. The view through the telescope tends to dominate over the view of the background seen by the other eye. For example, the two ocular images may have unequal clarity or blur such as in asymmetric convergence, or large unfusable disparities originating from targets behind or in front of the fixation plane may appear overlapped with other large diplopic images. Fortunately, when dissimilar images are formed within a fusable range of disparity that perception of the conflicting images is suppressed.

Four classes of stimuli evoke what appear to be different mechanisms of interocular suppression. The first is unequal contrast or blur of the two retinal images which causes interocular blur suppression. The second is physiologically diplopic images of targets in front or behind the singleness horopter which result in suspension of one of the redundant images.[33] The third is targets of different shape

presented in identical visual directions. Different size and shape result an alternating appearance of the two images referred to as either binocular retinal rivalry or percept rivalry suppression. The fourth is partial occlusion that obstructs the view of one eye such that the portions of the background are only seen by the unoccluded eye and the overlapping region of the occluder that is imaged in the other eye is permanently suppressed.

13.3 DISTORTION OF SPACE BY MONOCULAR MAGNIFICATION

The magnification and translation of images caused by optical aids will distort certain cues used for space perception while leaving other cues unaffected. This will result in cue misrepresentation of space as well as cue conflicts that will produce errors of several features of space perception. These include percepts of direction, distance, trajectory or path of external moving targets, heading and self-motion estimates, as well as shape and orientation (curvature, slant, and tilt) of external objects. Fortunately, if the optical distortions are long standing, the visual system can adapt and make corrections to their contributions to space perception.

Magnification and Perspective Distortion

Most optical systems magnify or minify images, and this can produce errors in perceived direction. When objects are viewed through a point other than the optical center of a lens, they appear displaced from their true direction. This is referred to as a prismatic displacement. Magnification will influence most of the monocular cues mentioned above except overlap. Magnification will produce errors in perceived distance and produce conflicts with cues of texture density and linear perspective. For example, the retinal image of a circle lying on a horizontal ground plane has an elliptical shape when viewed at a remote distance, and a more circular shape when viewed from a shorter distance. When a remote circle is viewed through a telescope, the uniformly magnified image appears to be closer and squashed in the vertical direction to form an ellipse (shape distortion). Uniform magnification also distorts texture-spacing gradients such that the ground plane containing the texture is perceived as inclined or tilted upward toward vertical. Normally, the change in texture gradient is greatest for near objects (Fig. 7). When a distant object is magnified, it appears nearer but its low texture density gradient is consistent with a plane inclined toward the vertical. Magnification also affects slant derived from perspective cues in the same way. For this reason, a tiled rooftop appears to have a steeper pitch when viewed through binoculars or a telescope, the pitcher-to-batter distance appears reduced in telephoto view from the outfield, and the spectators may appear larger than the players in front of them in telephoto lens shots.

Magnification and Stereopsis

Magnification increases both retinal image disparity and image size. The increased disparity stimulates greater stereo depth while increased size stimulates reduced perceived viewing distance.[34] Greater disparity will increase perceived depth while reduced perceived viewing distance will scale depth to a smaller value. Because stereoscopic depth from disparity varies with the square of viewing distance, the perceptual reduction of viewing distance will dominate the influence of magnification on stereoscopic depth. Thus, perceived depth intervals sensed stereoscopically from retinal image disparity appears smaller with magnified images because depth derived from binocular retinal image disparity is scaled by the square of perceived viewing distance. Objects appear as flat surfaces with relative depth but without thickness. This perceptual distortion is referred to as cardboarding. Most binocular optical systems compensate for this reduction in stereopsis by increasing the baseline or separation of the two ocular objectives. For example, the prism design of binoculars folds the optical path into

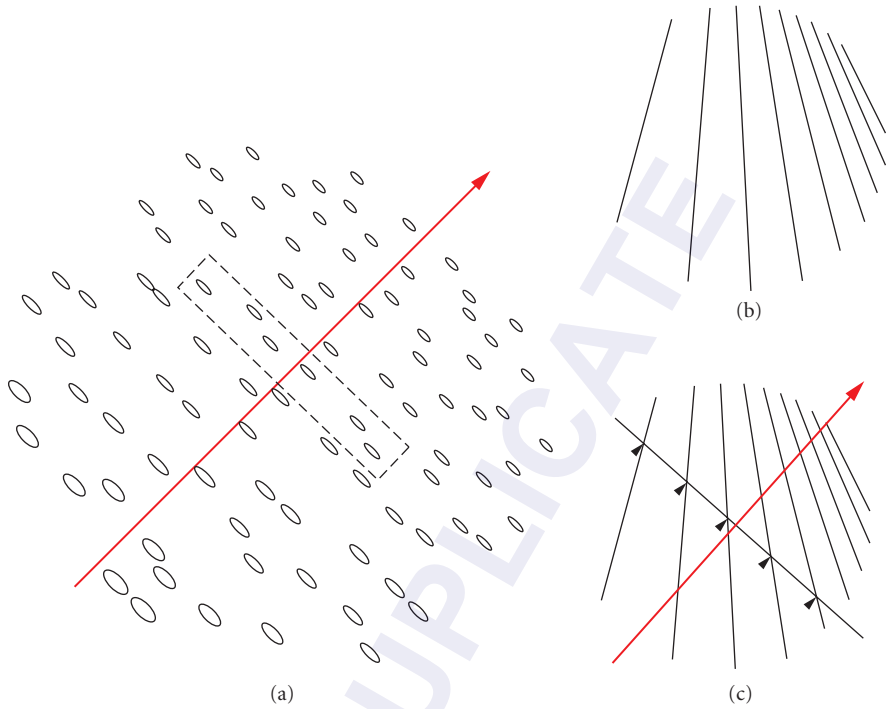

FIGURE 7 Texture gradients. The tilt of a surface is the direction in which it is slanted away from the gaze normal of the observer. (*a*) If the surface bears a uniform texture, the projection of the axis of tilt in the image indicates the direction in which the local density of the textures varies most, or, equivalently, it is perpendicular to the direction that the texture elements are most uniformly distributed (dotted rectangle). Either technique can be used to recover the tilt axis, as illustrated. Interestingly, however, the tilt axis in situations like (*b*) can probably be recovered most accurately using the second method, i.e., searching for the line that is intersected by the perspective lines at equal intervals. This method is illustrated in (*c*). (*Reprinted by permission from Stevens.*[35])

a compact package and also expands the distance between the objective lenses creating an expanded interpupillary distance (telestereoscope). This increase of effective separation between the two eyes' views exaggerates disparity and objects can appear in hyperstereoscopic depth if it exceeds the depth reduction caused by perceived reductions in viewing distance. The depth can be predicted from the formula in the preceding section that computes disparity from viewing distance, interpupillary distance, and physical linear depth interval.

Magnification and Motion Parallax—Heading

Magnification will produce errors in percepts derived from motion cues. Motion will be exaggerated by magnification and perceived distance will be shortened. As with binocular disparity, depth associated with motion parallax will be underestimated by the influence of magnification on perceived distance. Heading judgments in which gaze is directed away from the heading direction will be in error by the amount the angle of eccentric gaze is magnified. Thus if your car is headed north and your gaze is shifted 5° to the left, heading errors will be the percentage the 5° gaze shift is magnified by the optical system and you will sense a path that is northeast. Heading judgments that are constantly

changing, such as along a curved path, might be affected in a similar way, if the gaze lags behind the changing path of the vehicle. In this case, changes of perceived heading along the curved path would be exaggerated by the magnifier. Unequal magnification of the two retinal images in anisometropia will cause errors in sensing the direction of motion in depth by changing the amplitude ratio of the two moving images.

Bifocal Jump

Most bifocal corrections have separate optical centers for the distance lens and the near addition. One consequence is that objects appear to change their direction or jump as the visual axis crosses the top line of the bifocal segment (Fig. 8). This bifocal jump occurs because prism is introduced as the eye rotates downward behind the lens away from the center of the distance correction and enters the bifocal segment. When the visual axis enters the optical zone of the bifocal, a new prismatic displacement is produced by the displacement of the visual axis from the optical center of the bifocal addition. All bifocal additions are positive so that the prismatic effect is always the same; objects in the upper part of the bifocal appear displaced upward compared to views just above the bifocal. This results in bifocal jump. A consequence of bifocal jump is that a region of space seen near the upper edge of the bifocal is not visible. It has been displaced out of the field of view by the vertical prismatic effect of the bifocal. The invisible or missing part of the visual field equals the prismatic jump which can be calculated from Prentice's rule [distance (cm) between the upper edge and center of the bifocal times the power of the add]. Thus for a 2.5-D bifocal add with a top to center distance of 0.8 cm, approximately 1° of the visual field is obscured by bifocal jump. This loss may seem minor; however, it is very conspicuous when paying attention to the ground plane while walking. There is a clear horizontal line of discontinuity that is exaggerated by the unequal speed of optic flow above and below the bifocal boundary. Optic flow is exaggerated by the magnification of the positive bifocal

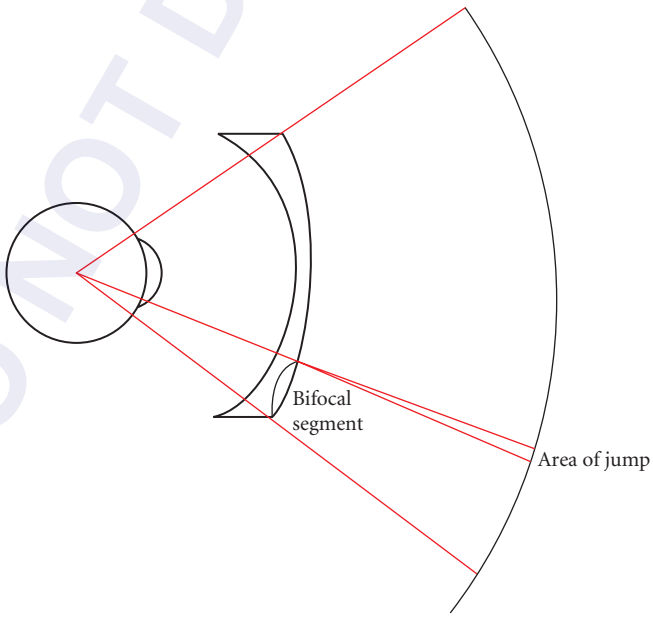

FIGURE 8 Jump figure. The missing region of the visual field occurs at the top edge of the bifocal segment as a result of prism jump.

segment. It can produce errors of estimated walking speed and some confusion if you attend to the ground plane in the lower field while navigating toward objects in the upper field. This can be a difficult problem when performing such tasks as walking down steps. It is best dealt with by maintaining the gaze well above the bifocal segment while walking, which means that the user is not looking at the ground plane in the immediate vicinity of the feet. Some bifocal designs eliminate jump by making the pole of the bifocal and distance portion of the lens concentric. The bifocal line starts at the optical centers of both lenses. This correction always produces some vertical displacement of the visual field since the eyes rarely look through the optical center of the lens; however, there is no jump.

Discrepant Views of Objects and Their Images

Translation errors in viewing a scene can lead to errors in space perception. A common problem related to this topic is the interpretation of distance and orientation of objects seen on video displays or in photographs. The problem arises from discrepancies between the camera's vantage point with respect to a 3-D scene, and the station point of the observer who is viewing the 2-D projected image after it has been transformed by the optics of the camera lens. Errors of observer distance and tilt of the picture plane contribute to perceptual errors of perspective distortion, magnification, and texture density gradients expected from the station point. The station point represents the position of the observer with respect to the view plane or projected images. To see the picture in the correct perspective, the station point should be the same as the location of the camera lens with respect to the film plane. Two violations of these requirements are errors in viewing distance and translation errors (i.e., horizontal or vertical displacements). Tilt of the view screen can be decomposed into errors of distance and translation errors. In the case of the photograph, the correct distance for the station point is the camera lens focal length multiplied by the enlargement scaling factor. Thus, when a 35-mm negative taken through a 55-mm lens is enlarged 7 times to a 10-in print, it should be viewed at a distance of 38.5 cm or 15 in (7×5.5 cm).

13.4 DISTORTION OF SPACE PERCEPTION FROM INTEROCULAR ANISO-MAGNIFICATION (UNEQUAL BINOCULAR MAGNIFICATION)

Optical devices that magnify images unequally or translate images unequally in the two eyes produce errors of stereoscopic depth and perceived direction as well as eye alignment errors that the oculomotor system is not accustomed to correcting. If these sensory and motor errors are longstanding, the visual system adapts perceptual and motor responses to restore normal visual performance. Patients who receive optical corrections that have unequal binocular magnification will adapt space percepts in 10 days to 2 weeks.

Lenses and Prisms Magnification produced by lenses is uniform compared to the nonuniform magnification produced by prisms, where the magnification increases toward the apex of the prism. Uniform magnification differences between the horizontal meridians of the two eyes produce errors in perceived surface tilt about a vertical axis (geometric effect). A frontoparallel surface appears to face the eye with the more magnified image. This effect is offset by vertical magnification of one ocular image that causes a frontoparallel surface to appear to face the eye with the less magnified image. Thus perceptual errors of surface tilt occur mainly when magnification is greater in the horizontal or vertical meridian. These meridional magnifiers are produced by cylindrical corrections for astigmatism. Nonuniform magnification caused by horizontal prism such as base-out or base-in (Fig. 5), cause surfaces to appear more concave or convex, respectively. Finally, cylindrical corrections for astigmatism cause scissor or rotational distortion of line orientations (Fig. 9). When the axes of astigmatism are not parallel in the two eyes, cyclodisparities are introduced. These disparities

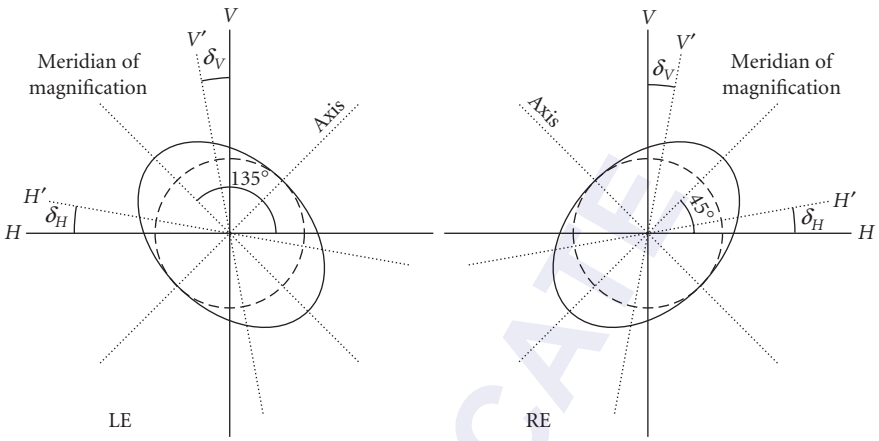

FIGURE 9 Magnification ellipse. Meridional magnification of images in the two eyes in oblique meridians cause "scissors" or rotary deviations of images of vertical (and horizontal) lines and affect stereoscopic spatial localization in a characteristic manner. (*Reprinted from Ogle and Boder.*[36])

produce slant errors and cause surfaces to appear inclinated or declinated. These spatial depth distortions are adapted to readily so that space appears veridical; however, some people are unable to cope with the size differences of the two eyes and suffer from an anomaly referred to as aniseikonia. While aniseikonic errors are tolerated by many individuals, they are subject of spatial distortions which, in given situations, may cause meaningful problems.

Aniseikonia

Unequal size of the two retinal images in anisometropia can precipitate a pathological mismatch in perceived size of the two ocular images (aniseikonia). Aniseikonia is defined as a relative difference in perceived size and/or shape of the two ocular images. Most difficulty with aniseikonia occurs when anisometropia is corrected optically with spectacles. Patients experience a broad range of symptoms including spatial disorientation, depth distortion, diplopia, vertigo, and asthenopia. These symptoms result from several disturbances including spatial distortion and interference with binocular sensory and motor fusion.

Two optical distortions produced by spectacle corrections of anisometropia are called axial and lateral aniseikonia. Axial aniseikonia describes size distortions produced by differences in the magnification at the optical centers of ophthalmic spectacle corrections for anisometropia. The magnification difference produced by the spectacle correction depends in part on the origin of the refractive error. Retinal images in the uncorrected axial and refractive ametropias are not the same. In axial myopia, the uncorrected retinal image of the elongated eye is larger than that of an emmetropic eye of similar refractive power. An uncorrected refractive myope has a blurred image of similar size to an emmetropic eye with the same axial length. Knapp's law states that image size in an axial ametropic eye can be changed to equal the image size in an emmetropic eye having the same refractive power by placing the ophthalmic correction at the anterior focal plane of the eye. The anterior focal plane of the eye is usually considered to correspond approximately to the spectacle plane. However, this is only a very general approximation. The anterior focal point will vary with power of the eye and in anisometropia, it will be unequal for the two eyes. Assuming the anterior focal point is the spectacle plane, then the abnormally large image of an uncorrected axial-myopic eye can be reduced to near normal with a spectacle correction, whereas a contact lens correction would leave the retinal image of the myopic eye enlarged. If the ametropia is refractive in nature (i.e., not axial), then the uncorrected

retinal images are equal in size and a contact lens correction will produce less change in image size than a spectacle correction. If the refractive myope is corrected with spectacles, the retinal image becomes smaller than that in an emmetropic eye of similar refractive power. This change in image size of refractive anisometropes corrected with spectacle lenses is one of several factors leading to ocular discomfort in aniseikonia.

Paradoxically, spectacle correction of axial myopes often produces too drastic a reduction in ocular image size. The ocular image of the axially myopic eye, corrected with spectacle lenses, appears smaller than that of the less ametropic eye in anisometropia.[37–42] As mentioned earlier, ocular image size depends not only upon retinal image size but also upon the neural factor.[22] For example, in cases of axial myopia, the elongation of the eye produces stretching of the retina and pigment epithelium. Accordingly, retinal images of normal size occupy a smaller proportion of the stretched retina than they would in a retina with normal retinal element density. Indeed, anisometropes with axial myopia report minification of the ocular image in their more myopic eye after the retinal images have been matched in size.[41,43,44] Thus, in the uncorrected state, myopic anisometropic individuals have optical magnification and neural minification. As a result, a spectacle correction would overcompensate for differential size of ocular images.

Surprisingly, not all patients with a significant amount of aniseikonia (4 to 6%) complain of symptoms. This could be due in part to suppression of one ocular image. However, normally we are able to fuse large size differences up to 15 percent of extended targets.[45] Sinusoidal gratings in the range from 1 to 5 cpd can be fused with grating differing in spatial frequency by 20 to 40 percent[46–48] and narrow band pass filtered bars can be fused with 100- to 400-percent difference in interocular size.[49,50] These enormous size differences demonstrate the remarkable ability of the visual system to fuse large size differences in axial aniseikonia. However, in practice, it is difficult to sustain fusion and stereopsis with greater than 8- to 10-percent binocular image size difference.

With extended targets, magnification produces an additional lateral displacement due to cumulative effects such that nonaxial images are enlarged and imaged on noncorresponding points. Given our tolerances for axial disparity gradients in size, it appears that most of the difficulty encountered in aniseikonia is lateral. Von Rohr[51] and Erggelet[52] considered this prismatic effect as the most important cause of symptomatic discomfort in optically induced aniseikonia.

Differential magnification of the two eyes images can be described as a single constant; however, the magnitude of binocular-position disparity increases proportionally with the eccentricity that an object is viewed from the center of a spectacle lens. Prentice's rule approximates this prismatic displacement from the product of distance from the optical center of the lens in centimeters and the dioptric power of the lens. In cases of ansiometropia corrected with spectacle lenses, this prismatic effect produces binocular disparity along the meridian of eccentric gaze. When these disparities are horizontal they result in distortions of stereoscopic depth localization, and when they are vertical, they can produce diplopia and eye strain. Fortunately, there is an increasing tolerance for disparity in the periphery provided by an increase in the binocular sensory fusion range with retinal eccentricity.[22] In cases of high anisometropia, such as encountered in monocular aphakia, spectacle corrections can cause diplopia near the central optical zone of the correction lens. In bilateral aphakia, wearing glasses or contact lenses does not interfere with the normal motor or sensory fusion range to horizontal disparity; however, stereothresholds are elevated.[53] In unilateral aphakia, contact lenses and intraocular lens implants support a normal motor fusion range; however, stereopsis is far superior with the interocular lens implants.[53] Tolerance of size difference errors varies greatly with individuals and their work tasks. Some may tolerate 6 to 8 percent errors while others may complain with only 0.25- to 0.5-percent errors.

Interocular Blur Suppression with Anisometropia

There is a wide variety of natural conditions that present the eyes with unequal image contrast. These conditions include naturally occurring anisometropia, unequal amplitudes of accommodation, and asymmetric convergence on targets that are closer to one eye than the other. This blur can be eliminated in part by a limited degree of differential accommodation of the two eyes[54] and by

interocular suppression of the blur. The latter mechanism is particularly helpful for a type of contact lens patient who can no longer accommodate (presbyopes) and prefer to wear a near contact lens correction over one eye and a far correction over the other (monovision) rather than wearing bifocal spectacles. For most people (66%), all of these conditions result in clear, nonblurred, binocular percepts with a retention of stereopsis[55] albeit with the stereothreshold elevated by approximately a factor of two. Interocular blur suppression is reduced for high contrast targets composed of high spatial frequencies.[55] There is an interaction between interocular blur suppression and binocular rivalry suppression. Measures of binocular rivalry reveal a form of eye dominance defined as the eye that is suppressed least when viewing dichoptic forms of different shape. When the dominant eye for rivalry and aiming or sighting is the same, interocular suppression is more effective than when dominance for sighting and rivalry are crossed (i.e., in different eyes).[56]

When the contrast of the two eyes' stimuli is reduced unequally, stereoacuity is reduced more than if the contrast of both targets is reduced equally. Lowering the contrast in one eye reduces stereo acuity twice as much as when contrast is lowered in both eyes. This contrast paradox only occurs for stereopsis and is not observed for other disparity-based phenomenon including binocular sensory fusion. The contrast paradox occurs mainly with low spatial frequency stimuli (<2.0 cycles/degree). Contrast reduction caused by lens defocus is greater at high spatial frequencies, and perhaps this is why stereopsis is able to persist in the presence of interocular blur caused by anisometropia.

13.5 DISTORTIONS OF SPACE FROM CONVERGENCE RESPONSES TO PRISM

Horizontal vergence responses to prism influence estimates of viewing distance.[24,57–59] The resulting errors in perceived distance will influence depth percepts that are scaled by perceived viewing distance such as stereopsis and motion parallax. Time of arrival or contact with external objects can be estimated from the distance to contact divided by the speed of approach. If distance is underestimated while wearing convergent or base-out (temporal) prism, then time to contact, computed from velocity and distance, will also be underestimated. In addition, prism stimuli to convergence will produce conflicts in distance estimates from vergence and retinal image size. When vergence responds to prism, retinal image size remains constant instead of increasing as it would in response to real changes in viewing distance. The conflict is resolved by a perceived decrease in perceived size. This illusion is referred to as convergence micropsia. An average magnitude of shrinkage is 25 percent for an accommodation and convergence increase equivalent to 5 D or 5 meter angles.[60] Very large prism stimuli to vergence present major conflicts between the fixed stimulus to accommodation and the new vergence stimulus. The oculomotor system compromises by partially responding to the vergence stimulus. If physical size of a target in a virtual display has been adjusted to correspond to an expected full vergence response, (increase retinal image size with convergence stimuli), but a smaller vergence response actually occurs, the perceptual compensation for size is based on the smaller vergence response. As a result, a paradoxical increase of perceived size accompanies convergence (convergence macropsia).[61–63] The incompletely fused images are perceived at the distance of convergence alignment of the eyes rather than at the intended distance specified by physical size and disparity. Thus, aniseikonic and anisophoric differences in the two eyes, which are made worse by anisometropia, can cause difficulty when performing binocular tasks associated with the use of optical instruments.

13.6 EYE MOVEMENTS

There are two general categories of eye movements. One class stabilizes the motion of the retinal image generated by our own body and head movements and the other class stabilizes the retinal image of an object moving in space. In the former case, the whole retinal image is moving in unison

whereas in the latter case only the retinal image of the moving object moves relative to the stationary background and when that image is tracked it remains stabilized on the fovea during target inspection. In all, there are five types of eye movements (VOR, OKN, saccades, pursuits, and vergence) and they are classified as either stabilizing or tracking movements.

Two classes of reflex eye movements perform the image stabilization task. The first class of stabilizing eye movement compensates for brief head and body rotation and is called the vestibulo-ocular reflex (VOR). During head movements in any direction, the semicircular canals of the vestibular labyrinth signal how fast the head is rotating and the oculomotor system responds reflexively to this signal by rotating the eyes in an equal and opposite rotation. During head rotation, this reflex keeps the line of sight fixed in space and visual images stationary on the retina. Body rotation in darkness causes a repetitious sequence of eye movements which move the line of sight slowly in the direction opposite to head rotation (slow phase) followed by a rapid (saccadic) movement in the direction the head moves (fast phase). This reflex is almost always active and without it we would be unable to see much of anything due to constant smear of the retinal image. The vestibulo-ocular reflex is extremely accurate for active head motion because it has an adaptive plasticity that makes it easily calibrated in response to altered visual feedback.[64,65] The VOR may be inhibited or suppressed by the visual fixation mechanism[66] as a result of the system's attempt to recalibrate to the head-stationary image.

Optokinetic reflex is an ocular following response that stabilizes whole field motion when we move about in a visual scene. Unlike the vestibulo-ocular reflex, this optokinetic reflex requires a visible retinal image whereas the vestibulo-ocular reflex operates in total darkness. Rotation or translation of the visual field causes the eyes to execute a slow following and fast reset phase sequence of eye movements that have the same pattern as the VOR. The optokinetic reflex supplements the vestibulo-ocular reflex in several ways. The vestibulo-ocular reflex responds to acceleration and deceleration of the head but not to constant velocity. In contrast, optokinetic reflex responds to constant retinal image velocity caused by constant body rotation or translation. The vestibulo-ocular reflex controls initial image stabilization and optokinetic reflex maintains the stabilization.

Tracking eye movements place the retinal image of the object of regard on the fovea and keep it there, even if the object moves in space. The class of eye movements that places the image on the fovea is called a saccade. This is a very fast eye movement that shifts the image in a step-like motion. Saccades can be made voluntarily, in response to visual, tactile, and auditory stimuli, and even in darkness to willed directions of gaze. Their chief characteristic is they are fast, reaching velocities of nearly 1000 deg/s. Once the target is on the fovea, slow following eye movements called pursuits maintain the image of the target on the fovea. They can keep images stabilized that are formed of objects moving as fast as 30 deg/s in humans. Generally, pursuits cannot be made voluntarily in the absence of a visual moving stimulus. However, they can respond to a moving sound or tactile sensation in darkness.

13.7 COORDINATION AND ALIGNMENT OF THE TWO EYES

If you observe the motion of the two eyes, you will notice that they either move in the same or opposite direction. When they move in the same direction they are said to be yoked, or conjugate, like a team of horses. These are also called version movements. At other times the eyes move in opposite directions, especially when we converge from far to near. These are called disjunctive or vergence movements. Both conjugate and disjunctive movements can be either fast or slow depending if the eyes are shifting fixation or maintaining foveation (stable fixation) of a target. A century ago, Ewald Hering described the movements of the two eyes as equal and symmetrical (Hering's law). Our eyes are yoked when we are born but the yoking can be modified in response to anisometropic spectacles that produce unequal image sizes and require us to make unequal eye movements to see bifoveally. This image inequality leads to the binocular anomalies of aniseikonia (unequal perceived image size) and anisophoria (noncomitant phoria or a phoria that varies with direction of gaze).

Targets are brought into alignment with corresponding points by movements of the eyes in opposite directions. These vergence movements have 3° of freedom (horizontal, vertical, and torsional). Horizontal vergence can rotate the eyes temporalward (divergence) or nasalward (convergence). Since near targets only require convergence of the eyes, there is a limited need for divergence other than to overcome postural errors of the eyes. Consequently, the range of divergence is less than half the range of convergence. The eyes are able to diverge approximately 4° and converge approximately 8 to 12° in response to disparity while focusing accurately on a target at a fixed viewing distance. Vergence movements serve the same function as conjugate movements of the eyes which is to preserve the alignment of the two retinal images on corresponding retinal points. Vergence is required when changing viewing distance, whereas versions accomplish the task when changing direction of gaze.

The stimulus to vergence depends upon both the viewing distance and the distance between the two eyes (interpupillary distance). It is equal to the angle subtended by a target in space at the entrance pupils of the two eyes (binocular parallax). As will be described in Sec. 13.9, "Prism-Induced Errors of Eye Alignment," the stimulus to vergence can be changed by stimulating accommodation with lenses, or changing disparity (binocular parallax) with prisms. The exact stimulus value of lenses and prisms to vergence depends upon the placement of the prism relative to the eye and this relationship will be described in Sec. 13.8, "Effects of Lenses and Prism on Vergence and Phoria." Vergence is measured in degrees of ocular rotation and prism diopters. The meter angle is also used in order to get a comparable metric for accommodation and convergence. Meter angles equal the reciprocal of the viewing distance in meters, and the value is approximately equal to the accommodative stimulus in diopters.

$$\text{MA} = \frac{1}{\text{target distance in meters}}$$

Meter angles (MA) can be converted into prism diopters simply by multiplying MA by the interpupillary distance (IPD) in cm. Prism diopters equal the 100 tan vergence angle in degrees. Vergence eye movements respond to four classes of stimuli described nearly a century ago by Maddox.

Intrinsic Stimuli to Vergence

There are four classes of stimuli to align the eyes with horizontal vergence at various viewing distances. The first is an intrinsic innervation that develops postnatally. During the first 6 weeks of life, our eyes diverge during sleep. This divergence posture is known as the anatomical position of rest and it represents the vergence angle in the absence of any innervation. As we develop during the first 1.5 months of life, the resting vergence angle is reduced to nearly zero by the development of tonic vergence which reduces the resting position from the anatomical position of rest to the physiological position of rest. The anatomical position of rest refers to eye alignment in the absence of all innervation, such as in deep anesthesia. The physiological position of rest refers to the angle that vergence assumes when we are awake and alert, in the absence of any stimulus to accommodation or binocular fusion or perceived distance. Usually, this physiological position of rest differs from the vergence demand, (i.e., the amount of vergence needed to fuse a distance target). The discrepancy between the vergence demand at a far viewing distance and the physiological position of rest is called the phoria. The phoria is an error of binocular alignment, but the error is only manifest during monocular viewing or any condition that disrupts binocular vision. If binocular vision is allowed (not disrupted) other components of vergence reduce the error nearly to zero. Adaptation of the phoria continually calibrates eye alignment and keeps the phoria constant throughout life.

There are two components of phoria adaptation that compensate for eye misalignment. One is a conjugate process that is called prism adaptation and it refers to our ability to adjust our phoria in response to a uniform prism. This prism is constant throughout the visual field and it produces a conjugate change in phoria in all directions of gaze. The conjugate adaptation is very rapid and can be completed in several minutes in a normal patient. The eyes are able to adapt horizontal vergence several degrees over a 1 h time span and larger amounts for unlimited adaptation periods. The slow-anomalous fusional movements reported by Bagolini[67] for strabismus patients are similar in time course to adaptive responses to prism and they indicate that the potential range of adaptation must exceed 10°.

The second component of phoria adaptation is a nonconjugate process that adjusts the phoria separately for each direction and distance of gaze. For example, anisometropic spectacle corrections disrupt the normal alignment pattern needed for fusion. A person wearing a plus (converging) lens over the right eye needs to over converge in left gaze and over diverge in right gaze. Our oculomotor system is able to make these noncomitant adjustments such that the phoria varies with direction and distance of gaze consistent to compensate for the problems encountered with anisometropic spectacle corrections. This disconjugate adaptation occurs in a matter of hours and it persists when the spectacle lenses are removed. It provides a means to align the eyes without retinal cues of binocular disparity. The adapted variations of phoria are guided by a synergistic link with the eye positions in which they were learned. For example when an anisometropic person first wears a plus lens spectacle over the right eye, the right eye is hypophoric in upgaze and hyperphoric in downgaze. After wearing this spectacle correction for several hours the vergence errors are adapted to so that there is no longer a phoria or vergence error while wearing the spectacles. However, when the spectacles are removed, the right eye is hyperphoric in upgaze and hypophoric in downgaze. This demonstrates a synergistic link between vertical eye position and vertical phoria where eye position guides the vertical vergence alignment of the two eyes, even when only one eye is open and the other is occluded.

Binocular Parallax

Horizontal vergence also responds to misalignment of similar images from corresponding retinal points (retinal image disparity). It reduces the disparity to a value within Panum's fusional area and causes images to appear fused or single. This fusional or disparity vergence is analogous to optical reflex accommodation. It serves as a rapid fine adjustment mechanism that holds or maintains fixation of a given target and corrects for minor changes of disparity caused by small movements of the head or the target being inspected. It has a range of approximately 3° of convergence and divergence. Rapid adaptations of the phoria account for increased ranges of fusion in response to disparity.

Vertical and cyclovergence eye movements also respond to binocular disparity. Vertical vergence can rotate one eye up or down relative to the other eye (skew movements) over a range of 2°. These movements respond to vertical disparity that is always associated with near targets in tertiary directions of gaze (targets at oblique eccentricities). Vertical disparity is a consequence of spatial geometry. Tertiary targets are closer to one eye than the other so that they subtend unequal image sizes in the two eyes. Unequal vertical eccentricities resulting from unequal image magnification requires a vertical vergence to align tertiary targets onto corresponding retinal regions. At near distances greater than 10 in, vertical disparities are very small and only require a limited range of movement.

Torsional or cyclovergence can twist one eye about its visual axis relative to the orientation of the other eye. Normally, torsional vergence keeps the horizontal meridians of the retinas aligned when the eyes are converged on a near target in the upper or lower visual field. Torsional vergence stimulated by cyclodisparities is limited to a range of approximately 10°. Like vertical vergence, torsional vergence responds to unequal orientations or torsional disparities that result from the perspective distortions of near targets viewed by the two eyes. Ocular torsion is mainly stimulated by lateral head roll and amounts to approximately 10 percent of the amount of head roll, up to a maximum of 6° (60° head roll). The head roll can produce vertical disparities of the near fixation targets if the eyes are not accurately converged. With the head tilted toward the right shoulder, a divergence fixation error can cause the right eye to be depressed from the target and a convergence fixation error will cause the right eye to be elevated with respect to the fixation target. However, no vertical fixation errors result from head roll if the eyes are accurately converged on the fixation target.

Defocus and Efforts to Clear Vision

Stimulation of either convergence or accommodation causes synergistic changes in convergence, accommodation, and pupil size. This synergy is called the near triad. During monocular occlusion, when the eyes focus from optical infinity to 1 m (1 D) they converge approximately 2 to 3° without

disparity cues. This accommodative/vergence response brings the eyes into approximate binocular alignment, and any residual alignment errors produce binocular disparity that is corrected by fusional vergence. The activation of convergence when accommodation is stimulated while one eye is covered is called accommodative vergence. The gain or strength of this interaction is called the accommodative convergence/accommodation (AC/A) ratio which describes the amount of convergence activated per diopter of accommodation. Similarly, if convergence is stimulated while wearing pinhole pupils, accommodation also responds without blur cues. This reflex is called convergence accommodation and the gain or strength of this interaction is the convergence-accommodation/convergence (CA/C) ratio. Normally these ratios are tuned appropriately for the geometry of our eye separation so that efforts of either accommodation or convergence bring the eyes into focus and alignment at nearly the same viewing distance. Occasionally, because of uncorrected refractive errors, or large abnormal phorias, or because of optical distortions caused by instruments, there is an imbalance of accommodation and vergence causing them to respond to different distances. The mismatch may result in fatigue and associated symptoms if the visual task is extended. The resulting mismatch needs to be corrected by fusional vergence and optical reflex accommodation. If the mismatch is beyond the range of the compensation, then vision remains blurred or double.

Variations of Cross-Coupling with Direction and Distance of Gaze

In straight-ahead gaze (zero azimuth), targets in the midsagittal plane produce equal magnitudes of disparity and defocus when they are expressed in meter angles [MA = 1/viewing distance (m) and diopters (D = 1/viewing distance (m)] respectively. However, when targets are viewed in asymmetric vergence [i.e., with some combination of horizontal version (azimuth) and vergence], conflicts arise between stimuli for accommodation and convergence as a consequence of 3-D spatial geometry. Figure 10 compares a plan view of the isoaccommodation circle to the isovergence circle. The isoaccommodation circle describes the locus of points that subtend a constant average accommodation

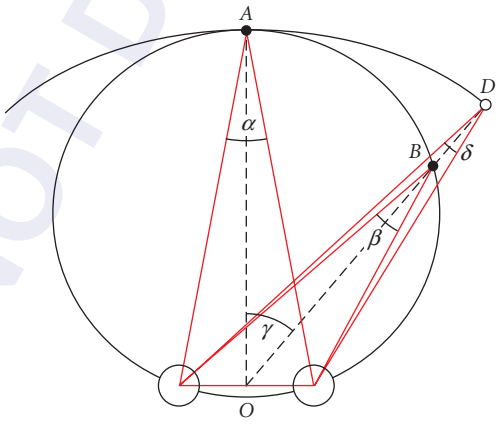

FIGURE 10 Diagram showing isovergence circle (large complete circle), isoaccommodation circle (shown as an arc) and various azimuth angles. The two small circles represent the right and the left eye. The point *A* in the figure represents the spatial location that corresponds to matched stimuli for accommodation and convergence. α = vergence angle at point *A* (angle made by the intersection of two lines of sight), β = vergence angle at point *B*, and $\alpha = \beta$ along the isovergence circle. γ = lateral gaze angle. Note that at point *D* on the isoaccommodation circle, the convergence and accommodation demand is lower than at point *B*.

stimulus to the two eyes with increasing azimuth. This circle has a radius equal to the viewing distance from the cyclopean eye to the object of regard in any horizontal direction of gaze lying in a common visual plane. The isovergence circle passes through the fixation point and two centers of eye rotation.[68] Its distance to the cyclopean eye varies with both viewing distance and direction of gaze (azimuth). The circle has a radius equal to the interpupillary distance (PD) divided by twice the sine of the angle of convergence (theta).

$$\text{Isovergence radius} = \frac{\text{PD}}{2 * \sin\theta}$$

The only spatial location that corresponds to matched stimuli for accommodation and convergence is straight ahead where these two circles intersect (Fig. 10). For points lying to the left or right, the stimulus to accommodation is always greater than the stimulus to convergence. This conflict is resolved by having the normal cross-link interaction between accommodative-convergence and accommodation (AC/A ratio) set for an ideal value for 50° azimuth.[69] This low ratio results in a small divergence error of vergence at lesser azimuths that is easily overcome with fusional convergence. The normal convergence accommodation/convergence interaction (CA/C ratio) is ideal for straight ahead. This produces a lag of accommodation in small lag of accommodation that increases with gaze eccentricity.

Perceived Distance

The eyes align and focus in response to perceived distance. The term proximal refers to perceived distance. Perceived distance is classified as a spatiotopic cue because it results in a conscious percept of distance and direction. Our perception of space is made up of an infinite number of different targets in different directions and distances. Our eyes can only select and fuse one of these target configurations at a time. One of the main tasks of the oculomotor system is to select one fixation target from many alternatives. This selection process usually results in a shift of binocular fixation from one distance and direction to another. Proximal vergence serves as a course adjustment mechanism and accounts for nearly 100 percent of the eye movement when gaze shifts are too large for us to sense them from blur and disparity. We perform these large gaze shifts without needing to see the new intended target clearly or even with both eyes.[70] We only need to have an estimate of target location using monocular cues for distance and direction. The majority of binocular shifts in fixation are stimulated by proximal vergence. Once the shift has been made another component of vergence (fusional vergence) takes over to maintain the response at the new target location. Errors in perceived distance can result in errors of eye alignment and focus. Mislocalization of large print or symbols in a head mounted display, or of the distance of a microscope slide can cause the eyes to accommodate excessively and produce a blurred image of a target that is imaged at optical infinity.

The Zone of Clear and Single Binocular Vision

These components of vergence add linearly to form a range of accommodative and disparity stimuli that the observer is able to respond to with single and clear binocular vision (Fig. 11).[2] The range is determined by the convergence and divergence fusional vergence range from the resting phoria position, plus the linkage between accommodation and vergence described in the section on "Defocus and Efforts to Clear Vision" that increases with accommodative effort until the amplitude of accommodation is reached. Geometrically matched stimuli for convergence and accommodation that correspond to common viewing distances normally lie within this range of clear single binocular vision unless there is an alignment error such as an eye turn or strabismus. Mismatches between stimuli for accommodation and convergence produced by lenses or prisms or optical instruments can be compensated for as long as the combined stimuli for accommodation and convergence lie within this stimulus operating zone for binocular vision. The ability to respond to unmatched stimuli for convergence and accommodation does not result from decoupled independent responses of the

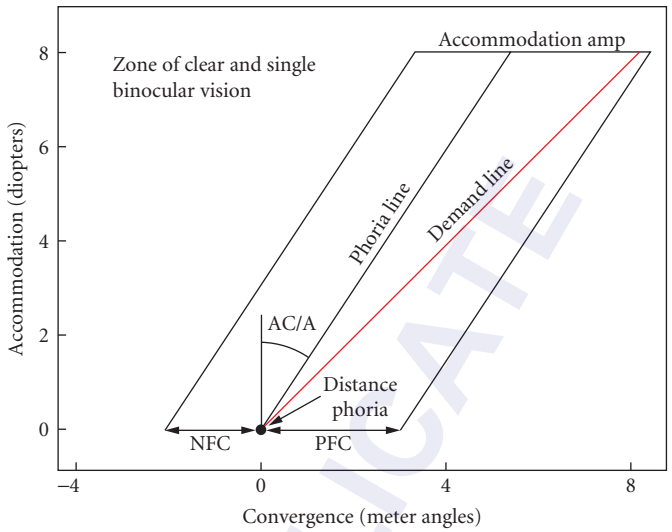

FIGURE 11 Figure of the ZCSBV. Schematic representation of the zone of clear single binocular vision in terms of five fundamental variables (amplitude of accommodation, distance phoria, AC/A ratio positive fusional convergence, negative fusional convergence).

two systems. Accommodation and convergence always remain cross-coupled, but fusional vergence and optical reflex accommodation are able to make responses to overcome differences in phorias produced by accommodative vergence and prisms.

13.8 EFFECTS OF LENSES AND PRISM ON VERGENCE AND PHORIA

Errors of horizontal and vertical vergence can result from differences in the two ocular images caused by differential magnification and translation. Optical power differences will cause magnification differences. Translation of the image is caused by prism or by decentration of the line of sight from the optical center of the lens system.

Magnification-Induced Errors of Eye Alignment

Magnification of the ocular image is influenced by several factors including index of refraction, lens thickness, front surface power, overall power of the lens, and the ocular distance from the eyepiece. For a spectacle lens the magnification is described by the product of a shape factor and a power factor. Magnification described by the shape factor (M_s) equals

$$M_s = \frac{1}{1 - F_1 t/n}$$

and by the power factor (M_p) equals

$$M_p = \frac{1}{1 - P_v h}$$

where F_1 is the front surface power, t is the lens thickness in centimeters, n is the index of refraction, h is the distance of the spectacle plane from the cornea in centimeters, and P_v is the thin lens power. Percent angular magnification caused by the power factor is approximately 1.5 percent per diopter power. The percent magnification (M%) can be approximated by the following formula:[22]

$$M\% = \frac{F_1 t}{n + P_v h}$$

Differences between the lenses before the two eyes will produce image size differences, depending on the source of refractive error. Two basic sources are an abnormal axial length (axial ametropia) or abnormal corneal and lenticular power (refractive ametropia). Magnification differences between the two eyes caused by interocular differences in axial length can be eliminated largely by correcting axial errors with spectacle lenses located in the primary focal plane (the spectacle plane) and placing the lenses not too near to the eyes. Magnification differences between the two eyes caused by unequal powers of the two corneas can be prevented by correcting refractive errors with contact lenses instead of spectacle lenses (Knapp's law). If Knapp's law is violated by correcting a refractive myope with spectacle lenses placed in the primary focal plane of the eye (16.67 mm), the myopic eye will have a smaller image than an emmetropic eye with a normal corneal power. Similarly, if an axial myope is corrected with a contact lens, the myopic eye will have a larger image than an emmetropic eye with a normal axial length. However, the perceived image size in axial refractive errors also depends on whether the retina is stretched in proportion to the axial length. If it is, then the contact lens correction for an axial ametrope would produce a perceived image size equal to that of an emmetropic eye with a normal axial length. This analysis only applies to perceived image size and it is an attempt to correct perceived image size differences between the two eyes (aniseikonia). However, it does not address the unequal ocular movements stimulated by anisometropic spectacle corrections (anisophoria) resulting, as described in Sec. 13.10 on gaze, from the separation of the entrance pupil and center of rotation.

Anisophoria is defined by Friedenwald[71] as a heterophoria which varies in magnitude with direction of gaze. It is produced by spectacle corrections for anisometropia independent of whether refractive errors are axial or refractive in nature and only concerns the refractive power of the spectacle lens correction. The lateral prismatic effect occurs even when size distortions of an axial refractive error have been properly corrected with a spectacle lens. A prismatic deviation will always exist whenever the visual axis of the eye and optical axis of a lens do not coincide. As a result, the initial movement of an ametropic eye that is corrected with spectacle lenses will be too small in hypermetropia and too large in myopia. These optical factors produce differential prism in ansiometropia corrected with spectacles. Initially, anisometropes corrected with spectacles will make vergence errors during versional movements to eccentric targets because the eyes follow Hering's law of equal innervation to the extraocular muscles. Interocular differences in power of spectacle lenses can stimulate vergence eye movements in all meridians of anisometropia (vertical, horizontal, and oblique). This optically induced anisophoria can be compensated for easily in the horizontal meridian by disparity vergence eye movements. The vertical errors will be the most troublesome because of the limited range and slow speed of vertical vergence.[72,73] Difficulty in compensating for optically induced anisophoria is believed to contribute to the symptoms of aniseikonia corrected with spectacle lenses.[71,74] Anisophoria may explain why both refractive and axial anisometropes prefer contact lens corrections that do not produce anisophoria. Contact lenses move with the eye, and the line of sight always passes through the optical center such that fixation errors of targets at infinity always equal the correct motor error to guide the oculomotor system during gaze shifts. Optically induced anisophoria can be very large. For example, Ogle[22] computes a 4.2 prism diopter phoria produced by a +4-D anisometropia spectacle correction during a 20° eye movement. This constitutes a 12-percent error. Normally the oculomotor system is capable of recalibration of Hering's law to compensate for optically induced anisophoria. For example, anisometropic patients wearing bifocal spectacle corrections do not exhibit the predicted change in vertical phoria while viewing in downgaze.[75,76] Adjustments of heterophoria in all directions of gaze occur in approximately 2.5 h for differential afocal magnification of up to 10 percent.[77,78] Similar oculomotor adjustments occur normally in asymmetric convergence whereby the abducted eye makes larger saccades than the adducted eye in order to compensate for geometrically induced aniseikonia.[79] Unequal prism before the two eyes produced by a 10-percent magnification difference,

such as observed in monocular aphakia corrected with spectacles or spectacle and contact lens combinations,[80] is extremely difficult to adapt to. Presumably a 10-percent magnification difference sets an upper limit to the degree of anisometropia that will not disrupt binocular versional eye movements and binocular alignment. It is possible that individuals who have symptoms of aniseikonia when corrected with spectacle lenses, are simply unable to make the necessary adjustments in conjugacy to overcome their optically induced anisophoria. Indeed Charnwood[81] observed that aniseikonia patients preferred prism incorporated into their spectacle corrections to reduce anisophoria and Field[82] reported that nearly all of 25 patients with clinically significant aniseikonia had oculomotor imbalance. Clearly anisophoria is an important by-product of anisometropia corrected with spectacles.

Torsional vergence errors can also result from optical corrections that have cylindrical corrections for astigmatism. The power of a cylindrical lens varies with the square of the cosine of the angular separation from the major power meridian. This power variation produces a meridian-dependent magnification of the ocular image described as a magnification ellipse. The ellipse produces rotational deviations of lines at different orientations toward the meridian of maximum magnification. The rotary deviation between a line and its image meridian (δ) depends on the angle between the orientation of the line (γ) and the major axis of the magnification ellipse (θ). The rotary deviation is approximated by the following equation:

$$100 \tan \delta = 1/2\, f \sin 2(\gamma\theta)$$

where f equals the percent of magnification produced by the cylinder.[22] This equation demonstrates that most of the shear or scissor distortion of lines will occur in meridians between the major and minor axes of the magnification ellipse. These rotary deviations produce limes imaged on noncorresponding retinal meridians or torsional disparities because the axis of astigmatism is normally not parallel in the two eyes. Rather, astigmatism tends to be mirror symmetric about oblique meridians such that an axis of 45° in one eye is often paired with an axis of 135° in the other eye. As a result, the shear or rotary deviations of vertical meridians tend to be in opposite directions. The resulting cyclodisparities produce perceptual declination errors of stereo surface slant (tilt of a surface about a vertical or horizontal axis). Cyclodisparities about horizontal axes stimulate cyclovergence movements of the two eyes (torsion of the two eyes in opposite directions). If the disparities are long lasting, the cyclovergence response adapts and persists even in the absence of binocular stimulation.[83]

13.9 PRISM-INDUCED ERRORS OF EYE ALIGNMENT

Errors of binocular eye alignment also result from translation of one ocular image with respect to the other. The translation can be caused by prism or by displacement of the optical center of the lens from the line of sight. When an object is viewed through a prism, it appears in a new direction that is deviated toward the prism apex and the eye must move in that direction to obtain foveal fixation. The amount the eye must rotate to compensate for the prismatic displacement of targets at finite viewing distances decreases as the distance between the eye and prism increases. This is because the angle that the displaced image subtends at the center of eye rotation decreases with eye-prism separation. This reduction is referred to as prism effectivity.[84] It does not occur for targets at infinity since the target distance is effectively the same to both the prism and center of rotation. The effective prism magnitude at the eye (Z_e) is described by the following equation:

$$Z_e = \frac{Z}{1 - C_{\text{rot}} \times V}$$

where Z is prism value, C is center of rotation to prism separation in meters, and V is the reciprocal of the object to lens separation in meters which corresponds to the dioptric vergence leaving the prism.[84]

Binocular disparities induced by a prism or lens determines the direction of the phoria or vergence error. For example, base-out prism produces a crossed disparity and divergence error (exophoria) which is corrected under binocular conditions by fusional convergence. Minus lenses stimulate accommodation and accommodative convergence, which under binocular conditions produce a convergence error (esophoria) that is corrected by fusional divergence. Similarly, base-in prism produces an uncrossed disparity and convergence error (esophoria) which is corrected under binocular conditions by fusional divergence, and plus lenses stimulate a relaxation of both accommodation and accommodative convergence, which produces a divergence error (exophoria) that is corrected by fusional convergence.

The prismatic translation caused by optical displacement is described by Prentice's rule, where the prism displacement (Z) equals the power of the lens in diopters (P) times the displacement of the lens center from the line of sight (d) in centimeters ($Z = dP$). The angular deviation of any paraxial ray that passes through a lens at a distance from the optical center is described by this rule. Prentice's rule can also be applied to cylindrical lenses where the magnification occurs in a power meridian. The axis of a cylindrical lens is perpendicular to its power meridian. The prism induced can be calculated from the vector component of the displacement that is perpendicular to the axis of the cylinder. This distance (Hp) equals the sine of the angle (θ) between the displacement direction and the axis of the cylinder times the magnitude of the displacement (h)

$$Hp = h \sin \theta$$

Thus, according to Prentice's rule, prism induced by displacing a cylindrical lens equals

$$Z = Ph \sin \theta$$

The magnitude of prism induced by lens displacement also depends on the separation between the lens and the center of rotation of the eye. Effective prism displacement (Z_e) decreases as the distance of the lens from the eye increases according to the following equation:[84]

$$Z_e = \frac{(Zc + Z)}{1 - C_{\text{rot}} \times V}$$

where Zc is 100 tan c, c is the angle formed between the object point and the displaced point from the optical center (major reference point) and the straight ahead line, V is the reciprocal of the image distance to the lens in meters which corresponds to the dioptric vergence leaving the prism, Z is the prism calculated from Prentice's rule, C_{rot} is separation between the lens and center of rotation of the eye. The reduction of prismatic displacement with eye to lens separation is referred to as prism effectivity with lenses.

When the two eyes view targets through lenses that are displaced from the optical axes, a disparity stimulus is introduced. Most typically, when the optical centers of a binocular optical system are separated by an amount greater or less than the interpupillary distance, disparate horizontal prism is introduced that requires the eyes to make a horizontal vergence adjustment to achieve binocular alignment. For example, when looking through a pair of plus lenses that are farther apart than the interpupillary distance, each eye is viewing through a point that is nasalward from the optical axis. This introduces base-out prism that stimulates convergence of the two eyes. This prism vergence stimulus may produce conflicts with the accommodative stimulus that is not affected by lens displacement so that the eyes need to focus for one distance and converge for another. Accommodation and convergence are linked synergistically so that their responses are closely matched to similar target distances. There is a limited degree of disparity vergence compensation available to overcome any discrepancy between the two systems, and these efforts can result in headaches and other ocular discomfort.

Anisometropic ophthalmic lens prescriptions with bifocal corrections in the lower segment of the lens can also introduce vertical prism while viewing near objects through the reading addition. The amount of vertical prism is predicted by Prentice's rule applied to the amount of anisometropia. Thus, for a 2-D anisometropic individual, a patient looking downward 1 cm through their bifocal has a vertical phoria of two prism diopters. The vertical phoria can be corrected with a slab-off

prism (a base-down prism that is cemented onto the bifocal over the lens with the most plus power). However, this procedure is rarely necessary, since the patient usually is able to adapt the vertical phoria to vary nonconjugately with vertical eye position as described above.

13.10 HEAD AND EYE RESPONSES TO DIRECTION (GAZE CONTROL)

When objects attract our attention in the peripheral visual field, we are able to fixate or shift our central gaze toward them using head and eye movements. The eyes move comfortably over a range of 15° starting from primary position. Larger gaze shifts require combinations of head and eye movements. Normally, the eyes begin the large movements, then the head moves toward the target while the eye movements are reduced by the VOR, and when the head stops the eyes refine their alignment. The reduction of eye motion during head rotation results from a gaze stabilization reflex that allows us to keep our eyes fixed on a stationary object as we move our body or head. This reflex operates with head motion sensors called the vestibular organs.

The manner in which we shift our gaze influences optical designs. Optical systems usually are mounted on the head. They need to provide a large enough viewing angle to accommodate the normal range of eye movements, and to remain stable on the head as it moves. They also need to provide peak resolution in all directions that the oculomotor system is able to shift gaze while the head remains stationary. Gaze shifts can be inaccurate because of interactions between spectacle refractive corrections and movements of the eyes.

The accuracy of eye movements is affected by stationary optical systems such as spectacles that are mounted in front of the eyes as opposed to optical systems such as contact lenses that move with the eye. The problem occurs when viewing distant targets because the entrance pupil of the eye and its center of rotation are at different distances from the spectacle plane. The entrance pupil is at a distance of about 15 mm from the spectacle lens and the ocular center of rotation lies about 27 mm behind the spectacle plane. Thus the center of rotation and entrance pupil are separated by about 12 mm and a target in space subtends different angles at these two points. The angle at the entrance pupil determines the visual error and the angle at the center of rotation determines the motor error. Whether a spectacle lens is worn or not, this difference alters retinal image feedback during eye rotations for any target imaged at a finite viewing distance from the eye. Images at infinity don't have this problem because they subtend equal angles at both the entrance pupil and center of rotation. Thus eye movements cause motion parallax between targets viewed at near and far viewing distances and some animals like the chameleon use this parallax to judge distance.[85]

Problems occur when the spectacle lens forms an image of an object at infinity at some finite distance from the eye. This image of the distant target subtends different angles at the entrance pupil and center of rotation because of their 12-mm separation. Thus, perceived visual angle and motor error are unequal. Depending on whether the image is formed in front (myopic error) or behind (hyperopic error) the eye, this discrepancy requires that a fixational eye movement must be smaller or larger, respectively, than the perceived eccentricity or retinal angular error of the target sensed prior to the eye movement. The amount of eye rotation can be computed from the equation describing prism effectivity with lenses (Z_e):[84]

$$Z_e = \frac{Zc}{1 - C_{\text{rot}} \times V}$$

where Zc equals 100 tan c (c equals angular eccentricity of the target measured at the lens plane), and V equals the dioptric vergence of the image distance from the lens plane, and C_{rot} equals the lens to center of rotation separation in meters. When different power spectacle lenses are worn before the two eyes to correct unequal refractive errors (anisometropia), a target that would normally require equal movements of the two eyes now requires unequal binocular movements. The oculomotor system learns to make these unequal movements and it retains this ability even when one eye is occluded after wearing anisometropic spectacle corrections for only 1 hour.

During head movements, magnification of the retinal image by spectacles increases retinal image motion during head rotation and causes the stationary world to appear to move opposite to the direction the head rotates. This can produce vertigo as well as stimulate a change in the vestibular stabilization reflex. When a magnifier is worn for only 1 h, the reflex can be exaggerated to compensate for the excessive retinal image motion. Following this adaptation, when the optical aid is removed, the exaggerated VOR causes the world to appear to move in the same direction that the head rotates. If you wear glasses, you can demonstrate this adaptation to yourself by removing your glasses and shaking your head laterally. If your wear negative lenses to correct for myopia, the minification they produce has caused a reduction in image stabilization and without your glasses, the world will appear to move opposite to the direction of head shake.

13.11 FOCUS AND RESPONSES TO DISTANCE

Our visual sense of space requires that we are able to accurately perceive objects at different distances. Single and clear views of targets at a finite viewing distance require that the visual system align the similar images of the target on corresponding retinal regions and that the optics of the eye adjust the focus to accommodate the near target (accommodation). The range of accommodation varies with age, starting at birth at about 18.5 D and decreasing 1 D every 3 years until approximately age 55 when it is no longer available (absolute presbyopia). The amplitude of accommodation available to an individual of a given age is remarkably stable across the population if extremes of refractive are not considered.

Spectacle corrections and other optical systems can influence both aspects of the near response. Accommodation declines with age until eventually, the near point is beyond the near working distance (functional presbyopia). In this situation, near targets can be imaged farther away from the eye with plus lenses so that they lie within the available range of remaining accommodation. The accommodative system is only able to maintain 2/3 of its full amplitude for long periods of time and when this range is exceeded by the optical demands of working distance, bifocals are typically prescribed. The magnitude of the bifocal correction depends upon the accommodative amplitude and the near working distance. For a typical 16-in or 40-cm near working distance that requires 2.5 D of accommodation, a bifocal correction is needed when the amplitude of accommodation is less than 3.75 D. Typically this amplitude is reached at about 45 years of age.

If spectacles are worn, the amplitude of accommodation is influenced by the sign (plus or minus) of the spectacle correction. Accommodation demand equals the difference in the dioptric value of the far point and the near point of the eye. These dioptric values can be described relative to the front surface of the eye or to the spectacle plane. The reciprocal of a specific viewing distance to the spectacle plane describes the spectacle accommodative demand, and this value is independent of the lens correction. However, the ocular accommodative demand (amount the eye needs to change power) required to focus targets at this distance does depend on the power and sign of the spectacle correction. Ocular accommodation is computed by the difference between the dioptric vergence subtended by the near point target at the cornea, after it is imaged by the spectacle lens, and the vergence subtended at the cornea by the far point of the eye. For myopes corrected with minus spectacle lenses, ocular accommodation through spectacles is greater than the spectacle accommodative demand and the reverse is true for hyperopes. For example, the ocular accommodative response to a target place 20 cm in front of the spectacle plane that is 14 mm from the eye is 4.67 D from an emmetrope, 4 D for a myope wearing a –6-D corrective spectacle lens, and 5.56 D for a hyperope wearing a +6 D corrective spectacle lens. Thus, near targets present unequal accommodative stimuli to the two eyes of anisometropes corrected with spectacles. Although the accommodative response is consensual (equal in the two eyes) the difference in the two stimuli will go unnoticed as long as it lies within the depth of focus of the eye (approximately 0.25 D). However, in the example given above, a 6-D anisometrope would have about a 1-D difference in the stimulus to accommodation presented by a target at a 20-cm viewing distance. Finally, this lens effectivity causes spectacle lens wearers who are hyperopic to become presbyopic before myopes.

13.12 VIDEO HEAD SETS, HEAD'S UP DISPLAYS AND VIRTUAL REALITY: IMPACT ON BINOCULAR VISION

A variety of head mounted visual display systems (HMD) have been developed to assist performance of a variety of tasks. Telepresence is an environment in which images from remote cameras are viewed on video screens to perform tasks at distal sites. In other applications, information in the form of symbology is added to a natural image to augment reality, such as in a heads up aviation application, and in still another application, virtual environments are simulated and displayed for entertainment or instructional value. The head mounted video systems usually display information in one of three configurations. These are monocular or monoscopic that present information to one eye, biocular where both eyes view an identical image, and binocular where slight differences in the two eyes' images stimulate stereoscopic depth perception. The biocular view avoids image conflicts between the two eyes that arise in the monoscopic systems, and stereopsis in the binocular systems helps to sort out or distinguish elevation and distance information in the perspective scene. Stereopsis also provides the user with fine depth discrimination and shape sensitivity for objects located within an arm's length. Each of these systems attempts to present coherent cues to space perception, however, due to physical limitations this is not always possible and cue conflicts result.

Distance Conflicts

The current designs of HMD devices introduce three stimulus conflicts. They present conflicting information about target distance to accommodation and convergence, conflicting visual-vestibular information, and conflicts concerning the spatial location of information to the two eyes. For example, the symbology presented to aviators in heads-up displays is set for infinity but large symbols appear to be near and this can initiate an inappropriate accommodative response. However, given sufficient time, subjects will accommodate correctly.[86] Currently all HMD units present a fixed optical viewing distance that is not always matched to the convergence stimulus in biocular units or the many states of convergence stimulated in binocular units. This situation is exacerbated by the presence of uncorrected refractive errors that can cause images to be blurred in the case of myopia or to force extra accommodation in the case of hyperopia, or to present unequal blur and accommodative stimuli in the case of anisometropia. Normally, observers with uncorrected refractive errors are able to adjust target distance to clear images but the HMD has a fixed target distance that is not adjustable. Units that provide self-adjusting focus run the risk of users introducing larger errors or mismatching the clarity of the two ocular images.

As described above, accommodation and convergence are tightly coupled to respond to approximately the same viewing distance. There is some flexibility to compensate for small differences between stimuli to accommodation and convergence but long periods of usage, particularly those requiring fusional divergence, to overcome an esophoria caused by excessive accommodation can produce eye strain. Tolerance for accommodative errors can be increased by extending the depth of focus with small exit pupils or with screens that have reduced resolution. It is also helpful to set the viewing distance at an intermediate value of approximately 2 m[87] to allow uncorrected mild myopes to see clearly while allowing a 3° range of stereo depth disparities. In biocular units where disparity is not varied, the optical distance can be set closer to 1 m to further compensate for uncorrected myopia and to place images near arm's length. Prolonged viewing at close distances can cause instrument myopia, a form of excessive accommodation, and postimmersion short-term aftereffects such as accommodative spasm.[88] Accommodative fatigue also can result after 30 min of stereo display use.[89] If refractive corrections are worn, the optimal image distance will depend on the tasks performed. Simulated computer screens should be at arm's length whereas views for driving simulators should be remote to provide more realism in the display.

Errors of perceived distance can occur when vergence distance is not matched to image size or perceptual task. These errors can result in perceptual image expansion (macropsia) or constriction (micropsia), particularly in binocular displays that stimulate a range of convergence values. These effects can be minimized by limiting the range of binocular disparities to a few degrees for near

objects and to use a biocular display when presenting views of distant objects simultaneously with foreground detail. Perspective cues along with motion parallax, overlap or superposition, and texture density gradients provide powerful depth cues for remote or complex scenes containing a wide range of depth information and binocular disparity adds little to these displays. Stereopsis is most useful for facilitating manual dexterity tasks with fine depth discrimination between objects and their 3-D shape located within an arm's length of the user. Static displays that don't utilize motion parallax will benefit more from the addition of stereoscopic cues.

Some HMDs and other virtual environments combine real and virtual information with a see-through visor or with remote rear projection systems that surround the viewer panoramically as in the Computer-Automatic Virtual Environment.[90] These mixed environments can introduce multiple and sometimes conflicting accommodative stimuli. When real variable focus and virtual fixed focus images are at different image distances, both cannot be cleared at the same time, though they may appear to be in similar locations in space. Conflicting near virtual targets can interfere with recognition of real distant targets.[91] Several optical solutions have been suggested to minimize these focus conflicts.[54] The depth of focus can be extended with pinhole pupils. A pinhole exit pupil projected to the eye pupil in a Maxwellian view system will preserve field of view. The virtual image is viewed through the Maxwellian pupil imaged via a beam splitter while the real environment is viewed through the natural pupil. Eye tracking might be necessary in Maxwellian systems to shift the exit pupil to follow eye movements.[92] Monovision is another possible solution in which a near lens is worn over one eye and a far lens over the other. A target that is in focus for one eye will be blurred for the other. The visual system is able to suppress the blurred image and retain the focused images of both eyes and also retain a large functional range of stereopsis.[93] Monovision has been used successfully in presbyopes with contact lens corrections, and it has been shown to work on prepresbyopes in most individuals.[55] The limitation of monovision is that it provides clear vision only for the two focal depths, plus and minus the depth of focus. The range of the two clear vision distance might be extended by aniso-accommodation; the ability of the two eyes to focus independently of each other while remaining binocular.[54] Another solution is a chromatic bifocal that takes advantage of the longitudinal chromatic aberration of the eye. Wavelengths of light at opposite ends of the visual spectrum have a 2-D difference in dioptric power for a given object distance. Given that nearer objects tend to be in the lower visual field, different monochromatic wavelengths combined with field segregation could be used in the virtual image control panel. Users viewing near objects could view long-wavelength images in the lower half of the virtual control panel. Thus, both real and red virtual images would stimulate an increase in accommodation. For distant real objects, the user could attend to the upper short wavelength images in the virtual display panel and real and blue virtual targets would stimulate a relaxation of accommodation. A simpler solution is to place a bifocal lens segment in the lower portion of the see-through window, bringing near real images to the same focal distance as the images seen on the virtual display.

Visual-Vestibular Conflicts

Virtual systems that are worn on the head or remain fixed in space both present conflicting visual-vestibular information. Normally, when the head rotates or translates, the eyes rotate in the opposite direction to keep the images of objects in space stabilized on the retina. The relationship between retinal image motion and head and eye motion is disrupted by the virtual display. In the case of an external virtual projection system like CAVE (Computer-Augmented Virtual Environment),[90] simulated movements of the visual scene that correspond to body movements are not accompanied by the appropriate vestibular signals. For example, a driving simulator displays changes in the road view while steering the virtual car. When making turns, the visual field appears to rotate but there is no corresponding vestibular signal. As a result, drivers of virtual systems tend to oversteer the turns because they underestimate the curved path of the automobile. Perceptual disturbances during similar phenomenon in flight simulators are referred to as simulator sickness. In contrast head mounted video displays can present a fixed visual stimulus while the head rotates such that vestibular signals are not accompanied by the appropriate visual motion stimuli. These conflicts can also

result in symptoms of nausea, vertigo, and general malaise even when very small head movements occur.[94–96] Visual-vestibular conflicts also occur with telepresence systems that present images that are either magnified or minified as a result of differences between the camera distance to objects and the viewer distance to the viewscreen. As a result, head movements that cause camera movements will stimulate excessive retinal image motion with magnification or too little retinal image motion with image minification. The mismatch will cause adaptive adjustments of the VOR and possible simulator sickness.

The oculomotor system responds to this visual-vestibular conflict during steady fixation by suppressing the VOR and adaptively reducing its gain. Thus, a user viewing a 2-h motion picture on an HMD while making a normal range of head movements during conversation with other persons will adapt their VOR to be less responsive to head motion. This adaptation can produce postimmersion symptoms where the adapted VOR remains suppressed such that head movements without the HMD will not stimulate a sufficient vestibular ocular movement to stabilize the retinal image. The user will perceive the world to move with his head and this can cause nausea, vertigo, and malaise. Attempts to move images with the head using a head tracking system that updates image position during head rotation have been unsuccessful[97] because of small delays in image processing that desynchronize expected image motion and head movements. It is possible that an image could be blanked during large head movements and stabilized with a head tracker during small head movements. The blanking would be similar to the normal suppression of vision during saccadic eye movements. Other solutions are to use see-through and see-around virtual displays so that real objects in the periphery are always visible during normal head movements so that some visual and vestibular stimuli remain coherent.

Spatial Location Conflicts

No existing HMD has the wide field of view of the human visual system in a natural environment. The horizontal field of view in currently available HMDs ranges from 22.5° to 155°.[98] The larger fields of view in binocular systems are expanded by partially overlapping the two monocular images. Note that the entire monocular and binocular portions of the field of view lie within the normal 114 to 120° binocular overlap of the normal visual system. Partial overlap in HMDs can be produced by displacing the right field to the right and left field to the left. Each eye has a monocular flanking component in its temporal visual field. It is also possible to reverse the displacement so that the monocular components are in the nasal-visual field of each eye (Fig. 12). These two organizations are consistent with two different occlusion aperture configurations. The former has the same organization as a binocular field seen on a near screen in front of a background. Thus the total image is seen as a discontinuous surface in depth with the central binocular portion at a proximal distance compared to the monocular portion that is seen farther away.[6] The latter case has the same organization as a single continuous surface viewed through an aperture (porthole effect). The former system is more likely to cause binocular rivalry in the monocular regions of the field than is the latter approach. This suppression can cause a moonlike crescent shape (luning) in the flanking monocular region that corresponds to the border of the image seen by the contralateral eye and this blocks visibility of the monocular field crescent seen by the ipsilateral eye. The luning can be reduced by blurring the edges of each eye's image borders or by using the crossed view configuration. Interestingly, the latter crossed-view approach is preferable in head mounted displays.[99]

Visual suppression and binocular rivalry suppression are also stimulated in monocular image displays. Rivalry occurs between the image presented to one eye and the natural scene presented to the other. Even if one eye is occluded, the dark image of the patched eye will rival with the visible image of the open eye. This rivalry can be minimized by presenting the patched eye with a uniform field with the same mean luminance and color as the open eye image. This can be accomplished easily by placing a diffusing filter over the nonseeing eye. In cases where the two eyes view independent images, it might be possible to control which eye is suppressed by moving the image in the seeing eye and keeping it stationary in the nonseeing eye. This technique is based on the observation that motion is a dominant feature for binocular rivalry.

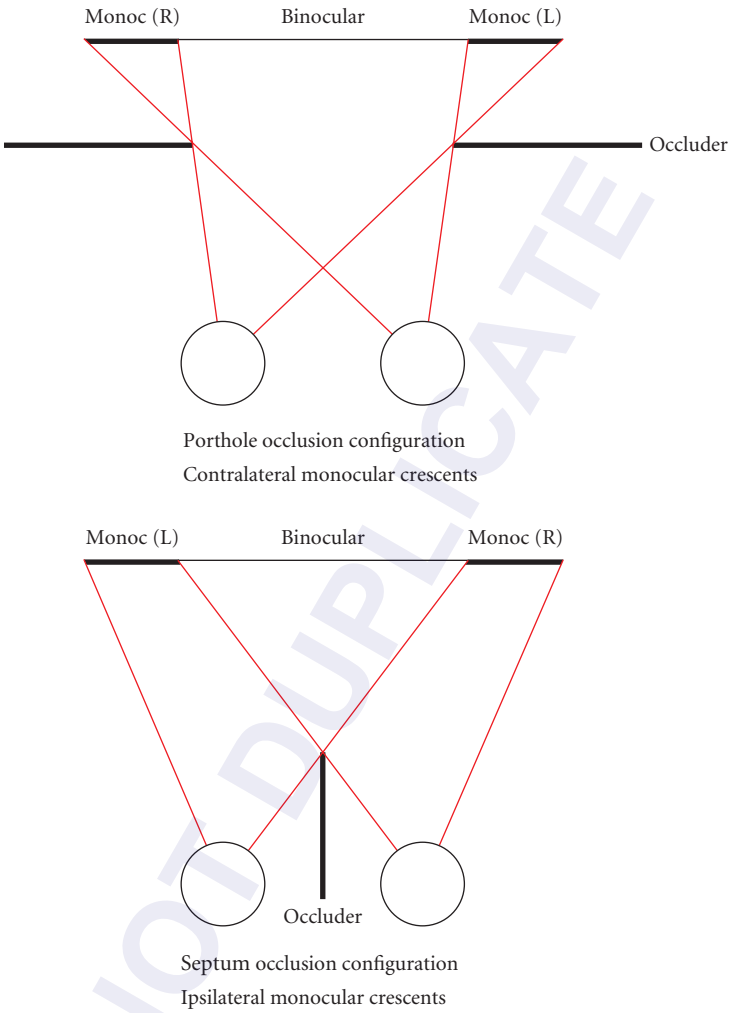

FIGURE 12 Occlusion figure with port hole and septum. Partial overlap of the visual field simulates obstructed views by a port-hole aperture or septum in the mid-sagittal plane.

Optical Errors

The success of any binocular viewing instrument depends in large part on the precision of alignment and quality of distortion free optics. Alignment errors can produce vertical, horizontal, and torsional disparities. Of these, the vertical errors are the most troublesome. There is limited range for vertical vergence and slow response times.[77] The oculomotor system can adapt its vertical alignment posture (vertical phoria) if the vertical disparity is constantly present; however, if the HMD is worn intermittently then no adaptation will occur. Horizontal errors, especially in the convergence direction, can be overcome easily by vergence eye movements. Torsional errors cause overall torsional disparities which can cause perception of slant about the horizontal axis if the virtual scene is superimposed

by see-through optics on the natural visual environment. However, if an opaque visor is used so that only the virtual display is visible, slant distortion will not be perceived with cyclotorsion disparity.[100] This is because the visual system only interprets slant when there is horizontal shear disparity between vertical lines but no vertical shear disparity between horizontal lines. When both forms of shear are present, this is interpreted as resulting from eye rotation rather than real object slant. Cyclodisparity in large field displays will stimulate cyclovergence responses that can have postimmersion aftereffects in the form of cyclophoria.[83] Errors in the baseline separation of the entrance pupils of the optical system can produce divergent disparities if it is set wider than the interpupillary distance. The oculomotor system has limited divergence ability and this stimulus can cause headaches and visual discomfort. Finally, low quality optics that have distortions such as barrel, pincushion, and keystone will introduce horizontal, vertical, and torsional disparities in both biocular and binocular displays if the distortions are not identical for the two eyes or if the visual fields are displaced slightly in the two eyes. Displacements could result from alignment errors or from partial field overlap used to expand the field of view. The disparities produced by these distortions can cause idiosyncratic warpage of the virtual image and vertical disparities that stress the oculomotor system.

14.1 GLOSSARY

Aphakia. An eye lacking a lens, usually as a result of cataract surgery.

Age-related macular degeneration (AMD). A disease that results in loss of vision in the central retina or macula due to damage to the photoreceptors and retinal pigment epithelium of the retina, often secondary to changes in the choroid (blood vessel layer) and Bruch's membrane. There are two major forms, called "wet," or exudative, and "dry," or atrophic. The dry form is more common, but the wet form is responsible for the majority of cases involving severe vision loss.

Cataract. An opacity or clouding of the lens resulting in a reduction in the amount of light transmitted to the retinal image and an increase in the light scatter. This is the leading cause of blindness worldwide, but can be treated successfully by removal of the lens.

Diabetic retinopathy. A disease of the eye caused by diabetes that leads to a proliferation of blood vessels. These blood vessels may swell and leak. When the resultant scar tissue shrinks the surrounding vitreous humor, it may cause the retina to detach, leading to loss of vision in the affected region of retina.

Glaucoma. A group of diseases, often but not always, associated with high intraocular pressure, resulting in death of ganglion cells.

Intraocular lens (IOL). A prosthetic lens usually implanted in the eye to replace the natural lens following its removal. IOLs may be placed in front of the pupillary plane (anterior chamber lenses) or

behind the pupil (posterior chamber lenses). They are manufactured from a variety of materials, the most common of which are polymethylmethacrylate, silicone, and hydrogels.

Phakia. An eye with a natural lens, from the Greek *phakos* or lens.

Presbyopia. Greek for "old sight," is a condition in which an individual has lost the ability to accommodate sufficiently for near work. This results in the need for "reading glasses" around the age of 40 or 50 years.

Pseudophakia. An eye with an artificial or intraocular lens implanted to replace the natural lens following its removal.

14.2 INTRODUCTION

Senescence occurs in the optics of all human eyes and the resulting changes in the spatial and spectral distribution of light comprising the retinal image can have a profound impact on vision. These optical changes have enormous economic consequences for health care and society, and although some effective treatments exist, optical quality in the senescent eye remains inferior to that of younger eyes. Before describing the optical and visual changes that characterize normal aging, it is useful to consider the scope of the problem in light of demographic changes in the world's aging population.

14.3 THE GRAYING OF THE PLANET

The proportion of the world's population that is elderly is higher now than at any other point in recorded history. In the last two decades, the number of individuals above age 65 years has increased at more than twice the rate as that of individuals below 65 years.[1] At present, every month, another 1 million of the world's population enters its sixth decade of life. As a result, the number of individuals age 60 and above is likely to change from one in ten today to one in five by 2050, and one in three by the year 2150. As illustrated by Fig. 1, the global growth rate for individuals over age 80 is occurring

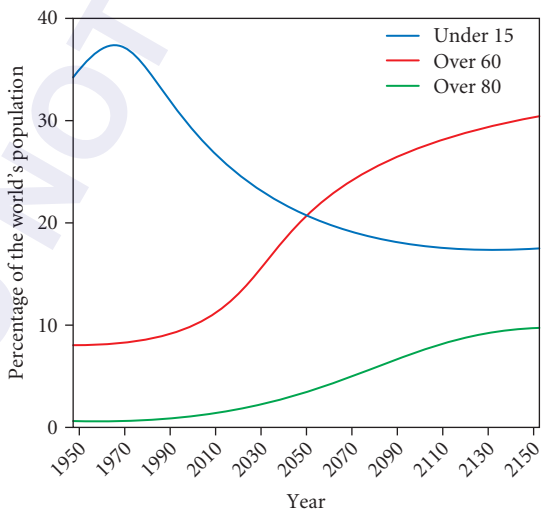

FIGURE 1 Percentage of the global population projected from 1950 to 2150 for three age groups based on statistics provided by the United Nations.[2]

at an even faster rate. Indeed, the number of centenarians in the United States has doubled every 10 years since 1960. At the same time, there is a corresponding decline in the proportion of the population below 15 years of age.

Many factors have contributed to this remarkable demographic shift in the age distribution, including a change in the fertility rate, improved hygiene, nutrition, disease control, and education. These trends are generally more apparent in less developed countries, and the demographic shift in the elderly population is now more rapid in these parts of the world. For example, in 1995 there was a global increase of 12 million persons at or above age 60 and nearly 80 percent of it was due to a change in less developed countries. The countries with the fewest resources at present will thus have less time to cope with the social and economic consequences of an elderly population. It is not clear how long these present demographic shifts will continue into the future and when they will reach equilibrium.

Some Implications of Living Longer

Some theoretical calculations place the maximum human life span at about 120 years, but there are reasons to think that this may not apply to the eye. The demographic shifts in longevity of the eye are apparently not keeping pace with that of the rest of the body. Research to Prevent Blindness estimates that the number of blind individuals will double between 1999 and 2030. If true, the social, health, and economic consequences will be profound. One eminent authority put it this way: "Mathematically speaking, it is permissible to say that those who prolong life promote blindness" (Ref. 3, p. 306).

Health Implications and the Problem of Defining Normal Aging Current projections for the future are that as the baby boomers (the cohort of 76 million Americans born between 1946 and 1964) start to turn age 65 in the year 2011, they will be better educated, have better health, and more financial resources than did their parents when they retired. All indications are that retiring baby boomers will read more and want to spend more time in outdoor leisure activities than their parents did at comparable ages. For the age group over 65 years of age, there are also some indications that the rates of disability and disease are decreasing compared to previous generations, but this is not so for vision. Older adults experience a higher rate of visual disability and ocular disease than younger individuals, and the rate accelerates after about 40 years of age. For example, glaucoma is about 8 times more common for individuals above age 65 than in the general population. In the Framingham study,[4] 50 percent of participants age 75 and over had at least one of four visual "diseases:" age-related macular degeneration, cataract, diabetic retinopathy, or glaucoma.

Many studies of "normal" aging eyes fail to include significant numbers of eyes older than 80 years (a notable exception being Haegerstrom-Portnoy[5]). Thus, most of the aging effects described in this chapter fail to describe very old (80 to 100 years) eyes. In addition, most studies of aging attempt to characterize the visual system with many factors controlled, such as by testing with optimal refraction rather than habitual refraction. These controls are essential for separating the factors underlying normal aging, but they necessarily overestimate the quality of vision experienced outside the laboratory.

There is little agreement about where to draw the line between senescent degradation in vision and some forms of ocular pathology. For many researchers, normal aging is defined by exclusion—the changes in vision that occur when overt ocular disorder and disease are not detected. An alternative distinction between aging and disease is based on the amount of tissue changed or when visual loss exceeds a criterion. Both of these definitions are used to define cataract, a loss of transparency of the lens resulting from cumulative changes in products of oxidation that can dramatically elevate intraocular light scatter. There are several different types of cataract that can degrade the optical quality of images formed on the retina and consequently undermine the quality of the "neural" image transmitted by the retina. The biochemical events leading up to these lenticular changes occur continuously across the life span so the presence of this disorder is largely a matter of where the criterion is set on the continuum of normal aging.

Most individuals will still be able to approach their golden years without frank visual pathology. However, no individual should expect to have the quality of vision experienced in youth. Indeed, perhaps 20 years prior to retirement, most individuals already will have experienced the need for

"reading glasses" to correct near vision due to the senescent reduction in or loss of accommodation. Some problems of optical origin can be corrected or compensated by optical means, but additional losses in vision may be expected due to neural changes for which there are no known remedies. Some current research has focused on factors that might contribute to normal aging of the eye that could be controlled by life style choices such as diet[6] or exposure to ultraviolet[7] and short-wave visible[8] radiation. Whatever the cause, any impairment of our dominant sensory system will inevitably have behavioral consequences. In some cases, this may be an inconvenience such as slower reading or the need for better lighting, while in other cases it may lead to more serious problems such as accidents, falls, and greater dependence on others for daily activities. For many, senescent changes in vision will become the dominant factor limiting their quality of life.[9]

Economic and Social Implications of Aging Eyes There is a gradual reduction in accommodative amplitude throughout adulthood resulting in a complete loss of accommodation during the sixth decade of life. Combining this information with the fact that each day 10,000 people in the United States reach the age of 50, there is little wonder that ophthalmic corrections for reading and near work will account for approximately half the revenues in the multibillion dollar ophthalmic lens industry.

Visual impairment secondary to diseases of the eye also creates a sizeable economic impact on our society. For example, visual impairment and blindness for individuals above age 40 have an estimated cost of $51 billion per annum in the United States alone.[10] In addition, approximately 2.8 million cataract surgeries are performed each year in the United States at an annualized cost of about $25 billion. The costs of presbyopic spectacle correction may be even higher. These numbers are almost certain to increase due to the increasing proportion of the population that is elderly.

Additional economic consequences of our aging population will be created because the elderly generally require more special services, housing needs, and medical care, often as a result of visual impairment or blindness. For example, vision impairment increases the risks of falls by sixfold.[11] Senescent changes in vision are also likely to impose new burdens on public transportation systems in view of the fact that about half the world's elderly population today live in cities, and that proportion is expected to increase to about three-fourths, at least in more developed countries. New demands will be made for housing these elderly individuals in order to promote independent living.[12] Being able to care for oneself is not only important for self-esteem, but it also has enormous economic impact. Architects and lighting designers will have to take into account age-related changes to the visual system in planning for new environments inhabited by the elderly. Current standards for lighting are almost entirely based on college-age students, although there have been new calls for explicit attention to the visual needs of aged individuals.[13] The goal of such standards would be to find conditions that can compensate for sensory losses, to be described later, while not introducing conditions that promote "disability glare." Such lighting considerations might promote greater safety in the home to facilitate independent mobility and support communication through computers and reading and other visual tasks involving hobbies and work.

14.4 SENESCENCE OF THE EYE'S OPTICS

Senescent changes influencing image formation are prevalent in all optical components of the eye. The following sections describe some of these changes in detail.

Senescent Changes in the Optical Components of the Eye

Tears The anterior surface of the eye is bathed by tears that produce an optically smooth air-tear interface mirroring the global shape of the cornea. The refractive index of the tears approaches that of the underlying corneal epithelium, therefore, the optical impact of the rough corneal epithelium surface is essentially eliminated by index matching. Because the tear film is so thin (3 μm)[14] it is vulnerable to evaporation effects, and it is inherently unstable. Stability and uniformity are enhanced by a

surface monolayer of lipids and blinking. Insufficient blinking and/or inadequate tear volume or lipid coating can cause the uniform tears to "break-up" into a patchwork of tears leaving regions of dehydrated mucins and the optically rough epithelium exposed, resulting in increased optical scatter and aberrations[15] and reduced visual performance.[16] The presence of dry eye is an indicator of inadequate tears, and the prevalence of dry eye syndrome increases with age.[17] With increasing age, tear production by the accessory and main lacrimal glands decreases,[3] the lipid layer gets thinner,[18] corneal innervation and sensitivity decline,[19] and in combination, these factors lead to reduced tear production[20,21] and blink rates. All of these factors may contribute to reduced optical quality of tears in older eyes, which may be most pronounced during activities such as reading which lowers blink rates.

Cornea The human cornea consists of three discrete layers separated by two basement membranes. The outermost epithelial layer, composed of basal, wing, and surface cells, acts as a barrier to the external environment and is subject to a rapid rate of renewal, with the result that its cells are replaced every 5 to 7 days.[22] The middle layer, or stroma, is a matrix of collagen fibers as well as fibroblast-like cells called keratocytes and accounts for approximately 90 percent of the corneal thickness. The stroma is sandwiched between two membranes. Anterior and posterior to the stroma are Bowman's and Decemet's membrane, respectively. The transparency of the stroma is due to the uniform density and subwavelength spacing of collagen fibers, and any disruption of this order caused by such factors as increased hydration will cause light scatter and loss of transparency. Because of the tendency of the stroma to imbibe water there must be a way to regulate corneal hydration. The extent of corneal hydration is largely controlled by energy-dependent-ion coupled fluid transport mechanisms located at the innermost layer of the cornea, the corneal endothelium. The endothelium is made up of a single layer of cells. At birth, the corneal endothelium has about 4500 cells/mm^2, but the number is reduced to about 2000 to 2500 cells/mm^2 by age 70 or 80. Although the surviving cells become larger to maintain approximately constant total tissue volume, a smaller total number of fluid transport mechanisms remain in the corneal endothelium. As a result, proper corneal hydration is sometimes a problem in the elderly. The rate of decline in endothelial cell density is accelerated by cataract surgeries,[23] but for the typical eye sufficient endothelial cells remain throughout life.

The cornea is the most powerful refractive element in the human eye, accounting for about 40 to 45 D of optical power. Although it has a lower refractive index than the lens, the difference of refractive indices, which is directly proportional to dioptric power, is highest at the air-tear/cornea interface. The cornea is not spherical; its reduced curvature in the periphery helps reduce the spherical aberration of the cornea. The refractive index of the cornea[24] and curvature of its anterior surface[25] appear to undergo little change with age, but with aging the axis of corneal astigmatism loses the "with the rule" bias seen in younger eyes.[26,27]

As can be seen from Fig. 2, the cornea absorbs most of the ultraviolet (UV) radiation below about 320 nm. Absorption of this radiation in sufficient intensity can damage the cornea (e.g., actinic keratitis), but long-term effects are rare because damage is typically confined to the corneal epithelium which is capable of rapid renewal. Stem cells in the corneal margins continue to generate epithelial cells, which then migrate across the cornea to generate the basal layer of the epithelium. This may be why the absorption spectrum of the cornea undergoes only small changes with advancing age.[28] Cumulative absorption of UV light may, however, lead to corneal abnormalities such as pterygium, a condition that involves the advancing growth of abnormal tissue from the border between the cornea and sclera, the limbus, onto the clear cornea. This increases in prevalence with increasing age.[29]

Anterior and Posterior Chambers The cornea and lens are separated by a fluid-filled space. This fluid (the aqueous humor) maintains the metabolism of the cornea and lens, as the transparency requirements of these structures necessitate that they have no blood supply. The much larger volume between the cornea and iris is the "anterior" chamber, and the smaller volume between the iris and the lens is the "posterior" chamber. The aqueous humor is produced by the ciliary body around the margins of the posterior chamber, flows to the anterior chamber, and is drained through the trabecular meshwork and into Schlemm's canal around the radial margins of the anterior chamber. The optical role of the aqueous, therefore, is twofold. It enables the avascular lens and corneal endothelium to function (and thus retain lens and corneal transparency) while maintaining its own

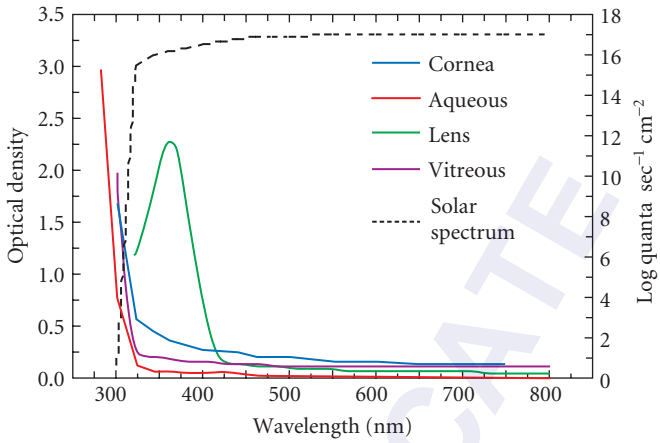

FIGURE 2 Optical density (decadic logarithm of the reciprocal of transmittance) of human ocular media is plotted as function of wavelength (left ordinates; from Boettner and Wolter[30]). Log quanta in sunlight reaching the surface of the earth from an angle of 30° from the horizon is plotted as a function of wavelength (right ordinates; from Brandhorst et al.[31]). (*After Werner.*[32])

transparency. The optical density of the aqueous changes negligibly with age[30] and any damage sustained by the aqueous resulting from absorption of light is likely to be unimportant for senescence because it is rapidly replaced.[22] Although there are pathological conditions that directly affect aqueous transparency (e.g., uveitis in response to infection), they are primarily transient and not related directly to age. There is a senescent reduction in both the production and drainage of aqueous,[33] and an increased likelihood of failure of the homeostatic production and drainage system. As drainage is unable to keep up with production, intraocular pressure rises, and glaucoma can ensue (see section "Glaucomas"). One optical side effect of glaucoma can occur when fluid in the corneal epithelial layer builds up between the basal epithelial cells,[34] causing colored diffraction halos similar to those generated by nocturnal eye closure, contact lens wear, or prolonged exposure to fresh water during swimming. A healthy epithelium maintains its high transparency by tight junctions between adjacent cells; however, as fluid builds up between the regular array of cells, classic wavelength-dependent diffraction occurs which is visible as colored halos. Glaucoma is generally associated with corneal epithelial edema only when pressures become very high, which is more typical of acute angle closure glaucoma. Interestingly, a much rarer condition in older eyes, ocular hypotony, can generate loss of corneal transparency because of stromal edema resulting from IOP being too low.[35] Both cases emphasize the critical role played by intraocular pressure in maintaining corneal hydration and thus corneal transparency.

Pupil The dilator and sphincter muscles of the iris control the size of the pupillary aperture that, for young adults, varies in diameter with the level of the prevailing illumination from approximately 2 to 8 mm. As in any optical system, the size of the aperture has important consequences for image formation. The smallest pupillary diameters can decrease optical quality through diffraction effects. The optimal pupil diameter is about 2.4 mm from the point of view of classic image quality.[36] Traditionally, larger pupils at lower light levels are considered to represent a compromise between improved sensitivity (more light entering the eye) and diminished image quality (more aberrations in peripheral optics). However, this view ignores the very significant role of photon noise on image quality.[37] Including photon noise in image calculations, Laughlin[38] argued that pupil dilation as light levels drop ensures optimal image quality. Employing a similar hypothesis (pupil size is adjusted to optimize retinal image quality), pupil miosis that accompanies senescence may also be considered as an adaptation to poorer optical quality in older eyes.

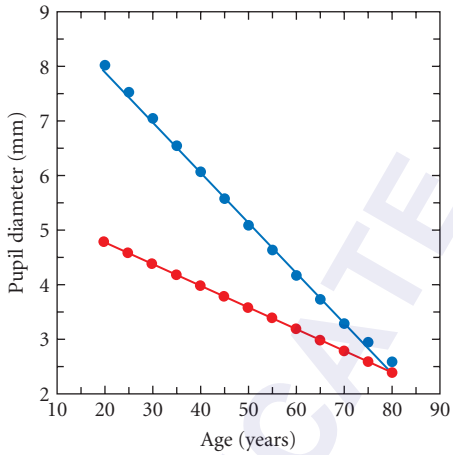

FIGURE 3 Mean diameter of the human eye pupil is plotted as a function of age. Blue and red symbols show dark- and light-adapted values, respectively. (*Data from Kornzweig.*[39])

Maximal pupil diameter occurs in adolescence and then progressively decreases with increasing age. As shown in Fig. 3, age-related change in diameter differs for dark-adapted and light-adapted conditions. Changes in pupil diameter with light level provide a mechanism of adaptation through adjustment of visual sensitivity with illumination. However, the change from maximum to minimum size influences retinal illuminance by only about a factor of 10, so the pupil plays only a small role in adaptation mechanisms that allow us to function over a range of ambient illumination covering about 12 log units.

Age-related changes in pupil size are noticeable in the elderly but actually begin in the early adult years. For example, when fully dark adapted, there is essentially a monotonic decrease in pupil diameter beyond 10 years of age.[40] Spatial vision depends on light level, and although a smaller pupillary diameter allows less incident light to fall onto the retina, it is unlikely that a smaller pupil accounts for significant age-related changes in spatial vision. For example, it has been demonstrated that age-related differences in contrast sensitivity under photopic and mesopic ambient light levels cannot be explained solely by differences in pupillary diameter.[41] In fact, there actually are some benefits associated with an age-related reduction in pupil diameter. The smaller pupil of older persons diminishes age-related changes in higher-order aberrations[42] and the optical transfer function of the eye at low luminance levels.[43] In addition, the smaller pupil in the elderly reduces the diameter of the retinal blur circle, thereby increasing the depth of focus by about 0.5 D between the ages of 30 and 70 years.[44] More significantly, since blur circle size (radians) = defocus (Diopters) * pupil diameter (m),[45] as pupil size is halved, blur circle size is also halved. For example, if defocus was 4 D, then the impact of halving the pupil would be the same as halving the defocus, or a 2-D change in image quality. Thus halving of the photopic pupil and the more than factor of 3 reduction in mesopic pupil diameters in older eyes will greatly reduce the level of blur. Senescent pupil miosis may be nature's attempt at minimizing the impact of presbyopia.

The Lens The lens consists of only one cell type, but its thickness increases throughout the entire life span due to the accumulation of cells to form a series of concentric layers.[46] This results in a continuous axial thickening and reduction in the depth of the anterior chamber.[47] The oldest cells are thus found in the center or nucleus (indeed these are the oldest cells in the body in that they are born early in gestation and are never replaced), while the youngest cells comprise the outer or cortical layers. As the cells of the lens age, they lose their organelles and become essentially metabolically inert.

Molecules that absorb UV and short-wave visible light are present in the newborn lens and their numbers increase continuously over the life span.[48] Thus, the curve for the lens shown in Fig. 2 can be, to a first approximation, scaled multiplicatively with age.[49] A number of studies have measured the optical density of the human lens as a function of age. Some have described these changes in density by a linear function of age[49,50] while other evidence demonstrates a bilinear function due to an acceleration in the aging function after about 60 years.[51] The precise form of the aging function is difficult to determine because of substantial individual differences at every age (on the order of 1.0 log unit at 400 nm). However, it should be noted that the average infant lens transmits about 25 times more light at 400 nm to the retina than the average 70-year-old eye!

Transparency/cataract Cataract refers to an opacity of the lens that decreases vision by a somewhat arbitrary criterion amount. An acceleration in the population mean rate of change in lens optical density beyond approximately 60 years of age could be due to the inclusion of subjects having cataract.[52] However, it is not clear where normal aging ends and cataract begins because this increase in optical density continues throughout life. In his comprehensive monograph on this subject, Young[53] summarized a substantial literature which lead him to conclude that: "No discontinuity between senescent and cataractous changes can be detected at the molecular level in the human lens….The most sophisticated techniques of modern biophysical and biochemical analysis have so far failed to uncover any feature of the cataractous lens that suggests cataract is anything more than an advanced stage of normal aging" (Ref. 53, p. 56).

It should be added that there are several forms of cataract depending on the part of the lens affected (nuclear, cortical, posterior subcapsular) or etiology (congenital, age-related, chemically induced, trauma induced, disease induced). Losses of lenticular transparency can sometimes occur through occupational hazards associated with infrared light exposure such as in "glassblowers cataract" due to the conduction of radiant heat that is absorbed by the cornea and, to a lesser extent, the iris.[54] Most often, changes in the transparency of the lens are associated with cumulative exposure to ultraviolet radiation. Weale[55] has proposed that the specific form of cataract depends on genetic factors while the common etiology is most often cumulative exposure to solar radiation (see section "Life-Span Environmental Radiation Damage").

Currently, the only effective treatment for cataract requires surgical removal of the lens and in more than 90 percent of such surgeries performed in the United States an intraocular lens (IOL) is implanted in its place. A properly selected IOL obviates the need to wear thick spectacle corrections or contact lenses for the hyperopia that would otherwise ensue. Most of these lenses now contain UV-absorbing chromophores, but this is a relatively recent design improvement.

Accommodation and presbyopia Accommodation refers to the ability of the eye to adjust its power to focus the images of objects located at varying distances in the environment. Contraction of the ciliary muscle located within the ciliary body of the eye allows the anterior, and to a lesser degree the posterior, surface of the lens to change shape thereby altering the dioptric power of the lens (see recent review by Charman[56]). The amplitude of accommodation refers to the *dioptric* difference between the farthest and nearest distances in which an object remains in focus. Age-related loss in accommodative amplitude (Fig. 4) has been attributed to various causes including reduced ciliary body function, changes in the geometric relationships of the lens and the surrounding zonules and ciliary body based on progressive circumferential enlargement of the crystalline lens, but primarily it is due to changes in the elastic properties of the lens and to a lesser extent the capsule.[56,57] The red symbols in Fig. 4 are from the Basel longitudinal study of individuals followed for 20 years, with different subjects starting the study at different ages.[58] These data agree well with the classic data of Donders[59] shown by blue symbols.

As the amplitude of accommodation decreases, a near correction for tasks such as reading may be required. This typically occurs within the fifth decade of life and is known as presbyopia (meaning "old sight"). Because the accommodative amplitude changes continuously, the definition of presbyopia and its onset are somewhat arbitrary. The two sets of data in Fig. 4, although separated in time by about a century, are from similar geographic locations. Age of onset of presbyopia depends on many factors including geographical latitude and average ambient temperature.[3]

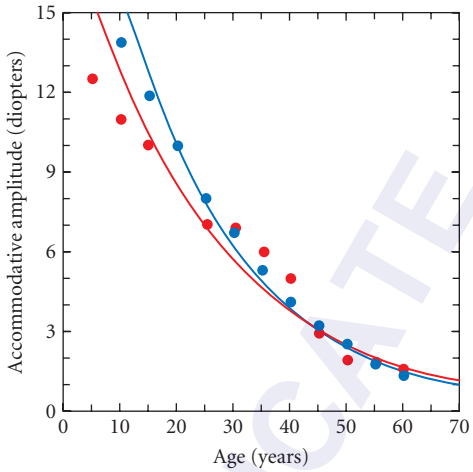

FIGURE 4 Amplitude of accommodation (diopters) is plotted as a function of age. Note that the tasks used for measurement involved both accommodation and depth of focus (which the clinical literature often calls pseudoaccommodation). This depends on both optical and neural factors. Red symbols (curve) from Brückner et al.[58] and blue symbols (curve) from Donders.[59] Curves are based on best-fitting exponential functions.

Vitreous Separating the lens from the retina is the vitreous chamber. This space, which occupies about 80 percent of the eye's volume, is filled with a colorless gelatinous substance called the vitreous humor. It is made up of about 99-percent water mixed into a gel-like mesh of collagen fibers and hyaluronic acid. Its role is primarily structural and not metabolic. In order to function it must retain its volume and remain transparent. As the vitreous ages, the gel is gradually replaced by unbound water. This liquefaction of the vitreous is responsible for the increased movement of the vitreous during and following eye movements in the aging eye.[61] Local shrinkage of the vitreous gel is responsible for the increased prevalence of posterior vitreous detachment which can be present in up to 65 percent of eyes older than 65 years.[60] The liquefaction and shrinkage can lead to increased numbers and movement of floaters (visible shadows and diffraction phenomena associated with clusters of fibers and other optical inhomogeneities in the vitreous) consistent with increased movement of the vitreous in old eyes.[61]

Retina The optical role of the retina is complex. Its primary optical role is to absorb photons in the photopigment. However, the secondary optical role reflects needs for transparency, opacity, and waveguiding. Because the retina is "inverted," light must pass through the neural retina prior to reaching the photopigment. Thus, the neural retina must remain highly transparent. For example, it is for this reason that retinal ganglion cell axons are generally unmyelinated until they have exited the eye. Even though most of the retinal tissue is transparent, the blood supply to the postreceptoral neurons remains opaque. The lateral displacement of the foveal postreceptoral neurons removes the need for any retinal blood supply in the central fovea. Thus, most eyes have a foveal avascular zone with an accompanying increase in transparency and presumably image quality in the central fovea.

External to the layer of photopigment (which resides in the outer segments of the photoreceptors) lies a second layer of pigment, melanin, in the pigmented epithelium cells (melanin and hemoglobin in the choroid are also effective pigments). It has been suggested that melanin in the RPE has a primary antioxidant role protecting the retina from age-related oxidative damage.[62] Optically, this pigment plays the same role as the black paint used to coat the inside of a camera; it reduces the

reflection of photons that are not absorbed by the photopigment. For example, at the peak sensitivity of the photopigment, about 2/3 of the photons entering the outer segment are absorbed by the photopigment (0.5 optical density), and the outer segments cover about 70 percent of the retinal area, and thus, slightly less than 50 percent of photons arriving at the retina will be absorbed. This percentage is lower in the peripheral retina where the outer segments are shorter, and will generally be lower due to photopigment bleaching (which never exceeds 50% under natural conditions), and of course will be lower at wavelengths other than the peak. The effectiveness of the photopigment and the pigment epithelium combine to improve image quality of the eye but make it difficult for clinicians to obtain high intensity images of the fundus as little light is reflected back out of the eye.

A third major pigment in the retina, most dense around the fovea, is a yellow pigment called the macular pigment (MP). It is located in the receptor fiber and inner plexiform layers[63] where it selectively absorbs short-wavelength light en route to the photoreceptors. Figure 5 shows the spectral absorbance of the foveal macular pigment for an average observer. The peak density is at 460 nm, near the peak sensitivity of the short-wave-sensitive cones (440 nm).

Several different methods (fundus photography, entoptic visualization, and psychophysics) indicate that the peak density of the MP is at the fovea and follows an exponential decay to negligible levels at approximately 5 to 10° retinal eccentricity.[65] There are large individual differences in the absorption of the macular pigment (from about 0 to 1.0 log unit at 460 nm), but there is little age dependency after early childhood.[66,67]

While the function of the MP is still uncertain, it has been suggested that the presence of this pigment improves the optical image quality at the retina and may aid in maintaining the health of the macula. Because MP selectively absorbs short-wave light, it has been proposed that it helps to minimize the effects of chromatic aberration[68] thereby improving polychromatic image quality in the central retina. With regard to the health of the eye, MP is made up of carotenoids that tend to neutralize photosensitized molecules[69] and inhibit free radical reactions that are toxic to retinal cells. Thus, it has been suggested that the MP may protect the retina from actinic damage that may lead to age-related changes in visual sensitivity and to the development of age-related macular degeneration.[8]

A fourth, rhodopsin-based, visual pigment has recently been observed in some retinal ganglion cells. It has peak sensitivity around 460 nm, and it has been suggested that it may be responsible for light-induced melatonin suppression and thus maintenance of the circadian rhythm. In a recent

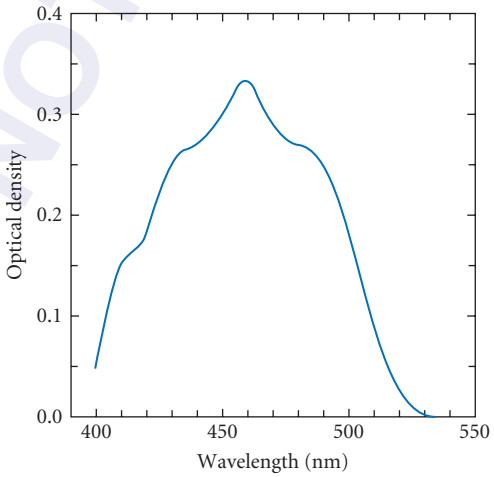

FIGURE 5 Optical density of the human macular pigment is plotted as a function of wavelength. (*Data from Vos.*[64])

analysis, Charman[56] showed that the combined effects of senescent miosis and lens yellowing would reduce the photon catch of this pigment in old eyes to only 10 percent of that of younger eyes and thus may contribute to age-related changes in circadian rhythms.

In addition to the transparency and pigmentation properties described above, the retinal photoreceptors have important optical waveguide properties. Photoreceptors must contain large numbers of photopigment molecules because large numbers of photons need to be captured, and photopigment regeneration is slow (half-life of 2 and 7 min for cones and rods, respectively). Also, in order to adequately sample the retinal image spatially, photoreceptors must be small. Typical photoreceptors contain long tubes filled with pigment with their axis aligned approximately perpendicular to the image plane (e.g., outer segments of foveal cones can be 60 μm long and only 2 μm in diameter). Such geometry creates fiber-optic or waveguide properties in these cells. These waveguide properties play an important role in reducing the impact of highly aberrated and scattered light so that they maximize the probability of photon catch for light entering in and around the pupil center [the Stiles-Crawford effect (SCE) see Chap. 8], and in so doing, enhance the optical quality of the retinal image.[70] A recent report[71] has demonstrated that retinal Müller cells may also act as optical fibers funneling light through the retina to the photoreceptors to avoid scattering by the neural and vascular cells of the retina. No significant senescent changes occur in the SCE implying stability in photoreceptor orientation.[72,73]

There are several senescent changes in the optics of the retina. The depth of the foveal pit decreases with increasing age,[74] while the pigmented epithelial cells accumulate lipofuscin throughout life as a by-product of phagocytosis of photoreceptor outer segments. Over age 70, lipofuscin and melanolipofuscin granules may occupy up to 20 percent to 33 percent of the free cytoplasmic space of the cell.[75] Also, between the ages of 10 and 90 years, there is a 2.5-fold decrease in melanin concentration within the retinal pigmented epithelial cells.[76] All of these changes can alter the final destination and distribution of photons within the retina. In addition, these cellular alterations are manifest in an age-related increase in lipofuscin autofluorescence,[77] which may serve as a possible marker for cellular aging, oxidative damage, and dysfunction associated with retinal disease.[78] The combined impact of cellular senescence on the retinal optics is unknown, but it likely contributes to the increased scatter observed in older eyes.[79]

Eye Size The globe of the eye grows rapidly in the first year of life and then more slowly until about 5 years of age when it reaches an asymptotic sagittal length of about 23.5 mm. While the globe of the eye changes relatively little over the adult years, the lens continues to grow. These and other structural changes alter the refractive state of the eye throughout the life span. The coordinated growth of eye size and optical power in many eyes enables a focused retinal image without need for accommodation or refractive treatments. Such eyes are said to be emmetropic, but emmetropia is not the norm during all stages of development and senescence. Infant eyes are almost always hyperopic but during the first 2 years of life they shift toward emmetropia. For many older children and adults, a further slow shift toward myopia relegates many to an adult life of near sightedness (e.g., recent estimates indicate that myopia rates can be has high as 71 and 84 percent in Hong Kong[80] and Taiwan,[81] respectively), whereas in later life there is an overall tendency for the refractive error of the eye to shift in a hyperopic direction. Although the prevalence of emmetropia can be high in modern populations, both eyes tend to maintain highly correlated growth resulting in similar refractive states in the two eyes. Recent reports, however, indicate that this correlated growth pattern begins to fail as the eyes age,[82] and can result in significant interocular differences in refractive error (anisometropia) among the population older than 70 years,[83] compared to children and younger adults.

Senescent Changes in Retinal Image Quality

Many factors act to alter the retinal image throughout the life span. In this section, their combined effects are described along with one aspect of the retinal image (chromatic aberration) that does not seem to be age dependent.

Intraocular Scatter The spatial distribution of light on the retina from a point source is described by the point spread function (PSF). The fraction of light transmitted from a point source in the forward direction is the total transmittance, while the fraction transmitted within a cone of a particular angle *a*, is the direct transmittance. The value of *a* is arbitrary, but typically is about 1°. The difference between the total and direct transmittances produces a "tail" in the PSF and is called stray light. However, because the photoreceptors are directionally selective (see Chap. 9), the optical PSF is not necessarily equivalent to the functional PSF. Westheimer and Liang[84] have used psychophysical methods to measure the PSF of younger and older observers for a broadband source. The total scattered light from 7′ to 90° is about 5 times larger in a 69-year-old observer compared to a young adult. Put another way, 90 percent of the light from a point source falls within a region of 7′ for a young subject, but only 50 percent of the light falls within 7′ for the older subject. (This analysis of the PSF does not take into account differences in the density of the ocular media which would further increase the difference between young and old.)

A number of studies have shown that large particle scatter by the human ocular media increases across the life span (e.g., Wolf[85]). The relation between light scatter and age has been described as nonlinear due to an acceleration in the function in middle age.[86] A more recent study[87] measured the integral of the scatter function of the eye from 2.2 to 90°. The results show little or no increase in scatter from 16 to 40 years of age but a rapid increase afterward (i.e., a factor of 5 increase at 65 years compared to young adults).

Stray light in the human eye is not strongly related to wavelength,[88,89] implying that it is not due to scatter by small particles (smaller than the wavelength of light). A small wavelength dependence, greater at long than middle wavelengths (opposite to Rayleigh scatter, where scatter = $k\lambda^{-4}$), has been attributed to fundal reflections, especially in lightly pigmented eyes.[90] A recent study[91] has proposed that intraocular scatter is a combination of small particle Rayleigh scatter and a red dominated scatter produced by light entering through the sclera. This latter source must pass through the choroidal blood and thus is red biased. The combination of these effects in lightly pigmented eyes produces scatter levels that vary little with wavelength. This can be important in evaluating stray light in the elderly because pigmentation levels in the RPE decrease with age. The lens seems to be the main source of age-related change in intraocular stray light.[85] The cornea produces light scatter as well, but the amount does not change significantly with age.[30]

Scattered light in the elderly may also be due to the age-related accumulation of two fluorophores in the lens.[92] These are molecules that emit light at one wavelength (e.g., 520 nm) when irradiated by another (e.g., 410 nm). As these emissions are scattered randomly, they would be expected to degrade visual resolution. Elliott et al.[93] demonstrated a small effect of fluorescence on resolution of low contrast targets.

Intraocular stray light reduces the contrast of the retinal image. Normal levels of scattered light do not affect color detection thresholds significantly, but high levels can affect chromatic saturation and estimates of color constancy.[94] The primary effect of intraocular stray light is to impair visual performance when lighting varies dramatically within a visual scene, such as when driving at night, because even small amounts of scatter from a high intensity source can dramatically reduce contrast of the retinal images of nearby low intensity targets. The effects of light scatter are sometimes referred to as disability glare. Discomfort glare, on the other hand, describes a subject's visual discomfort when high intensity glare sources are present. The level of discomfort glare shows large intersubject variability, but it is generally correlated with the amount of disability glare. The older eye is not necessarily more sensitive to glare, but it experiences more of it due to greater scatter.[79,95] Low luminance and low contrast visual acuity exhibit marked deficits with aging, which is further exacerbated by glare (veiling auto headlights, and so on). With the exception of cataract surgery, there are no treatments for increased ocular scatter, and therefore older people suffer the visual consequences of scatter or modify their behavior to avoid its most serious consequences, for example, changing night driving behavior.

Monochromatic Aberrations Almost 95 percent of the wavefront error measured monochromatically is caused by the lower-order aberrations of defocus and astigmatism,[96] and even in well-refracted eyes these lower-order aberrations continue to dominate.[97] However, there has been considerable interest generated recently in the higher-order aberrations of the eye.

Although the typical older eye exhibits appreciable levels of higher-order aberration, this results less from a specific ocular surface than from a decreased ability of lenticular aberrations to compensate for corneal aberrations—in contrast to younger eyes. With aging there is a change in meridian of the corneal astigmatism, the cornea develops negative spherical aberration, and the corneal coefficients for coma change as well. The changes are not accompanied by compensatory lenticular changes, resulting in greater whole-eye aberrations.[27,98] Thus, senescent changes in sign and not the magnitude of both the cornea and lens aberrations are the primary contributor to increased ocular aberrations seen in older eyes. The age dependence of this trend, however, is not completely clear for two reasons. First, population data show large variability between eyes, and most studies clearly show that the distribution of aberrations in older eyes is mostly overlapping with the distribution of younger eyes.[26,99] Thus, many older eyes have young eye levels of higher-order aberrations. Second, although most studies generally indicate best optical quality in young adult eyes (20 to 30 age group), one shows that optical quality is maximum at around age 40.[99] Finally, there is a shortage of data from eyes above 65 years.

A quantitative description of the quality of an optical system is provided by its modulation transfer function (MTF), the relation between contrast attenuation and spatial frequency. The eye's MTF can be derived from in vivo measurements of the optical point spread function on the retina. Guirao et al.[43] derived the MTFs from carefully collected point spread functions of 60 observers ranging in age from 20 to 70 years while controlling for such important factors as pupil size and the refractive state of the eye. In Fig. 6, the blue and red curves represent MTFs for observers with mean ages of 24 and 63 years, respectively. Modulation is scaled logarithmically to highlight differences at middle and high spatial frequencies that are obscured on a linear plot. Optical performance decreases with increasing spatial frequency for both age groups, and there is an age-related loss in performance at all spatial frequencies. Results similar to these have also been reported by Artal et al.[100] The results in Fig. 6 may be attributed to optical aberrations but not ocular scatter because it is factored out in the measurement procedure. Inclusion of intraocular scatter would tend to produce a more or less uniform "halo" in the retinal image that further reduces the contrast of stimuli in the elderly eye.

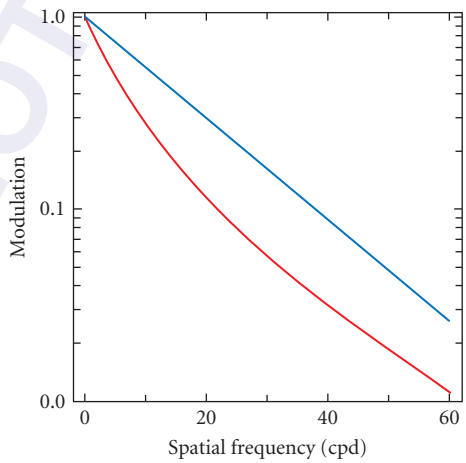

FIGURE 6 Modulation transfer functions for average individuals at 23 (blue curve) and 63 (red curve) years of age for a 3-mm pupil, 543-nm stimulus, calculated from equation and parameters from Guirao et al.[43]

Perhaps the most important finding is that a smaller pupil can compensate for the age-related increase in monochromatic aberrations. Indeed senescent miosis may provide a complete compensation for the failed correction of corneal aberrations by lenticular aberrations. That is, one compensation mechanism evolves as the other disappears, and this does not include additional compensation mechanisms at a neural level.[101] The bottom line is that the major loss in *optimal* retinal image quality with age will not be due to increased monochromatic or chromatic aberrations.

Chromatic Aberration The refractive index of the ocular media is wavelength dependent so that the spectral components of a broadband stimulus will not be imaged in the same plane within the eye. This is an example of chromatic aberration. Chromatic aberration can be appreciated from the colored fringes that can be observed in many telescopes and microscopes. Refractive indices of the optical elements of the eye decline as wavelength increases moving the long wavelength images farther from the cornea. The degree of chromatic aberration can be quantified in terms of the lens power required to image a particular wavelength on the retina when the eye is focused for a reference wavelength (change in refractive error as a function of wavelength). With a 578-nm reference, the aberration varies from − 1.70 D at 405 nm to 0.40 D at 691 nm.[102] Howarth et al.[103] (1988) measured the longitudinal chromatic aberration for four younger (27 to 33 years) and six older (48 to 72 years) participants using three different methods. All methods failed to show a change in axial chromatic aberration with age.

Interestingly, one suggestion for treating presbyopia employs a hyperchromatic lens design which can double the effective chromatic aberration of the eye. Experimental studies have shown that such a lens can increase the depth of field of the presbyopic eye.[104] Conversely, diffractive IOL designs have been proposed that can cancel the refractive chromatic aberration of the human pseudophakic eye.[105,106]

Summary of Optical Senescence

Senescent changes in the eye's optics are widespread and varied, but the overall effects are dominated by three important changes. First, the reflexive autofocus feature of the eye (accommodation), which allows objects at any distance to be well focused on the retina, slowly declines with age and disappears altogether during the sixth decade of life. From the fifth decade onward, the inability to focus objects in our three-dimensional world is a major source of retinal image degradation (due to spherical defocus). Second, due to senescent changes in lens and other ocular media transparency,[107] and pupil miosis, retinal image illuminance is chronically lower in older eyes, and this is particularly true for short wavelength light sources. Interestingly, the widely available low transparency yellow filters used in many sunglass prescriptions that mimic the older eye transmission characteristics indicate that this aging effect will have little impact in high light environments. The third significant and widespread optical change with age is the increased optical scatter (forward scatter by the eye's optics, and increased scatter by the retina and through the sclera due to reduced pigmentation). Scatter will always have the greatest impact at night when environmental light levels can vary by huge amounts from one location to another. In combination, the reduced transparency and the increased scatter will compromise vision at night. Also, the loss of accommodation and increased scatter will compromise retinal image quality when reading at near, particularly with high gloss materials that reflect light specularly, and thus can create local high intensity regions on the page.

14.5 SENESCENT CHANGES IN VISION

Age-related changes in visual performance are due to both optical and neural factors. Changes in performance that cannot be explained solely by optical factors are assumed to be due to senescent changes in neural pathways. An understanding of neuro-visual senescence thus depends on an understanding of the optics of the aging eye.

Senescent Changes in Sensitivity under Scotopic and Photopic Conditions

Visible radiation in natural viewing conditions is normally limited to the band between 400 and 700 nm. As can be inferred from Fig. 2, the limit at short wavelengths is due to the absorption characteristics of the ocular media; the limit at long wavelengths is due to the absorption spectrum of the photopigments contained in the rod and cone receptors.

Various studies using psychophysical procedures have demonstrated age-related losses in the sensitivity of scotopic and photopic mechanisms. Dark adaptation functions (absolute threshold versus time in the dark) have two scalloped-shaped branches, the first branch being mediated by cone photoreceptors and the second mediated by rods. A number of early studies have shown that the asymptotes of each of these branches become elevated as a function of age. In addition, it has been noted that the rate of photopic and scotopic dark adaptation decreases with increasing age.[108] This latter result has been confirmed by more recent studies.[109,110] It was not clear from some of the early studies whether these effects were entirely due to age-related changes in retinal illuminance caused by, among other factors, smaller pupils (see subsection "Pupils" in Sec. 14.4). Most, but not all,[111] of the studies that have taken age-related changes in pupil size and ocular media density into account have demonstrated age-related losses in scotopic sensitivity.[112,113] Based on those studies that have shown losses in sensitivity that cannot be explained solely by preretinal changes, it can be inferred that losses in sensitivity reflect neural changes that take place at or beyond the level of the photoreceptors.

Several studies indicate that changes at the receptor level may partially account for age-related changes in light and dark adaptation and for overall sensitivity under scotopic and photopic conditions. In vivo measurements of the photopigment kinetics indicate that a change in the rate of dark adaptation is due, at least in part, to a decrease in the rate of photopigment regeneration.[109,114] Other changes at the receptoral level involve the relative ability of "aging" rods to efficiently capture light quanta. Although there are substantial losses in numbers of rod photoreceptors with age,[115] the amount of rhodopsin photopigment in the retina decreases only slightly, if at all, with increasing age.[116] This implies that individual surviving rods must contain more photopigment in the older retina. However, some outer segments of these aged photoreceptors undergo morphological changes such that they appear to be more convoluted in shape.[117] These relatively deformed outer segments may contribute to reductions in scotopic sensitivity because rhodopsin molecules now possess less than optimal orientations for absorbing light.

Photopic vision is mediated by three different classes of cone photoreceptor, with each class of receptor having peak sensitivity at either short- (S), middle- (M), or long-(L) wavelengths. Several studies have shown that the sensitivity of the S cones decreases with age.[118–120] In addition, the results of Werner and Steele (Fig. 7) indicate that M and L cones also sustain significant sensitivity losses with age, and that the rate of loss is similar for all three cone types.

One complication in specifying the rates of age-related sensitivity loss for individual cone types is that the magnitudes of these losses depend on the level of light adaptation. For example, it has been shown for an S-cone mechanism that age-related differences are greatest near the absolute threshold and gradually diminish at higher light levels.[121] For this reason, Werner et al.[122] have measured the absolute threshold of cone mechanisms at the fovea, and at locations 4 and 8° eccentric to the fovea, along the horizontal meridian in the temporal retina. Their study revealed linear declines in sensitivity with age for all three cone mechanisms that could not be accounted for by age-related changes in preretinal structures of the eye. Thus, losses in sensitivity that occur during our life span reflect, in part, neural changes taking place in both scotopic and photopic mechanisms.

Color Vision

The ability to discriminate hue declines with age beginning in early adulthood, as assessed by color matching[123,124] and arrangement tasks.[125–127] These losses in discrimination may be due to age-related changes in retinal illuminance caused by smaller pupil size and increased short-wave absorption by the lens. Results from the Farnsworth-Munsell 100-hue test indicate that losses in discrimination

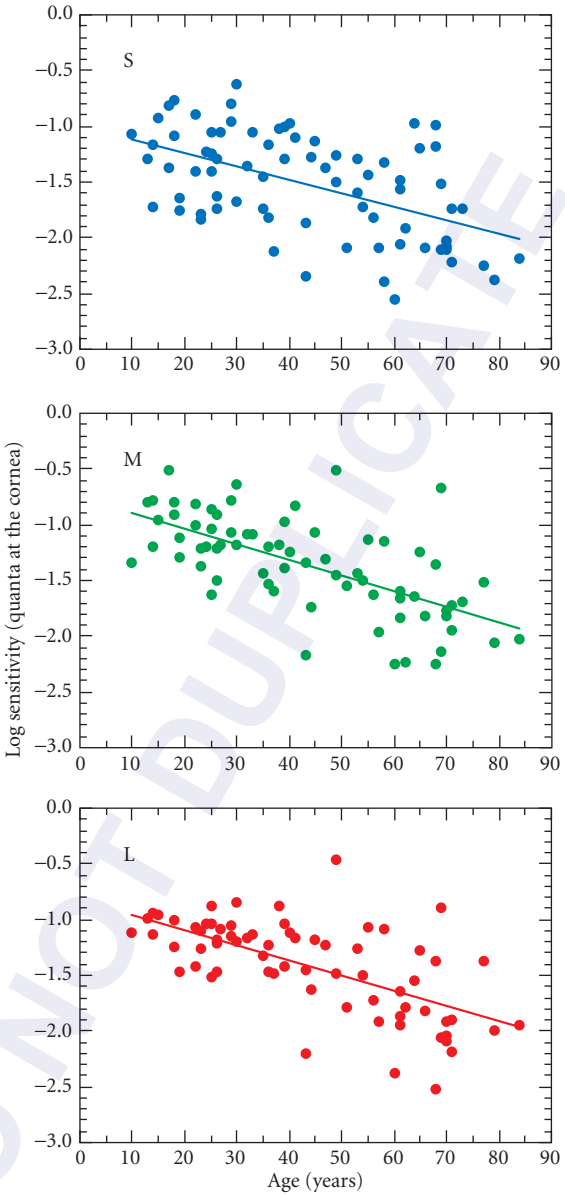

FIGURE 7 Log relative sensitivity (on a quantal basis) of S-, M-, and L-cone mechanisms is plotted as a function of age. (*Data from Werner and Steele.*[120])

mediated by S cones occur earlier in life than do discriminations mediated by M and L cones. However, this effect is due, at least in part, to the construction of the FM-100 test.[128] When chromatic discriminations are measured under conditions that equate the stimuli individually for retinal illuminance, losses occur not only for S-cone mediated discriminations,[129] but throughout color space for both spectral[130] and nonspectral stimuli.[131] These latter results indicate that age-related losses in chromatic discrimination are due, in part, to neural processes.

Senescence of the lens results in a reduction in retinal illuminance and a change in the spectral distribution of stimuli arriving at the retina. Concurrently, there is a reduction in sensitivity of the photoreceptors and numerous morphological changes in the visual pathways. Nevertheless, there is a remarkable degree of stability in color perception across the life span. Color naming of broadband reflective samples, the wavelengths of unique blue and yellow, saturation, and the achromatic locus are all relatively invariant with normal aging.[132] The proportion of different hue responses (e.g., blue or green) to a large set of simulated Munsell samples is independent of individual ocular media density.[133] Stability of color perception despite many changes in the retinal stimulus implies that the visual system continuously renormalizes itself to maintain constancy of perception. Thus, an elderly person may call the same stimulus "white" as he or she did 70 years ago, even though it must be based upon a markedly different retinal stimulus and strength of retinal signals.[134] To characterize the renormalization implicit in these findings, the chromaticity of the achromatic point was measured before and after cataract surgery.[135] There was a shift following cataract surgery (removal of a brunescent lens) that was initially toward yellow in color space, but over the course of months, it drifted back in the direction of the achromatic point before surgery. This long-term renormalization is as it should be; otherwise, the white of the young would be the yellow of the old. Such adjustments may occur by calibrating the average responses in color mechanisms according to the average color in scenes.

Spatial Vision

Visual acuity, the minimum angle of resolution, is the most time-honored measure of human visual performance, and in many clinical settings it is the only measured visual ability. It can be measured quickly and reliably with a variety of test patterns such as Snellen letters or Landolt C's. Traditionally, visual acuity is measured with letters having high contrast and moderate luminances. On average, such data suggest some stability in acuity until about age 50 and then a linear decrease with increasing age.[136] The results have been quite variable between studies, and the failures to screen subjects for disease and to optimize their refractions for the test distance make it difficult to know the true course of age-related change in visual acuity. Figure 8 shows results from several recent studies plotted in terms of log minimum angle of resolution (left axis) or equivalent Snellen and metric acuities (right axis). Data from Owsley et al.[137] resemble earlier studies, although participants were screened for visual disease and refracted for the test distance. However, with more stringent screening and optimized refraction, the change in visual acuity follows a somewhat different course according to more recent studies.[138,139] As shown in Fig. 8, these latter studies show better overall visual acuity with a progressive decline after about age 25 years. Conversely, when subjects are not screened for visual disease and are tested with their habitual refractive correction, their acuity is considerably worse than shown in Fig. 8.[5] Which data sets represent "normal" aging is unclear, but the better acuity values indicate that individuals can often reliably resolve finer details, or higher spatial frequencies, than suggested by earlier research, for example, 80 year olds can have 20/20 acuity.

A more general characterization of spatial vision is provided by the contrast sensitivity function (CSF), defined by the reciprocal of the minimum contrast required to detect sinusoidal gratings that vary in spatial frequency (the number of cycles per degree of visual angle, cpd). Figure 9 shows CSFs for nonflickering stimuli interpolated from a large data set by linear regression for hypothetical 20 (blue symbols) and 75-year-old (red symbols) observers. These functions could be computed in this way because the age-related changes in contrast sensitivity appear to be linear with age. A comparison of the photopic CSFs (circles) show little change in sensitivity with age at low spatial frequencies, but notable declines in sensitivity are found at middle and high spatial frequencies. These results are consistent with other studies that measured contrast sensitivity in subjects refracted for the test

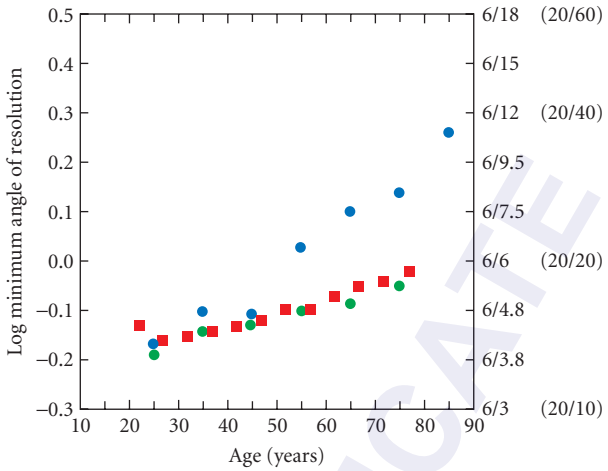

FIGURE 8 Log minimum angle of resolution (left) and Snellen equivalent acuity (right) plotted as a function of age. Blue circles are from Owsley et al.;[137] red squares and green circles are from Frisén & Frisén[138] and Elliott et al.,[139] respectively.

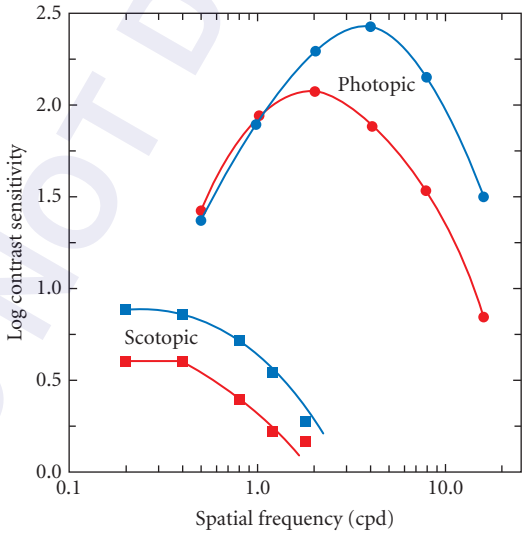

FIGURE 9 Log contrast sensitivity is plotted as a function of spatial frequency for static sinusoidal gratings. Blue and red circles represent average observers age 20 and 75 years, respectively, determined from regression equations for stimuli centered on the fovea. (*From Schefrin et al.*[144])

distance and free from ocular disease.[140–143] Currently it is unclear whether age-related differences in contrast sensitivity, especially at high spatial frequencies, become greater if the temporal modulation of luminance varying sinusoidal gratings is increased.[137,142,143]

Evidence from a number of studies suggests that preneural and neural factors are required to explain the decline in contrast sensitivity with age. Preretinal factors such as smaller pupils, increases in ocular media density and intraocular scatter can partially account for these results. However, losses in contrast sensitivity are still demonstrated by studies that have controlled for pupil size[141] and have attempted to mimic age-related reductions in retinal illuminance due to smaller pupils and increases in lens density.[143] In addition, age-related losses of contrast sensitivity at high spatial frequencies are found when measured with laser interferometry,[145] or when ocular aberrations, including dynamic higher-order aberrations, are corrected with adaptive optics.[146] It has been suggested that age-related changes in visual pathways account for less than half of the total decline in photopic contrast sensitivity at medium and high spatial frequencies with the remainder of the loss in sensitivity due to preretinal factors.[147] This point needs to be more thoroughly investigated.

Measurement of the CSF under scotopic conditions shows a pattern of loss quite different from photopic conditions, as illustrated by the squares in Fig. 9. These data were obtained following 30 min dark adaptation, using an artificial pupil and stimulus wavelength to minimize age-related variation in retinal illuminance.[144] The largest sensitivity loss to horizontally oriented sinusoidal gratings is at low spatial frequencies, a result that implies age-related change in neural mechanisms.

In Fig. 9, extrapolation of the CSFs to zero at high spatial frequencies provides a measure of visual resolution. At both photopic and scotopic light levels, age-related changes in the high frequency cutoff are noted even though participants were included only if they had retinae without pathology when examined by ophthalmoscopy.

Finally, spatial visual mechanisms have been characterized in terms of their chromatic sensitivity.[148] To be certain that the spatial variations are strictly chromatic, it is necessary to control for chromatic aberration and individual differences in luminosity functions. With these controls in place, Hardy et al.[149] used stimuli modulated along separate S-cone and L-M-cone axes. They found a significant difference in chromatic contrast sensitivity between younger and older observers at all spatial frequencies and for both chromatic axes. The difference in sensitivity is greater for S-axis stimuli than for L and M varying stimuli, prior to adjustments based upon ocular media density. Contrast sensitivities measured with controls for variation in ocular media density show that differences between young and old are reduced, at least for S-cone modulation. Nevertheless, when stimuli are equated at the retina, significant differences between younger and older observers remain. The difference is similar across spatial frequency and for the two chromatic axes. From these results, it may be concluded that both optical and neural factors contribute to age-related losses in chromatic contrast sensitivity.

Temporal Vision

The critical fusion frequency (CFF), the lowest frequency of flicker that is indiscriminable from a steady light, decreases with age.[150] Part of this loss in temporal resolution is due to retinal illuminance differences between young and old. Lower luminance levels are associated with a loss in temporal resolution. While the CFF measures the high temporal resolution limit, a more complete description of temporal processing is provided by the temporal contrast sensitivity function (tCSF), the amount of contrast needed for detection as a function of temporal frequency. Tyler[151] reported small age-related declines in temporal sensitivity for long-wavelength sinusoidal modulation, with the magnitude of the loss increasing with temporal frequency. The decrease in sensitivity began around age 20 years. Similar results were reported by Kim and Mayer,[152] but sensitivity losses were not observed until about the midforties, after which there was a loss in temporal sensitivity of about 0.78 decilog per decade. It was argued in both studies that these losses in sensitivity are greater than those expected from age-related changes in optical factors alone. Based on simultaneous recordings of pattern electroretinograms (PERG) and visually evoked potentials (VEPs) in young and elderly observers, Porciatti et al.[153] have suggested that at least some of the loss in temporal sensitivity with age is due to changes at postretinal sites.

Another approach to understanding age-related changes in temporal sensitivity is to measure the impulse response function (IRF), the theoretical response to a pulse of short duration.[154] This approach

is important theoretically because the IRF allows predictions of how the visual system should respond to any time-varying stimulus; it is related to the tCSF by its Fourier transform. The IRF was measured for 62 observers ranging in age from 16 to 85 years using a double-pulse method.[155] The IRFs with luminance modulation follow an exponentially damped sine function, with a fast excitatory response followed by an inhibitory phase.[156] Average IRFs and tCSFs are presented in Fig. 10 by red and blue curves. Note that while the amplitude of the IRF is reduced for older subjects, the timing is similar to

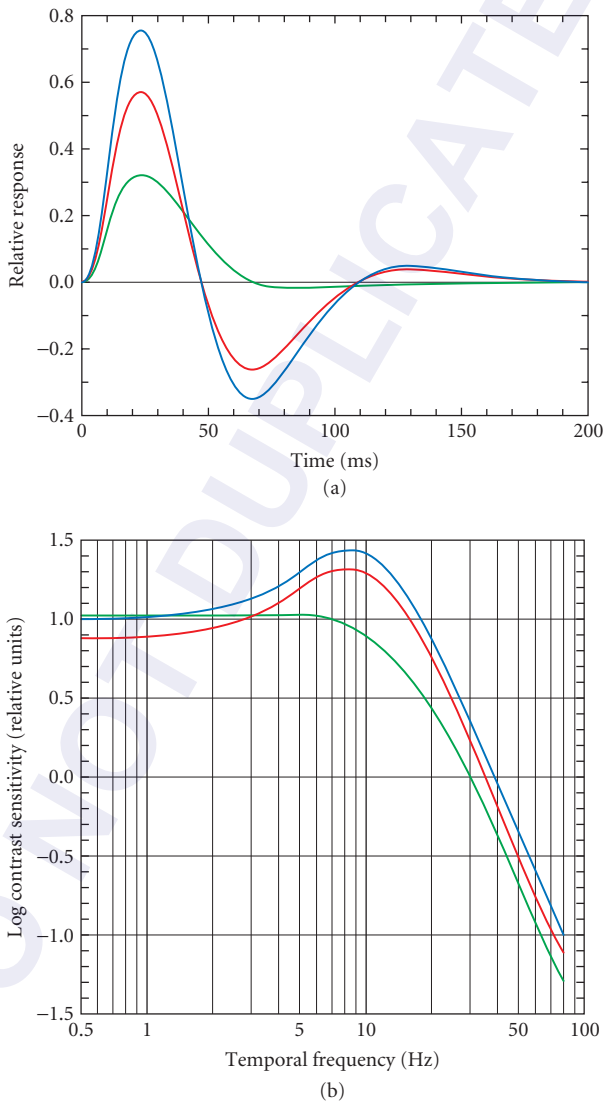

FIGURE 10 (*a*) Calculated impulse response functions for theoretical 20-year-old (blue curve) and 80-year-old observer with normal (red curve) or reduced second-phase (inhibitory) amplitude (green curve). (*b*) Corresponding temporal contrast sensitivity functions calculated from the impulse response functions. (*After Shinomori and Werner.*[155])

that for younger subjects. For 9 of 25 observers over 55 years of age, however, IRFs are relatively weak and show that the second (inhibitory) phase is reduced. Consequently, the IRF for these observers is quite slow and long, as shown by the IRF plotted as a green curve. The loss of inhibitory phase changes the tCSF from band-pass to low-pass as shown by the green tCSF in Fig. 10. It is not clear why older observers fall into two groups, as all observers met stringent inclusion criteria. Control conditions demonstrated that age-related changes in the IRF under these conditions cannot be ascribed to optical factors. Thus, in most cases, the human visual system maintains a stable speed of response to a flash until at least about 80 years of age, even while the response amplitude decreases with age.

The Visual Field

The extent of the visual field narrows over adulthood, by several degrees each decade until about age 50 to 60 years and then somewhat more rapidly with increasing age.[157] Iwase et al.[158] suggested that the "volume" of the visual field decreases starting at about 30 to 40 years of age and continues for the remainder of the life span.

Senescent constriction of and reduced light sensitivity within the visual field are due in part to age-related reductions in pupil diameter and increases in light absorbance by the ocular media. Johnson et al.[159] performed static perimetry using experimental conditions that notably lessen the effects of lenticular senescence and reduced pupil size. They demonstrated age-related losses in sensitivity that varied from approximately 0.5 to 1 dB per decade within the central 30° visual field. Their results suggest that at least part of the visual field loss must be ascribed to neural factors.

Another approach to perimetry is to define the functional or "useful field of view," or the area of the visual field over which information can be processed within a single fixation. The size of the useful field of view decreases when observers are engaged in additional tasks.[160] Ball et al.[161] compared sensitivity of groups of younger and older observers within the central 30°. Stimuli were presented in the presence and absence of distracting stimuli to measure the useful field of view. The older group was more impaired by the distracting stimuli, particularly at greater retinal eccentricities. This restriction of the functional visual field is apparently not due to optical or retinal factors. A more recent study of individuals ages 58 to 102 years[5] shows a dramatic impact of focal attention tasks on visual field changes with age, as shown in Fig. 11. For a typical light detection task, there is only a modest change even up to 90 years, but for a detection task with fixation attention demand, the visual field drops dramatically with age.

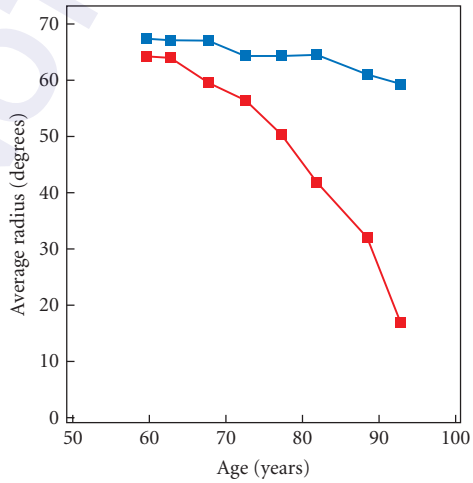

FIGURE 11 The median average radius of the visual field is plotted as a function of age for a standard light detection task (blue symbols) and with concurrent foveal attentional demand (red symbols). (*After Haegerstrom-Portnoy* et al.[5])

Depth and Stereovision

Our ability to perceive the distances of objects depends upon several different kinds of information. One of the most important depth cues is stereopsis. Stereopscopic depth information is provided by retinal disparity that occurs when a single object is imaged at different retinal locations between the two eyes. There is a paucity of investigations that have examined age-related changes in stereovision. This is unfortunate because the use of retinal disparity to extract three-dimensional depth could be used to probe cortical changes that may occur with aging.[162,163] In addition, based on the increased number of falls and other accidents that occur among the elderly, measures of stereoscopic depth perception across adulthood might be valuable.

Jani[164] used a standardized test of stereovision (flashlight diastereo test) to determine the percentage of 1207 individuals who failed the test at various ages. This percentage decreased from his 0 to 9 year group and remained stable from 10 to 19 through about 40 to 49 years. With further increases in age, there was a monotonic increase in the percentage of individuals failing the test. A more sensitive indicator of stereovision requires measurement of thresholds. Bell et al.[165] using a Verhoeff stereopter (based on the furthest distance at which the relative distance between three rods can be detected), showed that stereo resolution decreases slowly from 30 to 40 years of age and then more rapidly after about age 40. It is not clear whether these changes in stereovision are secondary to changes in the spatial CSF. This was controlled by using random-dot stereograms which varied in their binocular correlation.[166] Older observers required significantly higher binocular correlation than younger observers to perceive stereodepth.

Some Visual Functions That Change Minimally with Age

Senescent changes in visual function are widespread as might be expected given the optical and early neural changes that take place. It is perhaps surprising, therefore, that a number of visual functions change relatively little with age. The stability of color perception across the life span has already been described, but a number of other visual functions also appear resistant to aging.[167] For example, vernier acuity tasks have been used with subjects between 10 and 94 years of age. They were asked to align two or three lines or several points. This can be done with great precision (hence the name hyperacuity), and it does not change with age. The directional sensitivity of the retina (measured by the Stiles-Crawford effect of the first kind) also does not appear much affected by senescence. This task depends on the integrity of both physical and physiological mechanisms.

These and perhaps other (undiscovered) constancies in visual function across adulthood may provide insights into the types of neural changes that accompany age. In addition, such results might also serve as useful indices to distinguish between normal aging and changes in the same functions due to disease.

14.6 AGE-RELATED OCULAR DISEASES AFFECTING VISUAL FUNCTION

There are several ocular and retinal disorders that are so strongly correlated with increasing age that "age" has become a part of their name, for example, "age-related cataracts," "age-related macular degeneration," etc. Age, of course, represents only the passage of time, not a process, but the name does accurately imply that these problems are more likely to occur in the elderly.

Life-Span Environmental Radiation Damage

Unlike most of the human body, the eye is unique in that it contains highly transparent tissue that allows a large proportion of incident radiation to penetrate about 2.5 cm into the body. When considering radiation damage, transparency has the advantage that the energy passing through transparent

material is not absorbed and thus can do no damage. However, all of the quanta passing through the transparent portions of the eye will ultimately be absorbed deep within the eye, and thus, unlike the rest of the body in which only the surface is vulnerable to environmental radiation hazards, tissue deep within the eye can be damaged by radiation. Therefore, environmental radiation has the potential to contribute to the aging process of ocular tissue deep within the eye. The retina is additionally vulnerable to radiation hazards because flux densities at the retina can exceed those at the cornea due to the focusing characteristics of the eye's optics. The eye's susceptibility to the accumulated effect of chronic radiation damage is further exacerbated by the need for transparency across the visible spectrum and the fact that critical cells within the eye (e.g., lens fiber cells and photoreceptors) cannot regenerate. Not surprisingly, the primary ocular targets of life-span environmental radiation damage are the lens and the retina.

With the exception of those employed in professions with high levels of UV radiation (created by some welding techniques, polymer curing, electronic circuitry imaging, fluorescent testing, etc.), the primary source of environmental UV radiation is the sun. The spectral distribution of sunlight reaching different parts of the earth's surface will differ somewhat from that shown in Fig. 2 due to such factors as latitude, altitude, cloud cover, and aerosol content as well as time of day. It is important to note that just as Rayleigh scatter makes the sky blue, the atmosphere scatters an even larger proportion of UV light, and thus the sky itself is a significant source of UV radiation.

While it is straightforward to document surface UV light, it is very difficult to calculate ocular exposure because the eye is typically shaded by the brow and upper lid and thus is rarely directly irradiated by sunlight. Instead, environmental exposure to solar radiation will come primarily from reflections off surfaces or from scatter by the atmosphere. For example, while the sunlight stays constant when moving from a snowless to a snow-covered field, ocular UV irradiance increases substantially because of the high reflectivity of the snow in the UV range.[168] The combined effects of high altitude (little atmosphere to absorb UV) and snow (fresh snow reflects more than 90 percent of the incident UV) can rapidly create solar keratitis in any skier who fails to wear UV-filtering eye protection.

The impact of solar radiation on the eye depends on the proportion of this radiation that is absorbed. At very short wavelengths (UVB), it is the cornea (and primarily the surface epithelium) that absorbs most of the UV, and thus is at risk for UV light damage. However, due to the rapid regeneration of corneal epithelial cells (the entire corneal epithelium is regrown every 5 to 7 days), chronic UV damage is not easily accumulated. At longer UV wavelengths, corneal transparency increases to about 50 percent, and almost all of the remaining 50 percent that passes through the cornea is then absorbed by the lens. Thus, the lens is also vulnerable to UV-damage, and particularly to chronic UV damage because cells in the lens are not replaced or recycled.

Epidemiological evidence provides support for the view that UV radiation is associated with cataract formation. For example, there is a clear correlation between incidence of cataract and other diseases (e.g., pterygium and skin cancer) and exposure to sunlight. In addition, the age of cataract decreases and its incidence increases from the poles to the equator. Young's[53] summary of this literature indicates prevalence rates of about 14 percent for countries above 36°, 22 percent for mid-latitude (28 to 36°) countries and 28 percent for low-latitude (10 to 26°) countries. While epidemiological studies are complex due to the many factors that vary among groups, UV radiation appears to be the only factor that changes with latitude *and* has been shown to play a significant role in aging of the lens. A similar latitude dependency appears in the age of onset of presbyopia[3] indicating that both of the primary age-dependent changes in lens function (presbyopia and cataract) may be regulated by levels of UV exposure.

Because of the opacity of the cornea and lens to UV radiation, relatively little UV reaches the adult retina, however, the retina is vulnerable to photochemical damage caused by UV light as well as short-wave-visible light (the "blue light hazard"). A study comprised of pseudophakic patients who had undergone bilateral cataract extraction and implantation of two IOLs differing in the amount of UV absorption suggested that increased UV exposure in the eye with the UV transparent IOL reduced visual sensitivity of short-wave-sensitive cones. It was estimated that 5 years of exposure to light through an IOL without UV absorbing chromophores produced the equivalent of more than 30 years of normal aging.[7] Thus, the lens pigmentation responsible for UV absorption may be an adaptation to protect the retina from photochemical effects that are damaging.

Cataract

Cataracts are opacities of the lens that interfere with vision by reducing the amount of light transmitted while at the same time increasing its scatter within the eye. There are a number of different forms of cataract, and each form exhibits its own characteristic effects on vision and has different stages of development. For example, cataracts can form within the lens nucleus and cortex, and they may originate in either the axial or equatorial regions of the lens. Cataracts, depending on their type, can cause a host of visual problems including loss of visual acuity, changes in refractive error, aniseikonia, perceived spatial distortions, disability glare, and the formation of multiple images. Often times more than one form is present in a given eye, and the lens of each eye may develop cataract at different rates.

In the United States, cataract is found in about one in seven individuals above the age of 40, and the proportion increases with age. The rate is much higher and typically occurs at an earlier age in individuals with diabetes. It is known that UV and infrared light can cause cataracts. Most individuals exhibit changes in their crystalline lenses with advancing age and senescent cataract may be an extension of this process.[53] In developing countries, cataracts occur much earlier in life (e.g., 14 to 18 years earlier in India than the United States), perhaps due to nutritional factors or greater ultraviolet exposure (as many developing countries have lower latitudes).

Cataract is the leading worldwide cause of blindness. Fortunately, it is treated with a high success rate by surgically removing the cataractous lens. In most cases in developed countries, an intraocular lens (IOL) is implanted. Cataract surgery in the west is one of the most successful therapies known, with visual improvement in nearly all cases. Nearly three million cataract surgeries were performed in the United States in 2007 and over 14 million worldwide.

Cataracts generate both forward and backward scatter of light, and quantification of both can explain about 50 percent of the variability in the visual acuity of older Americans.[169] It is the forward scatter, and not the backscatter seen by the clinician, that interferes with vision. Wide angle forward scatter would be expected to generate a uniform drop in contrast sensitivity, but in patients with cataract Hess and Woo[170] observed reductions in contrast sensitivity that were larger at high and middle spatial frequencies (not unlike those seen with retinal image defocus). Their results indicate that forward scatter produced by cataracts is not wide angle, but, as predicted by the larger than wavelength size of the particles formed in a cataract,[171] much of the forward scattered light is distributed over a small angle (Mie as opposed to Rayleigh scattering).

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is generally a progressive, bilateral disease that compromises the integrity and functioning of the central retina. More than 13 million persons over the age of 50 in the United States have signs of macular degeneration. An individual in the early stages of AMD may experience declines in visual acuity, losses in sensitivity for central photopic[172] and scotopic mechanisms,[173,174] an inability to make fine distinctions between colors,[175] and metamorphopsia, a distortion in the appearance of objects in the visual scene. As the disease progresses, individuals afflicted with this condition undergo further declines in visual performance including the onset of central scotomas, defined areas of absolute or relative vision loss within the visual field, making it difficult to recognize readily faces of individuals encountered. However, because the disease does not spread past the macula or central retina, individuals can still navigate about in the environment and even "regain" some function through training to use unaffected adjacent portions of the macular region. About 1.2 million persons in the United States have reached sight-threatening late stages of AMD. This latter group is composed primarily of Caucasians aged 60 years and above, as the disease affects other ethnic groups with lower frequency. The numbers of affected individuals are increasing rapidly with the aging of the population, affecting more than 30 percent of individuals over the age of 75.

AMD is divided clinically into the exudative (wet) and nonexudative (dry) forms of the disease. In the more devastating wet form of this disease, choroidal neovascular membranes grow through

cracks in Bruch's membrane, the layer separating the choroid from the retinal pigment epithelium (RPE). Amongst other things, the RPE is responsible for regulating and providing nourishment to and removing waste products from the retina. Death of retinal cells occurs when the retina is separated for lengthy time periods from the underlying RPE as can happen when the leaky blood vessels comprising the neovascular membranes begin to exude their contents into the potential space between the RPE and photoreceptor layer of the retina. In addition, the presence of these subretinal neovascular membranes lead to scar formation beneath the macula, and this process of scarring is the primary cause of vision loss in the wet form of AMD. The wet form only comprises 10 to 15% of all cases of AMD but accounts for 90 percent of legal blindness from AMD.

In contrast to the wet form of AMD that may produce a sudden loss in vision, dry, or atrophic, AMD results in a slow progressive vision loss that usually takes place over many years. The dry form of AMD is characterized by the formation of drusen, deposits of accumulated waste products from the retina and atrophy of the RPE cells. Presently, it is unclear what causes retinal atrophy in the dry form of AMD, but it is thought to reflect ischemia from the choriocapillaris and/or a metabolic disturbance of the receptor/RPE complex leading to apoptosis.

Currently, clinical advances have been made to retard the progress of the wet form of AMD through medications and laser therapy. Fluorescein and indocyanine green angiography have been effective tools for both diagnosing wet AMD in its early stages of the disease process and defining the subretinal sites of neovascular membranes and exudative leakage from these blood vessels. By taking advantage of this valuable knowledge, laser photocoagulation is now used to destroy these vascular membranes thereby retarding the progress of the disease. For subfoveal lesions, intravitreal injection of anti-VEGF drugs can stabilize or improve vision in 95 percent of cases. Beyond these forms of treatment, visual rehabilitation has concentrated on the use of low vision aides and training AMD patients to use parafoveal and peripheral portions of their retina that are less affected by the disease.

Diabetic Retinopathy

Diabetic retinopathy is also a common disorder associated with aging. Juvenile-onset (Type I) diabetes is generally diagnosed during the first two decades of life, whereas adult-onset (Type II) diabetes is diagnosed later in life. Type II diabetes is associated with increasing age, obesity, and a family history of the disease; Mexican Americans and African Americans are affected relatively more often than Caucasian Americans. A patient with diabetes (either Type I or Type II) develops diabetic retinal changes over time; at least 40 percent of diabetic patients will eventually develop detectable retinopathy. The incidence of diabetic retinopathy is related to both blood sugar control and the duration of the disease, with most estimates suggesting clinical evidence of retinopathy occurs about 10 years after the onset of hyperglycemia. Approximately 8000 people are blinded each year by this disease.[176]

There are several stages to diabetic retinopathy. Early in the disease there is patchy loss of the endothelial cells lining the retinal capillaries which leads to increased permeability of these blood vessels and the formation of microaneurysms. The appearances of small punctate hemorrhages, microaneurysms, and proteinaceous deposits within the retina are hallmarks of the early or "background" stage of diabetic retinopathy. As the disease progresses, blood vessels may become occluded resulting in retinal ischemia. In response to disrupted blood flow, the ischemic retina releases growth factors which induce the proliferation of new blood vessels or increased permeability of the damaged retinal vessels. These new blood vessels formed in the "proliferative" stage of diabetic retinopathy are fragile and can spontaneously bleed, leading to loss of vision from vitreous hemorrhage. The permeable damaged vessels can cause exudation and swelling of the macula leading to vision loss. In the latter stages of the disease there is death of ganglion cells from intraretinal hypoxia and contraction of scar tissue leading to retinal traction and subsequent retinal detachment in areas adjacent to relatively high concentrations of neovascularization. Tractional retinal detachment may cause visual distortion and blindness, and requires retinal surgery to minimize vision loss.

Initial treatment of diabetic retinopathy involves controlling blood sugar levels via dietary changes, oral agents, and/or insulin to facilitate the uptake of glucose into body tissue. Poorly controlled blood

sugar levels can lead to fluctuations in vision due to changes in the refractive power of the crystalline lens and the early formation of cataracts. The Diabetes Control and Complications Trial[177] demonstrated that tight control of blood glucose reduced the incidence of diabetic retinopathy. Additionally, fluctuations in blood glucose levels have been shown to influence normal functioning of S-cone pathways[178] perhaps accounting for decreased chromatic discrimination along a tritan axis demonstrated by diabetic individuals.[179]

In the latter stages of diabetic retinopathy, laser photocoagulation is used in an attempt to maintain the integrity of the central retina. Laser photocoagulation is utilized to control retinal neovascularization associated with proliferative disease and reduced vision secondary to macular edema. These treatments have been shown to decrease severe vision loss by approximately 50 percent. Because laser photocoagulation to control neovascularization is a destructive form of treatment, newer strategies are being investigated that target specific growth factors causing neovascularization.

Glaucomas

The glaucomas are a group of chronic diseases that result in the progressive degeneration of retinal ganglion cells whose axons comprise the optic nerve. In most but not all cases of glaucoma, elevated intraocular pressure (IOP) is believed to be one of the primary risk factors for ganglion cell death. Ganglion cell death occurs through the process of apoptosis, brought on, it is believed, by the loss of trophic factors normally transported to the ganglion cell body by retrograde axoplasmic flow. In glaucoma, cell death is thought to occur following a disruption in axoplasmic flow of the retinal ganglion cell axons comprising the optic nerve; the site of this disruption is believed to be at the optic nerve head, where the insult may be mechanical[180] due to elevated IOP and/or a disruption in the vascular supply to the nerve head.[181]

Aqueous humor serves as the optically clear "nutritional supply" to the metabolically active but avascular structures of the lens and cornea. IOP is determined by a balance between production of aqueous humor (by the ciliary body, a secretory tissue that lies directly behind the iris) and drainage through the trabecular meshwork, a circumferential drainage system located just anterior to the iris at an angle formed by the cornea and iris root. Abnormalities in the trabecular meshwork are thought to underlie the elevated IOP in many forms of "open-angle" glaucoma.

Of the approximately 67 million persons affected by glaucoma worldwide, about equal numbers suffer from open-angle and angle-closure types, with the former being more prevalent in the United States and Europe and the latter being more prevalent in Asia and the Pacific Rim. Glaucoma accounts for about 10 percent of blindness in the United States. The frequencies of glaucomatous disorders increase with increasing age, particularly after the age of 40. By age 65 it affects about 10 percent of African Americans and about 3 percent of Caucasian Americans.

Angle-closure glaucoma typically occurs when a forward protruding iris covers the trabecular meshwork thus impeding the flow of aqueous humor from the eye. In this form of glaucoma, there can be sudden dramatic increases in IOP resulting in an abnormally hydrated cornea that leads to diminished visual acuity and accompanying ocular pain. In contrast, open-angle glaucoma is a slow progressive condition in which the IOP is too high for a particular eye resulting in ganglion cell death. Visual loss due to glaucoma occurs generally in the peripheral visual field and affects central vision only late in the disease process. Because the loss is gradual and usually occurs in areas overlapping "normal" vision in the fellow eye, patients are generally unaware of their visual loss until a great deal of damage has occurred. In addition to IOP, other risk factors associated with glaucoma include age, ethnicity, family history, corneal thickness, and myopia. Because increased IOP is not invariably associated with glaucoma, a complete eye examination is needed to make an accurate diagnosis. Often times these examinations will reveal pathognomonic changes such as an abnormal appearance of the optic nerve head, and on visual field testing, specific patterns of visual loss.

Because damage to optic nerve fibers is irreversible and the progress of glaucoma can, in most instances, be successfully controlled, early detection is of great importance. Decline in visual performance at earlier stages in the disease process can be detected through several forms of visual field testing targeting vulnerable ganglion cells.[182,183]

Current treatment regimens for glaucoma involve the use of pharmacological agents and surgical procedures aimed at controlling IOP. Drug therapy includes the use of topical and systemic agents used singly or in combination to inhibit the formation of aqueous or promote increased drainage of aqueous from the eye. Procedures involving lasers or incisional surgery typically aid in aqueous outflow and are used when drug therapy, by itself, fails to adequately retard the progress of the disease. In addition, ongoing research is currently investigating possible therapies involving neuroprotective agents designed to reduce ganglion cell death after mechanical or chemical damage and to promote new growth.[184]

14.7 THE AGING WORLD FROM THE OPTICAL POINT OF VIEW: PRESBYOPIC CORRECTIONS

Presbyopia refers to a loss of accommodation resulting in the near point, the closest distance on which the eye can focus, receding from the eye. This is a continuous process (see Fig. 4) and generally requires some optical aid once accommodative amplitude declines to less than 3 D. Every human suffers from this senescent loss of accommodation, and thus, optical substitutes for accommodation are widely available. Because there is no cure for this condition, and no treatment is perfect, many different treatment options have been developed. Historically, spectacle lenses have been the only option for treatment of presbyopia, but recent attempts have been made to provide presbyopes with contact lenses, IOLs, and other refractive surgery corrections to expand the depth of field of the aging eye. Most of these strategies make no claim to reinstate true accommodation, and thus, can be considered examples of "pseudoaccommodation," in that the eye's depth of field increases without any dynamic change in optical power. Reduced pupil size, increased aberrations, bifocal optics, and residual myopia can all lead to improved near vision without any accommodation.

During the last couple of years, several IOLs and a unique surgical procedure have all made claims that they actually restore accommodation; however, almost all of the evidence reported in support of these claims (e.g., improved near vision) could be generated by pseudoaccommodation. Thus, at this time, there is no effective treatment that can restore accommodation in presbyopic humans, but considerable research effort continues with this goal in mind.

Spectacles

To obtain a well-focused retinal image when viewing a near object, presbyopes that are emmetropic or corrected ametropes require a "near" optical correction. Since the invention of the bifocal lens by Benjamin Franklin, several ingenious approaches to this problem have been developed. With traditional bifocal lenses, the individual looks through different regions of a lens, each region having a different optical power, in order to see clearly objects at near or far. Extensions of this concept include trifocal lenses having three powers confined to three distinct zones, and aspheric lens designs in which the optical power continually changes in a prescribed manner from the top to the inferior portion of the lens. Peripheral zones of the latter designs often exhibit large amounts of astigmatism but are considered cosmetically superior. In each of these designs, the patient is able to select the preferred optical power by adjusting head and eye movements such that different regions of the lens are used to create the retinal image.

Contact Lenses

The principles of bifocal and multifocal corrections have been incorporated into contact lenses and intraocular lenses (see next section). Like their spectacle counterparts, bifocal and aspheric contact lenses have been designed to provide the presbyope with an increased depth of field. However, unlike the case of spectacle lenses, the patient cannot select a different region of the lens with which

to view different target distances. As the eye and head move, so does the contact lens. Thus, multifocal contact and intraocular lenses include two or more optical powers within the same region of the lens, and the retinal image is generated by two or more powers simultaneously. The obvious consequence is that, in a simple bifocal lens, if 50 percent of the light is well focused on the retina, then 50 percent will be defocused. The challenge for the patient is one of seeing the focused portion of the image with the simultaneously present defocused image. Such lenses are often called "simultaneous vision" lenses.

Some designs of bifocal contact lenses consist of concentric annuli that alternate in power between near and far optical corrections while other bifocal designs include only two regions, one with a distance correction and one with a near correction. A third type of simultaneous vision lens attempts to provide increased depth of field by employing a highly aberrated "multifocal" design. A fourth type of bifocal lens employs a diffractive optical element (DOE) and is often referred to as a "diffractive" lens.[185] Although most designs provide improved near vision compared to a standard monofocal lens,[186,187] this improvement is generally accompanied by a reduction in best-corrected distance vision.

Instead of including two different corrections in the same eye, an alternate approach called "monovision" consists of different monofocal optical corrections in each eye, one for near and the other for far. Thus, unlike simultaneous bifocal vision which adds the focused and defocused images linearly (light adds) at the retina, monovision patients employ nonlinear binocular neural summation[189] in the cortex which biases vision to the higher contrast and better focused image. Thus, the defocused image present in one eye when viewing a distant or near target generally goes unnoticed. This failure to observe the defocused image has led to the notion that the blurred image is somehow suppressed, by a process called "blur suppression."[190]

It should be noted that the retinal blur produced by monovision and simultaneous bifocal contact lens corrections leads to losses in contrast sensitivity, especially at high spatial frequencies. The magnitude of vision loss can be quite small at distance and near but large at intermediate distances where neither image is well focused.[187,191] Stereopsis can also be affected adversely by the unilateral blur and aniseikonia that accompany monovision corrections. In addition, patients with simultaneous vision corrections that may provide reasonable distance and near vision may experience "ghosting" caused by the defocused portion of the light.[192]

Intraocular Lenses

Following extraction of a cataractous lens, a refractive error of about 17 D remains to be corrected. A person without their natural lens is called an aphake. In most cases, an intraocular lens (IOL) is inserted, and the wearer is said to be pseudophakic. IOLs have traditionally been constructed from polymethylmethacrylate, but a variety of other materials have been developed (e.g., silicone, hydrogels) so that the lens can be folded and inserted through smaller incisions than are required to insert a hard plastic lens. Many IOLs in the past 15 years have incorporated UV-absorbing chromophores, but older IOLs were virtually transparent to UV radiation from 320 to 400 nm.

Bifocal and multifocal corrections have been incorporated into IOLs. While the optical principles are mostly the same as presbyopic contact lens corrections, some different problems may emerge because of the placement of the optic and maintenance of its position. For example, IOL tilt is associated with astigmatism. However, decentering a bifocal IOL will generate a lateral shift of the defocused images. These off-set defocused images are described as ghosts which are also observed by presbyopes with bifocal contact lens corrections.

A simple segmented bifocal design might have a distance correction in the center and a near correction in the lens surround. With the correct pupil size, light might be equally distributed between the distance and near optics, but as pupil size changes, this balance will be lost. For example, if the pupil is reduced in size such that it matched the size of the central distance portion, the bifocal lens becomes a monofocal correction. To avoid this pupil size dependence, both contact lenses and IOLs have been designed with multiple zones. One type of multizone lens employs standard refractive optics but has alternating near and distance rings across the lens ensuring that both near and distant

optics will contribute to the retinal image irrespective of the pupil size, and thus, the increased depth of field will be present at all times. A second type of multizone bifocal lens, a diffractive optical element, necessarily has multiple rings as part of its design,[193,194] and thus is inherently resistant to pupil size changes. These diffractive lenses control their refractive power by the size of the rings and control the balance between near and distance by the size of the step between successive zones. In addition to enabling bifocal optics, these diffractive lenses have the added potential advantage of correcting some of the eye's chromatic aberration because, unlike refractive lenses (and human eyes) which will always have more power at short wavelengths, diffractive lenses have more power at longer wavelengths.

As with bifocal contact lenses, reduced image contrast in any eye using a bifocal or multifocal IOL can be expected due to the superposition of this second out-of-focus image.[195] The consequence of these problems may be exacerbated in older patients due to their lower contrast sensitivity. Problems with glare and halos around light sources are greater in patients with bilateral multifocal compared to bilateral monofocal IOLs, but the former patients sometimes achieve less dependence on additional spectacle corrections.[196]

Noncataract Related Refractive Surgeries

There are three issues of ocular senescence related to refractive surgeries (see Chap. 16). First, as postrefractive emmetropes, many young ex-myopes will enjoy a spectacle or contact lens free life. However, as presbyopia progresses, these corrected myopes will now need reading aids for near work. Of course, if left uncorrected, many of these myopes would avoid the need for reading glasses or bifocals by simply removing their distance corrections. Second, some presbyopic patients opt for monovision refractive surgeries, essentially exchanging bilateral myopia for anisometropia. Third, some young adults opting for clear lens extraction or phakic IOLs to treat their high myopia will all experience a form of early and total presbyopia, and thus they will need a near reading aid. There is some concern that these early IOL surgeries will generate accelerated loss of endothelial cells which may lead to corneal failure in the distant future.

Accommodation Restoration

All of the standard treatments for presbyopia attempt to increase the depth of field without any attempt to restore the lens' ability to adjust its power. That is, pseudoaccommodation is used to replace true accommodation. In the last few years, however, attempts have been made to restore accommodation in presbyopic eyes and to enable true accommodation in pseudophakic eyes (see Ref. 197 for recent comprehensive review). These approaches are based upon the assumption that some useful ciliary muscle strength persists into senescence. There have been two general approaches tried so far. In one, the sclerotic senescent lens is replaced with a lens made from a pliable elastic material (e.g., silicone) that will change shape to achieve a change in power. However, physiological incompatibilities leading to capsule opacification, and problems in the balance between power and change in power, remain.[198] The second approach employs fixed power optical elements that generate a change in whole eye power by movement. Interestingly, although natural accommodation generates increased positive power by a combination of changing lens shape and position, the position changes required by this type of accommodating IOL are much larger than those exhibited by the natural lens. One other technique involves surgical implantation of scleral "expansion rings" to expand the equatorial diameter of the presbyopic eye with the goal of regaining accommodation. The theory of accommodation and loss of accommodation with age behind this surgical procedure is not generally accepted to be correct,[197,199] and careful study of one satisfied patient found no evidence of accommodative amplitude higher than those of untreated age-matched controls.[200]

IOL designs that employ structural changes in the eye created by contraction of the ciliary muscle to change the position or shape of the lens are called "accommodating" IOLs. Designs that employ lens movement to change power have already made it to the market place, whereas designs that employ pliable polymers continue to be tested in the lab.

Two general strategies have been employed to generate accommodating IOLs that work via lens movements. One type uses a single plus lens supported by a hinged haptic, and when the equatorial diameter of the eye decreases as the ciliary muscle contracts, lateral forces on the outer edge of the haptic, combined with potential forward movement of the vitreous, will push the lens forward. When the positive powered IOL and positive powered cornea are closer together, the net result is more plus power. A second design strategy employs a dual optic lens containing a high powered plus lens and a compensatory negative lens. Again, as the ciliary muscle contracts, the forces produced are intended to increase the separation of the two optical components of the dual optic lens, and in so doing, increase its power.[197,201] Optical theory predicts that the latter design has more potential for changing power than that produced by movement of the simple lens.[202] Experimental and clinical studies struggle to show evidence of accommodation.[197,203] Some evidence for lens movement has been demonstrated in response to "pharmacologically induced accommodation" in which lens position or eye refraction is compared in eyes in which ciliary muscle contraction is either blocked (e.g., with Cyclopentolate) or activated (e.g., with pilocarpine).[197,204] Disappointingly, stimulus driven accommodation restoration has yet to be demonstrated,[202,205] and future studies need to ensure that they carefully discriminate between genuine accommodation and pseudoaccommodation.

This is a rapidly evolving field in which new designs are expected to emerge in the next few years. Lens designs that employ elastic IOLs that can change shape in response to ciliary muscle contraction offer the greatest potential,[206] but these face very significant challenges. The translating designs that have made it to market seem to generate little if any true accommodation.[203] It is important to note that most people in their 40s with perhaps only 2 or 2.5 D of accommodation can function without a reading add, therefore accommodating IOLs only need to generate about this level of accommodation for most people to function.

14.8 CONCLUSIONS

The proportion of the population above age 65 years is increasing, and there is a parallel rise in the proportion of the population that is blind or in need of refractive corrections. Senescent deterioration in the eye's optics can lead to a wide range of changes in visual function due to reductions in retinal illuminance and degradations in image quality. Age-related changes in vision also result from neural losses. A few visual functions are spared, but substantial changes in the spatial, spectral, and temporal analysis of the retinal image have been well documented. The demographic shift in the proportion of the population that is elderly has not yet reached an equilibrium, so the social and economic consequences can be expected to be even more profound in the future. At this point in history, in spite of technical, optical, and surgical advances, the optical and visual quality of all eyes will deteriorate with advancing age, and for some, age-related pathology will precipitate serious disability due to dramatic loss of visual capability.

15.1 GLOSSARY

Adaptive optics. Opto-electro-mechanical method for dynamic closed-loop compensation of wavefront aberrations that reside between the object and image.

Bimorph mirror. Class of wavefront corrector distinguished by its piezoelectric material that is sandwiched between a continuous top electrode (reflective) and a bottom, patterned electrode array.

Contrast sensitivity. Reciprocal of the minimum perceptible contrast.

Deformable mirror. Mirror whose surface profile is controlled by applying voltages to a set of adjacent electrodes or actuators.

Discrete-actuator deformable mirror. Class of wavefront corrector distinguished by its continuous reflective surface and array of underlying actuators that alter the surface shape.

Higher-order aberrations. Aberrations higher than second order.

Influence function. Deflection of the corrector surface when a unit voltage is applied to a single actuator.

Low-order aberrations. Aberrations of first and second order.

Membrane mirror. Class of wavefront corrector distinguished by its edge-clamped, flexible, reflective membrane that is sandwiched between a transparent top electrode and an underlying array of electrodes.

Ophthalmoscope. Instrument for viewing and recording images of the back of the eye.

Optical coherence tomography. Interferometric-based imaging modality that optically sections tissue with micron-scale axial resolution. Axial resolution is inversely related to the spectrum of the imaging light source.

Photoreceptor. Cell that initiates the visual process in the retina by transducing the captured photons into an encoded neural signal.

Point spread function. Response (image) of an optical system to a point source of light (object).

Psychophysics. A branch of science that deals with the relationship between physical stimuli and sensory response.

Retinal microscopy. Observation of retinal features at the cellular level in the living eye.

Scanning laser ophthalmoscope. Imaging modality that raster scans a point source across the object and filters the reflected light with a confocal pinhole for enhanced contrast and axial sectioning.

Segmented corrector. Class of wavefront corrector distinguished by its array of small closely spaced reflective or transmissive elements that induce local piston and tilt on the incident wavefront.

Shack-Hartmann wavefront sensor. An objective wavefront sensor that measures the wave aberrations of the eye with principle components being a light source beacon, lenslet array, and areal CCD.

Spectacles. Ophthalmic appliance that corrects prism, defocus (sphere), and astigmatism (cylinder).

Strehl ratio. Ratio of the maximum light intensity in the aberrated point spread function to that in the aberration-free point spread function with the same pupil diameter. Values range from 0 to 1.

Visual acuity. Capacity for seeing distinctly the details of an object. In units of the Snellen fraction, average clinical visual acuity varies between 20/15 and 20/20.

Wave aberration. Optical deviations of a wavefront that degrade image quality and that can vary temporally and spatially across the pupil of the optical system.

Zernike polynomials. Specific set of polynomials frequently used to mathematically represent the wave aberration of the eye.

15.2 INTRODUCTION

Vision is a most acute human sense. Yet one need only to examine the first step in the visual process—the formation of an image on the retina—to realize that it is often far from perfect. Image quality at the retina is limited fundamentally by the wave aberrations intrinsic to the cornea and crystalline lens and diffraction due to the finite size of the eye's pupil. Together, aberrations and diffraction limit not only what the eye sees looking out, but also determine the smallest internal structures that can be observed when looking into the eye with a microscope. Conventional corrective methods such as spectacles, contact lenses, and refractive surgery provide a static amelioration of low-order sphere (defocus) and cylinder (astigmatism). However, ocular image quality can be significantly improved by dilating the pupil to minimize diffraction and correcting the aberrations across the larger pupil. The presence of aberrations in the human eye[1] has been recognized for some time. Indeed, Hermann von Helmholtz, commenting on the eye 150 years ago, put it as follows: "Now, it is not too much to say that if an optician wanted to sell me an instrument which had all these defects, I should think myself quite justified in blaming his carelessness in the strongest terms, and giving him back his instrument."[2]

Spectacles have been used to correct defocus since at least as early as the thirteenth century. They began to be used to correct astigmatism shortly after 1801, when Thomas Young discovered that condition in the human eye. However, it has only been in the last decade and a half—two centuries later—that additional, higher-order aberrations have been corrected. There are three reasons for this long period of seemingly little progress.

First, the most significant and troublesome aberrations in the eye are defocus and astigmatism. Correcting these two usually improves vision to an acceptable level. Second, for most of this period defocus and astigmatism were the only aberrations of the eye that could be easily measured. Third, even when higher-order aberrations could be measured by the cumbersome techniques available at that time, there was no simple or economical way to correct them. In 1961, for instance, M. S. Smirnov[3] measured many of the higher-order aberrations in the human eye for the first time. But his psychophysical method required 1 to 2 h of measurements per eye, followed by an additional 10 to 12 h of calculations. On the strength of his results, Smirnov surmised that it would be possible to manufacture custom lenses to compensate for the higher-order aberrations of individual eyes.

Recent technological advances, notably in adaptive optics (AO),[4] have provided solutions to the problems Smirnov encountered. The concept of AO was proposed in 1953 by astronomer Horace Babcock[5] as a means of compensating for the wavefront distortion induced by atmospheric turbulence.[6] Transforming AO into a noninvasive vision tool fundamentally consists of measuring the aberrations of the eye and then compensating for them. But the technique must be able to deal with the problem of variation of ocular and retinal tissue for a given person, as well as from person to person, and it must also take into account human safety.

Prior to the development of AO for the eye, several techniques showed promise for enhancing vision and improving the resolution of retinal imaging. These included use of interference fringes to probe the visual system without optical blurring;[7] a postdetection imaging technique coined speckle interferometry to recover high spatial frequencies of the cone mosaic;[8] and precise correction of defocus and astigmatism in conjunction with quick flashes of quasi-monochromatic light to image individual cone photoreceptors.[9] Success with the latter was confined to eyes of relatively low higher-order aberrations. In 1989, the first wavefront corrector was applied to the eye, a 13-actuator membrane mirror that corrected the astigmatism in one subject's eye using his conventional prescription for spectacles.[10] Correction of additional aberrations was not possible as there was no effective means at that time for measuring the aberrations.

These early techniques shared the common problem that the aberrations beyond defocus and astigmatism were largely unknown. To address this limitation, Liang et al.[11] developed a wavefront sensor based on the principles of Shack-Hartmann wavefront sensing (SHWS) and further refined it for measuring aberrations up through the first 10 radial orders (corresponding to the first 65 Zernike modes).[12] The SHWS was a watershed. It provided—for the first time—a rapid, automated, noninvasive, and objective measure of the wave aberrations of the eye. The method required no feedback from the patient; its measurements could be collected in a fraction of a second; and its near-infrared illumination was less intrusive to the subject than earlier techniques had been. That same year, the first AO retina camera was developed based on a SHWS and a 37-actuator deformable mirror.[13] The system included an additional channel for collecting images of the living retina and measuring the visual performance of subjects. With a pupil 6 mm in diameter, the system substantially corrected aberrations up through the fourth-Zernike order, where most of the significant aberrations in the eye reside. Thus, Liang et al. demonstrated for the first time that AO allows coma, spherical aberration, and other irregular aberrations to be corrected in the eye. The closed-loop speed of their system was on the order of tens of seconds and was incapable of tracking temporal fluctuations in the eye's aberrations. Their system may be more accurately characterized as an active rather than adaptive optics system.

In little more than a decade since AO for the eye has experienced exponential growth.[14] Essentially all facets of AO have undergone substantive development for use with the eye, including its wavefront sensor, wavefront corrector, and control algorithm. In addition, AO has been integrated into a variety of retina camera architectures to increase their resolution and sensitivity including the three principle types: flood-illuminated ophthalmoscope,[13,15–18] scanning laser ophthalmoscope (SLO),[19–24] and optical coherence tomography (OCT).[25–35] AO for the eye has also entered the commercial arena. The SHWS for measuring ocular aberrations has been commercially available for several years; commercial AO systems for vision testing for the last couple of years; and commercial AO retina cameras now entering the market.

While early AO retina cameras focused on imaging cone photoreceptors owing to their high reflectance and contrast, many other cellular structures have since been imaged in the living human retina including nerve fiber bundles, individual blood cells flowing through the smallest retinal capillaries, fibers of Henle, retinal pigment epithelium cells, and astrocytes. Ganglion cells and their axons have also been visualized with AO in primates when used in conjunction with a contrast-enhancing fluorescent dye. There is also an ever expanding list of fundamental and clinical research applications that are underway and which have been made possible by the increased resolution and sensitivity afforded by AO.

Several reviews of AO for vision science already exist,[36–40] including a textbook devoted to the topic.[41] Nevertheless, the field continues to grow rapidly and much has changed since the first *OSA Handbook* chapter on this topic was written in 2000.[42] Our aim here is to summarize the current understanding of the ocular aberration properties (pertinent for designing AO systems for the eye), detail the status of AO technologies for the eye, and review some of the latest scientific and clinical uses of this powerful technology.

15.3 PROPERTIES OF OCULAR ABERRATIONS

Aberrations of the eye vary spatially across the eye's pupil, vary over time, and vary with field location at the retina (isoplanatism). These fundamental properties (spatial distribution, temporal distribution, and field dependence) dictate the performance requirements of AO for effective correction of ocular aberrations. Here we summarize the most pertinent aspects of each for AO.

The spatial distribution of ocular aberrations varies considerably among subjects, and often does not correspond to the classical aberrations of manufactured optical systems (e.g., Seidel aberrations). Instead, Zernike polynomials are routinely used for representing ocular aberrations. The first-order Zernike polynomials represent tilt, the second order correspond to defocus and astigmatism, the third order are coma and trefoil, the fourth order are spherical aberration, secondary astigmatism, and quadrafoil, and so on. Third order and higher are collectively termed higher-order aberrations or irregular aberrations. Zernikes are not the most efficient polynomial representation of the eye's aberrations, but are only slightly less compact than the principal modes that derive from a principal components analysis.[43,44] Zernikes are also mathematically simpler and have well-established properties. Certainly the long history of Zernike polynomials in astronomy for representing atmospheric turbulence[45] influenced their early use by the vision community. The now ubiquitous use of Zernike polynomials is perhaps best reflected by the community's establishment and universal acceptance of a single naming convention for the Zernike coefficients and polynomials as described by the OSA/VSIA Standards Taskforce.[46]

Today detailed measurements of the spatial distribution of wave aberrations have been made in large populations of normal, healthy adult eyes with large pupils,[43,44,47] including the pooling of data collected at 10 laboratories (2560 eyes).[48] More recent studies have expanded this to include the effect of age, accommodation, refractive state, refractive surgery, and disease.[49–57]

The spatial characteristics of the ocular aberrations most important for AO are spatial fidelity (frequency composition of the aberrations) and magnitude [peak-to-valley (PV) wavefront error]. Both are captured by the Zernike representation—spatial fidelity by the Zernike order and magnitude by the Zernike coefficient, and both are strongly influenced by pupil size. As an example, Fig. 1*a* shows the wavefront variance decomposed by Zernike order for a population of about 100 normal subjects, most in their early twenties.[44] Data points are shown for three pupil sizes: 4.5, 6.0, and 7.5 mm, which span the range over which AO is typically applied to the human eye. For comparison, the maximum physiological pupil size for young subjects is nominally 8 mm. In Fig. 1*a*, the power decreases monotonically (approximately linear on a logarithmic scale) with second-order aberrations dominating the total wavefront error. Power also decreases monotonically with decreasing pupil size. The 7.5-mm pupil represents the most demanding condition for AO. For this pupil size, correction of Zernike polynomials up through at least 10th order is necessary to reach diffraction-limited imaging [$\lambda/14$ root-mean-square (RMS) error] in approximately 95 percent of the population, that is, two times the standard deviation of the $\log_{10}$ (wavefront variance).

Figure 1*b* shows the corresponding PV wavefront error that encompasses 95 percent of the population as a function of pupil size (4.5 to 7.5 mm). Three curves are shown that correspond to three different second-order states. As expected, the PV error increases monotonically with pupil size and depends strongly on the second-order state. The PV error for the 7.5-mm pupil ranges from 7 to 11 μm depending on the second-order state. The largest error of 11 μm represents the most demanding condition for AO correction. Note that for this study, each subject was meticulously refracted with trial lenses. Typically, AO systems operate under less ideal conditions in which the second-order aberrations are only coarsely corrected or not at all. Under these more realistic conditions, second-order aberrations can readily surpass the PV error shown in the figure by several times. As such, careful design of an AO system must take into account the anticipated refractive state of the population and the expected manner in which trial lenses or translating lenses will be applied.

The population measurements in Fig. 1 represent essentially static wave aberrations and therefore do not capture the temporal behavior of the ocular media. Two early studies investigated the temporal dynamics with attention to their impact on AO performance.[58,59] Both studies employed a SHWS to track the dynamics. Hofer et al. measured aberration changes up to approximately 5 to 6 Hz, and

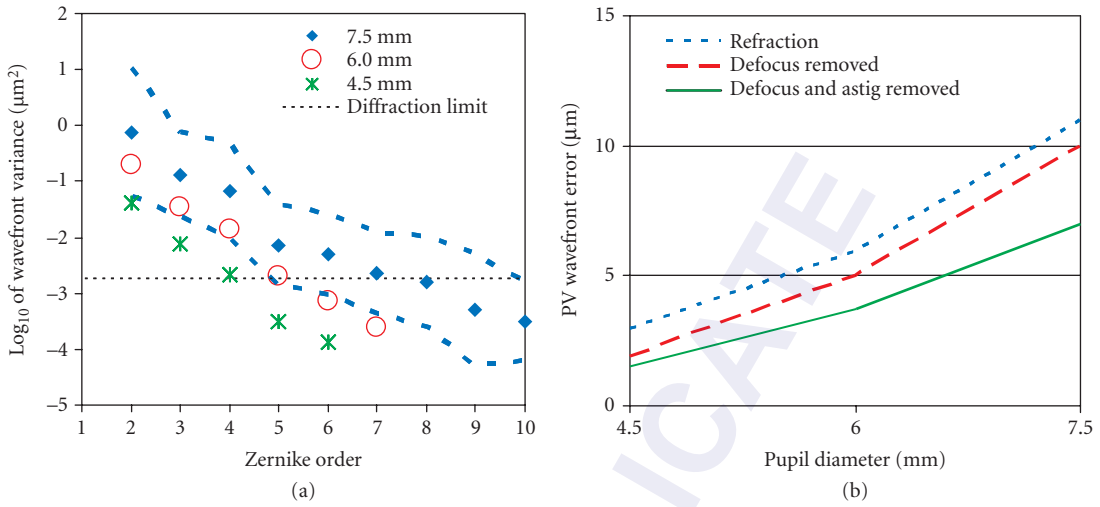

FIGURE 1 Spatial properties of ocular aberrations in a large population of 100 normal eyes.[44] (*a*) Log_{10} of the wavefront variance after a conventional refraction using trial lenses is plotted as a function of Zernike order and pupil size (4.5, 6.0, and 7.5 mm). Diamond and corresponding dashed curves represent the mean and mean ± two times the standard deviation of the log_{10} (wavefront variance), respectively, for a 7.5-mm pupil. Star and open circle correspond to 4.5- and 6.0-mm pupils. Thin, horizontal dashed line corresponds to $\lambda/14$ RMS for $\lambda = 0.6$ μm. (*b*) PV wavefront error that encompasses 95 percent of the population is plotted as a function of pupil diameter. Three second-order states are shown: (i) residual aberrations after a conventional refraction using trial lenses (short blue dashed line) (ii) all aberrations present with zeroed Zernike defocus (long red dashed line), and (iii) all aberrations present with zeroed defocus and astigmatism (solid green line).

Lois-Diaz et al. up to approximately 30 Hz. Figure 2*a* shows representative temporal traces of the total RMS wavefront error and several Zernike terms for one subject and a model eye over a 5 s interval. Figure 2*b* shows corresponding average temporal power spectra which reveal the frequency content of the traces. As depicted in the figure, temporal fluctuations are found in all of the eye's aberrations, not just defocus, even when the eye's accommodation is paralyzed. In both studies, the reported temporal fluctuations decreased at $f^{-4/3}$ or equivalently four dB/octave, where f is the temporal frequency. This decrease is evident in the temporal power spectrum shown in Fig. 2*b*. The vast majority of the aberration power lies below 1 to 2 Hz, suggesting effective AO correction needs only a temporal bandwidth of a couple of hertz. For comparison, the 1 to 2 Hz is approximately two orders smaller than that of atmospheric turbulence for ground-based telescopes.

Finally, aberrations of the eye also vary with field location at the retina. That is, image quality (or more precisely the point spread function or optical transfer function) at one point on the retina is not the same as at another point when the two points are separated sufficiently. This difference in image quality stems from the fact that the ocular aberrations originate at the cornea and crystalline lens rather than at the pupil of the eye. Rays originating from different field locations on the retina will therefore take slightly different paths through the ocular media, accumulating different phase delays or equivalently different aberrations. In general there is a local region about any point on the retina in which the path differences are sufficiently small that the ocular aberrations are effectively constant. This region is termed the isoplanatic patch.[60] The diameter of the patch depends on the properties of the eye, but also on the definition of image quality, as for example, use of the stringent Maréchal criterion, $\lambda/14$-μm RMS (Strehl ratio = 0.8) yields a narrower isoplanatic diameter than the more relaxed criterion of 1 rad^2 (Strehl ratio = 0.37). Which criterion to choose depends on the application, though it remains to be seen what criterion is optimal for common AO retinal imaging uses as well as AO psychophysical uses.

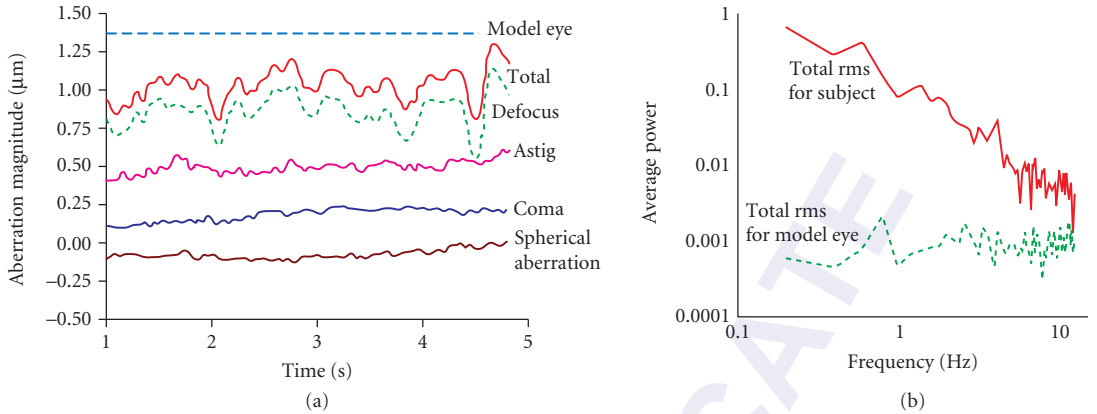

FIGURE 2 Temporal properties of ocular aberrations.[58] (*a*) Temporal traces of the total RMS wavefront error and Zernike terms: defocus, astigmatism, coma, and spherical aberration for one subject. A trace of the total RMS wavefront error for an artificial eye is also shown and reflects the sensitivity of the instrument. (*b*) Average temporal power spectra are shown for the fluctuations in the total RMS wavefront error for a model eye and one subject whose accommodation was paralyzed. Aberrations were computed for a 4.7-mm pupil size. (*Reproduced with permission from Ref. 58.*)

Anecdotal evidence in the AO literature indicates the isoplanatic patch diameter for the human eye is a couple of degrees. Experiments to directly measure the patch size have only recently been conducted. A detailed survey of efforts in this area coupled with a more thorough analysis were recently published by Bedggood et al.[61] Figure 3 shows a representative result from this study, plotting isoplanatic patch diameter as a function of the residual wavefront RMS at the patch edge. As expected, the patch size increases as the criterion relaxes, that is, larger residual RMS. As an example, AO systems

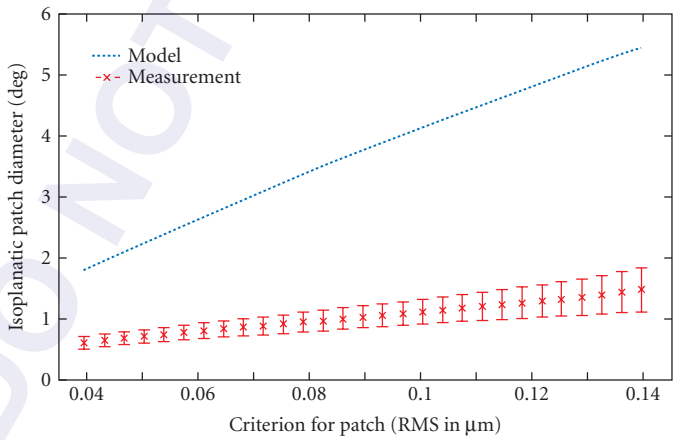

FIGURE 3 Isoplanatic properties of ocular aberrations. Isoplanatic patch diameter is plotted versus residual wavefront RMS at the patch edge after perfect correction of ocular aberrations at the patch center. Data points are average measurements across seven healthy subjects, aged 22 to 39, with error bars at ±1 standard deviation. Predicted patch diameter is also shown using the Liou Brennan schematic eye.[62] Pupil size for both is 6 mm. (*Reproduced with permission from Ref. 61.*)

typically correct the eye (with a large pupil) to within a wavefront RMS error of approximately 0.1 μm. Using this value as a realistic criterion for the residual RMS at the patch edge in Fig. 3, the corresponding isoplanatic diameter is approximately 1.1°, consistent with anecdotal evidence and other measurements reported in the literature. For comparison, this patch diameter is three orders of magnitude larger than that encountered with ground-based telescopes. Interestingly, optical models of the eye (e.g., the Liou Brennan schematic eye in Fig. 3) are not sufficiently developed yet to predict experimental findings, both in terms of the patch size and criterion dependence. As evident in Fig. 3, the Liou Brennan model overestimates the patch diameter by several times.

15.4 IMPLEMENTATION OF AO

The principle components of an AO system are the wavefront sensor, wavefront corrector, and control system. Figure 4 shows a simplified schematic of AO applied to the eye and highlights the principle components. The effectiveness of AO depends fundamentally on its ability to measure, correct,

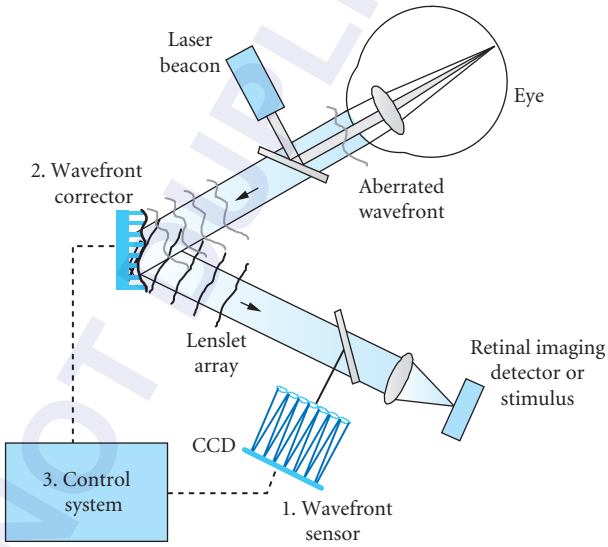

FIGURE 4 Concept schematic of AO applied to the eye. The three principle components of AO are (1) the wavefront sensor, (2) the wavefront corrector, and (3) the control system. The wavefront sensor (shown here as a Shack-Hartmann implementation) works by focusing a laser beam onto the subject's retina. This is analogous to the artificial-guide-star approach now being used to measure the wave aberrations of atmospheric turbulence.[63] The reflection from the retinal spot is distorted as it passes back through the refracting media of the eye. A two-dimensional lenslet array, placed conjugate with the eye's pupil, samples the exiting wavefront forming an array of images of the retinal spot. A CCD sensor records the displacement of the spots, from which first local wavefront slopes and then global wavefront shape are determined. Wavefront compensation is realized with a deformable mirror. The mirror lies in a plane conjugate with the subject's pupil and the lenslet array of the SHWS. For retinal imaging, a light source (not shown) illuminates the retina, some of which is reflected out of the eye, reflects from the wavefront corrector, and forms an aerial image at the retinal imaging detector. For visual testing, the retinal imaging detector is replaced with a visual stimulus that is viewed by the subject through the AO system.

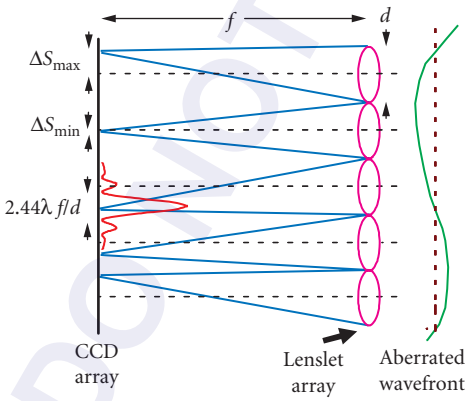
and track the ocular aberrations, the extent to which depends heavily on the spatial and temporal properties of the aberrations as described in the previous section. Measurement is accomplished by the wavefront sensor, correction by the wavefront corrector, and tracking by the control system in conjunction with the sensor and corrector. The status of each of these components and their requirements for effective use with the eye are described in order below.

Wavefront sensor

There is an abundance of optical sensors for wavefront measuring with many representing highly mature devices. These include the Shack-Hartman sensor, shearing interferometer, pyramid sensor, curvature sensor, phase diversity, laser ray tracing, phase-shifting interferometer, and common path interferometer. While several of these have been applied to the eye and others continue to attract interest, to date all operational AO systems for the eye have been constructed around the SHWS. As such, we confine our attention to this sensor type, though much of which will be applicable to the other sensors. The discussion that follows will reference Fig. 5, which shows an enlarged schematic of the SHWS (lenslet and CCD array) along with typical values of several key parameters.

A first-order design of the SHWS entails evaluation of several key properties: (1) spatial sampling, (2) dynamic range, (3) accuracy, and (4) signal-to-noise. These are primarily set by the characteristics of the lenslet and CCD arrays of the sensor, and therefore selection of these two components is critical. Figure 5*b* shows typical values in use. Spatial sampling of the sensor is specified by the number of lenslets that fills the pupil of the eye. The necessary number of lenslets for reliable representation of the ocular aberrations depends on the composition of the ocular aberrations, pupil size of the eye, and to a lesser extent the SH wavelength. It should be noted that while we assume here the lenslets to be uniformly distributed (as is the case of SH sensors in current AO systems), several nonuniform distributions have also been evaluated.[64]

Theoretical modeling in conjunction with measured aberrations of the eye indicates a one-to-one relationship between the number of Zernike modes and number of lenslets necessary to reliably reconstruct these modes.[65] Therefore, the number of required lenslets that fill the pupil must be at



Typical SHWS parameters	
Lenslet number:	200–350
Lenslet dia, *d*:	0.3–0.4 mm
Lenslet local length, *f*:	7–30 mm
# pixels across focal spot dia:	3–6 pixels
Wavelength, λ:	0.63–0.85 μm

(b)

FIGURE 5 (*a*) A two-dimensional lenslet array, placed conjugate with the eye's pupil, samples the exiting wavefront forming an array of images of the retinal spot. A CCD sensor records the displacement of the spots. Maximum and minimum detectable displacements of the spots are indicated by ΔS_{max} and ΔS_{min}. (*b*) Key SHWS parameters and typical values for use with the eye. Lenslet number refers to the number that fills the pupil of the eye. Lenslet diameter is referenced to the eye pupil. Pixels refer to the detector unit of the CCD array. λ is the wavelength of the SHWS laser beacon.

least equal to the number of Zernike modes, which is related to the maximum Zernike order by $(N+1)(N+2)/2 - 3$. N is the maximum Zernike order and piston, tip, and tilt are not included. Based on this, reliable representation up through 10th Zernike order requires at least 63 lenslets, that is, equals $(10+1)(10+2)/2 - 3$, that uniformly cover the pupil.

Figure 1*a* provides additional information—at least for normal healthy eyes—as to the number of Zernike orders necessary for reliably representing ocular aberrations. As an example, for the stringent condition of diffraction-limited imaging through a large 7.5-mm pupil in 95 percent of the population, Fig. 1*a* indicates Zernike representation up through at least 10th order is necessary. For this scenario, at least 63 lenslets are therefore required to reliably sample the aberrations. Fewer lenslets are necessary for a smaller pupil or a less stringent image quality metric. In practice, SHWSs routinely sample the pupil much higher. There is little cost to do so, since there is an over abundance of light for the sensor. Oversampling makes the measurements more robust (to pupil edge effects, eye motion, drying of the precorneal tear film, and system noise) and applicable to eyes with a wider range of aberrations.

Dynamic range refers to the maximum wavefront slope $\Delta\theta_{max}$ that can be measured by the SHWS (depicted in Fig. 5*a*). $\Delta\theta_{max}$ is typically expressed as $\Delta S_{max}/f$, where ΔS_{max} is the maximum displacement of the lenslet spot (= lenslet radius) and f the lenslet focal length. Since spherical and cylindrical refractive errors typically consume much of the dynamic range of the sensor, it is often more useful to convert ΔS_{max} to a maximum measurable defocus (diopters), expressed by $D = \Delta\theta_{max}$ / (pupil radius). For example, a lenslet diameter of 0.4 mm and a lenslet focal length of 24 mm, gives a $\Delta\theta_{max}$ and D of 8.3 mrad and 2.45 diopters, respectively, for a 6.8-mm eye pupil. Note that D represents the dioptric range at the wavefront sensor. The corresponding range at the eye is often different depending on the eye-to-sensor magnification. In general, the dynamic range can be increased by increasing the lenslet diameter, decreasing the lenslet focal length, or decreasing the pupil diameter. The pupil diameter, however, is usually not adjustable, being defined early in the design process of the retina camera.

Accuracy refers to the minimum wavefront slope, $\Delta\theta_{min}$, that can be measured by the SHWS. $\Delta\theta_{min}$ can be expressed as $\Delta S_{min}/f$, where ΔS_{min} is the minimum detectable displacement of the lenslet spot (see Fig. 5*a*). ΔS_{min} depends on the pixel size of the SHWS detector (typically a CCD array), diameter of lenslet spot at the detector (which is a function of the lenslet diameter and focal length), accuracy of the centroiding and thresholding algorithms, and signal-to-noise of the captured SHWS spot image. In general, subpixel accuracy is routinely achieved.[66] The above example (lenslet diameter = 0.4 mm and focal length = 24 mm) with a CCD pixel size of 26 μm yields approximately 4.4 pixels across the focal spot and $\Delta\theta_{min} << 1.1$ mrad. While the SHWS parameters can be manipulated to increase accuracy, dynamic range of the sensor depends inversely on the lenslet diameter and focal length, thereby creating a clear trade-off between dynamic range and accuracy. Additional discussion on this topic can be found in Ref. 66.

Signal-to-noise of the captured SHWS spot images is limited by the amount of light that can be safely directed into the eye, number of pixels per lenslet focal spot, quantum efficiency of the SHWS CCD, and throughput efficiency the SHWS. Unlike astronomical AO systems, however, that operate under light-starved conditions and covet each photon to achieve the approximately 100 photons/lenslet required to close the AO loop, vision AO systems operate under comparatively relaxed light requirements. A typical vision AO system has a minimum of approximately 500,000 detected photons/lenslet, this with hundreds of lenslets that sample the pupil. Such high light levels permit use of relatively low quantum efficient CCDs and tens of pixels that sample the core of the lenslet focal spot.

Wavefront Corrector

The effectiveness of AO to correct ocular aberrations is typically limited by the performance of the wavefront corrector, which is also by far the most expensive component. This device dynamically imparts an ideally conjugate aberration profile onto the passing wavefront, thus canceling the original aberrations. Numerous types of wavefront correctors have been employed in AO systems for the eye. Historically, correctors have been selected somewhat arbitrarily for the eye, that is, driven

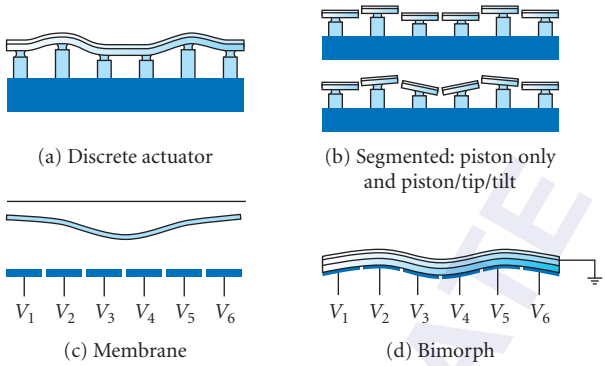


FIGURE 6 Four main classes of wavefront correctors. (*a*) Discrete actuator deformable mirrors consist of a continuous, reflective surface, and an array of actuators, each capable of producing a local deformation in the surface. (*b*) Piston-only segmented correctors consist of an array of small planar mirrors whose axial motion (piston) is independently controlled. LC-SLMs modulate the wavefront in a similar fashion, but rely on changes in refractive index rather than the physical displacement of a mirror surface. Piston/tip/tilt segmented correctors add independent tip and tilt motion to the piston-only correctors. (*c*) Membrane mirrors consist of a grounded, flexible, reflective membrane sandwiched between a transparent top electrode, and an underlying array of patterned electrodes, each of which is capable of producing a global deformation in the surface. (*d*) Bimorph mirrors consist of a layer of piezoelectric material sandwiched between a continuous top electrode and a bottom, patterned electrode array. A top mirrored layer is added to the top continuous electrode. An applied voltage causes a deformation of the top mirrored surface. (*Reproduced with permission from Ref. 41, chap. 4, Fig. 4.2.*)

primarily by availability and cost rather than performance, with the expectation that image quality will improve, the extent of which was empirically determined. More recently, several extensive theoretical studies have evaluated the performance of general wavefront corrector classes[67,68] as well as specific commercial devices.[69,70] The four main classes of wavefront correctors are depicted in Fig. 6. These include discrete actuator, membrane, bimorph, and segmented piston and piston/tip/tilt wavefront correctors. Regardless of class, performance is governed primarily by the corrector's actuator number, stroke, and influence function. Stroke refers to the dynamic range of the corrector and limits the largest wavefront error that can be corrected. Larger stroke provides better correction of large-magnitude aberrations. Actuator number across the eye's pupil and actuator influence function (localized deflection of the mirror surface that results when a single actuator is pushed or pulled) determine the fidelity of the correction. More actuators and a more localized influence provide better correction of high-spatial-frequency aberrations (i.e., aberration, that are of higher order). Other important corrector parameters include temporal response, surface reflectivity, diameter of mirror surface, and cost.

Wavefront correctors first applied to the eye were developed primarily for compensation of atmospheric turbulence. A common example being macroscopic discrete actuator deformable mirrors (DMs), such as those manufactured by Xinetics, Inc.[71] Specifically, their actuator number, stroke, influence function, and speed were tailored to the spatial and temporal properties of the atmosphere[4] rather than that of the eye.[43,44,58,59] The dynamic range of such devices often limited the compensation of ocular aberrations, especially second-order contributions, and their kilohertz response was overkill for the 1 to 2 Hz fluctuations of the ocular aberrations. While wavefront correctors represent a small fraction of the total cost of ground-based telescopes in which they are employed, they represent a significant fraction of the total cost of most retina cameras. Atmospheric wavefront correctors are also generally bulky, with large mirror surfaces (~several centimeters or more) that require long focal length relay optics to magnify the pupil of the eye. A smaller corrector comparable to the dilated pupil of the eye (4 to 8 mm) can substantially reduce the instrument size, which is attractive for research retina cameras and mandatory for commercial ones.

Alternative wavefront corrector technologies, which are more cost effective and smaller, have become commercially available and span the four corrector classes depicted in Fig. 6. Large stroke (up to 16 μm) bimorph mirrors having 13 to 35 actuators have been investigated by several groups.[15–17,28,30,72] An even larger stroke (50 μm) corrector, a magnetic membrane mirror with 52 actuators was recently evaluated by Fernandez et al.[73] Microelectromechanical systems (MEMS) promises batch fabrication of low cost, compact wavefront correctors. Bulk micromachined membrane MEMS mirrors, employing 37 electrodes and 3.5-μm stroke have been successfully applied to the eye.[74,75] Although bimorph and membrane mirrors have a large dynamic range for correction of low-order aberrations, the effective range drops rapidly with increasing order of the aberration mode.

Surface micromachined devices are another class of MEMS mirror whose mode of operation is comparable to discrete actuator DMs. Early performance results with a surface micromachined MEMS DM was reported by Doble et al.[76] Today, this mirror type is employed in numerous AO systems for the eye.[20,21,24,28,30,32] Liquid spatial light modulators (LC-SLMs) are an alternative wavefront corrector technology. Transmissive, pixelated designs with 69 and 127 pixels were examined by Thibos et al.[77] and Vargas et al.,[78] respectively. Prieto et al.[79] and Fernandez et al.[29] investigated an optically addressed LC-SLM. This reflective device has high spatial resolution (480 × 480 piston-only pixels) and operates with low control voltages (~5 V). LC-SLMS in general, however, are limited to 2π phase modulation of polarized light. Extended ranges can be achieved with phase wrapping.

Theoretical studies to predict the performance of wavefront correctors and guide their use with the eye have been undertaken with representative results from two such studies given in Fig. 7. Figure 7*a* shows the predicted corrected Strehl for three general types of wavefront correctors (discrete actuator, piston/tip/tilt, and piston) in conjunction with the measured ocular aberrations of Fig. 1. In this study, the effect of actuator stroke was separated from that of the actuator number and influence function by assuming sufficient stroke in the Fig. 7*a* plot. For the discrete actuator corrector in the figure, at least a 13 × 13 array of actuators is required to achieve diffraction-limited imaging (Strehl = 0.8) in 95 percent of the population, that is, ±2 standard deviations. Piston/tip/tilt correctors require somewhat less and piston correctors require substantively more. As shown in Fig. 7*a*, 100 to 150 piston

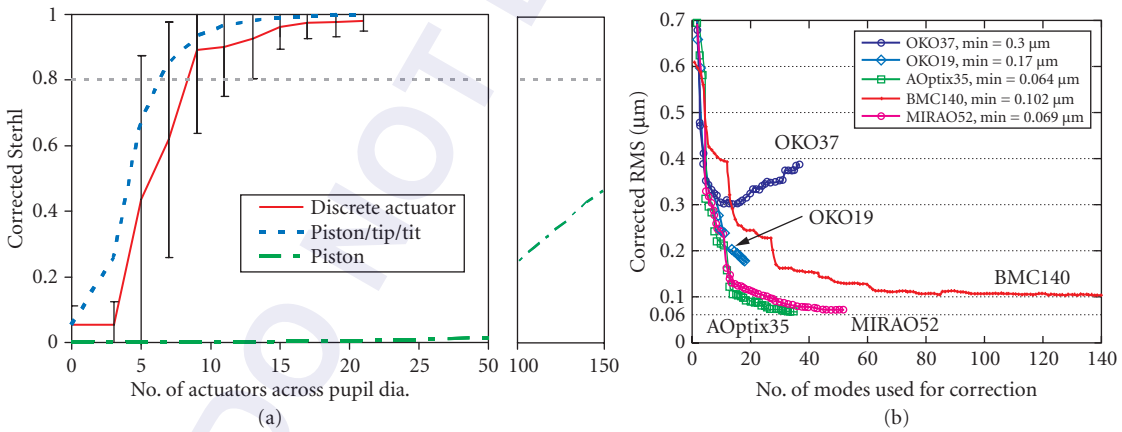

FIGURE 7 (*a*) Predicted corrected Strehl ratio for three general types of wavefront correctors (discrete actuator, piston/tip/tilt, and piston) as a function of actuator number across the pupil diameter.[68] Pupil diameter at the eye is 6 mm, wavelength is 0.6 μm, and the ocular aberrations are given in Fig. 1. Sufficient corrector stroke is assumed. The error bars for the single representative curve correspond to ±2 standard deviations. (*b*) Predicted corrected RMS for several commercial correctors is shown as a function of number of corrector modes used for correcton.[70] Model includes thresholding to account for the finite mirror stroke. Devices are from OKO Technologies (OKO19 and OKO37), Boston Micromachines Corp. (BMC140), AOptix Technologies (AOptix35), and Imagine Eyes (MIRAO52). Pupil diameter at the eye is 6 mm and the randomly generated ocular aberrations are based on the population statistics of Fig. 1.

segments (maximum sampling density of the study) across the pupil diameter are required to reach a corrected Strehl of only 0.4. As for the required stroke of the corrector, it should be at least one-half the PV error of the aberrations to be corrected, for example, the PV error in Fig. 1*b*. For example, in Fig. 1, the PV error for the 7.5 mm pupil ranges from 7 to 11 μm depending on the second-order state. Thus the required stroke must be at least one half of this (3.5 to 5.5 μm). Note that the required stroke can increase significantly if a larger portion of the second-order aberrations is corrected with AO rather than for example trial lenses. As an example, a 1-D spherical error across a 7.5-mm pupil increases the required stroke by an additional 3.5 μm based on the equation: stroke = 1/4 (refractive error in diopters) (pupil radius in millimeters)^2.

Figure 7*b* shows results from another study in which performance was predicted for several commercially available correctors. The modeling took into account the actual influence functions, finite stroke of each corrector (thresholding), and number of corrector modes included in the correction. The commercial devices evaluated included three membrane mirrors (OKO19, OKO37, and MIRAO52), one bimorph mirror (AOptix35), and a surface micromachined MEMS deformable mirror (BMC140). Of these only two (AOptix35 and MIRAO52) approach diffract limited performance.

In practice, AO retina cameras with a single wavefront corrector have not achieved sufficient correction to yield diffraction-limited imaging across large pupils (≥ 6 mm), more so in the presence of typical levels of second-order aberrations. Current correctors—while having improved noticeably in recent years—struggle to provide the necessary high spatial fidelity and high dynamic range to fully compensate both low- and higher-order aberrations of the eye. To overcome this barrier, other approaches have been explored, including a multipass configuration that traverses the same corrector more than once[80] and a cascade of two wavefront correctors, one of high spatial fidelity and the other of large stroke.[34,81,82]

Control System

The control system performs the critical step of rapidly and repeatedly converting the raw output of the wavefront sensor into voltage commands that shape the corrector surface, that is, the deformation created by the sum response of the corrector actuators. The control loop takes into account the number, arrangement, and interaction of lenslets and actuators; the influence function and stroke of actuators; temporal response of the AO components; and a desired performance criteria, for example, minimize the RMS wavefront error. The control loop can be characterized by distinct spatial and temporal properties, which are each discussed in order further.

Spatial control starts with the layout of lenslets and actuators. For AO astronomical telescopes, the lenslet-actuator arrangement typically follows a Southwell or Fried configuration in which each lenslet is centered on one actuator or centered between four adjacent actuators. Both geometries yield one lenslet per actuator. This ratio maximizes the number of photons per lenslet, critical for the photon starved conditions under which astronomical AO systems operate, while preserving sensitivity to actuator motion. The relative coarse sampling of the lenslets, however, makes the AO sensitive to misalignment of the lenslet and actuator arrays, and the wavefront sensor cannot detect certain corrector modes, as for example waffle mode. As discussed in section "Wavefront Sensor," the eye provides substantially more light than astronomical applications, allowing many more lenslets per actuator. Typical AO systems for the eye sample each actuator with two to ten lenslets. This oversampling greatly increases the tolerance to alignment errors and permits detection of all corrector modes.

Spatial (static) control of the wavefront corrector is normally realized through a multiplication of two matrices, one representing the wavefront sensor output (slope measurements) and the other a reconstructor matrix representing the interaction of each actuator with each lenslet. At its most basic level, the wavefront sensor output is an areal image of focus spots arranged in a quasi-regular pattern and resting on a noise floor, one spot formed behind each lenslet. The critical information in the image is the displacement of the focus spots relative to predetermined reference positions. Determining these displacements is nontrivial owing to noise in the image, and the finite width

and often irregular shape of the focus spots. Collectively, these reduce the accuracy to locate the spot centers. Centroiding based on center of mass is a common solution to this problem and is effective as it takes into account the full energy distribution of the spot. Following the mathematical notation by L. Chen,[83] the horizontal and vertical centroid positions for the kth lenslet in the array and a unit voltage applied to the mth actuator in the corrector can be expressed as

$$\Delta x_{k,m} = \frac{\sum_{i,j\in k} x_{i,j}\, I_{i,j,m}}{\sum_{i,j\in k} I_{i,j,m}} - x_{k,ref} \qquad \text{and} \qquad \Delta y_{k,m} = \frac{\sum_{i,j\in k} y_{i,j}\, I_{i,j,m}}{\sum_{i,j\in k} I_{i,j,m}} - y_{k,ref} \tag{1}$$

i and j represent coordinates for a pixelated detector, such as a CCD array. $I_{i,j,m}$ is the intensity distribution of the focus spots; $x_{k,ref}$ and $y_{k,ref}$ are reference coordinates, for example, those that minimize the wavefront error. The corresponding horizontal and vertical wavefront slopes are determined from the centroids by

$$s_{km_x} = \frac{\Delta x_{k,m}}{f} \qquad \text{and} \qquad s_{km_y} = \frac{\Delta y_{k,m}}{f} \tag{2}$$

where f is the focal length of the lenslets (see Fig. 5). In matrix notation, the wavefront slope output of the sensor can be expressed as

$$S_m = (s_{1mx}, s_{1my}, s_{2mx}, s_{2my}, \ldots, s_{kmx}, s_{kmy}, \ldots, s_{Kmx}, s_{Kmy})^T \tag{3}$$

where K is the total number of lenslets. Systematically applying a unit voltage to each of the M actuators in the corrector and recording the resulting displacement of the focus spots S_m, a $2K \times M$ matrix is constructed called the influence function matrix:

$$A = (S_1, \ldots, S_m, \ldots, S_M) \tag{4}$$

Because A is generated by systemically applying unit voltages to the actuators, A is mathematically related to the applied voltages, $V = (v_1, v_2, \ldots, v_M)^T$, and the resulting wavefront slopes, $S = (s_{1x}, s_{1y}, \ldots, s_{kx}, s_{ky}, \ldots, s_{Kx}, s_{Ky})^T$, by

$$S = A\,V \tag{5}$$

Equation (5) can be solved for V by first finding an inverse for A. Since A is typically singular (e.g., a nonsquare matrix), no inverse exists and mathematical techniques such as singular value decomposition (SVD) are commonly used to find an appropriate pseudoinverse, denoted A^+:

$$V = A^+\, S \tag{6}$$

A^+ is often referred to as a reconstructor matrix as a single matrix multiplication with S reconstructs the actuator voltages necessary to correct the measured aberrations. The single matrix multiplication is fast and efficient, and for SVD represents a least squares solution.

The control model described above assumes the AO operates in a linear fashion. While this is overly simplistic for actual AO systems, the AO control loop is much more robust than suggested, converging even when nonlinearities are present owing to its closed-loop operation. Equation (6) refers to what is called the direct slope reconstruction method. Another approach that is sometimes employed is the modal reconstruction method in which wavefront slope measurements are first converted to Zernike aberration modes that in turn are converted to applied voltages. While this approach is slower and less efficient, it has the advantage of allowing explicit control of individual modes, including which ones are sent to the corrector.

Equation (6) does not capture the closed-loop performance of AO as it neglects the temporal dynamics of the ocular aberrations and the time delays associated with measuring the wavefront slopes, and computing and applying the control voltages. The resulting error can be mathematically

expressed as $\phi_{resid}(x, t) = \phi_{aberr}(x, t) - \phi_{correct}(x, t)$, where $\phi_{aberr}(x, t)$ is the ocular aberrations at time t, $\phi_{correct}(x, t)$ the applied correction based on slope measurements acquired at an earlier time $t - \tau$, and $\phi_{resid}(x, t)$ the uncorrected portion at time t. τ is the closed-loop period of the AO. Note that $\phi_{correct}(x, t)$ is directly related to the voltages, V, that are applied iteratively to the corrector and expressed as $V(t) = V(t - \tau) - G\,V_{estimate}(t)$. $V(t - \tau)$ are voltages already on the corrector as determined from the previous loop iteration, $V_{estimate}(t)$ are adjustments to the voltages based on Eq. (6), and $V(t)$ represent the updated voltages. G is the variable loop gain (adjusted between 0 and 1) that controls the extent to which $V_{estimate}(t - \tau)$ is applied and represents the trade-off between stability and sensitivity of the AO system, for example, higher gain increases sensitivity to temporal fluctuations in the aberrations, but at the expense of decreased system stability. Typical values of G for AO vision science instruments are between 0.1 to 0.4.

Predicting the temporal performance of an AO system is critical for optimizing system design for the eye and is accomplished by modeling the system as a cascade of transfer functions, each representing an independent component of the system. Figure 8 shows a block diagram representation of an AO control loop with input/output parameters $M(s)$, $X(s)$, and $R(s)$ that depict the time-varying aberrations of the eye, residual aberrations after correction, and wavefront corrector voltages. s is a complex frequency and defined as $i2\pi f$, where f is the temporal frequency and $i^2 = -1$. Noise in the system is assumed negligible. For analysis, the AO system can be decomposed as a linear cascade of independent transfer functions, in this case the four AO stages that most often limit temporal performance in AO vision science systems: SHWS exposure, sensor readout and computation of V, integral compensator, and finally holding mirror position for one AO loop period. Common expressions for the four transfer functions are given by

$$H_{exp}(s) = \frac{1 - e^{-sT_1}}{sT_1} \tag{7}$$

$$H_{delay}(s) = e^{-st_1} \tag{8}$$

$$H_{comp}(s) = \frac{G}{1 - e^{-sT_2}} \tag{9}$$

$$H_{zoh}(s) = \frac{1 - e^{-sT_2}}{sT_2} \tag{10}$$

where T_1 is the exposure duration of the SHWS detector, T_2 is the sampling period of the AO loop, and t_1 is the total delay to readout the sensor and compute V.

Using the notation in Fig. 8, the open-loop transfer function (single iteration), $H_{OL}(s)$, is equal to $M(s)/R(s)$ and corresponds to the multiplication of the four transfer functions, that is, $H_{exp}(s)\,H_{delay}(s)\,H_{comp}(s)\,H_{zoh}(s)$. While this quantifies the extent to which fluctuations in the aberrations are

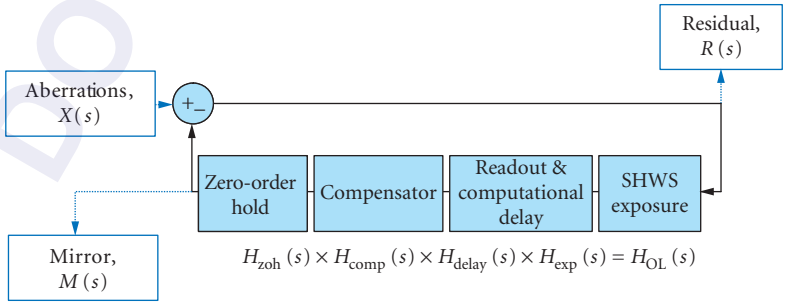

FIGURE 8 Block diagram of the AO system for modeling temporal performance.

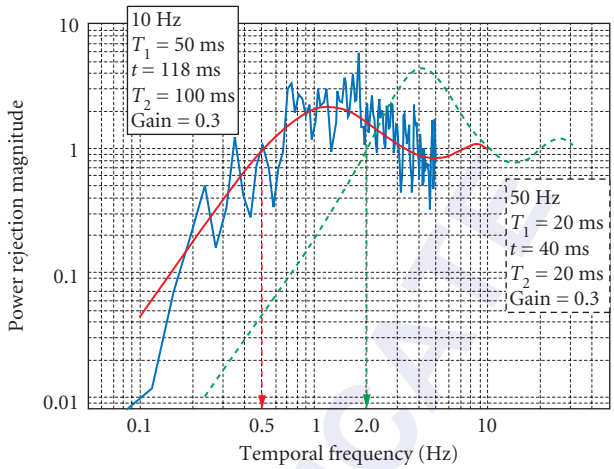

FIGURE 9 Experimental and theoretical curves for the power rejection magnitude of a representative AO system for vision science. Experimental curve (jagged blue line) was obtained on one eye using a gain of 0.3 for a 6.8-mm pupil. The corresponding theoretical curve (solid, red) was based on the actual system parameters as highlighted in the leftmost box. The second theoretical curve (dashed, green) predicts the performance of an AO system that is 5 times faster. System parameters are highlighted in the rightmost box. Cutoff frequencies for the two configurations are 0.5 and 2.0 Hz.

reliably transferred to the corrector, a more useful transfer function is the error transfer function, $H_{error}(s)$, defined as $R(s)/X(s)$. $H_{error}(s)$ quantifies the extent to which fluctuations in the aberrations are reduced by the AO. $H_{error}(s)$ is related to $H_{OL}(s)$ by the expression $1/[1 + H_{OL}(s)]$. As an example, Fig. 9 shows the power rejection magnitude (defined as $|H_{error}(s)|^2$) for two representative AO configurations, one being 5 times faster than the other. Both configurations employ double buffering, a common technique realized with a frame-transfer CCD camera, in which one SHWS frame is processed while the next frame is being acquired. The power rejection magnitude permits determining the cutoff frequency of the AO system, being defined as the frequency at which the power rejection magnitude first reaches 1. For the two configurations in Fig. 9, cutoff frequencies occur at 0.5 and 2.0 Hz, with the former consistent with the experimental measurements shown. Note that a cutoff of 0.5 Hz indicates that temporal frequencies below 0.5 Hz are (at least partially) corrected by the system, while those above 0.5 Hz are (at least partially) amplified. Because the vast majority of the aberration power in the eye lies below 1 to 2 Hz (see Fig. 2 and related discussion), the 2.0-Hz bandwidth AO configuration should be adequately fast and should provide somewhat improved performance over that of the 0.5-Hz system.

15.5 APPLICATION OF AO TO THE EYE

The sole function of AO in ophthalmic applications is to compensate or control the aberrations in the optics that lie between the eye's fundus and the rest of the world. As such, AO can be implemented into any vision or imaging application that employs these optics. This section will be split into applications where the goal is to get a better view of the retina and applications where the goal is to reduce or manipulate the blur of light delivered to the retina.

Applications Involving Imaging of the Retina

AO's role in a retina camera is to achieve diffraction-limited imaging through the highest possible numerical aperture in the eye. Most imaging applications that use AO correct over pupil sizes of 5 mm or greater, thereby taking advantage of the reduced diffraction. For example, a corrected pupil of 6 mm has a Rayleigh resolution limit about 2 μm, which is on the scale of the smallest cells in the retina (rods and foveal cones, for example).

Flood-Illuminated AO Ophthalmoscope The first ophthalmic imaging modality that demonstrated a high-order aberration correction with AO was a flood-illuminated ophthalmoscope.[13] In this system (Fig. 10), the camera looks at the retina through an optical system where the deformable mirror is placed in the path in a plane that is conjugate to the pupil of the eye. A low coherent collimated light source (SLD, superluminescent diode) is generally used to project a beacon onto the retina. The scattered light passes through the system, off the DM and to the wavefront sensor (LA & CCD). The AO system operates in a closed loop to correct the eye's aberration. At the same time, a separate light source is used to illuminate a patch of retina limited by the field stop (FS) at the location of the beacon. The scattered light emerges, its wavefront is compensated by the DM, and the light is directed to the science camera after reflection from a dichroic beamsplitter (DBS2) to form a sharp retinal image. The camera can be moved to focus on different layers of the retina. Keeping track of the retinal and pupil conjugate positions is critical and they are labeled throughout the schematic.

The flood-illuminated AO ophthalmoscope has been used effectively to measure basic optical properties of photoreceptors. A combination of AO imaging with retinal densitometry was used to provide the first maps of the arrangement of the three cone classes in the human retina (see Fig. 11).[84,85] It was

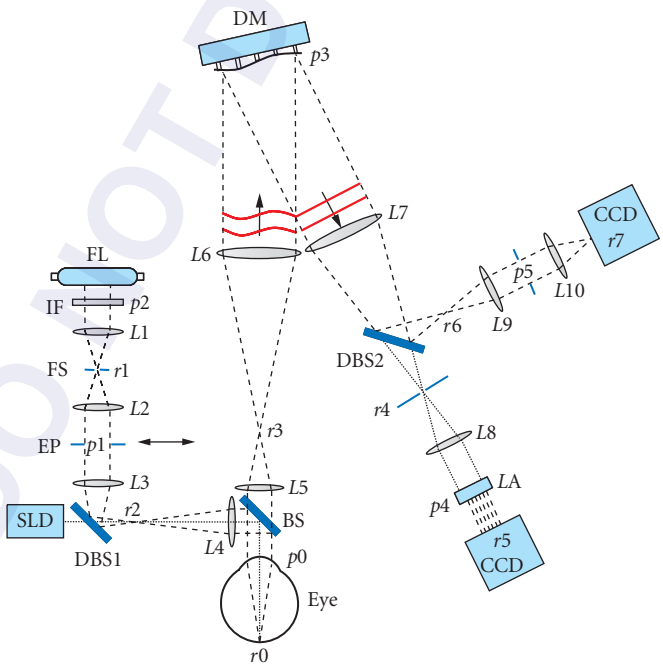

FIGURE 10 Schematic of a flood-illuminated AO retina camera.

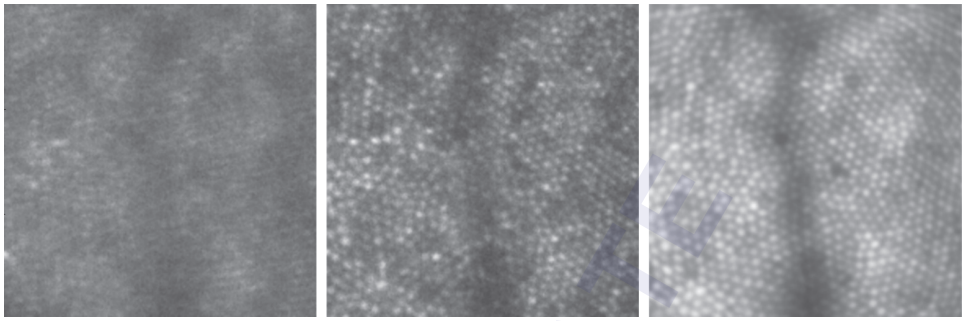

FIGURE 11 The three images are of the same location in a human retina about 1° (300 μm) from the foveal center. The left image is taken after careful correction of defocus and astigmatism. The center image is a single frame taken with higher-order aberrations correction. The right image is a registered sum of about 20 frames. The small spots are single cone photoreceptors and in the registered frame virtually all cone photoreceptors are resolved.

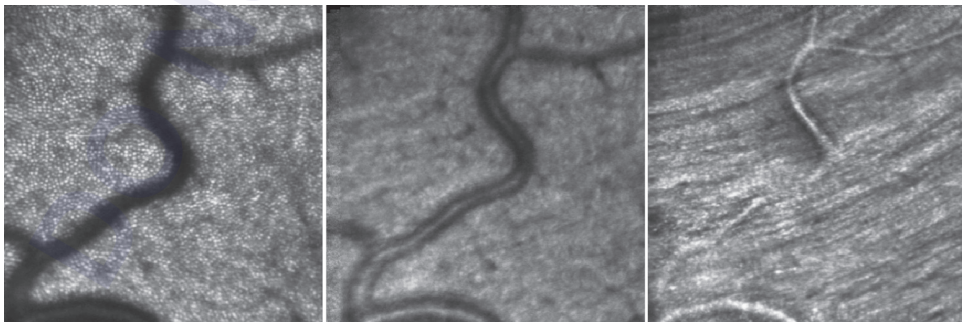
also used to measure the directional properties of individual cones,[86] measure the locus of fixation relative to the maximum density of foveal cones,[87] measure changes in reflectance of cones over a diurnal period,[88] reveal new information about photoreceptor packing and structure in eyes with retinal degenerations,[89–91] and detect fast scattering changes of cones in response to visual stimulation.[92,93]

Adaptive Optics Scanning Laser Ophthalmoscope The scanning laser ophthalmoscope (SLO)[94] is a special application of the scanning laser microscope, invented in 1955 by Marvin Minsky.[95] The main difference with an SLO is that the eye is used as the objective lens and the retina is always the sample being imaged. As such, the lateral and axial resolution of the SLO imaging is limited by the quality of the objective lens (cornea and lens), which is why AO can provide a significant benefit.

The main motivation to employ AO in an SLO is because of its confocal property. Unlike flood-illuminated cameras, confocal systems block scattered light from features that are outside the focal plane, thereby improving the contrast of features in the focal plane of interest. Moreover, by moving the focal plane, one can optically "section" the retinal tissue (see Fig. 12 for example). These features offer significant benefits for ophthalmoscopy because the retina is a thick, multilayered structure, which scatters throughout its depth.



(a) (b) (c)

FIGURE 12 Confocal optical sectioning with an AO SLO. The sequence of AO-SLO images shows a variation in retinal structure as the focal plane of the instrument is systematically shifted from the (*a*) photoreceptor layer, (*b*) the blood vesels, and (c) the nerve fiber layer.

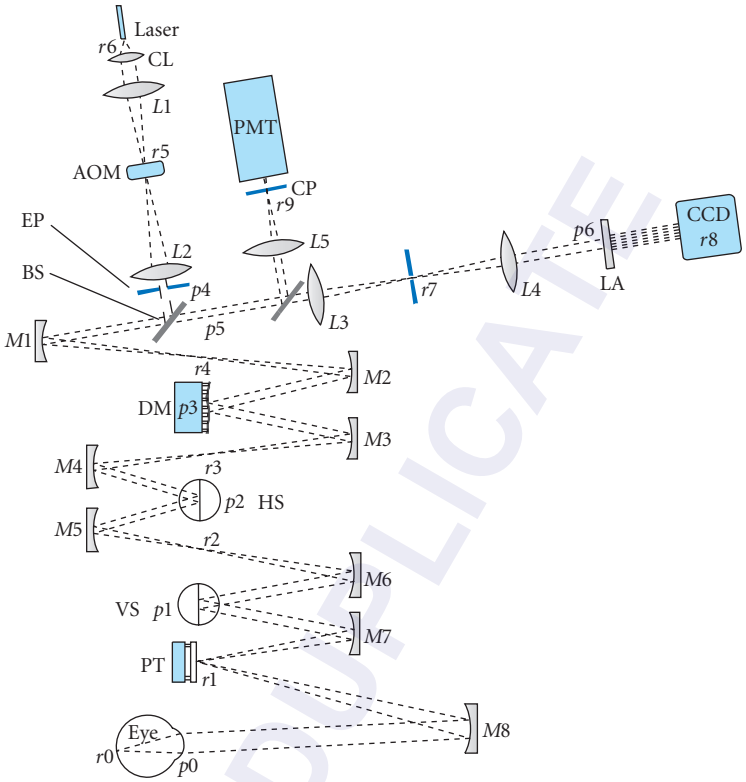


FIGURE 13 Schematic of an adaptive optics scanning laser ophthalmoscope. Key: CL—collimating lens; AOM—acousto-optic modulator; EP—entrance pupil; BS1—beamsplitter 1; DM—deformable mirror; HS—horizontal scanning mirror; VS—vertical scanning mirror; PT—pupil tracking mirror; LA—lenslet array; CP—confocal pinhole; PMT—photomultiplier tube. Pupil and retinal conjugates are labeled *p* and *r*, respectively. Mirrors and lenses are labeled *M#* and *L#* along the optical path. Telescope lens/mirror-pairs for relaying the pupil through the path are *L1–L2, L3–L4, M1–M2, M3–M4, M5–M6, and M7–M8.*

An SLO image is acquired over time as the scattered light is recorded from a focused spot on the retina as it scans in a raster pattern across the retina. The image is formed digitally in a frame grabber, which combines horizontal and vertical position information from the scanning mirrors with the digitized values of the analog intensity stream from the detector, to form an extended field image.

The concept of applying AO to an SLO was first proposed by Dreher et al.[10] but was not fully implemented with a wavefront sensor and a mirror capable of correcting high-order aberrations until Roorda et al.[19] The layout of a representative AO-SLO instrument is shown in Fig. 13.

In a confocal scanning laser imaging system, the effective PSF is computed as

$$\mathrm{PSF}_{\mathrm{SLO}} = \mathrm{PSF}_{\mathrm{in}} \times (\mathrm{PSF}_{\mathrm{out}} \otimes D) \tag{11}$$

where D represents the confocal aperture. When the confocal aperture approaches a size equal to the radius of the airy disk of the collection path of the system, the effective PSF is simply the product of the ingoing and outgoing PSFs. Under these optimal conditions, the lateral resolution exceeds conventional imaging by about 40 percent, as assessed by the full width at half maximum (FWHM)

of the PSF. If the confocal aperture is large, then image quality is governed only by PSF_{in}, effective optical sectioning disappears, and lateral resolution is the same as a flood-illuminated imaging system. Axial resolution in confocal SLOs can be defined and computed in several ways. The standard way to determine axial resolution is to measure the detected intensity from a flat, diffusely scattering surface as it moves relative to the focal plane of the SLO.[10] The FWHM of the resulting intensity distribution is a measure of the axial resolution of the SLO.[96]

The AO SLO employs a series of telescopes to relay the light to the elements that act on the beam. For example, wavefront sensing (*p*6 in Fig. 13), wavefront correcting (*p*3), and tip and tilt adjustments (*p*1 and *p*2) for raster scanning the beam all need to be done in pupil-conjugate planes. At present, each of these actions is done with a separate component and so a telescope is required to relay conjugate images of the pupil to the various components. Maintaining conjugacy of the pupil planes is critical in an AO SLO. If, for example, the eye's pupil was not conjugate to the scanning mirror, the beam would scan across the pupil, rather than pivoting about the pupil, and neither the wavefront sensor nor deformable mirror would see a stable aberration pattern. To avoid back reflections, the telescopes employ focusing mirrors rather than lenses. A consequence of using mirrors in the optical path is that they have to be used off-axis, which generates unwanted aberrations in the optical path. However, with the help of optical design software, each mirror in the system can be adjusted to compensate for the coma generated by the previous reflection, and the remaining astigmatism can be corrected by a cylindrical lens placed somewhere in the path.[97]

Wavefront sensing and compensation is done in a unique way in an AO SLO. First, AO is effective in both directions; to focus the light to a sharp point on the retina and to take the scattered light from the eye and focus it to a sharp point at the confocal pinhole. In the AO SLO, the wave aberration is measured with the same light that is used to form the image. This is possible because, although the light is being scanned in a raster pattern on the retina, the light is descanned on the return path, rendering it stationary again. Thus, the wavefront sensor sees the light from the retina as though it were coming from a single spot, which makes an aberration measurement possible. This method has several advantages. First, it automatically implements the method of Hofer et al. in which scanning on the retina is employed to remove speckle from the short-exposure retinal images.[58] A second advantage is that the average aberration is measured over the entire field of view of the system, thereby ensuring more uniformity in the correction over the field that is being imaged. The final advantage is that the wavefront sensing and the imaging portions of the system use the same light path and light source, which reduces noncommon path errors and eliminates noncommon aberrations between the wavefront sensor and imaging camera due to chromatic effects.

Adaptive Optics Optical Coherence Tomography OCT is a noninvasive, interferometric imaging modality that provides significantly higher-axial resolution and sensitivity than the flood-illuminated ophthalmoscope and SLO modalities discussed previously. The term OCT was coined in 1991 in reference to the first optical B-scan (*xz* plane) images collected of the in vitro human retina using interferometry.[98] Note that this was preceded by substantial work in the 1980s on a technique called low-coherence interferometry that provided depth-resolved A-scan (*z*) images of the retina using essentially the same interferometric principles.[99,100] Since the early 1990s, OCT technology and knowledge have grown rapidly. This has led to an increasingly large and diverse array of OCT designs that fall into two broad categories: time domain and spectral (or Fourier) domain. These domains refer to the temporal and spectral detection of the OCT signal, respectively. Details of time domain and spectral domain OCT, associated underlying theory, and other applications can be found in Chap. 18.

In an AO-OCT combination, OCT provides the high-axial resolution, and AO the complementary high-transverse resolution. Together, the AO-OCT combination provides a powerful imaging tool whose 3D resolution and sensitivity in the eye substantially surpass that of any current retinal imaging modality. Current state-of-the-art AO-OCT instruments have an isotropic 3D resolution approaching $3 \times 3 \times 3\ \mu m^3$ in retinal tissue. Most OCT designs have already been combined with AO and have demonstrated both an increase in transverse resolution and sensitivity beyond that realized with OCT alone. AO-OCT combinations include time-domain en face (*xy*) flood-illumination OCT using an areal CCD,[25] time-domain tomographic scanning (*xz*) ultrahigh-resolution OCT,[26] time-domain en face scanning OCT,[31,33] high-resolution spectral-domain OCT,[27,28,30–32] ultrahigh-resolution spectral-domain OCT,[29,34,35,82] and swept

source OCT.[101] AO-OCT instruments have been evaluated with a variety of wavefront correctors that cover the four types depicted in Fig. 6: discrete actuator, membrane, bimorph, and LC-SLM wavefront correctors, all in combination with a SHWS.

As a representative example, Fig. 14 shows a schematic of the Indiana AO-OCT instrument based on ultrahigh-resolution spectral-domain OCT. Use of a single mode fiber beam splitter provides true confocality [see Eq. (11)]. The sample arm is characteristic of an AO-SLO (see Fig. 13 and corresponding text), raster scanning a focused spot across the retina. The slower acquisition of OCT, however, precludes use of a resonant scanner, which is used with the SLO. For the AO OCT shown in the figure, improved aberration correction is realized by cascading two wavefront correctors, a bimorph that corrects low-order, large-magnitude ocular aberrations and a discrete actuator deformable mirror for higher-order, small-magnitude aberrations. As an added benefit, the large stroke of the bimorph reduces the need for trial lens correction of individual refractive error, which is important for OCT because trial lenses produce unequal dispersion in the sample and reference channels. A third advantage of two wavefront correctors is that the focus of the AO correction can be varied within the retina for optimal lateral resolution at a particular retinal layer of interest.

Figure 15 illustrates the optical benefit of AO OCT compared to the widely used OCT clinical instrument, the Stratus OCT3. The inset shows essentially the same cross-sectional patch of retina imaged with both instruments. While the cellular structures are clearly too small for the clinical instrument to resolve, the same structures (in particular the lateral and axial extent of individual cone photoreceptor outer segments) are observed with AO OCT with focus at the photoreceptor layer. An additional benefit of AO—readily apparent in the inset—is the much smaller speckle size due to the larger pupil through which the image is captured, in this case more than four times larger in diameter. The larger pupil also increases substantially the light collection capacity of the instrument.

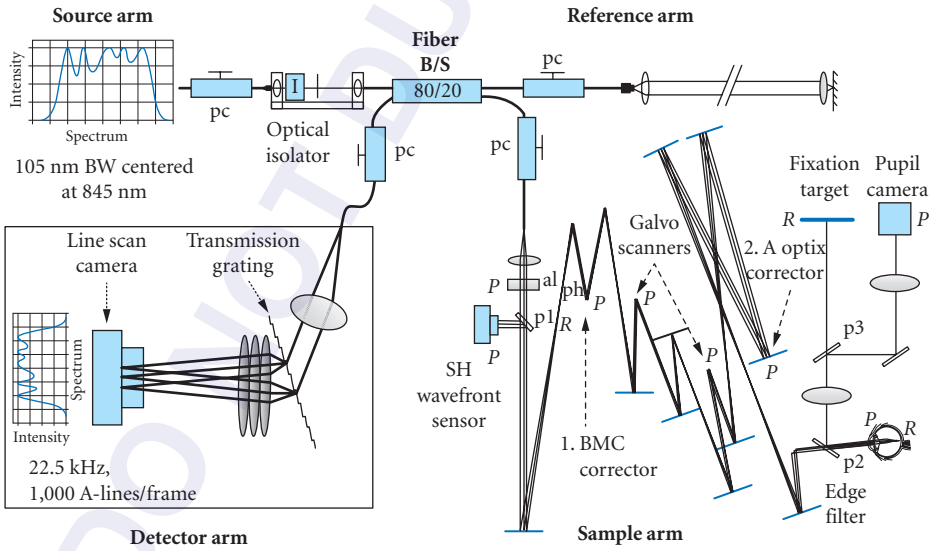

FIGURE 14 Schematic of an AO-OCT instrument based on ultrahigh-resolution spectral-domain OCT.[82] The AO system is located in the sample arm and consists of a Shack-Hartmann wavefront sensor, a 140-element Boston Micromachines MEMS deformable mirror, and a 37-element AOptix bimorph mirror. The MEMS corrects high-order, small-magnitude ocular aberrations and complements the low-order, large-magnitude correction of the AOptix DM. The AOptix DM is positioned close to the eye to prevent refractive errors of the eye from distorting the circular beam at the SHWS.[30] Key: al—customized achromatizing lens; B/S—beamsplitter; p1–3—pellicles; pc—polarization controller; ph—pinhole; P/R—pupil and retina conjugate planes. Footprint of the instrument is approximately 2.5 ft × 4 ft.

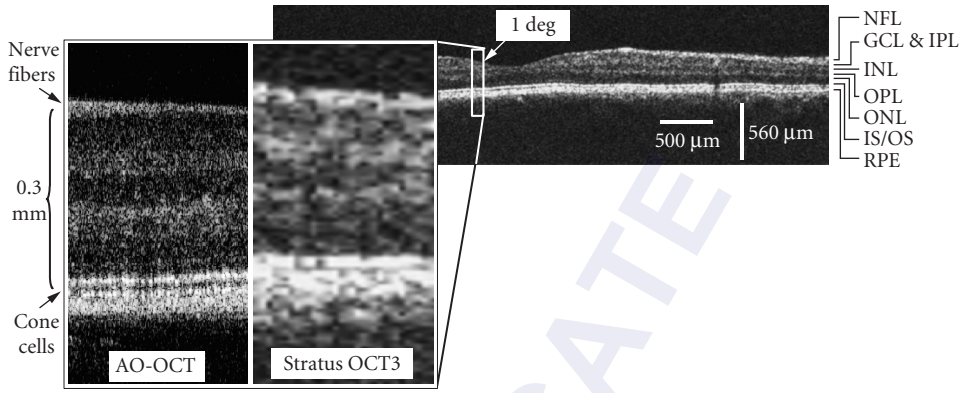

FIGURE 15 Cross-sectional images of the retina in the same subject obtained with (*a*) AO high-resolution spectral-domain OCT and (*b*) clinical OCT. Images were acquired at 1° retinal eccentricity. Key: NFL—nerve fiber layer; GCL—ganglion cell layer; IPL and OPL—inner and outer plexiform layers; INL and ONL—inner and outer nuclear layers; IS/OS—inner segment/out segment junction; RPE—retinal pigment epithelium.

For example, a 4 times increase in pupil diameter (e.g., 6 mm compared to 1.5 mm) leads to a nominal 12-dB upper limit increase in sensitivity. The actual increase is lower depending on the scattering properties of the retina and the throughput efficiency of the sample channel, which contains many more elements than conventional OCT.

Current AO-OCT systems have been used successfully to create 3D retinal images of structures previously only visible with histology, including the foveal microvasculature, bundles within the retinal nerve fiber layer, the fibers of Henle, the 3D photoreceptor mosaic, drusen in age-related macular degeneration, and the tiny pores of the lamina cribrosa of the optical nerve in normal and glaucoma patients. AO OCT is beginning to be employed for studying a number of other clinical conditions, including age-related macular degeneration, hereditary retinal dystrophies, and optic neuropathies.

Contrast and Resolution Image contrast is a key requirement for visualizing features in retinal images. There are three elements to achieving an image with sufficient contrast. The first is to transfer as much of the available contrast from the object to the image. This is achieved by making the modulation transfer function (MTF) as high as possible and where the role of AO is crucial. Additional increases in the MTF are obtained by judicious selection of the imaging modality. AO SLO, for example, uses confocal imaging to increase the lateral and axial MTF.[96,102] OCT uses coherence-gated detection to increase the MTF in the axial direction. The second key is to make the most of the signal that reaches the image plane. Proper selection of detectors and detection modalities can be used to achieve high signal-to-noise ratios with low levels of light. Flood-illuminated cameras use cooled scientific grade CCD cameras with low readout noise, AO SLOs use sensitive photomultiplier tubes and avalanche photodiodes with carefully designed amplification electronics,[103] and OCT uses heterodyning techniques to amplify weak signals. The third element is to have contrast in the object itself. Not only do retinal features need to scatter light, but they need to scatter light in such a way as to reveal their intrinsic structure. Cone photoreceptors, for example, have very high intrinsic contrast and lend themselves very well to imaging. The fiber optic property of cones[86] makes them appear as an array of regularly spaced point sources of nearly 100 percent contrast. But most other features in the retina scatter very little light and have less intrinsic contrast. The index of refraction of a ganglion cell body, for example, is well matched to its surrounding media and therefore scatters very little light. Under these situations, manipulation of the imaging wavelength and/or polarization might be used to improve contrast. Blood vessels, for example, are best viewed with shorter wavelengths[104] and the contrast of the photoreceptors and other retinal features can be enhanced by careful control of the incident and detected polarization.[105]

A common method to achieve contrast in many imaging systems is to use fluorescence, both intrinsic and extrinsic. Recently, an AO SLO at the University of Rochester has been equipped with a fluorescence channel where they imaged the autofluorescent lipofuscin to reveal the complete and contiguous array of retinal pigment epithelium cells in human and monkeys. By using extrinsic contrast agents in a monkey, they could image retinal capillaries (fluorescein angiography), and ganglion cell bodies and their dendrites.[21]

Applications Involving AO-controlled Light Delivery to the Retina

The pioneers of AO for the human eye appreciated that the benefits of AO work in both directions.[13] Human vision has always been limited by diffraction for small pupils and aberrations for large pupils. Consequently, the optimal pupil size for sharpest vision in a typical human eye often lies somewhere between 2 and 4 mm,[12,106–110] depending on image quality criteria and the specific individual. Even for the optimal pupil size, the image quality remains very poor by comparison with its diffraction limited condition and is far from what could be achieved if the aberrations of the largest anatomical pupil size were corrected.

Before AO, the only method to generate high frequency, high-contrast images on the retina was using interferometry. Two mutually coherent point sources, laterally displaced in the pupil would produce sinusoidal interference fringes of 100 percent contrast at spatial frequencies governed by the separation of the two points.[111–113] These techniques have been used effectively to understand some aspects of the limits of human vision and can produce higher-contrast images than any AO system. But, aside from a few modifications,[114] the stimuli were limited largely to sinusoidal gratings. The contrast of images projected through the AO system is still limited by the MTF of large pupils, but can generate complex images with more contrast and resolution than ever before. Moreover, an AO system need not be used only to correct the aberration, but can be used to manipulate them as well.

Challenges for AO Systems That Project Light into the Eye All AO systems face the challenge of how to ensure that the AO is working properly. In astronomy, the performance of the AO system is gauged by the quality of the images of distant stars, which are effective point sources. In the retinal image, where no point sources exist, two metrics are typically used to gauge how well an AO system is working, the residual wavefront error, and the relative improvements of the retinal image. Neither metric provides absolute, objective measures of system performance. In postprocessing, multiframe blind deconvolution can produce reasonable estimates of the residual point spread function,[115] but these cannot be used as feedback in closed-loop operation. When projecting light into the eye, it is even more difficult because feedback on image quality is not available in most cases, and we can only rely on residual wavefront error and the subject's perception or visual performance.

The challenge is made worse because the stimulus is viewed along a different optical path, it extends over a finite field angle, and often employs wavelengths or a span of wavelength that are different than the wavefront sensing beacon. The main challenges that one faces in developing an AO system for vision science are:

Longitudinal chromatic aberration (LCA) The eye has a lot of chromatic aberration. Refractive power from 400 to 900 nm will change by about 2.6 D[116–118] and the foci span an axial focus range in the eye approaching 1 mm. By comparison, the thickness of the neural retina is about 250 μm. This means that if one measures and corrects aberrations with IR light and tests vision with visible light, then they must adjust for the focus of the visual target. Fortunately, the LCA of the eye is fairly consistent between individuals so one can estimate where the correct focus must be.[116,119] But there is no element of the AO closed loop that will be able to provide feedback on the fine tuning of the visible wavelength. This forces the experimenter to use the subject's perceptual responses as feedback for alignment of the system.

Transverse chromatic aberration (TCA) Images of different wavelengths projected onto the retina will be displaced laterally because of TCA. Consider, for example, a collimated white light

beam entering the eye. Relative image shifts between both ends of the white light spectrum can be significant, depending on where the beam enters the eye. TCA arises because the chief ray of the beam does not correspond with the achromatic axis of the eye. Image displacements of ±3 arcmin can occur with pupil shifts of ±1 mm.[120–121] So, whenever a broadband visual stimulus is used off the achromatic axis of the eye, the spread can significantly degrade image quality and defeat the benefits of AO.

Alignment A final challenge in achieving the best AO performance for stimuli delivered to the retina is the alignment of the stimulus itself. The stimulus channel may be subject to noncommon path errors (discussed earlier) and therefore will present new aberrations that the AO system cannot detect or correct. Since there is no feedback from this optical path, the experimenter must be obsessive about its optical design and alignment. Perceived sharpness of the image is not sufficient to judge image quality as the human visual system is limited by its retina to detection of spatial frequencies at 60 cycles/degree at best, whereas the optics can transmit frequencies over 200 cycles/degree.[113] Moreover, perceived sharpness depends on context and on whether you are preadapted to a blurred or sharp stimulus.[122]

Conventional AO Vision Systems The most basic implementation of an AO system for vision testing is one in which a subject is given a view of a target through a deformable mirror that is conjugate to the optics of the eye. The optics are no different than for a AO flood-illuminated ophthalmoscope (Fig. 10), except that there is no illumination source and the retina camera is replaced by the stimulus. The first experiments were designed simply to test the extent to which the correction of aberration improved vision.[13,123] After correction of aberration and removal of chromatic aberration (by using monochromatic light), improvements of 20 times were reported for contrast sensitivity of a 32 cycles/degree gratings through a 6-mm pupil.[123] Of course, the largest improvements were realized for the largest pupils, for which diffraction is low and aberrations are high. As for visual acuity, improvements were significant, but absolute performance was limited because of the low luminances available in the display. The latter result begs the question about the practical visual benefit of correcting all aberrations. Large pupils, for which the visual benefits are greatest, are only reached under dim light conditions—the same conditions for which the retina starts to limit vision.[124–126] In a practical task (detection of the contrast threshold for a 20/60 letter) the visual benefit for all luminances after taking typical pupil sizes into account was improved with AO, but the improvements were relatively modest.[127]

AO-Controlled Stimulus Delivery in an AO SLO An alternate way to test vision with AO-corrected stimuli is to project the image directly onto the retina. By modulating the laser power during the raster scan, complex AO-controlled stimuli can be projected directly on the retina and be seen by the subject. Moreover, the same modulation patterns will appear in the retinal image.[128] This method for delivering stimuli to the retina offers some important advantages. First, the scanning beam and the stimulus can employ the same light source and are therefore not affected by TCA or LCA. Second, the recorded image can be used as a metric to determine the quality of the projected image as well as where the stimulus was presented, both axially and laterally. In some cases, two lasers might be used, one primarily for imaging (e.g., an infrared channel which is used to guide the location of the stimulus) and a second for delivery of the stimulus (e.g., small spot stimulus of a visible wavelength). In this situation, LCA and TCA do need to be taken into account so the operator knows exactly where the visible stimulus is landing.[23] Applications that employ stimulus delivery in an SLO have been used on numerous occasions,[94,129,130] but the application of the technique with AO SLO is relatively new and has been implemented on only a few systems.

What Will Vision AO Systems Be Used for?

The role of aberrations and visual performance How much can vision improve? Experiments with AO SLO have reported visual acuities better than 20/8 (letter size for 80% correct judgments of the orientation of a tumbling E).[128,131] Ultimately, acuity is limited by other factors in the visual system,

such as cone photoreceptor spacing, eye movements, and cortical processing limits. By bypassing the optics and simultaneously providing unprecedented views of retina structure as well as eye movements, AO SLO and other modalities provide the best tools to help us understand these limits. AO SLO studies of the role of eye movements on visual acuity are currently underway.

Measuring activity of individual cones The eye was never designed to allow stimulation of single cones. Nevertheless, recording sensations from single cones can help reveal how cones are connected to neurons further downstream in the human visual system. There are several applications where stimulation on the scale of single cones is useful. Hofer et al, for example, used an AO system to deliver brief flashes of light to individual cones, and recorded subject's perceived color sensation on each trial.[132] A simple hypothesis, termed the "elemental sensation hypothesis" was that color percepts would fall into three categories, red, green, and blue, corresponding to the three cone types in the eye. Instead, viewers required up to eight different color names, requiring a rethinking of how color sensations are developed.[133] From a clinical perspective, recording the sensitivity of individual cones can provide important relationships between retinal structure and function. In an elegant set of experiments, Makous et al. recorded light sensations in brief flashes to confirm that individuals with a rare genetic mutation leading to apparent loss in a subset of photoreceptors had small, cone-sized gaps across their visual field.[134] The most recent application involves the direct and targeting stimulation of individual cones in a monkey while simultaneously recording electrical activity in downstream neurons.[135] Although neuroscientists have been recording activity of single cells in the visual system for decades, AO allows, for the first time, stimulation of single cones as the input and promises to be a useful tool for mapping connections between the retina and brain.

Using AO to generate aberrations There are many cases where the presence of aberrations may be beneficial to human vision. Considering that most people are not really handicapped by their ocular aberrations, it is sensible to consider how one could work with tolerable levels of aberration to increase visual performance in some other way. The most promising application for controlling aberrations is for the relief of presbyopia, which refers to the age-related loss in ability to deform ones natural lens to focus on near objects. Although aberrations cannot restore accommodation, they can increase the eyes depth of focus and relieve these effects. AO vision systems are currently being used to test the benefits of specific aberration profiles, which can later be implemented into contact lenses or intraocular lenses.[136–138]

16.1 GLOSSARY

Definitions

Acellular. Containing no cells.

Accommodation. The ability of the crystalline lens to change its optical power allowing the eye to bring into focus the images of objects at different distances.

Collagen. The main structural protein found in animal connective tissues, yielding gelatin when boiled.

Endothelium. The tissue that forms a single layer of cells lining various organs and cavities of the body, especially the blood vessels, heart, and lymphatic vessels. It is formed from the embryonic mesoderm.

Epithelium. The thin tissue forming the outer layer of a body's surface.

Fibroblast. Type of cell that synthesizes and maintains the extracellular matrix of many animal tissues. Fibroblasts provide a structural framework (stroma) for many tissues, and play a critical role in wound healing. They are the most common cells of connective tissue in animals.

Hydrophilic. Having a tendency to mix with, dissolve in, or be wetted by water.

Keratocyte. A flattened connective tissue cell lying between the fibrous tissue lamellae which constitute the cornea. The keratocyte has branching processes that communicate with those of other keratocytes.

Lamella. A thin layer, membrane, scale, or platelike tissue.

Nomogram. A graphical calculating device, a two-dimensional diagram, designed to allow the approximate graphical computation of a function.

Refraction. Measurement of the focusing characteristics of an eye or eyes.

Equations

Equation (1). This is the field of a monochromatic scalar propagating wave as

$U(r)$ modulus of the wave
r position
$\phi(r)$ wavefront
k wave number
π 3.14159
ν optical frequency
t time

Equation (2). This is the definition of the wave number.

π 3.14159
ν optical frequency
c speed of light
λ optical wavelength

Equation (3). This is the wavefront aberration as a polynomial expansion.

ω wavefront aberration
x horizontal coordinate
y vertical coordinate
a_n nth weighting value or coefficient
P_n nth polynomial from an orthogonal set

Equation (4). This relates the back focal length of a correcting lens with the vertex distance and the eye's far point.

k distance from the eye to its far point
f_c' back focal length of the correcting lens
d correcting lens' vertex distance

Equation (5). This is the power of a correcting lens placed at a finite distance from the eye.

F_c' optical power of the correcting lens
K $1/k$
k distance from the eye to its far point
d correcting lens' vertex distance

Equation (6). This is an empirical equation to describe the dependence of the ablation rate on the fluence.

A ablation rate
F fluence
F_{thr} ablation threshold
m 0.3 μm/pulse

16.2 INTRODUCTION

Optics of the Human Eye

The human eye can be thought of as a photographic camera; an optical element(s) forms a real image of an object onto a photosensitive surface, the retina. The eye, like any other optical system, is formed from several different materials (tissues), each with a different refractive index and transmittance. The total optical power of the eye is about +60 diopters (D) of which +48 D are provided by its frontal part, the cornea. This tissue has refractive index of $n = 1.376$. The cornea is in contact with the air, giving it strong optical power. [1–3]

The eye is self-contained in an almost spherical "bag" of opaque white tissue, except on the cornea, called the sclera. The cornea is approximately oval in shape with average dimensions of 12.6-mm horizontal diameter and 11.7-mm vertical diameter. It absorbs most of the UV radiation with a peak at 270 nm, but transmits radiation with wavelengths from 310 to 2500 nm approximately. [1–3]

Immediately behind the cornea is a chamber known as the anterior chamber filled with a watery fluid: the aqueous humour. This fluid replenishes nutrients and takes away metabolic wastes from the posterior cornea, crystalline lens, and anterior vitreous. It also helps to keep intraocular pressure stable. Its refractive index is $n = 1.336$.

The iris marks the end of the anterior chamber. The volume behind it is known as the posterior chamber. The iris is the aperture stop of the eye. In a normal young eye the iris can expand or contract the pupil diameter from 2 or 3 mm to 7 or 8 mm. This reduces or increases the amount of light passing through the system and increases or decreases the depth of focus of the eye. The iris can be easily identified as it gives the eye its characteristic colour: blue, green, brown, and so on. In later life the ability of the iris to expand is severely reduced.[2–3]

Next to the iris is the crystalline lens of the eye. It has a complex layered structure and is remarkably transparent. It completely lacks a blood supply and innervations. It continues to grow in size and mass throughout life. It has a gradient refractive index which varies from about 1.406 in the inner core to approximately 1.386 at the outer core. It is a flexible structure and can change shape in order to provide a fine focusing mechanism.[2] By combining the cornea and the lens into a single optical system it is possible to treat the system as a thin lens in a medium. The nodal point of such a system lies at 17 mm from the retina and its posterior principal point lies on the cornea, 5.6 mm from the nodal point. A schematic eye representing this system is shown in Fig. 1.

The posterior chamber is filled with the vitreous. With a volume of almost 4 mL, it represents about the 80 percent of the total volume of the eye. It is a transparent collagen-based substance with a refractive index of 1.336. The vitreous plays an important role in several metabolic eye processes like oxygenation, depository for metabolic wastes, such as lactic acid, and as a medium for active transport of different substances throughout the eye. Immediately behind the vitreous lies the retina, the surface where the image is formed. The retina is a very complex multilayered structure, that not only captures the light, but some of the initial visual processes occur there. The central part of the retina, the fovea, contains the highest density of photoreceptors and is the region where the image formed by the optics of the eye must be of highest quality.[2,3]

The optics of the eye are covered in greater detail in Chap. 1.

The Cornea

The first optical surface of the eye is the cornea, and hence the interface between air and tissue produces the highest refractive power, and makes the cornea the most important optical surface in the eye. The most common refractive surgery procedures achieve a change in the overall optical power of the eye by changing the shape of the cornea. For this reason we will give more attention to its cellular structure.

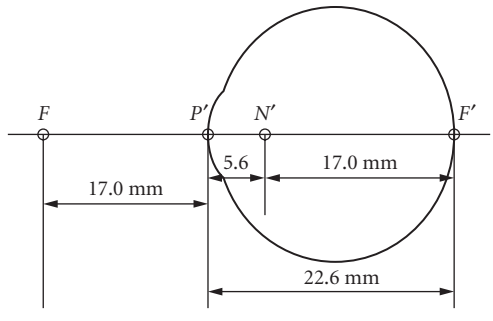

FIGURE 1 Schematic eye treating the whole optical system as a single thin lens. (*Adapted from Ref. 1.*)

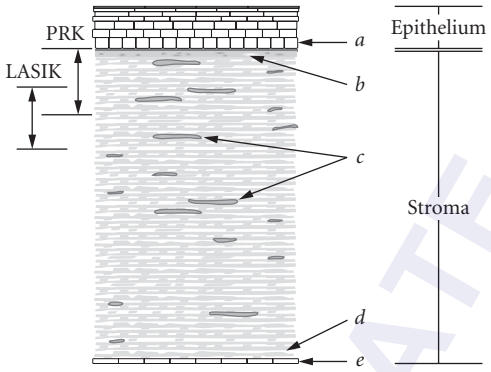

FIGURE 2 Schematic representation of the corneal layers.

The cornea is a remarkably transparent and mechanically stable tissue. The cornea features five layers with distinct roles as seen in Fig. 2. The anterior surface of the cornea is covered by the corneal epithelium (*a* in Fig. 2). The corneal epithelium is the outermost surface of the cornea and it is the surface that is wetted by the tear film.

The corneal epithelium (stratified squamous epithelium), has a thickness of approximately 50 μm. It is a multicellular layer, comprising fast regenerating cells that provide a barrier to water, ions, and bacteria. The epithelium consists of progressively flatter cells, so that its outer surface is capable of smoothing (to some extent) minor underlying irregularities or roughness. The epithelium is not a permanent tissue, in the sense that it is continuously regenerated. Consequently, in order to produce permanent changes to the corneal geometry, any modifications must be applied to the underlying layers.

Underneath the epithelium there is a layer of dense collagen (*b* in Fig. 2) having a thickness of about 12 μm, called Bowman's layer. This layer has no cells and it has been hypothesized that this structure provides mechanical strength to the cornea. The main part of the cornea representing approximately 90 percent of its thickness is the corneal stroma. The corneal stroma consists mainly of elongated bands of Type I and V collagen arranged in a lamellar configuration. Consecutive lamellas are organized in random orientations perpendicular to the optical axis to avoid anisotropy in the transverse orientations. The space around the collagen fibers is filled with a hydrophilic glycosaminoglycan and water. In the corneal stroma there are relatively sparse keratocytes (*c* in Fig. 2) that are the fibroblastic cells of the cornea. Keratocyte activity sustains proper collagen spacing and collagen fibril diameter in the cornea. In the case of injury, keratocytes produce collagen at accelerated rates in an attempt to restore stromal integrity. Often this new collagen is substantially less organized than normal collagen and is characterized by decreased transparency.

Descemet's membrane (also known as the posterior limiting lamina) (*d* in Fig. 2) of the cornea is an acellular membrane made mostly of collagen. The corneal endothelium is a monolayer of specialized cells that lines the posterior surface of the cornea. The corneal endothelium acts like a fluid pump across the posterior surface of the cornea that actively maintains the cornea in the relatively dehydrated state that maintains dense collagen organization and therefore transparency of the cornea.

Refractive Errors

The function of the optics of the eye is to form an image of the outside world onto the retina. In an *emmetropic* eye and in the absence of accommodation, the image of an object at infinity is sharply focused onto the retina. When the unaccommodated eye fails to produce a well-focused image of a distant object on the retina, it is said to be *ametropic* or to have a refractive error. The degradation in

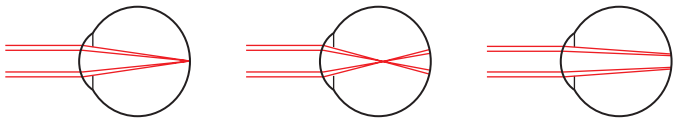

FIGURE 3 Schematic representation of refractive errors. (*a*) Normal emmetropic eye, (*b*) myopic eye, and (*c*) hyperopic eye.

the image seen by an ametropic eye is produced purely by the optics of the eye, and hence, in principle, it is possible to correct it by optical means alone.

The definition of refractive errors or ametropias characterize the excess or lack of optical power in the eye. In these definitions it is understood that the crystalline lens is meant to be relaxed, or *unaccommodated*. The case of an eye free of refractive errors or emmetropic is shown in Fig. 3*a*; the image of an object at infinity is formed on the retina. In ametropia this is no longer the case, an object at infinity appears blurred on the retina. Ametropias are divided in two main types: spherical ametropia and astigmatism.

The reader should be aware that *presbyopia* is not considered to be an ametropia. Presbyopia is the decrease in our ability to accommodate as we grow old. This process starts from youth and continues till the age of about 60 when our ability to accommodate disappeares completely. In presbyopia, the crystalline lens does not change shape any longer and we are left with a single focal plane. In addition to presbyopia, an eye can have any of the refractive errors or ametropias that will be defined in the following sections.

Spherical Ametropias In spherical ametropia, the optical power of the eye is symmetric around its optical axis, but there is a mismatch between the optical power of the eye and its axial length. It is divided in two cases: *myopia* and *hypermetropia*. Myopia occurs when the optical power of the eye is too large for its length and the image of an object at infinity is formed in front of the retina. This is shown in Fig. 3*b*. Hypermetropia, sometimes referred to as hyperopia, occurs when the optical power of the eye is too small for its length so that the image plane lies behind the retina. This situation is shown in Fig. 3*c*.

The point conjugated with the retina in the absence of accommodation is called the *far point*. In an unaccommodated emmetropic eye the far point lies at infinity. Hence, accommodation is only required when seeing objects closer than infinity. In myopia, the far point is placed at a finite distance from the eye. The larger the myopia the closer the far point will be. Accommodation can only bring into focus objects closer to the eye than the far point, as accommodation can only increase the optical power of the eye. In a myopic eye any object beyond the far point will always be out of focus.

In contrast, the hypermetropic eye must always accommodate. The far point lies behind the retina, and hence power must always be added in order to bring an image into focus. The young hypermetrope can accommodate, and this is usually done unconsciously. Hence hypermetropia can pass unnoticed for many years.

Astigmatism Myopia and hyperopia affect the optical power of the eye equally in all meridians. In *astigmatism* this is not the case. An astigmatic optical surface has two perpendicular principal meridians; the curvature varying from a maximum in one meridian to a minimum in the other. The astigmatism of such a surface is defined as the difference between the optical powers at each one of these meridians. Hence astigmatism as a refractive error has the same meaning as that of on-axis astigmatism normally found in geometrical optics. Oblique astigmatism, arises when the angle of incidence of a pencil of rays is not parallel to its optical axis. This can also arise in the eye, but it is not a refractive error and hence it will not be dealt in this chapter.

The simplest possible case of an astigmatic system is that of a cylindrical lens in which one meridian has zero curvature. A lens with a toroidal surface is another example, and is commonly used to make spectacle lenses. It is generated by the revolution of an arch *AB* around an axis *CD* not passing through the arch's center of curvature C_c.

In general astigmatism can be regarded as a combination of spherical and cylindrical elements. Optically this is equivalent to an sphero-cylindrical lens with cylindrical power equal to the difference

between the two principal powers. Additionally, in the case of toroidal surfaces the spherical power is that of the weakest principal meridian.

The angle of astigmatism is measured on a plane perpendicular to the eye's optical axis. It is defined as the angle at which the meridian with the maximum curvature lies. In optometric practice this angle is measured counterclockwise starting from the horizontal, when looking into the eye. The same system is used in both eyes. For horizontal astigmatism the angle used is 180, not 0. The ° symbol is not used to avoid confusion with the number zero, so that, for example, 13° is not mistaken with 130.

Astigmatism is present in practically all human eyes. There are several reasons for this. Firstly, the cornea is seldom perfectly spherical. It usually presents certain degree of astigmatism. Likewise, the crystalline lens may present astigmatic surfaces. Moreover, the mutual alignment between crystalline lens and cornea is not perfect. There is always certain amount of tilt or decentration between these elements.

Ocular Wavefronts The eye is a biological system, and as such it is not perfectly symmetric. The refractive errors discussed so far are only a first approximation. The eye presents other more irregular errors in its refractive power. Older texts refer to these errors as *irregular astigmatism*. The more modern literature and current research papers refer to these errors as *higher-order aberrations*. Strictly speaking refractive error is a measure of the error in optical power in the eye and has units of diopters. Instead, higher-order aberrations are a measure of phase error and can have units of microns or radians. The term higher-order aberrations originates from the description of an optical wavefront.

The field of a monochromatic scalar propagating wave may be written explicitly as

$$\mathbf{u}(r, t) = Re[U(r)\exp(-ik\phi(r))\exp(-i2\pi\nu t)] \tag{1}$$

where $U(r)$ and $k\phi(r)$ are, respectively, the modulus and phase of the wave at position r, k is the wave number

$$k = 2\pi\frac{\nu}{c} = \frac{2\pi}{\lambda} \tag{2}$$

and $Re[\cdot]$ is short notation meaning the "real part of." In the definition of the wave number ν is the optical frequency, λ is the optical wavelength, and c is the speed of light in free space.

The time dependence of the optical wave of fixed wave number in Eq. (1) is known a priori. Consequently the complex function $U(r) = U(r)\exp[-ik\phi(r)]$ is enough to describe the optical disturbance. The function $\phi(r)$ is typically referred to as the wavefront of the optical perturbation and the optical perturbation $U(r)$ is referred to as the optical field, the field, or the propagating wave.

A perfect optical system, in the presence of a point source produces at the exit pupil plane a perfectly spherical wavefront converging to an ideal focusing point. Any departures from this perfectly spherical shape are known as *aberrations* and the function describing them is usually represented by $\omega(x, y)$. If the reference spherical wavefront is known, then the wavefront aberration $\omega(x, y)$ not only contains all the information about the aberrations in the system, but it can be used to describe the phase of the propagating optical wave, keeping in mind that the reference sphere has been subtracted from this function.

The quantity $\omega(x, y)$ is a real function. In Cartesian coordinates, it can be expressed as a polynomial expansion of the form

$$\omega(x,y) = \sum_{n=0}^{\infty} a_n P_n(x,y) \tag{3}$$

where P_n are the expansion polynomials and a_n are the weighting values for each polynomial. In principle $\{P_n\}$ can be any polynomial base, however, in vision sciences the Zernike polynomials have gained popularity and are widely used. The American National Standards Institute (ANSI) has produced a standard for reporting optical aberrations of eyes which uses Zernike polynomials.[4]

When using Zernike polynomials, aberrations are split into higher- and lower-order aberrations. Table 1 shows the first 14 Zernike polynomials according to the ANSI standard (having ignoring the piston or constant term, as it is not possible to measure it in the eye). The first five terms are the lower-order

TABLE 1 The First 14 Zernike Polynomials According to the ANSI Standard;[4] ρ and θ Are Radial Coordinates on the Pupil Plane

No.	Polynomial	Description
1	$2\rho\sin\theta$	x tilt or horizontal prism
2	$2\rho\cos\theta$	y tilt or vertical prism
3	$\sqrt{6}\rho^2\sin2\theta$	45° astigmatism
4	$\sqrt{3}(2\rho^2-1)$	Focus or sphere
5	$\sqrt{6}\rho^2\cos2\theta$	0° astigmatism
6	$\sqrt{8}\rho^3\sin3\theta$	Trefoil
7	$\sqrt{8}(3\rho^3-2\rho)\sin\theta$	x Coma
8	$\sqrt{8}(3\rho^3-2\rho)\cos\theta$	y Coma
9	$\sqrt{8}\rho^3\cos3\theta$	Trefoil
10	$\sqrt{10}\rho^4\sin4\theta$	-
11	$\sqrt{10}(4\rho^4-3\rho^2)\sin(2\theta)$	-
12	$\sqrt{5}(6\rho^4-6\rho^2+1)$	Spherical aberration
13	$\sqrt{10}(4\rho^4-3\rho^2)\cos(2\theta)$	-
14	$\sqrt{10}\rho^4\cos4\theta$	-

aberrations and correspond to prism, sphere or defocus, and astigmatism. Aberrations described by any polynomials of order higher than two are referred to as higher-order aberrations.

Study of the wavefront error and higher-order aberrations on the eye has been possible thanks to the development of objective techniques to measure the ocular wavefront aberrations. The most popular of these techniques is the use of a Shack-Hartmann sensor, based the work by Liang et al.[5] Another popular technique is *laser ray tracing* which was developed simultaneously by Moreno-Barriuso et al.[6] and by Molebny.[7] Several other techniques exist; see for instance Refs. 8 to 10.

Currently, there is no consensus about how to estimate refractive error from wavefront data. A number of different metrics have been proposed.[11] Also a methodology to represent wavefront maps as refractive power maps has recently been proposed by Iskander et al.[12] The details of these works fall outside the scope of this chapter and will not be addressed here.

Correcting Refractive Errors

Refractive correction must be done for the unaccommodated eye and turn the compound system formed by the eye and its correction into an emmetropic "eye". That is, a well-corrected eye must be able to form a sharp image of an object at infinity on the retina in the absence of accommodation. We have already defined the far point of the eye as the optical conjugate of the retina in the absence of accommodation. Hence, refractive correction must shift that point to infinity. Alternatively, applying the reversibility of the optical path, a correcting lens must create an image of an object at infinity on the far point of the uncorrected eye.

Figure 4*a* shows the optical principle of the correction of a myopic eye. The dashed line shows the optical rays converging to the far point (F'_p) in the absence of correction. The red lines show the

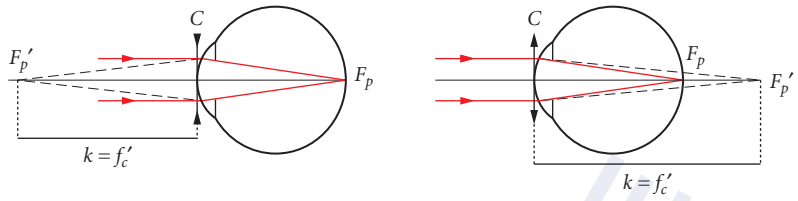

FIGURE 4 Optical principle for the correction of ametropias. (*a*) Myopia and (*b*) hypermetropia. (*Adapted from Ref. 13*)

light path after refractive correction. A lens of negative optical power is placed in front of the eye. Its back focal length (f_p') is equal to the distance between the eye and its far point (k). Under these circumstances a pencil of rays coming from an object at infinity will diverge after passing through the lens, and a virtual image will form on the eye's far point F_p'. The optical system of the eye will now be able to bring this image into focus on the retina F_p'.

The principle of correction for a hypermetropic eye is exactly the same as above, but in this case a correcting lens with positive power is required. This situation is shown Fig. 4*b*. The correcting positive lens creates the image of an object at infinity behind the eye, on its far point. As in the previous case, the unaccommodated eye can now form a sharp image of the object on the retina.

The inverse of the distance to the far point $1/k \equiv K$ is then equal to the optical power F_p' of the lens required to correct the refractive error and we have

$$k = f_c' \Rightarrow K = F_c'$$

The diagrams in Fig. 4 are both for the case when the correction lens is in contact with the eye, like the case of a contact lens. When correction is achieved with spectacle correction one must take into account the distance between the lens and the eye. This distance is always measured from the back vertex of the lens (the one closest to the eye), and is called the vertex distance and denoted by d. Diagrams illustrating this situation are shown in Fig. 5. It is clear that in this case

$$k = f_c' - d \tag{4}$$

and the power of the correcting lens must be adjusted as follows:

$$F_c' = \frac{K}{1 + dK} \tag{5}$$

It should be clear from Fig. 5 that if a refractive correction is measured with a lens at a distance d, changing this distance to d' will have an effect on the power of the correcting lens. The larger the power of

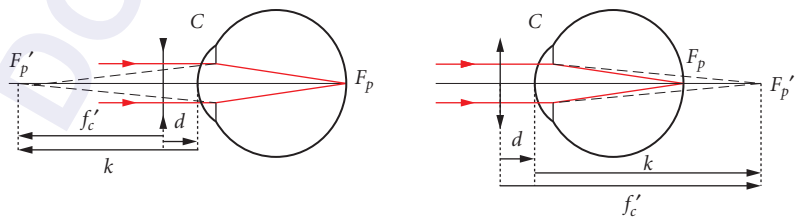

FIGURE 5 Optical principle for the correction of ametropias with a spectacle lens. (*a*) Myopia and (*b*) hypermetropia. (*Adapted from Ref.* 13.)

the lens the larger this impact. However, since the far point of the eye must coincide with the focal point of the correcting lens, it is straightforward to adjust the prescription. If the lens is to be moved by $d - d'$ mm closer to the eye's far point, then the focal length f'_p of the correcting lens must be reduced by $d - d'$ mm.

This is particularly important for refractive surgery, because refractive errors are typically prescribed using trial lenses placed 10 to 14 mm away from the cornea. The most common type of refractive surgery is aimed at changing the optical power of the cornea itself, so this distance must be taken into consideration.

An astigmatic eye can be treated as if it had two separate far points, each one corresponding to one of the principal meridians. The correction of astigmatism is achieved treating each principal meridian independently using the same principles described above. Namely, using an astigmatic lens, the focal point of each meridian of the lens must coincide with the far point of the corresponding meridian in the eye.

Correction of higher-order aberrations has been proposed by several authors.[14–18] Partial correction of aberrations has also been proposed as a way to improve visual performance.[19] Although these studies have shown an improvement in contrast sensitivity after correction of higher-order aberrations, this has only been possible in laboratory conditions. Moreover, Dalimier et al. found that aberration correction is most effective when the target was viewed in bright light. For lower light levels, the improvement in optical quality was masked out by a decrease in neural sensitivity. That is, for lower light levels, resolution is limited by neural mechanisms and not by optical quality.

These results mean that correction of higher-order aberrations, as an everyday solution, may not be practical for the majority of people. During the day, the pupil constricts reducing the benefit that correction could bring. At night the pupil dilates, but neural sensitivity is reduced. higher-order aberration correction may only benefit patients with pathologically abnormal corneas where they play a dominant role in image degradation. Nevertheless, understanding of important visual mechanisms like the triggering of accommodation may largely benefit from carefully designed studies where aberration-free images are projected on the retina.

Refractive corrections are covered in greater detail in Chap. 12.

16.3 REFRACTIVE SURGERY MODALITIES

As mentioned earlier, refractive surgical procedures are attempting to alter the optical power of the eye with permanent means in order to compensate for the eye's refractive error. There are three major categories of refractive procedures: *Intraocular lens (IOL) implantation, corneal incisions/implants,* and *laser corneal ablation*.

Intraocular Lenses, Corneal Incisions, and Implants

Intraocular Lenses Intraocular lenses (IOLs) were first developed for the substitution of the crystalline lens after cataract extraction. The first lenses were made of appropriate glass and were substantially heavy.[20,21] Modern lenses are made of appropriate biocompatible polymers (such as silicone or acrylic). Some types are designed to be implanted in the eye while the natural lens is present and therefore to compensate for possible refractive errors. These IOLs (phakic IOLs[22–24]) are either implanted in the posterior chamber (between the iris and the crystalline lens) or in the anterior chamber supported by the iris. The latter is the most common type currently used. The main advantage of IOL implantation is that the correction is reversible in the sense that the implant can be removed. Generally high corrections can be achieved.

Corneal Incisions/Implants A different approach for correcting ametropias and, historically, one of the first to be widely applied corneal incisions procedures. Corneal incisions are performed (typically using a diamond knife) either in a radial or in a circumferential manner. Depth of the incisions is typically adjusted to be 90 percent of the local thickness of the cornea. The rationale of corneal incisions is that local relaxation of mechanical stress results to a change in corneal geometry. Radial keratotomy is one of the most common incisional techniques (Fig. 6).

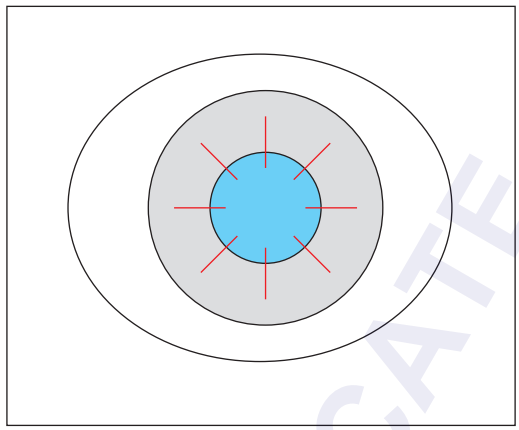

FIGURE 6 Schematic representation of radial incisions for the correction of myopia (radial keratotomy—RK).

The main drawbacks of radial keratotomy are the low predictability,[25] the large amount of induced aberrations,[26] and the compromised mechanical strength of the eye globe.[27] The low predictability of incisional surgery is associated with the fact that the long-term redistribution of stress in the corneal surface is not stable over time but is varying during the healing process. The final outcome must be examined several months after the incisions when healing has reached a stable condition.

The variability of the healing process may be attributed to individual factors such as the particular anatomy of the given cornea, age, and other biochemical and biological factors. In order to reduce this variability the desired refractive change is achieved by using empirical nomograms with different number, length, and positioning of the incisions that additionally take into consideration the factors mentioned above. Circumferential (arcuate) incisions have been employed for the correction of astigmatism usually in pairs across the steep meridian of the corneal astigmatism.

Another modality that has been employed to correct low refractive errors is the implantation of intracorneal ring segments.[28] These semicircular arcs are implanted in circumferential tunnels (created either mechanically or by means of femtosecond laser photodisruption) in the corneal stroma (Fig. 7).

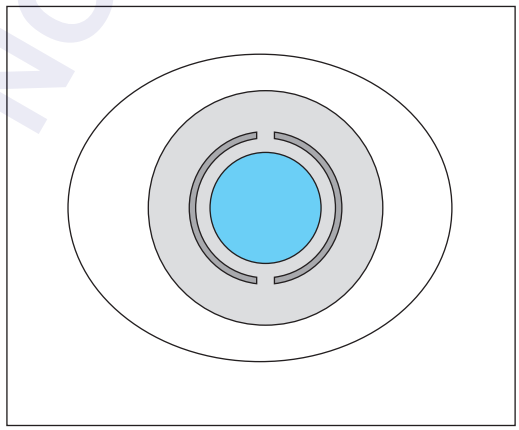

FIGURE 7 Schematic representation of intracorneal ring segments (ICRS) implanted around the pupil.

These segments are made of stiff material like polymethyl methacrylate (PMMA) and their rigid shape provides a new set of boundary conditions for corneal geometry. Their refractive effect is achieved by elevating the circumferential portion of the cornea over their implantation tunnel. The fact that they are rigid has been utilized in order to provide mechanical support to corneas with compromised mechanical stability such as in keratoconus[29] or keratectasia.[30]

Laser Corneal Refractive Procedures

The majority of the refractive procedures performed today are based on controlled ablation of corneal tissue in order to modify its central curvature. Among all the different approaches, the most critical differentiation is the depth at which the ablation is performed. In surface ablations (PRK, Epi-LASIK, LASEK) tissue removal involves the Bowman's layer and superficial stroma after appropriate removal of the corneal epithelium. In LASIK, tissue is removed from deeper stroma after creation of a hinged flap. Surface ablations are considered less invasive than LASIK in the sense that for any given correction a thinner part of the stroma is affected.

Photorefractive Keratectomy (PRK) PRK was the first laser procedure to be widely available.[31,32] It involves removal of corneal epithelium with a blunt instrument such as a spatula or a brush. After the Bowman's layer is exposed, laser ablation is performed using an appropriate superposition of a number of laser pulses. A schematic representation of this procedure is shown in Fig. 8. After

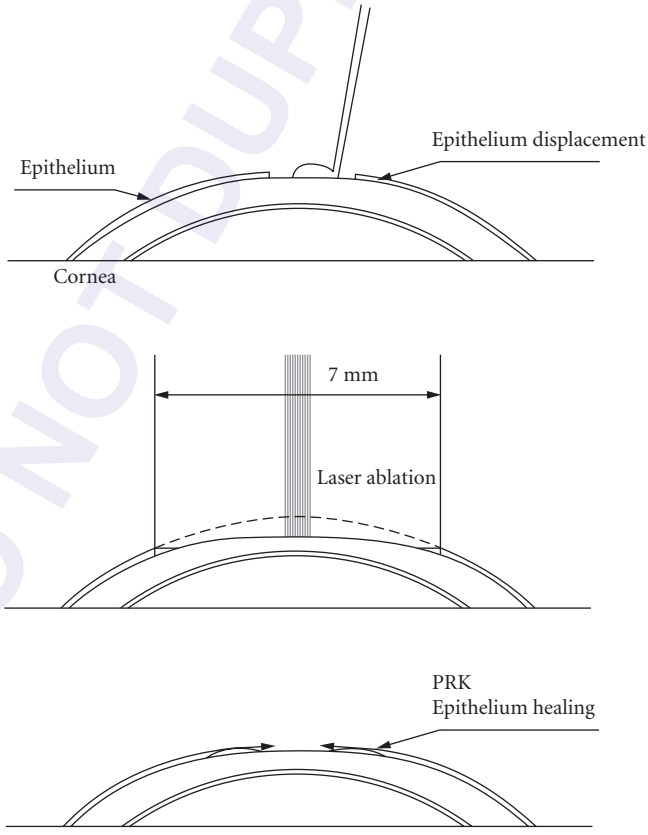

FIGURE 8 Schematic representation of photorefractive keratectomy.

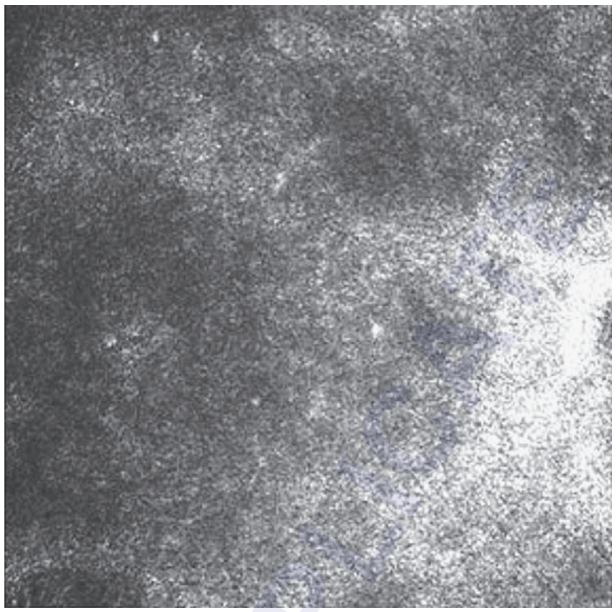

FIGURE 9 Confocal microscope image of the subepithelial scar tissue after PRK. Side is 400 μm, depth is at the epithelial—stromal interface (50 μm).

ablation, the corneal epithelium regenerates slowly and within 3 to 5 days completely covers the reshaped corneal surface. During this period of epithelial healing (that is characterized by pain or discomfort to the patient) the cornea is covered by a contact lens to reduce discomfort. Antibiotics are also administered as drops during this period of time to prevent infection of the exposed cornea. Additionally to antibiotics, anti-inflammatory treatment often in the form of steroids is prescribed. Time duration of the steroid treatment is not standard. Several months may be necessary depending on the physician's preferred scheme.

The technique is surgically simple and straightforward and is considered safe and effective for the treatment of low to moderate refractive errors.[33] Since treatment of the cornea with the excimer laser results to trauma and a transient inflammation, there is a healing response that not only modulates the refractive outcome, but additionally influences the transparency of the cornea due to the low organization of newly formed collagen. Figure 9 shows a confocal microscope image of corneal scar. This postoperative deterioration of corneal transparency (known as corneal haze) is not expressed with significant severity in the majority of the patients.[34]

In order to avoid scar tissue formation several different approaches have been developed, collectively called advanced surface ablations. These techniques are variants of the PRK where either special pharmaceutical treatment is applied in order to control the production of new collagen or the epithelial layer is preserved in order to cover the treated area immediately after laser ablation. The most common pharmaceutical is mitomycin C.[35] Mitomycin C is an anticancer drug known also to effectively inhibit keratocyte proliferation and therefore haze formation. However, there is skepticism about its use by many practitioners because its long-term effects and safety have not yet been documented. In order to reduce postoperative exposure to inflammation factors the LASEK procedure was developed.

LASEK/Epi-LASIK In these procedures, the epithelium is preserved as a whole sheet and is repositioned in order to cover the treated portion of the cornea. Presumably, this would reduce

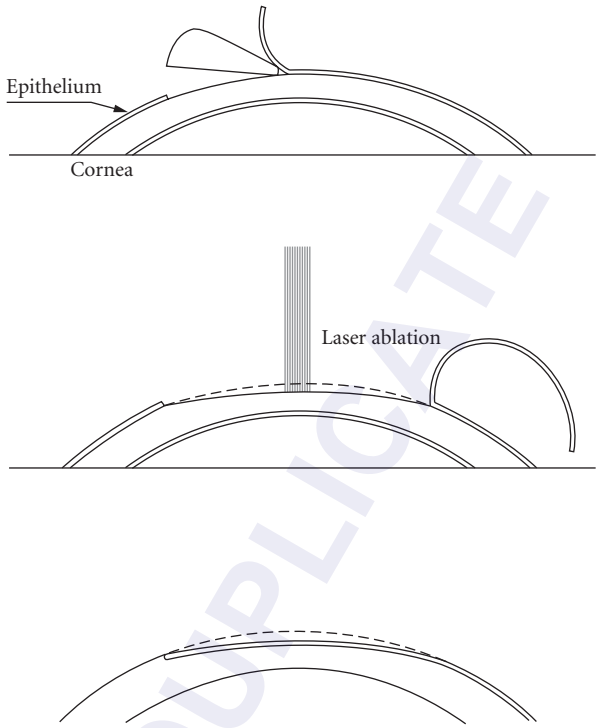

FIGURE 10 Schematic representation of the Epi-LASIK technique.

exposure of keratocytes to biochemical factors in the tears that trigger and enhance the healing response. In LASEK (laser subepithelial keratomileusis),[36] the epithelium is loosened by the application of an alcohol solution for a short-time interval (typically 20% alcohol in water for 30 s). After the treatment with alcohol, the epithelium can be delaminated using a blunt spatula in a manner that preserves its continuity. After laser ablation, the epithelium is repositioned onto the cornea. This epithelium is replaced in 3 to 5 days by new epithelial cell migrating from the periphery.

Epi-LASIK (epithelial laser in situ keratomileusis), is a similar technique (Fig. 10) where the epithelium is mechanically separated from the underlying Bowman's layer by means of a special device called epikeratome.[37,38]

Although promising, these techniques have not been proved to be more effective than PRK in terms of postoperative risk for haze development. Both LASEK and Epi-LASIK being essentially surface ablations are mostly preferred for low to moderate refractive errors.

Laser In Situ Keratomileusis (LASIK) The most common laser technique for the correction of moderate and high refractive errors is laser in situ keratomileusis (LASIK). LASIK was invented in the late 1980s by Pallikaris et al.[39,40] and has gained popularity due to its faster rehabilitation and less postoperative pain. In LASIK (Fig. 11) a thin (typically 120 μm) flap is created exposing deeper stromal layers while preserving epithelium and the Bowman's layer.

The flap is created using a special instrument called "microkeratome." The microkeratomes feature an oscillating blade and an applanator that flattens a portion of the cornea where the cut is performed. By this instrument, a flap of constant thickness can be produced where this thickness is controlled by the gap between the applanator and the knife's edge.

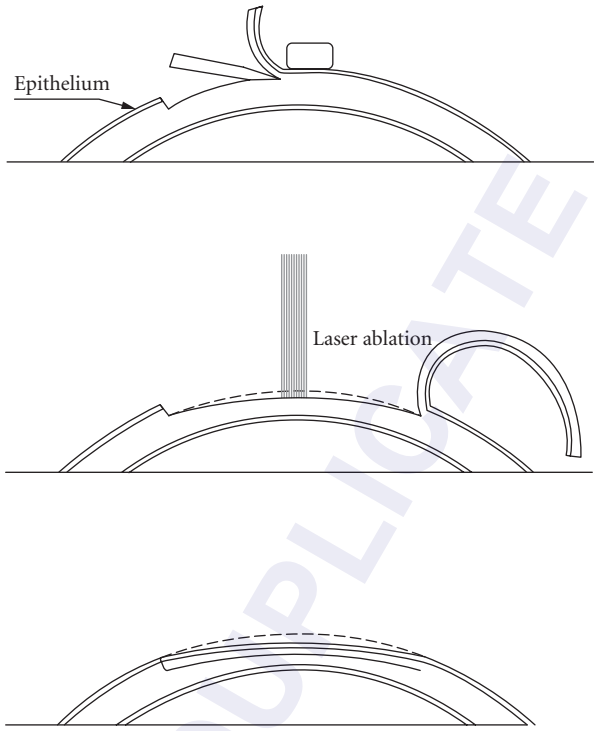

FIGURE 11 Schematic representation of laser in situ keratomileusis (LASIK).

After laser ablation, the flap is repositioned on the reshaped corneal stromal bed. This, effectively isolates the treated area from inflammation factors of the environment and therefore corneal transparency is less affected by the healing response. The creation of the flap along with the ablation may influence the mechanical stability of the cornea. There are different safety criteria related to how much ablation can be performed where the most common is that the remaining corneal stromal thickness under the ablation should be no thinner than 300 μm.

Ablation Profiles After the corneal stroma is exposed with either of the above-mentioned techniques, a sequence of overlapping laser pulses is delivered in order to excise corneal tissue in a controlled manner and modify the curvature of the corneal surface. The desired ablation profile is achieved by the appropriate superposition of—typically—a few tens of thousands of pulses, depending on the diameter of the treated zone, the desired refractive correction, and the type of ametropia.

Typically, only the portion of the cornea in front of the pupil is treated in order to minimize the tissue that needs to be excised. For this purpose, the diameter of the pupil in scotopic conditions is measured and the ablation profile is calculated for a zone preferably slightly larger than the scotopic pupil diameter.

For the correction of myopia, the refractive power of the cornea has to be reduced and therefore the ablation profile is designed to excise more tissue centrally than peripherally and therefore flatten the central cornea. Similarly, the correction of hyperopia requires steepening of the central cornea by the removal of peripheral tissue. The removed tissue has the shape of a positive or negative meniscus

lens respectively. In the case of astigmatism, the ablation profile has a toric shape introducing a relative change in dioptric power across two perpendicular meridians.

The ablation profiles typically attempt the modification of corneal curvature in a circular zone centred on the line-of-sight that has diameter of the order of 6 to 8 mm. This zone is known as the optical zone of the profile. The edges of the optical zone are treated with additional pulses in order to smooth out the border between corrected and noncorrected portion of the cornea creating a transition zone. The width of the transition zone is of the order of 1 mm and depends on the magnitude of the discontinuity that needs to be smoothened. It is clear that the wider the optical zone the more the tissue needs to be excised for any given dioptric correction. The exact shape that needs to be removed in any case is calculated by geometrical considerations known as the Munnerlyn's equations.[41,42]

Laser systems usually incorporate further empirical adjustments to compensate for biological factors such as the biomechanical response of the cornea and/or the effect of healing (especially at the border of the optical zone). Ablation profiles can be either calculated directly from the spherocylindrical refractive error or can be generated based on measurements of corneal topography or wavefront aberration of the eye. The advent of topography and wavefront-guided ablation profiles generated an interest in creating supernormal (aberration-free) optical systems for the human eye.[43] However, it is now understood that the outcome variability that originates from individual factors such as the healing response does not allow the precise sculpturing of corneal surface in order to eliminate high-order aberrations in a predictable manner.[35]

In the next section we turn our attention to the characteristics of the lasers used to perform the refractive surgery procedures and how they interact with the living tissue.

16.4 LASER ABLATION

Excimer lasers are pulsed ultraviolet (UV) lasers where the amplification medium is a biatomic system existing only at an electronically excited state.[44] Excited dimers (e.g., ArF) can be formed during electric discharges through gas mixtures of the corresponding elements and they do not exist in their ground electronic state (Fig. 12).[44,45] Excited dimers have a typical lifetime of a few nanoseconds. Their spontaneous dissociation is accompanied by the emission of a UV photon. In excimer lasers, typically excitation is provided by a transverse electric discharge (perpendicular to the optical axis) through a mixture of gases of pressure similar to that of atmospheric pressure. The dissociation of

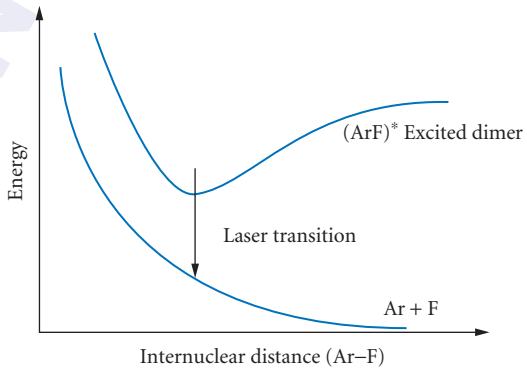

FIGURE 12 Potential energy for ArF in electronically excited and ground state.

the excited dimers renders the medium transparent to its emission wavelength. Typically, excimer lasers are characterized by high gain and low feedback therefore the beam has low coherence and generally has considerable inherent divergence.

The most common excimer lasers and their respective emission wavelengths are XeF (351 nm), XeCl (308 nm), KrF (248 nm), and ArF (193 nm). Typically, for surgical systems the pulse duration is of the order of 20-ns FWHM and the total energy per pulse is of the order of tens or hundreds of millijoule. The electric efficiency for a typical ArF laser system is of the order of 2 percent.[45] Applications of excimer lasers include material's processing, micromachining, and the excision of tissue.

Corneal Photoablation

The first experiments for the evaluation of excimer lasers as means to excise corneal tissue, were performed in the late 1980s.[46–48] These studies concluded that the most suitable wavelength was 193 nm (ArF excimer laser) due to its relatively limited thermal damage to the underlying tissue, the accuracy of the excision, and the smoothness of the resulting surface.[48] The interaction of high-power pulsed UV radiation with corneal tissue results from the process of ablative photodecomposition (or simply photoablation) described just below.

The UV pulse is absorbed by a thin surface layer. Precise measurement of the absorption coefficient in real conditions has not been accomplished; however, the penetration depth is estimated to be a few microns.[49] As energetic photons (6.4 eV) are absorbed, the molecules that form the extracellular matrix are decomposed (Fig. 13*a*). This process is primarily photochemical.[48]

According to a model proposed by Dougherty et al. to describe the role of corneal hydration in the photoablation process,[50] radiation with a wavelength of 193 nm is primarily absorbed by collagen, while water plays a more passive role absorbing a small fraction of the radiation and—mostly—affecting the thermal and mechanical properties of the tissue. As radiation is absorbed and molecular fragments are formed, more photons are absorbed by the fragments and this results to a portion of tissue from the surface to be effectively vaporized. For typical conditions (pulse energy/duration) the pressure near the surface may reach levels of the order of 100 bar.[51] The ablation products expand rapidly and are ejected perpendicularly to the surface with supersonic velocities.[52]

Based on the description above, it is reasonable to expect that the deeper a collagen fiber the larger the fragments and the less the kinetic energy of each fragment. Therefore, there is a critical depth (depending on the pulse energy density) for which fragments are energetic enough to be expelled from the material. Under this depth, the collagen has undergone direct photochemical damage but not to the extent required for ablation. For energy densities below a certain threshold photoablation does not occur. This threshold has been experimentally determined to be approximately 40 mJ/cm^2 for normal cornea and typical pulse durations.[53]

Ablation Rate

At any given conditions (pulse duration, pulse repetition rate) the ablation rate is defined as the depth of tissue excised by each pulse and is generally expressed in μm/pulse. As mentioned above, ablation rate depends on the incident energy density. Given that for a particular laser system the pulse duration is constant, the quantity that is empirically used to quantify the incident laser energy density is the surface density (fluence) typically expressed in mJ/cm^2.

The empirical equation to describe the dependence of the ablation rate on fluence is logarithmic[53]

$$A = m \cdot \ln \frac{F}{F_{\text{thr}}} \tag{6}$$

where A is the ablation rate in μm/pulse, F is the fluence, F_{thr} the ablation threshold, (in this equation it is equal to 50 mJ/cm^2) and m is an empirical constant equal to 0.3 μm/pulse

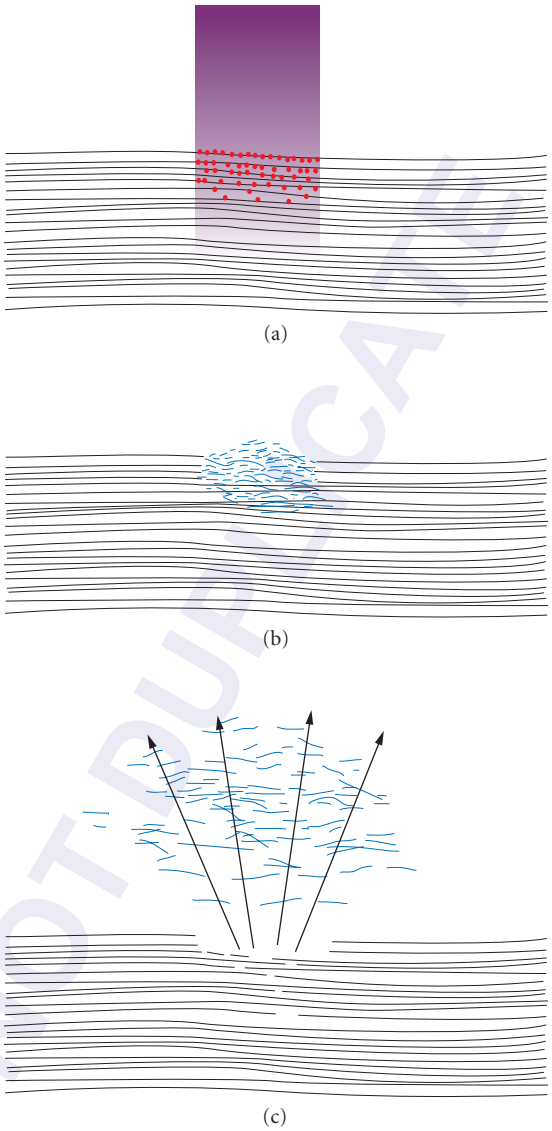

FIGURE 13 Schematic representation of the corneal photoablation process.

(Fig. 14). Typically, fluences employed in refractive surgery applications range[54] from 120 to 225 mJ/cm^2.

In practice, parameters such as pulse duration, beam profile, the presence of a gas stream for ablation debris aspiration, and the repetition rate may influence the ablation rate. These parameters as well as the temperature and humidity in the operating room are factors that are standardized in refractive surgery in order to minimize the variability of the delivered ablation. As mentioned earlier, the appropriate ablation profiles (that are designed to modify corneal geometry in a predetermined manner) are created with an appropriate superposition of pulses. Typical repetition rates are of the

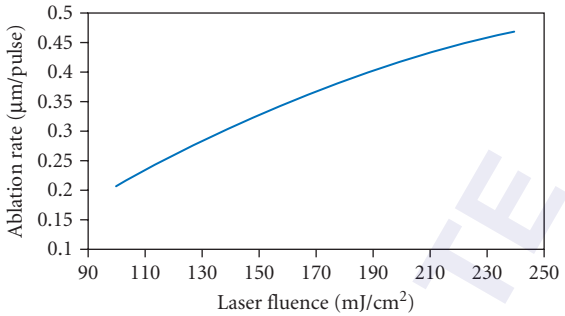

FIGURE 14 Corneal ablation rate as a function of fluence.

order of 400 Hz. For the removal of tissue necessary for the correction of moderate myopia, the total number of pulses depend on all of the parameters mentioned above and are of the order of a few tens of thousands of pulses. Besides standardization of laser and environmental parameters during ablation, the accuracy of tissue excision is enhanced by the utilization of empirical nomograms[55] where other parameters are taken into account such as attempted refractive correction, diameter of the treatment zone, patient age, corneal radius of curvature, corneal thickness, and others.

The main variable that may influence the effective ablation rate is corneal hydration.[50] Standardization of the procedures minimizes the variability associated to corneal hydration changes during surgery. It has been suggested that hydration could be measured spectroscopically and ablation parameters could be adjusted dynamically to compensate for possible changes of hydration.[56]

Thermal, Photochemical, and Photoacoustic Effects

As mentioned above, photoablation can be primarily seen as a fast photochemical decomposition of the structural elements of the cornea (the extracellular matrix) during which high-pressure gradients are developed removing fragments from the surface of the irradiated tissue.[46–48] In parallel to photoablation there are phenomena that their potential implications in the acute postoperative inflammation and long-term healing response of the cornea is not fully understood.

A significant part of the laser energy is used for the photochemical decomposition of the extracellular matrix. However, there is a part of the laser energy directly dissipated as heat (e.g., for depths greater than the ablation rate where energy density is subthreshold). Moreover, the highly energetic fragments deposit part of their energy to the surface as they are expanding. As a result of these two mechanisms each laser pulse results to a certain amount of heat dissipated on the free surface of the ablated cornea.

The temperature rise associated with this heat dissipation is highly variable and depends on the particular conditions (repetition rate, fluence, beam diameter pulse superposition pattern, etc.). In practical conditions the temperature rise has been reported to range from 0 to 8°C.[57,58] One of the parameters taken into account in pulse superposition pattern design is the effective reduction of repetition rate in the sense that irradiation of any point with consecutive pulses is avoided. In this manner, minimal changes in surface temperature of the cornea can be achieved.[59]

In principle, ArF excimer laser radiation is not capable of producing damage to the DNA of keratocytes as the penetration depth is smaller than the dimensions of one cell.[60] In that sense if the nucleus of a cell is exposed to this UV radiation a significant portion of the cell is already ablated and therefore the cell is not viable. It is the secondary radiation (fluorescence) that bears a potential risk for mutagenesis.[60,61] Fluorescence is primarily emitted at wavelengths in the region between 260 and 320 nm.[61] Photoreactivation experiments with yeast cell cultures showed a significant amount of DNA repair activity after 193-nm excimer laser irradiation. Although the role of

secondary radiation in the healing response is not yet fully understood[62] there seems to be minimal concern among the physicians as clinical experience of more than 20 years has not shown that the potential risk is significant.

Additionally, it has been hypothesised[51] that the mechanical stress of the cornea due to the pressure gradients associated to photoablation may result to structural changes in collagen and to the formation of scar tissue and loss of corneal transparency.

THREE-DIMENSIONAL CONFOCAL MICROSCOPY OF THE LIVING HUMAN CORNEA

Barry R. Masters

Department of Biological Engineering
Massachusetts Institute of Technology
Cambridge, Massachusetts

17.1 GLOSSARY

Adaptive optics. An optical system that consists of a wavefront sensor that can measure the wavefront of the light, that is, a Shack-Hartmann sensor, a deformable mirror that can alter the wavefront of the light, and a closed loop-feedback control system to minimize the wavefront error. An example is the use of adaptive optics in a scanning laser ophthalmoscope, in which the wave front distortions due to the cornea and the ocular lens are corrected by the adaptive optics.

Confocal microscope. A microscope that is based on spatial filtering with two pinholes or slit apertures located in conjugate planes. The word confocal means that both the point source of light and the point detector are cofocused on the same focal volume within the specimen. A point source of light (source aperture) illuminates a diffraction limited focal volume within the specimen. The scattered or emitted light from this focal volume is focused on a detection pinhole located in a plane that is conjugate to the source aperture. A large area detector is placed behind the photodetector pinhole.

Diffraction limited imaging. The theoretical resolution of an optical microscope is limited by the diffraction of light. Abbe defined this diffraction limit for microscopic resolution. The diffraction limited resolution is proportional to numerical aperture of the microscope objective, that is, its ability to collect light, and inversely proportional to the wavelength of the light from the specimen. A microscope that can image at the theoretical limit is a diffraction limited imaging system. Today, there are optical microscopes that exceed the Abbe diffraction limit.

Laser scanning confocal microscope. A confocal microscope in which the laser beam is scanned over the back focal plane of the microscope objective with the simultaneous scanning of the diffraction limited beam over the specimen. The scattered or emitted light from the focal volume is collected by an epi-illumination system, descanned, and passes through an aperture placed in front of a large area photodetector.

Linear optics. The response of the illuminated material to the electromagnetic field is linear with the amplitude of the field. Examples are one-photon absorption, scattering, and fluorescence.

Microlens Nipkow disk confocal microscope. This is a major improvement over the Nipkow disk tandem scanning confocal microscope that has an illumination efficiency of only 1 to 2 percent. In this new device a second Nipkow disk which contains about 20,000 microlenses is added to the

Nipkow disk microscope. The lower Nipkow disk contains another 20,000 pinholes that are arranged in the same pattern as the microlenses on the upper disk. The lower pinhole disk is located in the focal plane of the upper microlens disk. This arrangement increases the illumination efficiency to 50 percent and results in a high sensitivity even for weak reflecting specimens. The same pinholes are used for illumination (laser excitation light) and spatial filtering of the fluorescence light, and a dichroic mirror placed between the two disks separates the excitation light from the fluorescence that is focused on the detector. Both disks rotate together on the same axis to form a real-time scanned image of the specimen.

Nipkow disk tandem-scanning confocal microscope. A real-time, direct-view, tandem-scanning microscope based on a rotating Nipkow disk, contains sets of conjugate pinholes arranged in a set of spirals about the axis of rotation. On a given diameter of the disk there is one pinhole for the illumination and one pinhole for detection of the scattered or emitted light from the specimen. As the disk rotates, many conjugate sets of illumination and detection pinholes (arranged in conjugate planes on opposite sides of the Nipkow disk) operate in parallel to simultaneously scan the specimen with a diffraction limited illumination spot, and to detect the descanned scattered or emitted light.

Nonlinear optics. The response of the illuminated material to the electromagnetic field is nonlinear with the amplitude of the field. At high light intensities, the incident field modifies the optical properties of the material such that the light waves can interact and exchange energy and momentum. Examples of nonlinear optics are two-photon excitation fluorescence, second-harmonic generation, and third-harmonic generation.

Numerical aperture. The numerical aperture (NA) of a microscope objective is a measure of the range of angles that the lens can accept or emit light. The NA of a microscope objective is defined as: $NA = n \sin \theta$, where n is the index of refraction of the medium between the objective and the specimen, and θ is the half-angle of the maximum cone of light that can enter the objective.

Optical aberrations. They represent the failure of an optical system to produce a perfect image. Modern microscope objectives are made to minimize five categories of optical aberrations: spherical aberrations (results in a lack of sharp focus), coma (results when light is focused at points off the optical axis), astigmatism, field curvature, and distortion. In addition to these monochromatic Seidel aberrations, there are also axial chromatic aberrations and lateral chromatic aberrations in which different colors of light focus at different positions.

Scanning slit confocal microscope. A real-time, confocal microscope in which a slit of incident light is scanned over the back focal plane of the microscope objective. The reflected and the emitted light from the focal volume within the specimen is collected by the microscope objective, descanned by the scanning system, and detected by a wide-area detector.

Second-harmonic generation (SHG). A nonlinear process in which an incident wave of frequency ω interacts with a material that does not contain an inversion symmetry, and generates a new signal at the frequency 2ω.

Slit-lamp microscope. A microscope that is based on the principle of focal illumination. A slit of light is used to illuminate a volume within the eye. A biomicroscope collects the scattered and reflected light from a volume that intersects the illumination volume. The intersection of the illumination volume and the collection volume is in focus.

Specular microscope. A modification of the slit lamp in which one half of the microscope objective is used for illumination of the specimen and one half of the microscope objective is used to collect the scattered and the reflected light. For a plane reflecting surface when the angle between the normal to the surface and the illumination beam of light is equal to the angle between the normal to the surface and the reflected beam of light, the condition of specular reflection exists. The microscope that images this specular reflection is called a specular microscope. It is used to image the endothelial cells due to the strong specular reflection at the endothelial cell and the aqueous humor interface.

Third-harmonic generation (THG). A nonlinear process in which an incident wave of frequency ω interacts with any material, and generates a new signal at the frequency 3ω.

17.2 INTRODUCTION

This chapter presents the optical principles of the confocal microscope and its applications to the design of clinical confocal microscopes for imaging the living human cornea. A series of technical advances resulted in new optical designs from the early slit lamp with its focal plane illumination to the modern scanning slit and laser scanning clinical confocal microscopes. A carefully edited selection of papers, books, and commercial Web sites is presented as a further resource of clinical images, instrument designs, and clinical protocols. The emphasis of this chapter is to critically examine the limitations of the various designs of clinical instruments, and to present the author's perspective on the state of the art instruments and the proposed future instrument development that will incorporate the suggested improvements as well as those based on the emerging field of nonlinear optical microscopy,[1,2] specifically second- and third-generation harmonic microscopy. It is further suggested that future clinical biomicroscopes will incorporate correlative microscopy, that is, both linear reflected confocal microscopy together with nonlinear higher-harmonic microscopy.

17.3 THEORY OF CONFOCAL MICROSCOPY

The principles of the confocal microscope in both the transmission mode and in the epi-illumination mode were clearly stated and illustrated in the 1961 patent granted to Marvin Minsky.[3] To facilitate easy access to the key papers and the important patents in the field of confocal microscopy and its many biological applications SPIE Press published an edited collection of these documents.[3] Further theoretical and practical details on instrument design, theories of transverse, and axial optical resolution are contained in a modern book.[4]

A widefield optical microscope has no capability for axial optical sectioning; therefore, when the specimen is a thick, highly scattering tissue the images at the focal plane are degraded by out-of-focus contributions to the image. The confocal microscope solves this problem with the method of spatial filtering.[3] A point source of light from an incoherent or a coherent source illuminates a point in the specimen via the microscope objective. The back-scattered or the fluorescence light from that point is collected by the microscope objective and passes an aperture that is in a conjugate plane to the point source of illumination. Only light from the focal plane of the illumination spot passes the conjugate aperture and is detected by the detector located directly behind the detection aperture. Light from the out-of-focal plane cannot pass the detection aperture and therefore it is not detected. This confocal principle is shown in Fig. 1. The use of spatial filtering provides an enhanced axial resolution (z axis of the microscope) and is the source of the axial optical sectioning in the confocal microscope.

In order to acquire two-dimensional images of the focal plane it is necessary to scan the light beam over the back focal plane of the microscope objective and to descan the scattered or emitted light that is collected from the microscope objective. Typically two sets of oscillating galvanometer driven mirrors, one for the horizontal scan and one for the vertical scan, are used for laser scanning and descanning.

17.4 THE DEVELOPMENT OF CONFOCAL INSTRUMENTS

The late David Maurice is honored by the vision research community for his outstanding contributions to the development of optical ophthalmic instrumentation.[5] The development of the scanning slit confocal microscope is based on a series of linked technical advances that include parallel invention as well as unique creative invention, and the story of the development of live cell imaging in ophthalmology is described in a recent book.[6]

Two groups of confocal microscopes were developed for ophthalmology: the first was a laser scanning ophthalmoscope for imaging the retina was developed by Webb and his collaborators[7] and the

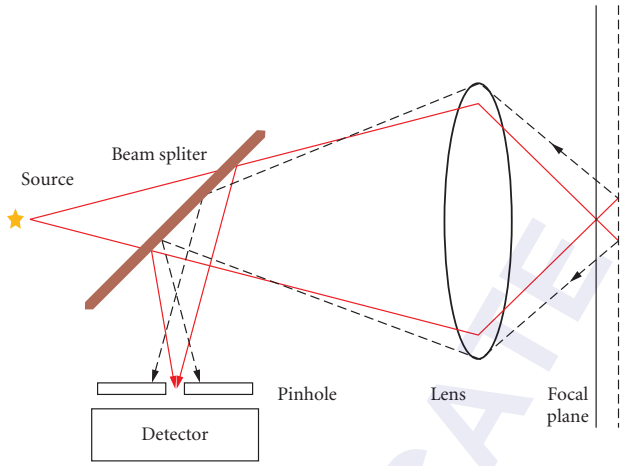

FIGURE 1 The principle of the confocal microscope. This schematic diagram shows the depth discrimination capability of a confocal microscope and how it discriminates against reflected light from out of the focal plane. The dashed vertical line to the right of the focal plane represents an out-of-focus plane. Only the light rays (solid lines) from the focal plane pass the pinhole and are detected. (*Reproduced with permission from Ref. 6.*)

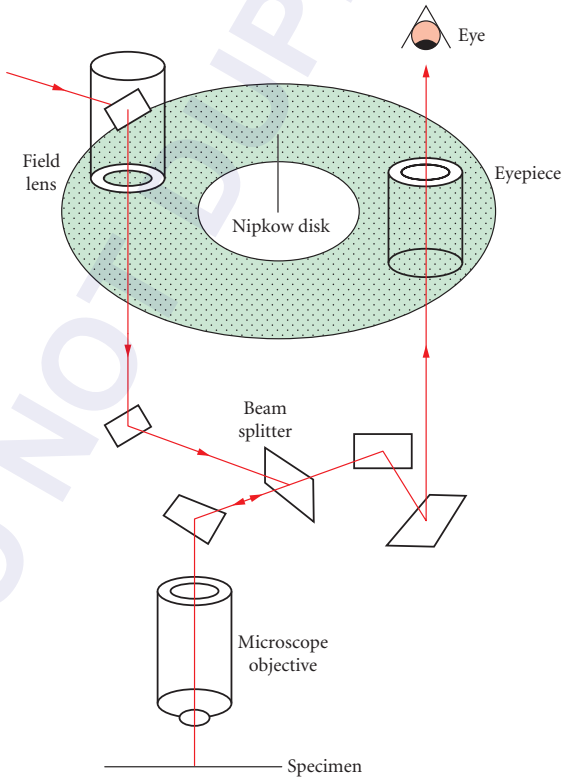

FIGURE 2 The principle of Nipkow disk confocal microscope. This schematic shows the real-time, direct-view, tandem-scanning Nipkow disk confocal microscope. The light source from the upper left is a mercury arc lamp or a tungsten filament lamp. (*Reproduced with permission from Ref. 6.*)

second group of confocal microscopes that typically used an incoherent light source was developed for imaging the cornea.[8]

Several early types of in vivo confocal microscopes were based on the spinning Niprow disk that contained spiral arrays of multiple sets of conjugate pinholes, one pinhole was used for illumination, and a conjugate pinhole was used for spatial filtering in front of the detector.[3,6] The design of the Nipkow disk based confocal microscope is shown in Fig. 2.

The Nipkow disk–based confocal microscope has a very poor illumination efficiency (1 to 2 percent) and therefore weak reflecting corneal cell layers such as the basal epithelial cell layer cannot be imaged. The solution to this problem was made by Akira Ichihara and his coworkers at the Yokogawa Institute Corporation in Japan with their invention of a microlens Nipkow disk confocal microscope.[6] The addition of an upper disk that contained 20,000 microlenses which focused the light on the 20,000 pinholes on the lower disk. The key point is that the lower pinhole disk is aligned and located in the focal plane of the upper disk. The resulting illumination efficiency is about 50 percent. Figure 3 shows the principle of the microlens Nipkow disk confocal microscope.

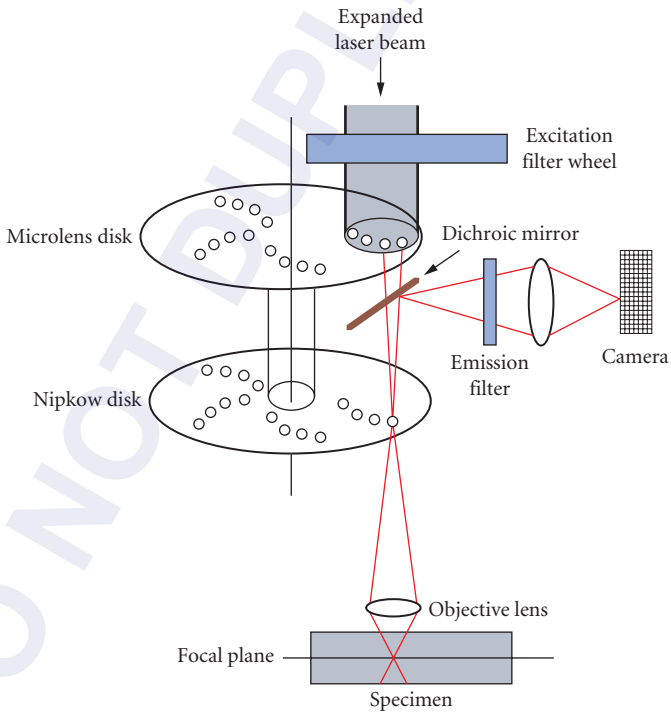

FIGURE 3 The principle of microlens Nipkow disk confocal microscope. Schematic drawing of the Yokogawa microlens Nipkow disk confocal microscope. The two disks rotate on a common axis. The upper microlens disk contains 20,000 microlenses arranged in a series of spirals. The lower Nipkow disk contains 20,000 pinholes arranged in a series of spirals. The lower disk containing the pinholes is in the focal plane of the microlenses in the upper disk. A dichroic mirror placed between the two disks passes the incident laser beam, but reflects the beam of emitted light to the emission filter and then it is focused on the camera. (*Reproduced with permission from Ref. 6.*)

17.5 THE SCANNING SLIT AND LASER SCANNING CLINICAL CONFOCAL MICROSCOPES

Based on the Svishchev confocal microscope design of a two-sided oscillating mirror for scanning a slit of light across the back focal plane of a high NA, water immersion microscope objective, a clinical confocal microscope with an incoherent halogen lamp light source was designed and constructed.[9] Figure 4 shows the principle of the two-sided, oscillating mirror in the scanning slit confocal microscope.

The advantage of this scanning slit confocal microscope is that the slit widths of the two conjugate slits, one for the illumination side and one for the detection side, are completely adjustable. They could be opened to increase the reflected signal from weak scattering corneas, or could be reduced to increase the resolution of the microscope.[10] Later commercial designs used fixed slits.

This scanning slit confocal microscope was placed in the clinic and was used to study a variety of normal and clinical conditions of the in vivo human cornea. Figure 5 shows the principle of the clinical scanning slit confocal microscope based on the Svishchev oscillating two-sided mirror design.

For example, this scanning slit confocal microscope was successfully used to study the basal epithelial cell layer, and its adjacent wing cell layer. In the clinic the confocal microscope was used to relocate the same cells within the cornea over different periods of time, this provided a method to track cell migration over time. Since the microscope objective contacted the anterior surface of the cornea there is the need for both an anesthetic and the application of a drop of an index matching gel to the tip of the microscope objective.

In recent years the scanning slit confocal microscope has been made into a commercial product that is now in the fourth generation.[11] One useful feature of the commercial version, the Confoscan 4, is the 20x microscope objective that works under noncontact conditions; therefore, there is no need

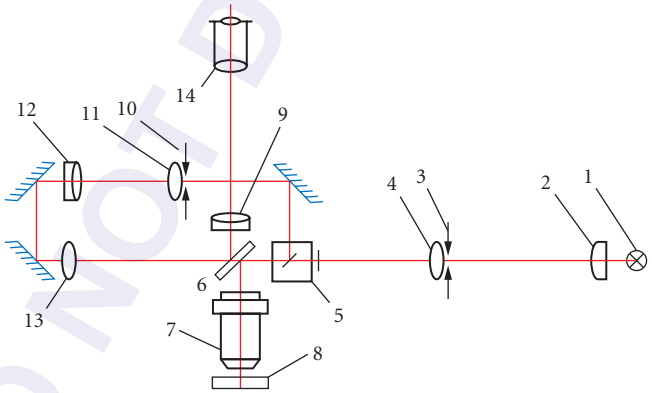

FIGURE 4 The principle of the Svishchev two-sided, oscillating mirror, scanning slit confocal microscope. The light source, 1, is projected by a condenser lens, 2, onto the first slit, 3; the light passes through a prism cube, 5; an image of the first slit is scanned over the back focal plane of the microscope objective, 7, by the two-sided oscillating mirror, 6, which descans the reflected light from the focal plane of the specimen. The second slit, 10, is conjugate with the first slit (confocal) and excludes the light that is not in the specimen's focal plane, 8. The two-sided oscillating mirror, 6, performs three functions: it scans the image of the slit 3 over the back focal plane of the microscope objective, descans the beam from the object, and rescans the beam for observation in the ocular, 14. The parts labeled 2, 4, 9, 11, 12, and 13, are lenses. (*Reproduced with permission from Ref. 6.*)

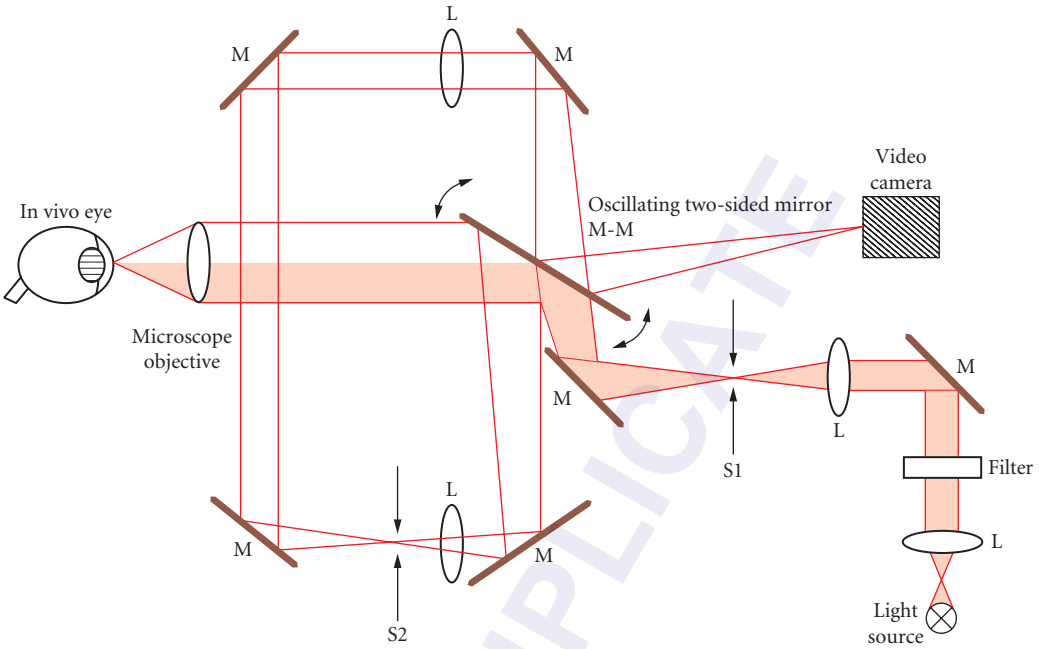

FIGURE 5 The optical principles of the clinical, video-rate, scanning-slit, in vivo, confocal microscope with two adjustable slits: S1 for illumination and S2 for imaging. An oscillating two-sided mirror M-M scans S1 over the back focal plane of the objective, descans the collected light and directs it to S2, then rescans the beam, which is imaged on the photocathode of a video camera. The dark ray path indicated the illumination light rays. The light ray path indicates the reflected light that is collected by the microscope objective. One half of the NA of the microscope objective is used for illumination, and one half of the NA is used for collection of the reflected light form the specimen. (*Reproduced with permission from Ref. 6.*)

for anesthetic nor for an index matching gel on the tip of the objective. Numerous publications based on the slit scanning confocal microscope are replete with confocal images of normal corneas and the diseased and altered corneas.[12–16] In addition, the Nidek Web site features many examples of confocal microscopic images of the cornea.[11]

Modern clinical confocal microscopes can acquire stacks of confocal images through the full thickness of the human cornea and produce three-dimensional visualizations of the a volume from the anterior surface to the posterior endothelial cell layer. This approach of three-dimensional visualization of the living cornea was first demonstrated on rabbit corneas by Masters and coworkers.[17–19]

An alternative to the commercial scanning slit confocal microscope is a laser scanning confocal microscope designed for retinal imaging by Heidelberg Engineering that can be modified with a Rostock Cornea Module (RCM) microscope that permits confocal microscopy of the cornea.[20] The Heibelberg Retinal Tomograph (HRT) is a confocal laser scanning microscope with a diode laser light source at 670 nm. The optical principle of this confocal microscope is shown in Fig. 1.

The RCM unit has the ability to change the focal plane within the cornea. A single-use planar cap is fitted over the tip of the module and it is in contact with the anterior surface of the cornea. The plastic cap stabilizes the distance between the module and the cornea. An index matching gel is placed between the instrument tip and cornea. Between the movable plastic cap is an index matching gel that serves to increase the numerical aperture of the objective which results in increased resolution and contrast. When it is desirable to use the confocal microscope in the noncontact mode, the water immersion microscope objective is removed together with its contact cap and is replaced with a long

focal length dry objective. Typically a noncontact Nikon 50X, NA 0.45 microscope objective is used to image the cornea in the noncontact mode. The specifications from the manufacturer include a focus range of 4 mm, the lateral image size of 380 by 380 μm, the lateral optical resolution of about 1 μm, and the depth of focus of about 1 to 2 μm.

17.6 CLINICAL APPLICATIONS OF CONFOCAL MICROSCOPY

The clinical utility of a clinical confocal microscope for the examination of the in vivo human cornea depends on the optical and mechanical design parameters of the confocal microscope, the optical condition of the subject's cornea, and finally, on the skill and the experience of the clinician who is making the examination.

A general introduction to the principles and the practice of clinical confocal microscopy is a rich resource of clinical protocols. A review on the confocal microscopy of the cornea by Böhnke and Masters provides the accumulated clinical experience of many years of patient examination.[21] This practical discussion of clinical techniques includes the following topics: technical setup of the confocal microscope, the technique of biomicroscopy with the confocal microscope, the suggested clinical examination procedure, patient data archiving and retrieval, and the dissemination, documentation, and publication of microscopic findings. This paper also contains an atlas of confocal images from the normal cornea, the effects of aging, the effects of contact lens wear, the cornea with known pathologies, and the postsurgical cornea.

Creative scientists, engineers, and clinicians have worked together in the last decades to develop new clinical confocal microscopes that have successfully been incorporated into clinical practice. Optics and optical engineering are in the forefront of the design and development of medical devices for both treatment and diagnostics providing rich career opportunities for highly trained people.

Two books are available with many clinical examples of the application of clinical confocal microscopy to the cornea.[22,23] These books are replete with confocal images from a wide variety of normal and pathological corneas and cover the effects of photorefractive surgery on the structure of the cornea. Another source of clinical corneal images is the World Wide Web. I include two commercial sites of companies that manufacture clinical confocal instruments.[11,20] Their Web sites include many examples of confocal images of the cornea in a variety of normal and pathological conditions.

As an exemplar of the use of the clinical confocal microscopy to investigate new clinical findings the following study is presented.[24] This paper illustrates the confounding effect of acquiring clinical confocal images of the human cornea with inappropriate optical resolution. The authors posed the following question: what are the long-term effects of contact lens wear on the human cornea? They answered this question by first acquiring confocal images through the full thickness of the in vivo human cornea, and then by a frame by frame analysis to determine morphological changes within the cornea that are correlated with long-term contact lens wear and do not occur in subjects that do not wear contact lenses.

The scanning slit confocal microscope with a 50X/1.0 NA water immersion objective was used to investigate the corneal morphology in long-term contact lens wearers. The authors investigated 13 patients with a history of up to 26 years of soft contact lens wear, 11 patients with a history of up to 25 years of rigid gas permeable contact lens wear, and a control group of 29 normal subjects without a history of contact lens wear. For contact lens wearers epithelial microcystic changes and alterations of endothelial cell morphology were found as described previously. The significant new finding was there were highly reflective panstromal microdot (submicron) deposits in the entire thickness of the stroma for the contact lens wearers. It was concluded that this newly observed stromal microdot degeneration scales with the years of contact lens wear and may be the early stage of a significant corneal disease. Further correlative microscopic studies involved electron microscopy of ex vivo human corneas, and spectroscopic studies of the microdots. Initially, other groups were not able to observe the stromal microdot deposits because they used a Nipkow disk confocal microscope with a low power and a low NA microscope objective. The low power, low NA microscope objective did not

provide the necessary resolution to image the stromal microdot deposits. This study illustrates the requirement of the appropriate optical resolution in studies with the clinical confocal microscope, as well as correlative electron microscopy to validate the clinical conclusions.

17.7 PERSPECTIVES

In the linear domain confocal microscopes can be developed that use different colored light-emitting diodes as the light source. The degree of penetration of the incident light is a function of the wavelength and the amount of absorbing and scattering material in a particular cornea. The selection of various colors of illumination light would provide the clinician with improved image contrast since the illumination could be tuned to optimize either the penetration depth or the contrast.

The use of noncontact confocal microscopes such as the Heidelberg Retina Tomograph II with the Rostock Corneal Module is a major improvement over the previous designs with an applanating microscope objective that flattens the corneal surface. The noncontact confocal microscope is less likely to transmit microbes from patient to patient and causes less trauma to the cornea. The Nidek ConfoScan4 clinical confocal microscope also operates in a noncontact mode.

Another problem that still requires further development to reach a solution is a method to determine the position of the focal plane within the cornea. The current use of movable lenses together with accurate position sensors do not provide the true position of the focal plane within the cornea with respect to the corneal surface.

Typically, the technical specifications of commercial clinical confocal microscopes do not include information on the point-spread function, or other metrics of the transverse and the optical resolution of the microscope with a stated frequency of illumination, and a stated numerical aperture of the microscope objective. Measurements of the image, a series of optical sections, through a subdiffraction of gold particle or a 0.1-μm fluorescent bead are readily made and would provide useful information.

Microscope images obtained through thick, scattering, and absorbing tissues such as a cornea containing scar tissues result in further degradation of the image quality. Even when a gel is used to approximately match the refractive index of the cornea and the microscope objective there are induced optical aberrations that degrade the image quality. For example, the refractive index varies within the cornea, both in depth and in the imaging plane of the microscope. One option to mitigate this problem is to incorporate adaptive optics (a closed loop-feedback system that corrects the wavefront distortions due to the cornea). Adaptive optics have successfully been incorporated into scanning-laser ophthalmoscopes for retinal imaging.[25]

All of the clinical confocal microscopes in use today are based on linear optics and generate contrast from the absorption and scattering of the incident light. There are many published studies of nonlinear higher-harmonic generation microscopy that were performed on ex vivo corneas, but there is a paucity of in vivo animal studies and no in vivo human studies have been reported.[26] Second- and third-harmonic generation can be explained by the theory of the nonlinear susceptibility in which for the time domain the polarization is expanded in a power series of the sum of products of the linear susceptibility and the electric field, the second-order susceptibility and the square of the electric field, and the third-order susceptibility and the cube of the electric field and higher-order terms. Second-harmonic generation (SHG) is described by the second-order susceptibility and third-harmonic generation (THG) is described by the third-order susceptibility. THG has a broad potential for tissue imaging since it occurs in all materials, including dielectric materials with inversion symmetry. In general THG is a weak process; however, it is dipole allowed. THG microscopy has a emerging potential for cell and tissue imaging. As new techniques are being developed for the surface-enhanced THG at interfaces, the technique may become useful for imaging the cornea. Another emerging development is the use of enhanced THG microscopy with nanogold particles to utilize the surface-plasmon-resonance effect.

Both SHG and THG imaging do not exhibit the saturation effects or the photobleaching effects that are associated with multiphoton excitation fluorescence microscopy. These microscopic techniques can

penetrate into millimeters of tissue and provide submicron three-dimensional optical sectioning. Collagen has a noncentrosymmetric structure and can convert the incident ultrashort laser pulse to its second harmonic, thus providing a noninvasive imaging modality for the cornea. The backward-scattered SHG signal may provide a sensitive clinical method to study corneal haze following photorefractive surgery.

Structures within the cornea, for example, collagen fibrils that are a few nanometers in diameter, can only be imaged with an electron microscope. When imaged with a confocal microscope or with a SHG or THG microscope the collagen fibrils, and all subdiffraction limit structures appear at the diffraction limit of the microscope. This optical phenomena is rarely explained in many papers on nonlinear microscopy of the cornea.

Finally, the image quality of a clinical corneal microscope is dependent on the microscope objective. Olympus Corporation has developed a new 25X, NA 1.05 water immersion microscope objective that is optimized for nonlinear microscopy based on femtosecond pulses of laser light. This lens that produced tightly focused light in the focal volume, a high collection efficiency due to the high NA, and a long free-working distance may enhance the performance of corneal microscope that operates in the nonlinear optical domain.

17.8 SUMMARY

The goals of biomicroscopy of the living human cornea are to improve our understanding of the cellular structure and function in the normal cornea and in diseased, aging, and surgically altered corneas. Biomicroscopy of the anterior segment of the eye has provided the clinician with a series of improved instruments from the early slit lamps to a variety of confocal microscopes; with each new design there were improvements in both the image resolution and the contrast. Modern clinical confocal microscopes provide transverse resolution and axial resolution of several microns. Both the scanning slit confocal microscope and the laser scanning confocal microscope provide high-resolution images with high contrast and are ideal to investigate nerve regeneration in the postsurgical cornea, the formation of scar tissue, and other morphological anomalies due to disease, contact lens wear, overnight lid closure, or surgical procedures such as photorefractive surgery. Routine confocal microscopy of the cornea reveals the cellular and subcellular structure of all the cells in the full thickness of the cornea. Nonlinear microscopy, especially higher-harmonic generation microscopy has the potential for molecular imaging with the benefit that it is based on a scattering process and, therefore, there is no net energy deposition within the ocular tissue. Future clinical biomicroscopes can incorporate correlative microscopy, that is, both linear reflected confocal microscopy and nonlinear higher-harmonic microscopy.

17.9 ACKNOWLEDGMENTS

The author and Professor M. Böhnke shared the 1999 Alfred Vogt-Prize for Ophthalmology (the highest award in Switzerland for scientific research in ophthalmology) from the Alfred Vogt-Stiftung zur Förderung der Augenheilkunde Zürich, for their work: "Confocal Microscopy of the Cornea." The author thanks Professor M. Böhnke, formerly of the Department of Ophthalmology, University of Bern, for many years of collaboration, and Dr. Andreas A. Thaer for his collaboration in the development of the clinical confocal microscope.

DIAGNOSTIC USE OF OPTICAL COHERENCE TOMOGRAPHY IN THE EYE

Johannes F. de Boer

Department of Physics
VU University, Amsterdam
Rotterdam Ophthalmic Institute
Rotterdam, The Netherlands

18.1 GLOSSARY

A-line. Depth scan along the beam direction in an OCT measurement.

Axial resolution. Resolution along the beam direction in an OCT measurement.

Birefringence. Optical property of a material where the refractive index of the material depends on the polarization state of light.

Bruchs membrane. The innermost layer of the choroid, connected to the retinal pigmented epithelium.

Capillary. The smallest blood vessels, approximately 5 to 10 μm in diameter.

Coherence length. The length along the beam path over which light is correlated.

Diattenuation or dichroism. Optical property of a material where the light absorption of the material depends on the polarization state of light.

Fourier transform. Operation that transforms one function of a variable into another, where the new function describes which frequencies are present in the original function.

Fovea. The area in the back of the inside of the eye located in the center of the macula, responsible for sharp central vision.

Choroid. The vascular layer of the eye lying between the retina and the sclera.

Jones matrix formalism. In the Jones matrix formalism the electromagnetic wave before and after interaction is described by Jones vectors with two complex-valued entries, and their transformation is described by the complex-valued 2×2 Jones matrix.

Michelson interferometer. Most common configuration for optical interferometry where the source light is split by a beam splitter into a sample and a reference arm. Reflected light is combined in the detection arm.

Mueller matrix formalism. In the Mueller matrix formalism the polarization properties of light are described by Stokes vectors with four real-valued entries, and their transformation is described by the real-valued 4×4 Mueller matrix.

Optical circulator. An optical circulator is a three-port device that allows light to travel in only one direction—from port 1 to port 2, then from port 2 to port 3.

Optical coherence tomography (OCT). Optical interferometric technique to create cross-sectional images of scattering media.

Optical frequency domain imaging (OFDI) or swept source OCT (SS-OCT). OCT configuration in which the reference arm length is stationary and the interference in the detection arm is spectrally resolved by scanning a narrow band source over a wavelength range.

Optic nerve head. The circular area in the back of the inside of the eye where the optic nerve connects to the retina.

Phase retardation. The retardation in phase that originates from the difference in refractive index for polarized light in a birefringent material.

Poincaré sphere. Graphical representation of the Stokes vector on a sphere.

Relative intensity noise. Noise associated with the instability in the power level of a laser or light source.

Retinal pigmented epithelium. The pigmented cell layer between the choroid and the photoreceptors.

Semiconductor optical amplifier. Semiconductor device that amplifies light by several orders of magnitude.

Shot noise. Fundamental noise generated by statistical fluctuations in a stream of particles (photons, electrons).

Signal to noise ratio. Ratio of a signal power to the noise power corrupting the signal.

Spectral or Fourier domain OCT. OCT configuration in which the reference arm length is stationary and the interference in the detection arm is spectrally resolved.

Stokes vector. Four element vector that describes the polarization properties of light.

Temporal coherence. The feature that light at different time points exhibit correlation.

Time domain OCT. OCT configuration in which the reference arm length is mechanically scanned.

Unitary matrix. A unitary matrix is an n by n complex matrix U satisfying the condition $UU^* = \begin{pmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 1 \end{pmatrix}$, where $\begin{pmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 1 \end{pmatrix}$ is the identity matrix and U^* is the conjugate transpose (also called the Hermitian adjoint) of U.

Vitreous humor. The clear gel that fills the space between the lens and the retina.

White noise. Noise that has a flat frequency distribution (all frequencies are equally present in the noise).

18.2 INTRODUCTION

Optical coherence tomography (OCT) is a low coherence interferometric method for imaging of biological tissue.[1,2] OCT creates cross-sectional images of tissue by measuring the location (lateral and depth) where light is backscattered. OCT has become a very powerful imaging tool in ophthalmology, since it provides high resolution cross-sectional images of the retina and the cornea that approach the resolution of histology. The development of objective criteria to characterize ophthalmic diseases based on OCT images is an active area of research.

OCT is analogous to ultrasound imaging, where a sound pulse is sent into tissue and the time delay is measured of reflected sound waves. The time delay is converted to a distance using the propagation speed of sound in tissue. The speed of light (3×10^8 m/s) is 5 orders of magnitude higher

than the speed of sound (1.5×10^3 m/s), and therefore it is not possible to measure directly the small time delay of a reflected optical pulse. This time delay can be measured however by interfering the light reflected from the tissue with a reference in a Michelson type interferometer. This principle will be explained in more detail further.

For more than a decade after its inception, the dominant implementation of OCT has been time domain OCT (TD-OCT), in which the length of a reference arm in a Michelson type interferometer is rapidly scanned. TD-OCT has been used extensively in ophthalmology, where cross-sectional OCT images of the retina have provided useful information regarding the presence or progression of specific ocular diseases.[3] The acquisition rate of clinical and preclinical TD-OCT systems is limited by sensitivity and the maximum permissible incident power on the eye[4] to about 400 depth profiles/s, preventing comprehensive screening of large retinal areas. Over the past 5 years, the dominant implementation of OCT in ophthalmology has become spectral or Fourier domain OCT (SD/FD-OCT). As will be discussed, SD/FD-OCT has a significant sensitivity advantage over TD-OCT. The sensitivity improvement of SD-OCT allows for dramatically increased acquisition speeds by approximately a factor of 100 without compromising image quality. Three-dimensional data sets can therefore be rapidly acquired, opening the possibility of comprehensive screening. The first SD/FD-OCT implementation was reported in 1995.[5] In SD-OCT the reference arm is kept stationary, and the depth information is obtained by a Fourier transform of the spectrally resolved interference fringes measured with a spectrometer in the detection arm of a Michelson interferometer.

An alternative method to SD/FD-OCT that provides the same sensitivity advantage is optical frequency domain imaging (OFDI) or swept source OCT.[6–9] In OFDI, the spectrally resolved interference fringes are not measured by a spectrometer in the detection arm of a Michelson interferometer, but by rapidly tuning a narrowband source over a wavelength range. A detector in the reference arm measures the spectrally resolved interference as a function of time.

OCT images provide structural information based on the scattering properties of the tissue under investigation. OCT can be enhanced by functional extensions such as Doppler sensitivity to detect flow, and polarization sensitivity to detect birefringent structures (structures for which the refractive index depends on the polarization state of light). In this chapter, the aforementioned techniques will be discussed and explained in more detail.

18.3 PRINCIPLE OF OCT: TIME DOMAIN OCT

Optical coherence tomography is a very sensitive interferometric method to measure the location of structures that reflect light with an axial resolution of 1 to 10 μm. OCT exploits the low temporal coherence properties of a broadband light source. For a low temporal coherence light source, electromagnetic waves will not interfere when the time delay between two beams is larger than the coherence time. The product of the coherence time and the speed of light gives the coherence length. This property can be used to measure the path length difference between two arms of a Michelson interferometer. When the path length difference is larger than the coherence length, light will not interfere. The path length difference for which the two arms match in length within the coherence length of the source produces an interference pattern. Figure 1 shows the principle of an OCT system with a scanning mirror in the reference arm.

In the sample arm is a structure with three reflecting layers. As the reference arm mirror is translated, the detector in the detection arm measures an interference pattern each time the reference arm path length matches the path length to one of the reflecting layers in the sample arm. In OCT the envelope of the interference pattern is detected and a single scan of the reference arm mirror provides a single axial (along the beam direction) reflectivity profile of the sample. A single depth profile is also called an A-line. Repeating many depth scans (A-lines) at lateral locations creates a cross-sectional image of, for example, the retina, as shown in Fig. 2.

In a more mathematical description the intensity at the detector is given by

$$\langle \mathrm{I}(\Delta z)\rangle = \langle \mathrm{I}_r\rangle + \langle \mathrm{I}_s\rangle + \langle E_r^* E_s(\Delta z)\rangle + \langle E_r E_s^*(\Delta z)\rangle \tag{1}$$

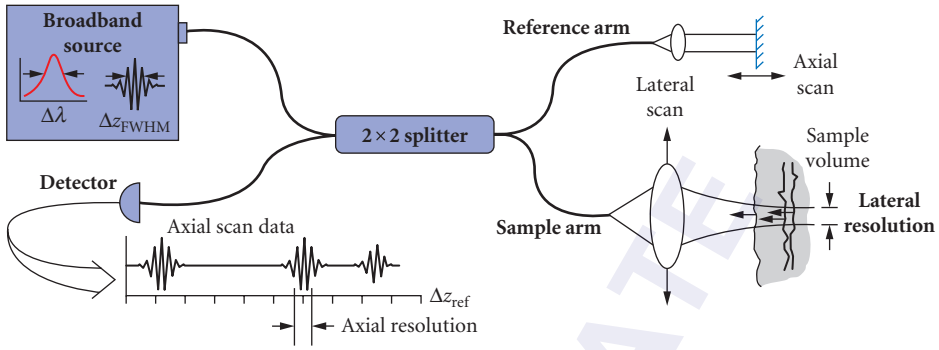

FIGURE 1 Basic OCT configuration. Light from a broadband source is split into a sample and a reference arm. The reference arm mirror scans in depth, creating interference fringes when the reference arm path length matches the sample arm path length to one of the three reflecting layers in the sample.

where $E_{r,s}$, $E^*_{r,s}$ are the electric field component and its complex conjugate, Δz is the path length difference between the two arms of the interferometer, and subscripts r and s denote fields reflected from the reference and sample arm, respectively. The angular brackets denote time averaging. The first two terms on the right-hand side of Eq. (1) give the intensity reflected from the reference and sample arm, respectively.

The last two terms of Eq. (1) correspond to the interference between reference and sample arm light. In our analysis, the electric field amplitude is represented by a complex analytic function,[10] $E(z)$, with

$$E(z)=\int \tilde{e}(k)\exp(-ikz)dk \tag{2}$$

where $\tilde{e}(k)$ is the field amplitude as a function of free space wave number $k=2\pi/\lambda$, with

$$\tilde{e}(k)=0 \quad \text{if} \quad k<0 \tag{3}$$

From the Wiener-Khinchine theorem, it follows,

$$\left\langle \tilde{e}(k)\tilde{e}(k')\right\rangle = S(k)\delta(k-k') \tag{4}$$

which defines $\tilde{e}(k)$ in terms of the source power spectral density $S(k)$. Using the Wiener-Khinchine theorem [Eq. (4)], the interference term in Eq. (1) is given by

$$I_{r,s}(z,\Delta z)=E^*_r E_s + E_r E^*_s \propto \sqrt{R(z)}\int \cos(2k\Delta z)S(k)dk \tag{5}$$

FIGURE 2 OCT image of a human retina. Arrow indicates the position of a blood vessel. (*Reproduced from Ref. 11 with permission from the Optical Society of America.*)

with z the depth in the tissue and Δz the optical path length difference between sample and reference arms, $\Delta z = z_r - z_s$. We will assume a Gaussian power spectral density for the source

$$S(k) \propto \exp\left[-\left(\frac{k-k_0}{\kappa}\right)^2\right] \tag{6}$$

with the FWHM spectral bandwidth of the source given by $\kappa 2\sqrt{\ln 2}$. The integration over k in Eq. (5) can now easily be performed

$$I_{r,s}(z,\Delta z) \propto \sqrt{R(z)}\cos(2k_0\Delta z)\exp\left[-(\Delta z/\Delta l)^2\right] \tag{7}$$

with the FWHM of the interference fringes envelope given $\Delta l 2\sqrt{\ln 2}$

$$\Delta l = \frac{1}{\kappa} = \frac{\lambda_0^2\sqrt{\ln 2}}{\pi\Delta\lambda} \tag{8}$$

and $\Delta\lambda$ the spectral FWHM of the source in wavelength. Equation (7) is an important result; it describes the interference fringe intensity that is observed for a reflective structure in the sample arm when the reference arm is scanned. The right-hand side of Eq. (7) consists of the reflected amplitude at depth z ($\sqrt{R(z)}$), the Doppler shift or carrier frequency generated by the variation of the optical path length difference between sample and reference arm ($\cos(2k_0\Delta z)$), and the interference fringes envelope ($\exp(-(\Delta z/\Delta l)^2)$), which describes the width of the interference pattern, respectively. The depth resolution is determined by the width Δl of the interference pattern, and Eq. (8) shows the relation between axial or depth resolution and the spectral width of the source in OCT. The broader the source (larger $\Delta\lambda$), the smaller the coherence length Δl, that is, the better the axial resolution. The availability of sources with very broad spectral widths over the past decade has increased the axial (depth) resolution of OCT from 15 μm to approximately 2 to 3 μm.[12] The lateral resolution in OCT is determined by the lateral size of the focused spot, in analogy to confocal microscopy.

18.4 PRINCIPLE OF OCT: SPECTRAL DOMAIN OCT

Spectral domain OCT is an alternative implementation of the time domain OCT technology. The first SD/FD-OCT implementation was reported in 1995.[5] Figure 3 shows the basic configuration of an SD/FD-OCT system.

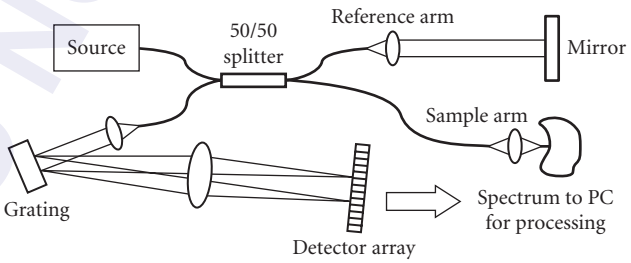

FIGURE 3 Basic configuration of an SD/FD-OCT system. Light from a broadband light source is split into a sample and a reference arm. The mirror in the reference arm is stationary. After reflection, the sample and reference arm light is recombined and interferes. In the detection arm, the light is dispersed by a grating and each wavelength is focused on an element in a detector array. (*Reproduced from Ref. 13 with permission from the Biophysical Society.*)

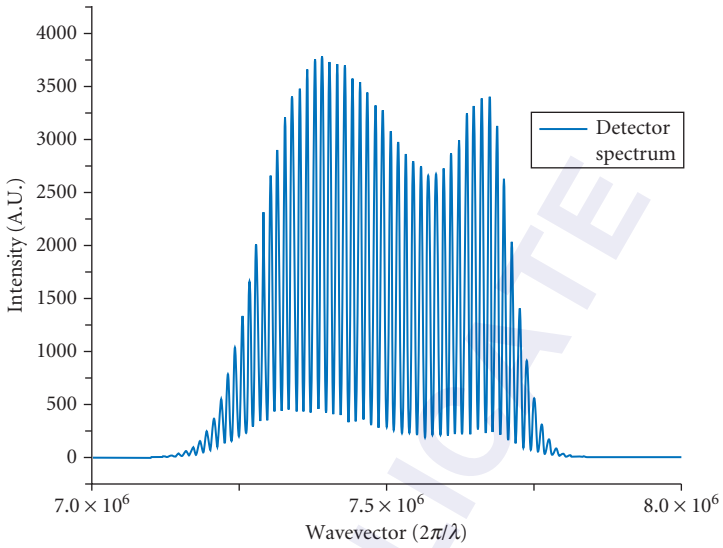

FIGURE 4 Spectrally resolved interference pattern as detected by the spectrometer in the detection arm of an SD-OCT system with a single reflector in the sample arm. (*Reproduced from Ref. 13 with permission from the Biophysical Society.*)

The source light is split into a reference and sample arm. At recombination in the detection arm, the light interferes. In the detection arm, the light is spectrally dispersed by a grating, and each wavelength is focused on an element in a linear detection array by a lens. The path length difference between the sample and reference arm is determined by the spectrally resolved interference detected by the linear detection array. In Fig. 4, an example of such a spectrally resolved interference pattern is shown for a single reflector in the sample arm. The power reflected from the sample and reference arm was approximately equal, giving nearly full constructive and destructive interference fringes.

The interference pattern shown in Fig. 4 can be understood as follows: for wavelengths for which the path length difference between sample and reference arm is exactly a multiple of the wavelength we observe constructive interference, and for wavelengths for which the path length difference between sample and reference arm is $(N+0.5)\lambda$ we observe destructive interference. Mathematically, the interference spectrum is described by

$$I(k) = I_r(k) + I_s(k) + 2\sqrt{I_s(k)I_r(k)}\sum_n \alpha_n \cos(kz_n) \tag{9}$$

where $I_r(k)$ and $I_s(k)$ are the wavelength-dependent intensities reflected from reference and sample arms, respectively, and k is the wave number. The last term on the right-hand side of Eq. (9) represents the interference between light returning from the reference and sample arms. α_n is the square root of the sample reflectivity at depth z_n, and z_n is the path length difference between sample and reference arm. The summation sums over all reflective structures at location z_n in the sample arm. Equation (9) shows that the path length difference is encoded on the spectrum by the modulation term $\cos(kz_n)$. The modulation frequency as a function of wave vector is determined by the path length difference z_n. The larger the path length difference, the higher the modulation frequency. This also illustrates that the maximum path length difference (depth range) that can be measured is determined by the ability to measure high modulation frequencies as a function of wave vector. The spectral resolution of the spectrometer plays a crucial role in measuring these high modulation frequencies. In SD-OCT, the depth range z is inversely proportional to the spectral resolution $\delta\lambda$ of the spectrometer and given by[14]

$$z = \lambda_0^2/4n\delta\lambda \tag{10}$$

A depth profile or depth scan is obtained from the spectrum through a Fourier transformation [see Eq. (18) later in this chapter].

SD-OCT provides a significant advantage in sensitivity or equivalently signal to noise ratio (SNR), that despite reports as early as 1997[14,15] has taken about half a decade to be recognized fully by the OCT community.[7,16,17] The first demonstration of SD-OCT for in vivo retinal imaging in 2002[18] was followed by a full realization of the sensitivity advantage by video rate in vivo retinal imaging,[10] including high speed three-dimensional volumetric imaging,[19] ultra high resolution video rate imaging,[20,21] and Doppler blood flow determination in the human retina.[22,23] The superior sensitivity of SD-OCT, combined with the lack of need for a fast mechanical scanning mechanism, has opened up the possibility of much faster scanning without loss of image quality and provided a paradigm shift from point sampling to volumetric mapping of biological tissue in vivo. The technology has been particularly promising in ophthalmology.[24,25] Later in this chapter a detailed analysis of the sensitivity advantage of SD-OCT is presented.

18.5 PRINCIPLE OF OCT: OPTICAL FREQUENCY DOMAIN IMAGING

In SD-OCT the spectrally resolved interference fringes are detected by a spectrometer in the detection arm. The same information can be obtained by scanning a narrowband source over a large wavelength range, and detecting the light with a single detector. In this case, the wavelength is encoded as a function of time. This technique, optical frequency domain imaging (OFDI) or swept source OCT (SS-OCT), gives the same sensitivity advantage as SD-OCT.[7,8] Figure 5 gives a basic

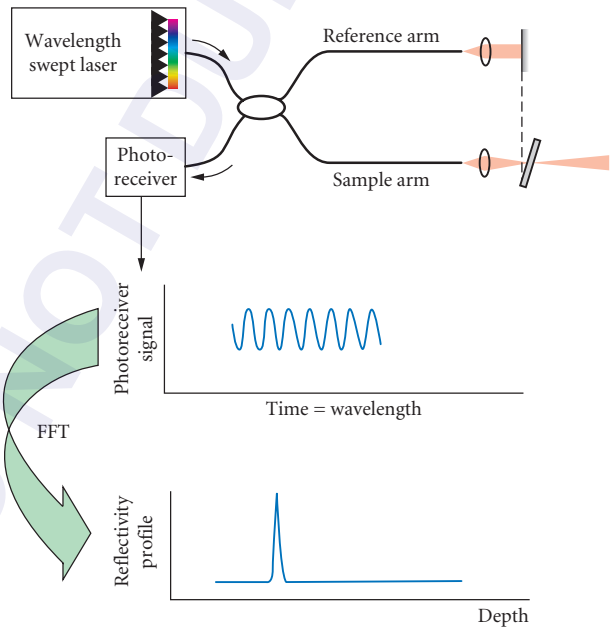

FIGURE 5 Basic OFDI configuration. A narrowband light source rapidly tunes over a wavelength range. Sample and reference arm light interferes in the detection arm. The light is detected by the photoreceiver as a function of time, where time is equivalent to wavelength or wave vector, giving the spectrally resolved interference fringes. A Fourier transform gives a reflectivity profile of the sample.

configuration of an OFDI or SS-OCT system. A narrowband laser source rapidly scans over a large wavelength range. The photo receiver detects the interference between sample and reference arm light as a function of time, where time is equivalent to wavelength or wave vector. A single wavelength scan gives the wavelength-resolved interference, which after a Fourier transform provides a single reflectivity profile of the sample.

OFDI has been demonstrated at 1300 nm in a variety of tissues. In ophthalmology, OFDI has been demonstrated at a wavelength of 1050 nm[26] and 840 nm.[27] Particularly 1050 nm is an interesting wavelength for ophthalmology. It is well known that longer wavelengths penetrate deeper into biological tissue. This suggests that 1300 nm would provide deeper penetration in retinal tissue; however, the water absorption of 1300 nm is too large to image the retina through the vitreous humor. At 1050 there is a window where the water absorption is lower than at 1300 nm. The better penetration of 1050 nm over 800 nm into the retinal layers and the choroid is demonstrated in Fig. 6 and Ref. 28 in a comparison between an OFDI system at 1050 nm and an SD-OCT system at 840 nm. The better visualization below of the retinal pigmented epithelium layer and into the choroid could be particularly useful for the diagnosis of age-related macular degeneration (AMD).[29]

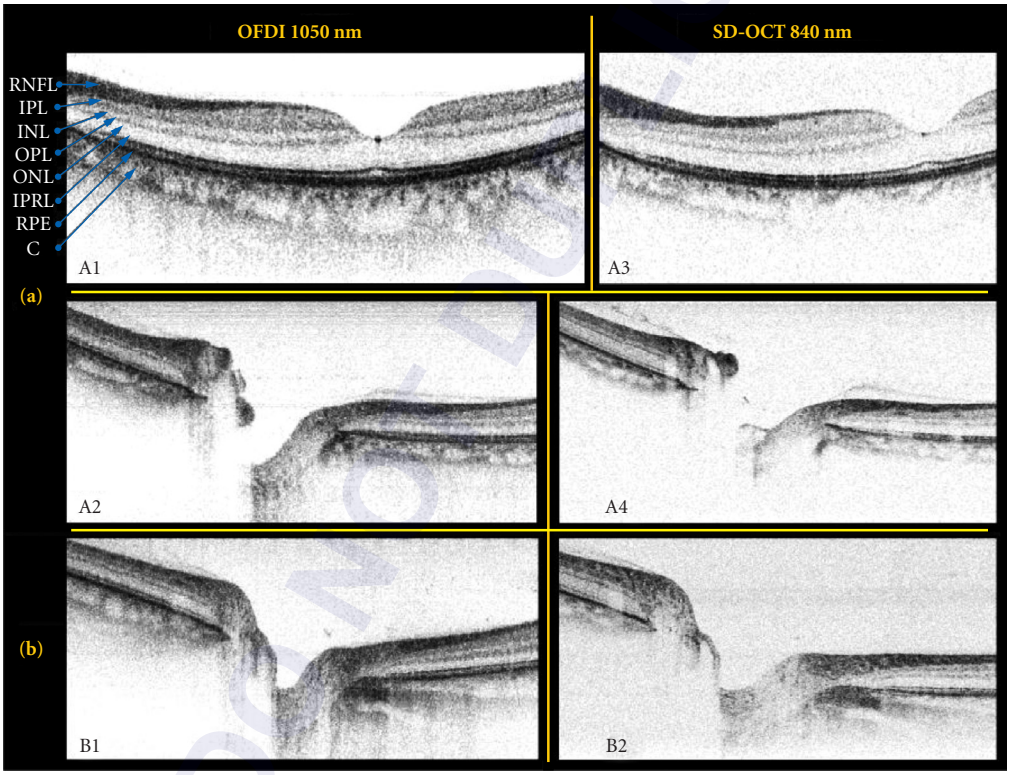

FIGURE 6 Comparison of two imaging systems (OFDI at 1050 nm and SD-OCT at 840 nm). **A1** and **A2**: OFDI images at fovea and optic nerve head, respectively, from volunteer A, 36-year-old Asian male. **A3** and **A4**: SD-OCT images from the same volunteer at similar tissue locations. **B1** and **B2**: OFDI and SD-OCT images, respectively, obtained from volunteer B, 41-year-old Caucasian male. OFDI images exhibit considerably deeper penetration in tissue than SD-OCT images in all the data sets. The OFDI image (**A1**) shows the anatomical layered structure: RNFL, retinal nerve fiber layer; IPL, inner plexiform layer; INL, inner nuclear layer; OPL, outer plexiform layer; ONL, outer nuclear layer; IPRL, interface between the inner and outer segments of the photoreceptor layer; RPE, retinal pigmented epithelium; and C, choriocapillaris and choroid. 18.6 SD-OCT VERSUS OFDI

The best choice for a particular OCT technology in ophthalmology depends on a number of factors. Currently, SD-OCT is the preferred implementation at wavelengths around 800 nm, due to the availability of high performance silicon array detectors and the difficulty to create robust rapid tunable sources in this wavelength range. At wavelengths of 1050 and 1300 nm, OFDI is the preferred implementation due to the availability of a key component for a rapid tunable source at these wavelengths, a high performance semiconductor optical amplifier (SOA), and the relatively poor performance of InGaAs detector arrays. Other considerations that play a role are the relative ease with which to construct a broadband light source compared to a broadband rapid tunable source, favoring SD-OCT. On the other hand, SD-OCT suffers from sensitivity decay as a function of depth, limiting the effective depth range to about 1 mm, that will be detailed further below. Experimental OFDI systems have in general demonstrated an effective depth range that is 2 to 4 times better than SD-OCT. In cases where a large effective depth range is required, for example, imaging the cornea, or imaging patients with deep optic nerve head cupping, OFDI has an advantage.

18.7 SENSITIVITY ADVANTAGE OF SD-OCT OVER TD-OCT

In the standard time-domain (TD) implementation of OCT, the position of the reference mirror in the interferometer is rapidly scanned by mechanical means in order to obtain a depth profile (A-line) within a sample. In SD/FD-OCT, no mechanical scanning of the reference arm is required. Instead, the cross-spectral density at the detection arm of the interferometer is measured by means of a spectrometer.[5,14,30] Although this method has long been proposed and demonstrated, only recently have there been efforts to explicitly show that SD-OCT can produce a better detection sensitivity than the time domain method.[7,16,17] SD-OCT does not require scanning of the reference arm length and therefore has the potential for faster image acquisition rates. High speed line scan cameras in the spectrometer with an integration time as small as 34 and even 16 μs permit the acquisition of A-lines at a rate of 30 to 60 kHz. Recent work has experimentally demonstrated a 148-fold (21.7 dB) sensitivity improvement of SD-OCT[10] and a near shot noise limited performance. Shot noise is a fundamental noise source that cannot be improved upon.

In essence the SNR advantage of SD-OCT over TD-OCT is based on the significant reduction of noise obtained by replacing the single-element detector with a multielement array detector. In a TD-OCT system, each wavelength is uniquely encoded as a frequency, and shot noise has a white noise characteristic. In a single detector TD-OCT system, the shot noise generated by the power density at one particular wavelength is present at all frequencies, and therefore adversely affects the SNR at all other wavelengths. By spectrally dispersing each wavelength to a separate detector, the cross shot noise term is eliminated in both hybrid and fully parallel SD-OCT systems.[17]

18.8 NOISE ANALYSIS OF SD-OCT USING CHARGE COUPLED DEVICES (CCDs)

The core of an SD-OCT system is the spectrometer in the detection arm. In general, light detection in the spectrometer is achieved by a charge coupled device (CCD) like a line array. Alternative implementations have been suggested that require individual processing of pixel charges.[31] Here we will treat the noise analysis based on a simple integrating CCD. To facilitate the noise analysis in the

case of detection by CCDs, the signal and noise terms will be expressed in charge squared (e^2). In SD-OCT the signal S_{SD} given by,[16,17]

$$S_{SD} = \frac{\eta^2 e^2 P_{ref} P_{sample} \tau_i^2}{E_v^2} \ (e^2) \tag{11}$$

with η the quantum efficiency of the detector, e the electron charge, P_{ref} and P_{sample}, respectively, the reference arm and sample arm power at the detection arm fiber tip, τ_i the integration time, and E_v the photon energy.

In the noise analysis, it is generally assumed that the reference arm power is much larger than the sample arm power, and the shot noise and relative intensity noise (RIN) contributions of the sample arm power to the noise are neglected.[32] The read-out and dark noise, shot noise, and RIN contributions to the overall noise in electrons squared per read-out cycle are then given by, respectively,[16,17]

$$\sigma_{noise}^2 = \sigma_{r+d}^2 + \frac{\eta e^2 P_{ref} \tau_i}{E_v} + \left(\frac{\eta e P_{ref}}{E_v}\right)^2 \tau_i \tau_{coh} \ (e^2) \tag{12}$$

with σ^2_{r+d} the sum of read-out noise and dark noise, and $\tau_{coh} = \sqrt{2\ln 2/\pi}\,\lambda_0^2/c\delta\lambda$ the coherence time, with c the speed of light.[33] A close look at Eq. (12) shows that the noise consists of a constant term (σ^2_{r+d}), a term that linearly increases with the reference arm power (shot noise) and a term that quadratically increases with the reference arm power (RIN). The signal [Eq. (11)] increases linearly with the reference arm power. The signal to noise ratio (SNR) determines the performance of the system. Since the shot noise is the limiting noise term that cannot be improved upon, the optimal signal to noise performance is achieved when shot noise dominates both read-out noise and RIN.[32] When shot noise dominates the noise, both the signal [Eq. (11)] and the noise [Eq. (12)] increase linearly with the reference arm power and the SNR is constant. Shot noise dominates read-out noise and dark noise when $\eta e^2 P_{ref} \tau_i / \sigma^2_{r+d} E_v > 1$, and shot noise dominates RIN when their ratio is larger than 1, that is, $E_v / \eta P_{ref} \tau_{coh} > 1$. The optimal reference arm power is found when read-out noise and dark noise are equal to the RIN.[34]

$$\sigma^2_{r+d} = \left(\frac{\eta e P_{ref}}{E_v}\right)^2 \tau_i \tau_{coh} \tag{13}$$

Thus for a system to operate close to shot-noise-limited performance, shot noise should dominate thermal and RIN noise at the optimal reference arm power

$$P_{ref} = \frac{\sigma_{r+d} E_v}{\eta e \sqrt{\tau_i \tau_{coh}}} \tag{14}$$

At this optimal reference arm power, the inequalities describing shot noise dominance over read-out noise and RIN, respectively, reduce to the same equation

$$\frac{e\sqrt{\tau_i}}{\sigma_{rd}\sqrt{\tau_{coh}}} > 1 \tag{15}$$

In general, one would like to choose the integration time τ_i as short as possible, and the coherence time τ_{coh} as long as possible. The coherence time is inversely related to the spectral resolution of the spectrometer which in turn relates linearly to the maximum depth range of the system. In conclusion, the parameter that most determines the system performance is the read-out and dark noise of the detector σ_{rd}.

18.9 SIGNAL TO NOISE RATIO AND AUTOCORRELATION NOISE

In the shot noise limit, the following expressions are found for the SNR in the time domain[32] and the spectral domain,[17] where the expression for the spectral domain can also be derived by the ratio of Eqs. (11) and (12)

$$\mathrm{SNR}_{\mathrm{TD}} = \frac{\eta P_{\mathrm{sample}}}{E_v \mathrm{BW}} \qquad \mathrm{SNR}_{\mathrm{SD}} = \frac{\eta P_{\mathrm{sample}} \tau_i}{E_v} \tag{16}$$

where η is the spectrometer efficiency, P_{sample} is the sample arm power returning to the detection arm, BW is the electronic detection bandwidth in a time domain system, τ_i is the detector integration time, and E_v is the photon energy. The electronic signal bandwidth BW is centered at the carrier frequency given by the Doppler shift [see Eq. (7)] and the bandwidth is proportional to the spectral width of the source and the velocity of the reference arm mirror. A detailed numerical comparison between the SNR in the time and spectral domain showed a more than 2 orders better SNR in the spectral domain.[10] Unlike the SNR in the time domain, Eq. (16) demonstrates that in the shot noise limit, SNR_{SD} is independent of the spectral width of the source. This implies that the axial resolution can be increased at no penalty to the SNR, provided that the full spectral width of the source can be imaged onto an array detector. However, this result should be interpreted with some care. The sample arm power returning to the detection arm is assumed to come from a single reflecting surface. In tissue, however, the reflected power comes from multiple structures along a depth profile. The SNR for a particular position along the depth profile is given on average by the total power reflected by all structures within the coherence length of the source. As the resolution increases (the coherence length decreases), the total reflected power within the coherence length decreases. As a consequence, the SNR at a particular position along the depth profile will reduce as the resolution increases by increasing the source optical bandwidth.

In SD-OCT the depth information is obtained by a Fourier transform of the spectrally resolved interference fringes. The detected interference signal at the spectrometer may be expressed as[14]

$$I(k) = I_r(k) + I_s(k) + 2\sqrt{I_s(k) I_r(k)} \sum_n \alpha_n \cos(k z_n) \tag{17}$$

where $I_r(k)$ and $I_s(k)$ are the wavelength-dependent intensities reflected from reference and sample arms, respectively, and k is the wave number. The last term on the right-hand side of Eq. (17) represents the interference between light returning from reference and sample arms. α_n is the square root of the sample reflectivity at depth z_n. Depth information is retrieved by performing an inverse Fourier transform of Eq. (16), yielding the following convolution[14]

$$\left| FT^{-1}[I(k)] \right|^2 = \Gamma^2(z) \otimes \left\{ \delta(0) + \sum_n \alpha_n^2 \delta(z - z_n) + \sum_n \alpha_n^2 \delta(z + z_n) + O\left[I_s^2 / I_r^2 \right] \right\} \tag{18}$$

with $\Gamma(z)$ representing the envelope of the coherence function. The first term in the braces on the right-hand side describes the autocorrelation signal from the reference arm and has magnitude unity. The second and third terms are due to interference between light returning from reference and sample arms and form two images, where each has magnitude on the order of I_s/I_r. These two terms provide mirror images, where one is retained. The final term, with magnitude on the order of I_s^2/I_r^2, describes autocorrelation noise due to interference within the sample arm.[14,18] I_s and I_r represent the total intensity reflected from sample and reference arm, respectively. Sample autocorrelation noise is generated by the interference of light reflected at different depth locations in the sample. Equation (18) indicates that the relative contribution of sample autocorrelation noise can be reduced by increasing the reference arm power with respect to the signal. Decreasing the detector

integration time permits an increase in the reference arm power without saturating the detector, decreasing the ratio I_s^2 / I_r^2 and consequently reducing the contribution of autocorrelation noise in ultrahigh-speed SD-OCT.

18.10 SHOT-NOISE-LIMITED DETECTION

In this section we take a closer look at the different noise components described in Eq. (12) for an actual system. In an SD-OCT system the sample arm was blocked, and only the reference arm light was detected by the spectrometer. One thousand spectra were recorded at an acquisition rate of 29.3 kHz. The read-out and shot noise are shown in Fig. 7.

The noise was determined by calculating the variance at each camera pixel over 1000 consecutive spectra. Dark noise measurements were taken with the source light off. Only light returning from the reference arm was used to measure the shot noise and RIN in the system. The shot noise and RIN are given by the second and third term on the right-hand side of Eq. (12), expressed in number of electrons squared. Taking into account only the shot and dark + read-out noise, the measured variance is proportional to

$$\sigma^2(\lambda) \sim \frac{P_{\text{ref}}(\lambda)}{E_v} + \sigma_{r+d}^2 \tag{19}$$

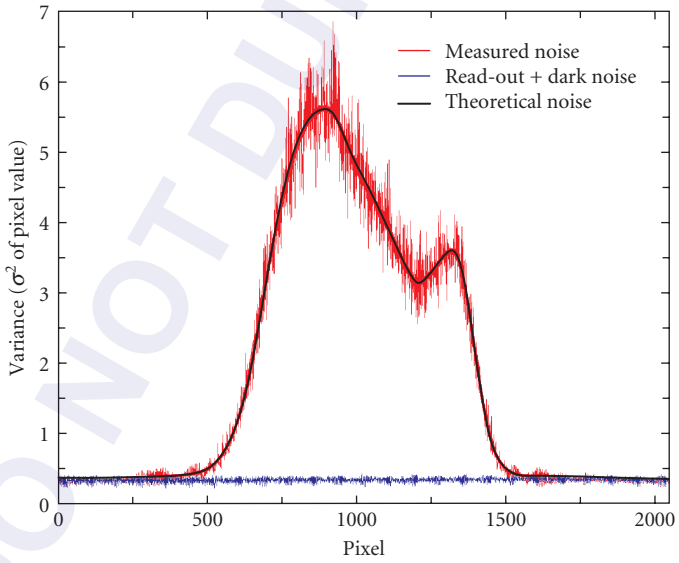

FIGURE 7 Noise analysis of an SD-OCT system. The variance (vertical axis) was calculated as a function of wavelength (pixel number, horizontal axis) for 1000 consecutive spectra. Both the read-out + dark noise (blue curve, no illumination) and the shot noise (red curve, illumination by reference arm only) were determined. The theoretical shot noise curve was fit using Eq. (19) to the measured noise. The excellent fit of the theoretical shot noise curve to the measured noise demonstrates that RIN was significantly smaller than shot noise and did not contribute. (*Reproduced from Ref. 19 with permission from the Optical Society of America.*)

The first term on the right-hand side of Eq. (19) is the shot noise contribution which is linearly proportional to the reference arm power, and the second term is the dark and read-out contribution to the noise. Equation (19) was fit to the measurements, limiting the fit to the central 700 pixels. Relative intensity noise (RIN) was not dominant in this setup, as experimentally demonstrated by the excellent fit of only the shot noise and dark and read-out noise to the measured noise in Fig. 7, and theoretically since the maximum power per pixel (4.6 nW) at a 34.1 μs integration time does not meet the criteria for RIN dominated noise.[10] This demonstrates shot-noise-limited performance of an SD-OCT system.

18.11 DEPTH DEPENDENT SENSITIVITY

In SD-OCT, signal sensitivity is strongly dependent on depth within an image. To characterize system sensitivity as a function of ranging depth, 1000 A-lines were acquired at an acquisition speed of 34.1 μs/A-line for 9 different positions of a weak reflector in the sample arm. The reflected sample arm power was 1.18 nW for all reflector positions. The noise floor decayed by 5 dB between a depth of 500 μm and 2 mm, and the peak signal dropped by 21.7 dB over the first 2 mm. Due to fixed-pattern noise, the true noise floor could not be determined between 0 and 500 μm. After zero-padding before the FFT to correct wavelength-mapping errors from pixel to wave vector, a 16.7 dB loss in peak signal was noted across the first 2 mm, whereas the noise level dropped by only 0.4 dB between 500 μm (35.1 dB) and 2 mm (34.7 dB) (Fig. 8). The zero-padding method produced a nearly constant noise level and improved the signal by more than 5 dB at the greatest depths in the scan. Although zero-padding did not change the local SNR, this method eliminated the shoulders that are present at larger scan depths.[7] The decay in both the signal and the noise level across the entire scan

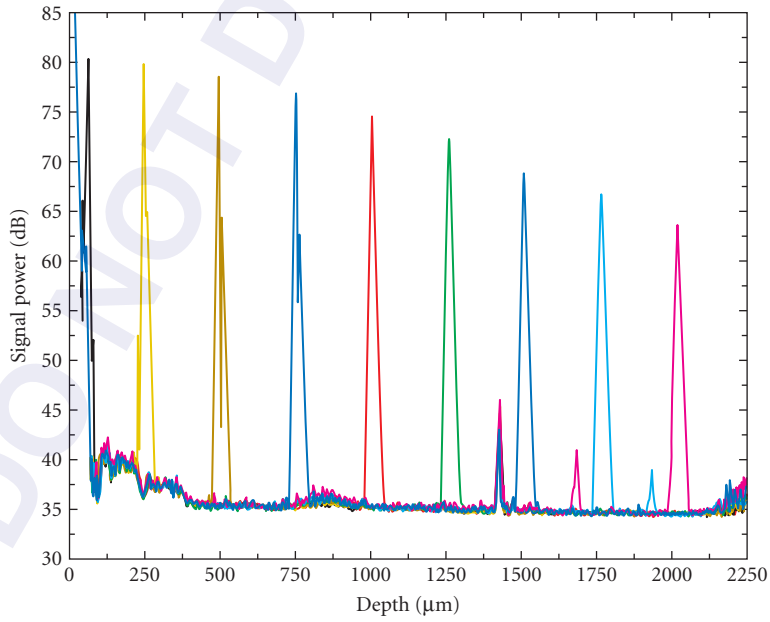

FIGURE 8 The depth dependent loss in signal sensitivity from a weak reflector. The signal decayed 16.7 dB between 0 and 2 mm. The peaks at 1.4, 1.6, and 1.85 mm are fixed-pattern noise. (*Reproduced from Ref. 19 with permission from the Optical Society of America.*)

length of 2.4 mm have been theorized to amount to 4 dB as a result of the finite pixel width.[16] As demonstrated by the experimental data, the noise level decayed by less than 4 dB over the entire scan length, which we attribute to the statistical independence of the shot noise between neighboring pixels of the array. Thus, the finite pixel width does not introduce a decay of the noise level.

The finite spectrometer resolution introduces a sensitivity decay[34] similar to that introduced by the finite pixel size.[16] Convolution of the finite pixel size with the Gaussian spectral resolution yields the following expression for the sensitivity reduction, R, as a function of imaging depth, z[34]

$$R(z) = \frac{\sin^2(\pi z/2d)}{(\pi z/2d)^2} \exp\left[-\frac{\pi^2\omega^2}{8\ln 2}\left(\frac{z}{d}\right)^2\right] \tag{20}$$

where d is the maximum scan depth and ω is the ratio of the spectral resolution to the sampling interval. Equation (20) was fit to the signal decay data presented in Fig. 8 with ω as a free parameter, and the result is shown in Fig. 9. Due to its proximity to the autocorrelation peak, the first data point was not included in the fit. The value for ω obtained from the fit was 1.85, demonstrating that the working spectral resolution was 0.139 nm.

The SNR was determined by the ratio of the peak at 250 μm (79.8 dB) and the noise level. Due to the fixed-pattern noise at 250 μm, the noise level was determined to be 35.2 dB by extrapolation of the linear region between 0.5 and 2 mm. The resulting SNR of 44.6 dB for 1.18 nW returning to the detection arm was 2.2 dB below the theoretical value given by Eq. (16) of 46.8 dB, for an integration time of 34.1 μs, a central wavelength of 840 nm, and a spectrometer efficiency of 28 percent. With 600 μW of power incident on an ideal reflector in the sample arm, the measured power returning to the detection arm was 284 μW. The sum of the SNR at 1.18 nW (44.6 dB) and the 10 log ratio of maximum (284 μW) over measured (1.18 nW) power (53.8 dB) gives a sensitivity of 98.4 dB.

18.12 MOTION ARTIFACTS AND FRINGE WASHOUT

As OCT utilizes lateral point-scanning, motion of the sample or scanning beam during the measurement causes SNR reduction and image degradation in SD-OCT and OFDI.[35] Yun et al. theoretically investigated axial and lateral motion artifacts in continuous wave (CW) SD-OCT and swept-source OFDI, and experimentally demonstrated reduced axial and lateral motion artifacts using a pulsed source and a swept source in endoscopic imaging of biological tissue.[35,36] Stroboscopic illumination in full field OCT was demonstrated, resulting in reduced motion artifacts for in vivo measurement.[37] In ophthalmic applications of SD-OCT, SNR reduction caused by high speed lateral scanning of the beam over the retina may be dominant over axial patient motion. Using pulsed illumination reduces lateral motion artifacts and provides a better SNR for in vivo high-speed human retinal imaging.[38]

18.13 OFDI AT 1050 NM

An alternative technique to SD-OCT is optical frequency domain imaging (OFDI).[8] In OFDI, a rapidly tuned laser source is used and the spectrally resolved interference fringes are recorded as a function of time in the detection arm of the interferometer. Published results in healthy volunteers have shown that OFDI has better immunity to sensitivity degradation due to lateral and axial eye motion, and has an effective ranging depth that is 2 to 2.5 times better than SD-OCT (depth dependent sensitivity decay of 6 dB over 2 to 2.5 mm).[8,26,27]

More importantly, recent research at 1050 nm spectral range has demonstrated a better retinal penetration depth,[26,28,39] particularly important for detecting retinal abnormalities at or below the retinal pigment epithelium (RPE). A wavelength of 1050 nm has less attenuation from scattering in opaque media, commonly seen in cataract patients.[40] Although the water absorption at 1050 nm is higher than in the 850 nm region, this is partially compensated by the approximately 3 times higher maximum permissible exposure according to the ANSI standards (1.9 mW at 1050 nm).[4]

Figure 10*a* depicts a schematic of a laser source for OFDI in a linear cavity configuration.[8,26] The gain medium was a commercially available, bi-directional semiconductor optical amplifier

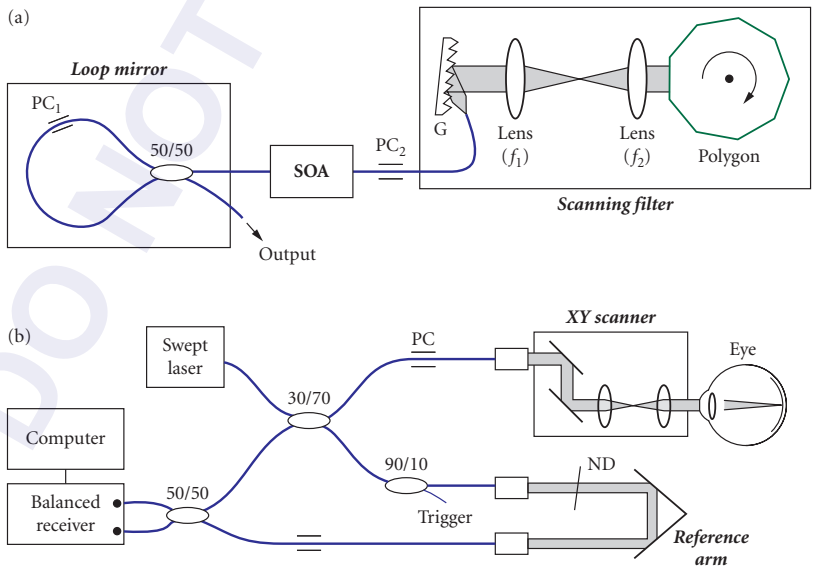

FIGURE 10 Experimental setup: (*a*) wavelength-swept laser and (*b*) OFDI system. (*Reproduced from Ref. 26 with permission of the Optical Society of America.*)

(QPhotonics, Inc., QSOA-1050) driven at an injection current level of 400 mA. One port of the amplifier was coupled to a wavelength-scanning filter[41] that comprises a diffraction grating (1200 lines/mm), a telescope ($f_1 = 100$ mm, $f_2 = 50$ mm), and a polygon mirror scanner (Lincoln Lasers, Inc., 40 facets). The design bandwidth and free spectral range of the filter were approximately 0.1 and 61 nm, respectively. The amplifier's other port was spliced to a loop mirror made of a 50/50 coupler. Sweep repetition rates of up to 36 kHz were possible with 100 percent duty cycle.

Figure 10*b* depicts the complete ophthalmic OFDI system.[26] The effective ranging depth was 2.4 mm (depth dependent sensitivity decay of 6 dB over 2.4 mm) due to the finite coherence length of the laser output.

The OFDI system acquired data as the focused sample beam was scanned over an area of 6 (horizontal) by 5.2 mm (vertical) across the macular region in the retina. Each image frame in the three-dimensional volume was constructed from a thousand A-line scans. Given three-dimensional tomographic data of the eye's posterior segment, integrating the pixel values along the entire depth axis readily produces a two-dimensional fundus-type reflectivity image.[42,43] Figure 11*a* depicts an integrated reflectivity

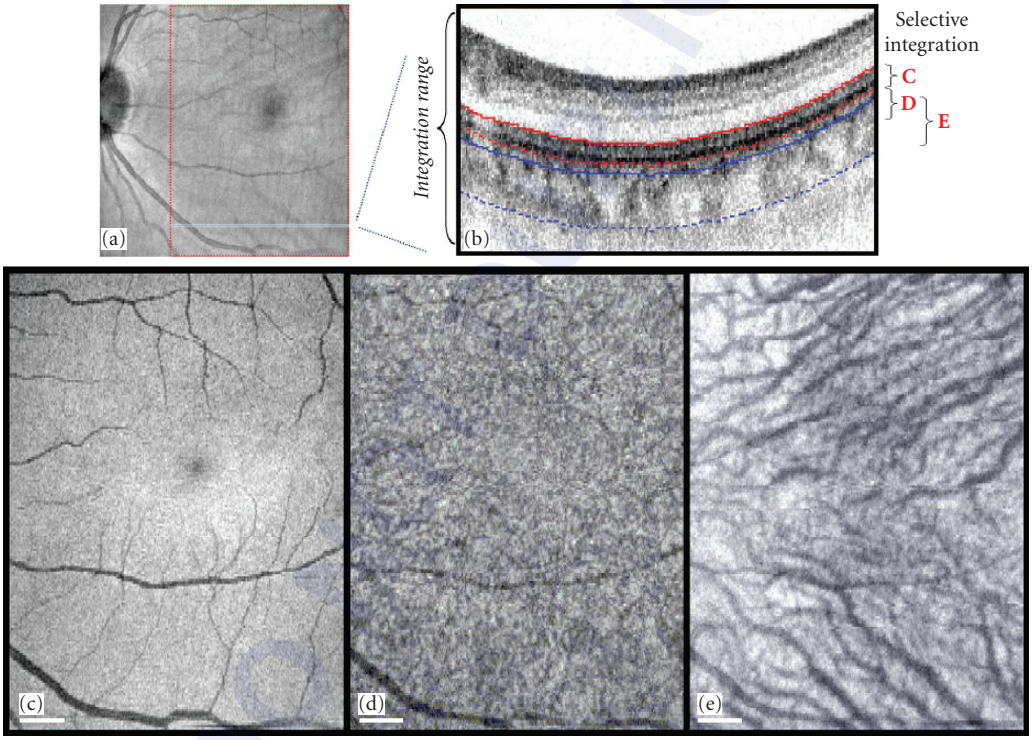

FIGURE 11 The retinal and choroidal vasculature extracted from a three-dimensional OFDI data set. (*a*) Two-dimensional reflectance image (5.3 × 5.2 mm^2) obtained with the conventional full-range integration method. Higher (lower) reflectivity is represented by white (black) in the grayscale. (*b*) Illustration of the axial-sectioning integration method, with the different integration regions labeled C,D,E corresponding to the following fundus-type reflectivity images, respectively: (*c*) retinal reflectivity image showing the shadow of retinal vasculature (3.8 × 5.2 mm^2), (*d*) reflectivity image obtained from the upper part of the choroid, and (*e*) reflectivity image from the center of the choroid revealing the choroidal vasculature. Shadows of retinal vasculature are also visible in (*d*) and (*e*). Scale bars: 0.5 mm. (*Figure reproduced from Ref. 26 with permission from the Optical Society of America.*)

image generated from the entire OFDI image sequence. The image visualizes the optic nerve head, fovea, retinal vessels, and the faint outline of the deep choroidal vasculature; however, the depth information is completely lost. To overcome this limitation of the conventional method, we integrated only selective regions based on anatomical structures. For example, to visualize the retinal vasculature with maximum contrast, we used automatic image segmentation techniques[43] and integrated the reflectivity in the range between IPRL and RPE (marked by red lines and labeled C in Fig. 11*b*), where the shadow or loss of signal created by the retinal vessels above appeared most distinctly.[42] Integrating over the entire retina, including the vessel, often results in a lower contrast in the vasculature because retinal blood vessels produce large signals by strong scattering. Figure 11*c* depicts the fundus-type reflectivity image (shadow) of the retinal vessels produced with this depth-sectioning method. The choriocapillary layer contains abundant small blood vessels and pigment cells. Using a thin integration region in the upper part of choroid (labeled D in Fig. 11*b*), we also obtained an image of the choriocapillary layer (Fig. 11*d*). To obtain an image of the complete choroid region, we used the bottom integration region (marked by blue lines and labeled E in Fig. 11*b*). The choroidal vasculature is clearly visualized in the resulting reflectivity image (Fig. 11*e*).

Figure 12 demonstrates OFDI at 1050 nm in an AMD patient. The left and right panel show images at the same location pre- and posttreatment with anti-VEGF therapy. The advantage of 1050 nm is a better penetration below the retinal pigmented epithelium (RPE), providing detailed information of what is believed to be type I vascularization between the RPE and Bruchs membrane (presumed sub-RPE CNV).

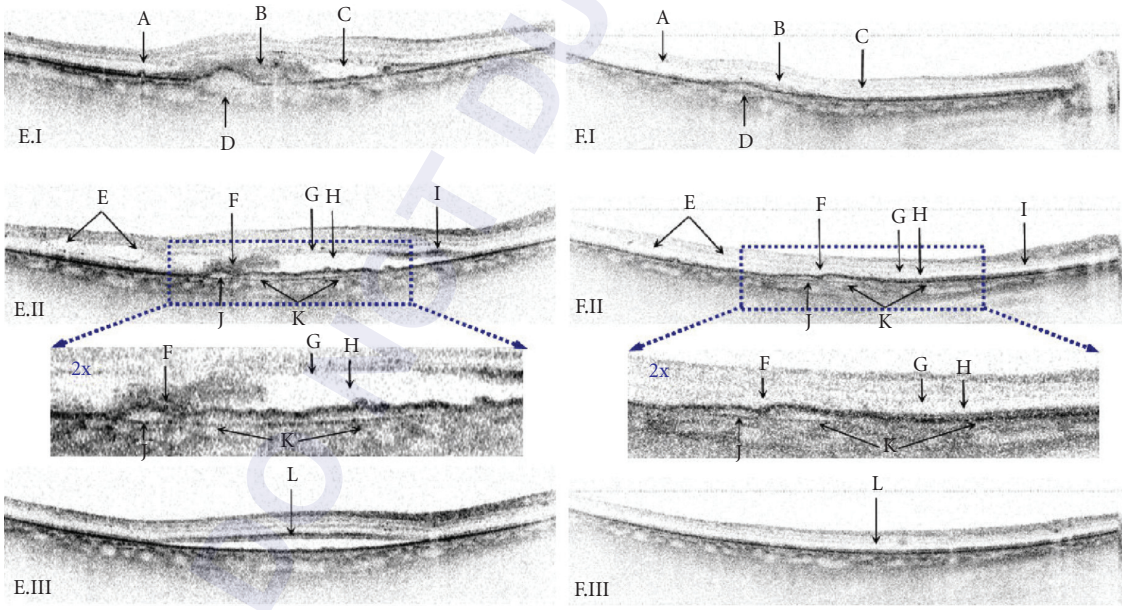

FIGURE 12 OFDI images at 1050 nm of an AMD patient pretreatment: E.I-III, and posttreatment: F.I-III. Features—A: drusen, B: blood clot, C: subretinal fluid, D: RPE detachment, E: cystic changes, F: blood clot, G: weak scattering in photoreceptors, H: subretinal fluid, I: strong scattering in photoreceptors, J: RPE detachment, K: presumed sub-RPE CNV, and L: strong scattering from photoreceptors in the periphery of the subretinal fluid. 18.14 FUNCTIONAL EXTENSIONS: DOPPLER OCT AND POLARIZATION SENSITIVE OCT

Optical coherence tomography is an interferometric technique capable of noninvasive high-resolution cross-sectional imaging by measuring the intensity of light reflected from within tissue.[2] This results in a noncontact imaging modality that provides images similar in scale and geometry to histology. Just as different stains can be used to enhance the contrast in histology, various extensions of OCT allow for visualization of features not readily apparent in traditional OCT. For example, optical Doppler tomography[44] can enable depth-resolved imaging of flow by observing differences in phase between successive depth scans.[45–47] Polarization-sensitive OCT (PS-OCT) utilizes depth-dependent changes in the polarization state of detected light to determine the light polarization changing properties of a sample.[48–53]

18.15 DOPPLER OCT AND PHASE STABILITY

In the past, phase-resolved optical Doppler tomography (ODT) based on time domain OCT (TD-OCT) has proven able to make high-resolution, high-velocity-sensitivity cross-sectional images of in vivo blood flow.[45–47,54–59] ODT measurements of blood flow in the human retina have been demonstrated,[60,61] yet the accuracy and sensitivity was compromised by a slow A-line rate and patient motion artifacts, which can introduce phase inaccuracy and obscure true retinal topography. Originally, Doppler shifts were detected by the shift in the carrier frequency in TD-OCT systems, where a trade-off between Doppler sensitivity and spatial resolution had to be made.[54–56,62] The detection of Doppler shifts improved significantly with the method pioneered by Zhao et al.[45,46] In this method two sequential A-lines are acquired at the same location. Phase-resolved detection of the interference fringes permits the determination of small phase shifts between the interferograms. The phase difference $\Delta\varphi$ divided by the time laps ΔT between the sequential A-lines gives a Doppler shift $\Delta\omega = \Delta\varphi / \Delta T$, associated with the motion of the scattering particle. Figure 13 gives a graphical example of this method.

Combining optical Doppler tomography with the superior sensitivity and speed of SD-OCT has allowed a significant improvement in detecting Doppler signals in vivo. In the first combination of these technologies, velocity of a moving mirror and capillary tube flow was demonstrated,[63] followed by in vivo demonstration of retinal blood flow.[22,23]

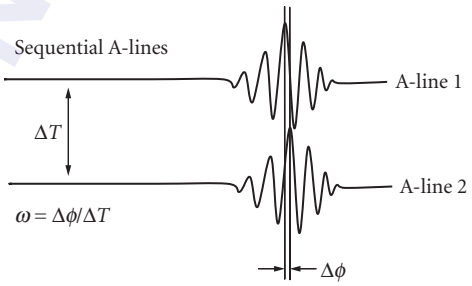

FIGURE 13 Principle of fast Doppler OCT. OCT depth profiles are acquired sequentially at the same location. Small motion of the scattering object results in a phase shift of the interference fringes. The phase difference divided by the time lapse between the sequential A-lines gives a Doppler shift due to the motion of the scattering object.

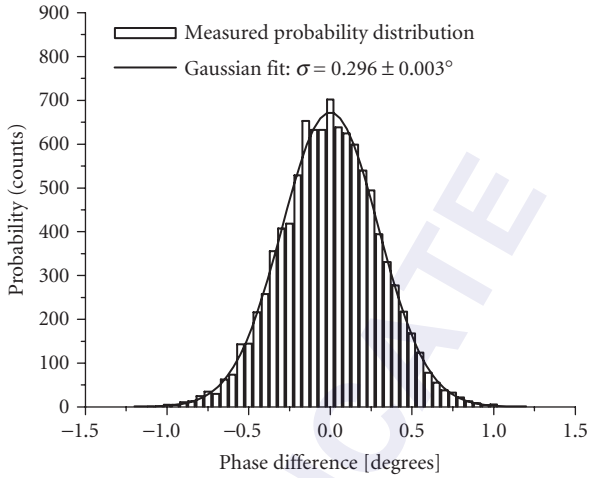

FIGURE 14 Probability distribution of the measured phase difference between adjacent A-lines, with a stationary reflector in the sample arm. Bars: Counted phase difference for 9990 A-lines. Bin size = 0.05°. Solid line: Gaussian fit to the distribution, with a measured standard deviation of 0.296 ± 0.003°. (*Reproduced from Ref. 23 with permission from the Optical Society of America.*)

In SD-OCT, a phase-sensitive image is generated by simply determining the phase difference between points at the same depth in adjacent A-lines. The superior phase stability of SD-OCT, due to the absence of moving parts, is demonstrated in Fig. 14. The data was acquired with a stationary mirror in the sample arm, without scanning the incident beam. Ideally, interference between sample and reference arm light should have identical phase at the mirror position for all A-lines. This condition underlies the assumption that any phase difference between adjacent A-lines is solely due to motion within the sample. The actual phase varies in a Gaussian manner about this ideal, as demonstrated in Fig. 14, where we present the measured probability distribution of phase differences with a standard deviation of 0.296 ± 0.003°. This value is over 25 times lower than previously quantified figures for time domain optical Doppler tomography systems,[59,64] and at an acquisition speed of 29 kHz corresponds to a minimum detectable Doppler shift of ±25 Hz. With a time difference of 34.1 μs between acquired A-lines, phase wrapping occurs at Doppler shifts greater than 15 kHz. Thus, the system dynamic range described by the ratio of maximum to minimum detectable Doppler shifts before phase wrapping occurs is a factor of 600.

In vivo images of structure and Doppler flow were acquired at 29 frames per second (1000 A-lines per frame) and subsequently processed. The images presented in Fig. 15 is 1.6 mm wide and has been cropped in depth to 580 μm, from their original size of 1.7 mm. The layers of the retina visible in the intensity image have been identified and described previously,[3] with the thick, uppermost layer being the nerve fiber layer, and the thinner, strongly scattering deep layer being the retinal pigmented epithelium. One can see the pulsatility of blood flow in the artery (a), while the flow in the vein (v) is less variable (see Ref. 23). At the lower left-center of the image, it is possible to distinguish blood flow deep within the retina (d). With reference to the intensity image, one can see that this blood flow is being detected *below* the retinal pigmented epithelium, and we believe this is the first time that optical Doppler tomography imaging techniques have been able to observe and localize blood flow within the choroid. To the left of the large vessel on the right-hand side of the image, note the appearance of a very small vessel (c). The diameter of this vessel is slightly under 10 μm.

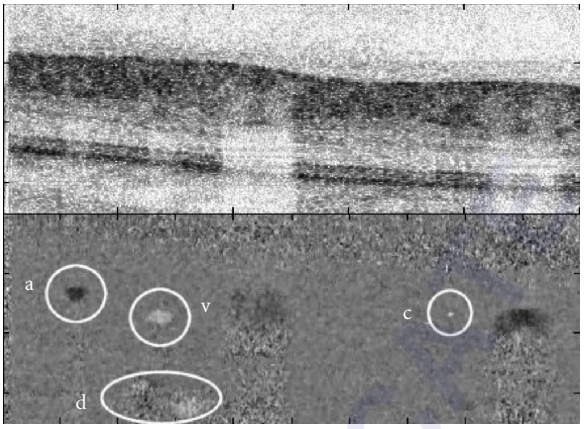

FIGURE 15 Movie of structure (top panel) and bi-directional flow (bottom panel) acquired in vivo in the human eye at a rate of 29 frames per second. The sequence contained 95 frames, totaling 3.28 s (see Ref. 23). Image size is 1.6 mm wide by 580 μm deep. a: artery; v: vein; c: capillary; and d: choroidal vessel. 18.16 POLARIZATION SENSITIVE OCT

Polarization-sensitive OCT (PS-OCT) utilizes depth-dependent changes in the polarization state of detected light to determine the light polarization changing properties of a sample.[48–53] These material properties, including birefringence, dichroism, and optic axis orientation, can be determined by studying the depth evolution of the Stokes parameters,[49–52,65–69] or by using the changing reflected polarization states to first determine Jones or Mueller matrices.[53,70–74] PS-OCT provides additional contrast to identify tissue structures. Nearly all linear tissue structures, like collagen, nerve fibers, and muscle fiber exhibit birefringence. PS-OCT has been used in a wide variety of applications. In dermatology the reduced birefringence in tumor tissue was observed due to the destruction of the extracellular collagen matrix by the tumor.[75] The reduced birefringence due to thermally denatured collagen was observed in burns.[67] In ophthalmology, the birefringence of the retinal nerve fiber was measured and found to depend on the location around the optic nerve head.[76,77] The onset and progression of caries lesions was associated with changes in birefringence of dental tissue.[78]

We will first treat the Jones formalism to describe polarization properties and use the Jones formalism to determine the polarization properties of tissue. The Jones formalism provides a convenient mathematical description of polarized light and polarization effects.[79] The complex electric field vector E can be decomposed into a pair of orthonormal basis vectors to yield

$$\mathbf{E} = E_p \hat{\mathbf{e}}_p + E_\perp \hat{\mathbf{e}}_\perp$$
$$E_p = a_p e^{-i\delta_p} \qquad E_\perp = a_\perp e^{-i\delta_\perp} \tag{21}$$

where $\hat{\mathbf{e}}_p$ and $\hat{\mathbf{e}}_\perp$ are unit vectors along the horizontal and vertical, a_p and $a_\perp$ are the amplitude along the horizontal and vertical, and δ_p and $\delta_\perp$ are the phase along the horizontal and vertical, respectively. In this case, the vibrational ellipse of the electric field can be reformulated as

$$\mathbf{E}_{\text{vib}}(t) = a_p \cos(\omega t + \delta_p)\hat{\mathbf{e}}_p + a_\perp \cos(\omega t + \delta_\perp)\hat{\mathbf{e}}_\perp \tag{22}$$

with ω the angular frequency and t time. The overall irradiance, or intensity, of the beam of light then can be expressed as the scalar quantity

$$I = a_p^2 + a_\perp^2 \tag{23}$$

It is worth noting that while the overall irradiance of a beam is not dependent on its polarization state, it is possible to measure irradiance along a particular orientation (e.g., the intensity of a beam in the horizontally polarized direction).

Linear polarization states occur for phase differences $\Delta\delta = \delta_p - \delta_\perp = m\pi$, where $m \in \mathbb{Z}$, as the vibrational ellipse collapses to a line described by

$$\mathbf{E}_{\text{vib}}(t) = (a_p \hat{\mathbf{e}}_p + (-1)^m a_\perp \hat{\mathbf{e}}_\perp)\cos(\omega t + \delta_p) \tag{24}$$

The orientation of the linear polarization state depends on the ratio of amplitudes a_p and $a_\perp$. The polarization state of light is horizontal or vertical when $a_\perp = 0$ or $a_p = 0$, respectively, and oriented at $\pm 45°$ if $|a_p| = |a_\perp|$. An orientation angle θ can then be defined according to the relations

$$\begin{aligned} a_p &= a\cos\theta \qquad a_\perp = a\sin\theta \\ a &= \sqrt{a_p^2 + a_\perp^2} \qquad \theta = \tan^{-1}\frac{a_p}{a_\perp} \end{aligned} \tag{25}$$

where a can be thought of as an overall amplitude of the electric field and $\Delta\delta = 0$.

Circular polarization states are obtained when $|a_p| = |a_\perp|$ and $\Delta\delta = \frac{\pi}{2} + n\pi$, which is evident through the form of the resultant vibrational ellipse

$$\mathbf{E}_{\text{vib}}(t) = a_p(\cos(\omega t + \delta_p)\hat{\mathbf{e}}_p \pm \sin(\omega t + \delta_p)\hat{\mathbf{e}}_\perp) \tag{26}$$

This describes a circle, the handedness (left- or right-circular) of which is determined by the sign between the orthogonal components. Circular polarization states differ only in their phase difference compared to linearly polarized light at 45°, and so the phase difference $\Delta\delta$ between orthogonal electric field components reflects the ratio between circular and linear components of the polarization state. Figure 16 gives a graphical representation of the different vibrational ellipses

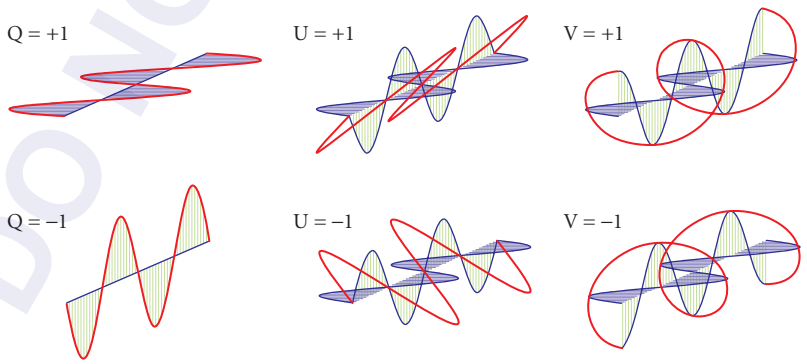

FIGURE 16 Vibrational ellipses for various polarization states Q = 1 and Q = –1 correspond to horizontal and vertical linear polarized light. U = 1 and U = –1 correspond to linear polarized light at +45 and –45°, and V = 1 and V = –1 correspond to circular polarized light, respectively.

The electric field decomposition in Eq. (21) can be rewritten as a complex 2-vector such that

$$\mathbf{E}=\begin{bmatrix}E_p\\E_\perp\end{bmatrix}=\begin{bmatrix}a_p e^{-i\delta_p}\\a_\perp e^{-\delta_\perp}\end{bmatrix}=ae^{-i\delta_p}\begin{bmatrix}\cos\theta\\e^{i\Delta\delta}\sin\theta\end{bmatrix} \tag{27}$$

while the time-invariant electric field vector **E**, also known as a Jones vector, does depend on the amplitude and exact phase of the electric field components, it should be noted that the polarization state itself is completely determined by the orientation angle θ and the phase difference $\Delta\delta$.

Just as two vectors of length n can be related using a matrix of dimension $n\times n$, two polarization states can be related using a complex 2×2 matrix known as a Jones matrix. The polarization properties of any nondepolarizing optical system can be described using a Jones matrix. The transmitted polarization state $\mathbf{E}'$ as a result of an optical system represented by a Jones matrix **J** acting on an incident polarization state **E** can be determined by

$$\mathbf{E}'=\begin{bmatrix}E'_p\\E'_\perp\end{bmatrix}=\begin{bmatrix}J_{11}&J_{12}\\J_{21}&J_{22}\end{bmatrix}\begin{bmatrix}E_p\\E_\perp\end{bmatrix}=\mathbf{JE} \tag{28}$$

Subsequent transmission of $\mathbf{E}'$ through an optical system $\mathbf{J}'$ results in a polarization state $\mathbf{E}''=\mathbf{J}'\mathbf{E}'=\mathbf{J}'(\mathbf{JE})=\mathbf{J}'\mathbf{JE}$. As a result, the combined polarization effect of a cascade of optical elements, $\mathbf{J}_1, \mathbf{J}_2, \ldots, \mathbf{J}$, can be described by the product $\mathbf{J}=\mathbf{J}_n\cdots\mathbf{J}_2\mathbf{J}_1$.

The Jones matrix for a birefringent material that induces a phase retardation η between electric field components parallel and orthogonal to a polarization state characterized by an orientation angle θ and a circularity related to ϕ is given by[80]

$$\mathbf{J}_b=\begin{bmatrix}e^{i\eta/2}C_\theta^2+e^{-i\eta/2}S_\theta^2 & (e^{i\eta/2}-e^{-i\eta/2})C_\theta S_\theta e^{-i\phi}\\(e^{i\eta/2}-e^{-i\eta/2})C_\theta S_\theta e^{i\phi} & e^{i\eta/2}S_\theta^2+e^{-i\eta/2}C_\theta^2\end{bmatrix} \tag{29}$$

where $C_\theta=\cos\theta$ and $S_\theta=\sin\theta$. The Jones matrix of a dichroic material with attenuation ratios of P_1 and P_2 for electric field components parallel and orthogonal, respectively, to a polarization state given by an orientation angle Θ and a circularity Φ has the form[80]

$$\mathbf{J}_d=\begin{bmatrix}P_1C_\Theta^2+P_2S_\Theta^2 & (P_1-P_2)C_\Theta S_\Theta e^{-i\Phi}\\(P_1-P_2)C_\Theta S_\Theta e^{i\Phi} & P_1S_\Theta^2+P_2C_\Theta^2\end{bmatrix} \tag{30}$$

As birefringence seems to be the primary polarization property exhibited by biological tissue, most PS-OCT analysis methods concentrate on determination of phase retardation. Schoenenberger et al.[81] analyzed system errors introduced by the extinction ratio of polarizing optics and chromatic dependence of wave retarders, and errors due to dichroism. System errors can be kept small by careful design of the system with achromatic elements, but can never be completely eliminated. In principle, dichroism is a more serious problem when interpreting results as solely due to birefringence. However, Mueller matrix ellipsometry measurements have shown that the error due to dichroism in the eye is relatively small,[82,83] and earlier PS-OCT work shows that dichroism is of minor importance in rodent muscle.[52] Despite this, a method for simultaneous determination of sample birefringence and dichroism is desirable, especially one that can be applied to systems with the unrestricted use of optical fiber and fiber components.

The nondepolarizing polarization properties of an optical system can be completely described by its complex Jones matrix, **J**, which transforms an incident polarization state, described by a complex electric field vector, $\mathbf{E}=[H,V]^T$, to a transmitted state, $\mathbf{E}'=[H',V']^T$. A Jones matrix can be decomposed in the form $\mathbf{J}=\mathbf{J}_R\mathbf{J}_P=\mathbf{J}_{P'}\mathbf{J}_{R'}$.[80] Birefringence, described by $\mathbf{J}_R$, can be parameterized by three variables: a degree of phase retardation η about an axis defined by two angles, γ and δ.

Diattenuation, described by $\mathbf{J}_P$, is defined as $d=\left(P_1^2-P_2^2\right)/\left(P_1^2+P_2^2\right)$ and can be parameterized by four variables, where P_1 and P_2 are the attenuation coefficients parallel and orthogonal, respectively, to an axis defined by angles Γ and Δ. These seven independent parameters, along with an overall common phase $e^{i\psi}$, account for all four complex elements of a general Jones matrix **J**. Assuming that birefringence and diattenuation arise from the same fibrous structures in biological tissue and thus share a common axis $\delta=\Delta$ and $\gamma=\Gamma$,[72] the number of independent parameters is reduced by two to five. In order to determine these five parameters, the sample needs to be probed by two unique polarization states. One incident and reflected polarization state yield three relations involving the two orthogonal amplitudes and the relative phase between them.[52] Therefore, it is possible to use the six relationships defined by two unique pairs of incident and reflected polarization states to exactly solve for the Jones matrix of a sample.

In general terms, a PS-OCT system sends polarized light from a broadband source into the sample and reference arms of an interferometer, and reflected light from both arms is recombined and detected. Figure 17 shows an example of a fiber-based PS-OCT system. The source light is send to a fiber-based polarization controller and a polarizer. The polarization of the incident state on the sample is modulate by a polarization modulator that allows switching between two polarization states. Light passes a circulator, which sends the light to a fiber-based beam splitter that splits the light into a sample and a reference arm. Upon reflection, the light is recombined in the beam splitter and the circulator sends the light to the detection arm where the light is split into two orthogonal polarization states before detection by two separate detectors. The optical path from source to detector can be described by three Jones matrices. Define $\mathbf{J}_{in}$ as the Jones matrix representing the optical path from the polarized light source (the polarization modulator) to the sample surface, $\mathbf{J}_{out}$ as that going from the sample surface to the detectors, and $\mathbf{J}_S$ as the round-trip Jones matrix for light propagation through a sample.[74] This nomenclature can be applied to all PS-OCT systems, ranging from bulk-optic systems[48,49,51–53,65] to those with fibers placed such that they are traversed in a round-trip manner,[73] to time-domain[66, 68] and spectral-domain[69] PS-OCT systems with the unrestricted use of optical fiber and nondiattenuating fiber components, and even for retinal systems,[76] where the polarization effects of the cornea can be included in $\mathbf{J}_{in}$ and $\mathbf{J}_{out}$. The electric field of light reflected from the

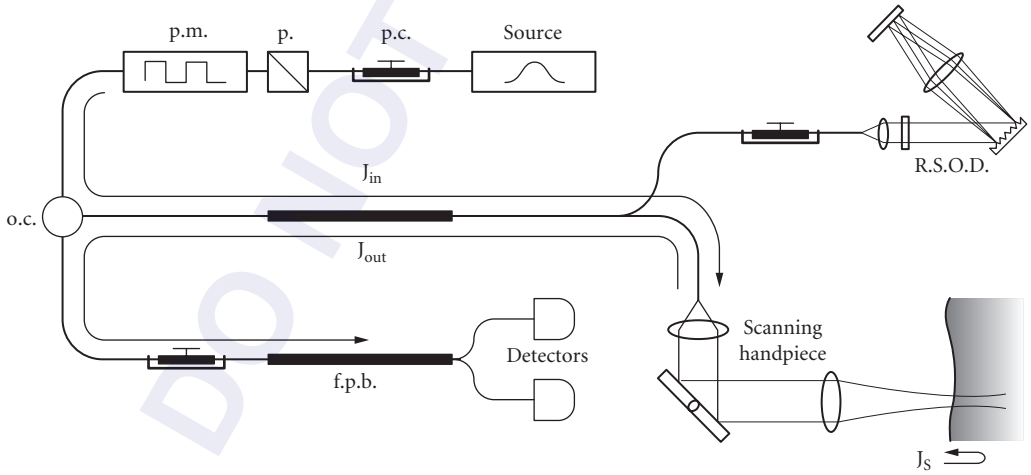

FIGURE 17 Schematic of the fiber-based PS-OCT system (p.c., polarization controller; p, polarizer; pm, polarization modulator; oc, optical circulator; RSOD, rapid scanning optical delay; and fpb, fiber polarizing beamsplitter). $\mathbf{J}_{in}$, $\mathbf{J}_{out}$, and $\mathbf{J}_S$ are the Jones matrix representations for the one-way optical path from the polarization modulator to the scanning handpiece, the one-way optical path back from the scanning handpiece to the detectors, and the round-trip path through some depth in the sample, respectively. (*Reprinted from Ref. 74 with permission from the Optical Society of America.*)

sample surface, $\mathbf{E}$, can be expressed as $\mathbf{E}=e^{i\psi}\mathbf{J}_{\text{out}}\mathbf{J}_{\text{in}}\mathbf{E}_{\text{source}}$, where ψ represents a common phase and $\mathbf{E}_{\text{source}}$ represents the electric field of light coming from the polarized source. Likewise, the electric field of light reflected from some depth within the tissue may be described by $\mathbf{E}'=e^{i\psi'}\mathbf{J}_{\text{out}}\mathbf{J}_S\mathbf{J}_{\text{in}}\mathbf{E}_{\text{source}}$. These two measurable polarization states can be related to each other such that $\mathbf{E}'=e^{i\Delta\psi}\mathbf{J}_T\mathbf{E}$, where $\mathbf{J}_T=\mathbf{J}_{\text{out}}\mathbf{J}_S\mathbf{J}_{\text{out}}^{-1}$ and $\Delta\psi=\psi'-\psi$. Thus, $\mathbf{J}_T$ can be determined by comparing the polarization state reflected from the surface and from a certain depth in the sample. Now we need to determine how to extract $\mathbf{J}_S$ from $\mathbf{J}_T$.

If the optical system representing $\mathbf{J}_{\text{out}}$ is nondiattenuating, $\mathbf{J}_{\text{out}}$ can be treated as a unitary matrix with unit determinant after separating out a common attenuation factor. $\mathbf{J}_{\text{out}}$ is assumed to be nondiattenuating since optical fibers are virtually lossless. $\mathbf{J}_S$ can be decomposed into a diagonal matrix $\mathbf{J}_C=\left[P_1e^{i\eta/2},\,0;\,0,\,P_2e^{-i\eta/2}\right]$, containing complete information regarding the amount of sample diattenuation and phase retardation, surrounded by unitary matrices $\mathbf{J}_A$ with unit determinant that define the sample optic axis, $\mathbf{J}_s=\mathbf{J}_A\mathbf{J}_C\mathbf{J}_A^{-1}$. $\mathbf{J}_T$ can be rewritten such that $\mathbf{J}_T=\mathbf{J}_{\text{out}}\mathbf{J}_S\mathbf{J}_{\text{out}}^{-1}=\mathbf{J}_{\text{out}}\left(\mathbf{J}_A\mathbf{J}_C\mathbf{J}_A^{-1}\right)\mathbf{J}_{\text{out}}^{-1}=\mathbf{J}_U\mathbf{J}_C\mathbf{J}_U^{-1}$, where $\mathbf{J}_U=\mathbf{J}_{\text{out}}\mathbf{J}_A$. Since unitary matrices with unit determinant form the special unitary group SU(2),[84] $\mathbf{J}_U$ must also be a unitary matrix with unit determinant by closure and can be expressed in the form

$$\mathbf{J}_U=e^{i\beta}\begin{bmatrix}C_\theta e^{i(\phi-\varphi)} & -S_\theta e^{i(\phi+\varphi)}\\ S_\theta e^{-i(\phi+\varphi)} & C_\theta e^{-i(\phi-\varphi)}\end{bmatrix} \tag{31}$$

$\mathbf{J}_T$ can be obtained from the measurements by combining information from two unique incident polarization states, $\left[H_1',H_2';V_1',V_2'\right]=e^{i\Delta\psi_1}\mathbf{J}_T\left[H_1,e^{i\alpha}H_2;V_1,e^{i\alpha}V_2\right]$, where $\alpha=\Delta\psi_2-\Delta\psi_1$. The polarization properties of interest can be obtained by equating the two expressions for $\mathbf{J}_T$ to yield

$$e^{i\Delta\psi_1}\begin{bmatrix}P_1e^{i\eta/2} & 0\\ 0 & P_2e^{-i\eta/2}\end{bmatrix}=\begin{bmatrix}C_\theta & S_\theta\\ -S_\theta & C_\theta\end{bmatrix}\begin{bmatrix}e^{-i\phi} & 0\\ 0 & e^{i\phi}\end{bmatrix}\begin{bmatrix}H_1' & H_2'\\ V_1' & V_2'\end{bmatrix}\begin{bmatrix}H_1 & e^{i\alpha}H_2\\ V_1 & e^{i\alpha}V_2\end{bmatrix}^{-1}\begin{bmatrix}e^{i\phi} & 0\\ 0 & e^{-i\phi}\end{bmatrix}\begin{bmatrix}C_\theta & -S_\theta\\ S_\theta & C_\theta\end{bmatrix} \tag{32}$$

In principle, parameters θ, ϕ, and α can be solved for with the condition that the off-diagonal elements of the matrix product on the right-hand side of Eq. (32) are equal to zero. In practice, real solution cannot always be found, as measurement noise can induce nonphysical transformations between incident and transmitted polarization states. To account for this, Eq. (32) can be solved by optimizing parameters θ, ϕ, and α to minimize the sum of the magnitudes of the off-diagonal elements. In principle, this can be achieved using two unique incident polarization states to probe the same volume of a sample. However, when two orthogonal incident polarization states are used,[73] birefringence cannot be retrieved under all circumstances.[85] A better choice is to use two incident polarization states perpendicular in a Poincaré sphere representation to guarantee that polarization information can always be extracted.[66–69,76,86] The degree of phase retardation can easily be extracted through the phase difference of the resulting diagonal elements, and the diattenuation by their magnitudes. It should be noted that these phase retardation values range from $-\pi$ to π, and can therefore be unwrapped to yield overall phase retardations in excess of 2π.

18.17 PS-OCT IN OPHTHALMOLOGY

Ophthalmological application of OCT has arguably driven a great deal of its development, and probably represents the most researched clinical application of the technology to date. PS-OCT in particular has been used to measure the birefringence of the human retinal nerve fiber layer in vivo[48,76,77,87–89] for potential early detection of glaucoma, the world's second leading cause of blindness.

Glaucoma causes damage to the retinal ganglion cells, resulting in a thinning of the retinal nerve fiber layer (RNFL). In addition, nerve fiber layer tissue loss may be preceded by changes in birefringence as ganglion cells become necrotic and axons in the RNFL are replaced by a less organized and amorphous tissue composed of glial cells. When glaucoma is detected at an early stage, further loss of vision can be prevented by treatment. The visual field test is the current standard method of detecting loss of peripheral vision in glaucoma. However, measurements show that up to 40 percent of nerves are irreversibly damaged before loss of peripheral vision can be clinically detected. PS-OCT has the potential to detect changes to the RNFL at an earlier time point through changes in its birefringence and thickness.

Ophthalmic studies can be performed using systems similar to that used by Cense et al.,[76] in which a slit lamp has been adapted for use with PS-OCT. Figure 18 is a typical example of a structural-intensity time-domain OCT image of the retina in the left eye of a healthy volunteer obtained with a circular scan with a radius of 2.1 mm around the optic nerve head (ONH). The image measures 13.3 mm wide and 0.9 mm deep and is shown at an expanded aspect ratio in depth for clarity. Structural layers such as the RNFL, the interface between the inner and outer segments of the photoreceptors, and the retinal pigmented epithelium can be seen.

The addition of polarization sensitivity allows for localized quantitative assessment of the thickness and birefringence of the RNFL. Figure 19 shows two examples of combined thickness and birefringence measurements, one of a region temporal to the ONH, the other of a region superior to the ONH. The depth of the RNFL can be determined by a decrease in backscattered intensity from the RNFL to the inner plexiform layer. The birefringence of the RNFL can then be estimated from a linear least-square fit of the measured double-pass phase retardation through the determined depth. Two main observations can be drawn from such graphs: the retinal layers directly below the RNFL are minimally birefringent, and that the thickness and birefringence of the RNFL are not constant. These observations can also be seen in Fig. 20, which overlays the thickness and birefringence determined

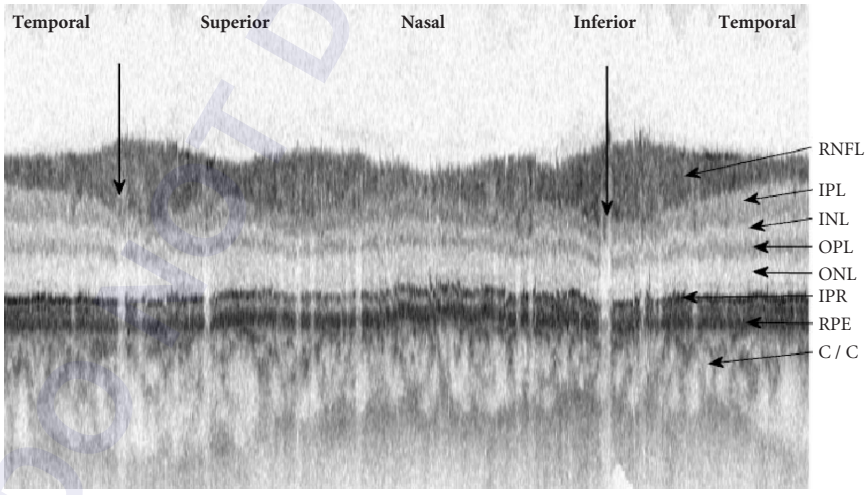

FIGURE 18 A realigned OCT intensity image created with a 2.1-mm radius circular scan around the ONH. The dynamic range of the image is −36 dB. Black pixels represent strong reflections. The image measures 13.3 mm wide and 0.9 mm deep. Visible structures: retinal nerve fiber layer (RNFL); inner plexiform layer (IPL); inner nuclear layer (INL); outer plexiform layer (OPL); outer nuclear layer (ONL); interface between the inner and outer segments of the photoreceptor layer (IPR); retinal pigmented epithelium (RPE); and choriocapillaris and choroid (C/C). Vertical arrows: locations of the two largest blood vessels. Other smaller blood vessels appear as vertical white areas in the image. (*Reprinted from Ref. 77 with permission from the Association for Research in Vision and Ophthalmology.*)

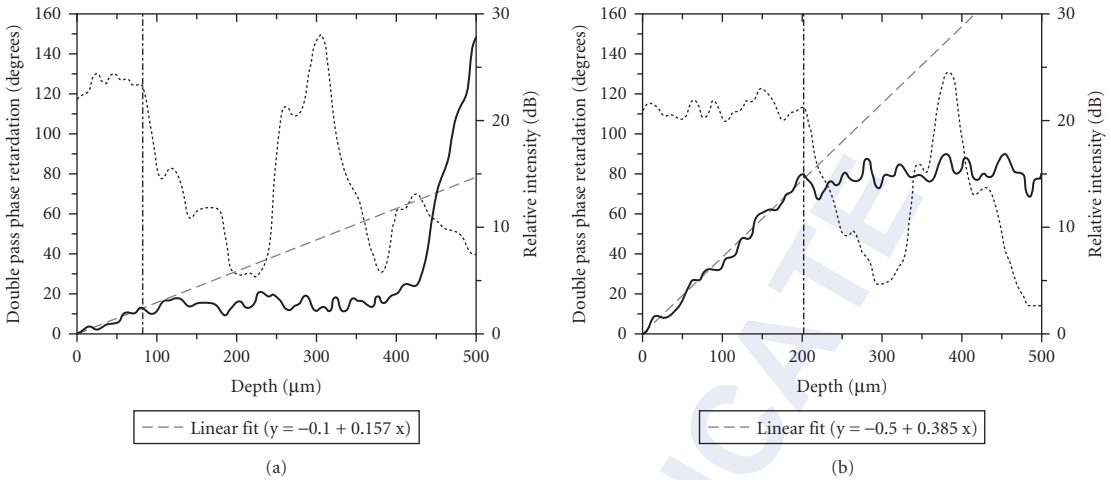

FIGURE 19 Thickness (dotted line) and birefringence (solid line) plots of an area temporal (*a*) and superior (*b*) to the ONH. DPPR data belonging to the RNFL is fit with a least-square linear fit. The slope in the equation represents the DPPR/UD or birefringence. The vertical line indicates the boundary of the RNFL, as determined from the intensity and DPPR data. (*a*) The increase in DPPR at a depth beyond 450 μm is caused by either a relatively low signal-to-noise ratio, or by the presence of a highly birefringent material—for instance, collagen in the sclera. (*Reprinted from Ref. 77 with permission from the Association for Research in Vision and Ophthalmology.*)

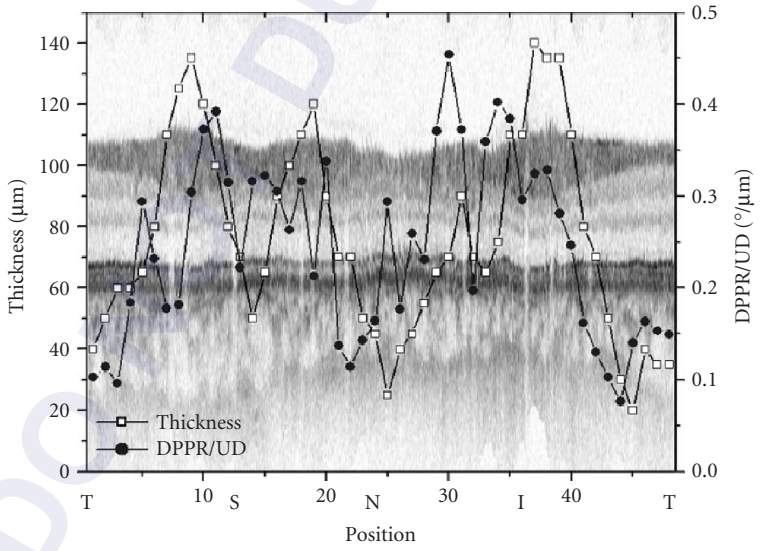

FIGURE 20 A typical example of combined RNFL thickness and birefringence measurements along a circular scan around the ONH. The intensity image is plotted in the background. The RNFL is relatively thicker superiorly (S) and inferiorly (I). A similar development can be seen in the birefringence plot. The birefringence is relatively higher in the thicker areas, whereas it is lower in the thinner temporal (T) and nasal (N) areas. (*Reprinted from Ref. 77 with permission from the Association for Research in Vision and Ophthalmology.*)

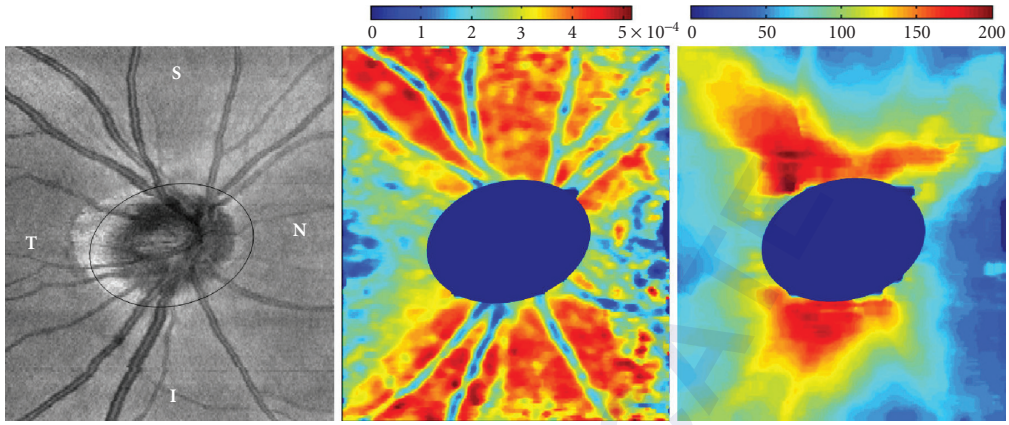

FIGURE 21 OCT scan (4.24 × 5.29 mm^2) of the retina of a normal volunteer, centered on the ONH. (*a*) Integrated reflectance map showing a normal temporal crescent (white area temporal to the ONH); (*b*) birefringence map; and (*c*) RNFL thickness map (color bar scaled in microns). The circle on the left indicates the excluded area in the birefringence and thickness maps as corresponding to ONH. (S = superior, N = nasal, I = inferior, T = temporal). *(Reprinted from Ref. 90 with permission from the International Society for Optical Engineering.)*

as in Fig. 19 on a circular scan across the ONH. The plots indicate that the RNFL is thickest and most birefringent superiorly and inferiorly to the ONH.

En face maps of RNFL thickness and birefringence can be generated from data obtained with recently developed spectral-domain ophthalmic PS-OCT systems.[90] A three-dimensional volume (4.24 × 5.29 × 1.57 mm^3) of the retina of a normal volunteer (right eye) was scanned at a rate of 29 fps with 1000 A-lines/frame, and contains 190 frames (B-scans) acquired in 6.5 s. The integrated reflectance, birefringence, and retinal nerve fiber layer (RNFL) thickness maps are shown in Fig. 21, confirming previous findings that the RNFL birefringence is not uniform across the retina. Superior, nasal, inferior, and temporal areas of the retina around the ONH are indicated by the letters S, N, I, and T. The integrated reflectance map, obtained by simply integrating the logarithmic depth profiles, illustrates the blood vessel structure around the ONH. The RNFL thickness map is scaled in microns (color bar on the top of the image) indicating a RNFL thickness of up to 200 mm. The central dark-blue area corresponds to the position of the ONH that was excluded from both the thickness and the birefringence maps. A typical bow-tie pattern can be seen for the distribution of the RNFL thickness around the ONH, showing a thicker RNFL superior and inferior to the ONH. The birefringence map illustrates a variation of the birefringence values between 0 and 5.16 × 10^{-4}, and it clearly demonstrates that the RNFL birefringence is not uniform across the retina; it is smaller nasal and temporal and larger superior and inferior to the ONH.

Given that measurements of the thickness and birefringence of the RNFL can be acquired with the speed and accuracy demonstrated, further research into changes in these parameters with glaucoma can be performed. Experiments—for instance, a longitudinal study with PS-OCT on patients at high risk for development of glaucoma—will either confirm or reject the hypothesis. In addition, PS-OCT can enhance the specificity in determining RNFL thickness in structural OCT images by using changes in tissue birefringence to determine the border between the RNFL and the ganglion cell layer.

18.18 RETINAL IMAGING WITH SD-OCT

Many examples of retinal imaging with SD-OCT are available in the literature. Commercial systems are being introduced into the market at this point. Below, two typical examples of high

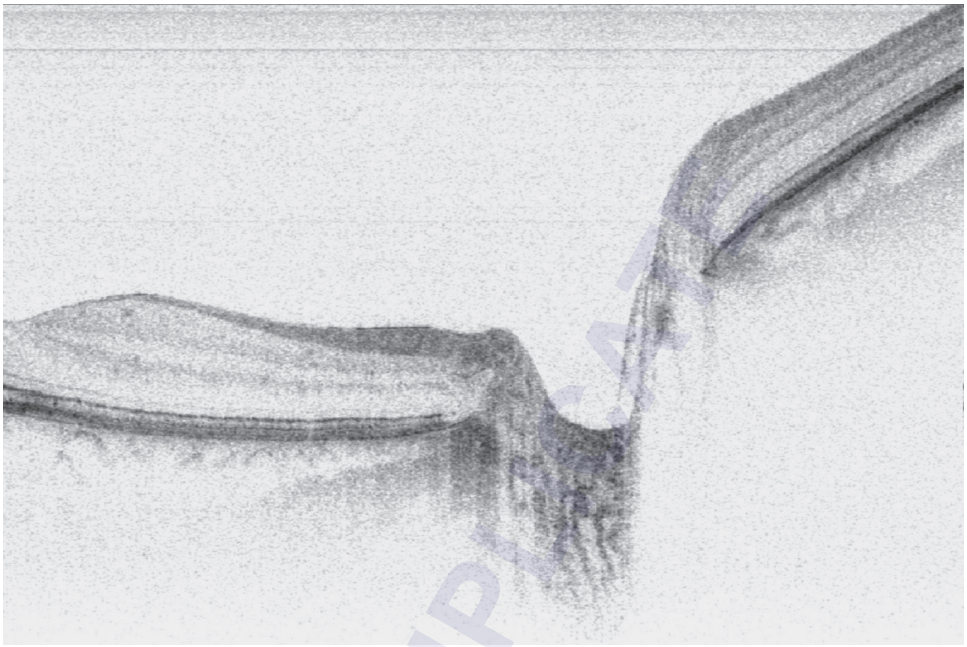

FIGURE 22 High resolution SD-OCT image of a human retina in vivo, centered on the optic nerve head. The image is magnified in depth by a factor of 2. Image size: 4.662 × 1.541 mm.

quality SD-OCT images are presented, acquired with a system providing a depth resolution of 3 μm in tissue. Both figures consist of approximately 1000 A-lines or depth profiles. Figure 22 shows a cross-section centered on the optic nerve head. Figure 23 shows an image centered on the fovea and the corresponding en face image (Fig. 24) generated from the three-dimensional data set.

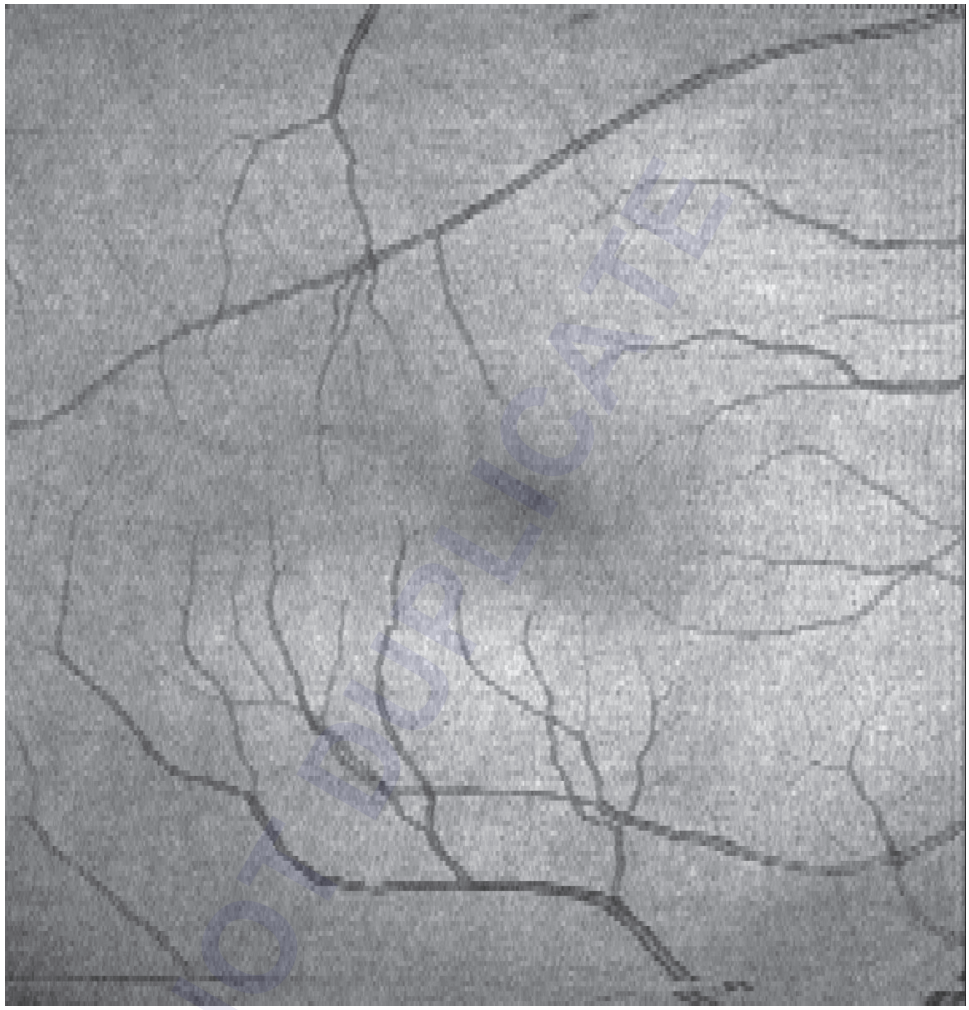

FIGURE 24 En face reconstruction of the fovea region of the retina from a three-dimensional volumetric SD-OCT data set of 200 images. Image size: 4.97 mm × 5.18 mm.

18.19 CONCLUSION

Spectral domain or frequency domain OCT (SD/FD-OCT) has become the preferred method for retinal imaging owing to its high imaging speed,[10,19] enhanced signal to noise ratio (SNR),[7,15–17] and the availability of broadband sources permitting ultrahigh resolution retinal imaging.[20,21] However, the state-of-the-art spectrometers are hindering further improvements (1) with limited detection efficiency (~25 percent)[19] and (2) the obtainable spectral resolution causes approximately a 6-dB sensitivity drop over a 1-mm depth range.[19] Furthermore, rapid scanning of the probe beam in SD-OCT has the adverse effect of fringe washout, which causes SNR to decrease.[36] Fringe washout can be addressed by pulsed illumination.[38] A competing technique such as optical frequency domain imaging

(OFDI), the dominant implementation of Fourier domain OCT technologies at 1.3 μm,[9] has the advantage of larger depth range and better immunity to motion artifacts. OFDI has recently been demonstrated in the 800 and 1050 nm range,[26,27,91] but has not reached the superior resolution of SD-OCT.[20,21]

18.20 ACKNOWLEDGMENTS

This research was supported in part by research grants from the National Institutes of Health (1R24 EY12877, R01 EY014975, and RR19768), Department of Defense (F4 9620-01-1-0014), CIMIT, and a gift from Dr. and Mrs. J. S. Chen to the optical diagnostics program of the Wellman Center of Photomedicine. The author would like to thank a number of graduate students and post doctoral fellows who have contributed to the results presented in this chapter, Barry Cense, Nader Nassif, Brian White, Hyle Park, Jang Woo You, Mircea Mujat, Hyungsik Lim, Martijn de Bruin, Daina Burnes, and Yueli Chen. Special thanks to Teresa Chen, MD, my invaluable collaborator at the Massachusetts Eye and Ear Infirmary, without whom all this work would not have been possible.

GRADIENT INDEX OPTICS IN THE EYE

Barbara K. Pierscionek

Department of Biomedical Sciences
University of Ulster
Coleraine, United Kingdom

19.1 GLOSSARY

Cataract. Opacification in the eye lens caused by changes in protein shape, structure, or interaction that causes light to be scattered or absorbed.

Crystallin proteins. The major structural proteins in the eye lens.

Equatorial plane. The plane of the eye lens that contains the lens equator.

Gradient index or GRIN. The property of a lens or medium that has a gradually varying refractive index.

Homogenous index. The property of a lens or medium that has a constant refractive index.

Isoindicial contours. Contours of constant refractive index.

Magnetic resonance imaging (MRI). Noninvasive method used for imaging body organs that utilizes the interaction of a static magnetic field, radio frequency pulses, and magnetic gradients to form images.

Myopia. Shortsightedness.

Optic fiber. A fiber made of glass or plastic that guides light along its length by total internal reflection.

Optical fiber perform. The precursor to an optical fiber: a rod with the refractive index distribution of the desired optical fiber that is stretched to form the fiber.

Raman microspectroscopy. A technique used to detect constituents of a system from the spectrum of molecular vibrations created by specific interactions of monochromatic light with matter. These interactions cause scattering of photons at lower frequencies than that of the incident light.

Ray tracing. Monitoring the path of rays as they traverse a lens or optical system. This is often used to measure a particular property of the lens or system.

Reflectometric sensor. A device that measures optical or material properties of a medium from the proportion of light that the medium reflects.

Refractive index. The property of a medium that contributes to its capacity to bend light and that is related to the density of the material.

Refractive power. The capacity of a lens or optical system to bend and focus light.

Sagittal plane. The vertical plane of the eye lens that contains the optic axis.

19.2 INTRODUCTION

This chapter considers the common forms of gradient index in optical media. The lens of the eye has a gradient of index and this is examined in detail; the form of the index profile as well as the magnitude of refractive index are described. The refractive index distribution has been measured or derived from a number of animal eyes as well as from the human eye. The different types of gradients are presented and compared.

19.3 THE NATURE OF AN INDEX GRADIENT

The refractive power of a lens is determined by its shape, the refractive index of its medium, and the refractive index of the medium that surrounds the lens. In terms of shape, the more curved the lens the greater is the refraction of light. The relationship between refractive index and refractive power is not as direct: light is not necessarily refracted to a greater degree in a higher-index medium. A ray of light will travel in a straight line whether it travels in air (refractive index = 1), in water (refractive index = 1.33), or in glass (refractive index around 1.5 to 1.6). The effect of refractive index on refraction occurs when there is a change in refractive index at the interface between two media or a gradual variation in index within a medium. The greater the difference between refractive indices at an interface or the steeper the gradient of refractive index in a medium, the greater the degree of refraction.

Gradient index (GRIN) deals with media which have a varying refractive index. The effect of varying or gradient index occurs in nature; changes in temperature or pressure can induce fluctuations or gradations in the refractive index of air. One of the most commonly cited examples of this is seen in the shiny reflective marks on a road that can be seen on a hot day. The heat of the road warms the air closest to it and gradients of temperature and of refractive index are formed. The higher the temperature, the less dense the air and the lower the refractive index. The index gradient has the effect of deflecting light that hits the surface of the road at certain angles so that it appears to have been reflected from the surface of the road.

The steepness of the index gradient controls the degree of bending of light in the GRIN medium and this is used in the creation of GRIN lenses and devices. A refractive contribution from the medium is particularly effective when the surface of the given structure is flat and cannot contribute to the refractive power.

19.4 SPHERICAL GRADIENTS

In a lens with a spherical refractive index distribution, the index varies with distance from the center of the lens. The most famous early GRIN lens was Maxwell's fish-eye lens[1] that has a refractive index distribution with spherical symmetry about a point and can be described as having the form

$$n(r) = \frac{n_0}{1+(r/a)^2} \tag{1}$$

where r is the distance from the center, $n(r)$ is the refractive index at r, n_0 is the refractive index at the center of the lens, and a is a constant.

The special property of a fish-eye lens is that all rays emanating from a given object point pass through the same image point.[2] This produces sharp imagery but only for those points on the surface and within the lens. There is no evidence that fish possess such lenses. The name possibly derives from the challenge posed by the Irish Academy of Sciences: to produce a medium with a refractive index distribution that was capable of forming images with the least depth possible. As the eye of the fish is

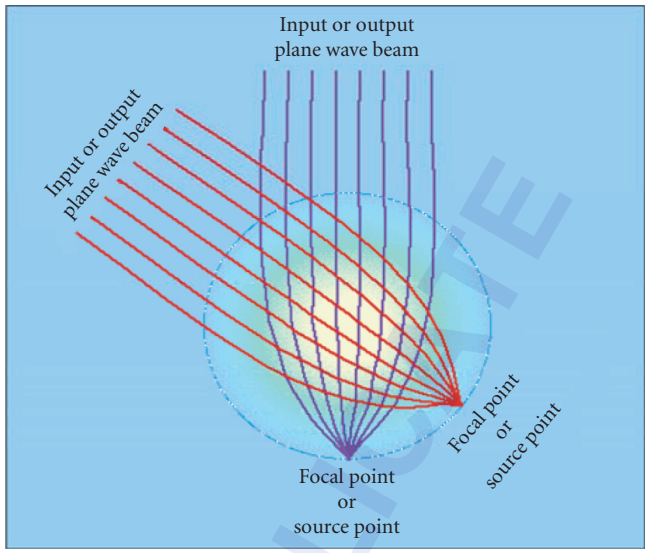

FIGURE 1 Light paths through a Luneberg lens in surround media index matched to the lens surface.

known to be relatively flat, Maxwell's solution to the problem was called the fish-eye.[3] The limitation of this lens is that sharp imagery of object points only occurs for those points that lie within or on the surface of the lens.[2,4]

This restriction does not apply to the Luneberg lens,[5] which, like the Maxwell fish-eye lens, has a refractive index distribution that is spherically symmetrical. This lens is a sphere with a refractive index distribution described by

$$n(r) = (2 - r^2)^{1/2} \tag{2}$$

where r is the distance from the center of the lens and $n(r)$ is the refractive index at r.

It has no intrinsic optical axis but focuses parallel rays, incident on any part of its surface, to a point on the opposite surface of the lens (Fig. 1).

The restriction of the Luneberg lens is that with this lens sharp images are only created for objects at infinity. In order to ensure that rays enter in a parallel bundle, the index of the surrounding media must match that of the lens surface. In air this would require an outer surface refractive index of 1, which is difficult to achieve for visible light but can be utilized for frequencies in the microwave range.[2] It has wide ranging applications in microwave antennas and as a radar device. A very useful modern application is in the design of broadband airborne antennas. These allow passengers on an aircraft to access the Internet, email, satellite television, and video.

19.5 RADIAL GRADIENTS

When the refractive index distribution is cylindrically symmetrical, that is, the refractive index varies with distance from a fixed line, it is described as a radial index gradient. A simple type of radial index lens is the Wood lens, named after its designer.[6] This lens has a radial refractive index gradient and flat surfaces.[2] In such a lens, parallel rays from objects at infinity are refracted purely by the

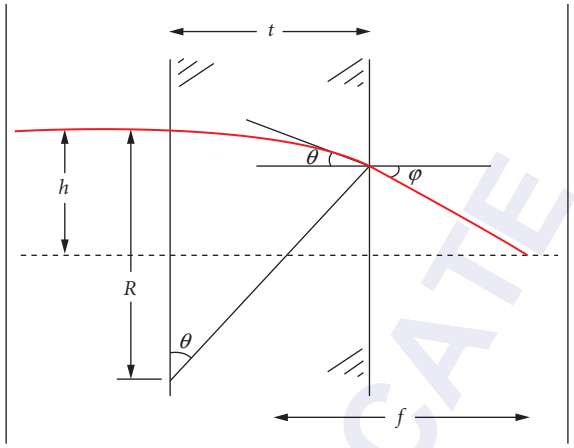

FIGURE 2 Refraction of a ray through a Wood lens. $R, f >> h, t$. [*From N. Morton, "Gradient Refractive Index Lenses," Phys. Educ.* ***19:****86–90 (1984).*]

index distribution within the lens (Fig. 2). When the refractive index decreases with distance from the axis, the lens acts as a converging lens; when the refractive index increases with distance from the axis, the lens diverges light. With a Wood lens, the object and image planes are external to the lens.[2]

Optical fiber cores with radial index gradients are, cross-sectionally, akin to a Wood lens. However, because optical fibers are elongated in the axial direction and have very small diameters, there is an additional periodicity to the ray path. In a graded index optical fiber core, the index distribution follows a general form[7]

$$n(r) = n_0[1 - 2(r/a)^{\alpha}\Delta]^{1/2} \tag{3}$$

where r is the radial distance from the center, $n(r)$ is the refractive index at r, n_0 is the refractive index along the axis of the fiber, a is the fiber radius, and Δ is the fractional refractive index difference between the center and edge of the fiber core.

For $\alpha = 2$ and $\Delta << 1$, the profile is parabolic and approximated as

$$n(r) = n_0[1 - (r/a)^2\Delta] \tag{4}$$

In an optical fiber, the core is surrounded by a single index cladding to minimize light losses along the length of the fiber and to protect the quality of the fiber core. Within the core, the rays follow a sinusoidal path along the axis of the fiber (as seen in Fig. 3).

Optical fibers have many uses particularly when the light needs to be sent some distance from the source or an image needs to be collected from a remote or hard to access location. Optical fibers have replaced wires in communication systems. They are now used routinely in medical instruments and applications, such as endoscopes and sensors.

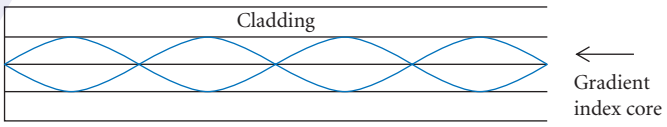

FIGURE 3 Light rays follow a sinusoidal path when traveling in the gradient index core of a GRIN fiber.

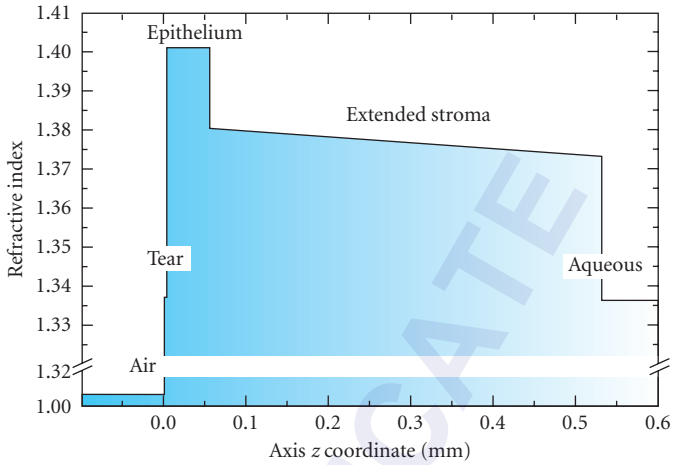

FIGURE 4 Variations in corneal refractive index along the optical axis. (*From Ref. 10.*)

19.6 AXIAL GRADIENTS

Refractive index can also vary as a function of distance from a reference plane. This is most often the plane perpendicular to the optic axis and in such case the refractive index varies along the optic axis. Such a gradient can be formed by thin films and has important use in the design of multilayer antireflection coatings.[8,9] Southwell[9] has shown that shape of the index gradient along the axis is a very important determinant that can be used to minimize adverse reflections. Measurement of axial gradients has application in the study of biological tissues, many of which are layered. The lamellar stroma, which constitutes the bulk of the cornea of the eye and has been considered to have a homogenous refractive index, has recently been modeled as an axial index structure[10]. The axial index model has been found to produce more spherical aberration, for larger pupil sizes, than homogenous index models. Any refractive index differences along the axis of the cornea are likely to be very small and the model introduced very slight variations (Fig. 4).

19.7 THE EYE LENS

The refractive index of the eye lens has a radial as well as an axial gradient. This is because of the three-dimensional structure as well as the nature of the growth mode of the lens. The lens grows by tissue accretion in layers on the lens surface, with no concomitant loss of existing cells, resulting in a layered structure. The refractive index varies across the layers resulting in a radial gradient, in the equatorial plane and an axial gradient along the optic axis. In spherical lenses (seen in some fish), the index gradient varies along a radial distance from the center in all directions.

The shapes and sizes of eye lenses, like any other part of the eye, vary widely across species. This variation bears no relationship to the size of the animal nor to the size of the eye. For example, the lens of a rabbit is larger than that of a human, while the rat's lens is highly curved and fills the eye almost entirely. With such a variety of lenticular shapes and sizes, it is not surprising that the refractive index distribution also varies between species and is not related to the size of the animal or to its eye but to its visual needs.

The refractive index gradients in human and several types of animal lenses have been measured or derived using various techniques. These have included ray tracing, optic fiber sensing, or calculation from protein and water concentration measurements and MRI scanning. Earlier studies on dispersion have provided refractive index measurements on inner and outer sections of lenses from a number of vertebrates.[11,12]

19.8 FISH

The fish lens contributes more to the refractive power of the eye than lenses from land living animals because the corneal power in the fish eye is significantly reduced by the very small difference in refractive index between the cornea and water. Fish lenses are spherical or nearly spherical with steep refractive index gradients and high maximal index values to provide the necessary refractive power to the eye whilst minimizing spherical aberration.[13–20] The refractive index gradients in fish lenses have been fitted with elliptical,[14] parabolic,[16–19] and sixth-order polynomial functions (Table 1).[20]

In spite of the differences in the size of fish and their lenses, the maxima of refractive index in the lens centers are very close in value and, with the exception of the Blue Eye Trevally lens, similar values are also found at the lens edge (Table 1). The edge index value in the trevally lens is substantially higher than that found in the other fish lenses. It is also notable that the trevally has an enormous eye relative to its size and its lens is the largest of any lens studied: a diameter of 26.6 mm and a weight of over 9.5 g.[17] It is a deep-sea fish, unlike the other fish listed in Table 1. From a structural aspect, almost a third of the trevally lens protein comprises γ-crystallin.[17] This crystallin protein contributes more to the refractive index of the lens than the other crystallins[21] and is capable of closer protein packing with less surrounding water.[22] Although the proportion of γ-crystallin is comparatively high, it is not high enough to alone account for the refractive index magnitude. This may also be attributed to the very high proportion of insoluble protein that was found on extraction.[17] This does not necessarily indicate that the proteins are in an insoluble state in the intact trevally lens but may suggest a propensity for proteins in this lens to aggregate with no loss of transparency. This will depend on protein types and relative distributions as well as protein-protein and protein-water interactions. It is not known whether the high proportions of γ-crystallin and insoluble protein found in the trevally lens apply to the lenses of other fish.

Ageing changes in the fish lens have not been studied but the effect on the index gradient with size and therefore growth has been investigated. Kroger et al.[19] reported that the refractive index in the center of the African Cichlid fish lens increases with lens size. The resultant steepening of the index gradient with growth causes a decrease in focal length. There is also a concomitant decrease in spherical aberration that is attributed to a smoothing of the index gradient.[19] It has been suggested that depressions in the index profile may have a discrete function in producing multiple focal points.[19]

Jagger[15] compared models of fish lenses and found that a higher-order polynomial function to describe the index gradient provided results that were most akin to measurements for fish lenses in terms of image quality, spherical, and chromatic aberration. It has also been pointed out that there may be internal asymmetries in the index distribution in fish lenses that would render erroneous measurements based on ray tracing assumptions.[23]

TABLE 1 Details of Refractive Index Profiles in a Variety of Fish Lenses

Fish	Refractive Index (max)	Refractive Index (min)	Wavelength (nm)	Gradient Shape
Goldfish[14]	1.55–7	1.35–8	633	Elliptical
African Cichlid[16]	1.540	1.361	633	Parabolic
Blue Eye Trevally[17]	1.546	1.408	633	Parabolic
Trout[18]	1.538	1.3716	550	Parabolic
Black Dory[20]	1.543	1.368	590	Sixth-order polynomial

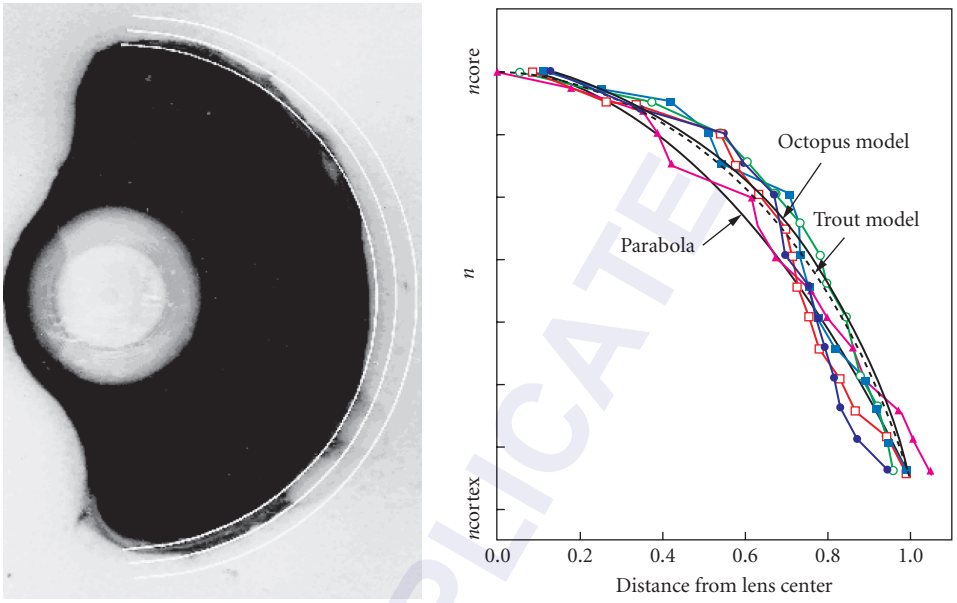

FIGURE 5 (*a*) Octopus eye showing lens and (*b*) refractive index gradient for five octopus lenses as measured in the equatorial plane. Model and experimental index profiles are shown together with the index profile for the trout lens. (*From Ref. 24.*)

19.9 OCTOPUS

The eye of the octopus has no cornea; the refractive power of the eye is provided by the lens (Fig. 5*a*).[24] It was found to have concentric isoindicial contours and an index gradient that could be fitted to a 10th order polynomial (Fig. 5*b*). The maximum refractive index was 1.509 decreasing to 1.357 for 550 nm.

19.10 RAT

The refractive index distribution in the rat lens was measured using ray tracing[25,26] following the method for determining the refractive index in optical fiber performs devised by Chu.[27] This method enabled the calculation of the gradient refractive index profile using, as parameters, the distance of the parallel incident rays from the optic axis and the corresponding angles formed by the exiting rays and the optic axis.

The studies of Campbell and Hughes[25] and Campbell[26] showed that the rat has the steepest refractive index gradient of all species yet measured, rising from around 1.38 at the edge of the lens to a maximum of around 1.5 at the lens center in a profile that can be fitted to a parabolic form. This rise occurs over a very short distance of 2 mm.[26] A refractive index value of 1.50 is approaching the refractive index range for glass and, in terms of protein concentration, is close to the refractive index of pure protein.[28] With such a high protein concentration, the rat lens cannot be deformed, and hence the rat eye has no accommodative capacity. The high magnitude of refractive index in the rat lens is

partially caused by the relatively high proportion of the protein γ-crystallin. In terms of shape, the rat lens is not quite spherical but tends to have a longer equatorial diameter than sagittal radius with little variation between the anterior and posterior curvatures.[26] The radial and axial gradient profiles will not be the same, the latter slightly less steep than the former. The curved nature of the rat lens, its high magnitude of refractive index, and the steep index gradient gives the lens a very high refractive power rendering the rat eye highly myopic. This accords with the animal's visual needs which are for very close distances and do not require a range of focus.

19.11 GUINEA PIG

The refractive index distribution of the guinea pig lens, measured with an optical fiber reflectometric sensor, has been found to be parabolic.[29] This was for a single lens, and the age of the animal was not known. Hence magnitudes of refractive index: a maximum value of 1.429 at the lens center and a minimum value of 1.389 at the edge can only be taken as applicable for that particular lens. Calculated protein content for the guinea pig lens was 48 percent[29] and the lens shape is almost spherical with a sagittal width of around 5 mm and an equatorial radius of 5.4 mm. The refractive index distribution will therefore be similar in the axial and radial directions. Because the guinea pig lens is relatively small, its refractive index gradient is quite steep and this adds to its refractive power. The steep distribution of refractive index may be linked to the structural proteins and the uncommon crystallin protein (ζ-crystallin) that comprises about 10 percent of the total soluble proteins.[30] This protein differs from the other major crystallins in structure[30,31] and in its response to the effects of heat and the protective action of α-crystallin.[32] ζ-crystallin requires a tenfold greater amount (w/w) of α-crystallin than the other crystallin proteins to prevent it forming aggregates and disturbing the smoothness of the refractive index gradient.[32] The greater level of protection required by ζ-crystallin could indicate a propensity to exist in regions of relatively higher protein concentration. The relatively steep refractive index gradient and the high curvature of the guinea pig lens are needed to meet the refractive requirements of the guinea pig: clear vision at close distances.

19.12 RABBIT

The refractive index gradient in the rabbit lens was measured in the equatorial and horizontal planes on thin slices.[33] Isoindicial curves were found as concentric circles in the equatorial plane and as eccentric ellipses in the horizontal plane, the eccentricity arising because of differences in curvature between the anterior and posterior lens surfaces. The three-dimensional refractive index distribution was represented by an elliptical paraboloid

$$n = n_0 - [Z^2/\mathrm{A}^2 + (X^2 + Y^2)/\mathrm{B}^2] \tag{5}$$

where n_0 is the refractive index at the lens center, X is the lateral axis (through the middle of the horizontal plane), Y is the vertical axis (through the middle of the equatorial plane), Z is the optic axis, A and B are constants (A differs in the anterior and posterior sections of the lens).

The refractive index for 589 nm was reported to vary from 1.464 to 1.431 at the lens center and 1.393 to 1.384 at the surface, which is not very different from the magnitudes of refractive index in the guinea pig lens. However, the rabbit lens is larger than that of the guinea pig (around 10 mm thickness in the horizontal and sagittal planes) and so the index gradient in the rabbit lens would not be as steep providing a lower contribution to refractive power than does the index gradient in the guinea pig lens.

19.13 CAT

The lens of the cat is shaped as a biconvex ellipsoid[34] and its refractive index follows a parabolic shape with a maximum of 1.4813 at the center and minimum of 1.3877 in the periphery (values averaged from five cat lenses) for a wavelength 550 nm. The parabolic shape was found in both the sagittal (axial) and equatorial planes and the index variations follow isoindicial contours that retain the geometric shape of the lens.[34]

Jagger[34] cites Matthiessen (1880),[35] who showed the index in a homogenous lens would give equivalent power to one with a variation of index (based on a parabolic gradient). This rule states that the difference between the total index and the core (maximum) index in a grin lens is equal to the difference between the core index and cortical (edge) index

$$n(\text{total}) - n(\text{core}) = n(\text{core}) - n(\text{cortex})$$

so

$$n(\text{total}) = 2 \times n(\text{core}) - n(\text{cortex})$$

According to the rule of Matthiessen,[35] the equivalent to a lens with a parabolic gradient index, with a maximum value of 1.48 and an edge value of 1.38, would require a homogenous index lens to have a refractive index of 1.58. This is higher than the refractive index of pure protein.[28]

19.14 BOVINE

The optical properties of the bovine lens have been investigated in a number of studies and the refractive index has been measured using ray tracing[36,37] and fiber optic reflectometric sensing methods.[38] In addition, the refractive index in the bovine lens has been measured in both equatorial and sagittal planes and in lenses from a wide age range from foetal[39] to approximately 15 years of age.[36]

The refractive index, measured in the equatorial plane using a ray tracing technique for a wavelength of 633 nm[36,37] was found to have some variations depending on the age of the lens. In all lenses the gradient followed the same general shape: that of a second-order polynomial, but the index magnitude increased across the gradient with age. The size and therefore the radius of the lens in the equatorial plane had to be incorporated into the equation to account for size and age differences. The general form of the refractive index gradient covering the wide range of lenses investigated is

$$n(r) = a_r - N_r/\rho^2 + C \tag{6}$$

where r is the radial distance from the center of the lens, $n(r)$ is the refractive index at r (mm), a_r is the refractive index at the center of the oldest lens investigated (approximately 15 years of age),[36] N_r is a non-normalized gradient function, ρ is the equatorial radius of the lens (mm), and C is a correction factor for age-related differences in the refractive index at the lens center.

With

$$N_r = 0.702 - 0.471r + 0.186r^2 \tag{7}$$

and

$$C = -0.0025 - 0.00583r + 0.00131r^2 \tag{8}$$

the final form of the equation is

$$n(r) = 1.4575 - 0.702/\rho^2 + 0.471r/\rho^2 - 0.186r^2/\rho^2 - 0.00583r + 0.00131r^2 \tag{9}$$

In a subsequent study the refractive index along the optic axis of the bovine lens was measured using a fiber optic sensor and a wavelength of 670 nm.[38] The lens age range was not as great as in the ray tracing study of the equatorial plane index: weights varied from 1.676 to 2.646 g corresponding to ages of around 1 to 8 years, respectively.[40] A second-order polynomial was again found to fit the profiles but here slight differences were found in the anterior and posterior sections of the lens. The anterior axial profile was found to fit the following equation

$$n(x) = 1.3790 + 0.018484x - 0.0014925x^2 \tag{10}$$

and the posterior axial profile could be described by

$$n(x) = 1.4102 + 0.009647x - 0.0010741x^2 \tag{11}$$

where x is the distance from the anterior pole (mm) and $n(x)$ is the refractive index at r.

It is not possible to definitively state whether the bovine lens does have contours of refractive index that follow the external shape of the lens but the forms of the gradients in the sagittal and equatorial planes are similar and using dimensional data from the lens it is possible to do approximate calculations to see if the magnitudes of refractive index following a given contour are close. If so, the assumption of concentric contours of refractive index may apply to the bovine lens. From the dimensions of bovine lenses[41] a lens of about 1.5 g weight has an equatorial radius of 7.5 mm, an anterior sagittal thickness of 5 mm and a posterior sagittal thickness of 6 mm.

Taking a contour at 2 mm from the anterior pole, this will be at a radial distance of 4.5 along the equatorial plane (2 mm is 40 percent of the anterior sagittal thickness and 4.5 mm is 40 percent of the equatorial radius) and 2.4 mm from the posterior pole (8.6 mm from the anterior pole). Putting these values into Eqs. (9), (10), and (11) gives refractive index values of 1.4099 (~1.41) along the anterior sagittal thickness, 1.416 along the equatorial plane, and 1.414 along the posterior sagittal thickness, respectively. Taking into account differences in measurement technique, the fact that measurements of radial and axial gradients were conducted on different lenses, and the recognition that in biological tissues there will always be individual variations in lens shape and size, the above calculations can only provide an estimate. This notwithstanding, the values are close and suggest that in the bovine lens isoindicial contours of refractive index may follow the surface shape.

The bovine lens is one of few in which age-related changes to the GRIN optics have been investigated. The changes with age to the index distribution should take into account the fact that the lens continues to grow, and are more correctly described as changes with time and not exclusively occurring as a result of senescence. The lens grows by successive tissue layering and, within each layer, the cells stretch from anterior to posterior pole. As there is an asymmetry between the anterior and posterior surface curvatures, the cells must stretch more and more asymmetrically with growth, and a greater component of the cellular length is found in the posterior part of the lens. How the cellular contents, mainly the proteins, are distributed along the cell length is not known. Nevertheless, as the anterior and posterior refractive index gradients meet in the equatorial plane, the refractive index at that point must be the same. Similarly, refractive indices at the anterior and posterior poles should be close in value, as these are from the same cell layers, and large difference in refractive index between the poles would not meet the refractive needs of the eye. Fiber optic sensing has shown that there is, indeed, very little difference in the refractive index at the anterior and posterior poles of lenses that have a relatively lower weight and were therefore likely to be younger.[38] However, whilst the refractive index does not appear to alter with age at the anterior pole, at the posterior pole a statistically significant correlation with age was found.[38] The consequence of this is that in very old bovine lenses, some differences in polar refractive index may occur. This is most likely to be a consequence of the growth mode and increasing asymmetry of shape that may affect and result in greater differences in anterior and posterior refractive index gradients in advanced age.

As both axial and radial gradients were measured with similar wavelength sources (633 nm for the radial gradient and 670 nm for the axial) wavelength differences would have a negligible impact on the results. Comparison of ray tracing and fiber optic sensing have shown consistent findings.[36,38]

A single study on development of the foetal bovine lens[39] has shown that the refractive index gradient starts to take on its parabolic form around the middle of the gestational period of 9.3 months. Prior to this, the refractive index distribution has no defined shape (Fig. 6).

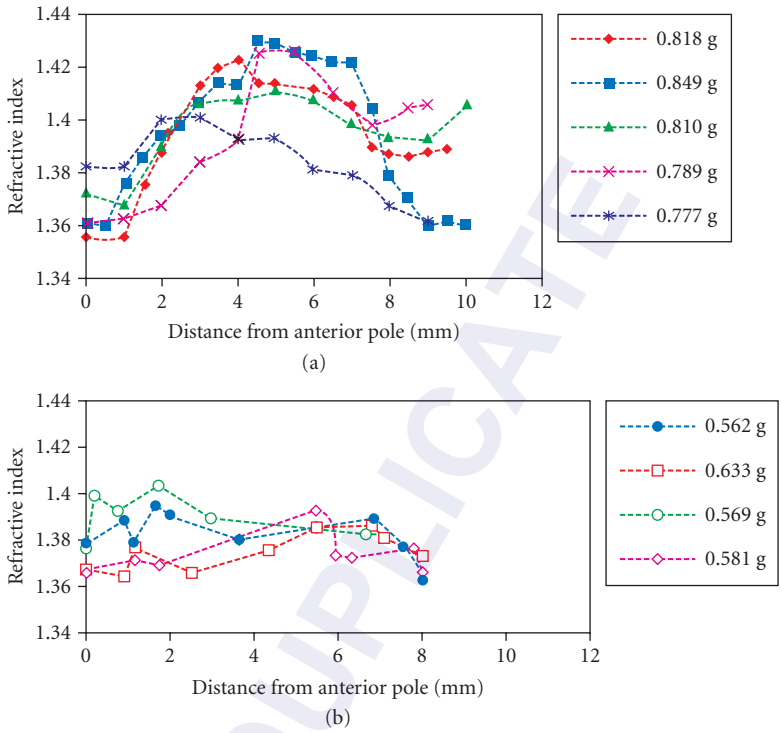

FIGURE 6 Refractive index profiles along optic axes of foetal bovine lenses. (*a*) Greater than 0.7 g and (*b*) lesser than 0.7 g wet weight. (*From Ref. 39.*)

19.15 PIG

The refractive index in the porcine lens is similar in shape to that found in the bovine lens.[42,43] It has been fitted with a second-order polynomial, a shape that has been found from ray tracing measurements of refractive index[42] (as shown as Fig. 7) and from protein concentration profiles determined using Raman microspectroscopy.[44]

Jones and Pope[43] using magnetic resonance imaging (MRI), found that parabolic, power function, and higher-order polynomial fits could be used to provide a very good description of the index profile. They reported that the power function provided the best fit but this was only by a very slight margin. Comparing the results of Pierscionek et al.[42] who measured the refractive index profile in the equatorial plane with those of Jones and Pope,[43] whose measurements were in the sagittal plane, there is very little difference in profile shapes. This suggests that there may be isoindicial contours of refractive index in the porcine lens that follow the surface shape. The porcine lens index gradient has been measured for wavelengths 633 and 532[42] and 589 nm (converted to 543.5 nm).[43] The index magnitude was reported to vary from an average of 1.354 at the edge of the lens up to 1.396 at the center for 633 nm[42] from 1.365 to 1.368 at the edge up to an average of 1.4374 at the center for 543.5 nm,[43] and from 1.358 at the edge to 1.404 at the center for 532 nm. The central index value found by Jones and Pope[43] concurs with measurements made by Sivak and Mandelman.[12]

The higher values of refractive index found by Jones and Pope[43] compared to Pierscionek at al.[42] could have reflected differences in ages of animals; it is not possible to determine whether the two studies[42,43] had used lenses of similar ages. Age-related variations in refractive index have not been studied in the porcine lens.

19.16 HUMAN/PRIMATE

The refractive index gradient of the human lens differs from index gradients in the lenses of most other species. The gradient of refractive index is only found in the cortex of the lens, which is generally taken to represent the outer one-third of the lens, approximately, in terms of radial distance. In the inner, nuclear region, the refractive index is relatively constant around a value of 1.39 to 1.41[12,45,46] (depending on wavelength) and remains so with age as long as there are no opacifications or cataractous changes.[47] This supports findings on protein[48] and water gradients.[49,50] Changes with age occur in the steepness of the cortical index gradient and have been proposed as an answer to why the human lens, in spite of continued growth and increased curvature[51,52] does not become myopic.[29,53] A recent study using MRI has suggested that there is a decrease, with age, in the nuclear

refractive index[54] and that this may explain the fact that eye does not become myopic. However, the results reported are not consistent with what is known about the protein/total water proportions in the human lens and their constancy with age.[29] It is most likely that Moffat et al.[54] were measuring the proportions of free water, which increases in the human lens with age.[55]

An overall decrease in the nuclear refractive index, would be physiologically unsound, as it would require an imbibing of water or a leakage of protein from the center of the lens. Given that the nuclear refractive index in the human lens is not a part of the gradient index but is constant, an overall decrease in magnitude would have a negligible effect on refractive power of the eye.

The constancy of the nuclear refractive index and the index gradient in the cortex require a higher-order polynomial to fit the index distribution in the human lens. A fourth-order polynomial was found to give a highly significant fit to the refractive index gradient in the equatorial plane of the human lens (Fig. 8).[29]

This form for the radial refractive index gradient (i.e., in the equatorial plane) has been found in studies that used ray tracing (for 633 nm)[45] and for measurements taken with a fiber optic sensor (for 670 nm).[46] The two techniques have also shown results with similar magnitudes for the nuclear refractive index.[45,46]

The refractive index along the optic axis similarly has a gradient in the cortical region with a constant index nucleus.[46,47] However, the assumptions of concentric, isoindicial contours that follow the surface shape of the lens, may not apply to younger lenses (from the third decade of life).[46] As with the bovine lens, and consistent with the asymmetry of shape in the sagittal plane, there is a slight difference in the refractive index gradients in the anterior and posterior sections of the lens and this is also affected by lens age.[29]

The difficulty in ascribing a single formulaic description to the refractive index gradient in the human lens is not only complicated by changes to the cortical gradient with age, and by differences in the axial and radial gradients. There is also the confounding factor of accommodation. The human lens, in individuals under the age of around 50, is capable of altering its shape to meet the focusing requirements of the eye. This capacity is greater in younger eyes and it is not certain, what accommodative state a young lens is in when it is removed from the eye. It may not be unreasonable to expect that when the lens is released from the tension applied by the ciliary muscle, in situ, it takes on its most accommodated, that is, most curved shape. This, however, assumes that the lens is an elastic body, with the fully accommodated state: the one to which it returns when applied stretching forces mediated by the ciliary muscle are removed. This assumption has and continues to court controversy and so it remains uncertain what accommodative state the lens is in when removed from the eye. Moreover, given that the capacity for accommodation diminishes with age, the accommodative state of the in vitro lens will vary depending on the age of the lens. How the refractive index gradient alters with accommodation is not known, although some studies have shown that the accommodative process is caused by a change

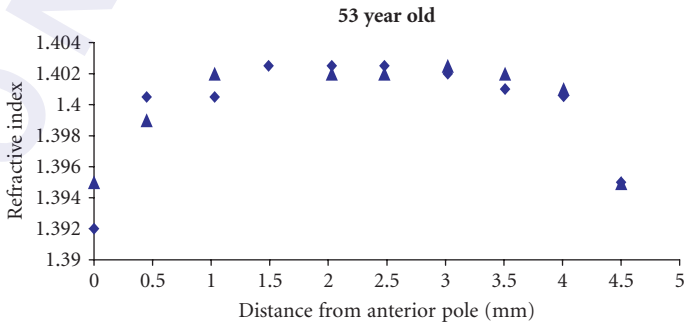

FIGURE 8 Variations in refractive index (for 670 nm) along the optic axis of a 53-year-old human lens plotted against the normalized distance from the anterior pole. (*From Ref. 29.*)

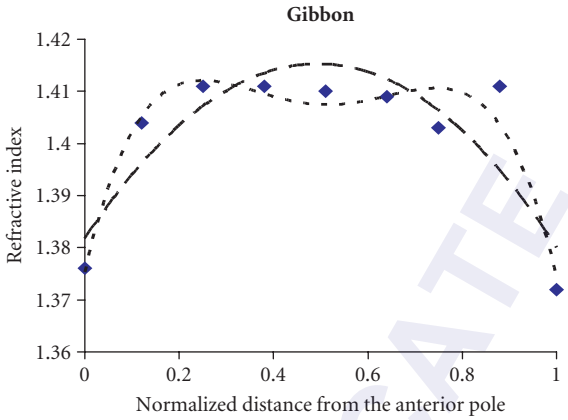

FIGURE 9 Variations in refractive index (for 670 nm) along the optic axis of the gibbon lens plotted against the normalized distance from the anterior pole. (*From Ref. 29.*)

in the length of the nucleus[51,56–58] with no change in the thickness of the cortex. This would suggest that the cortical refractive index gradient remains unchanged, the only alteration to the profile being an elongation to the constant index nuclear section.

There is very little information about the refractive index gradients in the lenses of lower-order primates. Results from a single gibbon lens show the same type of profile as for the human lens with a similar index magnitude (Fig. 9).[29]

It is not certain whether the same confounding factor of accommodation applies to the optics and refractive index gradient in the gibbon lens. However, studies on the rhesus monkey have shown that the species does accommodate.[59] As the gibbon belongs to a primate family that is more closely related to humans and its visual needs, from close range feeding to swinging from trees suggests that this species is likely to have an accommodating lens.

From the refractive index gradients, the primate lenses are the only ones that do not have a parabolic gradient but the refractive index gradient flattens to a region of constant refractive index in the nucleus. This constant, maximum value is lower than for other species thus far studied rendering these lenses softer and more pliable. This is consistent with the need for accommodation but also means that the refractive index gradient in a primate lens contributes less to the refractive power than the parabolic gradients, with higher-index magnitudes, found in other species.

19.17 FUNCTIONAL CONSIDERATIONS

Gradient index media are found in nature and the concept is exploited in the manufacture of lenses and optical devices for a wide range of applications. The fundamental difference between the biological and the manufactured lenses is that the former is not static in its optical qualities. Within any given species, the refractive index gradient will change with age because the lens continues to grow throughout life and it may change its shape in those species that possess accommodating lenses. Moreover, when considering the eye lens and its optical properties, it should not be considered in isolation. The eye lens functions as part of the optical system of the eye. The rays incident on its anterior surface will have been refracted by the cornea and traversed the anterior chamber. The shapes of the cornea and anterior chamber depths vary from species to species and individual variations within a species can be found. The humours that surround the lens in the eye will also impact on the contribution to refraction by the refractive index gradient. The more

closely the edge of the gradient is matched to the surrounding media, the more contribution is made by the refractive index gradient. No biological lens has yet been shown to have an edge index value matched to the refractive index of the aqueous and vitreous (around 1.336) and, with the techniques of ray tracing and optic fiber sensing, this is the most difficult part of the refractive index gradient to measure.

19.18 SUMMARY

The major types of index gradient found in lenses, optical devices, and created by nature have been described. These can be broadly categorized into gradients that vary parallel to the path of light, perpendicular to the path of light, or with radial distance from the center of the structure (found in spherical lenses). The eye lens is an excellent example of a GRIN structure with an index that varies both along and perpendicular to the optic axis. The refractive index distribution of the eye lens is related to its biological organization and to the properties of the major structural entities, the crystallin proteins. The concentration of proteins affects the magnitude of refractive index and the distributions of the different classes influence the shape of the index gradient. In spite of the complex structure of proteins and the changing interactions between protein subclasses and between proteins and water, it has been possible to measure the GRIN structure of the eye lens and in most species examined this appears to have a similar form. Transposing this form to an intraocular implant that cannot only mimic the GRIN structure but also provide some accommodative capacity is the subject of further research.

20 OPTICS OF CONTACT LENSES

Edward S. Bennett

College of Optometry
University of Missouri
St. Louis, Missouri

20.1 GLOSSARY

Accommodative demand. This represents the difference between distance and near refractive corrections.

Aspheric lens design. An aspherical surface, typically elliptical, often used on the back surface to align with an aspheric anterior cornea. In some presbyopic designs, either a back surface with a hyperbolic or high rate of flattening is used to provide plus power or an aspheric front surface is used for the same purpose.

Axial ametropia. Ametropia resulting from the axial elongation of the globe.

Axial edge lift. Pertains to the distance between the extension of the tangent of the base curve radius and the absolute edge; it is measured parallel to the lens optical axis or the vertical distance from the lens edge to an extension of the base curve radius.

Base curve radius (BCR). The radius of curvature of the central posterior optical section in millimeters.

Back vertex power (BVP). Commonly used to express the power of a contact lens, the power is determined from a fixed position with the concave surface of the lens against the lensometer lens stop.

Bitoric design. Gas permeable (GP) lens designs incorporating two base curve radii and multiple powers for correction of high corneal astigmatism, typically 2.50 D or greater.

Contact lens power. The dioptric power of the contact lens, usually expressed as back vertex power.

Edge clearance. The actual distance from the lens edge to the cornea. This value is less than the calculated edge lift due to the asphericity of the anterior cornea.

Effective power. The power of the contact lens at the corneal plane.

Fluoro-silicone/acrylate (F-S/A). The current generation of rigid gas-permeable contact lenses consisting primarily of fluorine, silicone, and methyl methacrylate.

Front vertex power (FVP). The power is determined from a fixed position with the convex surface of the lens against the lensometer lens stop.

High-order aberrations. Aberrations induced by the optics of the eye, notably spherical aberration and coma.

"K." This refers to the flatter keratometry reading. GP lenses are generally selected with a base curve radius slightly steeper or flatter than "K."

Lacrimal lens. The tear lens between a GP contact lens and the anterior corneal surface. It is a plus power if the lens exhibits apical clearance; it is minus if the lens exhibits apical bearing.

Multifocal contact lenses. Contact lenses that provide more than one correcting power within the lens; these are often used for the correction of presbyopia.

Optical zone diameter (OZD). This represents the linear equivalent of the base curve radius and provides the visual optics for both GP and soft lenses.

Overall diameter. This represents the linear, chord, edge-to-edge measurement of the lens in millimeters.

Oxygen permeability (Dk). The current term to describe the potential of a contact lens material to transmit oxygen which considers both, solubility and diffusion.

Prism (in contact lenses). Prism is produced by varying the thickness from the superior to the inferior region of a contact lens while maintaining the same front and back surface curvatures.

Radial edge lift. Pertains to the distance between the extension of the tangent of the base curve radius and the absolute edge; it is measured from the lens edge perpendicular to an extension of the base curve radius.

Refractive ametropia. Ametropia resulting from abnormal refractive component(s) of the eye.

Relative spectacle magnification (RSM). This compares the corrected ametropic retinal image to that of a standard emmetropic schematic eye. Ametropia can be purely axial, resulting from the axial elongation of the globe, refractive, resulting from abnormal refractive component(s) of the eye or a combination of both factors.

Residual astigmatism. With spherical GP lenses this pertains to the total ocular astigmatism (defined as the refractive cylinder) minus the corneal (often keratometric) cylinder. With spherical soft lenses, this pertains to the refractive cylinder.

Rigid GP contact lenses. Rigid lens materials, smaller in diameter with higher optical quality than soft lenses, which typically incorporate methyl methacrylate, silicone, and fluorine within the polymer matrix.

Silicone-hydrogel. The current generation of soft lens materials incorporating silicone within the matrix for higher oxygen permeability.

Soft toric lenses. Soft lens designs that correct for refractive astigmatism.

Spectacle magnification. This pertains to the ratio of retinal image size of the corrected ametropic eye to the retinal image size of the same eye uncorrected.

20.2 INTRODUCTION

The optics pertaining to contact lenses have several similarities to those of spectacle lenses. However, the primary differences pertain to such factors as the lesser thickness of contact lenses, the fact they are in direct contact with the tear film—not 11 to 15 mm away from the cornea—the differences present between soft and rigid gas permeable (GP) lens materials, as well as differences in accommodation and convergence effects on the eye. It is evident that, as a result of their optical properties, contact lenses are unique among the forms of correction available to wearers as well as, in many cases, a modality that exceeds other visual correction options in both the quality of vision and the visual freedom present to the wearer. The goal of this chapter is to emphasize the basic contact lens optics commonly used in eye care practices.

20.3 CONTACT LENS MATERIAL, COMPOSITION, AND DESIGN PARAMETERS

Contact Lens Materials

Contact lens materials can be considered either rigid or soft. The first modern rigid lens was the corneal polymethylmethacrylate (PMMA) lens which was popular from the late 1940s to the early 1980s. This material was essentially limited to the PMMA plastic and was, therefore, not oxygen permeable. GP lenses incorporating silicone (for oxygen permeability) as well as stability agents and wetting agents (the latter to help offset the hydrophobic nature of silicone) was introduced in 1979. However, the introduction of fluoro-silicone/acrylate (F-S/A) lenses in the mid 1980s was a major breakthrough and almost all GP lenses in use today are F-S/A materials. The addition of fluorine both assisted in surface wettability via encouraging the tear film mucin to form an even layer on the lens surface but also increased oxygen permeability—through increased oxygen solubility in fluorine—while allowing the silicone content to be reduced. GP materials have many benefits including high quality of vision resulting from the excellent optical quality of these materials and their ability to mold the front surface of the cornea and automatically correct for astigmatism.

Soft (or hydrogel) contact lenses were introduced in 1971. Soft lenses differ from GP lenses as a result of their ability to bind substantial amounts of water.[1] A loose or less tight cross-linking structure allows these materials to range in water content from 25 to greater than 70 percent when equilibrated in normal (0.9 percent) saline.[2] The water content can be expressed by the following equation:[3]

$$\text{Water content} = \frac{\text{Weight of lens water}}{\text{Total weight of hydrated lens}} \times 100$$

Soft lens materials are quite porous relative to GP lenses resulting in a reduction in optical quality which can impact vision. This pore size has been estimated at about 8 Å for low water content materials and 20 to 30 Å for high water content lenses.[4] However, as a result of their larger overall diameter resulting in less movement with the blink, soft lenses have the advantage of being more initially comfortable and easier to adapt to for lens wearers. As soft lenses allow very little oxygen via tear exchange with the blink and the oxygen transmission is achieved primarily through diffusion through the lens, they have not represented a highly successful long-term option for extended wear. However, recently silicone hydrogel lenses have been introduced with oxygen permeability values as much as 5 to 10 times greater than hydrogel lenses and have increased from 0 percent of new fits in the United States in 2002 to over 35 percent in 2006.[5] Silicone hydrogel lens materials combine the high oxygen permeability of silicone with other material characteristics of conventional hydrogel materials that facilitate fluid transport and lens movement.[6] The surfaces of these lenses are treated to make them more hydrophilic and, therefore, more biocompatible. These materials are FDA approved for up to 30 days of continuous lens wear.

Curvature, Diameter, and Thickness

To understand the optics associated with contact lenses, it is important to have a good working knowledge of contact lens design. A brief description of each parameter is discussed below and summarized in Table 1.

Base Curve Radius (BCR) The base curve radius of a contact lens is the radius of curvature of the central posterior optical section in millimeters[7] (Fig. 1). This has also been termed the back central optical radius (BCOR). For rigid GP lens materials the base curve radius is typically selected to be approximately the same curvature as the anterior cornea such that the lens will "align" with the anterior corneal surface. With soft or hydrogel lenses, the base curve radius is typically about 1.0 mm flatter than the anterior corneal curvature as they are much larger in diameter and simply drape over

TABLE 1 Contact Lens Design Parameters

Base Curve Radius	The radius of curvature of the central posterior optical section in millimeters.
Secondary Curve Radius/Width	In a tricurve or tetracurve GP lens design, the secondary curve radius is the curve adjacent to the central base curve radius and is typically flatter than the base curve radius. The width of this curve (often 0.2 to 0.5 mm) represents the linear size of this curve.
Intermediate Curve Radius/Width	In a tetracurve GP lens design, the intermediate curve radius is the curve adjacent to the secondary curve radius and is flatter than the secondary curve radius. The width of this curve (often 0.2 to 0.5 mm) represents the linear size of this curve.
Peripheral Curve Radius/Width	In a tricurve or tetracurve GP lens design, the peripheral curve radius is the outermost curve radius. It is the flattest curve and its parameter is most responsible for the resultant edge clearance (distance from edge to cornea). The width of this curve (often 0.2 to 0.5 mm) represents the linear size of this curve.
Transition Zone Blend	As the junction between two peripheral curves can be rather sharp, laboratories typically blend or smooth these junctions.
Overall Diameter	This represents the linear, chord, edge-to-edge measurement of the lens in millimeters.
Optical Zone Diameter	This represents the linear equivalent of the base curve radius and provides the visual optics for both GP and soft lenses.
Center Thickness	This is the thickness as measured at the exact center of the lens.
Edge Thickness	This is the thickness as measured at the edge of the lens. This value should be similar to the center thickness. As high minus lenses have thick edges, a plus lenticular is often manufactured to thin the anterior edge; likewise for low minus and plus power lenses, a minus lenticular is generated to increase the edge thickness.
Power	Lens power is the dioptric power of the contact lens, usually expressed as back vertex power.

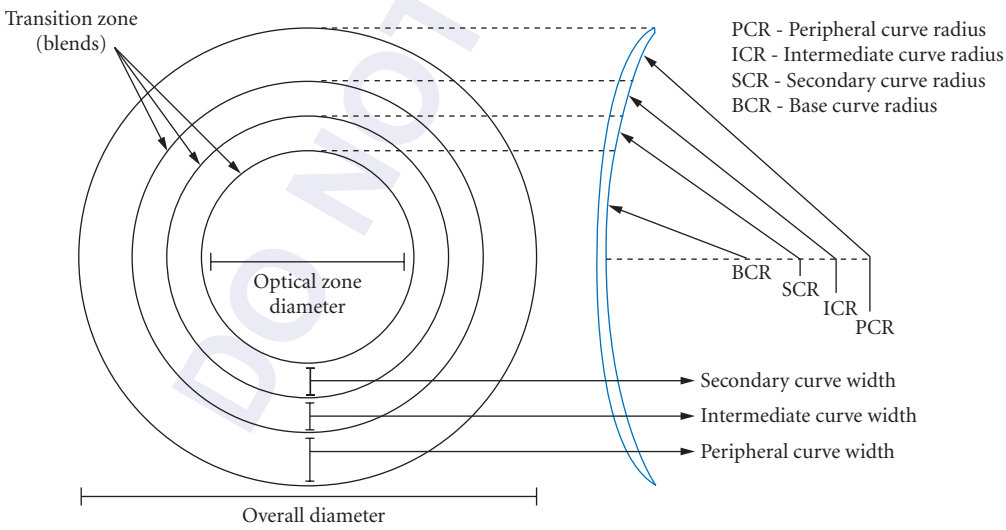

FIGURE 1 Cross-section of a tetracurve rigid GP contact lens showing overall diameter, optical zone diameter, secondary curve, intermediate curve, and peripheral curve radii and widths and transition zone blends. (*From Ref. 30.*)

the cornea and align with the adjacent sclera.[8] For GP lenses base curve radius is often specified in millimeters; however, it has also been denoted by its dioptric equivalent. The conversion formula is

$$\text{BCR (in diopters)} = \frac{n' - n}{r}$$

where n' = index surrounding the lens (although the tear layer is 1.336, the keratometer is calibrated for 1.3375 and this value is used)
n = refractive index of air or 1.0
r = base curve radius in meters

For example, if the base curve radius was verified to be 7.50 mm with the radiuscope, the dioptric equivalent would be 1.3375 – 1.0/0.0075 or 45 D. BCR values in diopters and their converted values in millimeters are provided in Table 2.

Overall Diameter (OAD)/Optical Zone Diameter (OZD) The linear, chord, edge-to-edge measurement of the lens in millimeters is the overall diameter. GP lenses typically have OAD values between 9.0 to 10.0 mm. Soft or hydrogel lenses typically have OAD values of approximately 14.0 mm. The optical zone diameter is the linear equivalent of the base curve radius and is the central section of the lens which provides usable optics for vision; the lens periphery has a primary function of optimizing tear exchange and the fitting relationship. By convention, the lens OZD for GP lenses is the overall diameter minus the posterior peripheral curve widths (often the OAD—approximately 1.0 to 1.5 mm). The OZD for soft lenses is the overall lens diameter minus twice the anterior peripheral curve width in millimeters.

Posterior Peripheral Curve Systems GP lenses have a standard curvature (i.e., the base curve radius) with typically two-to-three peripheral curve radii. These peripheral curve radii are progressively

flatter from the base curve to the outermost curve. As the cornea is aspheric and flattens from center to periphery, a monocurve GP lens would likely be too steep in the periphery and not allow tear exchange—important for oxygen exchange and debris removal—to occur. Therefore, if the base curve radius was 7.80 mm, one common philosophy recommends a secondary curve radius (SCR) equal to 1 mm flatter than the base curve radius, and a peripheral curve radius 2 mm flatter than the SCR.[9] Both of these curves would be 0.3 mm wide. This is termed a tricurve design. A tetracurve design would include a secondary curve, an intermediate curve, and a peripheral curve as diagrammed in Fig. 1. Some designs (to be discussed) are manufactured such that they have a gradual increase in flattening in the periphery, termed a peripheral aspheric design. Soft lens posterior curvature is either monocurve, bicurve (typically one peripheral curve on average about 0.5 mm wide and as flat as 12 mm in curvature), or aspheric. The nonmonocurve designs are intended to align the lens periphery with the peripheral limbal or scleral topography.[7]

Center Thickness Contact lenses are relatively thin lens designs (relative to spectacles) with lenses as thin as 0.035 mm for a high minus power ultrathin soft lens to as high as 0.5 to 0.6 mm for high plus power soft and GP lenses, especially if prism ballast is incorporated into the lens to stabilize it on the eye. Minus power GP lenses tend to vary from 0.09 mm (ultrathin) to 0.19 mm for low minus standard thickness designs. Low plus power lenses typically have center thicknesses in the 0.20 to 0.25 mm range and high plus power lenses have center thicknesses in the 0.26 to 0.60 mm range. Center thickness impacts both lens mass and oxygen transmission. Plus power lenses have greater mass and an anterior center of gravity making centration on the eye more challenging. In addition, oxygen transmission (i.e., Dk/t where "Dk" is the oxygen permeability of the material and "t" is the thickness—either t_{avg} for average thickness or t_c for center thickness) reduces as the center thickness increases. However, a minus power GP lens that is too thin will bend or flex on the eye and will negate one of the benefits of this modality, the ability to mold the anterior corneal surface into a sphere and correct astigmatism.

Edge Thickness Edge thickness varies for GP and soft lenses but values of 0.06 to 0.12 mm are not uncommon. With most GP designs, the apex is tapered and rounded toward the posterior surface. As high minus power (typically ≥5 D) lenses tend to have thick edges and both low minus power (typically ≤ 1.50 D) and all plus power lenses have thin edges, special manufacturing procedures are utilized to maintain a uniform edge thickness. With GP lenses this is typically a plus lenticular (a manufacturing process that thins the edge) for high minus power lenses and a minus lenticular (a manufacturing process that results in a thicker edge) for low minus and plus power lenses. This uniform edge thickness is important for allowing the upper lid to lift up the lens with the blink while not being so thick that the lid would push the lens inferiorly.

20.4 CONTACT LENS POWER

Contact lens power typically differs from spectacle lens power. For example, a spectacle lens power of –2.00 –1.00 × 180 would indicate that the horizontal meridian of the spectacles has a power of –2.00 D and the vertical meridian has a power of –3.00 D. If this patient has no residual astigmatism (i.e., the anterior corneal astigmatism is also equal to –1.00 × 180), the back surface of a spherical power GP lens will mold the front surface of the cornea into a sphere; therefore, the astigmatism is corrected. A spherical soft lens, however, simply drapes over the eye and does not correct for refractive astigmatism and, in theory, the –1.00 × 180 correction in the spectacles would not be corrected by such a soft lens and a special design, a soft toric lens (to be discussed) would be indicated.

The Contact Lens as a Thick Lens

Contact lenses are manufactured at a much lesser center thickness (typically 0.08 to 0.5 mm) than spectacle lenses. Nevertheless, they still need to be considered as thick lenses when determining the overall power. Therefore, instead of simply adding the refractive power of the front surface to the

back surface power (i.e., $F_T = F_1 + F_2$), the curvatures of both surfaces, center thickness and index of refraction of the lens material need to be considered. The thick lens formula used for spectacle lenses could be considered.[10] It is as follows:

$$F_T = F_1 + F_2 - (t/n)F_1F_2$$

where F_T = equivalent or true refractive power in diopters
$F_1 = (n' - n)/r_1$ = refractive power of the anterior lens surface
$F_2 = (n - n')/r_2$ = refractive power of the posterior lens surface
t = center thickness of the lens in meters
n' = refractive index of the lens material
n = refractive index of the medium surrounding the lens
r_1 = radius of curvature of posterior surface, in meters
r_2 = radius of curvature of anterior surface, in meters

However, as the positions of the principal planes vary with the design of the lens and its two surface powers, it is impractical to use the equivalent, or true, power of a contact lens as the absolute definition of refractive power. It is, instead, important to use a fixed position to measure refractive power.

Back Vertex Power and Front Vertex Power

A fixed position from which refractive power can be determined is via the use of either back vertex power (BVP) or front vertex power (FVP). The equations of these powers are as follows:

$$\text{BVP} = F_1 + \left[\frac{F_2}{1-(t/n')F_2}\right]$$

$$\text{FVP} = \frac{F_1}{1-(t/n')F_1} + F_2$$

The measurement of BVP and FVP is very straightforward on a lensometer. BVP is obtained with the back surface of the lens (concave surface) against the lens stop (see Fig. 2). Front surface

FIGURE 2 Determination of back surface power via the use of a lensometer.

TABLE 3 Differences between Back Vertex Power (BVP) and Front Vertex Power (FVP) in Air for GP Lenses ($N = 1.46$)

+20.00	+19.01	0.50	+0.99

power is obtained with the front surface of the lens (i.e., convex surface) against the lens stop. The focal lengths (in meters) are also easy to determine as they are simply the reciprocals of the vertex powers in diopters. For example, a BVP of –10 D would have a focal length of 1/10 or 0.1 m (or 10 cm).

The difference between BVP and FVP is often negligible, especially in all minus and low plus power lenses. This is the result of the smaller center thicknesses that are present in these lens powers. However, with moderate-to-high plus power lenses—notably aphakic powers—this difference becomes significant (see Table 3).

As it can be shown, BVP is always greater than FVP. This has been a source of confusion in the past when it was not uncommon to specify (and/or receive from the fabricating laboratory) aphakic lenses via FVP. However, if the practitioner ordered the lenses based on BVP, the amount of resulting error could be considerable.[11] Fortunately, the contact lens industry has—with rare exception—utilized back surface power for all contact lenses in recent years.

Effective Power

A primary difference between spectacle power and contact lens power—notably in high ametropia—pertains to the effective power at the corneal plane. A spectacle lens is often positioned 10 to 15 mm in front of the cornea. This distance from the spectacle lens to the corneal apex is termed "vertex distance." A contact lens, however, by virtue of being positioned adjacent to the cornea has a vertex distance of zero.

As a rule, as a plus power lens is brought closer to the cornea, its effective power decreases, such that its refractive power must be increased in order to maintain a constant amount of power relative to the eye. Likewise, when a minus power lens is brought closer to the eye, its effective power increases, such that its refractive power must be decreased in order to maintain a constant amount of power relative to the eye.[10] When correcting an individual with a myopic refractive error, a contact lens will require a longer focal length, therefore resulting in less minus power than a spectacle lens. Likewise, when correcting an individual with a hyperopic refractive error, a contact lens will require a smaller focal length, therefore resulting in a higher plus refractive power than with a spectacle lens. Effective power differences between spectacle and contact lens corrections become clinically significant at about ±4 D (see Table 4).

–18.00	–14.75	+18.00	+23.00

There are two methods of determining the power at the corneal plane. The first is simply to use the following equation

$$F(c) = \frac{F(\text{sp})}{1 - dF(\text{sp})}$$

where $F(c)$ = power at the corneal plane
$F(\text{sp})$ = power at the spectacle plane
d = vertex distance (in m)

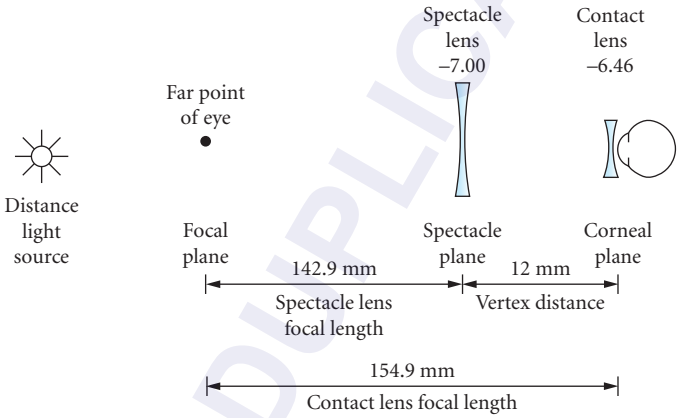
Whereas, the vertex distance should be carefully measured in high ametropia patients, an average value of 12 mm is commonly used and will be used in the calculations presented in this chapter. If a patient has a refractive power of –7.00 – 1.50 × 180, and the power in each meridian (i.e., –7.00 at 180 and –8.50 at 090) is "vertexed" to the corneal plane via this formula, the resulting powers would be –6.46 D and –7.71 D or –6.46 – 1.25 × 180, which can be rounded off to –6.50 – 1.25 × 180. If the individual was hyperopic and had a refractive error of +7.00 – 1.50 × 180, and the power in each meridian (i.e., +7.00 at 180 and +5.50 D at 090) was vertexed to the corneal plane, the resulting powers would be +7.64 D and +5.89 D or +7.64 – 1.75 × 180 or rounded off to +7.75 – 1.75 × 180.

It can observed that in compound myopic astigmatism, the spherical and cylinder power components decrease when referred to the corneal plane. In compound hyperopic astigmatism, the spherical and cylindrical power components increase or become greater when referred to the corneal plane.

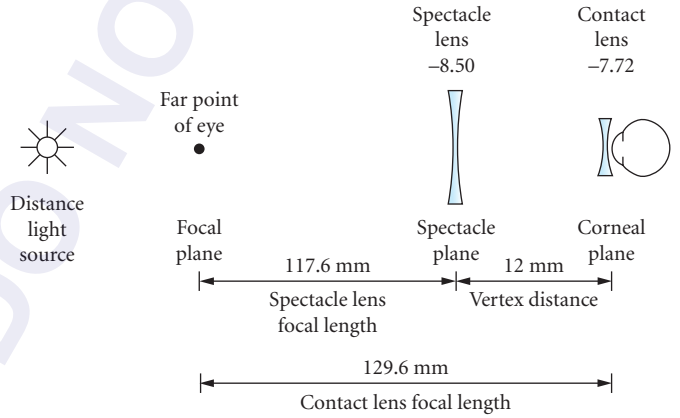
The second method of effective power calculation would refer back to the diagrams in Figs. 3 and 4 via the use of focal lengths. If the individual's refractive error is –7.00 – 150 × 180, the focal lengths of the two primary meridians are as follows:

$$\text{Horizontal meridian: } f\,180 = \frac{1}{F180} = \frac{1}{7\text{ D}} = 0.1429 \text{ m or } 142.9 \text{ mm (Fig. 3}a\text{)}$$

$$\text{Vertical meridian: } f\,090 = \frac{1}{F090} = \frac{1}{8.50\text{ D}} = 0.1176 \text{ m or } 117.6 \text{ mm (Fig. 3}b\text{)}$$



(a)



(b)

FIGURE 3 Determination of the effective power for the myopic patient in both the (*a*) horizontal meridian and (*b*) vertical meridian.

The focal lengths of the correction at the corneal plane will be 12 mm more; therefore, the final power per meridian is

$$\text{Horizontal meridian: } F180 = \frac{1}{0.1549 \text{ m}} = -6.46 \text{ D}$$

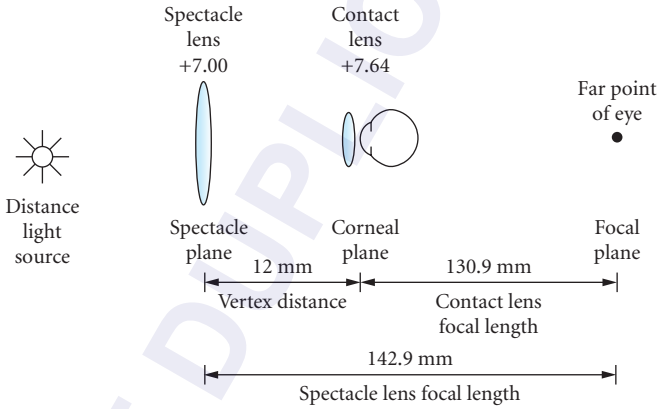
$$\text{Vertical meridian: } F090 = \frac{1}{0.1296 \text{ m}} = -7.72 \text{ D}$$

The corneal plane refraction is, therefore, $-6.46 - 1.26 \times 180$ or rounded off to $-6.50 - 1.25 \times 180$.

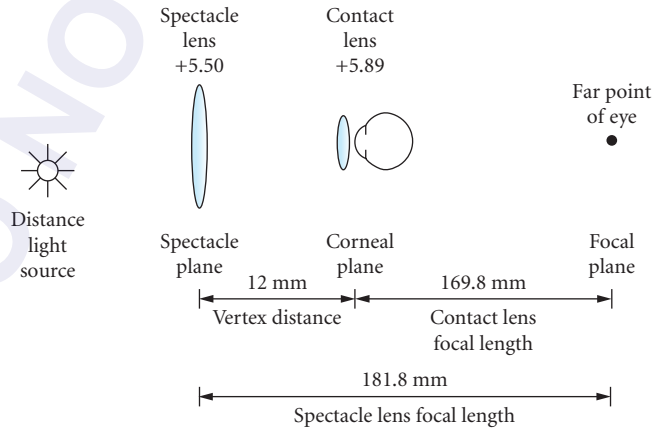
If the individual's refractive error is $+7.00 - 1.50 \times 180$, the focal lengths of the two primary meridians are as follows:

$$\text{Horizontal meridian: } f180 = \frac{1}{F180} = \frac{1}{7 \text{ D}} = 0.1429 \text{ m or } 142.9 \text{ mm (Fig. 4}a\text{)}$$

$$\text{Vertical meridian: } f090 = \frac{1}{F090} = \frac{1}{5.5 \text{ D}} = 0.1818 \text{ m or } 181.8 \text{ mm (Fig. 4}b\text{)}$$



(a)



(b)

FIGURE 4 Determination of the effective power for the hyperopic patient in both the (*a*) horizontal meridian and (*b*) vertical meridian.

The focal lengths of the correction at the corneal plane will be 12 mm less; therefore, the final power per meridian is

$$\text{Horizontal meridian: } F180 = \frac{1}{0.1309 \text{ m}} = +7.64 \text{ D}$$

$$\text{Vertical meridian: } F090 = \frac{1}{0.1698 \text{ m}} = +5.89 \text{ D}$$

The corneal plane refraction is, therefore, $+7.64 - 1.75 \times 180$ or rounded off to $+7.75 - 1.75 \times 180$.

Lacrimal Lens Considerations

Whereas effective power impacts both soft and GP lenses with patients who have a spherical refractive value equal to 4 D or greater, as soft lenses merely drape over the cornea, no compensation for the lacrimal or tear lens between the cornea and the contact lens is necessary. With GP lenses, however, a lacrimal or tear lens between cornea and contact lens often exists and needs to be factored into the final contact lens power determination. The baseline values to be considered when determining GP power pertain to the flatter keratometry reading and the spherical refractive value (at the corneal plane). The base curve radius selected for most GP wearers is very similar in curvature to the flatter keratometry reading; therefore, very little—if any—lacrimal lens is present. If fitted in alignment with the flatter keratometry reading, this is typically referred to as an "On *K*" lens-to-cornea fitting relationship. If the lens is fitted more curved or steeper in base curve radius than the baseline corneal curvature value it is termed "steeper than *K*." If the lens is fitted less curved or flatter than the baseline corneal curvature value, it is termed "flatter than *K*." The ideal GP lens-to-cornea fitting relationship would consist of an alignment or even tear film between lens and cornea as easily observed when fluorescein dye is applied to the tear film. Such a pattern is shown in Fig. 5. A base curve radius selected excessively steeper than "*K*" resulting in direct contact of the lens against the central cornea is shown in Fig. 6. This apical bearing relationship can ultimately result in central corneal distortion as well as excessive lens awareness due to the large amount of edge clearance present. A base curve radius selected excessively steeper than "*K*" can result in very little tear exchange peripherally, possibly resulting in edge sealoff and corneal edema. (See Fig. 7.)

In theory, as a result of the fact that the cornea is aspheric and gradually flattens in curvature from center to periphery, a slightly flatter than "*K*" base curve radius is often recommended. Of course the rate of flattening or corneal eccentricity can vary considerably and this will impact the fitting relationship and the base curve radius that will ultimately result in success. It is also important to remember

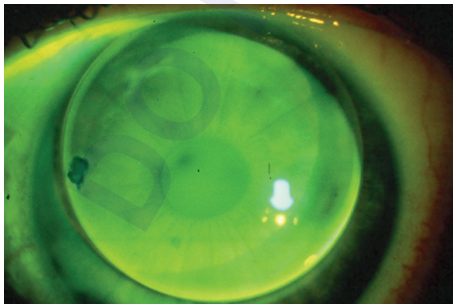


FIGURE 5 An alignment GP lens-to-cornea fitting relationship as demonstrated with fluorescein application.

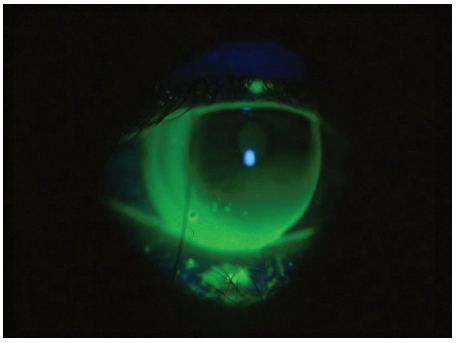

FIGURE 6 An apical bearing or flat GP lens-to-cornea fitting relationship as demonstrated with fluorescein application.

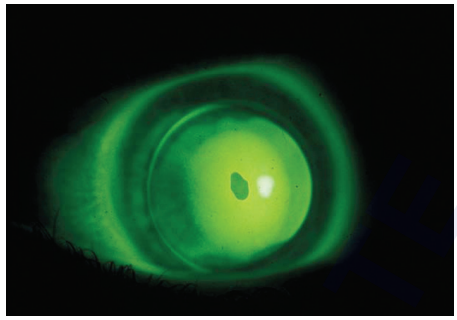

FIGURE 7 An apical clearance or steep GP lens-to-cornea fitting relationship as demonstrated with fluorescein application.

that a lens that is fitted flatter than "*K*" will induce a minus power lacrimal lens; for example, if a lens was fitted 0.50 D flatter than "*K*," a –0.50 D lacrimal lens would be present and +0.50 D would need to be incorporated into the contact lens power to compensate for the lacrimal lens. Likewise, a lens that is fitted steeper than "*K*" will induce a plus power lacrimal lens; for example, if a lens was fitted 0.50 D steeper than "*K*," a +0.50 D lacrimal lens would be present and –0.50 D would need to be incorporated into the contact lens power to compensate for the lacrimal lens.

The actual power can be derived in several ways. For example, the GP lenses were to be ordered empirically (i.e., from calculations only, not via the application of a diagnostic lens), the following formula can be used for predicting the power to be ordered

$$F_{cl} = F_{cp} - \text{LLP}$$

where F_{cl} = power of the contact lens
F_{cp} = power of the refraction at the corneal plane
LLP = lacrimal lens power

Using this formula, if the patient had the following refraction and keratometry values

Refraction: –3.00 – 0.75 × 180

Keratometry: 43.50 at 180; 44.25 at 090

and a base curve radius was selected 0.75 D flatter than "*K*" or 42.75 (7.89 mm), the following GP contact lens power would be predicted:

$$F_{cl} = -3.00 - (-)0.75 = -2.25 \text{ D}$$

If the base curve radius was selected to be 0.50 D steeper than "*K*," the predicted contact lens power would be

$$F_{cl} = -3.00 - 0.50 = -3.50$$

This example is shown in Fig. 8. An easy acronym to remember when factoring the tear lens into the contact lens power is "SAM-FAP" (i.e., "steep-add-minus" and "flat-add-plus").

The most accurate method of determining contact lens power is via the use of a diagnostic lens. The formula for deriving the power when a diagnostic lens is placed on the eye is very simple

$$F_{cl} = F_{dl} + \text{OR}$$

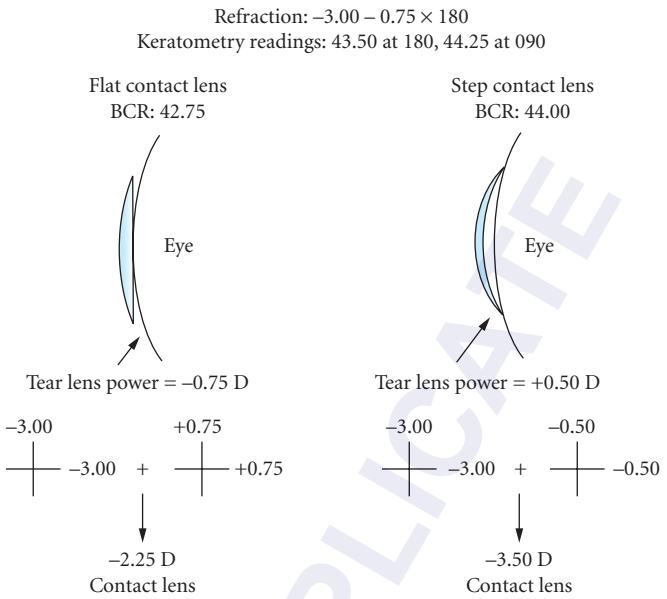

FIGURE 8 The "SAM (steep-add-minus)-FAP (flat-add-plus)" acronym as it applies to power determination based on the tear lens power.

where F_{cl} = final contact lens power
F_{dl} = power of the diagnostic lens
OR = spherical overrefraction

For example, if a patient has the following spectacle refraction and keratometry values

Refraction: –6.00 – 0.50 × 180
Keratometry: 43.50 at 180; 44.00 at 090

If a diagnostic GP lens with a power of –3.00 D and a base curve radius equal to 43.25 (7.80 mm) was selected, the predicted contact lens power would equal

$$F_{cl} = F_{cp} - \text{LLP}$$
$$= -5.50 \text{ (refraction at corneal plane)} - (-)0.25$$
$$= -5.25 \text{ D}$$

Once the contact lens has been evaluated and an overrefraction performed, it can be determined if the actual contact lens power to be ordered is equal to the predicted. If the spherical overrefraction was –2.25 D, this would be the case as

$$F_{cl} = F_{dl} + \text{OR} \qquad \text{or}$$
$$= -3.00 + (-)2.25$$
$$= -5.25 \text{ D}$$

As this example clearly demonstrates, the two most important factors when determining the power of a GP lens are effective power (if the ametropia is ≥ 4 D) and lacrimal lens power. If the contact lens power, as determined by overrefraction, deviates from the predicted power, the former is typically more accurate as inaccuracies in refraction and keratometry can impact the predicted value. The final lens order for this patient could be as follows:

Power: –5.25 D
OAD/OZD: 9.40/8.00 mm
BCR: 7.80 mm
SCR/W: 8.80/0.3 mm
PCR/W: 10.80/0.3 mm
CT: 0.12 mm
Material: Boston ES (fluoro-silicone/acrylate)

It is also important to understand how the lens design impacts the sagittal depth relationship between contact lens and cornea. As the optical zone diameter represents the linear equivalent to the base curve radius, if an alignment lens-to-cornea fitting relationship exists but the patient's pupil diameter is quite large, necessitating a larger optical zone diameter to optimize vision, the new lens should exhibit an apical clearance or steep fitting relationship due to the increase in sagittal depth. Essentially the steepest section of the contact lens, the base curve radius, has become larger. Therefore, the base curve radius should be designed to be flatter to compensate for this change in optical zone diameter; typically a 0.25 D change for every 0.5 mm change in OZD should maintain an alignment lens-to-cornea fitting relationship.

Residual Astigmatism

A factor that has to be considered when determining whether a patient should be fit into GP lenses is their residual astigmatism. This is defined as[12]

Total ocular astigmatism – astigmatism as measured by keratometry

In the previous examples, the refractive and anterior corneal astigmatism (as measured with a keratometer) were the same; therefore, no residual astigmatism would be predicted. If, however, a patient had the following refractive information:

Refraction: –2.00 – 1.50 × 180
Keratometry: 42.50 at 180; 43.00 at 090

the predicted residual astigmatism would equal the refractive (i.e., total ocular) astigmatism minus the keratometric astigmatism or

$$-1.50 \times 180 - (-)\ 0.50 \times 180 = -1.00 \times 180$$

As a GP lens only corrects anterior corneal astigmatism, this residual astigmatism would not be corrected and could result in symptoms of blurred vision and eyestrain. Typically, when there is –0.75 D or greater of residual astigmatism, a spherical GP lens is not recommended. Fortunately, this is quite uncommon.

Soft Lens Power

For spherical soft lenses, the primary factor to consider would pertain to effective power considerations when the ametropia equals or exceeds 4 D. As the back surface of a soft lens essentially conforms to—or drapes over—the anterior corneal surface, the power of the lacrimal lens is approximately

plano or afocal.[13] This conformation of lens to the topography of the cornea has been termed "flexure." Changes in base curve radius, diameter, or any other parameters do not appear to induce any lacrimal lens power. If the lens dehydrates during wear, the refractive index of the material will increase which will increase the magnitude of both plus and minus corrections, and the base curve radius will steepen and the lens will increase in minus power.[14] In addition, it has been reported that as the cornea steepens, the amount of back vertex power is predicted to increase for both plus and minus lenses.[10] Total flexure or conformation to the cornea may not be realistic with soft lenses, notably for plus power lenses.[15]

Another factor that impacts soft lens power as well as other design parameters pertains to the amount of expansion that occurs when the lens is hydrated (i.e., from the dry to wet state). According to Douthwaite[13] a –3.25 D 59 percent water content soft lens with a 13 mm overall diameter, 8.60 mm base curve radius, and center thickness of 0.085 mm will have—prior to hydration—a –5.82 D power, 6.10 mm base curve radius, 9.22 mm overall diameter, and 0.060 mm center thickness. Therefore, as a result of all of these factors (dehydration, incomplete flexure, and the parameter changes when hydrated), it cannot be assumed that the labeled lens power of a soft contact lens will represent the true power of the lens on the eye.

Toric Lens Powers

Soft Toric Lenses As spherical soft lenses do not correct for the refractive (ocular) astigmatism, lenses incorporating this correction on the front surface are termed "soft toric lenses." As it has been estimated that about 45 percent of interested contact lens patients have refractive astigmatism greater than or equal to 0.75 D[16] if the criterion for significant astigmatism is a minimum of 0.75 D, then close to half of the spectacle-wearing population are potential candidates for soft toric lenses.[17]

The astigmatism is typically corrected onto the vertical meridian of the front surface and the lenses use several types of stabilizing techniques that will minimize any rotation of the lens on the eye. Traditionally these designs were prism ballasted inferiorly to weight the lens. Several newer techniques have resulted in the necessary thickness differential between the central, superior, and inferior sections of the lens without prism use.

The cylinder axis of the soft toric lens should align with the axis of the refractive astigmatism of the eye. For example, if a patient has a refractive error of $-2.00 - 0.75 \times 180$, this should be the powers of the soft toric lens fit to this patient. The cylinder axis is typically identified by a laser mark; often marks are also present 20° to the left and to the right of the axis. If the axis shifts or rotates with the blink, a new lens should be attempted which compensates for this rotation. The acronym LARS (left-add; right subtract) is valuable in these cases (Fig. 9). If the laser mark shifts 15° to the observer's left, a new lens with an axis at 15° should be attempted; likewise if the lens shifts 15° to the observer's right, a lens with an axis of 165° should be attempted.

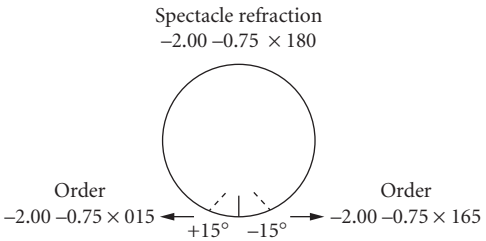

FIGURE 9 The "LARS" (i.e., left-add; right-subtract) concept as it pertains to determining axis for a soft toric lens.

If lens rotation is minimal, particularly with high spherical refractive errors (i.e., ≥5 D) and low astigmatic corrections (i.e., ≤1.25 D), little-to-no impact on vision should result. On average, relatively stable soft toric lenses usually average 0 to 10° of nasal rotation.[18] However, when the rotation is significant, a "crossed cylinder" problem is presented. When the axis of cylinder of a correcting contact lens does not align with the best refractive correction, an overrefraction will result in cylinder at an axis oblique to that of the axis of best correction.[10] Residual cylinder will be present in the overrefraction and this value will increase as axis rotation increases and with higher refractive cylinder corrections. The extent of the shift in position of the resultant plus cylinder axis for two cylinders of equal power but opposite sign has been calculated by Pascal.[19] The formula $(90 + a)/2$ is used, where "a" is the angular discrepancy between the two combined cylinders. Therefore, the resultant plus cylinder axis is 45° from the midpoint between the axes of the two combined cylinders. The axis of the resultant plus cylinder of the crossed cylinder combination will appear on the side of the axis of the original plus cylinder opposite to that of the original minus cylinder. If the axis of ocular astigmatism is, for example, 90° and a minus cylinder of equal power is placed at axis 70°, or 20° away, the resultant plus cylinder will appear 55°[i.e., (90 + 20)/2] from 070 on the opposite side, or "x125." The resultant plus cylinder will require a minus cylinder correction.

GP Bitoric Lens Powers Spherical GP wearing patients who exhibit a high amount of corneal astigmatism (typically ≥2.50 D) will not show the alignment fluorescein pattern demonstrated in Fig. 5 but will, instead, show a "dumbbell-shaped" pattern as shown in Fig. 10. In a high with-the-rule astigmatic patient, excessive edge clearance will exist in the steeper vertical meridian and bearing along the flatter horizontal meridian. As this fitting relationship often results in lens decentration on the eye, more edge awareness and corneal desiccation (dryness-induced epithelial cell loss), a lens that has a toric back surface with curvatures approximating the corneal curvatures in the two principle meridians is indicated. This design—termed bitoric lens design—essentially consists of two curvatures and two corresponding powers. A common method of selecting base curve radii is the Mandell-Moore bitoric lens guide philosophy.[20] This is provided in Table 5. For example, if the keratometry readings were

42.00 at 180 and 45.00 at 090

based on the Mandell-Moore base curve radius selection guide for three diopters of corneal cylinder, the flatter base curve radius would equal 0.25 D flatter than flat "K" or 41.75 D and the steeper base curve radius would equal 0.75 D flatter than steep "K" or 44.25 D. The base curve radii are selected to be flatter than their respective corneal curvatures due to the flattening of the cornea from center to periphery. The greater amount of flattening in the steeper meridian creates a slight amount of

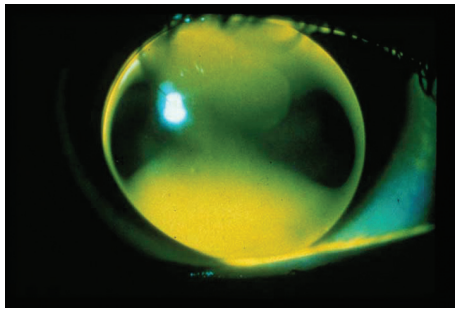

FIGURE 10 An astigmatic or "dumbbell-shaped" fluorescein pattern of a spherical GP lens on a highly with-the-rule astigmatic patient.

TABLE 5 Mandell-Moore Base Curve Selection

Corneal Cylinder	Flat Meridian	Steep Meridian
2.0 D	"On *K*"	0.50 D Flatter than "*K*"
2.5 D	0.25 D Flatter than "*K*"	0.50 D Flatter than "*K*"
3.0 D	0.25 D Flatter than "*K*"	0.75 D Flatter than "*K*"
3.5 D	0.25 D Flatter than "*K*"	0.75 D Flatter than "*K*"
4.0 D	0.25 D Flatter than "*K*"	0.75 D Flatter than "*K*"
5.0 D	0.25 D Flatter than "*K*"	0.75 D Flatter than "*K*"

toricity which has been found to enhance tear exchange. Determining the lens powers requires two tear lens calculations (vertical and horizontal meridians), not one as with conventional GP lenses. For example, if the patient's refraction in the above case was Pl – 3.00 × 180, the powers to be ordered for each meridian would consist of the following

$$F_{cph} - \text{LLP} \qquad \text{and} \qquad F_{cpv} - \text{LLP}$$

where F_{cph} = refractive power at the corneal plane in horizontal meridian and
F_{cpv} = refractive power at the corneal plane in vertical meridian

$$F_{cph} - \text{LLP} = \text{Pl} - (-0.25) = +0.25 \text{ D}$$

$$F_{cpv} - \text{LLP} = -3.00 - (-0.75) = -2.25 \text{ D}$$

Therefore, the final powers of this bitoric lens would be +0.25/–2.25. This can also be diagrammed via the use of optical crosses showing the refractive power per meridian in combination with the correction for the lacrimal lens power (i.e., using "SAM-FAP"). This is shown in Fig. 11.

Another method of determining the base curve radii and powers without the use of optical crosses is to use the Mandell-Moore guide. An example is provided in Fig. 12.

An alternative method, which appears to be equally popular and effective, is to fit the patient with bitoric diagnostic lenses.[21] In this case, a spherical overrefraction is typically all that is required and this value is added to the diagnostic lens power in each meridian. If, for example, in the above case, a bitoric diagnostic lens is selected that has base curve radii of 41.50/44.50 and powers of Pl/–3.00 D, and the overrefraction is +0.50 DS, the final powers would be

$$\text{Plano} + (+)\ 0.50 = +0.50 \text{ D}$$

$$-3.00 + (+)\ 0.50 = -2.50 \text{ D}$$

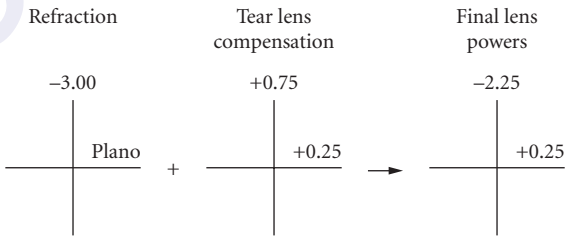

FIGURE 11 The use of optical crosses to show tear lens compensation in determining the final powers of a bitoric lens.

In this case there is no residual astigmatism. In these examples the bitoric lens has a spherical power effect in that it can rotate on the eye with no impact on vision as the corresponding vergence will be present to correct for the change in corneal curvature. (See Fig. 13.)

If the patient has significant residual astigmatism, a sphero-cylindrical overrefraction will be necessary and the overrefraction in a meridian will be added to the corresponding power in the bitoric diagnostic lens. For example, if a patient had the following refractive information

Refraction: +1.00 – 4.00 × 180

Keratometry: 42.00 at 180; 45.00 at 090

Diagnostic bitoric lens: 41.50/44.50 Pl/–3.00D

Overrefraction: +1.50 – 1.00 × 180

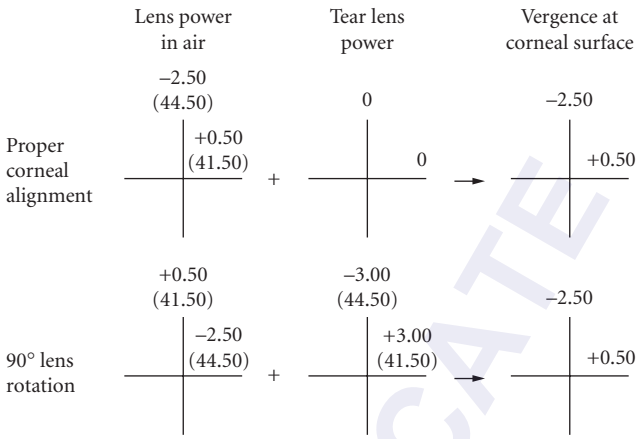

FIGURE 13 An example of how a bitoric lens can have spherical power effect optics. If the lens rotates 90°, the compensating vergences will be present.

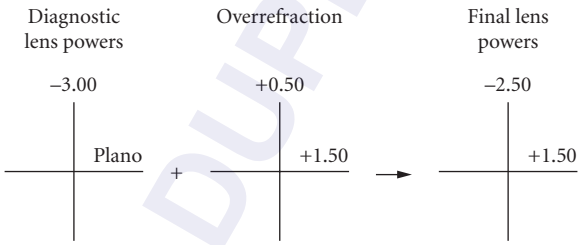

FIGURE 14 Determining the final powers of a bitoric lens in which a sphero-cylindrical overrefraction simply pertains to adding the overrefraction in a specific meridian to the power of the diagnostic lens in that meridian.

The final powers are determined by adding the overrefraction in the 180 meridian (+1.50) to the diagnostic lens power (Plano) and then adding the overrefraction in the 090 meridian [+1.50 + (–)1.00 = +0.50] to the diagnostic lens power in that meridian (–3.00 D). This is shown in Fig. 14.

20.5 OTHER DESIGN CONSIDERATIONS

Aspheric Lens Designs

An aspherical surface has been defined as a surface which is not spherical.[22] In contact lens design terminology, it was originally indicated by Feinbloom[23] that "(a) an ellipsoid represents a better approximation of the form of the surface of the cornea of the human eye, and (b) contact lenses with inner elliptical surfaces represent a marked improvement in the comfort and wearing time by the patient." This elliptical corneal shape consists of a central spherical zone which progressively flattens as the limbus is approached. The progressive flattening is representative of ellipses—and conic sections—in general.[24]

The shapes of conic sections are described mathematically by their eccentricity (e). As it pertains to conic sections, eccentricity can be defined as deviating from a circular path. A spherical central

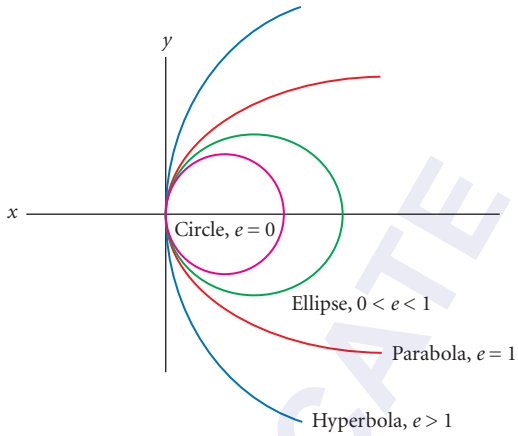

FIGURE 15 Different conic sections which have the same prolate apical radius but differ in eccentricity or *e*-value.

area of a given radius of curvature is combined in a model system with varying rates of paracentral flattening in the same scale as that of the cornea that it represents. The "*e*" increases, as does the rate of paracentral flattening. This can be demonstrated graphically by plotting the conic sections on the same set of axes with the vertex of each figure having the same radius of curvature at the origin of the coordinates (see Fig. 15). A circle has an "*e*" value of 0 with its radius of curvature the same for all points on the curve and the meridians all equal in length. An ellipse has an "*e*" value between 0 and 1; a parabola has an "*e*" value equal to 1; a hyperbola has an "*e*" value greater than 1. As will be discussed, most of the aspheric lens designs in common use mimic the average corneal eccentricity which is a prolate ellipse with an "*e*" value of approximately 0.45.[10,24] A prolate ellipse is produced by elongating the horizontal meridian of a circle (Fig. 16). If "*a*" is the major meridian of the ellipse and "*b*" the minor meridian, the eccentricity is calculated by the following equation:

$$e = \frac{\sqrt{1 - b_2}}{a_2}$$

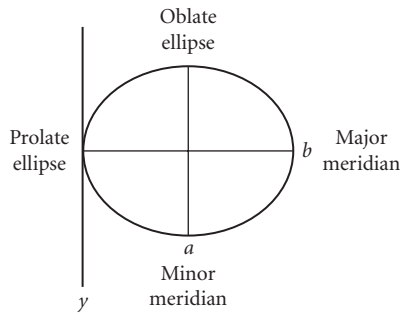

FIGURE 16 The major meridian of a typical ellipse is the "*a*" axis; rotation around this axis will produce a prolate ellipsoid, characterized by increasing radius of curvature outward from the origin. An oblate ellipsoid is produced by rotation around the minor axis "*b*." This is characterized by a decrease in radius of curvature outward from the origin.

Several GP aspheric lens designs are in common use. Some are manufactured with a spherical base curve radius and an aspheric periphery. In many of these designs, the aspheric section is tangential to the base curve radius, therefore creating an aspheric continuum or continuous curve. Several aspheric designs have a totally aspheric posterior surface; however, the posterior optical zone and the periphery are two different curves. One such design that has enjoyed some success in the United States is the Envision lens (Bausch & Lomb). Originally developed by Hanita Contact Lenses in Israel, this design has an elliptical posterior optical zone of 0.4 and a hyperbolic periphery that is tangential to the posterior optical zone.

Aspheric lens designs have become increasingly popular in the correction of presbyopia. Both center-near and center-distance power soft lenses are currently used which involve continuous change in power from the lens axis to the peripheral section of the lens, therefore creating a multifocal effect. These designs have the benefit of progressive power change resulting in distance, intermediate, and near image correction. This power change is typically on the front surface of the lens and these designs have been termed "simultaneous vision" lenses as the different powers are in front of the pupil at the same time; therefore, some compromise in vision may exist with these designs at any desired viewing distance. This type of presbyopic correction has been found to be preferred by 76 percent of individuals who wore both this correction and monovision (i.e., one eye optimally corrected for distance vision; the other eye optimally corrected for near vision).[25] GP aspheric multifocal designs have enjoyed greater success as a result of the rigidity, optical quality, and ability to provide high add powers. Although some designs are front surface aspherics with an increase in near power from center to periphery, most designs in common use today are center-distance back surface designs although this varies from region to region worldwide. These designs have much greater eccentricity than single vision designs, ranging from high "*e*" value elliptical to hyperbolic back surface designs.[26,27] This type of design has been found to result in similar visual performance to progressive addition spectacle lenses while performing significantly better than both monovision and soft lens multifocals.[28,29] Although the rapid increase in plus power required to provide optimal near vision for patients with high add requirements can compromise distance vision, recently introduced GP multifocal designs have addressed this issue by incorporating some of the add power in a paracentral annular region on the front surface of the lens (see Fig. 17). These designs also rely on some upward shifting of the lens—or translation—when the patient views inferiorly to take advantage of the paracentral/peripheral near power.

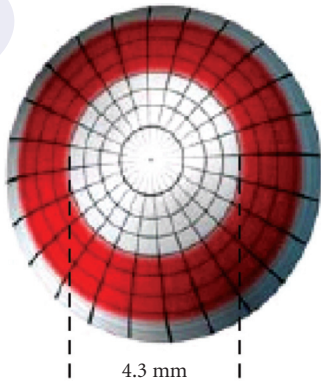

FIGURE 17 The Essentials CSA lens design with the near add power on the front surface shown in red.

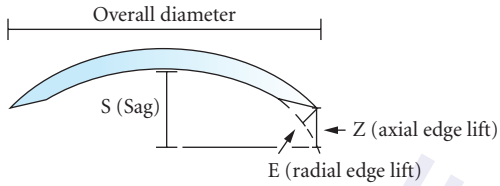

FIGURE 18 Axial versus radial edge lift.

Posterior Peripheral Curve Design Systems and Calculations

As previously discussed, there are several terms used to describe the peripheral curve radii and width, including secondary curve, intermediate curve, peripheral curve, and aspheric peripheries. Edge lift or edge clearance are terms used to indicate the distance from the GP lens edge to the cornea. Edge lift pertains to the distance between the extension of the tangent of the base curve radius and the absolute edge after the addition of peripheral curves. Radial edge lift (REL) is measured normal to the base curve radius extension (i.e., the distance from the lens edge perpendicular to an extension of the base curve radius.[9] (See Fig. 18.) Axial edge lift is measured parallel to the lens optical axis or the vertical distance from the lens edge to an extension of the base curve radius. Axial edge lift is often used and values of 0.10 to 0.15 mm are typically recommended.[30] In a tricurve design, for example, the peripheral curve often contributes approximately two-thirds of the overall axial edge lift. AEL values can be determined via the tables presented in Musset and Stone.[31]

Table 6 provides some representative AEL values for different designs. A more accurate estimate of the distance between the lens edge and the cornea is the actual edge clearance. As this does not pertain to an extension of the base curve radius, this value would be less than the axial edge lift. An ideal value for axial edge clearance has been found to be 0.08 mm.[32] Although this has traditionally been a difficult parameter to measure, Douthwaite[33] provides a very good overview of his recent efforts in calculating axial edge clearance and his text should be referred to for anyone desiring more information on this topic.

TABLE 6 Recommended Secondary and Peripheral Curve Radii

Axial Edge Lift = 0.10 mm

Secondary Curve Width = 0.3 mm

Peripheral Curve Width = 0.3 mm

Overall Diameter = 9.0; optical zone diameter = 7.8 mm

Base Curve Radius (BCR): varies from 7.5 to 8.3 mm

If secondary curve radius (SCR)/width contributes 0.04 and the peripheral curve radius(PCR)/width contributes 0.06 to the overall axial edge left, the following values would be calculated:

BCR (mm)	SCR (mm)	PCR (mm)
7.50	9.00	10.20
7.70	9.30	10.70
7.90	9.60	11.20
8.10	10.00	11.70
8.30	10.30	12.20

Source: From Ref. 32.

For practical purposes, if the peripheral curve is designed or modified to be flatter or wider, the resulting edge clearance is greater. Flattening the base curve radius will also "lift" the periphery away from the cornea and increase edge clearance. Reducing the optical zone diameter while keeping the overall diameter constant will increase edge clearance as the steepest part of the lens (i.e., the base curve radius) is reduced and the overall peripheral curve width is being increased. Conversely, edge clearance can be reduced by steepening the peripheral curve radius, reducing the peripheral curve width, steepening the base curve radius, or increasing the optical zone diameter.

Aberrations and Contact Lenses

As is well established, there are several aberrations induced by the optics of the eye which can influence the quality of vision. Lower-order aberrations include tilt or prism, astigmatism, and defocus. The most common high-order aberrations found in human eyes are spherical aberration and coma. Whereas in spectacle lens designs, the primary problems pertain to minimizing the effects of oblique astigmatism and curvature of field to optimize quality of vision in peripheral gaze, this is not a significant problem with contact lenses as the lens moves with the eye in all areas of gaze. However, spherical aberration and coma can be problematic with contact lens wear, notably when the lens decenters.[22] The latter can be especially important. If a lens is decentered 0.5 mm, an amount of coma approximately equivalent to the amount of spherical aberration is induced. If this decentration is 1 mm, a magnitude of coma equal to twice the level of spherical aberration is induced.[34] A well-centered lens is especially important as recent research has found that coma is, in fact, more visually compromising than spherical aberration.[35]

The introduction of sensitive, sophisticated aberrometers has been beneficial in evaluating the relationship of contact lenses and aberrations. Several studies have evaluated the optical quality of eyes wearing different types of contact lenses. Certain types of soft lenses (i.e., manufactured via cast-molding or spin-casting) induced more high-order aberrations, such as coma and spherical aberration as measured via aberrometry.[36] In comparing both soft and GP lenses it was found that, whereas both soft and GP lenses induce more aberrations for the eyes that have low wavefront aberrations, soft lens wear tends to induce more higher-order aberrations and GP lens wear tends to reduce higher-order aberrations.[37,38] CRT lenses used to dramatically reshape the cornea to reduce myopia when worn at night have been found to increase higher-order aberrations, especially spherical aberration.[39,40]

To correct for wavefront aberrations it is important to slow the propagation of the wavefront in areas of the pupil where it is advanced and speed up the propagation of the wavefront in areas where it's retarded.[41] This can be accomplished in a contact lens with localized changes in lens thickness. Essentially the lens must be thinner in areas where the eye it is correcting shows the greatest delays in wavefront and thickest where the eye's wavefront demonstrates its greatest advancement. This is shown in Fig. 19 in which the introduction of an aberration-correcting contact lens in both myopic (Fig. 19*a*) and comatic (Fig. 19*b*) wavefronts is demonstrated.[41]

Several contact lens designs, especially soft lenses, have been recently introduced with some aberration-correction ability. Keratoconic eyes reportedly have higher-order aberration levels as much as 5.5 times higher than normal eyes;[42] however, custom soft lenses have been found to provide a threefold reduction in aberration on keratoconic eyes.[43,44] A few designs have attempted to introduce a constant level of spherical aberration at all lens powers that is equal in magnitude but opposite in sign to the population mean for human eyes.[42] Some designs achieve this over part of the dioptric power range (i.e., PureVision from Bausch & Lomb); the Biomedics Premier lens from CooperVision achieved this goal over the entire dioptric range.[42,45] The Biomedics XC lens from CooperVision has been introduced with the strategy of having zero spherical aberration at all lens powers and, therefore, will neither add to or correct the eye's own spherical aberration. These lenses have the advantages of not introducing large amounts of spherical aberration often provided by standard spherical soft lenses and as these lenses have no spherical aberration, they will not introduce coma if they decenter.

It's evident that—although documented clinical success has not been definitely established with these designs—the future looks promising for aberration-controlling lenses. Likewise, manufacturers will introduce designs that either center well or decenter by a fixed amount. The introduction of

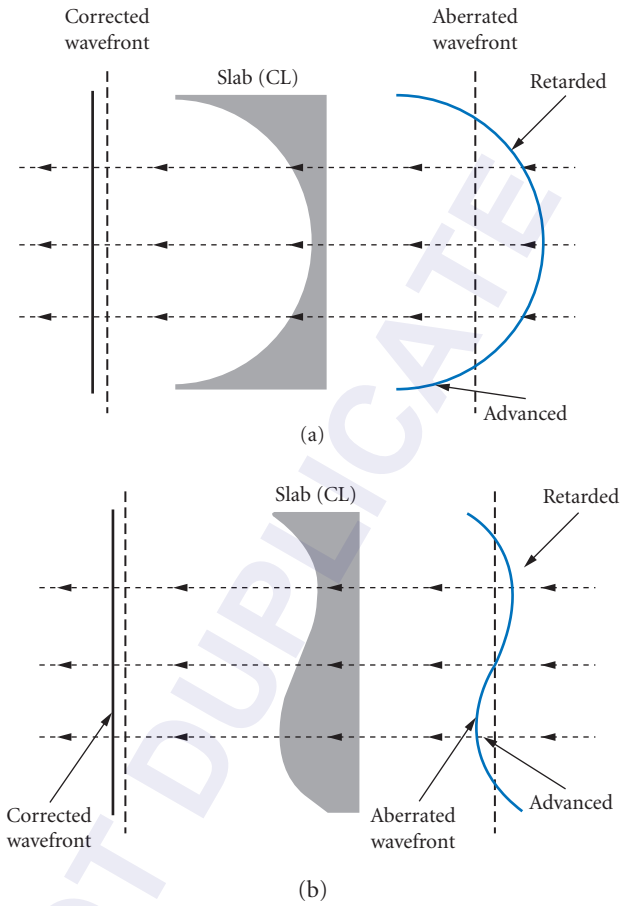

FIGURE 19 Schematic showing the correction of a (*a*) myopic and (*b*) comatic wavefront by the introduction of an aberration-correcting contact lens. (*From Ref. 41.*)

contact lens-only aberrometers, such as the ClearWave (AMO Wavefront Sciences), allows for a greater ability to monitor the aberration characteristics of these designs and ultimately introduce designs that are more effective in correcting for the aberrations of the eye.

20.6 CONVERGENCE AND ACCOMMODATION EFFECTS

Convergence

Spectacles which are well centered for distance vision but which are also used for all directions of gaze can induce a prismatic effect when the gaze is not straightahead. When viewing at near, a spectacle-wearing hyperopic patient will experience a base-out effect and a spectacle wearing myopic patient will experience a base-in effect. The fact that the optical center of a contact lens remains (or ideally should remain) centered in front of the eye in different directions of gaze results in several benefits

for the contact lens wearer via reducing or eliminating the following prismatic effects common to spectacle wear including:[10,46]

1. Decreased near convergence demand for bilateral hyperopic patients and increased near convergence demand for bilateral hyperopic patients.
2. Base right prism and base left prism for bilateral myopic patients, and base left prism and base right prism for bilateral hyperopic patients, in right and left gaze, respectively.
3. Vergence demand alterations in anisometropia or antimetropia, required for right and left gaze.
4. Vertical prismatic effects in up and down gaze, and imbalances in down gaze resulting from anisometropia or antimetropia.

There are a few potential problems, however, when changing a patient from spectacles to contact lenses. If the patient requires lateral prism correction to maintain alignment and fusional ability, this is not possible in contact lenses. For the young child this is an important consideration because of the cosmesis and freedom of vision provided by contact lenses. However, only after successful binocular vision training and/or surgical intervention should contact lenses be prescribed. Likewise, patients requiring correction for a vertical deviation will (almost always) not achieve that correction in a contact lens. It is possible to prescribe base down prism in a contact lens; however, this is unlikely to solve the problem unless prescribed binocularly as asthenopic complaints are likely due to the prism differential between the two eyes.

Finally, for a given distance, the contact lens-wearing hyperopic patient exhibits less convergence and the myope exerts more convergence than with spectacles. The binocular myopic patient loses the "base-in" effect received from spectacles and, therefore, if exophoria is present and the patient has an abnormally long or remote near point of convergence, eyestrain and even diplopia may result. This same problem may result for the esophoric hyperopic patient who loses the "base-out" effect provided by spectacles and—if borderline fusional divergence ability was initially present—the decreased convergence demand at near induced by contact lens wear may result in compromised binocularity. Fortunately, as will be discussed, accommodative vergence tends to compensate for the differences in vergence demands between the two modes of correction.

Accommodative Demands

The review of effective power considerations and, specifically, vertex distance, becomes especially appropriate as it pertains to accommodative demand. As will be discussed, the vergence entering the eye differs with light coming from a distance object versus a near object. Accommodative demand represents the difference between distance and near refractive corrections.[10]

Accommodative demand can best be described via reviewing the differences in demand between a hyperopic and myopic patient, both viewing at a 40 cm distance. Figure 20 shows the vergence of light for a +5 D spectacle-wearing patient, using a vertex distance of 15 mm. A vergence of 0 would arrive at the spectacle lens from a distant object. Via use of the effective power equation, the power at the corneal plane would equal

$$F(c) = \frac{F(\text{sp})}{1 - dF(\text{sp})}$$

$$= + \frac{5.00}{1 - 0.015(+5.00)}$$

$$= +5.41 \text{ D}$$

This value can also be obtained by simply subtracting the difference in focal lengths. The spectacle lens has a focal length of 1/+5.00 or 0.2 m (or 200 mm). At the corneal plane relative to the far point of the eye, the focal length is reduced by 15 mm or equals 185 mm (0.185 m). 1/0.185 m = +5.41 D

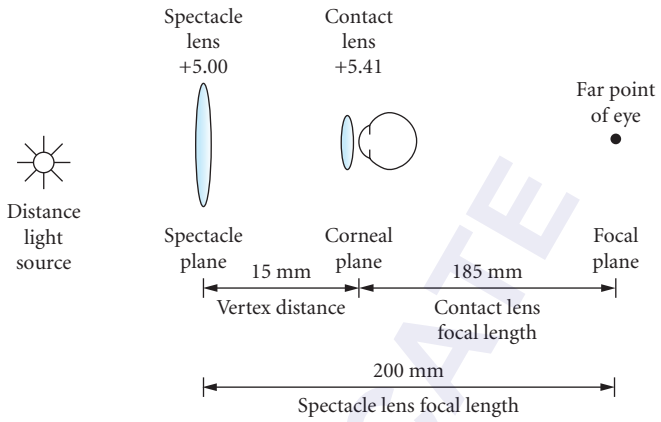

FIGURE 20 The power and corresponding focal lengths of a +5.00 D spectacle lens at the corneal plane when viewing a distant object.

which would equal the vergence of light at the corneal plane. For the emmetrope, it can be assumed that the vergence of light at the cornea is zero.

When viewing at a distance of 40 cm, a vergence of –2.50 D (i.e., 1/–0.40) would enter the spectacle lens (Fig. 21). A vergence of +2.50 D (i.e., –2.50 + (+)5.00) would exit the spectacle lens. To determine the power at the corneal plane, the effective power equation can be used.

$$F(c) = \frac{F(\text{sp})}{1 - dF(\text{sp})}$$

$$= + \frac{2.50}{1 - 0.015\,(+2.50)}$$

$$= +2.60 \text{ D}$$

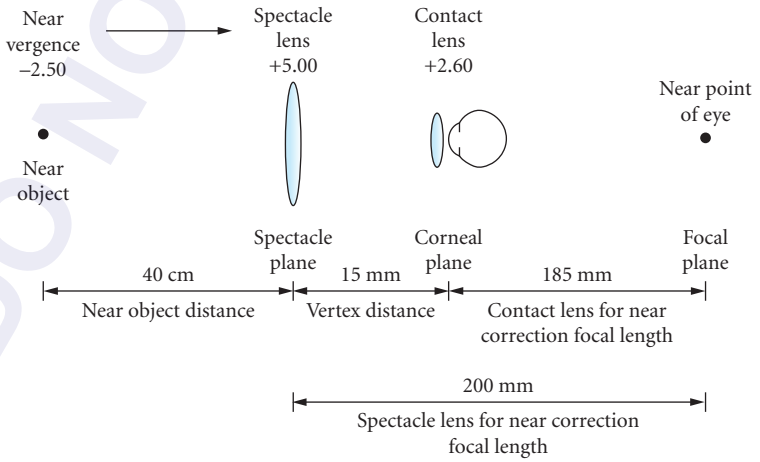

FIGURE 21 The power and corresponding focal lengths of a +5.00 D spectacle lens at the corneal plane when viewing a near object.

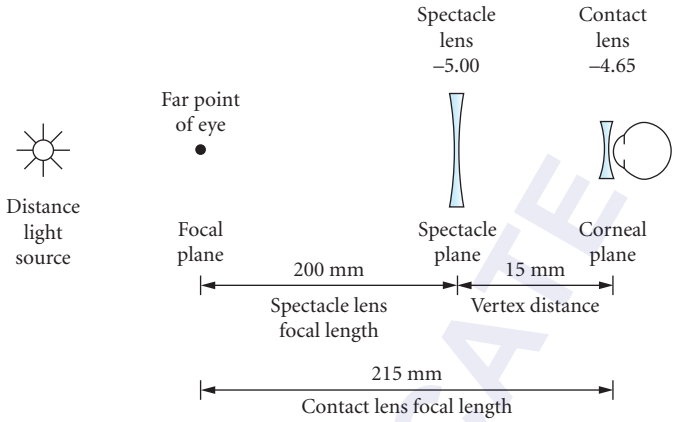

FIGURE 22 The power and corresponding focal lengths of a –5.00 D spectacle lens at the corneal plane when viewing a distant object.

Likewise, this value can also be determined by subtracting the difference in focal lengths. 1/+2.50 or 0.4 m (400 mm) provides the focal length of the power exiting the spectacle lens and, considering the 15 mm reduction at the corneal plane, the power at the corneal plane would be 1/0.385 or +2.60 D. Therefore, the corneal accommodative demand for the 5 D hyperope would equal the distance accommodative demand minus the near accommodative demand or +5.41 – (+)2.60 = +2.81 D. This can be compared to the emmetrope who would have a corneal accommodative demand of 1/0.415 (i.e., 40 cm plus the 15 mm vertex distance) or 2.41 D. Therefore, the hyperopic patient requires more accommodation than the emmetropic patients when viewing a near object with spectacles.

Figure 22 shows the vergence of light for a –5 D spectacle-wearing patient, using a vertex distance of 15 mm. A vergence of 0 would arrive at the spectacle lens from a distant object. Via use of the effective power equation, the power at the corneal plane would equal

$$F(c) = \frac{F(\text{sp})}{1 - dF(\text{sp})}$$

$$= \frac{-5.00}{1 - 0.015(-5.00)}$$

$$= -4.65 \text{ D}$$

This value can also be obtained by simply subtracting the difference in focal lengths. The spectacle lens has a focal length of 1/–5.00 or –0.2 m (or –200 mm). At the corneal plane relative to the far point of the eye, the focal length is increased by 15 mm or equals –215 mm (–0.215 m). 1/–0.215 m = –4.65 D which would equal the vergence of light at the corneal plane.

When viewing at a distance of 40 cm, a vergence of –2.50 D would enter the spectacle lens (Fig. 23). A vergence of –7.50 D (i.e., –2.50 + (–)5.00) would exit the spectacle lens. To determine the power at the corneal plane, the effective power equation can be used

$$F(c) = \frac{F(\text{sp})}{1 - dF(\text{sp})}$$

$$= \frac{-7.50}{1 - 0.015(-7.50)}$$

$$= -6.74 \text{ D}$$

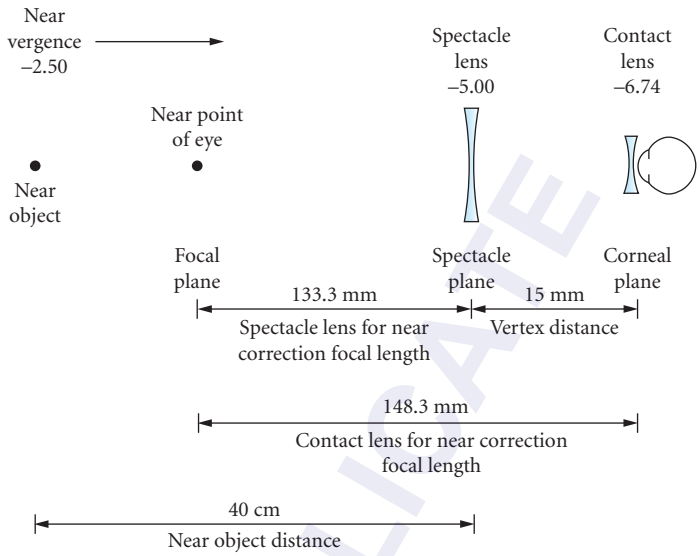

FIGURE 23 The power and corresponding focal lengths of a –5.00 D spectacle lens at the corneal plane when viewing a near object.

Likewise, this value can also be determined by subtracting the difference in focal lengths. 1/–7.50 or –0.1333 m (–133.3 mm) provides the focal length of the power exiting the spectacle lens and, considering the increase of 15 mm at the corneal plane, the power at the corneal plane would be 1/–0.1483 or –6.74 D. Therefore, the corneal accommodative demand for the 5 D myope would equal the distance accommodative demand minus the near accommodative demand or –4.60 – (–)6.74 = +2.14 D. This can be compared to the emmetrope who would have a corneal accommodative demand of 2.41 D; therefore, the myopic patient requires less accommodation than the emmetropic patient when viewing a near object with spectacles. The differences in corneal accommodative demand for myopic and hyperopic patients has been well documented.[46–49] Table 7 shows the difference in corneal accommodative demand at the corneal plane as it pertains to myopic and hyperopic spectacle lens powers.[10]

As contact lenses are positioned at the corneal plane, they induce accommodative demands equivalent to that of emmetropia. Therefore, the emergent presbyopic hyperope who changes from spectacles to contact lenses may find that the near symptoms are reduced. However, the emerging

TABLE 7 Accommodative Demands at the Corneal Plane with Spectacle Lens Wear

Difference in Corneal Plane Accommodative Demand Compared to Emmetropia	Back Vertex Power of Hyperopic Spectacle Lens (D)	Back Vertex Power of Myopic Spectacle Lens (D)
+/– 0.25	+3.25	–3.87
+/– 0.50	+6.00	–8.37
+/– 0.75	+8.62	–13.75
+/– 1.00	+10.87	–20.87

*Assume a near distance of 40 cm and a vertex distance of 15 m.
Source: From Ref. 10.

presbyopic highly myopic patient should be advised that a separate near correction (or a contact lens multifocal) may be necessary to satisfy all vision demands.

Overall, it can be concluded that hyperopic-correcting spectacle lenses will require an increase in convergence over that required when uncorrected whereas myopic-correcting lenses reduce the convergence required.[50] However, as indicated in this section, myopic patients accommodate more and hyperopic patients accommodate less when wearing a contact lens correction versus spectacles. Therefore, the overall accommodation-convergence ratio is only minimally impacted.

20.7 PRISMATIC EFFECTS

Prism-Ballasted Contact Lenses

Prism within a contact lens is produced by varying the thickness from the superior to the inferior regions while maintaining the same front and back surface curvatures. There are several types of contact lenses for which prism base down is incorporated within the design. The most popular design, including such prism, pertains to segmented, translating bifocal GP lenses. These lenses include a distance zone in the upper half of the lens, a near zone in the bottom half of the lens and (with some designs) an intermediate power zone between the near and distance segments. Typically, 1.5 to 3.0Δ base down is incorporated within the lens to stabilize it such that the thicker inferior edge will interact with the inferior lid margin on inferior gaze and push the lens up (termed "translation") such that the wearer will be viewing through the inferior near power zone when reading. Prism has also been used for stabilizing soft toric lenses as well as front toric GP lenses (i.e., used to correct residual astigmatism), although front toric GPs are little used due to the application of soft toric lenses in most of these cases and soft toric lenses tend to use other—reduced mass—options for stabilization.

The amount of prism within a contact lens can be computed using the following formula:[10]

$$P = \frac{100(n-1)(\mathrm{BT}-\mathrm{AT})}{\mathrm{BAL}}$$

where P = prismatic power in prism diopters (Δ)
n = refractive index of prismatic lens
BT = base thickness of prismatic component of lens
AT = apex thickness of prismatic component of lens
BAL = length of base-apex line or the diameter of the contact lens long the base-apex line of prism

For example, if the diameter of the lens was 9.0 mm, the thickness at the apex was 0.11 mm and the thickness at the base was 0.40 mm, and the refractive index of the material was 1.46, the amount of prism within this lens would be

$$P = \frac{100(n-1)(\mathrm{BT}-\mathrm{AT})}{\mathrm{BAL}}$$

$$= \frac{100(1.45-1)(0.40-0.11)}{9.0}$$

$$= 1.48 \text{ or approximately } 1.50\Delta \text{ base down}$$

Refractive power of a prismatic lens does vary along the base-apex line via the aforementioned formula for deriving back vertex power. This is the result of the fact that lens thickness is increased toward the base with an absence of change in surface curvature. Via Prentice's rule (to be discussed), back surface power becomes less minus/more plus as thickness increases toward the base of the prism.

Unintentional (Induced) Prism

Prentice's rule can also be used for determining the prism induced by lens decentration on the eye. This is due to the fact that a contact lens is considered to be separated from the tear lens by a thin layer of air.[51] Prentice's rule is

$$P = Fd$$

where P = prism induced in prism diopters
F = dioptric power of lens
d = decentration in centimeters

For example, if a +5.00 D lens decenters 2 mm, the resulting induced prism would be +6.00 D × 0.2 = 1.2Δ base down. If the other lens is well centered, this may be sufficient vertical imbalance to cause symptoms of eyestrain. Fortunately, soft lenses typically do not decenter on the eye due to their large size and the fact they drape over the cornea. GP lenses do move with the blink but typically, if decentration is present, it is essentially the same for both eyes. In cases of anisometropia, however, any decentration could result in asthenopic complaints. For example, if the patient was wearing a +2 D lens in the right eye and a +7 D lens in the left eye and both lenses decentered 2 mm inferiorly, the amount of induced prism would be OD: +2.00 × 0.2 = 0.4Δ; OS: +7.00 × 0.2 = 1.4Δ. The resulting difference would be 1.0Δ. Typically patients will not be symptomatic with less than 1Δ; however, in this case, asthenopic complaints are possible.

20.8 MAGNIFICATION

It has been well established that when a spectacle lens is moved toward the eye, the retinal image decreases in size for a plus lens and increases in size for a minus lens. Therefore, with contact lenses both of these effects would tend to be advantageous. The hyperopic patient with a high prescription—and most certainly the aphakic patient—are typically very satisfied to find that objects have returned to nearly a normal size. Myopic patients are pleased to find that everything looks larger with contact lenses. Several methods have been used to assess magnification effects, including magnification of correction and relative spectacle magnification.

Magnification of Correction (Spectacle Magnification)

Spectacle magnification (SM) is the ratio of retinal image size of the corrected ametropic eye to the retinal image size of the same eye uncorrected.[10] This has been used as an index of how corrective lenses alter retinal image size as compared by the patient before and after corrective lenses are placed on the eye. Spectacle magnification formulas include a power factor and a shape factor[10,47,52–54]

$$\text{SM} = \underbrace{\frac{1}{1 - h(\text{BVP})}}_{\text{Power factor}} \times \underbrace{\frac{1}{1 - (t/n')F_1}}_{\text{Shape factor}}$$

where SM = spectacle magnification or magnification of correction
BVP = back vertex power of correcting lens (D)
h = stop distance, from plane of correcting lens to ocular entrance pupil in meters (i.e., vertex distance +3 mm)
t = center thickness of correcting lens (m)
n' = refractive index of correcting lens
F_1 = front surface power of correcting lens (D)

With both contact lenses and spectacle lenses the shape factor is nearly always greater than 1.0, representing magnification, due to their respective convex anterior surfaces (i.e., F_1 is a positive number). However, for contact lenses, the lacrimal lens needs to be considered. Therefore, for a contact lens, the following shape factor should be used:

$$\text{Shape factor} = \frac{1}{1-(t/n')F_1} \times \frac{1}{1-(t_L/n_L)F_L}$$

where t = center thickness of correcting lens (m)
n' = refractive index of correcting lens
F_1 = front surface power of correcting lens (D)
t_L = center thickness of lacrimal lens in meters
n_L = refractive index of lacrimal lens (1.3375)
F_L = front surface power of lacrimal lens in keratometric diopters

The power factor for contact lenses is essentially the same as that for spectacle lenses with the exception that, as the vertex distance is 0, the stop distance would be only equal to 3 mm.

In high myopia, a significant minification (SM < 1.0) of the retinal image occurs with spectacle correction; this minification is greatly reduced with contact lens wear. Therefore, the highly myopic patient changing from spectacles to contact lenses may comment that their vision is clearer with contact lenses.

The change in spectacle magnification when changing from spectacle to contact lens correction can be compared with the following formula:

$$\frac{\text{Contact lens power factor}}{\text{Spectacle lens power factor}} = 1 - h(\text{BVP})$$

where h = stop distance, from plane of correcting lens to ocular entrance pupil in meters (i.e., vertex distance +3 mm) and
BVP = back vertex distance of spectacle lens (in D)

For the highly myopic (i.e., –10 D) patient, approximately 15 percent minification will be present with spectacles and only about 5 percent with contact lenses. For the aphakic patient, the magnification will be 25 to 30 percent with spectacles which would be reduced to 5 to 8 percent with contact lenses. Nevertheless, if the patient is a unilateral aphake wearing one contact lens, this image difference may still result in binocular vision problems. Therefore, intraocular lenses, with a stop distance of 0, is optimum in maintaining similar image sizes between the two eyes.

Relative Spectacle Magnification

Retinal image size can also be estimated via comparing the corrected ametropic retinal image to that of a standard emmetropic schematic eye. Relative spectacle magnification (RSM) is the ratio derived for spectacle lenses.[10,47,52–54] Ametropia can be purely axial, resulting from the axial elongation of the globe, refractive, resulting from abnormal refractive component(s) of the eye or a combination of both factors.

Relative spectacle magnification for axial ametropia can be derived from the following equation

$$\text{RSM} = \frac{1}{1+g(\text{BVP})}$$

where RSM = relative spectacle magnification for axial ametropia
g = distance in meters from anterior focal point of eye to correcting lens; $g = 0$ if lens is 15.7 mm in front of the eye
BVP = back vertex power of refractive correction (D)

with axial ametropia, g is equal to 0 or close to it for most spectacle lenses; therefore, the relative spectacle magnification is very close to 0. (See Fig. 24.)[51] In theory, anisometropia of axial origin is best corrected with spectacles and, in fact, aneisokonia problems may be encountered with contact lens wear. However, it has been suggested that in axial myopic eyes the retina will stretch to compensate

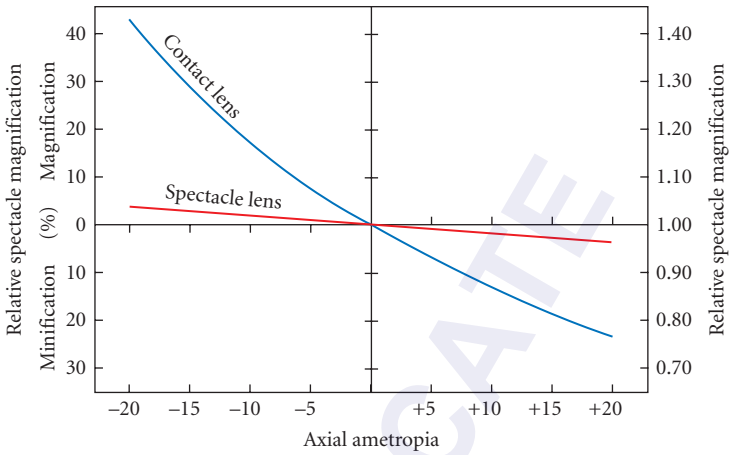

FIGURE 24 Relative spectacle magnification for axial ametropia when corrected by spectacles and contact lenses. (*From Ref. 51.*)

resulting in greater spacing between retinal receptors and receptive fields that effectively reduce the neurological image.[51]

Relative spectacle magnification for refractive ametropia can be derived from the following equation:

$$\text{RSM} = \frac{1}{1 - d(\text{BVP})}$$

where RSM = relative spectacle magnification for axial ametropia
d = stop distance in meters from correcting lens to entrance pupil (i.e., vertex distance +3 mm)
BVP = back vertex power of refractive correction (D)

This equation is the same for the shape factor for spectacle magnification. It can be observed in Fig. 25 that the RSM for contact lens wear is close to 1.00 but, conversely, it is quite minified for highly myopic lenses and very magnified for high plus lenses.[55]

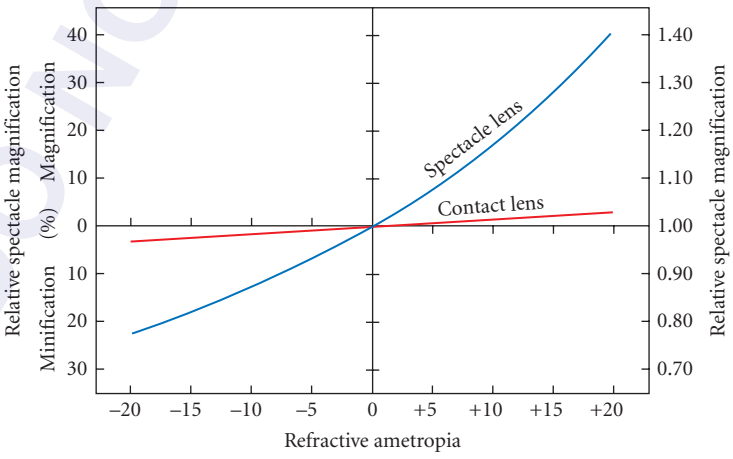

FIGURE 25 Relative spectacle magnification for refractive ametropia when corrected by spectacles and contact lenses. (*From Ref. 51.*)

20.9 SUMMARY

This chapter emphasizes the many optical benefits of contact lenses versus spectacles. In particular, the elimination of undesirable aberrations and induced prism when viewing away from the optical center and a lesser magnified (or minified) image size, it is important to emphasize that contact lenses will result in an increase in accommodative demand for the emerging presbyopic myope when changing from spectacles. In addition, children with binocular vision problems who benefit from the lateral prism in spectacles will not benefit from contact lens wear and may, in fact, be very poor candidates. This chapter also emphasizes contact lens optics that are in common use today. Determining the accommodative demand, induced prism and magnification are important in some contact lens wearers. Determination of contact lens power is important in all contact lens wearers.

21 INTRAOCULAR LENSES

Jim Schwiegerling
Department of Ophthalmology
University of Arizona
Tucson, Arizona

21.1 GLOSSARY

Accommodating intraocular lens. An artificial lens implanted in the eye that changes power and/or position in response to contraction of the ciliary muscle.

Accommodation. The ability to change the power of the eye and focus on objects at different distances.

Aphakia. A condition of the eye without a crystalline lens or intraocular lens.

Aspheric intraocular lens. An artificial implanted lens that has at least one aspheric surface. Typically used to compensate spherical aberration of the cornea.

Capsulorhexis. Removal of the lens capsule. Usually during cataract surgery, the anterior portion of the capsule is removed to allow access to the crystalline lens within the capsule.

Cataract. An opacification that occurs within the crystalline lens that reduces the quality of vision.

Chromophore. A molecule doped into the lens material that absorbs specific wavelength bands such as ultraviolet or blue light.

Dysphotopsia. Stray light effects encountered following implantation of intraocular lenses. Positive dysphotopsia causes streaks or glints of light seen in the peripheral vision. Negative dysphotopsia causes dark bands or shadows to appear in peripheral vision.

Haptic. A structure that aids in alignment and support of intraocular lenses within the eye. Typically two or three arms emanate from the edge of the lens. Plate haptics are rectangular flanges that protrude from the sides of the lens.

Intraocular lens. An artificial lens that is implanted into the eye to modify the eye's optical power.

Lens capsule. An elastic bag that encapsulates the crystalline lens. Most modern cataract procedures leave the capsule in place and only remove the crystalline lens within.

Limbus. The boundary between the cornea and the sclera, the white of the eye.

Multifocal intraocular lens. An artificial lens that incorporates two or more powers into the same lens. The purpose of these lenses is to allow objects at different distances to be in focus simultaneously.

Phacoemulsification. A technique for removing a cataractous crystalline where an ultrasonic probe is used to shatter the lens and then the lens bits are suctioned out of the eye.

Phakic lens. An artificial lens implanted into the eye while leaving the crystalline lens intact. Typically this procedure is used to alleviate refractive error and is not a treatment for cataracts.

Posterior capsule opacification. A potential side effect of the intraocular lens implant. The lens capsule can adhere to the implant and an opacification develops on the posterior side of the intraocular lens. Laser pulses are typically used to open a hole in the opacified capsule to restore vision.

Presbyopia. The state of the eye where accommodation has been completely lost due to stiffening and enlargement of the crystalline lens.

Pseudophakia. The state of having an artificial lens implanted within the eye.

Sclera. The white of the eye.

21.2 INTRODUCTION

The eye forms the optical system of the human visual system. A variety of references provide a good general introduction to the essential components of the eye and their function.[1,2] Here, a brief overview of the main optical elements and their mechanism of action will be provided. The eye consists of two separated lenses that ideally form an image on the retina, the array of photosensitive cells lining the back surface of the eyeball. The eye's first lens is the cornea, which is the clear membrane on the external portion of the eye. The cornea is a meniscus lens and has a power of about 43 diopters (D). The iris resides several millimeters behind the cornea. The iris is heavily pigmented to block light transmission and serves as the aperture stop of the eye. The diameter of the opening in the iris varies with light level, object proximity, and age. The crystalline lens is the second optical element of the eye. It lies immediately behind the iris and provides the focusing mechanism of the visual system. Together, the cornea and iris form images on the external environment onto the retina. At the retina, the light is converted to a neural signal and transmitted to the brain where the signals are interpreted into our perceived image of the surrounding scene.

The crystalline lens has several notable features that provide for a flexible optical system capable of focusing to a wide range of distances. First, the crystalline lens has a gradient index structure with its refractive index varying in both the axial and the radial directions. The maximum index of refractive occurs in the center or nucleus of the lens. The index then gradually decreases toward the lens periphery as well as the front and back surfaces. In addition, the crystalline lens is also flexible, allowing the lens to change shape and consequently power in response to muscular forces. The crystalline lens resides in an elastic bag called the capsule. In the young lens, this capsule causes a contraction of the periphery of the lens and an increase in the central thickness of the lens. As a result of this effect, the radii of curvature of the front and back surfaces of the lens decrease, leading to an increase in the optical power of the lens. In its maximally flexible state, the capsule can form the crystalline lens such that it gains a power up to a maximum 34 D.

The lens and capsule are suspended behind the iris by a series of ligaments called the zonules. One end of a zonule attaches to the perimeter of the lens/capsule and the other end attaches to the ciliary muscle. The ciliary muscle is a ring-shaped muscle that resides behind the iris. In its relaxed state, the ciliary muscle dilates, increasing tension on the zonules and exerting an outward radial force on the perimeter of the lens and capsule. This force causes the crystalline lens shape to flatten. The center thickness of the lens reduces and the radii of curvature of its front and back surfaces increase. The net effect of the lens flattening is a reduction in its power to about 20 D. Constriction of the ciliary muscle causes a reduction in the zonule tension and the elastic capsule causes the lens to thicken and increase its power. Accommodation is the ability to change the power of the crystalline lens through constriction or relaxation of the ciliary muscle. Accommodation allows the eye to bring objects at a variety of distances into focus on the retina. If the eye is focused at infinity when the ciliary muscle is in its relaxed state, then the fully accommodated crystalline lens allows objects at 70 mm from the eye to be brought into proper focus.

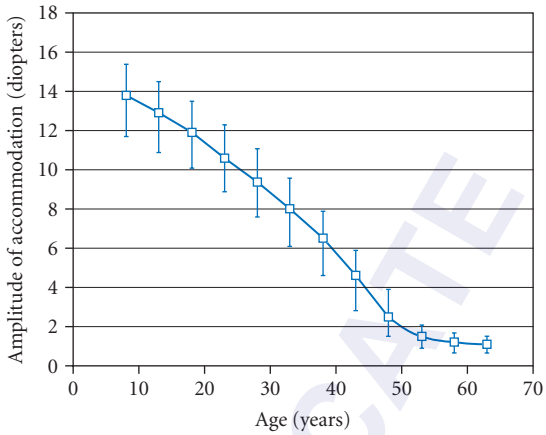

FIGURE 1 Loss of the amplitude of accommodation with age.

The eye is meant to provide a lifetime of vision. However, as with all parts of the body, changes to the eye's performance occur with aging. One effect is the continual decrease in the amplitude of accommodation that occurs almost immediately after birth. Figure 1 shows the accommodative amplitude as a function of age.[3] The preceding description of lens function described a lens that could change its power from 20 to 34 D. With age, this range gradually reduces. The changes are usually not noticeable until the fifth decade of life. At this point, the range of accommodation is usually 20 D in the relaxed state to 23 D in the maximally accommodated state. Under these conditions, if the eye is focused at infinity for a relaxed ciliary muscle, then with maximum exertion, objects at 33 cm from the eye can be brought into proper focus. This distance is a typical distance reading material is held from the eye. Objects closer than 33 cm cannot be brought into focus and ocular fatigue can rapidly set in from continual full exertion of the ciliary muscle. Moving into the sixth decade of life, the range of accommodation continues to reduce, leading to the inability to focus on near objects. This lack of focusing ability is called presbyopia. Reading glasses or bifocal spectacles are often used to aid the presbyope in seeing near objects. These lenses provide additional power to the eye that can no longer be provided by the crystalline lens. Presbyopia is caused by the continual growth of the crystalline lens.[4] The lens consists of a series of concentric layers and new layers are added throughout life. This growth has two effects. First, the lens size and thickness increases with age, leading to a lens that is stiffer and more difficult to deform. Second, the diameter of the lens increases, leading to a reduced tension on the zonules. The combination of these two effects results in the reduction in accommodative range with age and eventually presbyopia.

A second aging effect that occurs in the eye is senile cataract. Cataract is the gradual opacification of the crystalline lens that affects visual function.[5] An increase in lens scatter initially causes a yellowing of the lens. As these scatter centers further develop large opacities occur within or at the surface of the lens. The progression of cataract initially leads to a reduction in visual acuity and losses in contrast sensitivity due to glare and halos. The endpoint of cataract is blindness, with the opacifications completely blocking light from reaching the retina. It is estimated that 17 million people worldwide are blind due to cataract.[6] However, the distribution of these blind individuals is skewed toward less developed countries. The prevalence of blindness due to cataracts is 0.014 percent in developed countries and 2 percent in undeveloped countries. The most common cause of lens opacification is chronic long-term exposure to the UV-B radiation in sunlight. Other less common incidences include traumatic, pharmacological, and congenital cataracts. Risk factors such as smoking and poor diet can lead to earlier emergence of cataract. However, since exposure to sunlight occurs nearly daily, there is high likelihood of developing cataracts within a lifetime. Due to this prevalence, treatments for cataracts have long been sought after.

TABLE 1 Prevalence of Cataract in the Population of U.S. Residents

Age	Prevalence (%)
43–54	1.6
55–64	7.2
65–74	19.6
75–85	43.1

Currently, there exist no means for preventing cataract formation. Reducing risk factors such as UV-B exposure through limiting sun exposure and using sunglasses, quitting smoking, and healthy diet can delay the onset of cataracts, but still the opacifications are likely to emerge. Table 1 shows the prevalence of cataract in the United States.[7]

Treatment of cataracts is the main means for restoring lost vision caused by the opacifications. Variations in access to these treatments is a reason for the skew in blindness caused by cataracts in developed and undeveloped countries. In developed countries access to cataract treatment is high and usually provided when the cataractous lens has caused relatively mild loss in visual performance. In fact, cataract surgery is the most widely performed surgery in the United States.[6] In undeveloped countries, access may be nonexistent and severely limited leading to a high rate of blindness due to complete opacification of the lens.

21.3 CATARACT SURGERY

In restoring vision loss from cataracts, the opacified lens is removed to allow light to enter the eye again. This concept has been known in various evolutionary forms for thousands of years.[8] However, since the crystalline lens forms about one-third of the overall power of the eye, removing the lens leaves the patient severely farsighted. This condition is known as aphakia. Aphakia requires patients to wear high-power spectacle lenses to replace the roughly 20 D of power lost from the crystalline lens. These high-powered lenses are problematic for a variety of reasons. These effects include a 20 to 35 percent magnification of the image and peripheral distortion, since spectacles with spherical surface cannot be corrected for oblique astigmatism at such high positive powers and a ring scotoma due to a gap in the field of view between light entering just inside and just outside the edge of the spectacle lens.[9,10] The advent of intraocular lenses (IOLs) in 1949 served to "complete" cataract surgery.[11,12] IOLs are artificial lenses that are implanted into the eye following the removal of a cataractous lens and are designed to provide the needed optical power to allow normal image formation to occur within the eye. Placement of the IOL within the eye allows aphakic spectacles and their problems can be avoided.

Modern cataract treatments include extracapsular cataract extraction (ECCE) and more recently a variation of this technique known as phacoemulsification. ECCE was first performed over 250 years ago, and has been widely used to remove the opacified lens.[13] In this procedure, a large incision is made in the limbus, which is the boundary of the cornea. A capsulorhexis, which is the removal of the anterior portion of the capsule, is performed and then the crystalline lens is removed, leaving the remaining portion of the capsule intact within the eye. The corneal incision site is then sutured to seal the eye. Phacoemulsification was developed in 1967 by Charles Kelman.[14] In this technique, a small incision is made at the limbus. Tools inserted through this small opening are used to make a capsulorhexis. With the crystalline lens now exposed, a hollow ultrasonic probe is slipped though the opening. The vibrations of the probe tip cause the crystalline lens to shatter and suction is used to aspirate the lens fragments through the hollow center of the probe. The entire lens is removed in this fashion leaving an empty capsule. The incision in phacoemulsification is sufficiently small so that no sutures are needed to seal the wound. Phacoemulsification is similar to modern surgical techniques of orthoscopic and laproscopic surgery. Incisions are kept small to promote rapid healing and limit the risk of infection.

21.4 INTRAOCULAR LENS DESIGN

Sir Harold Ridley, a British surgeon specializing in ophthalmology, was dissatisfied with the existing form of cataract surgery since it left patients aphakic and dependent on poorly performing spectacle lenses for visual function.[12] Ridley gained a key insight into "fixing" cataract surgery while treating Royal Air Force pilots from World War II. The canopies of British fighter planes were constructed with a newly developed polymer, polymethyl methacrylate (PMMA), also known as Perspex, plexiglass, or acrylic. In some instances, when the gunfire shattered the canopies, shards of the PMMA would become embedded into the cornea of the pilot. Ridley, in treating these aviators, noted that the material caused little or no inflammatory response of the surrounding ocular tissue. The typical response of the body to a foreign body is to encapsulate and reject the material. However, the PMMA did not elicit this response and sparked the concept of forming a lens from a "biocompatible" material that could be implanted following extraction of the cataractous lens. In 1949, Ridley implanted the first IOL into a 45-year-old woman. Following surgery, the patient was 14 D nearsighted (as opposed to 20 D farsighted in aphakic patients). While the power of the implanted IOL was clearly wrong, Ridley successfully demonstrated that an artificial lens could be implanted into the eye that evokes a marked power change. The error in the power of the IOL stemmed from modeling the implant after the natural crystalline lens. The approximate radii of curvature of the crystalline lens were used for the implant, but the higher-refractive index of the PMMA was not taken into account. Ridley's second surgery resulted in a similar degree of nearsightedness, but by the third surgery, the IOL power had been suitably refined, leaving the patient mildly nearsighted.

Ridley's IOL invention is revolutionary, as it restored normal vision following cataract surgery. However, the medical establishment did not immediately accept the value of this invention. Instead, many leading figures in ophthalmology at the time thought the surgery to be reckless and unwarranted. Ridley met with disdain, criticism, and the threat of malpractice. The result of this animosity was a long delay in the evolution of the implant technology as well as a limited use of the lenses by the surgical community. The shift to acceptance of the technology did not begin to occur until the 1970s. In 1981, the Food and Drug Administration finally approved IOLs for implantation following cataract surgery in the United States. Today, phacoemulsification followed by IOL implantation is the most widely performed and successful surgery in the United States. Virtually no aphakic subjects exist anymore and the term "cataract surgery" now implicitly implies implantation of the IOL.

Intraocular Lens Power

As Ridley's first two surgeries illustrate, calculation of the IOL power is important to minimize the error in refractive power of the eye following surgery. Ridley ventured into unknown territory in designing the initial IOLs. Accurate determination of the IOL power remains the key component to a successful surgery. Cataract surgeons typically target slight nearsightedness following implantation of the IOL. Conventional IOLs leave the recipient presbyopic because the lens power and position are fixed within the eye. Unlike the crystalline lens, the conventional IOL does not change shape or position and consequently accommodation is lost. Extensive research into accommodating IOLs is currently being pursued and a description of emerging technologies is given further in the chapter. With the fixed-focus IOL, surgeons need to determine the proper power prior to surgery, which can be challenging for several reasons. First, the eye must be tested with the existing crystalline lens in place. The power of the crystalline lens must be deduced from the overall power of the eye and the shape of the cornea. The crystalline lens power must be subtracted from the overall ocular power since the crystalline lens is removed by the surgery. Next, the power of the IOL must be estimated based on its anticipated position within the eye following implantation. Finally, the power of the IOL must also be adjusted for any inherent refractive error in the eye. In other words, the IOL power and the cornea must work in conjunction to give a sharp image on the retina. To further complicate this calculation, the patient is receiving the implant because of cataract, so subjective measurement of refractive error may be confounded by the opacities in the lens.

The IOL power calculation formulas fall into two categories. Some formulas are based on multiple regression analysis of the variables associated with the eye and implant, while other formulas are based on a theoretical prediction of the IOL power. The SRK formula was originally the most widely used regression-type formula to predict IOL power. The SRK formula is given by[15,16]

$$\phi_{\text{IOL}} = \text{A} - 0.9\,K - 2.5\,L \tag{1}$$

where ϕ_{IOL} is the power of the IOL in diopters, A is the A-constant of the lens, K is the corneal keratometry, and L is the axial length of the eye. The A-constant is a value provided by the IOL manufacturer that is most closely associated with the position of the IOL within the eye. Modern IOLs are about 1 mm thick and about one-fourth the thickness of the natural crystalline lens. Consequently, there is a variation in the positioning of the IOL behind the iris that is dependent on the shape of the implant and surgical technique. The A-constant is empirically derived to account for these factors. Surgeons often customize the A-constants of lenses routinely implanted based on their specific outcomes.

Keratometry is a measure of corneal power. Keratometry is calculated measuring the radius of curvature R_a in mm of the anterior corneal surface. A power is then calculated as

$$K = 1000\frac{(n_k - 1)}{R_a} \tag{2}$$

where n_k is the keratometric index of refraction and K is in units of diopters. The keratometric index of refraction is an effective corneal index that attempts to incorporate the power associated with the posterior surface of cornea into the keratometry measurement. Values of 1.3315 to 1.3375 are routinely used for n_k in clinical devices used for measuring keratometry. Measurement of the posterior corneal radius of curvature has been difficult until recently, so historically keratometry measurements have been made based on an estimate of the contribution of this surface to the overall power of the cornea. Note that n_k is lower than the true refractive index of the cornea, 1.376, to account for the negative power induced by the posterior cornea. As an example, the radii of curvature of the anterior and posterior surfaces of the cornea are approximately 7.8 and 6.5 mm, respectively.[2] The refractive index of the cornea is 1.376 and of the aqueous humor on the back side of the cornea is 1.337. A typical thickness of the cornea is 0.55 mm. With these assumptions, the keratometry of the cornea, as given by Eq. (2), is

$$K = 1000\frac{(1.3315 - 1)}{7.8} = 42.50 \text{ D} \tag{3}$$

The true power of the cornea is given by

$$\phi_{\text{cornea}} = 1000\left[\frac{(1.376-1)}{7.8} + \frac{(1.337-1.376)}{6.5} - \left(\frac{0.55}{1.376}\right)\left(\frac{(1.376-1)}{7.8}\right)\left(\frac{(1.337-1.376)}{6.5}\right)\right] = 42.32 \text{ D} \tag{4}$$

Cleary, there are some small differences in the predicted keratometric and the corneal power. This discrepancy is one potential source for error in the calculation of the implant power. As can be seen from Eq. (1), a 0.9 D error in keratometry leads to a 1 D error in the calculated IOL power.

Traditionally, the axial length, L, of the eye is measured with A-scan ultrasonography. An ultrasonic probe, typically with a frequency of 10 MHz, is placed lightly in contact with the cornea to avoid deforming the surface. Echoes from the crystalline lens surfaces and the retina are then measured. The time of flight of these echoes is directly related to the speed of sound in the various materials of the eye. Table 2 summarizes typical values of these speeds used by commercial A-scan units. The longitudinal resolution of a 10-MHz ultrasound is 200 μm.[17,18] Consequently, Eq. (1) suggests this level of accuracy would lead to a limit of the accuracy of the IOL power of ±0.25 D.

TABLE 2 Speed of Sound in Various Ocular and IOL Materials

Material	Speed of Sound
Cornea	1,640 m/s
Aqueous	1,532 m/s
Lens—Normal	1,640 m/s
Lens—Cataractous	1,629 m/s
Vitreous	1,532 m/s
PMMA IOL	2,760 m/s
Silicone IOL	1,000 m/s

Partial coherence interferometry has recently become a popular technique for measuring axial length.[19] In this technique, a Michelson inteferometer is used to measure distances within the eye. A short-coherence-length narrow-band infrared source is shone into the eye. The return beam is interfered with light from the test arm. Since the beam has low-coherence, fringes only appear when the path lengths in the eye and the test arm are nearly identical. By changing the length of the reference arm and observing when fringes appear, the length of the eye can be accurately measured. The axial resolution of this technique is on the order of 12 μm, leading to a resolution of the IOL power of 0.015 D.

The first regression-type formulas are accurate for eyes that fall within "normal" parameters for axial length and corneal power. However, as the more extreme sizes and shapes are approached, the accuracy of formulas degrades markedly. The regression-type formulas were further refined to better handle these extreme cases.[20] While regression analysis is still used for these formulas, a piecewise linear approximation is used to better approximate the full range of variation of human eyes. The SRK II is an example of an evolved formula. The IOL power is defined as

$$\phi_{IOL} = A_1 - 0.9\,K - 2.5\,L \tag{5}$$

where

$A_1 = A + 3$ for $L < 20.0$ mm

$A_1 = A + 2$ for $20.0 \le L < 21.0$

$A_1 = A + 1$ for $21.0 \le L < 22.0$

$A_1 = A$ for $22.0 \le L < 24.5$

$A_1 = A - 0.5$ for $L \ge 24.5$

Figure 2 compares the SRK and SRK II formulas.

An alternative to regression-based formulas for IOL power prediction are theoretical formulas.[21] Theoretical formulas use geometrical optics to make predictions about the implant power, given knowledge of the axial length, corneal power, and position of the IOL following implantation. Figure 3 shows a simplified model of the eye. The cornea is modeled as a single surface of power K. In the aphakic eye shown in Fig. 3*a*, the cornea forms an image of a distant object at a distance $1000\,n_{aq}/K$ behind the corneal vertex for K in diopters. When the IOL is implanted into the eye, it sits at a location called the effective lens position (ELP). The ELP is deeper into the eye than the iris plane for posterior chamber IOLs. Figure 3*b* shows the IOL implanted into the aphakic of Fig. 3*a*. The image formed by the cornea becomes a virtual object for the IOL located at a distance

$$S = 1000 n_{aq} / K - \text{ELP} \tag{6}$$

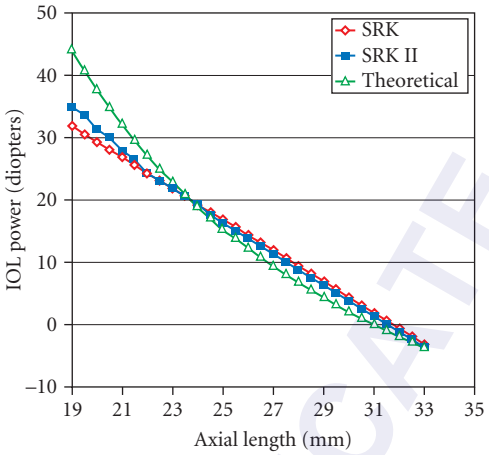

FIGURE 2 A comparison of the predicted IOL power for the SRK and SRK II formulas assuming A = 118 and $K = 43$ D. Also shown is a theoretical prediction of the IOL power assuming $n_{aq} = 1.337$, $K = 43$ D, and ELP = 5 mm.

from the plane of the IOL. The IOL, in turn, needs to image this virtual object onto the retina. If the distance from the IOL to the retina is given by S′, then

$$\frac{n_{aq}}{S'} - \frac{n_{aq}}{S} = \phi_{IOL} = n_{aq}\left[\frac{1}{L - \text{ELP}} - \frac{1}{1000n_{aq}/K - \text{ELP}}\right] \tag{7}$$

which can be rewritten as

$$\phi_{IOL} = \frac{n_{aq}}{K}\left[\frac{1000n_{aq} - \text{KL}}{(L - \text{ELP})(1000n_{aq}/K - \text{ELP})}\right] \tag{8}$$

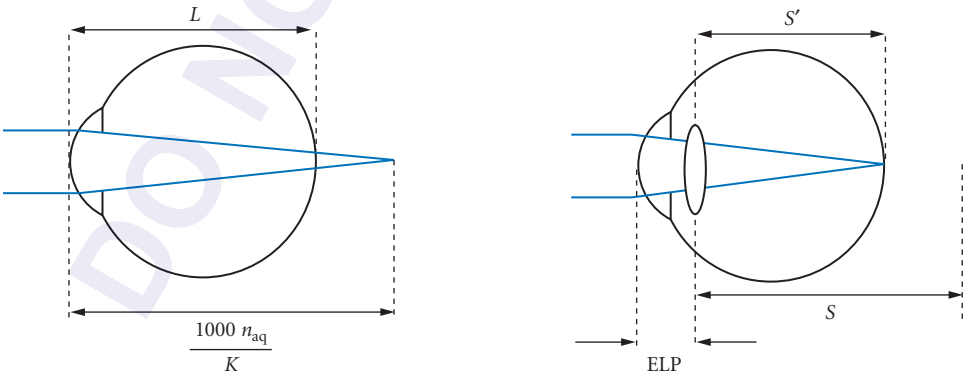

FIGURE 3 (*a*) In the aphakic eye, the image is formed at a distance $1000n_{aq}/K$, where n_{aq} is the refractive index of the aqueous and K is the power of the cornea. (*b*) When the IOL is inserted at the effective lens position (ELP), the aphakic image is reformed onto the retina.

Equation (8) is the theoretical IOL power based on thin lens analysis of the pseudophakic eye. Figure 2 also shows the predicted IOL power based on Eq. (8).

A variety of theoretical models exist.[22–25] They are all based on the preceding Eq. (8). Subtle differences exist, however, in the manner each of the variables is calculated. For example, the axial length provided by ultrasonography is slightly short because the echo occurs at the inner limiting membrane of the retina. Light absorption occurs at the photoreceptor layer that is approximately 20 μm deeper into the eye. The ELP is also affected by the anterior chamber depth, which is the distance from the cornea vertex to the iris plane. Eyes with flatter corneas or smaller diameter corneas can have shallower anterior chamber depths, causing a reduction in the ELP. Holladay has worked extensively to determine the location within the eye of available IOLs and to relate the A-constant to the ELP as well as what Holladay calls the surgeon factor (SF).[26–31] The SF is the distance from iris plane to the front principal plane of the IOL. The theoretical models in most cases provide excellent prediction of the IOL power. The typical error in power is less than 1 D in over 80 percent of patients.[20] Surgeons tend to err on the side of nearsightedness to allow the patient to have some plane in their field of vision conjugate to the retina. A farsighted patient would only have a virtual object in focus on their retina and consequently they tend to be less happy since additional refractive correction is required for all object distances. The current generation of IOL power calculations, however, has difficulty in predicting accurate IOL powers in patients who have undergone corneal refractive surgeries such as radial keratotomy (RK) and laser in situ keratomileusis (LASIK). These surgical procedures modify the shape of the cornea to correct for refractive error. However, this shape change can have marked effect on the measurement of the keratometry. The relationship between the shape of the front and back surfaces of the cornea and in the case of LASIK, the corneal thickness has been artificially modified by the refractive procedure. As a result, the keratometric index of refraction is no longer valid and gross errors in IOL prediction can occur as a result. A variety of techniques have been suggested for handling this subset of cataract patients.[32–42] Only a limited number of patients currently fall into this category. However, as the refractive surgery generation ages, an increasing percentage of cataract patients will require specialized techniques for predicting IOL power and much research is still needed in this area to achieve satisfactory results.

Intraocular Lens Aberrations

Since IOLs are singlets, only limited degrees of freedom exist to perform aberration correction. The human cornea typically has positive spherical aberration.[43] The natural crystalline lenses typically compensates for the cornea with inherent negative spherical aberration leaving the whole eye with low levels of positive spherical aberration.[44] The crystalline lens creates negative spherical aberration through its gradient index structure and aspheric anterior and posterior surfaces. Traditionally, IOLs have been made with spherical surfaces due to the ease of manufacturability. Smith and Lu analyzed the aberrations induced by IOLs using the thin lens Seidel aberration formulas described by Welford.[45,46] Spherical aberration is given by

$$\frac{y^4\phi_{\mathrm{IOL}}^3}{4n_{\mathrm{aq}}^2}\left[\frac{n_{\mathrm{aq}}^2(2n_{\mathrm{aq}}+n_{\mathrm{IOL}})}{n_{\mathrm{IOL}}(n_{\mathrm{aq}}-n_{\mathrm{IOL}})^2}X^2+\frac{4n_{\mathrm{aq}}(n_{\mathrm{aq}}+n_{\mathrm{IOL}})}{n_{\mathrm{IOL}}(n_{\mathrm{aq}}-n_{\mathrm{IOL}})}XY+\frac{2n_{\mathrm{aq}}+3n_{\mathrm{IOL}}}{n_{\mathrm{IOL}}}Y^2+\frac{n_{\mathrm{IOL}}^2}{(n_{\mathrm{aq}}-n_{\mathrm{IOL}})^2}\right] \tag{9}$$

where y is the height of the marginal ray at the IOL, ϕ_{IOL} is the power of the implant, $n_{\mathrm{aq}} = 1.337$ is the refractive index of the aqueous, and n_{IOL} is the refractive index of the IOL. Typical values for n_{IOL} range from 1.41 to 1.55 depending on the material. The shape factor X is defined as

$$X=\frac{C+C'}{C-C'} \tag{10}$$

where C is the curvature of the anterior surface of the IOL and C' in the curvature of the posterior surface. The conjugate factor Y is defined as

$$Y=\frac{S+S'}{S-S'} \tag{11}$$

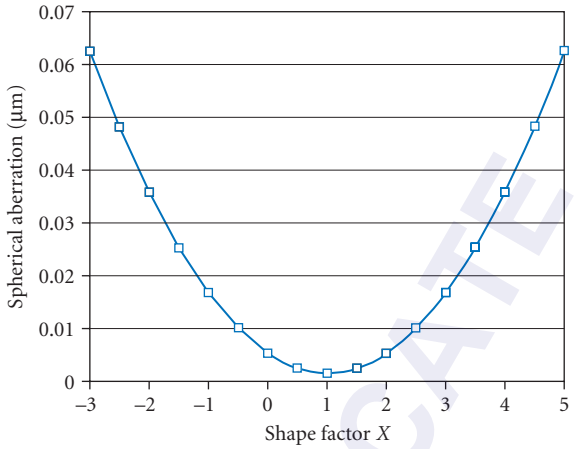

FIGURE 4 The spherical aberration as a function of shape factor for an IOL.

where S is the distance from the IOL to the virtual object formed by the cornea and S' is the distance from the IOL to the retina. In the eye, a 43-diopter cornea forms an image of a distant object about 31 mm behind the corneal vertex. The IOL typically resides in a plane 5 mm into the eye. Under these conditions, $S = 31 - 5 = 26$ mm. If the eye has an axial length of $L = 24$ mm, then $S' = 19$ mm. In this example, the conjugate factor $Y = 6.43$. Figure 4 shows the spherical aberration as a function of lens shape factor for a 20 D-PMMA lens with the preceding eye parameters and $y = 2$ mm. Two key features of this plot are apparent. First, the values of spherical aberration are strictly positive. This is true for any positive power lens with spherical surfaces. Since the corneal spherical aberration is typically positive as well, the spherical-surfaced IOL cannot compensate for this aberration, as the natural crystalline lens tends to do. Instead, the total ocular spherical aberration of the pseudophakic eye can only be minimized through the appropriate choice of IOL shape factor X. In the example in Fig. 4, a shape factor $X = +1.0$ minimizes the spherical aberration. This shape corresponds to a plano-convex lens with the flat side toward the retina. The shape factor $X = +1$ is ideal for a perfectly aligned cornea and IOL. However, natural variations in the tilt and decentration of the IOL and the orientation of the visual axis within the eye make this perfect alignment difficult. Typical values for the tilt and decentration of the IOL are less than 2.6° and 0.4 mm, respectively.[47] Atchison has shown that a shape factor of $X = +0.5$, double-convex lens with a less curved radius toward the retina, is less sensitive to these errors and modern spherical IOLs tend to target this shape factor.[48,49]

Aspheric Lenses

Recently, IOLs have shifted toward incorporating an aspheric surface for aberration control.[50] Whereas, conventional spherical-surfaced IOLs seek to minimize the aberrations induced by the implant, aspheric IOLs can be used to compensate spherical aberration induced by the cornea. The corneal spherical aberration stems mainly from its aspheric shape. The cornea over the entrance pupil of the eye is well represented by a conic section of radius R and conic constant Q. The sag of the cornea z is then described as

$$z = \frac{1}{Q+1}\left[R - \sqrt{R^2 - (Q+1)r^2}\right] \tag{12}$$

TABLE 3 Radius R and Conic Constant Q of the Human Cornea

References	R (mm)	Q	Technique

where r is the radial distance from the optical axis. Table 3 summarizes the values of R and Q of the anterior cornea found in several studies of corneal topography.[51–54] There is also a tendency for the cornea to become more spherical with age[54,55] leading to an increase in corneal spherical aberration.[56]

The spherical aberration of a surface can be found from paraxial raytracing values. The spherical aberration wavefront coefficient W_{040} of a spherical surface is given by[46]

$$W_{040} = -\frac{1}{8} r (ni)^2 \left(\frac{u'}{n'} - \frac{u}{n} \right) \tag{13}$$

where n is the refractive index, i is the paraxial angle of incidence of the marginal ray on the surface, and u the angle the marginal ray makes with respect to the optical axis. The primed terms denote variables following the surface, whereas the unprimed terms denote variable prior to the surface. Figure 5 shows the layout for calculating the spherical aberration of the anterior cornea for a distant object. In this case, $u = 0$, $n = 1.0$, u' is the marginal ray angle following the surface, $n' = 1.376$ is the refractive index of the cornea, and i is the paraxial angle of incidence of the marginal ray. From the figure it is evident that

$$i = \frac{r}{R} \tag{14}$$

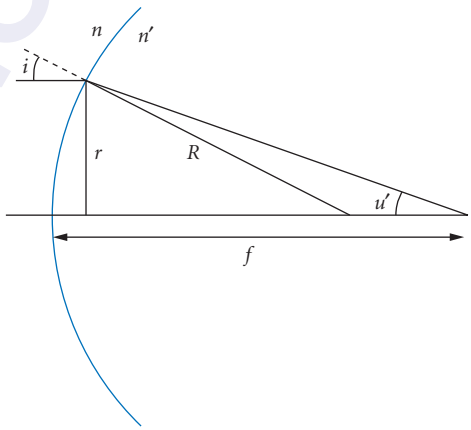

FIGURE 5 Variables in the calculation of the spherical aberration of the anterior cornea.

within the paraxial small angle assumption. Furthermore, the focal length f of the surface is given by

$$f = \frac{n'}{n'-1}R \tag{15}$$

which leads to a marginal ray angle of

$$u' = -\frac{(n'-1)r}{n'R} \tag{16}$$

Hopkins[57] showed that a correction factor can be added to the spherical surface aberration term to account for the asphericity of a conic surface. This correction factor is given by

$$\Delta W_{040} = \frac{Q(n'-1)r^4}{8R^3} \tag{17}$$

Combining Eq. (13) to Eq. (17), the total spherical aberration of the anterior cornea is given by

$$W_{040} + \Delta W_{040} = \frac{(n'-1)(1+n'^2Q)r^4}{8n'^2R^3} \tag{18}$$

If the preceding technique is repeated for the posterior corneal surface, then its spherical aberration typically is 2 orders of magnitude smaller than the spherical aberration of the anterior surface. Consequently, the contribution of the posterior cornea to the spherical aberration of the aphakic eye can be ignored. While Eq. (18) represents the wavefront coefficient of the corneal spherical aberration, the literature has somewhat adopted a different format. Typically, corneal spherical aberration has been given in terms of the Zernike polynomial expansion coefficient c_{40} for a normalization radius $r = 3$ mm.[58] In this case, the corneal spherical aberration is given by

$$c_{40} = W_{040}(r=3) + \Delta W_{040}(r=3) = \frac{1}{6\sqrt{5}}\frac{81(n'-1)(1+n'^2Q)}{8n'^2R^3} = \frac{0.15}{R^3} + \frac{0.284Q}{R^3} \tag{19}$$

The value of c_{40} is linear with respect to the corneal conic constant, as shown in Fig. 6. Table 4 summarizes the values of c_{40} from various studies in the literature.[59–62] Since the aberrations of the various elements of the eye add, the implanted aspheric IOL should compensate for the corneal spherical

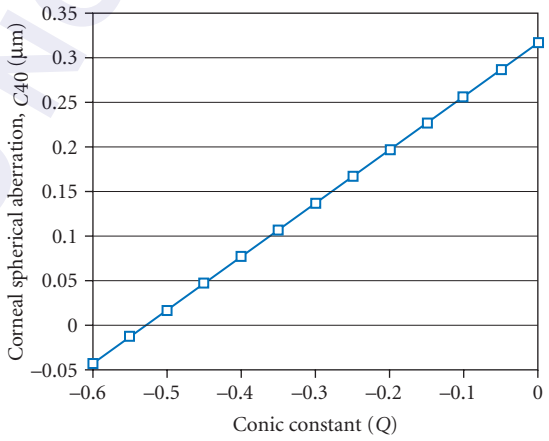

FIGURE 6 Corneal spherical aberration as a function of conic constant Q for a corneal radius $R = 7.8$ mm.

aberration given by Eq. (19). Examples of aspheric IOLs include the Tecnis Z9000 (Advanced Medical Optics, Irvine, CA) designed to correct 0.27 μm of corneal spherical aberration, the AcrySof SN60WF (Alcon Laboratories, Fort Worth, TX) designed to correct for 0.20 μm of corneal spherical aberration, and the SofPort Advanced Optics IOL (Bausch & Lomb, Rochester, NY) designed such that the implant has zero spherical aberration.

Toric Lenses

Astigmatism is another important consideration following cataract surgery. IOLs have been traditionally rotationally symmetric, again due to manufacturing ease. However, astigmatism may be present in the aphakic eye. This astigmatism is due to a toric shape in the cornea and, since the optical system is not rotationally symmetric, the astigmatism appears along the visual axis. Recently, toric IOLs have become available, but their use has been limited.[63] It is more common to reduce corneal astigmatism at the time of surgery with procedures known as corneal relaxing incisions or limbal relaxing incisions. In these procedures, arcuate incisions are made in the peripheral cornea or limbus, respectively. These incisions have the effect of making the cornea more rotationally symmetric after the incisions heal. Consequently, corneal astigmatism is reduced and a conventional rotationally symmetric IOL can be implanted. Corneal or limbal relaxing incisions are typically performed at the time of cataract surgery. An alternative to relaxing incisions is to perform a refractive surgery procedure such as LASIK to reduce corneal astigmatism. This procedure uses an excimer laser to ablate corneal tissue, leaving the postoperative cornea more rotationally symmetric. Toric IOLs are available and similar power calculations must be taken into account.[64–67] FDA-approved toric IOLs are available in the United States from Staar Surgical (Monrovia, CA) and Alcon Laboratories (Fort Worth, TX).

Testing IOLs

Clinical testing of implanted IOLs provides insight into the function of the lenses, but can also be difficult due to confounding factors such as cornea clarity, retina function, variations in surgical positioning of the implant, and neural processing. Furthermore, large numbers of subjects and long follow-up times make these types of studies expensive and slow. Several methods, including the Ronchi test and speckle interferometry, have been used to test isolated IOLs.[68,69] Alternatively, model eyes can be used to test the optical performance of IOLs in a configuration similar to their implanted state.[62,70–78] Model eyes allow for rapid evaluation of the lenses that avoids the confounding factors described above. In testing the optical performance of IOLs with a model eye, the geometry of how the lens is used within the eye is taken into account. Aberrations, which affect the IOL optical performance, are dependent on the vergence of light entering the implant. In general, the model eye consists of a lens that represents an artificial cornea and a wet cell, which is a planar-faced vial containing saline into which the IOL is mounted. The wet cell is placed behind the artificial cornea such that the corneal lens modifies incident plane waves and creates a converging beam onto the IOL. The vergence striking the IOL is meant to be representative of the vergence seen by an implanted IOL. An artificial pupil can also be introduced to simulate performance for different pupil sizes. The performance of the lens can then be evaluated at the image plane of the eye model. Several different types of artificial corneas have been used in eye models. The international standard ISO11979-2 recommends using a model cornea that is virtually free of aberrations in conjunction with the light

source used.[79] The standard provides an example model cornea made from a Melles-Griot LAO 034 lens. This lens is a commercially available cemented achromat and consequently is well corrected for both chromatic and spherical aberration. With this model cornea, the spherical aberration of the whole model eye is created solely from the IOL. This model eye specification predated the advent of aspheric IOLs. This type of model eye is therefore only suitable for earlier spherical surface IOLs to evaluate how well these implants minimize their inherent spherical aberration. However, this type of model cornea is not ideal for modern aspheric IOL designs. These newer designs are made to work in conjunction with the cornea and compensate for the corneal spherical aberration. Model corneas with representative levels of corneal spherical and chromatic dispersion have been proposed and used to test these advanced IOL designs.[62]

Measurement of the optical transfer function (OTF) or its modulus the modulation transfer function (MTF) are routine tests for measuring the optical quality of IOLs.[70–78] The MTF of an optical system describes the amount of contrast that is passed through the system. If a high contrast sinusoidal target is imaged by an optical system, then the contrast of the resultant image is reduced. In general, the contrast tends to decrease more severely with higher spatial frequency (i.e., finer spacing between the bars of the sinusoidal target). The MTF of a model eye is conveniently calculated by measuring the line spread function (LSF) of the model eye. The LSF, as its name implies, is simply the image of a narrow slit formed by the model eye. The image $i(x, y)$ of the vertically oriented slit on the retina is given by

$$i(x, y) = rect\left(\frac{x}{d}\right) * \mathrm{PSF}(x, y) \tag{20}$$

where d is the width of the unaberrated slit on the retina and $\mathrm{PSF}(x, y)$ is the point spread function of the eye. The Fourier transform of Eq. (12) gives

$$\Im\{i(x, y)\} = d\ \mathrm{sinc}(d\xi)\delta(\eta)\mathrm{OTF}(\xi, \eta) \Rightarrow \mathrm{OTF}(\xi, 0) = \frac{\Im\{i(x, y)\}}{d\ \mathrm{sinc}(d\xi)} \tag{21}$$

where $\Im\{\ \}$ denotes the Fourier transform and $\mathrm{sinc}(\xi) = \sin(\pi\xi)/(\pi\xi)$. Equation (21) says that the optical transfer function (OTF) is the ratio of the image spectrum and a sinc function. Note that the denominator of Eq. (13) goes to 0 for $\xi = 1/d$. Under this condition, the OTF approaches infinity. Consequently, the size of d must be made sufficiently small to ensure that the spatial frequencies ξ fall within a desirable range.

Multifocal Lenses

A variety of strategies have been employed to help alleviate presbyopia resulting from cataract surgery. The ideal situation would be to implant an IOL that had the capability to either change its power as the young crystalline does or change its position in response to contraction of the ciliary muscle. The latter case provides accommodation by changing the overall power of the eye through a shift in the separation between the cornea and IOL. These strategies and similar variations are being aggressively pursued as "accommodating" IOLs discussed in more detail in the following section. Clinical results demonstrating the ability of these IOLs to restore some degree of accommodation have been somewhat mixed, but improvement is likely as the accommodative mechanism becomes better understood and the lens designs incorporate these actions.

Multifocal IOLs represent a successful bridging technology between conventional IOLs and a true accommodating IOL. Multifocal optics have two or more distinct powers within their aperture. These lenses take advantage of simultaneous vision. In other words, both in-focus and out-of-focus images are simultaneously presented to the retina. The role of the brain then is to filter out the blurred component and interpret the sharp component providing suitable vision for two distinct distances. For example, suppose the required monofocal (single power) IOL power to correct distance vision in a patient undergoing refractive surgery is 20 D. If a multifocal lens containing dual powers of 20 and 24 D is implanted instead, the patient will have simultaneous vision following surgery. (Note that a 4 D add power in the

IOL plane is approximately equivalent to a 3 D add in the spectacle plane.) If the patient views a distant object, the distance portion of the IOL will form a sharp image on the retina, while the near portion of the lens will create a blurred image of the distant scene on the retina. Similarly, if the patient now views the text of a book, the near portion of the IOL will form a sharp image of the text on the retina, while the distance portion of the IOL will now create a blurred image of the page. In both cases, if the deleterious effects of the blurred portion of the retinal image are sufficiently low, then successful interpretation of the in-focus portion can be made. As a result of simultaneous vision, some contrast is lost in the in-focus image. Multifocal optics therefore represent a trade-off in visual performance. Monofocal lenses provide sharp, high contrast images for distance and horribly blurred low-contrast images for near objects. Multifocal lenses provide reasonably high contrast images for both distance and near vision, but there is some loss in contrast compared to monofocal distance vision. When designing multifocal lenses, control of the out-of-focus portion of the retinal image and understanding the conditions under which the lenses are used are important to optimizing the design. Proper understanding of these issues can provide high-quality multifocal images and lead to happy, spectacle-free patients.

Multifocal IOLs require two or more powers to be simultaneously present in the lens.[80] Zonal refractive lenses introduce multiple powers into the lens by having distinct regions or zones that refract light differently. The width or area of these zones is large compared to the wavelength of light. As a result of these large zones, the bending of the light rays is determined strictly by refraction. The local surface curvature of the lens determines the local lens power, and different powers can be incorporated simply by having regions with different curvatures. A simple example of a zonal refractive lens would be to bore a 2 mm hole in the center of a 20 D lens and then fill the region with a 2 mm region cookie cut from a 24 D lens. These resulting lens would act as a 20 D lens with a 4 D add in the center, providing multifocal optics. One clear problem arises in this design. The junction between the two lens regions will be abrupt and discontinuous leading the stray light effects. Zonal refractive lenses blend the transition between regions. This blend can be rapid, or the transition can be made slowly to introduce regions of intermediate power. Clearly, this concept can be extended to more than two discrete regions, so that multiple annular regions of alternating power can be created. Furthermore, the regions do not even need to be concentric circles. Instead, tear shaped, wedged, and even swirled regions have been demonstrated. The ReZoom IOL and its predecessor the Array IOL (Advanced Medical Optics, Irvine, CA) are examples of zonal refractive lenses. Figure 7 illustrates the power profile of such a lens. As can be expected with simultaneous vision, there exists a degradation in the optical quality of the retinal image with zonal refractive lenses. For example, starburst and halo patterns can result from these types of lenses.[81,82] However, these downsides provide roughly two-thirds of patients with near visual acuity of 20/40 or better, and the differences between zonal refractive and conventional monofocal lenses on complex tasks such as driving is small.[82,83] These lenses provide improved near vision at the expense of the quality of overall vision.

The second optical phenomenon that is exploited to create multifocal optics is diffraction.[84–86] Multifocal optics with diffractive structures are often misunderstood because they move away from the geometrical picture of light rays bending at the surface of the lens. Instead, these lenses take

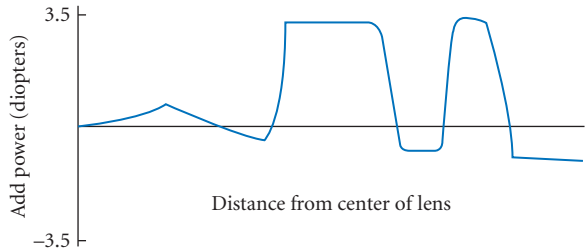

FIGURE 7 Power profile of the Array lens. The lens is formed from multiple concentric regions that oscillate between the base lens power and the higher add power.

advantage of the wave nature of light. In diffractive IOLs, concentric annular zones are created on the face of the lens. The *j*th zone occurs at a radius

$$r_j = \sqrt{2j\lambda_o F} \tag{22}$$

where λ_o is the design wavelength and F is the focal length of the add power. At the junction of each zone, an abrupt step appears. Both the height of the step and the dimensions of the zones control the degree of multifocality of the lens. The dimensions of the zones are related to the desired add power and in general, the spacing between zones gets progressively smaller from the lens center to its edge. The height of the step at the boundary of each zone determines how much light is put into the add portion. In typical multifocal diffractive lenses, this step height is chosen so that the peaks of one diffractive zone line up with the troughs of the next larger diffractive zone immediately following the lens. As these waves propagate to the retina, the waves from the various diffractive zones mix and there are two distinct regions of constructive interference that correspond to the two main foci of the multifocal lens. The optical phase profile $\phi(r)$ of a diffractive lens is given by[87]

$$\phi(r) = 2\pi\alpha\left(j - \frac{r^2}{2\lambda_o F}\right) \qquad r_j \le r < r_{j+1} \tag{23}$$

where α represents a fraction of the 2π phase delay. This phase pattern is superimposed onto one of the curved surfaces of the IOL. Note that if the change of variable $\rho = r^2$ is used, then the phase profile becomes periodic in ρ. Figure 8 shows the phase profile in both r- and ρ-space for a design wavelength of 555 nm, $\alpha = 0.5$, and $F = 250$ mm.

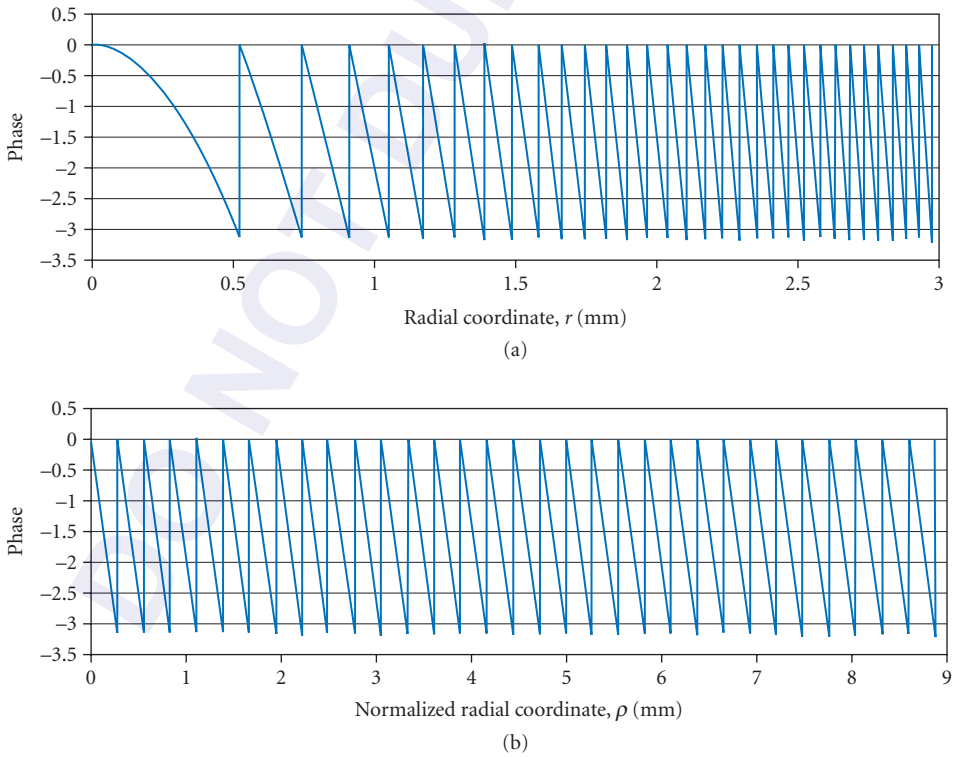

FIGURE 8 The phase profile of a diffractive lens as a function of r (*a*) and ρ (*b*). Note that (*b*) is periodic.

The periodic phase profile can be represented as a Fourier series such that

$$\exp[i\phi(\rho)] = \sum_m c_m \exp\left[-im2\pi\left(\frac{\rho}{2\lambda_o F}\right)\right] \tag{24}$$

where the coefficients c_m are given by

$$c_m = \frac{1}{2\lambda_o F}\int_0^{2\lambda_o F} \exp\left[-\frac{i\pi\alpha\rho}{\lambda_o F}\right]\exp\left[\frac{im2\pi\rho}{2\lambda_o F}\right]d\rho \tag{25}$$

Carrying out the integration in Eq. (25) gives

$$\exp[i\phi(r)] = \sum_m \exp[i\pi(m-\alpha)]\exp\left[-\frac{i\pi r^2}{\lambda_o(F/m)}\right]\mathrm{sinc}[m-\alpha] \tag{26}$$

Note that each term in the series in Eq. (26) acts like a lens of focal length F/m. The sinc function dictates how much energy is distributed into each foci. The diffraction efficiency η_m is defined as

$$\eta_m = \mathrm{sinc}^2[\mathrm{m}-\alpha] \tag{27}$$

The diffraction efficiency describes the percent of going into each diffraction order. In the case where $m = 0$, the focal length of this order becomes infinite (i.e., zero power). The underlying refractive carrier of the IOL provides all of the power of the implant. Consequently, the refractive power of the IOL is chosen to correct the eye for distance vision. For $m = 1$, energy is distributed into the +1 diffraction order. The power of the IOL for this diffraction order is the underlying refractive power of the IOL plus the power $+1/F$ provided by the diffractive structure. The amount of energy going into each of these diffractive orders is η_0 and η_1, respectively. Similarly, energy is sent to higher-diffractive orders that have efficiency η_m and add a power m/F to the underlying refractive power of the IOL. Table 5 summarizes the add power and the diffraction efficiency for a case where $\alpha = 0.5$. Clearly, most of the energy goes into the 0 and +1 diffraction orders.

The Tecnis ZM900 (Advanced Medical Optics, Irvine, CA) is an example of a diffractive lens with $\alpha = 0.5$ and $F = 250$ mm. The Acri.LISA IOL (Carl Zeiss Meditec, Oberkochen, Germany) is another example of a diffractive IOL. This IOL is currently only available outside the United States. This lens distributes about twice the energy into the zero-order as it does into the +1 order. This effect biases distance vision and can be achieved by making $\alpha = 0.414$. The ReSTOR IOL (Alcon Laboratories, Fort Worth, TX) is another variation of a diffractive lens.[88] These lenses have a diffractive structure over the central 3 mm of the lens and are purely refractive in their periphery. The refractive portion of the lens provides distance vision, while the diffractive portion of the lens provides both near and distance vision. The step heights between annular zones of the lens gradually decrease toward the edge of the diffractive zone. This decrease is called apodization. Traditionally in optics, apodization has referred to a variable transmission of the pupil of an optical system. However, apodization in this regard describes the gradual change in diffraction efficiency that occurs with these types of lenses. The net result of these types of lenses is that the energy sent to the distance and near foci is nearly equal for

TABLE 5 Add Power and Diffraction Efficiency for $\alpha = 0.5$ and $F = 250$ mm

Diffraction Order, m	Diffraction Efficiency, η_m	Add Power
–1	4.5%	–4 D
0	40.5%	0 D
+1	40.5%	4 D
+2	4.5%	8 D
+3	1.6%	12 D

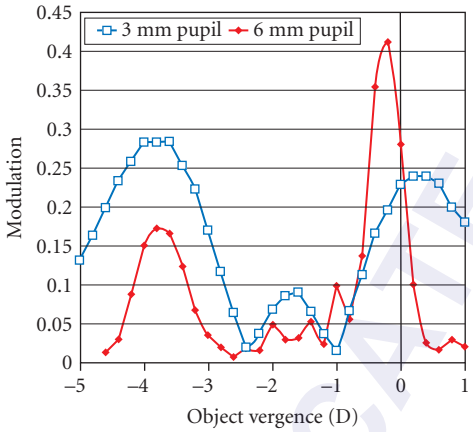

FIGURE 9 MTF measurements of the ReSTOR apodized diffractive IOL as a function of object vergence: 3- and 6-mm pupil.

small pupils, but is systematically shifted to a distance bias as the pupil size expands. Figure 9 shows the through-focus MTF of the ReSTOR lens for a 3- and 6-mm pupil. The horizontal axis of these plots is in units of vergence or the reciprocal of the object distance in units of inverse meters. As with zonal refractive lenses, there is some loss in visual performance with diffractive lenses.[89–91] This loss is offset by roughly 78 percent of patients achieving near visual acuity of 20/40 or better.[91] Biasing distance vision through modification of the step height or apodization tends to improve performance over conventional equal-split diffractive lenses for large pupil diameters.[92,93] Stray light effects, flares, and haloes can be seen with diffractive lenses as well. Apodization of the IOL tends to markedly dampen these stray light effects for large pupils.[93] Finally, diffractive lenses tend to provide superior visual performance when compared to zonal refractive lenses.[94,95]

Accommodating Lenses

Accommodating IOLs are the natural progression of implant technology. As shown in Fig. 1, accommodation is lost by about the age of 50. Implantation of IOLs may restore vision in cataract patients, but presbyopia remains. Multifocal IOLs have been developed to address the need of presbyopic pseudophakic patients, but there is always a trade-off with these types of lenses. Simultaneous vision by its nature reduces contrast and image quality, and designing multifocal IOLs is always a balance between providing functional near vision and minimizing artifacts attributed to multifocality. Accommodating lenses avoid the issues of simultaneous vision and provide high quality imaging at a variety of object distances. These types of lenses would function in a manner similar to the natural crystalline lens. Several accommodating IOLs are currently available; however, their performance has been marginal at best.[96] Advances in accommodating lens technology are rapidly occurring and this technology will likely replace multifocal IOLs once a suitable solution has been found. Furthermore, cataract surgery may no longer be the requirement for IOL implantation. Once solutions have been developed that offer reasonable levels of accommodation (likely allowing focusing from distance to 50 cm), a procedure known as refractive lens exchange (RLE) or clear lens extraction (CLE) is likely to rise in popularity.[97] In these procedures the noncataractous crystalline lens is removed and replaced with an IOL. These techniques are one option for patients with severe myopia, but surgeons are hesitant to perform these procedures on healthy, albeit presbyopic lenses with low degrees of refractive error. However, there was much resistance to implanting IOLs in the first place and once RLE or CLE demonstrates safe results that restore accommodation, the hesitancy will likely wane.

Two mechanisms are available for creating an accommodating IOL. The trigger for the lens action is the constriction of the ciliary muscle. The first mechanism is an axial shift of the position of the lens. Equation (8) describes the IOL power given the corneal curvature K, axial length L, and the effective lens position, ELP. Differentiating Eq. (8) with respect to the ELP gives

$$\frac{d\phi_{\text{IOL}}}{d(\text{ELP})} = \frac{(2K \cdot \text{ELP} - KL - 1000n_{\text{aq}})(KL - 1000n_{\text{aq}})n_{\text{aq}}}{(\text{ELP} - L)^2(K \cdot \text{ELP} - 1000n_{\text{aq}})^2} \tag{28}$$

Assuming a corneal power $K = 43$ D, and axial length $L = 24$ mm, $n_{\text{aq}} = 1.337$, ELP = 5 mm in the unaccommodated state and that the change in ELP is small compared to the total ELP, then the change in IOL power $\Delta\phi_{\text{IOL}}$ is approximately

$$\Delta\phi_{\text{IOL}} \approx 1.735\ \Delta\text{ELP} \tag{29}$$

Equation (29) shows that under these conditions, the 1 mm of movement of the IOL toward the cornea gives about 1.75 D of accommodation. Examples of IOLs that use axial movement are the FDA-approved Crystalens (Bausch & Lomb, Rochester, NY) and 1CU (HumanOptics AG, Erlangen, Germany) available in Europe. Both lenses have plate-type haptics or flat flanges emanating from the side of the lens. These flanges are hinged such that the lens vaults toward the cornea when the ciliary muscle constricts. Still there is much improvement needed in these technologies. The Synchrony accommodating IOL (Visiogen, Irvine, CA) is a variation on the axial movement concept that uses two lenses that move relative to one another instead of a single lens for the IOL.

The second mechanisms for an accommodating IOL would be a lens that changes its power in response to the constriction of the ciliary muscle. Examples of these types of lenses include the Fluid Vision IOL (Powervision, Belmont, CA) which pumps fluid from a peripheral reservoir into a lens with a deformable membrane surface to change its power, and the AkkoLens (AkkoLens International, Delft, The Netherlands) that uses two cubic phase plates that translate laterally to achieve a power change.[98] These accommodating IOLs represent emerging technologies but clinical demonstration of their capabilities is still needed.

Phakic Lenses

Phakic IOLs, as their name implies, are lenses that are implanted while the crystalline lens remains clear and intact. These lenses are used for treating nearsightedness instead of cataracts. Since the crystalline lens remains in place, phakic IOLs need to be implanted in the remaining space. There are two suitable locations for this implantation. The first is the anterior chamber, which is the space between the posterior cornea and the iris. Two techniques have been used to support anterior chamber IOLs. The first technique is to wedge the haptics into the angle where the peripheral cornea meets the iris. The second technique is to use specially designed haptics that clip to the peripheral iris to maintain the lens position. The main disadvantage of anterior chamber phakic IOLs is the risk to the corneal endothelium. The corneal endothelium is a thin layer of cells that coats the posterior surface of the cornea. These cells regulate the nutrition and health of the cornea and cannot be replaced if damaged. Mounting an IOL in the anterior chamber risks abrasions of these endothelial cells. Phakic IOLs can also be supported by the sulcus, which means the phakic IOL is placed on the area directly behind the iris, but in front of the crystalline lens. This second type of phakic IOL positioning requires a vaulting of the implant away from the surface of the crystalline lens since contact between the artificial and natural lenses are likely to lead to cataract formation. Examples of phakic IOLs include the Verisyse (Advanced Medical Optics, Santa Ana, CA), which is an iris-supported lens, and the Visian ICL (Staar Surgical, Monrovia, CA), which is a sulcus-supported lens. Excellent results have been achieved with phakic IOLs in extreme nearsightedness.[99] Phakic IOLs for the treatment of farsightedness and astigmatism as well as multifocal lenses are likely to be available in the United States in the near future.

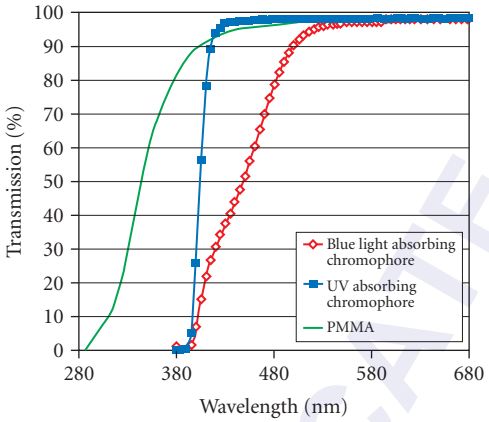

FIGURE 10 The transmission of a PMMA, and blue-light filtering, and UV-absorbing IOLs for ultraviolet and visible wavelengths.

Chromophores

The crystalline lens is the main absorber of wavelengths below 400 nm in the eye.[2,100] Removal of the crystalline lens causes a dramatic increase in the level of ultraviolet (UV) radiation that reaches the retina. These highly energetic wavelengths can cause phototoxicity, leading to damage the retinal neural structure and the underlying retinal pigment epithelium. Aphakic individuals are particularly susceptible to this type of damage since they no longer have the appropriate UV filtering. IOLs, in general, do little to mitigate the UV exposure. PMMA has significant transmission for wavelengths between 300 and 400 nm. Mainster recognized the risks to retinal health posed by transparent IOLs[101,102] and most IOLs incorporated a UV-absorbing chromophore by 1986.[103] These UV-absorbing chromophores typically have a cutoff wavelength of 400 nm, leaving high transmission of visible wavelengths, but negligible transmission of UV wavelengths. Blue-green wavelengths can also cause retinal phototoxicity, although much higher dosages are required for damage when compared to UV wavelengths. Several companies have introduced blue-light absorbing IOLs (AF-1 UY, Hoya, Tokyo, Japan and the Acrysof Natural, Alcon laboratories, Fort Worth, TX). These IOLs seek to have a transmission similar to the middle-aged human crystalline lens. Consequently, they partially absorb a portion of the spectrum between 400 and 500 nm. Figure 10 shows the transmission of a 3-mm slab of PMMA immersed in saline, along with the transmissions of IOLs containing UV-absorbing and blue-light absorbing IOLs.

Blue-light absorbing IOLs are somewhat controversial. Critics have suggested that scotopic and color vision are degraded by the lenses.[104,105] However, these claims have not been supported by theoretical analyses and clinical measures of in-eye lens performance.[106–113] Supporters of blue-light filtering lenses advocate their use to promote retinal health. Some laboratory studies have demonstrated protection to cell cultures afforded by the blue-light chromophores, but long-term clinical data remains unavailable.[114] Blue light has been shown to mediate the circadian rhythm[115] and an intermediate violet-absorbing chromophore that balances retinal protection and the circadian clock has been suggested.[116,117] Again, long-term validation of the benefits of such a lens are not available.

21.5 INTRAOCULAR LENS SIDE EFFECTS

A variety of optical deficits can arise following the implantation of intraocular lenses (IOLs). While artificial lenses replace cataractous lenses that have degraded markedly in optical quality, these IOLs can also introduce some visual side effects. These side effects include glare, halos, streaks, starbursts,

shadows, and haze. While the vast majority of pseudophakic patients are free from these effects under most circumstances and tolerate the problem in the few situations when they do arise, a small fraction of patients suffer from problems that are comparable or worse than their preoperative state. Understanding the cause of these optical phenomena allows for IOL manufacturers to improve their designs and minimize potential problems in future recipients.

Dysphotopsia

Dysphotopsia is the introduction of unwanted patterns onto the retina. These unwanted patterns are superimposed over the true retinal image and can cause degradation in visual performance. In pseudophakic dysphotopsia, the design and material of the artificial lens is typically responsible for redirecting the unwanted light to the retina. Dysphotopsia comes in two forms: positive and negative. Positive dysphotopsia is the introduction of bright artifacts onto the retina. These artifacts include arcs, streaks, rings, and halos and may only be present under certain lighting conditions or for certain locations of glare sources in the peripheral field. Negative dysphotopsia, conversely, is the blockage of light from reaching certain portions of the retina. Shadows and dark spots are perceived usually in the temporal field and again this phenomenon is affected by lighting conditions and position. Both positive and negative dysphotopsias affect visual performance because the unwanted images obscure the relevant retinal image formed directly by the IOL. Consequently, understanding their cause and eliminating these undesirable effects will lead to improve performance and satisfaction of patients.

Posterior Capsule Opacification

Another side effect of IOL implantation is posterior capsule opacification (PCO). Implantation of IOLs into the capsular bag provides a stable platform for the lens. However, in about 25 percent of patients, PCO can result. In PCO, the capsular bag gradually opacifies, and postcataract patients perceive many of the same symptoms seen prior to surgery, namely a gradual loss in acuity, glare, and blurred vision. YAG posterior capsulotomy is typically performed to open a hole in the capsule allowing light to pass through again. The large incidence of PCO causes dissatisfaction in patients and adds expense due to the need for additional equipment, procedures, and time to rectify the situation. Consequently, a reduction in PCO would be beneficial and strong efforts have been made to modify IOL designs and materials to drastically reduce the incidence of PCO. Acrylic materials and square edge designs have both appear to reduce the incidence of PCO.[118,119] However, dysphotopsia increased with introduction of these changes. To gain the benefit of reduced PCO, alterations were needed to acrylic lens edge designs.

Holladay et al.[120] compared the edge glare caused by sharp and rounded edge designs using a nonsequential raytracing technique. Nonsequential raytracing is routinely used for analyzing stray light and illumination effects. Typically, hundreds of thousands of rays are launched from a light source and allowed to refract, reflect, and scatter from various elements. Following the raytracing, the concentration of these rays in a given plane can be evaluated to determine the illumination pattern of the stray light. Holladay et al. found that both square and round edge IOLs produce stray light, but that only the square-edge design concentrated the light into a well-formed arc on the retina. Round-edge designs tended to disperse the stray light over a much larger portion of the retina, suggesting its visual consequences fall below a perceptible threshold. Clinical reports of dysphotopsia support that square-edge designs with a smooth finish are a likely culprit for many of the positive dysphotopsia problems.[121,122] Meacock et al.[123] performed a prospective study of 60 patients split between acrylic lenses with textured and nontextured edges. By prospectively analyzing the two groups, determination about the advantages of textured edges is assessed. One month post-operatively 67 percent of the nontextured IOL patients and 13 percent of textured-IOL patients had glare symptoms. The textured edges provided a statistically significant reduction in glare symptoms. Franchini et al.[124,125] used nonsequential raytracing methods to compare different types of edge design on positive dysphotopsia. They found similar result to Holladay et al.[120] in that the untextured square-edge design produced a

ring pattern on the retina, while a round edge distributed the light over a larger portion of the retina. This group also analyzed an "OptiEdge" design where the edge is beveled in an attempt to minimize stray light effects. In this case, they found an arc pattern is formed on the retina, but this arc in general has intensity far below the smooth edge pattern. Furthermore, Franchini et al. modeled a frosted square-edge design and found that the circular pattern retina is reduced, but the light is distributed over the retina and could possibly reduce contrast in the perceived image. The results of these efforts demonstrate that tailoring the shape and texture of the edge of the IOL can lead to an implant that reduces both PCO and dysphotopsia.

21.6 SUMMARY

The addition of IOL implantation following cataract removal revolutionized the procedure and enabled the restoration of high quality vision. While the technique was slow to be accepted by the medical establishment, the benefits of IOLs won over even the harshest critics to become the standard of care. IOLs are entering a postmodern era. Conventional IOLs are reliably fabricated and advances in materials and design have led to small incision surgeries that minimize risks to the patient and allowing outpatient procedures. Power calculations and the devices used to measure ocular dimensions have continued to improve, narrowing the residual error following implantation. Manufacturers are now turning to more subtle improvements to the technology. Aspheric surfaces are being incorporated to minimize ocular spherical aberration. Multifocal IOLs are providing simultaneous distance and near vision, enabling a spectacle-free lifestyle following surgery. Accommodating IOLs are emerging to fully restore accommodation. Furthermore, manufacturers are expanding the role of IOLs into the treatment of refractive error with phakic IOLs. Finally, chromophores are incorporated into IOLs to promote the health of the retina for the remainder of the patient's life. IOLs have been extraordinarily successful and a true benefit to the dim world of cataracts.

Department of Computer Science
University of Waterloo
Waterloo, Ontario, Canada

22.1 GLOSSARY

$D(\lambda)$	spectral reflectance of the diffuser
e_P	phosphor efficiency
I_B	beam current of a CRT
M_{ij}	coefficient *ij* in the regression matrix linking ΔX_i to ΔR_i
m_j	vector indicating the particular sample measured
N_P	number of monochrome pixels in a color pixel
n_j	vector indicating the particular sample measured
$R(\lambda)$	spectral reflectance of the faceplate of an LCD
R_j	input coordinates of the CRT: usually R_1 is the voltage sent to the red gun; R_2 is the voltage sent to the green gun; and R_3 is the voltage sent to the blue gun
V	voltage input to a CRT
V_A	acceleration voltage of a CRT
V_0	maximum voltage input to a CRT
υ_a	voltage applied to gun a of a CRT; $a = R, G, B$
υ_B	maximum scanning velocity for the electron beam
υ_h	horizontal velocity of the beam
υ_v	vertical velocity of the beam
X_{ai}	tristimulus values of light emitted from monochrome pixel of color a
X_i	tristimulus values of light emitted from a color pixel
X_i	tristimulus value i, that is, $X = X_1$; $Y = X_2$; and $Z = X_3$
X_{0i}	tristimulus value i of a reference color
x_p	horizontal interpixel spacing, $x_p = \upsilon_h \tau_p$
y_p	vertical interpixel (interline) spacing

γ	exponent in power law expressions of gamma correction
δ	interpolation parameter for one-dimensional characterizations
ΔR_i	change in input coordinate i
ΔX_i	change in tristimulus value i
ϵ	interpolation parameter for inverting one-dimensional characterizations
$\nu_{\max}$	maximum frequency of CRT input amplifiers
μ	index of color measurements taken along a curve in color space
Φ	power of the emitted light
$\Phi_{a\lambda}^{(AMB)}(V_a)$	spectral power distribution of light emitted from monochrome pixel of color a as a result of ambient light falling on an LCD
$\Phi_{a\lambda}^{(BL)}$	spectral power distribution of light emitted from monochrome pixel of color a as a result of the backlight
$\Phi_{a\lambda}(V_a)$	spectral power distribution of light emitted by monochrome pixel of color a, depending on the voltage with which the pixel is driven
$\Phi_{a\lambda}^{(R)}$	spectral power distribution of light reflected from the faceplate of an LCD
$\Phi(x, y)$	power of the emitted light as a function of screen position
Φ_λ	spectral power distribution of light emitted by all monochrome pixels in a color pixel
Φ_λ	spectral power of the emitted light
$\Phi_\lambda^{(AMB)}$	light output caused by ambient light falling on the faceplate of an LCD
$\Phi_\lambda^{(BL)}$	light output caused by the backlight of an LCD
Φ_0	maximum light power output from a CRT
$\Phi_{0\lambda}^{(AMB)}$	ambient light falling on the faceplate of an LCD
$\Phi_{0\lambda}^{(BL)}$	light emitted by the backlight-diffuser element of an LCD
$\Phi_\lambda(v_R, v_G, v_B)$	spectral power distribution of the light emitted when voltages v_R, v_G, v_B are applied to its inputs
$\tau_a(\lambda)$	spectral transmittance of the filter on monochrome pixel of color a
τ_d	phosphor decay time
τ_f	time spent scanning a complete frame
τ_l	time spent scanning a complete line, including horizontal flyback
τ_p	time the beam spends crossing a single pixel
$\tau(V)$	voltage-dependent transmittance of the light modulating element

22.2 INTRODUCTION

Complex images that are colorimetrically calibrated are needed for a variety of applications, from color prepress to psychophysical experimentation. Unfortunately, such images are extremely difficult to produce, especially using traditional image production technologies such as photography or printing. In the last decade technical advances in computer graphics have made digital imaging the dominant technology for all such applications, with the color television monitor the output device of choice. This chapter describes the operational characteristics and colorimetric calibration techniques for color television monitors, with its emphasis on methods that are likely to be useful for psychophysical experimentation. A short final section describes a newer display device, the color liquid crystal display, which is likely to become as important in the decade to come as the color monitor is today.

22.3 OPERATIONAL CHARACTERISTICS OF COLOR MONITORS

The color television monitor is currently the most common display device for digital imaging applications, especially when temporally varying images are required. Its advantages include good temporal stability, a large color gamut, well-defined standards, and inexpensive manufacture. A wide variety of different CRT types is now available, but all types are derived from a common technological base. This section describes the characteristics shared by most color monitors, including design, controls, and operation. Of course, a chapter such as this can only skim the surface of such a highly evolved technology. There is a vast literature available for those who wish a greater depth of technical detail. Fink et al.[1] provides a great deal of it, with a useful set of references for those who wish to dig even deeper. Colorimetry is discussed in Chap. 10 in this volume.

Output devices that go under a variety of names, color television receivers, color video monitors, color computer displays, and so on, all use the same display component. This chapter describes only the display component. Technically, it is known as a color cathode ray tube (CRT), the term that is used exclusively in the remainder of the chapter.

In this chapter several operational characteristics are illustrated by measurements of CRT output. These measurements, which are intended only to be illustrative, were performed using a Tektronix SR690, a now obsolete CRT produced for the broadcast monitor market. While the measurements shown are typical of CRTs I have measured, they are intended to be neither predictors of CRT performance nor ideals to be pursued. In fact, color CRTs vary widely from model to model, and any CRT that is to be used in an application where colorimetry is critical should be carefully characterized before use.

Color CRT Design and Operation

The color CRT was derived from the monochrome CRT, and shares many features of its design. Thus, this section begins by describing the construction and operation of the monochrome CRT. New features that were incorporated to provide color are then discussed.

Monochrome CRTs A schematic diagram of a monochrome CRT is shown in Fig. 1. The envelope is a sealed glass tube from which all the air has been evacuated. Electrons are emitted from the cathode, which is heated red hot. The flux of electrons in the beam, the beam current I_B, is determined by a control grid. A variety of magnetic and/or electrostatic electrodes then focus, accelerate, and deflect the beam. The beam strikes a layer of phosphor on the inside of the CRT faceplate, depositing

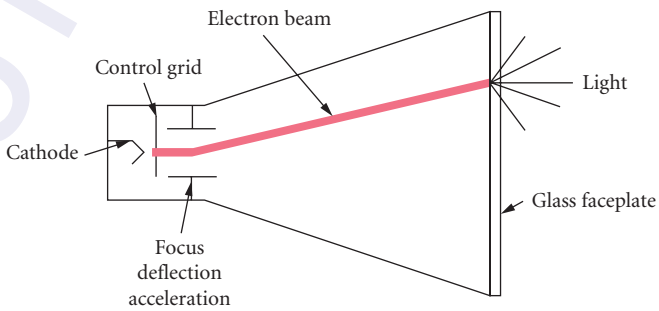

FIGURE 1 Schematic diagram of a monochrome CRT, showing the path of the electron beam and the location of the phosphor on the inside of the faceplate.

power $I_B V_A$, where V_A is the acceleration voltage. Some of this power is converted to light by the phosphor. The power Φ in the emitted light is given by

$$\Phi = \int \Phi_\lambda \cdot \frac{hc}{\lambda} d\lambda$$

Φ_λ, the spectral power distribution of the emitted light is determined, up to a single multiplicative factor, by the chemical composition of the phosphor. The multiplicative factor is usually taken to be a linear function of the beam power. Thus, the efficiency of the phosphor e_P given by

$$e_P = \Phi / I_B V_A$$

is independent of the beam current. Power not emitted as light becomes heat, with two consequences.

1. If the beam remains in the same spot on the screen long enough, the phosphor coating will heat up and boil the phosphor from the back of the faceplate leaving a hole in any image displayed on the screen.
2. Anything near the phosphor, such as the shadowmask in a color CRT, heats up.

A stationary spot on the screen produces an area of light. The intensity of the light is generally taken to have a gaussian spatial profile. That is, if the beam is centered at (x_0, y_0), the spatial profile of the light emitted is given by

$$\Phi(x,y) \propto \exp\left[\frac{1}{2\sigma_x^2}(x - x_0)^2 + \frac{1}{2\sigma_y^2}(y - y_0)^2\right]$$

The dependence of this spatial profile on the beam current is the subject of active development in the CRT industry. In most applications the beam is scanned around the screen, making a pattern of illuminated areas. The brightness of a given illuminated area depends on the beam current when the electron beam irradiates the area, with the beam current determined by the voltage applied to the control grid.

Shadowmask Color CRTs The basic technology of the monochrome CRT is extended to produce color. The standard method for producing color is to take several, usually three, monochrome images that differ in color and mix them additively to form a gamut of colors. (Even very unconventional technologies, such as the Tektronix bichromatic liquid crystal shutter technology, produce color by additive mixture.) This section describes the basic principles of shadowmask CRT technology, which is the dominant technology in color video.

Geometry of the shadowmask CRT A color CRT must produce three images to give a full range of color. To do so usually requires a tube with three guns. The three electron beams are scanned in exactly the way that monochrome beams are, but arrive at the screen traveling in slightly different directions. Near the faceplate is a screen called the shadowmask. It is made of metal, with a regular pattern of holes. Electrons in the beams either hit the screen to be conducted away or pass ballistically through the holes. Because the three beams are traveling in different directions, they diverge once they have passed the hole, striking the back of the faceplate in different places. The phosphor on the back of the faceplate is not uniform, but is distributed in discrete areas that radiate red, green, or blue light. The geometry is arranged so that electrons from the red gun hit red-emitting phosphor, electrons from the green gun hit green-emitting phosphor, and electrons from the blue gun hit blue-emitting phosphor. This geometry is illustrated in Fig. 2. Several different geometries of shadowmask tube exist:

1. *Delta guns.* The three guns are arranged at the corners of an equilateral triangle, irradiating phosphor dots arranged in a triad.

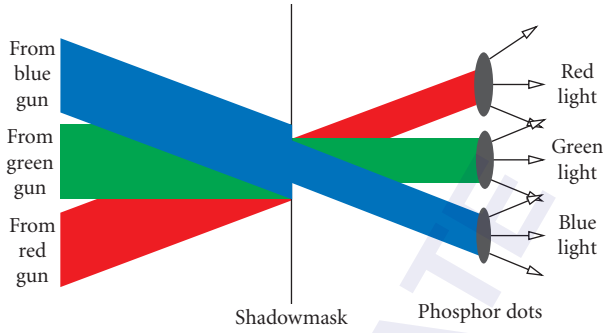

FIGURE 2 Electron beam/shadowmask/phosphor geometry in a shadowmask CRT.

2. *In-line guns.* The three guns are arranged in a line, irradiating phosphor dots side by side. The lines of phosphor dots are offset from line to line, so that the dot pattern is identical to that of the delta gun.
3. *Trinitron.* This is an in-line gun configuration, but the phosphor is arranged in vertical stripes. The holes in the shadowmask are rectangular, oriented vertically.

Other types of technology are also possible, though none is in widespread use. Beam index tubes, for example, dispense with the shadowmask, switching among the red, green, and blue signals as the electron beam falls on the different phosphor dots.

The most fundamental colorimetric property determining the colors produced by a shadowmask CRT is the light emitted by the phosphors. Only those colors that are the additive mixture of the phosphor colors (CRT primaries) can be produced. Because the color and efficiency of the phosphors are important determinants of perceived picture quality in broadcast applications phosphor chemistry undergoes continuous improvement, and varies from CRT to CRT. The emission spectra of the phosphors of a "typical" shadowmask CRT are shown in Fig. 3. The chromaticities of these phosphors are:

	x	*y*	*z*
Red phosphor	0.652	0.335	0.013
Green phosphor	0.298	0.604	0.098
Blue phosphor	0.149	0.064	0.787

Common problems in shadowmask CRTs The shadowmask is a weak point in color CRT design, so that color CRTs suffer from a variety of problems that potentially degrade their performance. The three most common problems are doming, blooming, and shadowmask magnetization. Doming occurs when the shadowmask heats because of the large energy density in the electrons it stops. It then heats up and expands, often not uniformly. The result is a distortion of its shape called "doming." This geometrical distortion means that the registration of holes and dots is disturbed, and what should be uniform colors become nonuniform. Trinitron tubes have a tensioning wire to reduce this problem. It is often visible as a horizontal hairline running across the whole width of the tube about a third of the way from the top or bottom of the tube, depending on which side of the tube is installed up.

Blooming occurs when too much energy is deposited in the electron beam. Then electrons arrive at the screen in the right position but their entire kinetic energy is not immediately absorbed by the phosphor. They then can move laterally and deposit energy on nearby dots which can be both the wrong color and outside the intended boundary of the bright area. Colors become desaturated, and edges of areas become blurred.

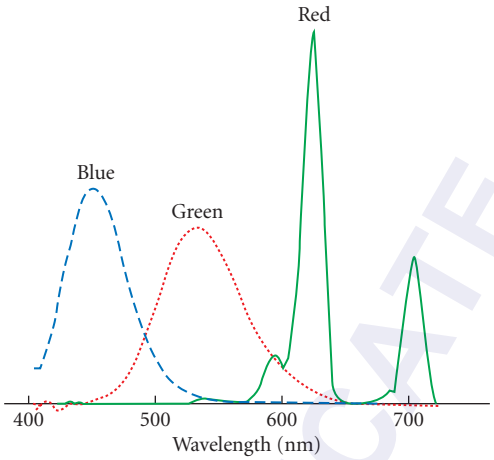

FIGURE 3 Spectral power distributions of the light output by a typical set of phosphors. The long wavelength peak of the red phosphor is sometimes missed in spectroradiometric measurements.

Magnetic fields build up in the shadowmask when the electromagnetic forces produced by electrons, assisted by the heat build-up, create magnetized areas in the shadowmask. These areas are nonuniform and usually produce large regions of nonuniformity in color or brightness on the screen. CRTs usually have automatic degaussing at power-up to remove these magnetic fields. If this is insufficient to remove the field buildup, inexpensive degaussing tools are available.

CRT Electronics and Controls The CRT receives voltage signals at its inputs, one for monochrome operation, three for color operation. The input signals must be suitably amplified to control the beam current using the grid electrode. The amplification process is described first, followed by the controls that are usually available to control the amplification.

Amplification Two properties of the amplification are important to the quality of the displayed image: bandwidth and gamma correction.

The bandwidth of the amplifiers determines the maximum frequency at which the beam current can be modulated. In most applications the beam is moved about the screen to produce the image, so that the maximum frequency translates into a maximum spatial frequency signal. Suppose, unrealistically, that the amplifiers have a sharp cutoff frequency ν_{max} and that the beam is scanned at velocity v_B. Then the maximum spatial frequency of which the CRT is capable is ν_{max}/v_B. In some types of CRT, particularly those designed for vector use, settling time is more important than bandwidth. It can be similarly related to beam velocity to determine the sharpness of spatial transitions in the image.

For colorimetric purposes, the relationship between the voltage applied at the CRT input and the light emitted from the screen is very important. It is determined by the amplification characteristics of the input amplifiers and of the CRT itself, and creating a good relationship is part of the art of CRT design. When the relationship must be known for colorimetric purposes, it is usually determined by measurement and handled tabularly. However, for explanatory purposes it is often written in the form

$$\Phi = \Phi_0 (V / V_0)^{\gamma}$$

where V is the voltage input to the CRT, normalized to its maximum value V_0. The exponent, which is conventionally written as γ, gives this amplification process its name, gamma correction.

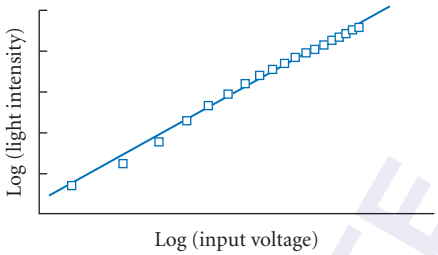

FIGURE 4 Graph of ln (light intensity) against ln (input voltage), sometimes used to determine the gamma correction exponent. Note the systematic deviation from a straight line.

Figure 4 shows some measured values, and a log-linear regression line drawn through them. Note the following features of this data.

1. The line is close to linear.
2. There are regions of input voltage near the top and bottom where significant deviations from linearity occur.
3. The total dynamic range (the ratio between the highest and lowest outputs) is roughly 100, a typical value. This quantity depends on the setting of brightness (black level) and contrast used during the measurement.

There will be additional discussion of gamma correction in the section on monitor setup.

Controls that affect amplification in monochrome CRTs Monochrome monitors have several controls that adjust several properties of the electron beam. Some controls are external to the monitor, some are internal, usually in the form of small potentiometers mounted on the circuit boards. The particular configuration depends on the monitor. In terms of decreasing likelihood of being external they are: brightness (black level), contrast, focus, underscan/overscan, pedestal, gain, horizontal and vertical size. A brief description of the action of each control follows. It is important, however, to remember that while names of controls tend to be constant from CRT to CRT, the action performed by each control often varies.

Brightness (black level) This control adjusts the background level of light on the monitor screen. It is designed for viewing conditions where ambient light is reflected from the monitor faceplate. It usually also varies the gamma exponent to a higher value when the background level (black level) is increased. A typical variation of the light intensity/input voltage relationship when brightness is varied is shown in Fig. 5.

Contrast This control varies the ratio between the intensity of the lightest possible value and the darkest possible value. High contrast is usually regarded as a desirable attribute of a displayed image, and the contrast control is usually used to produce the highest contrast that is consistent with a sharp image. A typical variation of the light intensity/input voltage relationship when this control is varied is shown in Fig. 6.

Focus This control varies the size of the electron beam. A more tightly focused electron beam produces sharper edges, but the beam can be focused too sharply, so that flat fields show artifactual spatial structure associated with beam motion. Focus is usually set with the beam size just large enough that no intensity minimum is visible between the raster lines on a uniform field.

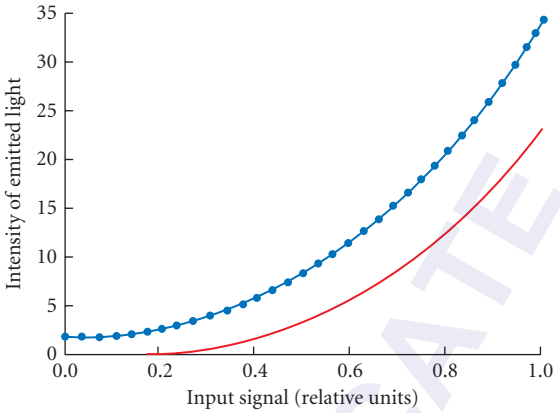

FIGURE 5 Variation of the light intensity/input voltage relationship when the brightness (black level) control is varied. The lower curve shows the relationship with brightness set near its minimum; the upper one with brightness set somewhat higher.

Pedestal and gain These controls, which are almost always internal, are similar to brightness and contrast, but are more directly connected to the actual amplifiers. Pedestal varies the level of light output when the input voltage is zero. Gain varies the rate at which the light output from the screen increases as the input voltage increases.

Controls specific to color CRTs Color monitors have a standard set of controls similar to those of monochrome monitors. Some of these, like brightness and contrast, have a single control applied simultaneously to each of the color components. Others, like gain and pedestal, have three controls, one for each of the color channels. There are several aspects of color that need to be controlled, however, and they are discussed in the paragraphs that follow.

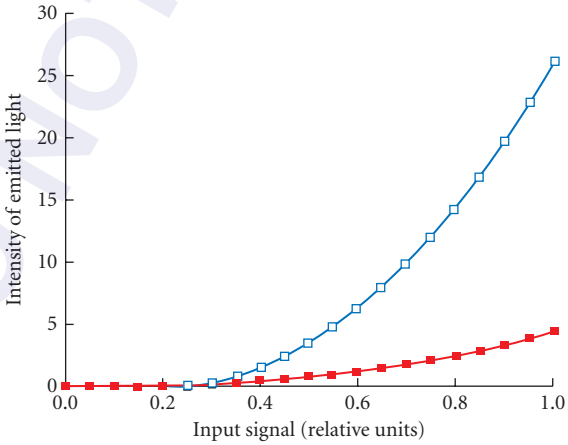

FIGURE 6 Variation of the light intensity/input voltage relationship when the contrast is varied. The lower curve shows the relationship with contrast set near its minimum; the upper one with contrast near its maximum.

Purity Purity is an effect associated with beam/shadowmask geometry. It describes the possibility that the electron beams can cause fluorescence in inappropriate phosphors. There is no standard set of controls for adjusting purity. Generally, there are magnets in the yoke area whose position can be adjusted to control purity, but this control is very difficult to perform. There will be no need to alter them under normal conditions. Purity is most influenced by stray magnetic fields, and can often be improved by moving the CRT.

White balance It is important for most monitor applications that when the red, green, and blue guns are turned on equally, calibration white (usually either D_{6500} or D_{9200}) appears on the screen. This should be true at all intensities. Thus, controls that alter the voltage input/light output relationship for each channel should be available. At a minimum, there will be the pedestal and gain for each channel.

Degauss Above we mentioned magnetic fields that build up in the shadowmask. There is generally a set of wires that run around the edge of the faceplate. At power-up a degaussing signal is sent through the wires and the ensuing magnetic field degausses the shadowmask. The degauss control can produce the degauss signal at any time.

CRT Operation The CRT forms an image on its screen by scanning the electron beam from place to place, modulating the beam current to change the brightness from one part of the image to another. A variety of scan patterns are possible, divided into two categories. Scan patterns that are determined by the context of the image (in which, for example, the beam moves following lines in the image) are used in vector displays, which were once very common but now less so. Scan patterns that cover the screen in a regular pattern independent of image content are used in raster displays: the scan pattern is called the raster. A variety of different rasters are possible; the one in most common use is a set of horizontal lines, drawn from top to bottom of the screen.

Raster generation Almost all raster CRTs respond to a standard input signal that creates a raster consisting of a set of horizontal lines. This section describes the path of the electron beam as it traverses the CRT screen; a later section discusses the signal configurations that provide the synchronization necessary to drive it.

Frames and fields The image on the screen is scanned out as a set of lines. Each line is scanned from left to right, as seen from a position facing the screen. Between the end of one line and the beginning of the next the beam returns very quickly to the left side of the screen. This is known as horizontal retrace or flyback. The successive lines are scanned from top to bottom of the screen. One field consists of a scan from top to bottom of the screen. Between the end of one field and the beginning of the next the beam returns very quickly to the top of the screen. This is known as vertical retrace or flyback.

One frame consists of a scan of all the lines in an image. In the simpler type of display a field is identical to a frame, and all the lines of the image are scanned out, from top to bottom of the display. The scan pattern is shown in Fig. 7. It is called noninterlaced.

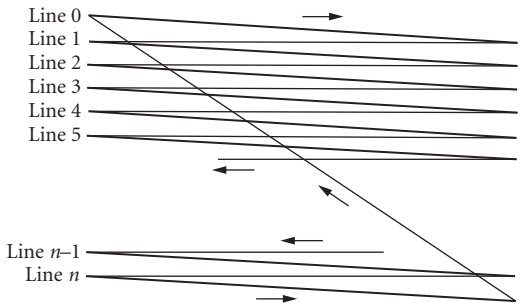

FIGURE 7 Scan pattern for a noninterlaced raster.

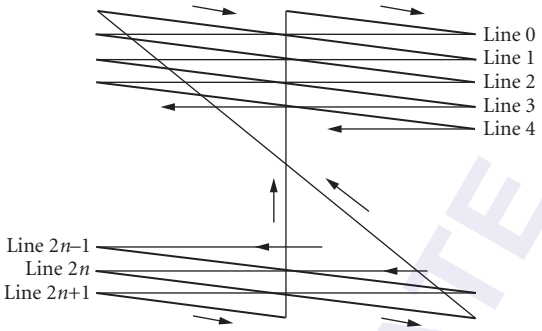

FIGURE 8 Scan pattern for an interlaced raster, two fields per frame. Line 3 eventually scans to line $2n - 1$ by way of the odd lines; line 4 scans to line $2n$.

A more complicated type of raster requires more than one field for each frame. The most usual case has two fields per frame, an even field and an odd field. During the even field, the even-numbered lines of the image are scanned out with spaces between them. This is followed by vertical retrace. Then, during the odd field the odd-numbered lines of the image are scanned out into the spaces left during the even-field scan. A second vertical retrace completes the frame. This scan pattern, known as interlaced, is shown in Fig. 8. The purpose of interlace is to decrease the visible flicker within small regions of the screen. It works well for this purpose, provided there are no high-contrast horizontal edges in the display. If they are present they appear to oscillate up and down at the frame rate, which is usually 30 Hz. This artifact can be very visible and objectionable, particularly to peripheral vision. Interlace having more than two fields per frame is possible, but uncommon.

In viewing Figs. 7 and 8 note that the vertical scan is produced by scanning the beam down continuously. Thus the visible lines are actually sloped down from left to right while the retrace, which is much faster than the horizontal scan, is virtually unsloped. The method used to put the odd field of the interlaced scan between the lines of the even field is to scan half a line at the end of the even field followed by half a line at the beginning of the odd field. Thus an interlaced raster has an odd number of lines.

Relationship of the raster to the CRT input signal The CRT receives a serial input signal containing a voltage that controls the intensity for each location in the image. This signal must be synchronized with the raster in order to make sure that each pixel is displayed in the right location. This section describes the relationship between the raster and the CRT input.

Horizontal scanning The input signal for one line is shown in Fig. 9. It consists of data interspersed with blank periods, called the horizontal blanking intervals. During the horizontal blanking interval the beam is stopped at the end of the line, scanned quickly back for the beginning of the next line, then accelerated before data for the next line begins. In the data portion, 0.0 V indicates black and 1.0 V indicates white. The signal shown would produce a line that is dim on the left, where the line starts, and bright on the right where it ends.

A second signal, the horizontal synchronization signal, has a negative-going pulse once per line, positioned during the horizontal blanking interval. This pulse is the signal for the CRT to begin the horizontal retrace.

When the synchronization signal is combined with the data signal the third waveform in Fig. 9 is produced. The intervals in the horizontal blanking interval before and after the synchronization are known as the front and back porch. They are commonly used to set the voltage level corresponding to the black level, a process known as black clamping. Black clamping reduces the effect of low-frequency noise on the color of the image, but requires good synchronization between the precise timing of the

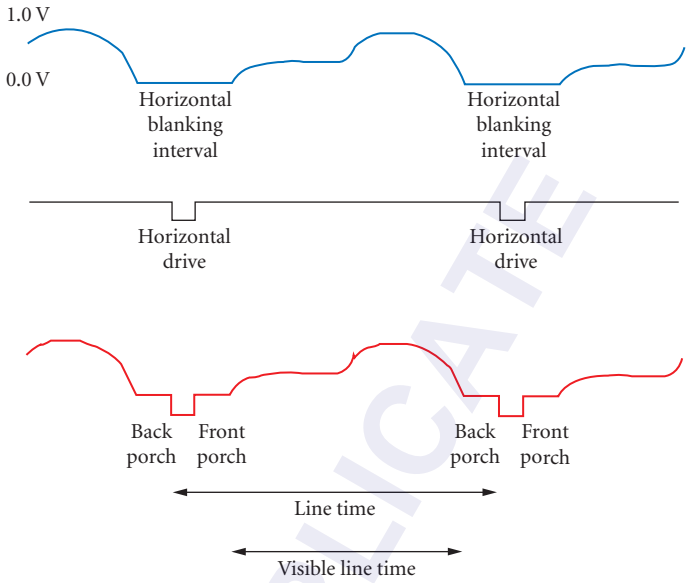

FIGURE 9 A schematic input signal that would generate a single line of raster, including the end of the preceding line and the beginning of the succeeding line. The top trace shows the signal that produces the image, including the blank between lines; the middle trace shows the synchronization signal with the horizontal drive pulse located during the blank; the bottom trace shows the synchronization signal and the picture signal in a single waveform.

signal and the raster production of the CRT. The ability of the monitor to hold synchronization with particular timing in this signal is an important parameter of the monitor electronics.

Vertical scanning Figure 10 shows the input signal for one complete field. There is data for each line, separated by the horizontal blanking period, which is too short to be visible in the figure. Separating the data portion of each field is the vertical blanking interval, during which the beam is scanned back to the top of the screen.

The synchronization signal consists of a vertical drive pulse signaling the time at which the beam should be scanned to the top of the screen. This pulse is long compared to the horizontal drive pulses so that it can easily be separated from them when the synchronization signals are combined into composite synch. In composite synch positive-going pulses in positions conjugate to the positions of the horizontal drive pulses are added during the vertical drive signal. These pulses are designed to keep the phase of the horizontal oscillator from wandering during vertical drive. When they are interpreted incorrectly, as was the case in some monitors early in the history of digital electronics, the result is a small shear in the first few lines at the top of the screen as the horizontal oscillator gets back into phase.

The composite synch signal can be added to the data, as shown in the fourth illustration in Fig. 10. Most real systems have this type of synchronization, which was designed for an era when signals were to be sent long distances by broadcast or wire. Today, in computer graphics applications, we often find that electronic circuitry in the source carefully folds the two synch signals into composite synch and the composite synch signal into the data signal. This signal is carried along a short piece of wire to the receiver, where electronic circuitry strips the signals apart. Bad synchronization is often caused by the malfunction of this superfluous circuitry, but it is unlikely that this situation will change in the immediate future.

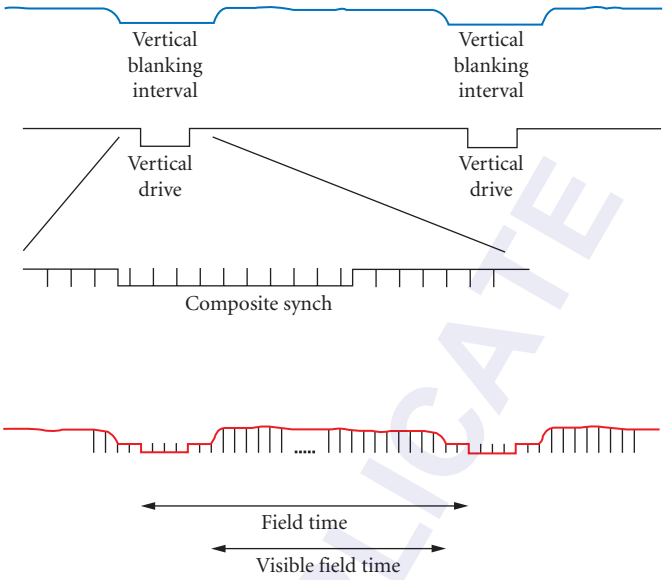

FIGURE 10 A schematic input signal that would generate a single field of a raster, including the end of the preceding field and the beginning of the succeeding field. The top trace shows the picture signal, with the vertical blank shown and the horizontal blank omitted. The second trace shows the vertical synchronization signal with the vertical drive pulse. The third trace shows the horizontal synchronization signal added to the vertical signal to give composite synch. The bottom trace shows composite synch added to the picture signal.

At the input to a color CRT, three or four signals like the ones described above are provided. The four signals are three input signals containing pixel intensities and blanking intervals, plus a fourth signal carrying the composite synchronization signal. To get three signals the synchonization signal is combined with one or more of the pixel signals. When only one pixel signal has synchronization information it is almost always the green one.

Controls that affect the raster Several controls affect the placement and size of the raster on the CRT. They are described in this section.

Horizontal/vertical size and position These controls provide continuous variation in the horizontal and vertical sizes of the raster, and in the position on the CRT faceplate where the origin of the raster is located.

Underscan/overscan Most CRTs provide two standard sizes of raster, as shown in Fig. 11. This control toggles between them. In the underscan position the image is smaller than the cabinet port, so that the whole image is visible, surrounded by a black border. In the overscan position the image is slightly larger than the cabinet port, so that no edges of the image are visible. There is a standard amount of overscan, which is used in home television receivers.

Convergence A shadowmask color CRT has, in effect, three rasters, one for each of the primary colors. It is essential that these rasters be positioned and sized exactly the same in all parts of the image; otherwise, spurious colored fringes appear at the edges in the image. To achieve this it is essential

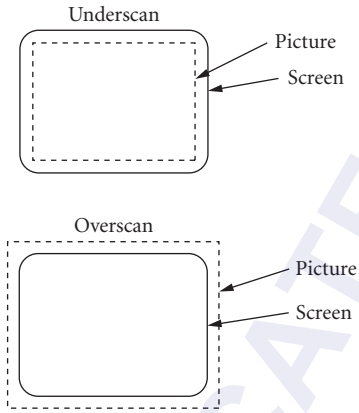

FIGURE 11 Schematic illustration of overscan and underscan. The rectangle with rounded corners is the cabinet mask that defines the viewing area; the rectangle with square corners is the displayed image.

that all three electron beams should be at the same place at the same time. For example, if the green gun is slightly to the left of the red and blue guns, a white line of a black background will have a green fringe on its left side and a magenta fringe on its right side. Good convergence is relatively easy to obtain with in-line gun configurations, so the usual practice is to adjust convergence at the factory using ring-shaped magnets placed over the yoke of the CRT, then to glue them permanently in place with epoxy cement. Satisfactory readjustment is very difficult to achieve.

Delta gun configurations have, by reputation, less stable convergence. Consequently, there are often controls available to the user for adjustment of convergence. The Tektronix 690SR was an extreme case, with a pullout drawer containing 52 potentiometers for controlling convergence on different areas of the screen. However, these controls, as might be expected, are not independent, so that "fine tuning" the convergence is very difficult, even when the controls are conveniently located.

Magnetic fields are generally the main culprit when convergence is objectionable, since the paths of electrons are curved in magnetic fields. Small fields from power transformers or from other electronic equipment or even the earth's magnetic field can be the problem. Thus, before considering redoing the convergence on a new monitor, try rotating it and/or moving other equipment around in the room. Another useful trick: some low-cost CRTs have poorly positioned power transformers, and convergence can be improved by moving the power transformer far outside the CRT cabinet.

Operational Characteristics of Color CRTs

Two factors influence the light output that is produced in response to input signals. One is conventional: the input signal must be sequenced and timed precisely to match what is expected by the CRT. This problem is handled by input signal standards of long standing in the television industry. Synchronization standards are described first, followed by colorimetric standards. The second is technical: the construction of CRTs produces certain variations, even when the input signal is constant. The section ends with a discussion of this variation, specifying the temporal and spatial characteristics of the light output from a CRT and describing reasonable expectations for stability and uniformity in CRT-produced images.

Timing and Synchronization Standards Figures 9 and 10 show how the information needed to specify a CRT image are arranged in the input signal. For practical use they need to be specified numerically, thereby allowing CRT manufacturers to ensure that their products will respond appropriately to

the input signals they will encounter in service. Two standards have been created by the Electronic Industries Association (EIA) for this purpose. They are actually standards for television studios, prescribing how signals should be distributed in closed-circuit applications, and specifically between television cameras and studio monitors. In practice they are more widely used. Among other applications, they specify the interface between the tuner and the CRT in television receivers, and the output of digital graphics systems allowing studio monitors to be used as display devices.

The two standards are RS-170,[2] which was designed for lower bandwidth applications, and RS-343,[3] which was designed for higher bandwidth applications. Each gives minimum and maximum timings for each part of the input signal in terms of several parameters that are allowed to vary from application to application. These parameters are then part of CRT input specification, allowing all timing characteristics to be deduced. The most important parameter is the line rate, the number of lines displayed per second. Most CRTs are intolerant of large variations in this parameter. Another important parameter is the field rate, the number of fields displayed per second. Older CRTs were quite intolerant of variations in this parameter, but most modern CRTs can handle signals with a very wide variety of field rates.

RS-170 and RS-343 are monochrome standards. When used for color they are tripled, with the input signal assumed to be in three parallel monochrome signals. As mentioned above, the synchronization signal is either placed on a fourth, or incorporated into a single color signal, usually the green one. However, although this practice is almost universal there is no official color standard for the RGB input to a monitor. This lack can have unfortunate consequences. For example, the NTSC color signal naturally decodes into three signals with peak-to-peak voltages of 0.7 V. Thus RGB monitors were built with inputs expecting this range. RS-170 and RS-343, on the other hand, specify a peak-to-peak voltage of 1.0 V. Early digital graphics systems were built to provide exact RS-170 and RS-343 output. These systems, naturally, overdrove standard monitors badly.

Colorimetric Standards In broadcast applications the image transmitter should be able to specify the precise color that will be displayed on the receiver's CRT. This requirement can be supplied by a colorimetric standard. The NTSC color standard was agreed upon for use in the North American broadcast television industry. It is a complete color standard, specifying phosphor chromaticities, color representation on the carrier signal, signal bandwidth, gamma correction, color balance, and so on. Thus, if the NTSC standard were followed in both transmitter and receiver, home television would provide calibrated colors. It is not followed exactly, however, since both television manufacturers and broadcasters have discovered that there are color distortions that viewers prefer to colorimetrically precise color. Furthermore, it is not useful for high-quality imagery since the low bandwidth it allocates to the chromatic channels produces edges that are incompatible with good image quality.

Spatial and Temporal Characteristics of Emitted Light The light emitted from a CRT is not precisely uniform, but suffers from small- and large-scale variations. The small-scale variations arise because the image is actually created by a spot that moves over the entire display surface in a time that is intended to be short compared to temporal integration times in the human visual system. In fact, a short enough glimpse of the CRT screen reveals only a single point of light; a longer one reveals a line as the point moves during the viewing time. These patterns are designed to be relatively invisible under normal viewing conditions, but often need to be considered when CRTs are used for vision experimentation, or when radiometric measurements are made. They are controlled largely by the input signal, so they are relatively constant from CRT to CRT.

The small-scale variations are described in this section; the large-scale variations, which occur as spatial nonuniformity and temporal instability in the emitted light, are discussed in the following section.

Spatial characteristics The electron beam scans the screen horizontally, making an image that consists of a set of horizontal lines. During the scan its intensity is modulated, so that the line varies in brightness—vertical edges, for example, being created by coordinated modulation in a series of horizontal lines. The sharpness of such a line depends on two factors: the ability of the video amplifiers to produce an abrupt change in intensity and the size of the spot of light on the screen, which is essentially the same as the cross section of the electron beam. Video amplifiers vary greatly in bandwidth

from one model of CRT to another, and adjusting their performance is beyond the reach of virtually all CRT users. Unfortunately, interactions between adjacent horizontal pixels are not even linear,[4–6] and the measurements needed to determine the nonlinearity of a given CRT are extremely demanding. Thus, compensating for amplifier bandwidth or even measuring its effects is beyond the scope of this chapter.

By contrast, the sharpness of a horizontal line is independent of the video amplifiers, but depends only on the spot size and its spatial profile, which is well modeled as a two-dimensional gaussian. The width of the gaussian depends on the focus electrodes, and is user-adjustable on most CRTs. The shrinking raster technique for CRT setup (discussed in subsection "CRT Setup for Image Display" discussed later in this chapter) determines a spot size that has a specific relationship to the interline spacing. Assuming this setup, it is possible to make reasonable assumptions about the contrast of images on a CRT,[7] and these assumptions can be extended to the small-scale spatial structure of arbitrary images. Note that many CRTs used primarily as display terminals are overfocused compared to the shrinking raster criterion because such overfocusing allows the display of smaller text. Overfocusing is easily detected as visible raster lines, usually in the form of closely spaced dark horizontal lines when a uniform field is displayed.

Temporal characteristics Because of the scan pattern the light emitted from any portion of the screen has a complicated temporal dependence. The next few paragraphs describe several levels of this dependence, assuming, for simplicity, that the scan is noninterlaced. Similar results for an interlaced scan are easy to derive. The relevant variables are

- τ_d phosphor decay time
- τ_p time the beam spends crossing a single pixel
- v_h horizontal velocity of the beam
- x_p horizontal interpixel spacing, $x_p = v_h \tau_p$
- τ_l time spent scanning a complete line, including horizontal flyback
- v_v vertical velocity of the beam
- y_p vertical interpixel (interline) spacing, $y_p = v_v \tau_l$
- τ_f time spent scanning a complete frame (identical to the time spent scanning a complete field)

These temporal factors usually change the colorimetry of the CRT. When one or more is changed, usually because the video source has been reconfigured, the color output for a given input to the CRT usually changes. Thus, a recalibration should be done after any such change. And it is probably practical to recommend that the system be used with the new video timing parameters for a while before the recalibration is done, since tuning or touch-ups will require further recalibration. The intensity of the light emitted from a vanishingly small area of the CRT screen is a function that is zero until the beam traverses the point t_s, then decays exponentially afterward,

$$\Phi(t) = \sum \Phi_0 \theta(t - t_s) \exp((t - t_s)/\tau_d)$$

τ_d ranges between 10^{-3} τ_f and τ_f, and usually varies from one phosphor to another. Most often the green phosphor has the largest τ_d, the blue one the smallest. Broadcast monitors tend to have small τ_d's since they are designed to display moving imagery; data display CRTs tend to have large τ_d's since they are intended to display static imagery. Occasionally a CRT primary (most often red) is a mixture of two phosphors with different decay times. In such cases, the chromaticity of the light emitted by the primary changes over time, though the change is not usually visible.

If a second pixel is n_h pixels to the right of a given pixel and n_v lines below it, the light emitted by the second pixel lags behind the light emitted by the first pixel by

$$n_h \tau_p + n_v \tau_l \approx d_h / v_h + d_v / v_v$$

where d_h and d_v are the horizontal and vertical screen distances.

Commonly, a detector measures a finite area of the CRT screen. Then intensity of the detected light is a closely spaced group of exponentials followed by a long gap, then another closely spaced group, and so on. Each peak in the closely spaced group is spaced about τ_p from the previous one, occurring when each line of the raster crosses the detection area. Each group is spaced about τ_f from the previous one, occurring each time a new field repaints the detected target. The time constant of this composite signal is τ_d, the decay time of the phosphor for each individual peak in the signal.

Stability and Uniformity of CRT Output The small-scale structure of the emitted light, discussed above, determines the specific form of visual stimuli produced by a CRT. The large-scale structure determines the scope of applicability of measurements made on a particular area of a CRT at a particular time.

Temporal stability How constant is the light emitted by a CRT that receives the same input signal? Figures 12 and 13 show the results of colorimetric measurements taken over a 24-hour period. In each figure the calibration bars shows a 2 percent variation compared to the average value. The variation decreases considerably in the latter part of the graph. It is the period from 5 p.m. until 9 the next morning, showing that variations in the building power are the largest source of temporal instability. Furthermore, this variation affected all guns similarly, as is shown by the smaller variation in Fig. 13, which shows the chromaticity coordinates, thereby factoring out overall changes in intensity.

Measurements like this one are important for establishing the precision at which calibration is sensible: it isn't worthwhile to calibrate to a greater precision than the variation in the colorimetry over the period between calibrations. While this CRT has excellent temporal stability, significantly better than most other light sources, the same is not true for all CRTs. Some vary in output by as much as 20 to 30 percent over times as short as a few minutes.

The measurements shown in Figs. 12 and 13 give an idea of the variation of light output over periods of hours or days, and illustrate the precision it is possible to expect from a recently calibrated CRT. CRTs also vary on a time scale of years, but the effects are not documented. Anecdotal reports suggest the following. First, electronic components change with age, so properties that depend on the

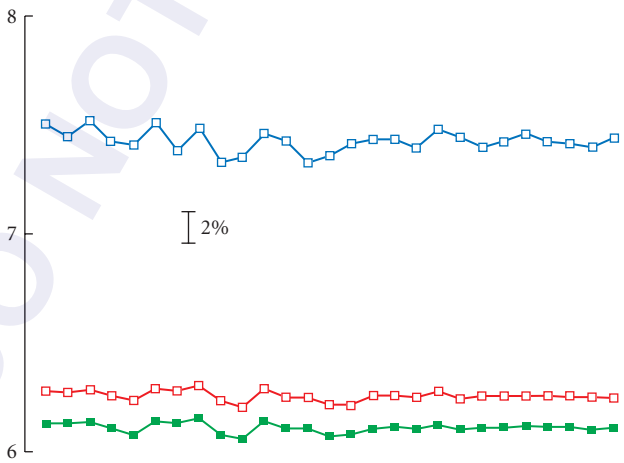

FIGURE 12 Variation of light output from a color CRT over 24 hours of continuous operation. This graph shows the three tristimulus values when a neutral color is displayed. The latter part of the graph is at night when almost all other equipment in the building is turned off.

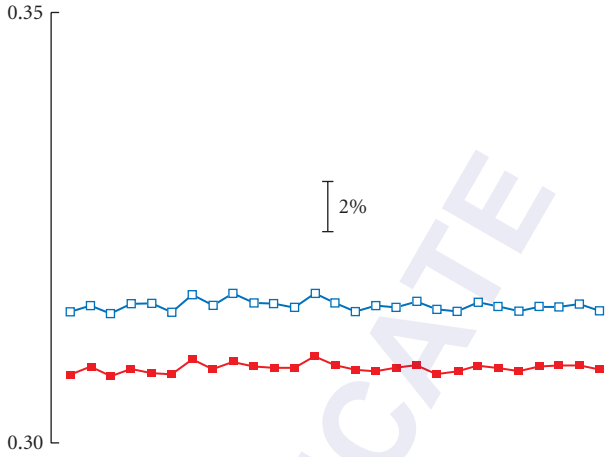

FIGURE 13 Variation of light output from a color CRT over 24 hours of continuous operation. This graph shows the chromaticity coordinates corresponding to Fig. 12. They show less variation than the tristimulus values which covary considerably.

CRT electronics, such as video amplifier gain and bandwidth, change with age, almost always for the worse. Second, chemical properties do not change with age, so properties such as the spectral power of light emitted by a specific phosphor do not change. One anecdotal report[8] describes no variation in chromaticity coordinates of phosphor emission spectra over several years of CRT operation. It is possible, however, that phosphor concentrations diminish as tubes age, probably because the phosphor slowly evaporates. Such an effect would reduce the intensity of light emitted from the phosphor without changing its chromaticity. The magnitude of this effect is controversial.

Spatial uniformity The light emitted by a specific input signal varies a surprising amount from one area of the screen to another. Figure 14 shows the variation of luminance at constant input voltage as

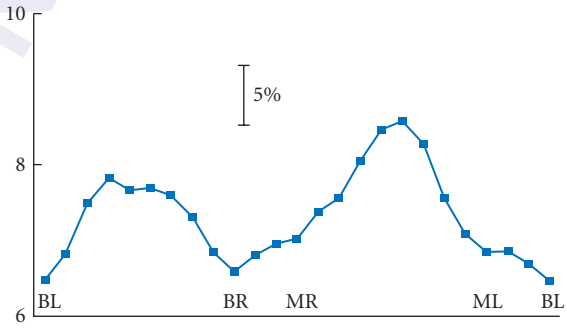

FIGURE 14 Variation of light output when different parts of a CRT screen are measured from a fixed point. Horizontal lines mark variations of about 5 percent.

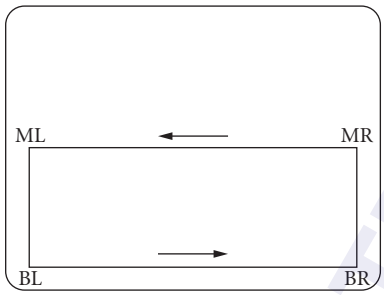

FIGURE 15 The measurement path used for the measurements shown in Fig. 14.

we measure different areas of the screen from a fixed measurement point. (Figure 15 shows the location on the screen of the measurement path.) Note that the light intensity decreases as the measurement point moves away from the center either horizontally or vertically, and is lowest in the corners. Two effects work together to create this effect. As the beam scans away from the center of the tube, it meets the shadowmask at more and more oblique angles, making the holes effectively smaller. Because of the curvature of the tube and the finite distance of the observer, the edges and corners are viewed at angles off the normal to the tube. Light is emitted in a non-Lambertian distribution, preferring directions closer to the normal to the tube face. The effects in Fig. 14 occur in all CRTs. How large they are, however, depends strongly on the type and setup of the monitor. Correcting for this nonuniformity is usually impractical. Doing so requires very extensive measurement.[9]

Closer examination of measured light shows, however, that many experimental situations are not hampered by this nonuniformity. Usually the chromaticity coordinates are very close to being constant, even though the luminance varies greatly. General intuition about color, as well as some recent experiments,[10] shows that humans are quite insensitive to smooth luminance gradients, even when they are as large as 20 percent. This fact, combined with commonsense layout of experimental displays (making them symmetrical with respect to the center of the screen, for example) overcomes spatial nonuniformity without extensive measurement. Important to mention in this respect is the difficulty of creating good stereoscopic viewing conditions on a single monitor. First, there is only a single area of the screen that is ideal for the position of the center of an image. Second, unless one image is horizontally inverted, two images from opposite sides of the screen combined into a single image present drastically different luminance gradients to the two eyes.

Setup and Viewing Environments for Color CRTs

Many adjustments of the CRT electronics change its performance substantially. Some, such as the purity and convergence, have specific "correct" settings and are not designed to be user-adjustable. Most CRTs with in-line guns, for example, have the ring magnets that adjust the convergence glued into place at the factory. Other controls, such as contrast and brightness, are user-adjustable and should be changed when viewing conditions change if an optimal image is to be produced. These controls are provided in the expectation that the CRT will be displaying an image that is broadcast to a large number of CRTs that are viewed in very different visual environments. There is, therefore, a correct way to adjust these controls; the next few paragraphs describe the basic adjustments to be done. The procedure is based on a technical manual produced by the Canadian Broadcasting Corporation.[11] This manual also provides recommended viewing conditions for critical assessment of displayed images. The procedures and viewing conditions are expected to form the basis of an SMPTE standard for CRT image display.

When CRTs are used for visual experimentation, of course, they are often displaying specifically controlled images in unusual viewing conditions, often total darkness. For such applications the

adjustment procedure described below is unlikely to be interesting, and extreme values of the controls are likely to be desired. For example, an experiment conducted in total darkness is likely to need the black level (brightness) set so that there is no background light emitted from the screen. Or an experiment to measure thresholds is likely to benefit from whatever value of the contrast control minimizes the gain of the CRT at the intensity levels where the measurement is performed. (The objective is to minimize intensity quantization of the stimulus.) In fact, modern CRTs with computer-controllable contrast and black level might be used with different control settings for different trials of a single experiment.

CRT Setup for Image Display When a CRT is set up for image display, four adjustments are usually made: focus, brightness, contrast, and color balance and tracking. These adjustments form a rough order, with changes to one often requiring changes to succeeding ones. The following procedures are simplified from Benedikt.[11]

Focus Focus should be adjusted by the shrinking raster method. A uniform gray field is displayed on the CRT, and the focus adjustment used to shrink the beam size until raster lines are clearly visible. The beam size is then increased until the raster lines just barely disappear. The smallest beam size for which no horizontal raster lines are visible indicates the correct setting for the focus control.

Brightness The brightness or black-level control is set so that zero input to the CRT produces a visual impression of black. This setting *must* be performed in lighting conditions that are exactly those in which the images will be viewed, and with the observer at exactly the viewing distance at which the images will be viewed. With no signal input to the CRT, and the image set to underscan if possible, the brightness control is increased until the image area is noticeably gray. It is then reduced to the highest setting at which the image area looks black.

Contrast An input that has all three guns fully on is used for this adjustment. With such a color displayed, the contrast control is adjusted until the luminance of the screen is the maximum luminance desired. This setting should be performed using either a luminance meter or a color comparator, a CRT adjustment device that allows an observer to view the CRT as half of a bipartite field, the other half containing a reference white at the correct luminance. In any case, it is essential that the CRT should not bloom at the contrast setting in use. Blooming occurs when a too-intense electron beam spreads after it has passed through the shadowmask, stimulating more than one phosphor. It reduces the purity of the image, with the visual consequence that bright saturated colors are washed out. Narrow lines of red, green, and blue at full intensity can be used to check for blooming.

Color balance and tracking A white with red, green, and blue inputs equal at maximum intensity and a gray with red, green, and blue inputs equal at half intensity are used to set the color balance. In addition, colorimetric capability is needed. Visual colorimetry using a luminous white reference is usual in the broadcast industry, but this measurement can also be made instrumentally. For visual colorimetry the white reference is usually supplied by a color comparator. Adjust the red, green, and blue gain controls until the displayed white matches the reference in chromaticity. Then adjust the red, green, and blue screen controls until the displayed gray matches the reference in chromaticity. It may now be necessary to readjust the brightness and contrast. Do so, then repeat the color balance and tracking adjustment until all the three adjustments are simultaneously satisfactory.

Viewing Environments In applications where image quality is critical, it is necessary to control the viewing environment very closely. The following viewing conditions are typical of those used in the broadcast television industry.

1. The luminance of reference white is about 70 cd/m^2.
2. The observer views the screen from a direction normal to the screen, with the screen-observer distance between 4 and 6 times the screen height.

3. The CRT should be surrounded by a neutral matte area at least 8 times the screen area. The surround should have the chromaticity of the CRT reference white, and a luminance of about 10 cd/m^2.
4. A narrow matte-black mask should frame the CRT image.
5. All room lighting should be as close as possible to the chromaticity of the CRT reference white.

22.4 COLORIMETRIC CALIBRATION OF VIDEO MONITORS

When users of color CRTs talk precisely about colorimetric calibration, a careful distinction between calibration and characterization is usually made. Measuring the input voltage/output color relationship well enough that it is possible to predict the output color from the input voltage, or to discover the input voltage needed to produce a given output color is a CRT characterization. The function mapping voltage to color characterizes the colorimetric performance of the CRT. Adjusting the CRT so that its characterization function matches the characterization function of a standard CRT is a CRT calibration. Talking loosely, however, calibration usually covers both characterization and calibration, and most CRT users are actually more interested in characterizations than in calibrations. Thus, this chapter describes several methods for creating colorimetric characterizations of CRTs. Some such characterization is an essential part of any calibration, but omits the detailed internal adjustment of a CRT, which requires significant electronic expertise if it is to be done safely.

There is no single characterization method that suits all needs. Thus, this chapter provides a variety of methods, each of which does some jobs well and others badly. They can be divided into three basic types.

1. *Exhaustive characterization methods (ECM)* Useful when good precision is needed over the complete monitor gamut. The same or similar algorithms can be used for the characterization of other output devices, such as printers. These methods tend to be both computationally and radiometrically expensive.
2. *Local characterization methods (LCM)* Useful when a precise characterization is needed for only a small portion of the monitor's output range.
3. *Model-dependent characterization methods (MDCM)* Useful when a characterization of moderate precision is needed for the complete monitor gamut. These methods tend to be specific to a given monitor and useful for only a small set of monitor setup methods, but they are computationally and radiometrically inexpensive. In addition they can be done so that the perceptual effects of mischaracterizations remain small, even when the colorimetric effects are large.

Here is a small set of criteria for deciding which type of method is best for a specific application:

1. High precision (better than 1 to 3 percent is impractical by any method discussed in this chapter)—ECM or LCM
2. Complete gamut characterization needed—ECM or MDCM
3. Minimal memory available for characterization tables—LCM or MDCM
4. No or slow floating point available—ECM or LCM
5. Fast inverse needed (we call the transformation from *RGB* to *XYZ* the characterization, the transformation from *XYZ* to *RGB* the inverse)—ECM, LCM, or MDCM
6. Forgiving behavior with out-of-gamut colors—LCM or MDCM
7. Photometry available but not radiometry—MDCM
8. Change of small number of parameters when monitor or monitor setup changes—LCM or MDCM

This list is not comprehensive; each type of characterization is actually a family of methods and there may be an effective method of a particular type even when general considerations seem to rule out that type. Undoubtedly more methods will be discovered as time goes on, leading to a broadening of these rules, and perhaps even a useful splitting of the characterization types into subtypes.

Important considerations when deciding on the characterization method to be used are measurement precision and monitor stability. There is no point in using a characterization method more precise than measurement precision, or more precise than the stability of the CRT over the range of conditions in which the characterization is to be used.

The characterization methods described below make use of a variety of measurements, but measurement methodology is not discussed. For reference, the methods used are (1) spectroradiometry, measurement of spectral power distributions; (2) colorimetry, measurement of tristimulus values; and (3) photometry, measurement of luminance.

The phrase "monitor coordinates" is used throughout this section. It denotes a set of controllable CRT inputs to which the experimenter has immediate access. For example, in applications where the CRT is computer controlled, it indicates the *RGB* values in the color lookup tables of the frame buffer that supplies the video signal to the CRT. The characterization techniques discussed below are independent of the monitor coordinates used. The single exception is the set of model-dependent characterization methods.

Exhaustive Characterization Methods

These are the most costly characterization methods in terms of time and computer storage. They are also the most precise and the most general. Their utility depends only on the stability of the monitor. (If the monitor doesn't have enough stability for exhaustive methods to be usable it is unlikely to have enough stability to use any other method.)

General Description The idea behind exhaustive characterization is to measure all the colors a monitor can produce and store them in a large table. When a color of given monitor coordinates (*RGB*) is displayed, its tristimulus values are determined by looking them up in the table. When a color of given tristimulus coordinates is desired, the table is searched and that set of monitor coordinates closest to the desired value is chosen for display. (Dithering among nearby colors is also possible if more precision is desired.) This method is also useful for any kind of device, not just for monitors. Thus, software designed for monitors can be reused when, for example, printers must be characterized. The obvious drawback to this method is the number of measurements that must be made. For example, with 24-bit color (8 bits per gun), over 16 million colors can be produced. If each measurement takes 1 s, the measurement process consumes over 4500 h, or almost 200 days, measuring around the clock. The solution to this problem is to sample the set of realizable colors, measure the samples, then interpolate between them. Thus, what we call exhaustive methods are only relatively exhaustive. Handling the practical problems is discussed in the following sections.

Sampling Densities and Interpolation Algorithms How many measurements should be made, and which colors should be selected for measurement? The answer depends on the nature of the sampling algorithm to be used, and is an open research question for general sampling. Thus, while it is possible to discuss the issues, practical decisions depend on the experience of the user.

Sampling procedures Most sampling algorithms sample the monitor coordinates linearly in the monitor coordinates. For example, if $512 = 2^9$ samples are to be taken for a color CRT, $8 = 2^3$ values on each of the red, green, and blue guns would be used, linearly interpolating the range of output voltages. The 512 samples would be the cartesian product of each set of gun values. Thus, if there were 256 possible values for each gun, running from 0 to 255, the 8 values chosen would be 0, 36, 72, 109, 145, 182, 218, and 255. If, as is often the case, saturation exists at the low and/or high ends of the input range, the full range is not used, and these values are scaled to the usable range. Behind this choice is the idea that a well-designed output device should have device coordinates that are close

to perceptually uniform. If so, linear sampling in device coordinates roughly approximates even sampling in a perceptually uniform space. The density of the sampling is related to the interpolation algorithm, which must approximate the exact value to within the desired precision of the characterization. This necessarily entails a trade-off between measurement time and online computational complexity when the characterization is being used: the more dense the sampling, the simpler the interpolation algorithm, and vice versa.

Interpolation Most often, linear interpolation is used. In this case, since we are interpolating in a cubic volume the interpolation is trilinear. Thus, given R_j (RGB), what are the tristimulus values?

1. We assume the existence of a table $X_i(R_j(n_j))$, consisting of the three tristimulus values X_i measured when the three guns are driven by the three voltages $R_j(n_j)$. Each three-vector n_j labels a different sample.
2. Find the sample m_j that has $R_j(m_j)$ less than and closest to the values to be estimated R_j.
3. Take the eight samples (m_0, m_1, m_2), $(m_0 + 1, m_1, m_2)$, $(m_0, m_1 + 1, m_2)$, . . . , and $(m_0 + 1, m_1 + 1, m_2 + 1)$ as the vertices of a polyhedron.
4. Interpolate in R_0 on the four sides running from (m_0, m_1, m_2) to $(m_0 + 1, m_1, m_2)$, from $(m_0, m_1 + 1, m_2)$ to $(m_0 + 1, m_1 + 1, m_2)$, from $(m_0, m_1, m_2 + 1)$ to $(m_0 + 1, m_1, m_2 + 1)$, and from $(m_0, m_1 + 1, m_2 + 1)$ to $(m_0 + 1, m_1 + 1, m_2 + 1)$. The interpolation algorithm for $X_i(*, l_1, l_2)$ is given by

$$X_i(*, l_1, l_2) = \frac{R_0 - R_0(m_0)}{R_0(m_0 + 1) - R_0(m_0)} X_i(R_0(m_0 + 1), R_1(l_1), R_2(l_2)) + \frac{R_0(m_0 + 1) - R_0}{R_0(m_0 + 1) - R_0(m_0)} X_i(R_0(m_0), R_1(l_1), R_2(l_2))$$

   where l_j is either m_j or $m_j + 1$.
5. Treat the four values as the corners of a polygon. Interpolate in R_1 along the two sides running from (m_1, m_2) to $(m_1 + 1, m_2)$ and from $(m_1, m_2 + 1)$ to $(m_1 + 1, m_2 + 1)$. The interpolation algorithm for $X_i(*, *, l_2)$ is given by

$$X_i(*, *, l_2) = \frac{R_1 - R_1(m_1)}{R_1(m_1 + 1) - R_1(m_1)} X_i(*, R_1(m_1 + 1), R_2(l_2)) + \frac{R_1(m_1 + 1) - R_1}{R_1(m_1 + 1) - R_1(m_1)} X_i(*, R_1(m_1), R_2(l_2))$$

6. Treat these two values as the endpoints of a line segment, and interpolate in R_2. The final value is given by

$$X_i = \frac{R_2 - R_2(m_2)}{R_2(m_2 + 1) - R_2(m_2)} X_i(*, *, R_2(m_2 + 1)) + \frac{R_2(m_2 + 1) - R_2}{R_2(m_2 + 1) - R_2(m_2)} X_i(*, *, R_2(m_2 + 1))$$

The above equations implement trilinear interpolation within a (possibly distorted) cube. It has recently been observed that tetrahedral interpolation has some desirable properties that are lacking in trilinear interpolation. It is accomplished by subdividing the cube into five or six tetrahedra, the corners of which coincide with the corners of the cube. Barycentric coordinates are then used to determine the tetrahedron in which the displayed color lies, and to interpolate within that

tetrahedron. More complex interpolation methods are also possible for nonuniform measurement sampling.[12]

Such interpolation methods implement the characterization directly in terms of the measured values. To test the adequacy of the interpolation it is important to choose regions of color space where curvature of the input/output response is expected to be high and to test the interpolation against exact measurements in that region of color space. If the interpolated values do not match the measured values there are two possible solutions: increase the measurement sampling density or improve the interpolation function. The first is expensive in terms of measurement time and computer memory; the second in terms of online calculation time. (There is a middle way, where a complicated algorithm is used to interpolate among coarsely sampled measurements for the purpose of generating a table large enough that linear interpolation can be done online. This has been used for hardcopy devices but not for monitors.) If the interpolation function is to be generalized it is possible to use higher-order interpolating functions, like splines, or to linearize the measurement space by transforming it before interpolating. For example, it is possible to build a characterization function that provides the logarithms of tristimulus values in terms of the logarithms of input coordinates. Any reasonable powerful generalization is bound to be computationally expensive. Much remains to be done to improve the sampling and interpolation process.

Inverses Calculating inverses for multidimensional tabular functions is not straightforward. Speed of computation can be optimized by creating an inverse table, giving values of R_j for regularly sampled values of X_i. The easiest way to construct this table is not by measurement, but by calculation (off-line) from the characterization table. Once the table is available, linear interpolation can be done online to provide voltages corresponding to given tristimulus values. Two possible methods exist for calculating inverses from tables.

1. Newton's method of finding zeros using derivatives to calculate an error function is possible, but can have bad numerical instabilities on tabular data that contains measurement error.
2. Examine the table that drives the forward transform to find the cell that contains the desired tristimulus values. Then subdivide the cell, using trilinear interpolation to determine new values for the corners. Determine which subcell contains the desired tristimulus values, and continue subdividing until the solution is sufficiently precise. This method is robust, but too expensive computationally to use online.

A promising alternative, not yet in wide use, takes advantage of barycentric coordinates in a tetrahedral lattice to find the appropriate cell quickly.

Nonlinear interpolation schemes can be used in the forward transformation when producing tables for linear inverse mappings. Presumably tables for nonlinear interpolation schemes in the inverse mapping can also be produced.

Three issues about inverses stand out.

1. Nonlinear schemes have not been sufficiently explored for their potential to be clear.
2. The straightforward application of well-understood computational methodology can provide substantial improvements over present methods.
3. Whatever inversion method is employed, out-of-gamut colors remain a serious unsolved problem.

Out-of-Gamut Colors What should be done when a program is asked to display a set of tristimulus values that are outside the color gamut of the monitor on which the color is to be displayed? The answer, of course, depends on the nature of the application. If the application demands drastic action when a request for an out-of-gamut color occurs, the solution is easy. The interpolation algorithm returns an illegal value of R_j. Then the application can display an error color in that area, or exit with an error. If, instead, the application must display a reasonable color within the monitor gamut, there is no natural solution. Solutions like projecting onto the surface of the monitor gamut have been used with success for some applications. Unfortunately, however, they are frequently computationally expensive and visually unsatisfactory.

Local Characterization Methods

In many applications only a small region of the color gamut of the monitor must be characterized, but that region must be characterized very precisely. A typical example is a threshold experiment in which there are a small number of reference stimuli. Only colors close to the reference stimuli need be characterized precisely since they are the only colors likely to arise in the experiment. Methods that are specialized for the characterization of small parts of the color gamut, such as the threshold stimulus set, are the subject of this section. They are the methods most often appropriate for vision experimentation.

General Description Local characterization methods try to take advantage of simplifications that arise because the set of colors to be characterized is small. For example, a small set of colors all very close to a reference color can be characterized by a linear approximation to the global characterization function. Such simplifications offer many desirable properties such as high precision with minimal measurement (individual colors), linear characterizations and inverses (local regions of color), and simple inverses over extended color ranges (one-dimensional color spaces). To realize this precision, colorimetric measurements of the required precision must be available and easily usable. Detailed descriptions of three limited-gamut characterization schemes follow. Others are certainly possible, and may be worked out by analogy.

Individual colors It is often the case that a small number of distinct colors is needed. Under such circumstances the best method available is to perform a colorimetric measurement on each color. This is easy if the colors are arbitrary but need to be known precisely. Then they can be chosen by their *RGB* coordinates, with colorimetric measurements used to establish their tristimulus values. It is less easy if a small number of colors of specified tristimulus values are needed. The best way to deal with the latter problem is to use online colorimetric measurement, adjusting *RGB* values until the required tristimulus values are produced. This should be repeated several times throughout the time during which the characterization is needed to establish the stability of the monitor while the characterization is in use.

This type of characterization leads most directly into the most difficult question that CRT characterization must face: how should a characterization handle spatial and angular variations of light emitted by the CRT? Suppose, for example, an experiment uses only two color stimuli, a red one and a green one. Suppose further that the red one always appears at one point on the screen, while the green one always appears at a different point. Clearly, a characterization method that performs a colorimetric measurement on each stimulus yields maximum precision for minimum effort. Now, should the green color be measured in its particular location and the red one be measured in its location, or should both be measured in a common location, probably the screen center? And how should possible variations in the color of a stimulus when the other is turned off and on be handled? There is no universal best way of resolving such questions. Each must be resolved in a way that suits the particular display application. Note that this problem does not arise only for individual color characterizations. Indeed, it arises with any characterization whatsoever. The fact that every other aspect of individual color characterizations is so simple makes it particularly noticeable in this case.

Local regions of color Somewhat more complicated than individual color characterizations are ones in which it is necessary to characterize a small part of the color gamut surrounding a particular color. This might arise, for example, in a matching experiment, where all matches are close to a fixed reference stimulus. In such cases a small region of the color gamut must be characterized very precisely, with an emphasis on exact presentation of differences of color between the reference color and other colors in the region. The procedure is to make a precise colorimetric measurement of the reference color. Call the result $\mathbf{X}_0$ with components X_{0i}, which is the result of measuring a color having input voltages R_{0i}. Then, for small changes in input voltage ΔR_i, measure the corresponding changes in tristimulus values ΔX_i. When the results are plotted they show a region in which the changes in tristimulus value are linearly related to changes in input coordinate with nonlinear effects growing in importance near the edge of the region. The size of the nonlinear effects, when compared

to the required prevision of the characterization, determines the size of the region that can be characterized linearly. Within this region the tristimulus values are given by

$$X_i = X_{0i} + \sum_{j=1}^{3} M_{ij} \Delta R_j$$

The matrix M_{ij} is determined by a multilinear regression of the data, with each component of the tristimulus values regressed simultaneously against all three input coordinates. Nonlinear effects and interaction terms are not included in the regression. The matrix entry M_{ij}, which arises as a regression coefficient, is the change of X_i for a unit change in R_j. Thus, for example, M_{23} describes how much the Y tristimulus value varies with changes in the B gun of the monitor. This type of characterization is probably the most common in color research. It is most important to remember to determine the limits of such a linear characterization, or at least to determine that the limits are outside the region in which the characterization is to be used.

One-dimensional color spaces Often it is necessary to characterize a one-dimensional set of colors, that is, a line, not necessarily straight, in color space. Here is a method for doing so easily. Make a set of colorimetric measurements spaced more or less evenly along the curve. Use the variable μ for the measurement number, numbering from one end of the line to the other. Plot the measured tristimulus values and the input voltages as functions of μ. The measurement points should be dense enough that intermediate values can be approximated by linear interpolation. Now any set of *RGB* values must correspond to a value of μ, not necessarily integral. How is this value determined?

1. Each measured μ has a corresponding set of *RGB* values.
2. Find two consecutive sets such that the desired *RGB* values are intermediate between the *RGB* values of the sets. Call the μ value of the sets μ_0 and $\mu_0 + 1$. Thus, mathematically,

$$R_i(\mu_0) \le R_i \le R_i(\mu_0 + 1) \quad \forall i$$

3. Now calculate "how far" between μ_0 and $\mu_0 + 1$ the desired *RGB* lies. The value for gun j is δ_j where

$$\delta_j = \frac{R_j - R_j(\mu_0)}{R_j(\mu_0 + 1) - R_j(\mu_0)}$$

4. If the three δ values are close together this method works. Otherwise, the line of colors must be measured more densely.
5. Use $\delta = (\delta_1 + \delta_2 + \delta_3)/3$ as the distance between μ_0 and the desired *RGB* value. This distance can then be used to interpolate in the tristimulus values.
6. The interpolated result is the characterized result.

$$X_i = X_i(\mu_0) + \delta(X_i(\mu_0 + 1) - X_i(\mu_0))$$

This method requires no special precautions if the line is relatively straight in *RGB* space. It is important to use the interpolation to calculate the tristimulus values of some measured colors to establish the precision of the measurement, or to decide if denser sampling is necessary.

Inverses The major reason for using this family of characterization methods is the computational simplicity of the characterizations and their inverses. Neither extensive memory nor expensive computation is needed to realize them.

Individual colors Since there is a small number of discrete colors, they can be arranged in a table. To get the characterization, you look up *RGB* in the table and read off the tristimulus values. To get the inverse, look up the tristimulus values in the output side of the table and the corresponding input gives *RGB* for the desired output. If the tristimulus values to be inverted are not in the table, then the color is not in the characterized set and it cannot be realized.

Local regions of color To derive the inverse for local regions of color, write the characterization equation as

$$X_i = X_{0i} = \Delta X_i = \sum_{j=1}^{3} \mathrm{M}_{ij} \Delta R_j$$

Then, inverting the matrix $\mathbf{M}_{ij}$ to get M_{ji}^{-1},

$$\Delta R_j = \sum_{i=1}^{3} \mathrm{M}_{ji}^{-1} \Delta X_i$$

which can be written explicitly as a solution for the RGB values needed to generate a color of given tristimulus values. That is,

$$R_j = R_{0j} + \sum_{i=1}^{3} \mathrm{M}_{ji}^{-1} (X_i - X_{0i})$$

It is important, after doing the above calculation, to check that the *RGB* values so determined lie within the region for which the characterization offers satisfactory precision. If not, however, unlike other methods, the inverse so determined is usually a reasonable approximation to the desired color.

Instead of inverting the matrix off-line, the three linear equations in R_j can be solved online.

One-dimensional color spaces For one-dimensional color sets the interpolation equations provide the inverse provided that *RGB* values and tristimulus values are reversed. To avoid confusion ϵ is used in place of δ.

1. To calculate ϵ find a consecutive pair of tristimulus values that contain the desired values. Call the first of the pair μ_0.
2. Then calculate ϵ_i using

$$\epsilon_i = \frac{X_i - X_i(\mu_0)}{X_i(\mu_0 + 1) - X_i(\mu_0)}$$

   If the three ϵ_i values are not close together, then the tristimulus values designate a color that is not in the set, or the wrong interval has been found in a line of colors that must be very convoluted, and the set must be measured more densely.
3. Use $\epsilon = (\epsilon_1 + \epsilon_2 + \epsilon_3)/3$ as the distance between μ_0 and the desired tristimulus values.
4. Then the *RGB* values corresponding to the desired tristimulus values are

$$R_j = R_j(\mu_0) + \epsilon(R_j(\mu_0 + 1) - R_j(\mu_0))$$

The results of this calculation should be checked to ensure that the *RGB* values do indeed lie in the color set. This is the second check that is performed, the first being a check for a small spread in the three ϵ_i values. The checks are needed if the set is convoluted, and are always passed if the set is simple.

One way of checking whether the measurement density is adequate is to cycle an *RGB* value through the characterization and its inverse. If it fails to meet the required precision, then the measurement density is probably insufficient.

Out-of-Gamut Colors Local gamut characterization methods are attractive because of their easy-to-use inverses. Their treatment of out-of-gamut colors is also appealing.

Individual colors Colors not in the set of individual colors do not have inverses, and are not found in a search of tristimulus values. Because this characterization method ignores colors near to or between the measured colors, no method is possible for representing colors that are not in the

measured set. However, if the search is done with finite precision, colors close to a measured color are aliased onto it in the search. The precision of the search determines the region of colors that is aliased onto any measured color.

Local regions of color When a color is outside the local region to which the characterization applies, this method returns the input coordinates that would apply to a linear characterization. The values are close to those produced by an exact characterization, but outside the bounds of the specified precision. The error increases as the color gets farther away from the characterized region, but slowly in most cases. Thus, this method clearly indicates when a color is outside the characterized region and fails gracefully outside the region, giving values that are close, if not exact.

One-dimensional color spaces When a set of *RGB* values or tristimulus values lies outside the one-dimensional space, the fact is indicated during the calculation. The calculation can be carried through anyway; the result is a color in the space that is close to the given color. Exactly how close, and how the characterization defines the "closest" color in the one-dimensional space, depends on the details of how the measurement samples are selected, the curvature of the color set, and the appropriate experimental definition of "close." If this method comes to have wider utility, investigation of sampling methods might be warranted to find the "best" sampling algorithms. In the meantime, it is possible to say that for reasonably straight sets colors close to the set are mapped onto colors in the set that are colorimetrically near the original color.

Model-Dependent Characterization Methods

The two types of characterization methods described above are independent of any particular monitor properties. In fact, they can be used for any color-generating device. The third type of characterization makes use of a parametrized model of CRT color production. A characterization is created by measuring the parameters that are appropriate to the CRT being characterized. The next few sections describe the most common model for color CRTs, which is tried and true. Some CRTs may require it to be modified, but any modifications are likely to be small. The emphasis in this description is the set of assumptions on which the model is based, since violations of the assumptions require modifications to the model.

General Description The standard model of a color CRT has the following parts.

1. Any displayed color is the additive mixture of three component colors. The component colors are generally taken to be the light emitted by a single phosphor.
2. The spectral power distribution of the light in each component is determined by a single input signal, *R*, *G*, or *B*, and is independent of the other two signals.
3. The relative spectral power distribution of the light in each component is constant. Hence, the chromaticity of the component color is constant.
4. The intensity of the light in each component is a power function of the appropriate input voltage.

Taken together, these parts form a mathematical model of CRT colorimetry.

The standard model has been described many times. For a concise presentation see Cowan;[13] for a historical one see Tannenbaum.[14]

Gun independence The light emitted when the input coordinates are the three voltages v_R, v_G, and v_B (generically called v_g) is $\Phi_\lambda (v_R, v_G, v_B)$. It turns out to be convenient to form slightly different components than the standard model does, following not the physical description of how a monitor operates, but the logical description of what is done to realize a color on the monitor. The first step when generating a color is to create the *RGB* input from the separate *R*, *G*, and *B* inputs. Imagine turning on each input by itself, and assume that the color when all guns are turned on together is the

additive mixture of the colors produced when the guns are turned on individually. This assumption is called "gun independence." In terms of tristimulus values it implies the condition

$$X_i = X_{Ri} + X_{Gi} + X_{Bi}$$

(Usually CRTs realize gun independence by exciting different phosphors independently,

$$\Phi_\lambda(v_R, v_G, v_B) = \Phi_\lambda(v_R, 0, 0) + \Phi_\lambda(0, v_G, 0) + \Phi_\lambda(0, 0, v_B)$$

This condition is, in fact, stronger than the gun-independence assumption, and only gun independence is needed for characterization.)

Gun independence was described by Cowan and Rowell,[15] along with a "shotgun" method for testing it. The tristimulus values of many colors were measured, then predictions based on the assumption of gun independence were tested. Specifically, gun independence implies consistency relationships that must hold within the set of measurements. Cowan and Rowell showed that a particular CRT had a certain level of gun independence, but didn't attempt to make measurements of many CRTs. Clearly, it is worth making measurements on a variety of monitors to determine how widely gun independence occurs, and how large violations of it are when they do occur. For CRTs without gun independence there are two ways to take corrective action:

1. Use a characterization method that is not model-dependent.
2. Modify the monitor to create gun independence. For most CRTs there are good, inexpensive methods for improving gun independence. They will be more widely available in the future as characterization problems caused by failures of gun independence become more widely known.

Extreme settings of the monitor controls can cause violations of gun independence in otherwise sound monitors. The worst culprit is usually turning the brightness and/or contrast up so high that blooming appears at high input levels.

Phosphor constancy When gun independence holds, it is necessary to characterize only the colors that arise when a single gun is turned on, since the rest can be derived from them. Usually, it is assumed that the colors produced when a single gun is turned on have constant chromaticity. Thus, for example, the tristimulus values of colors produced by turning on the red gun alone take the form

$$X_{Ri}(v_R) = E_R(v_R) \cdot x_{Ri}$$

where x_{Ri}, the chromaticity coordinates of the emitted light, x_R, y_R, and z_R, are independent of the voltage input. Thus the tristimulus values of the color produced depend on input voltage only through the intensity $E_R(v_R)$.

The engineering that usually lies behind phosphor constancy is the following. A CRT should be designed so that the beam current in a given electron gun is independent of the beam current in any other gun. The deflection and shadowmask geometries should be designed and adjusted so that the electrons from any gun fall only on a single phosphor type. The physical properties of the phosphor should guarantee that the phosphor emits light of which the chromaticity is independent of the intensity. Meeting these conditions ensures phosphor constancy. It is possible, but unusual, to have phosphor constancy under other conditions, if it happens that effects cancel out appropriately.

The measurement of phosphor constancy is described by Cowan and Rowell.[15] Here is a short description of how to make the required measurements for one of the guns.

1. Turn the gun on at a variety of input voltages, and make a colorimetric measurement at each input voltage.
2. Calculate chromaticity coordinates for each measurement, which are independent of input voltage if phosphor constancy is present.

3. Constancy of chromaticity should also obtain in the presence of varying input to the other guns. To consider this case, turn the two other guns on, leaving the gun to be measured off.
4. Measure the tristimulus values for a baseline value.
5. Then turn the gun to be measured on to a variety of input voltages, making a colorimetric measurement at each.
6. Subtract the baseline tristimulus values from each measurement, then calculate the chromaticity coordinates. These should be constant, independent of the input to the measured gun, and independent of the input to the other two guns as well.

One of the most common monitor characterization problems is a measured lack of phosphor constancy. This is a serious problem, since the functions derived from the CRT model cannot then be easily inverted. Sometimes the measured lack of phosphor constancy is real, in which case there is no solution but to use a different type of characterization procedure. More often, the measurement is caused by poor CRT setup or viewing conditions. This occurs as follows, first for viewing conditions. Ambient light reflected from the screen of the monitor is added to the emitted light. This light is independent of input voltage, and adds equally to all colors. Imagine a phosphor of constant chromaticity (x, y), at a variety of input voltages. The tristimulus values of light emitted from the screen are

$$X_i = X_{0i} + E(\upsilon) \cdot x_i$$

where X_{0_i} are the tristimulus values of the ambient light reflected from the screen. Note that subtracting the tristimulus values measured when the input voltage is zero from each of the other measurements gives phosphor constancy. (Failure to do the subtraction gives phosphor chromaticities that tend toward white as the input voltage decreases.) This practice should be followed when ambient light is present. Psychophysical experiments usually go out of their way to exclude ambient light, so the above considerations are usually not a problem. But under more normal viewing conditions ambient light is always present.

When the black level/brightness control is set above its minimum there is a background level of light emitted from the screen even when the input voltage is zero. This light should be constant. Thus, it can be handled in exactly the same way as ambient light, and the two can be lumped together in a single normalizing measurement.

Now let's put together this gun independence and phosphor constancy. Gun independence means that the tristimulus values $X_i(\upsilon_R, \upsilon_G, \upsilon_B)$ can be treated as the sum of three tristimulus values that depend on only a single gun:

$$X_i(\upsilon_R, \upsilon_G, \upsilon_B) = \sum_{a=R,G,B} X_{ai}(\upsilon_a)$$

Phosphor constancy means that the tristimulus values from a single gun, once the background has been subtracted away, have constant chromaticity:

$$X_i(\upsilon_R, \upsilon_G, \upsilon_G) = (X_0, Y_0, Z_0) + \sum_{a=R,G,B} E_a(\upsilon_a) \cdot x_{ai}$$

To complete the characterization a model is needed for the phosphor output intensity $E_a(\upsilon_a)$.

Phosphor output models Several different methods exist for modeling the phosphor output. The most general, and probably the best, is to build a table for each gun. To do so requires only photometric measurement, and the responsivity of the photometer need not be known. (This property of the model is very convenient. Colorimetric measurements are fairly easy to perform at light levels in the top 70 percent of the light levels produced by a CRT, but hard to perform for dark colors. In this model the top of the output range can be used when doing the colorimetric measurements required to obtain phosphor chromaticities. Then, photometric measurements can be performed easily using photodiodes to calibrate the output response at the low end of the CRT output.) Choose the largest

input voltage to be used, and call it $v_{a\max}$. Measure its light output with the photometer. Then measure the light output from a range of smaller values v_a. The ratio of the light at lower input to the light at maximum input is the relative excitation $e_a(v_a)$. Store the values in a table. When excitations for intermediate voltage values are needed, find them by linear interpolation.

$$e_a(v_a) = \mu e_a(v_{a1}) + (1 - \mu)e_a(v_{a2})$$

where the interpolation parameter μ is

$$\mu = \frac{v_a - v_{a2}}{v_{a1} - v_{a2}}$$

The memory requirements of the table can be reduced by using more complicated functions, but at the price of complexity of computation in the model.

It is also possible to approximate the measurements using a parameterized function. The most commonly used form is the gamma correction equation

$$e_a(v_a) = e_{a\max}(v_a / v_{a\max})^{\gamma_a}$$

with two parameters γ_a and $e_{a\max}$. Here, $v_{a\max}$ is the maximum input voltage, $e_{a\max}$ is the maximum relative excitation, usually taken to be 1.0, and γ_a is called the gamma correction exponent. It is determined empirically by regressing the logarithm of the measured excitation against the logarithm of the input voltage.

Normalization The excitation that enters the characterization equation $E_a(v_a)$ is the product of the voltage-dependent relative excitation $e_a(v_a)$ and a normalization coefficient N_a:

$$E_a(v_a) = N_a \cdot e_a(v_a)$$

The normalization coefficients complete the characterization model.

Summary equation The characterization is summarized by the single equation

$$X_i = X_{0i} + \sum_{a=R,G,B} N_a \cdot e_a(v_a) \cdot x_{ai}$$

which provides the tristimulus values for any set of *RGB* input coordinates.

Conditions for Use The assumptions discussed above are the conditions under which the model developed here can be used successfully. The assumptions should be checked carefully before this characterization method is used. The departure of the CRT from the ideal CRT, defined by perfect adherence to these conditions, is a measure of the imprecision in the characterization procedure. Note that when the CRT fails to meet the conditions, which occurs most frequently near the edges of its gamut, the erroneous colors are usually plausible. Thus, the model can be in error by a surprisingly large amount and still produce satisfactory characterizations in noncritical applications.

Partial models It is fairly clear that there are partial models meeting some of the conditions, and that they provide useful approaches to characterization. For example, suppose that the phosphor chromaticities vary with input voltage. They can be stored in a table indexed by input voltage (exact values are produced by interpolation) and used in a variant of the characterization equation:

$$X_i = X_{0i} + \sum_{a=R,G,B} N_a \cdot e_a(v_a) \cdot x_{ai}(v_a)$$

Such a generalization works well for the transformation from input voltages to tristimulus values, but the inverse transformation is virtually unusable.

Measurement of Parameters The characterization equation requires the measurement of a set of parameters that varies from CRT to CRT. Thus, they must be measured for the CRT to be characterized. Different types of measurements—spectral, colorimetric, and photometric—are needed, as described below.

Ambient light and black level X_{0i} A colorimetric measurement of the screen with all input voltages set to zero produces this value. It should be measured under the exact conditions in which the characterization will be used.

Phosphor chromaticities x_{ai} A colorimetric measurement of the screen with a single gun turned on produces these values. Careful subtraction of the ambient light and black level is important. Measuring at a variety of input voltages produces:

1. A measure of phosphor constancy
2. The range of input voltages over which phosphor constancy holds well enough for use of the characterization model
3. A value for the phosphor chromaticities, produced by averaging over the chromaticities in the characterization range

Gamma correction functions Measurement of the relationship between the input voltages and the excitation functions requires photometric measurement at a large variety of input voltages. If interpolation into a table is the method of choice, the sampling of input voltages must be dense enough that the interpolation method chosen, usually linear, is close enough to the exact values to yield the desired accuracy. If a functional relationship, like the power function, is chosen the validity of the function chosen must be inspected very carefully. Whatever method is chosen it is essential that the ambient light/black level be subtracted from the measurements. If it is not, it is counted three times when the contributions from the three guns are added together.

Normalization coefficients The normalization coefficients are determined through the characterization equation

$$X_i = \sum_{a=R,G,B} N_a \cdot e_a(v_a) \cdot x_{ai}$$

They may be determined in several ways, falling into two categories: measurement methods and comparison methods. A typical measurement method assumes a single color of known tristimulus values. This knowledge can be produced by a colorimetric measurement or by varying *RGB* to match a known sample such as the reference field of a color comparator. The tristimulus values are substituted into the equation above, giving three equations for the three normalization coefficients. Solving the equations gives the normalization coefficients. Note that the relative excitations and the phosphor chromaticities are both unitless. Thus, the normalization coefficients carry whatever units are used to measure the tristimulus values. The units enter naturally when the linear equations are solved.

The method for solving these linear equations utilizes the inverse transform. A matrix **M**, the entries of which are the phosphor chromaticities

$$\mathbf{M}_{ai} = x_{ai}$$

is defined, and its inverse, $\mathbf{M}_{ia}^{-1}$ determined. Multiplying it into the characterization equation gives

$$\sum_{i=1}^{3} \mathbf{M}_{ia}^{-1} X_i = N_a \cdot e_a(v_a)$$

Then N_a is calculated from

$$N_a = e_a(v_a) \cdot \sum_{i=1}^{3} \mathbf{M}_{ia}^{-1} X_i$$

Note that $e_a(v_a)$ is known since the input voltage that matches the standard, or of the color that has been measured, is known.

The second method is used when it is possible to match a known standard. For example, it might be possible to find voltages that make colors produced by individual guns equiluminous. Call the voltages v_{YR}, v_{YG}, and v_{YB}, and substitute them into the $Y = X_2$ characterization equation

$$N_R e_R(v_{YR}) x_{R2} = N_G e_G(v_{YG}) x_{G2} = N_B e_B(v_{YB}) x_{B2}$$

This equation is easily solved for the ratios N_G/N_R and N_B/N_R, leaving a single constant, an overall normalizing coefficient, undetermined. This constant, which carries the units in which the tristimulus values are measured, can be determined only by an absolute measurement (or, equivalently, a color match to an absolute standard). However, because vision is insensitive to variations in overall intensity, the precise value of the overall normalizing coefficient is unimportant in many applications.

Inverse Transformations One of the most attractive features of model-dependent characterizations is the simplicity of their inverses. It is simple to invert the characterization equation

$$X_i = \sum_{a=R,G,B} N_a \cdot e_a(v_a) \cdot x_{ai}$$

which determines the tristimulus values of a color in terms of the input voltages that cause it to be displayed, into the inverse equation, which specifies input voltages that create a color of given tristimulus values. Define the matrix of phosphor chromaticities

$$\mathbf{M}_{ai} = x_{ai}$$

Then determine its inverse $\mathbf{M}_{ia}^{-1}$ by conventional means. It is used to solve the characterization function

$$\sum_{i=1}^{3} \mathbf{M}_{ia}^{-1} X_i = N_a \cdot e_a(v_a)$$

Then, after the normalization coefficients are divided out

$$e_a(v_a) = \frac{1}{N_a} \sum_{i=1}^{3} \mathbf{M}_{ia}^{-1} X_i$$

It is then necessary to find the input voltages that give the appropriate excitations e_a, which requires inversion of the excitation function. Thus,

$$v_a = e_a^{-1}\left(\frac{1}{N_a} \sum_{i=1}^{3} \mathbf{M}_{ia}^{-1} X_i \right)$$

If the relative excitation function is specified in a closed form, the inverse can be calculated using only elementary algebra. Otherwise, it is necessary to develop a tabular inverse, which is most easily done by one-dimensional interpolation.

Violations of phosphor constancy When phosphor constancy does not hold, the inverse cannot be calculated using the methods given above. Numerical inversion techniques, which are beyond the scope of this section, can be used, but it is probably a better idea to use a different calibration method.

Out-of-Gamut Colors Most inversion methods fail internally if they are asked to produce the input coordinates needed to display an out-of-gamut color. For example, tabular inverses fail to find an interval or cell in which to interpolate. Because the functions in model-dependent characterizations are well defined beyond the gamut, these methods generally do not fail, but calculate values that

lie outside the domain of input coordinates. Thus, input coordinate values calculated from inverses of model-dependent characterizations should be checked, because writing out-of-range values to color lookup tables produces unpredictable results.

Absolute Characterization versus Characterization for Interaction

The characterization methods discussed above are designed to provide absolute characterizations, which are needed for color coordinates defined in terms of an external standard. Probably just as often characterization is needed to support specific interaction techniques. Suppose, for example, an experiment calls for the observer to have three CIELAB controls, one changing L^*, one changing a^*, and one changing b^*. To make this possible a characterization of the CRT in terms of CIE tristimulus values must be done to provide a basis for the transformation from tristimulus values to $L^*a^*b^*$. This type of characterization situation has several characteristics that are quite common:

1. At any given time there is a known color on the screen and the problem is to calculate a color slightly different from it. This situation arises because the control is sampled frequently enough that large color changes are produced only cumulatively over many color updates.
2. The new color coordinates must be calculated quickly and frequently.
3. Errors in the calculated color increments are errors in quantities that are already small. Thus, they can be considerably larger (in percentage terms) than would be tolerable for an absolute characterization.
4. The inverse transformation, tristimulus values to *RGB* is usually needed.

This combination of requirements is most easily met when the characterization has a linear inverse, and as little calculation as possible in the main loop. Exhaustive characterization methods have the necessary ingredients as they stand, provided an inverse table has been built, as do local methods. But nonlinear transformations, like the one from $L^*a^*b^*$ to tristimulus values violate the conditions imposed above, and it is necessary to linearize them. They can then be combined with whatever characterization is in use to linearize the entire transformation from input coordinates to color specification.

Linearization Consider a transformation f that takes a vector $\mathbf{x}$ into a vector $\mathbf{y}$. An example is the transformation between $L^*a^*b^*$ and XYZ. Suppose two vectors that are known to transform into each other are known: $\mathbf{x}_0$ $(L_0^*a_0^*b_0^*)$ corresponds to the set $\mathbf{y}_0$ $(X_0Y_0X_0)$. Now, if one vector undergoes a small change, how does the other change? If the transformation is suitably smooth (and the functions of color science are adequately smooth), small changes of one variable can be expressed in terms of small changes of the other by simple matrix multiplication

$$\Delta y_i = \sum_j \mathbf{M}_{ij} \Delta x_j$$

The entries in the matrix $\mathbf{M}$ are the partial derivatives of f with respect to $\mathbf{x}$, evaluated at $\mathbf{x}_0$. That is,

$$\mathbf{M}_{ij} = \left. \frac{\partial f_i}{\partial x_j} \right|_{\mathrm{x}=\mathrm{x}_0}$$

Even though the computation of the derivatives may be expensive, they need to be calculated only infrequently, and the calculation can be scheduled when the system has idle resources available.

Practical Comments

CRT characterization is essentially a practical matter. It is almost always done because a superordinate goal requires it. Thus, it is appropriate to end this chapter with several practical remarks that make characterization easier and less costly.

Do as little characterization as possible! Characterization is usually done within a fixed budget of time and equipment. Identifying the least characterization that provides all the information needed for the application allows the extra resources to be used to improve precision and to check measurements.

Characterize frequently! CRTs age and drift; colleagues turn knobs unaware that they change a critical characterization. Discovering that a CRT does not match its characterization function invalidates all data collected or experiments run since the characterization was last checked. There are only two defenses. First, measure the CRT as often as is feasible. Second, devise visual checks that can be run frequently and that will catch most characterization errors. It is possible to use luminance-matching techniques like minimally distinct border or minimum motion to check characterizations in a few seconds.

Understand the principles underlying the characterization methods and alter them to fit the specific stimuli needed for the application. In particular, CRTs have many ways of being unstable. The best defense is to characterize the CRT with stimuli that are as close as possible to those that are used in the application: same size, same position on the screen, measurement apparatus at the observer's eye point, same background color and intensity, and so on. Such adherence is the best defense against inadvertently finding a new type of CRT instability that invalidates months of work.

22.5 AN INTRODUCTION TO LIQUID CRYSTAL DISPLAYS

The purpose of this section is to provide an introduction to the operational principles that provide color output from liquid crystal displays (LCDs). No actual colorimetric measurements are shown, because LCDs are evolving too fast for them to be of any lasting interest. Instead, schematic illustrations are given, showing features that the author considers likely to be present in future displays.

At the time of writing, colorimetric quality of LCDs is uneven. Nonetheless, since LCDs are semiconductor components and since they are now being produced in large quantities for low-cost computers, it is reasonable to expect a rapid decrease in cost combined with an increase in quality over the next decade. As the succeeding sections should make clear, they have a variety of interesting properties which will often make them preferred to CRTs as visual stimulators. Only by actively following their development will it be possible to use them at the earliest opportunity.

Two properties make liquid crystal devices particularly interesting to the visual scientist. First, they are usable as self-luminous, transmissive, or reflective media. They combine this flexibility with the range of temporal and spatial control possible on a CRT. This property is likely to make them particularly valuable for studies of color appearance and color constancy. Second, they have the ability to produce temporal and spatial edges that are much sharper than those producible on a CRT. This property has been called "acutance" in the display literature.[16] High acutance is potentially a serious problem for image display, since the gaussian blur that occurs at edges in CRT images helps to hide artifacts of the CRT raster. But high acutance also presents an opportunity since many small-scale irregularities that cannot be controlled on the CRT can be controlled on the LCD.

Operational Principles of Monochrome LCDs

This section describes the operation of monochrome LCDs. The components of color LCDs are so similar to those of monochrome ones that they are most easily explained based on an understanding of monochrome LCDs.

Overview The important components of a monochrome LCD are shown schematically in Fig. 16. In the dark, the main source of light is the backlight. Its luminous flux passes through a diffuser. The uniformity of the backlight/diffuser pair determines the spatial uniformity of the display surface. Light from the diffuser then passes through a light-modulating element that consists of two crossed

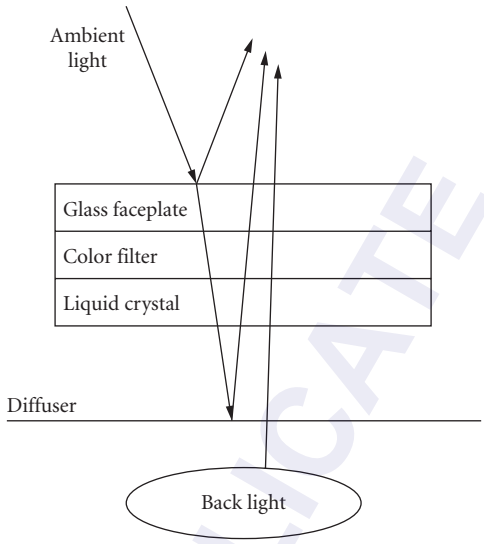

FIGURE 16 Illustration of the typical components of a single LCD pixel, seen side on. The arrows show the three light paths that contribute to the light emitted from the pixel.

polarizers and an intervening space, usually a few microns thick, filled with the liquid crystal. The liquid crystal rotates the polarization of light passing through it by an amount that depends on the local electric field. Thus, the electric field can be varied to vary the amount of light passing through the light-modulating element. The electric field is produced by a capacitor that covers the area of the pixel. The different varieties of LCD differ mainly in the electronics used to drive the capacitor. At present, the most common type is bilevel, with the capacitor controlled by a transistor that is either on or off, thus defining two light levels, white and black. More interesting are multilevel devices, in which an analog electric field allows more or less continuous variation of light output. Currently available analog devices are capable of 16 levels of gray scale with a pixel that is about 150 microns square.

In bilevel devices the array of pixels is very similar to the layout of memory cells in a random access seimconductor memory. Thus, the display itself can be considered a write-only random-access frame buffer. Most LCDs do not, at present, make use of the random-access capability, but accept input via the RS-170 analog signal standard used for CRTs. The multilevel variant is similar, except that an analog value is stored at each location instead of 0 or 1.

An interesting feature of this design is the ability of ambient light to enter the display. It then passes through the light-modulating element and is scattered with random phase by the diffuser. From there it passes back through the light-modulating element to the viewer. Thus, under high-ambient conditions there are two contributions to light emitted from the display: one from the backlight that is linear with respect to the transmittance of the light-modulating element and one from ambient light that is quadratic with respect to the transmittance of the light-modulating element. More specifically, the contribution from the backlight, $\mathbf{\Phi}_{\lambda}^{(BL)}$ is given by

$$\mathbf{\Phi}_{\lambda}^{(BL)} = \tau(V)\mathbf{\Phi}_{0\lambda}^{(BL)}$$

where $\mathbf{\Phi}_{0\lambda}^{(BL)}$ is the light emitted from the display when the light-modulating element is in its maximally transmissive state and $\tau(V)$ is the voltage-dependent transmittance of the light-modulating element. Note that the light-modulating process is assumed to be spectrally neutral. (In fact, chemists

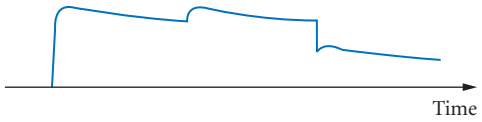

FIGURE 17 Illustration of the time dependence of the light output from an LCD pixel that is turned on for two refreshes, then turned to a lower level for the third refresh.

attempt to make the liquid crystal as spectrally neutral as possible.) The contribution from ambient light $\Phi_\lambda^{(AMB)}$ is

$$\Phi_\lambda^{(AMB)} = \tau^2(V)(1 - R(\lambda))D(\lambda)\Phi_{0\lambda}^{(AMB)}$$

where $\Phi_{0\lambda}^{(AMB)}$ is the ambient light incident on the display, $R(\lambda)$ is the reflectance of the faceplate of the display, and $D(\lambda)$ is the proportion of light reflected back by the diffuser. The second contribution is particularly interesting because the display is essentially characterized by a variable reflectance $\tau^2(V)(1 - R(\lambda))D(\lambda)$. Thus it is possible to create reflective images that are computer-controlled pixel by pixel. Note the importance of the front surface reflection in this pixel model. Light that is not transmitted at the front surface produces glare; light that is transmitted creates the image. Consequently, it is doubly important that the faceplate be treated to minimize reflection.

Pixel Structure The most interesting characteristic of the LCD is the shape and layout of its pixels, which are unlike the CRT pixel both spatially and temporally.

The time dependence of the light output from an LCD pixel is shown schematically in Fig. 17. Each refresh of the pixel produces a sharp rise followed by a slow fall. If the light output decreases from one frame to the next, the decrease occurs abruptly at the beginning of the pixel, without the exponential tail characteristic of CRTs with long persistence phosphors. The turnoff is limited only by the resistance of the circuit that removes charge from the capacitor. The slow fall is produced by loss of charge from the capacitor: the circuit is essentially a sample and hold and the flatness of the pixel profile is determined by the quality of the hold.

The spatial structure of the LCD display surface is shown schematically in Fig. 18. The pixels are nonoverlapping, with dark lines between them because an interpixel mask is used to hide regions

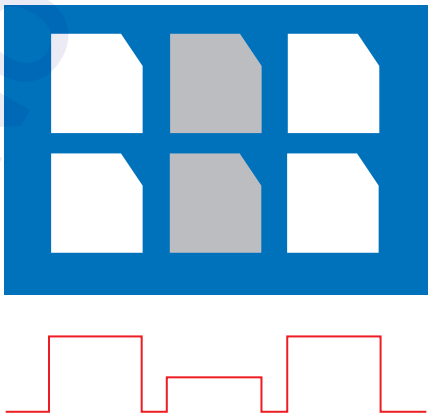

FIGURE 18 Illustration of the layout and shape of pixels on an LCD. The lower panel shows the spatial dependence of emitted light, on a cross section through the center of a row of pixels. The two middle pixels are turned on to a lower level than the outside ones.

where the electric fields of neighboring capacitors overlap. The light emitted is uniform over the pixel area, so that the intensity profile is uniform. Usually there is a small amount taken off the corner of the pixel to allow space for the electronic circuits that turn the pixel off and on. The pitch of the display, the distance from one pixel to the center of the next pixel, ranges from 100 to 500 μm.

Problems Current high resolution, analog, color LCDs suffer from a variety of problems, which may be expected to diminish rapidly in importance as manufacturing technology improves.

Thickness variation Uniformity of output depends critically on precise control of the thickness of the liquid crystal from pixel to pixel.

Heat Current displays are very temperature-dependent, changing their performance as they warm up and if anything warm, like a human hand, is held in contact with them.

Gray scale The present mass-produced LCDs have poor gray-scale capability: each pixel can be only off or on. The manufacturing processes needed to produce gray scale, which produce about 30 levels of gray scale on prototype displays, need considerable development.

Electronics A typical display depends on thousands of address wires, connected to the display at the pitch of the pixels. These wires are delicate and subject to failure, which produces a row or column of inactive pixels, called a line-out.

The Color LCD

The color LCD is a straightforward generalization of the monochrome LCD. Colored filters are placed in the light path to color the light emitted from each pixel. Three differently colored filters, and sometimes four, are used to create several interpenetrating colored images that combine additively to form a full-color image. The repetition pattern of the different images is regular, and it is usually possible to group a set of differently colored pixels into a single-colored pixel with three or four primaries, as shown in Fig. 19. (Terminology is important but nonstandard. In this chapter a single-colored pixel is called a monochrome pixel; a set of differently colored monochrome pixels that combines additively to produce a continuum of color at a given point is called a color pixel.)

Geometry of the Color Pixel There are a variety of different geometrical arrangements of monochrome pixels within a color pixel. Several are illustrated in Fig. 19. It is not currently known which

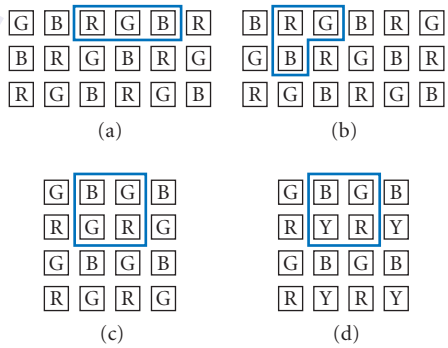

FIGURE 19 Schematic diagram of a variety of different monochrome pixel geometries: (*a*) and (*b*) show two triad geometries; (*c*) and (*d*) show two quad geometries. The color pixel is outlined in gray.

arrangement is best for which type of visual information. When the viewer is far enough back from the display the arrangement does not matter, only the relative number of each primary color. One strategy that is being tried is to add a fourth color, white or yellow, in a quad arrangement in order to increase brightness. Such a display offers interesting possibilities for experimentation with mesopic stimuli and for diagnosis and investigation of color-vision defects.

It is obvious that every geometry has directions in which the primaries form unwanted color patterns. Such patterns do not arise in CRT imagery because there is a random correlation between the dot triads that produce color and the pixel locations. Whether there is a regular geometry, as yet untried, that removes the patterns, whether software techniques similar to antialiasing can eliminate their visual effects, or whether a randomized primary arrangement is needed to remove the patterns is a problem as yet unresolved. (It should also be remembered that some stimuli may best be created by graphical techniques that take advantage of the existence of the patterns.) Whatever the solution, however, it must address the interrelationship between spatial and color aspects of the stimulus in the visual system of the perceiver.

Colorimetry of the Color Pixel The dominant factor in the colorimetry of LCDs is the interaction between the spectral power distribution of the backlight and the transmittances of the filters. Typically backlight and filter design deals with a trade-off between brightness and color gamut. The higher the excitation purity of the filter the more saturated the primary but the less bright the display. An additional factor considered in this trade-off is heating of the liquid crystal, which is greater when the filters have high excitation purity. Choice of a backlight that has as much as possible of its spectral power in wavelengths passed by the filters will improve performance.

The colorimetric properties of an LCD can be summed up in a few equations. The first is that the color of a pixel is the additive mixture of the colors of its monochrome pixel components. The sum of the spectral powers is

$$\Phi_\lambda = \sum_{a=1}^{N_p} \Phi_{a\lambda}(V_a)$$

where $\Phi_{a\lambda}$ is the spectral power emitted by monochrome pixel a, which depends on the voltage V_a applied to it. Similarly, the tristimulus values are the sum of the tristimulus values of the monochrome pixels

$$X_i = \sum_{a=1}^{N_p} X_{ai}$$

where X_{ai} is the set of tristimulus values for primary a. Note that "gun independence" is assumed.

The spectral power contributed by monochrome pixel a is the sum of three components: one from the backlight, $\Phi_{a\lambda}^{(BL)}(V_a)$, one from ambient light reflected from the front surface of the LCD, $\Phi(R)_{a\lambda}$, and one from ambient light reemitted from the display, $\Phi_{a\lambda}^{(AMB)}(V_a)$.

$$\Phi_{a\lambda}(V_a) = \Phi_{a\lambda}^{(BL)}(V_a) + \Phi_{a\lambda}^{(R)} + \Phi_{a\lambda}^{(AMB)}(V_a)$$

The contribution from the backlight is

$$\Phi_{a\lambda}^{(BL)}(V_a) = \tau_a(\lambda)\tau(V_a)\Phi_{0\lambda}^{(BL)}$$

where $\Phi_{0\lambda}^{(BL)}$ is the spectral power distribution of the backlight, $\tau(V_a)$ is the voltage-dependent transmittance of the liquid crystal/polarizer sandwich, and $\tau_a(\lambda)$ is the transmittance of the color filter. The function $\tau(V)$ is independent of the primary because the display uses the same light-modulating element for each primary. The function $\tau_a(\lambda)$ is independent of the applied voltage since the light-modulating element is spectrally neutral. In the absence of ambient light, this term is the only contribution to the light emitted by the LCD. The colorimetric properties are then identical to those of a CRT with primaries of the same chromaticity, which is the chromaticity of the product $\tau_a(\lambda)\Phi_{0\lambda}^{(BL)}$, though the equivalent of the gamma function $\tau(V_a)$ is certain to have a different functional form.

The contribution from light reflected from the front surface is

$$\Phi_{a\lambda}^{(R)} = R(\lambda)\Phi_{0\lambda}^{(AMB)}$$

where $R(\lambda)$ is the reflectance of the front surface and $\Phi_{0\lambda}^{(AMB)}$ is the ambient light incident on the surface. Usually, the reflectance is spectrally neutral (independent of wavelength) and the reflected light has the same color as the incident ambient light.

The contribution from light reemitted from the display is

$$\Phi_{a\lambda}^{(R)} = (1-R(\lambda))D(\lambda)\tau_a^2(\lambda)\tau^2(V_a)\Phi_{0\lambda}^{(AMB)}$$

where $D(\lambda)$ is the reflectance of the diffuser. This contribution can be modeled as a light of the same chromaticity as the spectral power distribution $(1-R(\lambda))D(\lambda)\tau_a^2(\lambda)\Phi_{0\lambda}^{(AMB)}$, with its intensity modulated by the function $\tau^2(V_a)$. Note that this chromaticity is not in general the same as the chromaticity produced by light from the backlight. (It will usually be more saturated than the backlight component since it passes through the color filter twice.) Note also that the voltage dependence of the intensity of this light differs from that of the backlight component. Thus, the chromaticity of the primary changes as the voltage changes when ambient light is present, and the effect cannot be subtracted off, as can the ambient component.

Controls and Input Standards LCDs will have standard sets of controls and input signals only when the technology is much more mature than it is at present. Currently, the most common input seems to be analog video, as used for CRTs. While this allows a one-for-one substitution of an LCD for a CRT, it seems quite inappropriate for computer applications. Specifically, information is extracted from the frame buffer, a random-access digital device, laboriously sequenced into the serial analog video signal, the reextracted for presentation for the random-access LCD. Thus, it seems likely that digital random-access input standards are likely to supersede video signals for LCD input, and that the display will be more tightly coupled to the image storage system than is common with CRTs.

Temporal and Spatial Variations in Output

LCD fabrication technology is changing too quickly for quantitative limits to spatial and temporal variability to be predictable. Nonetheless, it seems likely that certain qualitative properties are inherent in all LCD designs. They are discussed in general terms in the next few sections.

Short-Time Temporal Variation The light output over a short time (about 100 ms) is shown schematically in Fig. 17. The details shown in that figure, the rise and decay times and the turnoff time, are bound to change as fabrication techniques improve. Currently, the turnoff time is not very good for most LCDs, and images leave shadows that decay visibly for several seconds after they are removed. That defect is not inherent in LCD electronics and it should be expected to disappear as circuitry improves. The other possible defect is the ripple in the light output, which is nonetheless much smaller than the ripple of CRT light output. The size of the ripple is determined by the quality of the sample-and-hold circuit that maintains charge on the capacitor, and is likely to decrease as LCDs improve.

The interaction between ripple and turnoff time is quite different for an LCD than for a CRT. To decrease the ripple on a CRT it is necessary to increase the decay time of the phosphors; degradation of the turnoff time cannot be avoided. For an LCD, on the other hand, the turnoff is active, and independent of the ripple. Thus, it is possible to improve the ripple without degrading the turnoff. As a result, future LCDs are likely to be very useful for generating stimuli that require precise temporal control.

Long-Time Temporal Variation Even at the current state of development, the long-time stability of LCDs is quite good, with reports showing variations of about 2 percent on a time scale of several hours. This performance is comparable to good-quality CRTs and incandescent light sources.

The main contributor to instability is heat. LCDs are only stable once they are warmed up, and even small changes in cooling configuration can cause appreciable changes in light output. Thus, good stability of light output requires well-controlled temperature and a long warm-up time.

Small-Scale Spatial Variation Small-scale variation is determined by the spatial structure of the pixel, which is illustrated in Fig. 18. The important feature is the sharp edge of the pixel: unlike CRT pixels, there is no blending at the edges of adjacent pixels. This feature makes the creation of some stimulus characteristics easy—sharp vertical and horizontal edges, for example—and makes the creation of other stimulus parameters very difficult—rounded corners, for example. Many graphical techniques and image-quality criteria have evolved to take advantage of display characteristics that are peculiar to the CRT; there is likely to be a substantial investment in devising techniques that are well suited to the very different pixel profile of the LCD.

An interesting future possibility arises because of the similarity of LCD manufacturing technology to that of random-access memories. Consequently, it is likely that future LCDs will be limited in resolution not by pixel size but by input bandwidth. If so, it would be sensible to have logical pixels within the control system that consist of many physical pixels on the display, with enough processing power on the display itself to translate commands referring to logical pixels into drive signals for physical pixels. In fact, a physical pixel could even belong to more than one logical pixel. If such a development occurs, considerable control over the pixel profile will be possible, which may greatly extend the range of spatial variation that images can possess.

Large-Scale Spatial Variation Because LCDs have no large-scale structural features, like the beam deflection in the CRT, only manufacturing tolerances should induce spatial variation. The main source of manufacturing variability at the time of writing is the physical size of the pixels and the electronic components—capacitors, especially—that control them. Ideally, such variations would be random, so that spatial variation would add only gaussian noise to the displayed image.

Much more serious is angular variation of emitted light. The light-emitting element uses effects that have strong directional dependence, and it is sometimes even possible to find angles at which an LCD reverses contrast compared to perpendicular viewing. Although this effect is inherent in LC technology, it is reasonable to hope that display improvements will reduce the angular variability below its currently unacceptable level.

22.6 ACKNOWLEDGMENTS

The author would particularly like to express his gratitude to the late Gunter Wyszecki who provided impetus for his interest in this subject, and who provided intellectual and logistical support during the time in which the author carried out most of the work on which this chapter is based. A large number of other people have provided useful insights and technical assistance over the years, including, but not restricted to: John Beatty, Ian Bell, David Brainard, Pierre Jolicoeur, Nelson Rowell, Marueen Stone, and Brian Wandell. The author would also like to thank the editor, David Williams, for patience above and beyond the call of duty during the very difficult time when I was putting this material into the form in which it appears here.

23.1 GLOSSARY

Accommodation. In regard to the visual system, accommodation is the focusing ability of the eye.

Acuity. A measure of the ability of the eye to resolve fine detail, specifically to distinguish that two points separated in space are distinctly separate.

Afterimage. An optical illusion that refers to an image continuing to appear in one's vision after the exposure to the original image has ceased.

Anisometropia. A visual condition in which there is a significant refractive difference between the two eyes.

Astigmatism. A visual condition in which the light entering the eye is distorted such that it does not focus at one single point in space.

Binocularity. The use of two eyes at the same time, where the usable visual areas of each eye overlap to produce a three-dimensional perception.

Brightness. The subjective attribute of light to which humans assign a label between very dim and very bright (brilliant). Brightness is perceived, not measured. Brightness is what is perceived when lumens fall on the rods and cones of the eye's retina. The sensitivity of the eye decreases as the magnitude of the light increases, and the rods and cones are sensitive to the luminous energy per unit of time (power) impinging on them.

Cataracts. A loss of clarity of the crystalline lens within the eye which causes partial or total blindness.

Cathode ray tube (CRT). A glass tube that forms part of most video display terminals. The tube generates a stream of electrons that strike the phosphor coated display screen and cause light to be emitted. The light forms characters on the screen.

Color convergence. Alignment of the three electron beams in the CRT that generate the three primary screen colors—red, green, and blue—used to form images on screen. In a misconverged image, edges will have color fringes (e.g., a white area might have a blue fringe on one side).

Color temperature. A way of measuring color accuracy. Adjusting a monitor's color-temperature control, for example, may change a bluish white to a whiter white.

Convergence. That visual function of realigning the eyes to attend an object closer than optical infinity. The visual axes of the eyes continually point closer to each other as the object of viewing gets closer to the viewer.

Contrast. The difference in color and light between parts of an image.

Diplopia (double vision). That visual condition where the person experiences two distinct images while looking at one object. This results from the breakdown of the coordination skills of the person.

Disability glare. A type of glare that causes objects to appear to have lower contrast and is usually caused by scattering of light within the media in the eye.

Discomfort glare. Glare that produces ocular discomfort including eye fatigue, eyestrain, and irritation.

Dot matrix. A pattern of dots that forms characters (text) or constructs a display image (graphics) on the VDT screen.

Dot pitch. The distance between two phosphor dots of the same color on the screen.

Electromagnetic radiation. A form of energy resulting from electric and magnetic effects which travels as invisible waves.

Ergonomics. The study of the relationship between humans and their work. The goal of ergonomics is to increase worker's comfort, productivity, and safety.

Eyesight. The process of receiving light rays into the eyes and focusing them onto the retina for interpretation.

Eyestrain (asthenopia). Descriptive terms for symptoms of visual discomfort. Symptoms include burning, itching, tiredness, aching, watering, blurring, etc.

Farsightedness (hyperopia). A visual condition where objects at a distance are more easily focused as opposed to objects up close.

Font. A complete set of characters including typeface, style, and size used for screen or printer displays.

Focal length. The distance from the eye to the viewed object needed to obtain clear focus.

Foot-candle. The amount of illumination inside the surface of an imaginary 1 ft radius sphere would be receiving if there were a uniform point source of 1 cd in the exact center of the sphere. One foot-candle ≈ 10.764 lux.

Glare. The loss in visual performance or visibility, or the annoyance of discomfort, produced by a luminance in the visual field greater than the illuminance to which the eyes are adapted.

Hertz (Hz). Cycles per seconds. Used to express the refresh rate of video displays.

Illuminance. The luminous flux incident on a surface per unit area. The unit is the lux or lumen per square meter. The foot-candle (fc) or lumen per square foot is also used. An illuminance photometer measures the luminous flux per unit area at the surface being illuminated without regard to the direction from which the light approaches the sensor.

Interlaced. An interlaced monitor scans the odd lines of an image first followed by the even lines. This scanning method does not successfully eliminate flicker on computer screens.

Lag. In optometric terms, the measured difference between the viewed object and the actual focusing distance.

LASIK. A surgical procedure that alters the curvature of the cornea (front surface of the eye) which reduces the amount of nearsightedness or astigmatism.

LCD (Liquid crystal display). A display technology that relies on polarizing filters and liquid-crystal cells rather than phosphors illuminated by electron beams to produce an on-screen image. To control the intensity of the red, green, and blue dots that comprise pixels, an LCD's control circuitry applies varying charges to the liquid-crystal cells through which polarized light passes on its way to the screen.

Light. The radiant energy that is capable of exciting the retina and producing a visual sensation. The visible wavelengths of the electromagnetic spectrum extend from about 380 to 770 nm. The unit of light energy is the lumen.

Luminous flux. The visible power or light energy per unit of time. It is measured in lumens. Since light is visible energy, the lumen refers only to visible power.

Luminous intensity. The luminous flux per solid angle emitted or reflected from a point. The unit of measure is the lumen per steradian, or candela (cd). (The steradian is the unit of measurement of a solid angle.)

Luminance. The luminous intensity per unit area projected in a given direction. The unit is the candela per square meter, which is still sometimes called a nit. The foot-lambert (fL) is also in common use. Luminance is the measurable quantity which most closely corresponds to brightness.

Lux (see foot-candle). A unit of illuminance and luminous emittance. It is used in photometry as a measure of the intensity of light.

MHz (MegaHertz). A measurement of frequency in millions of cycles per second.

Myopia (nearsightedness). The ability to see objects clearly only at a close distance.

Musculoskeletal. Relating to the muscles and skeleton of the human body.

Nearpoint. The nearest point of viewing, usually within arms length.

Noninterlaced. A noninterlaced monitor scans the lines of an image sequentially, from top to bottom. This method provides less visible flicker than interlaced scanning.

Ocular motility. Relating to the movement abilities of the eyes.

Parabolic louver. A type of light fixture that is designed to direct light in a limited and narrowed direction.

Perception. The understanding of sensory input (vision, hearing, touch, etc.).

Pixel. The smallest element of a display screen that can be independently assigned color and intensity.

Phosphor. A substance that emits light when stimulated by electrons.

Photophobia. A visual condition of excessive sensitivity to light.

Presbyopia. A reduction in the ability to focus on near objects caused by the decreased flexibility in the lens, usually noticed around the age of 40 years old or later.

Polarity. The arrangement of the light and dark images on the screen. Normal polarity has light characters against a dark background; reverse polarity has dark characters against a light background.

Refractive. Having to do with the bending of light rays, usually in producing a sharp optical image.

Refresh rate. The number of times per second that the screen phosphors must be painted to maintain proper character display.

Resolution. The number of pixels, horizontally and vertically, that make up a screen image. The higher the resolution, the more detailed the image.

Resting point of accommodation (RPA). The point in space where the eyes naturally focus when at rest.

Specular reflection. The perfect, mirror-like reflection of light from a surface, in which light from a single incoming direction is reflected into a single outgoing direction.

Suppression. The "turning off" of the image of one eye by the brain, most often to avoid double vision or reduce excess stress.

SVGA (Super video graphics array). A video adapter capable of higher resolution pixels and/or colors) than the $320 \times 200 \times 256$ and $640 \times 480 \times 16$ which IBM's VGA adapter is capable of producing. SVGA enables video adapters to support resolutions of 1024 by 768 pixels and higher with up to 16.7 million simultaneous colors (known as true color).

VDT (Video display terminal). An electronic device consisting of a monitor unit (e.g., cathode ray tube) with which to view input into a computer.

Vision. A learned awareness and perception of visual experiences (combined with any or all other senses) that results in mental or physical action. Not simply eyesight.

Visual stress. The inability of a person to visually process light information in a comfortable, efficient manner.

Vision therapy. Treatment (by behavioral optometrists) used to develop and enhance visual abilities.

23.2 INTRODUCTION

Vision and eye problems are the most commonly reported symptoms among workers at computer monitors. The percentage of computer workers who experience visually related symptoms is generally reported to be from 70 up to almost 90 percent.[1] The current concern for, and popularization of these problems is likely related to the rapid introduction of this new technology into the workplace, the job restructuring associated with it, and a greater societal concern about discomfort associated with work.

The problems are largely symptoms of discomfort. There is little evidence of permanent physiological change or damage associated with extended work at a computer monitor. The vision and eye problems caused by working at a computer monitor have been collectively named "Computer Vision Syndrome (CVS)" by the American Optometric Association. The most common symptoms of CVS obtained from a survey of optometrists in order of frequency are: eyestrain, headaches, blurred vision, dry or irritated eyes, neck and/or backaches, photophobia, double vision, and colored afterimages.

A syndrome is defined as a "group of signs and symptoms that indicate a disease or disease process."[2] While CVS is not technically a "disease," it can also be properly characterized as a syndrome due to the fact that it is "a complex of symptoms indicating the existence of undesirable condition or quality." Thus, CVS is not a single disease entity, as the definition seems to require. However, it is a group of signs and symptoms related to a specific occupational usage of the eyes.

The causes for these symptoms are a combination of individual vision problems, poor office ergonomics, or work habits. Many individuals have marginal vision disorders that do not cause symptoms of less demanding visual tasks. On the other hand, there are numerous aspects of the computer monitor and the computer work environment that make it a more demanding visual task than others—therefore, more individuals are put beyond their threshold for experiencing symptoms.

23.3 WORK ENVIRONMENT

Lighting

Improper lighting is likely the largest environmental factor contributing to visual discomfort. The room lighting is a particular problem for computer workers because the horizontal gaze angle of computer work exposes the eyes to numerous glare sources such as overhead lights and windows. Other deskwork is performed with a downward gaze angle and the glare sources are not in the field of view.

Glare is the loss in visual performance or visibility, or the annoyance of discomfort, produced by a luminance in the visual field greater than the illuminance to which the eyes are adapted. There are generally four types of glare: distracting glare, discomfort glare, disabling glare, and blinding glare.

Distracting glare results from light being reflected from the surface of an optical medium and is usually below 3000 lumens. This form of glare most often results in an annoyance to the viewer and leads to eye fatigue. Discomfort glare ranges from 3000 to 10,000 lumens and produces ocular discomfort, including eye fatigue, eyestrain, and irritation. Disabling glare, also known as veiling glare, results when light reaches 10,000 lumens and can actually block visual tasks. This type of glare causes objects to appear to have lower contrast and is caused by scattering of light within the media in the

TABLE 1 Display and Glare Source Luminances

Visual Object	Luminance (cd/m^2)
Dark background display	20–25
Light background display	80–120
Reference material with 750 lumens/m^2	200
Reference material with auxiliary light	400
Blue sky (window)	2,500
Concrete in sun (window)	6,000–1,2000
Fluorescent light (poor design)	1,000–5,000
Auxiliary lamp (direct)	1,500–10,000

eye. Blinding glare results from incident light reflecting from smooth shiny surfaces such as water and snow. It can block vision to the extent that the wearer becomes visually compromised and recovery time is needed to be fully comfortable once again.

The threshold luminance ratios and locations of visual stimuli that cause glare discomfort have been determined,[3] but the physiological basis for glare discomfort is not known. Since large luminance disparities in the field of view can cause glare discomfort, it is best to have a visual environment in which luminances are relatively equal. Primarily because of glare discomfort, the Illumination Engineering Society of North America (IESNA) established maximum luminance ratios that should not be exceeded.[4] The luminance ratio should not exceed 1:3 or 3:1 between the task and visual surrounding within 25°, nor should the ratio exceed 1:10 or 10:1 between the task and more remote visual surroundings. Many objects in the field of view can cause luminance ratios in excess of those recommended by IESNA. Table 1 shows common luminance levels of objects in an office environment. Relative to the display luminance, several objects can greatly exceed the IESNA recommended ratios. A major advantage of using light background displays compared to dark background displays is that it enables better conformity with office luminance levels.

Good lighting design can reduce discomfort glare. Light leaving the fixture can be directed so that it goes straight down and not into the eyes of the room occupants. This is most commonly accomplished with parabolic louvers in the fixture. A better solution is indirect lighting in which the light is bounced off the ceiling—resulting in a large low luminance source of light for the room. Traditional office lighting recommendations have been suggested at about 100 fc (1000 lux) but computerized offices most often require less light, in the range of 50 fc (500 lux) to better balance with the light emanating from the computer display. Proper treatment of light from windows is also important. Shades or blinds should be employed to give flexibility to control outdoor light.

Screen Reflections

In most cases, the most bothersome source of cathode ray tube (CRT) screen reflections is from the phosphor on the inner surface of the glass. ("Monitor Characteristics" are discussed later.) The phosphor is the material that emits light when struck by the electron beam—it also passively reflects room light. The reflections coming from the phosphor are diffuse. Most computer monitors have a frosted glass surface; therefore, the light reflected from the glass is primarily diffuse with a specular component.

Since most of the screen reflections are diffuse, a portion of any light impinging on the screen, regardless of the direction from which it comes, is reflected into the eyes of the user and causes the screen to appear brighter. This means that black is no longer black, but a shade of gray. The diffuse reflections from the phosphor and from the glass reduce the contrast of the text presented on the screen. Instead of viewing black characters on a white background, gray characters are presented on a white background. Calculations[5] show that these reflections significantly reduce contrast—from 0.96 to 0.53 [contrast = $(L_t - L_b)/(L_t + L_b)$, where L_t and L_b are luminances of the task and background] under common condition. Decreased contrast increases demand upon the visual system.

A common method of treating reflections is with an antireflection filter placed on the computer monitor. The primary purpose of the filter is to make the blacks blacker, thereby increasing contrast. The luminance of light that is emitted by the screen (the desired image) is decreased by the transmittance factor of the glass filter, whereas light that is reflected from the computer screen (undesired light) is decreased by the square of the filter transmittance, since it must pass through it twice. For a typical filter of 30 percent transmittance, the luminances of black and white are reduced respectively to 9 percent and 30 percent of their values without the filter. This results in an increase in the contrast.

Some antireflection filters have a circular polarized element in them. This feature results in circular polarized lights being transmitted to the computer screen. The resulting reflection on the screen changes the rotation of the polarization of the light so that it is blocked from coming back out through the filter. Since only specular reflected light maintains its polarized properties after reflection, this polarizing feature provides added benefit for only the specular reflections. If significant specular reflections are present, it is beneficial to obtain an antireflection filter with circular polarization.

The influx of liquid crystal displays (LCDs) into the workplace has addressed some of the issues regarding reflections by using a matte surface to diffuse the reflections. However, the matte surface may be disappearing in the future; the trend in high performance LCDs is back to a glossy surface, reintroducing the problem of reflections on the surface of the display. Whichever surface, matte or glossy, users can still experience problems with glare and contrast reduction or image washout. A 2003 survey[6] of LCD users supports this, with 39 percent reported having a glare problem on the LCD and 85 percent of LCD users reacted favorably when an antireflection filter was used with their LCD, stating that they were bothered by glare on their display and preferred working with a glare reduction filter on the display.

Independent, scientific testing of a midtransmission level antireflection computer filter to the same international standard that computer monitors must comply with, ISO 9241–7, has shown that this filter can actually improve a monitor's performance against this standard for reflection reduction and contrast improvement. The significance of this testing is that the quality of the antireflection coatings and the level of absorption technology are important considerations. There are many products on the market today that claim to be antireflection computer filters. These filters offer very low quality, if any, antireflection performance and little to no absorption technology. It is because of these lower performance products that ergonomic specialists, when considering options for reducing reflections and glare on an electronic display, often ridicule antireflection computer filters.

It is important to discuss the counterargument to antireflection computer filters—that monitors today don't need them because they already have antireflection treatments. While this is the case for many computer displays, the amount of glare and reflection reduction can be misleading. A few key points to keep in mind regarding computer displays and antireflection treatments:

- Some simply change the state of the reflection from specular to diffuse through silica coatings or etching the surface of the display (a matte finish).
- Some use a spin coating process that may only reduce first surface reflections down about 1 to 2 percent. Good quality antireflection computer filters reduce first surface reflections to less than 1 percent.
- Flat screens are better, reduce off-axis angle reflections, but still do little for normal incidence reflections.
- Few have absorptive coatings to improve contrast.
- LCDs have many advantages over the older CRT technology, matte surfaces to reduce reflections, but they still have issues with glare and contrast reduction.

Moreover, the trend of going to glossy displays means increased reflections.

Monitor Characteristics

One obvious method of improving the visual environment for computer workers is to improve the legibility of the display at which they are working. The visual image on computer monitors is compromised in many ways compared to most paper tasks.

A major aspect of computer displays is that the images are composed of pixels—the "picture element" that creates the "dots" of an image. A greater pixel density will be able to display greater detail. Most older computer screens had pixel densities in the range of from 80 to 110 dots/in (dpi: 31 to 43 dots/cm). This pixel density can be compared to impact printers (60 to 100 dpi), laser printers (300 dpi), and advanced laser printers (400 to 1200 dpi). Computer monitors today have dpi specifications that are comparable to laser printers—greater pixel density would result in visually discernible differences, as for printers. Besides pixel density there are many other factors that affect display quality, such as pixel definition (measured by area under the modulation transfer function), font type, font size, letter spacing, line spacing, stroke width, contrast, color, gray scale, and refresh rate.[7] Several studies have shown that increased screen resolution characteristics increase reading speed and/or decrease visual symptoms.[5] Although technological advances have resulted in improved screen resolutions, there is still substantial room for improvement.

To adequately cover all aspects of computer monitor characteristics, it is necessary to discuss both the CRT and the LCD technologies used to generate these images.

The CRT is a light-emitting device. It was first demonstrated over 100 years ago and it is a fairly simple device to describe, but one requiring great precision to manufacture. It consists of a glass bottle under a high vacuum with a layer of phosphorescent material at one end and an electron gun at the other. The electron gun creates a stream of electrons that are accelerated toward the phosphor by a very high voltage. When the electrons strike the phosphor, it glows at the point of impact. A coil of wire called the yoke is wrapped around the neck of the CRT. The yoke actually consists of a horizontal coil and a vertical coil, each of which generates a magnetic field when a voltage is applied. These fields deflect the beam of electrons both horizontally and vertically, thereby illuminating the entire screen rather than a pinpoint. To create an image, the electron beam is modulated (turned on and off) by the signal from the video card as it sweeps across the phosphor from left to right. When it reaches the right side of the tube, the beam is turned off or "blanked" and moved down one line and back to the left side. This process occurs repeatedly until the beam reaches the bottom right-hand side and is blanked and moved to the top left.

The LCD or "flat panel" as it is sometimes called, is a totally different way of generating a computer image. Rather than being light emissive as the CRT is, the LCD is light transmissive. Each dot on the screen acts like an electrically controlled shutter that either blocks or passes a very high intensity backlight (or backlights) that is always on at full brightness. Whereas the dots comprising the image of a CRT-based display vary in size depending on the displayed resolution (if you display VGA resolution, the entire screen is lit with $640 \times 480 = 307{,}200$ dots while if you display UXGA, the screen is filled by $1600 \times 1200 = 1{,}920{,}000$ dots), an LCD panel has a fixed number of pixels. Each pixel is made up of three subpixels, a red, a green, and a blue. Since the backlight is white, the colors are achieved by means of tiny red, green, and blue filters.

Although the properties of a liquid crystal material were discovered in the late 1800s, it was not until 1968 before the first LCD display was demonstrated. Simply, light from the backlight is polarized, passed through the liquid crystal material (which twists the light 90°) and passed through a second polarizer that is aligned with the first one. This results in a structure that blocks the backlight. The liquid crystal material has a unique property, however, that causes its molecules to line up with an applied voltage. The 90° twist goes to 0 and the polarizer sandwich becomes transparent to the backlight. By applying more or less voltage, the light can be varied from 0 (black) to 100 percent (white). Modern displays can make the transition from full off to full on in 256 steps, which is 8 bits ($2^8 = 256$). Each pixel can display 256 shades each of red, green, and blue for a total palette of $256 \times 256 \times 256 = 16.7$ million colors.

It is interesting that many monitor manufacturers will use that 16.7 million-color number very prominently in their advertising. However, in this chapter we are considering the eyes and visual system. Just how many colors does the human visual system perceive? Well, as near as we can tell (and there are many estimates here), the human visual system perceives between 7 and 8 million colors (in the most generous estimates). So, here we have a display that produces 16.7 million colors, but we can only see about half of those! For this reason, high performance monochrome monitors are often measured in "just noticeable differences," or JNDs. However, color combinations can be a visual issue. It is important to maintain high contrast (color contrast, as well) between the letters and the background of the display, regardless of which colors are used.

So, which is the better technology? This can be very subjective, but the LCD exhibits no linearity or pincushion (straight lines looking curved) distortion and no flicker, all of which can contribute to computer vision syndrome. Furthermore, the LCD is always perfectly focused as long as it is set to display at its native resolution (the fixed number of pixels that may be addressed by the video card regardless of the resolution being displayed). When displaying a nonnative resolution, the LCD invokes a digital processor called a scaler to add enough pixels to fill the screen without distorting the image. This is a very complex procedure and the final result is a slightly softened image that many people find tiring. A good rule of thumb is to run an LCD monitor at its native resolution unless there is a compelling reason not to.

The electron beam in a CRT display is constantly scanning or drawing the image over and over. When it hits a specific spot on the screen, light is emitted, but as soon as the beam moves on, the spot starts to fade. It is critical that the beam scans all the points on the screen and returns to the first point in a short enough time that the eye does not perceive the dimming. The number of times an image is "painted" on the CRT is called the refresh rate or vertical sync frequency and it must be set to a value ≥ 75 Hz to avoid flicker. Some people are hypersensitive to flicker and need an even higher refresh rate. The LCD display does not flicker by design.

Workstation Arrangement

It is commonly stated that: "the eyes lead the body." Since working at the computer is a visually intensive task, our body will do what is necessary to get the eyes in the most comfortable position—often at the expense of good posture and causing musculoskeletal ailments such as sore neck and back.

The most common distance at which people view printed material is 40 cm from the eyes. This is the distance at which eye doctors routinely perform near visual testing and for which most bifocal or multifocal glasses are designed. Most commonly, the computer screen is farther from the eyes—from 50 to 70 cm. This distance is largely dictated by other workstation factors, such as desk space and having room for a keyboard. The letter sizes on the screen are commensurately larger compared to printed materials to enable the longer viewing distance.

Because we are now using a vertical, rather than horizontal work surface, the height of the computer screen is a very important aspect of the workstation arrangement. A person can adapt to the vertical location of their task by changing their gaze angle (the elevation of the eyes in the orbit) and/or by changing the extension/flexion of the neck. Typically, users will alter their head position rather than eye position to adjust to a different viewing height. This can cause awkward posture and result in neck and/or backache. The eyes work best with a depression of from 10 to 20°;[5] therefore, this is the preferred viewing angle. As a practical guide, it is often recommended that the computer user set their monitor just below their straight-ahead gaze, with the top of the display tilted back about 10°.

Whatever is viewed most often during daily work should be placed straight in front of the worker when seated at the desk. This applies to the computer and/or the reference documents—whichever is viewed most frequently. Although this seems self-evident, many computer workers situate their work so that they are constantly looking off to one side. If using hard copy on a regular basis, the material should be placed so that it is close in proximity to the monitor. Whether it is below the monitor (an "in-line" setup) or adjacent to it, the closer proximity will allow easier eye movements between the screen and the hard copy. In addition, the hard copy should reside on the same side as the handedness of the user: right side for a right-handed person. This will allow the person to either write or manipulate the hard copy without stretching into an awkward posture.

Work Habits

Since the computer has essentially taken over as the most essential piece of office equipment, office workers are spending an excessive number of hours viewing their display screens. To simplify a method to break up their viewing habits, one author has devised a method called "the 3 B's":

blink, breathe, and break. The rationale for blinking will be discussed in the next section on dry eyes. Breathing is an important aspect of computer use simply because we are sedentary for extended hours and our physical activity is reduced. This reduces blood flow and creates a condition for shallow breathing, which in turn tires the computer user making them lethargic and less productive.

Regarding breaks, this author recommends the "20/20/20" rule: Every 20 min, take just 20 s, and look 20 ft away. This short, more frequent break will allow the accommodative and convergence systems to relax and presumably regain some level of performance.

23.4 VISION AND EYE CONDITIONS

Many individuals have marginal vision disorders that do not cause symptoms on less demanding visual work, but will cause symptoms when the individual performs a demanding visual task. Given individual variation in visual systems and work environments, individual assessment is required to solve any given person's symptoms. Following are the major categories of eye and vision disorders that cause symptoms among computer users.

Dry Eyes

Computer users commonly experience symptoms related to dry eyes. These symptoms include irritated eyes, dry eyes, excessive tearing, burning eyes, itching eyes, and red eyes. Contact lens wearers also often experience problems with their contact lenses while working at a computer display—related to dry eyes. In response to dry eye and ocular irritation, reflex tearing sometimes occurs and floods the eyes with tears. This is the same reflex that causes tearing when we cry or are exposed to foreign particles in our eye.

Computer workers are at greater risk for experiencing dry eye because the blink rate is significantly decreased and, because of the higher gaze angle, the eyes are wide open with a large exposed ocular surface. Patel et al.[8] measured blink rate by direct observation on a group of 16 subjects. The mean blink rate during conversation was 18.4 blinks/min and during computer use it was 3.6 blinks/min—more than a fivefold decrease. Tsubota and Nakamori [9] measured blink rates on 104 office workers. The mean blink rates were 22 blinks/min under relaxed conditions, 10 blinks/min while reading a book on the table, and 7 blinks/min while viewing text on a computer screen. Although both book reading and computer work result in significantly decreased blink rates, a difference between them is that computer work usually requires a higher gaze angle, resulting in an increased rate of tear evaporation. Tsubota and Nakamore[9] measured a mean exposed ocular surface of 2.2 cm^2 while subjects were relaxed and 1.2 cm^2 while working at a computer. Since the primary route of tear elimination is through evaporation, and the amount of evaporation is a roughly linear function of ocular aperture area, the higher gaze angle when viewing a computer display results in faster tear loss. Even though reading a book and display work both reduce the blink rate, the computer worker is more at risk because of the higher gaze angle.

Other factors may also contribute to dry eye. For example, the office air environment is often low in humidity and can contain contaminants. Working under an air vent also increases evaporation. The higher gaze angle results in a greater percentage of blinks that are incomplete, resulting in poor tear film and higher evaporation rates.

Dry eyes are common in the population, reported as being 15 percent of a clinical population. For example, postmenopausal women, arthritis sufferers, post-LASIK patients, those taking some systemic medications, and contact lens wearers are more prone to dry eyes. All of these conditions should be explored as causative for dry eye symptoms. For many people with marginal dry eye problems, work at a computer will cause their dry eye problem to become clinically significant.

Resolving dry eye symptoms may take many approaches, depending on the source of the problem. The longstanding, traditional approach of simply adding an "artificial tear" to the eyes is losing favor because it has shown to be ineffective. Newer drops are available that create a better quality tear film.

In addition, a prescription drop that incorporates a mild antibiotic to reduce inflammation has shown to be effective in some cases. There is also a swell of attention to oral supplementation to stimulate better tear formation. Regardless of which approach the eye care practitioner takes, resolving dry eyes for the computer user should be a priority in the treatment of computer vision issues.

Refractive Error

Many patients simply need an accurate correction of refractive error (myopia, hyperopia, or astigmatism). The blur created by the refractive error makes it difficult to easily acquire visual information at the computer display. This reduces work efficiency and induces fatigue. A 2004 study by Daum[10] indicates that even a slightly inaccurate vision prescription at the computer can have a significant negative impact on a worker's productivity. Results indicate that uncorrected vision, even if no symptoms appear, can affect employee productivity and accuracy. In addition, a vision miscorrection of as little as 0.50 D can cause a decrease in productivity of 9 percent and accuracy by 38 percent.

Patients with hyperopia must exert added accommodative effort to see clearly at near distances. Therefore, many hyperopic computer patients require refractive correction that they may not require for a less visually demanding job. Patients with 2.00 to 3.50 D of myopia who habitually read without their glasses often have visual and musculoskeletal difficulties at the computer because, to see clearly without their glasses, they must work too closely to the computer screen. These patients often require a partial correction of their myopia for proper function at the computer display.

Some computer-using patients develop a late-onset myopia from 0.25 to 1.00 D. The preponderance of evidence supports the contention that near workplaces some people are greater risk for the development of myopia. However, there is no evidence that work at a computer monitor causes myopia more than other forms of extended near-point work. The fact is, however, that our society is dictating that we do more and more of our work on the computer, which translates into long hours viewing the display screen. Take for example some school districts that require all of their students to perform all of their work on computers. The consequences of this type of visual stress may take years to realize.

Accommodation

Accommodation is the mechanism by which the eye changes its focus to look at near objects. Accommodation is accomplished by constriction of the ciliary muscle that surrounds the crystalline lens within the eye. The amplitude of accommodation (dioptric change in power) decreases with age. Presbyopia (see later) is the age-related condition that results when the amplitude of accommodation is no longer adequate to meet near visual needs. (See Chaps. 12 and 14.)

Many workers have reduced amplitude of accommodation for their age, or accommodative *infacility* (inability to change the level of accommodation quickly and accurately). These conditions result in a blur at near working distances and/or discomfort. Extended near work also commonly results in *accommodative hysteresis*—that is, the accommodative mechanism becomes "locked" into the near focus and it takes time (a few minutes to hours) to fully relax for distance focus. This is effectively a transient myopia that persists after extended near work. Some theories on myopia development look at this transient myopia as a step in the progression to developed myopia. Accommodative disorders are diagnosed in approximately one-third of the prepresbyopic segment of a clinical population. Accommodative disorders in the younger or prepresbyopic patient are usually treated with near prescription spectacles that enable the worker to relax accommodation. Vision training can also work for some patients.

Most work with display screens are performed with a higher gaze than other near-point work and accommodative amplitude is shown to be reduced with elevation of the eye. Relative to a 40° downward viewing angle, elevations of 20° downward, straight ahead, and 20° upward result in average accommodative decreases of 1.22 D, or 2.05 D, and 2.00 D, respectively, in a group of 80 prepresbyopes

with an average age of 26.4 years.[11] The higher gaze angles at most computer workstations result in a viewing condition for which the amplitude of accommodation is reduced—thus placing a greater strain on accommodation than near tasks performed at lower gaze angles.

Binocular Vision

Approximately 95 percent of people keep both eyes aligned on the object of regard. Those individuals who habitually do not keep their eyes aligned have *strabismus*. Even though most people can keep their eyes aligned when viewing an object, many individuals have difficulty maintaining this ocular alignment and experience symptoms such as fatigue, headaches, blur, double vision, and general ocular discomfort (see Chap. 13).

Binocular fusion is the sensory process by which the images from each eye are combined to form a single percept. When the sensory feedback loop is opened (e.g., by blocking an eye), the eyes assume their *position of rest* with respect to one another. If the position of rest is outward or diverged, the patient has *exophoria*. If it is inward or converged, the condition is *esophoria*. Clinically, the phoria is measured by occluding one of the eyes and measuring the eye alignment while occluded.

If the patient has a phoric deviation, as is the case for most people, then a constant neuromuscular effort is required to keep the eyes aligned. Whether a person experiences symptoms depends on the amount of the misalignment, the ability of the individual to overcome that misalignment, and the task demands. The symptoms associated with excessive phoria deviations can be eyestrain, double vision, headaches, eye irritation, and general fatigue.

Eye alignment at near viewing distances is more complex than at far viewing distances because of the ocular convergence required to view near objects and because of the interaction between the ocular convergence and accommodative mechanisms. Treatment of these conditions can include refractive or prismatic correction in spectacles, or vision training.

Anisometropia

One of the possible causes of binocular vision dysfunction is a difference in the correction for each eye. If there is a significant refractive difference between the two eyes, the condition of *anisometropia* exists. While this can happen developmentally and genetically, it can also be induced with surgical intervention of cataracts. If one eye has a cataract procedure performed and surgery on the other eye is not needed, then there may be a difference in the refractive errors, creating an anisometropic condition.

This condition is more significant if the refractive error of each eye is corrected with spectacles. Wearing a correction for two variable prescriptions can create an image-size differential between the eyes. One solution is to fit the patient with contact lenses. Wearing the prescription directly on the eye will reduce the magnification differential and allow for equal-sized images.

Presbyopia

Presbyopia is the condition in which the normal age-related loss of accommodation results in an inability to comfortably maintain focus on near objects. This usually begins at about the age of 40. The usual treatment for presbyopia is to prescribe reading glasses or multifocal lenses that have a distance vision corrective power (if needed) in the top of the lens and the near vision corrective power in the bottom of the lens. The most common lens designs for correcting presbyopia are bifocals and progressive addition lenses (PALs). As usually designed and fitted, these lenses work well for the most common everyday visual tasks and provide clear vision at 30 cm with a downward gaze angles of about 25°. The computer screen is typically farther away (from 50 to 70 cm) and higher (from 10 to 20° of ocular depression). A presbyope who tries to wear their usual multifocal correction at the computer will either not see the screen clearly or will need to assume an awkward

posture, resulting in neck and back strain. This is because the zone of intermediate vision is most often too narrow for full-time computer use. Many, if not most, presbyopic computer workers require a separate pair of spectacles for their computer work. Several newer lenses are designed specifically for people with occupations that require intermediate viewing distances. (See Chaps. 12 and 14.)

24.1 INTRODUCTION

The field of *electronic imaging* has made incredible strides over the past decade as increased computational speed, bandwidth, and storage capacity have made it possible to perform image computations at interactive speeds. This means larger images, with more spatial, temporal, and chromatic resolution, can be captured, compressed, transmitted, stored, rendered, printed, and displayed. It also means that workstations and PCs can accommodate more complex image and data formats, more complex operations for analyzing and visualizing information, more advanced interfaces, and richer image environments, such as virtual reality. This, in turn, means that image technology can now be practically used in an expanding world of applications, including video, home photography, internet catalogues, digital libraries, art, and scientific data analysis. These advances in technology have been greatly influenced by research in human perception and cognition, and in turn, have stimulated new research into the vision, perception, and cognition of the human observer. Some important topics include spatial, temporal, and color vision, attentive and preattentive vision, pattern recognition, visual organization, object perception, language, and memory.

The study of the interaction between human vision and electronic imaging is one of the key growth areas in *imaging science*. Its scope ranges from printing and display technologies to image processing algorithms for image rendering and compression, to applications involving interpretation, analysis, visualization, search, design, and aesthetics. Different electronic imaging applications call on different human capabilities. At the bottom of the visual food chain are the visual phenomena mediated by the threshold sensitivity of low-level spatial, temporal, and color mechanisms. At the next level are perceptual effects, such as color constancy, suprathreshold pattern, and texture analysis.

Moving up the food chain, we find cognitive effects, including memory, semantic categorization, and visual representation, and moving to the next level, we encounter aesthetic and emotional aspects of visual processing.

Overview of This Chapter

In this chapter, we review several key areas in the two-way interaction between human vision and technology. We show how technology advances in electronic imaging are increasingly driven by methods, models, and applications of vision science. We also show how advances in vision science are increasingly driven by the rapid advances in technologies designed for human interaction. An influential force in the development of this new field has been the Society for Imaging Science and Technology (IS&T)/Society of Photographic and Instrumentation Engineers (SPIE) Conference on Human Vision and Electronic Imaging, which had its origins in 1988 and since 1989 has grown annually as a forum for multidisciplinary research in this area.[1–14] This chapter has been strongly influenced by the body of research that has been presented at these conferences, and reflects their unique perspectives.

A decade ago, the field of *human vision and electronic imaging* focused on the threshold sensitivity of the human visual system (HVS) as it relates to display technology and still-image compression. Today, the scope of human vision and electronic imaging is much larger and keeps expanding with the electronic imaging field. We have organized this chapter to reflect this expanding scope. We begin with early vision approaches in Sec. 24.2, showing how the explicit consideration of human spatial, temporal, and color sensitivity has affected the development of algorithms for compression and rendering, as well as the development of image quality metrics. These approaches have been most successful in algorithmically evaluating the degree to which artifacts introduced by compression or rendering processes will be detected. Section 24.3 considers how image features are detected, processed, and perceived by the human visual system. This work has been influential in the design of novel gaze-dependent compression schemes, new visualization and user interface designs, and perceptually based algorithms for image retrieval systems. Section 24.4 moves higher up the food chain to consider emotional and aesthetic evaluations. This work has influenced the development of virtual environments, high-definition TV, and tools for artistic appreciation and analysis. Section 24.5 concludes the chapter paper, and suggestions for further reading are given in Sec. 24.6.

24.2 EARLY VISION APPROACHES: THE PERCEPTION OF IMAGING ARTIFACTS

There are many approaches to characterizing image artifacts. Some approaches are based purely on physical measurement. These include measuring key image or system parameters to ensure that they fall within established tolerances, or comparing an original with a rendered, displayed, or compressed version, on a pixel-by-pixel basis, using a metric such as mean square error. These approaches have the advantage of being objective and relatively easy to implement; on the other hand, it is difficult to generalize from these data. Another approach is to use human observers to judge perceived quality, either by employing a panel of trained experts or by running psychological experiments to measure the perception of image characteristics. These approaches have the advantage of considering the human observer explicitly; on the other hand, they are costly to run and the results may not generalize. A third approach is to develop metrics, based on experiments measuring human visual characteristics, that can stand in for the human observer as a means of estimating human judgments. These perceptual models are based on experiments involving the detection, recognition, and identification of carefully controlled experimental stimuli. Since these experiments are designed to reveal the behavior of fundamental mechanisms of human vision, their results are more likely to generalize. This section reviews several models and metrics based on early human vision which have been developed for evaluating the perception of image artifacts.

Early vision models are concerned with the processes mediating the threshold detection of spatial, temporal, and color stimuli. In the early days of television design, Schade[15] and his colleagues introduced the notion of characterizing human threshold sensitivity in terms of the response to spatial-frequency patterns, thereby beginning a long tradition of work to model human spatial and temporal sensitivity using the techniques of linear systems analysis. The simplest model of human vision is a threshold contrast sensitivity function (CSF). A curve representing our sensitivity to spatial modulations in luminance contrast is called a spatial CSF. A curve representing our sensitivity to temporal modulations in luminance is a temporal CSF. These band-pass curves vary depending on many other parameters, including, for example, the luminance level, the size of the field, temporal modulation, and color. In early applications of visual properties to electronic imaging technologies, these simple threshold shapes were used. As the field has progressed, the operational model for early vision has become more sophisticated, incorporating interactions between spatial, temporal, and color vision, and making more sophisticated assumptions about the underlying processes. These include, for example, the representation of the visual system as a set of band-pass spatial-frequency filters,[16,17] the introduction of near-threshold contrast masking effects, and nonlinear processing.

One key area where these models of early vision have been applied is in the evaluation of image quality. This includes the psychophysical evaluation of image quality, perceptual metrics of image distortion, perceptual effects of spatial, temporal, and chromatic sampling, and the experimental comparison of compression, sampling, and halftoning algorithms. This work has progressed hand-in-hand with the development of vision-based algorithms for still image and video compression, image enhancement, restoration and reconstruction, image halftoning and rendering, and image and video quantization and display.

Image Quality and Compression

The basic premise of the work in perceptual image quality is that electronic imaging processes, such as compression and halftoning, introduce distortions. The more visible these distortions, the greater the impairment in image quality. The human vision model is used to evaluate the degree to which these impairments will be detected. Traditional metrics of image compression do not incorporate any models of human vision and are based on the mean squared error (i.e., the average squared difference between the original and compressed images). Furthermore, they typically fail to include a calibration step, or a model of the display device, thereby providing an inadequate model of the information presented to the eye.

The first perceptually based image quality metrics used the spatial contrast sensitivity function as a model of the human visual system.[18,19] The development of perceptual models based on multiple spatial-frequency channels greatly improved the objective evaluation of image quality. In these models, the visual system is treated as a set of spatial-frequency-tuned channels, or as Gabor filters with limited spatial extent distributed over the visual scene. The envelope of the responses of these channels is the contrast sensitivity function. These multiple channel models provide a more physiologically representative model of the visual system, and more easily model interactions observed in the detection of spatially varying stimuli. One important interaction is contrast masking, where the degree to which a target signal is detected depends on the spatial-frequency composition of the masking signal.

In 1992, Daly introduced the *visual differences predictor*,[6,20] a multiple-channel model for image quality that models the degree to which artifacts in the image will be detected, and thus will impair perceived image quality. This is a spatial-frequency model which incorporates spatial contrast masking and light adaptation. At about the same time, Lubin[21] proposed a similar metric that also accounts for sensitivity variations due to spatial frequency and masking. It also accounts for fixation depth and image eccentricity in the observer's visual field. The output of such metrics is either a map of detection probabilities or a point-by-point measure of the distance between the original and degraded image normalized by the HVS sensitivity to error at each spatial frequency and location. These detection probabilities or distances can be combined into a single number that represents the overall picture quality. While both models were developed for the evaluation of displays and high quality imaging systems, they have been adapted for a wide variety of applications.

Perceptually based image compression techniques were developed in parallel with perceptual models for image quality. This is not surprising since quality metrics and compression algorithms are closely related. The image quality metric is trying to characterize the human response to an image; an image compression algorithm is either trying to minimize some distortion metric for a given bit rate, or trying to minimize the bit rate for a given distortion. In both cases, a perceptually based distortion metric can be used.

In 1989, three important papers introduced the notion of "perceptually lossless" compression. (See Refs. 22–24.) In this view, the criterion of importance in image compression was the degree to which an image could be compressed without the user's perceiving a difference between the compressed and original images. Safranek and Johnston[25] presented the perceptual subband image coder (PIC) which incorporated a perceptual model and achieved perceptually lossless compression at lower rates than state-of-the-art perceptually lossy schemes. The Safranek-Johnston coder used an empirically derived perceptual masking model that was obtained for a given CRT display and viewing conditions. As with the quality metrics we discussed earlier, the model determines the HVS sensitivity to errors at each spatial frequency and location, which is called the *just noticeable distortion level* (JND). In subsequent years, perceptual models were used to improve the results of traditional approaches to image and video compression, such as those that are based on the discrete cosine transform (DCT). (See Refs. 26 to 28.)

Perceptually based image quality metrics have also been extended to video. In 1996, Van den Branden Lambrecht and Verscheure[29] described a video quality metric that incorporates spatio-temporal contrast sensitivities as well as luminance and contrast masking adjustments. In 1998, Watson extended his DCT-based still image metric, proposing a video quality metric based on the DCT.[30,31] Since all the current video coding standards are based on the DCT, this metric is useful for optimizing and evaluating these coding schemes without significant additional computational overhead.

In recent years, significant energy has been devoted to comparing these methods, models, and results, and to fine-tuning the perceptual models. The Video Quality Experts Group (VQEG), for example, has conducted a cross-laboratory evaluation of perceptually based video compression metrics. They found that different perceptual metrics performed better on different MPEG-compressed image sequences, but that no one model provided a clear advantage, including the nonperceptual measure, peak signal-to-noise ratio (Ref. 32). We believe that the advantages of the perceptual metrics will become apparent when this work is extended to explicitly compare fundamentally different compression schemes over different rates, image content, and channel distortions. An important approach for improving low-level image quality metrics is to provide a common set of psychophysical data to model. Modelfest (Ref. 33) is a collaborative modeling effort where researchers have volunteered to collect detection threshold data on a wide range of visual stimuli, under carefully controlled conditions, in order to provide a basis for comparing the predictions of early vision models. This effort should lead to a converged model for early vision that can be used to develop image quality metrics and perceptually based compression and rendering schemes. (Comprehensive reviews of the use of perceptual criteria for the evaluation of image quality can be found in Refs. 34 and 35.)

Image Rendering, Halftoning, and Other Applications

Another area where simple models of low-level vision have proven to be quite successful is image halftoning and rendering. All halftoning and rendering algorithms make implicit use of the properties of the HVS; they would not work if it were not for the high spatial-frequency cutoff of the human CSF. In the early 1980s, Allebach introduced the idea of halftoning based on explicit human visual models and models of the display device. However, the development of halftoning techniques that rely on such models came much later. In 1991, Sullivan et al.[36] used a CSF model to design halftoning patterns of minimum visibility and Pappas and Neuhoff[37] incorporated printer models in error diffusion. In 1992, methods that use explicit visual models to minimize perceptual error in image halftoning were independently proposed by Analoui and Allebach,[38] Mulligan and Ahumada,[39] and Pappas and Neuhoff.[40] Allebach et al. extended this model-based approach to color in 1993[41] and to video in 1994.[42] Combining the spatial and the chromatic properties of early vision, Mulligan[43] took advantage of the low spatial-frequency sensitivity of chromatic channels to hide high spatial-frequency halftoning artifacts.

Low-level perceptual models and techniques have also been applied to the problem of target detection in medical images (e.g., Ref. 44) and to the problem of embedding digital watermarks in electronic images (Refs. 45 and 46).

Early Color Vision and Its Applications

The trichromacy of the human visual system has been studied for over a hundred years, but we are just in the infancy in applying knowledge of early color vision to electronic imaging systems. From an engineering perspective, the CIE 1931 model, which represents human color-matching as a linear combination of three color filters, has been the most influential model of human color vision. This work allows the determination of whether two patches will have matching colors, when viewed under a constant illuminant. The CIE 1931 color space, however, is not perceptually uniform. That is, equal differences in chromaticity do not correspond to equal perceived differences. To remedy this, various transformations of this space have been introduced. Although CIE $L^*a^*b^*$ and CIE $L^*u^*v^*$ are commonly used as perceptually uniform spaces, they still depart significantly from this objective. By adding a nonlinear gain control at the receptor level, Guth's ATD model[47,48] provided a more perceptually uniform space and could model a wide range of perceptual phenomena. Adding a spatial component to a simplified version of Guth's model, Granger[49] demonstrated how this approach could be used to significantly increase the perceived similarity of original and displayed images. The observation that every pixel in an image provides input both to mechanisms sensitive to color variations and to mechanisms sensitive to spatial variations has provided other important contributions. For example, Uriegas[50,51] used the multiplexing of color and spatial information by cortical neurons to develop a novel color image compression scheme.

Understanding how to represent color in electronic imaging systems is a very complicated problem, since different devices (e.g., printers, CRT or TFT/LCD displays, film) have different mechanisms for generating color, and produce different ranges, or gamuts, of colors. Several approaches have been explored for producing colors on one device that have the same appearance on another. Engineering research in this field goes under the name of *device independent color*, and has recently been energized by the need for accurate color rendering over the Internet. (See Ref. 52.)

Limitations of Early Vision Models for Electronic Imaging

The goal of the early vision models is to describe the phenomena of visual perception in terms of simple mechanisms operating at threshold. Pursuing this Ockham's razor approach has motivated the introduction of masking models and nonlinear summation models, and has allowed us to extend these simple models to describe the detection and recognition of higher-level patterns, such as textures and multiple-sinewave plaids. These models, however, eventually run out of steam in their ability to account for the perception of higher-level shapes and patterns. For example, the perception of a simple dot cannot be successfully modeled in terms of the response of a bank of linear spatial-frequency filters.

In image quality, early vision approaches consider an image as a collection of picture elements. They measure and model the perceived fidelity of an image based on the degree to which the pixels, or some transformation of the pixels, have changed in their spatial, temporal, and color properties. But what if two images have identical perceived image fidelity, but one has a lot of blur and little blockiness while the other has little blur and a lot of blockiness? Are they equivalent? Also, since it is not always possible to conceal these artifacts, it is important to understand how their effects combine and interact in order to minimize their objectionable and annoying effects. This has led to the development of new suprathreshold scaling methods for evaluating the perceived quality of images with multiple suprathreshold artifacts (e.g., Refs. 53 and 54), and has led to the development of new dynamic techniques to study how the annoyance of an artifact depends on its temporal position in a video sequence (Ref. 55).

In color vision, a key problem for electronic imaging is that simply capturing and reproducing the physical color of individual color pixels and patches in an image is not sufficient to describe

the perceived colors in the image. Hunt,[56] for example, has shown that surrounding colors affect color appearance. Furthermore, as McCann[57] has demonstrated using spatially complex stimuli, the perception of an image depends, not simply on the local luminance and color values, and not simply on nearby luminance and color values, but on a more global consideration of the image and its geometry.

24.3 HIGHER-LEVEL APPROACHES: THE ANALYSIS OF IMAGE FEATURES

Higher-level approaches in vision are dedicated to understanding the mechanisms for perceiving more complex features such as dots, plaids, textures, and faces. One approach is to build up from early spatial-frequency models by positing nonlinear mechanisms that are sensitive to two-dimensional spatial variations, such as t-junctions (e.g., Ref. 58). Interesting new research by Webster and his colleagues[59] identifies higher-level perceptual mechanisms tuned to more complex visual relationships. Using the same types of visual adaptation techniques commonly used in early vision experiments to identify spatial, temporal, or color channel properties, they have demonstrated adaptation to complex visual stimuli, including, for example, the adaptation to complex facial distortions and complex color distributions.

Another interesting approach to understanding the fundamental building blocks of human vision is to consider the physical environment in which it has evolved, with the idea in mind that the statistics of the natural world must somehow have guided, or put constraints on, its development. This concept, originally introduced by Field,[60,61] has led to extensive measurements of the spatial and temporal characteristics of the world's scenes, and to an exploration of the statistics of the world's illuminants and reflective surfaces. One of the major findings in this field is that the spatial amplitude spectra of natural scenes falls off as $f^{-1.1}$. More recently, Field et al.[62] have related this function to the sparseness of spatial-frequency mechanisms in human vision. This low-level description of the global frequency content in natural scenes has been tied to higher-level perception by Rogowitz and Voss.[63] They showed that when the slope of the fall-off in the amplitude spectrum is in a certain range (corresponding to a fractal dimension of from 1.2 to 1.4), observers see nameable shapes in images like clouds. This approach has also been applied to understanding how the statistics of illuminants and surfaces in the world constrains the spectral sensitivities of visual mechanisms (Ref. 64), thereby influencing the mechanisms of color constancy (see also Refs. 65 and 66).

The attention literature provides another path for studying image features by asking which features in an image or scene naturally attract attention and structure perception. This approach is epitomized by Triesman's work on "preattentive" vision[67] and by Julesz' exploration of "textons."[68,69] Their work has had a very large impact in the field of electronic imaging by focusing attention on the immediacy with which certain features in the world, or in an image, are processed. Their work both identifies image characteristics that attract visual attention and guide visual search, and also provides a paradigm for studying the visual salience of image features. An important debate in this area is whether features are defined bottom up—that is, generated by successive organizations of low-level elements such as edges, as suggested by Marr[70]—or whether features are perceived immediately, driven by top-down processes, as argued by Stark.[71]

This section explores the application of feature perception and extraction in a wide range of electronic imaging applications, and examines how the demands of these new electronic tasks motivate research in perception. One important emerging area is the incorporation of perceptual attention or "importance" in image compression and coding. The idea here is that if we could identify those aspects of an image that attracted attention, we could encode this image using higher resolution for the areas of importance and save bandwidth in the remaining areas. Another important area is image analysis, where knowing which features are perceptually salient could be used to index, manipulate, analyze, compare, or describe an image. An important emerging application in this area is digital libraries, where the goal is to find objects in a database that have certain features, or that are similar to a target object. Another relevant application area is visualization, where the goal is to develop methods for visually representing structures and features in the data.

Attention and Region of Interest

A new idea in electronic imaging is to analyze images to identify their "regions of interest," features that draw our attention and have a special saliency for interpretation. If we could algorithmically decompose an image into its salient features, we could develop compression schemes that would, for example, compress more heavily those regions that did not include perceptual features, and devote extra bandwidth to regions of interest. Several attempts have been made to algorithmically identify regions of interest. For example, Leray et al.[72] developed a neural network model that incorporates both the response of low-level visual mechanisms and an attentional mechanism that differentially encodes areas of interest in the visual image, and used this to develop a compression scheme.

Stelmach and Tam[73] measured the eye movements of people examining video sequences and concluded that there wasn't enough consistency across users to motivate developing a compression scheme for TV broadcast based on user eye movements. Geissler and Perry,[74] however, demonstrated that by guiding a user's eye movements to a succession of target locations, and only rendering the image at high resolution at these "foveated" regions, the entire image appeared to have full resolution. If the system knew in advance where the eye movements would be directed, it could adjust the resolution at those locations, on the fly, thus saving bandwidth. Finding those perceptually relevant features, however, is a very difficult problem. Yarbus[75] showed that there is not a single stereotypic way that an image is viewed; the way the user's saccades are placed on the picture depends on the task. For example, if the goal is to identify how many people there are in the picture, the set of eye movements differs from those where the goal is to examine what the people are wearing.

A most important voice in this discussion is that of Stark.[76,77] Noton and Stark's classic papers[71,78] set the modern stage for measuring the eye movement paths, or "scanpaths," of human vision. They used this methodology to explore the role of particular visual stimuli in driving attention (bottom up) versus the role of higher-level hypothesis-testing and scene checking goals (top down) in driving the pattern of visual activity. Stark and his colleagues have contributed both to our basic understanding of the processes that drive these scanpaths, and to integrating this knowledge into the development of better electronic imaging systems. Recent evidence for top-down processing in eye movements has been obtained using an eye tracking device that can be worn while an observer moves about in the world (Ref. 79). As observers perform a variety of everyday tasks, they perform what the authors call "planful" eye movements, eye movements that occur in the middle of a task, in anticipation of the subject's interaction with an object in an upcoming task.

Image Features, Similarity, and Digital Libraries Applications

In digital libraries applications, the goal is to organize and retrieve information from a database of images, videos, graphical objects, music, and sounds. In these applications, the better these objects are indexed and organized, the more easily they can be searched. A key problem, therefore, is to identify features and attributes of importance, and to provide methods for indexing and searching for objects based on these features. Understanding which features are meaningful, or what makes objects similar, however, is a difficult problem. Methods from signal processing and computer vision can be used to algorithmically segment images and detect features. Since these databases are being designed for humans to search and navigate, it is important to understand which features are salient and meaningful to human observers, how they are extracted from complex objects, and how object features are used to judge image and object similarity. Therefore, these algorithms often incorporate heuristics gleaned from perceptual experiments regarding human color, shape, and pattern perception. For example, the work by Petkovic and his colleagues[80] includes operators that extract information about color, shape, texture, and composition. More recently, knowledge about human perception and cognition has been incorporated more explicitly. For example, Frese et al.[81] developed criteria for image similarity based on a multiscale model of the human visual system, and used a psychophysical model to weight the parameters of their model. Another method for explicitly incorporating human perception has been to study how humans explicitly judge image similarity and use

this knowledge to build better search algorithms. Rogowitz et al.,[82] for example, asked observers to judge the similarity of a large collection of images and used a multidimensional scaling technique to identify the dimensions along which natural objects were organized perceptually. Mojsilović et al.[83] asked observers to judge the similarity of textured designs, then built a texture retrieval system based on the perceptual results.

In this expanding area, research opportunities include the analysis of human feature perception, the operationalization of these behaviors into algorithms, and the incorporation of these algorithms into digital library systems. This includes the development of perceptual criteria for image retrieval, the creation of perceptual image similarity metrics, methods for specifying perceptual metadata for characterizing these objects, and perceptual cues for navigating through large multimedia databases. An important emerging opportunity lies in extending these methods to accommodate more complex multidimensional objects, such as three-dimensional objects and auditory patterns.

Visualization

One consequence of the expanding computer age is the creation of terabytes and terabytes of data, and an interest in taking advantage of these data for scientific, medical, and business purposes. These can be data from satellite sensors, medical diagnostic sensors, business applications, simulations, or experiments, and these data come in many different varieties and forms. The goal of visualization is to create visual representations of these data that make it easier for people to see patterns and relationships, identify trends, develop hypotheses, and gain understanding. To do so, the data are mapped onto visual (and sometimes auditory) dimensions, producing maps, bar charts, sonograms, statistical plots, etc. A key perceptual issue in this area is how to map data onto visual dimensions in a way that preserves the structure in the data without creating visual artifacts. Another key perceptual issue is how to map the data onto visual dimensions in a way that takes advantage of the natural feature extraction and pattern-identification capabilities of the human visual system. For example, how can color and texture be used to draw attention to a particular range of data values, or a departure from a model's predictions? (See Ref. 84 for an introduction to these ideas.)

One important theme in this research is the return to Gestalt principles of organization for inspiration about the analysis of complex visual information. The Gestalt psychologists identified principles by which objects in the visual world are organized perceptually. For example, objects near each other (proximity) or similar to each other (similarity) appear to belong together. If these fundamental principles could be operationalized, or if systems could be built that take advantage of these basic rules of organization, it could be of great practical importance. Some recent papers in this area include Kubovy's[85] theoretical and experimental studies, experiments by Hon et al.[86] on the interpolation and segmentation of sampled contours, and an interactive data visualization system based on Gestalt principles of perceptual organization (Ref. 87).

User Interface Design

As more and more information becomes available, and computer workstations and web browsers support more interactivity and more color, we move into a new era in interface design. With so many choices available, we now have the luxury to ask how best to use color, geometry, and texture to represent information. A key vision paper in this area has been Boynton's paper[88] on "the eleven colors which are almost never confused." Instead of measuring color discriminability, Boynton asked people to sort colors, to get at a higher-level color representation scheme, and found that the responses clustered in 11 categories, each organized by a common color name. That is, although in side-by-side comparison, people can discriminate millions of colors, when the task is to categorize colors, the number of perceptually distinguishable color categories is very small. In a related experiment, Derefeldt and Swartling[89] tried to create as many distinct colors as possible for a digital map application; they were only able to identify 30. More recently, Yendrikovskij[90] extracted thousands of images from the web and used a *K*-means clustering algorithm to group the colors of the pixels. He also found a small

number of distinct color categories. This suggests that the colors of the natural world group into a small number of categories that correspond to a small set of nameable colors. This result is important for many applications that involve selecting colors to represent semantic entities, such as using colors to represent different types of tumors in a medical visualization. It is also important for image compression or digital libraries, suggesting that the colors of an image can be encoded using a minimal number of color categories. Several groups have begun developing user-interface design tools that incorporate perceptually based intelligence, guiding the designer in choices of colors, fonts, and layouts based on knowledge about color discriminability, color deficiency, color communication, and legibility. Some examples include Hedin and Derefeldt[91] and Rogowitz et al.[92]

24.4 VERY HIGH-LEVEL APPROACHES: THE REPRESENTATION OF AESTHETIC AND EMOTIONAL CHARACTERISTICS

The higher-level applications discussed above, such as visualization and digital libraries, push the envelope in electronic imaging technology. They drive developers to address the content of the data, not just the pixel representation. As the technology improves and becomes more pervasive, new application areas are drawn into the web, including applications that use visual media to convey artistic and emotional meaning. For these applications, it is not just the faithfulness of the representation, or its perceptual features, that are of concern, but also its naturalness, colorfulness, composition, and appeal. This may seem an enormous leap, until we realize how natural it is to think of the artistic and emotional aspects of photographic imaging. Interest in using electronic media to convey artistic and emotional goals may just reflect the maturation of the electronic imaging field.

Image Quality

Although the world "quality" itself connotes a certain subjectivity, the major focus of the research in image quality, discussed so far, has been aimed at developing objective, algorithmic methods for characterizing the judgments of human observers. The research in Japan on high-definition TV has played a major role in shaping a more subjective approach to image quality. This approach is based on the observation that the larger format TV, because it stimulates a greater area of the visual field, produces images which appear not only more saturated, but also more lively, realistic, vivid, natural, and compelling (Ref. 93). In related work on the image quality of color images, DeRidder et al.[94] found that, in some cases, observers preferred somewhat more saturated images, even when they clearly perceived them to be somewhat less natural. The observers' responses were based on aesthetic characteristics, not judgments of image fidelity.

Virtual Reality and Presence

Virtual reality is a set of technologies whose goal is to immerse the user in a visual representation. Typically, the user will wear a head-tracking device to match the scene to the user's viewpoint and stereo glasses whose two interlaced views provide a stereoscopic view. A tracked hand device may also be included so that the user can interact with this virtual environment. Although these systems do not provide adequate visual resolution or adequate temporal resolution to produce a realistic visual experience, they do give the sense of "presence," a sense of being immersed in the environment. This new environment has motivated considerable perceptual research in a diverse set of areas, including the evaluation of depth cues, the visual contributions to the sense of presence, the role of auditory cues in the creation of a realistic virtual environment, and cues for navigation. This new environment also provides an experimental apparatus for studying the effects of large-field visual patterns and the interaction of vision and audition in navigation.

Color, Art, and Emotion

Since the beginning of experimental vision science, there have been active interactions between artists and psychologists. This is not surprising since both groups are interested in the visual impression produced by physical media. As artists use new media, and experiment with new visual forms, perceptual psychologists seek to understand how visual effects are created. For example, Chevreul made fundamental contributions to color contrast by studying why certain color dyes in artistic textiles didn't appear to have the right colors. The Impressionists and the Cubists read the color vision literature of their day, and in some cases, the artist and vision scientist were the same person. For example, Seurat studied the perception of color and created color halftone paintings. Artists have continued to inspire vision scientists to this day. For example, Papathomas,[95] struck by the impressive visual depth illusions in Hughes's wall sculptures, used this as an opportunity to deepen our knowledge of how the visual system constructs the sensation of depth. Koenderink[96] used three-dimensional sculptures to study how the human observer constructs an impression of three-dimensional shape from the set of two-dimensional views, where there is an infinite number of valid reconstructions. Tyler[97] brought psychophysical testing to the issue of portrait composition, and discovered that portrait painters systematically position one of the subject's eyes directly along the central median of the painting.

Another approach in this area is to understand the artistic process in order to emulate it algorithmically. The implementation, thus, is both a test of the model and a method for generating objects of an artistic process. For example, Burton[98] explored how young children express themselves visually and kinesthetically in drawings, and Brand[99] implemented his model of shape perception by teaching a robot to sculpt. Some of these goals are esoteric, but practical applications can be found. For example, Dalton[100] broadened the dialogue on digital libraries by exploring how algorithms could search for images that are the same, except for their artistic representation.

Also, as more and more artists, fabric designers, and graphic artists exploit the advances of electronic imaging systems, the more important it becomes to give them control over the aesthetic and emotional dimensions of electronic images. The MIT Media Lab has been a major player in exploring the visual, artistic, and emotional parameters of visual stimuli. In 1993, Feldman and Bender[101] conducted an experiment where users judged the affective aspects (e.g., "energy," "expressiveness") of color pairs, demonstrating that even such seemingly vague and subjective dimensions could be studied using psychophysical techniques. They found that color energy depended on the color distance between pairs in a calibrated Munsell color space, where complementary hues, or strongly different luminances or saturations, produced greater emotional energy. These authors and their colleagues have gone on to develop emotion-based color palettes and software tools for artistic design.

24.5 CONCLUSIONS

The field of human vision and electronic imaging has developed over the last decade, evolving with technology. In the 1980s, the bandwidth available to workstations allowed only the display of green text, and in those days people interested in perceptual issues in electronic imaging studied display flicker, spatial sampling, and gray-scale/resolution trade-offs. As the technology has evolved, almost all desktop displays now provide color, and the bandwidth allows for high-resolution, 24-bit images. These displays, and the faster systems that drive them, allow the development of desktop image applications, desktop digital libraries applications, and desktop virtual reality applications. Application developers interested in art, visualization, data mining, and image analysis can now build interactive image solutions, integrating images and data from multiple sources worldwide. This rapid increase in technology enables new types of imaging solutions, solutions that allow the user to explore, manipulate, and be immersed in images; and these in turn pose new questions to researchers interested in perceptually based imaging systems.

Some of these new questions include, for example: How do we measure the image quality of virtual reality environments? How do we measure presence, and what are the factors (including interactions of multiple media) that contribute to it? How do we model the interactive visualization of

multivariate data? How do we provide environments that allow people to search through a sea of images? How do we create tools that artists and designers can use? How do we use image technology to perform remote surgery? How do we build user interfaces that sense our mood? With each advance in technology, the systems we build grow increasingly richer, and the questions we ask about human observers become more complex. In particular, they increasingly require a deeper understanding of higher levels of human perception and cognition. Low-level models of retinal and striate cortex function are the foundation, but upon this base we need to consider other dimensions of the human experience: color perception, perceptual organization, language, memory, problem solving, aesthetic appreciation, and emotional response.

As electronic imaging becomes ever more prevalent in the home and the workplace, the two-way interaction between human vision and electronic imaging technology will continue to grow in scope and importance. Research in human vision and its interactions with the other senses will continue to shape the solutions that are developed to meet the requirements of the imaging industry, which in turn will continue to motivate our understanding of the complex process of vision that is the window to the world around us.

24.6 ADDITIONAL INFORMATION ON HUMAN VISION AND ELECTRONIC IMAGING

A number of archival journals and conferences have provided a venue for dissemination and discussion of research results in the field of human vision or in the field of electronic imaging. For human vision, these include the annual meeting of the Optical Society of America, the annual meeting of the Association for Research in Vision and Ophthalmology, and the European Conference on Visual Perception (ECVP). For electronic imaging, these include the IEEE Signal Processing Society's International Conference on Image Processing, the annual meeting of the Society for Information Display (SID), and several conferences sponsored or cosponsored by the Society for Imaging Science and Technology (IS&T), especially the International Conference on Digital Printing Technologies (NIP), the Color Imaging Conference (CIC), co-sponsored with SID, the Conference on Picture and Image Processing (PICS), and several conferences that are part of the Symposium on Electronic Imaging cosponsored by the Society of Photographic and Instrumentation Engineers (SPIE) and IS&T.

The major forum for human vision *and* electronic imaging is the Conference on Human Vision and Electronic Imaging cosponsored by the International Imaging Society (IS&T) and the Society for Photographic and Imaging Engineers (SPIE).

There are a number of excellent books on various aspects of human perception and electronic imaging, including *Human Color Vision* by Kaiser and Boynton,[102] *Foundations of Vision* by Wandell,[103] *Visual Perception* by Cornsweet,[104] *Spatial Vision* by De Valois and De Valois,[105] *The Senses*, edited by Barlow and Molon,[106] *The Artful Eye*, edited by Gregory, Harris, Rose, and Heard,[107] *How the Mind Works* by Pinker,[108] *Information Visualization: Optimizing Design For Human Perception*, edited by Colin Ware,[109] *Digital Image and Human Vision*, edited by Watson,[110] *Computational Models of Visual Processing*, edited by Landy and Movshon,[111] and *Early Vision and Beyond*, edited by Papathomas et al.[112]

Finally, we cite a number of review articles and book chapters.[34,35,113]

VISUAL FACTORS ASSOCIATED WITH HEAD-MOUNTED DISPLAYS

Brian H. Tsou

Air Force Research Laboratory
Wright Patterson AFB, Ohio

Martin Shenker

Martin Shenker Optical Design, Inc.
White Plains, New York

25.1 GLOSSARY

Aniseikonia. Unequal right and left retinal image sizes. (Also see Chaps. 12 and 13.)

C, F lines. Hydrogen lines at the wavelengths of 656 and 486 nm, respectively.

D (diopter). A unit of lens power; the reciprocal of focal distance in m. (Also see Chap. 12.)

Prism diopter. A unit of angle; 100 times the tangent of the angle. (Also see Chaps. 12 and 13.)

25.2 INTRODUCTION

Some virtual reality applications require a head-mounted display (HMD). Proper implementation of a binocular and lightweight HMD is quite a challenge; many aspects of human-machine interaction must be considered when designing such complex visual interfaces. We learned that it is essential to couple the knowledge of visual psychophysics with sound human/optical engineering techniques when making HMDs. This chapter highlights some visual considerations necessary for the successful integration of a wide field-of-view HMD.

25.3 COMMON DESIGN CONSIDERATIONS AMONG ALL HMDS

A wide field-of-view HMD coupled with a gimbaled image-intensifying (see Chap. 31 of Vol. II for details) or infrared (see Chap. 33 of Vol. II for details) sensor enables helicopter pilots to fly reconnaissance, attack, or search-and-rescue missions regardless of weather conditions. Before any HMD

can be built to specifications derived from mission requirements, certain necessary display performance factors should be considered. These factors include functionality, comfort, usability, and safety. A partial list of subfactors that affect vision follows:

Functionality	Comfort	Usability	Safety
Field of view	Eye line-of-sight/focus	Eye motion box	Center-of-mass
Image quality	Alignment	Range of adjustment	Weight

Safety

An analytic approach to considering these factors has been proposed.[1] In general, factors can be weighted according to specific needs. At the same time, safety—especially in the context of a military operation—cannot be compromised.[2] The preliminary weight and center-of-mass safety requirements for helicopters[3] and jets[4] have been published.

It is extremely difficult to achieve the center-of-mass requirement. Hanging eye lenses in front of one's face necessitates tipping the center-of-mass forward. A recent survey disclosed that pilots routinely resort to using counterweights to balance the center-of-mass of popular night-vision goggles[5] in order to obtain stability and comfort, even at the expense of carrying more weight.

Light yet sturdy optics and mechanical materials have already made the HMD lighter than was previously possible. In the future, miniature flat-panel displays (see Chap. 22 in this volume, Chaps. 17 and 19 in Vol. II, and Chap. 8 in Vol. V for details) and microelectromechanical system (MEMS) technology[6] might further lessen the total head-borne weight. Previous experience[7] shows that both the field-of-view and exit pupil have a significant impact on HMD weight. Although we can calculate[1] the eye motion box [see Eq. (1)] that defines the display exit pupil requirement, we still do not have a quantitative field-of-view model for predicting its optimum value.

Usability

In order to avoid any vignetting, the display exit pupil size should match the eye motion box. The eye motion box is the sum of lateral translation of the eye and the eye pupil projection for viewing the full field of view (FOV). We assume the radius of eye rotation is 10 mm.

$$\text{Eye motion box in mm} = 2\times 10\times \sin(\text{FOV}/2) + \text{eye pupil diameter}\times\cos(\text{FOV}/2) + \text{helmet slippage} \quad (1)$$

The range of pertinent optomechanical HMD adjustments for helicopter aviators[8] is listed as minimum-maximum in millimeters in the following table:

	Interpupillary Distance	Eye to Top of Head	Eye to Back of Head
Female	53–69	107.7–141.7	152.5–190.0
Male	56–75	115.1–148.2	164.4–195.4

Comfort

Levy[9] shows that, in total darkness, the eye line-of-sight drifts, on average, about 5° down from the horizon. Figure 1 shows the geometric relationship of the visual axis to the horizon. Levy argues that the physiological position of rest of the eye orbit is downward pointing. Menozzi et al.[10] confirm that

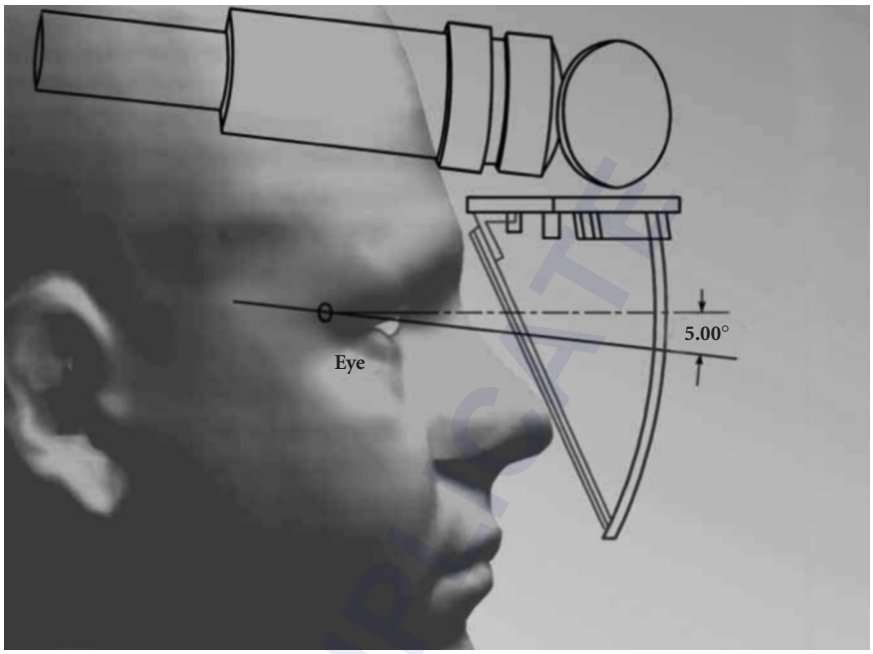

FIGURE 1 Geometric layout of the HMD showing the visual axis being 5° down from the horizon, as discussed in the text. Also shown are the schematic depictions of miniature CRT, folding mirror, beam-splitter, and spherical combiner. Its prescription is given in Table 1.

maximum comfort is in fact achieved when line of sight is pointed downward. The viewing comfort was determined by the perceived muscle exertion during gaze in a given direction for a given time. The median line of sight for the most comfortable gaze at 1 m is around 10° downward.

Our laboratory has also examined how normal ocular-motor behavior might improve the comfort of using any HMD. In a short-term wear study,[11] Gleason found that a range of eyepiece lens power of AN/AVS-6 Aviator Night Vision Imaging Systems (ANVIS) produced comparable visual acuity independent of luminance and contrast. The single best-overall eyepiece lens power produced visual acuity equal to, or better than, that of subject-adjusted eyepiece lens power, producing visual acuity within 2 percent of optimal. Infinity-focused eyepieces made visual acuity worse, reducing it by 10 percent. In his long-term wear (4 hours) study, −1.5 diopter (D) eyepiece lens power caused half of the subjects ($n = 12$) to complain of blurred or uncomfortable vision. These studies indicate that those users, who are optically corrected to a "most plus-best binocular visual acuity" endpoint (see Sec. 25.6, "Appendix"), achieve satisfactory comfort and near optimal binocular visual acuity for extended ANVIS viewing when an eyepiece lens power of approximately −0.75 D is added to the clinical refraction. This result, consistent with an earlier report by Home and Poole,[12] may extend to other binocular visual displays.

Alignment tolerances[13] are the maximum permissible angular deviation between the optical axes of a binocular device that displays separate targets to the two eyes (see Chap. 13, "Binocular Vision Factors That Influence Optical Design," in this volume for general issues). The ocular targets may be either identical or dichoptic (for stereoscopic presentation) but will be treated differently depending on whether there is a requirement for superimposition of the targets onto a direct view of the environment. If the direct view is either blocked out or too dark to see (e.g., flying at night), then it is classified as a nontransparent or closed HMD. A closed HMD resembles immersive virtual reality simulation where the real world is not needed.

Closed HMD Normal subjects have a substantial tolerance for angular deviation between the images in the two eyes for the three degrees of freedom of eye rotation: horizontal, vertical, and cyclorotational. These limits are especially of interest to optometrists and ophthalmologists. The optic axes of spectacle lenses must be aligned with the visual axes of the eyes of the wearer. Displacement of a spectacle lens from a centered position on the visual axis of the eye introduces a prismatic deviation that is entirely analogous to the misalignment of binocular devices. The American National Standards Institute (ANSI) has published ANSI 280.1–1987[14] and permits a maximum deviation of ⅔ prism diopter (23 arc minutes) horizontally and ⅓ prism diopter (11.5 arc minutes) vertically. This standard can be adopted for closed binocular HMD. These tolerance values are summarized as follows:

Recommended Tolerances for Closed HMD

	Tolerances (arc minutes)
Horizontal	±23
Vertical	±11.5
Cyclorotational	±12

Regarding the cyclorotational tolerances, both ophthalmic lenses and binocular displays can produce rotational deviation of the images about the line of fixation. ANSI spectacle standards do not exist for this alignment axis. Earlier research (dealing with distortion of stereoscopic spatial localization resulting from meridional aniseikonia at oblique axes) shows that there is considerable tolerance for cyclotorsional rotations of the images.[15] However, the effects of cyclorotational misalignment are complicated by the fact that these rotations may result in either an oculomotor (cyclofusional) or sensory (stereoscopic) response. If the eyes do not make complete compensatory cyclorotations, a declination error (rotational disparity) will exist. Declination errors result in an apparent inclination (rotation about a horizontal axis) of the display; that is, the display will appear with an inappropriate pitch orientation.

Sensitivity to declination (stereoscopic response to rotational disparity) is quite acute. Ogle[15] reports normal threshold values of ±6 arc minutes, which corresponds to an object inclination of 5° at 3 m distance. If this threshold value were adopted for the cyclotorsion tolerance measurement, it would be overly conservative, as it would deny any reflex cyclofusional capacity to compensate for misalignment errors. A 97 percent threshold[15] (±12 arc minutes) is suggested for adoption as the cyclofusional tolerance.

Transparent HMD Transparent HMD optically superimposes a second image upon the directly viewed image using a beam combiner (see Sec. 25.6, "Appendix"). The difference in alignment angles between the direct and superimposed images equals the binocular disparity between target pairs.[16] Horizontal binocular disparity is the stimulus to binocular stereoscopic vision. Consequently, sufficient lateral misalignment will lead to the perception of a separation in depth between the direct and superimposed images.

The exact nature of the sensory experience arising from lateral misalignment depends on the magnitude of the relative disparity. Although the threshold disparity for stereopsis is generally placed at about 10 arc seconds for vertical rods,[17] it can approach 2 arc seconds under optimal conditions using greater than 25 arc-minutes-long vertical line targets.[18] The normative value of threshold stereopsis in the standardized Howard-Dolman testing apparatus is 16 arc seconds. This defines 100 percent stereoacuity for clinical-legal requirements.

This extremely small stereothreshold (~2 arc seconds for optimal conditions) establishes an unpractically small tolerance for the design of displays. However, this precision is only required if the relative depths of the direct and superimposed fields need to correspond and the direct and superimposed fields are dissimilar (nonfusible). An example would be the need to superimpose a fiduciary marker over a particular location in the direct field, which is important to military operations. If this is not a requirement, the binocular disparity between the direct and superimposed fields merely needs to not exceed the range for pyknostereopsis in order to permit sensory averaging of the fields. When two

views are overlaid with small disparity separations (<20 arc minutes), they are depth averaged to form a single depth plane (called pyknostereopsis).[19,20] This sets an alignment tolerance of ±20 arc minutes (i.e., a maximum binocular disparity of 20 arc minutes). This limit is also within the disparity range required for maximum efficacy of oculomotor alignment of the eyes.[21] Because of the poor sensitivity of the human visual system to absolute disparity,[22] this amount of oculomotor misalignment will not influence the perception of absolute distances of objects in the display.

Vertical disparities do not result in local stereopsis, but they can have an effect on the overall stereoscopic orientation of objects in the binocular field. This response to vertical disparity is known as the *induced effect*. The sensitivity to vertical disparity for extended targets is similar to that of the horizontal disparity.[23] The other factor to consider when establishing vertical tolerances is the dimension of Panum's fusional area. Images falling within the Panum's area will fuse even if these images do not match exactly on the corresponding points between the two eyes. The vertical dimension of Panum's area can be as much as 2.5 times smaller than the horizontal dimension.[24]

The recommended cyclorotational tolerance is based on Ogle's[15] normal threshold value of ±6 arc minutes, as discussed in the previous section. Because reflex cyclofusional would be restricted in transparent HMD by the direct field, no relaxation for compensatory eye movements has been included in this tolerance recommendation.

In formulating the final recommendations, the range of pyknostereopsis was reduced by half to introduce a margin for individual differences. Summary recommendations for tolerance in transparent HMD are provided as follows:

Recommended Tolerances for Transparent HMD

	Tolerance (arc minutes)
Horizontal	±10
Vertical	±4
Cyclorotational	±6

Functionality

A larger field of view equates with larger optics and, hence, a heavier piece of equipment. As early as 1962, optical engineers partially overlapped the individual telescopes to achieve a wider field of view without greatly increasing weight.[25] The impact of partial overlap on image quality, however, was not fully addressed until recently.[26,27] These psychophysical studies on binocular summation, rivalry, and stereopsis support a 40° binocular overlap in the middle of the field of view as both necessary and sufficient, with a divergent configuration of the two optical axes preferred over a convergent configuration (please note the visual axes are still parallel or convergent). Quantitative flight data (eye gaze) and pilots' subjective assessment are consistent with laboratory predictions.[28]

Still, how large should the total field of view be? Everyday experience tells us that it should be as large as our visual field. On the other hand, most studies consistently show there is no significant human performance gain as the field of view extends beyond the 40° to 60° range.[29] Restricting head movements or manipulating field-of-view aspect ratio[30] does not seem to affect the performance except for the smaller field of view (from 15° to 30°). These studies suggest that (1) we are basically foviated beings,[31–33] and (2) unless compensated by large target size, our peripheral sensitivity is very poor.[34] Nevertheless, quantitative models for the useful field-of-view[35,36] requirement are urgently needed so that HMD field of view is optimized to suit each application and scenario.

Image quality is perhaps the most important parameter for the acceptance of HMD since it is the aspect most noticeable by the users. Various image quality metrics have been devised (see Chap. 1 of this volume for reviews). The fundamental limitation on image quality in any display is either the loss of resolution, or lack thereof. Historically, the poor resolution of the miniature image source has hampered HMD progress; soon, the expected higher pixel density should significantly improve perceived image quality. For example, with high-definition TV's approximate 2000 pixels, a 50° field-of-view

HMD will have 20 cy/deg resolution or a respectable 20/30. The loss of resolution in visual optics is primarily caused by the defocus and lateral chromatic smearing of an image point.[37] When the eye is centered in the exit pupil of a display, defocus is due to residual field curvature and astigmatism. As the eye is decentered (or off aperture) in the exit pupil, residual amounts of uncorrected spherical aberration and coma in the display cause additional astigmatism. Astigmatism is defined as the variation in focus as a function of orientation in the exit pupil. Recently, Mouroulis and Zhang[38] have shown that MTFa (the area under the modulation transfer function over a specified frequency range of from 5 to 24 cy/deg) gives good correlation with subjective sharpness judgment for all target orientations. There is another convenient approximation to use for image quality. Figure 2 shows plots of the variation in modulation transfer function (MTF) (see Chap. 1 of Vol. II for reviews) for a 3-mm aberration-free pupil out to a frequency of 1 arc minute per line pair (or 20/10) as its image is defocused from the best focus position. A 3-mm pupil has been chosen because the eye is generally considered to be diffraction-limited in image quality near this value; we conclude that for "each tenth of diopter defocus 1 arc minute of resolution is lost" (see Fig. 2). We arrived at the same conclusion using Greivendamp's schematic eye.[39] Greivendamp et al. showed their model correlates quite well with Snellen visual acuity. It should be noted that, for small defocus errors (<0.5 D), a real eye can see slightly better than our calculation predicts.[40] This may be attributable to the residual spherical aberration in the real eye. While this spherical aberration lowers the MTF for the exact in-focus image, it increases the depth-of-focus over which the maximum resolution is visible. Regardless, our rule of thumb is quite useful for the purpose of design evaluation.

Similarly, we approximate the residual chromatic smear as the sum of the lateral color plus the off-aperture manifestation of the residual longitudinal color by using a pair of wedges with zero deviation at a middle wavelength but a specific chromatic spread between the C and F spectral lines. The loss of MTF for a 3-mm, otherwise aberration-free exit pupil is shown in Fig. 3. It can be seen that these defects have a very significant effect on the resolution capabilities at both the high and low spatial frequencies. Therefore, a rule of thumb of "⅔ arc minute of resolution is lost for each arc minute of chromatic spread between C and F lines" is applicable.

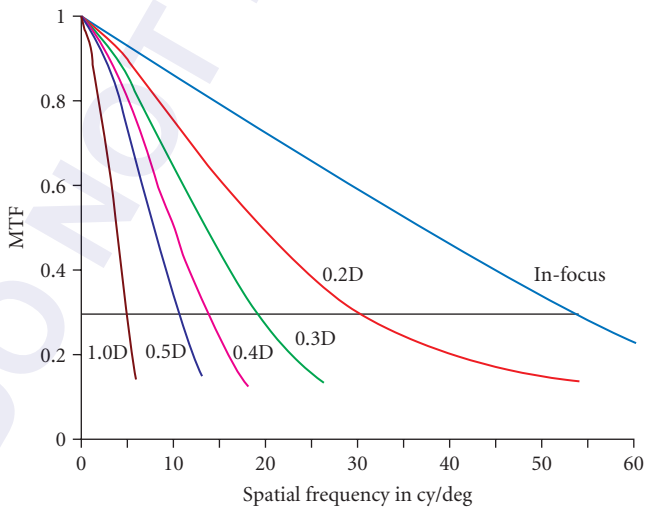

FIGURE 2 Loss of MTF in terms of resolution with defocus. The diopter values are the amount of defocus. At 30 percent modulation, the resolutions are about 1.1 arc minutes per line pair for in-focus, 2 for 0.2 D defocus, 3 for 0.3 D, 4.5 for 0.4 D, 6 for 0.5 D, and 12 for 1.0 D, respectively.

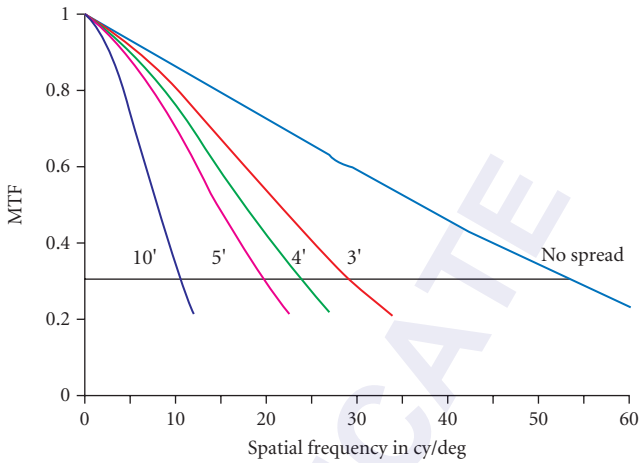

FIGURE 3 Loss of MTF with chromatic smear. The arc minute values represent smear between C and F lines. At 30 percent modulation, the resolutions are about 1.1 arc minutes per line pair for no chromatic spread, 2 for 3 arc minutes spread, 2.5 for 4′, 3.1 for 5′, and 6 for 10′, respectively.

25.4 CHARACTERIZING HMD

Traditionally, we design and evaluate the image at the focal plane of photographic lenses with a plane, aberration-free wavefront, entering the entrance pupil of the objective. This is likely the arrangement in which the photographic lens will be utilized. The design of visual optics is usually performed in a similar manner with a perfect wavefront at the exit pupil of the display (which is defined as the entrance pupil of the eye in the design process). However, the use and the real performance of such a system is best defined, from a visual point of view, by ray tracing from a perfect object and evaluating the nature of the light exiting the system. There are at least two characteristics of this light that are of interest to the display designer.

The first of these is the direction of a ray that is defined as intersecting the center of the eye pupil that is viewing a particular point on the object. This datum is used for evaluation of the system magnification (i.e., mapping and distortion). If the system is supposed to be displaying an image projected to infinity (collimated display), then the apparent direction of a point in the field of view should not change as the eyes move relative to the display. Any deviation of this ray direction across the field of view will bring about an apparent change of the display distortion as well. This variation of the display distortion is often referred to as "dynamic distortion" or "swimming." Next, if all the rays over the small (3 to 4 mm) entrance pupil of the eye are in focus, a relatively well-corrected display will demonstrate essentially diffraction-limited performance. However, if the eye cannot accommodate for the defocus, then this can cause a significant loss of modulation in the image.

Thus, our approach to evaluating the display image quality is to assess the instantaneous image quality available to the observer as he/she looks at different field angles from a particular point within the eye motion box. We define a small eye pupil at various positions in the larger exit pupil of the display; then we compute the apparent sagittal and tangential foci for various points in the field of view, as seen from this particular eye point. Both the exit pupils and the field of view are defined in terms of a clock face, as shown in Fig. 4. The displacement of the small eye pupil is in the 12:00 direction

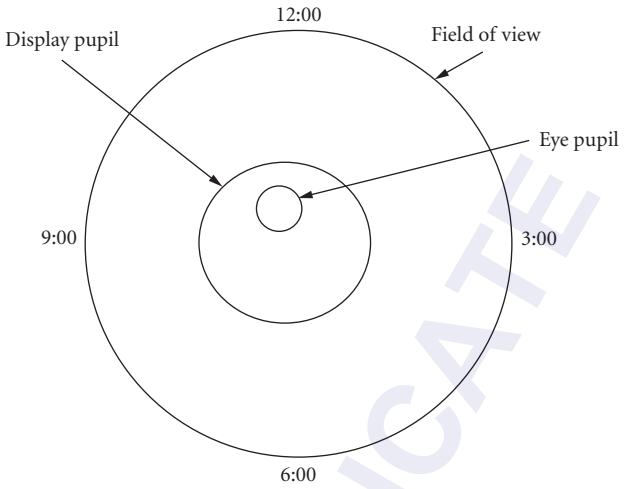

FIGURE 4 Spatial and directional relationships between display exit pupil and eye pupil with respect to field of view.

within the larger exit pupil of the display. This radial direction is the same as the direction of the off-axis point in the field of view. We make the following further definitions:

6:00 is the direction in the field-of-view opposite to the direction in which the eye pupil is displaced or off-aperture within the large exit pupil of the display.

3:00 and 9:00 are directions in the field perpendicular to the direction in which the eye pupil is off-aperture in the large exit pupil of the display. These values are identical.

We simply trace a matrix of object points on the object and calculate the tangential and sagittal foci in diopters for each of these points. We are thus assuming that the aberration variation across the 3- to 4-mm eye pupil is small and that the only residual defect is defocus. The three possibilities are as follows:

If the tangential and sagittal dioptric values are equal and the defocus is such that the observer can accommodate for this apparent distance, then the resolution potential of the display at this point in the field reverts to the diffraction limited potential of the aperture of his/her eye.

If the tangential and sagittal values are unequal but he/she can accommodate to either of the foci, then the image quality loss is defined by a focus halfway between the two foci.

If the tangential and/or sagittal values are such that the observer cannot accommodate for the defocus, then the loss of image quality is defined by this total defocus value.

In this manner, a particular optical design can be evaluated for image quality. An indication that the design is not sufficiently corrected is when focus conditions at various points in the field of view change rapidly for small displacements in the exit pupil. Our method for evaluating the potential display image quality is completely independent of their scale. It is valid for the 1.5-m focal length tilted mirrors used in the collimated displays for flight simulators, the 150- to 200-mm focal length refractive collimators used in heads-up displays, the 50- to 75-mm focal length eyepieces used in biocular magnifiers, and the 20-mm focal length erecting eyepiece systems used in HMD. However, for the HMD, the loss of image quality is likely to be the most severe. We will illustrate this method with a 50° field-of-view full-overlap binocular HMD, using only four elements to minimize weight. To conserve expense, all elements are simple spheres. The display has an overall focal length of 24.6 mm and is

dimensioned to provide a 19-mm exit pupil with a horizontal field of view of 50° provided by a 23-mm image source format. Our electronic driver bandwidth can only adequately display 1000 video lines, resulting in a resolution of slightly better than 20/60 (10 cy/deg). This resolution is deemed minimal in order to support flying nap-of-the-earth (terrain following) or contour flight.[41] The prescription is given in Table 1.

Table 2 lists the optical defocus values exhibited by this display example. A negative value indicates that the light exiting the display is convergent and corresponds to images focused beyond infinity. Objective measurement of the display system confirms the defocus table. The display focus is then set to 0.87 D (see subsection entitled "Comfort"). Table 3 lists the visual defocus values according to the

*Negative diopters indicate convergent rays or farther than where eye accommodates.
†Positive diopters indicate divergent rays or closer than where eye accommodates.

eye's ability to accommodate. Most observers cannot relax their accommodation beyond infinity (or > −0.87 D in our example) and thus suffer a loss in resolution corresponding to the full amount of defocus. The subjective evaluations agree with the predictions. Namely, while performance is satisfactory for the center of the field when the eye is positioned in the center of the display exit pupil, the performance falls off radically as the eye is decentered in the pupil. In addition, there is a significant falloff of performance across the field of view. We suspect the image quality would not be acceptable if the display resolution were much higher than the 20/60 used.[42]

25.5 SUMMARY

We have described various visual issues dealing with a 50° binocular HMD breadboard. Both optical axes point downward by 5° and converge and intersect at a point about 1 m in front. Preliminary evaluation of the breadboard in the laboratory has not revealed any problems with respect to usability and comfort. However, the optics are undercorrected for both spherical aberration and astigmatism as shown by the defocus calculations. The astigmatism causes the variation of focus across the field of view when viewed from the center of the eye motion box. The spherical aberration causes the variation of focus when the eye pupil is decentered in the eye motion box. We found that using the defocus to predict display resolution is both valuable and intuitive in assessing HMD image quality during design and initial evaluation.

25.6 APPENDIX

There has been a concern[43] with respect to the transparent HMD and heads-up display that virtual images appear closer than the directly viewed image, inducing an undesired accommodation of the viewer. After investigating the issue, we did not find any support for misaccommodation. First, let us define the following terms:

Refractive error is defined by the eye's far point, which is the farthest distance to which the eye can focus. Eye focus is the dioptric distance at which the eye is focused, making objects at that distance optically conjugate with the eye's retina. Therefore, eye focus equals the dioptric sum of refractive error plus accommodation.

Accommodation is the eye's ability to focus closer than the far point by increasing its optical power through the action of the ciliary muscles. The hyperope's far point is beyond optical infinity, and therefore negative in value. Hyperopes must accommodate to focus to optical infinity. Myopia has a positive refractive error—that is, the eye is optically too strong to focus on distance objects. Do not confuse this with the clinical convention of associating myopia with the negative lens power of the correcting spectacles.

How is refractive error[44] determined? Optometers and clinical refraction optometers (e.g., infrared,[45–48] laser,[49,50] and stigmatoscopy[51]) measure eye focus, not accommodation. Optometers cannot distinguish between nonaccommodating 1-D myopes, emmetropes accommodating 1 D, or 1-D hyperopes accommodating 2 D since all are focused 1 m away. Optometers approximate refractive error (i.e., far point) only when accommodation is minimized under cycloplegia. Cycloplegia is the pharmaceutically induced paralysis of accommodation.

Thus, clinical refraction does not determine refractive error in the strict sense. Clinical refraction determines the most-plus lens power resulting in best binocular visual acuity based on a subjective blur criterion (see Chap. 12, "Assessment of Refraction and Refractive Errors and Their Influence on Optical Design" and Chap. 13, "Binocular Vision Factors That Influence Optical Design," in this volume for general issues). Therefore, its theoretical endpoint places the distal end of the eye's depth-of-field (see Chap. 1, "Optics of the Eye," in this volume for reviews) at the eye chart, and does not place eye focus at optical infinity. Since eye charts are usually located about 6 m (+0.17 D) away and the eye's depth-of-field is +0.43 D for detecting blur of small sharp-edged high-contrast targets,[52] the clinical emmetrope is about +0.6 D myopic. This concept is supported by Morgan's[53] report that subjective tests tend to overcorrect by +0.75 D, and Bannon et al.'s[51] report that apparent emmetropes focused from +0.5 to +0.75 D closer than a fixated distant target. The presumed benefit of a myopic endpoint is that the eye's entire depth of field is maximized in real space when distant objects are viewed.

There are two potential causes for misaccommodation with transparent HMD: near-awareness of the virtual image and accommodative trap by the transparent combiner. While proximal accommodation would be the result of the former, the latter may be related to the Mandelbaum's phenomenon. However, Jones[54] found that unless the exit pupil is abnormally constrained (<3 mm), proximal accommodation does not affect the accommodative accuracy for targets in virtual image displays. Therefore, those deleterious proximal effects in virtual image displays may be avoided by utilization of an exit pupil in binocular HMD sufficiently large to encompass a natural pupil (e.g., display exit pupil matches eye motion box).

Contrary to accepted opinion, Gleason[55] found that Mandelbaum's phenomenon is not caused by accommodative capture. Almost fifty years ago, Mandelbaum[56] reported that distant scenery appears blurred when viewed through a window screen. The blur subsided with side-to-side head motion and returned after a delay when head motion ceased. These collective observations are called Mandelbaum's phenomenon. Mandelbaum hypothesized that the eye reflexively focused on the intervening screen instead of the desired distant scenery. Indeed, the assumed disruption of voluntary accommodation by intervening objects is now called the Mandelbaum effect.[57] Gleason investigated Mandelbaum's phenomenon using objective and continuous measurements of accommodation. In each trial, subjects looked directly at the distant E and were instructed to keep the E as clear as possible. After 7 s, a mesh screen was placed in the line of sight at the distance of either causing the greatest Mandelbaum phenomenon or at 40 cm in front. The 40-cm distance was near the subjects' dark focus. At 15 s, subjects were instructed to focus on the screen. At 23 s, subjects were instructed to refocus on the distant E. After the trial, the experimenter shook the screen side to side to verify that Mandelbaum's phenomenon was seen. Subjects were then questioned about what they saw during the trial. After each maximum Mandelbaum's phenomenon trial, subjects reported the distant letter blurred within 1 s of screen interjection; the letter remained blurred until the experimenter shook the screen at trial's end. These observations indicate that Mandelbaum's

phenomenon occurred during the trial. Mandelbaum's phenomenon was weak or nonexistent in 40-cm trials.

A narrow range of screen distances (0.7 to 0.9 D) produced maximum Mandelbaum's phenomenon. These results nearly match Mandelbaum's report of from 0.6 to 1.1 D. The screen distance of maximum Mandelbaum's phenomenon was at 0.8 D. At this distance, the screen strands subtended 0.8 arc minute and the nominal screen gap width was 5.5 arc minutes. Dark focus averaged 1.7 D, matching Leibowitz and Owens'[58,59] reports of 1.7 and 1.5 D for 124 and 220 college-age observers, respectively.

Gleason found that eye focus was essentially equal for all viewing tasks requiring fixation of the distant letter. If Mandelbaum's phenomenon were caused by the screen's capture of accommodation, then accommodation would shift eye focus toward the screen. But the eye focus is essentially unchanged before and after the introduction of the intervening screen, indicating that the screen did not influence accommodation. Eye focus shifted to the screen only after the instruction to focus on the screen. Moreover, eye focus returned to its initial level after the instruction to refocus on the distant letter. Clearly, the intervening screen did not disrupt volitional accommodation, either. Even more interesting is the fact that accommodative accuracy was not diminished by the perceptual blur as eye focus shifted from the screen back to the distant letter. In fact, it turns out that clinical emmetropia promotes Mandelbaum's phenomenon. Since clinical emmetropes are actually myopic (+0.6 D nearsighted), when they look at the mesh screen (placed at +0.8 D), the distant scenery (0.0 D) is defocused by 0.6 D, but the screen is only defocused by 0.2 D. Thus, the more blurred distant scenery may be suppressed for the benefit of the screen. This imbalance of retinal blur increases with uncorrected clinical myopia and, consequently, less time is needed to initiate Mandelbaum's phenomenon. On the other hand, an uncorrected hyperope can actually focus to the distant scenery, making the nearby screen blurrier. Now, the screen is suppressed instead of the distant scenery, precluding Mandelbaum's phenomenon. In summary, all five subjects in Gleason's study saw Mandelbaum's phenomenon without a concomitant shift in accommodation, which eliminates the misaccommodation concern over transparent HMD.

25.7 ACKNOWLEDGMENTS

The author (BT) thanks Tom Metzler, Mike Richey, Trang Bui, Luc Biberman, and Walter Hollis for the opportunities to be involved with Army HMD programs. We thank Jay Enoch, Neil Charman, and Vince Billock for their critical reviews of the manuscript. We also thank Sarah Tsou for her editorial support. Finally, we acknowledge the significant contributions by Jerry Gleason toward the advancements of HMD designs.

ABOUT THE EDITORS

Editor-in-Chief: Dr. Michael Bass is professor emeritus at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

Associate Editors:
Dr. Casimer M. DeCusatis is a distinguished engineer and technical executive with IBM Corporation, Poughkeepsie, New York.

Dr. Jay M. Enoch is dean emeritus and professor at the School of Optometry at the University of California, Berkeley.

Dr. Vasudevan Lakshminarayanan is professor of Optometry, Physics, and Electrical Engineering at the University of Waterloo, Ontario, Canada.

Dr. Guifang Li is a professor at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

Dr. Carolyn MacDonald is professor and chair of physics at the University at Albany, SUNY, and the director of the Albany Center for X-Ray Optics.

Dr. Virendra N. Mahajan is a distinguished scientist at The Aerospace Corporation.

Dr. Eric Van Stryland is a professor at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

COVER ILLUSTRATIONS

Left: Photograph of a femtosecond optical parametric oscillator pumped in the blue by the second harmonic of a Ti:sapphire laser and operating in the orange. The oscillator can deliver femtosecond pulses across the entire visible range from the blue-green to yellow-red by simple rotation of the nonlinear crystal. (*Courtesy of Radiantis, S. L., Barcelona, Spain.*) See Chapter 19.

Middle: Photograph of a thin-film-based sculpture showing the beautiful colors of thin films seen in reflection and transmission. The variety of properties one may achieve with optical thin films is demonstrated in this photo by the different colors of reflected and transmitted light seen as a result of different coating design and angle of incidence. See Chapter 7.

Right: This is an optical micrograph of the end face of a hollow core photonic crystal fiber with super continuum white light launched at the far end. It shows the separation of colors according to the lifetimes of Mie resonances in the hollow channels. This illustrates nonlinear optical phenomena as discussed in several chapters of this volume, but also uses fibers as discussed in Chapter 11 of Vol. V.

EDITORS' PREFACE

The third edition of the *Handbook of Optics* is designed to pull together the dramatic developments in both the basic and applied aspects of the field while retaining the archival, reference book value of a handbook. This means that it is much more extensive than either the first edition, published in 1978, or the second edition, with Volumes I and II appearing in 1995 and Volumes III and IV in 2001. To cover the greatly expanded field of optics, the *Handbook* now appears in five volumes. Over 100 authors or author teams have contributed to this work.

Volume I is devoted to the fundamentals, components, and instruments that make optics possible. Volume II contains chapters on design, fabrication, testing, sources of light, detection, and a new section devoted to radiometry and photometry. Volume III concerns vision optics only and is printed entirely in color. In Volume IV there are chapters on the optical properties of materials, nonlinear, quantum and molecular optics. Volume V has extensive sections on fiber optics and x ray and neutron optics, along with shorter sections on measurements, modulators, and atmospheric optical properties and turbulence. Several pages of color inserts are provided where appropriate to aid the reader. A purchaser of the print version of any volume of the *Handbook* will be able to download a digital version containing all of the material in that volume in PDF format to one computer (see download instructions on bound-in card). The combined index for all five volumes can be downloaded from www.HandbookofOpticsOnline.com.

It is possible by careful selection of what and how to present that the third edition of the *Handbook* could serve as a text for a comprehensive course in optics. In addition, students who take such a course would have the *Handbook* as a career-long reference.

Topics were selected by the editors so that the *Handbook* could be a desktop (bookshelf) general reference for the parts of optics that had matured enough to warrant archival presentation. New chapters were included on topics that had reached this stage since the second edition, and existing chapters from the second edition were updated where necessary to provide this compendium. In selecting subjects to include, we also had to select which subjects to leave out. The criteria we applied were: (1) was it a specific application of optics rather than a core science or technology and (2) was it a subject in which the role of optics was peripheral to the central issue addressed. Thus, such topics as medical optics, laser surgery, and laser materials processing were not included. While applications of optics are mentioned in the chapters there is no space in the *Handbook* to include separate chapters devoted to all of the myriad uses of optics in today's world. If we had, the third edition would be much longer than it is and much of it would soon be outdated. We designed the third edition of the *Handbook of Optics* so that it concentrates on the principles of optics that make applications possible.

Authors were asked to try to achieve the dual purpose of preparing a chapter that was a worthwhile reference for someone working in the field and that could be used as a starting point to become acquainted with that aspect of optics. They did that and we thank them for the outstanding results seen throughout the *Handbook*. We also thank Mr. Taisuke Soda of McGraw-Hill for his help in putting this complex project together and Mr. Alan Tourtlotte and Ms. Susannah Lehman of the Optical Society of America for logistical help that made this effort possible.

We dedicate the third edition of the *Handbook of Optics* to all of the OSA volunteers who, since OSA's founding in 1916, give their time and energy to promoting the generation, application, archiving, and worldwide dissemination of knowledge in optics and photonics.

PREFACE TO VOLUME IV

Volume IV is a compendium of articles on properties (Chapters 1 to 9), nonlinear optics (Chapters 10 to 19), and quantum and molecular optics (Chapters 20 to 23). As with the rest of the *Handbook*, articles were chosen for their archival nature. Clearly, optical properties of materials fit into the archival category well. This volume devotes a large number of pages to explain and describe the optical properties of water, crystals and glasses, metals, semiconductors, solids in general, thin films and coatings including optical blacks, and photonic bandgap materials. These articles have been updated to include new materials and understanding developed since the previous edition including, among other things, advances in thin-film materials. Nonlinear optics is a mature field, but with many relatively new applications, much of them driven by advances in optical materials. Areas covered here are frequency conversion via second-order nonlinearities including optical parametric oscillators, third-order nonlinearities of two-photon absorption and nonlinear refraction, as well as stimulated Raman and Brillouin scattering, photorefractive materials and devices, coherent optical transients, electromagnetically induced transparency, optical limiting, and laser-induced damage. Nonlinear optical processes for ultrashort pulses is included here and has been a major part of the revolution in sources for obtaining laser pulses now down to attoseconds; however, other chapters on these ultrashort pulses are included in Volume II. Clearly, advances in fiber optic telecommunications have been greatly impacted by nonlinear optics, thus much work in this field is included in the fiber optics chapters in Volume V. The new chapter on laser-induced damage is a much needed addition to the *Handbook* covering a problem from the earliest days of the laser. Chapters on quantum optics in general cover some more modern aspects of optics that have become archival: laser cooling and trapping, where multiple Nobel prizes have recently been awarded; high-field physics that result from the availability of the extreme irradiance produced by lasers; slow light, topics related to being able to slow and even stop light propagation in materials; and correlated states or quantum entanglement, the unusual behavior of quantum systems where optics has played a pivotal role in its understanding as well as some interesting applications in secure communication/cryptography. The chapter on the quantum theory of lasers is, however, included in Volume II. We thank all of the many authors who gave their input to this volume of the *Handbook of Optics*.

Guifang Li and Eric Van Stryland

GLOSSARY AND FUNDAMENTAL CONSTANTS

Introduction

This glossary of the terms used in the *Handbook* represents to a large extent the language of optics. The symbols are representations of numbers, variables, and concepts. Although the basic list was compiled by the author of this section, all the editors have contributed and agreed to this set of symbols and definitions. Every attempt has been made to use the same symbols for the same concepts throughout the entire *Handbook*, although there are exceptions. Some symbols seem to be used for many concepts. The symbol α is a prime example, as it is used for absorptivity, absorption coefficient, coefficient of linear thermal expansion, and more. Although we have tried to limit this kind of redundancy, we have also bowed deeply to custom.

Units

The abbreviations for the most common units are given first. They are consistent with most of the established lists of symbols, such as given by the International Standards Organization ISO[1] and the International Union of Pure and Applied Physics, IUPAP.[2]

Prefixes

Similarly, a list of the numerical prefixes[1] that are most frequently used is given, along with both the common names (where they exist) and the multiples of ten that they represent.

Fundamental Constants

The values of the fundamental constants[3] are listed following the sections on SI units.

Symbols

The most commonly used symbols are then given. Most chapters of the *Handbook* also have a glossary of the terms and symbols specific to them for the convenience of the reader. In the following list, the symbol is given, its meaning is next, and the most customary unit of measure for the quantity is presented in brackets. A bracket with a dash in it indicates that the quantity is unitless. Note that there is a difference between units and dimensions. An angle has units of degrees or radians and a solid angle square degrees or steradians, but both are pure ratios and are dimensionless. The unit symbols as recommended in the SI system are used, but decimal multiples of some of the dimensions are sometimes given. The symbols chosen, with some cited exceptions, are also those of the first two references.

RATIONALE FOR SOME DISPUTED SYMBOLS

The choice of symbols is a personal decision, but commonality improves communication. This section explains why the editors have chosen the preferred symbols for the *Handbook*. We hope that this will encourage more agreement.

Fundamental Constants

It is encouraging that there is almost universal agreement for the symbols for the fundamental constants. We have taken one small exception by adding a subscript B to the k for Boltzmann's constant.

Mathematics

We have chosen i as the imaginary almost arbitrarily. IUPAP lists both i and j, while ISO does not report on these.

Spectral Variables

These include expressions for the wavelength λ, frequency ν, wave number σ, ω for circular or radian frequency, k for circular or radian wave number and dimensionless frequency x. Although some use f for frequency, it can be easily confused with electronic or spatial frequency. Some use $\tilde{\nu}$ for wave number, but, because of typography problems and agreement with ISO and IUPAP, we have chosen σ; it should not be confused with the Stefan-Boltzmann constant. For spatial frequencies we have chosen ξ and η, although f_x and f_y are sometimes used. ISO and IUPAP do not report on these.

Radiometry

Radiometric terms are contentious. The most recent set of recommendations by ISO and IUPAP are L for radiance [$Wcm^{-2}sr^{-1}$], M for radiant emittance or exitance [Wcm^{-2}], E for irradiance or incidance [Wcm^{-2}], and I for intensity [Wsr^{-2}]. The previous terms, W, H, N, and J, respectively, are still in many texts, notably Smith[4] and Lloyd[5] but we have used the revised set, although there are still shortcomings. We have tried to deal with the vexatious term *intensity* by using *specific intensity* when the units are $Wcm^{-2}sr^{-1}$, *field intensity* when they are Wcm^{-2}, and *radiometric intensity* when they are Wsr^{-1}.

There are two sets to terms for these radiometric quantities, which arise in part from the terms for different types of reflection, transmission, absorption, and emission. It has been proposed that the *ion* ending indicate a process, that the *ance* ending indicate a value associated with a particular sample, and that the *ivity* ending indicate a generic value for a "pure" substance. Then one also has reflectance, transmittance, absorptance, and emittance as well as reflectivity, transmissivity, absorptivity, and emissivity. There are now two different uses of the word emissivity. Thus the words *exitance, incidence,* and *sterance* were coined to be used in place of emittance, irradiance, and radiance. It is interesting that ISO uses radiance, exitance, and irradiance whereas IUPAP uses radiance excitance [*sic*], and irradiance. We have chosen to use them both, i.e., emittance, irradiance, and radiance will be followed in square brackets by exitance, incidence, and sterance (or vice versa). Individual authors will use the different endings for transmission, reflection, absorption, and emission as they see fit.

We are still troubled by the use of the symbol E for irradiance, as it is so close in meaning to electric field, but we have maintained that accepted use. The spectral concentrations of these quantities, indicated by a wavelength, wave number, or frequency subscript (e.g., L_λ) represent partial differentiations; a subscript q represents a photon quantity; and a subscript v indicates a quantity normalized to the response of the eye. Thereby, L_v is luminance, E_v illuminance, and M_v and I_v luminous emittance and luminous intensity. The symbols we have chosen are consistent with ISO and IUPAP.

The refractive index may be considered a radiometric quantity. It is generally complex and is indicated by $\tilde{n} = n - ik$. The real part is the relative refractive index and k is the extinction coefficient. These are consistent with ISO and IUPAP, but they do not address the complex index or extinction coefficient.

Optical Design

For the most part ISO and IUPAP do not address the symbols that are important in this area.

There were at least 20 different ways to indicate focal ratio; we have chosen FN as symmetrical with NA; we chose f and efl to indicate the effective focal length. Object and image distance, although given many different symbols, were finally called s_o and s_i since s is an almost universal symbol for distance. Field angles are θ and ϕ; angles that measure the slope of a ray to the optical axis are u; u can also be sin u. Wave aberrations are indicated by W_{ijk}, while third-order ray aberrations are indicated by σ_i and more mnemonic symbols.

Electromagnetic Fields

There is no argument about **E** and **H** for the electric and magnetic field strengths, Q for quantity of charge, ρ for volume charge density, σ for surface charge density, etc. There is no guidance from Refs. 1 and 2 on polarization indication. We chose $\perp$ and $\|$ rather than p and s, partly because s is sometimes also used to indicate scattered light.

There are several sets of symbols used for reflection transmission, and (sometimes) absorption, each with good logic. The versions of these quantities dealing with field amplitudes are usually specified with lower case symbols: r, t, and a. The versions dealing with power are alternately given by the uppercase symbols or the corresponding Greek symbols: R and T versus ρ and τ. We have chosen to use the Greek, mainly because these quantities are also closely associated with Kirchhoff's law that is usually stated symbolically as $\alpha = \epsilon$. The law of conservation of energy for light on a surface is also usually written as $\alpha + \rho + \tau = 1$.

Base SI Quantities

length	m	meter
time	s	second
mass	kg	kilogram
electric current	A	ampere
temperature	K	kelvin
amount of substance	mol	mole
luminous intensity	cd	candela

Derived SI Quantities

energy	J	joule
electric charge	C	coulomb
electric potential	V	volt
electric capacitance	F	farad
electric resistance	Ω	ohm
electric conductance	S	siemens
magnetic flux	Wb	weber
inductance	H	henry
pressure	Pa	pascal
magnetic flux density	T	tesla
frequency	Hz	hertz
power	W	watt
force	N	newton
angle	rad	radian
angle	sr	steradian

Prefixes

Symbol	*Name*	*Common name*	*Exponent of ten*
F	exa		18
P	peta		15
T	tera	trillion	12
G	giga	billion	9
M	mega	million	6
k	kilo	thousand	3
h	hecto	hundred	2
da	deca	ten	1
d	deci	tenth	–1
c	centi	hundredth	–2
m	milli	thousandth	–3
μ	micro	millionth	–6
n	nano	billionth	–9
p	pico	trillionth	–12
f	femto		–15
a	atto		–18

Constants

c	speed of light vacuo [299792458 ms^{-1}]
c_1	first radiation constant = $2\pi c^2h = 3.7417749 \times 10^{-16}$ [Wm^2]
c_2	second radiation constant = hc/k = 0.014838769 [mK]
e	elementary charge [$1.60217733 \times 10^{-19}$ C]
g_n	free fall constant [9.80665 ms^{-2}]
h	Planck's constant [$6.6260755 \times 10^{-34}$ Ws]
k_B	Boltzmann constant [1.380658×10^{-23} JK^{-1}]
m_e	mass of the electron [$9.1093897 \times 10^{-31}$ kg]
N_A	Avogadro constant [6.0221367×10^{23} mol^{-1}]
R_∞	Rydberg constant [10973731.534 m^{-1}]
ϵ_o	vacuum permittivity [$\mu_o^{-1}c^{-2}$]
σ	Stefan-Boltzmann constant [5.67051×10^{-8} Wm^{-1} K^{-4}]
μ_o	vacuum permeability [$4\pi \times 10^{-7}$ NA^{-2}]
μ_B	Bohr magneton [$9.2740154 \times 10^{-24}$ JT^{-1}]

General

B	magnetic induction [Wbm^{-2}, kgs^{-1} C^{-1}]
C	capacitance [f, C^2 s^2 m^{-2} kg^{-1}]
C	curvature [m^{-1}]
c	speed of light in vacuo [ms^{-1}]
c_1	first radiation constant [Wm^2]
c_2	second radiation constant [mK]
D	electric displacement [Cm^{-2}]
E	incidance [irradiance] [Wm^{-2}]
e	electronic charge [coulomb]
E_v	illuminance [lux, lmm^{-2}]
E	electrical field strength [Vm^{-1}]
E	transition energy [J]
E_g	band-gap energy [eV]
f	focal length [m]
f_c	Fermi occupation function, conduction band
f_v	Fermi occupation function, valence band

FN	focal ratio (f/number) [—]
g	gain per unit length [m^{-1}]
g_{th}	gain threshold per unit length [m^1]
$\mathbf{H}$	magnetic field strength [Am^{-1}, Cs^{-1} m^{-1}]
h	height [m]
I	irradiance (see also E) [Wm^{-2}]
I	radiant intensity [Wsr^{-1}]
I	nuclear spin quantum number [—]
I	current [A]
i	$\sqrt{-1}$
Im()	imaginary part of
J	current density [Am^{-2}]
$\mathbf{j}$	total angular momentum [kg m^2 s^{-1}]
$J_1()$	Bessel function of the first kind [—]
k	radian wave number $=2\pi/\lambda$ [rad cm^{-1}]
$\mathbf{k}$	wave vector [rad cm^{-1}]
k	extinction coefficient [—]
L	sterance [radiance] [Wm^{-2} sr^{-1}]
L_v	luminance [cdm^{-2}]
L	inductance [h, m^2 kg C^2]
L	laser cavity length
L, M, N	direction cosines [—]
M	angular magnification [—]
M	radiant exitance [radiant emittance] [Wm^{-2}]
m	linear magnification [—]
m	effective mass [kg]
MTF	modulation transfer function [—]
N	photon flux [s^{-1}]
N	carrier (number)density [m^{-3}]
n	real part of the relative refractive index [—]
$\tilde{n}$	complex index of refraction [—]
NA	numerical aperture [—]
OPD	optical path difference [m]
P	macroscopic polarization [C m^{-2}]
Re()	real part of [—]
R	resistance [Ω]
$\mathbf{r}$	position vector [m]
S	Seebeck coefficient [VK^{-1}]
s	spin quantum number [—]
s	path length [m]
S_o	object distance [m]
S_i	image distance [m]
T	temperature [K, C]
t	time [s]
t	thickness [m]
u	slope of ray with the optical axis [rad]
V	Abbe reciprocal dispersion [—]
V	voltage [V, m^2 kgs^{-2} C^{-1}]
x, y, z	rectangular coordinates [m]
Z	atomic number [—]

Greek Symbols

α	absorption coefficient [cm^{-1}]
α	(power) absorptance (absorptivity)

ϵ	dielectric coefficient (constant) [—]
ϵ	emittance (emissivity) [—]
ϵ	eccentricity [—]
ϵ_1	Re (ϵ)
ϵ_2	Im (ϵ)
τ	(power) transmittance (transmissivity) [—]
ν	radiation frequency [Hz]
ω	circular frequency = $2\pi\nu$ [rads^{-1}]
ω	plasma frequency [H_2]
λ	wavelength [μm, nm]
σ	wave number = $1/\lambda$ [cm^{-1}]
σ	Stefan Boltzmann constant [Wm^{-2}K^{-1}]
ρ	reflectance (reflectivity) [—]
θ, ϕ	angular coordinates [rad, °]
ξ, η	rectangular spatial frequencies [m^{-1}, r^{-1}]
ϕ	phase [rad, °]
ϕ	lens power [m^{-2}]
Φ	flux [W]
χ	electric susceptibility tensor [—]
Ω	solid angle [sr]

Other

$\Re$	responsivity
exp (x)	e^x
$\log_a(x)$	log to the base a of x
ln (x)	natural log of x
log (x)	standard log of x: $\log_{10}(x)$
Σ	summation
Π	product
Δ	finite difference
δx	variation in x
dx	total differential
∂x	partial derivative of x
$\delta(x)$	Dirac delta function of x
δ_{ij}	Kronecker delta

OPTICAL PROPERTIES OF WATER

Curtis D. Mobley

Applied Electromagnetics and Optics Laboratory
SRI International
Menlo Park, California

1.1 INTRODUCTION

This article discusses the optical properties of three substances: pure water, pure sea water, and natural water. Pure water (i.e., water molecules only) without any dissolved substances, ions, bubbles, or other impurities, is exceptionally difficult to produce in the laboratory. For this and other reasons, definitive direct measurements of its optical properties at visible wavelengths have not yet been made. Pure sea water—pure water plus various dissolved salts—has optical properties close to those of pure water. Neither pure water nor pure sea water ever occur in nature. Natural waters, both fresh and saline, are a witch's brew of dissolved and particulate matter. These solutes and particulates are both optically significant and highly variable in kind and concentration. Consequently, the optical properties of natural waters show large temporal and spatial variations and seldom resemble those of pure water.

The great variability of the optical properties of natural water is the bane of those who desire precise and easily tabulated data. However, it is the connections between the optical properties and the biological, chemical, and geological constituents of natural water and the physical environment that define the critical role of optics in aquatic research. For just as optics utilizes results from the biological, chemical, geological, and physical subdisciplines of limnology and oceanography, so do those subdisciplines incorporate optics. This synergism is seen in such areas as bio-optical oceanography, marine photochemistry, mixed-layer dynamics, laser bathymetry, and remote sensing of biological productivity, sediment load, or pollutants.

1.2 TERMINOLOGY, NOTATION, AND DEFINITIONS

Hydrologic optics is the quantitative study of the interactions of radiant energy with the earth's oceans, estuaries, lakes, rivers, and other water bodies. Most past and current research within hydrologic optics has been within the subfield of oceanic optics, in particular the optics of deep ocean waters, as opposed to coastal or estuarine areas. This emphasis is reflected in our uneven understanding of the optical properties of various water types.

Although the optical properties of different water bodies can vary greatly, there is an overall similarity that is quite distinct from, say, the optical properties of the atmosphere. Therefore, hydrologic and atmospheric optics have developed considerably different theoretical formulations, experimental methodologies, and instrumentation as suited to each field's specific scientific issues. Chapter 3, "Atmospheric Optics," by Dennis K. Killinger, James H. Churnside, and Laurence S. Rothman in Vol. V discusses atmospheric optics. The text by Mobley[1] gives a comprehensive treatment of hydrologic optics.

Radiative transfer theory is the framework that connects the optical properties of water with the ambient light field. A rigorous mathematical formulation of radiative transfer theory as applicable to hydrologic optics has been developed by Preisendorfer[2] and others. Preisendorfer found it convenient to divide the optical properties of water into two classes: inherent and apparent. *Inherent optical properties* (IOPs) are those properties that depend only upon the medium and therefore are independent of the ambient light field within the medium. The two fundamental IOPs are the absorption coefficient and the volume scattering function(VSF). Other IOPs include the attenuation coefficient and the single-scattering albedo. *Apparent optical properties* (AOPs) are those properties that depend both on the medium (the IOPs) and on the geometric (directional) structure of the ambient light field and that display enough regular features and stability to be useful descriptors of the water body. Commonly used AOPs are the irradiance reflectance, the average cosines, and the various attenuation functions (K functions). (All of these quantities are defined below.) The radiative transfer equation provides the connection between the IOPs and the AOPs. The physical environment of a water body—waves on its surface, the character of its bottom, the incident radiance from the sky—enters the theory via the boundary conditions necessary for solution of the radiative transfer equation.

The IOPs are easily defined but they can be exceptionally difficult to measure, especially in situ. The AOPs are generally much easier to measure, but they are difficult to interpret because of the confounding environmental effects. (A change in the sea surface wave state or in the sun's position changes the radiance distribution, and hence the AOPs, even though the IOPs are unchanged.)

Hydrologic optics employs standard radiometric concepts and terminology, although the notation adopted by the International Association for Physical Sciences of the Ocean (IAPSO[3]) differs somewhat from that used in other fields. Table 1 summarizes the terms, units, and symbols for those quantities that have proven most useful in hydrologic optics. These quantities are defined and discussed in Secs. 1.3 to 1.5. Figure 1 summarizes the relationships among the various inherent and apparent optical properties. In this figure, note the central unifying role of radiative transfer theory. Note also that the spectral absorption coefficient and the spectral volume scattering function are the fundamental inherent optical properties in the sense that all inherent optical properties are derivable from those two. Likewise, spectral radiance is the parent of all radiometric quantities and apparent optical properties. The source term S in the radiative transfer equation accounts both for true internal sources such as bioluminescence and for radiance appearing at the wavelength of interest owing to inelastic scattering from other wavelengths.

Most radiative transfer theory assumes the radiant energy to be monochromatic. In this case the associated optical properties and radiometric quantities are termed *spectral* and carry a wavelength (λ) argument or subscript [e.g., the spectral absorption coefficient $a(\lambda)$ or a_λ, or the spectral downward irradiance $E_d(\lambda)$]. Spectral radiometric quantities have the SI unit nm^{-1} added to the units shown in Table 1 [e.g., $E_d(\lambda)$ has units $\mathrm{W\ m^{-2}\ nm^{-1}}$]. Many radiometric on the other hand, respond to a fairly wide bandwidth, which complicates the comparison of data and theory.

1.3 RADIOMETRIC QUANTITIES USEFUL IN HYDROLOGIC OPTICS

Consider an amount ΔQ of radiant energy incident in a time interval Δt centered on time t, onto a surface of area ΔA located at (x, y, z). The energy arrives through a set of directions contained in a solid angle $\Delta\Omega$ about the direction (θ, ϕ) normal to the area ΔA and is produced by photons in

TABLE 1 Terms, Units, and Symbols for Quantities Commonly Used in Hydrologic Optics

Quantity	SI Units	IAPSO Recommended Symbol*	Historic Symbol† (if different)
Fundamental quantities			
Most of the fundamental quantities are not defined by IAPSO, in which case common usage is given.			
geometric depth below water surface	m	z	
polar angle of photon travel	radian or degree	θ	
wavelength of light (in vacuo)	nm	λ	
cosine of polar angle	dimensionless	$\mu \equiv \cos\theta$	
optical depth below water surface	dimensionless	τ	
azimuthal angle of photon travel	radian or degree	ϕ	
scattering angle	radian or degree	ψ, γ or Θ	θ
solid angle	sr	Ω or ω	Ω
Radiometric quantities			
The quantities as shown represent broadband measurements. For narrowband (monochromatic) measurements add the adjective "spectral" to the term, add nm^{-1} to the units, and add a wavelength index λ to the symbol [e.g., spectral radiance, L_λ or $L(\lambda)$] with units $W\ m^{-2}\ sr^{-1}\ nm^{-1}$. PAR is always broadband.

*References 1 and 3.
†Reference 2.

a wavelength interval $\Delta\lambda$ centered on wavelength λ. Then an *operational* definition of the *spectral radiance* is

$$L(x, y, z, t, \theta, \phi, \lambda) \equiv \frac{\Delta Q}{\Delta t \, \Delta A \Delta\Omega \Delta\lambda} \qquad \mathrm{J\,s^{-1}\,m^{-2}\,sr^{-1}\,nm^{-1}}$$

In practice, one takes Δt, ΔA, $\Delta\Omega$, and $\Delta\lambda$ small enough to get a useful resolution of radiance over the four parameter domains but not so small as to encounter diffraction effects or fluctuations from photon shot noise at very low light levels. Typical values are $\Delta t \sim 10^{-3}$ to 10^{3} s (depending on whether or not one wishes to average out sea surface wave effects), $\Delta A \sim 10^{-3}$ m^2, $\Delta\Omega \sim 10^{-2}$ sr, and $\Delta\lambda \sim 10$ nm. In the conceptual limit of infinitesimal parameter intervals, the spectral radiance is defined as

$$L(x, y, z, t, \theta, \phi, \lambda) \equiv \frac{\partial^4 Q}{\partial t \partial A \partial\Omega \partial\lambda} \qquad \mathrm{J\,s^{-1}\,m^{-2}\,sr^{-1}\,nm^{-1}}$$

Spectral radiance is the fundamental radiometric quantity of interest in hydrologic optics: it specifies the positional (x, y, z), temporal (t), directional (θ, ϕ) and spectral (λ) structure of the light field. For typical oceanic environments, horizontal variations (on a scale of tens to thousands of meters) of inherent and apparent optical properties are much less than variations with depth, and it is usually assumed that these properties vary only with depth z. Moreover, since the time scales for changes in IOPs or in the environment (seconds to seasons) are much greater than the time required for the radiance field to reach steady state (microseconds) after a change in IOPs or boundary conditions, time-independent radiative transfer theory is adequate for most hydrologic optics studies. The spectral radiance therefore usually is written $L(z, \theta, \phi, \lambda)$. The exceptions are applications such as time-of-flight lidar.

There are few conventions on the choice of coordinate systems. Oceanographers usually measure the depth z positive downward from $z = 0$ at the mean water surface. In radiative transfer theory it is convenient to let (θ, ϕ) denote the direction of photon travel (especially when doing Monte Carlo simulations). When displaying data it is convenient to let (θ, ϕ) represent the direction in which the instrument was pointed (the viewing direction) in order to detect photons traveling in

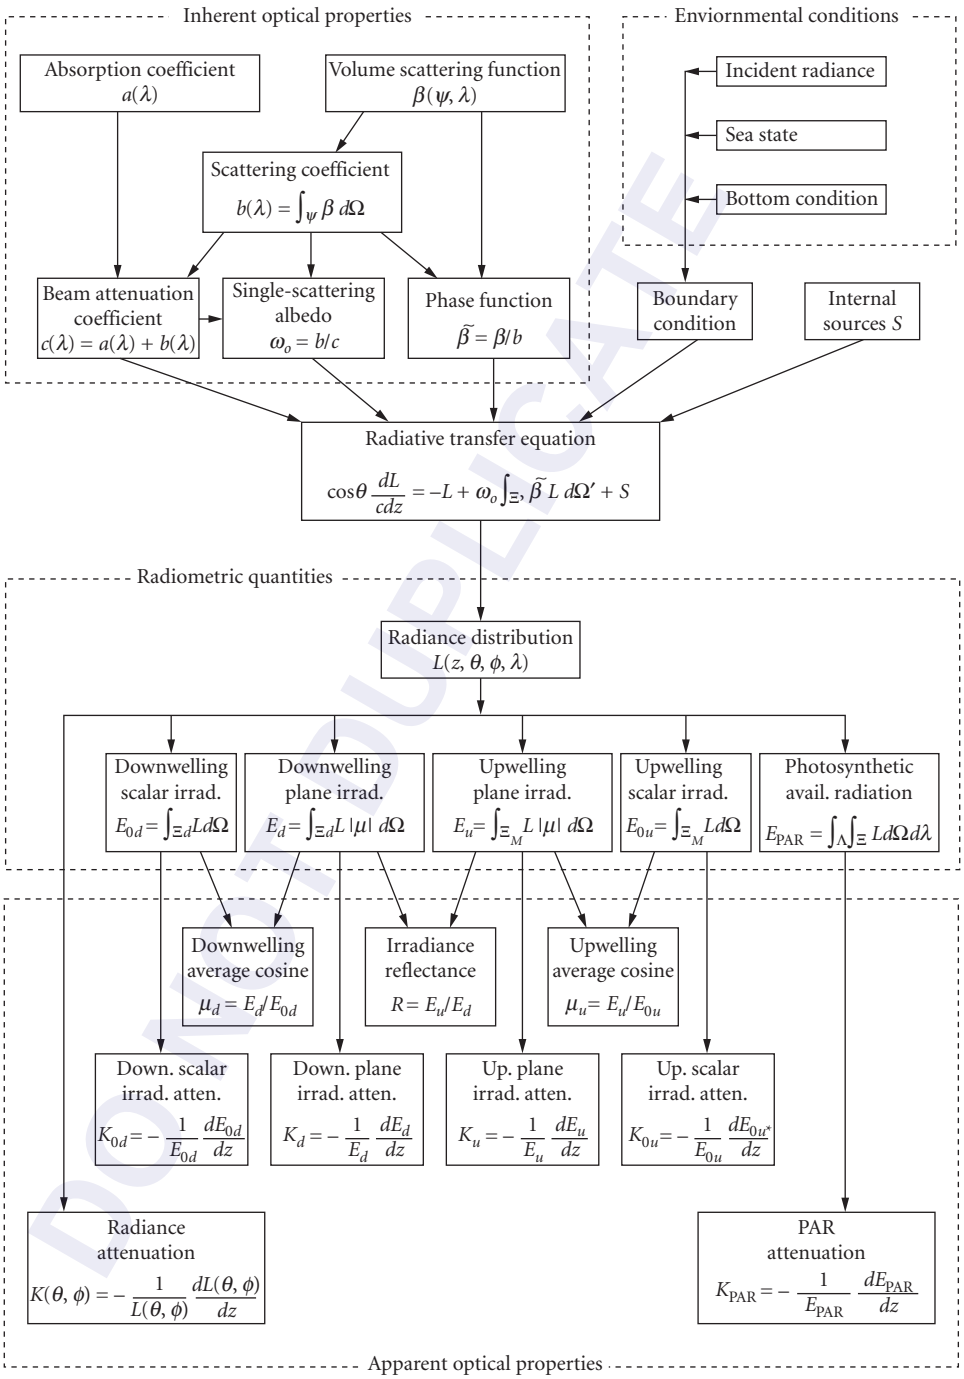

FIGURE 1 Relationships between the various quantities commonly used in hydrologic optics.

the opposite direction. Some authors measure the polar angle θ from the zenith (upward) direction, even when z is taken as positive downward; others measure θ from the $+z$ axis (nadir, or downward, direction). In the following discussion Ξ_u denotes the hemisphere of *upward* directions (i.e., the set of directions (θ, ϕ) such that $0 \le \theta \le \pi/2$ and $0 \le \phi \le 2\pi$ *if* θ is measured from the zenith direction) and Ξ_d denotes the hemisphere of *downward* directions. The element of solid angle is $d\Omega = \sin\theta\, d\theta\, d\phi$ with units of steradian. The solid angle measure of the set of directions Ξ_u or Ξ_d is $\Omega(\Xi_u) = \Omega(\Xi_d) = 2\pi$ sr.

Although the spectral radiance completely specifies the light field, it is seldom measured both because of instrumental difficulties and because such complete information often is not needed for specific applications. The most commonly measured radiometric quantities are various *irradiances*.

Consider a light detector constructed so as to be equally sensitive to photons of a given wavelength λ traveling in any direction (θ, ϕ) within a *hemisphere* of directions.[4] If the detector is located at depth z and is oriented facing *upward*, so as to collect photons traveling *downward*, then the detector output is a measure of the *spectral downward scalar irradiance* at depth z, $E_{0d}(z, \lambda)$. Such an instrument is summing radiance over all the directions (elements of solid angle) in the downward hemisphere Ξ_d. Thus $E_{0d}(z, \lambda)$ is related to $L(z, \theta, \phi, \lambda)$ by

$$E_{0d}(z, \lambda) = \int_{\Xi_d} L(z, \theta, \phi, \lambda)\, d\Omega \qquad \text{W m}^{-2}\ \text{nm}^{-1}$$

The symbolic integral over Ξ_d can be evaluated as a double integral over θ and ϕ after a specific coordinate system is chosen.

If the same instrument is oriented facing *downward*, so as to detect photons traveling *upward*, then the quantity measured is the *spectral upward scalar irradiance* $E_{0u}(z, \lambda)$:

$$E_{0u}(z, \lambda) = \int_{\Xi_u} L(z, \theta, \phi, \lambda)\, d\Omega \qquad \text{W m}^{-2}\ \text{nm}^{-1}$$

The *spectral scalar irradiance* $E_0(z, \lambda)$ is just the sum of the downward and upward components:

$$E_0(z, \lambda) \equiv E_{0d}(z, \lambda) + E_{0u}(z, \lambda) = \int_{\Xi} L(z, \theta, \phi, \lambda)\, d\Omega \qquad \text{W m}^{-2}\ \text{nm}^{-1}$$

Here $\Xi = \Xi_d \cup \Xi_u$ is the set of all directions; $\Omega(\Xi) = 4\pi$ sr. $E_0(z, \lambda)$ is useful[2] because it is proportional to the spectral radiant energy density (J m^{-3} nm^{-1}) at depth z.

Now consider a detector designed[4] so that its sensitivity is proportional to $|\cos\theta|$, where θ is the angle between the photon direction and the normal to the surface of the detector. This is the ideal response of a "flat plate" collector of area ΔA, which when viewed at an angle θ to its normal appears to have an area of $\Delta A\, |\cos\theta|$. If such a detector is located at depth z and is oriented facing *upward*, so as to detect photons traveling *downward*, then its output is proportional to the *spectral downward plane irradiance* $E_d(z, \lambda)$ (usually called *spectral downwelling irradiance*). This instrument is summing the downwelling radiance weighted by the cosine of the photon direction:

$$E_d(z, \lambda) = \int_{\Xi_d} L(z, \theta, \phi, \lambda)\, |\cos\theta|\, d\Omega \qquad \text{W m}^{-2}\ \text{nm}^{-1}$$

Turning this instrument upside down gives the *spectral upward plane irradiance* (*spectral upwelling irradiance*) $E_u(z, \lambda)$:

$$E_u(z, \lambda) = \int_{\Xi_u} L(z, \theta, \phi, \lambda)\, |\cos\theta|\, \mathrm{d}\Omega \qquad \text{W m}^{-2}\ \text{nm}^{-1}$$

E_d and E_u are useful because they give the energy flux (power per unit area) across the horizontal surface at depth z owing to downwelling and upwelling photons, respectively.

The *spectral net irradiance* at depth z, $\bar{E}(z, \lambda)$ is the difference in the downwelling and upwelling plane irradiances:

$$\bar{E}(z, \lambda) = E_d(z, \lambda) - E_u(z, \lambda)$$

Photosynthesis is a quantum phenomenon (i.e., it is the *number* of available photons rather than the *amount* of radiant energy that is relevant to the chemical transformations). This is because if a photon of, say, $\lambda = 350$ nm, is absorbed by chlorophyll it induces the same chemical change as does a photon of $\lambda = 700$ nm, even though the 350-nm photon has twice the energy of the 700-nm photon. Only a part of the photon energy goes into photosynthesis; the excess is converted to heat or reradiated. Moreover, chlorophyll is equally able to absorb and utilize a photon regardless of the photon's direction of travel. Therefore, in studies of phytoplankton biology the relevant measure of the light field is the *photosynthetically available radiation*, PAR or E_{PAR}, defined by

$$\text{PAR}(z) \equiv \int_{350\text{ nm}}^{700\text{ nm}} \frac{\lambda}{hc} E_0(z, \lambda)\, d\lambda \qquad \text{photons s}^{-1}\text{ m}^{-2}$$

where $h = 6.6255 \times 10^{-34}$ J s is Planck's constant and $c = 3.0 \times 10^{17}$ nm s^{-1} is the speed of light. The factor λ/hc converts the energy units of E_0 (watts) to quantum units (photons per second). Bio-optical literature often states PAR values in units of mol photons s^{-1} m^{-2} or einst s^{-1} m^{-2}. Morel and Smith[5] found that over a wide variety of water types from very clear to turbid, with corresponding variations in the spectral nature of the irradiance, the conversion factor for energy to quanta varied by only ±10 percent about the value 2.5×10^{18} photons s^{-1} W^{-1} (4.2 μeinst s^{-1} W^{-1}).

For practical reasons related to instrument design, PAR is sometimes estimated using the spectral downwelling plane irradiance and the visible wavelengths only:

$$\text{PAR}(z) \approx \int_{400\text{ nm}}^{700\text{ nm}} \frac{\lambda}{hc} E_d(z, \lambda)\, d\lambda \qquad \text{photons s}^{-1}\text{ m}^{-2}$$

However, it is now recognized[6,7] that the use of E_d rather than E_0 can lead to errors of 20 to 100 percent in computations of PAR. Omission of the 350–400-nm band is less troublesome since those wavelengths are rapidly absorbed near the water surface, except in very clear waters.

1.4 INHERENT OPTICAL PROPERTIES

Consider a small volume ΔV of water of thickness Δr as seen by a narrow collimated beam of monochromatic light of spectral radiant power $\Phi_i(\lambda)$ W nm^{-1} as schematically illustrated in Fig. 2. Some part $\Phi_a(\lambda)$ of the incident power $\Phi_i(\lambda)$ is absorbed within the volume of water. Some part $\Phi_s(\psi, \lambda)$ is scattered out of the beam at an angle ψ, and the remaining power $\Phi_t(\lambda)$ is transmitted through the volume with no change in direction. Let $\Phi_s(\lambda)$ be the total power that is scattered into all directions. Furthermore, assume that no inelastic scattering occurs (i.e., assume that no photons undergo a change in wavelength during the scattering process). Then by conservation of energy,

$$\Phi_i(\lambda) = \Phi_a(\lambda) + \Phi_s(\lambda) + \Phi_t(\lambda)$$

The *spectral absorptance* $A(\lambda)$ is the fraction of incident power that is absorbed within the volume:

$$A(\lambda) \equiv \frac{\Phi_a(\lambda)}{\Phi_i(\lambda)}$$

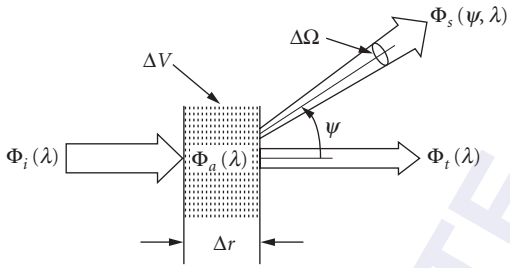

FIGURE 2 Geometry used to define inherent optical properties.

Likewise the *spectral scatterance* $B(\lambda)$ is the fractional part of the incident power that is scattered out of the beam,

$$B(\lambda) \equiv \frac{\Phi_s(\lambda)}{\Phi_i(\lambda)}$$

and the *spectral transmittance* $T(\lambda)$ is

$$T(\lambda) \equiv \frac{\Phi_t(\lambda)}{\Phi_i(\lambda)}$$

Clearly, $A(\lambda) + B(\lambda) + T(\lambda) = 1$. A quantity easily confused with the absorptance $A(\lambda)$ is the absorbance $D(\lambda)$ (also called *optical density*) defined as[8]

$$D(\lambda) \equiv \log_{10} \frac{\Phi_i(\lambda)}{\Phi_s(\lambda)+\Phi_t(\lambda)} = -\log_{10}[1-A(\lambda)]$$

$D(\lambda)$ is the quantity actually measured in a spectrophotometer.

The inherent optical properties usually employed in hydrologic optics are the spectral absorption and scattering coefficients which are, respectively, the spectral absorptance and scatterance *per unit distance* in the medium. In the geometry of Fig. 2, the *spectral absorption coefficient* $a(\lambda)$ is defined as

$$a(\lambda) \equiv \lim_{\Delta r \to 0} \frac{A(\lambda)}{\Delta r} \qquad \mathrm{m}^{-1}$$

and the *spectral scattering coefficient* $b(\lambda)$ is

$$b(\lambda) \equiv \lim_{\Delta r \to 0} \frac{B(\lambda)}{\Delta r} \qquad \mathrm{m}^{-1}$$

The *spectral beam attenuation coefficient* $c(\lambda)$ is defined as

$$c(\lambda) \equiv a(\lambda)+b(\lambda)$$

Hydrologic optics uses the term attenuation rather than extinction.

Now take into account the angular distribution of the scattered power, with $B(\psi, \lambda)$ being the fraction of incident power scattered out of the beam through an angle ψ into a solid angle

$\Delta\Omega$ centered on ψ as shown in Fig. 2. Then the angular scatterance per unit distance and unit solid angle, $\beta(\psi, \lambda)$, is

$$\beta(\psi, \lambda) \equiv \lim_{\Delta r \to 0} \lim_{\Delta\Omega \to 0} \frac{B(\psi, \lambda)}{\Delta r \, \Delta\Omega} = \lim_{\Delta r \to 0} \lim_{\Delta\Omega \to 0} \frac{\Phi_s(\psi, \lambda)}{\Phi_i(\lambda) \Delta r \, \Delta\Omega} \qquad \text{m}^{-1} \text{ sr}^{-1}$$

The spectral power scattered into the given solid angle $\Delta\Omega$ is just the spectral radiant intensity scattered into direction ψ times the solid angle: $\Phi_s(\psi, \lambda) = I_s(\psi, \lambda) \, \Delta\Omega$. Moreover, if the incident power $\Phi_i(\lambda)$ falls on an area ΔA, then the corresponding incident irradiance $E_i(\lambda) = \Phi_i(\lambda) / \Delta A$. Noting that $\Delta V = \Delta r \, \Delta A$ is the volume of water that is illuminated by the incident beam gives

$$\beta(\psi, \lambda) = \lim_{\Delta V \to 0} \frac{I_s(\psi, \lambda)}{E_i(\lambda) \Delta V}$$

This form of $\beta(\psi, \lambda)$ suggests the name *spectral volume scattering function* and the physical interpretation of scattered intensity per unit incident irradiance per unit volume of water; $\beta(\psi, \lambda)$ also can be interpreted as the differential scattering cross section per unit volume. Integrating $\beta(\psi, \lambda)$ over all directions (solid angles) gives the total scattered power per unit incident irradiance and unit volume of water or, in other words, the spectral scattering coefficient:

$$b(\lambda) = \int_{\Xi} \beta(\psi, \lambda) d\Omega = 2\pi \int_0^{\pi} \beta(\psi, \lambda) \sin\psi \, d\psi$$

The last equation follows because scattering in natural waters is azimuthally symmetric about the incident direction (for unpolarized sources and for randomly oriented scatterers). This integration is often divided into forward scattering, $0 \le \psi \le \pi/2$, and backward scattering, $\pi/2 \le \psi \le \pi$, parts. The corresponding spectral forward and backward scattering coefficients are, respectively,

$$b_f(\lambda) \equiv 2\pi \int_0^{\pi/2} \beta(\psi, \lambda) \sin\psi \, d\psi$$

$$b_b(\lambda) \equiv 2\pi \int_{\pi/2}^{\pi} \beta(\psi, \lambda) \sin\psi \, d\psi$$

The preceding discussion has assumed that no inelastic (transpectral) scattering processes are present. However, transpectral scattering does occur in natural waters attributable to fluorescence by dissolved matter or chlorophyll and to Raman or Brillouin scattering by the water molecules themselves (see Sec. 1.23). Power lost from wavelength λ by scattering into wavelength $\lambda' \ne \lambda$ appears in the above formalism as an increase in the spectral absorption.[9] In this case, $a(\lambda)$ accounts for "true" absorption (e.g., conversion of radiant energy into heat) as well as for the loss of power at wavelength λ by inelastic scattering to another wavelength. The gain in power at λ' appears as a source term in the radiative transfer formalism.

Two more inherent optical properties are commonly used in hydrologic optics. The *spectral single-scattering albedo* $\omega_0(\lambda)$ is

$$\omega_0(\lambda) \equiv \frac{b(\lambda)}{c(\lambda)}$$

The single-scattering albedo is the probability that a photon will be scattered (rather than absorbed) in any given interaction; hence, $\omega_0(\lambda)$ is also known as the *probability of photon survival*. The *spectral volume scattering phase function*, $\tilde{\beta}(\psi, \lambda)$ is defined by

$$\tilde{\beta}(\psi, \lambda) \equiv \frac{\beta(\psi, \lambda)}{b(\lambda)} \qquad \text{sr}^{-1}$$

Writing the volume scattering function $\beta(\psi, \lambda)$ as the product of the scattering coefficient $b(\lambda)$ and the phase function $\tilde{\beta}(\psi, \lambda)$ partitions $\beta(\psi, \lambda)$ into a factor giving the *strength* of the scattering, $b(\lambda)$ with units of m^{-1}, and a factor giving the *angular distribution* of the scattered photons, $\tilde{\beta}(\psi, \lambda)$ with units of sr^{-1}.

1.5 APPARENT OPTICAL PROPERTIES

The quantity

$$\bar{\mu}_d(z, \lambda) \equiv \frac{\int_{\Xi_d} L(z, \theta, \phi, \lambda) |\cos\theta| \, d\Omega}{\int_{\Xi_u} L(z, \theta, \phi, \lambda) \, d\Omega} \equiv \frac{E_d(z, \lambda)}{E_{0d}(z, \lambda)}$$

is called the *spectral downwelling average cosine*. The definition shows that $\bar{\mu}_d(z, \lambda)$ is the average value of the cosine of the polar angle of all the photons contributing to the downwelling radiance at the given depth and wavelength. The *spectral upwelling average cosine* is defined analogously:

$$\bar{\mu}_u(z, \lambda) \equiv \frac{E_u(z, \lambda)}{E_{0u}(z, \lambda)}$$

The average cosines are useful one-parameter measures of the directional structures of the downwelling and upwelling light fields. For example, if the downwelling light field (radiance distribution) is collimated in direction (θ_0, ϕ_0) so $L(\theta, \phi) = L_0 \delta(\theta - \theta_0)\delta(\phi - \phi_0)$, where δ is the Dirac δ function, then $\bar{\mu}_d = |\cos\theta_0|$. If the downwelling radiance is completely diffuse (isotropic), $L(\theta, \phi) = L_0$ and $\bar{\mu}_d = \frac{1}{2}$. Typical values of the average cosines for waters illuminated by the sun and sky are $\bar{\mu}_d \approx \frac{3}{4}$ and $\bar{\mu}_u \approx \frac{3}{8}$. Older literature generally refers to *distribution functions*, D_d and D_u, rather than to average cosines. The distribution functions are just reciprocals of the average cosines:

$$D_d(z, \lambda) = \frac{1}{\bar{\mu}_d(z, \lambda)} \qquad \text{and} \qquad \mathrm{D}_u(z, \lambda) = \frac{1}{\bar{\mu}_u(z, \lambda)}$$

The *spectral irradiance reflectance* (or *irradiance ratio*) $R(z, \lambda)$ is the ratio of spectral upwelling to downwelling plane irradiances:

$$R(z, \lambda) \equiv \frac{E_u(z, \lambda)}{E_d(z, \lambda)}$$

$R(z, \lambda)$ just beneath the sea surface is of great importance in remote sensing (see Sec. 1.22).

Under typical oceanic conditions for which the incident lighting is provided by the sun and sky, the various radiances and irradiances all decrease approximately exponentially with depth, at least when far enough below the surface (and far enough above the bottom, in shallow water) to be free of boundary effects. For example, it is convenient to write the depth dependence of $E_d(z, \lambda)$ as

$$E_d(z, \lambda) \equiv E_d(0, \lambda) \exp\left[-\int_0^z K_d(z', \lambda) dz'\right] \equiv E_d(\mathbf{0}, \lambda) \exp[-\bar{K}_d(\lambda) z]$$

where $K_d(z, \lambda)$ is the *spectral diffuse attenuation coefficient* for spectral downwelling plane irradiance and $\bar{K}_d(\lambda)$ is the average value of $K_d(z, \lambda)$ over the depth interval 0 to z. Solving for $K_d(z, \lambda)$ gives

$$K_d(z, \lambda) = -\frac{d \ln E_d(z, \lambda)}{dz} = -\frac{1}{E_d(z, \lambda)} \frac{dE_d(z, \lambda)}{dz} \qquad \mathrm{m}^{-1}$$

The distinction between *beam* and *diffuse* attenuation coefficients is important. The beam attenuation coefficient $c(\lambda)$ is defined in terms of the radiant power lost from a single, narrow, collimated beam of photons. The downwelling diffuse attenuation coefficient $K_d(z, \lambda)$ is defined in terms of the decrease with depth of the ambient downwelling irradiance $E_d(z, \lambda)$, which comprises photons heading in all downward directions (a diffuse or uncollimated light field). $K_d(z, \lambda)$ clearly depends on the directional structure of the ambient light field and so is classified as an apparent optical property. Other diffuse attenuation coefficients, e.g., K_u, K_{0d}, K_{0u}, K_{PAR}, and $K(\theta, \phi)$ are defined in an analogous manner, using the corresponding radiometric quantities.

In *homogeneous* waters, these "*K* functions" depend only weakly on depth and therefore can serve as convenient, if imperfect, descriptors of the water body. Smith and Baker[10] have pointed out other reasons why *K* functions are useful:

1. The *K*'s are defined as ratios and therefore do not require absolute radiometric measurements.
2. The *K*'s are strongly correlated with chlorophyll concentration (i.e., they provide a connection between biology and optics).
3. About 90 percent of the diffusely reflected light from a water body comes from a layer of water of depth $1/K_d(0, \lambda)$ (i.e., K_d has implications for remote sensing).
4. Radiative transfer theory provides several useful relations between the *K*'s and other quantities of interest, such as absorption and beam attenuation coefficients, the irradiance reflectance, and the average cosines.
5. Instruments are available for routine measurement of the *K*'s.

It must be remembered, however, that in spite of their utility *K* functions are apparent optical properties—a change in the environment (e.g., solar angle or sea state) changes their value, sometimes by a negligible amount but sometimes greatly. However, numerical simulations by Gordon[11] show how with a few additional but easily made measurements measured values of $K_d(z, \lambda)$ and $\bar{K}_d(\lambda)$ can be "normalized" to remove the effects of solar angle and sea state. The normalized K_d and $\bar{K}_d$ are equal to the values that would be obtained if the sun were at the zenith and the sea surface were calm. *If* this normalization is performed, the resulting $K_d(z, \lambda)$ and $\bar{K}_d(\lambda)$ can be regarded as *inherent* optical properties for all practical purposes. It is strongly recommended that Gordon's procedure be routinely followed by experimentalists.

1.6 THE OPTICALLY SIGNIFICANT CONSTITUENTS OF NATURAL WATERS

Dissolved Substances

Pure sea water consists of pure water plus various dissolved salts, which average about 35 parts per thousand (‰) by weight. These salts increase scattering above that of pure water by 30 percent (see Table 10 in Sec. 1.17). It is not well established what, if any, effect these salts have on absorption, but it is likely that they increase absorption somewhat at ultraviolet wavelengths.

Both fresh and saline waters contain varying concentrations of dissolved organic compounds. These compounds are produced during the decay of plant matter and consist mostly of various humic and fulvic acids.[8] These compounds are generally brown in color and in sufficient concentrations can color the water yellowish brown. For this reason the compounds are generically referred to as *yellow matter*, *Gelbstoff*, or *gilvin*. Yellow matter absorbs very little in the red, but absorption increases rapidly with decreasing wavelength. Since the main source of yellow matter is decayed terrestrial vegetation, concentrations are generally greatest in lakes, rivers, and coastal waters influenced by river runoff. In such waters yellow matter can be the dominant absorber at the blue end of the spectrum. In mid-ocean waters absorption by yellow matter is usually small compared to absorption by other constituents, but some yellow matter is likely to be present as the result of decaying phytoplankton, especially at the end of a bloom.

Particulate Matter

Particulate matter in the oceans has two distinct origins: biological and physical. The organic particles of optical importance are created as bacteria, phytoplankton, and zooplankton grow and reproduce by photosynthesis or by eating their neighbors. Particles of a given size are destroyed by breaking apart after death, by fiocculation into larger aggregate particles, or by settling out of the water column. Inorganic particles are created primarily by weathering of terrestrial rocks and soils. These particles can enter the water as wind-blown dust settles on the sea surface, as rivers carry eroded soil to the sea, or as currents resuspend bottom sediments. Inorganic particles are removed from the water by settling, aggregating, or dissolving. This particulate matter usually is the major determiner of both the absorption and scattering properties of natural waters and is responsible for most of the temporal and spatial variability in these optical properties.

Organic Particles These occur in many forms.

Viruses Natural marine waters contain virus particles[12] in concentrations of 10^{12} to 10^{15} particles m^{-3}. These particles are generally much smaller (2–200 nm) than the wavelength of visible light, and it is not known what, if any, direct effect viruses have on the optical properties of sea water.

Colloids Nonliving collodial particles in the size range 0.4–1.0 μm are found[13] in typical number concentrations of 10^{13} m^{-3} and colloids of size ≤ 0.1 μm are found[14] in abundances of 10^{15} m^{-3}. Some of the absorption traditionally attributed to dissolved matter may be due to colloids, some of which strongly resemble fulvic acids in electron micrographs.[14]

Bacteria Living bacteria in the size range 0.2–1.0 μm occur in typical number concentrations of 10^{11}–10^{13} m^{-3}. It only recently has been recognized[15–17] that bacteria can be significant scatterers and absorbers of light, expecially at blue wavelengths and in clean oceanic waters where the larger phytoplankton are relatively scarce.

Phytoplankton These ubiquitous microscopic plants occur with incredible diversity of species, size, shape, and concentration. They range in cell size from less than 1 μm to more than 200 μm, and some species form even larger chains of individual cells. It has long been recognized that phytoplankton are the particles primarily responsible for determining the optical properties of most oceanic waters. Their chlorophyll and related pigments strongly absorb light in the blue and red and thus when concentrations are high determine the spectral absorption of sea water. These particles are generally much larger than the wavelength of visible light and are efficient scatterers, especially via diffraction, thus influencing the scattering properties of sea water.

Organic detritus Nonliving organic particles of various sizes are produced, for example, when phytoplankton die and their cells break apart. They may also be formed when zooplankton graze on phytoplankton and leave behind cell fragments and fecal pellets. Even if these detrital particles contain pigments at the time of their production, they can be rapidly photo-oxidized and lose the characteristic absorption spectrum of living phytoplankton, leaving significant absorption only at blue wavelengths.

Large particles Particles larger than 100 μm include zooplankton (living animals with sizes from tens of micrometers to two centimeters) and fragile amorphous aggregates[18] of smaller particles ("marine snow," with sizes from 0.5 mm to tens of centimeters). Such particles occur in highly variable numbers from almost none to thousands per cubic meter. Even at relatively large concentrations these large particles tend to be missed by optical instruments that randomly sample only a few cubic centimeters of water or that mechanically break apart the aggregates. However, these large particles can be efficient diffuse scatterers of light and therefore may significantly affect the optical properties (especially backscatter) of large volumes of water, e.g., as seen by remote sensing instruments. Although such optical effects are recognized, they have not been quantified.

Inorganic Particles These generally consist of finely ground quartz sand, clay minerals, or metal oxides in the size range from much less than 1 μm to several tens of micrometers. Insufficient attention has been paid to the optical effects of such particles in sea water, although it is recognized that inorganic particles are sometimes optically more important than organic particles. Such situations can occur both in turbid coastal waters carrying a heavy sediment load and in very clear oceanic waters which are receiving wind-blown dust.[19]

At certain stages of its life, the phytoplankton coccolithophore species *Emiliania huxleyi* is a most remarkable source of crystalline particles. During blooms *E. huxleyi* produces and sheds enormous numbers of small (2–4 μm) calcite plates; concentrations of 3×10^{11} plates m^{-3} have been observed.[20] Although they have a negligible effect on light absorption, these calcite plates are extremely efficient light scatterers: irradiance reflectances of $R = 0.39$ have been observed[20] at blue wavelengths during blooms (compared with $R = 0.02$ to 0.05 in the blue for typical ocean waters, discussed in Sec. 1.22). Such coccolithophore blooms give the ocean a milky white or turquoise appearance.

1.7 PARTICLE SIZE DISTRIBUTIONS

In spite of the diverse mechanisms for particle production and removal, observation shows that a single family of particle size distributions often suffices to describe oceanic particulate matter in the optically important size range from 0.1 to 100 μm. Let $N(x)$ be the number of particles per unit volume with size greater than x in a sample of particles; x usually represents equivalent spherical diameter computed from particle volume, but also can represent particle volume or surface area. The Junge (also called *hyperbolic*) cumulative size distribution[21] is then

$$N(x) = k\left(\frac{x}{x_0}\right)^{-m}$$

where k sets the scale, x_0 is a reference size, and $-m$ is the slope of the distribution when log N is plotted versus log x; k, x_0, and m are positive constants.

Oceanic particle size distributions usually have m values between 2 and 5, with $m = 3$ to 4 being typical; such spectra can be seen in McCave,[22] Fig. 7. It often occurs that oceanic particle size spectra are best described by a segmented distribution in which a smaller value of m is used for x less than a certain value and a larger value of m is used for x greater than that value. Such segmented spectra can be seen in Bader,[21] and in McCave,[22] Fig. 8.

The quantity most relevant to optics, e.g., in Mie scattering computations for polydisperse systems, is not the *cumulative* size distribution $N(x)$, but rather the *number* size distribution $n(x)$. The number distribution is defined such that $n(x)\,dx$ is the number of particles in the size interval from x to $x + dx$. The number distribution is related to the cumulative distribution by $n(x) = |dN(x)/dx|$, so that for the Junge distribution

$$n(x) = kmx_0^{-m}x^{-m-1} \equiv Kx^{-s}$$

where $K \equiv kmx_0^{-m}$ and $s \equiv m + 1$; s is commonly referred to as the slope of the distribution. Figure 3 shows the number distribution of biological particles typical of open ocean waters; note that a value of $s = 4$ gives a reasonable fit to the plotted points.

It should be noted, however, that the Junge distribution sometimes fails to represent oceanic conditions. For example, during the growth phase of a phytoplankton bloom the rapid increase in population of a particular species may give abnormally large numbers of particles in a particular size range. Such bloom conditions therefore give a "bump" in $n(x)$ that is not well modeled by the simple Junge distribution. Moreover, Lambert et al.[23] found that a log-normal distribution sometimes better described the distributions of inorganic particles found in water samples taken from near the bottom at deep ocean locations. These particles were principally aluminosilicates in the 0.2- to 10.0-μm size range but included quartz grains, metal oxides, and phytoplankton skeletal parts such as coccolithophore plates. Based on the sampling location it was assumed that the inorganic particles were resuspended sediments. Lambert et al. found that the size distributions of the individual particle types (e.g., aluminosilicates or metal oxides) obeyed log-normal distributions which "flattened out" below 1 μm. For particles larger than ~1 μm, log-normal and Junge distributions gave nearly

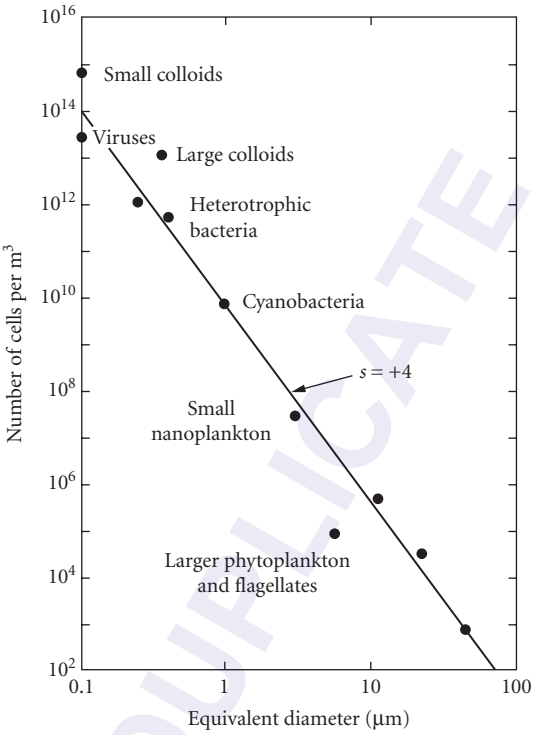

FIGURE 3 Number size distribution typical of biological particles in the open ocean. (*Based on Stramski and Kiefer*,[17] *with permission.*)

equivalent descriptions of the data. Biological particles were not as well described by the log-normal distribution, especially for sizes greater than 5 μm.

1.8 ELECTROMAGNETIC PROPERTIES OF WATER

In studies of electromagnetic wave propagation at the level of Maxwell's equations it is convenient to specify the bulk electromagnetic properties of the medium via the electrical permittivity ε, the magnetic permeability μ, and the elecrical conductivity σ. Since water displays no significant magnetic properties, the permeability can be taken equal to the free-space (in vacuo) value at all frequencies: $\mu = \mu_0 = 4\pi \times 10^{-7}$ N A^{-2}. Both ε and σ depend on the frequency ω of the propagating electromagnetic wave as well as on the water temperature, pressure, and salinity. Low-frequency ($\omega \to 0$) values for the permittivity are of order $\varepsilon \approx 80\varepsilon_0$, where $\varepsilon_0 = 8.85 \times 10^{-12}$ A^2 s^2 N^{-1} m^{-2} is the free-space value. This value decreases to $\varepsilon \approx 1.8\varepsilon_0$ at optical frequencies. Extensive tabulations of $\varepsilon/\varepsilon_0$ as a function of temperature and pressure are given for pure water in Archer and Wang.[24] The low-frequency conductivity ranges from $\sigma \approx 4 \times 10^{-6}$ siemen m^{-1} for pure water to $\sigma \approx 4.4$ siemen m^{-1} for sea water.

The effects of ε, μ, and σ on electromagnetic wave propagation are compactly summarized in terms of the complex index of refraction, $m = n - ik$, where n is the real index of refraction,

k is the dimensionless electrodynamic absorption coefficient, and $\mathrm{i} = \sqrt{(-1)}$; n and k are collectively called the *optical constants* of water (a time dependence convention of $\exp(+\mathrm{i}\omega t)$ is used in deriving wave equations from Maxwell's equations). The explicit dependence of m on ε, μ, and σ is given by[25]

$$m^2 = \mu\varepsilon c^2 - i\frac{\mu\sigma c^2}{\omega}$$
$$= (n - \mathrm{i}k)^2 = n^2 - k^2 - \mathrm{i}2nk$$

where $c = (\varepsilon_0\mu_0)^{-1/2}$ is the speed of light in vacuo. These equations can be used to relate n and k to the bulk electromagnetic properties. The optical constants are convenient because they are directly related to the scattering and absorbing properties of water. The real index of refraction $n(\lambda)$ governs scattering both at interfaces (via the laws of reflection and refraction) and within the medium (via thermal or other fluctuations of $n(\lambda)$ at molecular and larger scales). The spectral absorption coefficient $a(\lambda)$ is related to $k(\lambda)$ by[25]

$$a(\lambda) = \frac{4\pi k(\lambda)}{\lambda}$$

Here λ refers to the in vacuo wavelength of light corresponding to a given frequency ω of electromagnetic wave.

Figure 4 shows the wavelength dependence of the optical constants n and k for pure water. The extraordinary feature seen in this figure is the narrow "window" in $k(\lambda)$, where $k(\lambda)$ decreases by over nine orders of magnitude between the near ultraviolet and the visible and then quickly rises again in the near infrared. This behavior in $k(\lambda)$ gives a corresponding window in the spectral absorption coefficient $a(\lambda)$ as seen in Table 2. Because of the opaqueness of water outside the near-UV to near-IR wavelengths, hydrologic optics is concerned only with this small part of the electromagnetic spectrum. These wavelengths overlap nicely with the wavelengths of the sun's maximum energy output and with a corresponding window in atmospheric absorption, much to the benefit of life on earth.

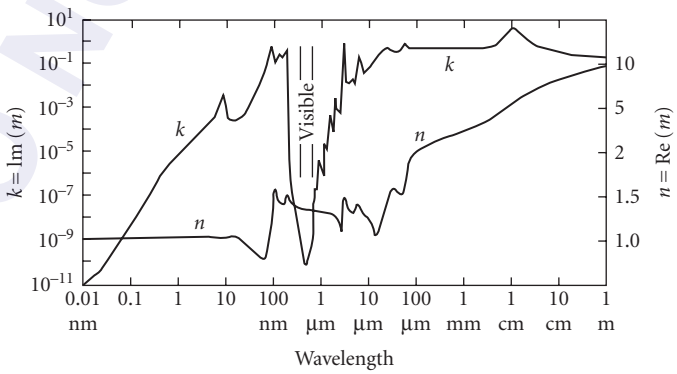

FIGURE 4 The optical constants of pure water. The left axis gives $k = \mathrm{Im}(m)$ and the right axis gives $n = \mathrm{Re}(m)$ where m is the complex index of refraction. (*Redrawn from Zoloratev and Demin*,[26] *with permission.*)

TABLE 2 Absorption Coefficient a of Pure Water As a Function of Wavelength λ*

λ	a (m^{-1})	λ	a (m^{-1})
0.01 nm	1.3×10^{1}	700 nm	0.650
0.1	6.5×10^{2}	800	2.07
1	9.4×10^{4}	900 nm	7.0
10	3.5×10^{6}	1 μm	3.3×10^{1}
100	5.0×10^{7}	10	7.0×10^{4}
200	3.07	100 μm	6.5×10^{4}
300	0.141	0.001 m	1.3×10^{4}
400	0.0171	0.01	3.6×10^{3}
500	0.0257	0.1	5.0×10^{1}
600 nm	0.244	1 m	2.5

*Data for 200 nm ≤ λ ≤ 800 nm taken from Table 6. Data for other wavelengths computed from Fig. 4.

1.9 INDEX OF REFRACTION

Seawater

Austin and Halikas[27] exhaustively reviewed the literature on measurements of the real index of refraction of sea water. Their report contains extensive tables and interpolation algorithms for the index of refraction (relative to air), $n(\lambda, S, T, p)$, as a function of wavelength (λ = 400 to 700 nm), salinity (S = 0 to 43‰), temperature (T = 0 to 30°C), and pressure ($p = 10^5$ to 10^8 Pa, or 1 to 1080 atm). Figure 5 illustrates the general dependence of n on these four parameters: n decreases with increasing wavelength or temperature and increases with increasing salinity or pressure. Table 3 gives the values of n for the extreme values of each parameter. The extreme values of n, 1.329128 and 1.366885, show that n varies by less than 3 percent over the entire parameter range relevant to hydrologic optics. Table 4 gives selected values of $n(\lambda, T)$ for fresh water (S = 0) and for typical sea water (S = 35‰) at atmospheric pressure ($p = 10^5$ Pa). The values in Table 4 can be multiplied by 1.000293 (the index of refraction of dry air at STP and λ = 538 nm) if values relative to vacuum are

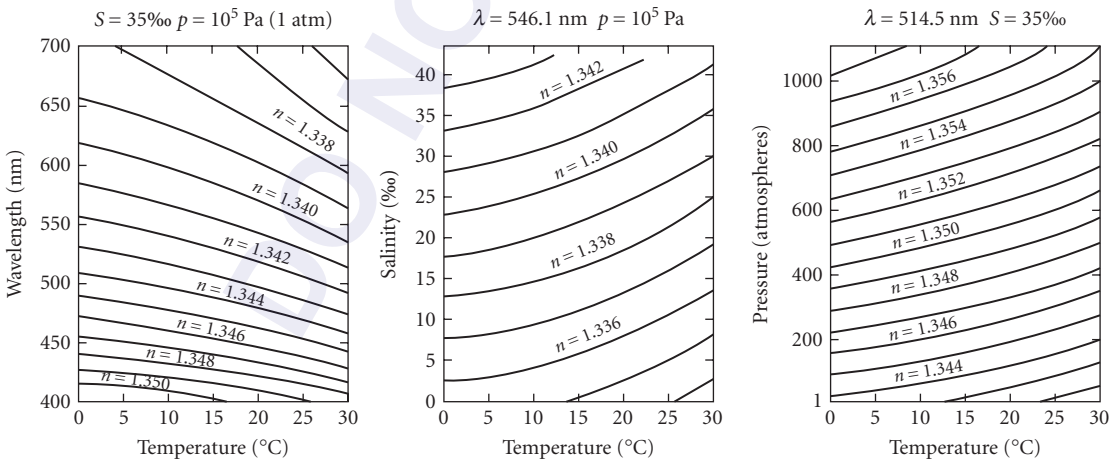

FIGURE 5 Real index of refraction of water for selected values of pressure, temperature, and salinity. (*Adapted from Austin and Halikas.*[27])

TABLE 5 Index of Refraction Relative to Water, n, of Inorganic Particles Found in Sea Water

Substance	n
Quartz	1.16
Kaolinite	1.17
Montmorillonite	1.14
Hydrated mica	1.19
Calcite	1.11/1.24

desired. Millard and Seaver[28] have developed a 27-term formula that gives the index of refraction to part-per-million accuracy over most of the oceanographic parameter range.

Particles

Suspended particulate matter in sea water often has a bimodal index of refraction distribution. Living phytoplankton typically have "low" indices of refraction in the range 1.01 to 1.09 relative to the index of refraction of seawater. Detritus and inorganic particles generally have "high" indices in the range of 1.15 to 1.20 relative to seawater.[29] Typical values are 1.05 for phytoplankton and 1.16 for inorganic particles.

Table 5 gives the relative index of refraction of terrigenous minerals commonly found in river runoff and wind-blown dust. Only recently has it become possible to measure the refractive indices of individual phytoplankton cells.[30] Consequently, little is yet known about the dependence of refractive index on phytoplankton species, or on the physiological state of the plankton within a given species, although it appears that the dependence can be significant.[31]

1.10 MEASUREMENT OF ABSORPTION

Determination of the spectral absorption coefficient $a(\lambda)$ for natural waters is a difficult task for several reasons. First, water absorbs only weakly at near-UV to blue wavelengths so that very sensitive instruments are required. More importantly, scattering is never negligible so that careful consideration must be made of the possible aliasing of the absorption measurements by scattering effects. In pure water at wavelengths of $\lambda = 370$ to 450 nm, molecular scattering provides 20 to 25 percent (Table 10) of the total beam attenuation, $c(\lambda) = a(\lambda) + b(\lambda)$. Scattering effects can dominate absorption at all visible wavelengths in waters with high particulate loads. Additional complications arise in determining the absorption of pure water because of the difficulty of preparing uncontaminated samples.

Many techniques have been employed in attempts to determine the spectral absorption coefficient for pure water, $a_w(\lambda)$; these are reviewed in Smith and Baker.[32] The most commonly employed technique for routine determination of $a(\lambda)$ for oceanic waters consists of filtering a sample of water to retain the particulate matter on a filter pad. The spectral absorption of the particulate matter, $a_p(\lambda)$, is then determined in a spectrophotometer. The absorption of pure water, $a_w(\lambda)$, must be added to $a_p(\lambda)$ to obtain the total absorption of the oceanic water sample. Even though this technique for determining absorption has been in use for many years, the methodology is still evolving[33–35] because of the many types of errors inherent in the $a_p(\lambda)$ measurements (e.g., inability of filters to retain all particulates, scattering effects within the sample cell, absorption by dissolved matter retained on the filter pad, and decomposition of pigments during the filtration process).

Moreover, this methodology for determining total absorption assumes that absorption by dissolved organic matter (yellow substances) is negligible, which is not always the case. If the absorption by yellow matter, $a_y(\lambda)$, is desired, then the absorption of the *filtrate* is measured, and $a_y(\lambda)$ is taken to be $a_{\text{filtrate}}(\lambda) - a_w(\lambda)$. Several novel instruments under development[36–38] show promise for circumventing the problems inherent in the filter-pad technique as well as for making in situ measurements of total absorption which at present is difficult.[39]

1.11 ABSORPTION BY PURE SEA WATER

Table 2 showed the absorption for pure water over the wavelength range from 0.01 nm (x-rays) to 1 m (radio waves). As is seen in the table, only the near-UV to near-IR wavelengths are of interest in hydrologic optics. Smith and Baker[32] made a careful but indirect determination of the *upper bound* of the spectral absorption coefficient of pure sea water, $a_w(\lambda)$, in the wavelength range of oceanographic interest, 200 nm $\le \lambda \le$ 800 nm. Their work assumed that for the clearest natural waters (1) absorption by salt or other dissolved substances was negligible, (2) the only scattering was by water molecules and salt ions, and (3) there was no inelastic scattering (i.e., no fluorescence or Raman scattering). With these assumptions the inequality (derived from radiative transfer theory)

$$a_w(\lambda) \le K_d(\lambda) - \tfrac{1}{2} b_m^{\text{sw}}(\lambda)$$

holds. Here $b_m^{\text{sw}}(\lambda)$ is the spectral scattering coefficient for pure sea water; $b_m^{\text{sw}}(\lambda)$ was taken as known (Table 10). Smith and Baker then used measured values of the diffuse attenuation function $K_d(\lambda)$ from very clear waters (e.g., Crater Lake, Oregon, U.S.A., and the Sargasso Sea) to estimate $a_w(\lambda)$. Table 6 gives their self-consistent values of $a_w(\lambda)$, $K_d(\lambda)$, $b_m^{\text{sw}}(\lambda)$.

The Smith and Baker absorption values are widely used. However, it must be remembered that the values of $a_w(\lambda)$ in Table 6 are upper bounds; the true absorption of pure water is likely to be somewhat lower, at least at violet and blue wavelengths.[40] Smith and Baker pointed out that there are uncertainties because K_d, an apparent optical property, is influenced by environmental conditions. They also commented that at wavelengths below 300 nm, their values are "merely an educated guess." They estimated the accuracy of $a_w(\lambda)$ to be within +25 and −5 percent between 300 and 480 nm and +10 to −15 percent between 480 and 800 nm. Numerical simulations by Gordon[11] indicate that a more restrictive inequality,

$$a_w(\lambda) \le \frac{K_d(\lambda)}{D_0(\lambda)} - 0.62 b_m^{\text{sw}}(\lambda)$$

could be used. Here $D_0(\lambda)$ is a measurable distribution function $[D_0(\lambda) > 1]$ that corrects for the effects of sun angle and sea state on $K_d(\lambda)$ (discussed earlier). Use of the Gordon inequality could reduce the Smith and Baker absorption values by up to 20 percent at blue wavelengths. And finally, the Smith and Baker measurements were not made in optically pure water but rather in the "clearest natural waters." Even these waters contain a small amount of dissolved and particulate matter which will contribute something to both absorption and scattering.

There is evidence[41] that absorption is weakly dependent on temperature, at least in the red and near infrared ($\partial a/\partial T \sim 0.0015\,\text{m}^{-1}\,^{\circ}\text{C}^{-1}$ at $\lambda = 600$ nm and $\partial a/\partial T \sim 0.01\,\text{m}^{-1}\,^{\circ}\text{C}^{-1}$ at $\lambda = 750$ nm) and perhaps also slightly dependent on salinity; these matters are under investigation.

1.12 ABSORPTION BY DISSOLVED ORGANIC MATTER

Absorption by yellow matter is reasonably well described by the model[42]

$$a_y(\lambda) = a_y(\lambda_0)\exp[-0.014(\lambda - \lambda_0)]$$

over the range 350 nm $\leq \lambda \leq$ 700 nm. Here λ_0 is a reference wavelength usually chosen to be λ_0 = 440 nm and $a_y(\lambda_0)$ is the absorption due to yellow matter at the reference wavelength. The value of $a_y(\lambda)$ of course depends on the concentration of yellow matter in the water. The exponential decay constant depends on the relative proportion of specific types of yellow matter; other studies have found exponents of −0.014 to −0.019 (Roesler et al.,[43] table 1). Both total concentration and proportions are highly variable. Table 7 gives measured values of $a_y(440)$ for selected waters. Because of the variability in yellow matter concentrations, the values found in Table 7 have little general

validity even for the particular water bodies sampled, but they do serve to show representative values and the range of influence of yellow matter in determining the total absorption. Although the above model allows the determination of spectral absorption by yellow matter if the absorption is known at one wavelength, no model yet exists that allows for the direct determination of $a_y(\lambda)$ from given concentrations of yellow matter constituents.

1.13 ABSORPTION BY PHYTOPLANKTON

Phytoplankton cells are strong absorbers of visible light and therefore play a major role in determining the absorption properties of natural waters. Absorption by phytoplankton occurs in various photosynthetic pigments of which the chlorophylls are best known to nonspecialists. Absorption by chlorophyll itself is characterized by strong absorption bands in the blue and in the red (peaking at $\lambda \approx 430$ and 665 nm, respectively, for chlorophyll *a*), with very little absorption in the green. Chlorophyll occurs in all plants, and its concentration in milligrams of chlorophyll per cubic meter of water is commonly used as the relevant optical measure of phytoplankton abundance. (The term "chlorophyll concentration" usually refers to the sum of chlorophyll *a*, the main pigment in phytoplankton cells, and the related pigment pheophytin *a*.) Chlorophyll concentrations for various waters range from 0.01 mg m^{-3} in the clearest open ocean waters to 10 mg m^{-3} in productive coastal upwelling regions to 100 mg m^{-3} in eutrophic estuaries or lakes. The globally averaged, near-surface, open-ocean value is in the neighborhood of 0.5 mg m^{-3}.

The absorbing pigments are not evenly distributed within phytoplankton cells but are localized into small "packages" (chloroplasts) which are distributed nonrandomly throughout the cell. This localized distribution of pigments means[8] that the spectral absorption by a phytoplankton cell or by a collection of cells in water is "flatter" (has less-pronounced peaks and reduced overall absorption) than if the pigments were uniformly distributed throughout the cell or throughout the water. This so-called "pigment packaging effect" is a major source of both inter- and intraspecies variability in spectral absorption by phytoplankton. This is because the details of the pigment

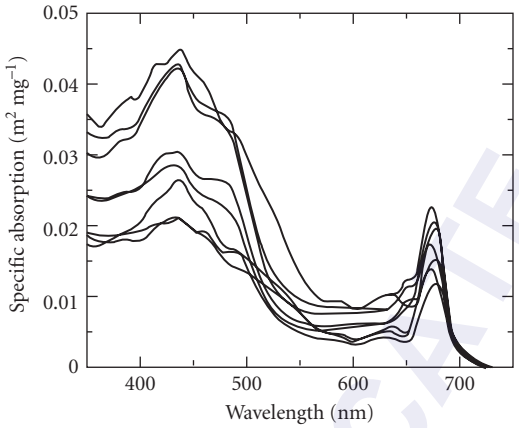

FIGURE 6 Chlorophyll-specific spectral absorption coefficients for eight species of phytoplankton. (*Redrawn from Sathyendranath et al.,*[44] *with permission.*)

packaging within cells depend not only on species but also on a cell's size and physiological state (which in turn depends on environmental factors such as ambient lighting and nutrient availability). Another source of variability in addition to chlorophyll *a* concentration and packaging is changes in pigment composition (the relative proportions of accessory pigments, namely, chlorophylls *b* and *c*, pheopigments, biliproteins, and carotenoids) since each pigment displays a characteristic absorption curve.

A qualitative feel for the nature of phytoplankton absorption can be obtained from Fig. 6 which is based on absorption measurements from eight different single-species laboratory phytoplankton cultures.[44] Measured spectral absorption coefficients for the eight cultures, $a_i(\lambda)$, $i = 1$ to 8, were first reduced by subtracting $a_i(737)$ to remove the effects of absorption by detritus and cell constituents other than pigments: the assumption is that pigments do not absorb at $\lambda = 737$ nm and that the residual absorption is wavelength independent (which is a crude approximation). The resulting curves were then normalized by the chlorophyll concentrations of the respective cultures to generate the *chlorophyll-specific spectral absorption* curves for phytoplankton, $a_i^*(\lambda)$.

$$a_i^*(\lambda) = \frac{a_i(\lambda) - a_i(737)}{C_i} \qquad \frac{\mathrm{m}^{-1}}{\mathrm{mg\ m}^{-3}} = \mathrm{m}^2\ \mathrm{mg}^{-1}$$

which are plotted in Fig. 6.

Several general features of phytoplankton absorption are seen in Fig. 6:

1. There are distinct absorption peaks at $\lambda \approx 440$ and 675 nm.
2. The blue peak is one to three times as high as the red one (for a given species) due to the contribution of accessory pigments to absorption in the blue.
3. There is relatively little absorption between 550 and 650 nm, with the absorption minimum near 600 nm being 10 to 30 percent of the value at 440 nm.

Similar analysis by Morel[45] yielded the average specific absorption curve shown in Fig. 7. Morel's curve is an average of spectra from 14 cultured phytoplankton species. The Morel curve is qualitatively the same as the curves of Fig. 6 and is as good a candidate as any for being called a "typical" phytoplankton specific absorption curve. The $a^*(\lambda)$ values of Fig. 7 are tabulated in Table 8 for reference.

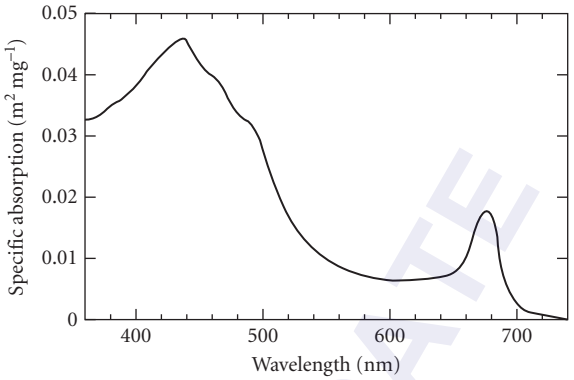

FIGURE 7 Average chlorophyll-specific spectral absorption coefficient for 14 species of phytoplankton. (*Redrawn from Morel,*[45] *with permission.*)

1.14 ABSORPTION BY ORGANIC DETRITUS

Only recently has it become possible to determine the relative contributions of living phytoplankton and nonliving detritus to the total absorption by particulates. Iturriaga and Siegel[46] used microspectrophotometric techniques capable of measuring the spectral absorption of individual particles as small as 3 μm diameter to examine the absorption properties of particulates from Sargasso sea waters. Roesler et al.[43] employed a standard filter-pad technique with measurements made before

TABLE 8 Average Chlorophyll-Specific Spectral Absorption Coefficient a^* for 14 Species of Phytoplankton As Plotted in Fig. 7 (The standard deviation is ~30% of the mean except in the vicinity of 400 nm, where it is ~50%.*)

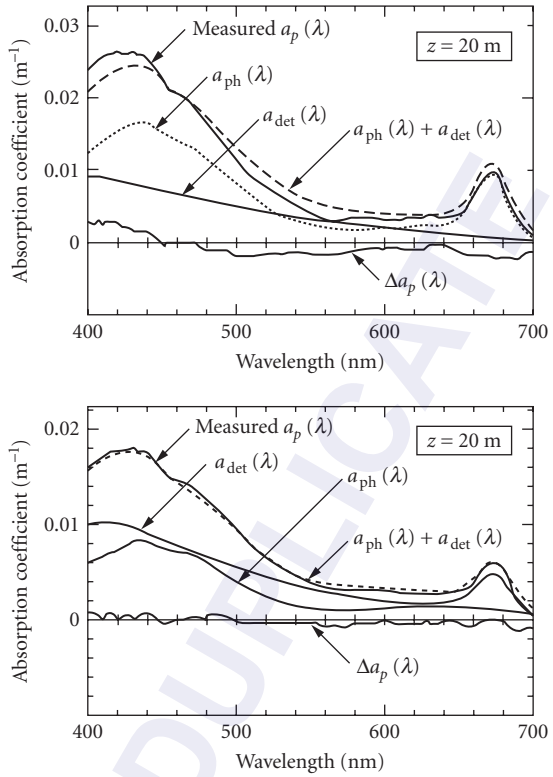

FIGURE 8 Examples of the relative contributions of absorption by phytoplankton $a_{ph}(\lambda)$, and by organic detritus $a_{det}(\lambda)$, to the total particulate absorption $a_p(\lambda)$, from Sargasso Sea waters. (*Redrawn from Iturriaga and Siegel,*[46] *with permission.*)

and after pigments were chemically extracted to distinguish between absorption by pigmented and nonpigmented particles from fjord waters in the San Juan Islands, Washington, U.S.A. Each of these dissimilar techniques applied to particles from greatly different waters found very similar absorption spectra for nonpigmented organic particles derived from phytoplankton.

Figure 8 shows the microspectrophotometrically determined contributions of absorption by phytoplankton, $a_{ph}(\lambda)$, and of absorption by detritus, $a_{det}(\lambda)$, to the independently measured (by the filter-pad technique) total particulate absorption, $a_p(\lambda)$, for two depths at the same Atlantic location. The small residual, $\Delta a_p(\lambda) = a_p(\lambda) - a_{ph}(\lambda) - a_{det}(\lambda)$ shown in the figure is attributed either to errors in the determination of the phytoplankton and detrital parts (particles smaller than ~3 μm were not analyzed) or to contamination by dissolved organic matter of the filter-pad measurements of total particulate absorption. Note that at the shallow depth the phytoplankton are relatively more important at blue wavelengths whereas the detritus is slightly more important at the deeper depth. There is no generality in this result (other locations showed the reverse)—it merely illustrates the variability possible in water samples taken only 60 vertical meters apart.

The important feature to note in Fig. 8 is the general shape of the spectral absorption curve for detritus. Roesler et al. found essentially identical curves in their determination of $a_{det}(\lambda)$. These curves are reminiscent of the absorption curves for yellow matter and, indeed, Roesler et al. found that the model

$$a_{det}(\lambda) = a_{det}(400)\exp[-0.011(\lambda - 400)]$$

provides a satisfactory fit to detrital absorption curves. Other studies have found coefficients of −0.006 to −0.014 (Roesler et al.,[43] table 1) instead of −0.011.

1.15 BIO-OPTICAL MODELS FOR ABSORPTION

Depending on the concentrations of dissolved substances, phytoplankton, and detritus, the total spectral absorption coefficient of a given water sample can range from almost identical to that of pure water to one which shows orders-of-magnitude greater absorption than pure water, especially at blue wavelengths. Figure 9 shows some $a(\lambda)$ profiles from various natural waters. Figure 9*a* shows absorption profiles measured in phytoplankton-dominated waters where chlorophyll concentrations ranged from $C = 0.2$ to 18.4 mg m^{-3}. In essence, the absorption is high in the blue because of absorption by phytoplankton pigments and high in the red because of absorption by the water. Figure 9*b* shows the absorption at three locations where $C \approx 2$ mg m^{-3} but where the scattering coefficient b varied from 1.55 to 3.6 m^{-1} indicating that nonpigmented particles were playing an important role in determining the shape of $a(\lambda)$. Figure 9*c* shows curves from waters rich in yellow matter, which is causing the high absorption in the blue. One of the goals of bio-optics is to develop predictive models for absorption curves such as those seen in Fig. 9.

Case 1 waters are waters in which the concentration of phytoplankton is high compared to nonbiogenic particles.[47] Absorption by chlorophyll and related pigments therefore plays a major role in determining the total absorption coefficient in such waters, although detritus and dissolved organic matter derived from the phytoplankton also contribute to absorption in case 1 waters. Case 1 water can range from very clear (oligotrophic) water to very turbid (eutrophic) water, depending on the phytoplankton concentration. *Case 2 waters* are "everything else," namely, waters where inorganic particles or dissolved organic matter from land drainage dominate so that absorption by pigments is relatively less important in determining the total absorption. (The cases 1 and 2 classifications must not be confused with the Jerlov water *types* 1 and 2, discussed later.) Roughly 98 percent of the world's open ocean and coastal waters fall into the case 1 category, and therefore almost all bio-optical research has been directed toward these phytoplankton-dominated waters. However, near-shore and estuarine case 2 waters are disproportionately important to human interests such as recreation, fisheries, and military operations.

Prieur and Sathyendranath[48] developed a pioneering bio-optical model for the spectral absorption coefficient of case 1 waters. Their model was statistically derived from 90 sets of spectral absorption data taken in various case 1 waters and included absorption by phytoplankton pigments,

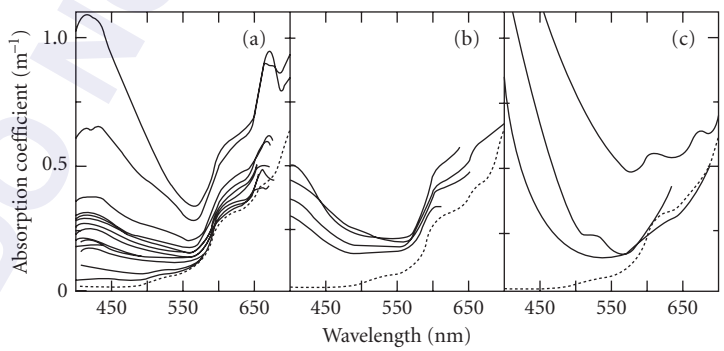

FIGURE 9 Examples of spectral absorption coefficients $a(\lambda)$ for various waters. Panel (*a*) shows $a(\lambda)$ for waters dominated by phytoplankton, panel (*b*) is for waters with a high concentration of nonpigmented particles, and panel (*c*) is for waters rich in yellow matter. (*Based on Prieur and Sathyendranath,*[48] *with permission.*)

by nonpigmented organic particles derived from deceased phytoplankton, and by yellow matter derived from decayed phytoplankton. The contribution of phytoplankton to the total absorption was parametrized in terms of the chlorophyll concentration C (i.e., chlorophyll a plus pheophytin a). The contributions of nonpigmented particles and of yellow matter were parametrized in terms of both the chlorophyll concentration and the total scattering coefficient at $\lambda = 550$ nm, $b(550)$. The essence of the Prieur-Sathyendranath model is contained in a more recent and simpler variant given by Morel:[6]

$$a(\lambda) = [a_w(\lambda) + 0.06a_c^{*\prime}(\lambda)C^{0.65}][1 + 0.2\exp(-0.014(\lambda - 440))] \quad (1)$$

Here $a_w(\lambda)$ is the absorption coefficient of pure water and $a_c^{*\prime}(\lambda)$ is a nondimensional, statistically derived chlorophyll-specific absorption coefficient; $a_w(\lambda)$ and $a_c^{*\prime}(\lambda)$ values are given in Table 9 [these $a_w(\lambda)$ values are slightly different than those of Table 6]. When C is expressed in mg m^{-3} and λ is in nm, the resulting $a(\lambda)$ is in m^{-1}.

Another simple bio-optical model for absorption has been developed independently by Kopelevich.[49] It has the form[50]

$$a(\lambda) = a_w(\lambda) + C[a_c^0(\lambda) + 0.1\exp[-0.015(\lambda - 400)]$$

where $a_c^0(\lambda)$ is the chlorophyll-specific absorption coefficient for phytoplankton (m^2 mg^{-1}), and $a_w(\lambda)$ and C are defined as for Eq. (1). The Kopelevich model as presently used[49] takes $a_w(\lambda)$ from Smith and Baker[32] (Table 6) and takes $a_c^0(\lambda)$ from Yentsch.[51]

Although these and similar bio-optical models for absorption are frequently used, caution is advised in their application. Both models assume that the absorption by yellow matter covaries with that due to phytoplankton; i.e., each implies that a fixed percentage of the total absorption at a given wavelength always comes from yellow matter. The general validity of this assumption is doubtful even for open ocean waters: Bricaud et al.[42] show data (Fig. 5) for which $a(375)$, used as an index for yellow matter concentration, is uncorrelated with chlorophyll concentration even in oceanic regions uninfluenced by freshwater runoff. Gordon[52] has developed a model that avoids assuming any relation between yellow matter and phytoplankton. However, his model becomes singular as $C \rightarrow 0.01$ mg m^{-3} and cannot be expected to work well for C much less than 0.1 mg m^{-3}. The Kopelevich model has the chlorophyll contribution proportional to C, whereas the Morel model has $C^{0.65}$. The exponent of 0.65 is probably closer to reality, since it reflects a change in the relative contributions to absorption by phytoplankton and by detritus as the chlorophyll concentration changes (absorption by detritus is relatively more important at low chlorophyll concentrations[52]). Moreover, the chlorophyll-specific absorption curve of Yentsch[51] used in the Kopelevich

*Condensed with permission from Prieur and Sathyendranath,[48] who give values every 5 mm.

model is based on laboratory cultures of phytoplankton, whereas the later work by Prieur and Sathyendranath used in situ observations to derive the $a_c^{*\prime}(\lambda)$ values of Table 9—an additional point in favor of Eq. (1). Either of these bio-optical models is useful but clearly imperfect. They may (or may not) give correct *average* values, but they give no information about the *variability* of $a(\lambda)$. It can be anticipated that the simple models now available will be replaced, perhaps by models designed for specific regions and seasons, as better understanding of the variability inherent in spectral absorption is achieved.

1.16 MEASUREMENT OF SCATTERING

Scattering in natural waters is caused both by small scale ($<<\lambda$) density fluctuations attributable to random molecular motions and by the ubiquitous large ($>\lambda$) organic and inorganic particles. Scattering by water molecules (and salt ions, in seawater) determines the minimum values for the scattering properties. However, as is the case for absorption, the scattering properties of natural waters are greatly modified by the particulate matter that is always present.

Scattering measurements are even more difficult than absorption measurements. The conceptual design of an instrument for measuring the volume scattering function $\beta(\psi, \lambda)$ is no more complicated than Fig. 2 and the defining equation $\beta(\psi, \lambda) = I_s(\psi, \lambda)/[E_i(\lambda)\ \Delta V]$: a collimated beam of known irradiance E_i illuminates a given volume of water ΔV and the scattered intensity I_s is measured as a function of scattering angle and wavelength. However, the engineering of instruments capable of the in situ determination of $\beta(\psi, \lambda)$ is quite difficult. The magnitude of the scattered intensity typically increases by five or six orders of magnitude in going from $\psi = 90°$ to $\psi = 0.1°$ for a given natural water sample, and scattering at a given angle ψ can vary by two orders of magnitude among water samples. The required dynamic range of an instrument is therefore great. Corrections must be made for absorption within the sample volume and also along the incident and scattered beam paths for in situ instruments. The rapid change in $\beta(\psi, \lambda)$ at small scattering angles requires very precise alignment of the optical elements, but rolling ships seem designed to knock things out of alignment. Because of these design difficulties only a few one-of-a-kind instruments have been built for in situ measurement of the volume scattering function, and measurements of $\beta(\psi, \lambda)$ are not routinely made. Petzold[53] gives the details of two such instruments, one for small scattering angles ($\psi = 0.085$, 0.17, and 0.34°) and one for larger angles ($10° \le \psi \le 170°$); these are the instruments used to obtain the data presented in Sec. 1.18. Other instruments are referenced in Kirk[8] and in Jerlov.[29]

Commercial instruments are available for laboratory measurement of $\beta(\psi, \lambda)$ at fixed scattering angles (e.g., ψ every 5° from ~20° to ~160°). These instruments are subject to their own problems, such as degradation of samples between the times of collection and measurement. Moreover, measurements of $\beta(\psi, \lambda)$ over a limited range of ψ are not sufficient for determination of $b(\lambda)$ by integration. In practice, the scattering coefficient $b(\lambda)$ is usually determined by the conservation of energy relation $b(\lambda) = c(\lambda) - a(\lambda)$ after measurements of beam attenuation and absorption have been made.

Both in situ and laboratory instruments sample (~cm^3) volumes of water and therefore may fail to detect the presence of optically significant large aggregates (marine snow) if such particles are too few in number to be reliably captured in the sample volume. However, such particles can affect the scattering properties of large volumes of water (e.g., as seen in remote sensing or underwater visibility studies).

Measurements at near forward ($\psi < 1°$) and near backward ($\psi > 179°$) angles are exceptionally difficult to make, yet the behavior of $\beta(\psi, \lambda)$ at these extreme angles is of considerable interest. Accurate determination of β at small angles is crucial to the determination of b by integration since typically one-half of all scattering takes place at angles of less than a few degrees. Scattering at small angles is important in underwater imaging and it is of theoretical interest for its connections to scattering theory, particle optical properties, and particle size distributions. The behavior of β very near $\psi = 180°$ is important in laser remote-sensing applications.

Spinrad et al.[54] and Padmabandu and Fry[55] have reported measurements at very small angles on suspensions of polystyrene spheres but no such measurements have been published for natural water samples. The Padmabandu and Fry technique is notable in that it allows the measurement of β at $\psi = 0°$ exactly by use of the coupling of two coherent beams in a photorefractive crystal to measure the phase shift that corresponds to 0° scattering. Measurement of $\beta(0, \lambda)$ is of theoretical interest because of its relation to attenuation via the optical theorem. Enhanced backscatter has been reported[56] in suspensions of latex spheres; a factor-of-two increase in scattered intensity between $\psi = 179.5$ and 180.0° is typical. Whether or not such backscattering enhancement ever occurs in natural waters is a subject of heated debate.

1.17 SCATTERING BY PURE WATER AND BY PURE SEA WATER

Morel[57] has reviewed in detail the theory and observations pertaining to scattering by pure water and by pure sea water. In pure water random molecular motions give rise to rapid fluctuations in the number of molecules in a given volume ΔV, where ΔV is small compared to the wavelength of light but large compared to atomic scales (so that the liquid within the volume is adequately described by statistical thermodynamics). The Einstein-Smoluchowski theory of scattering relates these fluctuations in molecular number density to associated fluctuations in the index of refraction, which give rise to scattering. In sea water the basic theory is the same but random fluctuations in the concentrations of the various ions (Cl^-, Na^+, etc.) give somewhat greater index of refraction fluctuations, and hence greater scattering. The net result of these considerations is that the volume scattering function for either pure water or for pure sea water has the form

$$\beta_w(\psi, \lambda) = \beta_w(90°, \lambda_0)\left(\frac{\lambda_0}{\lambda}\right)^{4.32}(1 + 0.835\cos^2\psi) \qquad \text{m}^{-1}\ \text{s r}^{-1} \tag{2}$$

which is reminiscent of the form for Rayleigh scattering. The wavelength dependence of λ^{-432} rather than λ^{-4} (for Rayleigh scattering) results from the wavelength dependence of the index of refraction. The 0.835 factor is attributable to the anisotropy of the water molecules. The corresponding phase function is

$$\tilde{\beta}_w(\psi) = 0.06225(1 + 0.835\cos^2\psi) \qquad \text{sr}^{-1}$$

and the total scattering coefficient $b_w(\lambda)$ is given by

$$b_w(\lambda) = 16.06\left(\frac{\lambda_0}{\lambda}\right)^{4.32}\beta_w(90°, \lambda_0) \qquad \text{m}^{-1} \tag{3}$$

Table 10 gives values of $\beta_w(90°, \lambda)$ and $b_w(\lambda)$ for selected wavelengths for both pure water and pure sea water ($S = 35$ to 39‰). Note that the pure sea water values are about 30 percent greater than the pure water values at all wavelengths. Table 11 shows the dependence of $b_w(546)$ on pressure, temperature, and salinity. Note that molecular scattering decreases as decreasing temperature or increasing pressure reduce the smallscale fluctuations.

1.18 SCATTERING BY PARTICLES

Heroic efforts are required to obtain water of sufficient purity that a Rayleigh-like volume scattering function is observed. As soon as there is a slight amount of particulate matter in the water—always the case for even the clearest natural water—the volume scattering function becomes highly peaked in the forward direction, and the scattering coefficient increases by at least a factor of 10.

†Computed from $b(\lambda) = 16.0\beta(90°, \lambda)$.

Even for the most numerous oceanic particles (e.g., colloids at a concentration of 10^{15} m^{-3}) the average distance between particles is greater than ten wavelengths of visible light. For the optically most significant phytoplankton the average separation is thousands of wavelengths. Moreover, these particles usually are randomly distributed and oriented. Ocean water therefore can be treated as a very dilute suspension of random scatterers and consequently the intensity of light scattered by an ensemble of particles is given by the sum of the intensities due to the individual particles. Coherent scattering effects are negligible except perhaps at extremely small scattering angles.[58] An overview of scattering by particles is given in Chap. 7 "Scattering by Particles" by Craig F. Bohren in Vol. I.

The contribution of the particulate matter to the total volume scattering function $\beta(\psi, \lambda)$ is obtained from

$$\beta_p(\psi, \lambda) \equiv \beta(\psi, \lambda) - \beta_w(\psi, \lambda)$$

Here the subscript p refers to particles, and w refers to pure water (if β is measured in fresh water) or pure sea water (for oceanic measurements). Figure 10 shows several particle volume scattering functions determined from in situ measurements of $\beta(\psi, \lambda)$ in a variety of waters ranging from very clear to very turbid. The particles cause at least a four-order-of-magnitude increase in scattering between $\psi \approx 90°$ and $\psi \approx 1°$. The contribution of molecular scattering to the total is therefore completely negligible except at backscattered directions ($\psi \geq 90°$) in the clearest natural waters. The top curve in Fig. 10 is shown for small scattering angles in Fig. 11. The scattering function shows

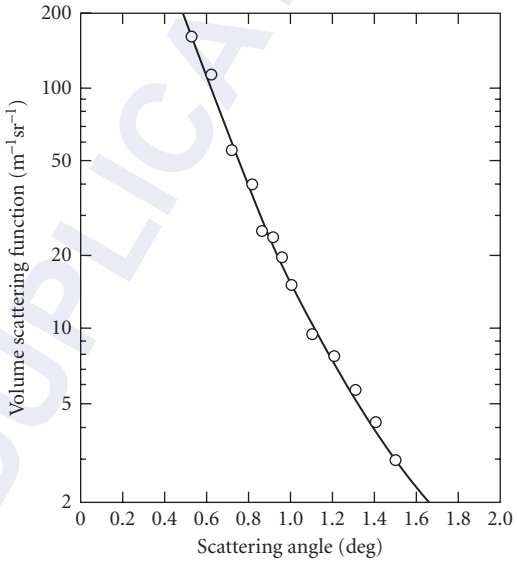

FIGURE 11 Detail of the forward scattering values of the "lake" volume scattering function seen in the top curve of Fig. 10. (*Redrawn from Preisendorfer.*[2])

no indication of "flattening out" even at angles as small as 0.5°. Note that the scattering function increases by a factor of 100 over only a one-degree range of scattering angle.

Highly peaked forward scattering such as that seen in Figs. 10 and 11 is characteristic of diffraction-dominated scattering in a polydisperse system. Scattering by refraction and reflection from particle surfaces becomes important at large scattering angles ($\psi \gtrsim 15°$). Mie scattering calculations are well able to reproduce observed volume scattering functions given the proper optical properties and size distributions. Early efforts along these lines are seen in Kullenberg[59] and in Brown and Gordon.[60] Brown and Gordon were unable to reproduce observed backscattering values using measured particle size distributions. However, their instruments were unable to detect submicrometer particles. They found that the Mie theory properly predicted backscattering if they assumed the presence of numerous, submicrometer, low-index-of-refraction particles. It is reasonable to speculate that bacteria and the recently discovered colloidal particles are the particles whose existence was inferred by Brown and Gordon. Recent Mie scattering calculations[61] have used three-layered spheres to model the structure of phytoplankton (cell wall, chloroplasts, and cytoplasm core) and have used polydisperse mixtures of both organic and inorganic particles.

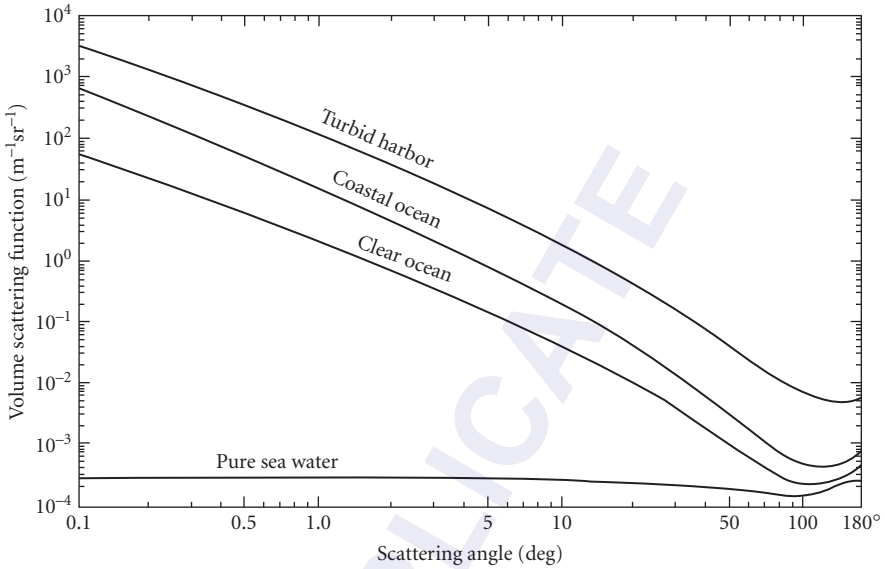

FIGURE 12 Measured volume scattering functions from three different natural waters and the computed volume scattering function for pure sea water, all at $\lambda = 514$ nm. (*Redrawn from Petzold.*[53])

The most carefully made and widely cited scattering measurements are found in Petzold.[53] Figure 12 shows three of his $\beta(\psi, \lambda)$ curves displayed on a log-log plot to emphasize the forward scattering angles. The instruments had a spectral response centered at $\lambda = 514$ nm with an FWHM of 75 nm. The top curve was obtained in the very turbid water of San Diego Harbor, California; the center curve comes from near-shore coastal water in San Pedro Channel, California; and the bottom curve is from very clear water in the Tongue of the Ocean, Bahama Islands. The striking feature of these volume scattering functions (and those of Fig. 10) from very different waters is the similarity of their shapes. Although the scattering coefficients b of the curves in Fig. 12 vary by a factor of 50 (Table 13), the uniform shapes suggest that it is reasonable to define a "typical" particle phase $\tilde{\beta}_p(\psi, \lambda)$. This has been done[62] with three sets of Petzold's data from waters with a high particulate load (one set being the top curve of Fig. 12), as follows: (1) subtract $\beta_w(\psi, \lambda)$ from each curve to get three particle volume scattering functions $\beta_p^i(\psi, \lambda)$, $i = 1, 2, 3$; (2) compute three particle phase functions via $\tilde{\beta}_p^i(\psi, \lambda) = \beta_p^i(\psi, \lambda) / b^i(\lambda)$; (3) average the three particle phase functions to define the typical particle phase function $\tilde{\beta}_p(\psi, \lambda)$. Table 12 displays the three Petzold volume scattering functions plotted in Fig. 12, the volume scattering function for pure sea water, and the average particle phase function computed as just described. This particle phase function satisfies the normalization $2\pi \int_0^\pi \tilde{\beta}_p(\psi, \lambda) \sin\psi \, d\psi = 1$ if a behavior of $\tilde{\beta}_p \sim \psi^{-m}$ is assumed for $\psi < 0.1°$ (m is a positive constant between zero and two, determined from $\tilde{\beta}_p$ at the smallest measured angles), and a trapezoidal rule integration is used for $\psi \geq 0.1°$, with linear interpolation used between the tabulated values. This average particle phase function is adequate for many radiative transfer calculations. However, the user must remember that significant deviations from the average can be expected in nature (e.g., in waters with abnormally high numbers of either large or small particles), although the details of such deviations have not been quantified.

Table 13 compares several inherent optical properties for pure sea water and for the three Petzold water samples of Fig. 12 and Table 12. These data show how greatly different even clear ocean water is from pure sea water. Note that natural water ranges from absorption-dominated ($\omega_0 = 0.247$) to scattering-dominated ($\omega_0 = 0.833$) at $\lambda = 514$ nm. The ratio of backscattering to total scattering is typically a few percent in natural water. However, there is no clear relation between b_b/b and the water type, at least for the Petzold data of Table 13. This lack of an obvious relation is likely the result of

differing particle types in the three waters. Since refraction and reflection are important processes at large scattering angles, the particle indices of refraction are important in determining b_b. Total scattering is dominated by diffraction and so particle composition has little effect on b values. The last row of Table 13 gives the angle ψ such that one-half of the total scattering occurs at angles between 0 and ψ. This angle is rarely greater than 10° in natural waters.

1.19 WAVELENGTH DEPENDENCE OF SCATTERING: BIO-OPTICAL MODELS

The strong $\lambda^{-4.32}$ wavelength dependence of pure-water scattering is not seen in natural waters. This is because scattering is dominated by diffraction from polydisperse particles that are usually much larger than the wavelength of visible light. Although diffraction depends on the particle size-to-wavelength ratio, the presence of particles of many sizes diminishes the wavelength effects that are seen in diffraction by a single particle. Moreover, diffraction does not depend on particle composition. However, some wavelength dependence is to be expected, especially at backward scattering angles where refraction, and hence particle composition, is important. Molecular scattering also contributes something to the total scattering and can even dominate the particle contribution at backscatter angles in clear water.[63]

Morel[64] presents several useful observations on the wavelength dependence of scattering. Figure 13 shows two sets of volume scattering functions, one from the very clear waters of the Tyrrhenian Sea and one from the turbid English Channel. Each set displays $\beta(\psi, \lambda)/\beta(90°, \lambda)$ for $\lambda = 366$, 436, and

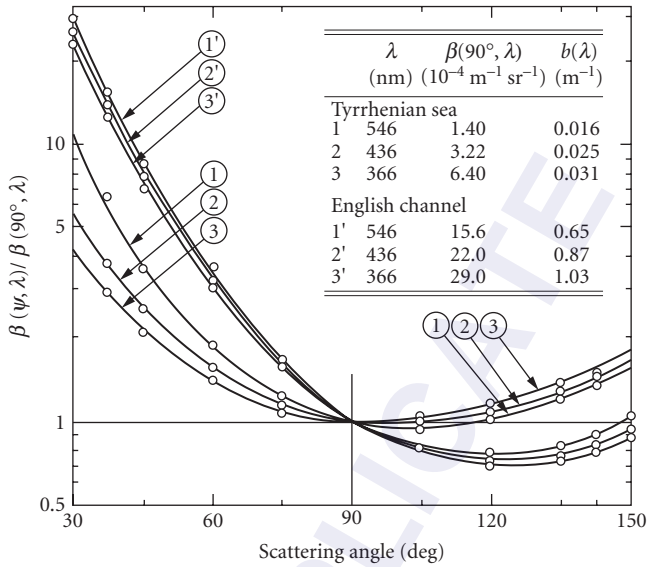

FIGURE 13 Wavelength dependence of total volume scattering functions measured in very clear (Tyrrhenian Sea) and in turbid (English Channel) waters. (*Redrawn from Morel.*[64])

546 nm. The clear water shows a definite dependence of the shape of $\beta(\psi, \lambda)$ on λ whereas the particle-rich turbid water shows much less wavelength dependence. In each case the volume scattering function of shortest wavelength is most nearly symmetric about $\psi = 90°$, presumably because symmetric molecular scattering is contributing relatively more to the total scattering at short wavelengths.

Figure 14 shows a systematic wavelength dependence of particle volume scattering functions. Figure 14*a* shows average values of $\beta_p(\psi, 366\text{ nm})/\beta_p(\psi, 546\text{ nm})$ for N samples as labeled in

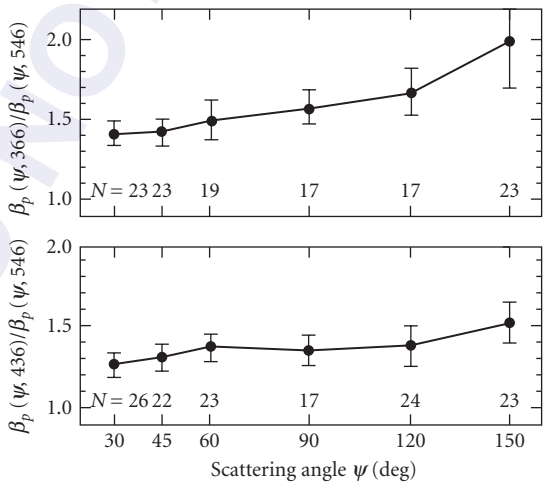

FIGURE 14 Wavelength dependence of particulate volume scattering functions. N is the number of samples. (*Redrawn from Morel.*[64])

TABLE 14 Exponents n Required to Fit the Data of Fig. 14 Assuming That $\beta_p(\psi, \lambda) = \beta_p(\psi, 546)(546/\lambda)^n$

	Scattering angle ψ

436	0.99	1.33	1.89

the figure. The vertical bars are one standard deviation of the observations. Figure 14*b* shows the ratio for $\lambda = 436$ to 546 nm. These ratios clearly depend both on wavelength and scattering angle. Assuming that $\beta_p(\psi, \lambda)$ has a wavelength dependence of

$$\beta_p(\psi, \lambda) = \beta_p(\psi, 546)\left(\frac{546\text{ nm}}{\lambda}\right)^n$$

the data of Fig. 14 imply values for n as seen in Table 14. As anticipated, the wavelength dependence is strongest for backscatter ($\psi = 150°$) and weakest for forward scatter ($\psi = 30°$).

Kopelevich[49,65] has statistically derived a two-parameter model for spectral volume scattering functions (VSFs). This model separates the contributions by "small" and "large" particles to the particulate scattering. Small particles are taken to be mineral particles less than 1 μm in size and having an index of refraction of $n = 1.15$; large particles are biologic particles larger than 1 μm in size and having an index refraction of $n = 1.03$. The model is defined by

$$\beta(\psi, \lambda) = \beta_w(\psi, \lambda) + v_s\beta_s^*(\psi)\left(\frac{550\text{ nm}}{\lambda}\right)^{1.7} + v_\ell\beta_\ell^*(\psi)\left(\frac{550\text{ nm}}{\lambda}\right)^{0.3} \tag{4}$$

with the following definitions:

$\beta_w(\psi, \lambda)$	the VSF of pure sea water, given by Eq. (2) with $\lambda_0 = 550$ nm and an exponent of 4.30
v_s	the volume concentration of small particles, with units of cm^3 of particles per m^3 of water, i.e., parts per million (ppm)
v_ℓ	the analogous volume concentration of large particles
$\beta_s^*(\psi)$	the small-particle VSF per unit volume concentration of small particles, with units of $m^{-1}\ sr^{-1}\ ppm^{-1}$
$\beta_\ell^*(\psi)$	the analogous large-particle concentration-specific VSF

The concentration-specific VSFs for small and large particles are given in Table 15. Equation (4) can be evaluated as if the two parameters v_s and v_ℓ are known; the ranges of values for oceanic waters are $0.01 \le v_s \le 0.20$ ppm $0.01 \le v_\ell \le 0.40$ ppm. However, these two parameters are themselves parametrized in terms of the total volume scattering function measured at $\lambda = 550$ nm for $\psi = 1$ and 45°:

$$\begin{aligned} v_s &= -1.45\times10^{-4}\beta(1°, 550\text{ nm}) + 10.2\beta(45°, 550\text{ nm}) - 0.002 \\ v_\ell &= 2.2\times10^{-2}\beta(1°, 550\text{ nm}) - 1.2\beta(45°, 550\text{ nm}) \end{aligned} \tag{5}$$

Thus $\beta(\psi, \lambda)$ can also be determined from two measurements of the total VSF.

The mathematical form of the Kopelevich model reveals its underlying physics. Large particles give diffractive scattering at very small angles; thus $\beta_\ell^*(\psi)$ is highly peaked for small ψ and the wavelength dependence of the large particle term is weak ($\lambda^{-0.3}$). Small particles contribute more to

scattering at large angles and thus have a more symmetric VSF and a stronger wavelength dependence ($\lambda^{-1.7}$). This model gives a reasonably good description of VSFs observed in a variety of waters (Shifrin,[58] fig. 5.20).

Several simple models are available for the scattering coefficient $b(\lambda)$. A commonly employed bio-optical model for $b(\lambda)$ is that of Gordon and Morel[66] (see also Ref. 6):

$$b(\lambda) = b_w(\lambda) + \left(\frac{550\text{ nm}}{\lambda}\right)0.30C^{0.62} \qquad \text{m}^{-1} \tag{6}$$

Here $b_w(\lambda)$ is given by Eq. (3) and Table 10. λ is in nm and C is the chlorophyll concentration in mg m^{-3}. A related bio-optical model for the backscatter coefficient $b_b(\lambda)$ is found in Morel.[45]

$$b_b(\lambda) = \tfrac{1}{2}b_w(\lambda) + \left[0.002 + 0.02(\tfrac{1}{2} - \tfrac{1}{4}\log C\left(\frac{500\text{ nm}}{\lambda}\right)\right]0.30C^{0.62}$$

The $\left(\frac{1}{2} - \frac{1}{4}\log C\right)$ factor gives $b_b(\lambda)$ a λ^{-1} wavelength dependence in very clear ($C = 0.01$ mg m^{-1}) water and no wavelength dependence in very turbid ($C = 100$ mg m^{-3}) water. These empirically derived models are intended for use only in case 1 waters.

A feeling for the accuracy of the $b(\lambda)$ model of Eq. (6) can be obtained from Fig. 15, which plots measured b (550 nm) values versus chlorophyll concentration C in both case 1 and case 2 waters. Note that even when the model is applied to the case 1 waters from which it was derived, the predicated b(550 nm) value easily can be wrong by a factor of 2. If the model is misapplied to case 2 waters, the error can be an order of magnitude. Note that for a given C value, b(550 nm) is higher in case 2 waters than in case 1 waters, presumably because of the presence of additional particles that do not contain chlorophyll.

Integration over ψ of the Kopelevich $b(\psi, \lambda)$ model of Eq. (4) yields another model for $b(\lambda)$:

$$b(\lambda) = 0.0017\left(\frac{500\text{ nm}}{\lambda}\right)^{4.3} + 1.34v_s\left(\frac{550\text{ nm}}{\lambda}\right)^{1.7} + 0.312v_\ell\left(\frac{550\text{ nm}}{\lambda}\right)^{0.3} \qquad \text{m}^{-1}$$

where v_s and v_ℓ are given by Eq. (5). Kopelevich claims that the accuracy of this model is ~30 percent.

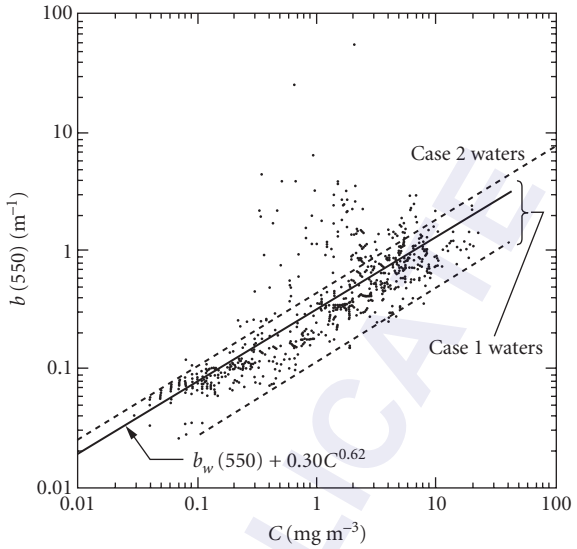

FIGURE 15 Measured scattering coefficients at $\lambda = 550$ nm, $b(550)$, as a function of chlorophyll concentration C. Case 1 waters lie between the dashed lines. Case 2 waters lie above the upper dashed line, which is defined by $b(550) = 0.45C^{0.62}$. The solid line is the model of Eq. (6). (*Redrawn from Gordon and Morel*,[66] *with permission.*)

A bio-optical model related to the Kopelevich model is found in Haltrin and Kattawar[50] (their notation):

$$b(\lambda) = b_w(\lambda) + b^0_{\text{ps}}(\lambda)P_s + b^0_{p\ell}(\lambda)P_\ell$$

Here $b_w(\lambda)$ is given by

$$b_w(\lambda) = 5.826\times10^{-3}\left(\frac{400}{\lambda}\right)^{4.322}$$

which is essentially the same as Eq. (3) and the data in Table 10. The terms $b^0_{\text{ps}}(\lambda)$ and $b^0_{p\ell}(\lambda)$ are the specific scattering coefficients for small and large particles, respectively, and are given by

$$b^0_{\text{ps}}(\lambda) = 1.1513\left(\frac{400}{\lambda}\right)^{1.7} \qquad \text{m}^2\ \text{g}^{-1}$$

$$b^0_{p\ell}(\lambda) = 0.3411\left(\frac{400}{\lambda}\right)^{0.3} \qquad \text{m}^2\ \text{g}^{-1}$$

P_s and P_ℓ are the concentrations in g m^{-3} of small and large particles, respectively. These quantities are parametrized in terms of the chlorophyll concentration C, as shown in Table 16. This work also presents a model for backscattering:

$$b_b(\lambda) = \tfrac{1}{2}b_w(\lambda) + B_s b^0_{\text{ps}}(\lambda)P_s + B_\ell b^0_{p\ell}(\lambda)P_\ell$$

TABLE 16 Parameterization of Small (P_s) and Large (P_ℓ) Particle Concentrations in Terms of the Chlorophyll Concentration C for Use in the Kopelevich-Haltrin-Kattawar Models for $b(\lambda)$ and $b_b(\lambda)$*

Here $B_s = 0.039$ is the backscattering probability for small particles and $B_\ell = 0.00064$ is the backscattering probability for large particles.

The bio-optical models for scattering just discussed are useful but very approximate.

The reason for the frequent large discrepancies between model predictions and measured reality likely lies in the fact that scattering depends not just on particle concentration (as parameterized in terms of chlorophyll concentration), but also on the particle index of refraction and on the details of the particle size distribution which are not well parameterized in terms of the chlorophyll concentration alone. Whether or not the Kopelevich model or its derivative Haltrin-Kattawar form which partition the scattering into large and small particle components is in some sense better than the Gordon-Morel model is not known at present. Another consequence of the complexity of scattering is seen in the next section.

1.20 BEAM ATTENUATION

The spectral beam attenuation coefficient $c(\lambda)$ is just the sum of the spectral absorption and scattering coefficients: $c(\lambda) = a(\lambda) + b(\lambda)$. Since both $a(\lambda)$ and $b(\lambda)$ are highly variable functions of the nature and concentration of the constituents of natural waters so is $c(\lambda)$. Beam attenuation near $\lambda = 660$ nm is the only inherent optical property of water that is easily, accurately, and routinely measured. This wavelength is used both for engineering reasons (the availability of a stable LED light source) and because absorption by yellow matter is negligible in the red. Thus the quantity

$$c_p(660\text{ nm}) \equiv c(660\text{ nm}) - a_w(660\text{ nm}) - b_w(660\text{ nm}) \equiv c(660\text{ nm}) - c_w(660\text{ nm})$$

is determined by the nature of the suspended particulate matter. The particulate beam attenuation c_p (660 nm) is highly correlated with total particle volume concentration (usually expressed in parts per million), but it is much less well correlated with chlorophyll concentration.[67] The particulate beam attenuation can be used to estimate the total particulate load (often expressed as g m^{-3}).[68] However, the dependence of the particulate beam attenuation on particle properties is not simple. Spinrad[69] used Mie theory to calculate the dependence of the volume-specific particulate beam attenuation (particulate beam attenuation coefficient c_p in m^{-1} per unit suspended particulate volume in parts per million) on the relative refractive index and on the slope s of an assumed Junge size distribution for particles in the size range from 1 to 80 μm; the result is shown in Fig. 16. Although the details of the figure are sensitive to the choice of upper and lower size limits in the Mie calculations, the qualitative behavior of the curves is generally valid and supports the statements made in the closing paragraph of Sec. 1.19.

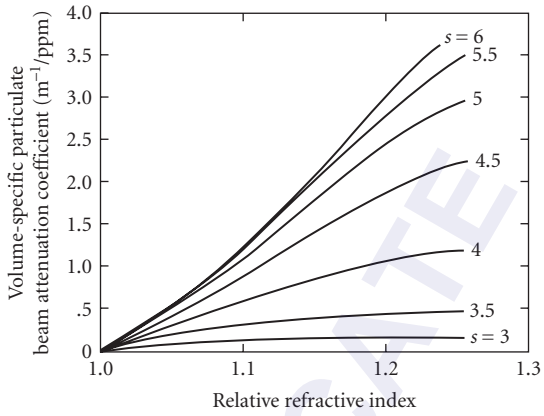

FIGURE 16 Computed relationship between volume-specific particulate beam attenuation coefficient, relative refractive index, and slope *s* of a Junge number size distribution. (*Reproduced from Spinrad,*[69] *with permission.*)

Because of the complicated dependence of scattering and hence of beam attenuation on particle properties, the construction of bio-optical models for $c(\lambda)$ is not easy. The reason is that chlorophyll concentration alone is not sufficient to parametrize scattering.[70] Figure 17 illustrates this insufficiency. The figure plots vertical profiles of c(665 nm), water density (proportional to the oceanographic variable σ_t), and chlorophyll concentration (proportional to fluorescence by chlorophyll and related pigments). Note that the maximum in beam attenuation at 46 m depth coincides with the interface (pycnocline) between less dense water above and more dense water below. Peaks in beam attenuation are commonly observed at density interfaces because particle concentrations are often greatest there. The maximum in chlorophyll concentration occurs at a depth of 87 m. The chlorophyll concentration depends not just on the number or volume of chlorophyll-bearing particles but also on their photoadaptive state, which depends on nutrient availability and ambient lighting. Thus chlorophyll concentration cannot be expected to correlate well with total scattering or with particulate beam attenuation $c_p(\lambda)$.

Voss[71] has developed an empirical model for $c(\lambda)$ given a measurement of c at $\lambda = 490$ nm:

$$c(\lambda) = c_w(\lambda) + [c(490\text{ nm}) - c_w(490\text{ nm})][1.563 - 1.149 \times 10^{-3}\lambda]$$

where λ is in nm and c is in m^{-1}. The attenuation coefficient for pure sea water, $c_w = a_w + b_w$, is given by the Smith-Baker data of Table 6. This model was statistically derived from data of global extent. Testing of the model with independent data usually gave errors of less than 5 percent, although occasional errors of ~20 percent were found.

Voss also determined a least-squares fit of c(490 nm) to the chlorophyll concentration. The result

$$c(490\text{ nm}) = 0.39C^{0.57} \tag{7}$$

is similar in form to the chlorophyll dependence of the $a(\lambda)$ and $b(\lambda)$ models seen in Eqs. (1) and (6), respectively. Figure 18 shows the spread of the data points used to determine Eq. (7). Note that for a given value of C there is an order-of-magnitude spread in values of c(490 nm). The user of Eq. (7) or of the models for $b(\lambda)$ must always keep in mind that large deviations from the predicted values will be found in natural waters.

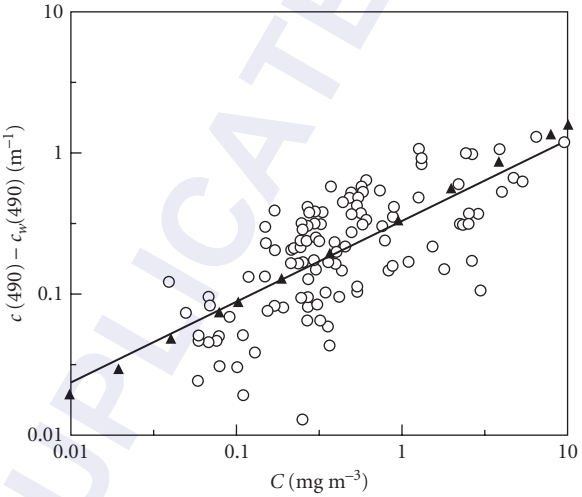

FIGURE 18 Particulate beam attenuation at 490 nm (open circles) as a function of chlorophyll concentration C as used to determine Eq. (7) which is given by the solid line. Solid triangles give values as predicted by the sum of Eqs. (1) and (6). (*Redrawn from Voss,[71] with permission.*)

1.21 DIFFUSE ATTENUATION AND JERLOV WATER TYPES

As seen in Fig. 1 and in Table 1 there is a so-called diffuse attenuation coefficient for any radiometric variable. The most commonly used diffuse attenuation coefficients are those for downwelling plane irradiance, $K_d(z, \lambda)$, and for PAR, $K_{\mathrm{PAR}}(z)$. Although the various diffuse attenuation coefficients are conceptually distinct, in practice they are often numerically similar and they all asymptotically approach a common value at great depths in homogeneous water.[2] The monograph by Tyler and Smith[72] gives tabulations and plots of $E_d(z, \lambda)$, $E_u(z, \lambda)$ and the associated $K_d(z, \lambda)$, $K_u(z, \lambda)$, and $R(z, \lambda)$ measured in a variety of waters.

Observation shows that $K_d(z, \lambda)$ varies systematically with wavelength over a wide range of waters from very clear to very turbid. Moreover, $K_d(z, \lambda)$ is often rather insensitive to environmental effects[73] except for extreme conditions[74] (such as the sun within 10° of the horizon) and in most cases correction can be made[11] for the environmental effects that are present in K_d. K_d therefore is regarded as a quasi-inherent optical property whose variability is governed primarily by changes in the inherent optical properties of the water body and not by changes in the external environment.

Jerlov[29] exploited this benign behavior of K_d to develop a frequently used classification scheme for oceanic waters based on the spectral shape of K_d. The *Jerlov water types* are in essence a classification based on water clarity as quantified by $K_d(z_s, \lambda)$, where z_s is a depth just below the sea surface.

This classification scheme can be contrasted with the case 1 and case 2 classification described earlier, which is based on the nature of the suspended matter within the water. The Jerlov water types are numbered I, IA, IB, II, and III for open ocean waters, and 1 through 9 for coastal waters. Type I is the clearest and type III is the most turbid open ocean water. Likewise, for coastal waters type 1 is clearest and type 9 is most turbid. The Jerlov types I to III generally correspond to case 1 water since phytoplankton predominate in the open ocean. Types 1 to 9 correspond to case 2 waters where yellow matter and terrigenous particulates dominate the optical properties. A rough correspondence between chlorophyll concentration and Jerlov oceanic water type is given by[45]

$$C: \quad 0-0.01\sim 0.05\sim 0.1\sim 0.5\sim 1.5-2.0 \text{ mg m}^{-3}$$

$$\text{water type:} \quad \text{I} \quad \text{IA} \quad \text{IB} \quad \text{II} \quad \text{III}$$

Austin and Petzold[75] reevaluated the Jerlov classification using an expanded database and slightly revised the $K_d(\lambda)$ values used by Jerlov in his original definition of the water types. Table 17 gives the revised values for $K_d(\lambda)$ for the water types commonly encountered in oceanography. These values are recommended over those found in Jerlov.[29] Figure 19 shows the percent transmittance of $E_d(\lambda)$ per meter of water for selected Jerlov water types. Note how the wavelength of maximum transmittance shifts from blue in the clearest open ocean water (type I) to green (types III and 1) to yellow in the most turbid, yellow-matter-rich coastal water (type 9).

Austin and Petzold also presented a simple model that allows the determination of $K_d(\lambda)$ at all wavelengths from a value of K_d measured at any single wavelength. This model is defined by

$$K_d(\lambda) = \frac{M(\lambda)}{M(\lambda_0)}[K_d(\lambda_0) - K_{\text{dw}}(\lambda_0)] + K_{\text{dw}}(\lambda)$$

Here λ_0 is the wavelength at which K_d is measured and K_{dw}, refers to values for pure sea water. $K_{\text{dw}}(\lambda)$ and the statistically derived coefficients $M(\lambda)$ are given in Table 18. (These K_{dw} values differ slightly from those seen in Table 6.) This model is valid in waters where $K_d(490) \le 0.16 \text{ m}^{-1}$ which corresponds to a chlorophyll concentration of $C \le 3 \text{ mg m}^{-3}$.

TABLE 17 Downwelling Irradiance Diffuse Attenuation Coefficients $K_d(\lambda)$ Used to Define the Jerlov Water Types As Determined by Austin and Petzold* (All quantities in the body of the table have units of m^{-1}.)

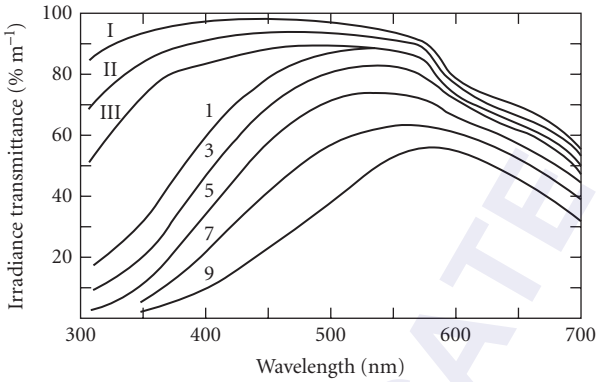

FIGURE 19 Percentage transmittance per meter of water of downwelling irradiance E_d as a function of wavelength for selected Jerlov water types. (*Reproduced from Jerlov,*[29] *with permission.*)

Unlike the beam attenuation coefficient $c(\lambda)$, the diffuse attenuation $K_d(z, \lambda)$ is highly correlated with chlorophyll concentration. The reason is seen in the approximate formula[11]

$$K_d(\lambda) \approx \frac{a(\lambda) + b_b(\lambda)}{\cos\theta_{sw}}$$

where θ_{sw} is the solar angle measured within the water. Since $a(\lambda) >> b_b(\lambda)$ for most waters, $K_d(\lambda)$ is largely determined by the absorption properties of the water, which are fairly well parametrized by the chlorophyll concentration. Beam attenuation on the other hand is proportional to the total scattering which is not well parametrized by chlorophyll concentration. Observations show[76] that the beam attenuation at 660 nm is not in general correlated with diffuse attenuation.

A bio-optical model for $K_d(\lambda)$ is given by Morel:[45]

$$K_d(\lambda) = K_{\mathrm{dw}}(\lambda) + \chi(\lambda) C^{e(\lambda)}$$

Here $K_{\mathrm{dw}}(\lambda)$ is the diffuse attenuation for pure sea water, and $\chi(\lambda)$ and $e(\lambda)$ are statistically derived functions that convert the chlorophyll concentration C in mg m^{-3} into K_d values in m^{-1}. Table 19

gives the K_{dw}, χ, and e values used in the Morel model. This model is applicable to case 1 waters with $C \leq 30$ mg m^{-3}, although the χ and e values are somewhat uncertain for $\lambda > 650$ nm because of sparse data available for their determination. Some feeling for the accuracy of the Morel $K_d(\lambda)$ model can be obtained from Fig. 20 which shows predicted (the line) and observed $K_d(450)$ values as a function of C. Errors can be as large as a factor of 2 in case 1 waters (dots) and can be much larger if the model is misapplied to case 2 waters (open circles). The Morel model allows the determination of $K_d(\lambda)$ if C is measured; the Austin and Petzold model determines $K_d(\lambda)$ from a measurement at one wavelength.

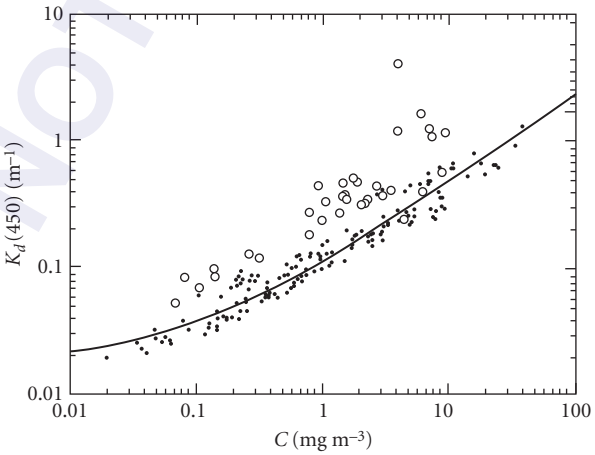

FIGURE 20 Measured K_d values at 450 nm as a function of chlorophyll concentration C. Dots are measurements from case 1 waters; open circles are from case 2 waters. The solid line gives $K_d(450)$ as predicted by the Morel bio-optical model. (*Redrawn from Morel,[45] with permission.*)

Morel[45] also presents a very simple bio-optical model for $\bar{K}_{PAR}(0, z_{eu})$ the value of $K_{PAR}(z)$ averaged over the euphotic zone $0 \le z \le z_{eu}$:

$$\bar{K}_{PAR}(0, z_{eu}) = 0.121C^{0.428}$$

where C is the mean chlorophyll concentration in the euphotic zone in mg m^{-3} and $\bar{K}_{PAR}$ is in m^{-1}. The euphotic zone is the region where there is sufficient light for photosynthesis to take place; it extends roughly to the depth where $E_{PAR}(z)$ is 1 percent of its surface value [i.e., $E_{PAR}(z_{eu}) = 0.01\, E_{PAR}(0)$]. Table 20 gives z_{eu} as a function of C as determined by the Morel model.

1.22 IRRADIANCE REFLECTANCE AND REMOTE SENSING

The spectral irradiance reflectant $R(\lambda) \equiv E_u(\lambda)/E_d(\lambda)$ is an important apparent optical property. Measurements of $R(z, \lambda)$ within the water have been used[77] to estimate water quality parameters such as the chlorophyll concentration, the particle backscattering coefficient, and the absorption coefficient of yellow matter. More importantly, $R(\lambda)$ just below the water surface can be related to the radiance leaving the water;[78] this radiance is available for detection by aircraft- or satellite-borne instruments. Understanding the dependence of $R(\lambda)$ upon the constituents of natural waters is therefore one of the central problems in remote sensing of water bodies.

Figure 21 illustrates the variability of $R(\lambda)$ in natural waters. Figure 21*a* shows $R(\lambda)$ in percent for various case 1 waters. For low-chlorophyll concentrations $R(\lambda)$ is highest at blue wavelengths, hence the blue color of clean ocean water. As the chlorophyll concentration increases, the maximum in $R(\lambda)$ shifts to green wavelengths. The enhanced reflectance near $\lambda = 685$ nm is due to chlorophyll fluorescence. Also note the exceptionally high values measured[20] within a coccolithophore bloom; $R(\lambda)$ is high there because of the strong scattering by the numerous calcite particles (see Sec. 1.6). Figure 21*b* shows $R(\lambda)$ from waters dominated by suspended sediments (i.e., by nonpigmented particles). For high-sediment concentrations $R(\lambda)$ is nearly flat from blue to yellow wavelengths, and therefore the water appears brown. Figure 21*c* is from waters with high concentrations of yellow substances; the peak in $R(\lambda)$ lies in the yellow. With good reason the term "ocean color" is often used as a synonym for $R(\lambda)$.

One of the main goals of oceanic remote sensing is the determination of chlorophyll concentrations in near-surface waters because of the fundamental role played by phytoplankton in the global ecosystem. Gordon et al.[78] define the *normalized water-leaving radiance* $[L_w(\lambda)]_N$ as the radiance that would leave the sea surface if the sun were at the zenith and the atmosphere were absent; this

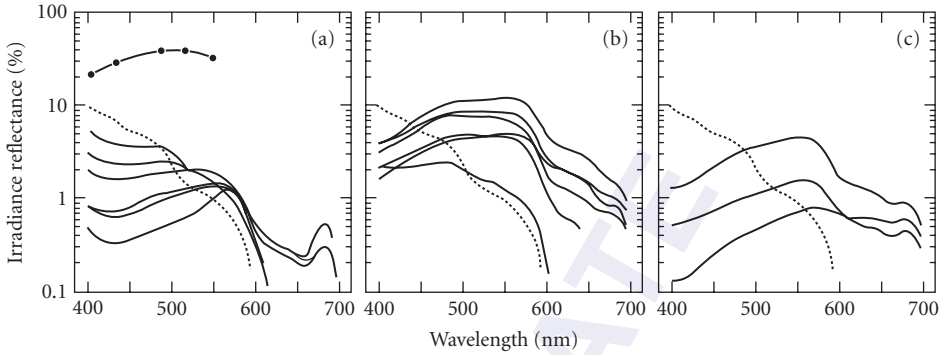

FIGURE 21 Measured spectral irradiance reflectances $R(\lambda)$ from various waters. Panel (*a*) is from case waters with different quantities of phytoplankton; the dotted line is $R(\lambda)$ for pure sea water. The heavy dots give values measured within a coccolithophore bloom.[20] Panel (*b*) is from case 2 waters dominated by suspended sediments and panel (*c*) is from case 2 waters dominated by yellow matter. (*Redrawn from Sathyendranath and Morel,*[79] *with permission.*)

quantity is fundamental to remote sensing. They then show that $[L_w]_N$ is directly proportional to R and that R is proportional to $b_b/(a + b_b)$ (i.e., to b_b/K_d). Although a or K_d are reasonably well modeled in terms of chlorophyll concentration C in case 1 waters, b_b is not well described in terms of C. Thus poor agreement is to be expected between observed values of $[L_w(\lambda)]_N$ and values predicted by a model parametrized in terms of C. This is indeed the case as is seen in Fig. 22*a* and *b* which shows observed and predicted $[L_w(443\text{ nm})]_N$ and $[L_w(550\text{ nm})]_N$ values as a function of chlorophyll concentration. Based on these figures there seems to be little hope of being able to reliably retrieve C from a remotely sensed $[L_w(\lambda)]_N$ value. However, in spite of the noise seen in Fig. 22*a* and *b*, the *ratios* of normalized water-leaving radiances for different wavelengths can be remarkably well-behaved functions of C. Figure 22*c* shows predicted (the line) and observed (dots) values of $[L_w(443\text{ nm})]_N/[L_w(550\text{ nm})]_N$; the agreement between prediction and observation is now rather good. Thus, measurement of $[L_w(\lambda)]_N$ at two (carefully chosen) wavelengths along with application of a bio-optical model for their *ratio* can yield a useful estimate of chlorophyll concentration. Such models are the basis of much remote sensing.

1.23 INELASTIC SCATTERING AND POLARIZATION

Although the basic physics of inelastic scattering and polarization is well understood, only recently has it become computationally practicable to incorporate these effects into predictive numerical models of underwater radiance distributions. For this reason as well as because of the difficulty of making needed measurements, quantitative knowledge about the significance of inelastic scattering and polarization in the underwater environment is incomplete.

Inelastic scattering processes are often negligible in comparison to sunlight or artificial lights as sources of underwater light of a given wavelength. However, in certain circumstances transpectral scatter is the dominant source of underwater light at some wavelengths. Figure 23 illustrates just such a circumstance.

Figure 23 shows a measured depth profile from the Sargasso Sea of irradiance reflectance at $\lambda = 589$ nm (yellow-orange light); note that $R(589\text{ nm})$ increases with depth. Because of the fairly high absorption of water at this wavelength $[a_w(589\text{ nm}) = 0.152\text{ m}^{-1}]$ most of the yellow-orange component of the incident solar radiation is absorbed near the surface and monochromatic radiative transfer theory shows that the reflectance should approach a value of $R(589\text{ nm}) \approx 0.04$ for the

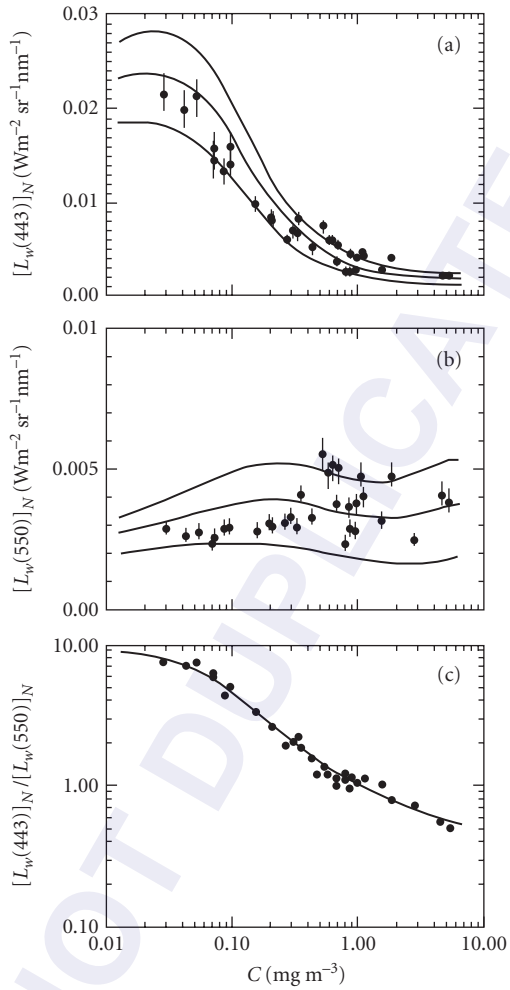

FIGURE 22 In panels (*a*) and (*b*) the solid lines are values of the normalized water-leaving radiances $[L_w(\lambda)]_N$ at $\lambda = 443$ and 550 nm, respectively, as predicted by various models that relate $[L_w(\lambda)]_N$ to the chlorophyll concentration C. The dots are measured values of $[L_w(\lambda)]_N$. Panel (*c*) shows the predicted (line) and observed ratio of the $[L_w(\lambda)]_N$ values of panels (*a*) and (*b*). (*Redrawn from Gordon et al.*,[78] with permission.)

water body of Fig. 22. Calculations by Marshall and Smith[80] explain the paradox. Light of blue-green wavelengths ($\lambda \sim 500$ nm) can penetrate to great depth in the clear Sargasso Sea water [$a_w(500\text{ nm}) \approx 0.026\text{ m}^{-1}$]. Some of this light is then Raman scattered from blue-green to yellow-orange wavelengths providing a source of yellow-orange light at depth. Moreover, since the phase function for Raman scattering is symmetric in the forward and backward hemispheres Raman scattered photons are equally likely to be heading upward [and thus contribute to $E_u(589\text{ nm})$] or downward [and thus contribute to $E_d(589\text{ nm})$] even though most of the blue-green light at depth is heading downward [e.g., $E_d(500\text{ nm}) >> E_u(500\text{ nm})$].

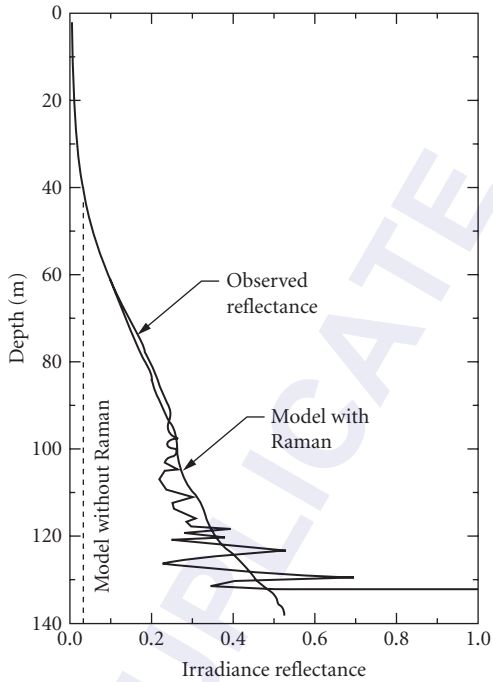

FIGURE 23 Observed irradiance reflectance R at 589 nm (light line) and values predicted by a model including Raman scattering (heavy line) and omitting Raman scattering (dashed line). (*Redrawn from Marshall and Smith,*[80] *with permission.*)

Thus as depth increases and Raman scattering becomes increasingly important relative to transmitted sunlight as a source of ambient yellow-orange light, E_u(589 nm) and E_d(589 nm) become more nearly equal and the irradiance reflectance R(589 nm) increases. Such an increase is not seen at blue-green wavelengths since E_d transmitted from the surface remains much greater than E_u at great depths. Since Raman scattering is by the water molecules themselves this process is present (and indeed relatively more important) even in the clearest waters. Another oceanographic effect of Raman scattering occurs in the filling of Fraunhofer lines in the solar spectrum as seen underwater; this matter is just now coming under detailed investigation.[81]

Fluorescence by chlorophyll or other substances can be significant if the fiuorescing material is present in sufficient quantity. Chlorophyll fiuoresces strongly near $\lambda = 685$ nm; this source of red light is responsible[82] for the enhanced reflectance near 685 nm noted in Fig. 21a. The spectral signature of fluorescence is a useful tool for analyzing many of the constituents of natural waters.[83]

Relatively little attention has been paid to the state of polarization of underwater light fields.[84] Some use of polarized light has been made in enhancing underwater visibility[85] and it is well established that many oceanic organisms sense polarized light when navigating.[86] Voss and Fry[87] measured the Mueller matrix for ocean water and Quinby-Hunt et al.[88] have studied the propensity of certain phytoplankton to induce circular polarization in unpolarized or linearly polarized light. Kattawar and Adams[89] have shown that errors of up to 15 percent can occur in calculations of underwater radiance if scalar (unpolarized) radiative transfer theory is used instead of vector (polarized) theory.

1.24 ACKNOWLEDGMENTS

This paper was written while the author held a National Research Council Resident Research Associateship (Senior Level) at the Jet Propulsion Laboratory, California Institute of Technology. This associateship was supported by the Ocean Biochemistry Program at NASA Headquarters. Final proofing was supported by SRI. Karen Baker, Annick Bricaud, Howard Gordon, Richard Honey, Rodolpho Iturriaga, George Kattawar, Scott Pegau, Mary Jane Perry, Collin Roesler, Shubha Sathyendranath, Richard Spinrad, and Kenneth Voss all made helpful comments on a draft of the paper; their efforts are greatly appreciated.

2.1 GLOSSARY

A, B, C, D, E, G	dispersion equation constants
a, b	partial dispersion equation constants
a, b, c	crystal axes
$\mathbf{B}$	inverse dielectric constant ($=1/\varepsilon = 1/n^2$)
B	bulk modulus
C	heat capacity
c	speed of light
$\mathbf{c}$	elastic stiffness tensor
$\mathbf{D}$	electric displacement
D	dispersion
d	piezoelectric coefficient
$d_{ij}^{(2)}$	nonlinear optical coefficient
E	Young's modulus
E	energy
$\mathbf{E}$	electric field
e	strain
G	shear modulus
G	thermal optical constant
g	degeneracy
Hi	Hilbert transform
h	heat flow
k	Index of absorption
k_B	Boltzmann constant
ℓ	phonon mean free path
L	length
MW	molecular weight
m	Integer, mass
$N(\ )$	occupation number density
n	refractive index

$\tilde{n}$	complex refractive index = $n + ik$
$\mathbf{P}$	electric polarization
P	relative air pressure = air pressure/one atmosphere (dimensionless)
P	pyroelectric constant
$P_{x,y}$	relative partial dispersion
$\mathbf{p}$	elasto-optic tensor
$\mathbf{q}$	piezo-optic tensor
r	electro-optic coefficient
r	amplitude reflection coefficient
r_{ij}	electro-optic coefficient
$S(\ )$	oscillator strength
$\mathbf{s}$	elastic compliance tensor
T	temperature
t	amplitude transmission coefficient
U	enthalpy
u	atomic mass unit
V	Volume
v	velocity of sound
x	displacement
x	variable of integration
Z	formulas per unit cell
α	linear thermal expansion coefficient
α	intensity (power) absorptance
α_m	macroscopic polarizability
α, β, γ	crystal angles
β	power absorption coefficient
$\gamma(\ )$	line width
γ	Gruneisen parameter
ε	relative dielectric constant, permittivity
ε	emittance
θ_D	Debye temperature
κ	thermal conductivity
λ	wavelength
$\Lambda(\ )$	complex function
μ	permeability
ν	wave number ($\omega/2\pi c$)
ν_d	Abbe number (constringence)
ρ	density
ρ	intensity reflectance
σ	stress
τ	intensity (power) transmittance
χ	susceptibility
$\chi^{(2)}$	second-order susceptibility
Ω	solid angle
ω	frequency

Subscripts

ABS	absorptance
abs	absolute
bb	blackbody
C	656.3 nm
d	587.6 nm
EXT	extinctance

F	486.1 nm
i	integers
P	constant pressure
r	relative
SCA	scatterance
V	constant volume
0	vacuum or constant terms (or $T = 0$)
1, 2, 3	principal axes

2.2 INTRODUCTION

Nearly every nonmetallic crystalline and glassy material has potential use in transparent optics. If a nonmetal is sufficiently dense and homogeneous, it will have good optical properties. Generally, a combination of desirable optical properties, good thermal and mechanical properties, and cost and ease of manufacture dictate the number of readily available materials. In practice, glasses dominate the available optical materials for several important reasons. Glasses are easily made of inexpensive materials, and glass manufacturing technology is mature and well-established. The resultant glass products can have very high optical quality and meet most design requirements.

Common glasses, however, are composed of low-atomic-weight oxides and therefore will not transmit beyond about 2.5 μm or below 0.3 μm. Some crystalline materials transmit at wavelengths longer (e.g., heavy-metal halides and chalcogenides) or shorter (e.g., fluorides) than common, oxide-based glasses. Crystalline materials are also used for situations that require the material to have very low scatter, high thermal conductivity, or exceptionally high hardness and strength, especially at high temperature. Other applications of crystalline optical materials make use of their directional properties, particularly those of noncubic (uni- or biaxial) crystals. Phase matching (e.g., in wave mixing) and polarization (e.g., in wave plates) are example applications. For these reasons, crystalline solids are used for a wide variety of specialized applications.

Polycrystalline materials form an intermediate class. Typically engineered from powders, polycrystalline materials approach the properties of crystals with reduced cost, particularly when made into complex shapes. Most polycrystalline materials are made with large grains ($>>\lambda$) to reduce scatter, and the properties of crystalline materials in this chapter are obtained from samples with large grains or single crystals. Recent work has produced materials with sub-micrometer grains ($<<\lambda$) for applications such as laser gain media and highly durable windows.

This chapter gives the physical, mechanical, thermal, and optical properties of selected crystalline, polycrystalline, and glassy materials. Crystals are chosen based on availability of property data and usefulness of the material. Unfortunately, for many materials, property data are imprecise, incomplete, or not wholly applicable to optical-quality material. Glasses are more accurately and uniformly characterized, but their optical property data are usually limited to wavelengths below 1.06 μm. Owing to the preponderance of glasses, only a small, representative fraction of available glasses are included below. SI-derived units, as commonly applied in material characterization, are used.

Property data are accompanied with brief explanations and useful functional relationships. We have updated the previous version of this chapter[1] by extracting property data from standard compilations[2–12] as well as recent literature. Unfortunately, property data are often sparse. For example, refractive index data may be available for only a portion of the transparent region or the temperature dependence of the index may not be known. Strength of many materials is poorly characterized. Thermal conductivity is frequently unavailable and other thermal properties are usually sketchy.

For brevity, we have reduced the number of materials in this chapter. Many seldom-used or no-longer-produced materials have been eliminated. New materials, principally used for laser gain media or wave mixing were added. Glasses have been updated to their new arsenic- and lead-free analogs.

2.3 OPTICAL MATERIALS

Crystalline and amorphous (including glass) materials are differentiated by their structural (crystallographic) order. The distinguishing structural characteristic of amorphous substances is the absence of long-range order; the distinguishing characteristic of crystals is the presence of long-range order. This order, in the form of a periodic structure, can cause directional-dependent (anisotropic) properties that require a more complex description than needed for isotropic, amorphous materials. The periodic structure of crystals are used to classify them into six crystal systems,* and further arrange them into 14 (Bravais) space lattices, 32 point groups, and 230 space groups based on the characteristic symmetries found in a crystal.

Glass is by far the most widely used optical material, accounting for more than 90 percent of all optical elements manufactured. Traditionally, glass has been the material of choice for optical systems designers, owing to its high transmittance in the visible-wavelength region, high degree of homogeneity, ease of molding, shaping, and machining, relatively low cost, and the wide variety of index and dispersion characteristics available.

Under proper conditions, glass can be formed from many different inorganic mixtures. Primary glass-forming compounds include oxides, halides, and chalcogenides with the most common mixtures being the oxides of silicon, boron, and phosphorous used for glasses transmitting in the visible spectrum. By varying the chemical composition of glasses (glasses are not fixed stoichiometrically), the properties of the glass can be modified. For optical applications, glass compositions are altered to vary the refractive index, dispersion, and thermo-optic coefficient, allowing glasses to be used in combination to make optics with excellent performance over wide spectral and temperature ranges.

Historically, emphasis was placed on optimizing optics for the visible spectrum. The approach was to produce a wide variety of glass and selecting the best combination of glasses to optimize a design. Early glass technologists found that adding BaO offered a high-refractive-index glass with lower than normal dispersion, B_2O_3 offered low index and very low dispersion, and by replacing oxides with fluorides, glasses could be obtained with very low index and very low dispersion. Later, others developed very high index glasses with relatively low dispersions by introducing rare-earth elements, especially lanthanum, to glass compositions. Other compounds are added to silica-based glass mixtures to help with chemical stabilization, typically the alkaline earth oxides and in particular Al_2O_3 to improve the resistance to attack by water.

Advances in detector and source technology pushed the design spectrum into both the UV and IR. To extend the transmission range of glasses into the ultraviolet, a number of fluoride and fluorophosphate glasses were developed. Nonoxide glasses are used for infrared applications requiring transmission beyond the transmission limit of typical optical glasses (cf., 2.4 to 2.7 μm for an absorption coefficient of $<1\ cm^{-1}$). These materials include chalcogenides such as As_2S_3 glass and heavy-metal fluorides such as ZrF_4-based glasses.

With today's computing power, optical designs are becoming far more elegant and simple, and require fewer optical glass types. Advances in polishing and use of aspheres have introduced a new design variable, reducing the dependence on a continuous range material properties. An increased awareness of the environment has led to the elimination of many hazardous materials from optical glasses. These factors lead to a major reduction of the glass library available from manufacturers.

Crystalline materials include naturally occurring minerals and manufactured crystals. Both single crystals and polycrystalline forms are available for many materials. Polycrystalline optical materials are typically composed of many small (cf., 50 to 200 μm) individual crystals ("grains") with random orientations and *grain boundaries* between them. These grain boundaries are a form of material defect arising from the lattice mismatch between individual grains. Polycrystalline materials are made by diverse means such as pressing powders (usually with heat applied), sintering, or chemical vapor deposition. Single crystals are typically grown from dissolved or molten material using a variety of techniques. Usually, polycrystalline materials offer greater hardness and strength at the expense of increased scatter and reduced thermal conductivity.

*Cubic (or isometric), hexagonal (including rhombohedral), tetragonal, orthorhombic, monoclinic, and triclinic are the crystallographic systems.

Uniformity of the refractive index throughout an optical element is a prime consideration in selecting materials for high-performance lenses, elements for coherent optics, laser harmonic generation, and acousto-optical devices. In general, highly pure, single crystals achieve the best uniformity, followed by glasses (especially those specially manufactured for homogeneity), and lastly polycrystalline materials. Similarly, high-quality single crystals have very low scatter, typically one-tenth that of the best glasses.

Applications requiring optical elements with direction-dependent properties, such as polarizers and phase-matching materials for harmonic generation, frequently use single crystals.

Purity of starting materials is a prime factor in determining the quality of the final product. High material quality and uniformity of processing is required to avoid impurity absorption, index nonuniformity, voids, cracks, and bubbles, and excess scatter. Practical manufacturing techniques limit the size of optics produced from a given material (glasses are typically limited by the moduli, i.e., deformation caused by the weight of the piece). Some manufacturing methods, such as hot pressing, also produce significantly lower quality material when size becomes large (especially when the thinnest dimension is significantly increased). Cost of finished optical elements is a function of size, raw material cost, and the difficulty of machining, polishing, and coating the material. Any one of these factors can dominate cost.

Information on general optical glass properties and classification can be found on select manufacturer's websites[13-15] and in the literature.[16,17] General information on the manufacturing methods for glasses and crystalline materials is available in several sources.[10,12,18,19] Information on cutting and polishing of optical elements can be found in the literature.[3,20,21] Further information on applications of optical material are found in this section of this *Handbook* and a variety of sources.[2,18,22,23]

2.4 PROPERTIES OF MATERIALS

Symmetry Properties

The description of the properties of solids depends on structural symmetry. The structural symmetry of crystalline materials dictates the number of appropriate directional-dependent terms that describe a property.[24] *Neumann's principle* states that physical properties of a crystal must possess at least the symmetry of the point group of the crystal. Amorphous (glassy) materials, having no long-range symmetry, are generally considered isotropic,* and require the least number of property terms. Macroscopic material properties are best described in tensor notation; the rank of the property tensors can range from zero (scalar property) up to large rank. Table 1 summarizes common material properties and the rank of the tensor that describes them.

The rank of the property tensor and the symmetry of the material (as determined by the point group for crystals) determine the number of terms needed to describe a property. Table 2 summarizes both the number of terms needed to describe a property and the number of unique terms as a function of property tensor rank and point group. Another important term in the definition of tensor characteristics is the *principal values* of a second-rank tensor property. The principal values of a property are those values referenced to (measured along) the crystal axes as defined in Table 2. For example, a second-rank tensor of a triclinic crystal has nine nonzero coefficients, and because of symmetry, six independent coefficients. These six coefficients can be separated into (1) three principal values of the quantity (e.g., thermal expansion coefficient, dielectric constant, refractive index, and stress), and (2) the three angles describing the orientation of the crystal axes (α, β, γ).

Properties of materials depend on several fundamental constants that are listed in Table 3.[25] These constants are defined as follows.

*Glass properties are dependent on cooling rate. Nonuniform cooling will result in density variation and residual stress which cause anisotropy in all properties. Such nonisotropic behavior is different from that of crystals in that it arises from thermal gradients rather than periodic structure order. Hence, the nature of anisotropy in glasses varies from sample to sample.

TABLE 1 Tensor Characteristics and Definitions of Properties

Tensor rank	Property	Symbol	Units	Relationship
0	Enthalpy (energy)	U	J/mole	—
	Temperature	T	K	—
	Heat capacity	C	J/(mole · K)	$C = \partial U/\partial T$
1	Displacement	x	m	—
	Heat flow	h	W/m^2	—
	Electric field	**E**	V/m	—
	Electric polarization	**P**	C/m^2	$\mathbf{P} = \varepsilon_0 \chi \mathbf{E}$
	Electric displacement	**D**	C/m^2	$\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P}$
	Pyroelectric constant	p	C/(m^2 · K)	$\mathbf{\Delta P} = p\,\Delta T$
2	Stress	σ	Pa	—
	Strain	e	—	—
	Thermal expansion	α	K^{-1}	$e = \alpha T$
	Thermal conductivity	k	W/(m · K)	$h = -k\,(\partial T/\partial x)$
	Dielectric constant (relative permittivity)	ε	—	$\mathrm{D} = \varepsilon_0 \varepsilon_r \mathrm{E}$
	Inverse dielectric tensor	**B**	—	$B = \varepsilon_r^{-1}$
	Susceptibility	χ	—	$\varepsilon_r = \chi + 1$
3	Piezoelectric coefficient (modulus)	d	m/V ≡ C/N	$\mathbf{P} = d \cdot \sigma$
	(converse piezoelectric effect)	d	m/V ≡ C/N	$e = d \cdot \mathbf{E}$
	Electro-optic coefficient (linear)	r	m/V	$\mathbf{\Delta B} = r \cdot \mathbf{E}$
	Second-order susceptibility	$\chi^{(2)}$	m/V	$\mathbf{P} = \in_0 \chi^{(2)} \mathbf{E}_1 \mathbf{E}_2$
4	Elastic stiffness	**c**	Pa	$\sigma = \mathbf{c} \cdot e$; $\mathbf{c} = 1/\mathbf{s}$
	Elastic compliance	**s**	Pa^{-1}	$e = \mathbf{s} \cdot \sigma$; $\mathbf{s} = 1/\mathbf{c}$
	Elasto-optic tensor	**p**	—	$\mathbf{\Delta B} = \mathbf{p} \cdot e$; $\mathbf{p} = q \cdot \mathbf{c}$
	Piezo-optic tensor	**q**	Pa^{-1}	$\mathbf{\Delta B} = \mathbf{q} \cdot \sigma$; $\mathbf{q} = \mathbf{p} \cdot \mathbf{s}$

Optical Properties: Introduction

Refractive Index Important optical properties, definitions, formulas, and basic concepts are derived from a classical description of propagation based on the macroscopic Maxwell's equations.[22] The standard wave equation for the electric field **E** is obtained from Faraday, Gauss, and Ampere laws in Maxwell's form:*

$$\nabla^2 \mathbf{E} = (-i\omega\mu\sigma - \omega^2 \mu\varepsilon)\mathbf{E} \tag{1}$$

where σ, ε, and μ are the frequency-dependent conductivity, permittivity, and permeability, respectively. These quantities are scalars in an isotropic medium. To simplify notation, a generalized permittivity is sometimes defined as:

$$\varepsilon_c(\omega) = \varepsilon_r(\omega)\left[1 + i\frac{\sigma(\omega)}{\omega\varepsilon(\omega)}\right] \tag{2}$$

where $\varepsilon_c(\omega)$ is a generalized relative permittivity of dielectric constant (i.e., with ε_0 removed from $\varepsilon = \varepsilon_0 \varepsilon_c$) that includes contributions from free charges [via the conductivity $\sigma(\omega)$] and bound charges [via the relative permittivity, $\varepsilon_r(\omega)$]. Assuming a nonmagnetic material ($\mu_r = 1$), and using the preceding generalized dielectric constant, the plane-wave solution to the wave equation is

$$\mathbf{E}(z, \omega) = \mathbf{E}(0)\exp\left[i(\omega z / c)\sqrt{\varepsilon_c(\omega)}\right] \tag{3}$$

*The definition of the dielectric constant and refractive index in this section is based on a harmonic field of the form exp ($-i\omega t$). Other definitions lead to different sign conventions (e.g., $\bar{n} = n - ik$) and care must be taken to ensure consistency.

TABLE 2 Crystal Classes and Symmetries

Crystal System	Crystal Axes	Space lattice		Point group		Space Group Nos.	Tensor coefficients*

In optics, it is frequently convenient to define a *complex refractive index*, $\bar{n}$, the square root of the complex dielectric constant (henceforth, the symbol ε will be used for the relative complex dielectric constant):

$$\begin{aligned} \bar{n} &= n + ik = \sqrt{\varepsilon} = \sqrt{\varepsilon' + i\varepsilon''} \\ \varepsilon' &= n^2 - k^2; \qquad \varepsilon'' = 2nk \\ n^2 &= \frac{1}{2}\left[\varepsilon' + \sqrt{\varepsilon'^2 + \varepsilon''^2}\right] \\ k^2 &= \frac{1}{2}\left[-\varepsilon' + \sqrt{\varepsilon'^2 + \varepsilon''^2}\right] = \left(\frac{\varepsilon''}{2n}\right)^2 \end{aligned} \tag{4}$$

where n is the (real) *index of refraction* and k is the *index of absorption* (or imaginary part of the complex refractive index). (The index of absorption is also called the absorption constant, index of extinction, or some other combination of these terms.) Using this definition of the complex index of refraction and the solution of the wave equation [Eq. (3)], the optical power density (proportional to $1/2|\mathbf{E}|^2$ from Poynting's vector) is

$$\text{Power density} = \tfrac{1}{2} n\sqrt{\mu_0/\varepsilon_0}\ |\mathbf{E}(z)|^2 = \tfrac{1}{2} n\sqrt{\mu_0/\varepsilon_0}\ |\mathbf{E}(0)|^2 \exp(-2\omega k z/c) \tag{5}$$

where the exponential function represents the attenuation of the wave. The meanings of n and k are clear: n contributes to phase effects (time delay or variable velocity) and k contributes to attenuation by absorption. In practice, attenuation is conveniently described by a power absorption coefficient, β_{ABS}, which describes the internal transmittance over a distance z, i.e.,

$$\tau = \frac{|\mathbf{E}(z)|^2}{|\mathbf{E}(z=0)|^2} = e^{-2\omega k z/c} = e^{-\beta_{\text{ABS}} z} \tag{6a}$$

and β_{ABS} (with units of reciprocal length, usually cm^{-1}) is

$$\beta_{\text{ABS}} = 2\omega k/c = 4\pi \nu k \tag{6b}$$

where ν is the wave number in reciprocal length, usually cm^{-1}.

Kramers–Krönig and Sum Rule Relationships The principal of causality—that a material cannot respond until acted upon—when applied to optics, produces important symmetry properties and relationships that are very useful in modeling and analyzing optical properties. As a consequence of these symmetry properties, the real and imaginary parts of the dielectric constant (and of the complex index of refraction) are Hilbert transforms of each other. The Hilbert transform, $\text{Hi}[\Lambda(\omega)]$, of the complex function $\Lambda(\omega)$ is defined as (the symbol P denotes the principal value of the integral)

$$\text{Hi}[\Lambda(\omega)] = \frac{i}{\pi} P \int_{-\infty}^{\infty} \frac{\Lambda(\omega)}{\omega - \omega'} d\omega' \tag{7}$$

and the relationships between the components of the dielectric constant or index of refraction are

$$\begin{aligned} \varepsilon' - 1 &= \mathrm{Hi}[\varepsilon''] \\ \varepsilon'' &= \mathrm{Hi}^{-1}[\varepsilon' - 1] \\ n - 1 &= \mathrm{Hi}[k] \\ k &= \mathrm{Hi}^{-1}[n-1] \end{aligned} \tag{8}$$

These are the *Kramers–Krönig relationships* (abbreviated KK). Usually the Hilbert transforms for the refractive index are written in single-sided form:

$$n(\omega) - 1 = \frac{2}{\pi} P \int_0^\infty \frac{\omega' k(\omega')}{\omega'^2 - \omega^2} d\omega' \tag{9a}$$

with the inverse transform given by

$$k(\omega) = \frac{2\omega}{\pi} P \int_0^\infty \frac{n(\omega') - 1}{\omega^2 - \omega'^2} d\omega' \tag{9b}$$

These are fundamental relationships of any causal system.

A number of useful integral relationships, or *sum rules* result from Fourier transforms and the Kramers–Krönig relationship.[26] For example, the real part of the refractive index satisfies

$$\int_0^\infty [n(\omega) - 1] d\omega = 0 \tag{10a}$$

and

$$\begin{aligned} n(\omega = 0) - 1 &= \frac{2}{\pi} \int_0^\infty \frac{k(\omega')}{\omega'} d\omega' \\ &= \frac{\mathrm{c}}{\pi} \int_0^\infty \frac{\beta_{\mathrm{ABS}}(\omega')}{\omega'^2} d\omega' \end{aligned} \tag{10b}$$

The dielectric constant and the refractive index also have the following symmetry properties:

$$\begin{aligned} \varepsilon(\omega) &= \varepsilon^*(-\omega) \\ \bar{n}(\omega) &= \bar{n}^*(-\omega) \end{aligned} \tag{10c}$$

Practical models of the dielectric constant or refractive index must satisfy these fundamental symmetry properties and integral relationships.

Optical Properties: Origin and Models

Intrinsic optical properties of a material are determined by three basic physical processes: electronic transitions, lattice vibrations, and free-carrier effects.[5-7,27,28] However, the dominant physical process depends on the material and spectral region of interest. All materials have contributions to the complex index of refraction from electronic transitions. Insulators and semiconductors also require the characterization of the lattice vibrations (or phonons) to fully understand the optical properties. Transparency of semiconductors, particularly those with small bandgaps, is additionally influenced by free-carrier effects. The strength of the free-carrier influence on transmission and absorption depends on the free-carrier concentration; thus free-carrier effects dominate the optical properties of metals in the visible and infrared.

In the range of transparency of a bulk material, more subtle effects such as multiphonon processes (see later discussion; also refer to Chap. 16, "Third-Order Nonlinearities," by Mansoor Sheik-Bahae

and Michael P. Hasselbeck), impurity and defect absorption, and scattering become the important loss mechanisms. Intrinsic atomic (Rayleigh) scattering is a very weak effect, but is important in long-path optical fibers and ultraviolet materials (refer to Chap. 9, "Volume Scattering in Random Media," by Aristide Dogariu and Jeremy Ellis in Vol. I). Extrinsic scattering, caused by density (local composition) variations, defects, or grains in polycrystalline solids, is typically much larger than intrinsic scattering in the visible and infrared spectral regions. Impurity and defect (electronic or vibrational) absorption features can be of great concern depending on the spectral region, incident radiation intensity, or material temperature required by the application.

Figure 1 illustrates the frequency dependence of n and k for an insulating polar crystal.[29] The value of $n(\omega, T)$ is essentially the sum of the contributions of all electronic and lattice vibration resonances, and is dominated by those with fundamental oscillation frequencies above ω. Figure 1*a* indicates regions of validity for the popular Sellmeier model (see discussion under "Electronic Transitions"). The frequency dependence of the imaginary part of the index of refraction $k(\omega, T)$ requires consideration of

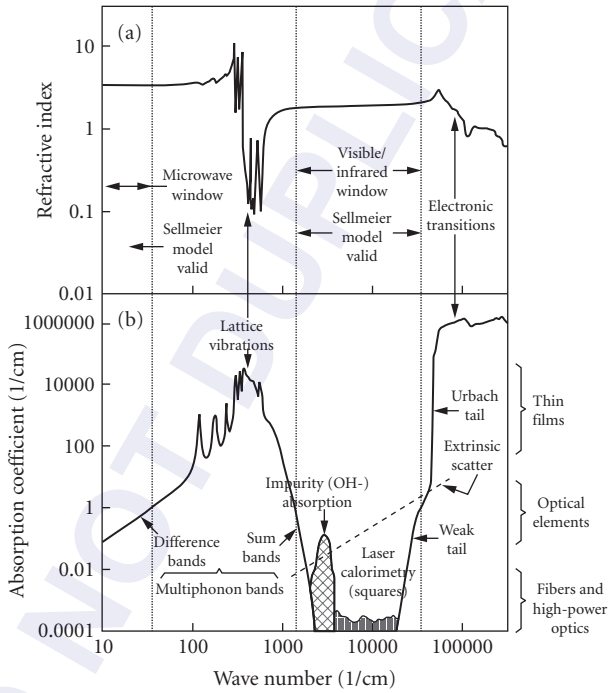

FIGURE 1 The wave number (frequency) dependence of the complex refractive index of Yttria[29] (*a*) shows the real part of the refractive index, $n(\omega)$. The real part is high at low frequency and monotonically increases, becomes oscillatory in the lattice vibration (phonon) absorption bands, increases monotonically (normal dispersion) in the optical transparent region, and again becomes oscillatory in the electronic absorption region; (*b*) shows the imaginary part of the refractive index, in terms of the absorption coefficient, $\beta(\nu) = 4\pi\nu k(\nu)$. The absorption coefficient is small in the transparent regions and very high in the electronic and vibrational (phonon) absorption bands. The optical transparent region is bounded by the "Urbach tail" absorption at high frequency and by multiphonon absorption at low frequency (wave number). In between, loss is primarily due to impurities and scatter. (*Reprinted by permission of McGraw-Hill, Inc.*)

not only the dominant physical processes but also higher-order processes, impurities, and defects as illustrated in Fig. 1*b*. The spectral regions of the fundamental resonances are opaque. The infrared edge of transparency is controlled by multiphonon transitions. Transparent regions for insulators are divided in two regions: microwave and visible/infrared.

Lattice Vibrations Atomic motion, or lattice vibrations, accounts for many material properties, including heat capacity, thermal conductivity, elastic constants, and optical and dielectric properties. Lattice vibrations are quantized; the quantum of lattice vibration is called a *phonon*. In crystals, the number of lattice vibrations is equal to three times the number of atoms in the primitive unit cell (see further discussion); three of these are acoustic vibrations (translational modes in the form of sound waves), the remainder are optical vibrations (or modes or phonons) for materials with more than one type atom per unit cell. For most practical temperatures, only the acoustic phonons are thermally excited because optical phonons are typically of much higher frequency, hence acoustic modes play a dominant role in thermal and elastic properties. There are three types of optical modes: infrared-active, Raman-active, and optically inactive. Infrared-active modes, typically occurring in the spectral region from 100 to 1000 cm^{-1}, are those that (elastically) absorb light (photon converted to phonon) through an interaction between the electric field and the light and the dipole moment of the crystal. Raman modes* (caused by phonons that modulate the polarizability of the crystal to induce a dipole moment) weakly absorb light through an inelastic mechanism (photon converted to phonon and scattered photon) and are best observed with intense (e.g., laser) light. Optically inactive modes have no permanent or induced dipole moment and therefore do not interact with light. Optically active modes can be simultaneously infrared- and Raman-active and are experimentally observed by either infrared or Raman spectroscopy, as well as by x-ray or neutron scattering.

Crystal symmetries reduce the number of unique lattice vibrations (i.e., introduce vibrational degeneracies). Group theory analysis determines the number of optical modes of each type for an ideal material. Defects and impurities will increase the number of observed infrared-active and Raman-active modes in a real material. As structural disorder increases (nonstoichiometry, defects, variable composition), the optical modes broaden and additional modes appear. Optical modes in noncrystalline (amorphous) materials such as glasses are very broad compared to those of crystals.

Lattice vibration contributions to the static dielectric constant, $\varepsilon(0)$, are determined from the longitudinal-mode (LO) and transverse-mode (TO) frequencies of the optical modes using the Lyddane-Sachs-Teller (LST) relationship[30] as extended by Cochran and Cowley[31] for materials with multiple optical modes:

$$\varepsilon(0) = \varepsilon(\infty) \prod_{j}^{j_{\max}} \frac{\omega_j^2(\mathrm{LO})}{\omega_j^2(\mathrm{TO})} \tag{11}$$

where ω is frequency (also expressible in wave numbers) and $\varepsilon(\infty)$ is the high-frequency (electronic transition) contribution to the dielectric constant (not the dielectric constant at infinite frequency). This relationship holds individually for each principal axis. The index j denotes infrared-active lattice vibrations with minimum value usually found from group theory (discussed later). This LST relationship has been extended to include the frequency dependence of the real dielectric constant (in transparent, i.e., nonabsorbing, spectral regions):

$$\varepsilon(\omega) = \varepsilon(\infty) \prod_{j}^{j_{\max}} \frac{\omega_j^2(\mathrm{LO}) - \omega^2}{\omega_j^2(\mathrm{TO}) - \omega^2} \tag{12a}$$

A modified form of this fundamental equation, including absorption, is used by Gervais and Piriou[32] and others to model the complete dielectric constant in the infrared:

$$\varepsilon(\omega) = \varepsilon(\infty) \prod_{j}^{j_{\max}} \frac{\omega_j^2(\mathrm{LO}) - \omega^2 - i\omega\gamma_j(\mathrm{LO})}{\omega_j^2(\mathrm{TO}) - \omega^2 - i\omega\gamma_j(\mathrm{TO})} \tag{12b}$$

*Brillouin scattering is a term applied to inelastic scattering of photons by acoustic phonons.

where γ is the line width of the longitudinal and transverse modes as denoted by the symbol in parentheses. This form of the dielectric constant is known as the *semiquantum* four-parameter model.

Frequently, the infrared dielectric constant is modeled in a three-parameter classical oscillator form (or Maxwell–Helmholtz–Drude[33] dispersion formula), namely

$$\varepsilon(\omega) = \varepsilon(\infty) + \sum_{j}^{j_{\max}} \frac{S_j \omega_j^2(\mathrm{TO})}{\omega_j^2(\mathrm{TO}) - \omega^2 - i\omega\gamma_j} \tag{13}$$

where S_j (=$\Delta\varepsilon_j$) is the oscillator strength and γ_j is the full width of the jth mode. This model assumes no coupling between modes and provides a good representation of the dielectric constant, especially if the modes are weak [small separation between ω(TO) and ω(LO)] and uncoupled. The static dielectric constant $\varepsilon(0)$ is merely the sum of the high-frequency dielectric constant $\varepsilon(\infty)$ and strengths S_j of the individual, IR-active modes. This formulation has been widely used to model infrared dispersion. This model can also be used to represent the high-frequency dielectric constant using additional modes [i.e., $\varepsilon(\infty)$ is replaced by 1, the dielectric constant of free space, plus the contribution of electronic modes; see later discussion in this chapter]. Strengths and line widths for the classical dispersion model can be derived from the values of the four-parameter model.[34]

Both the classical and four-parameter dispersion models satisfy the Kramers–Krönig relationship [Eqs. (7) and (8)] and are therefore physically realizable. The frequencies ω(TO) and ω(LO) arise from the interaction of light with the material, correspond to solutions of the Maxwell wave equation, $\nabla \cdot \mathbf{D} = 0$ (no free charges), and are obtained from measurements. A transverse field corresponds to an electromagnetic wave with **E** perpendicular to the wave vector. At higher frequencies [$\omega > \omega$(TO)], the external electric field counters the internal polarization field of the material until the real part of the dielectric constant is zero, hence **D** = 0 at ω(LO). The longitudinal frequency ω(LO) is always greater than the transverse frequency ω(TO). The separation of ω(LO) and ω(TO) is a measure of the strength (S_j or $\Delta\varepsilon_j$) of the optical mode. Raman modes are, by their nature, very weak and therefore ω(LO) ≈ ω(TO), hence Raman modes do not contribute appreciably to dielectric properties.

In Eq. (12*a*), the ω(TO) frequencies correspond to the poles and the ω(LO) frequencies correspond to the zeros of the dielectric constant. The real part of the dielectric constant continuously rises with frequency [except for a discontinuity at ω(TO)] and the dielectric constant is real and negative [i.e., highly absorbing, Eq. (3)] between the transverse and longitudinal frequencies. When damping is added to the dielectric constant model to represent the response of real materials [e.g., Eq. (12*b*) or (13)], the transverse and longitudinal frequencies become the maxima and minima of the dielectric constant. With damping, a negative dielectric constant is not a necessary condition for absorption, and the material will also absorb outside the region bounded by ω(TO) and ω(LO). Furthermore, damping allows the real part of the dielectric constant (and also the refractive index) to decrease with frequency near ω(TO). This dispersive condition is called *anomalous dispersion* and can only occur in absorptive regions.

As an example of lattice vibrations, consider the simple case of crystalline sodium chloride (NaCl) which has four molecules (eight atoms) per unit cell. Since the sodium chloride structure is face-centered cubic, a primitive cell has one molecule or two atoms. The number of unique vibrations is further reduced by symmetry: for sodium chloride, the lattice vibrations consist of one (triply degenerate) acoustic mode and one (triply degenerate) optical mode. Many metals have one atom per primitive unit cell and therefore have no optical modes. Group IV cubic materials (diamond, silicon, germanium) have two atoms per unit cell with one (triply degenerate) optical mode that is Raman-active only. Therefore, to first order, these nonpolar materials are transparent from their bandgap to very low frequencies. In practice, multiphonon vibrations, defects, impurities, and free carriers introduce significant absorption.

Figure 2 shows a typical crystal infrared spectrum and the corresponding classical oscillator[35] and four parameter model[36] fits to the data. Parameters for both the extended LST [Eq. (12)] and classical oscillator [Eq. (13)] vibration models are given at the end of this chapter for many materials.

Electronic Transitions Electronic transitions in a solid begin at the material's bandgap. This point generally marks the end (upper frequency) of a material's useful transparency. Above the bandgap, the

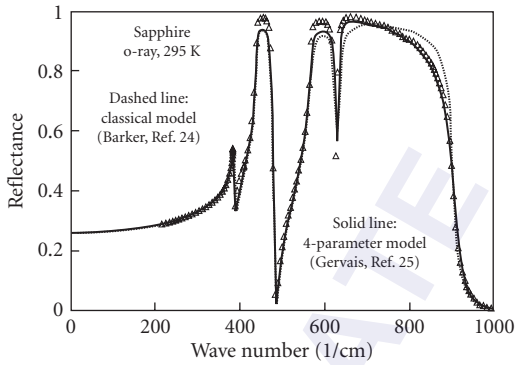

FIGURE 2 The infrared spectrum of sapphire (Al_2O_3) showing the fit to data of the three-parameter classic oscillator model of Barker (dashed line[35]) and the four-parameter model of Gervais (solid line[36]). The four-parameter model better fits experimental data (triangles) in the 650 to 900-cm^{-1} region.

material is highly reflective. The large number of possible electronic transitions produces broad-featured spectra. However, electronic structure is fundamental to understanding the nature of the bonds forming the solid and thus many of the material properties. In three dimensions, the band structure becomes more complicated, because it varies with direction just as lattice vibrations do. This point is illustrated in Fig. 3 for the case of the electronic *k*-space diagram for sapphire.[37] Also included in this figure is the corresponding electronic density of states that determines the strength of the absorption.

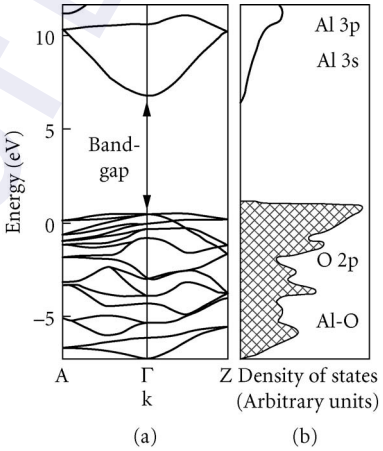

FIGURE 3 Electronic energy band diagram for sapphire at room temperature[37] (*a*) shows the complex k-space energy levels of the electrons of sapphire. The arrow denotes the direct bandgap transition and (*b*) shows the density of electronic states as a function of energy level. The many direct and indirect electronic transitions give rise to a broad electronic absorption with few features. (*Reprinted by permission of the American Ceramic Society.*)

In polar insulators, no intraband electronic transitions are allowed, and the lowest frequency electronic absorption is often caused by creation of an *exciton*, a bound electron-hole pair. The photon energy required to create this bound pair is lower than the bandgap energy. Excitons have many properties similar to that of a hydrogen atom. The absorption spectrum of an exciton is similar to that of hydrogen and occurs near the bandgap of the host material. The bond length between the electron-hole pair, hence the energy required to create the exciton, depends on the host medium. Long bond lengths are found in semiconductors (low-energy exciton) and short bond lengths are found in insulating materials.

Other lower-frequency transitions are caused by interband transitions between the anion valence band and the cation conduction band. For sapphire (see Fig. 3), the lowest energy transitions are from the upper valence band of oxygen ($2p^6$) to the conduction band of aluminum (3s + 3p). There are typically many of these transitions which appear as a strong, broad absorption feature. Higher energy absorption is caused by surface and bulk plasmons (quanta of collective electronic waves), and still higher energy absorption is attributable to promotion of inner electrons to the conduction band and ultimately liberation of electrons from the material (photoemission).

Classical electronic polarization theory produces a model of the real part of the dielectric constant similar to the model used for the real dielectric constant of lattice vibrations [Eq. (13)]. General properties of the real dielectric constant (and real refractive index) can be deduced from this model. Bound electrons oscillate at a frequency proportional to the square root of the binding energy divided by the electronic mass. Oscillator strength is proportional to the inverse of binding energy. This means that insulators with light atoms and strong bonding have large bandgaps, hence good UV transmission (cf., LiF). Furthermore, high bonding energy (hence high-energy bandgap) means low refractive index (e.g., fluorides).

When both electronic and lattice vibrational contributions to the dielectric constant are modeled as oscillations, the dielectric constant in the transparent region between electronic and vibrational absorption is (mostly) real and the real part takes the form

$$\varepsilon'(\omega) - 1 = n^2(\omega) - 1 = \sum_j \frac{S_j \omega_j^2}{\omega_j^2 - \omega^2} \tag{14}$$

which is the widely used *Sellmeier dispersion formula.*[38] The sum includes both electronic (UV) and vibrational (IR or *polar* or *ionic*) contributions. Most other dispersion formulas (such as the Schott glass power series) are recast, series expanded, or simplified forms of the Sellmeier model. The refractive index of most materials with good homogeneity can be modeled to a few parts in 10^5 over their entire transparent region with a Sellmeier fit of a few terms. The frequency (ω_j) term(s) in a Sellmeier fit are not necessarily TO modes, but are correlated to the strong TOs nearest the transparent region, with adjustments to the constants made to account for weaker modes, multiphonon effects, and impurities. The Sellmeier model works well because it is (1) based on a reasonable physical model and (2) adjusts constants to match data. The relationship between the Sellmeier equation and other dispersion formulas is discussed later.

The *Urbach tail* model is successfully applied to model the frequency and temperature dependence of the ultraviolet absorption edge in a number of materials, particularly those with a direct bandgap, over several orders of magnitude in absorption. Urbach[39] observed an exponential absorption edge in silver halide materials (which have an indirect bandgap). Further development added temperature dependence in the form

$$\beta_{\text{ABS}}(E, T) = \beta_0 \exp\left[-\sigma(T)\frac{(E_0 - E)}{k_B T}\right] \tag{15a}$$

where

$$\sigma(T) = \sigma_0(T)\frac{2k_B T}{E_p}\tanh\frac{E_p}{2k_B T} \tag{15b}$$

where E_0 is the bandgap energy (typically the energy of an exciton) at $T = 0$ K, T temperature in kelvins, and E_p a characteristic phonon energy. The interpretation of the Urbach tail is a broadening of the electronic bandgap by phonon interactions, and several detailed theories have been proposed.[28,40]

Below the Urbach tail, absorption continues to decrease exponentially, albeit much slower than predicted by the Urbach formula. This region of slowly decreasing absorption is sometimes called the "weak tail," and has been observed in both semiconductor[41] and crystalline materials.[42,43] Typically, the weak tail begins at the point when the absorption coefficient falls to 0.1 cm^{-1}.

Unfortunately, the optical properties of the electronic transitions, which drive optoelectronic device performance, can not be modeled in a straightforward manner like the vibrational transition models because most electronic transitions are coupled together to form broad homogeneous absorption bands. Thus, the shape of the density-of-states function that determines the spectral response is seldom in the simple functional form of a classical oscillator model.

Adachi[44] has developed models that successfully represent the complex permittivity of electronic transitions as a function of both frequency and temperature by considering the effect of various electronic interband transitions from valence to conduction band. These transitions peak at various critical point locations (e.g., Γ and L) and include energy level shifts caused by spin-orbit coupling. Various density-of-state models are used, including the classical oscillator to represent several closely spaced transitions.

The Adachi model accounts for first-order electronic transitions, and represents the complex refractive index over a wide frequency and temperature range. Model predictions agree well with experimental complex index of refraction data in transparent spectral regions ending at the bandgap. Model parameters are available for CdTe, GaAs, GaP, GaSb, InAs, InP, InSb, ZnTe, AlGaAs, InGaAsP, and others.[44-51]

The electronic transitions have a very different functional form than the vibrational modes, yet a Sellmeier model, an approximate form to the classical oscillator model, is commonly used to represent the real part of the relative permittivity in transparent spectral regions ending at the bandgap. However, a polynomial expansion of the electronic susceptibility functions shows similar structure to an expansion of the Sellmeier equation. It is expected that when high precision is needed (e.g., $<10^{-5}$) in the refractive index, the more physically correct (Adachi) model should be used. This is certainly the case for absorption near the bandgap.

Free Carriers Free carriers, such as electrons in metals, or electrons and holes in semiconductors, also affect the optical properties of materials. For insulators or wide-bandgap semiconductors (i.e., bandgap greater than 0. 5 eV) with a low number of free carriers at room temperature (low conductivity), the effect of free carriers on optical absorption is small [see Eq. (2)]. For nonmetals, the free-carrier concentration grows with temperature so that even an "insulator" has measurable conductivity (and free-carrier absorption) at very high temperature. Commonly used optical materials such as silicon and germanium have a significant increase in free-carrier absorption at moderately high temperature as illustrated in Fig. 4.[52]

Free-carrier effects can be modeled as an additional contribution to the dielectric constant model. For example, the classical model [Eq. (13)] takes the form

$$\varepsilon(\omega) = \varepsilon(\infty) + \sum_{j}^{j_{\max}} \frac{S_j \omega_j^2(\mathrm{TO})}{\omega_j^2(\mathrm{TO}) - \omega^2 - i\omega\gamma_j} - \frac{\omega_p^2}{\omega^2 + i\omega\gamma_c} \tag{16}$$

where ω_p is the plasma frequency, proportional to the square root of the free-carrier density, and γ_c is the damping frequency (i.e., determines the effective width of the free-carrier influence). Such a model is well known to accurately predict the far-infrared (≥10 μm) refractive index of metals[53] and also has been used to model the free-carrier contribution to the optical properties of semiconductors.

Multiphonon Absorption and Refraction Absorption at the infrared edge of insulators is principally caused by anharmonic terms in the lattice potential leading to higher harmonics of the lattice resonances. This phenomenon is called multiphonon absorption because the frequencies are harmonics

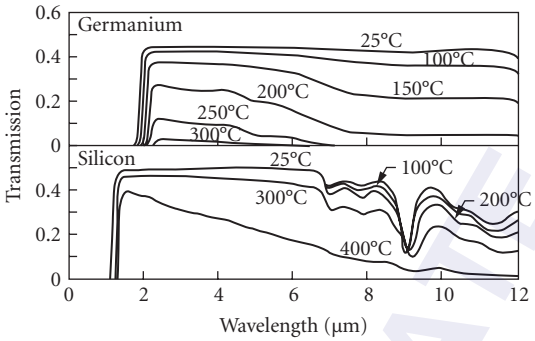

FIGURE 4 Decreased transmission of germanium and silicon with temperature is attributable to an increase in free-carrier concentration resulting in increased absorption.[52] The absorption is greater at longer wave lengths; see Eq. (16). (*Reprinted by permission of the Optical Society of America.*)

of the characteristic lattice phonons (vibrations). For absorption in the infrared, each successively higher multiple of the fundamental frequency is weaker (and broader) leading to decreasing absorption beyond the highest fundamental absorption frequency (maximum transverse optical frequency). At about three times ω(TO) the absorption coefficient becomes small and a material with thickness of 1 to 10 μm is reasonably transparent. The infrared absorption coefficient of materials (especially highly ionic insulators) can be characterized by an exponential absorption coefficient,[54] β_{ABS}, of the form

$$\beta_{ABS} = \beta_0 \exp\left(-\gamma \frac{\omega}{\omega_0}\right) \tag{17a}$$

where β_0 is a constant (dimensions same as the absorption coefficient, typically cm^{-1}), γ is a dimensionless constant (typically found to be near 4), ω_0 is frequency or wave number of the maximum transverse optical frequency (units are cm^{-1} for wave numbers; values are given in the property data tables), and ω is the frequency or wave number of interest. This formula works reasonably well for ionic materials at room temperature for the range of absorption coefficients from 0.001 to 10 cm^{-1}.

In the classical (continuum) limit, the temperature dependence of multiphonon absorption has a T^{n-1} dependence, where n is the order of the multiphonon process,[55] that is $n \approx \omega/\omega_0$. At low temperature, there is no temperature dependence since only transitions from the ground state occur. Once the temperature is sufficiently high (e.g., approaching the Debye temperature), transitions that originate from excited states become important and the classical temperature dependence is observed. Bendow et al.[56] has developed a simple model of the temperature dependence of multiphonon absorption based on a Bose–Einstein distribution of states:

$$\beta_{ABS}(\omega, T) = \beta_0 \frac{[N(\omega_o, T)+1]^{\omega/\omega_0}}{N(\omega, T)+1} \exp(-A\omega/\omega_0) \tag{17b}$$

where $N(\omega, T)$ is the phonon occupation density from Bose–Einstein statistics.

Thomas et al.[57] have successfully developed a semiempirical, quantum mechanical model of (sum band) multiphonon absorption based on the Morse interatomic potential and a gaussian function for the phonon density of states. Use of the Morse potential leads to an exact solution to the Schrödinger equation and includes anharmonic effects to all orders. The model contains parameters derived from room-temperature measurements of absorption, is computationally efficient, and has been applied to many ionic substances. Figure 5 shows a typical result compared to experimental data. Model parameters are available for oxides,[57] diamond,[58] glasses,[59] and semiconductors.[60]

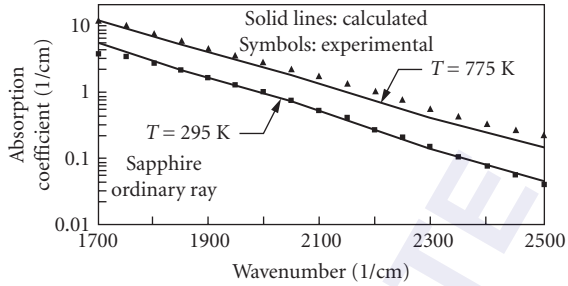

FIGURE 5 Temperature-dependent change of absorption in insulators is principally confined to the absorption edges, especially the infrared multiphonon absorption edge. This figure shows measured and predicted absorption coefficients at the infrared edge of transparency for the ordinary ray of crystalline sapphire. Increasing temperature activates higher multiphonon processes, resulting in a rapid increase in absorption. The multiphonon model of Thomas et al.[57-59] accurately predicts the frequency- and temperature-dependence of infrared absorption in highly ionic materials such as oxides and halides.

Multiphonon absorption modeling also contributes to the real refractive index. Although multiphonon contributions to the real index are small compared to one-phonon contributions, they are important for two cases in the infrared: (1) when the refractive index must be known beyond two decimal places, or (2) at high temperature. In the first case, multiphonon contributions to the index are significant over a large spectral region. In the second case, the contribution of multiphonon modes to the real refractive index grows rapidly at high temperature because of the T^{n-1} dependence of the nth mode strength.

Absorption in the Transparent Region In the transparent region, away from the electronic and vibrational resonances, absorption is governed by impurities and defects. The level of absorption is highly dependent on the purity of the starting materials, conditions of manufacture, and subsequent machining and polishing. For example, OH impurities are common in oxides,* occurring at frequencies below the fundamental (nonbonded) OH vibration at 3735 cm^{-1}. OH can be removed by appropriate heat treatment.

Low-level absorption coefficient measurements are typically made by laser calorimetry or photoacoustic techniques. Data are available for a number of materials in the visible,[42,61] at 1.3 μm,[62] and at 2.7 and 3.8 μm.[63]

Optical Properties: Applications

Dielectric Tensor and Optical Indicatrix Many important materials are nonisotropic (e.g., the crystals Al_2O_3, SiO_2, and MgF_2), and their optical properties are described by tensor relationships (see earlier section, "Symmetry Properties"). The dielectric constant, ε, a second-rank tensor, relates the electric field **E** to the electric displacement **D**:

$$\begin{vmatrix} \mathbf{D}_x \\ \mathbf{D}_y \\ \mathbf{D}_z \end{vmatrix} = \varepsilon_0 \cdot \begin{vmatrix} \varepsilon_{xx} & \varepsilon_{xy} & \varepsilon_{xz} \\ \varepsilon_{yx} & \varepsilon_{yy} & \varepsilon_{yz} \\ \varepsilon_{zx} & \varepsilon_{zy} & \varepsilon_{zz} \end{vmatrix} \cdot \begin{vmatrix} \mathbf{E}_x \\ \mathbf{E}_y \\ \mathbf{E}_z \end{vmatrix} \tag{18a}$$

*The OH vibrational impurity absorption in oxides is known for Al_2O_3, ALON, $MgAl_2O_4$, MgO, SiO_2, Y_2O_3, and Yb_2O_3.

From the symmetry of properties, this is a symmetric tensor with $\varepsilon_{ab} = \varepsilon_{ba}$. Usually, the dielectric constant components are given as principal values, that is, those values along the unit cell of the appropriate crystal class. In this case, the principal dielectric constants are

$$\begin{aligned} \varepsilon_{x'x'} &\equiv \varepsilon_1 \\ \varepsilon_{y'y'} &\equiv \varepsilon_2 \\ \varepsilon_{z'z'} &\equiv \varepsilon_3 \end{aligned} \tag{18b}$$

where the primes on the subscripts denote principal values (i.e., along the crystallographic axes, possible in a nonorthogonal coordinate system) and the subscripts 1, 2, and 3 denote reduced notation for these values (see "Elastic Properties"). The relationship between dielectric constant and refractive index, Eq. (4), means there are similarly three principal values for the (complex) refractive index. Also, the components of the dielectric tensor are individually related to the corresponding components of the refractive index. (Subscripts *a, b*, and *c* or *x, y*, and *z* as well as others may be used for the principal values of the dielectric constant or refractive index.)

Three important cases arise:

1. Isotropic and cubic materials have only one dielectric constant, ε, (hence one refractive $\bar{n}$). Therefore $\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = \varepsilon\ \bar{n}^2$.
2. Hexagonal (including trigonal) and tetragonal crystals have two principal dielectric constants, ε_1 and ε_3 (hence two refractive indices, $\bar{n}$ and $\bar{n}_3$). Therefore $\varepsilon_1 = \varepsilon_2 \neq \varepsilon_3$. Such materials are called *uniaxial*; the unique crystallographic axis is the *c* axis, which is also called the *optical axis.* One method of denoting the two unique principal axes is to state the orientation of the electric field relative to the optical axis. The dielectric constant for the $\mathbf{E} \perp c$ situation is ε_1 or $\varepsilon_\perp$. This circumstance is also called the *ordinary ray*, and the corresponding symbol for the refractive index is $\bar{n}_1, \bar{n}_\perp, \bar{n}_o$ (for ordinary ray), and $\bar{n}_\omega$ or ω (primarily in the older literature). The dielectric constant for $\mathbf{E} \parallel c$ situation is ε_3 or $\varepsilon_\parallel$. This condition is called the *extraordinary ray*, and the corresponding symbol for the refractive index is $\bar{n}_3, \bar{n}_\parallel, \bar{n}_e$ (for extraordinary ray), and $\bar{n}_\varepsilon$ or ε (again, primarily in the older literature). Crystals are called *positive uniaxial* when $n_e - n_o > 0$, and *negative uniaxial* otherwise. Since the dispersions of the ordinary and extraordinary wave are different, a crystal can be positive uniaxial in one wavelength region and negative uniaxial in another ($AgGaS_2$ is an example).
3. Orthorhombic, monoclinic, and triclinic crystals have three principal dielectric constants, ε_1, ε_2, and ε_3 (hence, three refractive indices, $\bar{n}_1, \bar{n}_2$, and $\bar{n}_3$). Therefore $\varepsilon_1 \neq \varepsilon_2 \neq \varepsilon_3 \neq \varepsilon_1$. These crystals are called *biaxial*. Confusion sometimes arises from the correlation of the principal dielectric constants with the crystallographic orientation owing to several conventions in selecting the crystal axes. [The optical indicatrix (see following discussion) of a biaxial material has two circular sections that define optical axes. The orientation of these axes are then used to assign a positive- or negative-biaxial designation.]

The existence of more than one dielectric constant or refractive index means that, for radiation with arbitrary orientation with respect to the crystal axes, two plane-polarized waves, of different speed, propagate in the crystal. Hence, for light propagating at a random orientation to the principal axes, a uniaxial or biaxial crystal exhibits two effective refractive indices different from the individual principal values. The refractive index of the two waves is determined from the *optical indicatrix* or *index ellipsoid*, a triaxial ellipsoidal surface defined by

$$\frac{x_1^2}{n_1^2} + \frac{x_2^2}{n_2^2} + \frac{x_3^2}{n_3^2} = 1 \tag{19a}$$

where the x_1, x_2, and x_3 are the principal axes of the dielectric constant. The indicatrix is illustrated in Fig. 6: for a wave normal in an arbitrary direction (OP), the two waves have refraction indices equal to the axes of the ellipse perpendicular to the wave normal (OA and OB). The directions

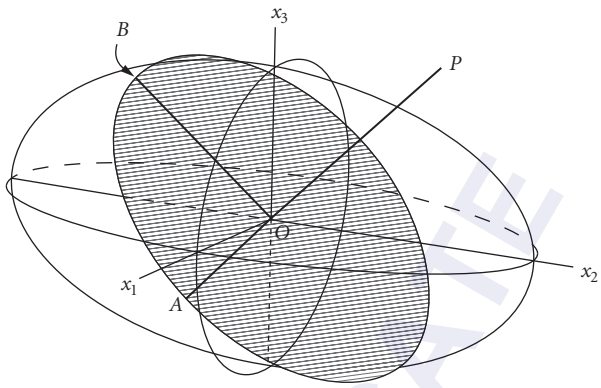

FIGURE 6 The *optical indicatrix* or *index ellipsoid* used to determine the effective refractive index for an arbitrary wave normal in a crystal. The axes of the ellipsoid correspond to the principal axes of the crystal, and the radii of the ellipsoid along the axes are the principal values of the refractive indices. For propagation along an arbitrary wave normal (OP), the effective refractive indices are the axes of the ellipse whose normal is parallel to the wave normal. In the illustrated case, the directions OA and OB define the effective refractive indices.[24] (*Reprinted by permission of Oxford University Press.*)

represented by OA and OB are the vibrational planes of the electric displacement vector **D** of the two waves. When the wave normal is parallel to an optic axis, the two waves propagate with principal refractive indices. For uniaxial materials and the wave normal parallel to the x_3 (or z or c crystallographic or optical) axis, the vibrational ellipsoid is circular and the two waves have the same refractive index (n_o), and there is no double refraction. Equation (19*a*) can also be written

$$B_1 x_1^2 + B_2 x_2^2 + B_3 x_3^2 = 1 \tag{19b}$$

where $B_i = 1/\overline{n}_1^2 = 1/\varepsilon_i$ is called the *inverse dielectric tensor*. The inverse dielectric tensor is used in defining electro-optic, piezo-optic, and elasto-optic relationships (see Table 1).

Fresnel formulas, found elsewhere in this *Handbook*, use the complex refractive index to calculate reflection and transmission at a material boundary as a function of incident angle, polarization, and (crystal) orientation (for uni- and biaxial crystals).

Total Power Law Incident light on a material is reflected, transmitted, or absorbed. Scattering is a term used to describe diffuse reflectance (surface scatter) and diffuse transmittance (bulk scatter). Conservation of energy dictates that the fractional amount reflected ρ, absorbed α_{ABS}, transmitted τ, and scattered α_{SCA} total to unity, hence

$$1 = \rho(\Omega_i, \omega) + \alpha_{\text{SCA}}(\Omega_i, \omega) + \alpha_{\text{ABS}}(\Omega_i, \omega) + \tau(\Omega_i, \omega) \tag{20}$$

where these time-averaged quantities, illustrated in Fig. 7, are

$$\rho(\Omega_i, \omega) = \frac{\Phi_r(\Omega_i, \omega)}{\Phi_i(\omega)} = \text{total integrated reflectance} \tag{21a}$$

$$\alpha_{\text{SCA}}(\Omega_i, \omega) = \frac{\Phi_s(\Omega_i, \omega)}{\Phi_i(\omega)} = \text{total integrated scatterance} \tag{21b}$$

$$\alpha_{\text{ABS}}(\Omega_i, \omega) = \frac{\Phi_s(\Omega_i, \omega)}{\Phi_i(\omega)} = \text{total integrated absorptance} \tag{21c}$$

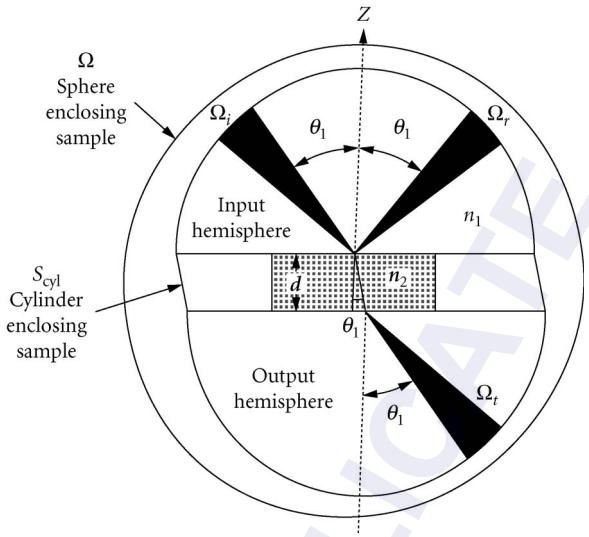

FIGURE 7 Geometry of incident, transmitted, and reflected beams for a plane transparent slab of thickness d. The power equals the reflected, refracted, and absorbed components, assuming no scatter.

and

$$\tau(\Omega_i, \omega) = \frac{\Phi_t(\Omega_i, \omega)}{\Phi_i(\omega)} = \text{total integrated transmittance} \tag{21d}$$

Notice that these quantities are functions of the angle of incidence and frequency only.

The sum of total integrated scatterance and total integrated absorptance can be defined as the total integrated extinctance α_{EXT},

$$\alpha_{EXT}(\Omega_i, \omega) = \alpha_{ABS}(\Omega_i, \omega) + \alpha_{SCA}(\Omega_i, \omega) \tag{22}$$

and the total power law becomes

$$1 = \rho(\Omega_i, \omega) + \alpha_{EXT}(\Omega_i, \omega) + \tau(\Omega_i, \omega) \tag{23}$$

Another useful quantity is emittance, which is defined as

$$\varepsilon(\Omega_i, \omega) = \frac{\Phi_e(\Omega_i, \omega)}{\Phi_{bb}(\omega)} = \text{total integrated emittance} \tag{24a}$$

where Φ_{bb} is the blackbody function representing the spectral emission of a medium which totally absorbs all light at all frequencies. When $\Phi_i(\omega) = \Phi_{bb}(\omega)$, then the total integrated emittance equals the total integrated absorptance:

$$\varepsilon(\Omega_i, \omega) = \alpha_{ABS}(\Omega_i, \omega) \tag{24b}$$

Dispersion Formulas for Refractive Index The dielectric constant and refractive index are functions of frequency, hence wavelength. The frequency or wavelength variation of refractive index is called *dispersion*. Dispersion is an important property for optical design (i.e., correction of chromatic aberration) and in the transmission of information (i.e., pulse spreading). Other optical properties are derived from the change in refractive index with other properties such as temperature (*thermo-optic* coefficient), stress or strain (*piezo-optic* or *elasto-optic* coefficients), or applied field (*electro-optic* or *piezo-electric* coefficients). Since the dielectric constant is a second-order tensor with three principal values, the coefficients defined here are also tensor properties (see Table 1).

Precise refractive index measurements give values as functions of wavelength. Frequently, it is desirable to have a functional form for the dispersion of the refractive index (i.e., for calculations and value interpolation). There are many formulas used for representing the refractive index. One of the most widely used is the Sellmeier (or Drude or Maxwell-Helmholtz-Drude) dispersion model [Eq. (14)], which arises from treating the absorption like simple mechanical or electrical resonances. Sellmeier[38] proposed the following dispersion formula in 1871–1872 (although Maxwell had also considered the same derivation in 1869). The usual form of this equation for optical applications gives refractive index as a function of wavelength rather than wave number, frequency, or energy. In this form, the Sellmeier equation is

$$n^2(\lambda)-1=\sum_{i=1}\frac{A_i\cdot\lambda^2}{\lambda^2-\lambda_i^2} \tag{25a}$$

The Sellmeier formula has the appropriate physical basis to accurately represent the refractive index throughout the transparent region in the simplest manner. The Sellmeier constants have physical meaning, particularly for simple substances. Most other dispersion formulas are closely related to (or are a disguised form of) the Sellmeier equation. Many of these other dispersion formulas are unable to cover as wide a spectral region, and unlike the Sellmeier form, do not lend themselves to extrapolation outside the interval of available measurements. For these reasons, we strongly urge that the Sellmeier model be universally used as the standard representation of the refractive index.

Modifications of the Sellmeier terms that include composition variation[64,65] and temperature dependence[66] have been applied to successfully model refractive index. The variation of the Sellmeier A_i and λ_i constants is usually modeled as linearly dependent on the mole fraction of the components and temperature.

An often-used, slight modification of this formula puts the wavelength of the shortest wavelength resonance at zero ($\lambda_1 = 0$), that is, the first term is a constant. This constant term represents contributions to refractive index from electronic transitions at energies far above the bandgap. Sellmeier terms with small λ_i (representing electronic transitions) can be expanded as a power series,

$$\frac{A_i\cdot\lambda^2}{\lambda^2-\lambda_i^2}=A_i\cdot\sum_{i=0}^{\infty}\cdot(\lambda_i^2/\lambda^2)^j=A_i+\frac{A_i\cdot\lambda_i^2}{\lambda^2}+\frac{A_i\cdot\lambda_i^4}{\lambda^4}+\cdots \tag{25b}$$

and the terms with large λ_i (representing vibrational transitions) are expanded as:

$$\frac{A_i\cdot\lambda^2}{\lambda^2-\lambda_i^2}=-A_i\cdot\sum_{j=1}^{\infty}(\lambda^2/\lambda_i^2)^j=-A_i\cdot\frac{\lambda^2}{\lambda_i^2}-A_i\cdot\frac{\lambda^4}{\lambda_i^4}-\cdots \tag{25c}$$

The first term of this expansion is occasionally used to represent the long-wavelength (infrared) contribution to the index of refraction (instead of the Sellmeier term).

A generalized form of the short-wavelength approximation to the Sellmeier equation is the Cauchy formula, developed in 1836. This was the first successful attempt to represent dispersion by an equation:

$$n=A_0+\sum_{i=1}\frac{A_i}{\lambda^{2i}}\quad or\quad n^2=A_0'+\sum_{i=1}\frac{A_i'}{\lambda^{2i}} \tag{26}$$

Power series approximations to the Sellmeier equation are expressed in many forms. One common form is the Schott glass formula used for glasses:

$$n^2 = A_0 + A_1\lambda^2 + A_2\lambda^{-2} + A_3\lambda^{-4} + A_4\lambda^{-6} + A_5\lambda^{-8} + \cdots \tag{27}$$

For typical high-quality glasses, this equation is accurate to $\pm 3 \cdot 10^{-6}$ in the visible (400–765 nm) and within $\pm 5 \cdot 10^{-6}$ from 365 to 1014 nm. A comparison of the Schott power series formula with a three-term Sellmeier formula showed equivalent accuracy of the range of the Schott fit, but that the Sellmeier model was accurate over a much wider wavelength range.[67] A number of other power series dispersion formulas (e.g., Ketteler–Neumann[68]) are occasionally used.

Frequently, Sellmeier terms are written in altered fashion such as this form used by Li[69] and others:

$$\frac{A_i}{(\lambda^2 - \lambda_i^2)} = \frac{A_i(\lambda^2/\lambda_i^2)}{(\lambda^2 - \lambda_i^2)} - \frac{A_i}{\lambda_i^2} \tag{28a}$$

which is the equivalent of the combination of two Sellmeier terms, one located at zero wavelength and the other at λ_i. The Zernike formula[70] also uses a term in this form. Another way to modify Sellmeier terms is to convert the wavelength of the resonances to wave number or energy [see Eq. (14)].

Another common formula for the index of refraction is the Hartmann[43] or Cornu equation:

$$n = A + \frac{B}{\lambda - \lambda_0} \tag{28b}$$

This equation is more distantly related to the Sellmeier formulation. Note that a two-term Sellmeier formula (with $\lambda_1 = 0$) can be written as

$$(n^2 - n_0^2)\cdot(\lambda^2 - \lambda_0^2) = (n - n_0)\cdot(\lambda - \lambda_0)\cdot(n + n_0)\cdot(\lambda + \lambda_0) = \text{constant} \tag{28c}$$

and the Hartmann formula can be written as a hyperbola

$$(n - n_0)\cdot(\lambda - \lambda_0) = \text{constant} \tag{28d}$$

Note that in a limited spectral region, the difference terms of the Sellmeier formula of Eq. (28*c*) vary much more rapidly than do the sum terms, hence the Hartmann and Sellmeier forms will have nearly the same shape in a limited spectral range.

Other equations that combine Sellmeier and power series terms (cf., Wemple formula) are often used. One such formulation is the Herzberger equation, first developed for glasses[71] and later applied to infrared crystalline materials:[72]

$$n = A + \frac{B}{(\lambda^2 - 0.028)} + \frac{C}{(\lambda^2 - 0.028)^2} + D\lambda^2 + E\lambda^4 \tag{28e}$$

where the choice of the constant $\lambda_0^2 = 0.028$ is arbitrary in that it is applied to all materials.

The Pikhtin-Yas'kov formula[73] is nearly the same as the Sellmeier form with the addition of another term representing a broadband electronic contribution (which is equal to the real part of one of the terms in Adachi's model[44]):

$$n^2 - 1 = \frac{A}{\pi}\ln\frac{E_1^2 - (\hbar\omega)^2}{E_0^2 - (\hbar\omega)^2} + \sum_i \frac{G_i}{E_i^2 - (\hbar\omega)^2} \tag{28f}$$

This formulation has been applied to some semiconductor materials. The unique term arises from assuming that the imaginary part of the dielectric constant is a constant between energies E_0 and E_1, and that infinitely narrow resonances occur at E_i. The formula is then derived by applying the Kramers–Krönig relationship to this model.

Dispersion Formulas Used for Glasses Dispersion in glasses (and most other materials) is accurately represented by a Sellmeier model [Eq. (25*a*)] with three terms, two representing electronic (short wavelength) absorption and one representing lattice vibration (long wavelength) absorption contribution to the refractive index. Typically for glasses, the *Abbe number*, or constringence v_d, is also given. The Abbe number is a measure of dispersion in the visible and is defined as $v_d = (n_d - 1)/(n_F - n_C)$, where n_d, n_F, and n_C are refractive indices at 587.6, 486.1, and 656.3 nm, respectively. The quantity $(n_F - n_C)$ is known as the *principle dispersion*. A relative partial dispersion $P_{x,y}$ can be calculated at any wavelengths x and y from

$$P_{x,y} = \frac{(n_x - n_y)}{(n_F - n_C)} \tag{29a}$$

For so-called "normal" glasses, the partial dispersions obey a linear relationship, namely

$$P_{x,y} = a_{x,y} + b_{x,y} v_d \tag{29b}$$

where $a_{x,y}$ and $b_{x,y}$ are empirical constant characteristics of normal glasses. However, for correction of secondary spectrum in an optical system (i.e., achromatization for more than two wavelengths), it is necessary to employ a glass that does not follow the glass line. Glass manufacturers usually list $\Delta P_{x,y}$ for a number of wavelength pairs as defined by:

$$P_{x,y} = a_{x,y} + b_{x,y} v_d + \Delta P_{x,y} \tag{29c}$$

The deviation term $\Delta P_{x,y}$ is a measure of the dispersion characteristics differing from the normal glasses. Schott glasses F2 and K7 define the normal glass line.

In the transparent region, refractive index decreases with increasing wavelength, and the magnitude of $dn/d\lambda$ is a minimum between the electronic and vibrational absorptions. The wavelength (λ_0) of minimum $dn/d\lambda$, called the "zero"-dispersion point, is given by

$$\left.\frac{d^2 n(\lambda)}{d\lambda^2}\right|_{\lambda=\lambda_0} = 0 \tag{30}$$

which is the desired operating point for high-bandwidth, information-carrying optical fibers, as well as the optimum wavelength for single-element refractive optical systems. For glassy silica fibers, the zero dispersion point is 1.272 μm.

The equation for the dispersion in a standard single-mode fiber is

$$D_{\text{chromatic}} = \frac{S_0}{4}\left(\lambda - \frac{\lambda_0^4}{\lambda^3}\right) \tag{31}$$

where the operating wavelength is λ, the zero-dispersion wavelength is λ_0, and S_0 is the slope of the dispersion curve. The dispersion units are picoseconds per wavelength bandwidth (nm) per unit length of fiber (km).

One approach to reducing both dispersion and loss is to use a material with a wide transparent region, that is, widely separated electronic and vibrational absorptions, hence the interest in materials such as heavy-metal fluoride glasses for fiber applications. Recent work in photonic bandgap (PBG) fibers and micro-structured optical fibers demonstrates that light can be guided in hollow cores. Index-guided fibers can operate below 800 nm but the effective mode area is small. PBG fibers have been theorized to work below 800 nm with an order of magnitude larger effective mode area.[74] Hence, dispersionless transmission of short pulses in the near visible range is achieved.[75–77]

Thermo-Optic and Photoelastic Coefficients Temperature is one of the main factors influencing the refractive index of solids. The thermo-optical coefficients $\partial n/\partial T$ (or $\partial \varepsilon/\partial T$) can be estimated from a derivation of the Clausius–Mossotti relationship:[78]

$$\frac{1}{(\varepsilon-1)(\varepsilon+2)}\left(\frac{\partial \varepsilon}{\partial T}\right)=-\alpha\left[1-\frac{V}{\alpha_m}\left(\frac{\partial \alpha_m}{\partial V}\right)_T\right]+\frac{1}{3\alpha_m}\left(\frac{\partial \alpha_m}{\partial T}\right)_V \tag{32}$$

where α_m is the macroscopic polarizability. The first two terms are the principal contributors in ionic materials: a positive thermal expansion coefficient results in a negative thermo-optic coefficient and a positive change in polarizability with volume results in a positive thermo-optic coefficient. In ionic materials with a low melting point, thermal expansion is high and the thermo-optic coefficient is negative (typical of alkali halides); when thermal expansion is small (indicated by high melting point, hardness, and high elastic moduli), the thermo-optic coefficient is positive, dominated by the volume change in polarizability (typical of the high-temperature oxides).

Thermal expansion has no frequency dependence but polarizability does. At frequencies (wavelengths) near the edge of transparency, the polarizability (and $\partial \alpha_m/\partial V$) rises, and $\partial n/\partial T$ becomes more positive (or less negative). Figure 8 shows the variation of refractive index for sodium chloride as a function of frequency and temperature.

An approach similar to that for the thermo-optic coefficient, above, can be used to estimate the photoelastic constants of a material. The simplest photoelastic constant is that produced by uniform pressure, that is, dn/dP. More complex photoelastic constants are tensors whose components define the effect of individual strain (elasto-optic coefficients) or stress (piezo-optic coefficients) tensor terms. Bendow et al.[79] calculate dn/dP and the elasto-optic coefficients for a number of cubic crystals and compare the results to experiment.

Thermo-Optic Coefficients for Glasses The effect of temperature on the refractive index is dependent upon several factors, including the material and wavelength. The refractive index also changes as a function of air pressure. A distinction is therefore made between absolute refractive index, which is measured in vacuum, and refractive index relative to normal air, which is defined as the refractive index at normal air pressure (1 atmosphere = 101.325 kPa). The standard temperature

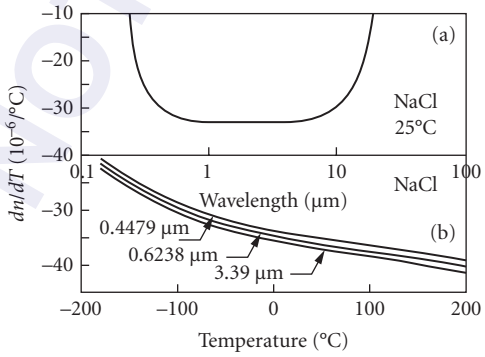

FIGURE 8 The thermo-optic coefficient (dn/dT) of sodium chloride (NaCl): (*a*) shows the wavelength dependence of room-temperature thermo-optic coefficient. The thermo-optic coefficient is nearly constant in the transparent region, but increases significantly at the edges of the transparent region and (*b*) illustrates the temperature dependence of the thermo-optic coefficient. The thermo-optic coefficient decreases (becomes more negative) with increasing temperature, primarily as the density decreases.

for refractive index measurements is 22°C, and manufacturer's quoted index of refraction values are always relative to normal air pressure.

The change in the absolute refractive index as a function of temperature is modeled as a first-order or linear change with temperature,

$$n_{\text{abs}}(\lambda, T) = n_{\text{abs}}(\lambda, T_0) + \frac{dn_{\text{abs}}(\lambda, T)}{dT}\Delta T \tag{33}$$

In the visible, the absolute refractive index as a function of wavelength can be well-approximated by a single-term Sellmeier model, Eq. (25*a*), and the temperature derivative of refractive index is then

$$\frac{dn_{\text{abs}}}{dT} = \frac{1}{2n_{\text{abs}}}\frac{d(n_{\text{abs}}^2 - 1)}{dT} = \frac{n_{\text{abs}}^2 - 1}{2n_{\text{abs}}}\left[\frac{1}{A}\frac{dA}{dT} + \frac{2\lambda_K}{\lambda^2 - \lambda_K^2}\frac{d\lambda_K}{dT}\right] \tag{34}$$

a function of the temperature dependence of the mode strength (A) and its location (λ_K). The mode strength is the product of the strength (polarizability) of the individual absorption oscillators and the density of those oscillators (i.e., is a function of the volume expansion).

The change in n with respect to T is then modeled by using constants D_0, D_1, and D_2 to represent the temperature dependence of mode strength, and constants E_0 and E_1 to represent the temperature dependence of mode location, namely,

$$\frac{dn_{\text{abs}}(\lambda, T)}{dT} = \frac{n^2(\lambda, T_0) - 1}{2n(\lambda, T_0)}\left[D_0 + 2D_1\Delta T + 3D_2\Delta T^2 + \frac{E_0 + 2E_1\Delta T}{\lambda^2 - \lambda_K^2}\right] \tag{35}$$

T_0 is the reference temperature, generally 20°C. T is the temperature of interest, and ΔT is the difference, $T - T_0$. The wavelength of interest is λ. The terms D_0, D_1, D_2, E_0, E_1, and λ_K are all constants dependent upon the glass type and are found by fitting to measurements. The relative index values found in catalogs can be used in Eq. (35) without loss of accuracy. This is why the abs subscript was dropped from the n terms on the right-hand side of the equation. Using Eq. (35) in Eq. (33) allows for the calculation of the change in the refractive index, as well as the new refractive index as a function of temperature.

The refractive index relative to air as a function of temperature, and the change itself as a function of temperature can be computed from the relationships[13]

$$n_{\text{rel}}(\lambda, T) = \frac{n_{\text{abs}}(\lambda, T)}{n_{\text{air}}(\lambda, T, P)} \tag{36a}$$

$$\frac{dn_{\text{rel}}(\lambda, T)}{dT} = \frac{\dfrac{dn_{\text{abs}}(\lambda, T)}{dT} - n_{\text{rel}}(\lambda, T)\dfrac{dn_{\text{air}}(\lambda, T, P)}{dT}}{n_{\text{air}}(\lambda, T, P)} \tag{36b}$$

The approximation that $n_{\text{rel}}(\lambda, T_0)$ can be substituted for $n_{\text{rel}}(\lambda, T)$ maintains sufficient accuracy, and simplifies the calculation.

The widely accepted equations for n_{air} and dn_{air}/dT of dry air are

$$n_{\text{air}}(\lambda, T, P) = 1 + \frac{n_{\text{air}}(\lambda, T_{15^\circ\text{C}}, P_0) - 1}{1 + 3.4785 \cdot 10^{-3}(T - 15^\circ\text{C})}P \tag{37a}$$

$$\frac{dn_{\text{air}}(\lambda, T, P)}{dT} = \frac{-0.00367 n_{\text{air}}(\lambda, T, P) - 1}{1 + 0.00367T} \tag{37b}$$

where P is the atmospheric pressure divided by the reference pressure ($P_0 = 1$ atmosphere).

The index of refraction in air at 15°C and 1 atmosphere of pressure is given by

$$n_{\text{air}}(\lambda, T_{15^\circ\text{C}}, P_0) = 1 + \left[6432.8 + \frac{2949810\lambda^2}{146\lambda^2 - 1} + \frac{25540\lambda^2}{41\lambda^2 - 1}\right] \times 10^{-8} \tag{37c}$$

The wavelength λ is in units of micrometers, and temperature is in units of degrees Celsius. P is the relative air pressure and is dimensionless. This completes the equations necessary to compute the absolute and relative index of refraction at any temperature and pressure, provided the proportionality constants in Eq. (33) and the parameters of Eq. (35) are available for the glass of interest. These equations are typically valid for temperature ranges of −100°C to 140°C, and a wavelength range of 0.3650 to 1.014 μm.

Athermal Glasses The environmental temperature affects glass in terms of thermal expansion coefficient [α, see Eq. (46*a*)] and the variation of the index of refraction, dn_{rel}/dT. Both effects deteriorate the wavefront due to the changed optical path and the change in the index of refraction. To mitigate the effect of temperature variations, the glass should ideally compensate for any thermal expansion effects by the refractive index change. Since all glasses exhibit a positive thermal expansion coefficient (increase in size with increased temperature), the ideal glass would have a negative temperature coefficient. This can be expressed in terms of the thermo-optical constant, G:

$$G = \alpha(n_{\text{rel}}(\lambda, T) - 1) + \frac{dn_{\text{rel}}(\lambda, T)}{dT} \tag{38}$$

Any glass with G near zero (e.g., $|G| < 1 \cdot 10^{-6}\ \text{K}^{-1}$) is referred to as athermal. Not all glasses with negative relative index temperature coefficients are athermal. Schott glasses N-PK51, N-FK51A, and N-PK52A show athermal behavior.

Nonlinear Optical Coefficients One of the most important higher-order optical coefficients is the nonlinear (or second-order) susceptibility. With the high electric fields generated by lasers, the nonlinear susceptibility gives rise to important processes such as second-harmonic generation, optical rectification, parametric mixing, and the linear electro-optic (Pockels) effect. The second-order susceptibility, $\chi^{(2)}$, is related to the polarization vector $\mathbf{P}$ by

$$\mathbf{P}_i(\omega) = \varepsilon_0[\chi_{\text{ij}}\mathbf{E}_j + g\chi^{(2)}_{\text{ijk}}\mathbf{E}_j(\omega_1)\mathbf{E}_k(\omega_2)] \tag{39}$$

where g is a degeneracy factor arising from the nature of the electric fields applied. If the two frequencies are equal, the condition of optical rectification and second-harmonic generation (SHG) arises, and $g = 1/2$. When the frequencies of $\mathbf{E}_j$ and $\mathbf{E}_k$ are different, parametric mixing occurs and $g = 1$. If $\mathbf{E}_k$ is a dc field, the situation is the same as the linear electro-optic (or Pockels) effect, and $g = 2$. The value of nonlinear susceptibility is a function of the frequencies of both the input fields and the output polarization ($\omega = \omega_1 \pm \omega_2$).

The nonlinear susceptibility is a third-order (3 by 3 by 3) tensor. A nonlinear optical coefficient $d^{(2)}$, frequently used to describe these nonlinear properties, is equal to one-half of the second-order nonlinear susceptibility, that is, $d^{(2)} = 1/2\chi^{(2)}$. Nonlinear optical coefficients are universally written in reduced (matrix) notation, $d^{(2)}_{\text{ij}}$, where the index $i = 1$, 2, or 3 and the index j runs from 1 to 6.[80] (Both the piezo-electric coefficient and the nonlinear optical coefficient are given the symbol d, and the resulting confusion is enhanced because both coefficients have the same units.) The relationship between the electro-optic coefficient r and the nonlinear optical coefficient $d^{(2)}$ is

$$r_{\text{ij}} = \frac{2gd^{(2)}_{\text{ij}}}{\varepsilon^2} \tag{40}$$

Units of the second-order nonlinear optical coefficient are m/V (or pm/V, where pm = 10^{-12}) in mks units.

TABLE 4 Typical Nonlinear Optical Coefficients

Crystal	Nonlinear Optical Coefficient (pm/V)
β-BaB_2O_4	$d_{11} = 1.60$
KH_2PO_4	$d_{36} = 0.39$
LiB_3O_5	$d_{32} = 1.21$
$LiNbO_3$	$d_{31} = 5.07$
$LiIO_3$	$d_{31} = 3.90$
$KTiOPO_4$	$d_{31} = 5.85$
Urea	$d_{14} = 1.17$

Typical values of the nonlinear optical coefficients are listed in Table 4.[81] Additional nonlinear optical coefficients are given in reviews (also refer to Chap. 10, "Nonlinear Optics" by Chung L. Tang).[80-83]

Scatter Scatter is both an intrinsic and extrinsic property. Rayleigh, Brillouin, Raman, and stoichiometric (index variation) contributions to scatter have been derived in simple form and used to estimate scatter loss in several fiber-optic materials.[84] Rayleigh scattering refers to elastic scatter from features small compared to the wavelength of light. In highly pure and defect-free optical crystals, Rayleigh scatter is caused by atomic scale inhomogeneities (much smaller than the wavelength) in analogy to Rayleigh scatter from molecules in the atmosphere. In most materials, including glasses, Rayleigh scatter is augmented by extrinsic contributions arising from localized density variations (which also limit the uniformity of the refractive index). Attenuation in high-quality optical materials is frequently limited by Rayleigh scatter rather than absorption.

Brillouin and Raman scatter are forms of inelastic scattering from acoustic and optical phonons (vibrations). The frequency of the scattered light is shifted by the phonon frequency. Creation of phonons results in longer-wavelength (low-frequency) scattered light (Stokes case) and annihilation of phonons results in higher-frequency scattered light (anti-Stokes case). Rayleigh, Brillouin, and Raman scatter all have λ^{-4} wavelength dependence. Polycrystalline and translucent materials have features such as grain boundaries and voids whose size is larger than the wavelength of light. This type of scatter is often called Mie scatter because the scattering features are larger than the wavelength of the light. Mie scatter typically has a measured λ^{-m} dependence where the parameter m typically lies between 1 and 2.[85,86] Rayleigh and Mie scatter may arise from either surface roughness or bulk nonuniformities.

Other Properties of Materials

Naming of Crystals and Glasses All materials are characterized by name(s) for identification, a chemical formula (crystalline materials) or approximate composition (glasses, amorphous substances), and a density (ρ, in kg/m^3). Crystalline materials are further identified by crystal class, space group, unit-cell lattice parameters, molecular weight (of a formula unit in atomic mass units, amu), and number of formula units per unit cell (Z). (See standard compilations of crystallographic data.[87,88])

Material Designation and Composition Crystals are completely identified by both the chemical formulation and the space group. Chemical formulation alone is insufficient for identification because many substances have several structures (called *polymorphs*) with different properties. Properties in the data tables pertain only to the specific structure listed. Materials in the data tables having several stable polymorphs at room temperature include SiO_2 (eight polymorphs), C (diamond, graphite, and amorphous forms), and SiC and ZnS (both have cubic and hexagonal forms).

The space group also identifies the appropriate number of independent terms (see Tables 1 and 2) that describe a physical quantity. Noncubic crystals require two or more values to fully describe thermal expansion, thermal conductivity, refractive index, and other properties. Often, scalar quantities are

given in the literature when a tensor characterization is needed. Such a characterization may be adequate for polycrystalline materials, but is unsatisfactory for single crystals that require knowledge of directional properties.

Historically, optical glasses have been identified by traditional names derived from their composition and their dispersion relative to their index of refraction. This dates back to the 1880s when low dispersion crown glasses (typically with Abbe number ν_d >50) and higher dispersion flint glasses (typically, ν_d <50) dominated the glass map.[89] It took Ernst Abbe, Carl Zeiss, and the work of Otto Schott to expand the glass by developing two new glass formers, fluorine and boron.[90,91] In addition, Schott's work with BaO network modifiers pioneered new variations in index of refraction within the same groups. This gave rise to classifications of "heavy" and "light" (index of refraction designation), in addition to crown and flint (Abbe number classification).

The next major advancement in glass technology came in the 1930s when rare earth elements and network-former phosphorous became readily available.[92,93] These new glass types were named by adding the compounds chemical symbol to the traditional nomenclature of crown or flint, heavy or light. This led to various groups evolving on the Abbe diagram, groups whose position gave strong indication of the chemical composition of the glass. This distinction and borders in the Abbe diagram remains till the present day. However the traditional nomenclature is rapidly ending as manufacturers, primarily in Japan, are adopting new naming conventions for their glasses.

The primary reason for this nomenclature change is advances in manufacturing techniques, raw material supply and purity, and the evolution of new materials have all led to new compositional families of glasses that cross traditional borders. So a given glass family name such as PSK may have glasses without any phosphorous. Furthermore, different manufacturers producing a glass with identical index of refraction and Abbe numbers may in fact have entirely different physical and chemical properties (e.g., Schott N-LaSF31A, Hikari's E-LaSF08, and Hoya's TaFD30.) A single name would be disingenuous.

The main classical groups are listed in Table 8, and a representative glass from each is shown. Figure 9 shows the classic Abbe diagram with traditional nomenclature and the newer style showing glass systems based more on constituent materials. A thorough discussion of the various glass systems is found in the literature.[17]

Regardless of the categorizing and naming of glasses and glass systems or groups, a specific glass identifier scheme, as defined in military standard MIL-G-174, remains in use today. This convention uses a six-digit number representing the first three digits of $(n_d - 1)$ and the first three digits of ν_d. Each manufacturer also has its own designator, usually based on traditional or new names, that uniquely identifies each glass. For example, the glass with code 517624 has the following manufacturer's designations:

Manufacturer	Designation for Glass 517642
Schott	N-BK7
Corning	B-16-64
Pilkington	BSC-517642B
Hoya	BSC-7
Ohara	S-BSL 7 (closest value 516641)

Properties of glass are primarily determined from the compositions, but also depend on the manufacturing process, specifically the thermal history. In fact, refractive index specifications in a glass catalog should be interpreted as those obtained with a particular annealing schedule. Annealing removes stress (and minimizes stress-induced birefringence) and minimizes the effect of thermal history, producing high refractive-index uniformity. Special (*precision*) annealing designed to maximize refractive index homogeneity may, however, increase refractive index slightly above a nominal (catalog) value. A complete discussion of the annealing process can be found in literature.[16,94]

In general, both glass composition and thermal processing are proprietary (so the compositions given are only illustrative). However, manufacturers' data sheets on individual glasses can provide detailed and specific information on optical and mechanical properties. Also, the data sheets supply useful details on index homogeneity, climate resistance, stain resistance, and chemical (acid and

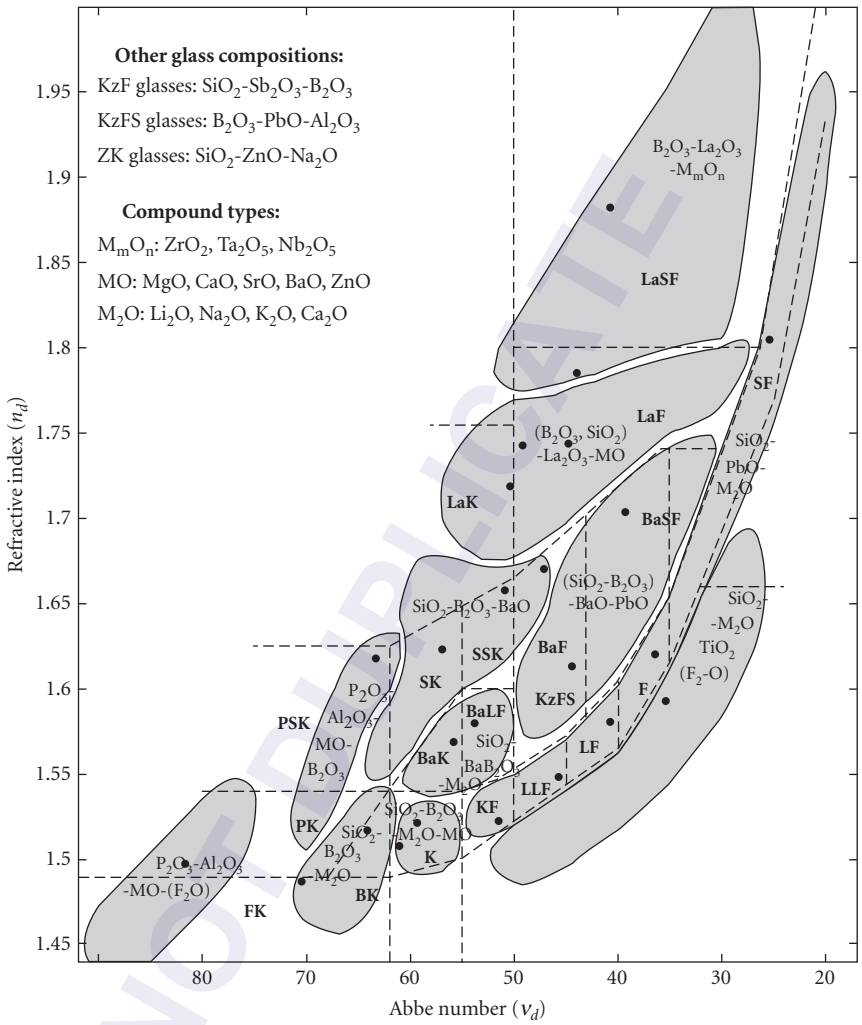

FIGURE 9 The Abbe diagram (refractive index, n_d, versus Abbe number, ν_d) showing the composition of common glass systems, the Schott glass classifications, and the sample glasses (dots) included in this chapter. (*Reprinted by permission of Springer-Verlag.*)

alkaline) resistance for a particular glass type. For very detailed work or demanding applications, a glass manufacturer can supply *a melt data sheet* providing accurate optical properties for a specific glass lot.

A driving force in the recent breaking of traditional glass manufacture practices has been a growing movement for environmentally responsible glass. The primary elements of contention were arsenic and lead, and other toxic elements. For example, thorium oxide use has been discontinued, and cadmium oxide is restricted to colored glass manufacture. The principal concerns lie not in the end user, despite the negative connotation lead and lead-based products have incurred the past few decades. In fact, lead-containing glass is still available and labeled as such. The concern rests in the manufacture and disposal of hazardous waste. No guarantee could be made that the workplace would be safe, and the waste disposed of properly.

The replacements for PbO are typically TiO_2, Nb_2O_5, ZrO_2, and WO_3. The replacement for As_2O_3 as a refining agent has been Sb_2O_3. For approximately 50 percent of the glasses containing As_2O_3 and no PbO, the use of Sb_2O_3 has not changed the properties of the glass. Using substitute materials for Glasses formerly containing PbO and As_2O_3 has modified the properties of the glass, sometimes significantly. One by-product of lead removal has been lighter weight. Manufacturers have begun to denote the reformulated glasses by specific designations. Schott uses "N-" to prefix the new glass materials, Hikari uses "E-", and Ohara uses "S-". References to environmental concerns are included in the reference section.[10,95]

Unit Cell Parameters, Molecular Weight, and Density The structure and composition of crystals can be used to calculate density. This calculated (theoretical or x-ray) density should closely match that of optical-quality materials. Density, ρ, is mass divided by volume:

$$\rho = \frac{Z \cdot (\mathrm{MW}) \cdot u}{a \cdot b \cdot c \sqrt{\sin^2\alpha + \sin^2\beta + \sin^2\gamma - 2(1 - \cos\alpha \cdot \cos\beta \cdot \cos\gamma)}} \tag{41}$$

where Z is the number of formula units in a crystal unit cell, MW is the molecular weight of a formula unit in amu, u is weight of an amu (Table 3), a, b, and c are unit cell axes lengths, and α, β, and γ are unit cell axes angles.

Typically, pure amorphous materials have lower density than the corresponding crystalline materials. Density of glasses and other amorphous materials is derived from measurements.

Elastic Properties Elastic properties of materials can be described with a hierarchy of terms. On the atomic scale, interatomic force constants or potential energies can be used to predict the vibrational modes, thermal expansion, and elastic properties of a material. On the macroscopic scale, elastic properties are described using elastic moduli (or constants) related to the directional properties of a material. The tensor relationships between stress (σ, a second-order tensor) and strain (e, a second-order tensor) are

$$\begin{aligned} \sigma_{ij} &= \mathbf{c}_{ijkl} \cdot e_{kl} \\ e_{ij} &= \mathbf{s}_{ijkl} \cdot \sigma_{kl} \end{aligned} \tag{42a}$$

where the fourth-rank tensors $\mathbf{c}_{ijkl}$ and $\mathbf{s}_{ijkl}$ are named elastic stiffness **c** and elastic compliance **s**, respectively. This is the tensor form of Hooke's law. Each index (i, j, k, and l) has three values (i.e., x, y, and z), hence the **c** and **s** tensors have 81 terms.

The stiffness and compliance tensors are usually written in a matrix notation made possible by the symmetry relationship of the stress and strain tensors. Symmetry reduces the number of independent terms in the stiffness and compliance tensors from 81 to 36. The usual notation for the reduced (matrix) notation form of the stiffness and compliance tensors is

$$\begin{aligned} \sigma_i &= \mathbf{c}_{ij} \cdot e_j \\ e_i &= \mathbf{s}_{ij} \cdot \sigma_j \end{aligned} \tag{42b}$$

where the indices, an abbreviation of the ij or kl components, run from 1 to 6. Table 5 shows the conversion from tensor to matrix notation. Thus, the stiffness and compliance tensors are written as 6 by 6 matrices which can again be shown to be symmetric, given 21 independent terms. Virtually all data will be found in matrix notation. These tensors (matrices) that relate stress and strain are sometimes called *second-order* stiffness and compliance. Higher-order tensors are used to describe nonlinear elastic behavior (i.e., third-order stiffness determines the stress tensor from the square of the strain tensor).

Stiffness and compliance tensors are needed to completely describe the linear elastic properties of a crystal. Even a completely amorphous material has two independent constants that describe the relationship between stress and strain. Usually, the elastic properties of materials are expressed in terms of engineering (or technical) moduli: Young's modulus (E), shear modulus (or modulus

TABLE 5 Matrix Notation for Stress, Strian, Stiffness, and Compliance Tensors

Tensor-to-matrix index conversion		Tensor-to-matrix element conversion	
Tensor Indices ij or kl	Matrix Indices m or n	Notation	Condition
11	1	$\sigma_m = \sigma_{ij}$ $e_m = \sigma_{ij}$	$m = 1, 2, 3$
22	2	$\sigma_m = \sigma_{ij}$ $e_m = 2e_{ij}$	$m = 4, 5, 6$
33	3	$\mathbf{c}_{mn} = \mathbf{c}_{ijkl}$	all m, n
23 or 32	4	$\mathbf{s}_{mn} = \mathbf{s}_{ijkl}$	$m, n = 1, 2, 3$
13 or 31	5	$\mathbf{s}_{mn} = 2\mathbf{s}_{ijkl}$	$m = 1, 2, 3$ and $n = 4, 5, 6$ $m = 4, 5, 6$ and $n = 1, 2, 3$
12 or 21	6	$\mathbf{s}_{mn} = 4\mathbf{s}_{ijkl}$	$m, n = 4, 5, 6$

of rigidity G), bulk modulus (B, compressibility^{-1}), and Poisson's ratio (ν). For example, Young's modulus is defined as the ratio of the longitudinal tension to the longitudinal strain for tension, a quantity which is anisotropic (i.e., directionally dependent) for all crystal classes (but is isotropic for amorphous materials). Therefore the engineering moduli only accurately describe the elastic behavior of isotropic materials. The engineering moduli also approximately describe the elastic behavior of polycrystalline materials (assuming small, randomly distributed grains). Various methods are available to estimate the engineering moduli of crystals.

Values of the engineering moduli for crystalline materials given in the data tables are estimated from elastic moduli using the Voigt and Reuss methods (noncubic materials) or the Haskin and Shtrikman method[96] (cubic materials) to give shear (G) and bulk (B) moduli. Young's modulus (E) and Poisson's ratio (ν) are then calculated assuming isotropy using the following relationships:

$$E = \frac{9 \cdot G \cdot B}{G + 3 \cdot B} \qquad \nu = \frac{3 \cdot B - 2 \cdot G}{6 \cdot B + 2 \cdot G} \tag{43}$$

Hardness and Strength Hardness is an empirical and relative measure of a material's resistance to wear (mechanical abrasion). Despite the qualitative nature of the result, hardness testing is quantitative, repeatable, and easy to measure. The first measure of hardness was the Mohs scale which compares the hardness of materials to one of 10 minerals. Usually, the Knoop indent test is used to measure hardness of optical materials. The test determines the resistance of a surface to penetration by a diamond indenter with a fixed load (usually 50 to 200 g). The Knoop hardness number (usually measured in kg/mm^2 = 9.8 MPa) is the indenter mass (proportional to load) divided by the area of the indent. Figure 10 compares the Mohs and Knoop scales.[9]

Materials with Knoop values less than 100 kg/mm^2 are very soft, difficult to polish, and susceptible to handling damage. Knoop hardness values greater than 750 are quite hard. Typical glasses have hardness values of 350 to 600 kg/mm^2. Hardness qualitatively correlates to Young's modulus and to strength. Hardness of crystals is dependent on the orientation of the crystal axes with respect to the tested surface. Coatings can significantly alter hardness.

Strength is a measure of a material's resistance to fracture (or onset of plastic deformation). Strength is highly dependent on material flaws and therefore on the method of manufacture, as well as the method of measurement. For optical materials, strength is most conveniently measured in flexure; tensile strengths are typically 50 to 90 percent of those measured in flexure. Because of high variability in strength values, quoted strength values should only be used as a guide for comparison of materials. Strength of crystals also is dependent on the orientation of the crystal axes with respect to the applied stress. Applications requiring high strength to avoid failure should use large safety margins (typically a factor of four) over average strength whenever possible.

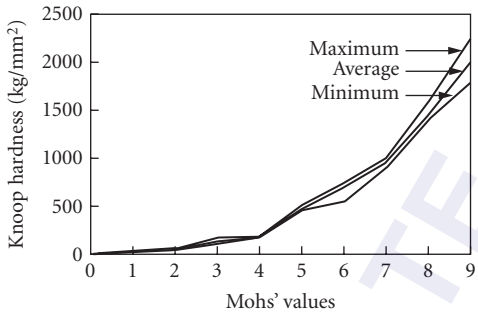

FIGURE 10 A comparison of Mohs and Knoop hardness scales.[12] The Mohs scale is qualitative, comparing the hardness of a material to one of 10 minerals: talc (Moh ≡ 1), gypsum (≡ 2), calcite (≡ 3), fluorite (≡ 4), apatite (≡ 5), orthoclase (≡ 6), quartz (≡ 7), topaz (≡ 8), sapphire (≡ 9), and diamond (Moh ≡ 10). The Knoop scale is determined by area of a mark caused by an indenter; the Knoop value is the indenter mass divided by the indented area. The mass of the indenter (load) is usually specified; 200 or 500 g are typical. (*Reprinted by permission of Ashlee Publishing Company.*)

Fracture toughness is another measure of strength, specifically, a material's ability to resist crack propagation. Fracture toughness measures the applied stress required to enlarge a flaw (crack) of given size and has units of $MPa \cdot m^{1/2}$. Values for representative materials are given in Table 6.

Characteristic Temperatures Characteristic temperatures of crystalline materials are those of melting (or vaporization or decomposition) and phase transitions. Of particular importance are the phase-transition temperatures. These temperatures mark the boundaries of a particular structure. A phase transition can mean a marked change in properties. One important phase-transition point is the Curie temperature of ferroelectric materials. Below the Curie temperature, the material is ferroelectric; above this temperature it is paraelectric. The Curie temperature phase transition is particularly significant because the change in structure is accompanied by drastic changes in some properties such as the static dielectric constant which approaches infinity as temperature nears the Curie temperature. This transition is associated with the lowest transverse optical frequency (the soft mode) approaching zero [hence the static dielectric constant approaches infinity from the Lyddane-Sachs-Teller relationship, Eq. (11)].

TABLE 6 Fracture Toughness of Some Materials

Fracture toughness		Fracture toughness	
Material	$MPa \cdot m^{1/2}$	Material	$MPa \cdot m^{1/2}$
Al_2O_3	3	$MgAl_2O_4$	1.5
ALON	1.4	MgF_2	1.0
AlN	3	$PbTiO_3$	1.1
N-BK7 glass	1.1	SF58 glass	0.38
C, diamond	2.0	Si	0.95
CaF_2	0.5	fused SiO_2	0.8
$CaLa_2S_4$	0.68	Y_2O_3	0.7
F2 glass	0.55	ZnS	0.5 (crystal) 0.8 (CVD)
GaP	0.9	ZnSe	0.33
Ge	0.66	ZrO_2:Y_2O_3	2.0
LaK10 glass	0.95	Zerodur	0.9

The term *glass* applies to a material that retains an amorphous state upon solidification. More accurately, glass is an undercooled, inorganic liquid with a very high viscosity at room temperature and is characterized by a gradual softening with temperature and a hysteresis between glass and crystalline properties. The gradual change in viscosity with temperature is characterized by several temperatures, especially the glass transition temperature and the softening-point temperature. The glass transition temperature defines a second-order phase transition analogous to melting. At this temperature, the temperature dependence of various properties changes (in particular, the linear thermal expansion coefficient) as the material transitions from a liquid to glassy state. Glasses can crystallize if held above the transition temperature for sufficient time. The annealing point is defined as the temperature resulting in a glass viscosity of 10^{13} poise and at which typical glasses can be annealed within an hour or so. In many glasses, the annealing point and the glass transition temperature are close. In an optical system, glass elements need to be kept 150 to 200°C below the glass transition temperature to avoid significant surface distortion. At the *softening temperature*, viscosity is $10^{7.6}$ poise and glass will rapidly deform under its own weight; glasses are typically molded at this temperature. Glasses do not have a true melting point; they become progressively softer (more viscous) with increased temperature. Other amorphous materials may not have a well-defined glass transition; instead they may have a conventional melting point. Glasses that crystallize at elevated temperature also have a well-defined melting point.

Glass-ceramics have been developed which are materials with both glasslike and crystalline phases. In particular, low-thermal-expansion ceramics comprise a crystalline phase with a negative thermal expansion and a vitreous phase with a positive thermal expansion. Combined, the two phases result in very high dimensional stability. Typically, the ceramics are made like other glasses, but after stresses are removed from a blank, a special heat-treatment step forms the nuclei for the growth of the crystalline component of the ceramic. Although not strictly ceramics, similar attributes can be found in some two-phase glasses.

Heat Capacity and Debye Temperature Heat capacity, or specific heat, a scalar quantity, is the change in thermal energy with a change in temperature. Units are typically J/(gm · K). Debye developed a theory of heat capacity assuming that the energy was stored in acoustical phonons. This theory, which assumes a particular density of states, results in a Debye molar heat capacity [units J/(mole · K)] of the form

$$C_V(T) = 9mN_A k_B \left(\frac{T}{\theta_D}\right)^3 \int_0^{\theta_D/T} \frac{x^4 e^x}{(e^x - 1)^2} dx \tag{44a}$$

where C_V is the molar heat capacity in J/(mole · K) per unit volume, θ_D is the Debye temperature, m the number of atoms per formula unit, N_A is Avogadro's number, and k_B is Boltzmann's constant. At low temperatures ($T \to 0$ K), heat capacity closely follows the T^3 law of Debye theory

$$C_V(T) = \frac{12\pi^4}{5} mN_A k_B \left(\frac{T}{\theta_D}\right)^3 = 1943.76 \cdot m \left(\frac{T}{\theta_D}\right)^3 \quad \text{J/(mole} \cdot \text{K)} \quad (T << \theta_D) \tag{44b}$$

and the high-temperature (classical) limit is

$$C_V(T) = 3mN_A k_B = 24.943 \cdot m \quad \text{J/(mole} \cdot \text{K)} \quad (T > \theta_D) \tag{44c}$$

If heat capacity data are fit piecewise to the Debye equation, a temperature-dependent θ_D can be found. Frequently, a Debye temperature is determined from room-temperature elastic constants, and is therefore different from the low-temperature value. The Debye temperature given in the tables is, when possible, derived from low-temperature heat capacity data.

The Debye equations can be used to estimate heat capacity C_V over the entire temperature range, typically to within 5 percent of the true value using a single Debye temperature value. Usually, however, C_P, the constant pressure heat capacity, rather than C_V, is desired. At low temperatures, thermal

expansion is small, and $C_p \approx C_V$. At elevated temperature, the relationship between C_V and C_p is given by the thermodynamic relationship

$$C_p(T) = C_v(T) + 9\alpha^2 TVB \tag{45}$$

where T is temperature (K), V is the molar volume (m^3/mole), α is the thermal expansion coefficient, and B is the bulk modulus (Pa = Nt/m^2).

Molar heat capacity can be converted to usual units by dividing by the molecular weight (see the physical property tables for crystals) in g/mole. Since molar heat capacity approaches the value of 24.943 J/(mole·K) the heat capacity per unit weight is inversely proportional to molecular weight at high temperature (i.e., above the Debye temperature).

Thermal Expansion The linear thermal expansion coefficient α is the fractional change in length with a change in temperature as defined by

$$\alpha(T) = \frac{1}{L}\frac{dL}{dT} \tag{46a}$$

and units are 1/K. The units of length are arbitrary. Thermal expansion is a second-rank tensor; nonisometric crystals have a different thermal expansion coefficient for each principal direction. At low temperature, thermal expansion is low, and the coefficient of thermal expansion approaches zero as $T \to 0$ K. The expansion coefficient generally rises with increasing temperature; Fig. 11 shows temperature dependence of the expansion coefficient for several materials. Several compilations of data exist.[97,98]

The volume expansion coefficient α_V is the fractional change in volume with an increase in temperature. For a cubic or isotropic material with a single linear thermal expansion coefficient

$$\alpha_V(T) = \frac{1}{V}\frac{dV}{dT} = 3\alpha \tag{46b}$$

can be used to estimate the temperature change of density.

The Grüneisen relationship relates the thermal expansion coefficient to molar heat capacity

$$\alpha(T) = \frac{\gamma C_V(T)}{3B_0 V_0} \tag{46c}$$

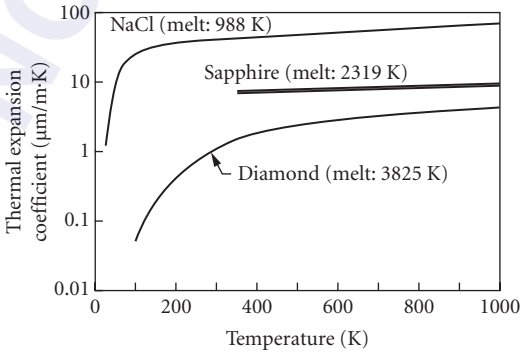

FIGURE 11 Thermal expansion of several materials. Expansion arises from the anharmonicity of the interatomic potential. At low temperature, expansion is very low and the expansion coefficient is low. As temperature increases, the expansion coefficient rises, first quickly, then less rapidly.

where B_0 is the bulk modulus at $T = 0$ K, V_0 is the volume at $T = 0$ K, and γ is the Grüneisen parameter. This relationship shows that thermal expansion has the same temperature dependence as the heat capacity. Typical values of γ lie between 1 and 2.

Thermal Conductivity Thermal conductivity κ determines the rate of heat flow through a material with a given thermal gradient. Conductivity is a second-rank tensor with up to three principal values. This property is especially important in relieving thermal stress and optical distortions caused by rapid heating or cooling. Units are W/(m · K)

Kinetic theory gives the following expression for thermal conductivity, κ

$$\kappa = \frac{1}{3} C_V \upsilon \ell \tag{47}$$

where υ is the phonon (sound) velocity and ℓ is the phonon mean free path. At very low temperature ($T < \theta_D/20$), the temperature dependence of thermal conductivity is governed by C_V, which rises as T^3 [see Eq. (36*b*)]. At high temperature ($T > \theta_D/10$), the phonon mean free path is limited by several mechanisms. In crystals, scattering by other phonons usually ℓ. In the high-temperature limit, the phonon density rises proportional to T and thermal conductivity is inversely proportional to T. Figure 12 illustrates the temperature dependence of thermal conductivity of several crystalline materials.

Thermal conductivity in amorphous substances is quite different compared to crystals. The phonon mean free path in glasses is significantly less than in crystals, limited by structural disorder. The mean free path of amorphous materials is typically the size of the fundamental structural units (e.g., 10 Å) and has little temperature dependence; hence the temperature dependence of thermal conductivity is primarily governed by the temperature dependence of heat capacity. At room temperature, the thermal conductivity of oxide glasses is a factor of 10 below typical oxide crystals. Figure 12 compares the thermal conductivity of fused silica to crystalline silica (quartz).

Thermal conductivity of crystals is highly dependent on purity and order. Mixed crystals, second-phase inclusion, nonstoichiometry, voids, and defects can all lower the thermal conductivity

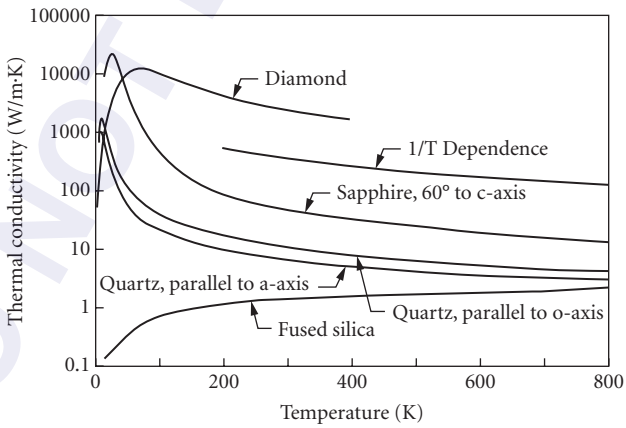

FIGURE 12 Thermal conductivity of several materials. Conductivity initially rises rapidly as the heat capacity increases. Peak thermal conductivity of crystals is high due to the long phonon mean free path of the periodic structure which falls with increasing temperature as the phonon free path length decreases (≈1/T). The phonon mean free path of amorphous materials (e.g., fused silica) is small and nearly independent of temperature, hence thermal conductivity rises monotonically and approaches the crystalline value at high temperature.

of a material. Values given in the data table are for the highest-quality material. Thermal conductivity data are found in compilations[98] and reviews.[99]

Correlation of Properties All material properties are correlated to a relatively few factors, for example, constituent atoms, the bonding between the atoms, and the structural symmetry. The binding forces, or chemical bonds, play a major role in properties. Tightly bonded materials have high moduli, high hardness and strength, and high Debye temperature (hence high room-temperature thermal conductivity). Strong bonds also mean lower thermal expansion, lower refractive index, higher-frequency optical vibrational modes (hence less infrared transparency), and higher energy bandgaps (hence more ultraviolet transparency). Increased mass of the constituent atoms lowers the frequency of both electronic and ionic resonances. Similarly, high structural symmetry can increase hardness and eliminate (to first order) ionic vibrations (cf., diamond, silicon, and germanium).

Combinations of Properties A given material property is influenced by many factors. For example, the length of a specimen is affected by stress (producing strain), by electric fields (piezo-electric effect), and by temperature (thermal expansion). The total strain is then a combination of these linear effects and can be written as

$$\Delta e_{ij} = \left(\frac{\partial e_{ij}}{\partial \sigma_{kl}}\right)_{E,T} \Delta\sigma_{kl} + \left(\frac{\partial e_{ij}}{\partial \mathbf{E}_k}\right)_{\sigma,T} \Delta\mathbf{E}_k + \left(\frac{\partial e_{ij}}{\partial T}\right)_{\sigma,E} \Delta T$$
$$\Delta e_{ij} = s_{ijkl}\Delta\sigma_{kl} + d_{ijk}\Delta\mathbf{E}_k + \alpha_{ij}\Delta T \tag{48}$$

Often, these effects are interrelated, and frequently dependent on measurement conditions. Some properties of some materials are very sensitive to measurement conditions (the subscripts in the preceding equation denote the variable held constant for each term). For example, if the measurement conditions for the elastic contribution were adiabatic, stress will cause temperature to fall, which, in turn, decreases strain (assuming positive thermal expansion coefficient). Thus the elastic contribution to strain is measured under isothermal (and constant **E** field) conditions so as not to include the temperature effects already included in the thermal expansion term.

The conditions of measurement are given a variety of names that may cause confusion. For example, the mechanical state of "clamped," constant volume, and constant strain all refer to the same measurement condition which is paired with the corresponding condition of "free," "unclamped," constant pressure, or constant stress. In many cases, the condition of measurement is not reported and probably unimportant (i.e., different conditions give essentially the same result). Another common measurement condition is constant **E** field ("electrically free") or constant **D** field ("electrically clamped").

Some materials, particularly ferroelectrics, have large property variation with temperature and pressure, hence measurement conditions may greatly alter the data. The piezoelectric effect contributes significantly to the clamped dielectric constant of ferroelectrics. The difference between the isothermal clamped and free dielectric constants is

$$\varepsilon_0 \cdot (\varepsilon_i^e - \varepsilon_i^\sigma) = -d_{ij} d_{ik} c_{jk}^{\mathbf{E}} \tag{49}$$

where d_{ij} is the piezo-electric coefficient and $c_{jk}^{\mathbf{E}}$ is the (electrically free) elastic stiffness. If the material structure is centrosymmetric, all components of d_{ij} vanish, and the two dielectric constants are the same.

2.5 PROPERTIES TABLES

The following tables summarize the basic properties for representative crystals and glasses. In general, the presented materials are (1) of general interest, (2) well-characterized (within the limitations imposed by general paucity of data and conflicting property values), and (3) represent a wide

range of representative types and properties. Few materials can be regarded as well-characterized. Crystalline materials are represented by alkali halides, oxides, chalcogenides, and a variety of crystals with nonlinear optical, ferroelectric, piezoelectric, and photorefractive properties.

A number of materials in the previous edition have been removed for the sake of brevity. Properties of the following crystals and glasses are found in this chapter:[1]

β-AgI (iodyrite)	InAs	PbS
AlAs	InP	PbSe
AlN	KCl	Se
BN	KF	β-SiC
BP	LaF_3	α-SiC
$CaLa_2S_4$	NaBr	Te
CsBr	NaF (valliaumite)	Tl_3AsSe_3 (TAS)
CsCl	NaI	TlCl
CuCl (nantokite)	PbF_2	ZnO (zincite)
TiK1	TiF1	PK2
BaLK1	KzF6	ZK1
PSK3	BaK1	LgSK2
SK4	SSK4	BaSF10
TaC2	TaD5	ULTRAN 30 (548743)
CORTRAN 9753	ZBL	ZBLA
ZBT	HBL	HBLA
HBT		

The physical property tables define the composition, density, and structure (of crystalline materials). Table 7 gives data for 71 crystalline materials. Table 8 compares glasses from different manufacturers and selects 24 representative "optical" glasses intended for visible and near-infrared use (typically to 2.5 μm). Table 9 gives physical property data for 17 specialty glasses and substrate materials. The specialty glasses include fused silica and germania, calcium aluminate, fluoride, germanium-, and chalcogenide-based glasses, many of which are intended for use at longer wavelengths. The three substrate materials, Pyrex, Zerodur, and ULE, are included because of their widespread use for mirror blanks.

Mechanical properties for crystals are given in two forms, room-temperature elastic constants (or moduli) for crystals (Tables 10 through 16), and engineering moduli, flexure strength, and hardness for both crystals (Table 17) and glasses (Table 18). Engineering moduli for crystalline materials should only be applied to the polycrystalline forms of these materials. Accurate representation of the elastic properties of single crystals requires the use of elastic constants in tensor form. Strength is highly dependent on manufacture method and many have significant sample-to-sample variability. These characteristics account for the lack of strength data. For these reasons, the provided strength data is intended only as a guide. Glasses and glass-ceramics flexure strengths typically range from 30 to 200 MPa, although glass fibers with strength exceeding 1000 MPa have been reported.

Thermal properties are given in Tables 19 and 20 for crystals and glasses, respectively. Characteristic temperatures (Debye, phase change, and melt for crystals; glass transitions, soften, and melt temperatures for glasses), heat capacity, thermal expansion, and thermal conductivity data are included. Directional thermal properties of crystals are given when available. Only room-temperature properties are reported except for thermal conductivity of crystals, which is also given for temperatures above and below ambient, if available.

Optical properties are summarized in Tables 21 and 22 for crystals and glasses, respectively. These tables give the wavelength boundaries of the optical transparent region (based on a 1 cm^{-1} absorption coefficient), characteristic refractive index ($\overline{n}_\infty$, the asymptote of the electronic contribution to the refractive index for crystals), or n_d and v_d for glasses), and values of dn/dT at various wavelengths. Tables 23 and 24 give dispersion formulas for crystals and glasses, respectively.

TABLE 7 Composition, Structure, and Density of Crystals

Material	Crystal System and Space Group	Unit Cell Dimension (Å)	Molecular Weight (amu)	Formulae/ Unit Cell	Density (g/cm^3)

[1]FCD = dense fluor crown; [2]PCS = special phosphate crown; [3]HC = hard crown; [4]FEL = ELF = extra light flint; [5]MBC = medium barium crown; [6]BaFL = light barium flint; [7]ADF = abnormal dispersion flint; [8]BACD = DBC = dense barium crown; [9]DF = dense flint; [10]BaCED = extra dense barium crown; [11]LaCL = light lanthanum crown; [12]FDS = special dense flint; [13]TaF = tantalum flint; [14]TaFD = tantalum dense flint.

TABLE 9 Physical Properties of Specialty Glasses and Substrate Materials

Glass type	Density (g/cm^3)	Typical composition
Fused silica (SiO_2) (e.g., Corning 7940 or Schott Lithosil-Q)	2.202	100%SiO_2
Fused germania (GeO_2)	3.604	100%GeO_2
BS-39B (Barr and Stroud)	3.1	50%CaO, 34%Al_2O_3, 9%MgO
CORTRAN 9754 (Corning)	3.581	33%GeO_2, 20%CaO, 37%Al_2O_3, 5%BaO, 5%ZnO
IRG 2 (Schott)	5.00	Germanium glass
IRG 9 (Schott)	3.63	Fluorophosphate glass
IRG 11 (Schott)	3.12	Calcium aluminate glass
IRG 100 (Schott)	4.67	Chalcogenide glass
HTF-1 (Ohara) [443930]	3.94	Heavy metal fluoride glass
ZBLAN	4.52	56%ZrF_4, 14%BaF_2, 6%LaF_3, 4%AlF_3, 20%NaF
Arsenic trisulfide (As_2S_3)	3.198	100%As_2S_3
Arsenic triselenide (As_2Se_3)	4.69	100%As_2Se_3
AMTRI-1/TI-20	4.41	55%Se, 33%Ge, 12%As
AMTIR-3/TI-1173	4.70	60%Se, 28%Ge, 12%Sb
Pyrex (e.g., Corning 7740)	2.23	81%SiO_2, 13%B_2O_3, 4%Na_2O, 2%Al_2O_3 [two-phase glass]
Zerodur (Schott)	2.53	56%SiO_2, 25%Al_2O_3, 8%P_2O_5, 4%Li_2O, 2%TiO_2 2%ZrO_2, ZnO/MgO/Na_2O/As_2O_3 [glass ceramic]
ULE (Corning 7971)	2.205	92.5%SiO_2, 7.5%TiO_2 [glass ceramic]

*Our dispersion equation from referenced data.
†Schott dispersion formula range; data available to 2.3 m.

Vibrational modes of many optical materials are summarized in Tables 25 through 40 for a number of common optical crystal types. These tables give number and type of zone-center (i.e., the wave vector ≈ 0, where Γ is the usual symbol denoting the center of the Brillouin zone) optical modes predicted by group theory (and observed in practice) as well as the frequency (in wave number) of the infrared-active and Raman modes. Mulliken notation is used. Table 41 summarizes the available lattice vibration dispersion models for many crystals.

Parameters for ultraviolet and infrared absorption models for crystals and glasses are not included in this edition. Please refer to the previous edition[1] for these parameters.

POLYMERIC OPTICS

John D. Lytle
Advanced Optical Concepts
Santa Cruz, California

3.1 GLOSSARY

A_{H_2O}	water absorption
K	thermal conductivity
T_s	maximum service temperature
α	thermal expansion coefficient
ρ	density

3.2 INTRODUCTION

A small number of carbon-based polymeric materials possesses some of those qualities which have made glass an attractive optical material. Most of these polymeric materials do exhibit certain physical deficiencies compared to glass. But, despite the fact that "plastic optics" has acquired an image as a low-end technology, it may nonetheless be a better choice, or even the best choice, in certain applications.

Selection Factors

Virtually all of the polymers having useful optical properties are much less dense than any of the optical glasses, making them worthy of consideration in applications where weight-saving is of paramount importance. Many of them exhibit impact resistance properties which exceed those of any silicate glass, rendering them well-suited to military applications (wherein high "g" loads may be encountered), or ideal for some consumer products in which safety may be a critical consideration.

Though the physical properties of the polymers may make them better matched to certain design requirements than glass, by far the most important advantage of polymeric optics is the considerable creative freedom they make available to the optical and mechanical design effort.[1] While the design constraints and guidelines governing glass optics design and fabrication are fairly well defined, the various replication processes which may be put to use in polymer optics fabrication make available unique

opportunities for the creation of novel optical components and systems which would be unthinkable or unworkable in glass. Oftentimes, the differences in the engineering approach, or in the production processes themselves, may make possible very significant cost reductions in high-volume situations.[2]

3.3 FORMS

Thermoset Resins

Optical polymers fall into basically two categories—the *thermoset* resins and the *thermoplastic* resins. The thermoset resin group consists of chemistries in which the polymerization reaction takes place during the creation of the part, which may be produced by casting, or by transfer replication. The part which has been created at completion of the reaction may then be postprocessed, if desired, by machining. In general, the thermoset resins cannot be melted and re-formed.

The most commonly encountered thermoset optical resin is that used to produce ophthalmic lenses for eyewear.[3] The monomer, which is stored in liquid form at reduced temperature, is introduced into a mold, where the polymerization reaction takes place, forming a part which assumes the shape of the cavity containing it. Alternatively, epoxy-based chemistries have been used with some success to form replicated reflecting surface shapes by a transfer process, and to produce aspheric figuring (at relatively modest expense) upon spherical refractive or reflective substrates.

Thermoplastic Resins

With the possible exception of eyewear, most polymeric optics are executed in thermoplastic materials which are supplied in already polymerized form.[4] These materials are normally purchased in bulk as small pellets. These pellets are heated to a temperature beyond the softening point, so that they flow to become a single viscous mass. This mass is then formed to assume the shape desired in the final part.

Parts may be created by the injection molding process, in which the heated polymer is squirted into a mold at high pressure and allowed to cool in the shape of the desired component. Or the pellets may be directly heated between the two halves of a compression mold, and the mold closed to effect formation of the part. Hybrid molding technologies combining these two processes are recently experiencing increasing popularity in optical molding applications, and have produced optical surface figures of very high quality.

The capability of modern molding technology to produce optics having very good surface-figure quality has made possible the creation of polymeric optical components for a wide variety of applications. Among these are medical disposables, intraocular lenses, a host of consumer products, military optics, and a number of articles in which optical, mechanical, and electrical functions are combined in a single part.[5]

3.4 PHYSICAL PROPERTIES

Density

Optical glass types number in the hundreds (if all manufacturers worldwide are counted). The glass types available from the catalogs cover a wide range of optical, physical, thermal, and chemical properties. The density of these materials varies from about 2.3 g/cm^3 to about 6.3 g/cm^3. The heaviest optically viable polymer possesses a density of only about 1.4 g/cm^3, whereas the lightest of these materials will readily float in water, having a density of 0.83 g/cm^3.[6] All other things being equal, the total element count in an optical system may often be reduced (at modest cost penalty) by the inclusion of nonspherical surfaces. All things considered, then, polymeric optical systems may be made much less massive than their glass counterparts, especially if aspheric technology is applied to the polymer optical trains.

Hardness

Although cosmetic blemishes rarely impact final image quality (except in the cases of field lenses or reticles), optical surfaces are customarily expected to be relatively free of scratches, pits, and

the like. Ordinary usage, especially cleaning procedures, are likely to result in some scratching with the passage of time. Most common optical glasses possess sufficient hardness that they are relatively immune to damage, if some modest amount of care is exercised.

The polymeric optical materials, on the other hand, are often so soft that a determined thumbnail will permanently indent them. The hardness of polymeric optics is difficult to quantify (in comparison to glass), since this parameter is not only material-dependent, but also dependent upon the processing. Suffice it to say that handling procedures which would result in little or no damage to a glass element may produce considerable evidence of abrasion in a polymeric surface, particularly in a thermoplastic. In fact, the compressibility of most thermoplastic polymers is such that the support for hard surface coatings is sufficiently low that protection provides immunity against only superficial abrasion. These deficiencies are of no particular consequence, however, if the questionable surfaces are internal, and thereby inaccessible.

Rigidity

A property closely related to hardness is the elastic modulus, or Young's modulus. This quantity, and the elongation factor at yield, are determinants of the impact resistance, a performance parameter in which the polymers outshine the glasses. These properties are, again, dependent upon the specified polymeric alloy, any additives which may be present, and processing history of the polymer, and cannot be dependably quoted.[7,8] The reader is referred to any of several comprehensive references listed herein for mechanical properties data. Those properties which create good impact resistance become liabilities if an optical part is subjected to some torsion or compressive stress. Since optical surface profiles must often be maintained to subwavelength accuracy, improper choice of the thickness/diameter ratio, or excessive compression by retaining rings, may produce unacceptable optical figure deformations.

Polymer chemistry is a complex subject probably best avoided in a discussion of polymer optics. Carbon-based polymers have been synthesized to include an extensive variety of chemical subgroups, however. Unfortunately, relatively few of these materials are actually in regular production, and only a handful of those possess useful optical properties for imaging purposes.

Service Temperature

Any decision involving a glass/plastic tradeoff should include some consideration of the anticipated thermal environment. While the optical glasses may exhibit upper service temperature limits of from 400 to 700°C, many of the glass types having the most interesting optical properties are quite fragile, and prone to failure if cooled too quickly. These failures are mostly attributable to cooling-induced shrinkage of the skin layer, which shatters because the insulating properties of the material prevent cooling (and shrinkage) of the bulk material at the same rate.

The polymeric materials, on the other hand, have much lower service temperature limits, in some cases no higher than about 60°C.[9] The limit may approach 250°C for some of the fluoropolymers. The thermal conductivity of many of these polymers may be as much as an order of magnitude lower than for the glasses and the thermal expansion coefficients characterizing the polymers are often an order of magnitude larger than those associated with optical glasses. Consequently, subjecting any polymeric optical element to a significant thermal transient is likely to create more severe thermal gradients in the material, and result in significant thermally induced optical figure errors.[10] Again, it is suggested that the interested reader consult the plastic handbooks and manufacturer's literature for a complete listing of this behavior, as additives and variation in molecular weight distribution may significantly affect all of these properties. Some of the most important physical properties of the more readily available optical polymers are tabulated in Table 1.

Conductivity (Thermal, Electrical)

Most materials which exhibit poor thermal conductivity are also poor electrical conductors. Since many unfilled polymers are very effective electrical insulators, they acquire static surface charge

TABLE 1 Physical Properties

Material	ρ	α	T_s	K	A_{H_2O}
P-methylmethacrylate	1.18	6.0	85	4–6	0.3
P-styrene	1.05	6.4–6.7	80	2.4–3.3	0.03
NAS	1.13	5.6	85	4.5	0.15
Styrene acrylonitrile (SAN)	1.07	6.4	75	2.8	0.28
P-carbonate	1.25	6.7	120	4.7	0.2–0.3
P-methyl pentene	0.835	11.7	115	4.0	0.01
P-amide (Nylon)	1.185	8.2	80	5.1–5.8	1.5–3.0
P-arylate	1.21	6.3		7.1	0.26
P-sulfone	1.24	2.5	160	2.8	0.1–0.6
P-styrene co-butadiene	1.01	7.8–12			0.08
P-cyclohexyl methacrylate	1.11				
P-allyl diglycol carbonate	1.32		100	4.9	
Cellulose acetate butyrate	1.20			4.0–8.0	
P-ethersulfone	1.37	5.5	200	3.2–4.4	
P-chloro-trifluoroethelyne	2.2	4.7	200	6.2	0.003
P-vinylidene fluoride	1.78	7.4–13	150		0.05
P-etherimide	1.27	5.6	170		0.25

fairly easily, and dissipate it very slowly. Not surprisingly, these areas of surface charge quickly attract oppositely charged contaminants, most of which are harder than the plastic. Attempts to clear the accumulated particles from the surfaces by cleaning can, and usually do, result in superficial damage. Application of inorganic coatings to these surfaces may do double duty by providing a more conductive surface (less likely to attract contaminants), while improving the abrasion resistance.

Outgassing

In contrast to glass optical parts, which normally have very low vapor pressure when properly cleaned, most polymers contain lubricants, colorants, stabilizers, and so on, which may outgas throughout the life of the part. This behavior disqualifies most plastic optical elements from serving in space-borne instrumentation, since the gaseous products, once lost, surround the spacecraft, depositing upon solar panels and other critical surfaces. Some, but few, thermoset resins may be clean enough for space applications if their reaction stoichiometry is very carefully controlled in the creation of the part.

Water Absorption

Most polymers, particularly the thermoplastics, are hygroscopic. They absorb and retain water, which must, in most cases, be driven off by heating prior to processing. Following processing, the water will be reabsorbed if the surfaces are not treated to inhibit absorption. Whereas only a very small amount of water will normally attach to the surfaces of a glass optical element, the polymer materials used for optics may absorb from about 0.003 to about 2 percent water by weight. Needless to say, the trapped water may produce dimensional changes, as well as some minor alterations of the spectral transmission. Physical properties of some of the more familiar optical polymers are listed in Table 1. Density = ρ (g/cm^3); thermal expansion coefficient = α (cm/cm °C $\times 10^{-5}$); max. service temperature = T_s (°C); thermal conductivity = K (cal/sec cm °C $\times 10^4$); and water absorption (24 h) = A_{H_2O} (%). Values are to be considered approximate, and may vary with supplier and processing variations.

Additives

Polymers are normally available in a variety of "melt flow" grades—each of which possesses viscosity properties best suited to use in parts having specific form factors. A number of additives are commonly present in these materials. Such additives may, or may not, be appropriate in an optical application. Additives for such things as flame retardancy, lubricants, lubrication, and mold release are best avoided if not included to address a specific requirement. Frequently, colorants are added for the purpose of neutralizing the naturally occurring coloration of the material. These additives create an artificial, but "clear," appearance. The colorants must, of course, absorb energy to accomplish this, resulting in a net reduction in total spectral transmission.

Radiation Resistance

Most of the optical polymers will be seen to exhibit some amount of fluorescence if irradiated by sufficiently intense high-energy radiation.[11] High-energy radiation of the ultraviolet and ionizing varieties will, in addition, produce varying amounts of polymer chain crosslinking, depending upon the specific polymer chemistry. Crosslinking typically results in discoloration of the material, and some amount of nonuniform energy absorption. Inhibitors may be added to the polymeric material to retard crosslinking, although, oddly enough, the polymers most susceptible to UV-induced discoloration are generally the least likely to be affected by ionizing radiation, and vice versa.

Documentation

Although polymeric materials suffer some shortcomings in comparison to glass (for optical applications), distinct advantages do exist. The major obstacle to the use of polymers, however, is the spotty and imprecise documentation of many of those properties required for good engineering and design. In general, the resin producers supply these materials in large quantity to markets wherein a knowledge of the optical properties is of little or no importance. With luck, the documentation of optical properties may consist of a statement that the material is "clear." In the rare case where refractive index is documented, the accuracy may be only two decimal places. In these circumstances, the optical designer or molder is left to investigate these properties independently—a complex task, since the processing itself may affect those properties to a substantial degree.

Unfortunately, optical applications may represent only a small fraction of a percent of the total market for a given resin formulation, and since these materials are sold at prices ranging from less than two dollars to a few dollars per pound, the market opportunity represented by optical applications seems minuscule to most polymer vendors.

3.5 OPTICAL PROPERTIES

Variations

It is only a fortuitous accident that some of the polymers exhibit useful optical behavior, since most all of these materials were originally developed for other end uses. The possible exceptions are the materials used for eyeglass applications (poly-diallylglycol), and the materials for optical information storage (specially formulated polycarbonate). Citation of optical properties for any polymeric material must be done with some caution and qualification, as different melt flow grades (having different molecular weight distribution) may exhibit slightly different refractive index properties. Additives to regulate lubricity, color, and so on can also produce subtle alterations in the spectral transmission properties.

Spectral Transmission

In general, the carbon-based optical polymers are visible-wavelength materials, absorbing fairly strongly in the ultraviolet and throughout the infrared.[12–14] This is not readily apparent from the absorption spectra published in numerous references, though. Such data are normally generated by spectroscopists for the purpose of identifying chemical structure, and are representative of very thin samples. One can easily develop the impression from this information that the polymers transmit well over a wide spectral range. Parenthetically, most of these polymers, while they have been characterized in the laboratory, are not commercially available. What is needed for optical design purposes is transmission data (for available polymers) taken from samples having sufficient thickness to be useful for imaging purposes.

Some specially formulated variants of poly-methylmethacrylate have useful transmission down to 300 nm.[15] Most optical polymers, however, begin to absorb in the blue portion of the visible spectrum, and have additional absorption regions at about 900 nm, 1150 nm, 1350 nm, finally becoming totally opaque at about 2100 nm. The chemical structure which results in these absorption regions is common to almost all carbon-based polymers, thus the internal transmittance characteristics of these materials are remarkably similar, with the possible exception of the blue and near-UV regions. A scant few polymers do exhibit some spotty narrowband transmission leakage in the far-infrared portion of the spectrum, but in thicknesses suitable only for use in filter applications.

Refractive Index

The chemistry of carbon-based polymers is markedly different from that of silicate glasses and inorganic crystals in common use as optical materials. Consequently, the refractive properties differ significantly. In general, the refractive indices are lower, extending to about 1.73 on the high end, and down to a lower limit of about 1.3. In practice, those materials which are readily available for purchase exhibit a more limited index range—from about 1.42 to 1.65. The Abbe values for these materials vary considerably, though, from about 100 to something less than 20. Refractive index data for a few of these polymers, compiled from a number of sources, is displayed in Table 2. In the chart, PMMA signifies polymethylmethacrylate; P-styr, polystyrene; P-carb, polycarbonate; SAN, styrene acrylonitrile; PEI, polyetherimide; PCHMA, polycyclohexylmethacrylate. The thermo-optic coefficients at room temperature (change in refractive index with temperature) are also listed. Note that these materials, unlike most glasses, experience a reduction in refractive index with increasing temperature. Figure 1, a simplified rendition of the

familiar glass map (n vs. v), shows the locations of some of the more familiar polymers. Note that these materials all occupy the lower and right-hand regions of the map. In the Schott classification system, the polymers populate mostly the FK, TiK, and TiF regions of the map.[16]

Homogeneity

It must be kept constantly in mind that polymeric optics are molded and not mechanically shaped. The exact optical properties of a piece cannot, therefore, be quantified prior to manufacture of the element. In fact, the precise optical properties of the bulk material in an optical element are virtually certain to be a function of both the material itself, and of the process which produced the part. Some materials, notably styrene and butyrate resins, are crystalline to some degree, and therefore inherently birefringent. Birefringence may develop in amorphous materials, though, if the injection mold and process parameters are not optimized to prevent this occurrence. Likewise, the bulk scatter properties of a molded optical element are a function of the inherent properties of the material, but are also strongly related to the cleanliness of the processing and the heat history of the finished part.

3.6 OPTICAL DESIGN

Design Strategy

Virtually all optical design techniques which have evolved for use with glass materials work well with polymer optics. Ray-tracing formulary, optimization approaches, and fundamental optical construction principles are equally suitable for glass or plastic. The generalized approach to optical design with polymeric materials should be strongly medium-oriented, though. That is, every

effort must be made to capitalize upon the design flexibility which the materials and manufacturing processes afford. Integration of form and function should be relentlessly pursued, since mechanical features may be molded integral with the optics to reduce the metal part count and assembly labor content in many systems.

Aberration Control

The basic optical design task normally entails the simultaneous satisfaction of several first-order constraints, the correction of the monochromatic aberrations, and the control of the chromatic variation of both first-order quantities and higher-order aberrations. It is well known that management of the Petzval sum, while maintaining control of the chromatic defects, may be the most difficult aspect of this effort.[17,18] It is also widely recognized that the choice of optical materials is key to success. While the available polymer choices cover a wide range of Abbe values, ensuring that achromatization may be accomplished in an all-polymer system, the refractive index values for these materials are not well-positioned on the "glass" map to permit low Petzval sums to be easily achieved.

Material Selection

Simultaneous correction of the Petzval sum and the first-order chromatic aberration may, however, be nicely accomplished if the materials employed possess similar ratios of Abbe number to central refractive index. This implies that the *best* material combinations (involving polymers) should probably include an optical glass. Also implied is the fact that these hybrid material combinations may be inherently superior (in this respect) to all-glass combinations. Ideally, the chosen materials should be well-separated (in Abbe value) on the glass map, so that the component powers required for achromatization do not become unduly high. This condition is satisfied most completely with polymers which lie in the TiF sector of the glass map, coupled with glasses of the LaK, LaF, and LaSF families.

Most lens designers would prefer to utilize high-refractive-index materials almost exclusively in their work. Optical power must be generated in order to form images, and because the combination of optical surface curvature and refractive index creates this refractive power, these two variables may be traded in the lens design process. Since it is well known that curvature generates aberration more readily than does a refractive index discontinuity, one generally prefers to achieve a specified amount of refractive power through the use of low curvature and high-refractive index. From this perspective, the polymers are at a distinct disadvantage, most of them being low-index materials.

Aspheric Surfaces

An offsetting consideration in the use of polymeric optical materials is the freedom to employ nonspherical surfaces. While these may be awkward (and very expensive) to produce in glass, the replication processes which create plastic optical parts do not differentiate between spherical and nonspherical surfaces.

As any lens designer can attest, the flexibility that aspheric surfaces make available is quite remarkable.[19,20] Spherical surfaces, while convenient to manufacture by grinding and polishing, may generate substantial amounts of high-order aberration if used in any optical geometry which departs significantly from the aplanatic condition. These high-order aberrations are often somewhat insensitive to substantial changes in the optical prescription. Thus, profound configurational alterations may be necessary to effect a reduction in these image defects.

On the other hand, the ability to utilize surface shapes which are more complex than simple spheres permits these high-order aberration components to be moderated at their point of origin, which may in turn reduce the amount of "transferred aberration" imparted to surfaces downstream in the optical train. In a multielement optical system, especially one employing cascaded aspheric surfaces, the required imagery performance may be achieved using fewer total elements. And due to

the fact that the surface aberration contributions are diminished, the sensitivity to positioning errors may also be reduced, with the result that an aspheric optical system may actually be more forgiving to manufacture than its spherical counterpart.

In practice, the use of aspheric surfaces in polymer optical elements appears to more than compensate for the handicap imposed by low-refractive index values. Using aspheric surfaces, it is possible to bend, if not break, many of the rules which limit design with spherical surfaces. Aspherics create extra leverage to deal with the monochromatic aberrations, and with the chromatic variation of these image defects. A designer experienced with aspherics, given a capable set of software tools, can frequently create optical constructions which deliver high performance, despite the fact that they appear odd to those accustomed to the more "classical" spherical surface configurations. Quite often, unfavorable design constraints such as an inconvenient aperture stop location, may be handled with less difficulty using aspherics.

Athermalization

The thermal behavior of the polymers, mentioned previously, may cast a shadow upon some applications where the temperature is expected to vary over a significant range, but the focal surface location must be fixed in space. In such cases, the variation of refractive index usually accounts for the largest share of the variation, with the dimensional changes playing a secondary role. In such situations, the thermally induced excursions of the focal surface may be compensated by modeling these functions and designing mechanical spacers of the proper material to stabilize the detector/image location.

Alternatively, the optical system may be designed to exhibit inherently athermal behavior over the operational temperature range.[21] Unfortunately, this is not strictly possible using only polymeric materials, as the thermo-optic coefficients display so little variation among themselves that the component powers would be absurdly high.

In combination with one or more glass elements, however, very nicely athermalized design solutions may be obtained with polymer elements.[22] Athermal designs may be generated by modeling the optical system in multiconfiguration mode in the lens design software, much as one would develop a zoom lens. The parameters to be "zoomed" in this case are the refractive indices at two or more temperatures within the operating range. The resulting designs frequently concentrate most of the refractive power in the glass elements, with the polymer elements functioning to achieve achromatism and control of the monochromatic aberrations. See also Chap. 8, "Thermal Compensation Techniques," by Philip J. Rogers and Michael Roberts in Vol. II of this *Handbook*.

Processing Considerations

In much the same manner that optical design with polymer materials is different from optical design with glass, the treatment of the fabrication and assembly issues are also quite different matters. The major issues requiring examination are those related to the materials themselves. While it is possible to characterize the glass for an optical system with complete certainty prior to performing any fabrication operations, with polymers, one's knowledge of the starting materials is only a rough indication of the properties of the finished optical parts.

When optical properties data are offered by the polymer supplier, it should be realized that these numbers apply *only* to measurement samples which have been predried to specification, have experienced a specified residence time in the extrusion barrel under specific temperature conditions, have been injected into the mold cavity at specific rates and pressures, and so on. Consequently, it is unlikely that the refractive properties of a polymer element will conform closely to catalog values (if such values are indeed supplied). Moreover, homogeneity, bubble content, scatter properties, and so on, are all process-dependent. So while the melt sheets may fix the optical properties of glass materials very precisely, the uncertainty associated with the polymers demands that refractive variations be allocated a significant portion of the fabrication and assembly error budget.

Manufacturing Error Budget

Other constructional parameters, conversely, may be implemented with great precision and repeatability in plastic. The molding process, executed by means of modern equipment, can be exceedingly stable. Vertex thickness, curvature, and wedge may often be maintained to a greater level of precision, with greater economy than is possible with glass fabrication technology. It is not unusual to see part-to-part variations in vertex thickness of less than 0.01 to 0.02 mm over a run of thousands of parts from a single cavity.

Multiple Cavities

The economic appeal of injection molding is the ability to create several parts in one molding cycle. In a multicavity scenario, the parts from different cavities may exhibit some small dimensional differences, depending upon the level of sophistication of the tool design and the quality of its construction. Cavity variations in axial thickness, fortunately, may be permanently minimized by implementing small tooling adjustments after the mold has been exercised. Consequently, part thickness variation rarely consumes a significant fraction of the constructional error budget.

Dimensional Variations

Surface radii, like axial thickness, may be replicated with great repeatability *if* the molding process is adjusted to a stable optimum. Radius errors, if they are present, are usually attributable to incorrect predictions of shrinkage, and may be biased out by correcting the radii of the mold inserts. Thus, the consistency of surface radii achievable with glass may often be equaled in plastic. Thus, radius errors, as well as axial thickness errors, frequently constitute a small portion of the polymer optics manufacturing error budget.

Element wedge, like axial thickness, may be minimized by careful attention to precision in the tool design and construction. It is quite possible to achieve edge-to-edge thickness variations of less than 0.01 mm in molded plastic lenses. With polymer lenses, the azimuthal location of the part gate may be used, if necessary, to define rotational orientation of the element in the optical train. Consequently, rotational alignment of plastic optical parts may be easily indexed.

Optical Figure Variations

Control of optical figure quality is obviously key to the successful execution of a good optical design. In glass, achievement of subfringe of figure conformance is accomplished routinely, albeit at some cost penalty. In polymeric optics, the nonlinear shrinkage, surface tension, and other processing-related effects cause surface figure errors to scale with part size, sometimes at a rate proportional to some exponent of diameter. This limits the practical size range for polymeric optics, although capable optics molders may routinely produce elements in the 10-mm-diameter range to subfringe accuracy.[23]

On one hand, it can probably be stated that processing-induced variations in properties, and a dearth of dependable optical data, preclude any serious discussions of such things as apochromatic polymeric optics, or of large polymeric optics operating at the diffraction limit. On the other hand, the consistency with which some dimensional parameters may be reproduced in quantity, and the design freedom and flexibility afforded by molded aspherics, make possible the satisfaction of some design requirements which would be out of range for conventional glass optics.[24,25]

Specification

Given the fact that the guidelines and restrictions for design and implementation are very different for glass and polymeric optics, it is not surprising that the approach to specification of polymer optical parts and systems should be tailored to the materials and processes of polymer optics. Attempts

to convert a glass optics concept to plastic are frequently unsuccessful if the translation overlooks the fundamental themes of the molding and tooling technologies involved. Much as optimum tube and solid-state electrical circuit topologies should be significantly different, so must the execution of a conceptual optical system, depending upon whether glass or polymer material is the medium.

It follows naturally that manufacturing drawings for polymer optics may contain annotations which seem unfamiliar to those versed in glass optics manufacture. Furthermore, some specifications which are universally present on all glass optics drawings may be conspicuously absent from a polymer optics print.

For example, thermal and cosmetic damage considerations preclude the use of the familiar test glasses in the certification of polymeric optics. Figure conformance, then, need only be specified in "irregularity" or asphericity terms, since the alternative method, use of a noncontacting interferometer, implies that the focus error (*fringe power* in test plate language) will be automatically removed in the adjustment of the test setup.

References to ground surfaces may be omitted from polymer optics drawings, since no such operation takes place. Discussions of "chips" inside the clear aperture, staining, and the like are also superfluous. Beauty defect specifications do apply, although such imperfections are almost always present in every sample from a specific cavity, probably implying the need to rework a master surface.

In general, the lexicon of optics, and that of the molding industry, do not overlap to a great extent. Molding terms like *flash* and *splay* are meaningless to most optical engineers. Those endeavoring to create a sophisticated polymeric optical system, anticipating a successful outcome, are advised to devote some time to the study of molding, and to discussions with the few experts in the arcane field of optics molding, before releasing a drawing package which may be unintelligible to or misunderstood by the vendor.

3.7 PROCESSING

Casting

As mentioned above, polymeric optics may be produced by any of several processes. These include fabrication, transfer replication, casting, compression molding, injection molding, and some combinations of the aforementioned.[26] The earliest polymeric optical parts were probably produced by fabrication or precipitation from solution. Large military tank prisms have been made by both processes. In the latter case, the polymer (typically PMMA) was dissolved, and the solvent then evaporated to produce a residue of polymer material in the shape of the mold—a very inefficient technique indeed.

Many of the polymers may be fabricated by cutting, grinding, and polishing, much as one would deal with glass materials. The thermoset resin tradenamed CR-39 (poly-diallylglycol) was formulated specifically to be processed using the same techniques and materials as those used to fabricate glass optics. And this material does indeed produce good results when processed in this manner. It is used extensively in the ophthalmic industry to produce spectacle lenses. The processing, in fact, usually involves casting the thermoset resin to create a lens blank which emerges from the mold with the optical surfaces polished to final form. More conventional fabrication techniques may then be utilized to edge the lens, or perhaps to add a bifocal portion.

Abrasive Forming

Unfortunately, the softness of most of the polymers, coupled with their poor thermal conductivity, complicates the achievement of a truly high quality polish using conventional methods. Even in the case of CR-39, which is relatively hard for a polymer material, some amount of "orange peel" in the polished surface seems unavoidable. Many thermoplastics, most of them softer than CR-39, may be conventionally ground and polished to give the appearance of an acceptable optical surface. Closer

examination, however, reveals surface microstructure which probably does not fall within the standards normally associated with precision optics. Nonetheless, fabrication of optical elements from large slabs of plastic is often the only viable approach to the creation of large, lightweight refractive lenses, especially if cost is an issue.

In general, the harder, more brittle polymers produce better optical surfaces when ground and polished. PMMA and others seem to fare better than, say, polycarbonate, which is quite soft, exhibits considerable elongation at the mechanical yield point, but is in great demand due to its impact resistance.

Single-Point Turning

An alternative approach to fabrication, one that is especially useful for the production of aspheric surfaces, is the computer numerical control (CNC) lathe turning of the bulk material using a carefully shaped and polished tool bit of single-crystal diamond or cubic boron nitride. See also Chap. 10, "Fabrication of Optics by Diamond Turning," by Richard L. Rhorer and Chris J. Evans in Vol. II of this *Handbook*. The lathe required to produce a good result is an exceedingly high precision tool, having vibration isolation, temperature control, hydrostatic or air bearings, and so on. On the best substrate materials (PMMA is again a good candidate), very good microroughness qualities may be achieved. With other materials, a somewhat gummy character (once more, polycarbonate comes to mind) may result in microscopic tearing of the surface, and the expected scatter of the incident radiation.

The diamond-turning process is often applied in conjunction with other techniques in order to speed progress and reduce cost. Parts which would be too large or too thick for economical stand-alone injection molding are frequently produced more efficiently by diamond-turning injection molded, stress-relieved preforms, which require minimal material removal and lathe time for finishing. Postpolishing, asymmetric edging, and other postoperations may be performed as necessary to create the finished part. Optics for illumination and TV projection applications are often produced by some combination of these techniques. Given the fact that the technology in most widespread use for the production of plastic optics involves some form of molding (a front-loaded process, where cost is concerned), diamond-turning is often the preferred production method for short production runs and prototype quantities.

Compression Molding

Most high-volume polymeric optics programs employ a manufacturing technology involving some form of molding to produce the optical surfaces, if not the entire finished part.[27] Of the two most widely used approaches, compression molding is best suited to the creation of large parts having a thin cross section. In general, any optical surface possessing relief structure having high spatial frequency is not amenable to injection molding, due to the difficulty of forcing the material through the cavity, and due to the fact that the relief structure in the mold disrupts the flow of the polymer. In addition, the relief structure in the master surfaces may be quite delicate, and prone to damage at the high pressures often present in the mold cavity.

The compression molding process is capable of producing results at considerably lower surface pressure than injection molding, and as long as the amount of material to be formed is small, this molding technology can replicate fine structure and sharp edge contours with amazing fidelity. Since the platens of a compression molding press are normally heated using steam or electrical heaters, most compression molded parts are designed to be executed in polymers having a relatively low temperature softening point, and materials like polyethersulfone are rarely utilized.

Injection Molding

Optical parts having somewhat smaller dimensions may be better suited to production by the injection molding process.[28] This is probably the preferred polymer manufacturing technology for optical elements having a diameter smaller than 0.1 m and a thickness not greater than 3 cm. Not only do the economics favor this approach in high production volume, but if properly applied, superior optical surfaces may be produced.[29]

It should be kept firmly in mind that the basic injection molded process (as it is known to most practitioners) requires a great deal of refinement and enhancement in order to produce credible optical parts.[30] Unfortunately, very few molders possess either the molding know-how, or the testing and measurement sophistication to do the job correctly. Given a supply of quality polymer material, the molding machine itself must be properly configured and qualified. Relatively new machinery is a must. The platens to which the mold halves are mounted must be very rigid and properly aligned. And this alignment must be maintainable on a shot-to-shot basis for long periods. The screw and barrel must be kept scrupulously clean, and must be carefully cleaned and purged when switching materials. The shot capacity, in ideal circumstances, should be more carefully matched to the part volume than for non-optical parts. The process control computer must be an inordinately flexible and accurate device, able to profile and servo a number of operational functions that might be of little importance if the molded part were not optical in nature.[31]

Since much of the heating of the injected polymer resin occurs as a result of physical shear and compression (due to a variable pitch screw), the selection of these machine characteristics is critical to success. In addition, the energy supplied to the machine barrel by external electric heaters must be controlled with more care than in standard industrial applications. A failure of a single heater, or a failure of one of the thermal measurement devices which close that servo loop, may result in many defective parts.

Vendor Selection

The injection mold itself requires special attention in both design and execution in order to produce state-of-the-art molded lenses. A number of closely held "trade tricks" normally characterize a mold designed to produce optical parts, and these subtle variations must be implemented with considerably greater accuracy than is normally necessary in ordinary molding. The mold and molding machine are often designed to operate more symbiotically than would be the case in producing non-optical parts. Control of the mold temperature and temperature gradients is extremely critical, as is the control bandwidth of those temperatures and the temperature of the molding room itself. The most important conclusion to be drawn from the preceding paragraphs is that *the molding vendor for polymer optical parts must be selected with great care.* A molding shop, no matter how sophisticated and experienced with medical parts, precision parts for electronics, and so on, will probably consume much time and many dollars before conceding defeat with optical parts.

Although success in molding optical elements is a strong function of equipment, process control, and engineering acumen, *attention to detail in the optical and mechanical design phases will consistently reduce the overall difficulty of manufacturing these items.* An awareness of the basic principles of injection molding procedures and materials is very helpful here, but it is necessary to be aware that, in the optical domain, we are dealing with micrometer-scale deformations in the optical surfaces. Thus, errors or oversights in design and/or molding technique which would totally escape notice in conventional parts can easily create scrap optics.

Geometry Considerations

The lens design effort, for best results, must be guided by an awareness of the basic physics of creating an injection molded part, and of the impact of part cross section, edge configuration, asymmetry, and so on. In general, any lens having refractive power will possess a varying thickness across its diameter. Unfortunately, meniscus-shaped elements may mold best due to the more uniform nature of the heat transfer from the bulk.[32] Positive-powered lens elements will naturally shrink toward their center of mass as they cool, and it may be difficult to fill the mold cavity efficiently if the edge cross section is only a small fraction of the center thickness.

Negative lenses, on the other hand, tend to fill in the outer zones more readily, since the thinner portion of the section (the center) tends to obstruct flow directly across the piece from the part gate. In extreme circumstances, it is possible that the outer zones of the lens element will be first to

fill, trapping gases in the center, forming an obvious *sink* in molding terminology. Parts designed with molded-in bores may exhibit the '*weld-line*' phenomenon, which is a visible line in the part where the flow front of the molten plastic is divided by the mold cavity obstruction forming the bore. In the case of both negative and positive lens elements, it is good policy to avoid element forms wherein the center-to-edge thickness ratio exceeds three for positive elements, or is smaller than 0.3 for negative elements.

Shrinkage

Surface-tension effects may play a significant role in the accuracy to which a precision optical surface may be molded.[33,34] Particularly in areas of the part where the ratio of surface area/volume is locally high (corners, edges), surface tension may create nonuniform shrinkage which propagates inward into the clear aperture, resulting in an edge rollback condition similar to that which is familiar to glass opticians. Surface tension and volumetric shrinkage may, however, actually aid in the production of accurate surfaces. Strongly curved surfaces are frequently easier to mold to interferometric tolerances than those having little or no curvature. These phenomena provide motivation to oversize optical elements, if possible, to a dimension considerably beyond the clear apertures. A buffer region, or an integrally molded flange provides the additional benefit of harmlessly absorbing optical inhomogeneities which typically form near the injection gate. Figure 2 depicts several optical element forms exhibiting favorable $(a-e)$ and unfavorable $(f-j)$ molding geometries. In some cases, a process combining injection and compression molding may be used to improve optical figure quality. Several variants of this hybrid process are in use worldwide, with some injection molding presses being specifically fitted at the factory to implement this procedure.[35]

Mechanical Assembly

In order to appreciate fully the design flexibility and cost-saving potential of polymer optics, it is necessary to modify one's approach to both optical and mechanical design. A fully optimized polymeric optical system not only makes use of aspheric technology and integrally molded features in the optical elements, but embodies an extension of this design philosophy into the lens housing concept and assembly strategy. These issues should ideally be considered in concert from the very

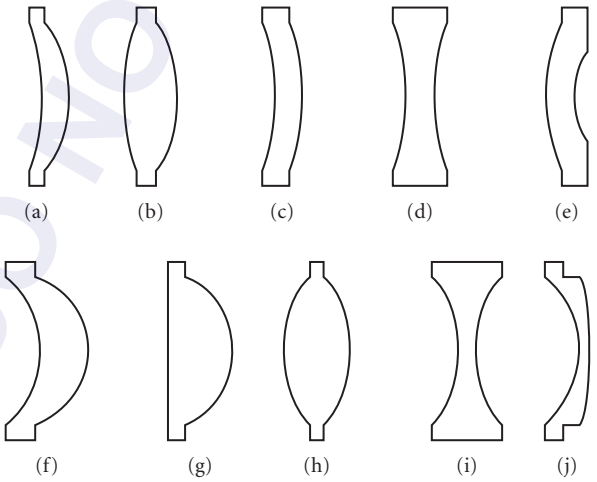

FIGURE 2 Some polymer lens element cross-sectional configurations.

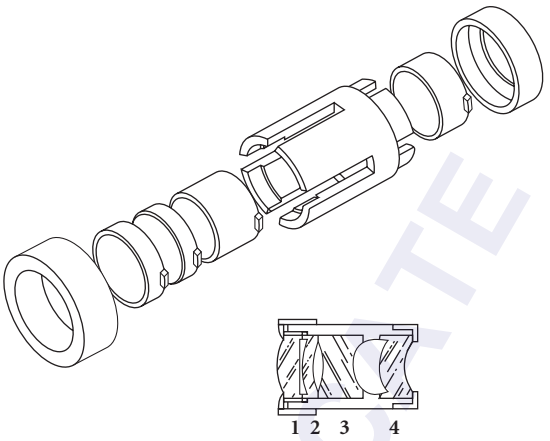

FIGURE 3 Collet-type lens housing. Joining by ultrasound eliminates the possibility of pinching lens elements.

beginning, so that design progress in one aspect does not preclude parallel innovation in other facets of the development process.

It is important to resist the urge to emulate glass-based optomechanical design approaches, since the polymer technology permits design features to be implemented which would be prohibitively expensive (or even impossible) in metal and glass. Spacers required to separate elements may be molded as part of the elements (Fig. 2), reducing the metal part total and simplifying assembly operations. See also Chap. 6, "Mounting Optical Components," by Paul R. Yoder, Jr. in Vol II of this *Handbook*. Housings may be configurations which would be either improbable or unmanufacturable using machine tool technology. The collet-and-cap design shown in Fig. 3 is one such example. Joining might be accomplished by ultrasonic bonding. The clamshell concept shown in Fig. 4 may be designed so that the two halves of the housing are actually the same part, aligned by molded-in locating pins. Joining might be performed by a simple slip-on C ring.

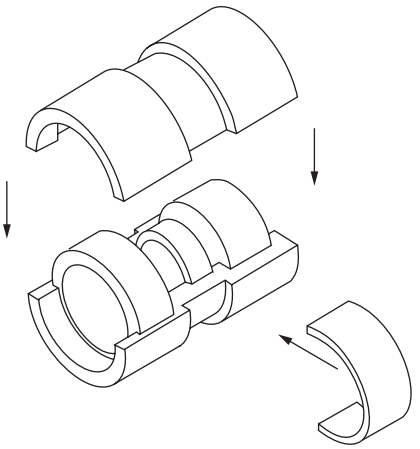

FIGURE 4 Clamshell lens housing. Possibility of lens jamming during assembly is minimized.

Whereas lens assemblies in glass and metal are normally completed by seating threaded retaining rings, their plastic counterparts may be joined by snap-together pieces, ultrasonic bonding, ultraviolet-curing epoxies, expansion C rings, or even solvent bonding.[36] Solvent bonding is dangerous, however, since the errant vapors may actually attack the polymer optical surfaces.

Following the basic polymeric optics philosophy, the lens element containment and assembly approach should probably not even consider the disassembly option in the event of a problem. In order to maximize assembly precision and minimize unit cost, the design of the lens cell should evolve alongside that of the optical system, and this cell should be visualized as an extension of a fixture conceived to minimize the labor content of the assembly.

An in-depth treatment of optical mold design and tooling technology is obviously beyond the scope of this discussion. Many of the methods and procedures parallel those in use in the molding industry at large. However, a number of subtle and very important detail differences do exist, and these are not extensively documented in the literature. Issues having to do with metallurgy, heat treatment, chemical passivation, metal polishing, and so on, have little to do with the actual design and engineering of a polymeric optical system. In a modern tool design exercise, though, the flow behavior of the polymer material in the mold, and the thermal behavior of that mold, are carefully modeled in multinode fashion, so that part quality may be maximized, and cycle time minimized.[37] A nodding awareness of these methods, and the underlying physics, may be helpful to the person responsible for the engineering of the polymer optical system.

Testing and Qualification

In the process of implementing any optical system design, the matters of testing and certification become key issues. In molded optics, the master surfaces, whose shapes are ultimately transferred to the polymer optical parts, must be measured and documented. A convenient testing procedure for the optical elements replicated from these surfaces must likewise be contrived, in order to optimize the molding process and ensure that the finished assembly will perform to specification. The performance of that assembly must itself be verified, and any disparities from specification diagnosed.

In general, mechanical dimensions of the polymer parts may be verified by common inspection tools and techniques used in the glass optics realm. The possibility of inflicting surface damage, however, dictates that noncontact interferometric techniques be used in lieu of test glasses for optical figure diagnosis. This is a straightforward matter in the case of spherical surfaces, but requires some extra effort in the case of aspherics. See also Chap. 13, "Optical Testing," by Daniel Malacara-Hernández in Vol. II of this *Handbook*.

Obviously, aspheric master surfaces must be scrupulously checked and documented, lest the molder struggle in vain to replicate a contour which is inherently incorrect. The verification of the aspheric masters and their molded counterparts may be accomplished in a variety of ways. Mechanical gauging, if properly implemented, works well, but provides reliable information through only one azimuthal section of the part. Measurement at a sufficient number of points to detect astigmatism is awkward, very time consuming, and expensive. And this is not exactly consistent with the spirit of polymer optics.

Null Optics

An optical *null corrector* permits the aspheric surface to be viewed in its entirety by the interferometer as if it were a simple spherical surface.[38,39] This is a rapid and convenient procedure. The null optics consist of very accurately manufactured (and precisely aligned) spherical glass elements designed to introduce aberration in an amount equal to, but of opposite sign from, that of the tested aspheric. Thus, interspersing this device permits aspherics to be viewed as if they were spherical. Since there exists no simple independent test of the null compensator, one must depend heavily upon the computed predictions of correction and upon the skill of the fabricator of the corrective optics. See also Chap. 14, "Use of Computer-Generated Holograms in Optical Testing," by Katherine Creath and James C. Wyant in Vol. II of this *Handbook*.

The concept of greatest importance regarding the use of aspheric surfaces is that *successful production of the total system is cast into considerable doubt if a surface is present which is not amenable to convenient testing*. While some aspheric optics may be nulled fairly easily, those which appear in polymer optical systems are frequently strong, exhibiting significant high-order derivatives. If the base curves are strong, especially strongly convex, there may exist no practical geometry in which to create a nulling optical system. And if a favorable geometry does exist, several optical elements may be necessary to effect adequate correction. One can easily approach a practical limit in this situation, since the manufacturing and assembly tolerances of the cascaded spherical elements may themselves (in superposition) exceed the theoretical correction requirement. The bottom line is that one should not proceed with cell design, or any other hardware design and construction, until the aspheric testing issues have been completely resolved.

3.8 COATINGS

Reflective Coatings

Given the fact that optical polymers exhibit specular properties similar to those of glass, it is not surprising that optical coatings are often necessary in polymeric optical systems. The coatings deposited upon polymer substrates fall mostly into four general categories. These include coatings to improve reflectivity, to suppress specular reflection, to improve abrasion resistance, and to retard accumulation of electrostatic charge.

Reflective coatings may be applied by solution plating, or by vacuum-deposition. These are most often metallic coatings, usually aluminum if vacuum-deposited, and normally chromium if applied by plating. The abrasion resistance and general durability of such coatings is rather poor, and susceptibility to oxidation quite high, if no protective coating is applied over the metal film. In some applications, especially involving vacuum deposition, the overcoat may be a thin dielectric layer, deposited during the same process which applies the metal film. If the reflective coating has been applied by plating, the overcoat may be an organic material, perhaps lacquer, and may be deposited separately by spraying or dipping. Not surprisingly, the quality of a surface so treated will be poor by optical standards, and probably suitable only for toy or similar applications.

Antireflection Coatings

Antirefiection coatings are frequently utilized on polymer substrates, and may consist of a single layer or a rudimentary multilayer stack yielding better reflection-suppression performance. Due to the stringent requirements for control of the layer thicknesses, such coating formulations may be successfully deposited only in high-vacuum conditions, and only if temperatures in the chamber remain well below the service temperature of the substrate material. Elevated temperatures, necessary for baking the coatings to achieve good adhesion and abrasion resistance, may drive off plasticizing agents, limiting the "hardness" of the chamber vacuum. Such temperatures can ultimately soften the optical elements, so that their optical figure qualities are compromised. Relatively recent developments in the area of ion beam-assisted deposition have made possible improvements in the durability of coatings on polymer materials without having to resort to significantly elevated chamber temperatures.[40] See also Chap. 7, "Optical Properties of Films and Coatings," by Jerzy A. Dobrowolski in this volume of *Handbook*.

Antiabrasion Coatings

In general, many polymeric optical systems which could benefit from application of coatings are left uncoated. This happens because the expense incurred in cleaning, loading, coating, unloading, and inspecting the optical elements may often exceed that of molding the part itself. Some optics, particularly those intended for ophthalmic applications, are constantly exposed to abuse by abrasion,

and must be protected, cost notwithstanding. Antiabrasion coatings intended to provide immunity to scratching may be of inorganic materials (normally vacuum-deposited), or may be organic formulations.[41]

Inorganic antiabrasion coatings may be similar to those used for simple antireflection requirements, except that they may be deposited in thicknesses which amount to several quarter-wavelengths. The practical thickness is usually limited by internal stress buildup, and by differential thermal expansion between coating and substrate. In general, the inorganic coatings derive their effectiveness by virtue of their hardness, and provide protection only superficially, since sufficient pressure will collapse the underlying substrate, allowing the coating to fracture.

Organic coatings for abrasion resistance normally derive their effectiveness from reduction of the surface frictional coefficient, thereby minimizing the opportunity for a hard contaminant to gain the purchase required to initiate a scratch. These coatings are often applied by dipping, spraying, or spinning. Coatings thus deposited usually destroy the smoothness which is required if the piece is to be qualified as a precision optical element.

Antistatic Coatings

Coatings applied for the purpose of immunization against abrasion, or suppression of specular reflection, often provide a secondary benefit. They may improve the electrical conductivity of the host surface, thus promoting the dissipation of surface static charge, and the accumulation of oppositely charged contaminants. In circumstances where antireflection or antiabrasion coating costs cannot be justified, chemical treatments may be applied which increase conductivity. These materials typically leave a residue sufficiently thin that they are undetectable, even in interferometric testing.

4.1 GLOSSARY

a	absorptance, absorptivity
a	plate radius (m)
B	support condition
C_{ij}	elastic stiffness constants (N/m^2)
C_p	specific heat (J/kg K)
CTE	coefficient of thermal expansion (K^{-1})
D	flexural rigidity ($N\ m^2$)
D	thermal diffusivity (m^2/s)
E	elastic modulus (Young's) (N/m^2)
$\mathbf{E}$	electromagnetic wave vector (J)
e	electron charge (C)
E_o	amplitude of electromagnetic wave at $x = 0$ (J)
G	load factor (N/kg)
G	shear modulus, modulus of rigidity (N/m^2)
g	acceleration due to gravity (m/s^2)
I	light intensity in medium (W/m^2)
i	$(-1)^{1/2}$
I_0	light intensity at interface (W/m^2)
I_0	section moment of inertia (m^4/m)
K	bulk modulus (N/m^2)
k	extinction coefficient
k	thermal conductivity (W/mK)
L	length (m)
M	materials parameter (kg/Nm)
m	electron mass (kg)
$\mathbf{N}$	complex index of refraction

N number of dipoles per unit volume (m^{-3})
n index of refraction
P plate size (m^4)
q load (N/m^2)
r Reflectance, reflectivity
R_I intensity reflection coefficient
S structural efficiency (m^{-2})
T temperature (K)
t time (s)
t transmittance, transmissivity
V_0 volume per unit area of surface (m)
x distance (m)
α coefficient of thermal expansion (K^{-1})
α absorption coefficient (m^{-1})
β deflection coefficient
β dynamic deflection coefficient
Γ damping constant
δ skin depth (nm)
δ deflection (m)
δ_{DYN} dynamic deflection (m)
ϵ emittance, emissivity (W/m^2)
ε complex dielectric constant
ε_0 permittivity of free space (F/m)
ε_1 real part of dielectric constant
ε_2 imaginary part of dielectric constant
$\ddot{\theta}$ angular acceleration (s^2)
λ wavelength (m)
λ_0 wavelength in vacuum (m)
μ magnetic susceptibility (H/m)
ν frequency (s^{-1})
ν Poisson' ratio
ρ mass density (kg/m^3)
σ conductivity (S/m)
ω radian frequency (s^{-1})

4.2 INTRODUCTION

Metals are commonly used in optical systems in three forms: (1) structures, (2) mirrors, and (3) optical thin films. In this article, properties are given for metal mirror substrate and structural materials used in modern optical systems. Many other materials have not been included due to their limited applicability. Metal film properties are discussed in the context of thick films (claddings) rather than optical thin films that are covered in Chap. 7, "Optical Properties of Films and Coatings." Since mirrors are structural elements, the structural properties are equally important as the optical properties to the designer of an optical system. Therefore, the properties addressed here include physical, mechanical, and thermal properties in addition to optical properties. Mechanical and thermal properties of silicon (Si) and silicon carbide (SiC) are included, but not their optical properties since they are given in Chap. 5, "Optical Properties of Semiconductors."

After brief discussions of optical properties, mirror design, and dimensional stability, curves and tables of properties are presented, as a function of temperature and wavelength, where available. For more complete discussions or listings, the reader should consult the references and/or one of the available databases.[1–3] A concise theoretical overview of the physical properties of materials is given by Lines.[4]

Nomenclature

The symbols and units used in this subsection are consistent with usage in other sections of this *Handbook* although there are some unavoidable duplications in the usage of symbols between categories of optical, physical, thermal, and mechanical properties. Definitions of symbols with the appropriate units are contained in the table at the beginning of this chapter.

Optical Properties

The definitions for optical properties given in this section are primarily in the geometric optics realm and do not go into the depth considered in many texts dealing with optical properties of solids.[5–8]

There is obviously a thickness continuum between thin films and bulk, but for this presentation, bulk is considered to be any thickness of material that has bulk properties. Typically, thin films have lower density, thermal conductivity, and refractive index than bulk; however, current deposition techniques are narrowing the differences. Optical properties of thin films are presented only when bulk properties have not been found in the literature.

The interaction between light and metals takes place between the optical electric field and the conduction band electrons of the metal.[9] Some of the light energy can be transferred to the lattice by collisions in the form of heat. The optical properties of metals are normally characterized by the two optical constants: index of refraction n and extinction coefficient k that make up the complex refractive index $\mathbf{N}$ where:

$$\mathbf{N} = n + ik \tag{1}$$

The refractive index is defined as the ratio of phase velocity of light in vacuum to the phase velocity of light in the medium. The extinction coefficient is related to the exponential decay of the wave as it passes through the medium. Note, however, that these "constants" vary with wavelength and temperature. The expression for an electromagnetic wave in an absorbing medium contains both of these parameters:

$$\mathbf{E} = E_o e^{-2\pi kx/\lambda_0} e^{-i(2\pi nx/\lambda_0 - \omega t)} \tag{2}$$

where E_o is the amplitude of the wave measured at the point $x = 0$ in the medium, E is the instantaneous value of the electric vector measured at a distance x from the first point and at some time t, ω is the angular frequency of the source, and λ_0 is the wavelength in vacuum.

The absorption coefficient α is related to the extinction coefficient by:

$$\alpha = 4k/\lambda_0 \tag{3}$$

and for the general case, the absorption coefficient also appears in the absorption equation:

$$I = I_0 e^{-\alpha x} \tag{4}$$

However, this equation implies that the intensities I and I_0 are measured within the absorbing medium. The complex dielectric constant $\boldsymbol{\varepsilon}$ for such a material is:

$$\boldsymbol{\varepsilon} = \varepsilon_1 + i\varepsilon_2 \tag{5}$$

where the dielectric constants are related to the optical constants by:

$$\varepsilon_1 = n^2 - k^2 \tag{6}$$

$$\varepsilon_2 = 2nk \tag{7}$$

Two additional materials properties that influence the light-material interaction are magnetic susceptibility μ and conductivity σ that are further discussed later.

The equations describing the reflection phenomena, including polarization effects for metals, will not be presented here but are explained in detail elsewhere.[5–8,10,11] After a brief description of Lorentz and Drude theories and their implications for metals, and particularly for absorption, the relationship among reflection, transmission, and absorption is discussed.[9]

The classical theory of absorption in dielectrics is due to H. A. Lorentz[12] and in metals to P. K. L. Drude.[13] Both models treat the optically active electrons in a material as classical oscillators. In the Lorentz model, the electron is considered to be bound to the nucleus by a harmonic restoring force. In this manner, Lorentz's picture is that of the nonconductive dielectric. Drude considered the electrons to be free, and set the restoring force in the Lorentz model equal to zero. Both models include a damping term in the electron's equation of motion that in more modern terms is recognized as a result of electron-phonon collisions.

These models solve for the electron's motion in the presence of the electromagnetic field as a driving force. From this, it is possible to write an expression for the polarization induced in the medium and from that to derive the dielectric constant. The Lorentz model for dielectrics gives the relative real and imaginary parts of the dielectric constant ε_{1R} and ε_{2R} in terms of N, the number of dipoles per unit volume; e and m, the electron charge and mass; Γ, the damping constant; ω and ω_0, the radian frequencies of the field and the harmonically bound electron; and ε_0, the permittivity of free space. These functions are shown in Fig. 1. The range of frequencies where ε_1 increases with frequency is referred to as the *range of normal dispersion*, and the region near $\omega = \omega_0$, where it decreases with frequency is called the *range of anomalous dispersion*.

Since the ionic polarizability is much smaller than the electronic polarizability at optical frequencies, only the electronic terms are considered when evaluating optical absorption using the Lorentz model for dielectrics. The Drude model for metals assumes that the electrons are free to move. This means that it is identical to the Lorentz model except that ω_0 is set equal to zero. The real and imaginary parts of the dielectric constant are then given by

$$\varepsilon_{1R} = 1 - (Ne^2\varepsilon_0 m)\frac{1}{\omega^2 + \Gamma^2} \tag{8}$$

$$\varepsilon_{2R} = (Ne^2\varepsilon_0 m)\frac{\Gamma}{\omega(\omega^2 + \Gamma^2)} \tag{9}$$

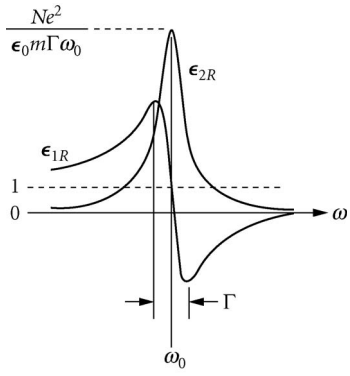

FIGURE 1 Frequency dependences of ε_{1R} and ε_{2R}.[9]

The quantity Γ is related to the mean time between electron collisions with lattice vibrations, and by considering electronic motion in an electric field **E** having radian frequency ω, an expression for the average velocity can be obtained. An expression for the conductivity σ is then obtained and the parts of the dielectric constant can be restated. At electromagnetic field frequencies that are low, it can be shown that $\varepsilon_2 >> \varepsilon_1$ and therefore it follows that:

$$\alpha = (\omega\mu\sigma/2)^{1/2} \tag{10}$$

In other words, the optical properties and the conductivity of a perfect metal are related through the fact that each is determined by the motion of free electrons. At high frequencies, transitions involving bound or valence band electrons are possible and there will be a noticeable deviation from this simple result of the Drude model. However, the experimental data reported for most metals are in good agreement with the Drude prediction at wavelengths as short as 1 μm.

From Eq. (10) it is clear that a field propagating in a metal will be attenuated by a factor of 1/*e* when it has traveled a distance:

$$\delta = (2/\omega\mu\sigma)^{1/2} \tag{11}$$

This quantity is called the *skin depth*, and at optical frequencies for most metals it is ~50 nm. After a light beam has propagated one skin depth into a metal, its intensity is reduced to 0.135 of its value at the surface.

Another aspect of the absorption of light energy by metals that should be noted is the fact that it increases with temperature. This is important because during laser irradiation the temperature of a metal will increase and so will the absorption. The coupling of energy into the metal is therefore dependent on the temperature dependence of the absorption. For most metals, all the light that gets into the metal is absorbed. If the Fresnel expression for the electric field reflectance is applied to the real and imaginary parts of the complex index for a metal-air interface, the field reflectivity can be obtained. When multiplied by its complex conjugate, the expression for the intensity reflection coefficient is obtained:

$$R_I = 1 - 2\mu\varepsilon_0\omega/\sigma \tag{12}$$

Since the conductivity σ decreases with increasing temperature, R_I decreases with increasing temperature, and at higher temperatures more of the incident energy is absorbed.

Since reflection methods are used in determining the optical constants, they are strongly dependent on the characteristics of the metallic surface. These characteristics vary considerably with chemical and mechanical treatment, and these treatments have not always been accurately defined. Not all measurements have been made on freshly polished surfaces but in many cases on freshly deposited thin films. The best available data are presented in the tables and figures, and the reader is advised to consult the appropriate references for specifics.

In this article, an ending of *-ance* denotes a property of a specific sample (i.e., including effects of surface finish), while the ending *-ivity* refers to an intrinsic material property. For most of the discussion, the endings are interchangeable.

Reflectance *r* is the ratio of radiant flux reflected from a surface to the total incident radiant flux. Since *r* is a function of the optical constants, it varies with wavelength and temperature. The relationship between reflectance and optical constants is:[5]

$$r = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} \tag{13}$$

The reflectance of a good, freshly deposited mirror coating is almost always higher than that of a polished or electroplated surface of the same material. The reflectance is normally less than unity—some transmission and absorption, no matter how small, are always present. The relationship between these three properties is:

$$r + t + a = 1 \tag{14}$$

Transmittance t is the ratio of radiant flux transmitted through a surface to the total incident radiant flux and absorptance a is the ratio of the radiant flux lost by absorption to the total incident radiant flux. Since t and a are functions of the optical constants, they vary with wavelength and temperature. Transmittance is normally very small for metals except in special cases (e.g., beryllium at x-ray wavelengths). Absorptance is affected by surface condition as well as the intrinsic contribution of the material.

The thermal radiative properties are descriptive of a radiant energy-matter interaction that can be described by other properties such as the optical constants and/or complex dielectric constant, each of which is especially convenient for studying various aspects of the interaction. However, the thermal radiative properties are particularly useful since metallic materials are strongly influenced by surface effects, particularly oxide films, and therefore in many cases they are not readily calculated by simple means from the other properties.

For opaque materials, the transmission is near zero, so Eq. (14) becomes:

$$r + a = 1 \tag{15}$$

but since Kirchhoff's law states that absorptance equals emittance, ϵ, this becomes:

$$r + \epsilon = 1 \tag{16}$$

and the thermal radiative properties of an opaque body are fully described by either the reflectance or the emittance. Emittance is the ratio of radiated emitted power (in W/m^2) of a surface to the emissive power of a blackbody at the same temperature. Emittance can therefore be expressed as either *spectral* (emittance as a function of wavelength at constant temperature) or *total* (the integrated emittance over all wavelengths as a function of temperature).

Physical Properties

The physical properties of interest for metals in optical applications include density, electrical conductivity, and electrical resistivity (the reciprocal of conductivity), as well as crystal structure. Chemical composition of alloys is also included with physical properties.

For density, mass density is reported with units of kg/m^3. Electrical conductivity is related to electrical resistivity, but for some materials, one or the other is normally reported. Both properties vary with temperature.

Crystal structure is extremely important for stability since anisotropy of the elastic, electric, and magnetic properties and thermal expansion depend on the type of structure.[14] Single crystals of cubic metals have completely isotropic coefficient of thermal expansion (CTE), but are anisotropic in elastic properties—modulus and Poisson's ratio. Materials with hexagonal structures have anisotropic expansion and elastic properties. While polycrystalline metals with randomly oriented small grains do not exhibit these anisotropies they can easily have local areas that are inhomogeneous or can have overall oriented crystal structure induced by fabrication methods.

The combined influence of physical, thermal, and mechanical properties on optical system performance is described under "Properties Important in Mirror Design," later in this chapter.

Thermal Properties

Thermal properties of metals that are important in optical systems design include: coefficient of thermal expansion α, referred to in this section as CTE; thermal conductivity k; and specific heat C_p. All of these properties vary with temperature; usually they tend to decrease with decreasing temperature. Although not strictly a thermal property, the maximum usable temperature is also included as a guide for the optical designer.

Thermal expansion is a generic term for change in length for a specific temperature change, but there are precise terms that describe specific aspects of this material property. ASTM E338 Committee recommends the following nomenclature:[15]

Coefficient of linear thermal expansion (CTE or thermal expansivity):

$$\alpha \equiv \frac{1}{L}\frac{\Delta L}{\Delta T} \tag{17}$$

Instantaneous coefficient of linear thermal expansion:

$$\alpha' \equiv \lim_{\Delta T \to 0}\left(\frac{1}{L}\frac{\Delta L}{\Delta T}\right) \tag{18}$$

Mean coefficient of linear thermal expansion:

$$\bar{\alpha} \equiv \frac{1}{T_2 - T_1}\int_{T_1}^{T_2} \alpha'\, dT \tag{19}$$

In general, lower thermal expansion is better for optical system performance, as it minimizes the effect of thermal gradients on component dimensional changes. CTE is the prime parameter in materials selection for cooled mirrors.

Thermal conductivity is the quantity of heat transmitted per unit of time through a unit of area per unit of temperature gradient with units of W/mK. Higher thermal conductivity is desirable to minimize temperature gradients when there is a heat source to the optical system.

Specific heat, also called heat capacity per unit mass, is the quantity of heat required to change the temperature of a unit mass of material one degree under conditions of constant pressure. A material with high specific heat requires more heat to cause a temperature change that might cause a distortion. High specific heat also means that more energy is required to force a temperature change (e.g., in cooling an infrared telescope assembly to cryogenic temperatures).

Maximum usable temperature is not a hard number. It is more loosely defined as the temperature at which there is a significant change in the material due to one or more of a number of things, such as significant softening or change in strength, melting, recrystallization, and crystallographic phase change.

Mechanical Properties

Mechanical properties are divided into elastic/plastic properties and strength, and fracture properties. The elastic properties of a metal can be described by a 6×6 matrix of constants called the elastic stiffness constants.[16–18] Because of symmetry considerations, there are a maximum of 21 independent constants that are further reduced for more symmetrical crystal types. For cubic materials there are three constants, C_{11}, C_{12}, and C_{44}, and for hexagonal five constants, C_{11}, C_{12}, C_{13}, C_{33}, and C_{44}. From these, the elastic properties of the material, Young's modulus E (the elastic modulus in tension), bulk modulus K, modulus of rigidity G (also called shear modulus), and Poisson's ratio ν can be calculated. The constants, and consequently the properties, vary as functions of temperature. The properties vary with crystallographic direction in single crystals,[14] but in randomly oriented polycrystalline materials the macroproperties are usually isotropic.

Young's modulus of elasticity E is the measure of stiffness or rigidity of a metal—the ratio of stress, in the completely elastic region, to the corresponding strain. Bulk modulus K is the measure of resistance to change in volume—the ratio of hydrostatic stress to the corresponding change in volume. Shear modulus, or modulus of rigidity, G is the ratio of shear stress to the corresponding shear strain under completely elastic conditions.

Poisson's ratio ν is the ratio of the absolute value of the rate of transverse (lateral) strain to the corresponding axial strain resulting from uniformly distributed axial stress in the elastic deformation region.

For isotropic materials the properties are interrelated by the following equations:[18]

$$G = \frac{E}{2(1+\nu)} \tag{20}$$

$$K = \frac{E}{3(1-2\nu)} \tag{21}$$

The mechanical strength and fracture properties are important for the structural aspect of the optical system. The components in the system must be able to support loads with no permanent deformation within limits set by the error budget and certainly with no fracture. For ductile materials such as copper, the yield and/or microyield strength may be the important parameters. On the other hand, for brittle or near-brittle metals such as beryllium, fracture toughness may be more important. For ceramic materials such as silicon carbide, fracture toughness and modulus of rupture are the important fracture criteria. A listing of definitions for each of these terms[19] follows:

creep strength: the stress that will cause a given time-dependent plastic strain in a creep test for a given time.

ductility: the ability of a material to deform plastically before fracture.

fatigue strength: the maximum stress that can be sustained for a specific number of cycles without failure.

fracture toughness: a generic term for measures of resistance to extension of a crack.

hardness: a measure of the resistance of a material to surface indentation.

microcreep strength: the stress that will cause 1 ppm of permanent strain in a given time; usually less than the microyield strength.

microstrain: a deformation of 10^{-6} m/m (1 ppm).

microyield strength: the stress that will cause 1 ppm of permanent strain in a short time; also called precision elastic limit (PEL).

ultimate strength: the maximum stress a material can withstand without fracture.

yield strength: the stress at which a material exhibits a specified deviation from elastic behavior (proportionality of stress and strain), usually 2×10^{-3} m/m (0.2 percent).

Properties Important in Mirror Design

There are many factors that enter into the design of a mirror or mirror system, but the most important requirement is optical performance. Dimensional stability, weight, durability, and cost are some of the factors to be traded off before an effective design can be established.[20–23] The loading conditions during fabrication, transportation, and use and the thermal environment play a substantial role in materials selection. To satisfy the end-use requirements, the optical, structural, and thermal performance must be predictable. Each of these factors has a set of parameters and associated material properties that can be used to design an optic to meet performance goals.

For optical performance, the shape or optical figure is the key performance factor followed by the optical properties of reflectance, absorptance, and complex refractive index. The optical properties of a mirror substrate material are only important when the mirror is to be used bare (i.e., with no optical coating).

To design for structural performance goals, deflections due to static (or inertial) and dynamic loads are usually calculated as a first estimate.[24] For this purpose, the well-known plate equations[25] are invoked. For the static case,

$$\delta = \beta q a^4 / D \tag{22}$$

where δ = deflection
β = deflection coefficient (depends on support condition)
q = normal loading (uniform load example)
a = plate radius (semidiameter)
D = flexural rigidity, defined as:

$$D = EI_0/(1-\nu^2) \tag{23}$$

where, in turn E = Young's modulus of elasticity
I_0 = moment of inertia of the section
ν = Poisson's ratio

But

$$q = \rho V_0 G \tag{24}$$

where ρ = material density
V_o = volume of material per unit area of plate surface
G = load factor (g's)

After substitution and regrouping the terms:

$$\delta = \beta \frac{\rho(1-\nu^2)}{E} \frac{V_0}{I_0} a^4 G \tag{25}$$

or

$$\delta \times B = M \times S \times P \times G \tag{26}$$

where B = support condition
M = materials parameters
S = structural efficiency
P = plate size
G = load factor

This shows five terms, each representing a parameter to be optimized for mirror performance. B, P, and G will be determined from system requirements; S is related to the geometric design of the part; and M is the materials term showing that ρ, ν, and E are the important material properties for optimizing structural performance.

For the dynamic case of deflection due to a local angular acceleration $\ddot{\theta}$ about a diameter (scanning applications), the equation becomes:

$$\delta_{\text{DYN}} = \beta_D \frac{\rho(1-\nu^2)}{E} \frac{V_0}{I_0} a^5 \frac{\ddot{\theta}}{g} \tag{27}$$

The same structural optimization parameters prevail as in the static case. Note that in both cases maximizing the term E/ρ (specific stiffness) minimizes deflection.

The determination of thermal performance[26,27] is dependent on the thermal environment and thermal properties of the mirror material. For most applications, the most significant properties are the coefficient of thermal expansion CTE or α, and thermal conductivity k. Also important are the specific heat C_p, and thermal diffusivity D, a property related to dissipation of thermal gradients that is a combination of properties and equal to $k/\rho C_p$. There are two important thermal figures of merit, the coefficients of thermal distortion α/k and α/D. The former expresses steady-state distortion per unit of input power, while the latter is related to transient distortions.

Typical room-temperature values for many of the important properties mentioned here are listed for a number of mirror materials in Table 1. It should be clear from the wide range of properties and figures of merit that no one material can satisfy all applications. A selection process is required and a tradeoff study has to be made for each individual application.[20]

Metal optical components can be designed and fabricated to meet system requirements. However, unless they remain within specifications throughout their intended lifetime, they have failed. The most often noted changes that occur to degrade performance are dimensional instability and/or environment-related optical property degradation. Dimensional instabilities can take many forms with many causes, and there are any number of ways to minimize them. Dimensional instabilities can only be discussed briefly here; for a more complete discussion, consult Refs. 28 to 31. The instabilities most often observed are:

- temporal instability: a change in dimensions with time in a uniform environment (e.g., a mirror stored in a laboratory environment with no applied loads changes figure over a period of time)

TABLE 1 Properties of Selected Mirror Materials

	ρ Density (10^3 kg/m^3)	E Young's Modulus (GN/m^2)	E/ρ Specific Stiffness (arb. units)	CTE Thermal Expansion (10^{-6}/K)	k Thermal Conductivity (W/m K)	C_p Specific Heat (J/kg K)	D Thermal Diffusivity (10^{-6} m^2/s)	Distortion coefficient: CTE/k Steady State (μm/W)	Distortion coefficient: CTE/D Transient (s/m^2 K)
Preferred	small	large	large	small	large	large	large	small	small

- thermal/mechanical cycling or hysteresis instability: a change in dimensions when the environment is changed and then restored, where the measurements are made under the same conditions before and after the exposure (e.g., a mirror with a measured figure is cycled between high and low temperatures and, when remeasured under the original conditions, the figure has changed)
- thermal instability: a change in dimensions when the environment is changed, but completely reversible when the original environment is restored (e.g., a mirror is measured at room temperature, again at low temperature where the figure is different, and finally at the original conditions with the original figure restored)

There are other types of instabilities, but they are less common, particularly in metals. The sources of the dimensional changes cited here can be attributed to one or more of the following:

- externally applied stress
- changes in internal stress
- microstructural changes
- inhomogeneity/anisotropy of properties

In general, temporal and cycling/hysteresis instabilities are primarily caused by changes in internal stress (i.e., stress relaxation). If the temperature is high enough, microstructural changes can take place as in annealing, recrystallization, or second-phase precipitation. Thermal instability is a result of inhomogeneity and/or anisotropy of thermal expansion within the component, is completely reversible, and cannot be eliminated by nondestructive methods.

To eliminate potential instabilities, care must be taken in the selection of materials and fabrication methods to avoid anisotropy and inhomogeneity. Further care is necessary to avoid any undue applied loads that could cause part deformation and subsequent residual stress. The fabrication methods should include stress-relief steps such as thermal annealing, chemical removal of damaged surfaces, and thermal or mechanical cycling. These steps become more critical for larger and more complex component geometries.

Instabilities can also be induced by attachments and amounts. Careful design to minimize induced stresses and selection of dissimilar materials with close thermal expansion matching is essential.[32]

4.3 SUMMARY DATA

The properties presented here are representative for the materials and are not a complete presentation. For more complete compilations, the references should be consulted.

Optical Properties

Thin films and their properties are discussed in Chap. 7, "Optical Properties of Films and Coatings," and therefore are not presented here except in the case where bulk (surface) optical properties are not available.

Index of Refraction and Extinction Coefficient The data for the optical constants of metals are substantial, with the most complete listing available in the two volumes of *Optical Constants of Metals,*[33,34] from which most of the data presented here have been taken. Earlier compilations[35,36] are also available. While most of the data are for deposited films, the references discuss properties of polished polycrystalline surfaces where available. Table 2 lists room-temperature values for n and k of Al,[37] Be,[38] Cu,[39] Cr,[40] Au,[39] Fe,[40] Mo,[39] Ni,[39] Pt,[39] Ag,[39] W,[39] and α-SiC.[41] Figures 2 to 14 graphically show these constants with the absorption edges shown in most cases.

Extensive reviews of the properties of aluminum[37] and beryllium[38] also discuss the effects of oxide layers on optical constants and reflectance. Oxide layers on aluminum typically reduce the optical constant values by 25 percent in the infrared, 10 to 15 percent in the visible, and very little in the ultraviolet.[37] As a result of the high values of n and k for aluminum in the visible and infrared, there are relatively large variations of optical constants with temperature, but they result in only small changes in reflectance.[37] The beryllium review[38] does not mention any variation of properties with temperature. The optical properties of beryllium and all hexagonal metals vary substantially with crystallographic direction. This variation with crystallography is shown for the dielectric constants of beryllium in Fig. 15.[42] The optical constants can be obtained from the dielectric constants using the following equations:[9]

$$n = \left\{ [(\varepsilon_1^2 + \varepsilon_2^2)^{1/2} + \varepsilon_1]/2 \right\}^{1/2} \tag{28}$$

$$k = \left\{ [(\varepsilon_1^2 + \varepsilon_2^2)^{1/2} - \varepsilon_1]/2 \right\}^{1/2} \tag{29}$$

This variation in optical properties results in related variations in reflectance and absorptance that may be the main contributors to a phenomenon called *anomalous scatter*, where the measured scatter from polished surfaces does not scale with wavelength when compared to the measured surface roughness.[43–47]

The optical constants reported for SiC are for single-crystal hexagonal material.

Reflectance and Absorptance

Reflectance data in the literature are extensive. Summaries have been published for most metals[35–36] primarily at normal incidence, both as deposited films and polished bulk material. Reflectance as a function of angle is presented for a number of metals in Refs. 48 and 49. Selected data are also included in Ref. 50. Temperature dependence of reflectance is discussed in a number of articles, but little measured data are available. Absorption data summaries are not as readily available, with one summary[35] and many articles for specific materials, primarily at laser wavelengths and often as a function of temperature. Table 3 lists values of room-temperature normal-incidence reflectance as a function of wavelength, and Figs. 16 to 26 show r and a calculated from η and k in the range of 0.015 to 10 μm.[35] Figure 27[35] shows reflectance for polarized radiation as a function of incidence angle for three combinations of n and k, illustrating the tendency toward total external reflectance for angles greater than about 80°.

Figures 28 to 34 show reflectance for polished surfaces and thin films of Al, Be, SiC, and Ni, including effects of oxide films on the surface.[51] One effect of absorption is to limit the penetration depth of incident radiation. Penetration depth is shown in Fig. 35 as a function of wavelength for Al, Be, and Ni.[51]

Absorption is a critical parameter for high-energy laser components, and is discussed in hundreds of papers as a function of surface morphology, angle of incidence, polarization state, and temperature. Only a few representative examples of this body of work can be cited here. When absorptance measurements were made of metal mirrors as a function of angle of incidence, polarization state, and wavelength,[52] it was found that measured values agreed with theory except at high angles of incidence where surface condition plays an undefined role. With the advent of diamond-turning as a mirror-finishing method, many papers have addressed absorptance characteristics of these unique surfaces as a function of surface morphology and angle of incidence, particularly on Ag and Cu mirrors.[53,54] It has been observed that mirrors have the lowest absorptance when the light is **s**-polarized and the grooves are oriented parallel to the plane of incidence.[54] The temperature dependence of optical absorption

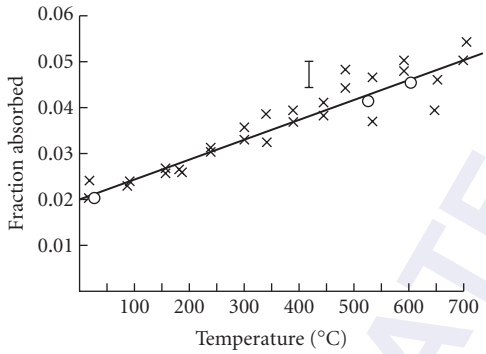

FIGURE 36 The 10.6-μm absorptance of Mo vs. temperature.[53] × is heating and O is cooling. The straight line is a least-squares fit to the data.

has long been known,[55] but measurements and theory do not always agree, particularly at shorter wavelengths. Figure 36 shows absorptance of Mo as a function of temperature at a wavelength of 10.6 μm.[55]

Mass absorption of energetic photons[56] follows the same relationship as described in Eq. (4), but with the product mass attenuation coefficient μ and mass density ρ substituted for absorption coefficient α. Table 4 lists mass attenuation coefficients for selected elements at energies between 1 keV (soft x rays) and 1 GeV (hard gamma rays). Units for the coefficient are m^2/kg, so that when multiplied by mass density in kg/m^3, and depth x in m, the exponent in the equation is dimensionless. To a

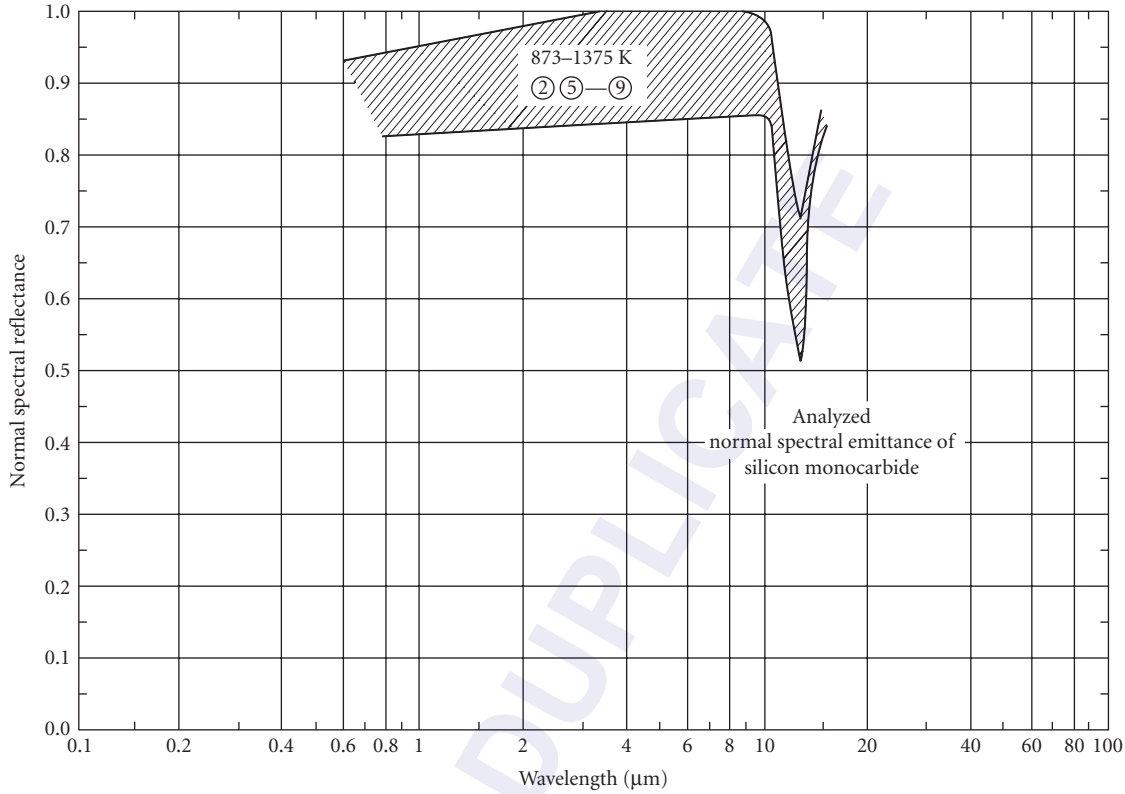

FIGURE 37 Analyzed normal spectral emittance of silicon carbide vs. wavelength.[57]

high approximation, mass attenuation is additive for elements present in a body, independent of the way in which they are bound in chemical compounds. Table 4 is highly abridged; the original[56] shows all elements and absorption edges.

Emittance Where the transmittance of a material is essentially zero, the absorptance equals the emittance as described above and expressed in Eqs. (15) and (16). Spectral emittance ϵ_s is the emittance as a function of wavelength at constant temperature. These data have been presented as absorptance curves in Figs. 16 to 22, 25, and 26. For SiC, ϵ_s is given in Fig. 37.[57] Spectral emittance of unoxidized surfaces at a wavelength of 0.65 μm is given for selected materials in Table 5.[58]

Total emittance ϵ_t is the emittance integrated over all wavelengths and usually given as a function of temperature. The total emittance of SiC is given in Fig. 38,[59] and for selected materials in Table 6.[60] Numerous papers by groups at the University of New Orleans (Ramanathan et al.[61–65]) and at Cornell University (Sievers et al.[66,67]) give high- and low-temperature data for the total hemispherical emittance of a number of metals including Ag, Al, Cu, Mo, W, and AISI 304 stainless steel.

Physical Properties

The physical properties at room temperature of a number of metals are listed in Table 7. the crystal form does not appreciably affect the physical properties, but is a factor in the isotropy of thermal and mechanical properties. For most metals, resistivity is directly proportional to temperature and

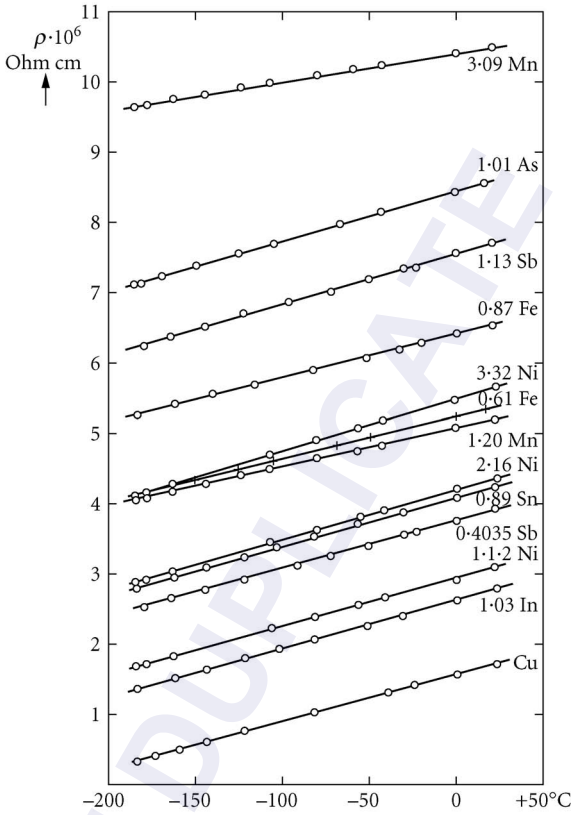

FIGURE 39 Electrical resistance of Cu and Cu alloys vs. temperature;[68] composition is in atomic percent.

pure metals generally have increased resistivity with increasing amounts of alloying elements. This is shown graphically for copper in Fig. 39.[68] Resistivity for a number of pure, polycrystalline metals is listed as a function of temperature in Table 8.[69]

Thermal Properties

The thermal properties of materials were documented in 1970 through 1977 in the 13-volume series edited by Touloukian et al.[70] of the Thermophysical Properties Research Center at Purdue University. The properties database continues to be updated by the Center for Information and Numerical Data Analysis and Synthesis (CINDAS).[1]

Selected properties of coefficient of thermal expansion, CTE, thermal conductivity k, and specific heat C_p at room temperature, are listed in Table 9. Maximum usable temperatures are also listed in the table.

The CTE of a material is a measure of length change at a specific temperature, useful for determining dimensional sensitivity to local temperature gradients. The total expansion (contraction) per unit length $\Delta L/L$ for a temperature change ΔT is the area under the CTE vs. T curve between the temperature extremes. Table 10 and Figs. 40 through 42 show recommended[71,72] CTE vs. T relationships for a number of materials. More recent expansion data have been published for many

materials that are too numerous to list here, but those for beryllium[73] and beta silicon carbide[74] are included in Table 10.

Thermal conductivities of many pure polycrystalline materials have been published by the National Bureau of Standards[75,76] (now National Institute for Science and Technology) as part of the National Standard Reference Data System. Selected portions of these data, along with data from Touloukian et al.,[77,78] and specific data for beryllium[79] and beta silicon carbide,[80] are listed in Table 11 and shown in Figs. 43 through 46.

The specific heat of metals is very well documented.[73,81–83] Table 12 and Figs. 47 through 49 show the temperature dependence of this property. Table values are cited in J/kg K, numerically equal to W s/kg K.

Mechanical Properties

Mechanical properties are arbitrarily divided between the elastic properties of moduli, Poisson's ratio, and elastic stiffness, and the strength and fracture properties. All of these properties can be anisotropic as described by the elastic stiffness constants, but that level of detail is not included here. In general, cubic materials are isotropic in thermal properties and anisotropic in elastic properties. Materials of any of the other crystalline forms will be anisotropic in both thermal and elastic properties. For an in-depth treatment of this subject see, for example, Ref. 4.
